The *t*-BuO^-/*i*-PrO^- data in Tables 1 and 5 were likewise treated twice in a reiterative manner and the nominal C.R. of *t*-BuO^-/*i*-PrO^- of 0.111 was recalculated successively as 0.0972 and 0.0969. The nominal relative acidity of *t*-BuOH/*i*-PrOH of 0.993 was recalculated successively as 0.872 and 0.869. Multiplying the relative acidity of *i*-PrOH/EtOH of 0.236 by the *t*-BuOH/*i*-PrOH relative acidity of 0.869 gives the corrected relative acidity of *t*-BuOH/EtOH of 0.205 as given in Table 5.

Typical Relative Nucleophilicity Determination

Freshly cut sodium (0.2 atom) was added to the alcohol (2 mol) in an oversized test tube (3.5 × 30 cm) and after dissolution was complete, the phenol (0.1 mol) (or *m*-cresol) was added and the solution thoroughly mixed. The *n*-butyl bromide (0.1 mol) was added from a burette, and the solution was again thoroughly mixed. The test tube was stoppered, sealed with "Parafilm", and placed in a bath thermostated at 25 ± 0.1°C. The reaction was considered to be complete when *n*-butyl bromide could no longer be detected by glc. Two aliquots were removed and each was analyzed by glc using multiple injections. For example, in the experiment using ethanol and phenol, the program (Lutensol column) involved holding the column at 30°C for 10 min, raising the temperature to 150°C at 30°C/min, and holding the column at this final temperature. The *n*-butyl ethyl ether and *n*-butyl phenyl ether retention times were 7 and 25 min, respectively. The area data from six injections (three from each aliquot) for the peaks representing BuOEt and BuOPh as read by the disc integrator follows: 2335/2204, 2362/2340, 2450/2430, 2492/2370, 2868/2815, and 2730/2784. These data give an average area ratio of 1.02 with a standard deviation of 0.01. Two other experiments carried out four months later gave average area ratios of 1.02 ± 0.01 and 0.992 ± 0.006. The instrument response factor was determined from known mixtures to be 1.67 and the mole ratio of the BuOEt and BuOPh ethers was therefore 1.70, or 63:37. (The 64:36 value given in Table 3 is an averaged value and includes data from runs in which a phenol – *m*-cresol mixture in ethanol solution reacted with *n*-butyl bromide.) The

initial concentrations of EtO^- and PhO^- were each 0.1 mol per volume of the reaction mixture, and the final concentrations were 0.037 and 0.063, respectively. Applying eq. [10] gives the relative nucleophilicity of EtO^-/PhO^- as 2.15 for this set of data.

Absolute rate constants for hydrocarbon autoxidation. 27. On the question of a reversible rate controlling propagation reaction[1]

J. A. HOWARD AND SHIU BOR TONG[2]

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received January 29, 1979

J. A. HOWARD and SHIU BOR TONG. Can. J. Chem. **57**, 2755 (1979).

Autoxidations of cumene, 3-methylpentane, cyclopentane, and cyclohexane have been performed to high conversion in the presence of $(CH_3)_3COOD$ from 0.1 to 1 atm of oxygen and it has been found that very low yields of $C_6H_5C(CH_3)_2D$, $C_6H_{13}D$, *c*-C_5H_9D, and *c*-$C_6H_{11}D$ are produced. Furthermore, autoxidation of $C_6H_5C(CH_3)_2D$ in the presence of $(CH_3)_3COOH$ does not give detectable concentrations of $C_6H_5C(CH_3)_2H$ and relative reactivities of cumene and 3-methylpentane to the *tert*-butylperoxy radical in solution do not depend on the pressure of oxygen above the liquid from 1 to 100 atm. These results have been interpreted in term of a slow reaction of the alkyl radical with alkyl hydroperoxide outside the solvent cage in competition with a fast reaction of the alkyl radical with oxygen. A rate constant for the former reaction has been estimated from the relative yields of 5-hexene and methylcyclopentane produced by decomposition of 5-hexenylformyl peroxide in an inert solvent containing *tert*-butyl hydroperoxide.

The relative reactivity of the tertiary hydrogens in cumene and 3-methylpentane to the *tert*-butylperoxy radical in the gas phase is about 0.8 times the value in solution. This relative reactivity difference between the two phases is probably due to the involvement of *tert*-butoxy radicals in rate controlling propagation reactions in the gas phase rather than to significant reversal of the H-atom transfer reaction between the peroxy radical and the substrate inside the solvent cage.

J. A. HOWARD et SHIU BOR TONG. Can. J. Chem. **57**, 2755 (1979).

On a réalisé l'autoxydation du cumène, du méthyl-3 pentane du cyclopentane et du cyclohexane, avec de très bons rendements en présence du $(CH_3)_3COOD$ sous une pression d'oxygène allant de 0.1 à 1 atmosphère et on a trouvé qu'il se forme de très faibles quantités de $C_6H_5C(CH_3)_2D$, $C_6H_{13}D$, *c*-C_5H_9D et *c*-$C_6H_{11}D$. De plus l'autoxydation du $C_6H_5(CH_3)_2D$ en présence du $(CH_3)_3COOH$ ne produit pas des quantités décelables de $C_6H_5C(CH_3)_2H$ et les réactivités relatives du cumène et du méthyl-3 pentane par rapport au radical *tert*-butylperoxy en solution ne dépend pas de la pression de l'oxygène au-dessus du liquide entre 1 et 100 atmosphères. On a interprété ces résultats en fonction d'une réaction lente du radical alkyle avec l'hydroperoxyde d'alkyle à l'intérieur de la cage du solvant, en compétition avec une réaction rapide du radical alkyle avec l'oxygène. On a évalué la constante de vitesse de la première réaction à partir des rendements en hexène-5 et en méthylcyclopentane produits par la décomposition du peroxyde d'hexenyl-5 formyle dans un solvant inerte contenant de l'hydroperoxyde de *tert*-butyle.

La réactivité relative des hydrogènes tertiaires du cumène et du méthyl-3 pentane par rapport au radical *tert*-butylperoxy dans la phase gazeuse est environ 0.8 fois la valeur en solution. Cette différence de réactivité relative entre les deux phases est due probablement à l'entrée en jeu des radicaux *tert*-butylperoxy dans l'étape déterminante des réactions de propagation dans la phase gazeuse plutôt qu'à une inversion significative de la réaction de transfert d'un atome d'hydrogène entre le radical peroxy et le substrat à l'intérieur de la cage du solvant.

[Traduit par le journal]

Introduction

It has been reported that rates of free-radical bromination of alkanes and alkyl halides (RH) in solution are influenced by reaction of the chain carrying alkyl radical (R•) with hydrogen bromide both inside and outside the solvent cage, reactions [−1] and [2], and with HBr_3•, reaction [3] (1–4),

$$[1] \quad Br^{\bullet} + RH \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} (BrH + R^{\bullet})_{cage}$$

$$[2] \quad R^{\bullet} + HBr \xrightarrow{k_2} RH + Br^{\bullet}$$

$$[3] \quad R^{\bullet} + HBr_3 \longrightarrow RH + Br_3^{\bullet}$$

Thus the relative reactivity of two substrates to the bromine atom obtained from the yields of alkyl bromides produced by competitive brominations will

[1]NRCC No. 17735.

0008-4042/79/202755-06$01.00/0

be in error if the rates of reactions [−1], [2], and [3] depend on the structure of R.

Now the heat of the reaction of an alkylperoxy radical with RH is very similar to ΔH for reaction [1] because the strength of the O—H bond in an alkyl hydroperoxide (5) is almost equal to D(H—Br) (6). Hydrocarbon autoxidations in the presence of large concentrations of *tert*-butyl hydroperoxide (*t*-BuOOH) may, therefore, be influenced by reversal of the rate controlling propagation reaction as shown in Scheme 1.

$$[4] \quad t\text{-BuO}_2^{\bullet} + \text{RH} \underset{k_{-4}}{\overset{k_p}{\rightleftharpoons}} (t\text{-BuOOH} + \text{R}^{\bullet})_{\text{cage}}$$

$$[5] \quad (t\text{-BuOOH} + \text{R}^{\bullet})_{\text{cage}} \xrightarrow{k_5} t\text{-BuOOH} + \text{R}^{\bullet}$$

$$[6] \quad \text{R}^{\bullet} + \text{O}_2 \xrightarrow{k_O} \text{RO}_2^{\bullet}$$

$$[7] \quad \text{RO}_2^{\bullet} + t\text{-BuOOH} \xrightarrow{k_7} \text{ROOH} + t\text{-BuO}_2^{\bullet}$$

$$[8] \quad \text{R}^{\bullet} + t\text{-BuOOH} \xrightarrow{k_r} \text{RH} + t\text{-BuO}_2^{\bullet}$$

SCHEME 1

where $RO_2^{\bullet}$ and ROOH are the peroxy radical and hydroperoxide derived from the hydrocarbon RH and t-$BuO_2^{\bullet}$ is the *tert*-butylperoxy radical.

Reactions [4] to [8] along with the usual chain initiation and termination reactions give the following expression for the rate of autoxidation,

$$[9] \quad \frac{-\text{d}[\text{O}_2]}{\text{d}t} = \frac{k_5 k_p [\text{RH}] R_i^{1/2} k_O [\text{O}_2]}{(k_{-4} + k_5)(2k_t)^{1/2}(k_O[\text{O}_2] + k_r[t\text{-BuOOH}])}$$

where k_p and $2k_t$ are the rate controlling propagation and termination rate constants and R_i is the rate of chain initiation.

Clearly absolute values of k_p calculated from the usual rate expression [10] (7)

$$[10] \quad \frac{-\text{d}[\text{O}_2]}{\text{d}t} = \frac{k_p[\text{RH}]R_i^{1/2}}{(2k_t)^{1/2}}$$

will be in error if reactions [−4] and [8] are important. It also follows that relative reactivities obtained from competitive autoxidations (7, 8) could be influenced by reversible rate controlling propagation reactions.

We have attempted to resolve this problem by employing the experimental techniques used by Tanner and co-workers (1–4) to demonstrate the importance of reversal in free-radical bromination. Thus we have studied the autoxidation of cumene, 3-methylpentane, cyclohexane, and cyclopentane in the presence of *t*-BuOOD to high conversion and analyzed the unreacted hydrocarbon for incorporation of deuterium. We have also investigated the autoxidation of cumene-α-d_1 in the presence of *t*-BuOOH and the co-oxidation of cumene and 3-methylpentane in solution at oxygen pressures from 1 to 100 atm and in the gas phase. The results of this study, which are reported here, indicate that reversible hydrogen atom transfer has no significant influence on kinetic data obtained from autoxidations in the presence of high concentrations of hydroperoxide.

In addition, we have estimated the rate constant for reaction of an alkyl radical with a hydroperoxide, k_r, by measuring the yields of 5-hexene and methylcyclopentane produced by decomposition of 5-hexenylformyl peroxide in the presence of *tert*-butyl hydroperoxide.

Experimental

Materials

Cumene (Anachemia) was washed with concentrated sulphuric acid, 10% aqueous sodium bicarbonate, and water; it was then dried over anhydrous magnesium sulphate and distilled. Analysis by gas chromatography showed it to be >99.8% and it did not contain any α-cumyl alcohol It was stored under argon at −20°C. Cumene-α-d_1 was obtained from Merck, Sharpe, and Dohme (Canada) Limited. 3-Methylpentane (Chemical Samples Co.), cyclohexane (Fischer Scientific Co.), and cyclopentane (Phillips Research Grade) were >99.9% pure and contained no alcoholic impurity. These substrates were used without further purification. *tert*-Butyl hydroperoxide (Aldrich) was fractionally distilled at reduced pressure. The fraction with bp 39–40°C at 20 Torr was collected and was 99.9% pure by gas chromatography. $(CH_3)_3COOD$ was prepared by shaking $(CH_3)_3COOH$ with an equal volume of 99% D_2O (9). The D_2O was then removed and the procedure repeated until the O—H band in the infrared spectrum (ν = 3530 cm^{-1}) was replaced by the O—D band (ν = 2610 cm^{-1}). A sample of $(CH_3)_3COOD$ (99% pure by nmr) was kindly provided by Professor D. D. Tanner (University of Alberta). 5-Hexenylformyl peroxide was prepared from 6-heptenoic acid (K and K) by Staab's carbonyldiimidazole route (10, 11). 2,2′-Azoisobutane was prepared from *tert*-butyl amine by the method of Stevens (12). *tert*-Butyl hyponitrite was prepared by the method of Kiefer and Traylor (13).

Procedure

Liquid-phase Autoxidations

Reactions at 1 atm of oxygen and below were performed in the automatic recording gas apparatus described previously (14). In a typical experiment cumene (6.45 *M*) containing α,α′-azo-bis-isobutyronitrile (0.05 *M*), $(CH_3)_3COOD$ (1.1 *M*) and D_2O (0.5 mL) was shaken with oxygen at 720 Torr and 30°C. Oxygen (0.69 *M*) was absorbed in 120 h and the hydroperoxides in the reaction mixture were reduced with triphenylphosphine. Volatile products were pumped into a trap maintained at the temperature of liquid nitrogen and the concentration of α-cumyl alcohol was determined by gas chromatography (Varian 2800 chromatograph equipped with a 12 ft 12% OV-101 on Chromosorb W column and flame ionization detector). High pressure experiments were conducted in a glass tube in a stainless steel bomb. Oxygen concentrations in the

various hydrocarbons were calculated using solubility data from the literature (15).

Gas-phase Autoxidations

Solutions of 3-methylpentane, cumene, initiator (2,2′-azoisobutane or di-*tert*-butyl hyponitrite), and *tert*-butyl hydroperoxide were injected through a serum cap into a 1-litre reaction vessel containing oxygen (400 Torr). The reaction vessel was immersed in an oil bath maintained at a constant temperature, and for azoisobutane initiated reactions the reaction mixture was irradiated with a Westinghouse 275W Sun-lamp for 160–260 h. The reaction mixture was then pumped into a trap maintained at the temperature of liquid nitrogen, and enough triphenylphosphine was added to reduce all the hydroperoxides present. The reduced sample was distilled into a cold trap and analyzed by gas chromatography.

Decomposition of 5-Hexenylformyl Peroxide

These reactions were performed at 50°C in degassed carbon tetrachloride or chlorobenzene containing *tert*-butyl hydroperoxide. The volatile products were distilled from the reaction mixture and analyzed by gas chromatography.

Mass Spectroscopic Analysis

Percentages of monodeuterated hydrocarbon in cumene, 3-methylpentane, cyclohexane, and cyclopentane and normal cumene in $C_6H_5C(CH_3)_2D$ after autoxidation were determined from a comparison of the mass spectrum of the starting material and the spectrum of the recovered unreacted hydrocarbon after at least 10% conversion. Mass spectra were obtained with a Finnigan 4000 automated gas chromatograph–mass spectrometer system.

Results and Discussion

Cumene

Oxygen at a pressure of 720 Torr was absorbed very rapidly by cumene (6.45 *M*) at 30°C containing AIBN (0.05 *M*), *t*-BuOOD (1 *M*), and D_2O (0.5 mL). In 93 h 0.69 *M* of oxygen had been absorbed and α-cumene hydroperoxide (0.69 *M*) was the major reaction product. The unoxidized cumene was found to contain ~1.5% cumene-α-d_1.

If this autoxidation is described by the reactions shown in Scheme 1 with R = $C_6H_5C(CH_3)_2$ the rate of formation of cumyl hydroperoxide is given by

$$\frac{d[C_6H_5C(CH_3)_2OOH]}{dt} = k_O[C_6H_5\dot{C}(CH_3)_2][O_2]$$

and the rate of formation of $C_6H_5C(CH_3)_2D$ by

$$\frac{d[C_6H_5C(CH_3)_2D]}{dt} = k_r[C_6H_5\dot{C}(CH_3)_2][(CH_3)_3COOD]$$

The concentration of monodeuterated cumene will, therefore, be governed by

$$[11]\quad \frac{k_r}{k_O} = \frac{[C_6H_5C(CH_3)_2D]_t[O_2]_0}{[C_6H_5C(CH_3)_2OOH]_t[(CH_3)_3COOD]_0}$$

where $[C_6H_5C(CH_3)_2D]_t$ and $[C_6H_5C(CH_3)_2OOH]_t$ are the concentrations after time *t* and the subscript 0 refers to initial concentrations.

In order to calculate the rate constant ratio k_r/k_O from [11] it is necessary to know $[(CH_3)_3COOD]_0$. Now it is not known whether cumyl radicals will react with the associated form of the hydroperoxide. We have, therefore, assumed for the purpose of this work that reaction only occurs with free hydroperoxide, the concentration of which has been calculated from the thermodynamic data provided by Walling and Heaton (9).

Substitution of the reactant concentrations and the yields of α-cumyl hydroperoxide and $C_6H_5C(CH_3)_2D$ reported above in eq. [11] gives $k_r/k_O \sim 2 \times 10^{-4}$.

The rate constant ratio k_r/k_O should be proportional to the first-power of the oxygen concentration and inversely proportional to the first-power of the hydroperoxide concentration. The latter concentration exponent could not be confirmed experimentally because below a hydroperoxide concentration of 1 *M* the percentage of deuterated cumene in unreacted cumene was too low to be measured accurately while above 1 *M* most of the hydroperoxide was associated by hydrogen bonding.

In an attempt to determine the oxygen concentration exponent reactions were performed at low oxygen pressures (95 Torr) and the percentage cumene-α-d_1 was found to be identical, within experimental error, to the percentage at 720 Torr. This unexpected result probably reflects the difficulty in accurately determining low percentages of deuterated cumene by mass spectrometry rather than a zero-order dependence on the oxygen concentration.

The results of several experiments conducted under different experimental conditions are listed in Table 1 and suggest that $k_r/k_O < 10^{-3}$ which means that if k_O is $10^{9.5}$ M^{-1} s^{-1} (16), $k_r < 10^{6.5}$ M^{-1} s^{-1}.

Cumene-α-d_1

This compound was oxidized at 30°C under 700 Torr of oxygen in the presence of *t*-BuOOH (2 *M*) to approximately 10% conversion. The mass spectrum of the unoxidized cumene was identical with that obtained from the starting material indicating negligible loss of deuterium by reaction of cumyl radicals with the hydroperoxide.

Alkanes

3-Methylpentane (6.94 *M*) containing AIBN (0.09 *M*), *t*-BuOOD (1.1 *M*), and D_2O (0.3 mL) was allowed to react with oxygen (5 atm) at 30°C for 29 days. After this length of time ~10% of the alkane had been oxidized. There was, however, no evidence for $CH_3CH_2C(CH_3)DCH_2CH_3$ in the unreacted alkane.

In an attempt to increase the percentage yield of monodeuterated alkane cyclopentane and cyclo-

hexane were used instead of 3-methylpentane, the oxygen pressure was decreased to 1 atm and the temperature was increased to 50°C. Data obtained for these substrates are summarized in Table 2 and it can be seen from these data that the percentage yields of monodeuterated cyclane were so low that the reproducibility was extremely poor. In fact the only conclusion that can be drawn from these data is that k_r/k_O is somewhat less than 10^{-2}.

Co-oxidation of Cumene and 3-Methylpentane

The relative reactivity of cumene and 3-methylpentane to t-$BuO_2^{\bullet}$ obtained from co-oxidations in the presence of high concentrations of t-BuOOH would depend on the concentration of oxygen dissolved in the reaction mixture if the rate controlling propagation reactions are reversible and the rate of the reverse reaction depends on the nature of R. We have therefore determined the relative reactivity of these substrates at 1, 10, and 100 atm of oxygen at 30°C and find that k_p(cumene)/k_p^{ref} (where k_p^{ref} is the reactivity of the t-C—H bond in 3-methylpentane) = 21.8 at 1 atm, 22.6 at 10 atm, and 19.9 at 100 atm. Clearly this rate constant ratio is unchanged over a 100-fold variation in the oxygen concentration.

Gas-phase Autoxidation

Although the experiments described above indicate that reaction of an alkyl or substituted alkyl radical with alkyl hydroperoxide outside the solvent cage (reaction [7]) is not important enough to effect either rates of autoxidation or product ratios from co-oxidations, they give no indication of the importance of cage reversal (reaction [5]) on these rates and product ratios. Thus the efficiency with which an alkyl radical escapes the solvent cage will depend on the rate of its reaction with ROOH inside the cage. Now the strength of the t-C—H bond in 3-methylpentane is at least 10 kcal mol^{-1} stronger than the strength of the t-C—H bond in cumene (17) and the 3-methyl-3-pentyl radical could in theory react more rapidly than the cumyl radical with ROOH. Therefore, if cage reversal is important cumyl radicals will escape the solvent cage more efficiently than 3-methyl-3-pentyl radicals and k_p(cumene)/k_p^{ref} will be anomalously large in solution because a disproportionate amount of cumyl hydroperoxide will be formed.

We have attempted to assess the importance of cage reversal by investigating the co-oxidation of cumene and 3-methylpentane in the presence of t-BuOOH initiated by thermolysis of di-*tert*-butyl hyponitrite and by photolysis of 2,2′-azoisobutane in the gas phase and comparing the results with those obtained in solution.

The di-*tert*-butyl hyponitrite (0.009 *M*) initiated autoxidation of cumene (0.86 *M*) and 3-methylpentane (6.32 *M*) containing $(CH_3)_3COOH$ (0.6 *M*) at 45°C in the gas phase gave 3-methylpentan-3-ol (0.0043 *M*), α-cumyl alcohol (0.0094 *M*), and di-*tert*-butyl peroxide (0.264 *M*) as the major reaction products. The relative yield of these two alcohols gives k_p(cumene)/k_p^{ref} = 16. The kinetic chain length (ν), based on the total alcohol yield and the yield of di-*tert*-butyl peroxide was, however, only 0.02.

When this reaction was conducted in the liquid phase at 45°C the product yields were 3-methylpentan-3-ol (0.035 *M*), cumyl alcohol (0.076 *M*), and di-*tert*-butyl peroxide (0.004 *M*), giving k_p(cumene)/k_p^{ref} = 16, cf., k_p(cumene)/k_p^{ref} = 20 (7), and the kinetic chain length was 14.

[a]$[O_2] = 1.3 \times 10^{-2}$ *M*.
[b]Monomer concentration.

These di-*tert*-butyl hyponitrite initiated co-oxidations were repeated several times and the average relative reactivities were $k_p(\text{cumene})/k_p^{ref} = 15 \pm 2$ in the gas phase ($\nu = 0.01$–0.6) and $k_p(\text{cumene})/k_p^{ref} = 19 \pm 3$ in the liquid phase ($\nu = 13$–35).

2,2′-Azoisobutane initiated gas phase autoxidations gave $k_p(\text{cumene})/k_p^{ref} = 15.5$ at 45°C ($\nu = 0.2$) and 10 at 55°C ($\nu = 4$).

It would, therefore, appear from these experiments that $k_p(\text{cumene})/k_p^{ref}$ in the gas phase is about 0.8 times the relative reactivity in solution, which could be interpreted as being indicative of cage reversal in solution. Kinetic chain lengths for the gas phase reactions were, however, very short and it is quite possible that the gas phase rate constant ratios are low because of H-atom abstraction by *tert*-butoxy radicals formed by nonterminating interactions of *tert*-butylperoxy radicals. These radicals are more reactive and less selective than *tert*-butylperoxy radicals and would be expected to lower the reactivity difference between cumene and 3-methylpentane.

Measurement of k_r

The kinetic data given in Table 2 suggest that the rate constant ratio k_r/k_O is $<10^{-2}$ for the cyclopentyl and cyclohexyl radicals, and since k_O is $\sim 10^{9.5}$ (16) k_r is $<10^{7.5}\ M^{-1}\ s^{-1}$. On the other hand yields of $C_6H_5C(CH_3)_2D$ obtained from autoxidation of cumene in the presence of $(CH_3)_3COOD$ suggest that k_r for cumyl radicals is $<10^{6.5}$.

It should be possible to estimate the value of k_r from the relative concentrations of 5-hexene and methylcyclopentane produced by decomposition of 5-hexenylformyl peroxide in the presence of *tert*-butyl hydroperoxide. This peroxide decomposes readily at 50°C to give the 5-hexenyl radical which either abstracts the hydroperoxidic hydrogen to give 5-hexene or isomerizes to the cyclopentylmethyl radical which picks up a hydrogen atom to give methylcyclopentane.

[12] 
[13] 
[14] 
The rate constant ratio k_c/k_r is given by

[15] $$\frac{k_c}{k_r} = \frac{[\text{cyclopentyl}][t\text{-BuOOH}]}{[\text{5-hexenyl}]}$$

and since $k_c = 2.36 \times 10^5\ s^{-1}$ at 50°C (18) k_r can be calculated from the relative concentrations of the two hydrocarbons formed by reaction with the hydroperoxide and the concentration of *tert*-butyl hydroperoxide.

Methylcyclopentane and 5-hexene were formed in the ratio 1.72 ± 0.02 after decomposition of 5-hexenylformyl peroxide (0.05 *M*) in degassed chlorobenzene containing *t*-BuOOH (0.9 *M*). There is, however, no way of estimating from this experiment the amount of hydrocarbon formed via reactions [13] and [14] and the amount formed by other processes, such as radical–radical disproportionation reactions. In order to resolve this problem 5-hexenylformyl peroxide was decomposed in the presence of 2.0 *M* *t*-BuOOD (and a trace of D_2O) and the yields of monodeuterated methylcyclopentane and 5-hexene relative to C_6H_{12} were measured by mass spectrometry. This experiment gave 10.15 ± 0.4 for the total ratio of methylcyclopentane to 5-hexene and indicated that 92% of the methylcyclopentane was $C_6H_{11}D$ whereas only 35% of the 5-hexene was $C_6H_{11}D$. Clearly most of the methylcyclopentane was formed by abstraction of the hydroperoxidic deuterium while a significant fraction of 5-hexene was formed by another route. Calculation of k_r from the formula

$$\frac{k_c}{k_r} = \frac{[\text{D-cyclopentyl}]\,[t\text{-BuOOD}]_{monomer}}{[\text{5-hexenyl-D}]} = 27 \times 0.75$$

gave $k_r = 8.7 \times 10^3\ M^{-1}\ s^{-1}$ and a slightly larger value if the alkyl radicals react with deuterium bonded hydroperoxide.

Abstraction of a hydroperoxidic hydrogen by an alkyl radical probably has a primary deuterium isotope effect no greater than 2 and we can conclude that k_r for normal *tert*-butyl hydroperoxide is $\sim 2 \times 10^4\ M^{-1}\ s^{-1}$.

Conclusions

It is apparent from the results presented in this paper that reversal of the rate controlling propagation reaction for hydrocarbon autoxidation in the presence of large amounts of alkyl hydroperoxide is not important enough to influence the magnitude of cross-propagation rate constants determined by the hydroperoxide method (7, 8, 17).

The rate constant for reaction of an alkyl radical with *t*-BuOOH in solution is about five orders of magnitude smaller than the rate constant for reaction of the alkyl radical with oxygen and the former reaction is unimportant even at hydroperoxide to oxygen ratios of 100:1. Consequently it is not surprising that estimates of k_r/k_O made from the

yields of c-$C_6H_{11}D$ and c-C_5H_9D produced by autoxidation of c-C_6H_{12} and c-C_5H_{10} in the presence of *tert*-BuOOD (Table 2) were erratic. The maximum mole fraction of monodeuterated cyclane that could be expected if $k_r = 2 \times 10^4\ M^{-1}\ s^{-1}$ is 5×10^{-6} which is outside the limits of detection by mass spectrometry.[3]

In contrast, Tanner *et al.* (2) have found that the cyclohexyl radical is only about 0.3 times less reactive to HBr than it is to Br_2. This difference between autoxidation and bromination may be because a peroxy radical is less reactive to a hydroperoxide than a bromine atom is to HBr or because an alkyl radical is more reactive to oxygen than it is to bromine.

Acknowledgements

The authors were prompted to perform the experiments described in this paper by discussions with Professor D. D. Tanner. They also wish to thank Mr. M. Bednas for mass spectroscopic analyses and a referee for helpful suggestions.

[3]NOTE ADDED IN PROOF: Reanalysis of oxidized cyclopentane and cyclohexane in the presence of $(CH_3)_3COOD$ using a capillary column in the gas chromatograph gave even *lower* yields of monodeuterated cyclane than the values reported in Table 2.

Organometallic peroxy radicals. Part 5. Trialkylsilylperoxy and trialkylstannylperoxy radicals[1]

JAMES ANTHONY HOWARD,[2] JOHN CHARLES TAIT,[3] AND SHIU BOR TONG[4]

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received March 6, 1979

JAMES ANTHONY HOWARD, JOHN CHARLES TAIT, and SHIU BOR TONG. Can. J. Chem. **57**, 2761 (1979).

A variety of organosilylperoxy and organostannylperoxy radicals, $R_3MO_2^{\bullet}$ (R = Me, Et, *n*-Bu, *t*-Bu, and Ph and M = Si and Sn) have been prepared and studied by electron spin resonance spectroscopy. Trialkylsilylperoxy radicals exist in equilibrium with a tetroxide at temperatures below 233 K with $\Delta H^0 = -11 \pm 2$ kcal mol^{-1} and $\Delta S^0 < -30$ cal deg^{-1} mol^{-1}. Above 233 K these radicals decay either with first-order, one half-order, or zero-order kinetics depending on the radical and its concentration. Trialkylstannylperoxy radicals do not exist in reversible equilibrium with a dimer below ambient temperature and they undergo self-reaction with second-order kinetics. Tri-*n*-butylstannylperoxy radicals react with 2,6-di-*tert*-butyl-4-methylphenol and cobalt(II) acetylacetonate and Arrhenius parameters for these two reactions are reported. The structure of $R_3SiO_2^{\bullet}$ resembles the structure of alkylperoxy radicals whereas the two oxygen nuclei of $R_3SnO_2^{\bullet}$ are magnetically equivalent and the peroxy group becomes a bidentate ligand. This structural difference has a significant effect on radical reactivity.

JAMES ANTHONY HOWARD, JOHN CHARLES TAIT et SHIU BOR TONG. Can. J. Chem. **57**, 2761 (1979).

On a préparé et étudié par résonance paramagnétique électronique une série de radicaux organosilylperoxy et organostannylperoxy $R_3MO_2^{\bullet}$ (R = Me, Et, *n*-Bu et M = Si et Sn). Les radicaux trialkylperoxy existent en équilibre avec le tétroxyde à des températures inférieures à 233 K avec un $\Delta H^0 = -11 \pm 2$ kcal mol^{-1} et un $\Delta S^0 < -30$ cal deg^{-1} mol^{-1}. Au dessus de 233 K, ces radicaux se désintègrent avec des cinétiques soit de premier ordre, d'ordre égal à une demi ou à zéro, dépendant du radical et de sa concentration. Les radicaux trialkylstannylperoxy n'existent pas en équilibre avec le dimère au dessous de la température ambiante et subissent une auto-réaction avec une cinétique de second ordre. On rapporte les paramètres d'Arrhénius pour les réactions des radicaux tri-*n*-butylstannylperoxy avec le di-*tert*-butyl-2,6 méthyl-4 phénol et l'acétylacétonate de cobalt(II). La structure de $R_3SiO_2^{\bullet}$ s'apparente à la structure des radicaux alkylperoxy où les deux noyaux d'oxygène du $R_3SnO_2^{\bullet}$ sont magnétiquement équivalents et où le groupe peroxy devient un ligand bidentate. Cette différence structurale a un effet significatif sur la réactivité du radical.

[Traduit par le journal]

Introduction

Recent reports from this laboratory have been concerned with kinetic and spectroscopic properties of the peroxy radicals resulting from addition of oxygen to group 4b organometallic radicals, $R_3M^{\bullet}$, where M is silicon, germanium, tin, and lead and R is methyl, *n*-butyl, and phenyl. Thus we have shown that spectroscopic *g*-factors can be used to identify these radicals (1), that trimethylgermylperoxy and triphenylgermylperoxy radicals at low temperatures exist in equilibrium with their tetroxides and decay irreversibly by a first-order process (2), and that the two oxygen atoms of the tri-*n*-butylstannylperoxy radical are magnetically equivalent rather than, as is usually found for peroxy radicals, nonequivalent (3).

In the first part of this series (1) we reported briefly on the spectroscopy of the trimethylsilylperoxy radical and the kinetics of the self-reaction of the trimethylstannylperoxy radical. Here we report a more thorough study of the free-radical chemistry of these and related radicals.

Experimental

Materials

Trimethylsilane (Chemical Procurement Labs Inc.), triethylsilane (Columbia Organic Chemicals Inc.), tri-*n*-butylsilane (K and K), triphenylsilane, tri-*n*-butyltin hydride, and hexa-*n*-butylditin (Ventron, Alfa Division) were purified by standard methods. Trimethyltin hydride was prepared from trimethyltin bromide and tri-*n*-butyltin hydride. Triphenyltin hydride was synthesized by reduction of tri-phenyltin bromide with $LiAlH_4$ (4). Tri-*tert*-butyl silane was a gift from Dr. K. U. Ingold.

Procedure

The peroxy radicals were prepared directly in the cavity of a Varian E-4 EPR spectrometer by photolysis of the appropriate hydride in an oxygen saturated solvent (cyclopropane, CF_2Cl_2, toluene, CF_3Cl) containing di-*tert*-butyl peroxide.

$$[1]\quad t\text{-BuOOBu-}t \xrightarrow{h\nu} 2t\text{-BuO}^{\bullet}$$

$$[2]\quad t\text{-BuO}^{\bullet} + R_3MH \rightarrow t\text{-BuOH} + R_3M^{\bullet}$$

$$[3]\quad R_3M^{\bullet} + O_2 \rightarrow R_3MO_2^{\bullet}$$

where R = Me, Et, *n*-Bu, and Ph and M = Si and Sn or, in the case of the trialkylstannylperoxy radicals, by photolysis of hexaalkylditin in oxygen or air saturated toluene.

The kinetics of irreversible decay and the thermochemistry of reversible dimerization of $R_3MO_2^{\bullet}$ were investigated by following the influence of time and temperature on the radical concentration after the initiating light was masked (2). Absolute radical concentrations were measured relative to a standard solution of 2,2-diphenyl-1-picrylhydrazyl (DPPH).

Peroxy radicals tagged with ^{17}O were prepared from oxygen enriched to 60% in this isotope (Yeda Research and Development Company).

Results and Discussion

Trialkylsilylperoxy Radicals

The electron spin resonance parameters of the radicals which were formed when triethylsilane, tri-*n*-butylsilane, and tri-*t*-butylsilane were photolyzed in an oxygen saturated solvent containing di-*t*-butyl peroxide (DTBP) are summarized in Table 1. All three silanes gave two radicals, a trialkylsilylperoxy radical centred at $g = 2.027$ to 2.0294 and an alkylperoxy radical near $g = 2.015$. The esr spectrum of the alkylperoxy radical produced from Et_3SiH consisted of two lines separated by ~ 5 G indicating that the unpaired electron was interacting with one proton on the carbon adjacent to the peroxy group (5). An almost identical coupling constant was obtained for the alkylperoxy radical from *n*-Bu_3SiH. These radicals were almost certainly α-substituted secondary alkylperoxy radicals which were generated as shown in reaction [4]

$$[4]\quad t\text{-BuO}^{\bullet} + (RCH_2)_3SiH \rightarrow \begin{cases} (RCH_2)_2SiH\dot{C}HR \xrightarrow{O_2} (RCH_2)_2SiH\underset{\displaystyle R}{C}HO_2^{\bullet} \\ (RCH_2)_3Si^{\bullet} \xrightarrow{O_2} (RCH_2)_3SiO_2^{\bullet} \end{cases}$$

The spectrum of the alkylperoxy radical from *t*-Bu_3SiH had no hyperfine structure and the radical was extremely persistent at low temperatures (~ 173 K). These two observations suggest that this radical was *t*-$BuO_2^{\bullet}$.

The esr spectrum from tri-*tert*-butylsilylperoxy radical tagged with ^{17}O consisted of three superimposed spectra, a central line from *t*-$Bu_3SiO_2^{\bullet}$ and two sets of six lines from *t*-$Bu_3Si^{17}OO^{\bullet}$ and *t*-$Bu_3SiO^{17}O^{\bullet}$. The two oxygen coupling constants are 14.6 and 25.4 G indicating nonequivalent oxygen nuclei. The spectrum with the larger coupling constant can be assigned to *t*-$Bu_3SiO^{17}O^{\bullet}$ and this hyperfine interaction is ~ 1.2 G larger than a_0 for the terminal oxygen in *t*-$BuO_2^{\bullet}$ (6). The smaller oxygen coupling constant is from *t*-$Bu_3Si^{17}OO^{\bullet}$ and it is approximately 3 G smaller than a_0 for *t*-$Bu^{17}OO^{\bullet}$. These differences can be interpreted in terms of a trialkylsilylperoxy radical that has a larger π spin density on the terminal oxygen and a smaller π spin density on the inner oxygen than *t*-$BuO_2^{\bullet}$ (7).

Since the publication of our paper on organogermylperoxy radicals (2) we have measured ^{17}O hyperfine coupling constants for $Ph_3GeO^{17}O^{\bullet}$ ($a_0 = 24.9$ G, $A_{xx} = 91.8$ G) and $Ph_3Ge^{17}OO^{\bullet}$ ($a_0 = 15.4$ G and $A_{xx} = 64.5$ G). The isotropic parameters for this radical are closer to the values of a_0 for *t*-$Bu_3SiO_2^{\bullet}$ than they are to the values of a_0 for *t*-$BuO_2^{\bullet}$, implying that organogermyl- and organosilyl-peroxy radicals have about the same distribution of unpaired spin in the peroxy group and probably the same geometry.[5]

The secondary alkylperoxy radicals prepared from Et_3SiH and *n*-Bu_3SiH decayed more rapidly than $R_3SiO_2^{\bullet}$ and could be removed from the system by annealing at 193 K. $Et_3SiO_2^{\bullet}$ and *n*-$Bu_3SiO_2^{\bullet}$ were extremely persistent between 183 and 223 K and in this temperature range an increase in temperature gave an increase in the radical concentration while a decrease in temperature produced a decrease in the radical concentration with no apparent irreversible radical decay. Trialkylsilylperoxy radicals, therefore, behave like $RO_2^{\bullet}$ (8), $Me_3GeO_2^{\bullet}$, and $Ph_3GeO_2^{\bullet}$ (2) at low temperatures and must exist in equilibrium with bistrialkylsilyl tetroxide.

$$[5]\quad 2R_3SiO_2^{\bullet} \rightleftharpoons R_3SiO_4SiR_3$$

Plots of 2 log $[R_3SiO_2^{\bullet}]$ against the reciprocal of the absolute temperature gave $\Delta H^0 = -11 \pm 2$ kcal mol^{-1} for $Et_3SiO_2^{\bullet}$ and *n*-$Bu_3SiO_2^{\bullet}$. This value for the enthalpy change associated with [5] is very

[5]We were unable to obtain anisotropic parameters for ^{17}O labelled *t*-$Bu_3SiO_2^{\bullet}$ because of extremely low radical concentrations in the frozen solution. The ^{17}O anisotropic interactions associated with g_{yy} and g_{zz} for $Ph_3GeO_2^{\bullet}$ were too small to be resolved (3).

similar to the value for $Me_3GeO_2^{\bullet}$ and $Ph_3GeO_2^{\bullet}$ (2) and it would appear that the central O—O bond strength in $R_3SiO_4SiR_3$ is of the order of 11 kcal mol^{-1} and is about 3 kcal mol^{-1} stronger than the central O—O bond strength in di-*tert*-alkyl tetroxides (8). As is the case with most peroxy radicals ΔS^0 for $R_3SiO_2^{\bullet}$ could only be estimated to be < -30 cal deg^{-1} mol^{-1} because irreversible radical decay commenced before complete dissociation of the dimer.

Triethylsilylperoxy decayed irreversibly at temperatures above 223 K with first-order kinetics and steady-state radical concentrations were linearly dependent on the light intensity. Values of the first-order rate constant $k_{epr}^{(1)}$ are given in Table 2. This radical has a half-life ($\tau_{1/2}$) = 27 s at 252 K and it is about 10 times more persistent than $Me_3GeO_2^{\bullet}$ at this temperature (2). Decays of n-$Bu_3SiO_2^{\bullet}$ exhibited even more unusual kinetics in that plots of the square root of the radical concentration against time in the temperature range 243–273 K were linear indicating an overall concentration exponent of 0.5.

We have previously concluded (2) that the unusual irreversible decay kinetics exhibited by $Me_3GeO_2^{\bullet}$ and $Ph_3GeO_2^{\bullet}$ are caused by the fact that these radicals are in equilibrium with substantial concentrations of dimer and decay irreversibly with true first-order kinetics.

where K_6 is the equilibrium constant for [6] and k_7 is either a true or pseudo-first-order rate constant. The results presented above for $Et_3SiO_2^{\bullet}$ suggest that irreversible decay of this radical can be rationalized by an expression analogous to [8].

It should, however, be noted that a change from zero- to first-order kinetics cannot be invoked to explain the apparent half-order kinetics for the decay of n-$Bu_3SiO_2^{\bullet}$ because even if ΔS_5^0 is -25 cal deg^{-1} mol^{-1} and $\Delta H_5^0 = -11$ kcal mol^{-1} the concentrations of n-$Bu_3SiO_2^{\bullet}$ were too low for $K_5[n$-$Bu_3SiO_2^{\bullet}]$ to approach 1. It is possible that in this case radical decays after the light was switched off were influenced by a thermally unstable compound which accumulated during the light period (9).

We have had little success to date identifying the products from decay of $R_3SiO_2^{\bullet}$ and $R_3GeO_2^{\bullet}$. Ph_3GeOOH undergoes free-radical induced decomposition initiated by thermolysis of di-*tert*-butyl hyponitrite in PhCl at 50°C. The major organogermanium product appeared to be $(Ph_3Ge)_2O$ which offered no clues with regards to reaction mechanisms. Interestingly little or no oxygen was evolved by this reaction supporting a pseudo rather than true first-order radical decay. It should, however, be noted that kinetic electron spin resonance spectroscopy has indicated first-order decay for some tertiary alkylperoxy radicals (10, 11) which are generally believed to undergo bimolecular self-reactions with second-order kinetics (8). Anomalous decay kinetics of this nature have so far not been explained.

Somewhat surprisingly photolysis of oxygen saturated solutions of DTBP and Me_3SiH did not give an esr spectrum even though an intense spectrum is obtained from $Me_3Si^{\bullet}$ in the absence of oxygen (12–15). There was some evidence for a very broad singlet at $g = 2.024$ if the oxygen pressure was reduced below 100 Torr. The signal intensity was, however, much too low for kinetic studies to be performed on this radical. Intuitively it seems very odd that $Me_3SiO_2^{\bullet}$ is so extremely difficult to detect by the esr method while very intense spectra from t-$BuO_2^{\bullet}$ and $Me_3GeO_2^{\bullet}$ are readily obtained.

$Ph_3SiO_2^{\bullet}$ ($g = 2.0271$) was readily prepared from Ph_3SiH and decayed rapidly at temperatures in the range 233 to 183 K with second-order kinetics and $k_{epr}^{(2)} = 1 \times 10^7$ M^{-1} s^{-1} at 167 K and 4.3×10^7 M^{-1} s^{-1} at 218 K. Superficially this radical would appear to decay with kinetics that are different to those for $Ph_3GeO_2^{\bullet}$ and $R_3SiO_2^{\bullet}$. The values of $k_{epr}^{(2)}$ for $Ph_3SiO_2^{\bullet}$ are, however, almost certainly rate constants for reversible dimerization and not rate constants for irreversible decay. Although this radical disappeared rapidly when the light was masked, temperature jump experiments did indicate the presence of a radical–dimer equilibrium.

The aralkylsilylperoxy radical $MeSiPh_2O_2^{\bullet}$ (g = 2.026) was prepared from $MeSiHPh_2$ but photolysis of $PhSiMe_2H$ gave a singlet at g = 2.004. The intensity of this spectrum was, however, too weak to determine the number of oxygen nuclei, if any, associated with this radical by ^{17}O tagging experiments.

Trialkylstannylperoxy Radicals

The esr spectrum from $Me_3SnO_2^{\bullet}$ (g = 2.024), n-$Bu_3SnO_2^{\bullet}$ (g = 2.025), and $Ph_3SnO_2^{\bullet}$ (g = 2.020) consisted of a rather broad singlet with no evidence, even under optimum conditions of high intensity and narrow line width, for satellite lines from interaction of the unpaired electron with ^{119}Sn and ^{117}Sn nuclei. The narrowest line width that we obtained was 8 G and since A_0 is ~15 500 G for Sn (16) the 5s spin density on this nucleus is <0.05% which is at least one tenth the 2s spin density on the central carbon of the *tert*-butylperoxy radical (17).

The line width of n-$Bu_3SnO_2^{\bullet}$ increased from 8 G at 183 K to 15 G at 153 K whereas the line width of alkylperoxy radicals (18) and organogermylperoxy radicals decrease with decreasing temperature in this temperature range. In this respect n-$Bu_3SnO_2^{\bullet}$ behaves (at these temperatures) like most other radicals and line broadening from reduced averaging of anisotropic processes must overshadow line narrowing from spin–orbit relaxation mechanisms (18).

n-$Bu_3SnO_2^{\bullet}$ was extremely long-lived below 193 K and the radical concentration was independent of the temperature in the range 193 to 143 K (Table 3). Clearly this radical does not undergo reversible dimerization at low temperatures. Similar experiments demonstrated that $Me_3SnO_2^{\bullet}$ and $Ph_3SnO_2^{\bullet}$ do not exist in equilibrium with their tetroxides at low temperatures.

Above 183 K $Me_3SnO_2^{\bullet}$ decayed irreversibly with *second-order* kinetics and the second-order rate constant $k_{epr}^{(2)}$, given in Table 4, can be represented by the Arrhenius equation

$$\log (k_{epr}^{(2)}/M^{-1}\,s^{-1}) = (11.8 \pm 1.0) - (7.8 \pm 0.7)/\theta$$

where $\theta = 2.303RT$ kcal mol^{-1}, which is very close to our original preliminary equation (1).

n-$Bu_3SnO_2^{\bullet}$ is more persistent than $Me_3SnO_2^{\bullet}$ and did not begin to decay irreversibly until about 213 K. This radical decayed with second-order kinetics and $\log (k_{epr}^{(2)}/M^{-1}\,s^{-1}) = (12.0 \pm 1.0) - (13 \pm 1)/\theta$. It is, therefore, more persistent than $Me_3SnO_2^{\bullet}$ because of a larger activation energy for self-reaction.

$Ph_3SnO_2^{\bullet}$ also decayed irreversibly with second-order kinetics and $k_{epr}^{(2)} = 6.3 \times 10^4\ M^{-1}\ s^{-1}$ at 238 K, $2.6 \times 10^3\ M^{-1}\ s^{-1}$ at 223 K, and $7.3 \times 10^2\ M^{-1}\ s^{-1}$ at 213 K.

The low reactivity of n-$Bu_3SnO_2^{\bullet}$ towards self-reaction has enabled us to determine absolute reactivities of this radical to two typical alkylperoxy radical scavengers, 2,6-di-*tert*-butyl-4-methylphenol (BMP) and cobalt(II) acetylacetonate. In both cases radical decays were first-order in the presence of excess scavenger (A) and pseudo-first-order rate constants were linearly dependent on the concentration of the scavenger. The second-order rate constants for reaction of n-$Bu_3SnO_2^{\bullet}$ with BMP (k_{BMP}) and $Co(acac)_2$ ($k_{Co(acac)_2}$) were determined over a temperature range and

$$\log (k_{BMP}/M^{-1}\,s^{-1}) = (7.5 \pm 1) - (7 \pm 1)/\theta$$

and

$$\log (k_{Co(acac)_2}/M^{-1}\,s^{-1}) = (12 \pm 1) - (11.5 \pm 1)/\theta$$

The corresponding Arrhenius equations for reaction of t-$BuO_2^{\bullet}$ with BMP and $Co(acac)_2$ are

$$\log (k/M^{-1}\,s^{-1}) = (4.6 \pm 0.2) - (0.8 \pm 0.2)/\theta \quad \text{(ref. 16)}$$

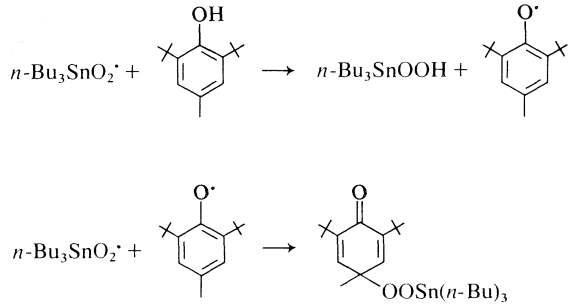
and

$$\log (k/M^{-1}\,s^{-1}) = (8.9 \pm 1) - (4.7 \pm 0.5)/\theta$$

respectively (19, 20).

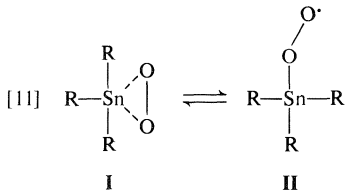
The reaction of n-$Bu_3SnO_2^{\bullet}$ with BMP must involve the rate determining transfer of the phenolic hydrogen to the peroxy radical because rate constants for 2,6-di-*tert*-butyl-4-methyl O—D were smaller than rate constants for normal BMP. This was

substantiated by the observation that 2,6-di-*tert*-butyl-4-methylphenoxy (g = 2.0046, $a_H^{CH_3}(4)$ = 11.23 G, $a_H(3) = a_H(5)$ = 1.64 G) was produced when n-$Bu_3SnO_2^{\bullet}$ ($\sim 10^{-4}$ M) was destroyed in the dark at 200 K by 2,6-di-*tert*-butyl-4-methylphenol (0.08 M). It is probable that a total of two n-$Bu_3SnO_2^{\bullet}$ were destroyed by each molecule of BMP. The overall reaction can probably be represented by



although we have no unambiguous experimental evidence for a stoichiometric factor of 2, or for the production of tri-*n*-butylstannyl hydroperoxide and 1-methyl-1-tri-*n*-butylstannylperoxy 3,5-di-*tert*-butylcyclohexadiene-2,5-dione.

It is apparent from this work that pre-exponential factors and activation energies for reaction of $R_3SnO_2^{\bullet}$ with itself and with a peroxy radical scavenger are significantly larger than the corresponding parameters for reactions of the *tert*-butylperoxy radical. We have previously concluded (3) from ^{17}O labelling experiments that n-$Bu_3SnO_2^{\bullet}$ has a pentacoordinate, trigonal bipyramidal structure in which the vacant Sn 5*d* orbitals are used to form a dative bond with the lone pair of electrons on the terminal oxygen of the peroxy function. Now it is possible that this structure (**I**) is in equilibrium with the more usual structure for a peroxy radical (**II**)



I **II**

and it is the acyclic form which undergoes self-reaction and reaction with BMP and $Co(acac)_2$.

If this is the case, the overall rate constant for self-reaction $k_{epr}^{(2)} = 2K_{11}k_t$ where K_{11} is the equilibrium constant for [11] and $2k_t$ is the termination rate constant for **II**. If we then assume that $2k_t$ has the normal pre-exponential factor of 10^9 M^{-1} s^{-1} and a low activation energy of 2 kcal mol^{-1} we can calculate values of $\Delta S_{11}^0 \sim 5.5$ cal deg^{-1} mol^{-1} and $\Delta H_{11}^0 = 6$ kcal mol^{-1}. Extending this argument to reaction of n-$Bu_3SnO_2^{\bullet}$ with BMP and $Co(acac)_2$ it is possible that the large activation parameters for these reactions result from the fact that k_{BMP} and $k_{Co(acac)_2}$ are made up of K_{11} and the rate constant for reaction of **II** with the scavenger.

Summary

Trialkylsilylperoxy radicals behave like alkylperoxy and organogermylperoxy radicals at low temperatures and exist in equilibrium with a tetroxide. The thermodynamic parameters for this reversible dimerization are closer to the values for organogermylperoxy radicals than alkylperoxy radicals. Irreversible radical decays follow first or lower order kinetics and in this respect they behave like organogermylperoxy radicals.

^{17}O hyperfine splitting constants indicate that the two oxygen nuclei in $R_3SiO_2^{\bullet}$ are magnetically nonequivalent and that these radicals have more π spin density on the terminal oxygen than alkylperoxy radicals.

Trialkylstannylperoxy radicals do not exist in equilibrium with bistrialkylstannyl tetroxide and decay irreversibly with clean second-order kinetics. These radicals react with typical alkylperoxy radical scavengers but they do so more slowly than alkylperoxy radicals. Arrhenius parameters and activation energies for self-reaction and destruction by a radical scavenger suggest that $R_3SnO_2^{\bullet}$ exist primarily in a form in which both oxygen atoms are bonded to the tin atom and that this peroxide structure is in equilibrium with the more usual acyclic peroxy structure.

On the basis of the magnetic resonance parameters for n-$Bu_3SnO_2^{\bullet}$ it is possible to conclude that the unpaired electron occupies a π orbital made up exclusively of $O(2p_z)$ atomic orbitals and that the two oxygen nuclei are equivalent. These radicals which can be considered to have a formal valency of $Sn^{IV}O_2^-$ are not analogous to cobalt, iron, or chromium dioxygen complexes which have a high spin density on nonequivalent oxygens (21, 22) or to manganese dioxygen complexes which have low spin density on equivalent oxygen nuclei (23). Trialkylstannylperoxy radicals can, therefore, be considered to be examples of a new class of dioxygen–metal complexes.[6]

RAMANATHAN GOPAL, W. DAVID CHANDLER, and BEVERLY E. ROBERTSON. Can. J. Chem. **57**, 2767 (1979).

The structure of 2-(4′-carbomethoxy-2′-aminophenoxy)-1,3,5-trimethylbenzene, $C_{17}H_{19}NO_3$, has been determined by X-ray diffraction. The crystals are monoclinic, $a = 23.895(9)$, $b = 7.821(4)$, $c = 16.641(8)$ Å, $\beta = 99.26(3)$, $C2/c$, $Z = 8$. The integrated intensities of 3540 independent reflections were measured on a four-circle diffractometer. A total of 2403 of these reflections was used in the refinement to give a final least-squares weighted residual of 0.069 and a conventional R factor of 0.096. The molecule adopts the skew-amino-*distal* conformation as does the analogous *ortho*-nitro-substituted compound. The lengths of the bonds from the amino substituted ring and the mesityl ring are 1.404(3) and 1.376(4) Å respectively and the torsional angles about those bonds are ± 5.8 and $\mp 79.5°$. The angle subtended at the bridging oxygen atom is 120.1°. Variations in the endocyclic angles subtended at substituted ring carbon atoms in this and other bridged diphenyls may be understood in terms of a combination of hybridization effects, and the spatial requirements of the bonds to substituents.

RAMANATHAN GOPAL, W. DAVID CHANDLER et BEVERLY E. ROBERTSON. Can. J. Chem. **57**, 2767 (1979).

Par diffraction de rayons-X, on a déterminé la structure du (carbométhoxy-4′-aminophénoxy-2′)-2 triméthyl-1,3,5 benzène, $C_{17}H_{19}NO_3$. Les cristaux sont monocliniques $a = 23.895(9)$, $b = 7.821(4)$, $c = 16.641(8)$ Å, $\beta = 99.26(3)$, $C2/c$, $Z = 8$. On a mesuré, avec un diffractomètre à quatre cycles, les intensités totales de 3540 réflexions indépendantes. On a utilisé avec soins 2403 de ces réflexions pour obtenir par la méthode des moindres carrés un résidu moyen final de 0.069 et un facteur conventionnel de 0.096. La molécule adopte la conformation amine-*gauche* la plus *éloignée* comme le font les composés ayant un substituant nitro en position *ortho*. Dans les cycles substitués par une amine et dans le cycle mésityle, les longueurs de liaisons sont respectivement 1.404(3) et 1.375(4) Å et les angles de torsion autour de ces liaisons sont de ± 5.8 et $\mp 79.5°$. L'angle sous-tendu à l'atome d'oxygène du pont est de 120.1°. Les variations des angles endocycliques sous-tendus aux atomes de carbone du cycle substitué dans ce composé et dans d'autres diphényles pontés peuvent être compris en fonction d'une combinaison d'effets d'hybridation et d'arrangements spatiaux des liaisons par rapport aux substituants.

Introduction

In previous parts of this series we have considered the role of substituents and the bridging group in determining the conformation of bridged diphenyl compounds (1) and have established that in most cases proton chemical shifts may be used to infer the approximate conformation of bridged diphenyl compounds and to study their internal rotations (2). Most of the compounds studied to date have been tri-*ortho*-substituted with the single *ortho* substituent on one ring being a nitro group. In the compound whose structure is reported here the single substituent is an amino group. The electronic properties of the latter substituent are quite different from those of the nitro group and we therefore will expect a change in the ring distortions associated with these effects and in the interaction between the NH_2 group and the bridging group.

Paulus has recently determined the structures of 3-trifluoromethyl-1-(2′-carboxy-6′-methylanilino)-benzene (**I**) and 3-trifluoromethyl-1-(2′-carboxy-4′-methylanilino)benzene (**II**) (3). Both compounds show evidence of an intramolecular N—H---O hydrogen bond. The strength of the hydrogen bond is not the same in the two compounds, as manifested both by their biological activity and by differences in their observed conformations. The six-atom ring formed by the NH bridge, the carbonyl group, and the two ring carbon atoms, to which the NH and COOH groups are bonded, is planar in **II**. This causes one of the torsional angles (associated with

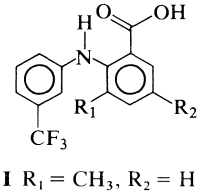
[2]Revision received July 10, 1979.

0008-4042/79/202767-08$01.00/0

the COOH substituted ring) to be 35.9° while the other ring is nearly coplanar with the bridging plane, with a torsional angle of 8.6°. Using our nomenclature the conformation is planar-carboxy-*distal*-trifluoromethyl-*proximal*, but borders on the twist conformation.

The formation of the hydrogen bond is therefore crucial in determining the conformation of the aforementioned molecule. In **I** the methyl group prevents the formation of a planar six-membered ring and weakens the hydrogen bond, thereby changing the biological activity of this compound from that of the former. The torsional angle associated with the COOH substituted ring becomes 60.1° and that associated with the other ring 14.1°. The conformation then is skew-trifluoromethyl-*distal*, but also borders on the twist conformation. Intramolecular hydrogen bonding involving the bridging group is therefore a factor that must be considered in determining the probable conformation of bridged diphenyl compounds. The bridged diphenyl whose structure is reported here offers the possibility for the formation of an intramolecular hydrogen bond with the bridging atom playing the role of the hydrogen bond acceptor.



I $R_1 = CH_3$, $R_2 = H$
II $R_1 = H$, $R_2 = CH_3$

In previous reports of the structures of bridged diphenyls we have noted systematic deviations in the symmetry of the phenyl groups from the D_{6h} symmetry of unsubstituted benzene. We have argued that, in large part, these deviations are associated with the electronic properties of the substituents of the ring. A comprehensive treatment of the relation between electronic properties and ring distortion has appeared recently in a series of papers by Domenicano, Vaciago, Coulson and co-workers (4). They find that spatial effects, conjugation, and perturbations to the hydridization of ring carbon atoms associated with the properties of the substituent at that carbon atom may all affect the endocyclic angle. We will attempt to rationalize the systematic variations in the endocyclic angles of 2-(4′-carbomethoxy-2′-aminophenoxy)-1,3,5-trimethylbenzene and the other bridged diphenyl compounds whose structures have been reported in earlier papers of this series.

Experimental

2-(2′-Nitro-4′-carbomethoxyphenoxy)-1,3,5-trimethylbenzene was reduced to 2-(4′-carbomethoxy-2′-aminophenoxy)-1,3,5-trimethylbenzene using W2 Raney nickel and hydrogen in absolute ethanol according to the method used by Bergman and Chandler (5). The mp after four recrystallizations from absolute ethanol was 115–116°C. A colourless rectangular sample with approximate dimensions 0.4 × 0.4 × 0.7 mm was chosen for data collection on a Picker FACS I automated four-circle diffractometer equipped with a graphite monochromator. The cell constants were determined by a least-squares fit to the positions of 22 reflections between the 2θ settings of 37 and 43° where the MoKα_1 and MoKα_2 peaks were well resolved. The estimated standard deviations in the cell constants are taken directly from the least squares.

The crystal data are as follows:

$C_{17}H_{19}NO_3$ fw = 285.19
Monoclinic, $C2/c$, a = 23.895(9), b = 7.821(4), c = 16.641(8) Å, β = 99.26(3)°, ρ_o = 1.23(1) g cm^{-3} (flotation), ρ_c = 1.237 g cm^{-3}, Z = 8, $F(000)$ = 1216 e, μ(MoKα) = 0.875, λ(MoKα_1) = 0.70926 Å, T = 22 ± 2°C.

The integrated intensities of 3540 independent reflections with 2θ values between 2 and 55° were collected with MoKα radiation using the θ–2θ scan mode, a minimum base width of 3.0° in 2θ and 40 s background counts at each limit of the scan, and a scan rate of 2° min^{-1}. The data were reduced to structure factors using standard procedures. No corrections were made for extinction or absorption. The standard deviation in $|F_o|$, $\sigma(F_o)$, was calculated from $\sigma(F_o) = 1.0 + 0.01|F_o| + \sigma'(F_o)$ where $\sigma'(F_o)$ is based on counting statistics.

The scattering factors for carbon, oxygen, and nitrogen atoms were taken from those given by Cromer and Mann (6). The scattering factor for hydrogen was taken from Stewart, Davidson, and Simpson (7). The systematic extinctions ($h + k = 2n + 1$; $h0l$, $l = 2m + 1$) indicate the space groups $C2/c$ or Cc. The average values of $|E|$ and $|E^2 - 1|$ were 0.739 and 1.041 respectively, and therefore $C2/c$ was assumed to be the correct space group. The 446 reflections with $|E| > 1.48$ were used to solve the structure using the logical symbolic addition method.[3] The E-map calculated from the solution with the highest figures of merit yielded all the non-hydrogen positions. The structure was refined anisotropically by least-squares and the hydrogen atoms were then found from a difference Fourier map. The 2459 reflections for which $|F_o| > \sigma(F_o)$ were used in the final cycles of refinement with the least-squares weight, w, calculated as $w = \sigma(F_o)^{-2}$.

The final values of R_w and the conventional R factor were 0.069 and 0.096 respectively. The relatively large residuals reflect the low counting rates used during data collection and the inclusion of many weak reflections in the least squares. The observed and calculated structure factors have been placed in the Depository of Unpublished Data.[4] The final positional and thermal parameters are listed in Table 1, with standard deviations. The bond lengths, bond angles, and atomic numbering are given in Fig. 1.

Discussion of the Structure

The angles between the planes of 2-(4′-carbomethoxy-2′-aminophenoxy)-1,3,5-trimethylbenzene

[3]The direct methods program LSAM, written by Germain and Woolfson (8), was used for structure solution. The program FORDAP written by Zalkin (9) was used for all Fourier calculations. The program ORFLS, written by Busing *et al.* (10), was used for least-squares refinement. Stereograms were prepared with the aid of the program ORTEP, written by Johnson (11).

[4]Complete set of tabular data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

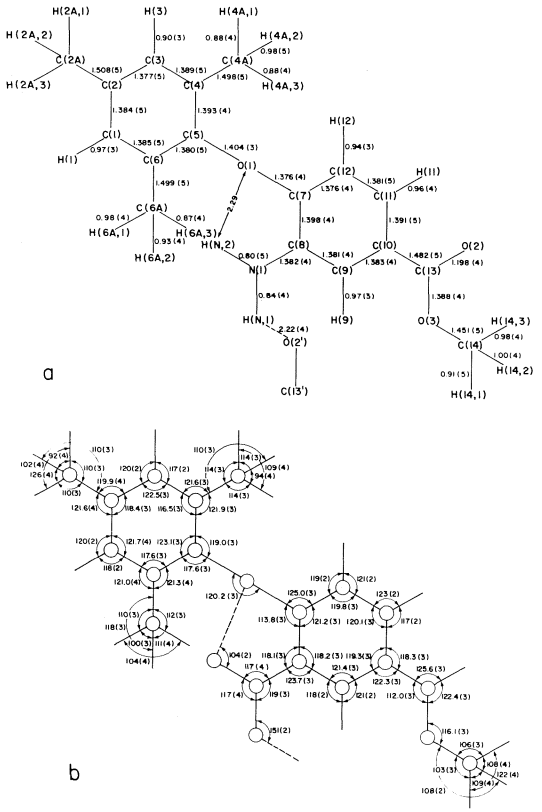


FIG. 1. (*a*) Bond lengths (Å) and atom labeling. (*b*) Bond angles (deg). The numbers in parentheses are estimated standard deviations.

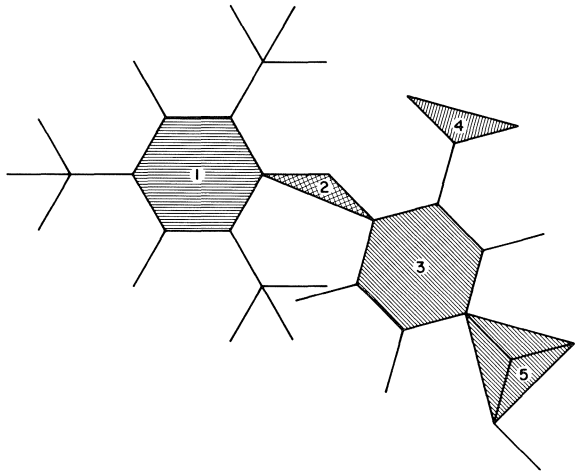

FIG. 2. Labeling of the least-squares planes.

as defined in Fig. 2 are given in Table 2. The molecule has the skew-amino-*distal* conformation. The packing of the molecules is shown in Fig. 3. The molecules pack in pairs with the amino-substituted rings of a pair coplanar and separated by 3.4 Å. The pairs are repeated by the centers of symmetry at $[\frac{1}{2}00]$ and $[\frac{1}{2}0\frac{1}{2}]$ to form a continuous stack in the *c* direction. The dihedral angles *1,2* and *2,3* which correspond to the torsional angles ϕ[C(7)—O(1)—C(5)—C(4)] and ψ[C(5)—O(1)—C(7)—C(12)] are $\pm 79.5°$ and $\mp 5.8°$ respectively. The two sets of signs refer to the two enantiomers which must be present in a centrosymmetric space group. In all of the structures which we have studied to date the angles occur in (+,+) and (−,−) pairs (1). In all conformations, the pairing of equivalent signs reduces the steric interaction between *ortho* hydrogen atoms or substituents and the π electrons and *ortho* hydrogen atoms or substituents of the other ring.

A feature of the structure which relates to the unusual pairing of the signs of the torsional angles is the nature of the distortions of the phenyl rings from idealized symmetry. The distance of the *proximal-ortho* hydrogen atom above the plane of the mesityl ring is 2.40 Å, which is similar to the value in other bridged diphenyls, even though the signs of the torsional angles in the other compounds are more favourably disposed to maintaining this distance at an adequate value. The distance would also be increased by (*i*) increasing the C(5)—O(1)—C(7) angle, and (*ii*) a bending of the amino-substituted ring at the bridgehead carbon [C(7)] away from the mesityl ring over the value that would occur in an undistorted molecule. The C(5)—O(1)—C(7) angle (120.1°) compares with an average of 119.0° for the eight other independent bridged diphenyl ether molecules whose structures have been determined as part of this series. The bending at the bridgehead carbon atom is 5.6° which compares with an average of 2.8° for the other eight ether molecules. Therefore both effects appear to be present.

The aforementioned large bending angle at the bridgehead carbon atom would appear to be facilitated by the presence of the amino group in the *distal-ortho* position. The amino group itself is bent 2.8(4)° towards the ether oxygen atom. {([N(1)—C(8)—C(9)] − [N(1)—C(8)—C(7)])/2 = 2.8°.} In other cases of small *ortho* substituents (Cl or CH_3) in bridged diphenyl ethers the equivalent angle differs insignificantly from zero. For nitro groups, carbomethoxy groups, or large aryl groups, the sense of the bending is away from the ether oxygen atom. The bending of the groups at both C(7) and C(8) therefore suggests a positive interaction between those groups; i.e. between the atom H(N2) and the lone pair on O(1). Other relevant parameters are: [H(N2)—O(1)] = 2.29(4) Å, [N(1)—O(1)] = 2.606(4) Å, [N(1)—H(N2)—O(1)] = 104(2)°.

We compare this geometry with a related one in 4-hydroxy-L-proline, the structure of which has been determined by neutron diffraction (12). The [H—O] distance and N—H---O angle are 2.082(3) Å and 113.2(2)° respectively, indicating the presence of an

intramolecular hydrogen bond. In 2-(4′-carbomethoxy-2′-aminophenoxy)-1,3,5-trimethylbenzene the amount by which the [H(N2)—O(1)] distances is less than the sum of Van der Waals radii of the two atoms involved (ca. 0.1 Å) is not sufficient to indicate the presence of a hydrogen bond, according to the usual conventions of nomenclature. Nevertheless, the interaction appears to be of sufficient strength to affect the conformation of the molecule and perhaps thereby its molecular packing.

The other amino hydrogen atom forms a hydrogen bond to the carbonyl oxygen atom, O(2), of an adjacent molecule removed by one *b* translation from the first. The [N(1)—O(2)] and [H(N1)—O(2)] distances are 2.984(4) and 2.22(4) Å respectively. The next shortest intermolecular distance involving at

least one non-hydrogen atom is 2.71(4) Å. The [C(13)—O(2)] bond length is 1.198(4) Å which compares with 1.187(3) Å in the similar nitro-substituted compound (1) where there is no opportunity for hydrogen bonding.

Substituent Effects and Endocyclic Angles

The difference in the bond lengths from the bridgehead carbon atoms to the ether oxygen atom is 0.028 Å. This value [Δ(C—G)] is compared with others from related bridged biphenyls in Table 3 which also summarizes the endocyclic angles of several bridged diphenyl compounds. Compound **4** in Table 3 is that reported here. The details of the structure of compound **2** will be reported shortly (13). The structures of all the other compounds have been reported previously (1). The angles and substituent positions in Table 3 are defined in Fig. 4. Some values given in Table 3 are averages from two molecules in the asymmetric unit. The average standard deviation in a bond length is 0.003 Å. The average standard deviation in a bond angle is 0.3°.

Among the diphenyl ethers of Table 3 (compounds **1** through **5**), the C—O distances to the bridging oxygen atoms (and therefore the values of Δ(C—O)) appear to be related to the electron withdrawing or donating ability of substituents on the phenyl ring to which the C atom belongs.

The electron withdrawing or donating ability of a substituent may be inferred from the concept of charge dependent electronegativity as expounded by Huheey (14). The electronegativity is given by $\chi = a + b\delta$ where δ is the transferred partial charge, *a* is the inherent electronegativity, and *b* is the charge coefficient. The electron withdrawing or donating ability (i.e., the value of δ) is then determined by both the difference in inherent electronegativities and the charge coefficient of the substituent, with small values of the charge coefficient leading to large values of δ.

We observe that the compound whose structure is reported here (compound **4**) has weakly electron withdrawing substituents R_2 and R_3 and the largest C_7—O length among the ethers. Compound **1** has

two strong electron withdrawing substituents and has the shortest C_7—O distance. The largest C_5—O distance occurs for compound **1** for which R_1 is the electron donor $(CH_3)_3C$, and which has a very low charge coefficient. The shortest C_5—O distance occurs with compound **3** for which R_1 is Cl which is weakly electron withdrawing. We attribute this variation in bond lengths to the bridging oxygen atom to variation in the conjugative effects between electrons on the oxygen atom and the π electrons of the ring. The unsubstituted ring (compound **2**) shows a C_5—O distance similar to that of the mesityl rings (compounds **4** and **5**).

In the case of the C=O and CH_2 bridging groups, the variations in the bond lengths to the bridging atom are small as expected. In the case of the SO and SO_2 bridges, the greater interaction is between the electron donating phenyl ring and the bridge. The shorter bond length is therefore between the mesityl ring and the bridging atom.

Several authors have recognized the effect of the electronegativity of the substituent on the hybridization of the substituted carbon atom and on its endocyclic angles, but the most complete discussion of this and related phenomena is probably that of Domenicano and co-workers (4). They identify (*i*) a spatial effect which reduces the endocyclic angle at substituents by 2.0 to 2.5°, (*ii*) a hybridization effect, previously described by Bent and by Walsh (15), that increases the endocyclic angle at electron withdrawing substituents and decreases it at electron donating substituents, and (*iii*) a conjugation effect which decreased the endocyclic angle at all substituents which conjugate with the π electrons in the ring. We would add a fourth (*iv*) effect which is based on the fact that in a planar six-membered ring, the angles must add up to 720°.

We now wish to determine if these four phenomena can be used to explain adequately the deviation of the endocyclic angles from 120° in the ten compounds listed in Table 3, and if so, their relative importance.

We note first the values of ϕ_2 and the average of the two similarly affected angles, ϕ_4 and ϕ_6, in compounds **4** to **10** inclusive. These angles may be influenced by the spatial effect, the hybridization effect, and for $(\phi_4 + \phi_6)/2$, the deviations of angle ϕ_5 from 120°. In compound **2** only the latter effect applies. It would appear that substitution by a methyl group or an increase in ϕ_5 from 120° cause similar and small decreases in the average of ϕ_4 and ϕ_6. The angle ϕ_2 is also decreased slightly by the substitution of methyl at C_2. The relative importance of the spatial effect and the hybridization effect for methyl substituents cannot be inferred from these observations. However, the greater deviations of the angles ϕ_2 and $(\phi_4 + \phi_6)/2$ in the case of compound **1** can be attributed to the greater electron donating ability of *tert*-butyl over that of the methyl substituents. In compound **1**, the Cl substituents are electron acceptors and lead to angles greater than 120°. The average of the two similar angles ϕ_1 and ϕ_3 adjusts to accommodate the changes at the substituted carbons (fourth effect).

Among the five diphenyl ethers, the angle ϕ_5 correlates closely with the length of the C_5—O bond. In compounds **1**, **2**, **4**, and **5** the angle is large and it would appear that the bridging oxygen atom, the other ring, and its electron withdrawing substituents are, from the point of view of C_5, a large electron withdrawing substituent with a low charge coefficient.

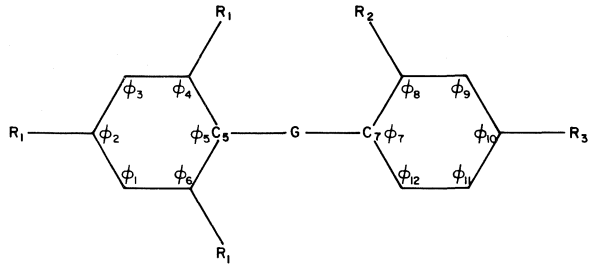

FIG. 4. Labeling of substituents and endocyclic angles.

In the Cl substituted ether (compound **3**), $(\phi_4 + \phi_6)/2$ is greater than 120°, thus forcing ϕ_5 to be smaller than 120°. In the other five bridged diphenyls the electron withdrawing effect at C_5 is smaller and the value of ϕ_5 appears to be more closely dependent on $(\phi_4 + \phi_6)/2$. The large value of ϕ_5 for the ethers reinforces the decrease of $(\phi_4 + \phi_6)/2$ below 120° with the result that $\phi_2 - (\phi_4 + \phi_6)/2$ averages to 1.6° and for the remaining bridged diphenyls it averages to 0.1°.

Carbomethoxy substituents tend to give endocyclic angles less than 120° even though carbomethoxy is a weakly electron withdrawing substituent. We therefore assume the presence of a combination of the spatial effect and the hybridization effect with the former being the larger. Other endocyclic angles at substituted ring carbon atoms are presumably influenced in a similar manner and the electron withdrawing or donating substituents should therefore be viewed as promoting deviations from a base endocyclic angle of approximately 118°, a value consistent with the observations of Domenicano and co-workers (4). Therefore the angles ϕ_8 and ϕ_{10} properly reflect the electronegativity of the substituents at their respective carbon atoms. Furthermore they do not seem to be affected in any systematic way by other substituents or the bridging group. An examination of those endocyclic angles which might be expected to be affected by conjugation (ϕ_2 and ϕ_5 for compounds **7** and **8**, ϕ_7 and ϕ_{10} for compounds **1** through **5**) yields no evidence of conjugation effects.

We conclude that the most important factors in determining distortions in endocyclic angles in these compounds is the hybridization effect of electron donating or withdrawing substituents. The spatial demands of the bonds from the substituent to the ring and the indirect effect of highly distorted endocyclic angles on neighboring endocyclic angles have secondary importance.

TABLE 3. Variations in the bridging bond lengths and endocyclic angles associated with substituent effects. The angles (deg) and atomic distances (Å) are labeled in Fig. 4

Further studies on the use of the thallium salt of *N*-hydroxysuccinimide for the preparation of succinimidyl esters[1]

ALENKA PAQUET

Food Research Institute, Canada Department of Agriculture, Ottawa, Ont., Canada K1A 0C6

Received April 6, 1979

ALENKA PAQUET. Can. J. Chem. **57**, 2775 (1979).

An efficient preparation of four alkyl (ethyl, *tert*-butyl, *p*-nitrobenzyl, trichloroethyl) succinimidyl carbonates from the thallium salt of *N*-hydroxysuccinimide and corresponding chloroformates is described. The general utility of trichloroethyl succinimidyl carbonate is demonstrated by its reaction with glycine to give trichloroethoxycarbonylglycine. The preparation of succinimidyl esters of numerous fatty acids using the thallium salt of *N*-hydroxysuccinimide and the corresponding acid chlorides is described. The advantage of this method over the *N*,*N*′-dicyclohexylcarbodiimide method for the preparation of these esters is demonstrated. Succinimidyl *p*-toluenesulfonate and chloroacetate were also prepared.

ALENKA PAQUET. Can. J. Chem. **57**, 2775 (1979).

On décrit une préparation efficace de quatre alkylcarbonates de *N*-hydroxysuccinimide (éthyle, *tert*-butyle, *p*-nitrobenzyle, trichloroéthyle) à partir des sels de thallium de la *N*-hydroxysuccinimide et des chloroformates correspondants. On utilise la préparation de la trichloroéthoxycarbonylglycine à partir de trichloroéthylcarbonate de *N*-hydroxysuccinimide pour faire ressortir l'utilité de ce dernier. On décrit également la préparation des esters de *N*-hydroxysuccinimide de plusieurs acides gras à partir du sel de thallium de la *N*-hydroxysuccinimide et des chlorures d'acide correspondants. On met en évidence l'avantage de cette méthode sur celle à la *N*,*N*′-dicyclohexylcarbodiimide. On a également préparé les *p*-toluènesulfonate et chloroacétate de *N*-hydroxysuccinimide.

[Traduit par le journal]

We have recently described a simple preparation of the thallium salt of *N*-hydroxysuccinimide (TlONSu) and its reaction with acid chlorides, which affords the corresponding succinimidyl (ONSu) esters in high yields (1). Within the extension of the research in this laboratory, we have explored the TlONSu for further preparation of various succinimidyl esters.

Alkyl succinimidyl carbonates (**1**) can be used for facile introduction of urethane type (ROCONH—) protecting groups in amino acid chemistry, essentially as described for acylation of amino acids by ONSu esters (2–4). The TlONSu provides a convenient starting material for the preparation of these compounds. We report here the preparation of two known compounds, ethyl succinimidyl carbonate, **1***a* (5), and *tert*-butyl succinimidyl carbonate, **1***b* (5, 6), and two new analogues, *p*-nitrobenzyl succinimidyl carbonate, **1***c*, and trichloroethyl succinimidyl carbonate, **1***d*. The succinimidyl carbonates (**1***a–d*) were prepared from corresponding chloroformates and TlONSu in an inert solvent as described previously for the preparation of benzyl succinimidyl carbonate (1). All chloroformates were commercially available except for *tert*-butyl chloroformate, which was prepared *in situ* from phosgene, *tert*-butanol, and pyridine at −30°C (7, 8). In addition, **1***b* was prepared by reaction of succinimidyl chloroformate with *tert*-butanol. The succinimidyl chloroformate was obtained in 90% yield from TlONSu and phosgene. This yield is superior to that reported for the preparation of this compound using KONSu and phosgene (5). The compounds **1** are described in Table 1.

The utility of **1***a* and **1***b* has been demonstrated previously (5, 6, 9). The compound **1***d* could be used instead of trichloroethyl chloroformate for the introduction of the trichloroethoxycarbonyl group (10, 11), namely for the selective protection of an amino group in the presence of a hydroxy group. A general example of the utility of **1***d* is described in this communication by its reaction with glycine in the presence of 1 equivalent of sodium bicarbonate giving an 85% yield of trichloroethoxycarbonylglycine.

The TlONSu was also found to be useful for the preparation of ONSu esters of fatty acids (**2**). Its reaction with corresponding acid chlorides does not give any side products and affords high yields. Thus, succinimidyl butyrate (**2***a*) and succinimidyl caproate (**2***b*) were prepared by refluxing equivalent amounts of TlONSu and butyryl and caproyl chlorides for 2–4 h giving yields of 88 and 90%, respectively. When working with long and medium chain fatty

acids, milder reaction conditions (room temperature and shorter reaction time) can be used, giving the pure ONSu esters in 92–95% yields after recrystallization from ethanol.

We have found that the TlONSu method is superior to the *N*,*N*′-dicyclohexylcarbodiimide (DCC) method for the synthesis of these esters. The DCC method gives high yields of ONSu esters of acylamino acids (2, 3, 4), but it is less convenient for work with the less reactive fatty acids. When fatty acids were coupled with *N*-hydroxysuccinimide using DCC, several side products were formed in all cases. Moreover, complete removal of the *N*,*N*′-dicyclohexylurea (DCU) was not always possible. Purification of ONSu esters by repeated crystallization gave satisfactory results with medium and long chain fatty acids (starting with caprylic), but was not efficient when working with shorter fatty acids. For example, succinimidyl butyrate (**2***a*) was prepared from butyric acid and *N*-hydroxysuccinimide, using DCC in ethyl acetate, according to the usual procedure for the preparation of ONSu esters of acylamino acids (2, 3, 4). The DCU was separated by filtration and the material remaining in solution was isolated by fractional crystallization. The first compound which crystallized was identified as *N*-butyryl-*N*,*N*′-dicyclohexylurea on the basis of its melting point, infrared spectrum, and elemental analysis. The low melting **2***a* could not be completely freed from *N*-acylurea, despite the fact that only a small amount of it was formed during the reaction. Attempts to purify **2***a* by means of column chromatog-

[a]Infrared and nmr spectra of all compounds were in accord with their structures. Compounds 2*c*–2*h* prepared using DCC method were obtained in yields 85–88%. Compounds 2*a*–2*j* prepared using TlONSu method were obtained in yields 90–95%.
[b]The elemental analyses of ONSu esters were obtained by analyzing products from the TlONSu method. The esters obtained using DCC method were identified by comparing their R_f values on tlc, physicochemical constants, and infrared spectra with the products obtained using the TlONSu method.

raphy failed due to its partial decomposition. Thus, sufficient quantities of pure **2***a* for further work could not be obtained using the DCC method.

N-Acylurea formation has previously been observed during peptide synthesis (12, 13). It arises from the intermediate *O*-acylisourea by internal nucleophilic substitution (14). It is likely that the formation of fatty *N*-acylurea assumes the same pathway. The fatty acid chain must interfere with the reaction of the intermediate *O*-acylisourea with the *N*-hydroxysuccinimide, thus promoting intramolecular reaction to give the *N*-acylurea.

When **2***a* was prepared in dioxane, another side-product precipitated out together with the *N*-acylurea and was isolated by fractional crystallization from dioxane. On the basis of its melting point and elemental analysis, this compound is considered to be the succinimidyl ester of succinimidoxycarbonyl-β-alanine, a compound previously isolated by others during the preparation of ONSu esters of less reactive amino acids (15). The structure of this compound has been established by Gross and Bilk (16), who also showed that it is formed from *N*-hydroxysuccinimide, itself, in the presence of DCC, and that it can be expected to form during the conversion of slowly reacting acids into their ONSu esters using DCC.

Succinimidyl ester of succinimidoxycarbonyl-β-alanine was also detected by tlc during the preparation of **2***a* in ethyl acetate, but was not isolated.

The next even chain fatty acid derivative, succinimidyl caproate (**2***b*) behaved similarly to **2***a* during purification. Compound **2***b* was eventually obtained in a pure state, in 78% yield after three recrystallizations from ethanol. However, yields varied due to partial decomposition during repeated crystallization. The esters obtained by the two different methods are described in Table 2.

Two other esters, succinimidyl chloroacetate (**2***i*) and *p*-toluenesulfonate (**2***j*) were also obtained in high yields using TlONSu and chloroacetyl and *p*-toluenesulfonyl chloride respectively. Compound **2***i* may in some cases conveniently replace chloroacetyl chloride for the introduction of the chloroacetyl group in amino acid chemistry (17). Furthermore, there exist claims in the patent literature to the use of succinimidyl chloroacetate as a starting material for the preparation of succinimidyl esters of various acids (18). Thus, the simple preparation of **2***i* may bring some improvement in this field as well.

We have previously described the acylation of the side chain amino group of α-unprotected lysine using succinimidyl palmitate in the presence of triethylamine (1). Further studies have shown that for work with shorter fatty acids, sodium hydroxide should be used instead of triethylamine in some cases (results to be published). Reinvestigation of the previously reported reaction between lysine and benzyl succinimidyl carbonate in the presence of methanolic potassium hydroxide (1) leads us to the conclusion that the yield reported (85%) was higher than that which can actually be obtained. The product of the reaction was not, in fact, homogeneous.

Experimental

Melting points were determined on a Koffler Block and are uncorrected. Nuclear magnetic resonance spectra were recorded on a Varian T-60 spectrometer in deuteriochloroform. Infrared spectra were determined with a Beckman-IR-20 spectrometer in chloroform. Thin layer chromatography was carried out on precoated plates (Analtech, Inc., Newark, DE,

U.S.A.). Fatty acid chlorides were purchased from NU CHEK PREP, Inc., Elysian, MN, U.S.A.

Derivatives **2***b* and **2***c* were synthesized using the TlONSu method as indicated for **2***a*. The esters **2***d–h* were prepared using this method as described for the preparation of succinimidyl myristate **2***f*. The preparations of ONSu esters using DCC were carried out as described for the preparation of succinimidyl myristate **2***f*.

*Succinimidyl Butyrate (***2**a*)*

To a stirred solution of 2.13 g (20 mmol) of freshly distilled butyryl chloride in 25 mL of dry methylene chloride was added 6.36 g (20 mmol) of TlONSu in small portions. The mixture was refluxed and stirred under a stream of nitrogen for 3–4 h (until the tlc analysis did not show any chloride present). The thallium chloride was removed by filtration through a Celite pad, resuspended in methylene chloride, and filtered. The combined filtrate was washed with 10% aqueous sodium bicarbonate and water, dried over sodium sulfate, and the solvent was evaporated under reduced pressure. The oily residue upon addition of ether and chilling gave 32.5 g (88%) of **2***a*.

*Succinimidyl Myristate (***2**f*) using TlONSu*

A mixture of 2.46 g (10 mmol) of myristyl chloride and 3.18 g (10 mmol) of TlONSu in 20 mL of dry methylene chloride was stirred at room temperature for 1–2 h (until the tlc analysis did not show any chloride present). Workup as described for **2***a* followed by crystallization from ethanol gave **2***f* in 95% yield.

*Succinimidyl Myristate (***2**f*) using DCC*

To a stirred solution of 5.8 g (50 mmol) of *N*-hydroxysuccinimide and 11.42 g (50 mmol) of myristic acid in 75 mL of dioxane was added 10.3 g (50 mmol) of DCC in small portions. The mixture was kept overnight at 0°C and then DCU was filtered off. The solvent was removed under reduced pressure and the crude product was recrystallized twice from ethanol to give 13.8 g (85%) of **2***f*.

Isolation of N-*Butyryl*-N,N′-*dicyclohexylurea*

To a suspension of 26.4 g (0.23 mol) of *N*-hydroxysuccinimide in 980 mL of ethyl acetate, 20.2 g (0.23 mol) of freshly distilled butyric acid and 4.74 g (0.23 mol) of DCC were added. The mixture was stirred at room temperature for 1 h and kept at 5°C overnight. The DCU was removed by filtration, and two further crops were separated from the concentrated filtrate. Three crystallizations of the residue from ether gave 3.77 g of *N*-butyryl-*N*,*N*′-dicyclohexylurea. A sample, recrystallized from dioxane had mp 149°C. Infrared: 1510–1540, 1660, 1705 cm^{-1}. *Anal.* calcd. for $C_{17}H_{30}N_2O_2$: C 69.34, H 10.27, N 9.51; found: C 69.33, H 10.13, N 9.70.

*Isolation of Succinimidyl Ester of Succinimidoxycarbonyl-*β*-alanine*

This compound was isolated from the attempt to synthesize **2***a* in dioxane using 0.023 mol of each reagent essentially as described above for the synthesis of **2***f* using DCC. After the removal of DCU by filtration and concentration of the filtrate, 370 mg of a mixture of *N*-acylurea, DCU, and succinimidoxycarbonyl-β-alanine *N*-hydroxysuccinimide ester was obtained. Fractional crystallization from dioxane gave 250 mg of the pure β-alanine derivative, mp 163–165°C (lit. (16) mp 156–163°C, dioxane–ether or acetonitrile–ether). *Anal.* calcd. for $C_{12}H_{13}N_3O_8$: N 12.83; found: N 12.48.

*Succinimidyl Chloroacetate (***2**i*)*

A suspension of 112.9 mg (1 mmol) of chloroacetyl chloride and 318.4 mg (1 mmol) of TlONSu in 3 mL of dry chloroform was stirred at room temperature for 2–3 h. The thallium chloride was filtered off, resuspended in chloroform, and filtered. The combined filtrate was washed with 10% aqueous sodium bicarbonate and water, dried over sodium sulfate, and evaporated to dryness. The crude product was recrystallized from ether to give 176.3 mg (92%) of the product.

Succinimidyl p-*Toluensulfonate (***2**j*)*

A mixture of 190.6 mg (1 mmol) of *p*-toluenesulfonyl chloride and 318.4 mg (1 mmol) of TlONSu in 5 mL of dry chloroform was stirred at room temperature for 2–3 h. Work-up as described for **2***i*, followed by crystallization from chloroform–hexane gave 242.5 mg (90%) of **2***j*.

Trichloroethoxycarbonylglycine

To the stirred solution of 450 mg (6 mmol) of glycine and 540 mg (6 mmol) of sodium bicarbonate in a mixture of water (12 mL) and tetrahydrofuran (3 mL) was added 1.74 g (6 mmol) of **1***d*. After stirring overnight, the mixture was acidified, and then concentrated to a small volume *in vacuo*. Addition of a small amount of water and chilling afforded 1.26 g (84%) of crystalline trichloroethoxycarbonylglycine; mp 126–127°C. *Anal.* calcd. for $C_5H_6O_4Cl_3N$: C 23.97, H 2.41, N 5.59; found: C 24.00, H 2.48, N 5.58.

Received April 26, 1979

K. C. KHULBE, R. S. MANN, N. TAN, and A. MANOOGIAN. Can. J. Chem. **57**, 2779 (1979).

The electron spin resonance of Mn^{2+} impurities in the MoO_3–pumice system is studied along with the behavior of the system in the oxidation of methanol to formaldehyde. The intensity of the Mn^{2+} esr lines and the rate of catalytic conversion were both found to pass through a maximum at the same catalyst concentration. The results can be qualitatively explained in terms of the ion sites at the MoO_3–pumice surface.

K. C. KHULBE, R. S. MANN, N. TAN et A. MANOOGIAN. Can. J. Chem. **57**, 2779 (1979).

On a étudié le spectre de résonance paramagnétique électronique des ions Mn^{2+} contenus comme impureté dans le système de catalyseur MoO_3 déposé sur de la ponce ainsi que le comportement de ce dernier lors de l'oxydation du méthanol en formaldéhyde. On a trouvé que l'intensité des lignes spectrales des ions Mn^{2+} et la vitesse de conversion catalytique atteignent un maximum pour la même concentration de catalyseur. Ces résultats peuvent être expliqués qualitativement en fonction de la position des ions à la surface du système MoO_3–ponce.

[Traduit par le journal]

Catalysts based on molybdenum oxide are widely used in oxidation, hydrodesulfurization, and hydrocarbon reactions (1–7). A mixture of two or more metal oxides has been found to be very useful for obtaining high yields of formaldehyde from methanol oxidation. Molybdenum on several supports was studied by electron spin resonance (esr) and a number of correlations were obtained between catalytic activity and intensity of the molybdenum esr signal (1, 5, 7). No esr studies have been reported for MoO_3–pumice catalyst even though pumice is widely used as a support material. The purpose of the present work is to study the esr of Mn^{2+} impurities which exist in the MoO_3–pumice system, and to correlate the results with the behavior of the catalysts in the oxidation of methanol to formaldehyde, which is also studied.

Pumice is a hard glossy lava of volcanic origin, and is a complex silicate of sodium, potassium, magnesium, iron, and aluminum. It has a low surface area, is a porous material, and is a relatively inert support. Manganese is a natural impurity in pumice but it exists in a valence state which does not produce any esr lines. However, when MoO_3 is added to pumice the esr lines of Mn^{2+} are observed. Mn^{2+} ($S = 5/2$, $I = 5/2$) produces five fine structure esr lines, each of which is split into six hyperfine lines due to the interaction term $A\boldsymbol{I}\cdot\boldsymbol{S}$, where A is the hyperfine parameter. In powders only the central fine structure line ($M_s = 1/2 \rightarrow -1/2$) with its sextet of hyperfine lines is normally observed, since its position is nearly independent of the external magnetic field direction. The outer four fine structure lines are broadened due to their strong magnetic field dependence in crystalline electric fields with symmetry lower than cubic. The esr spectrum due to these lines is usually observed as only a broad hump superimposed on the resolved central line. The esr was done at X-band microwave frequency (~9.4 GHz) using a commercial spectrometer. Most of the measurements were performed at room temperature but some were done at liquid nitrogen temperature (−196°C) in order to check for extra lines which might appear more favorably at low temperature.

In the preparation of the catalyst, pumice (Fisher, size 8 mesh sieve) was ground and only 30–40 mesh size grains were used. The grains were washed with concentrated hydrochloric acid and then with distilled water until no precipitate was formed after applying a silver nitrate solution. They were then dried overnight in an oven at 110°C. The molybdenum doped pumice was prepared by impregnating the required amount of pumice with a calculated amount of ammonium molybdate solution in water. The mixture was then slowly dried over a hot water bath and then dried further for 3 h at 110°C. It was finally calcined from 200 to 650°C by raising the temperature continuously at the rate of 100°C/h and then heating continuously for 18 h at 650°C. The catalytic air oxidation of methanol was investigated

0008-4042/79/202779-04$01.00/0

in an isothermal fixed bed integral flow reactor, using an apparatus described previously (8).

Chemical analysis of pumice was carried out in order to determine the impurity concentration of manganese. In the analysis procedure 0.0789 g pumice was dissolved in a mixture of 2 mL perchloric acid plus 5 mL hydrochloric acid, and the solution was evaporated to dryness. The residue was dissolved in 5 mL of 6 *N* HCl and the volume was then increased to 30 mL by adding distilled water. The manganese concentration of the solution was measured quantitatively by atomic absorption spectroscopy and found to be 0.053 wt.% in the pumice. The ammonium molybdate was also analyzed for manganese content but no trace of the impurity was found.

The esr spectrum of pumice itself did not show the presence of any Mn^{2+} esr lines. Only two broad low intensity humps were observed, one at $g \simeq 4$ and the other at $g \simeq 2$, which are likely due to Fe^{3+} impurities. Figure 1*a* shows the esr spectrum obtained when 10 wt.% of MoO_3 was doped on pumice. The six line spectrum can be attributed to Mn^{2+} ions which are likely formed from non-paramagnetic manganese impurities originating in the pumice. The six lines have nearly equal spacings and intensities, and are due to the hyperfine splitting of the Mn^{2+} $M_s = 1/2 \rightarrow -1/2$ fine structure line. The hump on which the six lines are superimposed is due to the broadened $M_s = \pm 3/2 \rightarrow \pm 5/2$ fine structure lines. This result indicates that the crystalline electric field at the Mn^{2+} site contains a small non-cubic component. From the average magnetic field position of the hyperfine lines the Mn^{2+} *g*-value was calculated to be 2.000. The average separation of the hyperfine lines is 81 (10^{-4}) cm^{-1} and, to first order in perturbation theory, this spacing represents the magnitude of the hyperfine parameter *A*. The *A* value can be used to give information about the number and type of ligands surrounding the Mn^{2+} ion in the material. From a plot of the average value of the hyperfine parameter vs. the covalency parameter divided by the number of coordinated ligands (9) it is seen that the value of $A = 81$ (10^{-4}) cm^{-1} corresponds to an environment of six O^{2-} ions. When the esr spectrum was run at low temperature (−196°C) it was observed that sharp low intensity doublet lines exist between each pair of hyperfine lines. This is the pattern expected for Mn^{2+} first-forbidden hyperfine lines ($\Delta M_I = \pm 1$) for the $M_s = 1/2 \rightarrow -1/2$ transition.

Figure 2 shows the relative intensity of the Mn^{2+} allowed hyperfine lines for various concentrations of MoO_3 on pumice. It is observed that the intensity of the Mn^{2+} lines increases steadily up to 6.9 wt.% of MoO_3, after which it declines. It was also noted during the course of the experiment that the color of the 6.9 wt.% MoO_3 catalyst was creamish brown while the others were yellow grey to dark yellow grey, depending on the concentration of MoO_3. When the MoO_3–pumice catalyst was calcined further at 700°C the esr spectrum changed as shown in Fig. 1*b*. The Mn^{2+} lines become superimposed on a large broad line centered at $g = 1.965$. There is no effect on the Mn^{2+} line intensities due to the calcination. The broad line can be attributed to Mo^{5+} or Mo^{3+} ions, which are paramagnetic and have *g*-values known to be near the measured value of 1.965 (1, 7, 10).

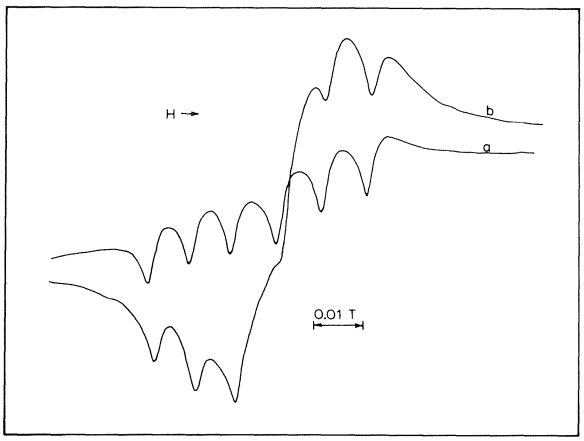

FIG. 1. (*a*) Electron spin resonance spectrum of Mn^{2+} impurities in 10 wt.% of MoO_3 doped on pumice, and (*b*) esr spectrum obtained when calcined further at 700°C.

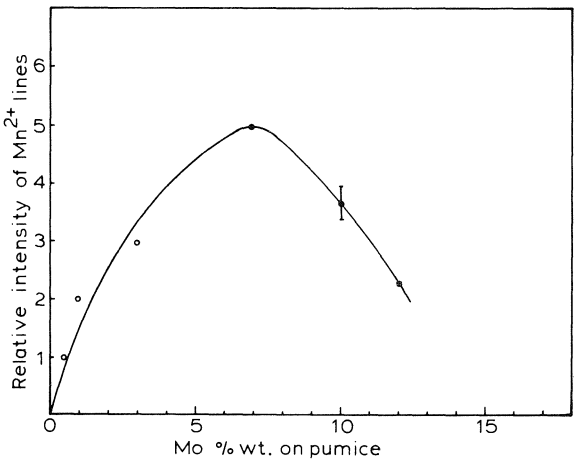

FIG. 2. Relative intensity of Mn^{2+} esr lines for various concentrations of MoO_3 on pumice.

In the conversion of methanol to formaldehyde it was observed that the relative conversion increased with increasing MoO_3 concentration on pumice up to a maximum of 6.9 wt.% MoO_3 and then decreased (Fig. 3). The selectivity of formaldehyde formation for the catalysts was always 100% since only formaldehyde could be detected after reaction. Figures 2 and 3 show that both the Mn^{2+} esr line intensities and the conversion rate maximize at the same catalyst concentration. It was observed in the used catalysts that the Mn^{2+} line intensities did not change after reaction.

In order to check if the existence of manganese ions in the Mn^{2+} state was dependent on the doping material, catalysts of 1 wt.% Mn, Cu, Ni, and Fe doped on pumice were prepared in a similar way as for the MoO_3–pumice catalyst. However, no esr signals due to Mn^{2+} ions were observed in any of these systems. This result suggests that the close relationship which was found to exist between the Mn^{2+} esr line intensities and the catalytic activity of the MoO_3–pumice system is dependent on the Mo ion or on the nature of the Mo ion sites.

We also studied the esr spectrum of 2 wt.% MoO_3 doped on kieselguhr. The catalyst was prepared in a similar way as that described for MoO_3–pumice. Kieselguhr is a naturally occurring low surface area material and is derived from marine life. It has a diatomic cellular structure and is composed entirely of semi-amorphous silica. The esr spectrum obtained (Fig. 4) is due to Mn^{2+} ions and is similar to that obtained in pumice except that the hyperfine lines are now broadened. The broadening may be due to a spread in A values for the Mn^{2+} ions, but the average A value is the same as that obtained in the MoO_3–pumice catalyst. No Mn^{2+} lines were observed in undoped kieselguhr.

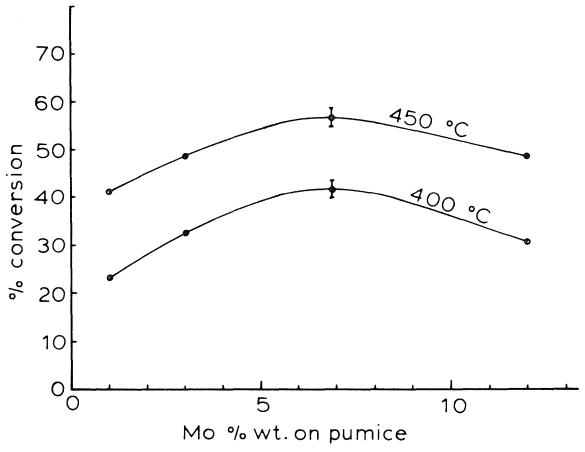

FIG. 3. Percent conversion of methanol to formaldehyde vs. the concentration of MoO_3 on pumice.

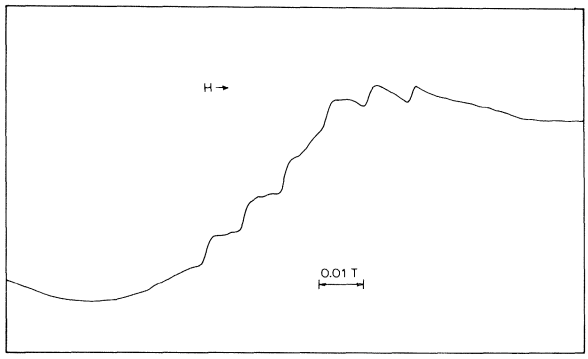

FIG. 4. Electron spin resonance spectrum of 2% MoO_3 on kieselguhr.

A qualitative explanation can be made regarding the behavior of the MoO_3–pumice catalyst. When molybdenum oxide is added to the support it forms a chemical bond with the surface atoms. For low dopant concentrations the molybdenum oxide likely forms a monolayer on the pumice surface, with Mo atoms in tetrahedral ($Mo{\cdot}4O^{2-}$) and octahedral ($Mo{\cdot}6O^{2-}$) sites, as is its usual habit (5). As the molybdenum oxide concentration is increased then normal MoO_3 is formed (5). This material possesses a rhombic lattice and consists of Mo^{6+} ions in strongly deformed octahedra of oxygens. A correlation between catalytic activity and Mn^{2+} esr line intensities can be made if the Mn^{2+} sites are located in the MoO_3–pumice interface structure. As the loading of MoO_3 increases, the exposed surface area of MoO_3 will increase up to the point where all the pumice surface is covered. The increasing MoO_3 surface area will account for the increased catalytic activity up to the point of maximum coverage. The area of the MoO_3–pumice interface also increases up to this point, hence accounting for the increased Mn^{2+} ion content. Beyond the point of maximum loading the state of the molybdenum oxide layer is likely affected by the thickness of the layer, causing both the catalytic activity and the Mn^{2+} presence to decrease.

Acknowledgments

Rate–acidity profiles for exchange of the 4-methyl protons in amino, imino, and keto pyrimidines

ROSS STEWART, STEWART J. GUMBLEY, AND R. SRINIVASAN

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received April 24, 1979

ROSS STEWART, STEWART J. GUMBLEY, and R. SRINIVASAN. Can. J. Chem. **57**, 2783 (1979).

The rate of exchange of deuterium for protium in the 4-methyl groups of 2-imino-1,4-dimethyl-1,2-dihydropyrimidine (**1**), 1,4-dimethyl-2-pyrimidone (**2**), and 4-methyl-2-amino-pyrimidine (**3**) has been determined in aqueous solution over an acidity range of some 21 pH(H_0) units. The various exchange routes involve attack by base (water, hydroxide ion, buffer anion) on substrate (neutral, singly protonated, doubly protonated) and the identities of the principal components across the acidity spectrum have been established for all three compounds. The Brønsted slope, kinetic isotope effect, and activation parameters for **1** have also been determined. Protonating **1** activates it toward exchange by a factor of 10^3; addition of a second proton has a further effect of $> 10^5$. The activating effects of the imino group, the carbonyl group, and the protonated imino group in these compounds are in the ratio $10^{-1}:1:10^2$.

ROSS STEWART, STEWART J. GUMBLEY et R. SRINIVASAN. Can. J. Chem. **57**, 2783 (1979).

On a déterminé, en solution aqueuse sur une large échelle d'acidité de quelque 21 unités de pH(H_0), la vitesse d'échange des protons par des deutérium des groupes méthyl-4 de l'imino-2 diméthyl-1,4 dihydro-1,2 pyrimidine (**1**), de la diméthyl-1,4, pyrimidone-2 (**2**) et de la méthyl-4 amino-2 pyrimidine. Les différentes voies d'échange impliquent l'attaque du substrat (neutre, simplement ou doublement protoné) par une base (eau, ion hydroxyle, tampon anionique) et on a identifié les principaux composants à travers le spectre d'acidité des trois composés. On a également déterminé pour le composé **1** la courbe de Brønsted, l'effet isotopique cinétique et les paramètres d'activation. La protonation de **1** l'active vis-à-vis de l'échange par un facteur de 10^3, l'addition d'un second proton a un effet plus grand de l'ordre $> 10^5$. Dans ces composés, les effets d'activation des groupements imine, carbonyle et des groupements imines protonés sont dans un rapport $10^{-1}:1:10^2$.

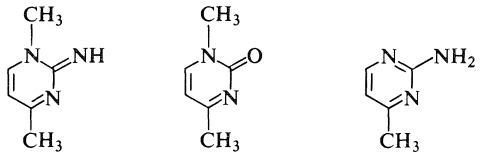
Introduction

Proton loss from an activated carbon–hydrogen bond is the critical step in enolization, and thus is the step that initiates a number of important reactions of organic chemistry and biochemistry. The usual activating unit in the enolization process is the carbonyl group, either free or protonated, and the activation that accompanies protonation of the carbonyl group has been the subject of a number of papers from this laboratory (1–6).

In 1964 Bender and Williams (7) pointed out that the equilibrium concentration of protonated ketone would be too low to provide effective activation at physiological pH and they considered the possibility that the protonated imino analog (protonated ketimine or Schiff's base) might fulfill this role. They estimated that a typical protonated ketimine is 10^3 times less reactive than the protonated ketone with respect to proton loss from the methyl group, but 10^8 times more reactive than the ketone itself. Hine (8), Spencer (9), and others have also been concerned with this alternative mode of activation and their results suggest that the latter factor is only of the order of 10^3 (8*b*, 9*b*).

The present work examines three derivatives of pyrimidine, the imino and keto compounds **1** and **2**, and the fully aromatic aminopyrimidine **3**. All have a methyl group at the 4-position that undergoes exchange in D_2O, brought about by attack of base on the neutral substrates or their conjugate acids. Comparing the rate of reaction of **2** with that of the conjugate acid of **1** will give the relative effectiveness of the carbonyl and protonated imino groups at activating the 4-methyl group with respect to proton loss. We have shown elsewhere (6) that the proton activating factor, **paf**, for **2** is 3×10^3, that is the 4-methyl group in the conjugate acid of **2** reacts 3×10^3 times faster with bases than does **2** itself. It should be noted that the conjugate acids of **1** and **2** have the quite different structures **1***a* and **2***a*, the former closely resembling **3***a*, one of the tautomeric

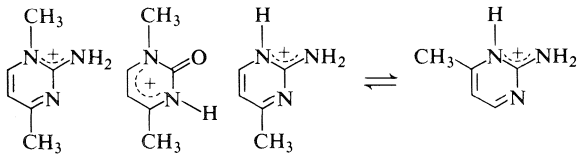


1 **2** **3**

0008-4042/79/202783-07$01.00/0

pair that are the conjugate acids of the true pyrimidine **3**.

Compounds **1** and **3** are of interest since they should behave quite differently in their neutral forms but almost identically in their cationic forms **1***a* and **3***a*.



We herein report the rate–acidity profiles for exchange of the 4-methyl groups in **1**–**3** in D_2O over an acidity range that covers some 21 pH(H_0) units (10). It is not clear which acidity function is the most appropriate for the present systems and we have chosen to use D_0, the analog of H_0, throughout, partly because of its familiarity and partly because the principal alternative function H_A has not been determined for deuterated media.

Results and Discussion

The effect of acidity on the rate of exchange of the 4-methyl groups in **1**, **2**, and **3** is shown in Figs. 1 and 2. The measurements for the points in Fig. 1 were made in 0.2 *M* aqueous phosphate buffer over most of the acidity range; aqueous sulfuric acid was used in the strongly acidic (D_0) region, and aqueous sodium hydroxide for solutions more basic than pD 12.

Since the reactions are subject to general acid and general base catalysis the rate at any acidity will depend on the identity and concentration of the buffer acids present, and the curves in Fig. 1 can be considered as simple log (rate) vs. pD profiles in which the only acids and bases involved in the exchange would be D^+, DO^-, and D_2O, on which are superimposed contributions from the buffer components and from self-catalysis. The latter phenomenon, in which the neutral heterocycle acts as the base in removing the exchanging proton from the conjugate acid, can be important at acidities near the pK of the substrate.

Figure 2 refers to solutions in which no buffer was used. Control of acidity in these experiments depended to a large extent on the buffering ability of the substrates, which in turn varied considerably across the pD spectrum. By measuring pD before and after exchange with a glass electrode reasonably reliable values of the acidity could be obtained.

*1,4-Dimethyl-2-imino-1,2-dihydropyridine (**1**)*

Acid and base catalyzed exchange in D_2O of the

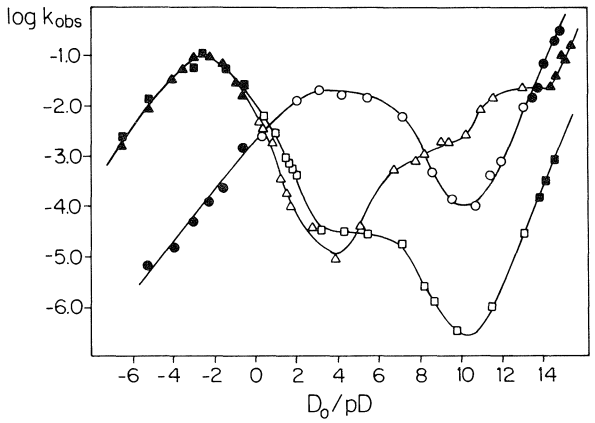


FIG. 1. Log rate–acidity profiles for **1** (triangles), **2** (circles), and **3** (squares) in D_2O containing 0.2 *M* phosphate buffer, except for points represented by closed symbols, which contain D_2SO_4 or NaOD instead of buffer; k_{obs} in units of min^{-1}; substrate concentrations 0.2 *M*.

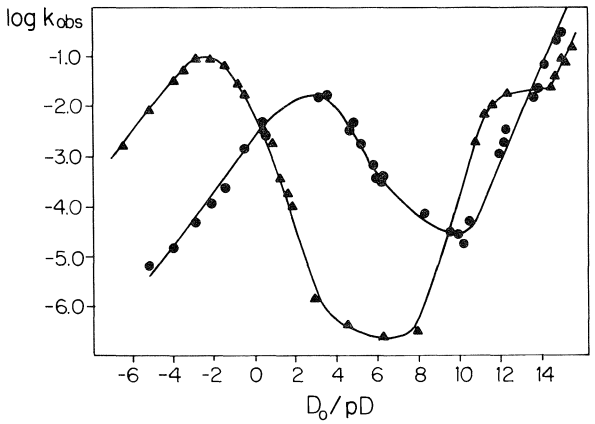

FIG. 2. Log rate–acidity profiles for **1** (triangles) and **2** (circles) in unbuffered D_2O using D_2SO_4, DCl, or NaOD to control the acidity; k_{obs} in units of min^{-1}; substrate concentrations 0.2 *M*.

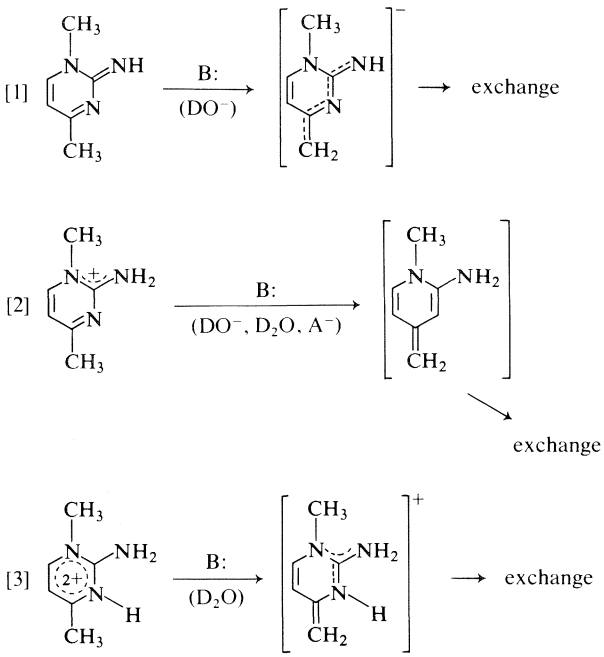
4-methyl group in this compound has previously been observed by Batterham, Brown, and Paddon-Row, who produced a partial rate–acidity profile for the closely related 1,4,6-trimethyl compound (11). Their results for the latter compound are compatible with our more extensive study of **1**.

The curves in Fig. 1 (buffered) and Fig. 2 (unbuffered) represent essentially the three exchange mechanisms shown in eqs. [1]–[3]. Only the immediate exchanging intermediate formed in the rate-controlling step when base removes a proton from the 4-methyl group is shown in each case. For the sake of convenience the hydrogen atoms attached to oxygen and nitrogen atoms in the formulas are represented by the symbol H rather than D. The bases that contribute significantly to the three reac-

tions are identified in parentheses below the arrows, the various buffer anions being represented by the symbol A^-.



In the most basic systems studied the principal exchange reaction for **1**, $pK_{BD^+} = 11.4$, is given by [1]. The rate is roughly proportional to the deuteroxide ion concentration, as can be seen from the results of Fig. 2 where the straight line has been drawn with unit slope. The plateau near pD 12 presumably corresponds to the contribution from pathway [2] with the role of base being played by deuteroxide ion. This reaction will be pD-independent in solutions in which the concentration of the conjugate acid is small, i.e., when the pD is greater than about 12.

The **paf** (1) for **1**, that is the ratio of the rate constants for **1***a* and **1** reacting with the same base, is determined from the curve in Fig. 2, as follows. For hydroxylic catalysis, routes [1] and [2] make equal contributions to the rate of exchange when the overall rate is twice that at the plateau, that is at about pD 14.5. At this point eq. [4] is satisfied and, thus, **paf** is equal to $10^{-11.4}/10^{-14.5}$ or $10^{3.1}$. In other words, protonating **1** to give **1***a* activates the molecule towards prototropic exchange at the 4-methyl group by a factor of about one thousand.

$$[4] \quad \mathbf{paf} = K_{ZH^+}/[H^+]$$

This value is about one-third that previously observed (6) for the analogous keto compound **2**, a very modest difference in view of the dissimilar charge distributions in the two cations **1***a* and **2***a*.

As the basicity is reduced below the pK_{BD^+} (11.4) the rate drops in both the buffered and unbuffered systems as a result of the hydroxide ion concentration decreasing while the concentration of **1***a* remains the same. The slope of the log k vs. pD plot is linear in the pD region 7–11 in the unbuffered systems but a large contribution from buffer catalysis and possibly self-catalysis is apparent from the curve in Fig. 1. At pD 8 the uncatalyzed rate is less than 1% of the buffer catalyzed rate. The more thorough analysis of buffer catalysis and self-catalysis that was made for **2** is described in the next section.

The rate minimum for **1** occurs near pD 4 in phosphate buffer and near 6 in the unbuffered systems. As the acidity is increased the rate of exchange rises and the difference between the unbuffered and buffered system vanishes. We assign this exchange path to reaction of the dication with water, eq. [2]. The slope of the line between pD 0 and 2 is close to unity, as required for such a reaction path. We have measured the $pK_{BH_2^{2+}}$ for **1** by nmr and find the position of half-protonation to be at -2.61 on the H_0 scale. It is clear from Figs. 1 and 2 that this pK (which will not be drastically different in the deuterated system) is somewhere near the peak of the curve. The principal cause of the decrease in rate as the acidity is further increased is almost certainly the decrease in activity of the base, water, as the sulfuric acid concentration is raised. In going from 46.2% to 74.3% D_2SO_4 the observed rate of exchange decreases by a factor of 52 while the D_2O activity decreases by a factor of 30 (12). A plot of log k_{obs} (ordinate) against the logarithm of a_{D_2O} is linear with a slope of 1.35 (Fig. 3).

The second **paf**, that is the difference in the rate constants for reactions [2] and [3] with the same base, can be estimated from the curve in Fig. 2. The trough of the curve represents the maximum rate for reaction [3] with water acting as the base. This difference is at least a factor of 10^5 and may be considerably more, since the depth of the trough is not easily measured and since the water activity has already begun to drop at the rate maximum. It is thus clear that the second **paf** is larger than the first for **1**, that is, the second proton has a greater effect than the first in activating the 4-methyl group toward bases. This effect is presumably a result of the second unit of positive charge being located near the exchanging methyl group. (Compare the cations in [2] and [3].)

The reaction of **1** in aqueous buffers in the pH region 3.6–6.0 was examined using iodometry. This technique allows very low substrate concentrations to be used and hence avoids any interference by self-catalysis. In addition, isotope effects can be

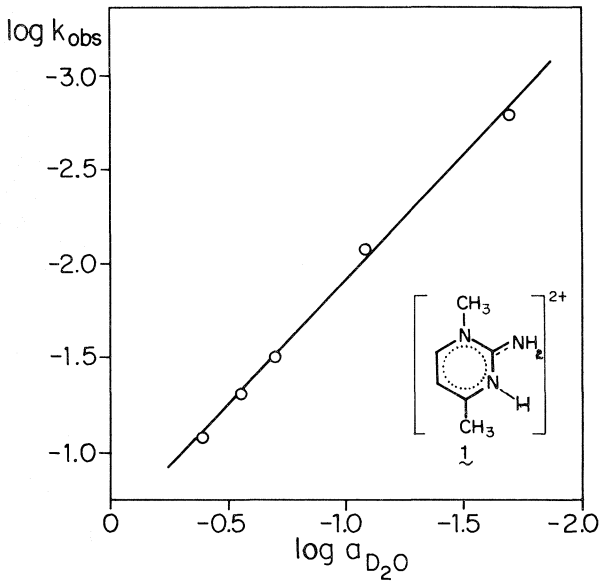


FIG. 3. Logarithm of rate of exchange of **1** in sulfuric acid as a function of the activity of D_2O; slope = 1.35; k_{obs} in units of min^{-1}; substrate concentration 0.2 *M*.

Nicotinamide	3.63	5.6
Methoxyacetate	3.57	3.5

[a]Statistical corrections made as heretofore (4).

determined since the solvent is H_2O rather than D_2O.

The data for the reaction of **1** with buffer acids HA are given in Table 1. Considering the pK_{BH^+} of **1** (11.1) (ref. 15) and the acidities used, the rate constants actually refer to the reaction of **1***a* with the buffer anions A^-. The Brønsted plot shown in Fig. 4 thus refers to the general base-catalyzed removal of a proton from the 4-methyl group of the conjugate acid of the substrate. The value of β is 0.50.

The isotope effect for the reaction of the conjugate acid of the 4-CD_3 analog of **1***a* with acetate ion is 7.4 at 25°C; $\Delta H^{\dagger}$ is 100.0 kJ mol^{-1} and $\Delta S^{\dagger}$ is -17.6 J $mol^{-1}K^{-1}$ for the reaction of **1***a* with the same base.

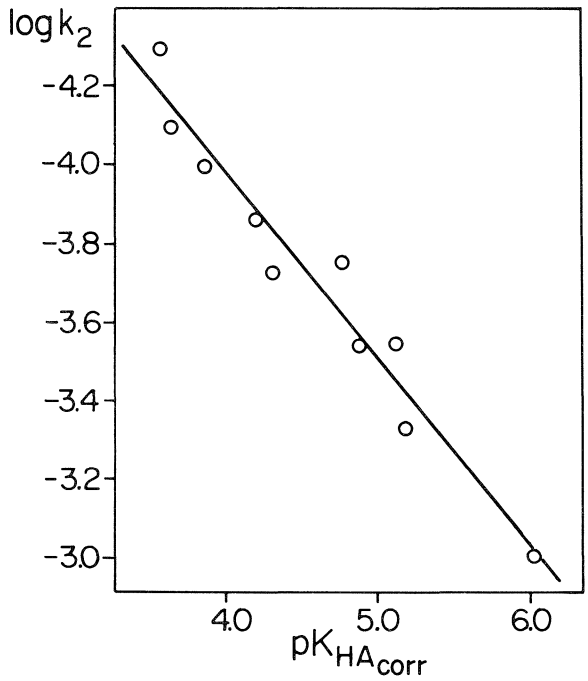

FIG. 4. Brønsted plot for the reaction of **1** with anionic bases in H_2O. From right to left the bases follow the order of descent in Table 1. Brønsted slope = 0.50; k_2 in units of M^{-1} min^{-1}.

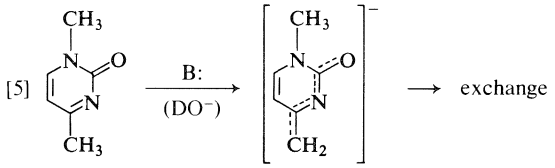
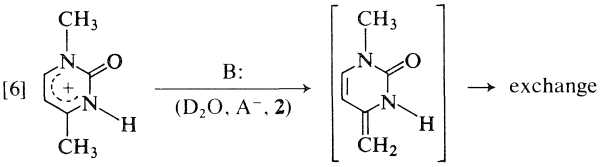
The Brønsted slope, the isotope effect, and the activation parameters all appear to be unexceptionable.

1,4-Dimethyl-2-pyrimidone (2)

In D_2O this compound undergoes exchange of the hydrogens of the 4-methyl group by the following reaction paths.





In solutions more basic than pD 11 the rate is first-order in hydroxide ion and there is virtually no buffer catalysis. (See Fig. 5 where the straight line in this region of the curve has been drawn with unit slope.)

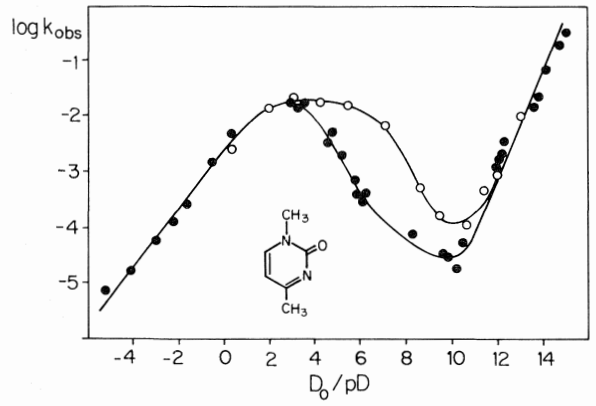


FIG. 5. Log rate–acidity profile for **2** in buffered (0.2 *M* phosphate, open circles) and unbuffered (D_2SO_4, NaOD, closed circles) solution; k_{obs} in units of min^{-1}; substrate concentration 0.2 *M*.

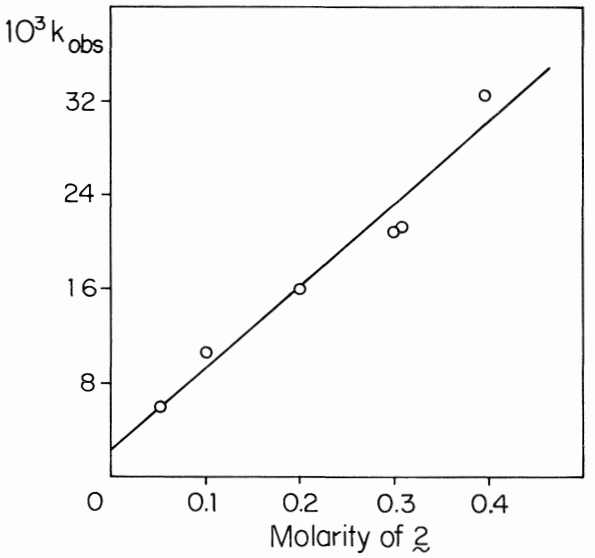

FIG. 6. Dependence on the rate of reaction of **2** on the compound's concentration; pD 3.4–3.5; k_0(intercept) = 2.1 × 10^{-3} min^{-1}.

A minimum occurs in both buffered and unbuffered systems near pH 10 and as the solution is made more acidic pathway [6] becomes dominant, with phosphate buffer catalysis being clearly evident in the pD region between 3 and 11. The pK_{BD^+} of **2** is 3.60 and if water and phosphate anions were the only bases involved in deprotonating cation **2***a* the rate should level off at a pD value about one unit below the p*K* and remain unchanged until the solution is made so acidic that the activity of water begins to drop. However, a decrease in the rate of exchange occurs long before the latter effect should be evident, as can be seen from the curves in Fig. 5. This effect has been traced to self-catalysis by the pyrimidine, which can itself act as the base in deprotonating its conjugate acid. This route will be most important at the p*K* of the substrate, 3.60. Decreasing the concentration of **2** markedly lowers the exchange rate in unbuffered solution in the pD region 3.4–3.5; even though acidity control was a problem at low substrate concentrations it was possible to show (Fig. 6) that the exchange rate is markedly dependent on solute concentration. Thus the drop in the curve in Fig. 5 as the acidity is increased is due to self-catalysis becoming less important as the pD moves away from the pK_{BD^+}, with the continuing decrease that occurs in the sulfuric acid region being due to the drop in water activity. The line in this region is roughly parallel to that observed with **1**, the imino analog.

4-Methyl-2-aminopyridine (3)

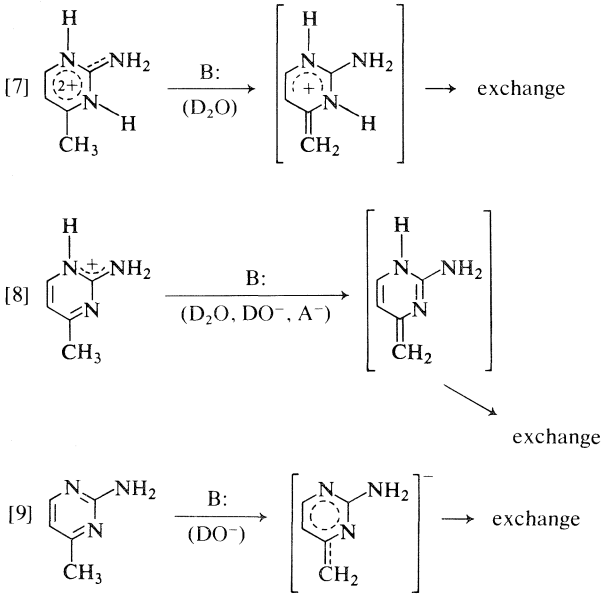
The first and second conjugate acids of this compound differ from those of **1** only in having a hydrogen atom instead of a methyl group on one of the ring nitrogen atoms. Experience tells us that such substitution should have only a minor effect on the reactivity of the 4-methyl group (2) and the close correspondence of the curves for **1** and **3** in the acid region is in agreement with this expectation (Fig. 1). The pK_{BD^+} of **3** is approximately 4.6 ($1.005\,pK_{BH^+}$ + 0.48) (13) and the two curves diverge sharply near this point. Whereas the cationic form of **1** predominates up to pD 11, **3** exists principally as the less reactive neutral molecule above pD 6 and the decrease in the rate of exchange of the 4-methyl group as the solution is made basic can be attributed to this factor. Buffer catalysis and self-catalysis probably contribute to the exchange in the region pD 3–5.

The increase in rate with increasing acidity beginning near pD 3 culminates in the curves for **1** and **3** merging. The diprotonated form of **3** is doubtless the reactive intermediate here (eq. [7]) since we have found the $pK_{BH_2^{2+}}$ value of **3** to be very close to the value of −2.61 that we obtain for **1**.

At the minimum in the curve, near pD 10, the reaction shown in eq. [8] gives way to that shown in eq. [9].

At the minimum of the curve, just above pD 10 the concentration of the cation **3***a* (or **3***a*′) has been reduced to 10^{-6} times that of the neutral compound **3** and the latter takes over as the principal exchanging intermediate. The increase in the rate as the solution is made more basic is directly proportional to the increase in hydroxide concentration (see Fig. 2 where the straight line in this region is drawn with unit slope). The reaction, therefore, is that shown in eq. [9].

It is clear that ionization of the amino group does not have a significant effect on the exchange of the



4-methyl protons even under the most basic conditions we have used, since the pK_{HA} of 2-aminopyrimidine is 20.5 (14) and the presence of the 4-methyl group will raise this value to about 20.9 (16).

The bottom of the trough in the rate vs. pD profile near pD 10 provides us with the maximum value possible for the rate of the reaction of cation **3***a* (and **3***a'*) with hydroxide ion, a pH-independent reaction. Now the principal exchange route of **1** at this acidity is also the reaction between hydroxide ion and a cation, **1***a*, which is, moreover, identical to **3***a* except for the replacement of methyl by hydrogen. The very large effective rate difference for these virtually identical reactions ($>10^5$) is due to **1** being largely protonated whereas **3** is protonated to only a minute degree at this acidity.

The minimum in the trough that occurs at pD 10 also gives us the maximum rate for the reaction of **3** with water. Were this the principal pH-independent route, rather than the kinetically equivalent counterpart discussed in the previous paragraph or the reaction with buffer anions, then at pD 10 the hydroxide- and water-catalyzed routes would be equally productive and hydroxide ion would be 10^6 times as effective as water at the same concentration. This quantity, called the deprotonating factor (1) **dpf**, is given for reactions of protium compounds by eq. [10] where $[H^+]^*$ is the hydrogen ion concentration where the two routes make equal contributions (1).

$$[10]\quad \mathbf{dpf} = [H^+]^*/1.8 \times 10^{-16}$$

Most **dpf** (HO^-/H_2O) values previously observed are 10^8 or greater and it is thus probable that the water-catalyzed route does not make a major contribution to the exchange even at the rate minimum at pD 10. An exact profile of the trough is not readily obtained since reaction half-life at the minimum is many years.

Activation by Carbonyl and Imino Groups

In strongly basic solution compounds **1** and **2** undergo exchange by identical mechanisms: hydroxide ion removes a proton from the 4-methyl group of the neutral substrates. The lines in Fig. 2 are parallel in this region with that for **2** being displaced above that for **1** by 1.0 logarithmic units. Thus the carbonyl group is more effective than the imino group in activating the 4-methyl group by a factor of about ten. This is a rather modest difference and it may be that the two ring nitrogen atoms provide such a large degree of activation that the effect of the other groups is damped.

The activating effect of the protonated imino group in these compounds is, of course, greater than that of imino but is also greater than that for the carbonyl group, in agreement with previous observations on aliphatic systems (7–9). The relative effects of carbonyl and protonated imino can be simply determined from the crossover point of the curves for **1** and **2** that occurs at pD 13.5. At this point **2** is completely in the neutral form, whereas **1** (pK_{BD^+} 11.4) is only about 1% protonated. Since the protonated form is responsible for essentially all of the exchange at this basicity, the protonated imino group is 100 times more reactive than the carbonyl group. This number is much closer to the values of Hine *et al.* (8*b*) and Spencer *et al.* (9*b*), $\sim 10^3$, than to that of Bender and Williams (7), 10^8. It should be noted, however, that all their values refer to aliphatic compounds, whereas ours refers to a heterocyclic system in which there is resonance stabilization of both the carbonyl and protonated imino groups.

Experimental

Materials

1,4-Dimethyl-1,2-dihydro-2-iminopyrimidine (**1**) was prepared as the hydrochloride salt essentially by the method of Brown and Paddon-Row (15). 2-Amino-4-methylpyrimidine was methylated with methyl iodide to give pale yellow needles mp 257°C (dec.) (lit (13) 253–254°C (dec.)), and the iodide exchanged for chloride using Dowex 1-X8 (Cl^-) resin, mp of chloride 257°C (dec.) (lit (15) 227°C (dec.)).

1,4-Dimethyl-2-pyrimidone (**2**) was prepared by methylating 2-hydroxy-4-methylpyrimidine, essentially by the method of Brown and Foster (16) except that the reaction was conducted at room temperature. Chromatographic purification (chloroform/alumina and methanol – carbon tetrachloride/silica gel) gave deep yellow crystals, mp 159.5–160.5°C (lit. (16) 156–157°C).

2-Amino-4-methylpyrimidine (**3**) was obtained commercially and sublimed twice before use, mp 161.5°C (lit. (17) 159–160°C).

Kinetics

The compounds were dissolved in solutions of the appropriate pD/D_0 to a concentration of 0.2 *M* and the rate of exchange measured by nmr or by iodometry at 36°C, essentially as previously described (3, 4, 6).

Ionization Constants

The pK_{BD^+} values of **1** and **2** were determined by spectrophotometry at 335 and 309 nm respectively in 0.05 *M* sodium phosphate in D_2O. They were found to be 11.4 and 3.66, respectively.

The second protonation constants, $pK_{BH_2^{2+}}$, for **1** and **3** were determined by the change in the nmr chemical shift of the 4-methyl peak in aqueous H_2SO_4 solution. They were found to be −2.61 and −2.65, respectively, using the H_0 acidity function.

Electrophilie du ligande η^3-allylique de complexes η^3-allyl-dicarbonyl-nitrosyl-fer

J. L. A. ROUSTAN ET F. HOULIHAN

Faculté des Sciences et de Génie, Département de Chimie, Université d'Ottawa, Ottawa, Ont., Canada K1N 9B4

Reçu le 22 mai 1979

J. L. A. ROUSTAN et F. HOULIHAN. Can. J. Chem. **57**, 2790 (1979).

Les complexes neutres η^3-allyl-dicarbonyl-nitrosyl-fer réagissent rapidement dans le THF à température ambiante avec des nucléophiles du type doublement activé tel l'anion malonate. Les composés organiques de monoallylation sont obtenus avec de bons rendements (80–95%). Avec des ligandes η^3-allyliques dissymmétriques le carbone le moins substitué est alkylé préférentiellement.

J. L. A. ROUSTAN and F. HOULIHAN. Can. J. Chem. **57**, 2790 (1979).

Neutral η^3-allyl-dicarbonyl-nitrosyl iron complexes react rapidly in THF at room temperature with nucleophiles of the doubly activated type such as malonate anion. Monoallylated organic products are obtained in good yields (80–95%). With unsymmetrical η^3-allyl ligands the less substituted carbon is alkylated preferentially.

Introduction

L'augmentation de l'électrophilie d'un ligande organique η^2-oléfinique ou η^3-allylique, par coordination sur un centre métallique approprié, est une propriété bien documentée (1, 2).

Le plus souvent la réaction s'effectue au niveau d'un complexe cationique (3–6) ou s'accompagne de l'expulsion d'un ligande négativement chargé (7); il en résulte un complexe η^1-alkyl ou η^2-oléfinique globalement électriquement neutre. Dans les cas beaucoup plus rares où la réaction s'effectue sur un complexe neutre (tel un complexe η^2-oléfinique (8)) un complexe anionique est formé.

Dans une telle réaction mettant en jeu un ligande η^3-allylique (schéma 1), la facilité d'approche du nucléophile ainsi que la stabilisation du complexe anionique intermédiaire doivent augmenter en même temps que la capacité des ligandes auxiliaires L_n à délocaliser la charge négative qui apparaît sur le métal.

Le ligande nitrosyle NO véritable "puit d'électrons" (9) apparaît parfaitement approprié à jouer ce rôle. Pour examiner la validité de cette hypothèse les complexes η^3-allyliques du dicarbonyl-nitrosyl-fer, aisement accessibles à partir d'halogénures (10) ou de diènes 1–3 (11) ont été sélectionnés et opposés à divers nucléophiles du type doublement activé.

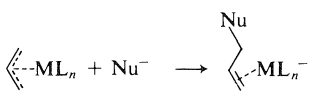

SCHÉMA 1

Partie expérimentale

Le THF est distillé sur $LiAlH_4$ avant usage. Les complexes η^3-allyliques sont préparés selon des modes opératoires déjà décrits (10).

Réactions d'alkylation

Les anions du type utilisé dans cette étude sont préparés dans le THF à température ambiante par la réaction de NaH avec le composé organique approprié en quantité stoechiométrique. A la solution contenant le nucléophile est ajoutée une quantité stoechiométrique de complexe η^3-allylique en solution dans le même solvant à température ambiante et sous CO. Après agitation durant 30 min, les composés organométalliques présents (seul $Fe(CO)_3NO^-$, Na^+ est détecté par ir) sont oxydés par barbotage d'air dans la solution durant 30 min. Le THF est évaporé, remplacé par l'éther diéthylique, puis le milieu est hydrolysé. Après séchage sur $MgSO_4$, le solvant est évaporé et l'huile obtenue est analysée par ^1H nmr, ^{13}C nmr et chromatographie en phase vapeur (colonne DEGS 10% sur Chromosorb W, $T = 130°C$, oxalate d'éthyle comme étalon interne).

Dans le cas de la réaction d'alkylation du complexe η^3-crotylique ***1b*** par le diéthyl malonate de sodium (un excès de 20% de diéthyl malonate est utilisé dans cette réaction) deux produits isomères de monoallylation sont formés. Ils sont séparés du diéthyl malonate en excès et d'une trace de produits de bis allylation par chromatographie sur colonne de silice (60–200 mesh) en éluant avec un mélange hexane – chlorure de méthylène (25–75).

Résultats

Les résultats sont présentés dans les tableaux 1 et 2. Dans tous les cas étudiés la réaction principale est la réaction de monoallylation du nucléophile qui s'effectue avec de bons rendements (schéma 2). La seule réaction secondaire qui a été mise en évidence est une bis allylation du nucléophile.

La réaction est effectuée à température ambiante,

0008-4042/79/202790-02$01.00/0

sous atmosphère de CO, dans le THF anhydre. Le complexe η^3-allylique solubilisé dans le THF est ajouté à la solution contenant le nucléophile. L'évolution du milieu réactionnel est suivie par un examen périodique de la solution par spectroscopie infrarouge.

La présence de substituants sur le ligande allylique n'a que peu d'influence sur la vitesse de disparition des complexes **1** qui est complète en moins de 10 min. De même que lors de la réduction électrochimique ou chimique du complexe **1***a* (R = H) dans l'acétonitrile (12), un intermédiaire réactionnel **3** est détecté (THF, $\nu(cm^{-1})$: CO = 1950, 1870, NO = 1630). Sa structure reste pour le moment spéculative. Il se décompose par la suite en anion **4**.

L'étude de la distribution des produits de monoallylation **5** et **6** issus de la réaction des complexes η^3-allyliques substitués **1***b* (R = CH_3) et **1***c* (R = C_6H_5) révèle une régiosélectivité marquée (tableau 2), le carbone le moins substitué du ligande allylique réagissant préférentiellement. Un effet analogue avait déjà été constaté dans les réactions de complexes η^3-allyliques cationiques du fer (4).

TABLEAU 2. Réaction de **1***b* (R = CH_3) et **1***c* (R = C_6H_5) avec l'anion diéthyl malonate Nu^- = $^-CH(COOEt)_2$

R	 (%)	 (%)
—CH_3	78	16
—C_6H_5	89	0

En conclusion, cette étude démontre la possibilité d'utiliser des fragments métalliques neutres pour réaliser l'activation de ligandes η^3-allyliques vis-à-vis de réactifs nucléophiles.

Le prolongement naturel de ce travail est l'incorporation dans un cycle catalytique de la séquence réactionnelle précédente établie à l'échelle stoechiométrique, afin de réaliser une alkylation catalytique de substrats allyliques peu réactifs tel que les acétates ou les formates.

Les résultats positifs obtenus dans ce contexte seront publiés ultérieurement.

Received March 23, 1979

HUW O. PRITCHARD and ARUNACHALAM LAKSHMI. Can. J. Chem. **57**, 2793 (1979).

The $(n - 1)$-fold degenerate set of transition probabilities used in our recent reformulation of unimolecular reaction theory is operationally equivalent to the set of effective strong-transition probabilities introduced recently by Nordholm. We have found that the relaxation matrix corresponding to these transition probabilities commutes with *any* other relaxation matrix which will drive the same system to a Boltzmann distribution at infinite time. Some useful results stemming from this commutative property are presented; we expect that these results will help to clarify further the nature of the assumptions underlying strong- and effective strong-collision theories.

HUW O. PRITCHARD et ARUNACHALAM LAKSHMI. Can. J. Chem. **57**, 2793 (1979).

L'ensemble des probabilités de transition qui sont dégénérées $(n - 1)$ fois que nous avons utilisé dans notre récente reformulation de la théorie des réactions unimoléculaires est opérationnellement équivalent à l'ensemble des probabilités de fortes transitions efficaces introduit récemment par Nordholm. Nous avons trouvé que la matrice de relaxation correspondant à ces probabilités de transition s'échange avec toute autre matrice de relaxation qui conduira le même système à une distribution de Boltzmann à temps infini. Nous présentons quelques résultats pratiques issus de cette propriété commutative; nous espérons que ces résultats aideront à clarifier d'avantage la nature des hypothèses sous-jacentes aux théories des collisions fortes et des collisions fortes efficaces.

[Traduit par le journal]

Introduction

Nordholm, Freasier, and Jolly (1) have recently given a somewhat more precise definition of a strong collision as it appears in the description of unimolecular reactions. In quantum form, the transition probabilities corresponding to strong collisions may be written as

$$[1] \quad p_{j\to i} = \exp(-\beta E_i)/\sum \exp(-\beta E_i)$$

where E_i is the energy, $\beta = (kT)^{-1}$, and the summation is over all possible states. Transition rates given by [1] are about an order of magnitude larger than the accepted rates, and subsequently Nordholm (2) replaced the usual collision frequency by an effective collision frequency defined so as to allow the correct relaxation rate of the internal energy to be reproduced.

Meanwhile, as a result of examining information theoretic aspects of bulk relaxation, we (3) had constructed a set of transition rates for which the decay of both the total energy *and* all the populations is pure exponential; the elements of the relaxation matrix **A** are given by (4)

$$[2] \quad a_{ij} = \mu\{(1 - \delta_{ij})\tilde{n}_i - \delta_{ij}(1 - \tilde{n}_i)\}$$

where μ is a constant of proportionality, $\tilde{n}_i$ is the equilibrium population of state i, with $\sum \tilde{n}_i$ normalised to unity, and δ_{ij} is either zero or one. The meaning of eq. [2] is that for $i \neq j$

$$[3] \quad p_{j\to i} = \mu\tilde{n}_i/Z[\mathrm{M}]$$

and is clearly the same as eq. [1] apart from the proportionality factor $\mu/Z[\mathrm{M}]$; since μ is the time constant for relaxation, Z is the collision number, and [M] is the particle density, eq. [2] is equivalent to the "effective strong collision" modification of [1] introduced by Nordholm (2) as far as energy-transfer rates are concerned.

0008-4042/79/212793-05$01.00/0

The only point of difference between the two approaches is in the qualitative description of the fraction of events which leave the molecule unchanged, i.e. $p_{i\to i}$: according to eq. [1], it is always the same fraction of the collisions because the collision number is made proportional to the relaxation rate, whereas according to eq. [2], the fraction of collisions leaving the molecule of interest in an unchanged state increases as the relaxation rate constant μ decreases. However, at the simplest levels of theory, this distinction has no operational consequences, as can easily be seen algebraically by considering a chemical activation process.

We may represent the steady-state chemical activation experiment by the set of simultaneous equations

$$[4]\quad \frac{dn_i}{dt} = \sum_j a_{ij}n_j + d_i n_i + R_i \equiv [\mathbf{A} + \mathbf{D}]\mathbf{n} + \mathbf{R} = 0$$

where R_i is the rate of production of each state i by chemical activation, and d_i is (minus) the rate constant for the decay of state i to products, and the subscripts denote groups of levels or grains. This equation cannot be solved as it is unless one of two assumptions is made, either that **R** contains a sink term for the stabilised products, or the temperature is assumed to be so low that once products are stabilised, they can never again become interesting; the former approach is difficult to implement, and the latter is the one generally used. Treating the stabilised products as one grain and labelling it $i = 0$, we simply write all $p_{0\to i} = 0$ and discard the equation for dn_0/dt, giving

$$[5]\quad [\mathbf{A}' + \mathbf{D}']\mathbf{n}' + \mathbf{R}' = 0$$

where the prime indicates that the first row and the first column, representing transfers into and out of the stabilised state, are missing from all matrices. The submatrix **A**′ differs from a normal relaxation matrix for the subset of levels because it still contains in each diagonal element the term $-\mu\tilde{n}_0$, corresponding to the rate of transfer of molecules at that level out of the subsystem. Consequently, eq. [5] is equivalent to the standard strong-collision treatment of chemical activation processes (5, 6), except that ω, the collision rate, is replaced by $\mu\tilde{n}_0$; likewise, in the effective strong-collision case, ω would be replaced by $\lambda\omega$ (2).

Recognising this, it becomes clear that there is a very close connection between our reformulation of unimolecular reaction theory (4) and Nordholm's effective strong-collision modification of RRKM theory (2), and this renders it possible to place the former in its proper position in the hierarchy of unimolecular reaction theories. Standard RRKM theory uses an (independent channel) generalised Lindemann expression (eq. [27] of ref. 4), and is usually used in a scaled form which renders it an effective strong-collision theory (2). On the other hand, our reformulation (4) is an effective strong-collision theory in which proper allowance is made for the mutual perturbation of the competing reaction channels,[1] through a more complicated generalised Lindemann expression (eq. [46] of ref. 4). It would appear that if iterated to convergence, the first term in eq. [22] of ref. 2 would yield the same numerical results as this latter generalised Lindemann form: the second term in this equation allows for the possibility of differing collisional efficiencies for molecules of different internal energies, for which there is no counterpart in our formulation. Other intermediate levels of approximation are described in eqs. [16], [18], and [20] of ref. 2.

In the following sections, we first describe the commutative property of eq. [2] for non-reacting systems: then we show briefly how reacting systems, treated as a perturbation of [2], behave; finally, we try to predict some uses for, and to give a physical description of, this commutative property. We believe that this short exposition will not only complement the efforts of Nordholm, Freasier, and Jolly (1, 2) in trying to clarify the relationship between strong- and weak-collision theories, but that the algebraic properties we describe could be helpful in the construction of explicit formulae for strong-collision models of reaction rates.

Non-reacting Systems

Let **M** be the symmetrised form of **A**, viz.,

$$[6]\quad \mathbf{M} = \mathbf{E}^{-1/2}\mathbf{A}\mathbf{E}^{1/2}$$

where $e_{ij} = \tilde{n}_i\delta_{ij}$, and let **L** be the symmetrised form of *any* other relaxation matrix **B** for the same system of energy levels. **L** has a set of eigenvalues defined by

$$[7]\quad \mathbf{L} = \mathbf{S}\Lambda\mathbf{S}^{\mathrm{T}}$$

where[2]

$$[8]\quad 0 = \lambda_0 \gg \lambda_1 > \lambda_2 > \ldots > \lambda_{n-1}$$

and

$$[9]\quad S_{i,0} = \tilde{n}_i^{1/2}$$

M has the eigenvalues

$$[10]\quad 0 = m_0 \text{ and } m_1 = m_2 = \ldots = m_{n-1} = -\mu$$

[1]In the strong-collision regime, the neglect of the mutual perturbation between reactive channels has only a small effect, but it becomes progressively more serious as the collisions become weaker.

[2]Note the change of subscript ordering from all of our previous works.

The two matrices share one common eigenvector, $S_{i,0}$, given by eq. [9], but the other $(n-1)$ eigenvectors of **M** are undetermined.

While studying the relaxation behaviour of a model molecule diluted in a heat bath consisting of a mixture of two gases (7), the relaxation matrix $[(1-x)\mathbf{L} + x\mathbf{M}]$ (where x is the mole fraction) was examined and it was found that for all $x \neq 1$ and $i \neq 0$

$$[11] \quad [(1-x)\mathbf{L} + x\mathbf{M}]\boldsymbol{S}_i = [(1-x)\lambda_i - x\mu]\boldsymbol{S}_i$$

Thus, $[\mathbf{L} + \mathbf{M}]$ commutes with **L**, whence it follows that **M** commutes with **L**, and **A** with **B**. Following this discovery, it was demonstrated numerically that

$$[12] \quad \mathbf{M}\boldsymbol{S}_i = -\mu\boldsymbol{S}_i \qquad i \neq 0$$

to machine accuracy for several other relaxation matrices **L**, where the $\boldsymbol{S}_i$ were *any* of the vectors of the respective **L** matrices.

We have presented the commutative property of the relaxation matrix **A** (or its symmetrical form **M**) in this way, since this is the manner in which we discovered the property. Both referees have suggested that a formal proof should be given, and, in hindsight, such a proof is almost trivial. We may use the property (8) that *if* **A** *is a simple matrix with* s *distinct eigenvalues, every matrix which commutes with* **A** *has at least* s *independent right eigenvectors in common with* **A**. In our case, **A** has two distinct eigenvalues, 0 and $-\mu$, and we know that it shares one common eigenvector (cf. eqs. [8]–[10]) with **B** (when $\lambda_{\mathbf{B}} = 0$). Since the remaining eigenvectors of **A** corresponding to $\lambda_{\mathbf{A}} = m_i = -\mu$ are completely arbitrary except for the fact that they must be orthogonal to the known common eigenvector, we may choose any vector of **B** as the second vector of **A**; thus, the commutative property is established. Even more trivially, **A** and **B** share one common vector, and we may choose an acceptable second vector for **A** to be one of the remaining vectors of **B**; a third vector of **A** must be orthogonal to the first two, and so a third vector of **B** will be acceptable, and so on. Consequently, the vector set of **B** is an acceptable set for **A**. Likewise, vector sets of other matrices **C**, **D**, etc. are also acceptable sets of vectors for **A**: thus **A** will commute with **B**, **C**, **D**, etc. where **A**, **B**, **C**, **D**, etc. all refer to the relaxation of the same physical system at the same temperature (otherwise, they would not share a common eigenvector).

Reacting Systems

In our earlier paper (4), the rate constant for a unimolecular decomposition k_{uni} was taken as minus the eigenvalue of smallest numerical magnitude (i.e. $-\gamma_0$ in the present notation) of the perturbed relaxation matrix $[\mathbf{A} + \mathbf{D}]$ (unsymmetrised) or $[\mathbf{M} + \mathbf{D}]$ (symmetrised). If, for example, the system were grained so that all the bound states constitute one grain, **D**, the matrix of decay rate constants, would have the form diag$|0, -k_1, -k_2, \ldots, -k_{n-1}|$. Thus **D** would have one zero eigenvalue, but it does not commute with **A** or **M** since **D** will not drive the system to a Boltzmann distribution: the final distribution obtained by operating with **D** is that all reactive states are removed, but the bound-state population remains unchanged; in other words, the eigenvector corresponding to the zero eigenvalue is not [9], but is $\{1, 0, 0 \ldots\}$. Consequently, the eigenvalues of $[\mathbf{A} + \mathbf{D}]$ are not given exactly by the analogue of [11], viz.

$$[13] \quad \gamma_i = -(k_i + \mu),\ i \neq 0, \text{ or zero, } i = 0$$

However, under those conditions, i.e.

$$[14] \quad |\gamma_0| \ll k_i$$

when $\gamma_0 = -k_{\text{uni}}$ is adequately represented by eq. [46] of ref. 4, all the other γ_i fall in a sequence

$$[15] \quad \gamma_i = -(k_i + \mu - \delta_i) \qquad i \neq 0$$

with[3]

$$[16] \quad \delta_i > \delta_{i+1} \quad \text{and} \quad \sum_{i=1}^{n-1} \delta_i = k_{\text{uni}} = -\gamma_0$$

A further set of examples of the commutation of **M** with all other **L** (and the absence of extreme ill-conditioning in practical application) is provided by examination of the key equation (eq. [20*a*]) of ref. 4 for the eigenvectors ψ of the perturbed matrix $[\mathbf{M} + \mathbf{D}]$, i.e.

$$[17] \quad \psi_{ki} = \sum_l \sum_m \frac{S_{km} S_{lm}}{\gamma_i - \lambda_m} d_l \psi_{li}$$

where the γ_i are the true eigenvalues of $[\mathbf{M} + \mathbf{D}]$, the λ_m are those of **M** (i.e. 0 or $-\mu$) and **S** can now be the eigenvectors of any matrix **L** which commutes with **M**. We examined this relationship for three sets of surrogate vectors **S**, one for a full matrix **L** of arbitrary transition probabilities, one for a matrix **L** corresponding to the tridiagonal sum rule (3), and one for the continuant matrix [18] described below; in each case [17] held to machine accuracy.

Equation [17] is difficult to use, of course, if the γ_i are not known. However, $\gamma_0 = -k_{\text{uni}}$ is given explicitly by eq. [46] of ref. 4 and under all conditions where this is valid, the remaining γ_i, $i \neq 0$ may be very accurately approximated using [13] since by [14] and [16] *all* the δ_i are necessarily very small compared with the k_i.

[3]With the reactive region grained according to [18] and [19], it appears that $\delta_{i+1} \simeq c\delta_i$ with c typically about 0.5 or 0.6.

Possible Applications of Commuting Relaxation Matrices

Any computational advantage of using the commutative property will emerge only when one is interested in problems requiring a knowledge of the eigenvectors, e.g. the population distributions during a reaction, or the behaviour during the transient period, i.e. induction or incubation period. In isolated calculations, one would normally solve for the eigenvalues and eigenvectors of the relaxation matrix in the usual way, but when a series of very similar models is to be compared, eq. [17] (with [13] as an approximation for the γ_i, $i \neq 0$) would have real advantages.

In the strong- or effective strong-collision case, where we can have no significant information about the transients, we may be limited to comparing population distributions in the long-time regime: at infinite pressure, such information follows directly from eq. [22] of ref. 4, but in the fall-off region, all the eigenvectors would be required to evaluate the population evolution, using eq. [11] of ref. 4. According to [17], we need the eigenvalues and eigenvectors of *any* matrix **B** which commutes with **A**, and we are free to choose the most simple and convenient form of **B** (or **L**) if we wish to describe a coupled relaxation and reaction process governed by **A** (and **M**). One form which has interesting possibilities for unimolecular reaction theory is the continuant

$$[18] \quad \mathbf{L} = \begin{pmatrix} 1 & 1 & 1 & & 1 \\ d_0 & d_1 & d_2 & d_3 \ldots . & d_{n-1} \\ 1 & 1 & 1 & & 1 \end{pmatrix}$$

This implies that the elements of the unsymmetrised surrogate transition probability matrix are

$$[19] \quad p_{i\rightarrow j} = \tilde{n}_i{}^{-1/2}\tilde{n}_j{}^{1/2} \times \text{constant} \times (\delta_{i-1,j} + \delta_{i+1,j})$$

and the diagonal elements of **B** (or **L**) are then

$$[20] \quad d_j = -\tilde{n}_j{}^{-1/2}(\tilde{n}_{j-1}{}^{1/2} + \tilde{n}_{j+1}{}^{1/2}) \times \text{constant}$$

with $\tilde{n}_{-1}$ and $\tilde{n}_n$ taken to be zero. Suppose that we now grain the system in such a way that all $\tilde{n}_j/\tilde{n}_{j+1}$ $(0 \leq j < n-1)$ are constant, this causes all the d_j (except d_0 and $d_{n-1} = d_0{}^{-1}$) to be constant: we then subtract d_1 from all the diagonal elements in [18] to give

$$[21] \quad \mathbf{L}^* = \begin{pmatrix} 1 & 1 & 1 & & 1 \\ d_0{}^* & 0 & 0 & 0 \ldots . & d_{n-1}{}^* \\ 1 & 1 & 1 & & 1 \end{pmatrix}$$

If $d_0{}^*$ and $d_{n-1}{}^*$ were also zero, then the eigenvalues of $\mathbf{L}^*$ would be (9)

$$[22] \quad \lambda_j{}^0 = 2\cos[(j+1)\pi/(n+1)] \qquad j = 0, 1, 2, \ldots, n-1$$

$\mathbf{L}^*$, in fact, corresponds to a Hückel molecular orbital determinant for a polyene with two terminal hetero-atoms, one of higher and one of lower electronegativity, and the true eigenvalues λ_j' can be calculated by known methods (10); they will not be very different from the values given by [22], and the correspondence between the true eigenvalues λ_j' and the approximations $\lambda_j{}^0$ is shown in Fig. 1. The proper values λ_j of the eigenvalues of **L** are then found by adding d_1 to all the λ_j', and the un-normalised surrogate vectors are themselves simple continuants (11, 12), i.e.

$$[23] \quad S_{ij} = \begin{pmatrix} -1 & -1 & -1 & & -1 \\ a_i & -\lambda_j' & -\lambda_j' & -\lambda_j' \ldots . & a_0 \\ -1 & -1 & -1 & & -1 \end{pmatrix} S_{0j}$$

where $a_i = d_i{}^* - \lambda_j'$. A slightly simpler result, more appropriate for high temperatures, would be obtained by choosing the grain sizes so that all the $\tilde{n}_i$ were equal.

At the present time, unimolecular reaction theories are classified generally as strong-collision or weak-collision theories, and the intermediate ground between these two extremes is not well understood (1, 2). It has been suggested (13) that the transition from weak-collision to strong-collision behaviour could be explored using a reaction matrix

$$[24] \quad \mathbf{R} = \mathbf{E}^{-1/2}[x\mathbf{A} + (1-x)\mathbf{B} + \mathbf{D}]\mathbf{E}^{1/2} = [x\mathbf{M} + (1-x)\mathbf{L} + \mathbf{D}]$$

where x is now simply a weighting factor and **A** and **B** are respectively the strong- and weak-collision transition rate matrices. As a result of [11], only one set of eigenvalues and eigenvectors, those of **L** itself, are required for the implementation of [17] over the whole range of x, i.e., the transition from weak- to strong-collision behaviour.

The Physical Meaning of Commuting Relaxation Matrices

In quantum mechanics, the commutation of two operators gives rise to very specific conclusions about simultaneous observation, and is a very powerful conceptual tool. It does not appear that in chemical kinetics, commutation of operators (i.e. relaxation matrices) is of such far-reaching importance.

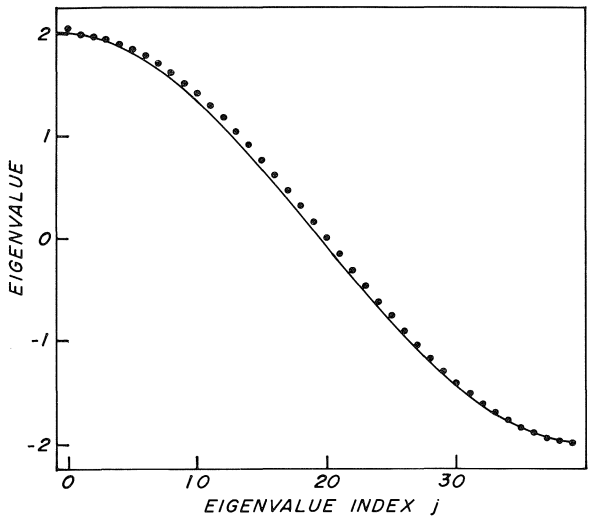

FIG. 1. Comparison of the eigenvalues of the shifted matrix **L*** of eq. [21] with the values given by the formula of Moffitt and Coulson, eq. [22].

In the absence of reaction, the relaxation of a system under the simultaneous influence of a transition matrix **B** and the $(n - 1)$-fold degenerate matrix **A** always has the form of the relaxation by **B** alone, in the sense that the eigenvectors of [**A** + **B**] are those of **B**, and these determine the form of the relaxation through the normal modes (14).

The important feature of the transition rates described by [2], as far as the commutation relationships are concerned, is that (3, 4)

$$[25] \quad n_i(t) = \tilde{n}_i + [n_i(0) - \tilde{n}_i]\, e^{-\mu t}$$

and, in fact, it is this property that renders the master-equation reformulation of unimolecular reactions (4) at all tractable. If we partition the nonstationary distribution at any time during a relaxation into a part which is Boltzmann for the temperature of the heat bath and a remainder, the operation of **A** on the remainder does not alter the ratios of population within the remainder, it simply shrinks all the unbalanced populations towards a Boltzmann distribution with the same time constant μ, according to eq. [25]. Thus, no matter what the form of **B**, **A** does not *interfere* with it, but simply changes the time constant according to eq. [11], and provides the only condition under which the linear mixture rule can be obeyed rigorously; similarly, the linear mixture rule for chemical reaction is only obeyed rigorously when the *reaction* matrices commute (15).

Notice also that eq. [25] provides one of the only two known idealised conditions under which a relaxation time can be defined uniquely (3, 4) whereas for all real molecular systems, the apparent relaxation time must depend somewhat upon the method of measurement (13, 14, 16).

In the reaction case, at least when k_{uni} is slow compared with the specific dissociation rate constants k_i, we would have, according to [15], a series of consecutive processes of time constant approximately $(k_i + \mu)$, and it is the smallness of the coupling terms δ_i (which together make up the rate constant [16]) which accounts for the fact that there is very little difference in numerical magnitude between the master-equation and RRKM generalised Lindemann forms (4); [15] and [16] may also be used to understand the convergence properties of eq. [22] of ref. 2.

JAN J. SPITZER, INGER V. OLOFSSON, PREM PAUL SINGH, and LOREN G. HEPLER. Can. J. Chem. **57**, 2798 (1979).

We have used a flow calorimeter and a flow densimeter for measurements at 25°C of heat capacities and densities of aqueous solutions of four electrolytes of high charge type: $LaCl_3$, $Cr(NO_3)_3$, $K_3Fe(CN)_6$, and $K_4Fe(CN)_6$. Results of these measurements have been used for calculating corresponding apparent molar heat capacities and apparent molar volumes, which have been extrapolated to infinite dilution to obtain the corresponding standard state apparent molar and partial molar properties. Uncertainties resulting from extrapolations of heat capacities are discussed. Results of our measurements are compared with those of earlier related investigations.

JAN J. SPITZER, INGER V. OLOFSSON, PREM PAUL SINGH et LOREN G. HEPLER. Can. J. Chem. **57**, 2798 (1979).

Nous avons utilisé un calorimètre et un densimètre à flux continu pour mesurer, à 25°C, les capacités calorifiques et les densités de solutions aqueuses de quatre électrolytes de type fortement chargés: $LaCl_3$, $Cr(NO_3)_3$, $K_3Fe(CN)_6$ et $K_4Fe(CN)_6$. Les résultats de ces mesures ont été utilisés pour calculer les capacités calorifiques molaires apparentes et les volumes molaires apparents correspondants. Par extrapolation à dilution infinie on obtient les propriétés molaires apparentes et molaires partielles apparentes de l'état fondamental correspondant. Nous discutons des incertitudes résultants des extrapolations des capacités calorifiques. Les résultats de nos mesures sont comparés à ceux obtenus au cours de recherches antérieures apparentées.

[Traduit par le journal]

Introduction

As part of our continuing program of measurements leading to thermal and volumetric properties of aqueous solutions, we have made calorimetric measurements leading to apparent molar heat capacities and density measurements leading to apparent molar volumes of four electrolytes of high charge type.

These heat capacities and volumes of solutes are useful for calculation of the temperature and pressure dependences of various thermodynamic properties; this usefulness has provided one reason for undertaking these measurements on electrolytes of high charge type, for which there are relatively few reliable volumes and even fewer heat capacities.

Experimental

Heat capacity measurements were made with a flow calorimeter of the Picker type that has been described previously (1). A small systematic error in some of the measurements has been identified and corrected as recently described (2, 3). Densities of solutions have been measured with a flow densimeter that has also been described (4). All results obtained with these instruments refer to 25.00 ± 0.01°C; temperatures were controlled to ±0.001°C during each measurement.

A few solutions of $K_3Fe(CN)_6$ and $K_4Fe(CN)_6$ were prepared by mass from distilled water and BDH Analar salts that had been dried to constant mass at 110°C. Most solutions of these electrolytes were prepared by mass from distilled water and BDH Analar salts that had been recrystallized from distilled water and then dried to constant mass at 105°C.

Fisher certified "$LaCl_3 \cdot 6H_2O$" samples were recrystallized from distilled water and then dissolved in distilled water to form two solutions that were close to 0.1 *M* lanthanum chloride with pH = 5.3. Small known amounts of hydrochloric acid were added to these solutions to lower the pH values to 4.9 and 4.3. These solutions were then analyzed gravimetrically for Cl^- by precipitation of AgCl; allowances were made for the very small amounts of added Cl^- in the calculations of concentrations of lanthanum in the solutions.

Fisher certified $Cr(NO_3)_3 \cdot 9H_2O$ was recrystallized from dilute nitric acid. Two different samples of the recrystallized material were dissolved in distilled water containing a little added nitric acid to form stock solutions. Aliquots of these stock solutions were analyzed for chromium as previously described (5). The two stock solutions were found to be 0.1159 *M* (pH = 2.2) and 0.3373 *M* (pH = 1.2). Further solutions for measurements of heat capacities and densities were prepared by dilution with distilled water; knowledge of densities permitted expression of final composition of solutions in terms of molalities of $Cr(NO_3)_3$(aq).

Results and Discussion

Apparent molar properties of solutions (ϕ_Y) are defined by

$$[1] \quad \phi_Y = [Y(\text{soln}) - n_1 Y_1^0]/n_2$$

in which the symbols have the following meanings:

*Stock solution for the first five measurements was 0.1159 M $Cr(NO_3)_3$ and had initial pH = 2.2; stock solution for the last six measurements was 0.3373 M $Cr(NO_3)_3$ and had initial pH = 1.2. In both cases, solutions used in the measurements were prepared by dilution with distilled water.

Y is the property (heat capacity or volume for our purposes) of a specified quantity of solution, n_1 is the number of moles of solvent in this specified quantity of solution, Y_1^0 is the property (heat capacity or volume) of 1 mol of pure solvent, and n_2 is the number of moles of specified solute in the specified quantity of solution.

Our experimental results (compositions of solutions, heat capacities, densities) have been used to obtain apparent molar heat capacities (ϕ_C) and apparent molar volumes (ϕ_V) that are listed in Table 1. In obtaining these tabulated quantities we have used $c_p^0 = 4.1793$ J K^{-1} g^{-1} and $d_1^0 = 0.997044$ g cm^{-3} for the heat capacity and density of pure water. Rather than tabulate our experimental heat capacities and densities of various solutions, we point out that these quantities can be recovered from the tabulated m, ϕ_C, and ϕ_V values by way of

$$[2] \quad c_p = (m\phi_C + c_p^0)/(1 + mM_2)$$

and

$$[3] \quad d = (1 + mM_2)d_1^0/(1 + md_1^0\phi_V)$$

Apparent molar properties of dilute aqueous solutions of strong electrolytes are accurately described by equations of the form

$$[4] \quad \phi_Y = \phi_Y^0 + A_Y(d_1^0 m)^{1/2} + B_Y m$$

in which ϕ_Y^0 is the limiting value of ϕ_Y at infinite dilution (identical to the corresponding partial molar property $\bar{Y}^0$), A_Y is the limiting slope derived from the Debye–Hückel theory, and B_Y is an adjustable parameter. We begin by applying [4] to our apparent molar volumes and then turn to similar application to our apparent molar heat capacities.

Millero (6) has thoroughly reviewed the applicability of the Debye–Hückel theory and eq. [4] to apparent molar volumes and also evaluated the limiting slopes. Following Millero (6) we use $A_V(d_1^0)^{1/2} = 27.413$ cm^3 mol$^{-3/2}$ kg$^{1/2}$ for electrolytes of 3:1 charge type and $A_V(d_1^0)^{1/2} = 58.984$ cm^3 mol$^{-3/2}$ kg$^{1/2}$ for electrolytes of 4:1 charge type. Least-squares analysis of our ϕ_V values in Table 1 in terms of eq. [4] leads to the ϕ_V^0 ($= \bar{V}^0$) and B_V values that are summarized in Table 2.

We do not know of any previous measurements on aqueous chromic nitrate leading to a ϕ_V^0 value to compare with our result in Table 2. We can, how-

TABLE 2. Volumetric parameters for eq. [4]

Solute	ϕ_V^0 / cm^3 mol^{-1}	B_V / cm^3 mol^{-2} kg
$Cr(NO_3)_3$	45.4	−41.1
$K_3Fe(CN)_6$	146.6	−24.6
$LaCl_3$ (all points)	13.8	−39.4
($m < 0.04$)	14.3	−54.9
$K_4Fe(CN)_6$	113.3	−43.4

ever, make indirect comparisons of our result with those of earlier workers by way of conventional ionic volumes based on $\phi_V^0(H^+) = 0$. Using $\phi_V^0(NO_3^-)$ from Millero (6) with our ϕ_V^0 from Table 2 leads us to our conventional $\phi_V^0(Cr^{3+}) = -41.6$ cm^3 mol^{-1}. Millero (6) has previously listed $\phi_V^0(Cr^{3+}) = -39.5$ cm^3 mol^{-1} based on earlier work. Lumme (7) has used densities of relatively concentrated (0.40 to 1.99 *M*) solutions of chromic perchlorate to calculate a ϕ_V^0 that we combine with $\phi_V^0(ClO_4^-)$ from Millero (6) to obtain a conventional $\phi_V^0(Cr^{3+}) = -47$ cm^3 mol^{-1}. We judge that our ϕ_V^0 for aqueous chromic nitrate and that our derived conventional $\phi_V^0(Cr^{3+})$ are the best ones available for this solute.

As shown in Table 2, we have analyzed our results for lanthanum chloride in two ways, obtaining ϕ_V^0 values that differ by 0.5 cm^3 mol^{-1}. We judge that the value based only on solutions with $m < 0.04$ mol kg^{-1} is better than the other value, which is based on these results *and* on those for more concentrated solutions. As can be seen from a graph of our ($\phi_V - 27.413m^{1/2}$) against m, there is a hint of a slight "break" or change in slope in the concentration range near 0.04 mol kg^{-1}. We therefore select $\phi_V = 14.3$ cm^3 mol^{-1} as the best value to be obtained from our measurements on aqueous lanthanum chloride and combine with the conventional $\phi_V^0(Cl^-)$ from Millero (6) to obtain a conventional $\phi_V^0(La^{3+}) = -39.2$ cm^3 mol^{-1}.

Dilatometric measurements by Dunn (8) have led him to $\phi_V^0 = 14.28$ cm^3 mol^{-1} for aqueous lanthanum chloride. Density measurements by two methods have led Spedding *et al.* (9, 10) to report $\phi_V^0 = 14.51$ and 14.688 cm^3 mol^{-1} for aqueous lanthanum chloride; we judge the first of these values to be better than the second because the first is based on densities for more dilute solutions than is the second.

We can also compare our conventional $\phi_V^0(La^{3+})$ from aqueous lanthanum chloride with similar conventional $\phi_V^0(La^{3+})$ values derived from ϕ_V^0 values for other salts of lanthanum. Results of this comparison, for which we have used $\phi_V^0(Cl^-$, ClO_4^-, and $NO_3^-)$ from Millero (6), are presented in Table 3. On the basis of our assessments of all of the investigations cited in Table 3, with particular

TABLE 3. Conventional $\phi_V^0(La^{3+})$ values

bias in favor of ϕ_V^0 values derived from measurements on the most dilute solutions, we choose $\phi_V^0(La^{3+}) = -39.1$ cm^3 mol^{-1} as the best available conventional ionic volume for La^{3+}(aq) at 25°C.

For aqueous $K_3Fe(CN)_6$, a 3:1 electrolyte, we have $\phi_V^0 = 146.4$, 146.2, and 146.8 cm^3 mol^{-1} from previous investigations (16–18), all in excellent agreement with our present $\phi_V^0 = 146.6$ cm^3 mol^{-1}.

Previous investigations of aqueous $K_4Fe(CN)_6$, a 4:1 electrolyte, have led to the following. Hepler, Stokes, and Stokes (18) obtained $\phi_V^0 = 110$ cm^3 mol^{-1} by way of measurements with a dilatometer.[3] More recently, Billi *et al.* (16) have reported $\phi_V^0 = 108.5$ cm^3 mol^{-1}, based on similar measurements; it is desirable to recalculate their results by way of an equation like [4], but their results are not presented in a way that permits such recalculation. Still other dilatometric measurements by Curthoys and Matheson (17) have led them to report $\phi_V^0 = 112.3$ cm^3 mol^{-1}; our recalculation (omitting the ϕ_V for their most dilute solution, for reasons discussed by Curthoys and Matheson) leads us to $\phi_V^0 = 112.7$ cm^3 mol^{-1}. Our present $\phi_V^0 = 113.3$ cm^3 mol^{-1} is not in ideal agreement with any of the previous results, which are not in good agreement with one another. There is, at present, no way to make a rational selection of a best ϕ_V^0 for aqueous $K_4Fe(CN)_6$.

Previous experience here and elsewhere with flow densimeters of the type we have used has provided good evidence that total uncertainties in derived ϕ_V^0 values are usually less than ± 0.5 cm^3 mol^{-1}. The agreement of our present ϕ_V^0 values for aqueous $LaCl_3$ (see Table 3) and aqueous $K_3Fe(CN)_6$ (discussed in the text earlier) is consistent with a similar estimate of our present uncertainties in ϕ_V^0 values for these solutes.

Because previous results for salts of Cr^{3+}(aq) have

[3]In ref. 18 we reported $\phi_V^0 = 147.8$ cm^3 mol^{-1} for aqueous $K_3Fe(CN)_6$; R. A. Robinson has kindly pointed out errors in our calculations and has provided a corrected $\phi_V^0 = 146.8$ cm^3 mol^{-1}.

quite large uncertainties, we are unable to use comparisons as a guide in estimating the uncertainty in our ϕ_V^0 for aqueous $Cr(NO_3)_3$. Instead, we estimate that the uncertainties in our *density measurements* are about the same as for other solutions, and also recognize that there is an additional source of uncertainty in the derived ϕ_V and ϕ_V^0 values. Because of the tendency of Cr^{3+}(aq) to hydrolyze to such species as $CrOH^{2+}$(aq), it was necessary for us to work with solutions that contained some nitric acid as well as the chromic nitrate of interest to us. The resulting additional uncertainty associated with treatment of our experimental data leads us to estimate that the *total* uncertainty in our reported ϕ_V^0 for aqueous $Cr(NO_3)_3$ is about ± 1.2 cm^3 mol^{-1}.

Uncertainties in ϕ_V^0 values based on dilatometric measurements of the type used in the three earlier investigations (16–18) of aqueous $K_4Fe(CN)_6$ are typically less than ± 0.5 cm^3 mol^{-1}, as they are for the flow densimeter we have used. It is obvious from the range of reported values (108.5, 110, 112.3 or 112.7, and 113.3 cm^3 mol^{-1}) that true uncertainties for at least some of these results are larger than normally found in this kind of work. We have no reliable way of selecting the best value or of assessing individual uncertainties.

In connection with our previous investigations of heat capacities of aqueous electrolytes of charge types 1:1 and 2:1 we have used $A_C(d_1^0)^{1/2} = 28.95$ and 150.4 J K^{-1} mol$^{-3/2}$ kg$^{1/2}$. These values are based on the earlier analyses of Philip and Desnoyers (19) and Leduc, Fortier, and Desnoyers (20), and have been used in connection with many similar investigations at the Université de Sherbrooke and elsewhere. Calculations by Spitzer (22) and by Silvester and Pitzer (23) have led to values of $A_C(d_1^0)^{1/2}$ about 10% and about 25% larger, respectively, than the values quoted above. Nearly all of the differences between these limiting slopes can be attributed to differences in the second derivatives of the dielectric constant of water with respect to temperature that have been selected by the various investigators (19, 20, 22, 23). Desnoyers and co-workers (19–21) and Spitzer (22) have tried to obtain the best limiting slopes for 25°C and other "ordinary" temperatures, all at 1 atm, while Silvester and Pitzer (23) have tried (24) to obtain the best complete set of limiting slopes for a much wider range of temperatures and pressures. These different approaches have necessarily been substantially based on different sets of dielectric constants and have therefore led to different second derivatives, which accounts for part of the discrepancy in $A_C(d_1^0)^{1/2}$ values.

If it were possible to make heat capacity measurements of sufficient accuracy on *very* dilute solutions, it would then be possible to obtain accurate ϕ_C^0 values and also limiting slopes by simply plotting ϕ_C against $m^{1/2}$. Since this simple approach is made unsatisfactory by our inability to make sufficiently accurate heat capacity measurements on sufficiently dilute solutions, we are forced to make use of some approach based on an equation like [4]. Application of eq. [4] with *three adjustable* parameters (ϕ_C^0, A_C, and B_C) to presently available heat capacities is generally unsatisfactory because it is possible to fit the experimental results with a range of values of the three parameters that is unacceptably large. We note, however, that modest improvements in our ability to measure heat capacities of dilute solutions may suffice to make one of the approaches described in this paragraph useful in the future.

Our best presently available approach to analysis of heat capacities of dilute solutions is based on eq. [4] with limiting slope derived from the Debye–Hückel theory and the properties (density and dielectric constant) of water. In the following discussion of this approach, we will focus on the slopes from Desnoyers and co-workers (19, 20) and from Silvester and Pitzer (23) because Spitzer's limiting slope falls in between these other values.

Application (25) of eq. [4] to typical heat capacities of 1:1 electrolytes at 25°C is not critically dependent on whether we use Desnoyers' (19, 20) or Pitzer's (23) limiting slope because derived ϕ_C^0 values ordinarily differ by only about 1 J K^{-1} mol^{-1}, which is about one-third of the commonly estimated uncertainty associated with heat capacities obtained recently in both Sherbrooke and Lethbridge. Similar application (25) of eq. [4] to heat capacities of solutions of 2:1 electrolytes shows that ϕ_C^0 values derived on the basis of the two different limiting slopes under present consideration differ by about 6 J K^{-1} mol^{-1}, which is a little larger than previously estimated uncertainties in these values. Because of the way (19, 20, 22, 23) in which electrolyte charge enters A_C, we anticipate that the ϕ_C^0 values derived from applications of eq. [4] to our present heat capacities of solutions of electrolytes of 3:1 and 4:1 charge types will depend significantly on our choice of limiting slope.

Our calculations with eq. [4] for 3:1 electrolytes have been based on $A_C(d_1^0)^{1/2} = 425.5$ and 523 J K^{-1} mol$^{-3/2}$ kg$^{1/2}$ from Desnoyers and co-workers (19, 20) and from Silvester and Pitzer (23), respectively. Similar calculations for the 4:1 electrolyte $K_4Fe(CN)_6$ have been done with $A_C(d_1^0)^{1/2} = 915.5$ and 1126 J K^{-1} mol$^{-3/2}$ kg$^{1/2}$ from the same sources. Results of all of these calculations are summarized in Table 4.

We do not know of any heat capacities of solutions of $Cr(NO_3)_3$, $K_3Fe(CN)_6$, or $K_4Fe(CN)_6$ that can be compared with our results in Tables 1 and 4.

TABLE 4. Heat capacity parameters for eq. [4]

	$m < 0.06$	−242	−1628	−251	−1887
	visual	−230		−240	
$K_3Fe(CN)_6$		$-206._5$	−300	$-218._7$	−478
$K_4Fe(CN)_6$		−460	−688	−481	−1141

Spedding and Jones (26) have measured heat capacities of aqueous solutions of lanthanum chloride, all having molalities greater than 0.1 mol kg^{-1}, and have treated their results with an equation of the form of

$$[5] \quad \phi_C = A + Bm^{1/2} + Cm + Dm^{3/2} + Em^2$$

in which A, B, C, D, and E are adjustable parameters. They report $A = -466$ J K^{-1} mol^{-1}. It is our opinion that the uncertainty in this value (mostly due to a lack of data below 0.1 m) is too large to justify its use in choosing between the various ϕ_C^0 values listed for aqueous $LaCl_3$ in Table 4.

We also note that heat capacities of solutions of $La(NO_3)_3$ and $La(ClO_4)_3$ have been measured (27, 28) at concentrations above 0.1 mol kg^{-1}. Extrapolations of the results to infinite dilution by way of equations like [5] have led (27, 28) to $\phi_C^0 = -286$ J K^{-1} mol^{-1} for aqueous $La(NO_3)_3$ and to $\phi_C^0 = -222$ J K^{-1} mol^{-1} for aqueous $La(ClO_4)_3$. Combinations of these values with conventional ϕ_C^0 values (29) for aqueous Cl^-, NO_3^-, and ClO_4^- leads to $\phi_C^0 = -448$ and -525 J K^{-1} mol^{-1} for aqueous $LaCl_3$. Again we are unable to use these results from other investigations to help us choose between the various ϕ_C^0 values listed in Table 4.

Heat capacities of solutions of a few other MCl_3 salts are worth mentioning. Measurements by Vasilev and co-workers (30, 31) have led to $\phi_C^0 = -418$ J K^{-1} mol^{-1} for aqueous YCl_3 and to $\phi_C^0 = -466$ J K^{-1} mol^{-1} for aqueous $CeCl_3$. Spedding, Walters, and Baker (32) have measured heat capacities of solutions of eight different rare earth chlorides and have reported corresponding ϕ_C^0 values ranging from -434 to -519 J K^{-1} mol^{-1}; we particularly note their $\phi_C^0 = -493$ J K^{-1} mol^{-1} for aqueous $GdCl_3$. Jekel, Criss, and Cobble (33) have used enthalpies of solution at several temperatures to derive $\phi_C^0 = -435$ J K^{-1} mol^{-1} for aqueous $GdCl_3$ at 25°C. Once again we are unable to use these results from other investigations to help us choose between the various ϕ_C^0 values listed in Table 4.

In spite of the uncertainties in our measurements and those from our calculations based on different limiting slopes in the heat capacity eq. [4], we believe that our ϕ_C^0 values in Table 4 are the best ones now available for aqueous electrolytes of 3:1 and 4:1 charge types.

NOTE ADDED IN PROOF: Bradley and Pitzer (33) have reported results of their new calculations of Debye–Hückel parameters. Because the "best" A_C now appears to be intermediate between values we have used, corresponding "best" ϕ_C^0 values are probably intermediate between values listed in Table 4.

Bottomley, Glossop, and Staunton (34) have reported a new and apparently reliable $\phi_V^0 = 111.7$ cm^3 mol^{-1} for aqueous $K_4Fe(CN)_6$.

Erratum: Phase-transfer catalyzed synthesis of activated cyclopropanes

JOHN M. MCINTOSH AND HAMDY KHALIL
Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

(Ref.: Can. J. Chem. **56**, 2134 (1978))
Received August 20, 1979

The experimental directions regarding the amounts of reagents and solvent are in error. Thus the first three sentences of the experimental procedure should read:

To a mixture of 40 mL of methylene chloride and 4.1 mL of 9.5 *N* aqueous sodium hydroxide (0.04 mol) was added ca. 100 mg of benzyltriethylammonium chloride (TEBAC). The system was cooled to 0°C in an ice–salt bath. To this solution was added a mixture of 0.04 mol of each of the acceptor and donor molecules at 0°C with good stirring.

Mechanistic and theoretical studies of the photochemistry of 5,6-dihydro-2-cyanobenzobarrelene

CHRISTOPHER OWEN BENDER AND SEAMUS F. O'SHEA

Department of Chemistry, University of Lethbridge, Lethbridge, Alta., Canada T1K 3M4

Received May 1, 1979

CHRISTOPHER OWEN BENDER and SEAMUS F. O'SHEA. Can. J. Chem. **57**, 2804 (1979).

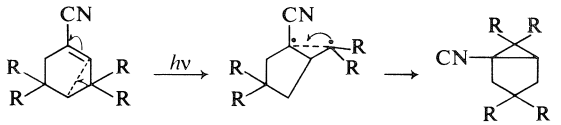
The direct ($\Phi_6 = 0.04$) or acetone sensitized ($\Phi_6 = 0.51$) photolysis of 2-cyano-1,4-dihydro-1,4-ethanonaphthalene (**5**) yields 1-cyanobenzotricyclo[3.3.0.0^{2,8}]octa-3-ene (**6**). Deuterium labelling studies suggest that **6** derives from a Zimmerman di-π-methane rearrangement and not from the McCullough 1-cyanocyclohexene rearrangement. The observed rearrangement and regioselectivity are in accord with predictions based upon CNDO-CI calculations of changes in atom–atom interaction energies on excitation to the S_1 and T_1 excited states of **5**.

CHRISTOPHER OWEN BENDER et SEAMUS F. O'SHEA. Can. J. Chem. **57**, 2804 (1979).

La photolyse directe ($\Phi_6 = 0.04$) ou sensibilisée par l'acétone ($\Phi_6 = 0.51$) du cyano-2 dihydro-1,4 éthano-1,4 naphtalène (**5**) conduit au cyano-1-benzotricyclo[3.3.0.0^{2,8}]octa-3-ène (**6**). Des études de marquages au deuterium suggèrent que **6** dérive d'un réarrangement di-π méthane de Zimmerman et non pas par un réarrangement cyano-1 cyclohexène de McCullough. Le réarrangement et la régiosélectivité observés sont en accord avec les prédictions qui proviennent de calculs des changements d'energies d'interactions atome–atome sur excitation à l'état singulet (S_1) et à l'état triplet (T_1) de **5**.

Introduction

The topic of photo-regioselectivity in triplet sensitized di-π-methane rearrangements of polar-substituted dihydrobenzobarrelene and related (e.g., benzonorbornadiene) derivatives is of current theoretical and experimental interest (1). Since cases where the polar substituent is on the alkene moiety have not been reported we undertook the study of the photochemistry of the cyanolated dihydrobenzobarrelene **5**. The choice of the cyano group as substituent was prompted by the recent discovery of McCullough and Manning that the 1-cyanocyclohexene derivatives **1***a*, *b* photorearrange to bicyclo[3.1.0]hexane-1-carbonitriles (**3***a*, *b*) according to the general mechanism proposed in Scheme 1 (2).[1] Thus



1*a* (R = H)
1*b* (R = CH_3)

2*a*,*b*

3*a*,*b*

SCHEME 1

in addition to providing regioselectivity information the investigation of **5** was conceived to examine the intramolecular competition between the 1-cyanocyclohexene and di-π-methane rearrangements.

Results

Compound **5** was isolated as a colourless solid from the diimide reduction of the less polar double bond of the known (3) 2-cyanobenzobarrelene (**4**) (see Scheme 2). The nmr data support the structure assigned to **5**: δ6.60–7.05 (m, 5H, H-3 and aromatics), δ3.76–4.03 (m, 2H, bridgeheads), and δ1.12–1.80 (m, 4H, methylenes). Particularly informative is the Eu(fod)$_3$ shifted spectrum, which, after the addition of 12 mol% of the LIS reagent, reveals one olefinic hydrogen, H-3, at δ7.70 (d, $J_{3,4} = 6.0$ Hz), coupled, as shown by double irradiation techniques, to H-4 at δ4.30 (broad d, $J = 6.0$ Hz); H-1 is a broad singlet at δ4.65 and the four methylene protons at C-5 and C-6 occur as a complex multiplet centred at δ1.83. In further accord with the structure, the deshielding effect of the cyano group on the adjacent coplanar vinyl proton, H-3, (δ6.90 in the absence of Eu(fod)$_3$; one limb of the doublet is hidden by the aromatic multiplet) relative to the corresponding proton in 2,3-dihydrobenzobarrelene (4) is 0.74 ppm which compares well with the reported chemical shift substituent constant of 0.8 for the *cis* proton of acrylonitrile (5).

On direct irradiation at 254 nm **5** gave the dihydrosemibullvalene derivative **6** as the major product isomeric with starting material; variable

[1]The experimental evidence does not exclude a concerted $2\sigma_a + 2\pi_a$ conversion of **1***a*, *b* to **3***a*, *b* (2).

SCHEME 2

amounts of polymer were also formed together with minor amounts of other products which polymerized during work-up. By contrast, the acetone sensitized irradiation of **5** at 313 nm yielded only **6**. Photoproduct **6** is identical to the unique product isolated from the diimide reduction of the known (3) 1-cyanobenzosemibullvalene **7**.

The interpretation of the 400 MHz nmr spectrum of **6** is straightforward. In addition to the aromatic proton signals which occur as two sets of multiplets at δ7.20 (3H) and δ7.02 (1H) the spectrum contains seven distinctly separated nearly first order one-proton resonances for the seven non-aromatic protons (see Experimental).

The couplings between protons were confirmed by double irradiation techniques. The fact that H-5 occurs as a doublet, being coupled to H-6 (J = 5.0) but not to H-6′, is not unexpected since the dihedral angle between H-5 and H-6′ is 90° (Drieding Model). Furthermore, Paquette and co-workers have reported that H-5 and H-6′ are also not coupled in the semibullvalene derivative **8** (*6*).

Support for the proton assignments was provided by observing the effect of $Eu(fod)_3$ addition to the nmr solution of **6** (see Fig. 1). The hydrogens at C-2, C-5, and C-8 are closest and approximately equidistant from the cyano group, and consequently their signals are shifted the most and to approximately the same extent; the signals of the methylene hydrogens H-6 and H-7 *syn* to the cyano group are

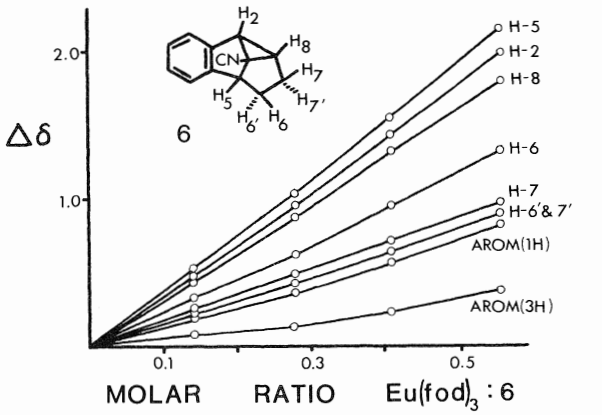

FIG. 1. Variation of chemical shift for the protons in **6** with increasing addition of the shift reagent $Eu(fod)_3$.

shifted more than those of the H-6′ and H-7′ *anti* methylene hydrogens.

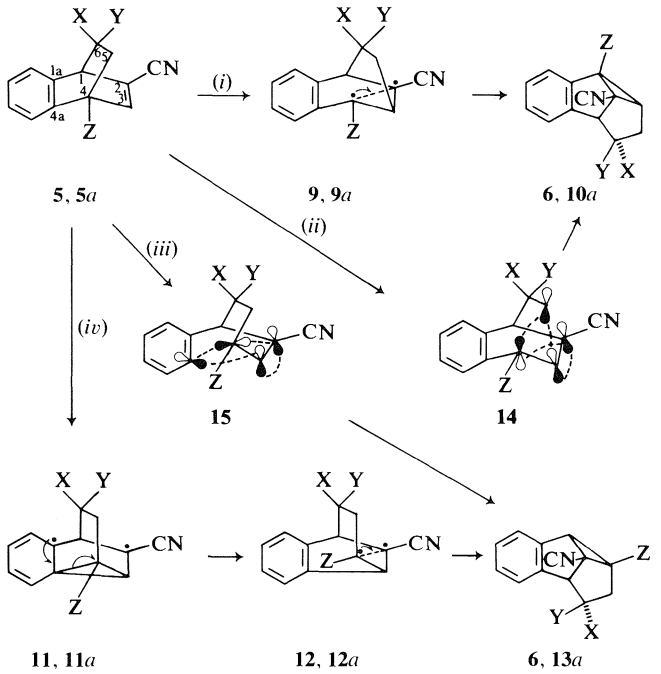
Quantum Yields and S_1 *and* T_1 *Energies of* **5**

The quantum yields for the transformation of **5** to **6** were investigated to ascertain the relative efficiencies of the sensitized and unsensitized processes; in cyclohexane with 254 nm light the appearance Φ for **6** is 0.04 whereas in neat acetone with 313 nm light Φ is 0.51.

The singlet energy of **5** in cyclohexane solution at room temperature was determined to be 102 kcal mol^{-1} from intersection of the absorption and fluorescence spectra. The triplet energy of **5** could not be obtained spectrometrically since no phosphorescence in isopentane – methylcyclohexane glass at 77 K could be detected. However, an "effective" triplet energy at room temperature in cyclohexane solution of $74 \gtrsim E_T > 69$ kcal mol^{-1} is suggested by triplet sensitization experiments; the conversion of **5** to **6** can be sensitized efficiently by acetone (Φ = 0.51; E_{T_1} = 78 kcal mol^{-1}), less efficiently by acetophenone (Φ = 0.16; E_{T_1} = 74 kcal mol^{-1}) but apparently not by benzophenone (E_{T_1} = 69 kcal mol^{-1}) or by thioxanthone (E_{T_1} = 65 kcal mol^{-1}).

Mechanistic Considerations

The formation of **6** from **5** can be accounted for in terms of the McCullough 1-cyanocyclohexene rearrangement (Scheme 3, route *i*, stepwise; route *ii*, concerted, $2\sigma_a + 2\pi_a$), or the Zimmerman di-π-methane rearrangement (7) (Scheme 3, route *iv*, stepwise; route *iii*, concerted, $2\sigma_a + 2\pi_a$). A means of determining the route *i* (or *ii*) versus route *iv* (or *iii*) competition was provided by examining the photolyses of the mixture of deuterated dihydrobarrelenes **5***a*. Mixture **5***a* was prepared from the diimide



SCHEME 3. For **5**, **6**, **9**, **11**, and **12**, X = Y = Z = H. For series *a*, individual structures represent a 1:0.6:0.4 mixture of three component isotopes, **20**, **21**, and **22** respectively (see Scheme 4), each singly labelled with deuterium at the positions designated by Z, X, and Y.

reduction of the previously available (3) 50:50 mixture of deuterated barrelenes **18** and **19** (containing 94 ± 3% *d*, at C-4 and 92 ± 4% *d*, at C-6 respectively) obtained from the addition of benzyne to *meta* deuterobromobenzene followed by treatment with cuprous cyanide (see Scheme 4).

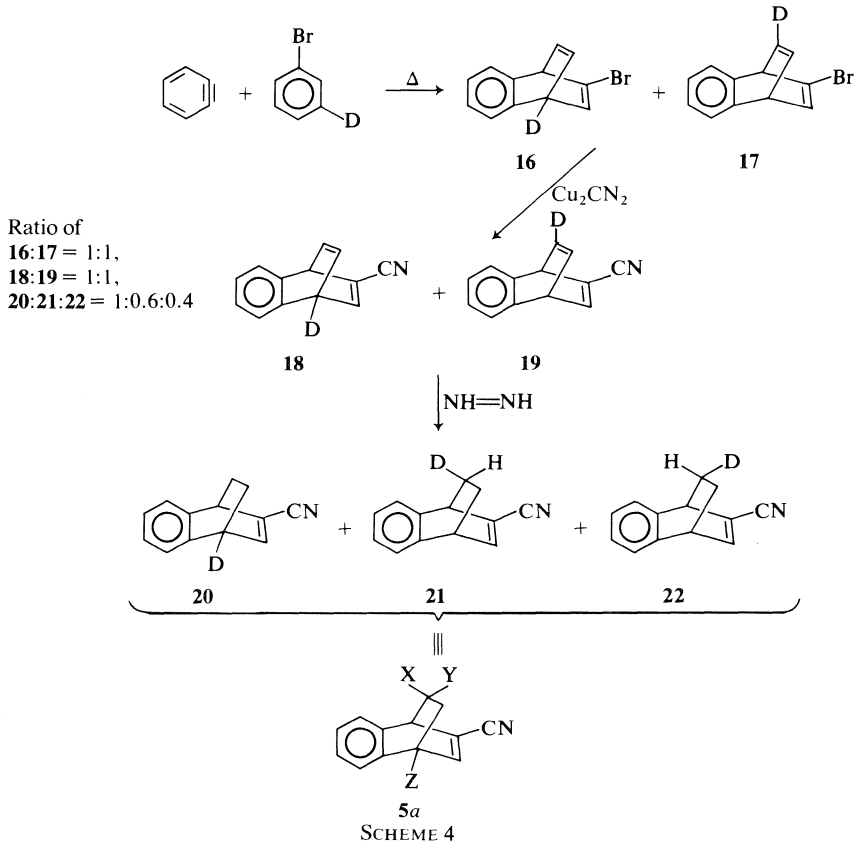
Nuclear magnetic resonance evidence indicates that this synthetic sequence leads to the formation of three isotopes **20**, **21**, and **22**. Comparison of the integrated areas of the bridgehead (H-1, H-4) and the methylene proton signals in the Eu(fod)$_3$ shifted spectrum reveals that the total deuterium content of mixture **5***a* is 94 ± 5% (assuming 0%-d_1 in the aromatics) and that the ratio of **20**:(**21** + **22**) is ca. 1.0:1.0. The relative amounts of **21** and **22** present in the mixture could not be ascertained directly from the nmr data of **5***a* because of overlap of the methylene proton signals. However, a ratio of 1.5 (**21**):1.0(**22**) is suggested from inspection of the nmr spectrum of the deuterated dihydrosemibullvalene photoproducts **13***a* (*vide infra*).

The hydrogen distributions of the dihydrosemibullvalene material isolated from the direct, acetone and acetophenone sensitized, irradiations of the deuterated mixture **5***a* are the same within experimental error (see Table 1); half of the deuterium is located at C-8 and the other half at C-6, i.e., consistent with **13***a*. Thus the McCullough 1-cyanocyclohexene rearrangement (routes *i* and *ii*, Scheme 3) does not participate in the formation of **6** during direct or sensitized irradiations of **5**.

Inspection of Table 1 also reveals that the H-6:H-6′ ratio accords with a distribution of 1.5:1.0 (*anti*:*syn*) for the deuterium on C-6, a result that suggests that the ratio of **21**:**22** is also 1.5:1.0 in the deuterated starting mixture **5***a* (assuming that no deuterium scrambling at C-6 occurs during the course of rearrangement to **13***a*), which in turn implies that the reduction of **4** is 60% stereoselective in favour of the vinyl–vinylcyano rather than benzo–vinyl approach of diimide.

Discussion

The excited state of **5** yielding **6** upon sensitized irradiations with acetone or acetophenone is assumed to be T_1. This assumption is based on the finding that when either sensitizer is used the deuterated dihydrobarrelene **5***a* gives dihydrosemibullvalene product containing the same label distributions, i.e., **13***a*. The observation that the quantum yield for the formation of **6** (Φ = 0.51) is much higher in the case of acetone (E_{T_1} = 78 kcal mol^{-1}) sensitization than



SCHEME 4

in acetophenone sensitization ($\Phi = 0.16$) is taken to mean that T_1 of **5** is close to T_1 of acetophenone, i.e., 74 kcal mol^{-1}.[2]

In the case of the direct irradiation of **5** the excited state leading to **6** is not clear. T_1 is a reasonable candidate on the grounds that (*a*) the formation of **6** from the direct irradiation of **5** ($\Phi = 0.04$) is much less efficient than in the case of acetone sensitized runs ($\Phi = 0.51$) as expected for a process involving intersystem crossing, and (*b*) the deuterium labelled mixture **5***a* leads to dihydrosemibullvalene material (i.e., **13***a*) containing the same label distributions from direct and sensitized irradiations. However, there is no evidence to rule out involvement of S_1. In fact our CNDO/2-CI calculations (*vide infra*) suggest that S_1 should follow the same overall mechanistic course as T_1.

With respect to the mechanistic considerations, the observed preference for route *iii* (or *iv*) over route *i* (or *ii*) (Scheme 3) is in excellent agreement with predictions derived from CNDO/2-CI calculations of changes of atom–atom interaction energies in the singlet (S_1) and triplet (T_1) excited states of **5** (see Table 2). In these calculations (3) (see Experimental) the electronic excitation energy for the lowest singlet and triplet states are rewritten as sums of changes in single-atom energies and atom-pair interaction energies. By interpreting these changes in interaction energies as forces which give rise to initial nuclear motion and by assuming that in rigid systems[3] these motions determine the ultimate products, we can make predictions about preferences between competing processes.

For the non-concerted transformations (Scheme 3, routes *i* and *iv*) of **5** to **6** the calculations suggest that for both the S_1 and T_1 excited states of **5** the largest attractive 1,3 non-bonded carbon–carbon interaction is that between C-3 and C-4a (case 1) while the greatest weakening in existing bonds occurs between C-2 and C-3 (case 13) and between C-1a and C-4a

[2]Interestingly, theoretical calculations (CNDO/2-CI, *vide infra*) for the lower excited states of **5** give relative theoretical energy ratios of $1.000(S_1):0.709(T_1):1.070(S_2):0.927(T_2)$. Since the singlet ($S_1$) energy of **5** was determined to be 102 kcal mol^{-1} (*vide supra*) the following scaled estimates for the energies of the other excited states can be obtained: $T_1 = 72$ kcal mol^{-1}, $S_2 = 109$ kcal mol^{-1}, and $T_2 = 95$ kcal mol^{-1}.

[3]Zimmerman and co-workers have recently reported similar calculations on excited states of some non-rigid systems (8).

[a]Calculated by the CNDO/CI method using the theoretical parametization (11).
[b]Negative values are interpreted as "forces" tending to bring the atoms together, while positive values cause the atoms to move further apart.
[c]Calculations on the full molecule **5** were performed; only values for the dihydrobarrelene portion are given here.
[d]The numbering of the atoms is that given in Scheme 3.

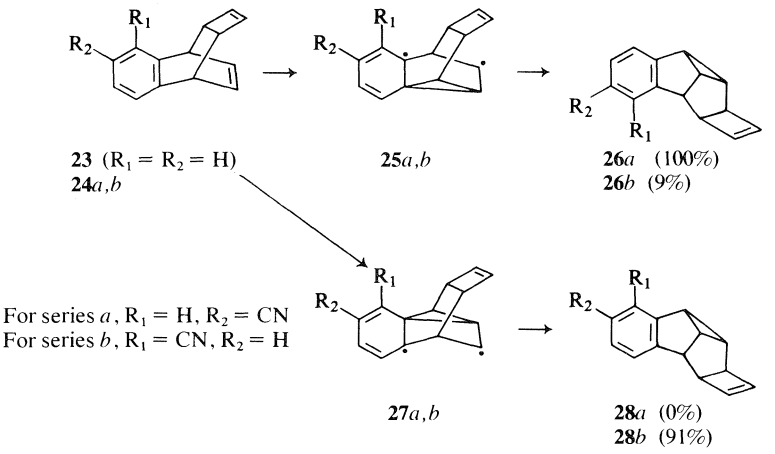
(case 14). These predictions precisely coincide with the initial bonding reorganizations that would be engendered in the formation of the first diradical intermediate **11** in the di-π-methane mechanism (route *iv*). The formation of the initial diradical **9** in the 1-cyanocyclohexene mechanism (route *i*) is seen by inspection of Table 2 (cases 3, 13, and 18) to be less favourable.

Likewise, for the concerted alternatives for the transformations of **5** to **6** (Scheme 3, routes *ii* and *iii*) the di-π-methane rearrangement ($2\sigma_a + 2\pi_a$ version, route *iii*) is, according to the calculations, more favourable than the 1-cyanocyclohexene rearrangement ($2\sigma_a + 2\pi_a$ version, route *ii*) (cf. cases 1, 6, 13, and 15 with cases 3, 6, 13, and 18 respectively).

Turning now to the topic of di-π-methane regioselectivity, it should be noted that Paquette and coworkers have reported the striking control on the directionality of benzo–vinyl bonding exerted by the cyano group when substituted in the aromatic ring of the dihydrobenzobarrelene **23** (Scheme 5); in the case of the *meta* cyano derivative (**24***a*) the di-π-methane rearrangement proceeds with complete regiospecificity, to give **26***a* (1*a*) while for the *ortho* cyano derivative (**24***b*) it proceeds with high regioselectivity to produce 91% **28***b* and 9% **26***b* (1*b*). In the case of **5** where the cyano group is on the alkene moiety its effect is also profound; the triplet di-π-methane rearrangement is regiospecific, proceeding via C_3—C_{4a} bonding. Inspection of Table 2 (case 1) reveals that the CNDO/2-CI atom–atom approach predicts a preference for the observed initial C_3—C_{4a} bonding over the alternative di-π-methane initial C_{1a}—C_2 bonding option (case 2).

Experimental

The nmr spectra were recorded on Bruker 400 MHz or Varian (EM-360) 60 MHz instruments with TMS as internal standard. The ir spectra were recorded on a Perkin-Elmer 337 spectrometer, the uv spectra on a Cary 15 spectrophotometer, and the mass spectra on an MS 9 (A.E.I.). All melting points are uncorrected. Elemental analyses were performed by Galbraith Labs. Inc., Knoxville, TN. Cyclohexane solvent was



SCHEME 5

prepared for photolyses by scrubbing with 10% of its volume of 30% fuming sulfuric acid, followed by washing with 10% aqueous sodium hydroxide, drying ($MgSO_4$), and finally distilling from calcium hydride. Solid triplet sensitizers were sublimed and recrystallized prior to use, and acetophenone was distilled. Acetone sensitizer was obtained by refluxing spectroscopic grade acetone with neutral potassium permanganate, followed by distillation and then redistillation from anhydrous potassium carbonate. Nuclear magnetic resonance chemical shifts are given in δ units and J values in hertz; uv maxima are given in nanometers (ε); ir bands are given in reciprocal centimeters. Thin-layer chromatographic separations were carried out on Merck plates, 20 cm × 20 cm, 0.25 mm layer of Silica Gel 60 F-254.

2-Cyano-1,4-dihydro-1,4-ethanonaphthalene (5)

To a stirred mixture of 741.7 mg (4.2 mmol) of **4** (3) and 1.6858 g of potassium azodicarboxylate (8.7 mmol) in 30 mL of methanol at −30°C, 1.5 mL of acetic acid was added in one portion. The reaction mixture was allowed to warm to room temperature during 1.5 h after which time the solution was added to 300 mL of cyclohexane and was washed with 5% aqueous sodium hydroxide (200 mL) followed by water (2 × 200 mL). The cyclohexane solution was dried ($MgSO_4$), concentrated *in vacuo*, and the residue column chromatographed on silicic acid (100–200 mesh) with 1% ether–cyclohexane. Crystallization of the contents of the first band from hexane gave 175.2 mg (23%) of colourless **5**, mp 66–68°C; ir (KBr): 2200, C≡N; uv (cyclohexane): 222 sh (6200), 238 sh (1120), 253 sh (720), 260 (540), 267 (330), and 269 (280); nmr (60 MHz, CCl_4): 6.60–7.05 (m, 5H, H-3 and aromatics), 3.76–4.03 (m, 2H, bridgeheads), and 1.12–1.80 (m, 4H, methylenes); LIS nmr (60 MHz) with 11.1 mg of **5** and 8.3 mg of Eu(fod)$_3$ in 0.25 mL CCl_4: 7.70 (d, 1H, H-3, $J_{3,4}$ = 6.0), 7.24 (m, 4H, aromatics), 4.65 (br s, 1H, H-1), 4.30 (br d, 1H, H-4, $J_{3,4}$ = 6.0), and 1.83 (m, 4H, methylenes); spin-decoupling experiments on LIS spectrum: irradiation of H-3 collapsed H-4 to a broad singlet. Mass spectrum (70 eV, direct inlet) showed molecular ion at m/e 181.0892 (10%), $C_{13}H_{11}N$ requires 181.0891. *Anal.* calcd. for $C_{13}H_{11}N$: C 86.15, H 6.12, N 7.73; found: C 85.91, H 6.13, N 7.63.

Crystallization (hexane) of the contents of the second band from the column chromatography yielded 554.0 mg (75%) of recovered starting material (**4**).

1-Cyanobenzotricyclo[3.3.0.0^{2,8}]octa-3-ene (6)

To a stirred mixture of 113.1 mg (0.62 mmol) of **7** (3) and 650.2 mg of potassium azodicarboxylate (3.4 mmol) in 30 mL of methanol at −30°C, 1.5 mL of acetic acid was added in one portion. The reaction mixture was allowed to warm to room temperature during 1.5 h and was then worked up and chromatographed as described for the preparation of **5** (*vide supra*). Crystallization (hexane) of the contents of the first band off the column gave 42.6 mg (37%) of colourless **6**, mp 64–66°C; ir (KBr): 2230, C≡N; uv (cyclohexane): 220 sh (4070), 257 sh (260), 262 (440), 267 sh (600), 268 (680), and 276 (830); nmr (400 MHz, $CDCl_3$): 7.20 (m, 3H, aromatic), 7.02 (m, 1H, aromatic), 3.87 (d, 1H, H-5, $J_{5,6}$ = 5.0, $J_{5,6'}$ = 0.0), 3.15 (d, 1H, H-2, $J_{2,8}$ = 8.0), 2.60 (m, 1H, H-8, $J_{2,8}$ = 8.0, $J_{7,8}$ = 2.0, $J_{7',8}$ = 6.6), 2.45 (m, 1H, H-6, $J_{6,7}$ = 11.5, $J_{5,6}$ = 5.0, $J_{6,6'}$ = 10.8, $J_{6,7'}$ = 8.5), 2.01 (m, 1H, H-7′, $J_{7',8}$ = 6.6, $J_{6',7'}$ = 0.0, $J_{6,7'}$ = 8.5, $J_{7,7'}$ = 11.0), 1.76 (q, 1H, H-6′, $J_{6',7}$ = 6.0, $J_{6',7'}$ = $J_{5,6'}$ = 0, $J_{6,6'}$ = 10.8), and 1.20 (m, 1H, H-7, $J_{7,8}$ = 2.0, $J_{6',7}$ = 6.0, $J_{6,7}$ = 11.5, $J_{7,7'}$ = 11.0); spin-decoupling experiments: irradiation of H-7 collapsed H-6′ to a d ($J_{6,6'}$ = 10.8), collapsed H-8 to a q ($J_{2,8}$ = 8.0, $J_{7',8}$ = 6.6), and modified the H-7′ and H-6 multiplets; irradiation of H-6′ collapsed H-7 to a broad t ($J_{7,7'}$ = 11.0, $J_{6,7}$ = 11.5, $J_{7,8}$ = 2.0) and modified the H-6 m; irradiation of H-7′ collapsed H-8 to a broad doublet ($J_{2,8}$ = 8.0, $J_{7,8}$ = 2.0) and modified the H-6 and H-7 multiplets; irradiation of H-6 collapsed H-5 to an s, collapsed H-6′ to a d ($J_{6',7}$ = 6), and modified the H-7 and H-7′ multiplets; irradiation of H-8 collapsed H-2 to an s, collapsed H-7′ to a q ($J_{7,7'}$ = 11.0, $J_{6,7'}$ = 8.5), and modified the H-7 m; irradiation of H-2 collapsed H-8 to two doublets ($J_{7,8}$ = 2, $J_{7',8}$ = 6.6); irradiation of H-5 collapsed H-6 to six lines (1:1:2:2:1:1) ($J_{6,7}$ = 11.5, $J_{6,7'}$ = 8.5, $J_{6,6'}$ = 10.8). Mass spectrum (70 eV, direct inlet) showed molecular ion at m/e = 181.0886 (13%). *Anal.* found: C 86.16, H 6.22, N 7.58.

The second band off the column yielded 61.7 mg (55%) of starting material (**7**).

Effect of Lanthanide Shift Reagent on the Nuclear Magnetic Resonance Spectrum of 6

The nmr spectrum of **6** was recorded (60 MHz) in CCl_4 (0.40 mL containing 1% TMS) in the presence of increasing amounts of a solution of Eu(fod)$_3$ in CCl_4 (28.8 mg in 0.10 mL). The results are summarized in Fig. 1.

*Deuterio 2-Cyano-1,4-dihydro-1,4-ethanonaphthalene Mixture 5*a

The 50:50 mixture of deuterated barrelenes **18** and **19**, containing 94 ± 3% *d*, at C-4 and 92 ± 4% *d*, at C-6, respectively, was available from a previous study (3). To a stirred

solution of 355.9 mg (2.0 mmol) of the 50:50 mixture of **18** and **19** in 35 mL methanol at −30°C, 957.8 mg (4.9 mmol) of potassium azodicarboxylate was added followed by 2 mL of acetic acid. The reaction mixture was allowed to warm to room temperature during 2 h and was worked up as previously described for the preparation of **5**; 82.1 mg (23%) of colourless **5***a*, mp 66–68°C, was obtained along with 254.6 mg (72%) of recovered starting material. The LIS nmr spectrum (60 MHz) with 11.9 mg of **5***a* and 27.4 mg of $Eu(fod)_3$ in 0.25 mL CCl_4: 7.80–8.03 (m, 0.98 ± 0.04 H, H-3), 6.25–6.93 (m, 4.00 H, aromatics), 4.96 (broad s, 1.01 ± 0.03 H, H-1), 3.73–3.98 (m, 0.53 ± 0.03 H, H-4), and 1.00–1.93 (m, 3.54 ± 0.03 H, methylenes), i.e., this corresponds to a ratio of ca. 1.0:1.0 for **20**:(**21** + **22**), **20** containing 94 ± 6% *d*, at C-4 and **21** + **22** containing a total of 92 ± 6% *d*, at C-6.

Preparative and Quantum Yield Apparatus for Sensitized Irradiations

The apparatus consisted of a "merry-go-round" fitted with a 450W Hanovia medium pressure mercury arc which was surrounded by a water-cooled quartz immersion well. Light of wavelength 313 nm was isolated by a two compartment quartz cell fitting concentrically around the immersion well. The first compartment contained a 2.0 cm path length of a solution of 306 g of cobaltous sulfate heptahydrate and 552 g of nickel sulfate hexahydrate per litre of 5% aqueous H_2SO_4. The second compartment contained a 0.2 cm path length of a solution of 1 g of potassium chromate in 300 mL of 1% aqueous sodium carbonate. This combination showed transmittance between 302–323 nm with a maximum at 313 nm (20%).

Before irradiation, solutions (35 mL) of reactants contained in calibrated 20 mm × 150 mm quartz test-tube-like photolysis cells were deoxygenated by flushing with argon. The tubes were sealed under a positive pressure of argon which was maintained throughout the course of the irradiation.

Acetone Sensitized Photolysis of **5**

A solution of 29.0 mg (0.16 mmol) of **5** in 35 mL of acetone was photolysed with 313 nm light for 137 min. The photolysate was concentrated *in vacuo* and the residue was applied to a tlc plate; after two irrigations with 6% ether–cyclohexane, 13.0 mg (45%) of recovered starting material was obtained from the first band, and 11.7 mg (40%) of a colourless solid from the second band, which after crystallization from hexane gave 8.2 mg of material, mp 64–66°C, which was identical in all respects to **6**.

Sensitized Photolyses of Deuterated Dihydrobarrelene Mixture **5**a

(a) With Acetone

A solution of 30.4 mg (0.17 mmol) of mixture **5***a* in 35 mL of acetone was photolysed with 313 nm light for 183 min. The photolysate was worked up as in the undeuterated case to give 10.4 mg (34%) of starting material and 13.0 mg (43%) of deuterated dihydrosemibullvalene mixture **13***a*, mp 64–66°C; see Table 1 (case 4) for the nmr H distributions.

(b) With Acetophenone

A solution of 53.3 mg (0.29 mmol) of mixture **5***a* and 326.1 mg of acetophenone in 35 mL of cyclohexane was photolysed with 313 nm light for 453 min. The photolysate was concentrated *in vacuo* and the acetophenone sensitizer was removed by short-path distillation at 30°C/0.1 Torr. The residue was thereafter worked up as in the case of the acetone sensitized run, except that two tlc plates were employed, to give 32.7 mg (61%) of starting material and 4.2 mg (8%) of deuterated dihydrosemibullvalene mixture **13***a*, mp 64–66°C; see Table 1 (case 5) for the nmr H distributions.

Sensitized Quantum Yield Determinations

Sensitized quantum yields for the conversion of **5** to **6** with 313 nm light were determined on the "merry-go-round" apparatus. Sample solutions (35 mL) of ca. 0.3 mmol of **5** and ca. 6.0 mmol of the sensitizer (acetophenone, benzophenone, or thioxanthone; acetone sensitizer was used neat) were contained in separate, calibrated (for differences in light transmittance) test-tube-like cells and were irradiated in the same run. The lamp output was determined by potassium ferrioxalate actinometry (9). The photolysates were concentrated *in vacuo*, a known quantity of **4** was added as internal standard and the product compositions were determined by nmr analysis. In all cases nmr peak areas were calibrated against authentic mixtures of similar constitution. Conversions were kept below 18% and the quantum yields were determined from the average of two runs. The Φ for the appearance of **6** were: Φ(acetone) = 0.51 ± 0.05, Φ(acetophenone) = 0.16 ± 0.04, Φ(benzophenone) < 0.01, Φ(thioxanthone) < 0.01.

Direct Irradiation of **5**

A solution of 46.1 mg (0.25 mmol) of **5** in 250 mL of cyclohexane contained in a 250 mL water cooled photolysis well was stirred under an argon atmosphere and irradiated for 247 min with Vycor-filtered light provided by a 2 W U-shaped Hanovia cold cathode low pressure Mercury discharge lamp (>90% of emitted light is 254 nm). The photolysate was concentrated *in vacuo* and the residue was applied to two tlc plates; after two irrigations with 6% ether–cyclohexane 21.7 mg (47%) of recovered starting material was obtained from the first major band and 7.8 mg (17%) of **6**, mp 64–66°C, from the second. Variable amounts of polymer are formed during the reaction depending on the conversion; the direct irradiation of photoproduct **6** also gives rise to the efficient formation of polymer.

Direct Irradiation of Deuterated Dihydrobarrelene Mixture **5**a

A solution of 51.6 mg (0.29 mmol) of **5***a* in 250 mL of cyclohexane was photolysed for 250 min with 254 nm light (provided as described for the direct irradiation of **5**). The photolysate was worked up as in the undeuterated case to give 22.4 mg (43%) of recovered **5***a* and 6.7 mg (13%) of **13***a*, mp 64–66°C; see Table 1 (case 3) for the nmr H distributions.

Quantum Yield Apparatus and Measurement for Direct Irradiation of **5**

Quantum yields were performed on an optical bench. Light from a fan-cooled 450 W Hanovia medium pressure lamp was roughly focussed by 4 cm diameter quartz biconvex lens (focal length 5.0 cm) located at one end of a collimating tube of 10 cm length and 4 cm diameter. At the other end of the collimating tube a square (5 cm × 5 cm) Ealing-TFP Interference Filter (20% transmission at 254 nm, 20 nm band width at half-height) was located. The light was beamed onto a cell holder (15 cm from lamp) containing a calibrated 20 mm × 150 mm quartz test-tube-like photolysis cell. The light entered the cell via a narrow slotted window (3 cm × 1 cm, 1 cm deep). In a typical run, a solution of 0.15 mmol of **5** in 25 mL of cyclohexane was deoxygenated by flushing with argon and sealed under a slightly positive pressure. The magnetically stirred solution was irradiated for ca. 65 h. The lamp output was determined via potassium ferrioxalate actinometry (9) prior to, several times during, and after irradiation of the sample solution of **5**. The light fluctuations were found to be less than 20% during the course of irradiations. After irradiation, the photolysate was worked up and analyzed by nmr spectroscopy as described for the sensitized quantum yield determinations. The Φ for the appearance of **6**, determined from the average of three runs of less than 10% conversion, was 0.04 ± 0.02.

Fluorescence and Phosphorescence Studies of Dihydrobarrelene **5**

The fluorescence spectrum of **5** was measured in cyclohexane solution at room temperature on an Aminco-Bowman Spectrometer. Intersection of the fluorescence (λ_{max} = 360 nm) and absorption spectra of **5** occurred at 280 nm, suggesting a singlet energy of 102 kcal mol^{-1}.

The phosphorescence study was carried out on a modified Aminco-Bowman apparatus (10) in an isopentane–methylcyclohexane (1:4) glass at 77 K. No detectable phosphorescence peak could be observed.

Calculations

The calculations were performed on a DEC-20 system computer using a modified version of the CNDO/M-CI program (QCPE #315) of Jaffé and co-workers (11); the theoretical parametization was used. The lowest singlet and triplet excited states were calculated using a limited CI (60 determinants) in the virtual orbital approximation.

As a result of the CI each excited state is written as a mixture of configurations; each configuration is constructed by removing electrons from MO's occupied in the ground state and placing them in MO's which are vacant in the ground state. Using the CI mixing coefficients, and the coefficients of expansion of the molecular orbitals in terms of the atomic basis functions, the energies of both the ground and excited states can be written as a sum of energies of interaction between pairs of orbitals and shifts in single orbital energies. In the zero differential overlap approximation used in CNDO, INDO, etc., interactions involving three or more orbitals simultaneously are assumed to be zero. By summing the appropriate groups of orbital–orbital energies one can write the state energies in terms of atom–atom interactions energies and single atom energies, as is done for the ground state energy in ref. 12. By subtraction of ground and excited state energies, or directly resolving the excitation energy, one can calculate the changes in the atom–atom interactions resulting from excitation. These changes reflect the decreased (positive values) or increased (negative values) bonding between atoms. When the bonding is reduced the distance between the atoms is assumed to increase and vice versa. The pattern of changes in atom–atom energies can thus be interpreted as a pattern of initial molecular distortion. The atomic basis set used in these calculations is the unhybridized valence set normally employed in CNDO calculations. This atom–atom energy approach was developed because in non-planar molecules such as **5** σ–π separation is not strictly valid. Further details of the calculations are available from the authors.

Photochemical α-cleavage and hydrogen abstraction in deoxybenzoin: a laser spectroscopy investigation

JEAN-PIERRE FOUASSIER AND ANDRÉ MERLIN

Laboratoire de Photochimie Générale, Equipe de recherche Associée au C.N.R.S. no 386, Ecole Nationale Supérieure de Chimie, 68093 Mulhouse Cedex, France

Received May 8, 1979

JEAN-PIERRE FOUASSIER and ANDRÉ MERLIN. Can. J. Chem. **57**, 2812 (1979).

Transient absorptions in the range 380–500 nm in deoxybenzoin are investigated for the first time by nanosecond laser spectroscopy. This study gives evidence for absorption by a triplet state, and by benzoyl and benzyl radicals. Photoreduction of the triplet state and generation of a ketyl radical are also obtained. This enables some peculiar results of the polymerization of vinyl monomers photoinduced by deoxybenzoin to be explained. Our results show that deoxybenzoin exhibits a peculiar behaviour since the two photoprocesses occur with the same efficiency. Hydrogen abstraction and α-cleavage rate constants, quenching rate constants of the species by oxygen, lifetimes of the transients, and absorption spectra are derived. The influence of the solvent is discussed as a function of the excited states involved. A complete diagram of the evolution of the energy levels is thus obtained.

JEAN-PIERRE FOUASSIER et ANDRÉ MERLIN. Can. J. Chem. **57**, 2812 (1979).

Les absorptions transitoires dans la désoxybenzoine sont étudiées pour la première fois dans la région de 380 à 500 nm, à l'aide de la spectroscopie laser au nanoseconde. Cette étude fournit la preuve que l'absorption se fait par un état triplet et par les radicaux benzoyle et benzyle. On a également obtenu la photoréduction de l'état triplet et la génération du radical cétyle. Ceci permet d'expliquer quelques résultats particuliers obtenus lors de la polymérisation photoinduite des monomères vinyliques par la désoxybenzoine. Nos résultats montrent que la désoxybenzoine fait preuve d'un comportement particulier puisque les deux processus photochimiques se produisent avec la même efficacité. On a déduit les constantes de vitesse de l'élimination de l'hydrogène et du clivage en α, les constantes de vitesse de l'inhibition des espèces par l'oxygène, les durées de vie des espèces transitoires et leurs spectres d'absorption. On a discuté de l'influence des solvants comme étant une fonction des états excités impliqués. On a ainsi obtenu un diagramme complet des nivaux d'énergie et de l'évolution des états excités.

[Traduit par le journal]

Introduction

For a long time, it has been known that ketones in solution can undergo photochemical α-cleavage (Norrish type I) or/and hydrogen abstraction yielding a ketyl radical. The latter process was extensively studied by laser spectroscopy and under steady state conditions. In contrast, most of the substantial work devoted recently to the photochemistry of aromatic acyloins has been carried out using continuous light illumination (1–2) and accurate information has been derived concerning the formation of the photoproducts.

These molecules represent an important group of initiators, and under uv light they produce radicals which initiate the polymerization of vinyl monomers (3). In the case of deoxybenzoin, which was studied by Lewis *et al.* (4), it was postulated that the origin of the photolysis products could be explained by the formation of a benzoyl–benzyl radical pair (reaction [1]).

However, a preliminary investigation of this molecule under laser excitation (5) and recent experiments

[1] 
on the photoinduced polymerization of methylmethacrylate by deoxybenzoin (6) suggest also the formation of a ketyl radical (reaction [2]) which has never been mentioned to occur by laser spectroscopy of this molecule. However, the formation of pinacol under continuous uv light illumination suggests a ketyl radical as intermediate (7).

Since there are both practical and fundamental interest to this problem, the present investigation by laser spectroscopy is devoted to direct evidence for the Norrish type I photoscission and for the hydrogen abstraction reaction. It provides a better insight into the evolution of the excited states and permits subsequent discussion on the mechanism of the polymerization initiation.

0008-4042/79/212812-06$01.00/0

[2] 
Experimental

Deoxybenzoin was purchased from Kodak Eastman Company. Benzene was a commercial product of the highest grade (99.9%). THF was purified before use. The nanosecond laser apparatus and the analyzing system were described previously (8). The excitation consisted of a train of 6 pulses (200 ps FWHM, 10 ns separated). The output energy density was about 50 mJ cm^{-2} at 347 nm.

Results and Discussion

Solvent Effect upon the Transients

Laser excitation of deoxybenzoin (DB) in benzene solution leads to transient absorptions in the near uv and visible wavelength range. A typical oscilloscope trace is shown in Fig. 1. According to previous experiments (5), the first part of the relaxation curve may be ascribed to the triplet state decay of DB. The second part of the curve appears to be the sum of two absorptions. On a longer time scale of evolution (> 10 μs), a residual absorption appears: it is due to a transient we call *LLR* (*L*ong *L*ived *R*adical). In the time range of some hundred nanoseconds, the absorption curve can be accounted for by the relaxation of a transient which decays according to a second order kinetics, the rate constant of which at 430 nm in nitrogen atmosphere is about $k/\varepsilon l = 38 \times 10^7$ s^{-1}. This transient will be called *SLR* (*S*hort *L*ived *R*adical). We note that the absorption seems also to follow a first order kinetics ($k = 1.4 \times 10^6$ s^{-1}): the precision of the kinetic treatment is not sufficient to decide between the two possibilities. It can be concluded that the relaxation of the transient obeys rather complex kinetics (see the explanation suggested below).

In aerated solutions, the time scale of evolution of the transient SLR is shortened. This demonstrates a quenching process by oxygen which becomes the major deactivation pathway of this species. If we assume that the bimolecular deactivation is negligible, a first order law will hold. Indeed first order kinetics is obtained and the lifetime of the radical is about 380 ns. Thus the quenching rate constant $k_q^{O_2}$ is 1.3×10^9 M^{-1} s^{-1} (a lower value of k_q is determined if a first order rate constant is assumed for the relaxation in nitrogen atmosphere: $k_q^{O_2} = 0.6 \times 10^9$ M^{-1} s^{-1}). First order plots are also obtained for the first part of the relaxation curves which lead to triplet state values of 240 ns in nitrogen atmosphere and 115 ns in aerated solution. The separation of the two contributions (triplet and SLR) is very difficult and the estimated error is large (~30%). Moreover, we believe that 240 ns is the lower limit of the triplet lifetime. The quenching rate constant of the triplet state $k_q^{O_2}$ is about 2×10^9 M^{-1} s^{-1} (Table 1). This value is close to the diffusion limit for benzene $k_q = 5 \times 10^9$ M^{-1} s^{-1} (9). Values with a similar order of magnitude have also been obtained in previous experiments upon carbonyl compounds (7). The triplet lifetime in degassed benzene solution appears to be lower than the value calculated from the Stern–Volmer plot reported by Lewis and Heine (4). In fact, irradiation of DB in presence of naphthalene gives Stern–Volmer plot for quenching of benzaldehyde formation. The slope is about 3100 ± 1500 M^{-1}. A direct measurement of the quenching rate constant (5) gives $k_q = (5 \pm 0.5) \times 10^9$ M^{-1} s^{-1} which is in agreement with the value commonly used. The deduced triplet lifetime is 600 ± 300 ns which is slightly higher than our value. A quenching by an hydrogen donating impurity seems to be ruled out since one should have $k_q[Q] \sim 1.6 \times 10^6$ s^{-1} and $[Q] \sim 1.2$ M if we use the bimolecular rate constant of the photoreduction of benzophenone by isopropanol ($k_r = 1.2 \times 10^6$ M^{-1} s^{-1}).

As the relative concentrations of the triplet and of SLR are a function of the oxygen concentration in the solution (Fig. 1), the following reaction scheme holds in benzene solution (reaction [3]).

[3] ^{3}DB triplet $\xrightarrow{k_\alpha}$ SLR

^{3}DB triplet $\xrightarrow{k_q[O_2]}$ O_{DB+O_2}

Thus the ratio between the concentrations of the radical SLR and of the triplet generated by the picosecond pulse number i can be expressed by:

$$[SLR]_i/[Triplet]_i = k_\alpha/(k_\alpha + k_q[O_2])$$

The total amount of SLR created by the whole train of picosecond pulses is

$$[SLR] = \frac{k_\alpha}{k_\alpha + k_q[O_2]} \sum_i [Triplet]_i$$

Thus

$$\left(\frac{[SLR]}{[Triplet]}\right)_{air} \Big/ \left(\frac{[SLR]}{[Triplet]}\right)_{N_2} = \frac{k_\alpha}{k_\alpha + k_q[O_2]_{air}}$$

where $[O_2]_{air}$ is the oxygen concentration in an aerated solvent solution. As the triplet and the radical relax during the running time of the pumping train

TABLE 1. Kinetic parameters of the triplet state and radical transient of deoxybenzoin as a function of the solvent

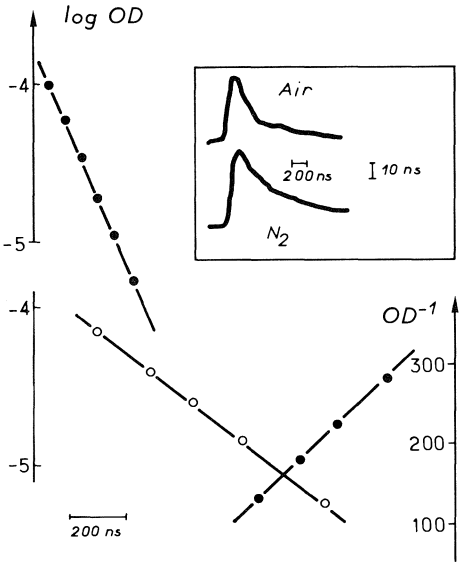

FIG. 1. Typical oscilloscope trace of the transient absorptions observed after laser excitation of deoxybenzoin in benzene under nitrogen atmosphere (λ = 430 nm). First order plot of the triplet relaxation (upper curve). First and second order plot of the fast decaying radical transient (lower curve).

of pulses, the concentrations are corrected to take into account the evolution of the populations between the moment where the *i*th pulse strikes the sample and a chosen value of time (at which the optical densities are measured, t = 100 ns), according to a formula developed elsewhere (10). A corrected value of 0.48 is calculated which is very close to the ratio calculated from the values of k_α, k_q, and $[O_2] = 2 \times 10^{-3}$ M (this value is 0.5). This value corroborates the proposed reaction scheme. Similar results are obtained for LLR. It may be concluded that both SLR and LLR are generated through the triplet state.

In a mixture of benzene and THF (9/1), DB exhibits three transients (Fig. 2). As in benzene, the first one corresponds to the triplet state but its lifetime is shortened, which means that a photoreduction with the solvent occurs as mentioned previously (5). The two other transients are ascribed to radicals. One of them seems to exhibit a very long decay time

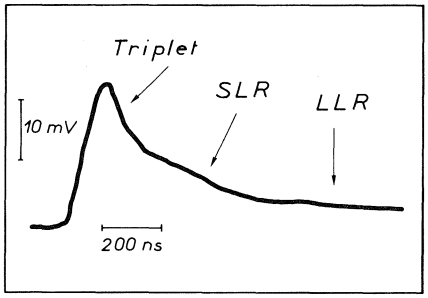

FIG. 2. Typical oscilloscope trace of the transient absorptions observed after laser excitation of deoxybenzoin in aerated solution of a mixture THF–benzene (λ = 430 nm): triplet state, benzoyl radical (SLR), benzyl and ketyl radicals (LLR).

and is still called LLR; its nature will be described later.

By increasing the concentration of THF in benzene, one observes that the relaxation times of both the triplet and the SLR decrease whereas the LLR seems unaffected. From the plot of Fig. 3, a value of the quenching rate constant of the triplet state by THF may be calculated; its value is 4×10^6 M^{-1} s^{-1}. For higher values of the THF concentration, no calculations are available since the triplet absorption at the end of the laser excitation decreases drastically due to the short lifetime of the transient.

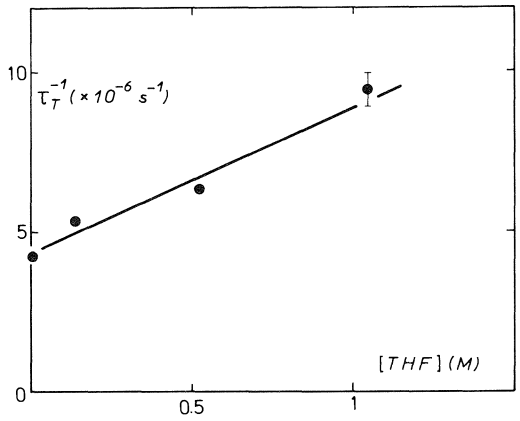

FIG. 3. Stern–Volmer plot of the triplet state lifetime of deoxybenzoin in deaerated benzene solutions as a function of the THF concentration (λ = 430 nm).

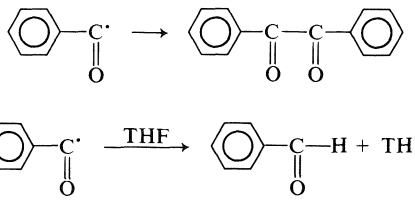
The quenching by both O_2 and an hydrogen donating solvent, the value of the lifetime of SLR, and the results of steady state experiments strongly suggest that the SLR radical is the benzoyl radical which is known to yield benzil and benzaldehyde (4) through the reactions



The LLR may be attributed to the benzyl radical. Thus in benzene, it is not surprising that the relaxation of the SLR radical obeys complex kinetics since it has been shown (4) that the quantum yields of benzaldehyde and benzil have the same order of magnitude: the relaxation follows a mixture of a first order law (quenching by benzene) and a second order law (bimolecular recombination). No Stern–Volmer plot can be drawn for the quenching of SLR by THF, in the range of the low THF concentrations, because of the superposition of at least three transients (triplet, benzoyl, benzyl).

In pure THF, we observed mainly the two radicals whose lifetimes are 200 ns for SLR and 470 ns for LLR in aerated solutions, and 370 ns for SLR and in the >10 μs range for LLR in degassed solutions. It is reasonable to assume that the value of 370 ns corresponds to the reciprocal value of the quenching rate constant of SLR by THF. A value of $k_q^{THF} = 2.1 \times 10^5\ M^{-1}\ s^{-1}$ can be derived (a lower value can also be calculated if we take into account the relaxation of the benzoyl radical: $k_q^{THF} = 1.1 \times 10^5\ M^{-1}\ s^{-1}$). The quenching rate constants by oxygen estimated for the two radicals are $1.1 \times 10^9\ M^{-1}\ s^{-1}$ and $1 \times 10^9\ M^{-1}\ s^{-1}$ for SLR and LLR, respectively.

Similar experiments were performed in isopropanol. We observed a triplet state (its lifetime is 90 ns and 60 ns in degassed and aerated solutions, respectively) and two radicals of the same type, a short-lived radical and a long-lived radical. Both of them are quenched by oxygen. The lifetime of SLR in degassed solution is 460 ns which leads to a quenching rate constant of the radical by isopropanol of $1.6 \times 10^5\ M^{-1}\ s^{-1}$, a value which is of the same order of magnitude as the rate constant of the quenching by THF.

The relative values of the α-cleavage and the hydrogen abstraction rate constants can be deduced from the above experiments. With $k_\alpha = 4.2 \times 10^6\ s^{-1}$, values of the rate constant k_r of the photoreduction are estimated to be $2.8 \times 10^6\ s^{-1}$, $6.8 \times 10^6\ s^{-1}$, and $50 \times 10^6\ s^{-1}$ in methanol, isopropanol, and THF respectively (a similar high rate constant in THF, compared with isopropanol, is observed during the photoreduction of benzophenone (9)).

The Ketyl Radical

If we consider the relative concentration of the two radicals originating from the triplet state after the laser excitation, it is found that their ratio is not constant, the concentration of LLR increasing with the hydrogen donating character of the solvent (Table 2). The same phenomenon is observed in the mixture of benzene–THF (Fig. 4). As mentioned above, in benzene solution, the long-lived radical LLR is the benzyl radical resulting from Norrish type I cleavage which appears concomitant to the benzoyl radical. However, the ratio of the concentration of the benzoyl and benzyl radicals must not depend upon the solvent. In agreement with the decrease of the lifetime of the triplet state in hydrogen donating solvents, it is deduced that a ketyl radical formation is observed in these solvents as in benzophenone systems. Thus, the long-lived radical should be the

TABLE 2. Ratio of the absorbances of the short- and the long-lived radicals as a function of the solvent

Solvent	Absorbance
Benzene	0.35
Benzene + THF (1:1)	3.4
THF	3.8
Isopropanol	3.7

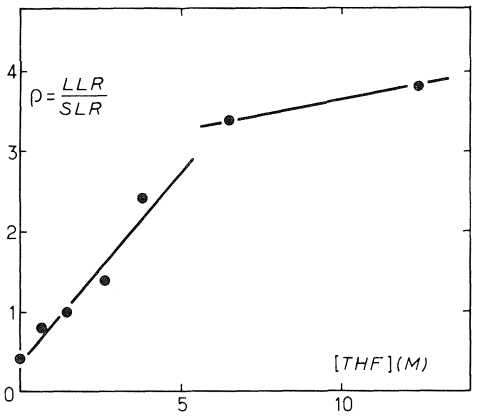


FIG. 4. Ratio of the absorbances of the short and long lived radicals (SLR and LLR) in benzene solutions, under nitrogen atmosphere, as a function of the THF concentrations (λ = 430 nm). The absorbances are taken at $t = 100$ ns and are corrected as in ref. 8. It is assumed that the extinction coefficients of the transients are not (or slightly) dependent upon the wavelength. This is reasonable by considering the shape of the transient absorption band (cf. Fig. 5*b*).

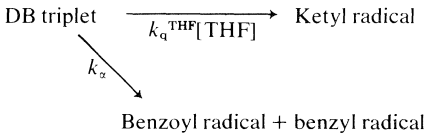
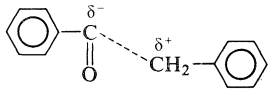
superposition of the two benzyl and ketyl radicals. The following reaction scheme may be written:



From experiments performed in benzene solution, we conclude that the ratio of the absorption of these two radicals (benzyl and benzoyl) is about 0.35 at 430 nm. Thus, the absorbances of the three transients may be expressed as follows:

$$\frac{\varepsilon_1[\text{benzyl}] + \varepsilon_2[\text{ketyl}]}{\varepsilon_3[\text{benzoyl}]} = \frac{\varepsilon_2 k_q^{THF}[THF] + 0.15\varepsilon_3 k_\alpha}{\varepsilon_3 k_\alpha} = \frac{LLR}{SLR}$$

where LLR and SLR are related to the absorbances of the radicals. With $k_\alpha = 4.2 \times 10^6\ s^{-1}$ (reciprocal value of the triplet lifetime in degassed benzene solution) and $k_q^{THF} = 4 \times 10^6\ M^{-1}\ s^{-1}$, the ratio LLR/SSR is at a first approximation a linear function of the THF concentration; the slope of the straight line is $0.95 \times \varepsilon_2\varepsilon_3^{-1}$. The experimental value is 0.45 (Fig. 4), which means that $2\varepsilon_2 = \varepsilon_3$ at 430 nm. At higher concentrations ($> 6\ M$), the ratio seems to reach a limiting value. This can be interpreted on the assumption that the benzoyl and the benzyl radicals can escape from the solvent cage more easily in THF than in benzene, which increases the benzoyl concentration at the same moment as the ketyl concentration increases. This assumption is in agreement with the conclusion of Lewis *et al.* (4) about the existence of an early transition state with a moderate degree of ionic character depicted as follows:



Absorption spectra of the triplet state in benzene and of the radicals in THF are reported in Fig. 5*a* and *b*. The main contribution to the absorption of LLR is due to the ketyl radical, the benzyl radical exhibiting a very low absorption in the visible wavelength range (as observed by recording the absorption spectrum in benzene) which is in agreement with the very weakly structured transition observed in the 4500 Å region (11) (the main absorptions are in the 3100 and 2600 Å regions). Moreover, the lifetime of LLR determined previously in THF can be attributed to the ketyl radical (a lifetime of the same order of magnitude was also measured for the ketyl radical of benzophenone (12)).

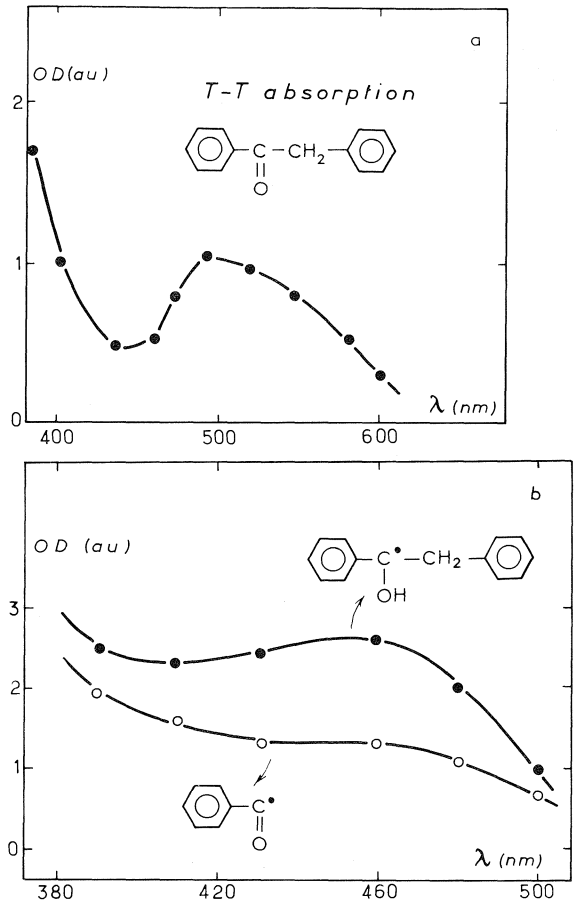


FIG. 5. (*a*) Transient absorption spectrum of deoxybenzoin: triplet state in benzene. (*b*) Transient absorption spectra of deoxybenzoin: benzoyl and ketyl radicals in THF.

DB is known to initiate the uv light induced polymerization of methylmethacrylate (MMA). By adding MMA to solutions of DB in benzene, one observes a substantial decrease of the triplet state lifetime (a quenching rate constant $k_q^{MMA} = 6 \times 10^8\ M^{-1}\ s^{-1}$ is calculated) whereas the relaxations of the radicals seem to be only slightly affected in the concentration range used (10^{-3}–$10^{-1}\ M$). Complete results about the initiation process of the polymerization of MMA will be published elsewhere.

The overall results are summarized in Fig. 6 which shows the evolution of the excited states of DB after uv light excitation. This allows us to explain the photochemistry of DB in benzene solution (4), the influence of the hydrogen donating system, the reactivity of DB in photocrosslinking reactions (13), and the ability of DB to initiate the polymerization of MMA under uv light excitation (6).

After this work had been submitted to publication

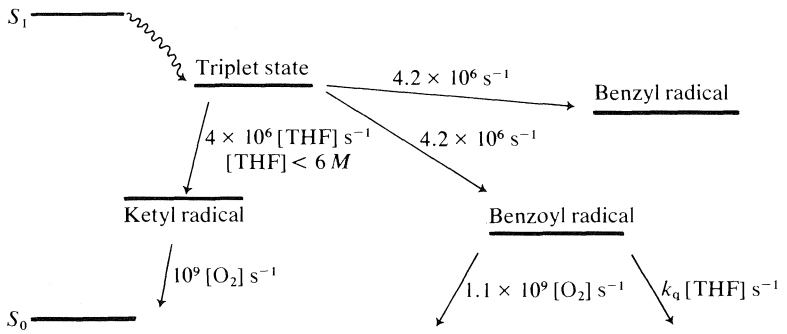

FIG. 6. Diagram showing the evolution of the excited states of deoxybenzoin.

we noted a paper (14) in which the reaction between deoxybenzoin compounds and thiol was investigated. Some measurements were also performed in benzene and in THF which give evidence for the ketyl radical as previously determined (5). However, the benzoyl radical is not observed whereas the absorption of the benzyl radical is reported. This is in contrast with our present work and with measurements on 2,2-dimethoxy-2-phenylacetophenone (15).

Acknowledgments

The authors wish to express their appreciation to Professor J. Faure for helpful comments. We greatly appreciated the help of F. Wieder in operating the ruby laser.

A synthetic route to 4-*C*-methyl-*xylo*-furanose

TIM FAT TAM AND BERT FRASER-REID

Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received May 7, 1979

TIM FAT TAM and BERT FRASER-REID. Can. J. Chem. **57**, 2818 (1979).

3-*O*-benzyl-1,2-isopropylidene-α-D-*xylo*-pentodialdofuranose could not be α-methylated by direct or indirect methods. The aldol product from reaction of the dialdofuranose with formaldehyde could not be trapped, but underwent a Cannizzaro reaction to give the *C*-4-bis-hydroxymethyl product. The latter can be regioselectively sulfonated at the pro-(*S*) hydroxymethyl group. Reduction with lithium aluminum hydride then affords 3-*O*-benzyl-1,2-isopropylidene-4-*C*-methyl-α-D-*xylo*-furanose as the major isomer, the configuration of which is proved by transformation into an oxetane.

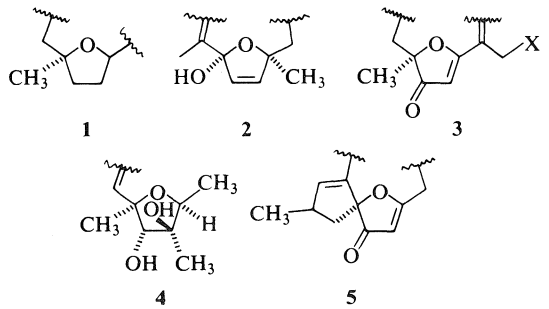
TIM FAT TAM et BERT FRASER-REID. Can. J. Chem. **57**, 2818 (1979).

L'utilisation des méthodes directe ou indirecte ne permet pas de méthyler en position α le *O*-benzyl-3 isopropylidène-1,2 α-D-*xylo*-pentodialdofurannose. La réaction du dialdofurannose avec le formaldéhyde conduit à un aldol qui n'a pu être isolé, mais qui, par une réaction de Cannizzaro, peut être transformé en un produit bis-hydroxyméthylé en position C-4. Ce composé peut être sulfoné d'une façon régiosélective au niveau du groupe hydroxyméthyl-pro (*S*). La réduction par l'hydrure double d'aluminium et de lithium conduit alors au composé *O*-benzyl-3 isopropylidène-1,2 *C*-4-méthyl α-D-*xylo*-furannose comme isomère principal. La transformation de cet isomère en oxétanne fournit la preuve de sa configuration.

[Traduit par le journal]

During the past few years there have been impressive developments in the syntheses of *C*-glycofuranosides (1), prompted undoubtedly by the fact that these substances provide easy access to *C*-nucleosides which are chemotherapeutic agents of considerable promise (2). In addition to this substantive goal, these *C*-glycofuranosides may also be viewed as chiral synthons of tetrahydrofuran compounds having functionalized alkyl substituents at positions 2 and 5 which occur in a variety of natural products. Examples of the latter are nonactic acid (3) and many polyether ionophores (4).

A structural feature which presents an added complication is the existence of a methyl group at position 2 (or 5) as shown in the part-structures **1**, **2**, and **3** (Scheme 1) which occur respectively in ipomeamarone and its congeners (5), liatrin (6), and a large number of elemanolides (7). The presence of methyl groups at both positions 2 and 5 (**4**) is found, for example, in citreaviridin (8), and the structural element of jatropone (9), **5**, which may be viewed as an elaborate congener of **3**, presents an even higher degree of complexity.



SCHEME 1

In view of the foregoing, we have been investigating synthetic routes to furanose derivatives bearing methyl and (or) functionalized methyl groups at C-4 which might provide access to structures such as those in Scheme 1. It would of course be imperative to know the orientation of the methyl group, and this paper reports some of our work related to this study.

The only example that we could find of a furanose derivative having different functionalized geminal substituents at C-4, was that obtained by Rosenthal and Ratcliffe from photoamidation of a 3-enofuranose (10). Unfortunately the conversions in this otherwise excellent procedure were low and so we decided to examine other substrates.

We turned our attention to the bis-hydroxymethyl derivatives such as **8***a* whose preparation from the readily available aldehyde **7***a* had been reported by Schaffer (11). This reaction indicated that it was possible for a suitable electrophile to capture the enolate derived from **7***a*. However all attempts to α-methylate **7***b* by direct (e.g., LDA/HMPA/MeI) or indirect (Stork enamine alkylation (12)) methods caused the substrate to decompose. Evidently alkylation of **7***b* requires an electrophile which is stronger than methyl iodide.

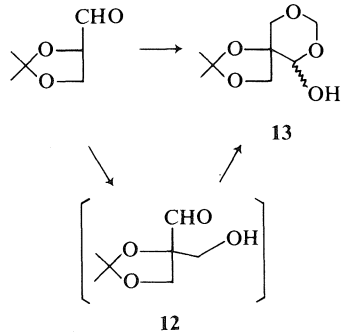
SCHEME 2

The work of Just and coworkers summarized in Scheme 3 had shown that by using *potassium carbonate* as base, the initial aldol product (**12**) could be captured as the acetal **13** and therefore prevented from undergoing the Cannizzaro reaction (13). In confirmation of this, Ho had subsequently found that 2,3-*O*-isopropylidene ribose upon treatment with formaldehyde and *potassium carbonate* gave the 2-hydroxymethyl adduct without any Cannizzaro



13

12

SCHEME 3

product (14). If **7***b* could be induced to undergo a similar reaction, the product would be **9** which, in view of the different oxidation levels of the two C-4 substituents, would be an attractive synthon for the structures in Scheme 1. However application of these conditions to **7***b* gave, instead of **9**, two products whose structures were shown to be **8***b* and **8***c*.

Identification of the *O*-benzyl derivative **8***b* is based upon an agreeable elemental analysis, and assignment of L-*threo* rather than D-*erythro* (i.e., **11***b*) configuration follows from the fact that the latter, which has recently been prepared by Moffatt and coworkers (15), melts at 101–102°C while our compound **8***b* melts at 73–74°C.

With regard to the *O*-methyl derivative **8***c*, elemental analysis was in agreement with the assigned structure, and from a comparison of the 220 MHz nmr parameters with those of **8***b* (Table 1), it was apparent that both compounds were configurationally related. The formation of **8***c* is most readily explained by invoking the intermediacy of **10**. In fact Leland and Kotick had reported that **7***a* upon treatment with base had given both **8***a* and **11***a*; compound **10** also accounts for their observed "epimerisation" (16). The fact that Just *et al.* (13) (Scheme 3) and Ho (14) observed no comparable unsaturated products is undoubtedly due to the circumstance that the anion in their cases is at position 4 of a dioxolane residue and therefore not well aligned for β-elimination.

In contrast to the foregoing, when sodium hydroxide was used as the base for the condensation on **7***b*, compound **8***b* was obtained in 61% yield without any evidence of products (**8***a* or **11***a*) arising from the elimination–addition sequence. Since the two hydroxyl groups of **8***b* are in very different steric environments it seemed that they might react regioselectively. Consequently the molecule was treated with one equivalent of *p*-toluenesulfonyl chloride.

The product (Scheme 4) consisted of unreacted **8***b*, the disulfonate **14***c* which was obtained in crystalline form, and a mixture of monosulfonates **14***a* and **14***b*. These proved to be unresolved in a variety of tlc systems but an analysis of the 220 MHz spectrum (Experimental) did indicate that an unequal mixture of both had been produced. Based on the integrated ratio of H-1 protons, the two isomers were present in the ratio of 2.2:1.

Some regioselectivity between the two hydroxymethyl groups of **8***b* was therefore possible, but at this stage we were unable to determine whether it was the pro-(*R*) or pro-(*S*) group that had been preferentially sulfonated. This question was answered in the following manner.

The mixture of monotosylates **14**(*a* + *b*) was

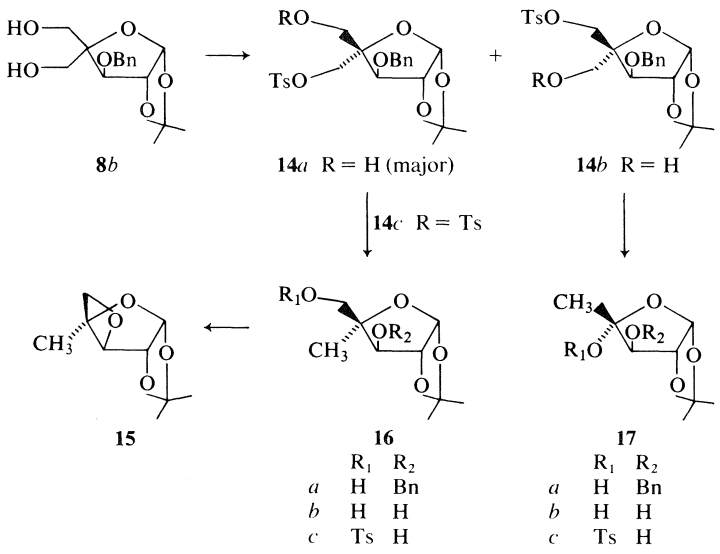
*Assignment is based on an 8:1 enriched mixture of **16***b*:**17***b*.



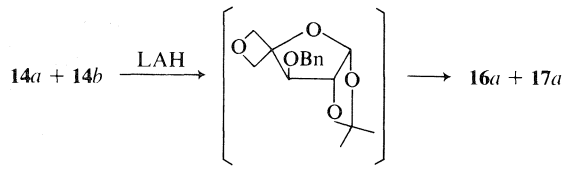
SCHEME 4

reduced with lithium aluminum hydride which afforded another mixture judged to be the *C*-methyl substances **16***a* and **17***a*. This mixture also proved to be non-crystalline and unresolvable on tlc, however debenzylation with sodium in liquid ammonia afforded the mixture of diols, **16***b* and **17***b* in the ratio 2.2:1, as a crystalline material. Fractional crystallization gave a batch of new crystals which was shown by gc analysis to be a 8:1 mixture of **16***b* and **17***b*; in the mother liquors the ratio of the isomers was 1:2, showing an enrichment in the minor product.

The major component of this recrystallized mixture was shown to be **16***b* by transformation into an oxetane by means of a procedure patterned after the work of Hough and Otter (17). Thus the (8:1) diol mixture, **16***b* and **17***b*, was selectively sulfonated at the primary positions, and the crystalline monotosylates obtained, **16***c* and **17***c*, were treated with sodium methoxide in methanol. Only the major component reacted and the newly formed substance was shown to be the oxetane **15**. The unreacted sulfonate **17***c* was recovered and crystallized.

The foregoing results would seem to indicate that in the processing of the mixture **14***a* + **14***b*, the former gave **16***a* while the latter gave **17***a*. However it is conceivable (Scheme 5) that upon treatment with lithium aluminum hydride, both **14***a* and **14***b* react to give the same oxetane **18** as an intermediate which is then cleaved to give the *C*-methyl substances **16***a* and **17***a*.[1] The sequence in Scheme 4 was supported by observing that the relative intensities for

[1]We are grateful to a referee for suggesting this alternative.



18

SCHEME 5

the anomeric protons (H-1) in the 220 MHz spectra were the same (2.2:1) in the crude mixture of **14**(*a* + *b*) as in the deoxygenated mixtures (**16***a* + **17***a*) and debenzylated mixtures (**16***b* + **17***b*). On the other hand the proposition in Scheme 5 is excluded by our observation that the mixture **14**(*a* + *b*) was recovered unchanged after treatment for five days with sodium methoxide, conditions which had been used for preparing compound **15**. The fact that the oxetane **18** was not formed under these favourable conditions makes it very unlikely that it would have been produced in the manner indicated in Scheme 5.

Other approaches to the preparation of *C*-alkyl furanoses related to the structures in Scheme 1 are being explored in our laboratory and will be reported in due course.

Experimental

General

Melting points were determined on a Fisher-Johns heating stage or a Mel-Temp apparatus, and are uncorrected. The nmr spectra were determined, unless otherwise stated, in deuteriochloroform containing 1% tetramethylsilane as internal standard with a Varian HR 220 or a Varian T-60 spectrometer. Coupling constants were obtained by measuring spacings of spectra judged to be first order.

Thin-layer chromatography (tlc) was performed on precoated 0.2 mm silica gel sheets (E. Merck, F-254) and developed with the solvent indicated. The chromatograms were first viewed under ultraviolet light, then sprayed with concentrated sulfuric acid and heated in an oven for complete visualization.

For column chromatography, E. Merck silica gel (0.05–0.20 mm, 70–325 mesh A.S.T.M.) was used.

Microanalyses were done by the Microanalyses Laboratory, Toronto.

*3-O-Benzyl-4-C-(hydroxymethyl)-1,2-O-isopropylidene-*β*-*L*-threo-pentofuranose* **8***b and its 3-O-Methyl Analogue* **8***c*

(*a*) To a solution of 3-*O*-benzyl-1,2-isopropylidene-α-D-*xylo*-pentodialdofuranose, **7***b* (18) (2.1 g, 7.55 mmol) in methanol (15 mL) was added potassium carbonate (3.6 g, 26 mmol) in water (8 mL) and 14 mL of 37% formaldehyde (172 mmol). The mixture was stirred at room temperature for 16 h at which time tlc in ether indicated that all of the starting material had disappeared. The methanol was removed by evaporation and the residue partitioned between water and methylene chloride. Standard processing afforded a syrup which was chromatographed over silica gel using ether as eluant. In addition to some benzyl alcohol, 0.5 g of **8***b* (24%) and 0.5 g of **8***c* (28%) were obtained, each of which was recrystallized from ether – petroleum ether (30–60°C) mixtures.

For **8***b* mp 73–74°C; $[\alpha]_D^{23}$ −347.7° (*c* 0.26, $CHCl_2$); R_f(ether): 0.55; (ether–benzene (1:1)): 0.16.^{13}Cmr data (TMS): 104.9 (C-1), 84.8 (C-2), 86 (C-3), 89.8 (C-4), 63.4, 63.6 (C-5/C-6), 72.7 (Ph—Ch_2), 26.8, 113.1, 27.4 (CH_3—C—CH_3), 127.6, 128, 128.5 (Ph). *Anal.* calcd. for $C_{16}H_{22}O_6$: C 61.93, H 7.10; found: C 61.87, H 7.24.

For **8***c* mp 86–87°C; $[\alpha]_D^{23}$ −341.5° (*c* 0.7, $CHCl_3$); R_f (ether): 0.30. ^{13}Cmr data (TMS): 104.9 (C-1), 87.1 (C-2), 85.5 (C-3), 89.9 (C-4), 63.4 (C-5/C-6), 26.3, 113.1, 27.3 (CH_3—C—CH_3), 58.3 (O—CH_3). *Anal.* calcd. for $C_{10}H_{18}O_6$: C 51.20, H 7.69; found: C 51.21, H 7.63.

220 MHz nmr data for **8***b* and **8***c* are shown in Table 1.

(*b*) The aldehyde **7***b* (5.0 g; 18 mmol) dissolved in dioxane (10 mL) was treated with formaldehyde (5 mL of 37%; 61.6 mmol) and sodium hydroxide (1.5 g; 37.5 mmol) in water (10 mL) was added, After 2 h at room temperature the solution was neutralized with acetic acid and extracted with methylene chloride. The latter phase was washed with water and sodium bicarbonate and dried (Na_2SO_4). Evaporation afforded a crystalline residue which was recrystallized from ether – petroleum ether (30–60°C) mixture and was found identical to **8***b* obtained in part (*a*). The yield was 3.42 g, 61%.

*3-O-Benzyl-4-C(hydroxymethyl)-1,2-O-isopropylidene 5-O-p-toluenesulfonyl-*α*,D-xylo-furanose* **14**b, *its* β-L-Arabino-*furanose Analogue* **14**a, *and 3-O-Benzyl-4-C-(p-toluenesulfonyloxymethyl)-1,2-O-isopropylidene-5-O-p-toluenesulfonyl-*β*-L-threo-pentofuranose* **14**c

The diol **8***b* (3.42 g, 11 mmol) was dissolved in a mixture of pyridine (5 mL) and dry methylene chloride (10 mL) and a solution of *p*-toluenesulfonyl chloride (2.5 g; 13.2 mmol) dissolved in a small amount of dry methylene chloride was added. The solution was allowed to stand in the freezing compartment of a refrigerator for 20 h and then poured into aqueous sodium bicarbonate. Extraction with methylene chloride and standard processing yielded a syrup which was freed from traces of pyridine by azeotroping with toluene. Column chromatography over silica gel using ether–toluene (1:1) as eluant gave the ditosylate **14***c* (0.7 g, 10.3%), a mixture of monotosylates **14**(*a* + *b*) (2.31 g; 46%), and 0.70 g of unreacted starting material.

The mixture of monotosylates **14**(*a* + *b*) ($M^+ - CH_3$ = 605) failed to crystallize, but the ditosylate **14***c* did, and was recrystallized from hexane.

For **14***c*: mp 81–82°C; $[\alpha]_D^{23}$ −284.8° (*c* 0.4, $CHCl_3$). *Anal.* calcd. for $C_{30}H_{34}O_{10}S_2$: C 58.25, H 5.5, S 10.42; found: C 58.10, H 5.44, S 10.31.

For **14**(*a* + *b*) spectral data, nmr 220 MHz, δ: 4.75 (m, H-2), 4.15 (m, H-3), 3.63 (t, —CH_AH_BOH), 3.84 (d, —CH_AH_BOH, J_{AB} = 15 Hz), 4.08–4.22 (m, —CH_2OTs), 4.56 (d, PhCH_AH_B, J_{AB} = 12 Hz), 4.82 (m, PhCH_AH_B), 1.32, 1.42 (2s, $(CH_3)_2$C).

Tentative assignments for **14***a*: 6.01 (d, H-1, J_{12} = 4.5 Hz); 2.45 (s, Ar—CH_3); for **14***b*: 5.95 (d, H-1, J_{12} = 4.5 Hz); 2.43 (s, Ar—CH_3). Based on the integrated intensities of H-1 protons, the two monotosylates were formed in about 2.2:1 ratio.

*1,2-O-Isopropylidene-4-C-methyl-*α*,D-xylo-furanose* **16**b *and 1,2-O-Isopropylidene-4-C-methyl-*β*,L-arabino-furanose* **17**b

The monotosylate mixture **14**(*a* + *b*) (9.57 g, 20.62 mmol) was dissolved in dry dimethoxyethane (0.30 mL) and lithium aluminum hydride (1.0 g; 26.3 mmol) was added slowly. After hydrogen evolution ceased, the mixture was refluxed for 2.5 h when tlc indicated that all the starting material had disappeared. The solution was diluted with ether and poured into 60 mL of ice cold 2% dilute hydrochloric acid. Ether extraction and evaporation gave a syrupy mixture of **16***a* and **17***a* (3.65 g, 60.5%) which was unresolved on tlc; R_f: 0.5 (15% ether in methylene chloride).

For **16***a* and **17***a* spectral data, nmr 220 MHz, δ: 4.73 (d, H-2), 3.93 (s, H-3), 3.45–3.75 (m, —CH_2OH), 4.56 (d, $PhCH_AH_B$, J_{AB} = 12 Hz), 4.68 (m, $PhCH_AH_B$), 1.55 (s, CH_3). Tentative assignments for **16***a*: 6.05 (d, H-1, J_{12} = 4.5 Hz); 1.38, 1.34 (2s, $(CH_3)_2C$). For **17***a*: 5.91 (s, H-1), 1.27, 1.32 (2s, $(CH_3)_2C$). Mass spectra *m/e*: 279 (M^+—CH_3), 263 (M^+—CH_2OH). Based on the integrated intensities of H-1 protons the two methyl isomers are in 2.2:1 ratio.

The mixture of benzyl ethers **16***a* and **17***a* (3.65 g; 12.5 mmol) was dissolved in dry dimethoxyethane (10 mL) and liquid ammonia (~30 mL) at −40°C. Small pieces of clean sodium were added slowly until a deep blue colour persisted. Solid ammonium chloride was then added until the blue colour disappeared. The solution was allowed to warm up slowly to room temperature and then diluted with ether (25 mL). The ethereal solution was washed twice with water (10 mL) and dried (Na_2SO_4). Evaporation afforded a crystalline residue. Based on the integrated intensities of the H-1 protons, the ratio of the two isomers remained 2.2 to 1.

The residue was recrystallized from ether – petroleum ether (30–60°C) (1.85 g, 73% from **16***a* and **17***a*). Gas–liquid chromatographic analysis of the recrystallized product indicated the presence of the two components **16***b* and **17***b* in the ratio of 8:1. Evaporation of the mother liquors afforded a pale yellow semi-solid syrup. Analysis (glc) of this residue showed the presence of the two isomers in the ratio of 1:2.

For **16***b* and **17***b* (8:1 mixture) mp 92–93°C. ^{13}Cmr data for major isomer (TMS): 105.4 (C-1), 88.6 (C-2), 81.8 (C-3), 87.2 (C-4), 67.2 (C-5), 22.7 (C-6), 26.3, 112.5, 26.8 (CH_3—C—CH_3). *Anal.* calcd. for $C_9H_{16}O_5$: C 52.94, H 7.8; found: C 53.06, H 7.78.

R_f(10% methanol CH_2Cl_2): 0.55 (major isomer); 0.30 (minor isomer).

*1,2-*O*-Isopropylidene-4-*C*-methyl-5-*O*-*p*-toluenesulfonyl-*α*,*D*-xylo-furanose* **16***c and 1,2-*O*-Isopropylidene-4-*C*-methyl-5-*O*-*p*-toluenesulfonyl-*β*-*L*-arabino-furanose* **17**c

A portion (0.646 g; 3.17 mmol) of the recrystallized mixture of the diols **16***b* and **17***b* (8:1 ratio) was dissolved in a mixture of dry pyridine (3 mL) and methylene chloride (5 mL), and *p*-toluenesulfonyl chloride (0.664 g; 3.39 mmol) in methylene chloride (5 mL) was added. The solution was stored in the freezing compartment of a refrigerator for 16 h and then worked up as described above for **14**(*a* + *b*). Column chromatography on silica using a 7:3 mixture of ethyl acetate and petroleum ether (30–60°C) afforded 0.751 g of the monotosylate mixture **16***c* and **17***c*, and 0.229 g of unreacted starting material. Although the 220 MHz nmr spectrum was consistent with the mixture as assigned, the material did crystallize from ether – petroleum ether (30–60°C) mixtures and was recrystallized from ether–hexane.

For **16***c* + **17***c* mp 99–102°C. *Anal.* calcd. for $C_{16}H_{22}O_7S$: C 53.63, H 6.14, S 8.94; found: C 53.35, H 6.23, S 8.54.

*3,5-Anhydro-1,2-*O*-isopropylidene-4-*C*-methyl-*α*,*D*-xylo-furanose* **15**

Clean sodium (0.360 g) was dissolved in dry methanol (25 mL) and the mixture of sulfonates (0.704 g; 1.97 mmol) was added. After standing at room temperature for 30 h, tlc (35% ethyl acetate in petroleum ether) indicated the formation of a major new substance. The reaction mixture was evaporated to dryness and the syrupy residue partitioned between water and ether. The ether extract was washed with water, dried (Na_2SO_4), and evaporated to yield a pale syrup which was chromatographed on a column of silica gel using 35% ethyl acetate in petroleum ether as eluant. The oxetane **15** (R_f (35% EtOAc in petroleum ether): 0.55) was isolated in 71% yield and 81 mg of the monotosylate **17***c* (R_f (35% EtOAc in petroleum ether): 0.32 (30–60°C)), was recovered unchanged.

Compound **17***c* was recrystallized from ether – petroleum ether (30–60°C), mp 134–135°C; $[\alpha]_D^{23}$ −186.2° (*c* 0.34, $CHCl_3$).

For **15** $[\alpha]_D^{23}$ −33.7° (*c* 1.34, $CHCl_3$); *m/e*: 186 (M^+), 171 ($M^+ - CH_3$), 156 ($M^+ - 2CH_3$), 128 ($M^+ - CH_3$-$COCH_3$).

Nuclear magnetic resonance data for **15** and **17***c* are shown in Table 1.

Reçu le 17 avril 1979

JEAN-PIERRE AYCARD, RONALD LAFRANCE et BERNARD BOYER. Can. J. Chem. **57**, 2823 (1979).

L'influence d'un substituant cyano est étudiée à travers la réduction par $NaBH_4$ des *R*-3 cyano-4 cyclohexanones *cis* et *trans*, nulle pour R = H, la diastéréosélectivité est respectivement de 74 et 62% (R = CH_3), et de 74 et 50% (R = $(CH_3)_3C$), avec formation préférentielle de l'isomère thermodynamiquement le plus stable. Ces stéréosélectivités sont justifiées à partir des valeurs expérimentales des différences d'enthalpie libre entre conformères et des diastéréosélectivités observées pour les *t*-butyl-3 (et 4) cyclohexanones et les *cis* dimethyl-3,5 et trimethyl-3,3,5 cyclohexanones sans qu'il soit nécessaire de tenir compte d'une influence spécifique du groupement cyano. La diminution de la diastéréosélectivité pour R = $(CH_3)_3C$, isomère *trans*, est associée aux déformations issues des contraintes stériques entre les substituants.

JEAN-PIERRE AYCARD, RONALD LAFRANCE, and BERNARD BOYER. Can. J. Chem. **57**, 2823 (1979).

The cyano group effect on diastereoselectivity is studied through the reduction of *cis* and *trans* 3-*R* 4-cyano cyclohexanones with $NaBH_4$; the diastereoselectivity (zero for R = H) is 74 and 62% respectively (R = CH_3) and 74 and 50% (R = $(CH_3)_3C$), the more stable isomer being always the major one. These stereoselectivities are rationalized from the experimental values of free enthalpy between conformers and from the diastereoselectivities of the 3-*t*-butyl (and 4-*t*-butyl) cyclohexanones, *cis* 3,5-dimethyl and 3,3,5-trimethyl cyclohexanones, without taking account of a cyano group specific effect. The decrease in diastereoselectivity for R = $(CH_3)_3C$ (*trans* isomer) is associated with deformation induced by steric strain between the substituents.

Introduction

Depuis les travaux d'Akhrem et ses collaborateurs sur la réduction des *t*-butyl-3 méthoxy-4 cyclohexanones *cis* et *trans* (2), il est généralement admis que la position conformationnelle du substituant polaire en 4 influence sérieusement la diastéréosélectivité de la réduction des cyclohexanones qui évolue de 76 à 40% en passant de l'isomère *cis* à l'isomère *trans*. Ce point de vue a été renforcé par les travaux de Moreau (3) portant sur la réduction des *t*-butyl-2 X-4 cyclohexanones *cis* et *trans*.

Cependant, dans ces deux exemples, les auteurs considèrent uniquement une structure chaise classique des substrats. Or, il a été montré que pour les *t*-butyl-3 X-4 cyclohexanones *trans* (4, 5), qui présentent une forte interaction stérique entre les substituants, les conformères twist (6) sont appréciablement peuplés. De même, en relation avec le second exemple, nous devons rappeler que la *t*-butyl-2 cyclohexanone présente un équilibre conformationnel correspondant à une différence d'enthalpie libre de 1.6 kcal mol^{-1} (7).[2] De plus, dans ce type de structure, le groupement *t*-butyl vicinal du centre de réaction exerce très certainement dans les états de transition des contraintes stériques très importantes (8, 1).

Dans ces conditions, et au vu de plusieurs travaux récents faisant intervenir des chemins réactionnels issus de conformères de haute énergie (9, 10), l'influence de la position conformationnelle du substituant polaire sur la diastéréosélectivité reste un problème ouvert que nous pouvions aborder aisément compte tenu de nos études conformationnelles sur les *R*-3 cyano-4 cyclohexanones isomères (5).

Résultats et discussion

A partir des pourcentages des alcools mesurés par cppv (cf. partie expérimentale), nous précisons dans

[1]Pour partie III voir ref. 1.

[2]Il est possible d'envisager ici, l'existence d'un conformère de structure twist 1,4 avec un pseudo axe C_2 passant par les carbones C_1 et C_4.

0008-4042/79/212823-04$01.00/0

TABLEAU 1. Diastéréosélectivités expérimentales des réductions par $NaBH_4$; ( ) valeurs calculées

	R	X	%2	%5	%2–%3	%5–%6
a	H	CN	50		0	
b	CH_3	CN	87	81	74 (72)	62 (60)
c	$(CH_3)_3C$	CN	87	75	74 (76)	50
d(2)	$(CH_3)_3C$	OCH_3	88	70	76 (76)	40
e	$(CH_3)_3C$	H	85		70	
f(12)	H	$(CH_3)_3C$	83		66	

le tableau 1, les diastéréosélectivités de la réduction de nos composés (voir schéma 1), ainsi que celles obtenues lors de la réduction des *t*-butyl-3 méthoxy-4 cyclohexanones et des *t*-butyl-4 (11) et *t*-butyl-3 cyclohexanones (12).

Dans ce tableau, les valeurs indiquées entre parenthèses ont été calculées à partir de l'équation d'Eliel (13, 14), en considérant une structure chaise des différents conformères. Ces valeurs sont obtenues en utilisant les valeurs des équilibres conformationnels déterminés pour les différentes cétones (4, 5) et les diastéréosélectivités de cétones modèles (*t*-butyl-3 et *t*-butyl-4 cyclohexanones pour les cétones **1***c*, **1***d*, **4***c* et **4***d*; diméthyl-3,5 cyclohexanone *cis* (12) et triméthyl-3,3,5 cyclohexanone (12) pour les cétones méthylées **1***b* et **4***b*).

Dans ces conditions, la diastéréosélectivité nulle observée pour la réduction de la cyano-4 cyclohexanone **1***a* peut s'expliquer facilement en tenant compte de la valeur de la différence d'enthalpie libre conformationnelle de ce composé ($\Delta G^0 = 0$ kcal·mol^{-1}). Un calcul identique effectué à partir de la chloro-4 cyclohexanone qui présente 67% de forme axiale (15), conduit à une diastéréosélectivité de 28% (32% expérimentalement (16)).

La deuxième remarque que nous pouvons faire est le bon accord observé entre les valeurs calculées, sans tenir compte d'un effet spécifique du groupement CN, et les valeurs expérimentales issues de la réduction des cétones bloquées **1***c* et **1***d*, ou présentant un équilibre entre deux conformations chaises (**1***b* et **4***b*).

	a	*b*	*c*	*d*	*e*	*f*
R	H	CH_3	$(CH_3)_3C$	$(CH_3)_3C$	$(CH_3)_3C$	H
X	CN	CN	CN	OCH_3	H	$(CH_3)_3C$

SCHÉMA 1. Numérotation des composés.

Cette concordance des valeurs montre que contrairement au cas des cétones portant un substituant polaire en position 3, et en particulier un groupement cyano (17, 18), l'existence d'un tel substituant en position 4 ne modifie aucunement la diastéréosélectivité de la réduction du carbonyle par $NaBH_4$.

Dans ces conditions, la diminution observée pour les cétones **4***c* et **4***d* (cf. tableau 1) par rapport à **1***c* et **1***d* ne peut être imputée à un effet de champ du groupement polaire en position 4. Par contre, pour ces cétones, l'existence d'une importante interaction *gauche* entre les groupements *t*-butyle et X-4 conduit à la présence d'un équilibre conformationnel entre une forme chaise à substituants diéquatoriaux et une forme twist (6).

On peut donc considérer que pour ces composés la perte de diastéréosélectivité peut, soit être due à une intervention importante des conformères twist, soit à une diminution de l'entrée axiale dans le conformère chaise.

Afin de vérifier ces deux hypothèses, nous avons effectué une étude cinétique de la réduction des cétones **1***a*, **1***c* et **4***c* et comparé les valeurs obtenues (cf. tableau 2) aux résultats de Rickborn et Wuesthoff (19) et Boyer (20).

La première observation que nous pouvons faire au vu des résultats du tableau 2, est l'effet d'accélération du groupement cyano; cet effet est par ailleurs analogue à celui d'un groupement chlore placé dans une situation semblable (16).

De plus, nous devons noter que cet effet d'accélération est peu dépendant de la position conformationnelle du groupement CN puisque les rapports k(**1***c*)/k(**1***e*) et k(**1***a*)/k(cyclohexanone) sont voisins et égaux à 11.8 et 14.3 respectivement. En effet, alors que **1***c* possède un groupement CN axial, la préférence conformationnelle de ce groupement est nulle dans **1***a*. Donc, ici encore l'effet d'un substituant polaire en position 4 est très différent de celui observé lorsqu'il est en position 3, position pour laquelle Agami *et al.* (18) ont montré qu'il existait

TABLEAU 2. Constantes de vitesse expérimentales

Cétones	k (M^{-1} s^{-1})	k (relatif)
Cyclohexanone (16)	0.173	100
1*e*	0.105	61
1*a*	2.469	1427
Chloro-4 cyclohexanone (16)	2.34	1352
1*c*	1.242	7.8
4*c*	0.641	371
tert-Bu-3,5 cyclohexanone *cis* (20)	0.00139	0.80

une accélération de 100 environ pour l'attaque équatoriale d'un carbonyle substitué en β par un groupement cyano.

Si nous considérons maintenant la valeur de la constante de vitesse obtenue pour **4***c* ($k = 0.641\ M^{-1}\ s^{-1}$), nous voyons qu'elle est pratiquement de l'ordre de grandeur des constantes de vitesse obtenue pour la cyclohexanone et la *t*-butyl-3 cyclohexanone **1***e* ($k = 0.173$ et $0.105\ M^{-1}\ s^{-1}$ respectivement); mais cent fois plus grande que celle obtenue lors de la réduction d'une cétone de conformation twist, la *t*-butyl-3,5 cyclohexanone *cis* ($k = 0.139 \times 10^{-1}\ M^{-1}\ s^{-1}$) (20). Par contre, si nous considérons la cétone **4***c* comme un mélange équimolaire de forme chaise et de forme twist, nous obtenons une constante de vitesse

$$k = \frac{k\ \text{twist}}{2} + \frac{k\ \mathbf{1}c}{2} = 0.622\ M^{-1}\ s^{-1}$$

soit une valeur très proche de la valeur expérimentale.

Dans ces conditions et en accord avec les travaux de Geneste *et al.* (21), nous devons considérer que **4***c* a une réactivité trop grande par rapport à celle d'une forme croisée, et que seule doit intervenir dans la réaction de réduction la conformation chaise. Aussi devons nous attribuer la perte de diastéréosélectivité de **4***c* et vraisemblablement celle de **4***d* à une réactivité particulière du conformère chaise de ces dérivés, due aux contraintes stériques existant entre les substituants *trans* diéquatoriaux. En effet, il faut rappeler que ce type de dérivés cyclohexaniques présentant un groupement *t*-butyle *trans* d'un substituant X-vicinal est fortement déstabilisé par rapport à leur isomères *cis* (22).

Conclusion

Ce travail nous a permis de montrer que la perte de diastéréosélectivité observée lors de la réduction des *t*-Bu-3 X-4 cyclohexanones n'est pas due à un effet de champ spécifique du groupement polaire en position 4, mais très certainement à une modification de réactivité issue des contraintes stériques existant dans ce type de composés.

Partie expérimentale

Synthèse des composés

La réduction des cétones est effectuée dans un mélange eau/méthanol (50/50) à température ambiante.

Dans un ballon de 100 cc pourvu d'une agitation magnétique, et contenant 0.02 mol de $NaBH_4$ dans 10 cc du mélange eau/méthanol 50/50, on verse 10 cc d'une solution $2 \times 10^{-4}\ M$ de cétone. L'avancement de la réaction est suivi par cppv. Lorsque toute la cétone a réagi, le mélange est hydrolysé, puis extrait à l'éther. La phase organique est séchée sur $MgSO_4$ puis évaporée.

Les pourcentages d'alcool sont mesurés par cppv à l'aide d'un intégrateur LTT 4000, et corrigés de l'effet de réponse par l'utilisation de mélanges étalons. Dans tous les cas, nous avons vérifié que le pourcentage n'évoluait pas dans le mélange réactionnel. Les différents alcools sont séparés par cppv puis identifiés par rmn et ir.

Conditions d'analyses

Les analyses chromatographiques ont été effectuées sur un appareil GIRDEL 3000 à 160°C sur une colonne de longueur 3m, diamètre 3.5 mm, phase stationnaire Carbowax 4000 10% sur chromosorb W 60/80.

La séparation des composés est effectuée sur un appareil Aérograph 90 P.

Identification des composés

Pour les composés **2***a* et **5***a*, ainsi que pour les dérivés *t*-butylés **2***c* et **5***c* l'identification a été effectuée à partir des spectres rmn des alcools deutériés en position 2,2,6,6 (23).

L'infrarouge (ir)

2*a*: 3600, 3450, 2960, 2880, 2240 cm^{-1}; **5***a*: 3600, 3460, 2980, 2960, 2240 cm^{-1}; **2***c*: 3610, 3460, 2960, 2860, 2240 cm^{-1}; **5***c*: 3610, 3490, 2980, 2870, 2240 cm^{-1}; **6***c*: 3620, 3490, 2990, 2880, 2440 cm^{-1}.

La résonance magnétique nucleaire (rmn)

L'étude rmn des alcools **2***a*, **5***a*, **2***c* et **5***c* spécifiquement deutériées en positions 2,2,6,6 a été décrite par ailleurs (23). Tous les spectres ont été enregistrés à température ambiante sur un appareil EM 360 en solution dans $CDCl_3$. **2***b* CH_3 1.8, *H*—C—CN 2.45–2.7, CH_2 et *H*—C—R 1.1–2.1, *H*—COH 3.6; **3***b* CH_3 1.2; **5***b* CH_3 1.15, *H*—CN, CH_2 et *H*—C—R 1.1–2.4, *H*—C—OH 3.6; **6***b* CH_3 1.1, *H*—CN, CH_2 et *H*—CR 1.1–2.4, *H*—C—OH 4.0; **3***c* $C(CH_3)_3$ 4.0; **6***c* $C(CH_3)_3$ 1.0, *H*—C—CN 2.2, CH_2 et *H*—C—R 1.1–2, *H*—CO—H 4.0. Les produits **3***b* et **3***c* en trop petite quantité n'ont pas pu être isolés.

Conditions cinétiques

Les conditions de concentration et de solvant sont les mêmes que celles de Geneste et Lamaty (24): eau–dioxanne 50/50 en volume, 0.05 *N* en soude. La réaction est suivie à 25.0 ± 0.1°C par spectrophotométrie uv à une longueur d'onde ($\lambda = 285$ nm) pour laquelle seule la cétone de départ absorbe. Les constantes de vitesse d'addition de BH_4^- ont été mesurées selon un procédé décrit par ailleurs (25). Pour chaque produit nous avons effectué 6 mesures.

The structure and fragmentation of protonated carboxylic acids in the gas phase

NORA E. MIDDLEMISS AND ALEX. G. HARRISON

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received May 28, 1979

NORA E. MIDDLEMISS and ALEX G. HARRISON. Can. J. Chem. **57**, 2827 (1979).

Gaseous protonated acids fragment in the first drift region of a double focussing mass spectrometer to yield the corresponding acylium ion and water. The metastable peaks for this fragmentation reaction have been recorded for the protonated acids from acetic to valeric and the kinetic energy release distributions evaluated from the metastable peak shapes. The protonated acids were produced by dissociative ionization of the ethyl, propyl, and butyl esters. The results provide evidence for two structures for gaseous protonated acids. Fragmentation of the hydroxyl protonated structure, a minor contributor to the metastable peak intensity, shows a low kinetic energy release (T(most probable) = 0.02 eV) as would be expected for a simple bond fission reaction. Fragmentation of the carbonyl protonated acid, which represents the major part of the metastable peak, is accompanied by a much larger kinetic energy release (T(most probable) = 0.30 to 0.43 eV). This result is interpreted in terms of an activation barrier for fragmentation of the carbonyl protonated acid which is considerably greater than the reaction endothermicity, with the excess energy being partitioned between internal energy and kinetic energy of the fragments. The results indicate that the addition of the acylium ion to water in the gas phase to produce the carbonyl protonated acid has an activation energy barrier.

NORA E. MIDDLEMISS et ALEX G. HARRISON. Can. J. Chem. **57**, 2827 (1979).

Les acides protonés à l'état gazeux se fragmentent dans la première région de dérive d'un spectromètre de masse à double champ en donnant les ions acylium correspondants et de l'eau. On a enregistré les pics métastables provenant de la fragmentation d'une série d'acides protonés allant de l'acide acétique à l'acide valérique et on a évalué, à partir de la forme de ces pics, les distributions de l'énergie cinétique libérée. Les acides protonés proviennent d'une dissociation ionique des esters éthylique, propylique et butyrique. Ces résultats prouvent que les acides protonés existent sous deux formes structurales. La fragmentation de la forme protonée au niveau du groupe hydroxyle, forme qui contribue faiblement à l'intensité du pic métastable, libère une faible énergie cinétique (T = 0.02 eV probablement) ce qui correspond à l'énergie libérée lors d'une simple rupture de liaison. La fragmentation de l'acide protoné au niveau du groupe carbonyle, forme qui contribue principalement à l'intensité du pic métastable, est accompagnée d'une plus grande libération d'énergie cinétique (T = 0.30 à 0.43 eV probablement). On interprète ces résultats en fonction d'une barrière d'énergie d'activation, de la réaction des acides protonés au niveau du carbonyle considérablement plus élevée que l'endothermicité de la réaction. L'excès d'énergie étant réparti entre l'énergie interne et l'énergie cinétique des fragments. Ces résultats révèlent que la formation de l'acide protoné au niveau du groupe carbonyle, par suite de l'addition de l'ion acylium à l'eau dans la phase gazeuse, a une barrière d'énergie d'activation.

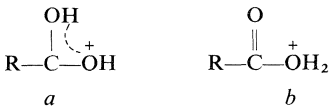
[Traduit par le journal]

Introduction

A common fragmentation reaction in the electron impact mass spectra of carboxylic esters is the double hydrogen transfer reaction [1], leading to formation of the protonated acid ion $RCO_2H_2^+$.

[1] $RCO_2R' + e \rightarrow RCO_2H_2^+ + [R' - 2H] + 2e$

Although both the mechanisms[1] and the energetics (2–5) of the rearrangement process have been studied extensively, only recently has it been established (6) that the ion formed at the appearance potential threshold has the carbonyl protonated structure *a*,



a

b

rather than the hydroxyl protonated structure *b*, although the results do not preclude the formation of *b* at higher electron energies. From proton affinity – O(1*s*) ionization energy correlations it has been established (7) that structure *a* is more stable than *b* by $\gtrsim$ 1 eV.

Protonated carboxylic acid ions also are observed (8–13) as major fragment ions in the chemical ionization mass spectra of ethyl and higher esters. Although the structure of these fragment ions is not known

[1]The earlier mechanistic studies are summarized in refs. 1*a* and *b*, more recent studies are reported in refs. 1*c* and *d*.

0008-4042/79/212827-07$01.00/0

arguments have been presented (12) which support the carbonyl protonated structure *a*.

As expected, protonated carboxylic acid ions are observed (14, 15) in the chemical ionization mass spectra of carboxylic acids, and from the effect of *ortho* substituents on the CI mass spectra of benzoic acid it has been suggested that H_2O elimination from the carbonyl protonated structure has a high activation barrier. Kebarle and co-workers (16) have observed protonated acetic acid in high-pressure studies of the equilibrium

[2] $CH_3—C{\equiv}O^+ + H_2O \leftrightharpoons CH_3CO_2H_2^+$

for which they obtained $\Delta H^0 = -25$ kcal mol^{-1}. This reaction exothermicity is compatible only with the carbonyl protonated structure *a* for the $CH_3CO_2H_2^+$ ion.

More recently Mackay *et al.* (17) have reported a study of dissociative proton transfer to formic acid and acetic acid in the gas phase. They observed significant fragmentation by reaction [3]

[3] $RCO_2H_2^+ \rightarrow R—C{\equiv}O^+ + H_2O$

and, by analogy with the unimolecular acyl oxygen, $A_{Ac}1$, mechanism commonly invoked for the cleavage of esters, amides, and carboxylic acids in acid solution (18), they proposed protonation at the hydroxylic hydrogen (structure *b*) for those ions undergoing fragmentation. As they pointed out the alternative of initial protonation at the carbonyl oxygen to give *a*, followed by [1,3]-hydrogen migration to form *b* also is possible, however, there is some evidence (19–21) that such hydrogen shifts have high activation barriers in excess of the reaction endothermicity.

In summary, although there is direct evidence for structure *a* for protonated carboxylic acids, the evidence for structure *b* is only indirect. We have observed that a major fragmentation route for protonated carboxylic acids generated by the dissociative ionization reaction [1] involves the loss of H_2O (reaction [3]) and that this fragmentation reaction is accompanied by a metastable peak. The utility of metastable ion studies, particularly those involving ion kinetic energy spectroscopy, in the elucidation of ion structures and fragmentation mechanisms is well established (22–24). Further, it has been amply demonstrated (21, 25, 26) that these fragmentation reactions which have an activation energy in excess of the reaction endothermicity (i.e., a reverse activation energy) usually show a large kinetic energy release in the ion decomposition reaction. It appeared that a detailed study of the kinetic energy release associated with the fragmentation reaction [3] occurring in the drift region of a double focussing mass spectrometer not only could provide evidence concerning the structure(s) of the fragmenting protonated carboxylic acid ions but also should provide direct information concerning the presence of an activation barrier for the interconversion of *a* and *b*.

Experimental

Fragmentation reactions occurring in the drift region between the ion source and the electric sector of an AEI MS-902 mass spectrometer were studied using the ion accelerating voltage scan technique (27) at constant electric sector voltage and constant magnetic field. Unless otherwise noted all experiments were done at 70 eV ionizing electron energy, a source temperature of 180°C, and a β (energy defining) slit width of 0.008 in.

For the metastable ion scans the electric sector voltage was supplied by a separate power supply (Northeast Scientific Model PQE-0503). The starting ion accelerating voltage was set by adjusting the reference input voltage to the high voltage supply of the MS-902. An adjustable linear ramp voltage from an external generator was applied to the reference input thus scanning the ion accelerating voltage. By adjustment of the constant input voltage and the ramp voltage amplitude any desired ion accelerating voltage range could be repetitively scanned. The ion signal output was accumulated in a 1024-channel signal averager (Varian Associates C-1024). The kinetic energy release distribution was obtained from the metastable ion peak shape, with correction for the main beam width, using the analytical method of Holmes and Osborne (28).

The acetate and propionate esters were commercially available. The remaining esters were prepared by reaction of the appropriate acid and alcohol with purification by fractional distillation. The ethyl-d_5 alcohol was obtained from Merck, Sharp and Dohme. Samples were admitted to the ion source using an all-glass heated inlet system at 150°C.

Results and Discussion

The fragmentation reactions investigated were

[4] $CH_3CO_2H_2^+ \rightarrow CH_3—C{\equiv}O^+ + H_2O$

[5] $C_2H_5CO_2H_2^+ \rightarrow C_2H_5—C{\equiv}O^+ + H_2O$

[6] $n\text{-}C_3H_7CO_2H_2^+ \rightarrow n\text{-}C_3H_7—C{\equiv}O^+ + H_2O$

[7] $n\text{-}C_4H_9CO_2H_2^+ \rightarrow n\text{-}C_4H_9—C{\equiv}O^+ + H_2O$

with the fragmenting ions in each case being prepared from several different precursor esters. A typical trace of the metastable ion signal as a function of ion accelerating voltage is shown in Fig. 1 for reaction [5] for ions produced by 70 eV electron impact on *n*-butyl propionate. The metastable peak clearly is composite with a major broad component and a minor narrow component. All metastable peaks observed exhibited this characteristic shape as is shown by the kinetic energy release distributions presented in Figs. 2 to 6. In each case the distribution is normalized to $n(T) = 1$ at the maximum and in several figures the vertical scale has been displaced for clarity.

The presence of two components is indicative of two structures for the fragmenting $RCO_2H_2^+$ ions. We assign the minor component with a small ki-

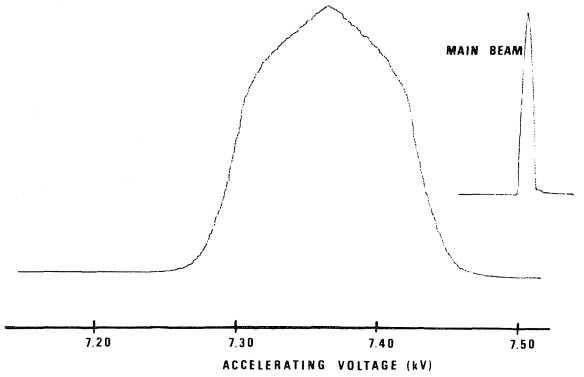


FIG. 1. Metastable peak for $C_2H_5CO_2H_2^+ \rightarrow C_2H_5CO^+ + H_2O$, *n*-butyl propionate. Summation of 50 scans. Main beam peak shown on same voltage scale.

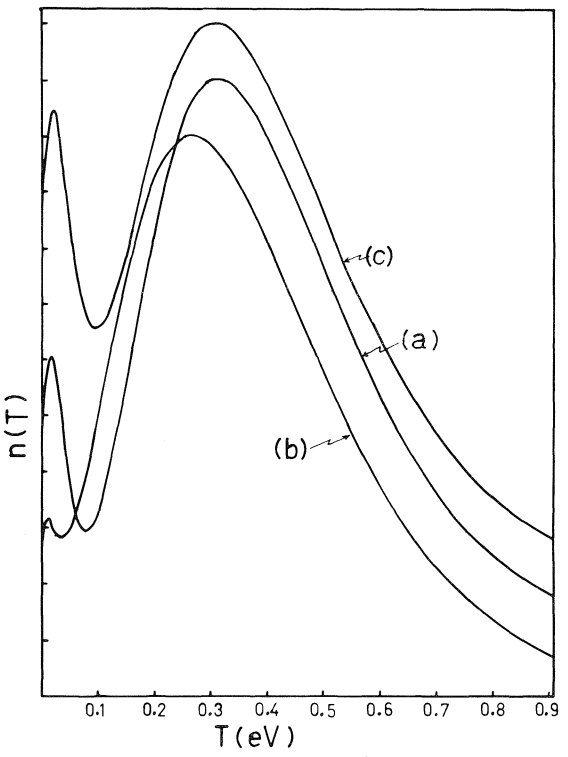

FIG. 2. Energy release distributions for $CH_3CO_2H_2^+ \rightarrow CH_3CO^+ + H_2O$. Precursors (*a*) $CH_3CO_2C_2H_5$, (*b*) $CH_3CO_2C_3H_7$, (*c*) $CH_3CO_2C_4H_9$.

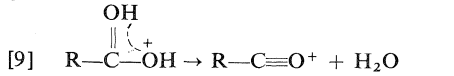
netic energy release to the fragmentation reaction.

[8] $R—\overset{\overset{O}{\|}}{C}—\overset{+}{O}H_2 \rightarrow R—C\equiv O^+ + H_2O$

and the major component with the larger kinetic energy release to the fragmentation reaction.



[9] $R—\overset{\overset{OH}{\|}}{C}—\overset{+}{O}H \rightarrow R—C\equiv O^+ + H_2O$

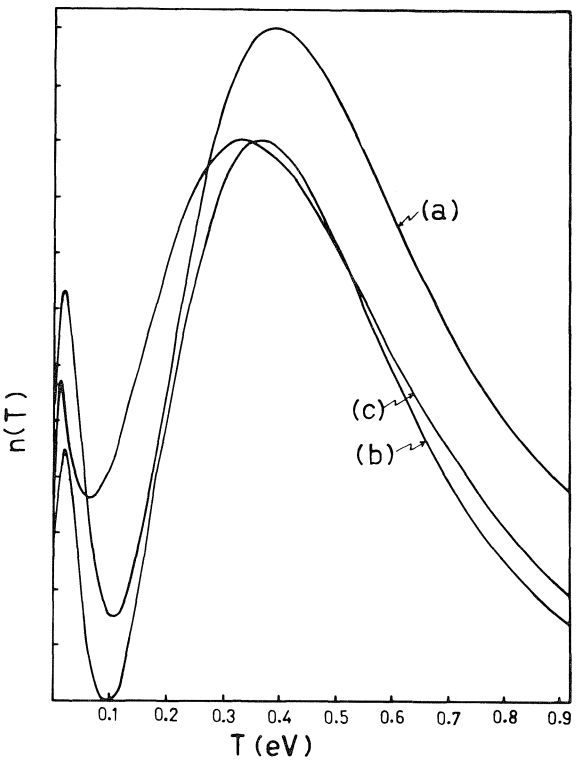


FIG. 3. Energy release distributions for $C_2H_5CO_2H_2^+ \rightarrow C_2H_5CO^+ + H_2O$. Precursors (*a*) $C_2H_5CO_2C_2H_5$, (*b*) $C_2H_5CO_2C_4H_9$, (*c*) $C_2H_5CO_2C_5H_{11}$.

The reasoning for these assignments is given below. The alternatives of two structures for the product ion, i.e., $R''CH_2—C\equiv O^+$ and $R''CH=C=OH^+$, is precluded by the observations that the $CD_3CO_2H_2^+$ ion produced from *n*-propyl acetate-d_3 showed a metastable peak for loss of H_2O only, while the $C_3H_7CO_2D_2^+$ ion produced from ethyl-d_5 butyrate showed a metastable peak for loss of D_2O only.

The individual fragmentation reactions are discussed in detail below in relation to their thermochemistry.

[4] $CH_3CO_2H_2^+ \rightarrow CH_3—C\equiv O^+ + H_2O$

From $\Delta H_f^0(CH_3CO_2H) = -103.3$ kcal mol^{-1} (29) and $PA(CH_3CO_2H) = 187$ kcal mol^{-1} (30), referring to protonation of the carbonyl oxygen (12, 31–33), we derive $\Delta H_f^0(CH_3C(OH)_2^+) = 76$ kcal mol^{-1}. From the PA–IE(O1*s*) correlation (12) we derive a proton affinity of 161 kcal mol^{-1} for the hydroxylic oxygen of CH_3CO_2H leading to ΔH_f^0-

$(CH_3—\overset{\overset{O}{\|}}{C}—\overset{+}{O}H_2) = 102$ kcal mol^{-1}. Although the standard compilation (34) lists a value $\Delta H_f^0(CH_3—C\equiv O^+) = 151$ kcal mol^{-1}, on the basis of an or-

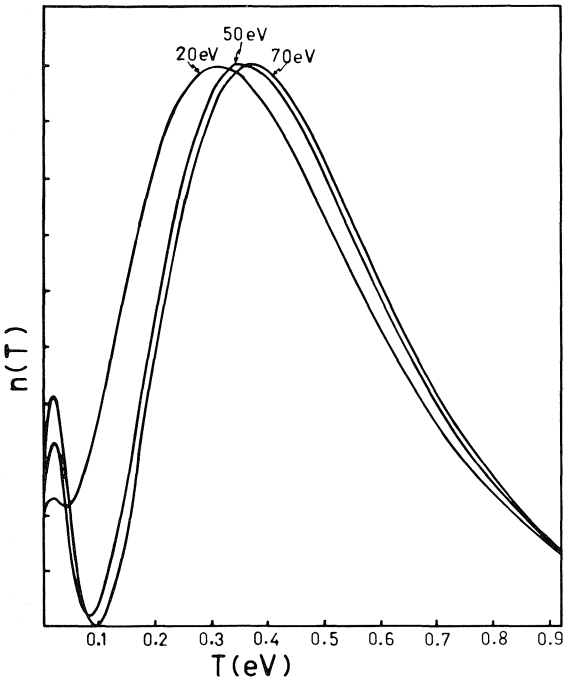

FIG. 4. Energy release distributions for $C_2H_5CO_2H_2^+ \rightarrow C_2H_5CO^+ + H_2O$ for ions produced from *n*-propyl propionate, effect of electron energy variation.

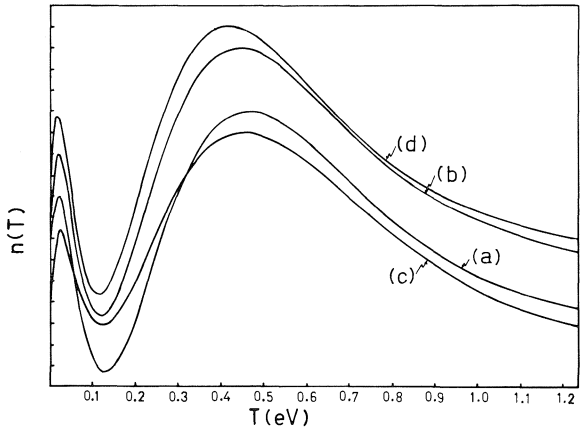

FIG. 5. Energy release distributions for $C_3H_7CO_2H_2^+ \rightarrow C_3H_7CO^+ + H_2O$. Precursors (*a*) $C_3H_7CO_2C_2D_5$, (*b*) $C_3H_7CO_2C_3H_7$, (*c*) $C_3H_7CO_2C_4H_9$, (*d*) $C_3H_7CO_2C_5H_{11}$.

dering of the stabilities of carbonium ions based on ion–molecule reaction studies Beauchamp and co-workers (35) derived $\Delta H_f^0(CH_3—C\equiv O^+) = 158$ kcal mol^{-1}. This higher value is supported by two recent measurements (16, 36) of the proton affinity of ketene which yield, as an average, $\Delta H_f^0(CH_3—C\equiv O^+) = 160$ kcal mol^{-1}. Using this value along with the data above and $\Delta H_f^0(H_2O) = -58$ kcal mol^{-1} (29) we derive the thermochemistry

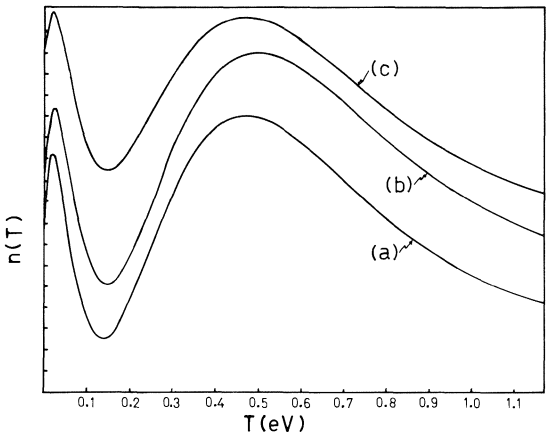

FIG. 6. Energy release distributions for $C_4H_9CO_2H_2^+ \rightarrow C_4H_9CO^+ + H_2O$. Precursor (*a*) $C_4H_9CO_2C_2H_5$, (*b*) $C_4H_9CO_2C_3H_7$, (*c*) $C_4H_9CO_2C_4H_9$.

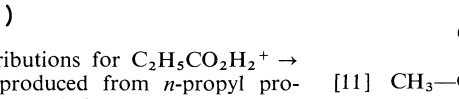
[10] $CH_3—\overset{\overset{OH}{\|}}{C}—\overset{+}{O}H \rightarrow CH_3—C\equiv O^+ + H_2O$

$\Delta H^0 = +26$ kcal mol^{-1}



[11] $CH_3—\overset{\overset{O}{\|}}{C}—OH_2^+ \rightarrow CH_3—C\equiv O^+ + H_2O$

$\Delta H^0 = 0$ kcal mol^{-1}

The simple bond fission reaction [11], which is essentially thermoneutral, should show only a very small kinetic energy release and is identified with the low kinetic release component of Fig. 2 (T(most probable) = 0.02 eV). Indeed, it is rather surprising to observe a metastable for the thermoneutral reaction and the small number of *b* ions fragmenting in the drift region presumably reflect a slow formation of $R\overset{\overset{O}{\|}}{C}—OH_2^+$ by dissociation of the ester molecular ion. The variations in metastable ion abundance presumably reflect the variations in the fraction of ester ions which fragment by the energetically disfavoured route to give $CH_3—\overset{\overset{O}{\|}}{C}—OH_2^+$.

The broad metastable component (T(most probable) = 0.3 eV (6.9 kcal mol^{-1})) must be assigned to fragmentation reaction [10]. The large kinetic energy release is characteristic of a fragmentation reaction with a reverse activation energy (24–26) with partitioning of this excess energy between internal modes and translational modes of the product species. The results therefore provide direct evidence that the elimination of H_2O from protonated carboxylic acids of structure *a* has an activation energy in excess of the endothermicity of the reaction. This

activation barrier presumably refers to the symmetry-forbidden (1,3)-H migration converting structure *a* to structure *b* with fragmentation occurring from *b*.

[5] $C_2H_5CO_2H_2^+ \rightarrow C_2H_5C{\equiv}O^+ + H_2O$

From $\Delta H_f^0(C_2H_5CO_2H) = -108.4$ kcal mol^{-1} (29) and PA($C_2H_5CO_2H$) = 189 kcal mol^{-1} (30) we derive $\Delta H_f^0(C_2H_5{-}\overset{\overset{OH}{|}}{C}{-}\overset{+}{O}H) = 69$ kcal mol^{-1}, while from the PA–IE(O1*s*) correlation (12) we estimate the hydroxyl oxygen proton affinity of $C_2H_5CO_2H$ to be 161 kcal mol^{-1} leading to $\Delta H_f^0(C_2H_5{-}\overset{\overset{O}{\|}}{C}{-}OH_2^+) = 97$ kcal mol^{-1}. From photon impact studies $\Delta H_f^0(C_2H_5{-}C{\equiv}O^+) = 144$ kcal mol^{-1} has been derived (34), however, from ion–molecule reaction studies Beauchamp *et al.* (35) have derived $\Delta H_f^0(C_2H_5{-}C{\equiv}O^+) = 151$ kcal mol^{-1} (for a similar discrepancy see discussion of $CH_3{-}C{\equiv}O^+$ (above). Using the latter value we derive the thermochemistry

[12] $C_2H_5{-}\overset{\overset{OH}{|}}{C}{-}\overset{+}{O}H \rightarrow C_2H_5{-}C{\equiv}O^+ + H_2O$

$\Delta H^0 = +24$ kcal mol^{-1}

[13] $C_2H_5{-}\overset{\overset{O}{\|}}{C}{-}OH_2^+ \rightarrow C_2H_5{-}C{\equiv}O^+ + H_2O$

$\Delta H^0 = -4$ kcal mol^{-1}

The kinetic energy release distribution curves (Figs. 3 and 4) show a minor component with a most probable kinetic energy release of ~0.02 eV (0.5 kcal mol^{-1}) which we identify with the simple bond fission reaction [13]. Although this reaction is probably slightly exothermic it has been suggested (37) that for such reactions very little of the exothermicity will appear as kinetic energy of the fragments. The metastable peak shapes for reaction [5] for ions produced from *n*-propyl propionate were studied as a function of ionizing electron energy with the results shown in Fig. 4. With decreasing electron energy the contribution of the low kinetic energy release component decreases. This is consistent with its identification with reaction [13] since the onset potential for formation of $C_2H_5\overset{\overset{O}{\|}}{C}{-}OH_2^+$ is >1 eV higher than the onset potential for formation of $C_2H_5{-}C(OH)_2^+$, the fragmenting ion in reaction [12].

There is a small shift to lower values in the most probable kinetic energy release of the broad component as the contribution of the narrow component decreases (Fig. 4), although the shift is not much greater than the reproducibility of the measurements. It is not clear whether this is a real phenomenon or an artefact arising from the curve fitting routine. Trials with artifically constructed curves of similar shapes showed a similar behaviour suggesting that the shift is an artefact arising from the analytical procedure used to derive the $n(T)$ distribution. The dominant metastable peak component, identified with reaction [12], has a most probable kinetic energy release of ~0.35 eV (8.1 kcal mol^{-1}) somewhat larger than that associated with reaction [10]. The distribution curve also extends to slightly higher kinetic energy release values.

[6] n-$C_3H_7CO_2H_2^+ \rightarrow$ n-$C_3H_7{-}C{\equiv}O^+ + H_2O$

The kinetic energy release distribution curves for this fragmentation reaction are shown in Fig. 5. For the ethyl ester the fragmentation of $C_3H_7CO_2D_2^+$ (produced from ethyl-d_5 butyrate) was studied to avoid interference from the isotopic peak of the intense metastable for H_2O loss from $[M - C_2H_4]^+$ ($CH_2{=}C(OH)OC_2H_5^+$). Two components are clearly visible in the metastable peak. The minor component, with a most probable kinetic energy release of ~0.02 eV, is associated with fragmentation of structure *b* (reaction [14]) while the major component with T(most probable) = 0.45 eV (10 kcal mol^{-1}) is identified with fragmentation of structure *a* (reaction [15]).

[14] n-$C_3H_7{-}\overset{\overset{O}{\|}}{C}{-}OH_2^+ \rightarrow n$-$C_3H_7{-}C{\equiv}O^+ + H_2O$

[15] n-$C_3H_7{-}\overset{\overset{OH}{|}}{C}{-}\overset{+}{O}H \rightarrow n$-$C_3H_7{-}C{\equiv}O^+ + H_2O$

Neither the proton affinities of butyric acid nor $\Delta H_f^0(n$-$C_3H_7{-}C{\equiv}O^+)$ are reliably established, however, by analogy with the acetic and propionic acid systems, reaction [14] undoubtedly is thermoneutral or slightly exothermic while reaction [15] will be endothermic. It should be noted that T(most probable) for [15] is larger than for the similar fragmentations of protonated acetic and propionic acids and the kinetic energy distribution extends to higher values.

[7] n-$C_4H_9CO_2H_2 \rightarrow$ n-$C_4H_9{-}C{\equiv}O^+ + H_2O$

The kinetic energy release distribution curves for this fragmentation reaction are shown in Fig. 6. As for the lower analogues two components to the metastable peak are clearly seen. The low kinetic energy release component (T(most probable) = 0.025 eV) is identified with the structure *b* and the

major component with T(most probable) = 0.48 eV (11 kcal mol^{-1}) is identified with fragmentation of protonated butyric acid of structure *a*. Thermochemical data are almost completely absent for this system.

In summary, the metastable peak shapes and the kinetic energy release distributions calculated therefrom show clear evidence for two structures for protonated carboxylic acids fragmenting in the first drift region of the double focussing mass spectrometer. Fragmentation of the hydroxyl protonated structure *b* proceeds with little release of kinetic energy, consistent with a simple bond fission reaction of low or negligible activation energy. The relative importance of this fragmentation reaction increases as the size of the alkyl group in $RCO_2H_2^+$ increases. This probably is attributable to the increase in the degrees of freedom of the ion which will increase its mean lifetime with the result that a larger proportion will fragment in the drift region. Fragmentation of the carbonyl protonated structure *a* proceeds with a much greater kinetic energy release (T(most probable) = 0.3–0.48 eV). This kinetic energy release is too large to be associated with partitioning of the non-fixed energy of the fragmenting species between internal and translational modes and is consistent only with a reaction for which there is a reverse activation energy, with this energy in excess of the endothermicity being partitioned between internal and translational modes. In the absence of detailed knowledge of this partitioning the magnitude of the reverse activation energy cannot be estimated from the present data, however, the magnitude of the T(most probable) values would indicate that it must be at least 1 eV (23 kcal mol^{-1}).

Both the range of kinetic energy released and the most probable kinetic energy release increase through the series from protonated acetic acid to protonated butyric acid. The most likely rationale is that the activation energy for H_2O loss from *a* remains essentially constant through the series while the reaction endothermicity decreases, thus leading to an increase in the reverse activation energy. If the fraction of the reverse activation energy partitioned into kinetic energy remains constant the kinetic energy released will increase through the series.

Olah and White (38) have determined an enthalpy of activation of 16.3 kcal mol^{-1} for dissociation of protonated acetic acid into the acetyl ion and water in solution. As Kebarle and co-workers (16) have noted this is considerably smaller than the gas phase reaction endothermicity of 26 kcal mol^{-1}, indicative of strong solvent participation. The present results indicate that the activation energy for the gas phase reaction is considerably greater than the endothermicity. Kinetic studies of the addition of water to acyl ions in the gas phase (reaction [2]) in addition to equilibrium studies such as reported by Kebarle and co-workers (16) would be of interest in evaluating the magnitude of this activation energy.

The thermal decomposition of 1-(2-cyano-2′-propoxy)-4-oxo-2,2,6,6-tetramethylpiperidine in solution has been studied as a function of solvent, temperature, and the presence of radical scavengers. In the absence of a scavenger, decomposition produces a hydroxylamine and methacrylonitrile, whereas in the presence of a scavenger such as oxygen, a nitroxide and 2-cyano-2-propyl radicals result. Decomposition in the presence of a scavenger is ~50 times more rapid than decomposition in its absence. By using various free radical scavengers, scission of the NO—C bond is confirmed, that is the reverse of the normal nitroxide – alkyl radical reaction. Increasing solvent polarity causes a marked decrease in thermal stability, both in the presence or absence of radical traps. The importance of the thermal decomposition reactions in the interpretation of nitroxide scavenging of radicals is discussed.

D. W. GRATTAN, D. J. CARLSSON, J. A. HOWARD et D. M. WILES. Can. J. Chem. **57**, 2834 (1979).

La décomposition thermique du (cyano-2′-propoxy-2′)-1-oxo-4-tétraméthyl-2,2,6,6-pipéridine en solution est étudiée en fonction du solvant, de la température et de la présence de pièges à radicaux. En l'absence de piège, la décomposition produit une hydroxylamine et de la méthacrylonitrile, tandis qu'en présence d'un piège tel que l'oxygène, un nitroxyde et des radicaux cyano-2-propyl-2 sont produits. La décomposition en présence d'un piège est ~50 fois plus rapide que la décomposition sans piège. En utilisant différents pièges à radicaux libres, on a confirmé la scission de la liaison NO—C, ce qui est l'inverse d'une réaction normale de radical nitroxyde – alkyle. L'augmentation de la polarité du solvant provoque une diminution marquée dans la stabilité thermique et ce, en l'absence ou en présence de pièges à radicaux. On a discuté de l'importance des réactions de décomposition thermique dans l'interprétation de l'action des nitroxydes comme pièges à radicaux.

[Traduit par le journal]

Nitroxides derived from the hindered amine 2,2,6,6-tetramethylpiperidine have been widely used to scavenge alkyl or aralkyl free radicals, both in kinetic studies of free radical processes (1–4) and in the stabilization of hydrocarbons and polymers against oxidative degradation (5–9). Nitroxide scavenging produces an O-substituted hydroxylamine (reaction [1]) (5, 6). The use of the nitroxide in kinetic studies usually involves the implicit assumption that the >NOR species is stable. In addition

[1] $>NO\cdot + R\cdot \rightarrow >NOR$

this species may well play an important role in preventing further oxidative degradation of polymers (10, 11) and in the "catalytic inhibition" of the autoxidation of hydrocarbons (9). However, the O-substituted hydroxylamines have been reported to be thermally unstable (4, 9, 12) which is not entirely unexpected in view of the low values of the O—H bond strength in hydroxylamines (13). In an early study Kovtun *et al.* (4) used electron spin resonance (esr) spectroscopy to show that nitroxide can be reformed under certain conditions. More recently Bolsman *et al.* (9) have monitored the production of the unsubstituted hydroxylamine and olefin from the decomposition of *N,N,O*-tri-*tert*-butylhydroxylamine. In the most thorough analytical study of >NOR decomposition, Howard and Tait (12) showed that hydroxylamine and olefin resulted from the slow decomposition of O-aralkyl substituted hydroxylamine in the absence of O_2, whereas nitroxide was formed rapidly in the presence of O_2. Indirect evidence indicated the intermediacy of the aralkyl radical in the presence of O_2.

In this paper, the thermal decomposition reactions of an O-alkyl-substituted hydroxylamine (1-(2′-cyano-2′-propoxy)-4-oxo-2,2,6,6-tetramethylpiperidine, **1**) are examined in various solvents, both in the presence and absence of oxygen. This compound is quite similar to the species expected from the nitroxide scavenging of macro-radicals during polyolefin

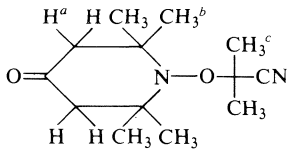
oxidative degradation (6, 7), and it is important to understand the behaviour of >NOR species both in hydrocarbon and highly polar environments, simulating respectively the unoxidized and oxidized regions of the polymer.



1

Experimental

Preparation of O-substituted Hydroxylamines

Heating a hexane solution of 4-oxo-2,2,6,6-tetramethylpiperidine-*N*-oxyl (**2**) with an excess of α,α′-azo-bis-*iso*-butyronitrile at 55°C gave 1-(2′-cyano-2′-propoxy)-4-oxo-2,2,6,6-tetramethylpiperidine **1**, as described previously (11, 14). 1-Cyclohexyloxy-4-oxo-2,2,6,6-tetramethylpiperidine (**3**) solutions were prepared by the photolysis of di-*tert*-butyl peroxide in a cyclohexane solution of **2** under nitrogen until colourless (11). Gas chromatography (gc) showed the steady loss of **2** and formation of **3**.

Other Materials

The unsubstituted hydroxylamine (1-hydroxyl-2,2,6,6-tetramethylpiperidine-4-one, **4**) was prepared for comparison with the products from **1**. Hydrogenation of **2** (0.09 g) in isooctane (17 mL) over 5% palladium on charcoal (0.2 g) with H_2 at 1 atmosphere for ~30 min gave a mixture of **4** (~70%), **2** (~10%), and 4-oxo-2,2,6,6-tetramethylpiperidine **5** (~20%). Prolonged hydrogenation gave a quantitative yield of **5**. The hydroxylamine oxidized steadily back to the nitroxide, so that the pure product was not isolated in quantity. However, gas chromatography – mass spectrometry (gc–ms) analysis during the hydrogenation gave firm evidence for the **2** → **4** → **5** conversion, and the characteristic mass spectrum of **4** was obtained.

The nitroxide **2** (Aldrich) was recrystallized from methanol. 4-Oxo-2,2,6,6-tetramethylpiperidine (**5**) was obtained from Eastman.

For the radical trapping experiments, 2-methyl-2-nitrosopropane (a gift from K. U. Ingold) was prepared by the method of Stowell (15) and benzenethiol was supplied by Fisher. For comparison with products from the nitroso compound, 2-methylpropyl-2,2′-cyano-2′-propyl nitroxide **6** was prepared from the decomposition of α,α′-azo-bis-*iso*-butyronitrile in the presence of the nitroso compound in degassed cyclohexane. This preparation also produced the 2-cyano-2-propyl adduct to **6** (*O*,*N*-di-(2-cyano-2-propyl)-*N*-2′-methyl-2′-propyl hydroxylamine, **7**).

Thermal Decompositions

Degassed or air saturated aliquots (0.5 mL) of **1** (1.35×10^{-2} *M*) were heated in sealed ampules at preselected temperatures. Decomposition under air employed a large air/liquid volume ratio so that an excess of oxygen was available. After each set decomposition period, tubes were quenched in liquid nitrogen and stored at −15°C. For analysis, the samples were warmed to room temperature, the ampules broken open and analysed within ~5 min.

Product Analysis

Products from the thermal decompositions of **1** were analysed by a combination of liquid chromatography (hplc), gc, gc – ms, and esr spectroscopy. The liquid chromatograph was a Waters ALC 201 fitted with both uv and refractive index detectors and an SiO_2 column (Waters 0.65 cm id × 27 cm, Micro-Porasil, 10 μm particles). Isochratic elutions were made with isopropanol (3 vol%) in *n*-hexane at 1.0 mL min^{-1}. For gc separations, a Hewlett-Packard 5730A (flame ionization detector) was fitted with a 10% UCW-982 coated, Chromosorb W column (20 in. × 1/8 in. od); gc-ms analysis used a similar column with a Finnigan 4000 automated gas chromatograph/EI-CI mass spectrometer system, operated in the electron impact mode.

Electron spin resonance spectra of the nitroxides were measured on a Varian E-4 spectrometer. For unsubstituted hydroxylamines, the highly sensitive triphenyltetrazolium chloride (TTZC) test of Snow (16) was used to quickly identify products and hplc fractions containing free hydroxylamines. When benzenethiol was used to trap radical products from the decomposition of **1**, perdeuterobenzene (Merck, Sharp, and Dohme) was used as solvent and the products analysed by gc, esr, or by nmr spectroscopy at 60 MHz using a Varian EM360 spectrometer. Chemical shifts of products and of **1** were compared with standards in the thiol–C_6D_6 mixture. Shift values are given in ppm relative to tetramethylsilane as internal standard.

Results

Thermal decomposition of **1** in various O_2-free solvents gave a >90% yield of the unsubstituted hydroxylamine **4** and ~80% yield of methacrylonitrile. The loss of **1** and accumulation of **4** at various temperatures in cyclohexane are shown in Fig. 1. Decomposition products were separated by gc and lc and confirmed by gc–ms. The effect of different solvents at constant temperature (82°C) is shown in Fig. 2. Blank experiments showed that methacrylonitrile was unchanged after 20 h at 82°C in the O_2-free solvents used; **4** is also quite stable, decomposing only slowly to **2** (Fig. 2). However, hydroxylamines are destroyed very rapidly in the presence of hydroperoxides (2). This was confirmed by addition of *tert*-butyl hydroperoxide to reaction products containing **4**. Gas chromatographic analysis showed the immediate (<10 s at 25°C) quantitative conversion of **4** to **2**. Hydroperoxide impurities in the solvents

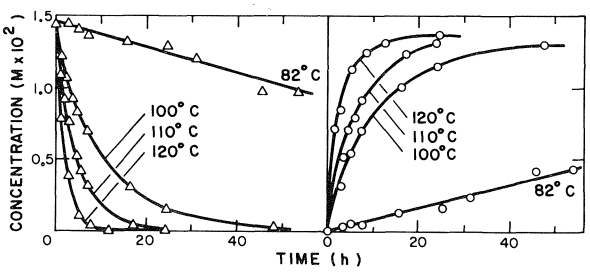


FIG. 1. Thermal decomposition of **1**, cyclohexane solution, O_2-free. Concentrations of **1** (△) and **4** (○) from lc and gc.

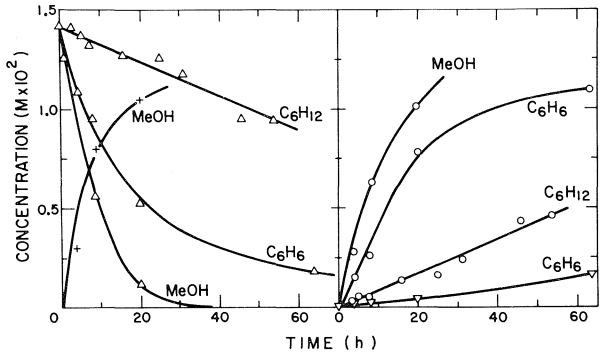

FIG. 2. Effects of solvents on the thermal decomposition of **1** in the O_2-free solvents shown at 82°C. Concentrations of **1** (△), **4** (○), methacrylonitrile (+), and **2** (▽) from gc and lc.

had the same effect. Deliberate addition of *tert*-butyl hydroperoxide to hydroxylamine-containing mixtures was used as a cross check on the assignment of the hydroxylamine gc peak initially identified by a comparison of the retention time with that of the hydroxylamine synthesized by hydrogeneration of the parent nitroxide.

In the air-saturated solutions, decomposition of **1** is much faster than in O_2-free solutions, and the products are distinctly different. Decomposition of **1** at two temperatures in cyclohexane is shown in Fig. 3, with O_2-free data included for comparison. The major product from **1** is now **2** (~80%); **4** is not detected (<2% yield) despite being fairly stable in blank experiments. For example, the half life for decomposition of **4** to **2** in air-saturated solvents at 82°C was ~4 h. Appreciable amounts of a second substituted hydroxylamine **3** accumulated in the presence of oxygen (Fig. 3). High yields of **2** were also observed in methanol and *tert*-butyl hydroperoxide (Fig. 4).

Only trace amounts of methacrylonitrile (~2%) were found after the complete decomposition of **1** in each air-saturated solvent despite the olefin being quite stable either in pure solvents at the temperatures studied, or in decomposing **1** solutions in the presence of oxygen. A new product from the butyronitrile moiety of **1** was 2-cyanopropan-2-ol, found in ~50% yield in the first few hours of **1** decomposition in air-saturated solutions but in much lower yields at higher conversions. Control experiments showed that 2-cyanopropan-2-ol is quite unstable in dilute solutions, decomposing to a quantitative yield of acetone (and presumably HCN), with a half life of ~6 h in methanol at 50°C. Increasing acetone concentrations were found during the decomposition of **1** in the presence of O_2. The combined accumulation of acetone and 2-cyanopropan-2-ol is shown in Fig. 4.

In air-saturated cyclohexane, methanol, or *tert*-butyl hydroperoxide, decomposition of **1** was sufficiently rapid that loss of **1** and formation of **2** could be measured at room temperature. (The half life of **1** at 23°C was ~9 days in the polar solvents.)

Saturation of solutions of **1** with oxygen gave the same products and rates as found with air-saturated solutions.

Decomposition of **1** in air-saturated benzene again produces **2**, but in only ~50% yield at 82°C (Fig. 4). Another major product (~30% of **1**) and a minor (~10% of **1**) product were found by gc. Their mass spectra were quite similar to those from **5** (the minor product) and **2** (the major product) although their gc retention times were much greater than both of these compounds. Electron spin resonance confirmed only the nitroxide level equivalent to the **2** yield observed by gc. Other possible products precluded by

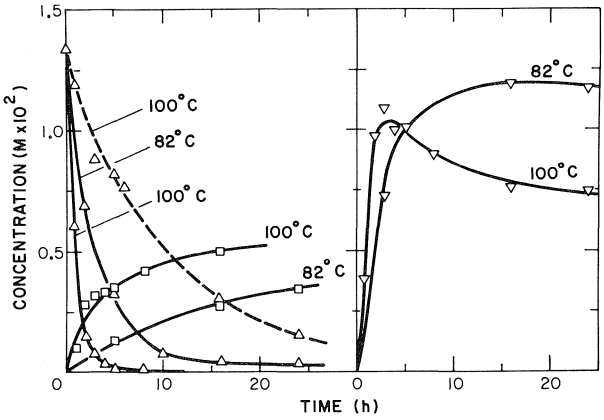

FIG. 3. Effects of temperature on the thermal decomposition of **1**, (—) in air-saturated cyclohexane; (---) in O_2-free cyclohexane for comparison. Concentrations of **1** (△), **2** (▽), and **3** (□) from gc and lc.

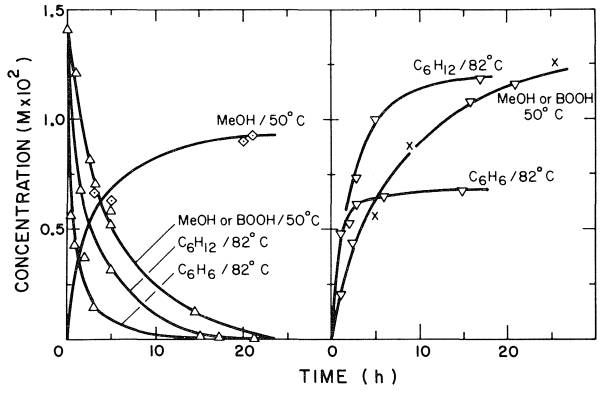

FIG. 4. Decomposition of **1** in various air-saturated solvents. Concentrations of **1** (△), **2** (▽), and acetone + 2-cyanopropane-2-ol (◇) determined by lc and gc. Concentrations of **2** (×) also determined by esr after reactions in methanol.

gc–ms included phorone and 1-methoxy-4-oxo-2,2,6,6-tetramethylpiperidine. The major unidentified product from the decomposition of **1** in benzene was also found in small amounts (~5%) after the decomposition of **1** in other solvents, and as an impurity in commercial **2**.

To investigate the possibility of O_2 acting as a trap for free radical decomposition products from **1**, the spin traps 2-methyl-2-nitrosopropane (16) or benzenethiol were added to O_2-free solutions of **1** at 55°C. The formation of **2** and 2-methyl-2-propyl-2′-cyano-2′-propyl nitroxide **6** in the presence of 2-methyl-2-nitrosopropane were indicated by gc and esr (a_N = 14.7 and 15.2 G respectively). In the presence of the nitroso spin trap, the O_2-free decomposition of **1** was found to proceed initially at a rate very close to the rate observed in air-saturated cyclohexane at the same temperature to give **2** together with a similar yield of **6**. This implies that the nitroso compound is not trapping radicals from a minor side reaction (17), but a product from the main decomposition mechanism of **1**. However, after virtually complete decomposition of **1**, only ~10% of the theoretical yield of **6** was observed, with a large yield of the adduct **7** (~60%, based on 2-cyano-2-propyl radicals from the decomposition of **1**).

In the presence of the nitroso compound, neither the parent piperidine **5**, nor the substituted hydroxylamine **3**, nor 2-methyl-2-propyl-2′-cyano-2′-propoxyl nitroxide (which should have been easily detectable by esr because a_N = 27.25 G, despite being somewhat unstable (18)) were detected after the decomposition of O_2-free solutions of **1**.

The decomposition of **1** at 55°C in O_2-free benzenethiol/perdeuterobenzene (1:2 by volume) produced a quantitative yield of **5** and 2-cyanopropane as shown by nmr and gc. The well characterized nmr spectrum of **1** ($4H^a$ multiplet at 2.14; $12H^b$ doublet at 1.05, 1.10; $6H^c$ singlet at 1.32 ppm) (14) was replaced by the combined spectrum of **5** ($4H^a$ singlet at 1.96; $12H^b$ singlet at 0.96) (19) and 2-cyanopropane ($6H^c$ doublet at 0.79, 0.68; 1H septet at 2.23, 2.12, 1.99, 1.88, 1.78, 1.68, 1.57 — but only 1.88, 1.78, 1.57 clear of other absorptions in the reaction mixture). Examination of the reaction mixture by nmr at high amplification showed the absence (<5% based on **1** decomposed) of methacrylonitrile and 2-cyanopropan-2-ol. Addition of **2** to degassed C_6H_5SH–C_6D_6 at 23°C also gave a quantitative yield of **5** within seconds of solution as shown by nmr, gc, and the loss of the esr nitroxide signal, together with a high yield of diphenyl disulfide.

Discussion

Rates of decomposition of **1** measured over a concentration range of $1 - 100 \times 10^{-4}$ *M* were found to follow first order kinetics (Fig. 5), with rate constants in a given solvent which were independent of the method of concentration determination (gc, lc, or esr). Some of the calculated rate constants are collected in Table 1.

Decomposition of **1** in O_2-free solvents can be rationalized in terms of a unimolecular homolysis (reaction [2]). The process is strongly solvent

[2] 
dependent (Fig. 2). Arrhenius plots for the data in cyclohexane and methanol are shown in Fig. 6. Activation energies and pre-exponential factors are collected in Table 2, together with other literature values. The slow generation of nitroxide from **4** in the absence of O_2 (Fig. 2) probably occurs by the process (2)

$$\text{>NOH} + \text{HON<} \rightarrow \text{>NO}\cdot + H_2O + \cdot\text{N<}$$

Keana *et al.* (20) have reported that the substituted hydroxylamine 1-benzyloxy-4-hydroxyl-2,2,6,6-tetramethylpiperidine is stable at 170°C. However this substituted hydroxylamine has no reactive β-hydrogens and so cannot undergo reaction [2].

Superficially, the thermal decomposition of **1** in the presence of O_2 appears to follow a different mechanism from reaction [2]. In the presence of O_2, the observed products (nitroxide and some 2-cyano-

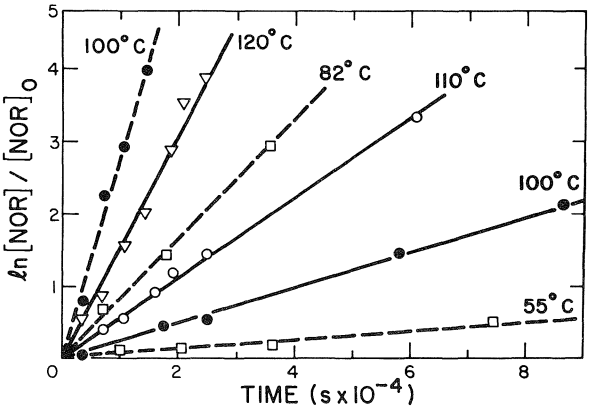

FIG. 5. First order kinetic dependence of the decomposition of **1** in cyclohexane, O_2-free (—) or air-saturated (---).

[d]O_2-free, but in the presence of 8.5×10^{-3} M 2-methyl-2-nitrosopropane.

propan-2-ol) are consistent with reaction [3] followed by [4*a*] where RH is the solvent.

The progressive production of **3** in cyclohexane (Fig. 3) probably results from the scavenging of an alkyl radical (from reactions [4*a* and *b*]) by the nitroxide (3, 10, 11, 17). In the absence of an effective scavenger such as O_2 to remove radicals produced in reaction [3], **2** will rapidly recombine with this radical with a rate constant k_{-d} of $\sim 4 \times 10^8$ M^{-1} s^{-1} to reform **1** (3, 10, 11, 17).

The products from the decomposition of **1** in the presence of 2-methyl-2-nitrosopropane (but in the absence of O_2) are also consistent with reaction **3**. This nitroso compound is known to trap alkyl (or alkoxy) radicals, with the formation of a new nitroxide (16) (**6** in reaction [5], $k_5 \sim 1 \times 10^7$ M^{-1} s^{-1} at 55°C (17)) together with **2** from reaction [3]. Further scavenging of the 2-cyano-2-propyl radicals by **6** gives the tri-alkyl substituted hydroxylamine **7**. The adduct **7** appeared to be quite stable at 55°C in comparison with **1**. The k_d value for reaction [3] in the presence of 2-methyl-2-nitrosopropane was very similar to that found in the presence of air, and is listed in Table 1. The quantitative production of

[3] 
[4] 
[5] 
6

2-cyanopropane from the decomposition of **1** in O_2-free C_6H_5SH–C_6D_6 is again consistent with [3], followed by hydrogen abstraction from the thiol. In addition the production of **5** from this decomposition can be explained by the known reaction of nitroxide with a thiol (21).

Two other processes might lead to the products observed from the decomposition of **1** in the presence of O_2. These are scission at the N—O link (rather than the O—C link as in [3]) or the homolysis [2] followed by a rapid reaction of the hydroxylamine with hydroperoxides (from the thermal oxidation of the solvent) to give **2** (2). This latter route to nitroxide formation is, however, precluded by the absence of methacrylonitrile from the decomposition of **1** in C_6H_5SH and the immediate accumulation of **2** (Figs. 3 and 4) even in benzene (Fig. 4) which cannot peroxidize. However Toda *et al.* (22) have observed products from radical attack on nitroxides and shown that the 3-position is particularly vulnerable in **2**. Thus the two new products from the decomposition of **1** found in appreciable quantities only in C_6H_6 most likely result from some attack of 2-cyano-2-propyl or peroxy on the piperidine species, favoured by the resistance of the solvent itself to attack. The slow decomposition of **1** to give **4** must obviously still occur in the presence of O_2. However, $-d[\mathbf{1}]/dt$ is 20–30 times faster in the presence of O_2 (cf. Fig. 6). The detection of only traces of **4** must in part be due to the rapid reaction of **4** with peroxy radicals (2) and other oxidizing species. Scission at the N—O bond of **1** to give an amine radical and a 2-cyano-2-propoxy radical is not consistent with the products observed in the presence of either 2-methyl-2-nitrosopropane or benzenethiol.

The ability of nitroxide radicals to scavenge many alkyl radicals in oxidations has been suggested to result from the attack of peroxy radicals on the O-alkyl hydroxylamine (reaction [6]) (4, 9, 11). This

$$[6]\quad R'O_2\cdot + \mathbf{1} \xrightarrow{k_1} \mathbf{2} + [ROOR']$$

could contribute to the loss of **1** in the presence of O_2. However $-d[\mathbf{1}]/dt$ was unaffected by the presence of an efficient peroxy radical scavenger (2,6-di-*tert*-butyl-4-methylphenol at 4.5×10^{-4} *M*, $[\mathbf{1}]_0 = 5 \times 10^{-4}$ *M* at 75°C). Similarly the published rate constants for reactions [6] (11) and [4*a*] (23) imply that **6** can only account for the loss of **1** and

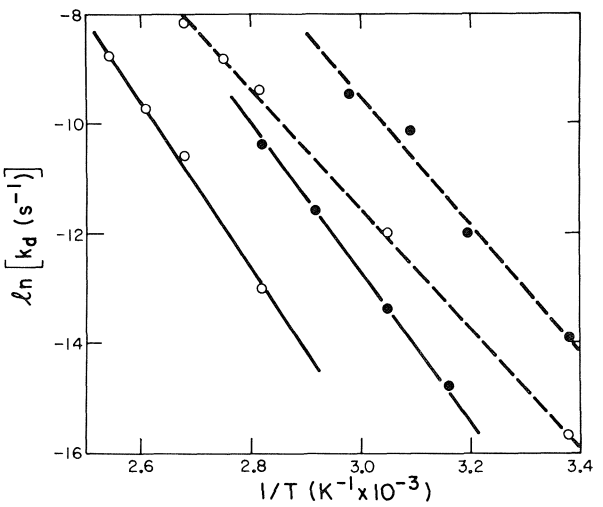

FIG. 6. Temperature dependence of the decomposition of **1** in cyclohexane (○) and methanol (●), O_2-free (—) or air-saturated (---).

reaction [3] appears to be the dominant decomposition route.

In any one O_2-free solvent, the rate of decomposition of **1** is very much slower than in air-saturated solutions (Fig. 3 and cf. Figs. 2 and 4). In air-saturated methanol and cyclohexane, the activation energies and pre-exponential factors shown in Table 2 were derived from the Arrhenius plots in Fig. 6. Both the activation energies and pre-exponential factors were appreciably lower than the air-free values for the respective solvents. This contrasts with the behaviour of the aralkyl substituted hydroxylamine shown in Table 2, where only the activation energy is influenced by solvent. The rates of decomposition of **1** via [2] or [3] increase with changing solvents in the sequence cyclohexane < benzene < methanol ≃ *tert*-butyl hydroperoxide. Both solvent viscosity decrease and polarity increase follow the order cyclohexane < benzene < methanol, and both effects could influence the reaction rates. The reaction rates in methanol (low viscosity) and *tert*-butyl hydroperoxide (high viscosity) are, however, very similar, implying that solvent polarity is the key factor. This was substantiated when the decomposition of **1** in cyclohexane and in Nujol was compared (air-saturated solutions at 55°C). From esr spectroscopy, k_d was only marginally slower (~10%) in Nujol despite the wide difference in viscosities (about 0.7–90 cp (24)). Kiefer and Traylor (24) have reported a four-fold decrease in the rate of photodissociation of di-*tert*-butyl peroxide on going from pentane to Nujol as solvent. However the rate constant for *tert*-butoxy radical self-combination may be close to diffusion controlled (23), about 10 times

faster than the nitroxide – alkyl radical constant for reaction [1] (3, 10–12). The accelerating effect of increasing solvent polarity on decomposition reactions has been extensively reviewed by Martin (25). The similarity in solvent effects on the rates of product formation from O_2-free and O_2-containing solutions might result from a common precursor. This could be the NO—C cleavage (reaction [3]) followed by either recombination (dominant unless a scavenger is present) or disproportionation of the radicals from [3] to give hydroxylamine and olefin, i.e., equivalent to reaction [2].

The thermal stability of O-substituted hydroxylamines has been suggested to be markedly dependent on the nature of the substituent (4), and this is confirmed by the calculated data collected in Table 3. In particular the O-alkyl substituted compounds shown are at least 18 times more stable than the O-aralkyls in the presence of O_2. Such a large difference in thermal stability implies that the transition state for decomposition occurs early in the reaction coordinate and that the stability of O-alkylhydroxylamines is governed principally by strain in the ground state of the molecule (26). Our k_d in the absence of O_2 for **1** is within a factor of 2 of the value found by Bolsman *et al.* (9) for *N,N,O*-tri-(2-methyl-2-propyl)hydroxylamine decomposition (Table 3) with very similar Arrhenius parameters (Table 3). However these latter workers failed to appreciate the effects of O_2 and solvent on the decomposition process, and consequently were unable to explain the catalytic inhibition by nitroxide in terms of the (relatively) low k_d under O_2-free conditions. Kovtun *et al.* (4) observed only the scavenger I_2-assisted decomposition of **1** (reaction [3]), and ignored the formation of a hydroxylamine in the absence of a scavenger. Their reported k_d values in the presence of I_2 are all 16–20 times higher than our values found with O_2, I_2, or 2-methyl-2-nitrosopropane scavenging. This may result from complicating side reactions in the presence of I_2. For example, in contradiction to the data of Kovtun *et al.* (4), we found no effect of I_2 concentration (Table 1) on k_d, but found gross deviations from first order kinetics for the decomposition of **1** in the presence of I_2 at >10% conversion with only ~30% of the theoretical yield of **2** after ~4 half lives of **1** at 61°C.

The thermal instability of $\rangle NOR$ compounds has

some very important implications for the interpretation of published data on nitroxide or >NOR scavenging of radicals. In several instances, >NOH (10, 27) or >NO· (28–30) formation from >NOR decomposition must have played a part in the observed kinetics. For example, Sudnik *et al.* have reported rate constant values for reaction [6] (28) and the rate constant for nitroxide scavenging of alkyl radicals (29), both derived from experiments at temperatures where the substituted hydroxylamine can be expected to have a half life of below 1.0 h. Similarly, the reaction conditions used by Kovtun *et al.* (27) (amine or alcohol solvents at 75°C) in the nitroxide reaction with alkyl radicals would rapidly decompose any >NOR to give the observed hydroxylamine, rather than their suggestion of direct nitroxide attack on the amine or alcohol. It is also worth emphasizing that stabilization by nitroxides at low O_2 levels will give >NOR which would decompose to olefin and >NOH. The latter can then rapidly scavenge a peroxy radical (2) and regenerate >NO· so that many chains would be terminated by each nitroxide molecule (9). However, at high O_2 pressures, >NOR may function as an initiator, and the nitroxide would lose some of its overall scavenging efficiency.

Acknowledgements

The authors thank Mr. R. T. Pon for assistance with syntheses and analytical procedures and Mr. M. E. Bednas for performing the gc–ms work. We are indebted to Dr. K. U. Ingold for a gift of the 2-methyl-2-nitrosopropane. The authors are grateful to both referees for valuable comments.

Molecular and group relaxation studies in parasubstituted benzenes in various media

J. CROSSLEY, J. P. SHUKLA, S. P. TAY, M. S. WALKER, AND S. WALKER
Department of Chemistry, Lakehead University, Thunder Bay, Ont., Canada P7B 5E1

Received February 16, 1979

J. CROSSLEY, J. P. SHUKLA, S. P. TAY, M. S. WALKER, and S. WALKER. Can. J. Chem. **57**, 2843 (1979).

Dielectric absorption studies have been made on molecules of the type X—aromatic—Y where X—Y is —OCH_3, —$COCH_3$, —CH_2Cl, and —CH_2CN. The molecules have been dissolved in (*a*) a polystyrene matrix and (*b*) in the viscous liquid *o*-terphenyl. For 1,4-dimethoxybenzene the group process dominates in both media, and estimates have been made of the activation enthalpy for group relaxation. For 1,4-dimethoxybenzene in benzene, decalin, Nujol, and *o*-terphenyl solutions, however, there appears to be a small contribution from the molecular process. No such contribution was detected in the matrix studies on this solute molecule. For 1,4-diacetylbenzene, 1,4-bis(chloromethyl)benzene, and 1,4-bis(cyanomethyl)benzene in *o*-terphenyl solution it again seems that the group and molecular processes overlap. However, in polystyrene the enthalpies of activation which emerge are characteristic of the group relaxation process as determined by the nmr approach. Altogether, the work illustrates that *o*-terphenyl may be a useful solvent in helping to decide whether a solute has contributions from an intramolecular motion.

J. CROSSLEY, J. P. SHUKLA, S. P. TAY, M. S. WALKER et S. WALKER. Can. J. Chem. **57**, 2843 (1979).

On a effectué des études d'absorbtion diélectrique sur des molécules du type X—aromatique—Y où X—Y représente —OCH_3, —$COCH_3$, —CH_2Cl et —CH_2CN. On a dissous les molécules dans (*a*) une matrice de polystyrène et (*b*) un liquide visqueux, le *o*-terphényle. Dans le cas du diméthoxy-1,4 benzène le mouvement des groupes domine dans les deux milieux et on a évalué l'enthalpie d'activation pour la relaxation du groupe. Dans le cas du diméthoxy-1,4 benzène en solution dans le benzène, la décaline, le Nujol ou le *o*-terphényle, il semble que le processus moléculaire fournit une petite contribution. On n'a pas détecté de telles contribution lors des études dans des matrices de cette molécule de soluté. Dans les cas des diacétyl-1,4, bis(chlorométhyl)-1,4 et bis(cyanométhyl)-1,4 benzènes en solution dans le *o*-terphényle, il semble de nouveau que les processus impliquant les groupes et la molécule se recouvrent. Toutefois dans le polystyrène les enthalpies d'activation qui se dégagent sont caractéristiques d'un processus de relaxation de groupe, tel que déterminé par une méthode rmn. Dans l'ensemble, le travail illustre que le *o*-terphényle peut être un solvant utile pour déterminer si un soluté a des contributions dues à un mouvement intramoléculaire.

[Traduit par le journal]

Introduction

Molecules which have a flexible group attached to an aromatic ring have been widely studied by dielectric techniques. Usually the molecules have been examined either as a pure liquid or as a solute in a dilute solution of a non-polar solvent, and the dielectric absorption has been observed in the microwave region. In all cases the absorption due to the molecular and group reorientations overlap, and the relaxation times for these processes must be deduced from a Budó analysis (1). Such analyses are often subject to appreciable errors which in turn lead to serious uncertainties in the enthalpies of activation obtained for the intramolecular processes.

It has been found possible in a number of cases studied by Davies *et al.* (2, 3) and Walker *et al.* (4–6) to separate completely the absorption due to the intramolecular and molecular processes for molecules by dispersing the solute in a polystyrene matrix. The enthalpies of activation for the intramolecular process have, on the whole, compared quite well with those from the other direct methods of nmr and ultrasonics (7).

A number of dielectric studies (8–10) has been made of acetyl group relaxation in aromatic compounds dissolved in non-polar solvents of low viscosity (~ 1 cP). Typically, the enthalpy of activation for group relaxation in such solvents is ~ 5 kJ mol^{-1}. However, for similar solutes dispersed in a polystyrene matrix (6) the corresponding values are ~ 30 kJ mol^{-1}, and these are of the same order as that estimated for acetophenone by Grindley, Katritzky, and Topsom (11, 12) who obtained a value of 26 kJ mol^{-1}.

0008-4042/79/212843-05$01.00/0

Studies of group relaxation in five aromatic methoxy compounds in a polystyrene matrix yielded ΔH_E values between 11 and 14 kJ mol^{-1} for methoxy group relaxation (13). However, dielectric studies on similar solutes in non-polar solvents (14, 15) gave values of ~6 kJ mol^{-1}. This significant difference in the enthalpies of activation for the acetyl and methoxy groups between these two different dielectric approaches merited further study. The molecules chosen for investigation were of the type X—aromatic—X (Y, Y) ; such molecules have a common feature in that the fixed component of the main dipole along the main principal axis is zero; thus, if molecular relaxation is to be detected, it has to result from a (temporary) stable isomer which has a dipole component perpendicular to this long axis (e.g. a *cis* or *gauche* form). More information on molecular relaxation contributions in X—aromatic—X (Y, Y) systems — or their absence — was also sought.

Experimental and Results

Studies in o-*Terphenyl Solvent*

All the solutes were purified before use. The *o*-terphenyl solvent (Polyscience Inc.) was used without further purification. The apparatus and procedure used in the *o*-terphenyl studies to determine the permittivity (ε') and the dielectric loss (ε'') at frequencies between 1 and 6 GHz have been described previously (16). The low frequency permittivity (ε_0) was measured at 2 MHz with a WTW Dipolmeter. The refractive index (n_D) was measured with an Abbé refractometer and the viscosities (η) determined by means of calibrated Ubbelohde type viscometers and density bottles.

The dielectric data for all the solutions were analyzed in terms of a Cole–Cole symmetrical distribution function for a mean relaxation time τ_0 and a distribution parameter α. The dielectric loss due to the solvent was comparable to the experimental error for these dielectric data. The very high frequency permittivity values, ε_∞, obtained from the Cole–Cole analyses, were similar to $n_D{}^2$.

Dipole moments μ were calculated by means of the equation:

$$\mu = 0.012812\left[\frac{3T(\varepsilon_0 - \varepsilon_\infty)M_2}{(\varepsilon_1 + 2)^2 w_2 d_1}\right]^{1/2}$$

where M_2 and w_2 are the molecular weight and weight fraction respectively of the solute and ε_1 and d_1 the permittivity and density of the solvent respectively at the absolute temperature T.

The mean relaxation times, τ_0, distribution parameters, α, viscosities and dipole moments are listed in Table 1.

Enthalpies of activation for dielectric relaxation (ΔH_E) and viscous flow ($\Delta H_\eta{}^*$) were obtained from the plots of $\log \tau T$ against T^{-1} and $\log \eta$ against T^{-1} respectively and are presented in Table 2.

Studies in Polystyrene Matrix

Dielectric measurements on solutes dispersed in a polystyrene matrix and the evaluation of the results have been described previously (4–7). The polystyrene matrix was prepared in the way described by Davies and Swain (2). We have also adopted their experimental and analytical procedures for obtaining relaxation times and distribution parameters by means of the Fuoss–Kirkwood equation and the enthalpy of activation from the Eyring equation. The polystyrene used here had a weight average molecular weight, $\bar{M}_w$, of 230 000. The relaxation data and the results of Eyring equation analyses of these data are given in Table 3.

Standard statistical techniques were employed to fit the function of temperature data to the Eyring equation. The 95% confidence intervals on ΔH_E were typically ±10% of the nominal values or ±3 kJ mol^{-1} whichever is the greater and in agreement with the work of Davies *et al.* (2, 3). For the ΔS_E term, these confidence intervals were of the order of ±50% of the nominal values in some cases, since this term is often a small part of the intercept, $\{\ln(h/k_B) - \Delta S_E/R\}$, of the $\ln(T\tau)$ versus $(1/T)$ plot.

TABLE 1. Relaxation times (τ_0), solution viscosities (η), distribution parameters (α), and dipole moments (μ) for some polar solutes in liquid *o*-terphenyl at four temperatures and weight fraction ($\bar{w}_2$)

T (K)	τ_0 (ps)	α	η (cP)	μ (D)
1,4-Dimethoxybenzene (w_2 = 0.1498)

343	9.4	0.32	7.88	2.09

TABLE 2. Activation energy data* for solutes in *o*-terphenyl above its melting point

Solute	ΔH_η* (kJ mol^{-1})	ΔH_E (kJ mol^{-1})
1,4-Bis(cyanomethyl)benzene	51.3	57
1,4-Bis(chloromethyl)benzene	40.3	37
1,4-Diacetylbenzene	51.2	33
1,4-Dimethoxybenzene	36.5	20

*See text for discussion of these ΔH_E values since when overlap of the group and molecular processes occurs then the values are not meaningful in terms of a particular process.

Discussion

1,4-Dimethoxybenzene and 4,4'-Dimethoxybiphenyl

Both these solute molecules were examined in a polystyrene matrix, but only the 1,4-dimethoxybenzene proved soluble in *o*-terphenyl above its melting point and only one set of symmetrical absorption peaks were detected. However, the enthalpies of activation for both solutes resulting from this process are virtually identical (Table 3). The ΔH_E values shown are very similar to the 11 kJ mol^{-1} determined by Katritzky *et al.* (11, 12) for methoxy group rotation in anisole and to values obtained in previous studies on five aromatic methoxy compounds dispersed in a polystyrene matrix (13). It is to be noted that values of ΔH_E of about 13 to 14 kJ mol^{-1} are quite unacceptable for molecular relaxation in these compounds. Molecular relaxation enthalpies are quite sensitive to the length of the long axis of the molecule, e.g. ΔH_E values for 4-bromotoluene and 4-iodobiphenyl are 42 and 102 kJ mol^{-1} respectively. These rigid solute molecules are, in fact, fairly similar in size to 1,4-dimethoxybenzene and 4,4-dimethoxybiphenyl respectively. The fact that the two molecules of such a different size have enthalpies of activation, which are virtually identical, indicates that molecular relaxation makes a negligible contribution to their dielectric absorption.

The study of 1,4-dimethoxybenzene in *o*-terphenyl yielded an Eyring activation enthalpy of 20 $\pm$ 5 kJ mol^{-1} which is almost of the same order as the value obtained in polystyrene. Further, the free energies of activation estimated at 333 K for this solute in polystyrene and *o*-terphenyl, 12 and 14 kJ mol^{-1} respectively, are virtually identical.

Grubb and Smyth favoured a small contribution from the molecular process ($C_1 \sim 0.15$) for 1,4-dimethoxybenzene in Nujol and also in decalin solution (14). A comparison of the relaxation times at 333 K in benzene ($\eta \sim 0.5$ cP), $\tau_0 = 4.6$ ps with that in *o*-terphenyl solution ($\eta \sim 25$ cP), $\tau_0 = 19.7$ ps, strongly supports contributions from both group and molecular processes. The approximately four-fold increase in τ_0 cannot be accounted for by an intramolecular process, and the τ_0 values are too short to be attributed solely to molecular relaxation. In fact, the sequence of τ_0 values with increasing solvent viscosity is quite revealing (see Table 4).

It is evident from Table 4 that τ_0 lengthens quite appreciably with increasing viscosity. The most likely explanations are *either*: (*a*) the presence of a molecular process which is significantly dependent on the viscosity; *or* (*b*) the hindrance of group rotation with increasing viscosity so that the role of molecular relaxation becomes enhanced. Since the diameter of the sphere swept out by methoxy group rotation is not appreciably greater than the thickness of the benzene ring little perturbation of the surrounding solvent molecules would be expected. Hence explanation (*a*) is preferred.

Comparison of the τ_0 values in Nujol and *o*-terphenyl suggests that, despite the appreciably greater macroscopic viscosity in Nujol, it is *o*-terphenyl which has the larger microscopic viscosity. This could be accounted for by much closer packing of the solvent molecules in the *o*-terphenyl case.

1,4-Diacetylbenzene

This molecule had been examined previously in a polystyrene matrix (6) and as the pure solid (6). The enthalpies of activation for group relaxation were 27 and 29 kJ mol^{-1} respectively. The former value is similar to that for acetyl group relaxation in 4-acetylbiphenyl (6) where both group and molecular relaxations were separated and established. For 1,4-diacetylbenzene in the solid phase it seems likely that only group relaxation would occur. Certainly the ΔH_E value of 29 kJ mol^{-1} is a typical value for acetyl group relaxation as determined by the dielectric matrix approach and also from nmr data (6).

The study of 1,4-diacetylbenzene in liquid *o*-terphenyl has yielded a very similar enthalpy of activation (33 kJ mol^{-1}). However, 4-ethylbromobenzene, which is a fairly similar-sized rigid (effectively from the dielectric point of view) molecule, in *o*-terphenyl gives a similar enthalpy of activation of 32 kJ mol^{-1}. Thus, the ΔH_E value of 33 kJ mol^{-1} for 1,4-diacetylbenzene in *o*-terphenyl could be accounted for by either group or molecular relaxation or an overlap of the two processes. However, a comparison of the τ_0 values of 1,4-diacetylbenzene in benzene (16.2 ps) and *o*-terphenyl (154 ps) at 333 K reveals that there is an appreciable increment between the two solvents. Such lengthening of the observed relaxation time for an increase in macroscopic viscosity from $\sim$0.6 to $\sim$25 cP clearly indicates a substantial contribution from the molecular reorientation process. This is in agreement with the findings of Fong and Smyth (9) who attributed a weight factor of $\sim$0.9 to the molec-

TABLE 3. Relaxation data and Eyring activation parameters for some solutes dispersed in a polystyrene matrix

Solute	Temperature range (K)	Relaxation time (s) at 200 K	ΔG_E (kJ mol^{-1}) at 200 K	ΔH_E (kJ mol^{-1})	ΔS_E (J K^{-1} mol^{-1})

ular process. It would seem likely that for 1,4-diacetylbenzene in *o*-terphenyl the group and molecular processes overlap.

1,4-Bis(cyanomethyl)benzene

This solute, when examined in a polystyrene matrix, yielded only one set of absorption peaks and a very low enthalpy of activation (3 kJ mol^{-1}). If this value is compared with the enthalpy of activation of 38 kJ mol^{-1} for a fairly similar-sized rigid molecule, 4-bromoethylbenzene, it is apparent that the value for 1,4-bis(cyanomethyl)benzene is to be ascribed to —CH_2CN group relaxation. For this same solute in *o*-terphenyl ΔH_E is 57 kJ mol^{-1} (Table 2) whereas ΔH_E for 4-bromoethylbenzene in *o*-terphenyl (18) is 32 kJ mol^{-1}. This suggests, at the very least, an appreciable contribution from a molecular relaxation process in 1,4-bis(cyanomethyl)benzene. In addition, the difference between the τ_0 values at 333 K in *o*-terphenyl, 96 ps (Table 1), and in benzene, 4.6 ps, for this solute cannot be accounted for solely by an intramolecular process. Similarly, comparison of the τ_0 in *o*-terphenyl solution at 333 K (Table 1) with that for 4-bromoethylbenzene (203 ps) at the same temperature (18) reveals that the process is not solely molecular. Clearly in this case there is an overlap of the group and molecular processes for 1,4-bis(cyanomethyl)benzene in *o*-terphenyl.

Thus, in this instance, it is apparent for 1,4-bis(cyanomethyl)benzene in *o*-terphenyl solution that, although the dipole moment components along the long principal axis cancel, there must be some temporary restriction of the —CH_2CN groups in the potential energy troughs which leads to molecular dipole moment reorientation.

1,4-Bis(chloromethyl)benzene

Smyth *et al.* (19) examined this solute in benzene solution and obtained a very short relaxation time of 3.72 ps at 333 K. This indicated the predominance of a —CH_2Cl group relaxation process. However, the relaxation time observed for this solute in *o*-terphenyl is 13.5 ps at this temperature. Such a lengthening would suggest that the absorption is not entirely due to an intramolecular process. One possibility is that the proportion of polar isomers increased in *o*-terphenyl over benzene solution. The ΔH_E value of 37 kJ mol^{-1} in *o*-terphenyl is to be compared with the molecular relaxation value of 32 kJ mol^{-1} for the somewhat smaller molecule, 4-bromoethylbenzene, and contrasted with the value of 8.8 kJ mol^{-1} obtained by Schaeffer *et al.* (17) for group rotation in benzylchloride. Clearly, there is at least an appreciable contribution from a molecular process for 1,4-bis(chloromethyl)benzene in *o*-terphenyl.

The dielectric absorption of this solute in a polystyrene matrix gives one symmetrical absorption peak at each temperature in the low temperature region. The enthalpy of activation of 9 kJ mol^{-1} is in excellent agreement with the value obtained by Schaeffer *et al.* (20) and is to be ascribed to CH_2Cl group reorientation.

Conclusions

For 1,4-dimethoxybenzene, in a polystyrene matrix, non-polar low viscosity solvents and in the relatively high viscosity *o*-terphenyl a group reorientation process dominates the dielectric absorption. In polystyrene and *o*-terphenyl the enthalpies of activation for methoxy group relaxations are quite similar and are of the order of the literature values for a direct method. However, the enthalpy value in the non-polar low viscosity solvents is significantly lower.

For 1,4-diacetylbenzene, 1,4-bis(chloromethyl)benzene, and 1,4-bis(cyanomethyl)benzene in *o*-terphenyl it seems probable that the group and molecular pro-

cesses overlap. It is possible that the proportion of isomers differs in this solvent from that in the non-polar solvents such as benzene. Further, the enthalpies of activation which emerge from the slope of the $\ln \tau T$ versus $1/T$ plots are more characteristic of the molecular than of the group process.

For the 1,4-diacetylbenzene and 1,4-bis(chloromethyl)benzene dispersed in a polystyrene matrix the enthalpies of activation are consistent with the literature values for group rotation as determined from nmr data.

It is concluded that in favourable cases the dielectric approach employing the matrix technique yields accurate ΔH_E values for a group relaxation process.

It is to be noted that liquid *o*-terphenyl is a most useful solvent in dielectric work and sometimes may assist in deciding whether a solute has contributions from both intramolecular and molecular relaxation processes. It is apparent that the host medium, *o*-terphenyl, exerts a pronounced effect on the relaxation data. This is to be attributed to the macroscopic tending more to the microscopic (16) than is the case for solvents of relatively low viscosity such as benzene, *p*-xylene, and cyclohexane.

Les constantes de vitesse d'addition du borohydrure de sodium sur les cyclanones stériquement encombrées, triméthyl-3,3,5 cyclohexanone (**2**), tétraméthyl-3,3,5,5 cyclohexanone (**3**), bicyclo[3,2,1]octanone-3 (**4**), tricyclo[5,2,1,$0^{3,8}$]décanone-3 (**5**), tricyclo[5,3,1,$0^{3,8}$]undécanone-5 (**6**) et bicyclo[3,3,1]nonanone-3 (**7**), ont été mesurées dans un mélange H_2O/dioxanne 50/50 en volumes, à 25.0°C. Elles mettent en évidence les énergies dues aux interactions diaxiales-1,3, interactions qui apparaissent lorsque l'on passe de l'état initial à l'état de transition. Les énergies d'activation mesurées, représentant presque la totalité de l'énergie conformationnelle correspondant à ces interactions, sont significatives d'un état de transition tardif.

La comparaison des constantes de vitesse de réduction de ces cétones, où le carbone siège de la réaction passe d'une hybridation sp^2 à une hybridation sp^3, avec les vitesses d'oxydation chromique des alcools correspondants, qui implique le changement d'hybridation opposé, montre que l'importance des interactions diaxiales-1,3 peut servir de critère pour déterminer la position de l'état de transition le long du chemin réactionnel.

Les différences de réactivité observées peuvent en outre contribuer à l'élucidation de problèmes conformationnels.

BERNARD BOYER, GÉRARD LAMATY, CLAUDE MOREAU, and PATRICK GENESTE. Can. J. Chem. **57**, 2848 (1979).

The rate constants for the addition of sodium borohydride to the sterically hindered cyclic ketones, 3,3,5-trimethylcyclohexanone (**2**), 3,3,5,5-tetramethylcyclohexanone (**3**), bicyclo[3,2,1]-3-octanone (**4**), tricyclo[5,2,1,$0^{3,8}$]-3-decanone (**5**), tricyclo[5,3,1,$0^{3,8}$]-5-undecanone (**6**) and bicyclo[3,3,1]-3-nonanone (**7**) have been determined at 25°C in a 50/50 by volume mixture of water and dioxane. The values demonstrate energies due to 1,3-diaxial interactions that arise on passing from the initial to the transition states. The measured energies of activation represent almost the total conformational energy corresponding to these interactions, suggesting a late transition state.

Comparison of the rates of reduction of these ketones where the carbon atom at the site of attack passes from sp^2 to sp^3 hybridisation, with the rates of chromic acid oxidation of the corresponding alcohols showing therefore the opposite change in hybridisation, indicates that the magnitude of the 1,3-diaxial interactions can serve to determine the position of the transition state along the reaction coordinate.

The observed differences in reactivity can also contribute to the elucidation of conformational problems.

Introduction

L'interprétation des résultats obtenus dans les réactions d'addition nucléophile sur les dérivés carbonylés est souvent rendue difficile à cause de la diversité et de la multiplicité des facteurs mis en jeu (1), à l'origine de la controverse concernant la position de l'état de transition dans la réduction des cétones par le borohydrure de sodium; à la suite des travaux effectués dans notre laboratoire, l'hypothèse d'un état de transition tardif a été émise pour cette réaction (2). Cette hypothèse, critiquée par certains auteurs (3), a reçu un accueil beaucoup plus favorable ces dernières années (4).

Le recours à des composés cycliques et polycycliques rigides permet d'utiliser plus rationnellement les données conformationnelles; il permet dans

le travail que nous présentons ici de faire varier sélectivement un seul facteur de réactivité: les interactions diaxiales-1,3. Les modèles, dont le squelette est une cyclohexanone chaise, ont en effet été choisis de façon à maintenir constants les autres facteurs de réactivité tels que la tension angulaire, l'hyperconjugaison ou les barrières de torsion.

Notre étude a porté sur la réduction des cyclanones stériquement encombrées **1** à **7** et sur la comparaison avec l'oxydation chromique des cyclanols correspondants **8** à **13**, résultats obtenus dans notre laboratoire (5) ou cités par d'autres auteurs (6).

Résultats expérimentaux

Les constantes de vitesse d'addition du borohydrure de sodium ont été déterminées à 25.0°C, dans un mélange eau/dioxanne 50/50 en volumes, la phase aqueuse contenant 0.05 mol/L de soude; dans ces conditions les solutions de BH_4Na sont stables (2).

Les constantes de vitesse partielles correspondant à l'attaque équatoriale, k_e, ont été calculées à partir des constantes de vitesse totales k et des résultats stéréochimiques obtenus dans la réduction des cétones **1** à **7** ($k_e = k \times$ % alcool axial), malgré les réserves que ce genre de calculs a suscitées (7).

Nos résultats expérimentaux sont rassemblés dans le tableau 1.

Interprétation des résultats expérimentaux et discussion

Nous admettons en première approximation que les cycles portant la fonction cétone ont une conformation chaise. Les différentes méthodes physiques (rmn ^1H et ^{13}C, Rayons X sur les cétones ou les oximes) ont montré que ces cycles étaient des chaises peu déformées (11–14).

Bien que la conformation chaise de la tétraméthyl-3,3,5,5 cyclohexanone (**3**) ne fasse, à l'heure actuelle, aucun doute, il n'était cependant pas déraisonnable, étant donné la présence de deux méthyles axiaux, d'envisager dans l'attaque équatoriale de l'ion borohydrure, une conformation réagissante autre que chaise, en particulier une forme croisée qui permet de diminuer les interactions diaxiales-1,3 entre les deux groupes Me et le groupe OH qui se forme.

Pour différencier entre la conformation stable et la conformation réagissante, nous avons synthétisé les cétones tricycliques **5** et **6** qui sont des modèles rigides de **3** (15). Le fait que les vitesses de réduction de ces cétones soient du même ordre de grandeur que celle de **3** est une forte indication que ce dernier composé, chaise à l'état fondamental, reste chaise dans le complexe activé.

Par comparaison avec les pourcentages obtenus dans la réduction des cétones **5** et **6** ces deux modèles permettent d'estimer à environ 70% le pourcentage d'attaque équatoriale sur la tétraméthyl-3,3,5,5 cyclohexanone (**3**).

Une approche de l'évaluation du pourcentage d'attaque équatoriale a déjà été tentée par Wigfield *et al.* (16) mais elle a l'inconvénient d'introduire un dipôle en position 4 qui peut modifier *et* la vitesse *et* la stéréochimie de la réduction par BH_4Na.

TABLEAU 1. Constantes de vitesse de réduction des cétones **1** à **7** par BH_4Na dans le mélange H_2O/dioxanne 50/50 en volumes à 25.0°C

Cétones	$k \times 10^3$ (M^{-1} s^{-1})	% Attaque équatoriale	$k_e \times 10^3$ (M^{-1} s^{-1})	$\delta\Delta G_{red}^{\neq}$ [a] (kcal/mol)
1	188.5	20 (8)	37.7	0
2	3.35	55 (7)	1.84	1.8
3	0.213	$\simeq 70$[b]	0.149	3.3
4	0.245	40 (9)	0.098	3.5
5	0.240	67	0.161	3.3
6	0.116	72	0.084	3.6
7	0.00109	88 (10)	0.00096	6.2

[a] $\delta\Delta G_{red}^{\neq} = -RT \ln k_e(n)/\ln k_e(1)$; $n = 2, 3, 4, 5, 6, 7$.
[b] Estimation de l'attaque équatoriale (voir texte).

Si les cycles cétoniques ont une conformation chaise, l'influence sur la vitesse des hydrogènes axiaux en 2 et 6 sera pratiquement la même. Si l'état de transition est tardif et si nous considérons les vitesses d'addition équatoriale k_e (schéma 1) les différences d'énergies $\delta\Delta G_{red}^{\neq}$ doivent correspondre aux interactions diaxiales-1,3 qui se développent entre l'état initial et l'état de transition et ce quelle que soit la structure, linéaire ou cyclique, que l'on admette pour le complexe activé (17).

La présence d'un méthyle axial, cas de la triméthyl-3,3,5 cyclohexanone (**2**), nécessite une énergie supplémentaire de 1.8 kcal/mol par rapport à la *t*-butyl-4 cyclohexanone (**1**) pour passer de l'état initial à l'état de transition. Les valeurs de ΔG^0 données par la littérature pour les interactions diaxiales-1,3 Me ··· OH, et qui se manifestent en totalité dans l'état final, varient de 1.9 à 2.4 kcal/mol (18); la valeur $\delta\Delta G_{red}^{\neq} = 1.8$ kcal/mol constitue donc un nouvel argument en faveur d'un état de transition tétragonal dans l'addition nucléophile de BH_4^- sur les dérivés carbonylés (2). Les mêmes calculs faits à partir des données de Wigfield et Phelps (7), de Rickborn et Wuesthoff (19) et de Calvet et Levisalles (20) conduisent respectivement à 1.6, 1.7 et 1.6 kcal/mol pour l'interaction diaxiale-1,3 qui apparaît dans le complexe activé; les derniers auteurs concluent également à un état de transition tardif.

La présence d'un second méthyle axial, cas de la tétraméthyl-3,3,5,5 cyclohexanone (**3**), nécessite 1.5 kcal/mol de plus par rapport à la triméthyl-3,3,5 cyclohexanone (**2**), valeur plus faible puisque la répulsion entre les méthyles axiaux tend à diminuer les interactions diaxiales-1,3 Me ··· OH; l'étude radiocristallographique de l'oxime de la tétraméthyl-3,3,5,5 cyclohexanone montre que les méthyles axiaux sont distants de 3.24 Å alors qu'ils seraient à

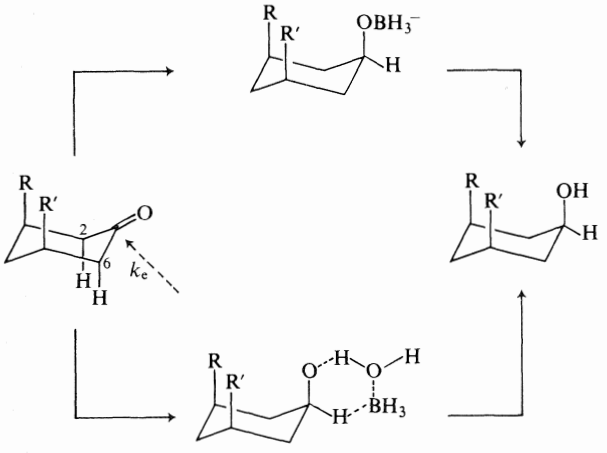

SCHÉMA 1

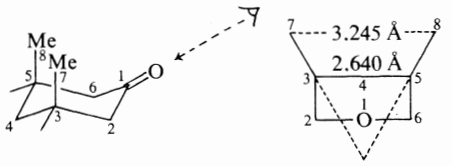

SCHÉMA 2

une distance de 2.64 Å si les deux liaisons C_3—Me et C_5—Me étaient parfaitement parallèles.[2]

La présence de deux méthyles axiaux nécessite donc une énergie d'activation supplémentaire de 3.3 kcal/mol pour la tétraméthyl-3,3,5,5 cyclohexanone (**3**) par rapport à la *tert*-butyl-4 cyclohexanone (**1**). Si l'on compare avec les systèmes rigides correspondants, bicyclo[3,2,1]octanone-3 (**4**), tricyclo[5,2,1,$0^{3,8}$]décanone-5 (**5**) et tricyclo[5,3,1,$0^{3,8}$]undécanone-5 (**6**), les différences d'énergies dues aux interactions diaxiales-1,3 sont respectivement égales à 3.5,3.6 et 3.3 kcal/mol. La réactivité de la tétraméthyl-3,3,5,5 cyclohexanone, comparable à celle d'autres cétones rigides, confirme donc la conformation chaise préférentielle de cette cétone même dans le complexe activé.

L'étude de la réactivité permet ainsi de résoudre des problèmes conformationnels puisqu'elle est directement liée à la conformation des molécules étudiées et que, dans le cas présent, un seul facteur influence de façon prépondérante la réactivité. La relation existant entre réactivité et conformation, démontrée dans le cas de la tétraméthyl-3,3,5,5 cyclohexanone, peut également s'appliquer au cas de la bicyclo[3,3,1]nonanone-3.

L'étude conformationnelle du bicyclo[3,3,1]nonane fait apparaître deux conformations: double-chaise (c.c.) et chaise-bateau (c.b.) (schéma 3, X = H_2) (21).

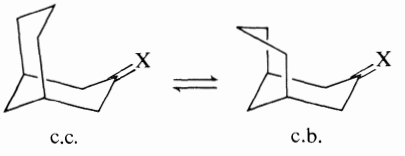

SCHÉMA 3

Des études rmn sur l'oxime de la bicyclo[3,3,1]nonanone-3 ont montré que le cycle portant la fonction cétone existait sous une conformation chaise (11); il n'existe donc que deux conformations possibles pour cette cétone (schéma 3, X = O): double-chaise et chaise-bateau.

Si la bicyclo[3,3,1]nonanone-3 existe sous la conformation chaise-bateau sa réactivité devrait alors être comparable à celle de la bicyclo[3,2,1]octanone-3

[2]J. Lapasset, S. Toure, B. Boyer et G. Lamaty. Acta Crystallogr. Sect. B. Envoyé pour publication.

TABLEAU 2. Constantes de vitesse relatives de réduction des cétones **1** à **7** et d'oxydation des alcools correspondants **8** à **13**

Cétones	k_e rel.	$\delta\Delta G_{red}^{\neq}$ (kcal/mol)	$\delta\Delta G_{ox}^{\neq}$ (kcal/mol)	k_{ox} rel.	Alcools
1	1	0	0	1 (5)	**8**
2	0.049	1.8	−1.5	14 (6)	**9**
3	0.0040	3.3	—	—	—
4	0.0026	3.5	−2.1	38 (6)	**10**
5	0.0043	3.3	−2.7	94	**11**
6	0.0022	3.6	−2.9	132	**12**
7	0.000025	6.2	−1.4	12 (6)	**13**

(**4**) ou des deux cétones tricycliques **5** et **6**: $\delta\Delta G_{red}^{\neq} \simeq$ 3.5 kcal/mol. Les résultats expérimentaux (6.2 kcal/mol) sont incompatibles avec une telle conformation chaise-bateau et sont en faveur de la conformation double-chaise (21).

Comparaison avec l'oxydation chromique des alcools

La comparaison de la réactivité des cyclanones vis-à-vis de BH_4^-, où le carbone siège de la réaction passe d'une hybridation sp^2 à une hybridation sp^3, avec la réaction inverse c'est-à-dire l'oxydation chromique des alcools secondaires correspondants (5) qui implique le changement d'hybridation opposé met en évidence un comportement symétrique (22). L'origine des différences de réactivité entre les substrats dans chaque cas provient principalement du changement dans la tension interne (I-strain) qui accompagne le changement d'hybridation en allant de l'état initial à l'état de transition.

Il était donc intéressant de comparer les réactivités dans le cas de nos composés et à côté de nos résultats obtenus dans la réduction des cétones nous avons fait figurer les résultats relatifs à l'oxydation chromique des alcools correspondants, résultats obtenus dans notre laboratoire (5) ou cités par d'autres auteurs (6) (Tableau 2).

Ce tableau montre qu'à une diminution de la vitesse de réduction correspond une augmentation de la vitesse d'oxydation. Si les interactions diaxiales-1,3 Me ··· OH sont responsables du ralentissement observé dans la réduction des cétones **2** à **7** elles doivent être également responsables de l'accélération de l'oxydation des alcools **9** à **13**; c'est ce que l'on constate en portant sur un diagramme $\delta\Delta G_{ox}^{\neq}$ en fonction de $\delta\Delta G_{red}^{\neq}$ (Fig. 1).

Une exception apparaît cependant avec le bicyclo-[3,3,1]nonanol-3 (**13**). L'oxydation chromique procède environ 500 fois moins vite que ce que l'on était en droit d'attendre si la conformation de cet alcool était double-chaise (○ voir Fig. 1) ce qui correspond à une perte d'énergie d'environ 3.5 kcal/mol. Or des études physiques ont montré

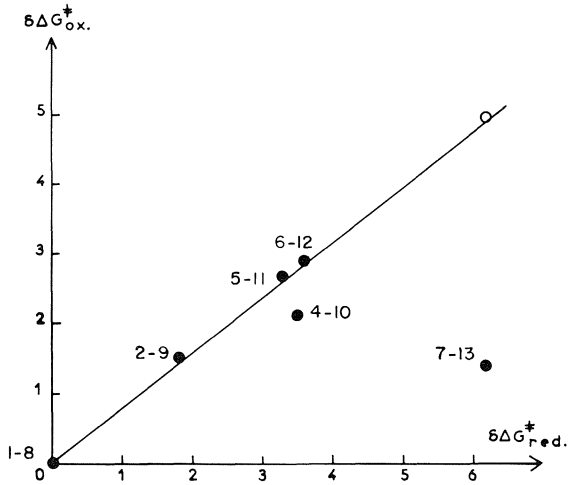

FIG. 1. Variation de $\delta\Delta G_{ox}^{\neq}$ en fonction de $\delta\Delta G_{red}^{\neq}$ (kcal/mol).

que l'alcool (**13**) existait préférentiellement sous une forma chaise-bateau plutôt que double-chaise (10), la différence de tension entre les deux formes étant justement de l'ordre de 4 kcal/mol (6, 23). Dans ces conditions le résultat expérimental (● voir Fig. 1) correspond bien à la conformation préférentielle chaise-bateau.

Conclusion

L'utilisation de systèmes rigides judicieusement choisis permet de limiter certains facteurs de réactivité pour n'en dégager qu'un seul. Dans le travail présenté nous avons mis en évidence par des méthodes cinétiques les interactions diaxiales-1,3 qui se développent ou disparaissent entre l'état initial et l'état de transition aussi bien dans l'addition de BH_4Na sur des cyclanones stériquement encombrées que dans l'oxydation des alcools correspondants. Les résultats expérimentaux confirment donc les hypothèses émises sur la position de l'état de transition dans la réduction des cétones par le borohydrure de sodium.

Partie expérimentale

Synthèse des produits

Les cétones **1**, **2** et **3** sont des produits commerciaux (Aldrich). La synthèse des autres cétones est décrite dans la littérature: **4** (24), **5** et **6** (15) et **7** (25).

La réduction de la cétone **5** par $AlLiH_4$ conduit à l'alcool **11** (OH axial, 67%) et à son isomère (OH équatorial, 33%); dans les mêmes conditions la réduction de la cétone **6** permet d'obtenir l'alcool **12** (OH axial, 72%) et de l'isomère (OH équatorial, 28%). Les isomères ont été séparés par chromatographie préparative sur plaques de silice. L'attribution de structure a été effectuée à partir des spectres rmn ^1H (Varian HA 100 MHz, $CDCl_3$) et ^{13}C (Bruker 20, 115 MHz, $CDCl_3$) (26). Alcool **11** (OH axial): H5, multiplet centré à 4.12 ppm; C5, 67.0 ppm. Isomère (OH équatorial): H5, multiplet centré à 3.88 ppm; C5, 63.6 ppm. Alcool **12** (OH axial): H5, multiplet centré à 4.13 ppm; C5, 67.3 ppm. Isomère (OH équatorial): H5, massif centré à 3.97 ppm; C5, 64.1 ppm.

Pour les alcools **8**, **9**, **10** et **13**, nous avons utilisé les données de la littérature (5, 6).

Méthodes cinétiques

Les études cinétiques de réduction et d'oxydation ont été effectuées par spectrophotométrie uv selon les méthodes déjà décrites dans la littérature (5, 27).

The synthesis of bicyclo[2.2.2]octenones via intramolecular Diels–Alder reactions of modified Wessely oxidation products[1]

PETER YATES AND HILLAR AUKSI

Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received May 4, 1979

PETER YATES and HILLAR AUKSI. Can. J. Chem. **57**, 2853 (1979).

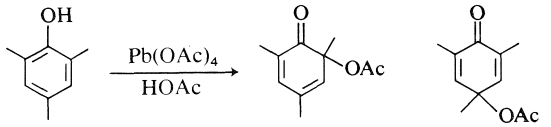
"Modified" Wessely oxidation of 2,6-dimethylphenol with lead tetraacetate in the presence of acrylic acid, cinnamic acid, *cis*-β-bromoacrylic acid, *trans*-β-bromoacrylic acid, methyl hydrogen maleate, methyl hydrogen fumarate, and tiglic acid followed by intramolecular cycloaddition gives *exo*-6-hydroxy-4,6-dimethyl-5-oxobicyclo[2.2.2]oct-7-ene-*exo*-2-carboxylic acid lactones. Analogous products have been obtained from *o*-cresol. Structural assignments have been made on the basis of the ir, uv, and ^{1}H nmr spectra of the products; analysis of the last shows that the geometry of the bicyclo[2.2.2]octenone system is distorted by the presence of the lactone ring. Chemical transformations of two of the products from the "modified" Wessely oxidation – intramolecular cycloaddition sequence have demonstrated that this route may be used to prepare regioisomers or stereoisomers of products obtained by the conventional Wessely oxidation – intermolecular cycloaddition sequence.

PETER YATES et HILLAR AUKSI. Can. J. Chem. **57**, 2853 (1979).

En présence des acides suivants: acrylique, cinnamique, β-bromoacrylique *cis* et *trans*, l'hydrogénomaléate de méthyle, l'hydrogénofumarate de méthyle et l'acide tiglyque, l'oxygénation de Wessely "modifiée" du diméthyl-2,6-phénol par le tétraacétate de plomb, suivi d'une cycloaddition intramoléculaire conduit aux *exo*-hydroxy-6-diméthyl-4,6-oxobicyclo-[2,2,2]oct-5-ène-7-*exo*-carbolactones-2. Des produits semblables sont obtenus à partir du *o*-crésol. Les structures des produits ont été établies à partir des spectres ir, uv et rmn du proton; l'analyse des derniers spectres met en évidence une distorsion du système bicyclo[2 2,2] octénone en présence du cycle de la lactone. Les transformations chimiques de deux des produits obtenus par la séquence oxydation de Wessely "modifiée" – cycloaddition intramoléculaire ont démontré que cette méthode peut être utilisée pour préparer les régioisomères et les stéréoisomères des produits de la séquence normale oxydation de Wessely – cycloaddition intermoléculaire.

[Traduit par le journal]

The oxidation of *o*- or *p*-substituted phenols with lead tetraacetate in acetic acid to give 2,4-cyclohexadienones and 2,5-cyclohexadienones was first reported by Wessely and Sinwel in 1950 (2); thus mesitol (**1**) was observed to give the dienones **2** and **3**.

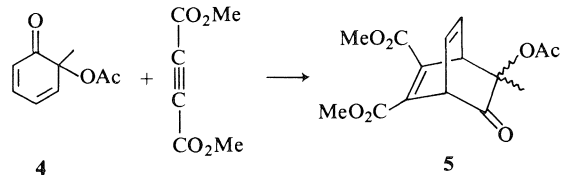


1 **2** **3**

In addition to products of these types quinones and bimolecular oxidation products may also be formed (2, 3). Because the Wessely oxidation provides a simple one-step route to 2,4-cyclohexadienones from *o*-substituted phenols, it is one of the best methods for the synthesis of such compounds, in spite of the fact that in some cases only modest yields are obtained because of the accompanying formation of the other types of products referred to above.

The 2,4-cyclohexadienones obtained in this way can serve as the diene component in Diels–Alder reactions, as demonstrated by Wessely and Budzikiewicz; thus 2-methyl-*o*-quinol acetate **4**, formed by oxidation of *o*-cresol with lead tetraacetate, gives with dimethyl acetylenedicarboxylate an adduct **5** (4). They can also serve as the dienophile component in Diels–Alder reactions and thus can undergo Diels–Alder dimerization (5). The formation of adducts of type **5** in two steps from phenols represents one of the simplest entries into the bicyclo[2.2.2]octenone series.

It was recently found (6) that reaction of **1** with lead tetraacetate in the presence of an excess of acrylic acid gave a mixture of **6** and **7**.[2] When the



4 **5**

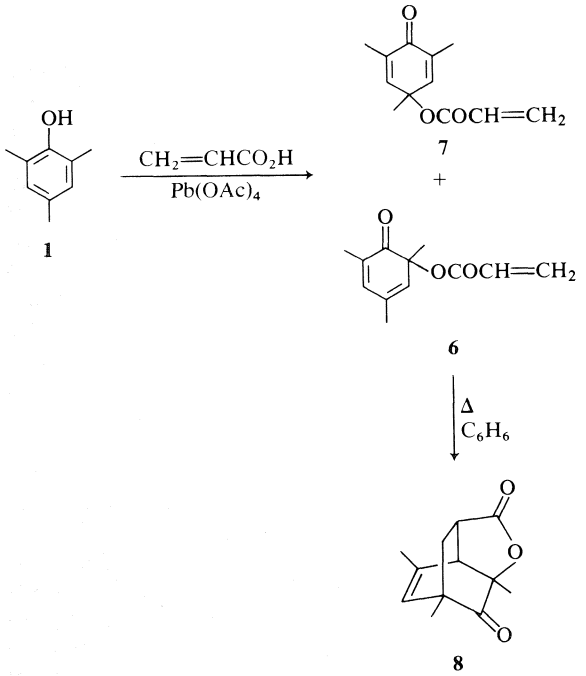
[1]For a preliminary account of part of this work, see ref. 1.

[2]Introduction of a *saturated* acyloxy group other than acetoxy had earlier been observed when **1** was treated with lead tetraacetate in propionic acid to give the propionyloxy analogue of **2** (3).

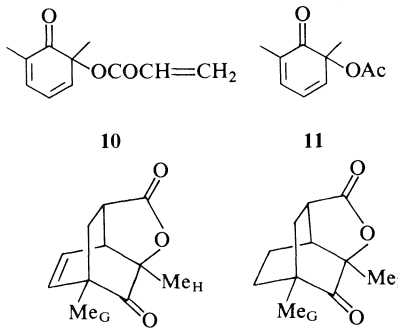
0008-4042/79/212853-11$01.00/0

mixture was heated in boiling benzene, **6** underwent an *intramolecular* Diels–Alder reaction to give **8**, which could readily be separated from the remaining, unchanged **7**. An analogous product was shown to be formed by similar treatment of 4-methyl-3-xanthenol. We now report on an investigation that has established the generality of this route for the synthesis of bicyclo[2.2.2]octenones, with particular reference to variation of the α,β-unsaturated acid used in the "modified" Wessely oxidation. We also describe some reactions of the products obtained.

2,6-Dimethylphenol (**9**) was chosen as the phenolic substrate for most of the modified Wessely oxidation



reactions because it is the most readily available *o,o'*-disubstituted phenol with identical substituents and is known to undergo the conventional Wessely oxidation in good yield (3). Its reaction with acrylic acid and lead tetraacetate was investigated first to establish that this is analogous to the reaction of **1**. Addition of **9** to a solution of lead tetraacetate and a large excess of acrylic acid in dichloromethane gave a mixture of **10** and **11**, identified by ir and ^{1}H nmr spectroscopy (an authentic sample of **11** was prepared by oxidation of **9** with lead tetraacetate in acetic acid (3)). The products were not separated, but when the mixture was heated in boiling benzene **10** was converted to the intramolecular Diels–Alder product **12**, which was isolated in 45% yield based on **9**. The structural assignment **12** is based on the product's spectra (*vide infra*) and their similarities to those of **8** (6). Hydrogenation of **12** over palladium/carbon proceeded rapidly and cleanly to give the



dihydro compound **13**, whose ^{1}H nmr spectrum shows methyl singlets at δ 1.05 and 1.50. These are assigned to Me_G and Me_H, respectively; the chemical shift of the latter is similar to that of Me_H in **12** (δ 1.45), while the signal of the former is at significantly higher field than that of Me_G in **12** (δ 1.32).

Similar modified Wessely oxidation followed by intramolecular cycloaddition of **9** in the presence of cinnamic acid (**14**), *cis*-β-bromoacrylic acid (**15**), *trans*-β-bromoacrylic acid (**16**), methyl hydrogen maleate (**17**), methyl hydrogen fumarate (**18**), and tiglic acid (**19**) gave the corresponding keto lactones **20**–**25**. In some cases the Wessely oxidation products underwent spontaneous cycloaddition and it was unnecessary to heat them in boiling benzene. The yields based on **9** were 30–62%, except in the case of **25**, derived from the trisubstituted ethylene **19**, where the yield was reduced to 14%. Similar reaction sequences with *o*-cresol and **16** and **17** gave **26** and **27**, respectively, monomethyl analogs of **22** and **23**, in low yield.

28

The structures of compounds **12** and **20–27** are assigned on the basis of their spectra (Tables 1–3). Their ir spectra show two carbonyl-stretching bands in the regions 5.56–5.63 and 5.70–5.76 μm. The former band is assigned to the lactonic and the latter to the ketonic carbonyl group (superimposed on the ester band in the cases of **23**, **24**, and **27**). They are at lower wavelength than normal for simple γ lactones and bicyclo[2.2.2]octenones (7), which is attributed to strain and dipolar effects. The uv spectra of **12** and **20–27** show maxima in the region 308–316 nm (ε 100–130) ascribed to the enhanced intensity $n \rightarrow \pi^*$ absorption characteristic of bicyclo[2.2.2]octenones (8). As expected the enhancement is greater in the case of **8**, which has a methyl substituent on the ethylenic double bond, and is much reduced or absent in the case of the dihydro compound **13** (λ_{max} 306 nm (ε 35)). The maxima of **12** and **20–27** occur at significantly longer wavelengths than those of simple bicyclo[2.2.2]octenones (9) and this can be attributed to the presence of the lactone ring which exerts a bathochromic effect similar to that of an axial α-acetoxy substituent in cyclohexanones (9); this effect is also evident in the case of **13**. An interesting aspect of the uv spectra is that compounds **21**, **23**, and **27**, which have a bromo or carbomethoxy substituent *syn* with respect to the ketone show two similar maxima in the 308–316 nm region whereas all of the other compounds, including the *anti* isomers of **21** and **23**, show a single maximum.

In most cases 220 MHz ^{1}H nmr spectra were used for analysis of the coupling patterns and assignment of the signals and coupling constants (Tables 2, 3). The vinyl protons of **12** and **20–25** give signals in the ranges δ 5.8–6.2 (H_A) and 6.3–6.6 (H_B). The signals of the H_A and H_B protons in the parent bicyclo[2.2.2]octenone (**28**) occur at δ 6.20 and 6.42, respectively, and the difference in their chemical shifts has been attributed to a homoconjugative effect (10). It is of interest that if it were not for shielding of H_A by the C—Me_G bond (11)[3] in **12**, **21**, and **23** the H_A signal would be very similar in position to the H_B signal (this conclusion is in accord with the relationship of the vinyl proton signals of **23** and **27**, although individual assignments could not be made in the latter case). This effect could arise, at least in part, from a diminution of homoconjugation resulting from the distortion in geometry in the bicyclo[2.2.2]-octenone system engendered by the lactone ring (*vide infra*). It may be noted that a related effect is observed in the ^{13}C nmr spectra of these compounds.[4] The H_C signals of **12** and **20–24** fall in the narrow range δ 3.5–3.7; the corresponding signals for **26** and **27** have similar chemical shifts although overlap with the H_G signals precludes exact assignments. These signals may be compared with the bridgehead proton signals of **28**, which give rise to overlapping multiplets at δ ~ 3.1. The downfield shift is presumably associated with the inductive and the geometrical effect of the lactone ring referred to above. The C—Me_H bond may also exert an effect in the opposite sense; the relationship of this bond to H_C is similar to that of the C—Me_D bond in **26**, where the H_C signal is shifted upfield to δ 3.02. The H_D signal of **12** appears at δ 2.83 and is shifted downfield to δ 3.1–3.25 by phenyl, bromine, or carbomethoxy substituents on the adjacent carbon in **20–24** and **26–27**. The H_E and H_F signals of **12** at δ 1.85 and 2.01, respectively, are also shifted downfield in **20–24** by these substituents, but with a much greater range of effects, as expected for substituents on the same carbon as the protons. It is noteworthy that although the absence of the Me_G group in **26** results in a downfield shift of the H_F signal relative to that in **22** (Δδ 0.32), the difference in the chemical shifts of the H_E signals of **23** and **27** (Δδ 0.03) is negligible. This may be accounted for in terms of the geometry of these lactones (*vide infra*) which results in different dihedral angles between the C—Me_G bond and the C—H_E and C—H_F bond and thus leads to greater anisotropic shielding by the C—Me_G bond in the latter case (11). The signal of the Me_G protons of **12** at δ 1.32 is shifted to δ 1.47–1.48 in the spectra of **21** and **22**, presumably largely as a result

TABLE 1. Infrared and ultraviolet spectra of *exo*-6-hydroxy-5-oxobicyclo[2.2.2]octene-*exo*-2-carboxylic acid lactones

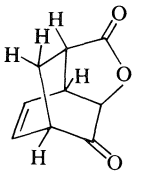
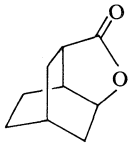
[d]Signal broadening indicates unresolved coupling.

of an inductive effect of the bromine atom, which is independent of the stereochemistry. In the case of **23** and **24**, however, while the carbomethoxy substituent shifts the Me_G signal in the latter downfield to δ 1.46, it has little effect on that of the former (δ 1.33), a difference that must stem from a difference in the anisotropic effect of the carbomethoxy group in the two locations. The Me_H signals of **12** and **20–27** all fall in the narrow range δ 1.4–1.5, reflecting the isolation of this group from the sites at which the changes are rung.

Examination of molecular models indicates that the presence of the three sp^2 carbon atoms in bicyclo[2.2.2]octenone makes the molecule much more rigid than bicyclo[2.2.2]octane and as a result it has the eclipsed geometry shown in **28**. Introduction of the lactone ring in compounds **12** and **20–27** results in a significant distortion of the skeletal geometry, as represented in **29**, and allusion has already been made to some possible manifestations of this. The resulting changes in certain of the dihedral angles would be expected to evidence themselves also in abnormal H—H coupling constants, although electronegativity and strain effects are also expected to influence these. Indeed, such abnormalities have been observed in systems of type **30** (12). The coupling constants in the spectra of **12** and **20–25** are given in Table 3. The vicinal J_{AB} and J_{BC} and the allylic J_{AC} values, 8–8.5, 6–7.5, and 2–2.5 Hz, respectively, are similar to those observed for simple bicyclo[2.2.2]octenones (7, 10, 13). This is expected since the relevant dihedral angles, all ~0°, are very similar in both **28** and **29**. The J_{CD} values, 5–5.5 Hz, are larger than the expected value of ~3 Hz for **28** and are considered to reflect the decrease of the ~60° dihedral angle in **28** to ~45° in **29**. Similarly the J_{DF} values are reduced to



29

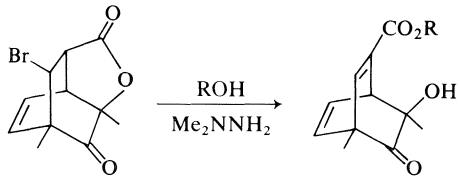


30

1–2 Hz in accord with the decrease of the ~120° dihedral angle in **28** to ~100° in **29**: exceptionally, no coupling is observed in the case of **22**, perhaps because of an electronegativity effect on the coupling constant. The J_{DE} values, 9–10.5 Hz, are also reduced from the value of ~12 Hz expected for **28** (12, 14), in accord with the increase in the dihedral angle from ~0° to ~20°. An unusual long range coupling is observed in the spectra of **20**, **22**, and **25** between the ethylenic H_A and the *anti* H_F protons, the values of J_{AF} falling in the range 1–2 Hz; an analogous, but unresolved, coupling occurs in the spectra of **12** and **24**, as vouchsafed by signal broadening. Again it may be suggested that this arises as a result of geometrical distortion, which leads to a closer approach of the two protons involved to the W pattern that favors long range coupling (15). The spectra of **26** and **27** are more complex than those of the compounds with the Me_G group and have not been analyzed fully; where coupling constants can be extracted they are similar to those found for **12** and **20–25**. It may be noted that **26**, like **22**, shows no coupling between H_D and H_F. Two additional coupling constants are observed in the spectra of **26** and **27**, J_{FG} = 4 Hz and J_{EG} = 1 Hz, and once again these reflect the distorted geometry of the ring system. As expected $J_{FG} < J_{CD}$ since the introduction of the lactone ring has a greater effect on the H_C–H_D dihedral angle than on the H_F–H_G dihedral angle. It may finally be pointed out that the sole geminal coupling constant, J_{EF} in **12**, has the normal value 13.5 Hz, suggesting that little of the strain in the system is felt at the carbon bearing these hydrogens (12).

Base-induced Reactions of 22 and 23

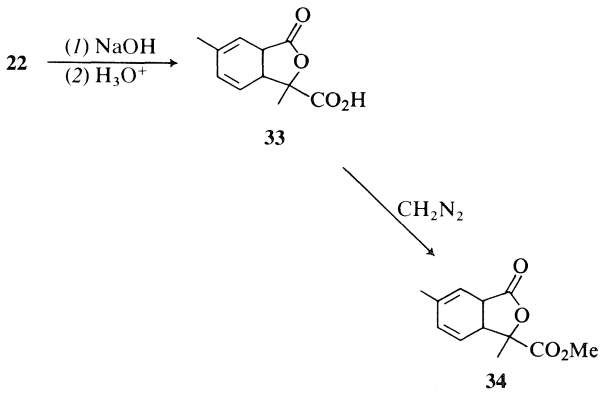
Treatment of **22** with 1,1-dimethylhydrazine in boiling methanol gave a product, $C_{12}H_{14}O_4$, that is assigned structure **31**. Its ir spectrum shows a hydroxyl-stretching band at 2.87 μm together with carbonyl-stretching bands at 5.80 and 5.84 μm, assigned to the ketonic and α,β-unsaturated ester carbonyl groups. Its ^{1}H nmr spectrum (Table 4) shows three three-proton singlets corresponding to the two C(sp^3)—Me groups and the CO_2Me group. The only other C(sp^3)—H signal occurs at δ 4.35 and is assigned to the bridgehead proton; it shows the expected vicinal coupling with a single vinyl proton and equivalent allylic coupling with two vinyl protons. The chemical shifts and multiplicities of the three vinyl protons are in accord with structure **31** when account is taken of accidentally equivalent coupling of H_B with H_A and H_C. The uv spectrum of **31** shows the large enhancement of the intensity of the ketonic $n \rightarrow \pi^*$ band, 312 nm (ε 360), expected for bicyclo[2.2.2]octadienones (16). Treatment of **22** with 1,1-dimethylhydrazine in boiling ethanol gave **32**, the ethyl ester corresponding to **31** (see Table 4).



22

31 R = Me
32 R = Et

Reaction of **22** with slightly more than 2 equivalents of aqueous sodium hydroxide followed by acidification gave an acid, $C_{11}H_{12}O_4$, that was converted with ethereal diazomethane to the corresponding methyl ester, isomeric with **31**. These compounds are assigned structures **33** and **34**, respectively. The ir spectrum of the acid shows bands at 3–4, 5.66, and 5.88 μm characteristic of carboxylic acid and γ-lactone functions. Its ^{1}H nmr spectrum (CD_3OD) was not fully interpreted because of extensive long range coupling; however, the following features can be discerned. A three-proton singlet at δ 1.71 and a three-proton signal with fine splitting at δ 1.77 can be assigned to the C(sp^3)—CH_3 and C(sp^2)—CH_3 groups, respectively, the latter showing allylic and homoallylic coupling. The vinylic proton involved in the former coupling gives rise to a multiplet at δ 5.4, while the other vinylic protons give rise to a complex two-proton multiplet at δ 5.5–6.0. The two C(sp^3)—H methine proton signals each appear as doublets at δ 3.23 and 3.70 (J = 13



33

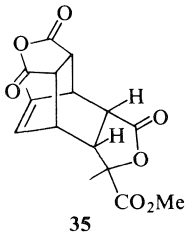
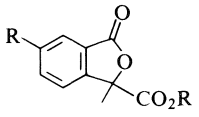
[b]Overlapping signals.

Hz) with extensive further splitting. The uv spectrum of **33** has maxima at 270 (ε 3300) and 260 nm (ε 3600) consonant with a homoannular conjugated diene. The spectra of **34** are closely similar to those of **33**, *mutatis mutandis*. The presence of a conjugated diene system was corroborated by the formation of a Diels–Alder adduct, **35** (stereochemistry tentative), from **34** and maleic anhydride, and the full structures were confirmed by dehydrogenation of **34** over palladium/carbon to give an aromatic compound whose spectra (see Experimental) are in full accord with the assignment to it of structure **36**; in particular the relationship of its uv spectrum to that of **37**(17) may be noted.

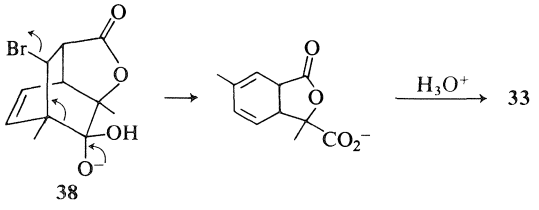


35

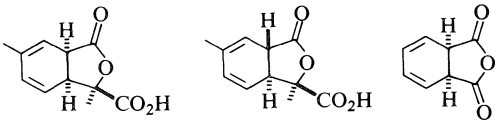


36 R = Me
37 R = H

The formation of **33** from **22** is most simply interpreted as involving a Grob fragmentation (18) of **38**, formed by attack of hydroxide ion on the ketonic carbonyl of **22**. However, hydrolysis of the lactone ring followed by such fragmentation and reclosure of the lactone ring upon acidification would also account for its formation. In either event **33** would be expected to have the relative configuration shown in **33***a*, and this stereochemistry is assigned to the product. Because of the magnitude of the coupling constant ($J \sim 13$ Hz) between the angular methine protons, consideration was given to the possibility that epimerization of **33***a* has occurred in the basic reaction medium and that the product isolated was **33***b*. However, the product is isolated in 95% yield and it seems hardly likely that equilibration of the *cis*-fused **33***a* and the *trans*-fused **33***b* would give the latter exclusively. Furthermore, the appreciable departure from coplanarity of the double bonds required by *trans* fusion would be expected to result in a significant difference between the uv extinction coefficient of the product and that of the *cis*-fused compound **39**,[5] which is not observed. Thus structure **33***a* is assigned to the product.



38



33*a* **33***b* **39**

The alternative base-catalyzed reaction of **22** with alcohols in the presence of 1,1-dimethylhydrazine to give **31** or **32** can be interpreted as involving initial opening of the lactone ring by alkoxide ion to give **40** followed by alkoxide-catalyzed dehydrobromina-

[5]Compound **39** is reported to show λ_{max}^{EtOH} 260 nm (ε 3200), $\lambda_{max}^{CH_3CN}$ 258 nm (ε 3860) (19).

TABLE 5. Infrared, ultraviolet, and ^{1}H nmr spectra of compounds **45** and **47**[a]

Spectrum		**45**	**47**
λ_{max}^{KBr}, μm		3.08 (m), 3.0–3.9, 5.84, 6.33 (br), 7.11	2.90 (m), 2.9–3.5, 5.56 (sh), 5.65, 5.76, 5.81 (sh)
λ_{max}^{MeOH}, nm (ε)		308 (100)	312 (95)

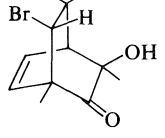
	H_B	6.72 (dd, *J* 8, 6.5 Hz)	6.35 (dd, *J* 8, 6.5 Hz)
	H_C	3.1–3.4 (m)	3.60–3.87 (m)
	H_D		3.13–3.33 (m)
	H_E		3.00 (br s)
	Me_F	1.18 (s)	1.43 (s)[b]
	Me_G	1.29 (s)	1.43 (s)[b]
	OMe	3.68 (s)	—

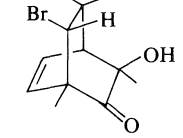
[a]The signal intensities in the ^{1}H nmr spectra are in accord with the assignments.
[b]Superimposed signals.

tion. The latter could proceed directly from **40** via *cis*-elimination or via epimerization of **40** to **41** followed by *trans*-elimination (20). The difference between the hydroxide- and alkoxide-induced reactions of **22** can be attributed to one or more of the following factors: (*i*) readier attack on the sterically hindered ketonic carbonyl carbon by the smaller hydroxide ion, (*ii*) readier dehydrobromination of **40** than of **42**, and (*iii*) readier epimerization of **40** than of **42**.

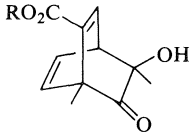
The formation of **31** and **32** via the intramolecular Diels–Alder product **22** stands in striking contrast to the formation of **43** from the intermolecular Diels–Alder reaction of **11** with propiolic acid (21).[6] Methylation of **43** gives **44**, the regioisomer of **31**.



40 X = CO_2R
42 X = CO_2^-



41

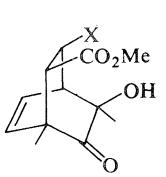


43 R = H
44 R = Me

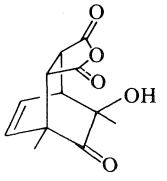
Thus the modified Wessely oxidation – intramolecular cycloaddition sequence can serve as a source of bicyclo[2.2.2]octane derivatives that differ in their regiochemistry from products obtained by the conventional Wessely oxidation – intermolecular cycloaddition sequence.

Treatment of **23** in water with one equivalent of sodium hydroxide opened the lactone ring and gave the salt **45**, which was isolated as its dihydrate. Its structure follows from its spectra (Table 5) and the fact that on acidification it gave the corresponding hydroxy acid **46**, which could be detected by ^{1}H nmr spectroscopy but could not be isolated because it lactonized rapidly in solution to regenerate **23**. The formation of the latter established that no epimerization occurs in the conversion of **23** to **45**. It is of interest that the uv spectrum of **45** shows a single maximum in the $n \rightarrow \pi^*$ region, while that of **23** shows two maxima. This must reflect the considerable change in the geometry of the system that results upon opening of the lactone ring (*vide supra*). A further point of interest concerning the salt is its solubility in methanol; this can be ascribed to cryptate character in **45**.

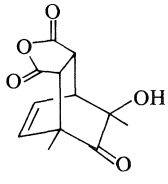
Treatment of **23** with two equivalents of sodium hydroxide in boiling water followed by acidification gave the anhydride **47**. Its gross structure is established by its spectra (Table 5) and its stereochemistry follows from the fact that it is different from the *endo* anhydride **48** obtained via intermolecular cycloaddition of maleic anhydride and 2,6-dimethyl-



45 X = $CO_2^-Na^+$
46 X = CO_2H



47



48

[6]The intermolecular reaction is very much slower than the intramolecular reaction, and during its course the acetoxyl group is converted to a hydroxyl group (21).

o-quinol acetate (**11**) (21). Thus in this case the modified Wessely oxidation – intramolecular cycloaddition sequence serves as a source of a bicyclo[2.2.2]octane derivative that differs in its stereochemistry from the product obtained by the conventional Wessely oxidation – intermolecular cycloaddition sequence.

Experimental

Melting points are uncorrected. The ir and uv spectra were recorded for $CHCl_3$ and MeOH solutions, respectively, unless otherwise specified. Proton magnetic resonance spectra (^1H nmr) were recorded for $CDCl_3$ solutions, unless otherwise specified, with Varian HR 220 and T-60 spectrometers; coupling assignments were verified in representative cases by decoupling experiments. Carbon-13 magnetic resonance spectra (^{13}C nmr) were recorded for $CDCl_3$ solutions with Varian CFT-20 and XL-100-15 spectrometers operating in the pulsed Fourier transform mode; both proton-noise decoupled and single frequency off-resonance decoupled spectra were recorded in each case. The chemical shifts (δ) for the ^1H and ^{13}C nmr spectra were measured with reference to internal Me_4Si and are reported in ppm. Spectroscopic data not given in the Experimental section are given in Tables 1–5. Solutions in organic solvents were dried over anhydrous magnesium sulfate.

exo-*6-Hydroxy-4,6-dimethyl-5-oxobicyclo*[*2.2.2*]*oct-7-ene*-exo-*2-carboxylic Acid Lactone* (***12***)[7]

Lead tetraacetate (8.18 g, 18.45 mmol) was dissolved in dry dichloromethane (300 mL). Acrylic acid (4.32 g, 60.0 mmol) was added and the solution was stirred at room temperature for 20 min. A solution of 2,6-dimethylphenol (**9**) (1.83 g, 15.0 mmol) in dry dichloromethane (15 mL) was added dropwise over a 3 min period and stirring was continued at room temperature for an additional 15 min. Ethylene glycol (1 mL) was added to destroy excess Pb(IV). Evaporation gave an orange oil which was taken up in benzene (250 mL); the solution was gravity filtered and extracted with water (2 × 250 mL) and aqueous 1% sodium bicarbonate (250 mL). The organic layer was dried and evaporated to give a yellow oil. This was taken up in benzene (100 mL), and the solution was boiled under reflux for 21 h. Evaporation gave a yellow oil, which on crystallization from chloroform–cyclohexane gave a dark yellow solid (2.4 g). Sublimation at 100°C (0.005 Torr) followed by sublimation at 60°C (0.005 Torr) gave **12** as a white crystalline solid (1.29 g, 45% based on **9**). A further sublimation gave **12**, mp 111.5–112.5°C; *m/e* (relative abundance): 192(4). *Anal.* calcd. for $C_{11}H_{12}O_3$: C 68.73, H 6.29; found: C 68.38, H 6.31.

exo-*6-Hydroxy-4,6-dimethyl-5-oxobicyclo*[*2.2.2*]*octane*-exo-*2-carboxylic Acid Lactone* (***13***)

Compound **12** (304 mg, 1.58 mmol) was dissolved in acetic acid (30 mL), 5% Pd/C (50 mg) was added, and **12** was hydrogenated at room temperature and one atmosphere pressure until uptake of hydrogen ceased. Filtration followed by evaporation gave a colorless oil, which solidified slowly on standing. Sublimation at 80°C (0.005 Torr) gave crystalline **13** (294 mg, 96%), mp 84.5–86°C; ir λ_{max}: 5.63, 5.76 μm; uv λ_{max} (ε): 306 (35) nm; ^1H nmr δ: 1.05 (s, 3H), 1.50 (s, 3H), 1.97 (m, 6H), 2.77 (m, 2H); ^{13}C nmr δ: 208.1 (s), 177.8 (s), 85.2 (s), 43.5 (d), 42.2 (s), 40.1 (d), 33.4 (t), 33.2 (t), 19.8 (q), 15.4 (q), 15.2 (t); *m/e* (relative abundance): 194(9). *Anal.* calcd. for $C_{11}H_{14}O_3$: C 68.02, H 7.27; found: C 67.95, H 7.28.

exo-*6-Hydroxy-4,6-dimethyl-5-oxo*-endo-*3-phenylbicyclo*-[*2.2.2*]*oct-7-ene*-exo-*2-carboxylic Acid Lactone* (***20***)

Lead tetraacetate (23.97 g, 53.8 mmol) and cinnamic acid (42.9 g, 290 mmol) were dissolved in dry dichloromethane (600 mL) and the solution was stirred at room temperature for 30 min. A solution of **9** (5.13 g, 42.0 mmol) in dry dichloromethane was added dropwise over a 5 min period and stirring was continued at room temperature for 45 min. The reaction mixture was worked up as for **12**, except that the benzene solution of the Wessely oxidation product was not boiled. The crude product was a bright orange oil (10.65 g) which crystallized on standing. Three recrystallizations from chloroform–cyclohexane gave **20** (4.79 g) as a white crystalline solid. The washings and filtrates were combined and evaporated to give a deep orange oil which was distilled at 60°C (0.005 Torr). The distillation residue was dissolved in benzene and passed through a Florisil plug (75 g). Evaporation gave a pale yellow solid. Recrystallization from cyclohexane gave 1.87 g of a white crystalline solid which was combined with the first crop to give 6.66 g of **20** (59% based on **9**). Two recrystallizations from cyclohexane gave **20**, mp 160.5–161°C; uv λ_{max} (ε): 310 (100), 270 (200), 265 (270), 263 (280), 259 (315), 252 (290) nm; *m/e* (relative abundance): 268(0.5). *Anal.* calcd. for $C_{17}H_{16}O_3$: C 76.10, H 6.01; found: C 76.01, H 6.02.

cis-β-*Bromoacrylic Acid* (***15***) *and* trans-β-*Bromoacrylic Acid* (***16***)

Propiolic acid (19.7 g, 0.28 mol) and 48% hydrobromic acid (143 g, 0.84 mol) were heated together on a steam bath for 30 min. On cooling 26.9 g of **16** separated as white crystals. The supernatant was concentrated to approximately three-quarters of the original volume, and a second crop (1.02 g) of **16** was deposited when the reaction mixture cooled to room temperature. The filtrate was saturated with sodium chloride and extracted with ether (3 × 100 mL). Evaporation of the extract gave 14.6 g of a clear yellow liquid which crystallized on standing. The yellow solid was taken up in benzene (150 mL) and the solution was stirred with Florisil (2 g). Filtration followed by evaporation gave **15** as a white crystalline solid. Recrystallization from cyclohexane gave 10.4 g, (25%) of **15**. The 66% yield of **16** and 25% yield of **15** contrast with the report that under these reaction conditions only **16** is produced (22).

exo-*3-Bromo*-exo-*6-hydroxy-4,6-dimethyl-5-oxobicyclo*-[*2.2.2*]*oct-7-ene*-exo-*2-carboxylic Acid Lactone* (***21***)

Compound **21** was prepared from lead tetraacetate (9.88 g, 22.3 mmol), **15** (17.08 g, 113 mmol), and **9** (2.44 g, 20.0 mmol) as above. The crude product was obtained as a bright yellow oil which crystallized on standing. Three recrystallizations from chloroform–cyclohexane gave **21** as white crystals (3.38 g, 62% based on **9**). Recrystallization from chloroform–cyclohexane gave **21**, mp 133–134.5°C; *m/e* (relative abundance): 270(0.5), 272(0.5). *Anal.* calcd. for $C_{11}H_{11}BrO_3$: C 48.73, H 4.09, Br 29.47; found: C 48.78, H 4.11, Br 29.58.

[7]The *Chemical Abstracts* name for **12** is 3a,7a-dihydro-6,7a-dimethyl 3,6-methanobenzofuran-2,7(3*H*, 6*H*)-dione. We have preferred to name this and related compounds as bicyclo[2.2.2]octanone derivatives, which better describes their relationship to their parent carbocyclic ring system and, with the following conventions, permits a ready description of their stereochemistry. Substituents are designated as being *exo* or *endo* with respect to the unsaturated bridge of lowest priority, and in saturated compounds to the bridge of lowest priority.

endo-*3-Bromo*-exo-*6-hydroxy-4,6-dimethyl-5-oxobicyclo-[2.2.2]oct-7-ene*-exo-*2-carboxylic Acid Lactone (22)*

Compound **22** was prepared from lead tetraacetate (13.0 g, 29.4 mmol), **16** (17.2 g, 114 mmol), and **9** (3.05 g, 25.0 mmol) as above, except that the benzene solution of the Wessely oxidation product was not boiled. The crude product was obtained as a bright yellow oil (5.03 g). This was taken up in benzene, and the solution was passed through a Florisil column (75 g). Evaporation gave a bright yellow oil which crystallized on standing. Two recrystallizations from chloroform–cyclohexane gave **22** as white crystals (2.33 g, 34% based on **9**). Recrystallization from cyclohexane gave **22**, mp 108–109°C; *m/e* (relative abundance): 273(0.5), 272(0.5), 271(0.5), 270(0.5). *Anal.* calcd. for $C_{11}H_{11}BrO_3$: C 48.73, H 4.09, Br 29.47; found: C 48.81, H 4.12, Br 29.71.

exo-*3-Carbomethoxy*-exo-*6-hydroxy-4,6-dimethyl-5-oxo-bicyclo[2.2.2]oct-7-ene*-exo-*2-carboxylic Acid Lactone (23)*

Compound **23** was prepared from lead tetraacetate (20.2 g, 45.6 mmol), methyl hydrogen maleate (23.7 g, 182 mmol), and **9** (5.25 g, 43.0 mmol) as above. The crude product was obtained as a pale yellow solid (9.61 g). Two recrystallizations from chloroform–cyclohexane gave **23** as a white crystalline solid (3.10 g). The filtrates were combined and evaporated to give a bright yellow oil. Crystallization from ether followed by recrystallizations from ether and chloroform–cyclohexane gave a further 1.30 g of **23** as a white crystalline solid (total 4.40 g, 41% based on **9**). Recrystallization from methanol gave **23**, mp 149–150°C; *m/e* (relative abundance): 251(4) ($M + 1$). *Anal.* calcd. for $C_{13}H_{14}O_5$: C 62.39, H 5.64; found: C 62.23, H 5.63.

endo-*3-Carbomethoxy*-exo-*6-hydroxy-4,6-dimethyl-5-oxo-bicyclo[2.2.2]oct-7-ene*-exo-*2-carboxylic Acid Lactone (24)*

Compound **24** was prepared from lead tetraacetate (7.08 g, 16.0 mmol), methyl hydrogen fumarate (12.5 g, 95.8 mmol), and **9** (1.83 g, 15.0 mmol) as above without boiling in benzene. The crude product was obtained as a bright yellow oil (2.28 g). Three crystallizations from chloroform–cyclohexane gave **24** (1.13 g, 30% based on **9**) as white crystals. Recrystallization from chloroform–cyclohexane gave **24**, mp 122.5–124°C; *m/e* (relative abundance): 250(2). *Anal.* calcd. for $C_{13}H_{14}O_5$: C 62.39, H 5.64; found: C 62.53, H 5.75.

exo-*6-Hydroxy-2*-endo-*3,4,6-tetramethyl-5-oxobicyclo*[*2.2.2*]-*oct-7-ene*-exo-*2-carboxylic Acid Lactone (25)*

Compound **25** was prepared from lead tetraacetate (11.06 g, 24.95 mmol), tiglic acid (5.00 g, 49.9 mmol), and **9** (2.44 g, 20.0 mmol) as above. The crude product was chromatographed on a Florisil column with elution with benzene – 2% ether. Evaporation gave a pale yellow solid which was recrystallized from chloroform–cyclohexane to give **25** (0.57 g, 13% based on **9**) as white crystals. Sublimation at 65°C (0.1 Torr) gave **25**, mp 70–72°C; *m/e* (relative abundance): 220(0.5). *Anal.* calcd. for $C_{13}H_{16}O_3$: C 70.89, H 7.32; found: C 70.83, H 7.32.

endo-*3-Bromo*-exo-*6-hydroxy-6-methyl-5-oxobicyclo*[*2.2.2*]-*oct-7-ene*-exo-*2-carboxylic Acid Lactone (26)*

Compound **26** was prepared from lead tetraacetate (51.6 g, 116 mmol), **16** (63.7 g, 422 mmol), and *o*-cresol (10.8 g, 100 mmol) as above. The benzene solution was evaporated to give a deep red oil (13.75 g) which was distilled at 120°C (10 Torr). The distillation residue was taken up in benzene and passed through a Florisil plug (75 g). Evaporation gave a red oil which was distilled at 120°C (10 Torr). The distillation residue was sublimed at 80°C (0.0005 Torr) and resublimed at 70°C (0.005 Torr) to give a white crystalline solid. Recrystallization from chloroform–cyclohexane gave **26** (3.47 g, 14% based on *o*-cresol). Sublimation at 70°C (0.005 Torr) gave **26**, mp 122–123.5°C; *m/e* (relative abundance): 256(7), 258(7). *Anal.* calcd. for $C_{10}H_9BrO_3$: C 46.72, H 3.53, Br 31.08; found: C 46.87, H 3.63, Br 31.00.

exo-*3-Carbomethoxy*-exo-*6-hydroxy-6-methyl-5-oxobicyclo-[2.2.2]oct-7-ene*-exo-*2-carboxylic Acid Lactone (27)*[8]

o-Cresol (1.00 g, 9.25 mmol) and methyl hydrogen maleate (13.0 g, 100 mmol) were dissolved in dry benzene (100 mL), and the solution was heated to 40°C. Red lead oxide (6.86 g, 10.0 mmol) was added portionwise over a 3 h period. The solution was stirred at 40°C for 12 h and gravity filtered, and the solid residue was washed several times with benzene to bring the volume of the filtrate to 500 mL. The benzene solution was extracted with water (2 × 500 mL) and aqueous 1% sodium bicarbonate (500 mL). The organic layer was dried and evaporated to give a dark oil (1.32 g). The oil was dissolved in methanol (75 mL) and stirred with Florisil (1 g) and activated charcoal (0.5 g) for 30 min. Gravity filtration followed by evaporation gave a red oil which was dissolved in 25% chloroform–cyclohexane (100 mL) and gravity filtered to give a dark yellow solution. The solution was reduced in volume to 25 mL, when a pale yellow solid crystallized. Recrystallization from chloroform–cyclohexane gave **27** (0.76 g, 35% based on *o*-cresol) as white crystals. Recrystallization from methanol gave **27**, mp 145–146.5°C; *m/e* (relative abundance): 236(3). *Anal.* calcd. for $C_{12}H_{12}O_5$: C 61.01, H 5.12; found: C 60.97, H 5.12.

Methyl exo-*6-Hydroxy-4,6-dimethyl-5-oxobicyclo*[*2.2.2*]*octa-2,7-diene-2-carboxylate (31)*

Compound **22** (383 mg, 1.41 mmol) was dissolved in methanol (25 mL) and 1,1-dimethylhydrazine (383 mg, 6.37 mmol) was added. The mixture was boiled under reflux for 21 h and then evaporated to give a yellow oil which was taken up in benzene. The solution was washed with water, dried, and evaporated to give a pale yellow oil (249 mg), which crystallized on standing. Sublimation at 80°C (0.005 Torr) gave **31** as white crystals (231 mg, 75%), mp 118–119°C; ir λ_{max}: 2.87 (w), 5.80, 5.84, 6.10 (w), 6.28 (w) μm; uv λ_{max} (ε): 312 (360), 236 (4,350) nm; *m/e* (relative abundance): 223(0.5) ($M + 1$). *Anal.* calcd. for $C_{12}H_{14}O_4$: C 64.85, H 6.35; found: C 64.77, H 6.35.

Ethyl exo-*6-Hydroxy-4,6-dimethyl-5-oxobicyclo*[*2.2.2*]*octa-2,7-diene-2-carboxylate (32)*

Compound **22** (401 mg, 1.48 mmol) was dissolved in 95% ethanol (100 mL) and 1,1-dimethylhydrazine (200 mg, 3.33 mmol) was added. The mixture was boiled under reflux for 19 h and then evaporated to give a yellow oil which was taken up in benzene (75 mL). The solution was extracted with water (3 × 25 mL). The organic layer was dried and evaporated to yield a pale yellow oil (266 mg), which crystallized on standing. Sublimation at 65°C (0.005 Torr) gave **32** as white crystals (248 mg, 71%). Recrystallization from cyclohexane gave **32**, mp 110–112°C; ir λ_{max}: 3.03 (w), 5.79, 5.85, 6.10 (w), 6.28 (w) μm; uv λ_{max} (ε): 312 (370), 325 (4550) nm; *m/e* (relative abundance): 236(0.5). *Anal.* calcd. for $C_{13}H_{16}O_4$: C 66.08, H 6.83; found: C 66.14, H 6.93.

[8]This procedure represents a variant of the general procedure in which red lead oxide is used in place of lead tetraacetate; its generality is being investigated. Compound **27** was also prepared in lower yield by the standard procedure with lead tetraacetate.

*1,3,3a,7a-Tetrahydro-1,5-dimethyl-3-oxo-1-isobenzofurancarboxylic Acid (**33**)*

Compound **22** (1.13 g, 4.17 mmol) and aqueous sodium hydroxide (0.5 *N*; 20.0 mL, 10.0 mmol) were added to water (10 mL), the mixture was stirred for 6 h and then acidified with concentrated hydrochloric acid, giving a white precipitate (0.62 g). Concentration of the filtrate, evaporation to dryness, and extraction with dichloromethane gave additional product (0.23 g; total 95%). Recrystallization from ethyl acetate gave **33**, mp 163.5–166°C; ir (KBr) λ_{max}: 3.0–4.2 (m), 5.66, 5.88 μm; uv λ_{max} (ε): 270 (3300), 260 (3600) nm; ^{1}H nmr δ: (CD_3OD) 1.71 (s, 3H), 1.77 (t, J = 1.5 Hz, 3H), 3.23 (dm, J = 13 Hz, 1H) 3.70 (dm, J = 13 Hz, 1H), 5.04 (s, 1H, variable), 5.3–5.5 (m, 1H), 5.5–6.1 (m, 2H); ^{13}C nmr (CD_3OD) δ: 179.6 (s), 173.6 (s), 131.9 (s), 129.6 (d), 123.0 (d), 115.5 (d), 90.2 (s), 45.0 (d), 41.6 (d), 24.1 (q), 21.5 (q); *m/e* (relative abundance): 208 (27). *Anal.* calcd. for $C_{11}H_{12}O_4$: C 63.45, H 5.81; found: C 63.20, H 5.91.

*Methyl 1,3,3a,7a-Tetrahydro-1,5-dimethyl-3-oxo-1-isobenzofurancarboxylate (**34**)*

Compound **33** (0.384 g, 1.84 mmol) was dissolved in ether (100 mL) and the solution was titrated with ethereal diazomethane until the yellow color persisted. Evaporation gave a white solid which was sublimed at 65°C (0.005 Torr) to give **34** (0.396 g, 97%), mp 92–92.5°C; ir λ_{max}: 5.60, 5.73 μm; uv λ_{max} (ε): 270 (3650), 260 (3900) nm; ^{1}H nmr δ: 1.73 (s, 3H), 1.78 (t, J = 1.5 Hz, 3H), 3.10 (dd, J = 14, 4 Hz, 1H), 3.4–3.8 (m, 1H), 3.63 (s, 3H), 5.3–5.6 (m, 1H), 5.6–6.0 (m, 2H); ^{13}C nmr δ: 177.4 (s), 171.1 (s), 130.3 (s), 128.7 (d), 121.2 (d), 115.1 (d), 88.9 (s), 52.2 (q), 44.2 (d), 40.9 (d), 23.6 (q), 21.3 (q); *m/e* (relative abundance): 222 (32). *Anal.* calcd. for $C_{12}H_{14}O_4$: C 64.85, H 6.35; found: C 64.97, H 6.48.

*Reaction of **34** with Maleic Anhydride. Formation of **35***

Compound **34** (0.144 g, 0.65 mmol) and maleic anhydride (0.064 g, 0.65 mmol) were dissolved in benzene (50 mL) and the solution was boiled under reflux for 70 h. Evaporation gave a white crystalline solid. Recrystallization from chloroform at −30°C gave **35** (0.187 g, 90%). Sublimation at 130°C (0.005 Torr) gave **35**, mp 226–227°C; ir λ_{max}: 5.36 (w), 5.62, 5.74 (w) μm; ^{1}H nmr δ: 1.65 (s, 3H), 1.80 (d, J = 2 Hz, 3H), 2.57 (dd, J = 4.5, 1.5 Hz, 1H), 3.0–3.4 (m, 3H), 3.4–3.7 (m, 1H), 3.85 (s, 3H), 5.5–5.7 (m, 1H); *m/e* (relative abundance): 320 (24). *Anal.* calcd. for $C_{16}H_{16}O_7$: C 60.00, H 5.04; found: C 60.04, H 5.16.

*Methyl 1,3-Dihydro-1,5-dimethyl-3-oxo-1-isobenzofurancarboxylate (**36**)*

Compound **34** (302 mg, 1.36 mmol) was dissolved in methanol (10 mL), 10% Pd/C (750 mg) was added to the solution, and the mixture was stirred under nitrogen for 10 h. Filtration followed by evaporation gave a white solid which was sublimed at 70°C (0.005 Torr). The sublimate was recrystallized from methanol at −30°C to give **36** as a white crystalline solid (0.210 g, 70%), mp 86.5–88°C; ir λ_{max}: 5.64, 5.75 μm; uv λ_{max} (ε): 290 (1850), 280 (1800), 230 (9500) nm; ^{1}H nmr δ: 1.88 (s, 3H), 2.48 (s, 3H), 3.73 (s, 3H), 7.50 (d, J = 1.5 Hz, 2H), 7.68 (bs, 1H); ^{13}C nmr δ: 169.9 (s), 169.2 (s), 146.6 (s), 140.6 (s), 135.7 (d), 125.8 (d), 125.3 (s), 121.8 (d), 84.7 (s), 53.2 (q), 23.7 (q), 21.3 (q); *m/e* (relative abundance): 220 (2). *Anal.* calcd. for $C_{12}H_{12}O_4$: C 65.44, H 5.49; found: C 65.39, H 5.56.

Sodium exo-*3-Carbomethoxy*-exo-*6-hydroxy-4,6-dimethyl-5-oxo-bicyclo[2.2.2]oct-7-ene*-exo-*2-carboxylate Dihydrate (**45**)*

Compound **23** (1.46 g, 5.85 mmol) and sodium hydroxide (0.232 g, 5.80 mmol) were added to water (60 mL), and the mixture was stirred for 45 min at room temperature. The reaction mixture was extracted with dichloromethane (3 × 50 mL), and the aqueous fraction was evaporated to give 1.77 g of a pale yellow solid. Two recrystallizations from water gave **45** (0.405 g) as a white crystalline solid which decomposed at 280°C. *Anal.* calcd. for $C_{13}H_{15}O_6Na{\cdot}2H_2O$: C 47.86, H 5.86; found: C 47.57, H 5.91.

When an aqueous solution of **45** in D_2O was acidified a solid was deposited, whose ^{1}H nmr spectrum showed signals corresponding to **23** together with signals at δ: 1.25 (s), 1.38 (s), 3.08 (br s), 3.55 (m), 3.75 (s), 5.74 (dd, J = 8, 2 Hz), 6.27 (br s), 6.57 (dd, J = 8, 6 Hz) attributed to **46**.

exo-*6-Hydroxy-4,6-dimethyl-5-oxobicyclo[2.2.2]oct-7-ene*-exo-*2*-exo-*3-dicarboxylic Acid Anhydride (**47**)*

Compound **23** (1.00 g, 4.00 mmol) and sodium hydroxide (0.311 g, 7.77 mmol) were added to water (5 mL) and the mixture was heated on a steam bath for 2 h. The mixture was cooled to room temperature and acidified with concentrated hydrochloric acid to pH 5. Evaporation gave a white solid which was extracted with several portions of ether (125 mL). The ethereal extract was filtered, dried, and evaporated to give a pale yellow oil. This was taken up in chloroform (20 mL), and the solution was allowed to stand at room temperature for 18 h to give crystals (0.349 g). Recrystallization from ether–chloroform gave **47** (0.308 g, 33%) as a white crystalline solid, mp 178–179.5°C; *m/e* (relative abundance): 236 (9). *Anal.* calcd. for $C_{12}H_{12}O_5$: C 61.01, H 5.12; found: C 60.96, H 5.20.

Etude empirique de la stabilité des hydrocarbures polycycliques non alternants

JEAN PIERRE GASTMANS, DENISE FROMANTEAU GASTMANS ET STÉFANO FERNANDES SLADE
Instituto de Química da Universidade Estadual Paulista, Julio de Mesquita Filho, 14800 Araraquara (SP), Brasil

Reçu le 17 mars 1979

JEAN PIERRE GASTMANS, DENISE FROMANTEAU GASTMANS et STÉFANO FERNANDES SLADE. Can. J. Chem. **57**, 2864 (1979).

Une méthode empirique destinée à prévoir la stabilité des hydrocarbures non alternants est proposée. Cette méthode se base sur les travaux de Krygowski et Randic.

JEAN PIERRE GASTMANS, DENISE FROMANTEAU GASTMANS, and STÉFANO FERNANADES SLADE. Can. J. Chem. **57**, 2864 (1979).

An empirical method for the prediction of the stability of hydrocarbons has been detailed. This method is based on the works of Krygowski and Randic.

Récemment, plusieurs travaux (1–3) ont eu pour but de découvrir des relations simples et empiriques permettant de prévoir le caractere aromatique d'un hydrocarbure insaturé. Comme plusieurs auteurs (*4a*)[1] l'ont remarqué avant nous, la propre notion d'aromaticité est assez confuse et peut recouvrir des comportements les plus divers.

Comme nous nous intéressons au comportement purement chimique d'un composé, nous avons préféré définir deux indices (5); l'indice de stabilité et l'indice d'aromaticité. Le premier sert à prévoir si un hydrocarbure sera stable ou non, le second, s'il est aromatique (au point de vue chimique) ou non.

Le calcul de ces indices se fait de la manière suivante: on calcule systématiquement $\Delta E_{\text{stabilité}}$ pour tous les carbones, la valeur retenue étant la plus basse. On procède de la même manière pour toutes les paires de carbones susceptibles de réagir par addition pour obtenir $\Delta E_{\text{aromaticité}}$.

Nous prétendons, par ce présent travail, énoncer une méthode empirique simple qui permet de prévoir uniquement la stabilité d'un hydrocarbure.

Méthode

Notre méthode se base sur les théories de Kruszewski et Krygowski (1) et Randic (3). Elle en est d'ailleurs la somme.

Le procédé est le suivant:

1. Comme dans la théorie de Krygowsky, on calcule l'indice R:

$$R = S - F$$

où S est le nombre du cycles du type $4N + 3$ et F est le nombre de cycles du type $4N + 1$.

2. On recherche ensuite les cycles de base de grande stabilité qui sont: le naphtalène, l'azulène, le diphenyle et le sesquifulvalène.

Si aucun de ces cycles n'est apparent, on choisit simplement le (ou les) benzène(s).

3. Si $R = 0$ ou ± 1, la stabilité de l'hydrocarbure sera la moyenne arithmétique entre la stabilité des ensembles de carbones restants. Il est utile de rappeler que la stabilité des polyènes (P_n) diminue à mesure que "n" augmente.

Si $R = \pm 2$, la stabilité sera inversement proportionnelle à la moyenne arithmétique entre la stabilité des ensembles restants.

Si $R = \pm 2$ et si aucun cycle de base n'est apparent, l'hydrocarbure sera instable.

Si R est supérieur à 2 ou inférieur à -2, l'hydrocarbure sera problement instable, bien que l'on ne dispose pas de données expérimentales à ce sujet.

Prenons l'acénaphtylène comme exemple (schéma 1):

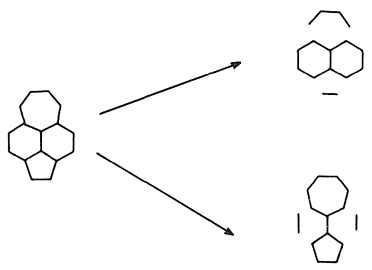

SCHÉMA 1

On peut reconnaître comme cycle de base, respectivement: le naphtalène et le sesquifulvalène. Dans le premier cas, les ensembles restants sont P_4 et P_2 (P_n représente le polyène), dans le second, P_2 et P_2. Dans les deux cas, les polyènes restants sont stables à température ordinaire; l'acénaphtylène sera donc stable, ce que est réellement le cas.

Les cycles de base mentionnés antérieurement ont

[1] On trouvera également une mise au point intéressante dans réf. 4*b*.

0008-4042/79/212864-05$01.00/0

TABLEAU 1. Cycles de base

Composé	IS	REPE (6)[a]	Randic
Benzène	3.47	0.065	0.87
Naphtalène	3.00	0.055	1.32
Diphényle	3.30	0.060	1.74
Sesquifulvalène	2.82	0.022	—
Azulène	2.88	0.023	0.25
Bicyclo(6,2,0)decapentaène	2.07	−0.028	−1.2
Cyclobutadiényl cyclooctatetraène	0.68	−0.08	−2.05

[a]Certaines valeurs de REPE ont été calculées pour ce travail.

été choisis en fonction de leur comportement experimental sur la base des critères suivants:

(*a*) Les cycles de base polycondensés doivent former un circuit conjugué stable R_n, où $n = 1$ ou 2, pour lequel les valeurs de REPE, IS (indice de stabilité) et de l'indice de Randic permettent de prévoir une grande stabilité, comme le montre le tableau 1. Les hydrocarbures formés par la condensation de trois cycles n'ont pas été choisis comme cycle de base. C'est en effet un phénomène bien connu que, généralement, dans une même série, la stabilité diminue à mesure que le nombre de cycles présents augmente. Le bicyclo(6,2,0) décapentaène n'a pas été retenu car ses indices sont trop bas.

(*b*) Les cycles de base polynucléaires linéaires retenus doivent contenir 12 carbones et les valeurs de REPE et IS doivent indiquer une certaine stabilité (l'indice de Randic n'est pas calculable pour tous ces composés). Le cyclobutadiényl cyclooctatétraène n'a pas été retenu à cause de ses indices trop bas.

Dans les tableaux suivants, nous avons reproduit les résultats obtenus pour différents types d'hydrocarbures non alternants.

Il est intéressant de noter le comportement des heptindènes (**D** et **E**). Suivant les théories de Randic et Krygowski, les deux seraient aromatiques. Cependant, tant le REPE que l'IS montrent que l'hydrocarbure angulaire devrait être plus stable. Notre

NOTE: "Isolable" signifie que le composé peut être isolé, mais qu'il est thermiquement instable ou polymérise facilement.

méthode empirique arrive au même résultat. Expérimentalement, l'heptindène linéaire semble être instable.

Son isomère angulaire n'a pas fait l'objet, à notre connaissance, de tentatives de synthèse. Cette augmentation de stabilité due à la non-linéarité des hydrocarbures est un fait connu dans le cas des hydrocarbures alternants; par exemple, le chrysène angulaire est stable, tandis que le naphtacène linéaire réagit facilement par photooxydation. Il semble que le même phénomène se reproduise pour les hydrocarbures non alternants. Les composés **M** et **N** du tableau 3 constituent un autre exemple.

Lorsque l'on étudie le cas des hydrocarbures pour

$R = 1$		**A + B**	o-quinodiméthyde	Instable	1.46	0.025	Instable	25
$R = 1$		**A, B, C**	P_4	Stable	3.20	0.011	Stable	4*b*

lesquels $R = 2$ ou -2, nous avons observé que la stabilité du composé est inversément proportionnelle à celle des résidus. Ce comportement qui nous semble bien marqué, au vu des données expérimentales, est très curieux. Nous n'avons pas trouvé de raison logique pour expliquer cette inversion.

Lors de l'analyse des résultats du tableau 4, il faut garder de vue qu'il s'agit d'hydrocarbures structuralement instables, tant dans théorie de Randic que dans celle de Krygowski. Dans le cas présent, si l'étude des residus prévoit une stabilité, il faut sous-entendre que l'hydrocarbure en question sera plus stable que ne le laisse prévoir sa structure.

On peut voir que dans tous les cas étudiés, les prévisions empiriques sont très acceptables, sans compter que l'analyse de l'hydrocarbure se fait en quelques secondes. Il peut même paraître curieux qu'une méthode si simple et grossière puisse conduire à des résultats aussi précis.

La méthode que nous proposons n'est, en fait, qu'une image approximative de la réalité; c'est à dire que le composé se comporte comme si, réellement, il pouvait être scindé en cycle de base et un ou plusieurs résidus.

Si nous prenons comme exemple l'acénaphtylène et le cycloheptazulène, dont les distances de liaison sont connues, nous pouvons vérifier, suivant les données du tableau 5, que les liaisons entre les cycles de base et les résidus sont particulièrement longues. Ce fait montre qu'en première approximation, la résonance entre le cycle de base d'une part et les résidus d'autre part est faible. Dans le cas de l'acénaphtylène, on peut voir que la stabilité d'un cycle de base par rapport à l'autre se reflète dans les valeurs de distances. Ainsi les liaisons "*c*" et "*d*" sont plus courtes à cause de la grande stabilité du naphtalène comparée à celle du sesquifulvalène. En conséquence, les cycles de base BC interviennent pour une part plus importante dans la structure et stabilité de l'acénaphtylène.

La méthode que nous avons développée, s'applique principalement aux cycles de 5 et 7 carbones, qui sont d'ailleurs les plus nombreux. Récemment, plusieurs hydrocarbures contenant des cycles de 8 et 4 carbones ont été préparés. Bien que l'on ne dispose pas de données suffisantes pour énoncer, sans risque d'erreur, des lois empiriques concernant leurs stabilités, il nous semble que notre méthode puisse être appliquée en y apportant les modifications suivantes:

1. Les hydrocarbures qui contiennent un cyclobutadiène "non vide" suivant Krygowski sont instables.

2. Pour les autres hydrocarbures, les lois antérieures restent valables, mais R et S représentent maintenant le nombre de cyclobutadiène et cyclooctatétrène respectivement.

A titre d'exemple, nous avons relationné dans le tableau 6, le cas de quelques hydrocarbures connus.

Il faut cependant garder de vue que les lois de Krygowski et Randic, ainsi que les nôtres sont basées essenciellement sur l'équilibre qu'il doit exister entre le nombre de cycles du type $4N + 1$ et celui du type $4N + 3$. Cet équilibre occasionne une migration électronique à partir des cycles de 7 carbones vers ceux de 5 carbones. Dans le cas des cycles de 4 et 8 carbones, qui forment des hydrocarbures alternants, cette migration ne se vérifie pas. De telle sorte que nous ne pouvons considérer les lois énoncées antérieurement que comme des tentatives.

Un autre facteur qui peut invalider ces règles est l'existence de déviation sensibles de la coplanarité, comme c'est le cas pour le cyclooctatétraène.

M. NAKAHARA, P. T. T. WONG, G. J. LEWIS, and E. WHALLEY. Can. J. Chem. **57**, 2869 (1979).

The Raman spectrum of trioxane II at ~110 K and zero pressure, and the effect of pressure up to 21 kbar on the spectrum of trioxane I and up to 25 kbar on the spectrum of trioxane II, have been measured to determine if the puckered ring of trioxane goes flat. It does not. In trioxane II, many of the bands that are degenerate in the free molecule are split, showing that the C_3 axis of the isolated molecule does not exist. A few volumetric measurements were made on the I–II boundary line.

M. NAKAHARA, P. T. T. WONG, G. J. LEWIS et E. WHALLEY. Can. J. Chem. **57**, 2869 (1979).

On a examiné le spectre Raman du trioxanne II à ~100 K et à pression nulle, et on a mesuré l'effet de la pression, allant jusqu'à 20 kbar, sur le spectre du trioxanne I et jusqu'à 25 kbar, sur le spectre du trioxanne II afin de déterminer si le cycle plissé du trioxanne s'aplatit. Cela ne se produit pas. Dans le trioxanne plusieurs des bandes qui sont dégénérées sont découplées dans la molécule libre montrant ainsi que l'axe C_3 n'existe pas dans la molécule isolée. On a effectué quelques mesures volumétriques à la limite de démarcation entre les trioxannes I et II.

1. Introduction

It has been suggested (1) on the basis of the infrared spectrum under pressure that the trioxane molecule becomes flat when squeezed, probably at a phase transition at about 18 kbar from the ordinary phase I to the high-pressure phase II. Trithiane certainly flattens when it is squeezed (2), and the internal rotation angles of 1,2-dichloroethane and 1,2-dibromoethane change significantly towards the *cis* conformation at pressures of a few kilobars (3). However, a detailed analysis of the effect of flattening on the infrared spectrum, which is reported in Section 3.1, showed that the observed (1) effects of pressure are not consistent with flattening. Nevertheless, if trithiane becomes flat, trioxane would be expected to do so, although perhaps at a higher pressure, and evidence for it has been sought in the Raman spectrum. The effect of pressure on the Raman spectra of trioxane I and II at room temperature, and the Raman spectrum of trioxane II recovered at 77 K and zero pressure have been measured.

Preliminary measurements showed that trioxane could not be transformed to phase II at pressures below about 25 kbar. Consequently, a few measurements of the I–II equilibrium line and its hysteresis have been made up to 150°C to help choose the best conditions for the preparation of phase II.

2. Experimental Methods and Results

s-Trioxane was obtained and purified as described in the preceding paper (4).

2.1 Volumetric Measurements

About 4 g of trioxane was melted in a Teflon capsule having 12.5 mm od and 1 mm wall thickness, and the capsule was placed in a 12.5 mm piston-cylinder apparatus (5) lubricated with molybdenum disulphide. The apparatus was heated in an oil bath controlled at ±1°C, and was pressurized by a 100-ton press. The piston displacement was measured 5 min after each change of pressure by an Ames dial gauge graduated to 25 μm. Runs at 50 and 100°C are plotted for both increasing and decreasing pressure in Fig. 1.

The pressures at which the maximum slopes occurred when raising and lowering the pressure differed by 6, 3.4, and 3.2 kbar at 50, 100, and 150°C respectively. The hysteresis in the pressure between up and down runs at the same displacement, when there is little friction in the sample, is about 12% of the pressure, as determined by measuring the ice VI–VII and other transitions (6), and is approximately symmetrical about the transition pressure. This corresponds to a hysteresis of about 2.2 kbar at the I–II transition in trioxane. There is therefore significant friction in the sample even at 150°C. The friction was assumed to be symmetrical about the equilibrium transition pressure, and the transition pressure was taken as the mean of the pressures at which the maximum slopes occurred. They were 16.8, 18.6, and 17.4 kbar at 50, 100, and 150°C respectively, with an uncertainty of about ±1 kbar. Within experimental error the transition pressure is 17.6 ±

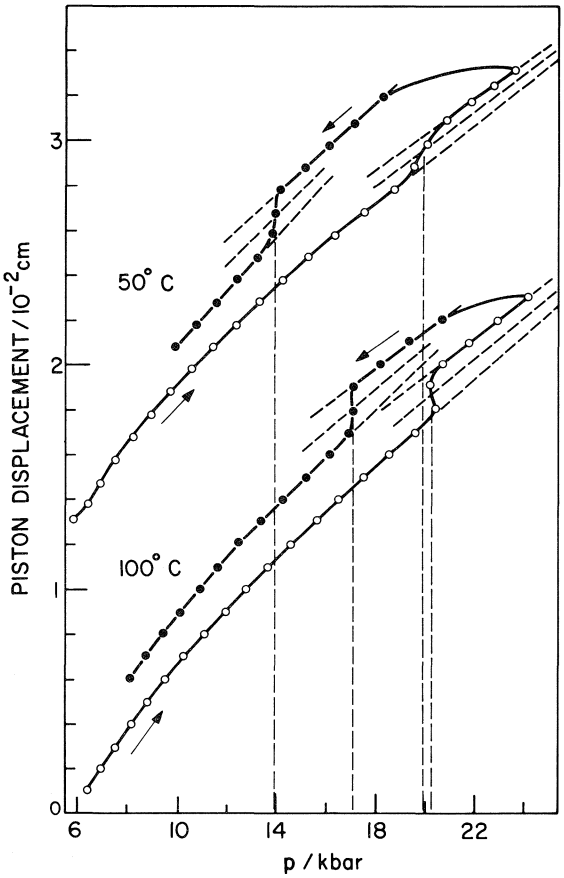

FIG. 1. Graph of piston displacement against pressure for the compression of *s*-trioxane at 50 and 100°C. The dashed lines are extrapolations and interpolations to help estimate the transition pressures and volume changes.

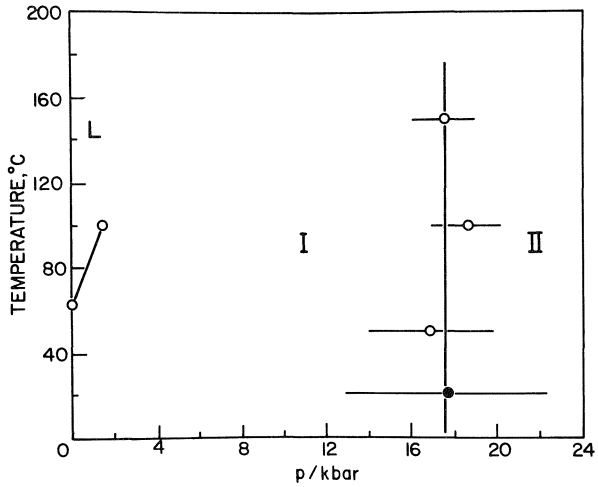

FIG. 2. Phase diagram of trioxane. The ends of the bars indicate the transition pressures for increasing and decreasing pressures. The solid circle at 22°C represents the measurements of Hamann *et al.* (7).

$\sim$1 kbar at all temperatures, which is consistent with the measurement of Hamann *et al.* at 22°C (7).

The volume of transition was determined by extrapolating the apparently straight compression curves well above and well below the transition to the pressures of maximum slope, and the volume changes were determined from the differences in displacement at these pressures. The volume change at the equilibrium pressure was taken as the mean of the apparent volume changes for raising and lowering the pressure. It was $\sim$1.0 and $\sim$1.2 cm^3 mol^{-1} at 50 and 100°C respectively. At 150°C, enough polymer was formed (8) to make the measured volume change unreliable. The melting point was observed at 100°C at 1.4 kbar on decreasing the pressure. By allowing 12% for friction an approximate melting pressure of 1.2 kbar was obtained.

The phase diagram is plotted in Fig. 2, which includes the zero-pressure melting point of 64°C (9). The slope of the melting line near zero pressure is $27 \pm \sim 3$ K kbar^{-1}. The volume of melting at zero pressure from the densities (10, 11) adjusted to 64°C is $12 \pm \sim 1$ cm^3 mol^{-1}, and so the entropy and heat of melting are $44 \pm \sim 6$ J K^{-1} mol^{-1} and $15 \pm \sim 2$ kJ mol^{-1}.

2.2 Raman Spectrum of Recovered Trioxane II

The quenched samples of trioxane II were made by placing a small copper channel in a Teflon capsule, compressing it to make phase II, quenching to 77 K at high pressure, and removing the pressure. The sample held in the copper channel was recovered and mounted on the cold finger of a low-temperature Raman cell, as described elsewhere (12). The recovered sample was opaque, so no polarization measurements could be done. The temperature of the sample was measured with a thermocouple embedded in it and was 110 K. The spectrum is shown in Fig. 3. The frequencies and qualitative relative intensities of the bands are listed in Table 1, along with the frequencies and relative intensities of the spectrum of trioxane I at 110 K taken using a similar technique.

The internal vibrations are similar to those of trioxane I, and most of the bands can be straightforwardly correlated as in Table 1, in which the symmetry species listed (4, 13) are those of the isolated C_{3v} molecule. The species in phase I, which belongs to the space group $R3c$, C_{3v}^6 with two molecules in the primitive cell on sites of symmetry C_3, are the same except that the A_2 vibrations become weakly active as A_1 crystal vibrations. The species in phase II are, of course, not known.

Only a few points deserve comment. Most of the hydrogen-atom vibrations that are degenerate under

the C_{3v} symmetry of phase I split into two bands of approximately equal intensity in phase II. The splitting of the 3033- and 2887-cm^{-1} (at room temperature) bands confirms that the A_1 and E asymmetric and symmetric CH_2 stretches overlap in phase I, as was discussed in an earlier paper (4). Kobayashi's (13) interpretation, in which the components of the asymmetric and of the symmetric stretch are separated by several tens cm^{-1}, seems incorrect. Several new bands occur in phase II. Most are probably combinations, but the bands at 1375 and 1236 cm^{-1} may correspond to the A_2 CH_2 wagging and twisting vibrations of the isolated molecule made active by the distortion. The splitting of the degenerate vibrations shows that the C_3 symmetry which molecules in phase I have is destroyed in phase II. In trithiane, the sulphur analogue of trioxane, there are two molecules in the unit cell of symmetry $Pmn2_1$, C_{2v}^7, and they are on sites of C_s symmetry (14, 15). Trioxane II could have a similar structure.

Brasch *et al.* (1), on the basis of the infrared spectrum under pressure taken in a diamond-anvil apparatus, suggested that trioxane became flat at the I–II transformation. The Raman spectrum shows clearly that trioxane II is not flat at ~110 K and zero pressure. If it were, the A_1 (on the basis of the C_{3v} symmetry of the isolated molecule) asymmetric CH_2 stretch, the A_1 CH_2 rock, and the A_1 ν_3 internal rotation would have lost their Raman intensity. The A_1 asymmetric CH_2 stretch may be present (4, 13) as a weaker band on the low-frequency component of the E asymmetric CH_2 stretch. The A_1 CH_2 rock has been assigned to a very strong infrared band in trioxane I at 1222 cm^{-1} (16), but has not been observed in the Raman spectrum either in ref. 4 or in this work. The A_1 ν_3 internal rotation is also still present as a medium band at 496 cm^{-1}.

2.3 Effect of Pressure on the Raman Spectrum of Trioxane I

The Raman spectra were taken with a 25-kbar hydrostatic optical cell with glass windows (17). The pressure was measured with a manganin gauge calibrated against a 20-kbar pressure balance. The spectral slit widths were 3 cm^{-1}, counting rates 500 s^{-1}, time constant 10 s, and scan speed 10 cm^{-1} min^{-1}. The 514-nm argon line was used at a power of ~1 W. Spectra of phase I were taken at intervals of ~3 kbar at 22°C.

Two sets of spectra were taken. In the first, the trioxane was separated from the naphtha, in which it is soluble, by the apparatus shown in Fig. 4. The sample holder was a quartz tube that was closed at one end except for a 2-mm-diameter hole and was optically flat at the other. The sample was held in

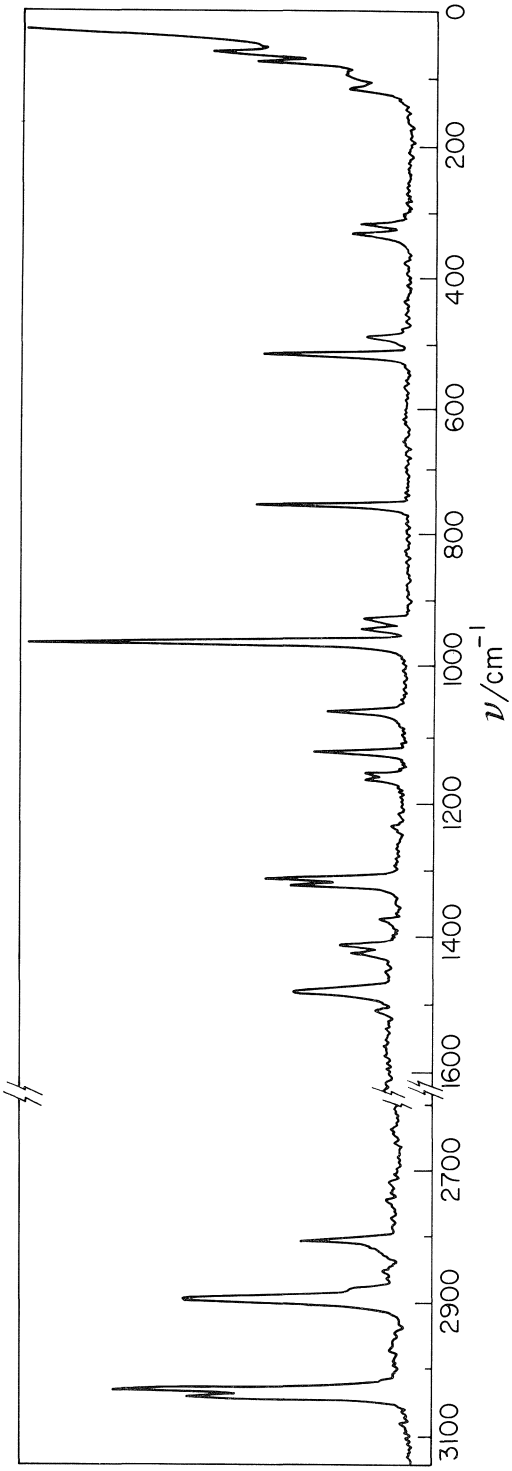

FIG. 3. Raman spectrum of trioxane II at 100 K and zero pressure. The region not shown contained no detected bands.

the tube by a Viton plug at the closed end and by the window of the high-pressure cell, which the sample cell was wrung to. The assembly was held on the window plug of the Raman cell by a brass holder cushioned with a rubber pad. The holder had apertures for passage of the laser beam. This set-up is particularly suitable for samples that dissolve in the pressure-transmitting fluid, and can be used for liquids that would corrode the Raman cell. It can, of course, be used only for liquids and soft solids. Spectra were measured up to 21 kbar.

In the second set of spectra, naphtha saturated

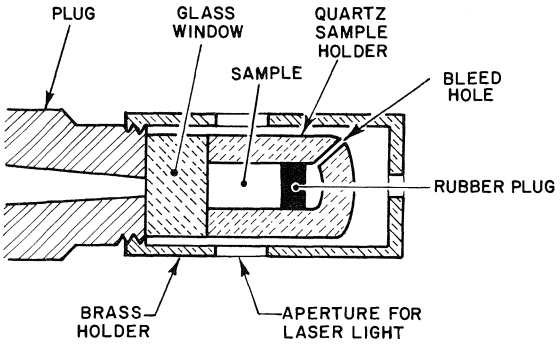

FIG. 4. Sketch of sample holder used to isolate the sample from the pressure-transmitting fluid.

with trioxane was used as the pressure-transmitting fluid, and the samples were either single crystals, clear samples made by cooling the melt slowly, or opaque samples made by cooling the melt rapidly. The clear samples had strong polarization effects characteristic of oriented polycrystals. The relative intensities of the bands of the spectra of both clear samples and single crystals, taken with a linearly polarized exciting beam, changed greatly in the first few kilobars in a way showing that the exciting beam was becoming strongly depolarized. The windows depolarize relatively little even at 20 kbar (18) and it is likely that the depolarization was caused by finely divided trioxane precipitated from the saturated solution by increasing the pressure. To confirm the depolarization, spectra were run with circularly polarized exciting light, which should give the same spectrum as depolarized light and so should be unaffected by the depolarization. The relative intensities were not significantly affected by pressure. Opaque samples behaved similarly, and both these observations confirm the depolarization. Spectra were measured up to 20 kbar.

The changes of intensity due to the depolarization of the exciting light did not significantly affect the frequencies, and so these have been reported. The relative intensities obtained only with either circularly polarized light or with opaque samples were used. They were taken to 16 kbar for all bands and to 21 kbar for the 486- and 520-cm^{-1} bands.

The frequencies of the vibrations changed linearly with pressure, except for the CH_2 stretching vibrations, which were slightly non-linear. Their variation was also non-linear with opaque samples and when circularly polarized exciting light was used, and is undoubtedly real. The slope of the frequency against pressure for each band is listed in Table 1. The results obtained when the sample was held in the quartz tube shown in Fig. 4 or when an opaque polycrystal was held in naphtha saturated with trioxane were essentially the same.

When the trithiane was compressed to 18 kbar, the A_1 ν_3 ring flattening vibration at 309 cm^{-1} lost 75% of its intensity relative to neighboring bands, and it was concluded that the molecule was half way to being flat (2). The corresponding band in trioxane is at 486 cm^{-1} (4). The relative areas of the 486 and 520 cm^{-1} bands and of several other bands were determined by tracing them carefully on high quality paper, cutting them out, and weighing them. There was no significant change in the ratio of the intensity of the 486-cm^{-1} band to the intensity of the 520-cm^{-1} band up to 21 kbar and its ratio to the intensity of the 3033-, 2888-, 1482-, 1319-, 1160-, 951-, 927-, 746-, or 59-cm^{-1} bands up to 16 kbar.

The A_1 asymmetric CH_2 stretch should also lose intensity if the molecule flattens. It is, however, weak compared with the overlapping E asymmetric stretch, and flattening should have only a small effect on the ratio of intensities of the CH_2 asymmetric and symmetric stretches. The data in the preceding paragraph imply that the relative intensity of the 3033- and 2888-cm^{-1} bands was independent of pressure, and a graph of the ratio verified that this is so.

The intensity of the 308-cm^{-1} band (frequency at ambient conditions) (4), relative to the 520-cm^{-1} band, however, appeared to decrease from 0.33 to 0.22 in the range 0–16 kbar, as is clearly evident in the plot in Fig. 5. The intensity of the 308-cm^{-1} band no doubt decreases significantly relative to the rest of the spectrum.

2.4 Effect of Pressure on the Raman Spectrum of Trioxane II

A sample of trioxane II for high-pressure spectroscopy was made in a 25-kbar hydrostatic Raman cell (17) from a single crystal of phase I by heating the cell to 65°C and raising the pressure to 25 kbar.

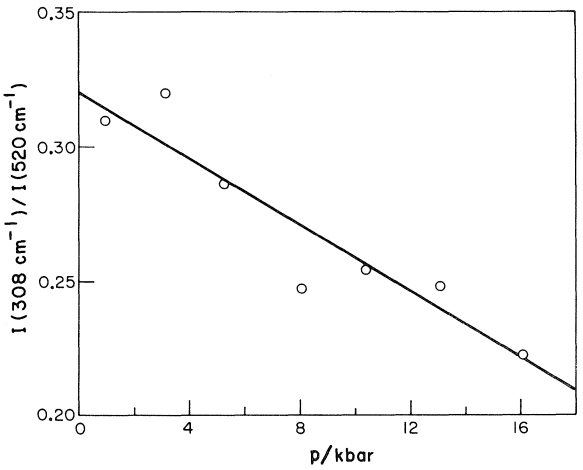

FIG. 5. Pressure dependence of the ratio of the Raman intensities of the 308- and 520-cm^{-1} bands.

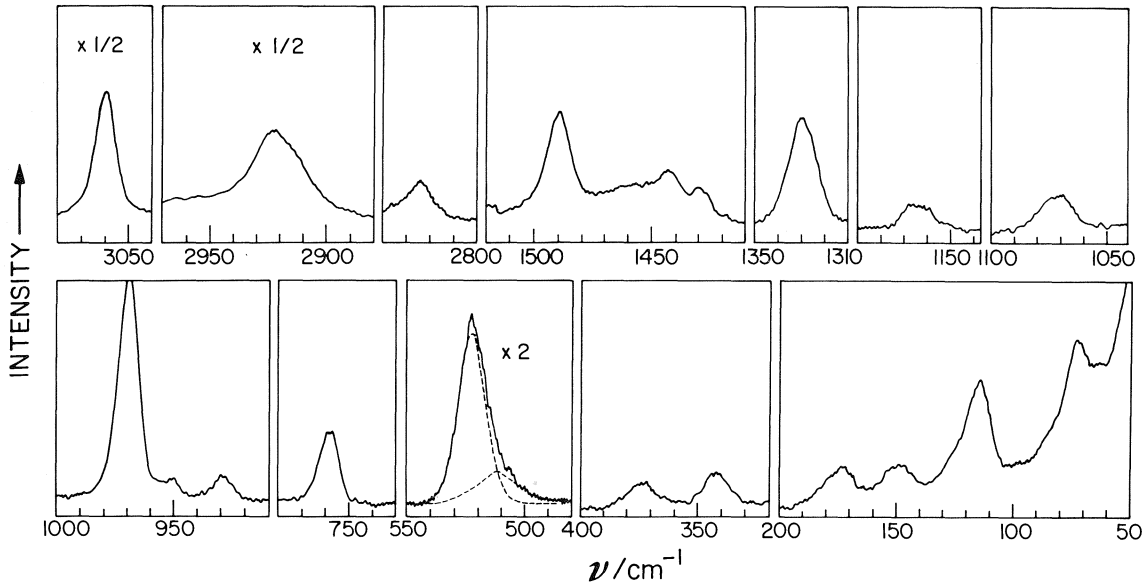

FIG. 6. Raman spectrum of trioxane II at 295 K and 25 kbar. The regions not shown contained no detected bands. An approximate resolution of the 526- and 518-cm^{-1} bands is suggested.

The pressure was determined from the pressure applied to the hydraulic jack, using the experimentally determined intensification ratio. The transformation was monitored by the *c a* Raman spectrum of the band at 3033 cm^{-1}. At the transformation, which occurred at 22.5 kbar, the intensity of the scattered exciting light increased by an order of magnitude because the single crystal was destroyed. The sample was cooled to 22°C and its spectrum was recorded at about 2.5-kbar intervals from 25 kbar to its transformation to phase I. The slit width was 5 cm^{-1}, scan speed 2 or 5 cm^{-1} min^{-1}, and time constant 40 s. The spectrum at 25 kbar is shown in Fig. 6 and the frequencies at 25 kbar are listed in Table 1.

The spectrum is similar to that of phase II at ~110 K except for frequency shifts that can be attributed to the difference of temperature and pressure, a broadening of the bands and a decrease in the splitting of the bands that are degenerate in the isolated molecule. For some bands the splitting disappears. Phase II survived a reduction to 11.4 but not to 8.8 kbar at 22°C. The effect of pressure on the frequencies is summarized in Table 1.

In phase II under pressure at 22°C, the ν_3 internal rotation is a weak low-frequency shoulder of the 525-cm^{-1} band. It should be absent if the molecule is flat. The two bands were resolved by the curve resolver using Gaussian–Lorentzian-product line shapes, and widths that were independent of pressure, as shown in Fig. 6. The relative intensities were about the same as in phase I and did not change significantly with pressure. The molecules in phase II are therefore not significantly flattened at pressures up to 25 kbar.

3. Discussion

3.1 Effect of Pressure on the Spectrum

There is no doubt from the spectra reported in this paper that trioxane does not go flat under the experimental pressures in either phase I or phase II. This is consistent with the reported infrared spectrum (1), as the following arguments show.

As was discussed in connection with the flattening of trithiane (2), the A_1 vibrations that become symmetric to the horizontal plane that is formed on flattening, and so belong to species A_1', and E vibrations that become antisymmetric to the horizontal plane, and so belong to species E'', lose their infrared activity. In the CH stretching region, the A_1 symmetric stretch at 2883 cm^{-1} in phase I and the E asymmetric stretch at 3031 cm^{-1} (the frequencies are those of ref. 15) should lose infrared intensity. Both bands are doublets, but the band that should disappear on flattening is the stronger of both pairs, and is much the stronger of the pair at 3031 cm^{-1}. Neither loses infrared intensity and so there is no evidence for flattening.

The A_1 CH_2 bend at 1494 cm^{-1} should lose infrared intensity on flattening. Brasch *et al.* (1) reported that the 1495-cm^{-1} (their frequency) band was absent from the high-pressure spectrum, although a new band appeared at 1515 cm^{-1}, and the 1420-cm^{-1} band also disappeared. The 1420-cm^{-1} band

was assigned (16) to the E CH_2 wag, which remains active in the planar conformation.

The E CH_2 rock at 918 cm^{-1} and the A_1 ν_1 ring symmetric stretch at 951 cm^{-1} should disappear. In fact, they merge to form "a very intense broad band from 920 to 980 cm^{-1}".

The A_1 ν_2 ring deformation at 744 cm^{-1} and the E ν_8 internal rotation at 305 cm^{-1} should lose infrared intensity. The 744-cm^{-1} band is not reported (1) to lose intensity under pressure, but it was reported by Kobayashi *et al.* (16) to be very weak, and may not have been observed in the high-pressure spectra. The 305-cm^{-1} band is beyond the experimental range. The 480-cm^{-1} band (1), which is the A_1 ν_3 ring flattening vibration at 486 cm^{-1} in the Raman spectrum (4), also disappears, whereas it is predicted to disappear on flattening only in the Raman spectrum. It is clearly present in Raman spectra reported in this paper, but it is merged with the 526-cm^{-1} band in phase II at room temperature in the range 11.4–25 kbar, which explains its disappearance from the infrared spectrum.

3.2 Resistance to Flattening

The potential barrier to flattening the trithiane molecule, according to the potential function

$$V = V_0(1 - \theta^2)^2$$

where V is the potential energy, V_0 the potential energy of the flat relative to the equilibrium conformation, and $\theta = x/x_0$ where x and x_0 are the instantaneous and equilibrium distances between the carbon and oxygen planes, and the flattening frequency at zero pressure of 309 cm^{-1} (2) is about 0.87 perg (picoerg). The force constant that resists flattening is $8V_0/{x_0}^2$, and is 1.6 and 2.8 mdyn $Å^{-1}$ for trithiane and trioxane respectively. The ratio of the volumes of trithiane and trioxane is ~1.4 (11, 14, 15), and so the ratio of surface areas is ~1.25. The ratio of the forces exerted on a molecule by an applied pressure is therefore about 1.25. The force on a molecule divided by the force constant is therefore ~2.2 times larger for trioxane than for trithiane.It should therefore be significantly more difficult to flatten, in agreement with the conclusions of this paper.

Summary

1. The Raman spectrum of trioxane I up to 21 kbar and of trioxane II at ~110 K and zero pressure and at 295 K in the range 11.4–25 kbar have been measured.

2. The spectra show no evidence that the molecules in either trioxane I or trioxane II become flatter in the experimental range.

Les oxazolines-4 précurseurs de sels d'iminium fonctionnels. Ouverture en milieu anhydre de ces hétérocycles par des acides protoniques: obtention de sels d'iminium fonctionnels, étude de leur structure

MICHEL VAULTIER, GURBACHAN MULLICK[1] ET ROBERT CARRIÉ

Reçu le 26 avril 1979

MICHEL VAULTIER, GURBACHAN MULLICK et ROBERT CARRIÉ. Can. J. Chem. **57**, 2876 (1979).

La protonation des oxazolines-4 en milieu anhydre, à basse température ou à température ambiante, par des acides protoniques conduit généralement à des sels d'iminium fonctionnels acycliques. Lorsque le carbone 4 du cycle oxazoline porte un hydrogène, deux sels d'iminium cycliques diastéréoisomères sont formés. Les conditions d'obtention et la structure de ces espèces sont établies à l'aide de la rmn du proton et du ^{13}C.

MICHEL VAULTIER, GURBACHAN MULLICK, and ROBERT CARRIÉ. Can. J. Chem. **57**, 2876 (1979).

The protonation of 4-oxazolines with protic acids in anhydrous medium, both at low or at room temperature, generally leads to acyclic functional iminium salts. In those cases where the oxazoline ring bears a hydrogen atom in the four position, two diastereoisomeric cyclic iminium salts are obtained. The conditions for preparation of these salts along with the characterization of their structures were determined by the aid of ^{1}H and ^{13}C nmr.

Introduction

Les oxazolines-4 ont été peu étudiées (1). Cependant il a été montré que certains de ces composés sont des ylures d'azométhine potentiels qui peuvent donner des cycloadduits avec divers dipolarophiles (2, 3). L'instabilité des oxazolines-4 en présence d'eau est également connue et les produits d'hydrolyse ont été identifiés (3, 4).

Lors d'une étude sur la réactivité des aziridines, ylures d'azométhine potentiels, vis à vis des réactifs électrophiles et nucléophiles (5), nous avons montré que l'oxazoline-4 **1***a* réagit à température ambiante (*1*) avec les ylures de soufre pour conduire à des azétidines (6). Il n'a pas été clairement établi dans ce cas si la réaction procède par une addition nucléophile sur l'ylure d'azométhine éventuellement en équilibre avec l'oxazoline-4 **1***a* ou par une attaque directe du cycle oxazoline par les ylures du soufre; (*2*) avec certains nucléophiles (5) (phosphite de triméthyle, anions ambivalents . . .) uniquement en présence d'un acide protonique.

Nous avons donc entrepris une étude du comportement des oxazolines-4 en présence d'acides protoniques pour: (*1*) montrer que les oxazolines-4 sont des précurseurs de sels d'iminium fonctionnalisés sur le carbone en α de l'atome d'azote. Ces sels sont d'accès difficile, seule la protonation d'aziridines dans les conditions où elles sont en équilibre avec les ylures d'azométhine correspondants permet de les obtenir (5). L'introduction de fonctions dans cette position ouvre de nouvelles possibilités d'hétérocyclisation; (*2*) établir les conditions d'obtention de ces sels d'iminium et leurs structures, afin de permettre une meilleure compréhension des mécanismes réactionnels et un meilleur choix de conditions expérimentales.

Présentation générale du problème

La schéma 1 donne les diverses possibilités d'évolution d'une oxazoline-4 de formule **1** en présence d'acide protonique AH dans un milieu anhydre.

Ces différentes possibilités résultent de la structure de l'oxazoline-4 qui peut être à la fois considérée comme une énamine, un éther d'énol ou un aminoacétal. Seule la formation des entités de structure **3** et **4** a été observée sauf dans le cas de l'oxazoline **1***e* où deux diastéréoisomères de structure **9** ont été mis en évidence. Les composés **1**, **3** et **4** sont en équilibre. L'ensemble de ces équilibres est complexe et n'a pas été étudié dans le détail, le but de nos recherches étant de dégager les facteurs les plus importants qui interviennent.

Les structures des entités formées ont été établies à l'aide de la rmn du proton et du ^{13}C. Le pourcentage relatif des différents composés est déduit de l'intégration des signaux de leur spectre de rmn ^{1}H.

Protonation à basse température

FSO_3H (−30°C)

L'addition d'un équivalent d'acide fluorosul-

[1]Chercheur associé invité. Adresse actuelle: Explosives Research and Development Laboratory, Pashan, Poona-411021, India.

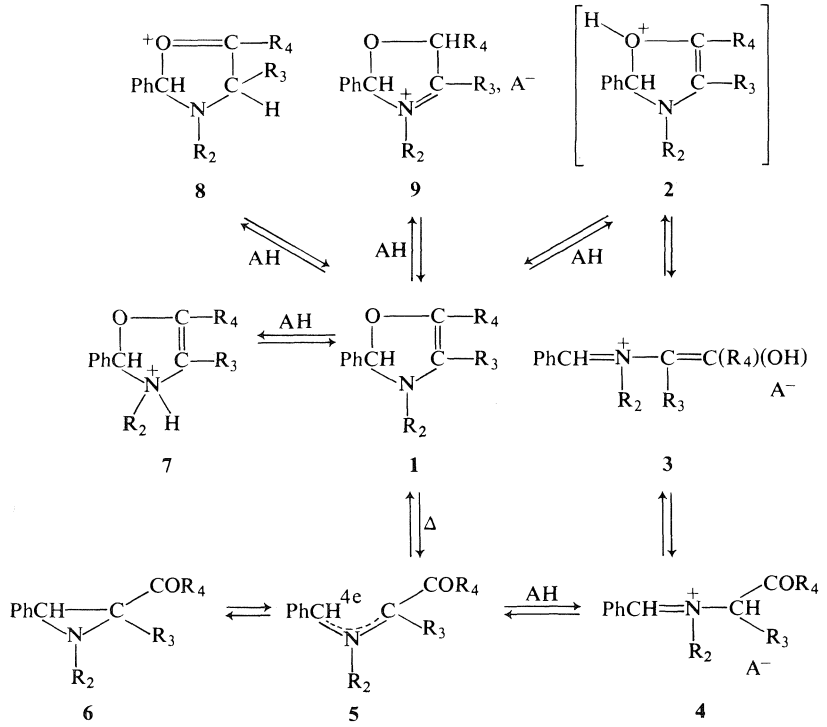
fonique FSO_3H à une solution des oxazolines **1***a–d* dans l'acétonitrile conduit quantitativement aux sels de structure **3**. Les caractéristiques spectroscopiques des composés **1** et **3** figurent dans le tableau 1 et sont en accord avec les structures.

Le déplacement chimique du proton H_a des composés **3** est en accord avec une structure iminium (7) et est comparable aux valeurs que nous avons trouvées pour des structures voisines (5). Il en est de même en ^{13}C pour δC_a et la constante de couplage $J_{C_aH_a}$. L'existence dans chaque cas de 2 carbones sp^2 ne portant pas d'hydrogène, l'un lié à un atome d'azote ($\delta \sim 110$ ppm) l'autre à un atome d'oxygène ($\delta \sim 170$ ppm) montre que **3** est formé (et non la cétone correspondante **4**). Le proton énolique, résonnant à champ relativement fort ($\delta \sim 10$ ppm) il semble logique de penser que le composé n'est pas chélaté. On est donc conduit à attribuer aux sels **3***a*,



1*a*: R_2 = Ph, R_3 = CO_2Me, R_4 = Me
1*b*: R_2 = Ph, R_3 = CO_2Me, R_4 = Ph
1*c*: R_2 = Ph, R_3 = CN, R_4 = Ph
1*d*: R_2 = Me, R_3 = CO_2Me, R_4 = Ph
1*e*: R_2 = Ph, R_3 = H, R_4 = CO_2Me

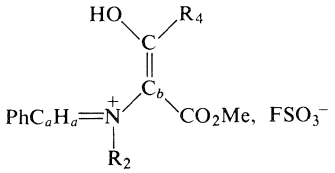
[i]Composé trop instable pour obtenir un enregistrement convenable.

3*b* et **3***d* la structure suivante:



3*a*: R_2 = Ph; R_4 = Me
3*b*: R_2 = R_4 = Ph
3*d*: R_2 = Me; R_4 = Ph

Lorsque R_3 = CN, le résultat est différent, on obtient deux sels d'iminium **3***c* et **3**′*c* dont la stéréochimie n'est pas déterminée. Il faut noter, enfin, que dans ces conditions, la formation de sels d'iminium cétonique **4** n'est pas mise en évidence.

CF_3CO_2H (−40°C)

L'acide trifluoroacétique est beaucoup plus faible que l'acide fluorosulfonique et les oxazolines **1** ne sont pas complètement protonées avec un équivalent d'acide trifluoroacétique. Les caractéristiques spectroscopiques des sels d'iminium **3** et **4** obtenus par addition de 4 équivalents de CF_3CO_2H aux solutions dans $CDCl_3$ des composés **1** figurent au tableau 2. Elles sont en accord avec les structures proposées.

L'analyse de ce tableau montre la diversité du comportement des oxazolines étudiées. L'oxazoline **1***a* conduit à deux couples d'isomères géométriques: un couple d'énols *Z* et *E*, **3***a* et **3**′*a*, et le couple de cétones *Z* et *E*, **4***a* et **4**′*a*. Les hydroxyles de **3***a* et **3**′*a* ne sont pas chélatés avec le groupement ester. Lorsqu'on réchauffe à la température ambiante ces deux composés s'isomérisent en énols chélatés **3**″*a* et **3**‴*a*; il est alors possible, comme nous le verrons, de mettre en évidence, à basse température, le proton énolique à champ faible alors que celui de **3***a* et **3**′*a* est en échange rapide avec l'acide trifluoroacétique en excès (même à 190 K).

L'oxazoline **1***b* conduit au mélange d'un seul énol **3**′*b* dont le proton est chélaté avec le groupement ester (δOH = 13.45 ppm, singulet étroit à 200 K) et d'une seule cétone (80%).

Le comportement de l'oxazoline **1***c* est analogue en présence des acides trifluoroacétique ou sulfonique.

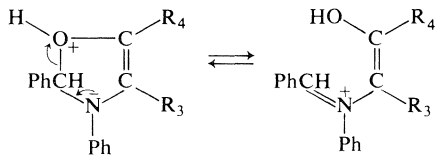
L'addition de quantités croissantes d'acide trifluoroacétique fait disparaître les oxazolines **1** comme le montre le tableau 3. Pour **1***a*, **1***b*, **1***c* la quantité de sels d'iminium formés est toujours inférieure à la quantité d'acide ajoutée. L'existence d'une équilibre entre l'oxazoline-4 de départ et les sels d'iminium est ainsi mise en évidence; elle est confirmée par le fait que les spectres de carbone 13 de l'oxazoline **1***c* additionnée de 4 équivalents de CF_3CO_2H doivent être enregistrés à −90°C pour obtenir des signaux distincts pour **3***c*, **3**′*c* et **1***c* (à −50°C, on observe un signal moyen pour ces trois entités).

La quantité d'acide nécessaire pour faire disparaître l'oxazoline de départ dépend de la basicité relative des composés. Ainsi, comme on pouvait s'y attendre **1***d* est plus basique que **1***a* elle-même plus basique que **1***b* et **1***c*. Il convient également de remarquer que le pourcentage de cétone augmente avec l'acidité du milieu.

L'analyse des résultats de la protonation, à basse température, fait apparaître les points suivants.

Dans des conditions pour lesquelles l'existence d'un équilibre entre l'oxazoline **1** et l'ylure d'azométhine **5** paraît très peu probable, la formation des sels **3** est observée et ne résulterait donc pas de la protonation de l'ylure **5**.

Il semble plus logique d'admettre que le proton se fixe sur l'oxazoline conduisant ainsi à **2** dont l'ouverture est assistée par la paire libre de l'azote (schéma 2). Ce mécanisme est compatible avec la configura-



2 **3**

SCHÉMA 2

tion de double liaison carbone–carbone de l'énol formé lors de la protonation de **1***a*, **1***b* et **1***c* avec FSO_3H.

La base conjuguée de l'acide trifluoroacétique, beaucoup moins fort que l'acide fluorosulfonique, est relativement nucléophile. Son utilisation rend les résultats plus complexes et les diverses entités formées sont en équilibre. Dans le cas de l'oxazoline **1***a*, on observe un couple d'énols et un couple de cétones, chaque couple étant composé de deux isomères géométriques au niveau de la fonction iminium. Ce phénomène peut résulter de la nucléophilie de l'ion trifluoroacétate qui par un processus d'addition élimination provoque une isomérisation de l'énol (schéma 3).

La substitution du méthyle en 5 par un phényle modifie considérablement les résultats. L'effet du phényle paraît difficile à analyser, ce groupement modifie non seulement l'acidité des énols mais également les équilibres cétoénoliques et sels d'iminium **3** – amine **10**.

dans CD_3CN des oxazolines **1***a–d* conduit à la formation de sels d'iminium dont les caractéristiques spectroscopiques figurent dans le tableau 4. Il faut noter que ces mêmes résultats sont obtenus si on laisse réchauffer à la température ambiante les solutions étudiées à basse température (par addition également d'un équivalent d'acide FSO_3H). On peut remarquer les points suivants. (*i*) le comportement de l'oxazoline **1***c* est inchangé, les mêmes espèces qu'à basse température sont obtenues; (*ii*) **1***a* donne un mélange de l'énol obtenu à basse température **3***a* (32%), de deux énols à haute température **3**″*a* et **3**‴*a* (60%) pour lesquels l'hydrogène énolique est chélaté (δ = 12.9 ppm) et enfin d'une forme cétonique (8%). Les phénomènes d'isomérisation et de tautomérie céto–énolique se manifestent donc à la température ambiante alors qu'ils étaient inhibés à basse température; (*iii*) **1***b* conduit à un mélange de l'énol

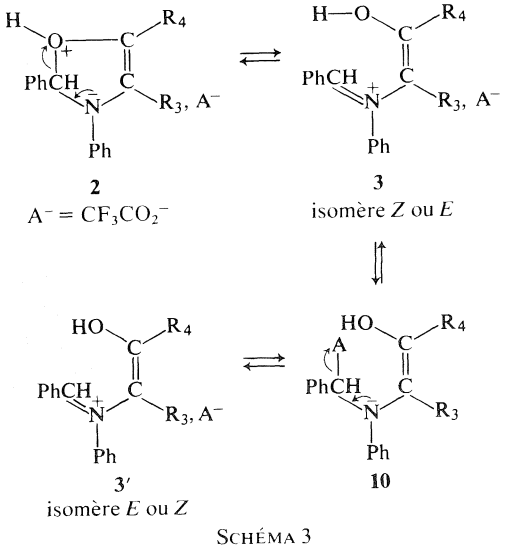

SCHÉMA 3

obtenu à basse température (10%) d'un énol de structure chélatée **3**″*b* (77%) très majoritaire et d'une forme cétonique (13%).

Protonation par l'acide trifluoroacétique

L'addition, à la température ambiante, de 4 équivalents de CF_3CO_2H à des solutions de **1***a*, **1***b* et **1***c* dans $CDCl_3$ et le réchauffage à l'ambiante de solutions préparées à basse température conduisent au même résultat. Les caractéristiques spectroscopiques des espèces formées figurent au tableau 5.

On remarque que le comportement de **1***c* est inchangé. L'oxazoline **1***b* conduit aux mêmes entités qu'à basse température mais, les pourcentages sont inversés, la forme énolique chélatée (δOH = 13.38 ppm) étant devenue majoritaire. L'oxazoline **1***a* conduit au mélange d'un énol chélaté très majoritaire (85%) de structure **3**″*a* (A = $CF_3CO_2^-$) et des deux énols de basse température **3***a* et **3**′*a* (15%). Les formes cétoniques ne sont pas détectables mais, le passage des formes non chélatées **3***a* et **3**′*a* à la forme chélatée **3**″*a* s'effectue sans doute par l'intermédiaire des formes cétoniques.

Cas particulier: protonation de l'oxazoline **1***e*

En raison de l'instabilité des entitées formées l'étude de la protonation de l'oxazoline **1***e* s'est avérée difficile. Cependant, à très basse température, dans SO_2 liquide, et en présence d'acide fluorosulfonique, il a été possible de mettre en évidence la formation des deux sels d'iminium cycliques diastéréoisomères de structures **5**′*e* et **5**″*e*. Leurs caractéristiques spectroscopiques ainsi que celles de l'oxazoline **1***e* figurent dans le tableau 6. Elles sont en accord avec les structures proposées. On notera en particulier la présence d'un carbone de sel d'iminium cyclique (C_β) avec une grande constante de couplage carbone–hydrogène ($J_{C_\beta H_\beta}$ = 207 Hz) caractéristique de ce type de sel (7). De plus, l'existence de 2 carbones sp^3 dans la molécule (C_α, carbone

acétalique le plus déblindé et C_γ) confirme les structures **5′***e* et **5″***e*.

Le comportement différent de **1***e* comparativement aux autres oxazolines étudiées résulte vraisemblablement de la substitution en 5 par le groupement ester qui modifie la nucléophilie du carbone 5 et contribue à la délocalisation de la paire libre de l'azote la rendant moins disponible pour assister l'ouverture d'une oxazoline protonée sur l'oxygène de type **2**.

Partie expérimentale

Les spectres de rmn du proton ont été enregistrés à 100 MHz sur un appareil JEOL MH 100, ceux du carbone 13 sur un appareil Bruker WP 80 DS à 20 115 MHz. Le TMS est utilisé comme référence interne. Dans le cas du carbone 13, les constantes de couplage ont été mesurées sur des spectres obtenus à l'aide de la technique du découplage en fenêtre ("gated decoupling"), la résolution digitale étant alors d'environ 1 Hz.

Produits de départ

Oxazoline-4 ***1***a

Elle est obtenue quantitativement par thermolyse à sec de la triazoline correspondante à 155°C sous atmosphère d'azote ou d'argon (5). C'est un composé huileux, très facilement hydrolysable, utilisé "in situ".

Oxazoline-4 ***1***b

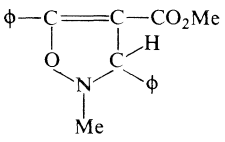
Elle est préparée selon le mode opératoire décrit par Niklas (3): la *C,N*-diphénylnitrone (1.50 g, 7.6 mmol) et le phénylpropiolate de méthyle (1.22 g, 7.6 mmol) sont dissous dans 20 cm^3 d'acétate d'éthyle anhydre. La solution est maintenue à reflux 15 h sous atmosphère d'azote. L'acétate d'éthyle est distillé sous vide. L'huile résiduelle cristallise au réfrigérateur. La recristallisation dans l'acétonitrile donne 1.5 g de l'oxazoline **1***b*, pf = 115°C, Rdt = 56%.

Oxazoline ***1***c

Elle est préparée selon Texier et Carrié (2). L'α-benzoyl cinnamonitrile (1.86 g, 8 mmol) et le phénylazide (2.86 g, 24 mmol) sont mélangés puis maintenus à 90°C, sous atmosphère d'azote, pendant 18 h à l'aide d'un bain d'huile. Après refroidissement, on additionne de l'éther sec. Les cristaux jaunes d'oxazoline **1***c* sont filtrés, lavés avec un peu d'éther froid. La recristallisation dans l'acétonitrile donne 1.6 g (Rdt = 61.5%), pf = 117°C.

Oxazoline-4 ***1***d

L'isoxazoline-4 correspondante **11** est d'abord préparé



11

selon le mode opératoire de Niklas (3) légèrement modifié. La *C*-phényl *N*-méthylnitrone (1.35 g, 10 mmol) et le phénylpropiolate de méthyle (1.6 g, 10 mmol) sont mélangés puis maintenus à 80°C pendant 3 h à l'aide d'un bain d'huile. L'huile obtenue est alors refroidie et additionnée de méthanol. L'isoxazoline **11** précipite; elle est recristallisée dans le méthanol (1.5 g, Rdt = 50%, pf = 104°C).

L'isoxazoline **11** est dissoute dans le solvant choisi puis la solution transférée dans un tube en verre qui est ensuite scellé sous atmosphère d'azote (par exemple: 295 mg (1 mmol) d'isoxazoline **11** sont dissous dans 0.5 cm^3 de C_6D_6). Le tube scellé est maintenu 3 h à 135–140°C dans un bain d'huile. Le spectre de rmn de la solution indique une transposition totale et quantitative de l'isoxazoline en oxazoline **1***d* (caractéristiques rmn dans le tableau 1).

Oxazoline-4 ***1***e

C,N-diphénylnitrone (2.0 g, 5.08 mmol) et 0.86 g de propiolate de méthyle (5.10 mmol) sont mélangés dans 30 cm^3 de benzène anhydre. La solution est maintenue 3 h à reflux

sous atmosphère d'azote. Le benzène est alors distillé sous vide. Le solide résiduel est recristallisé dans l'acétonitrile conduisant à 1.0 g d'oxazoline-4 **1***e* (Rdt = 40%, pf = 170°C).

Les composés **1***b*, **1***c*, **1***d* et **1***e* doivent être conservés au réfrigérateur sous atmosphère d'azote.

Protonation des oxazolines-4

Les entités observées sont très fragiles. Il est nécessaire de travailler en milieu anhydre sous atmosphère d'argon sec. Les solvants deutériés sont conservés sur tamis moléculaire 4 Å.

D'une façon générale, les analyses à l'aide de la rmn du proton ont été réalisées sur des solutions de 0.5 mmol d'oxazoline-4 dans 0.3 cm^3 de solvant deutérié. Les spectres de rmn du carbone 13 ont été enregistrés sur des solutions de concentration de 1 à 3 mol/L suivant le nombre d'entités formées.

Protonation par l'acide fluorosulfonique FSO_3H dans CD_3CN

Les fluorosulfonates d'iminium obtenus n'étant pas solubles dans $CDCl_3$, nous avons utilisé l'acétonitrile deutérié CD_3CN. Le mode opératoire utilisé est le même pour les oxazolines **1***a–d*: à une solution (ou à une suspension) de 0.5 mmol d'oxazoline-4 dans 0.3 cm^3 d'acétonitrile deutérié, dans un tube de rmn, fermé par un septum, on ajoute sous argon, à l'aide d'une microseringue, lentement, 50 mg de FSO_3H (soit 28.7 μL). La solution est alors agitée et le spectre enregistré. Lors d'une protonation à basse température, la solution d'oxazoline-4 est amenée à −60°C. L'acide lui-même préalablement refroidi est alors ajouté lentement puis la solution agitée. Le même protocole est utilisée pour l'enregistrement des spectres de carbone 13 (2 cm^3 de CD_3CN, 2 mmol d'oxazoline-4 et 2 mmol de FSO_3H (115 μL) lorsqu'une ou deux entités sont formées et 2 cm^3 de CD_3CN, 6 mmol d'oxazoline-4 et 6 mmoles de FSO_3H (345 μL) dans les autres cas).

*Protonation de **1**e par FSO_3H dans SO_2 liquide*

L'oxazoline-4 **1***e* est placée dans un tube de rmn fermé par un septum et purgé à l'argon. Ce tube est refroidi à −40°C et la quantité de SO_2 liquide nécessaire est condensée directement dans le tube à l'aide d'une grande aiguille (140.5 mg de **1***e* et 0.3 cm^3 de SO_2 liquide pour le proton, et 3 mmol de **1***e* (843 mg) et 2 cm^3 de SO_2 liquide pour le carbone 13). La solution est alors congelée à −100°C et l'acide ajouté lentement, le tube étant incliné, de telle façon qu'il n'y ait pas d'échauffement notable lors du contact. On laisse alors revenir lentement à −70°C et on agite à cette température; 10% de C_6D_6 sont ajoutés pour verrouiller le champ de l'appareil de rmn. Les spectres sont enregistrés à −40°C.

Protonation par l'acide trifluoroacétique

Ces études sont réalisées dans $CDCl_3$; 0.3 cm^3 de solution contenant 0.5 mmol d'oxazoline-4 pour le proton et 2 cm^3 de solution contenant de 2 à 6 mmol d'oxazoline pour le carbone 13. Les échantillons sont préparés comme indiqué précédemment (1 mmol de CF_3CO_2H = 76.5 μL).

Acid-catalysed cleavage of 4-halonortricyclenes in deuterated medium; evidence that the norbornyl cation is an unsymmetrical species

NICK HENRY WERSTIUK, DALJIT DHANOA, AND GEORGE TIMMINS
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received August 24, 1979

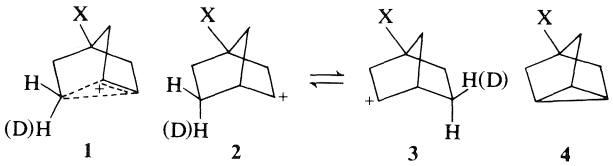
NICK HENRY WERSTIUK, DALJIT DHANOA, and GEORGE TIMMINS. Can. J. Chem. **57**, 2885 (1979).

We have determined the *endo*:*exo* deuterium ratios at C(6) of the *exo*-acetates obtained by D_2SO_4-catalysed cleavage of nortricyclene (**4***a*), 4-chloronortricyclene (**4***b*), 4-bromonortricyclene (**4***d*), and 4-iodonortricyclene (**4***e*). That the ratios are 1.09 ± 0.03, 1.30 ± 0.04, 1.40 ± 0.02, and 1.48 ± 0.02 for ring-opening of **4***a*, **4***c*, **4***d*, and **4***e*, respectively, establishes that the norbornyl cation is an unsymmetrical rapidly-equilibrating species.

NICK HENRY WERSTIUK, DALJIT DHANOA et GEORGE TIMMINS. Can. J. Chem. **57**, 2885 (1979).

Nous avons déterminé les rapports *endo*:*exo* du deutérium au niveau du carbone 6 des acétates obtenus par clivage catalytique à l'aide du D_2SO_4 du nortricylène ayant en position 4 les substituants suivants: Cl (**4***b*), Br (**4***d*), I (**4***e*). Ces rapports qui sont respectivement de 1.09 ± 0.03, 1.30 ± 0.04, 1.40 ± 0.02 et 1.48 ± 0.02 pour l'ouverture des cycles **4***a*, **4***c*, **4***d* et **4***e* établissent que le cation norbornyle est une espèce non symétrique en équilibre rapide.
[Traduit par le journal]

The norbornyl-cation controversy has held the attention of physical organic chemists for the past two and one-half decades (1). We, along with many researchers, were drawn to make a contribution, and thereby provide a solution to the problem (2, 3). The enormous effort which has been expended world-wide to solve the problem has heen documented clearly by Brown (1).[1] As we see it, the central issue of the controversy is stated simply in the following question. Is the symmetrical norbornonium (non-classical) ion (**1***a*) an intermediate or does it best represent the transition state between the rapidly-equilibrating unsymmetrical (classical) ions **2***a* and **3***a*?



a X = H
b X = F
c X = Cl
d X = Br
e X = I

By employing classical substituent effect studies to ascertain the structure of the norbornyl cation, researchers have introduced substituents on the 2.2.1-framework and thereby destroyed the symmetry of **1***a* and rendered the equilibrating classical ions non-degenerate. Since C(4) is the only site where a single substitution does not destroy symmetry or clutter the front-face of the cation, we reasoned that the critical question (*vide supra*) could be answered if we established whether or not the mass of the substituent at C(4) affects the chemistry of the norbornyl cation. To that end we chose to study the stereochemistry of the acid-catalysed cleavage of 4-halonortricyclenes **4***a*, **4***b*, **4***c*, **4***d*, and **4***e*. If cleavage yields non-classical cations **1***a–e*, then the stereochemistry of the ring-opening, as monitored by the *endo*:*exo* deuterium ratio at C(6), would be unaffected by the mass of the substituent at C(4). However, if cleavage yields classical cations and the ponderal effect[2] (4) of the substituent becomes progressively larger as the mass of the substituent increases, a change in the stereochemical outcome of the reaction would be observed because the rate of rearrangement of ions **2***a–e* to **3***a–e* should decrease through the series. Consequently, reaction of the first-formed 6-*endo*-*d*-cation with solvent should compete more effectively with rearrangement. We wish to report that the *endo*:*exo* deuterium ratio at C(6) of the *exo*-acetate obtained

[1]With comments by P. von R. Schleyer.

[2]de la Mare (4) has suggested that the ponderal effect is derived from non-polar, non-steric, entropy effects which depend on mass.

0008-4042/79/212885-02$01.00/0

TABLE 1. *Endo*:*exo* deuterium ratios at C(6) of norbornyl acetates*

Substrate	*Endo*:*exo* deuterium ratio
4*a*	1.09±0.03
4*c*	1.30±0.04
4*d*	1.40±0.02
4*e*	1.48±0.02

*The errors quoted are the average deviations from the mean that was obtained by analysis of at least three ^{2}Hmr spectra of the deuterated norbornanol obtained from three ring-openings.

TABLE 2. Percent deuterium at C(1) and C(2) of norbornyl acetates

Substrate	Percent deuterium* C(1)	C(2)
4*a*	7.4±0.7	6.8±0.5
4*c*	3.0±0.5	3.1±0.7
4*d*	3.2±0.2	3.9±0.9
4*e*	4.3±0.3	3.9±0.3

*The errors quoted are the average deviations from the mean that was obtained by analysis of at least three ^{2}Hmr spectra.

by D_2SO_4-catalysed[3] ring-opening of nortricyclene (**4***a*), 4-chloronortricyclene (**4***c*), 4-bromonortricyclene (**4***d*), and 4-iodonortricyclene (**4***c*)[4] does indeed become larger as the mass of the substituent at C(4) is increased (Table 1).

To determine the deuterium distribution, we transformed the deuterated acetates into deuterated *exo*-2-norbornanol[5] and recorded at least three FT ^{2}Hmr spectra for each norbornanol complexed with Pr(fod)$_3$. The *endo*:*exo* deuterium ratios of C(6) were derived from the relative peak areas which we obtained from the ^{2}Hmr spectra by means of a computerized curve-fitting routine.

Our value of 1.09 ± 0.03 for the ring-opening of **4***a* agrees well with the ratio of 1.08 ± 0.05 obtained by Nickon and Hammons (7). To check for deuterium scrambling in the products, we determined the deuterium distributions at two stages[6] during the ring-openings of **4***a*, **4***c*, and **4***d*. Within experimental error the distributions were identical at both stages. That optically active *exo*-2-norbornyl acetate does not racemize at a detectable rate under the reaction conditions (7) is further evidence that deuterium-scrambling is not important.

Since the *endo*:*exo* deuterium ratios become larger as the mass of the substituent increases, a ponderal effect contributes to the activation energy of the degenerate rearrangement. Clearly then, the norbornyl cation is an unsymmetrical rapidly-equilibrating species. It is interesting to note also that the $\Delta G^{\neq}$ ($\simeq$ 6 kcal/mole) for the 6,2 hydride shift is also affected by mass of the substituent at C(4) (Table 2).

Effect of solvent (benzene, ethanol, cyclohexane) on the partial molal volumes of organic compounds

JOHN T. EDWARD, PATRICK G. FARRELL, AND FEREIDOON SHAHIDI[1]
Department of Chemistry, McGill University, 801 Sherbrooke St. W., Montreal, P.Q., Canada H3A 2K6

Received May 11, 1979

JOHN T. EDWARD, PATRICK G. FARRELL, and FEREIDOON SHAHIDI. Can. J. Chem. **57**, 2887 (1979).

The partial molal volumes of *n*-alkanes and *n*-alkanols dissolved in benzene, ethanol, or cyclohexane are given with satisfactory accuracy by the equation previously developed for solutions in carbon tetrachloride, if certain parameters (the covolume, the volume increment for the hydroxyl group, and the volume decrement for some *gauche* interactions) are changed. Additionally, it is necessary to postulate a greater coiling of the alkyl chains when dissolved in cyclohexane.

JOHN T. EDWARD, PATRICK G. FARRELL et FEREIDOON SHAHIDI. Can. J. Chem. **57**, 2887 (1979).

On obtient avec une précision suffisante les volumes molaires partiels des *n*-alcanes et *n*-alcanols dissous dans le benzène, l'éthanol ou le cyclohexane en se servant de l'équation développée antérieurement pour les solutions dans le tétrachlorure de carbone, si on change certains paramètres (comme le co-volume, l'incrément du volume pour le groupe hydroxyle et le décrément du volume pour quelques interactions *gauches*). De plus il est nécessaire de concevoir un plus grand encombrement des chaînes alkyles en solution dans le cyclohexane.

[Traduit par le journal]

Introduction

The partial molal volumes $\bar{V}^0$ of organic solutes reflect not only the intrinsic volumes of the solute molecules, but the extent to which they interact with solvent. Furthermore, when the solute is made up of flexible chain molecules, $\bar{V}^0$ depends on the extent to which the molecules are extended or coiled in solution. In the present paper we report $\bar{V}^0$ values in the three solvents, benzene, ethanol, and cyclohexane, for several *n*-alkanes, which should interact feebly with the solvents, and several *n*-alkanols, which should interact more strongly. Additionally, we compare the $\bar{V}^0$ behaviour of these flexible chain molecules with that of the rigid adamantane and the relatively rigid cycloalkanes.

In previous work we have shown that in carbon tetrachloride at 25°C, $\bar{V}^0$ of straight- and branched-chain alkanes (1), haloalkanes (2), ketones (3), ethers (3), alcohols (3), and of cyclic compounds (4) is given with reasonable accuracy by the equation

$$[1] \quad \bar{V}^0 = V_c + \sum_1^m n^k I^k + \sum_1^n Z_g{}^l \delta^l + C$$

where V_c is a constant covolume of 11.6 mL mol^{-1}, n^k is the number of, and I^k the volume increment associated with, groups of type k, $Z_g{}^l$ is mol fraction of, and δ^l the decrement associated with, *gauche* interactions of type l, and C is a cyclization parameter whose magnitude depends on the number of skeletal atoms in the ring or cage. Z_g was calculated by a method much used by Mann (5), which assumed an enthalpy difference ΔH_g of 700 cal mol^{-1} between an *anti* and *gauche* ($g_{C-C}^{C/C}$) arrangement in a hydrocarbon chain. The I and δ parameters were obtained by systematic study of a large number of compounds (128 chain and 47 ring or cage compounds), including many isomers.

It would be interesting to test [1] in a similar fashion for solvents other than carbon tetrachloride, but for this to be done with any pretence to thoroughness $\bar{V}^0$ values of large numbers of isomeric compounds must be obtained. Such a project is beyond our means at the moment, and the present paper reports only a brief reconnoitering expedition into unexplored territory. This shows that $\bar{V}^0$ in other solvents can be accommodated by [1], and indicates the desirability of more extensive studies to test [1] in a range of solvents.

Results

Partial molal volumes in benzene and in ethanol are reported in Tables 1 and 5, and in cyclohexane in Tables 4 and 5. Where comparison with data in the literature is possible (6, 7), agreement for the most part is excellent (taking account, where necessary (6), of small differences in temperature of the measurements). The result for methanol in cyclohexane (Table 4) is exceptional, but the value reported in the literature (6) was obtained by extrapolation from higher concentrations than those used by us, and under these conditions the effects of dimerization, trimerization, etc., can be important (8).

A preliminary analysis of these results was made using the equation (9):

$$[2] \quad \bar{V}^0 = 4\pi N(r_w + \Delta)^3/3$$

where N is the Avogadro number, r_w the van der Waals radius (10) of the solute molecule (assumed spherical), and Δ a parameter measuring the void or empty volume (11) associated with the solute molecule. We had expected Δ to diminish in roughly linear fashion with increase in the internal pressure P_i (12) or cohesive energy density (*c.e.d.*) (13) of the solvent, but instead Δ remained approximately constant, as shown in Table 2. It can also be seen in Table 2 that the a parameter for alkanes, defined by the equation (14):

$$[3] \quad \bar{V}^0 = aV_w + b$$

where V_w is the van der Waals volume of N solute molecules, likewise remains roughly constant. This empirical equation holds well for cylindrical molecules such as *n*-alkanes, the parameter a depending on the amount of empty volume associated with the repeating methylene unit (15).

This analysis indicates that about the same empty volume is associated with methyl, methylene, and methine groups in the three solvents under investigation as in carbon tetrachloride. Accordingly, we shall assume (as an approximation) the same values for the increments I for methyl, methylene, and methine in all four solvents. On the other hand, the empty volume associated with the hydroxyl group, which has a substantial dipole moment and hence can interact with solvents by dipole – induced dipole effects, would be expected to vary with polarizability and hence with solvent. For this reason I also would be expected to vary with solvent. We have found the best agreement between experimental and calculated values of $\bar{V}^0$ using the values of I listed in Table 3.

We now consider the results for solutions of *n*-alkanes and *n*-alkanols in benzene. Values of $\bar{V}^0$ calculated by [1] using the parameters of Table 3, and Z_g values already reported (1, 3) for these solutes in carbon tetrachloride, are shown in Table 1. Agreement with experimental values is almost within the limits of experimental error, except for methanol, a compound aberrant also in carbon tetrachloride.

Values of $\bar{V}^0$ calculated in the same way for these solutes in ethanol also agree well with experimental values. In ethanol (unlike carbon tetrachloride (3)) it was assumed that $Z_{g(C—C)}^{O/C} = 0$ for *n*-propanol and higher alcohols, hydrogen bonding of the hydroxyl group to solvent tending strongly to inhibit the $g_{O—C}^{O/C}$ arrangement.

The accommodation of [1] to the experimental $\bar{V}^0$ values in cyclohexane (Table 4) offers a more serious challenge: $\bar{V}^0$ of *n*-pentane is larger in cyclohexane than in carbon tetrachloride, but $\bar{V}^0$ of *n*-decane is smaller. These results cannot be accommodated if $Z_{g(C—C)}^{C/C}$ values remain the same in the two solvents, but require $Z_{g(C—C)}^{C/C}$ to increase more rapidly with chain length in cyclohexane. This in turn requires the enthalpy difference ΔH_g between *gauche* and *anti* to be smaller in cyclohexane. The calculated

TABLE 3. Parameters for calculation of $\bar{V}^0$ using [1]

Solvent	V_c (mL mol^{-1})	Hydroxyl I (mL mol^{-1})	$\delta^{C/C}_{C-C}$ (mL mol^{-1})	ΔH_g (cal mol^{-1})
Ethanol	12.6	1.1	−2.5	700
Benzene	11.4	5.8	−1.1	700
Carbon tetrachloride	11.6	6.1	−2.5	700
Cyclohexane	13.3	9.7	−2.5	500

values of $\bar{V}^0$ shown in Table 4 have been obtained assuming $\Delta H_g = 500$ cal mol^{-1}. Again, agreement between calculated and experimental values is reasonable, considering the simplicity of the approach; the data at present are too sparse to warrant a more elaborate analysis.

The solute molecules so far considered have been chain molecules existing in solution as mixtures of conformers. In Table 5 we give partial molal volumes of adamantane and cyclohexane, which have fixed or relatively fixed structures, and of several cycloalkanes, most of them existing in one or more mobile conformations. From these values of $\bar{V}^0$, C values have been calculated from [1] using the parameters of Table 3. Trends in C with ring size run parallel in the different solvents. Possible interpretations of C have been given earlier (4).

Discussion

It is apparent that with adoption of the parameters of Table 3, $\bar{V}^0$ in the three solvents under investigation may be calculated from [1] with reasonable accuracy. We now consider whether the relative magnitudes of these parameters accord with the intuitive picture of partial molal volumes developed in our previous papers.

The covolume V_c is the volume of the solvent cavity required to accommodate a point kinetic particle of no intrinsic volume

$$\left(\sum_1^m n^k I^k = 0, \qquad \sum_1^n Z_g{}^l \delta^l = 0, \qquad C = 0\right)$$

It should accordingly be related to the b parameter of Terasawa *et al.* (14) ($\bar{V}^0 = b$ when $V_w = 0$), and this relationship is shown in Fig. 1*A*. We have already given reasons why V_c should be expected to be less than b (1).

There is also an indication (Fig. 1*B*) that V_c may be related to the van der Waals volume v_w of the solvent molecules. Bondi (16) has discussed the effect to be expected from varying particle size on the closeness of packing of spheroids, but without firm conclusions. The present work indicates the desirability of a systematic study of the variation of V_c and b in solvents made up of spherical, aprotic molecules of varying size. The point for the protic solvent, ethanol (not shown), lies far above the straight line

TABLE 5. Partial molal volumes $\overline{V}^0$ and cyclization factors C (both in mL mol^{-1}) for cyclic compounds and adamantane in various solvents

[a]From ref. 4.

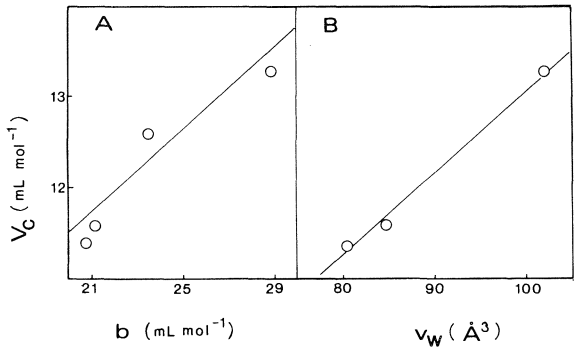

FIG. 1. Relation between V_c and b (A), and between V_c and v_w (B).

of Fig. 1*B*, but the introduction of a partially inert solute molecule into a highly structured, hydrogen-bonded solvent would be expected to break hydrogen bonds and hence to lead to an increase in volume greater than expected from the mere formation of a cavity in the solvent.

We now consider the increment I for the hydroxyl group. If this group interacted with benzene, carbon tetrachloride, or cyclohexane as weakly as do methyl and methylene, it would have $I \simeq 16.6$ mL mol^{-1} (3). The increments in all three solvents are smaller, and reflect the strength of dipole – induced dipole interactions in the order: benzene > carbon tetrachloride > cyclohexane, the order of decreasing polarizability (17). In the protic solvent, ethanol, strong interaction through hydrogen bonding is also possible, and hence I is smallest in this solvent.

Explanations for the differences of $\delta^{C/C}_{C-C}$ (Table 3) and C (Table 5) in the different solvents are less obvious. Variability of δ (e.g., $\delta^{Cl/Cl}_{C-C}$, $\delta^{Br/C}_{C-C}$ (2)) with solvent has been noticed before but with molecules containing polar groups, and for which changes in conformation should result in changes in dipole moment.

The reduction of ΔH_g on changing solvent from carbon tetrachloride to cyclohexane is also remarkable. Latest studies (reviewed in ref. 18) indicate an enthalpy increase of about 900 cal mol^{-1} on going from *anti* to *gauche* butane in the gas phase. This difference is reduced when *n*-butane is in solution, perhaps because the internal pressure exerted by the solvent favours formation of the more compact *gauche* form (19). However, there is no simple correlation, as might be expected (19), between ΔH_g (Table 3) and P_i or *c.e.d.* (Table 2). Possibly a more important parameter is the London dispersion force between the hydrocarbon chain and the solvent molecules, which would favour a more extended chain and closer solvent–solute contacts; this would be weakest in cyclohexane solution.[2] The extent of coiling of polymer chains has been explained in similar fashion (20).

Accepting a smaller ΔH_g in cyclohexane, we can expect *n*-alkane chains to be more coiled in this solvent than in carbon tetrachloride. Hence each successive addition of CH_2 to the chain causes a smaller increase in $\overline{V}^0$ in cyclohexane than in carbon tetrachloride. This explains the smaller a parameter in this solvent (Table 2).

In summary, the present work indicates that [1] will probably prove valid for a variety of organic solvents made up of spherical molecules. It would be desirable to test it more stringently by obtaining $\overline{V}^0$ values for large numbers of isomeric alkanes in each single solvent, and thence obtaining *ab initio* the parameters I and δ, as was done for carbon tetrachloride solutions (1).

Experimental

Solvents and solutes were commercial products, and were purified by methods described earlier (1). The technique for measuring the densities of solutions has also been described (1). In all cases linear variation of the apparent molal volume with concentration was observed over the concentration range (< 0.5% w/w) employed.

Partial molal volumes of organic compounds in carbon tetrachloride. V. Cyclic alkanes, ethers, alcohols, ketones, and bromides

JOHN T. EDWARD, PATRICK G. FARRELL, AND FEREIDOON SHAHIDI[1]

Department of Chemistry, McGill University, 801 Sherbrooke St. W., Montreal, P.Q., Canada H3A 2K6

Received May 11, 1979

JOHN T. EDWARD, PATRICK G. FARRELL, and FEREIDOON SHAHIDI. Can. J. Chem. **57**, 2892 (1979).

The partial molal volumes $\overline{V}^0$ or 47 mono- or polycyclic alkanes, ethers, alcohols, ketones, and bromides have been determined in carbon tetrachloride at 25°C. $\overline{V}^0$ of most of these compounds can be calculated with moderate (±1–2%) accuracy using an equation containing parameters previously developed for acyclic compounds, and an additional cyclization parameter C, which is roughly linear with the number n of atoms in the ring, from $n = 3$ ($C = +5.3$ mL mol^{-1}) to $n = 10$ ($C = -21.0$ mL mol^{-1}). Substituted cyclohexanols and some polyfunctional compounds had $\overline{V}^0$ considerably lower than calculated.

JOHN T. EDWARD, PATRICK G. FARRELL et FEREIDOON SHAHIDI. Can. J. Chem. **57**, 2892 (1979).

On a déterminé le volume molaire partiel $\overline{V}^0$ de 47 composés mono ou polycycliques du type: alcanes, éthers, alcools, cétones et bromures, en solution dans le tétrachlorure de carbone à 25°C. Pour la plupart de ces composés, $\overline{V}^0$ peut être calculé avec une précision modérée de (±1–2%) en utilisant une équation contenant les paramètres développés antérieurement pour les composés acycliques et un paramètre additionnel de cyclisation C qui est grossièrement proportionnel au nombre n d'atomes du cycle, à partir de $n = 3$ ($C = +5.3$ mL mol^{-1}) à $n = 10$ ($C = -21.0$ mL mol^{-1}). Les cyclohexanols substitués et quelques composés polyfonctionnels ont des valeurs de $\overline{V}^0$ nettement plus faibles que celles calculées.

[Traduit par le journal]

Introduction

Straight- and branched-chain aliphatic compounds dissolved in carbon tetrachloride exist as mixtures of rapidly equilibrating conformers. If the mole fraction of a conformer is γ, and $z_g{}^l$ represents the number of *gauche* arrangements of type l along the chain, the mole fraction of *gauche* arrangements of this type due to all conformers of the compound is $Z_g{}^l = \sum \gamma z_g{}^l$. γ, and thence $Z_g{}^l$, may be calculated by well-established methods (1, 2). The partial molal volumes $\overline{V}_0$ of aliphatic chains are reduced by an amount linearly related to $Z_g{}^l$ (2–4).

The looping of an extended chain into a ring necessarily involves the creation of a number of *gauche* or eclipsed arrangements, and so might be expected to result in a diminished volume. This indeed has been found true in other additive schemes for molecular volumes (5, 6) which, however, have taken no account of conformational effects and have consequently had only limited usefulness. We shall allow for the effect of cyclization by adding the parameter C to the equation previously employed to account for conformational effects with chain compounds (2–4):

$$[1] \quad \overline{V}^0 = V_c + \sum_1^m n^k I^k + \sum_1^n Z_g{}^l \delta^l + C$$

(see ref. 3 for definition of other symbols). In applying this equation $Z_g{}^l$ will refer only to the mole fraction of *gauche* arrangements of type l due to groups attached to a ring, and not to *gauche* arrangements found within the ring or cage portion of the molecule, for which account is taken in C.

Results

The partial molal volumes of 47 ring and cage compounds in carbon tetrachloride have been determined and are given in Table 1. For 21 of these compounds devoid of side groups or chains ($Z_g = 0$), C has been calculated from [1] using V_c and the other parameters determined in previous work (2–4). A plot of C for these compounds against n, the number of ring atoms, shows a roughly linear relationship changing slope at $n = 10$ (Fig. 1). The values of C given by the two straight lines of Fig. 1 for different values of n are given in Table 2.

Using these values of C, $\overline{V}^0$ has been calculated for 42 of the 47 compounds of Table 1 by [1]. ($\overline{V}^0$ for adamantane and two adamantane derivatives was calculated using C footnoted in Table 2.) For compounds having an atom other than hydrogen or carbonyl oxygen attached to the ring, it was necessary

[i] $Z_{g(C-C)}^{Br/C} = 2$.

to calculate Z_g[l]. When the atom or group is completely or almost completely in the equatorial position, as in 1-bromoadamantane or *trans*-4-methylcyclohexanol (7), $Z_g = 0$. For other compounds the mole ratios of conformers may be calculated by well-established methods (7). For example, cyclohexanol (**24**) can be shown to be made up of two conformers, one ($\gamma = 0.76$) having the hydroxyl group equatorial ($z_{g(C-C)}^{O/C} = 0$), and one ($\gamma = 0.24$) having it axial ($z_{g(C-C)}^{O/C} = 2$), whence $Z_{g(C-C)}^{O/C} = 0.5$. The other cyclic alcohols (**22**, **23**, **25**, **30**) will have the hydroxyl group to some extent in a *quasi-axial* arrangement, and hence a proportion of molecules having arrangements not very different from $g_{(C-C)}^{O/C}$ found in *axial* cyclohexanol. However, information which would enable us to calculate the mole fraction of such arrangements is lacking, and so we have applied [1] to the cyclic alcohols **22**, **23**, **25**, and **30** assuming $Z_{g(C-C)}^{O/C} = 0.5$ for all of them.

These and other values of Z_g are given as footnotes to Table 1. In some cases (e.g., **13**, **14**) these cannot be better than guesses, since not only the shape but also the configuration (*cis* or *trans*) of the molecules is not known.

Discussion

The scatter about the straight lines of Fig. 1 shows that the values of C in Table 2 are only rough averages, and so close agreement between calculated and experimental values in Table 1 cannot be expected. However, for many of the cyclic alkanes (**1–5**), alcohols (**22–25**, **30**), and ketones (**32–38**) agreement is within the limits of experimental error. However, for some substituted cyclohexanols (**27–29**) the discrepancy is great. More data on substituted cyclohexanes and substituted cyclohexanols would be desirable.

Some of the polyfunctional compounds (**15**, **17**) also have partial molal volumes appreciably smaller than calculated. Newman and Mackle (9) have pointed out that the polar character of compounds such as **15** is usually greater than that of their acyclic analogues; this should have the effect of making $\overline{V}^0$ of the cyclic compounds less than expected on the basis of I and δ values derived from a study of acyclic compounds. On the other hand, the cyclic ketones (**32–41**) tend to have $\overline{V}^0$ values slightly higher than calculated; it is possible that complexation of the carbonyl group by solvent carbon tetrachloride molecules (4) is slightly less effective in the cyclic than the acyclic compounds. However, such speculations must remain highly tentative until more data have been accumulated.

The central problem raised in this paper is the interpretation of C. The following points should be noted:

(*a*) Cyclization does not necessarily involve a reduction in volume: C for three- and four-membered rings is positive.

(*b*) Similarly, C cannot be explained primarily by a reduction in V_w (and thence in $\overline{V}^0$ (10)). The compression of the van der Waals radii of some hydrogen atoms pointing inwards in medium-sized rings reaches a maximum for $n = 9$–10, and thereafter diminishes (11), while C continues to become more negative after $n = 10$ (Fig. 1).

It seems likely that an explanation of C requires a more profound understanding of the effect of relative size of solute and solvent molecules on the efficiency of packing in the solution. It may be noted that the limited data available for cycloalkanes in other solvents (benzene, cyclohexane) indicate that relationships of the sort shown in Fig. 1 are general, but that for a given n, C becomes larger in solvents having molecules of larger size (12).

Experimental

The compounds investigated were commercial products, except for **28** and **29**, which were the gift of Dr. F. L. Chubb, and **45–47**, the gift of Professor M. A. McKervey. Purification of materials and techniques of measurement were carried out as described previously (2–4).

Hydrogen exchange and isomerization in *ortho* substituted benzamides. On the question of free rotation in an *N*-protonated amide

ROBERT A. MCCLELLAND AND WILLIAM F. REYNOLDS

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received May 1, 1979

ROBERT A. MCCLELLAND and WILLIAM F. REYNOLDS. Can. J. Chem. **57**, 2896 (1979).

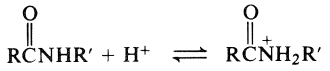
Rate constants have been obtained for the acid-catalyzed N–H exchange of *N*-methyl, 2,*N*-dimethyl, and 2,4,6,*N*-tetramethylbenzamide and the acid-catalyzed isomerization of the three corresponding *N*,*N*-dimethylbenzamides. The ratio $k_{H^+}{}^{ex}/k_{H^+}{}^{iso}$ increases significantly with increased number of *ortho* methyl substituents. This is explained in terms of a suggestion of Perrin, that C—N bond rotation is not completely free in the *N*-protonated amide, since it must compete with a diffusion limited deprotonation reaction. The isomerization reaction, which requires such a rotation, is therefore slowed by *ortho* methyl substituents which hinder rotation, relative to the exchange reaction, which does not require rotation.

ROBERT A. MCCLELLAND et WILLIAM F. REYNOLDS. Can. J. Chem. **57**, 2896 (1979).

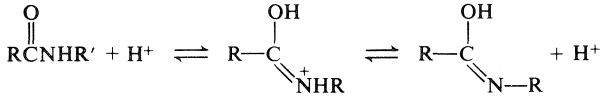
On a obtenu les constantes de vitesse de la réaction d'échange N–H, catalysée par les acides, dans le case de trois *N*-méthylbenzamides, soit le produit non substitué et ceux substitués par un méthyle en position 2 ou trois méthyles en 2, 4 et 6 ainsi que dans le cas de l'isomérisation, catalysée par les acides, des trois *N*,*N*-diméthylbenzamides correspondants. Le rapport $k_{H^+}{}^{ex}/k_{H^+}{}^{iso}$ augmente d'une façon importante avec le nombre de substituants méthyles en position *ortho*. Ceci est expliqué à l'aide de la suggestion de Perrin qui veut que la rotation de la liaison C—N ne soit pas complètement libre dans l'amide protoné puisqu'elle doit entrer en compétition avec une diffusion limitée de la réaction de protonation. Par rapport à la réaction d'échange qui n'implique pas de rotation, la réaction d'isomerisation est ralentie par les substituants méthyles en position *ortho*, qui gênent la rotation.

[Traduit par le journal]

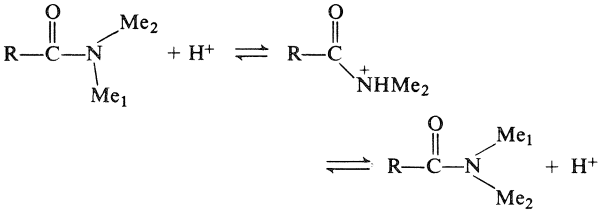
Two mechanisms have now been proposed for the acid-catalyzed hydrogen exchange reaction of amides, one involving protonation–deprotonation on the amide nitrogen (1)



and a second more circuitous route involving an intermediate imidic acid, formed from the oxygen protonated amide (2, 3)

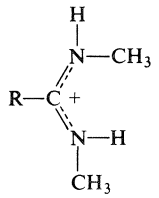


The latter mechanism was based on the observation that rates of exchange of *N*-methyl amides are generally greater than rates of isomerization of corresponding *N*,*N*-dimethyl amides. The isomerization must occur via the nitrogen protonated amide,

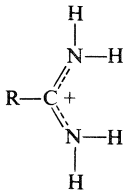


leading to the suggestion that the larger rate of exchange is due to the additional route available to that reaction.

More recently Perrin (4) claims to have ruled out the imidic acid mechanism for the acid-catalyzed exchange of primary amides ($RCONH_2$). This proposal was based on the observation that the two hydrogens undergo exchange at different rates, and the order of reactivity is not that expected for the imidic acid pathway. The diastereotopic hydrogens of amidinium ions (**I** (5) and **II** (6)) also undergo acid-catalyzed exchange at different rates.



I



II

Perrin argues (4, 6) that such observations can be explained in terms of intermediate nitrogen protonated species, providing that the hydrogens on the nitrogen in those species do not become equivalent. Perrin points out that although rotation about the C—N single bond in the nitrogen protonated species is

undoubtedly very fast, so is the deprotonation process, which should be very nearly a diffusion limited reaction.

In this paper we consider the question of the mechanism of the exchange and isomerization reactions in *N*-methyl and *N*,*N*-dimethyl amides respectively. Our reasoning was that if C—N single bond rotation is indeed important, the introduction of groups which might hinder this process should show up in the rates. We have therefore measured rates of exchange and isomerization for amides containing one and two *ortho* methyl substituents, and indeed find that there is a pronounced effect.

Experimental Section

Amides were prepared by passing methylamine or dimethylamine through a solution in ether of the appropriate acid chloride. Physical properties of known compounds agreed with literature values. In the case of new compounds satisfactory analyses were obtained.

Spectra were recorded on a Varian T-60 NMR spectrometer, with a probe temperature of 33 ± 0.5°C. Concentrations of amides ranged from 0.04 to 0.2 *M*; rate constants were established to be independent of this concentration. Except where noted, second-order rate constants for the H^+ catalyzed exchange or isomerization were determined by varying the acid concentration until the pair of signals due to the *N*-methyl group or groups was just coalesced into one broad signal with a maximum at the mean position (7). The second-order rate constant was calculated from the formula (3, 7)

$$k = (\pi \cdot \Delta)/(1.41 \cdot [H^+])$$

where Δ ≡ separation in cps of the signals when no acid is present, and $[H^+]$ = concentration of acid.

While more precise values could be obtained by a complete line shape analysis, this approach should yield rate constants which are accurate to ca. 10%, particularly since the line width in the absence of exchange was less than 10% of the doublet splitting and since Δ was insensitive to acidity in the absence of exchange. Rate constants of this accuracy seemed more than sufficient for our purpose.

Results

Table 1 lists second-order rate constants for the acid-catalyzed N–H exchange of three *N*-methyl benzamides ($k_{H^+}^{ex}$) and the acid-catalyzed isomerization ($k_{H^+}^{iso}$) of the three corresponding *N*,*N*-dimethylbenzamides. For the unsubstituted compounds reasonable agreement can be seen between our results and those taken from the literature. In the case of 2,*N*,*N*-trimethylbenzamide, an acid concentration of 5.6 *M* is required to reach the coalescence point. For this compound the rate constant was also calculated from the broadened signals in 1.0 *M* HCl, and the number shows reasonable agreement with that obtained from the coalescence point. The compound 2,4,6,*N*-tetramethylbenzamide was not sufficiently soluble in water to obtain suitable nmr spectra, and we were forced to employ solutions containing 33% acetone-d^6. For 2,*N*-dimethylbenzamide the rate constant for exchange in water is 1.34 times that in 33% acetone-d^6. This factor was used to estimate the rate constant for the exchange of 2,4,6,*N*-tetramethylbenzamide in water alone. With 2,4,6,*N*,*N*-pentamethylbenzamide there is no broadening of the two *N*-methyl peaks in any acid solution. We have placed an upper limit on the second-order rate constant for isomerization in the following way. In any acid solution a first-order rate of isomerization of 1 s^{-1} would result in a 0.3 Hz broadening of the signals in the doublet, and this would have been detectable. Cox (8) has previously shown that rates of isomerization of *N*,*N*-dimethylbenzamide remain reasonably linear in H^+ concentration up to 3–4 *M* HCl, although above this point they reach a maxi-

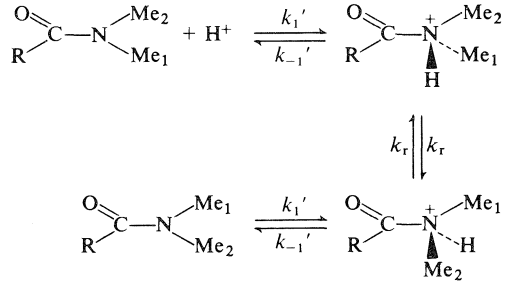
mum value and then decrease with increasing acidity. Assuming that a 1 s^{-1} rate of isomerization would be observed, and assuming that the rate of isomerization is still linear in H^+ concentration in 4 *M* HCl, the lack of broadening in that acid means that $k_{H^+}{}^{iso}$ is less than 0.25 M^{-1} s^{-1}. (This argument depends very strongly on the pK_a value of the amide, since the levelling-off in the rate observed by Cox (8) is associated with protonation. Some preliminary measurements were carried out to determine the basicity of the pentamethylbenzamide, and suggest that this amide is not substantially protonated (<25%) in 4 *M* HCl. Unfortunately, this compound does not exhibit a predominant spectral change on protonation, and accurate protonation data are therefore difficult to obtain.)

Discussion

The results reported in Table 1 show that successive introduction of *ortho* methyl groups causes a decrease in the rates of both the acid-catalyzed N–H exchange reaction of an *N*-methylbenzamide and the acid-catalyzed isomerization of an *N,N*-dimethylbenzamide, with the effect being considerably more pronounced on the isomerization reaction.

Isomerization of N,N-*Dimethyl Amides*

The dramatic effect on this reaction can be explained in simple terms by recognizing that in order for isomerization to occur there must be a rotation of some sort about the C—N bond of the *N*-protonated intermediate. This suggests that the *ortho* methyl groups are slowing the isomerization by hindering this rotation. The argument can be illustrated in more detailed terms using a scheme such as shown below.



We have drawn for the *N*-protonated amides in this scheme a particular conformational form, the one favored in Perrin's arguments (6), but other conformations also suffice. What is required is (*a*) that the conformation of the *N*-protonated amide which is initially produced be one in which the two methyl groups are not equivalent, and (*b*) that deprotonation occur via the microscopic reverse of protonation or, in other words, from the same or equivalent conformation. With these requirements it can be seen that immediate deprotonation of the initially formed cation can only return the system back to amide with the *N*-methyl groups in their original configuration. For isomerization to occur there must be rotation about the C—N bond, to a conformation of equivalent energy, followed then by deprotonation. Making a stationary state assumption in the two conformations of the *N*-protonated amide, the second-order rate constant for isomerization is given by eq. [1].

$$[1] \quad k_{H^+}{}^{iso} = k_1'k_r/(k_{-1}' + 2k_r)$$

This equation predicts that $k_{H^+}{}^{iso} = k_1'/2$ only when $k_r \gg k_{-1}'$, *but* if the rotation step and the deprotonation step proceed at similar rates, or if rotation is slower, this is not true and $k_{H^+}{}^{iso}$ is less than $k_1'/2$. In fact, the slower the rotation occurs relative to deprotonation the smaller will be the value of $k_{H^+}{}^{iso}$ relative to $k_1'/2$, and, in the limit where $k_{-1}' \gg k_r$ the isomerization can be viewed as involving a pre-equilibrium protonation step, followed by a rate-determining rotation. The *ortho* effect is therefore explained simply in terms of an increasing value of the ratio k_{-1}'/k_r as *ortho* groups are added, attributable to steric hindrance to rotation and decreasing values of k_r.

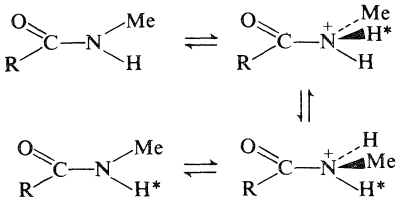
The various rate constants in eq. [1] cannot be factored out in quantitative terms. We regard the key conclusion to be simply that for the decrease in k_r to have an effect in the first place, the rotation and deprotonation steps *must* occur at comparable rates, even in the compound with no ring substituents. Otherwise, the rate of rotation, regardless what it is, has no influence on the isomerization rate constant, which is simply equal to $k_1'/2$ for all the compounds. In such a case the large rate decreases caused by *ortho* substitution must be explained in terms of a steric effect on k_1', and it seems to us that these rate decreases are too large for such an explanation to be satisfactory.

We should point out that it has not been claimed here that the rotation process is slow, in the sense that it has a high activation barrier. The barrier in fact need not be any greater than that normally found for single bond rotations. The crux of the argument, as we will discuss later, is that the deprotonation reaction is rapid, and that the rotation is only slow compared to this process.

Exchange of N-*Methyl Amides*

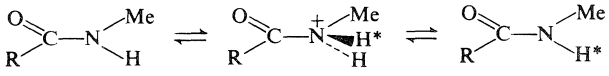
Several possibilities exist to explain the smaller effect observed in the rate constants for exchange, and these of course depend on the mechanism assumed for this reaction. In terms of a mechanism involving the *N*-protonated amide, the possibility again arises that rotation is required, if, for example, the incoming proton takes up a position in which it

is not equivalent to the N–H proton already present. This is illustrated below for the *Z* form of the amide, the configuration which is most stable (9).



This situation corresponds exactly to that for the isomerization reaction, and the arguments for the slower rate of exchange for the *ortho* substituted benzamides are the same as those just discussed. The major drawback of this interpretation is its prediction of similar effects of *ortho* substituents on both the exchange and isomerization processes, and this clearly is not seen.

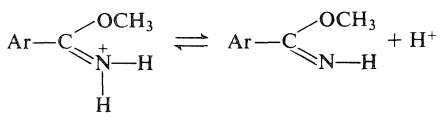
Unlike the isomerization process, an exchange mechanism can be written which involves the *N*-protonated amide but does not require carbon–nitrogen bond rotation in this species. As outlined in the equation below, this situation arises when the incoming proton goes into a position in which it is equivalent to the proton already present.



This is the viewpoint expressed by Perrin (6). In this case N–H exchange occurs on every two acts of protonation, so that the rate of exchange is given by eq. [2].

$$[2] \quad k_{H^+}{}^{ex} = k_1/2$$

In terms of such a mechanism the steric effect must be explained only on the rate of *N*-protonation, and it can in fact be argued that a small effect might exist, perhaps of the order of magnitude actually observed. The reasoning is based on the fact that the introduction of *ortho* methyl substituents in an acid–base system generally results in an increase in equilibrium acidity or conversely a decrease in equilibrium basicity. For example, the pK_a values of benzoic acid, *o*-toluic acid, and mesitoic acid are 4.2, 3.9, and 3.4 respectively (10). Another example involves the imidates below whose protonation resembles amide *N*-protonation. Again the 2,4,6-trimethyl compound is more acidic, this time by 1.1 pK_a unit (11).



Ar ≡ C_6H_5 or 2,4,6-$(Me)_3C_6H_2$

If such an effect is also in operation for amide *N*-protonation, it should be seen mainly in the protonation rate constant. The *N*-protonation of an amide by the hydronium ion is a proton transfer in the thermodynamically disfavored direction, meaning that the reverse reaction, the deprotonation, will occur at the diffusion limit (12) (see later). Any change in the equilibrium basicity is therefore due to a change in the protonation rate constant k_1. In particular a decrease in basicity caused by the introduction of *ortho* groups would lead to a decrease in k_1. This would appear as a rate retardation for the exchange reaction proceeding by the mechanism of eq. [3].

For the imidic acid mechanism an argument for a small steric rate retardation could be made along similar lines, in terms of a steric effect on the equilibrium basicity of the amide oxygen. This reaction also involves a deprotonation step involving the N–H proton of the *O*-protonated amide, and the effect of steric congestion on the rate of this step must also be considered. All things considered, however, the small rate decreases in the rate constants are compatible with either mechanism for exchange, or even a combination of both.

Question of the Imidic Acid Mechanism

What we like to suggest is that although neither our results nor probably those of Perrin can be taken to rule out the imidic acid mechanism, they do furnish an alternative explanation for the observation which led to the suggestion of that mechanism in the first place — namely, the fact that the rate of N–H exchange in an *N*-methyl amide is generally greater than the rate of isomerization in the corresponding *N*,*N*-dimethyl amide. The imidic acid mechanism accounts for this by providing a second route for the exchange reaction, a route not available to the isomerization process which must proceed through the *N*-protonated amide. An essential part of this argument, however, is that the rate of isomerization is equal to half the rate of *N*-protonation (2, 3). Our results show that this is not necessarily true, the rate of isomerization could be significantly less than half the rate of protonation. The imidic acid argument supposes that it is the exchange reaction which is anomalously fast. We propose that an equally acceptable explanation is that the isomerization reaction is anomalously slow.

Quantitatively we can adapt the following simplified viewpoint by assuming that the rate constants of exchange and isomerization are in fact given by eqs. [2] and [1], so that their ratio becomes

$$\frac{k_{H^+}{}^{ex}}{k_{H^+}{}^{iso}} = \frac{k_1}{k_1'}\left(1 + \frac{k_{-1}'}{2k_r}\right)$$

This equation contains the ratio k_1/k_1', representing

TABLE 2. Relative rate constants for deprotonation and isomerization of *N*,*N*-dimethylbenzamides

	k_{-1}/k_r for

2,4,6-Trimethyl	> 720	> 240	> 80

the relative rates of *N*-protonation of an *N*-methylbenzamide and an *N*,*N*-dimethylbenzamide. The protonation of an *N*-methyl aniline and the corresponding *N*,*N*-dimethylaniline can be taken as a model, since this also involves protonation on a nitrogen atom which is strongly conjugated with an adjacent π system. For the parent anilines the order of basicity is unsubstituted < *N*-methyl < *N*,*N*-dimethyl (1:1.7:3.5) (13). There are few other cases in which the basicity of the *N*-methyl compound is known, but it probably lies between the unsubstituted and *N*,*N*-dimethyl derivatives as above. The relative order of these latter two is observed to vary somewhat irregularly, but the difference is never greater than a factor of about three. We have therefore chosen this factor as a limit, and used three values of k_1/k_1' (3, 1, and 1/3) to calculate values of the ratio k_{-1}'/k_r (Table 2). This operation shows that for *N*-protonated *N*,*N*-dimethylbenzamide the rate of C—N rotation is of the same order of magnitude as the rate of deprotonation, *and* cannot be ignored. Thus the rate of isomerization is slower than half the rate of *N*-protonation, although in this case the difference between the two is not that great. However, with the close balance in the rates of rotation and deprotonation in the unsubstituted compound, addition of substituents which retard the rotation has a significant effect. A decrease in k_r by a factor of 4–5 on addition of one *ortho* methyl group followed by a further decrease in k_r by a factor of ten (or greater) for the second *ortho* methyl group is sufficient to explain the decreased $k_{H^+}{}^{ex}/k_{H^+}{}^{iso}$ ratios.

Nitrogen Basicity of Amides

The pK_a value of an *N*-protonated amide can be estimated by assuming that the rate constant in the protonation direction (k_1) is equal to twice the rate of isomerization ($2k_{H^+}{}^{iso}$) and that the rate constant in the deprotonation direction (k_{-1}) is of the order of 10^{10} s^{-1}, that is, that deprotonation is diffusion limited (2, 3, 14). Our results suggest that the first assumption is not completely valid. It is likely however that, with the exception of sterically hindered amides, $k_{H^+}{}^{iso}$ and k_1 differ by less than one order of magnitude, and the pK_a estimates using $2k_{H^+}{}^{iso}$ are at most one log unit too negative, that is, make the nitrogen appear slightly less basic than it actually is. This furthermore does not alter the fact that the pK_a estimates (2, 3, 14) are substantially more negative (by 5–6 pK_a units) than pK_a values obtained from spectroscopic changes, an observation which suggests that the latter values do not refer to the *N*-protonated amide but rather to the *O*-protonated amide. This is, in our opinion, one of the most compelling arguments in favour of predominant *O*-protonation.

This approach could be criticized on the grounds that it has not been proven that the deprotonation reaction is diffusion limited. However, proton transfer reactions to and from nitrogen atoms are generally diffusion limited in the thermodynamically favoured direction (12), even in cases where there is strong resonance interaction between the lone pair being protonated and an adjacent π electron system (15) (as in the case of amides). As noted by Kresge (16), one piece of evidence favouring a deprotonation rate constant near the diffusion limit in the case of amides is that an independent estimate of the nitrogen pK_a value based on a thermodynamic analysis (17) agrees within an order of magnitude with the estimates using the coalescence rate constants and the value of 10^{10} s^{-1} for the deprotonation. Our results provide a second piece of evidence since they suggest that the deprotonation reaction occurs at a rate comparable to (or faster than) that of rotation about a single bond. The latter process is undoubtedly very fast. For example, the rate constant of 10^{10} s^{-1} corresponds to an activation barrier of 4 cal/mol; the sort of barrier normally associated with single bond rotation (18). In order for the estimated pK_a for *N*-protonation to be consistent with the observed spectroscopic pK_a would require a rate constant for deprotonation of the order of 10^4–10^5 s^{-1}. Taking this as an upper limit for the rotational rate constant yields a lower limit for the barrier of rotation of 10–12 kcal/mol, a highly improbable value for single bond rotation. In other words, the assumptions of a diffusion limited deprotonation and a C—N single bond rotation occurring at a similar rate are fully consistent with each other.

In summary, methyl isomerization in *N*,*N*-dimethylbenzamides is slowed more by *ortho* methyl substitution than is the proton exchange rate in *N*-methylbenzamides. Therefore, the observed smaller rate for methyl isomerization than for proton exchange can be explained by assuming that deprotonation of the *N*-protonated amide occurs at a rate comparable to or faster than rotation about the C—N single bond, in agreement with an earlier suggestion of Perrin (4). While the alternative imidic acid route for proton exchange cannot be ruled out, it is clearly unnecessary to postulate this second mechanism to account for the results. In addition,

analysis of the observed rate constants provides further support for the view that amides predominantly *O*-protonate.

NOTE ADDED IN PROOF: Perrin and Johnston (21) have recently presented further arguments for an exchange reaction occurring via an *N*-protonation mechanism.

HAROLD J. JENNINGS, KARL-GUNNAR ROSELL, and C. PAUL KENNY. Can. J. Chem. **57**, 2902 (1979).

The capsular polysaccharide antigen from *Neisseria meningitidis* serogroup Z contains equimolar quantities of 2-acetamido-2-deoxy-D-galactose, glycerol, and phosphate. Carbon-13 nuclear magnetic resonance indicates that the polysaccharide is composed by a repeating unit of 1′-*O*-2-acetamido-2-deoxy-α-D-galactopyranosyl-glycerol joined through phosphate diester groups at O-3′ of glycerol and O-3 of the galactosamine residue. Assignments of the signals in the carbon-13 nuclear magnetic resonance spectrum were made by consideration of the previously assigned signals of related monomers and oligomers. When applied to a Karplus type relationship the values of the $^3J(^{13}C–^{31}P)$ coupling constants were consistent with the polysaccharide having an extended conformation.

HAROLD J. JENNINGS, KARL-GUNNAR ROSELL et C. PAUL KENNY. Can. J. Chem. **57**, 2902 (1979).

L'antigène polysaccharide capsulaire du séro-groupe Z de la *Neisseria meningitidis* contient des quantités équimolaires d'acétamido-2 déoxy-2 D-galactose, de glycérol et de phosphate. La résonance magnétique nucléaire du ^{13}C indique que ce polysaccharide est composé d'un motif *O*-1′-acétamido-2 déoxy-2 α-D-galactopyranosyl-glycérol réuni par un groupe diester phosphorique à l'oxygène en position 3′ du glycérol et à l'oxygène en position 3 du résidu galactosamine. On a interprété les signaux des spectres de résonance magnétique nucléaire du ^{13}C en tenant compte des identifications faites antérieurement dans le cas des monomères et des oligomères apparentés. Les valeurs des constantes de couplage, $^3J(^{13}C–^{31}P)$ appliquées à une relation de type Karplus, sont en accord avec celles des polysaccharides ayant une conformation allongée.

[Traduit par le journal]

Introduction

Slaterus first reported the isolation of the new serogroup Z of *Neisseria meningitidis* (1). We now report the structure of the group Z capsular polysaccharide which completes the structural studies on the capsular polysaccharide antigens mainly responsible for the serological group classification of the meningococci (2, 3). Although all the meningococcal polysaccharides are linear, acidic, and contain acetamido groups, they can be divided into two categories based on their acidic components, those containing phosphate diester bonds (4), and those containing 2-keto-3-deoxy acid residues (3, 5, 6). The serogroup Z falls into the former category having a repeating unit of 1′-*O*-2-acetamido-2-deoxy-α-D-galactopyranosyl-glycerol 3′-phosphate, the phosphate linkage to the galactosamine residue being at O-3. Thus it differs from the similarly categorized group A and X polysaccharides (4) in that its phosphate diester moiety is not glycosidically linked to the amino sugar residue. As far as we are aware this is the first reported case of a capsular polysaccharide containing the glycerol phosphate moiety previously associated with some teichoic acid structures (7, 8), although the ribitol phosphate moiety characteristic of other types of teichoic acid (7, 9) has been reported as a structural component of other capsular polysaccharides (10, 11, 12). Like the other meningococcal polysaccharides containing phosphate diester linkages the group Z polysaccharide has an extended conformation as determined from the $^{13}C–^{31}P$ coupling constants measured from its ^{13}C nuclear magnetic resonance spectrum.

Experimental

Materials

The cells of *N. meningitidis* serogroup Z (strain 565) were obtained from the culture collection of the Laboratory Center for Disease Control, Ottawa, and were grown as previously described (13). The capsular polysaccharide was isolated and purified as previously described using an initial Cetavlon precipitation to obtain the crude polysaccharide (13). D-Galactosamine HCl was obtained from Pfansteil Laboratories Inc., Waukegan, IL.

Analytical Methods

Amino sugars were detected using a Technicon auto analyser

[1]NRCC No. 17741

0008-4042/79/222902-06$01.00/0

and their quantitation was carried out by the modified Elson-Morgan method (14), in which the hydrolysate was first incubated with alkaline phosphatase (Worthington Biochemical Corp., Freehold, NJ) in ammonium bicarbonate at pH 8.5. Acid hydrolyses of the polysaccharide were carried out using 4 *M* HCl at 100°C and the amino sugar determinations were carried out at intervals between 4 h and 24 h. The total 2-amino-2-deoxygalactose content was determined by extrapolation to zero time. Phosphorous was determined by the method of Chen *et al.* (15).

Optical rotations were recorded at 23 ± 1°C on a Perkin Elmer 141 polarimeter and all solutions were concentrated below 50°C under diminished pressure.

Periodate oxidations were performed on the Z polysaccharide (10 mg) using a 0.02 *M* sodium metaperiodate solution (10 mL) and the periodate uptake was determined spectrophotometrically (16).

Nuclear Magnetic Resonance Spectroscopy

^{13}C nmr spectra were recorded at 37°C on a Varian XL-100-15 spectrometer operating at 25.16 MHz and a Varian CFT20 spectrometer operating at 20 MHz, both in the pulsed Fourier transform mode with complete proton decoupling. Chemical shifts are reported in parts per million (ppm) downfield from external tetramethylsilane and the ^2H resonance of deuterium oxide was used as the field-frequency lock signal. All the monomers and polysaccharides were run as deuterium oxide solutions at concentrations of 50–100 mg per mL.

^1H nmr spectra were measured at 37°C on a Varian CFT20 spectrometer operating in the pulsed Fourier transform mode. Samples were lyophylised (× 2) from 99.7% D_2O and run in the same solvent. The apparent first-order coupling constants (Hz) were measured directly and the chemical shifts (δ) are expressed relative to internal sodium 3-trimethylsilylpropionate-2,2,3,3-d_4.

Paper Chromatographic Analysis

Whatman No. 1 paper was used for descending paper chromatography using the following solvent systems (A) propan-1-ol – ammonia (specific gravity 0.88) – water (6:3:1), (B) butan-1-ol – ethanol – water (4:1:5), and (C) propan-2-ol – acetic acid – water (54:8:18). Compounds were detected with alkaline silver nitrate (17) and molybdate for sugar phosphates (18).

Hydrolysis of the Z Polysaccharide

Acid hydrolysis of the polysaccharide was carried out at concentrations of 5 mg per mL using 0.1 *N* HCl at 100°C for 2 h. Excess HCl was removed by repeated evaporation with water under vacuum to yield a residue. This residue when applied to a paper chromatogram in solvent (A) gave two major elongated molybdate positive spots indicating the presence of two different phosphorylated components. Dephosphorylation of the residue using alkaline phosphatase with subsequent removal of the NH_4HCO_3 by repeated co-distillations from water yielded only one non-reducing oligosaccharide component as indicated by paper chromatographic analysis.

Gel Filtration

Gel filtration was performed on a Sephadex G-200 column (2.4 cm × 70 cm) with a 0.1 *M* phosphate buffer (pH 7.0). The column was calibrated with blue dextran (MW 2 000 000) and the phosphate content of the eluates was monitored by the method of Chen *et al.* (15).

Gas–Liquid Chromatography

Gas–liquid chromatography (gc) was performed on a Hewlett-Packard 5830 A instrument equipped with a flame ionization detector and a model 18850A electronic integrator. The glass columns (180 cm × 0.15 cm) used contained the following liquid phases on 100–120 mesh Gas Chrom Q (*i*) 3% ECNSS-M at 170°C, (*ii*) 3% OV-1 at 200°C, and (*iii*) 3% OV-17 at 200°C. Combined gas chromatography – mass spectrometry (gc–ms) was carried out on a Finnigan 3100D instrument using the above columns.

Analysis of the Oligosaccharide

Glycose analyses were carried out by the method of Dmitriev *et al.* (19). The oligosaccharide (2 mg) was hydrolysed with 0.5 *M* sulfuric acid (3 mL) at 100°C for 16 h. The solution was neutralized with barium carbonate, filtered, and lyophylised. The residue was treated with water (0.6 mL), 33% aqueous acetic acid (1.0 mL), and 5% sodium nitrite (1.0 mL) at room temperature for 1 h. The solution was then passed through Dowex 50 (H^+) ion-exchange resin and lyophylised, redissolved in water, and treated with sodium borohydride for 2 h at room temperature. Following deionization with Dowex 50 (H^+) ion-exchange resin the solution was evaporated to dryness and methanol was distilled repeatedly from the residue. The final residue was acetylated with pyridine – acetic anhydride (1:1) at 100°C for 15 min and the resulting acetates were analysed by gc–ms using column (*i*) (20).

Methylation of the Oligosaccharide

The oligosaccharide was methylated with methyl iodide in the presence of methyl sulfinyl anion according to the method of Hakomori (21). The methylated product was recovered by partitioning between water and chloroform. The chloroform phase was dried (anhydrous magnesium sulfate), concentrated to small volume, and analysed by gc–ms using column (*ii*).

The permethylated oligosaccharide was treated with 90% formic acid (2 mL) at 100°C for 2 h and then concentrated to dryness. This residue was further hydrolysed with 0.25 *M* H_2SO_4 at 100°C for 16 h, neutralised with barium carbonate, and filtered. The filtrate was treated with sodium borohydride at room temperature for 2 h and excess sodium borohydride was destroyed by the addition of acetic acid. Following evaporation to dryness and several co-distillations of methanol from the residue, the residue was acetylated in pyridine – acetic anhydride (1:1) for 1 h at 100°C. After removal of the reagents by evaporation the residue was dissolved in water and the partially methylated acetate derivatives were extracted into chloroform. The chloroform solution was dried (anhydrous magnesium sulfate), concentrated to small volume, and analysed by gc–ms using column (*iii*) (22).

Results and Discussion

Isolation and Characterisation of 1′-O-2-acetamido-2-deoxy-α-D-galactopyranosylglycerol

Mild acid hydrolysis of the group Z polysaccharide of $[\alpha]_D$ +84° (*c* 0.5 in water), gave two chromatographically separable phosphorylated components both of which on treatment with alkaline phosphatase yielded the same chromatographically pure disaccharide with an optical rotation of $[\alpha]_D$ +59° (*c* 0.7 in water). Hydrolysis of the disaccharide using stronger conditions with subsequent deamination yielded 2,5-anhydro-D-talose, originating from the D-galactosamine residues in the original polysaccharide, and glycerol as determined by gc–ms anal-

ysis; the D-configuration was assigned to the galactosamine residue by virtue of the positive rotation of the original disaccharide. Methylation of the disaccharide and subsequent gc–ms analysis of the permethylated product indicated a single component which gave a fragmentation pattern in its mass spectrum consistent with 1′-*O*-3,4,6-tri-*O*-methyl-2-(*N*-methylacetamido)-α-D-galactopyranosyl-2,3-di-*O*-methyl-glycerol (Fig. 1). The following fragments with their relative intensities (in parentheses) were obtained: 45 (79), 71 (59), 87 (64), 88 (100), 101 (50), 103 (21), 111 (7), 129 (32), 132 (41), 142 (18), 145 (23), 163 (23), 173 (5), 205 (18), 228 (3), and 260 (2). This structure was also confirmed by hydrolysis of the permethylated disaccharide which yielded two methylated sugars identified by gc–ms of their alditol acetate derivatives (22) as 2-deoxy-3,4,6-tri-*O*-methyl-2-(*N*-methylacetamido)-D-galactopyranose and 1,2-di-*O*-methyl-glycerol.

The ^{13}C nmr spectrum of the disaccharide is also consistent with the above structural evidence and the assignments of its individual eleven carbon signals are listed in Table 1. Except for the highly characteristic anomeric signal (C-1) at 98.6 ppm all the other carbons of the galactosamine residue can be readily assigned by comparison with previous assignments made on 2-acetamido-2-deoxy-α-D-galactopyranose (23). Thus the glycosidic linkage is in the α-D-configuration and this was confirmed by ^{1}H nmr studies on the Z polysaccharide which indicated one anomeric doublet at δ 4.95 ppm with a coupling constant of 3.5 Hz, consistent with a *gauche* disposition of the anomeric H-1 and H-2 protons (24). The remaining three signals in the spectrum are assignable to the glycerol moiety and are only consistent with a C-1′ linkage because in comparison with the previously assigned glycerol resonances (11) C-1 experiences a downfield shift of +5.9 ppm whereas the vicinal β-carbon (C-2′) experiences an upfield shift of −1.7 ppm. The magnitude and direction of these shifts are highly characteristic of the linkage being at C-1′ (25).

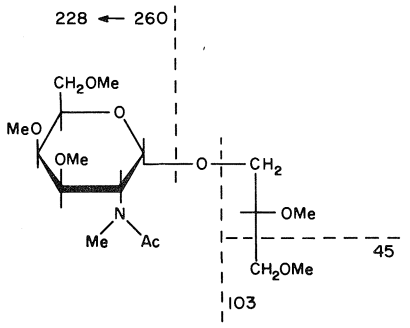

FIG. 1. Methylated oligosaccharide obtained from the group Z polysaccharide with some primary mass fragments.

Structure of the Group Z Polysaccharide

Chemical analyses indicate that the Z polysaccharide contains phosphate in a molar ratio of 1:1 with galactosamine. That glycerol was also present in the same molar ratio could be ascertained from the approximately equal intensities of comparable individual carbon resonances of both the glycerol and galactosamine residues in the ^{13}C nmr spectrum of the Z polysaccharide (Fig. 2). Therefore to complete the structural analysis of the Z polysaccharide it is only necessary to assign the position of the phosphate diester linkages joining the disaccharide repeating units. This proved to be a difficult task using conventional methods. The polysaccharide consumed 0.2 mol periodate per phosphorus atom which could be explained either by the presence of some 6-linked galactosamine in a mixed linked polysaccharide or by end-group oxidation of a 3- or 4-linked galactosamine-containing polysaccharide. The latter explanation is certainly consistent with the finding of large quantities of low molecular weight material in the polysaccharide preparation. However periodate oxidation of the polysaccharide does not discriminate between either the 3- or 4-linkage. Although a modified periodate technique has been devised to accomplish this based on the prior release of the reducing sugar phosphate residues by mild acid hydrolysis (9), it is not applicable to the Z polysaccharide because of the extreme acid-stability of its glycosidic bonds. Therefore the evidence for the presence of 3-linked galactosamine residues in the Z polysaccharide can only be obtained from its ^{13}C nmr spectrum.

The eleven resonance ^{13}C nmr spectrum of the native Z polysaccharide shown in Fig. 2 is only consistent with the polysaccharide having a repeating unit of 1′-*O*-2-acetamido-2-deoxy-α-D-galactopyranosyl-glycerol 3′-phosphate, the phosphate diester linked at C-3 of the galactosamine residue. The ^{13}C chemical shifts for the polysaccharide are listed in Table 1 together with ^{13}C–^{31}P coupling constants. Previous ^{13}C resonance assignments for the disaccharide aided the identification of signals due to carbons in the repeating unit of the polysaccharide. Thus C-1, C-2, C-5, C-6, and the two acetamido carbons were readily assigned. Characteristic shielding of C-2 (−1.1 ppm) by an adjacent phosphate group (25), combined with the observation that the resonance for C-2 is a doublet due to three-bond ^{13}C–^{31}P coupling, places one end of the phosphate linkage on C-3. Geminal coupling to ^{31}P (4.5 Hz) combined with typical deshielding (+5.0 ppm), as in the case of other sugar carbons bearing a phosphate substituent (4, 25), identified the signal for C-3. Previous ^{13}C resonance assignments made on the model compound 1′-*O*-α-D-glucopyranosyl-glycerol 3′-phos-

phate (11) were used to identify the signals for the corresponding carbons in the glycerol residue of the polysaccharide. Thus the signal at 67.4 ppm which was split into a doublet by two bond ^{13}C–^{31}P coupling (3.8 Hz) was assigned to C-3′, the carbon at the other end of the phosphate linkage. The signal at 70.2 ppm was assigned to C-2′ because the corresponding carbon in the model compound had only a slightly different chemical shift, and both of these carbons were similarly three-bond ^{13}C–^{31}P coupled. Conformational considerations discussed below also support this assignment. The remaining signals at 68.9 and 69.4 ppm could not be individually assigned to C-1′ and C-4 on chemical shift grounds alone. Tentative assignment of the signal at 69.4 ppm to C-4 was based on the premise that slight coupling of this carbon to ^{31}P would broaden the resonance and thus reduce its peak height relative to the uncoupled carbon signals. This reduction in peak height of the C-4 signal is not as large as that reported for other unresolved ^{13}C–^{31}P coupled signals (approximately 50%) (25) and indicates that extreme care must be exercised in the indentification of ^{13}C–^{31}P coupled signals on the basis of intensity alone.

The dihedral angle-dependency of ^{13}C–^{31}P coupling constants has been demonstrated in a series of glycose phosphates (4, 26, 27). However only recently using a series of rigid cyclic phosphite ester derivatives has a Karplus-type of relationship between the above two properties been established (28). The maximum and minimum values of the coupling constants used in construction of the curve were 12.2 Hz and 1.8 Hz respectively, although by interpolation of the curve at its base, the probability of even smaller coupling constants (approximately 0.5 Hz) can be envisaged. These would occur when the dihedral angle was in the vicinity of 90° and this situation could readily occur in the phosphate linkage to C-3 of the galactosamine residue of the Z polysaccharide. For rotamers about O—C_3 (Fig. 3) there are two possible positions (P_I and P_{II}) where the dihedral angle between the P—O and C4—C3 bond is approximately 90°. Of these two positions P_I is preferred because an examination of models (Dreiding) indicates the presence of highly unfavourable steric interactions in position P_{II}. This preferred position (P_I) could also be confirmed using the alternate $^3J_{C2,P}$ coupling constant (5.3 Hz) in the Karplus curve which yielded values of approximately 45° and 130°. This latter value is consistent with the theoretical dihedral angle (150°) between the P—O and C3—C2 bonds. Despite the linear non-rigid structure of the Z polysaccharide the extremely small $^3J_{C4,P}$ coupling constant would indicate a fairly restricted disposition of the phosphorus atom (P_I) because any significant contribution of other rotamers

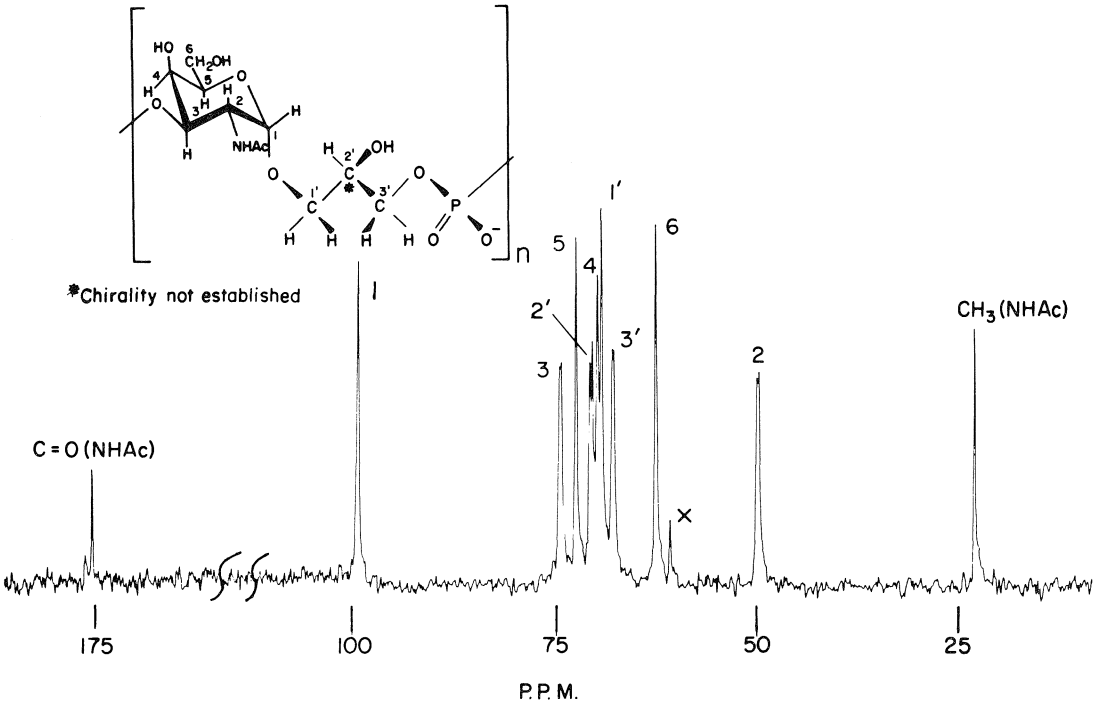

FIG. 2. Fourier-transformed ^{13}C nmr spectrum of the native group Z polysaccharide antigen taken with an acquisition time of 0.4 s, and spectral width 5 kHz. The number of free induction decays was 127 000. Inset: the repeating unit of the group Z polysaccharide.

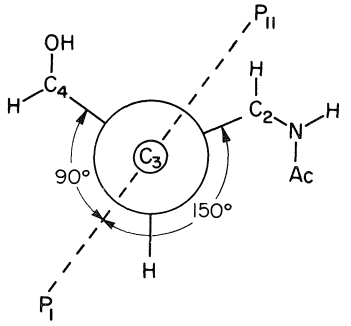

FIG. 3. Classical orientations of the oxygen–phosphorus bond in the group Z polysaccharide looking along the O—C3 bond of the 2-acetamido-2-deoxygalactopyranose residue.

would have resulted in a larger value. Models (Dreiding) also show that this restricted disposition (P_I) could be due to the adverse steric interactions of the phosphate ester group with the proton on C-3, the hydroxyl group on C-4, and the acetamido group on C-2. The $^3J_{C2',P}$ coupling on the glycerol moiety (7.8 Hz) yielded values of approximately 40° and 160° when applied to the Karplus curve. The latter value is compatible with a *trans* disposition of the P—O and C3′—C2′ bonds (Fig. 2) which again could be predicted on steric grounds. Thus the calculated dihedral angles of the phosphorus atom to both the galactosamine and glycerol residues of the Z polysaccharide indicate that it has an extended conformation similar to that found for other linear and highly phosphorylated polysaccharides (4).

Structural features normally associated with teichoic acids have been previously discovered in several bacterial polysaccharide antigens, the most ubiquitous being the ribitol phosphate moiety of the polysaccharide antigens of *H. influenzae* types *a* (12) and *b* (10) and some types of *S. pneumoniae* (29). The Z polysaccharide differs from the above capsular antigens in that it contains glycerol phosphate like some teichoic acids (7). This contrasts with the teichoic acid from *S. lactis* 7944 which has the same structural components as the Z polysaccharide, but has the phosphate group linked exclusively to the glycerol residues (8). It is interesting to note that it should be possible to differentiate between these two structures very easily using ^{13}C nmr. This is because the spectrum of the teichoic acid should manifest only three ^{13}C—^{31}P coupled signals none of which would be associated with the galactosamine residue. This particular case is well illustrated in the ^{13}C nmr spectrum of a related glucose-containing teichoic acid from *B. subtilis* Var. niger (11). Also any alternate structural variation involving glycosidic phosphate linkages as in the teichoic acid from *S. lactis*

I3 (9) would also have been easily recognisable using ^{13}C nmr. This type of structure would give a distinctive ^{13}C nmr spectrum having $^{13}C—^{31}P$ couplings on its highly characteristic and therefore readily assignable anomeric C-1 and C-2 signals.

P. J. SMITH, C. B. NYATHI, J. R. DIMMOCK, and L. M. SMITH. Can. J. Chem. **57**, 2908 (1979).

The mass spectra of several ring substituted acyclic styryl ketoximes and analogous ketones have been determined at 70 eV and also at low ionization voltages. The major fragmentation pathways for the oximes are loss of the *ortho* substituent from the parent ion as well as loss of the hydroxyl and hydroxylamine radicals. Other fragmentation pathways include γ- and δ-cleavages as well as the McLafferty rearrangement. While there was a total absence of α-cleavage from the parent ions, the facility of loss of the *ortho* substituents from the oxime molecular ions was compared with the same process occurring in the corresponding acyclic ketones, as well as the related cyclic derivatives, namely the substituted 2-benzylidinecyclohexanones and oximes. Stabilization of the resultant cyclized ion as well as steric factors are considered as factors favouring the cyclization process.

P. J. SMITH, C. B. NYATHI, J. R. DIMMOCK et L. M. SMITH. Can. J. Chem. **57**, 2908 (1979).

On a déterminé les spectres de masse de plusieurs oximes de styril cétones acycliques ayant le cycle substitué, et de cétones analogues en opérant à 70 eV et à de faibles énergies d'ionisation. Le schéma principal de fragmentation implique la perte des substituants en position *ortho* à partir de l'ion moléculaire aussi bien que la perte de radicaux hydroxyle et hydroxylamine. Le clivage en γ et en δ ainsi qu'une transposition de McLafferty ont lieu dans une autre type de fragmentation. La facilité avec laquelle l'ion moléculaire de l'oxime perd ses substituants en position *ortho*, en l'absence totale de clivage α, est comparée au même type de fragmentation que subissent les cétones acycliques et les composés cycliques apparentés comme les benzylidine-2 cyclohexanones substitués et les oximes. On considère la stabilisation de l'ion cyclisé résultant et les facteurs stériques comme étant des éléments qui favorisent la réaction de cyclisation.

[Traduit par le journal]

Introduction

Apart from the early work of Djeressi *et al.* (1), the mass spectra of aliphatic and alicyclic ketoximes have received little attention. In an earlier publication (2) we considered the mass spectra of a series of 2-benzylidenecyclohexanone oximes, while recently the mass spectra of a series of aryl heteryl ketoximes have been studied (3) with the view of investigating a gaseous phase Beckmann rearrangement.

The *ortho* effect as applied to aromatic compounds generally involves the loss of a neutral molecule from a 1,2-disubstituted aromatic derivative (reaction [1]). A less common process is

[1] 
cyclization via the *ortho* effect permitting ring formation. Coutts and Malicky (4) have observed the loss of OCH_3 from *o*-methoxyphenyl-2-propanone oximes via the *ortho* effect, reaction [2].

[2] 
As well, we have studied the cyclization reaction for several styryl ketones (5), reaction [3], and 2-benzylidenecyclohexanones (6), reaction [4].

In order to elucidate the fragmentation directing qualities of the oxime group, the mass spectra of a series of nuclear substituted styryl ketoximes and some deuterated analogs are planned to be investigated in the present study. In addition, the structural and electronic factors involved in the intramolecular aromatic substitution reaction with loss of an *ortho* substituent to give an aromatic species will be considered for several ring substituted styryl oximes and ketones. In order to determine the relative ability of

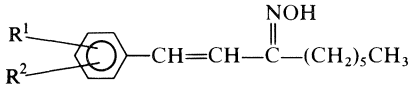
[4] 
the carbonyl function and the oxime group to promote cyclization, a comparison of the M − H (*ortho*)/M and M − Cl(*ortho*)/M ratios for both the styryl ketone and oxime series and the 2-benzylidenecyclohexanone and corresponding oxime series will be made.

Results and Discussion

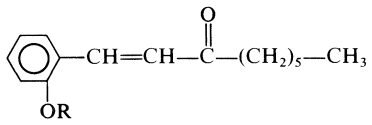
The following styryl oximes (**1**–**6**) were prepared and their mass spectra obtained. The mass spectral data for selected ions of these compounds are recorded in Table 1.[3]



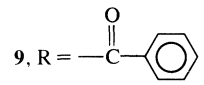
1, $R^1 = R^2 = H$
2, R^1 = 2-Cl; $R^2 = H$
3, R^1 = 4-Cl; $R^2 = H$
4, R^1 = 3-Cl; R^2 = 4-Cl
5, R^1 = 2-Cl; R^2 = 6-Cl
6, R^1 = 4-$N(CH_3)_2$; $R^2 = H$

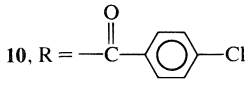
Several styryl ketones (**7**–**11**) with different *ortho* substituents were examined in addition to the ring chlorinated ketones described earlier (5). Compound **12**, the 2,3,4,5,6-pentafluorostyryl ketone was also investigated. The mass spectral data for selected ions of compounds **7**–**12** are recorded in Table 2.[3]

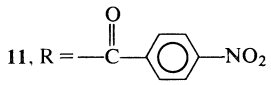
Due to the paucity in the literature concerning the mass spectra of oximes, it is worthwhile to consider the spectra of oximes **1**–**6** in some detail. A striking feature of the spectra of the six oximes is the total

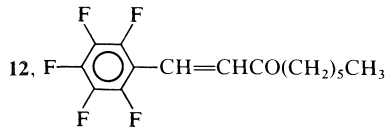


7, R = $-CH_2OCH_3$
8, R = $-CH_2-O-CH_2-CH_3$

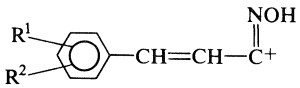




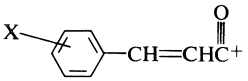




absence of ions corresponding to α-cleavage,

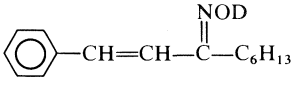


This result is in contrast to the α-cleavage process which occurs in the corresponding ketones leading to the formation of an ion,



In these acyclic ketones, the α-cleavage process is a major fragmentation pathway and in the case of the unsubstituted compound (X = H), this α-cleavage ion is the base peak.

A significant peak in the mass spectra of compounds **1**–**6** corresponds to the loss of 17 mass units $(M - OH)^+$ from the molecular ion as confirmed by the appropriate metastable peak. This ion has a relative intensity of 73 and 80%, Table 2, in the spectra of the unsubstituted and 4-dimethylamino compounds (**1** and **6**), respectively. The loss of the hydroxyl radical from the molecular ion was further confirmed by high resolution mass spectrometry. When the specifically deuterated oxime,



was examined, a loss of 18 mass units from the molecular ion was noted.

[3]A complete listing of the mass spectral peaks for all the compounds down to 2% intensity is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

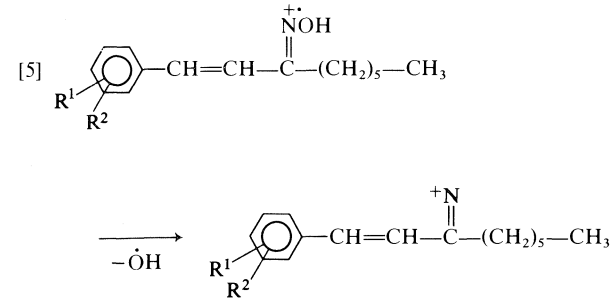
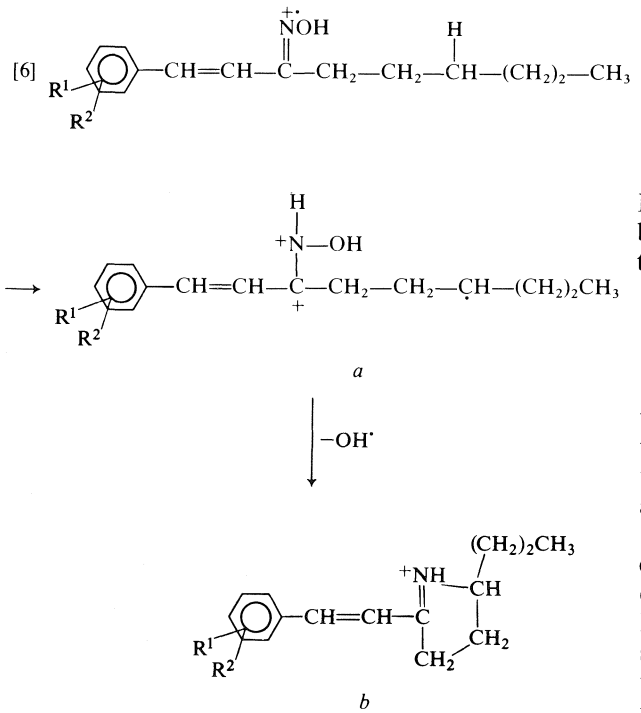
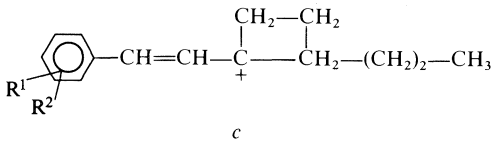
The M – OH ion could be formed directly from the molecular ion, reaction [5],



and have a nitrenium ion structure analogous to the ion proposed by loss of the hydroxyl radical from benzophenone oxime (7). Alternatively, the M – 17 ion could result from loss of hydroxyl from an intermediate structure *a* formed by a stepwise hydrogen rearrangement, reaction [6], with the formation of the conjugated cyclic ion in *b*.

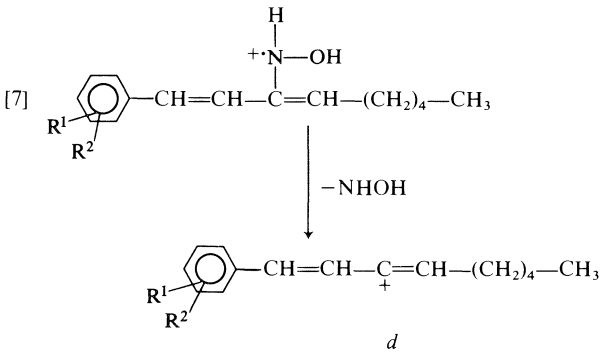


Support for the proposal of an intermediate *a* comes from the observation that the molecular ion of the oximes **1–6** loses 32 mass units, (M – 32), Table 1, as confirmed by the observation of the appropriate metastable peak. High resolution mass spectroscopy indicated that the NHOH radical is lost from the molecular ion. Intermediate *a*, rather than losing solely OH as in reaction [6] could also lose NHOH and after cyclization give ion *c* which would be expected to be stable

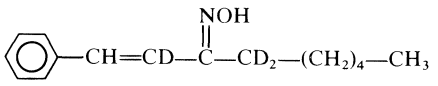


Observation of ions *b* and *c* indicates that *b* would be more stable and, in fact, for all the oximes **1–6** the loss of OH was a preferred fragmentation pathway than the loss of NHOH, Table 1.

An alternative route for the formation of the M – NHOH ion is from the "enol" form of the molecular ion, reaction [7], to give an ion *d*.



However, the vinylic ion *d* would not be expected to be stable and in order to test this hypothesis, the trideuterated substrate,



was prepared. It was found that the molecular ion of this substrate lost 32 mass units and not 33 mass units as would be expected if enolization occurred and NDOH were lost from the molecular ion.

It is noted that the molecular ions of all the oximes except **6** lost 57 mass units (γ-cleavage) and to a lesser extent 43 mass units (δ-cleavage), M – 57 and M – 43, Table 1. Oxime **6** does not fragment to the same degree as the other oximes presumably due to the fact that the *para*-dimethylamino group provides increased stabilization to the molecular ion of **6**.[4] The γ- and δ-cleavages presumably occur with cyclization to nitrogen as proposed by Djerassi and co-workers (1).

A major ion *e*, M – 70, Table 1, found in the spectrum of all the oximes except **6** corresponds to the McLafferty rearrangement, reaction [8]. The ion *e*

[4]The molecular ion of oxime **6** is the base peak in the spectrum while the molecular ions of oximes **1–5** range in relative intensity from 26–55%, Table 1.

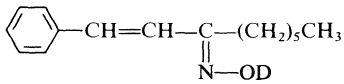
[8] 
e

could be formed directly from ion *a* proposed as an intermediate for loss of both OH and NHOH from the molecular ion (reaction [6]). In all cases, except for oxime **5**, the McLafferty ion *e* loses OH. In fact, $e - 17$ has a relative intensity of 100% in the spectrum of compound **1** ($m/z = 144$). As well, for all the oximes, an ion corresponding to the loss of NHOH from *e* also was observed. It is noteworthy that in all cases the McLafferty ion *e* loses a hydrogen and, as well, where a chlorine is a ring substituent the loss of a chlorine atom is also observed from *e* as confirmed by the observation of the appropriate metastable peaks.

An examination of the data in Table 1 indicates that the loss of Cl from *e* appears to be more favoured when the chlorine is in an *ortho* position. For example, for the 2,6-dichloro oxime, **5**, ion *e* loses Cl to give an ion with $m/z = 194$ with a relative intensity of 85%. The loss of halogen from the McLafferty rearrangement ion, *e*, could presumably proceed via a combination of either a simple bond cleavage process or via a cyclization similar to that represented in reaction [1], the *ortho* effect, which will be discussed subsequently. It is of interest to note that the McLafferty ions observed in the mass spectra of the corresponding ketones (5) also lose hydrogen and chlorine in a similar fashion with loss not being exclusively restricted to the *ortho* substituent.

As mentioned in the Introduction, the *ortho* effect leading to cyclization has not been studied in detail (8). Since we have examined this process for styryl ketones (5) and for other α,β-unsaturated ketones (6) it was thought of interest to examine whether the reaction is a general one and can be promoted by the oxime function as well as the carbonyl group.

A striking feature of the spectra of the oximes **1–6** is the exclusive loss of an *ortho* substituent from the molecular ion, M − 1 and M − 35, Table 1. A chlorine atom is lost only when it is in an *ortho* position as seen by the data for compounds **2** and **3** and also **4** and **5**. The appropriate metastable peaks were observed for the loss of chlorine from the molecular ions. It was shown that the hydrogen atom which is lost does not come from the oxime function since when the specifically deuterated compound **13** was examined there was no loss of deuterium from the molecular ion. As well, a hydrogen atom is not lost from the molecular ion when *both ortho* positions are substituted with chlorine atoms (compound **5**).



13

A cyclization mechanism identical to that proposed for the corresponding ketones (5) is consistent with the observed loss of only the *ortho* substituent. Nucleophilic attack[5] of the electron rich hetero atom, nitrogen, on the aromatic ring is followed by loss of the *ortho* group (R) to give a stable aromatic system, *f*, reaction [9].

[9] 
f

Attack of oxygen rather than nitrogen would lead to a less stable fragment ion. It is noteworthy that the cyclization product ion *f* receives stabilization from the oxygen and consequently this ion does not lose the hydroxyl radical.

In order to investigate the factors which affect the cyclization process, it is useful to evaluate this process quantitatively and hence the M − H/M and M − Cl/M ratios were determined at low ionization voltage where the only significant fragmentation process is cyclization with loss of the *ortho* substituent. These ratios are shown in Table 3 for the styryl ketones and corresponding oximes, as well as the 2-benzylidenecyclohexanones (6) and their corresponding oximes (2).

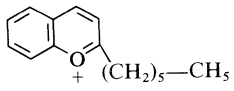
It is noted that for both systems the M − H/M ratios[6] are significantly greater for the oximes than for the corresponding ketones. Thus, in the 2-benzylidenecyclohexanone system, M − H/M = 1.37

[5]Nucleophilic attack on the aromatic ring has been proposed by other workers (9–11) to account for *ortho* rearrangement.

[6]The same trends in M − H/M and M − Cl/M ratios for the oximes as compared with the ketones were observed at 15 eV and 70 eV.

and 0.38 for the ring unsubstituted oxime and ketone, respectively. That the hydrogen which is lost comes from the *ortho* positions is confirmed since the molecular ion of both of the 2,6-dichloro styryl oxime and ketone does not lose a hydrogen.

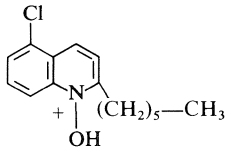
The preferred formation of the M − H ion in the oximes as compared with the corresponding ketones is probably a result of either the greater availability of electron density, which promotes cyclization, in the C=N bond as compared with the C=O bond or the greater stability of *f* as compared with the product of ketone cyclization.



g

A comparison of the M − H/M and M − Cl/M ratios in both the styryl ketones and oximes and benzylidenecyclohexanone and their corresponding oximes shows that the M − Cl/M ratios in all cases are greater than the M − H/M ratios where there is at least one chlorine atom in an *ortho* position. This observation presumably reflects the fact that chlorine is a better leaving group than hydrogen and, thus allows cyclization to be more facile.

The stability of the resultant cyclic ion also partially determines the ease of ring formation. An examination of the M − Cl/M ratios for both the 2-Cl and 2,6-diCl styryl ketones and oximes indicates that the ratio decreases when two chlorines are placed on the aromatic ring; i.e. for the styryl oximes, M − Cl/M = 1.51 and 1.14, for the 2-Cl and 2,6-diCl compounds, respectively. The decrease in M − Cl/M ratio is probably due to greater stability of *f* than *h*,



h

which has an electron-withdrawing, destabilizing, chlorine atom on the ring. Consistent with this conclusion is the observation that the mass spectrum of the 2,3,4,5,6-pentafluorostyryl ketone **12** does not lose a fluorine atom. This result can be rationalized either by considering the poor leaving group qualities of fluorine or the considerable deactivation of the cyclic ion due to *five* electron-withdrawing fluorine atoms.

Surprisingly, the trend in the M − Cl/M ratios in both systems from the oximes to the ketones is opposite to that observed for the M − H/M ratios.

	(**9**)	12	2.76
	(**10**)	15	1.93
	(**11**)	15	8.44

Whereas the M − H/M ratios are greater for the oximes than for the ketones the M − Cl/M ratios are smaller for the oximes compared with the corresponding ketones. This phenomenon may be due to the fact that steric effects are more important in the cyclization process of the oximes than for the ketones. It is more difficult for the bulky oxime function, as compared with the smaller carbonyl group, to attack an *ortho* position containing a large chlorine atom. These effects are unimportant when the *ortho* positions contain the small hydrogen atom.

In order to see whether *ortho* substituents other than hydrogen and chlorine are specifically lost via the ring formation process, several styryl ketones containing ether and ester substituents were examined. The major ions in the mass spectra of **7–11**, Table 2, are as expected with the ethers giving base peaks at $m/z = 45$ and 59 and the benzoate esters giving base peaks for the substituted benzoyl ions.[7]

The M − OR/M ratios were measured at low ionization voltages for compounds **7–11** and are shown in Table 4. It appears that the ethyl ether **8** is a better leaving group than the methyl analog **7** and that the *para*-nitro ester **11** is the best leaving group in the series of esters **9–11**.

Experimental

Mass spectra were determined with an MS-12 mass spectrometer. Source temperatures were varied between 120 and 130°C, depending on the sample. The samples were introduced using the direct probe technique. The high resolution spectra were determined by Dr. A. Boulton, Psychiatric Research Unit, University of Saskatchewan.

The preparation of the oximes **1–6** was by the literature methodology (12) and the styryl ketones **7**, **9–11** by the reported procedures (13).

*1-(2-Ethoxymethoxyphenyl)-1-nonen-3-one (**8**)*

A mixture of 2-octanone (76.9 g, 0.60 mol) and 2-ethoxymethoxybenzaldehyde (0.50 mol) was added to a solution of sodium hydroxide (10 g, 0.25 mol) in 300 mL of water and the resultant mixture was heated under reflux with mechanical stirring for 12 h. On cooling, the two layers were separated and the aqueous layer washed with benzene (3 × 100 mL). The washings were added to the organic layer and the solvent and excess 2-octanone removed under reduced pressure. The product bp 170°C/0.10 mm was prepared in 59% yield. *Anal.* calcd. for $C_{18}H_{26}O_3$: C 74.45, H 9.02; found: C 74.17, H 9.00.

*1-(Pentafluorophenyl)-1-nonen-3-one (**12**)*

To a vigorously stirred solution of 2,3,4,5,6-pentafluorobenzaldehyde (0.13 mol) and 2-octanone (0.15 mol) in dry benzene (200 mL) was added glacial acetic acid (0.13 mol) and piperidine (0.13 mol). The mixture was heated under reflux for 1 h using a condenser attached to a Dean-Stark trap. The benzene solution was cooled, extracted with water, 3 × 100 mL, and the benzene removed *in vacuo* to give a yellow oil, 27%, bp 114°C/1.0 mm. *Anal.* calcd. for $C_{15}H_{15}F_5O$: C 58.82, H 4.94; found: C 58.37, H 4.76.

Oxime of 1-Phenyl-1-nonen-3-one-OD

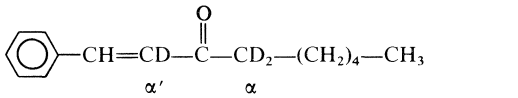
The oxime of 1-phenyl-1-nonen-3-one, 0.5 g, was dissolved in 10 mL of acetonitrile and 5 mL of D_2O was added. The solvent was removed under reduced pressure and this process was repeated six times. The oxime-OD was recrystallized from 30–60°C petroleum ether and was shown by infrared analysis to be approximately 70% deuterated. The oxime-OD was introduced into the source of the mass spectrometer in a solution of D_2O. This was repeated three times.

Oxime of 1-Phenyl-1-nonen-3-one-α-d_2

The oxime was prepared from 1-phenyl-1-nonen-α-d_2 by the previously published oximation process (12).

1-Phenyl-1-nonen-3-one-α,α,α′-d_3

1-Phenyl-1-nonen-3-one, 0.5 g, was dissolved in CH_3OD, 15 mL, and 1 g of dried sodium acetate was added. The solution was refluxed overnight. The ketone was recovered and the exchange process repeated two more times. The product,



was shown to be completed exchanged at C_α by nmr but there was incomplete exchange at α′.

Cinétique de la formation de la métalloporphyrine Cu(II)—dérivé tétra éthylènediamino de la protoporphyrine IX (ENP) en milieu aqueux

GUY PAQUETTE[1] ET MIKLOS ZADOR

Département de Chimie, Université de Montréal, C.P. 6210, Succursale A, Montréal (Qué.), Canada H3C 3V1

Reçu le 8 mai 1979

GUY PAQUETTE et MIKLOS ZADOR. Can. J. Chem. **57**, 2916 (1979).

La cinétique de la formation de la métalloporphyrine Cu(II)–ENP est dépendante du pH suite à la protonation des *N* pyrroliques et aussi suite à la protonation des groupes diamines des chaînes latérales. Le degré de protonation de ces chaînes latérales influence également le degré d'association de la porphyrine et de la métalloporphyrine en solution. L'ordre de réaction par rapport à la porphyrine est différent de 1 par suite d'une inhibition par le produit de réaction; cette inhibition s'opère via la formation d'une nouvelle espèce, un complexe mixte porphyrine–métalloporphyrine qui est peu réactif. L'ordre de réaction par rapport au Cu(II) est également différent de 1, dû à la chélation du Cu(II) par les groupes diamines des chaînes latérales. La présence de ligands du Cu(II) influence à la fois la cinétique de la réaction et la nature du produit final de réaction.

GUY PAQUETTE and MIKLOS ZADOR. Can. J. Chem. **57**, 2916 (1979).

The kinetics of formation of the metalloporphyrin Cu(II)–ENP is dependent on the pH due to the protonation of the pyrrol nitrogen atoms and the protonation of the diamino groups of the side chains. The degree of protonation of these side chains also influences the degree of association of the prophyrin and the metalloporphyrin in solution. The order of reaction with respect to the porphyrin is not unity, a consequence of an inhibition by the reaction product; this inhibition operates via the formation of a new species, a mixed complex of porphyrin–metalloporphyrin of low reactivity.

The order of reaction with respect to Cu(II) is also not unity, a consequence of the chelation of Cu(II) by the diamino groups of the side chains. The presence of Cu(II) ligands influence both the reaction kinetics and the nature of the final reaction product.

Introduction

Les porphyrines, sous forme de complexes avec des ions métalliques, sont impliquées dans plusieurs systèmes biologiques importants, tels l'hémoglobine, les cytochromes et la chlorophylle. Suite aux nombreux travaux sur le sujet (1–4), il ne semble pas qu'on puisse dégager un mécanisme vraiment général concernant l'incorporation de l'ion métallique à la porphyrine. La nature de la porphyrine et du métal, ainsi que le milieu réactionnel, jouent un rôle important lors de ces réactions. La très faible solubilité de la majorité des porphyrines en milieu aqueux est certainement une cause importante de la diversité des résultats obtenus: les solvants non-aqueux ou mixtes (5–22), de même que les détergents (19) ont été fréquemment utilisés, ce qui implique la présence en solution d'espèces métalliques souvent mal connues et de réactivité différente des espèces aqueuses.

La présente étude porte sur l'interaction du Cu(II) avec une porphyrine synthétique soluble en milieu aqueux, dérivé tétra-éthylènediamino de la protoporphyrine IX (fig. 1). Selon le symbolisme utilisé par White et Plane (20), elle sera désignée par ENP (forme base libre).

Partie expérimentale

Réactifs

La solution stock de Cu(II), sous forme de perchlorate, a été préparée à partir du sel double $CuCO_3 \cdot Cu(OH)_2$ (B.D.H.) et d'acide perchlorique (J. T. Baker).

La force ionique du milieu a été maintenue constante à 0.2 *M* à l'aide de $NaClO_4$. En présence de ligands ajoutés, il a été tenu compte des équilibres de protonation de ceux-ci et des complexes Cu(II)–ligand(s) dans le calcul de la force ionique.

Le dérivé de la protoporphyrine a été synthétisé selon la méthode décrite dans la littérature (20, 21), à partir de l'ester diméthylique de la protoporphyrine IX (Sigma) et d'éthylènediamine (Fischer) préalablement distillé. La pureté du produit a été vérifiée en comparant la position des maximums du spectre uv–visible et les valeurs calculées des absorptivités molaires avec les données publiées (20).

Méthode cinétique

Les réactions ont été étudiées à 25°C par spectrophotométrie en enregistrant la diminution de l'absorption de la bande Soret de la porphyrine dûe à la formation de la métalloporphyrine, dans la région de $\lambda = 360$ à 405 nm. Un spectrophotomètre Zeiss PMQ II, avec un porte-cuvettes thermostaté, a été utilisé. La température à l'intérieur des cuvettes optiques a été mesurée à l'aide d'un thermocouple. Les résultats ont été enregistrés sur un enregistreur logarithmique Sargent-Welsh

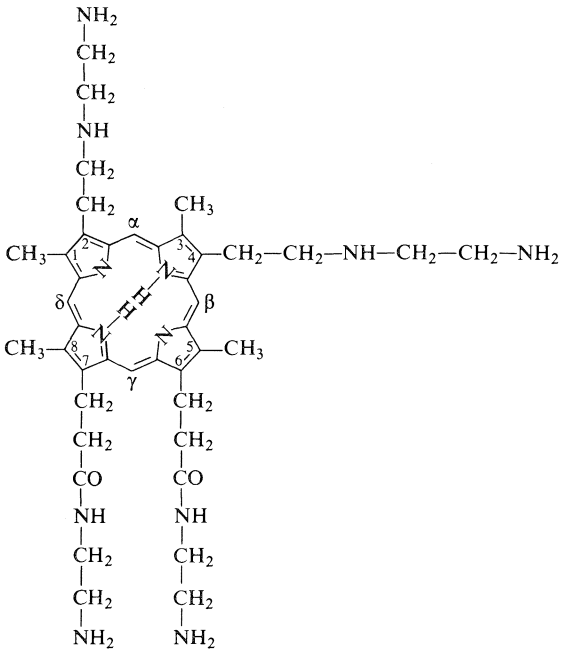

FIG. 1. ENP, forme base libre.

modèle SRLG. La concentration en porphyrine était de 1.0×10^{-5} *M*. Alors que celle du Cu(II) variait de 2.5×10^{-4} à 2.5×10^{-2} *M*. Les constantes de vitesse ont été obtenues à partir de la relation $kt = \ln [A_0 - A_\infty)/(A - A_\infty)]$, où A_0, A et A_∞ représentent les absorbances aux temps de 0, t et infini respectivement. A cause de problèmes particuliers discutés plus loin, la majorité des réactions ont été analysées en cinétique initiale, i.e. sur une période couvrant environ les premiers 25% de réaction. La force ionique a été maintenue constante, puisque des expériences ont montré que la force ionique influence l'état de la porphyrine en solution, de même que la vitesse de réaction.

Résultats et discussion

(a) Etat de la porphyrine en solution

La ENP peut exister en solution sous plusieurs formes (20): la base libre (ENP, fig. 1), le mono et le dication ($HENP^+$ et H_2ENP^{2+}) en milieu acide, sans compter les divers degrés de protonation des chaînes latérales. Les formes dimériques de la base libre et des espèces acides sont également possibles.

L'existence de ces diverses formes de la porphyrine a été proposée suite à une étude spectrale (20), mais l'influence du degré de protonation des chaînes latérales n'a pas été élucidée.

Nos résultats préliminaires indiquaient un rôle probable des chaînes latérales (voir plus loin); il a été décidé alors de réexaminer cette question.

(i) Titrage acide–base

La fig. 2 montre la courbe de titrage obtenue. La solution de pH = 3.3[5] après dissolution de la ENP, a été amenée à pH 2.2 puis titrée par NaOH.

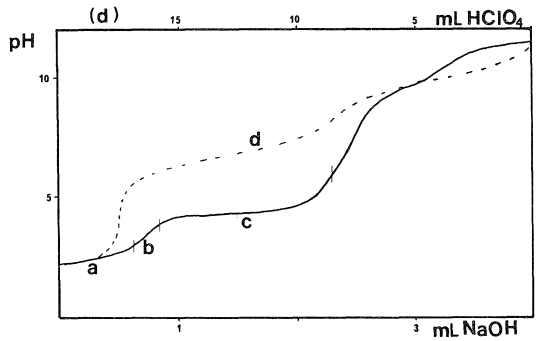

FIG. 2. Courbe de titrage. [ENP] = 2.5×10^{-3} *M*, courbe *a*: excès de $HClO_4$. [NaOH] = 4.7×10^{-2} *M*, courbe *b*: *N* pyrroliques, courbe *c*: chaînes latérales. [En] = 5×10^{-2} *M*; [$HClO_4$] = 5×10^{-2} *M*: courbe *d*.

La courbe se divise en trois parties: (*a*) neutralisation de l'excès d'acide perchlorique ajouté; (*b*) titrage des hydrogènes internes de la forme acide; (*c*) neutralisation des six protons des groupes amines des chaînes latérales.

Deux points particuliers sont à noter. Premièrement, il n'est pas possible de distinguer le départ successif des deux protons de la forme acide, ce qui est fréquent pour les porphyrines (22). Un calcul de la quantité de H^+ impliquée dans la neutralisation des hydrogènes internes indique un rapport 1:1 pour H^+/ENP. Ceci implique la présence soit du monomère monoprotoné, soit du dimère diprotoné comme espèces dominantes. La deuxième possibilité est retenue, en accord avec les constantes publiées (20), à cette concentration élevée de porphyrine (2.5×10^{-3} *M*).

Le point le plus important concerne les chaînes latérales (partie *c*). Dans ce cas, il est également impossible de distinguer le départ des différents protons des groupes amines. Ceci indique que les différences d'acidité entre ces protons sont trop faibles pour être perceptibles dans ces conditions. Le comportement des chaînes éthylènediamines est donc très différent de l'éthylènediamine seule (courbe *d* de la fig. 2).

(ii) Titrage spectrophotométrique

L'évolution des spectres en fonction du pH (fig. 3) fait ressortir deux points importants. D'abord, les spectres 1 à 3 (pH = 1.3 à pH = 2.5) montrent la transformation de la forme acide (λ_{max} = 402 nm) en base libre (λ_{max} = 372 nm) et il semble qu'il n'y ait que deux espèces présentes en solution puisqu'on distingue deux points isobestiques à λ = 386 nm et à λ = 405 nm. Or, comme la bande à λ_{max} = 372 nm a été attribuée au dimère de la base libre (20), ceci indique que la forme acide est très probablement dimérique (20, 21). La réaction acide–base est alors

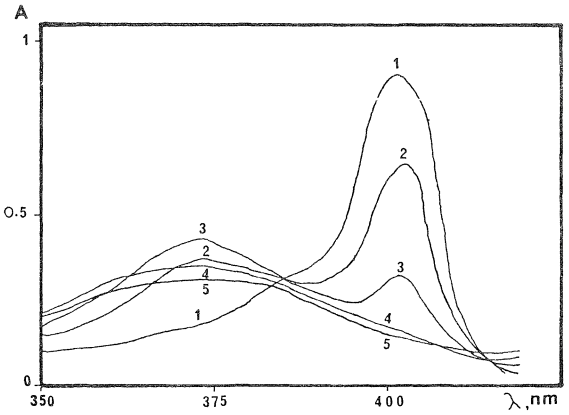

FIG. 3. Evolution des spectres de ENP en fonction de pH. [ENP] = 8×10^{-6} *M*; *1*, pH = 1.3; *2*, pH = 1.9; *3*, pH = 3.5; *4*, pH = 4.9; *5*, pH = 6.4.

représentée par l'équation suivante:

[1] $H_2(ENP)_2^{2+} \rightleftharpoons (ENP)_2 + 2H^+$

Ceci est en accord avec la valeur des constantes d'acidité et de dimérisation obtenues par White et Plane (20) et aussi avec les conclusions tirées de l'analyse de la courbe de titrage acide–base.

A pH $\geq$ 4, les résultats du titrage acide–base, ainsi que les valeurs des constantes d'acidité (20) impliquent, que les azotes internes sont déprotonées; les bases libres subissent alors progressivement la déprotonation des chaînes latérales par l'augmentation du pH.

Les spectres 4 et 5 de la fig. 3 montrent que la bande du dimère de la base libre s'élargit et ne passe plus par les points isobestiques. Les nouvelles espèces qui apparaissent sont probablement des formes oligomériques (trimère etc.). La déprotonation des chaînes latérales a comme effet de diminuer les répulsions électrostatiques des chaînes protonées et d'augmenter les interactions hydrophobes, responsables de la formation d'aggrégats.

L'existence de ces oligomères a été suggérée pour d'autres porphyrines, la protoporphyrine IX et la deuteroporphyrine IX (23), suite à l'analyse de spectres dont les caractéristiques sont semblables à celles des spectres de la fig. 3.

Pour certaines autres porphyrines telle la tetra-*N*-méthylpyridylporphine (TMPyP) il a été démontré que les charges positives périphériques (4^+) empêchent l'association en milieu aqueux (24). C'est le cas contraire de la ENP, qui s'explique par le fait que les substituants *N*-méthylpyridyles de la TMPyP sont joints au noyau porphyrinique aux positions α, β, γ, δ (cf. fig. 1), donc directement liés au système π résonant du noyau. Ce système résonant, responsable de l'association (25), est beaucoup moins influencé par les charges périphériques de la ENP qui sont séparées du noyau par quelques carbones aliphatiques (fig. 1). De plus la longueur des chaînes permet une flexibilité suffisante pour les orienter dans des directions opposées. Les divers groupes chargés sont alors suffisamment éloignés les uns des autres pour permettre la formation du dimère. Cette possibilité n'existe pas chez la TMPyP.

(iii) Cinétique de la réaction en fonction du pH

La fig. 4 montre la variation de la constante de vitesse initiale en fonction du pH. On y remarque les trois points suivants:

(*1*) De pH = 3.75 (point équivalent du titrage acide–base) à pH = 2.0, la vitesse de réaction diminue, selon un ordre approximatif -2 en H^+, ce qui indique une très faible réactivité de la forme acide de la porphyrine par rapport aux formes base libre. Une réaction effectuée à pH = 1.0 est au moins 10^3 fois plus lente qu'à pH = 3.75. C'est le comportement normal des porphyrines dans la région de pH correspondant à la protonation des azotes pyrroliques (9).

(*2*) Aux pH > 3.75, la courbe indique un comportement particulier de la ENP. A ces pH, la plus grande partie de la porphyrine a déjà été transformée en base libre; or la vitesse de réaction continue d'augmenter avec le pH. Par contre, tel que montré par l'étude de White et Plane (20), les caractéristiques spectrales ne changent plus dans le même domaine de pH; il est donc impossible de connaître la nature exacte des espèces, protonées différemment sur les chaînes latérales, dans ces milieux et d'avoir une interprétation quantitative de l'augmentation importante de vitesse observée. Qualitativement, ce phénomène est dû à la réduction de la charge portée par la porphyrine ce qui entraîne la diminution de

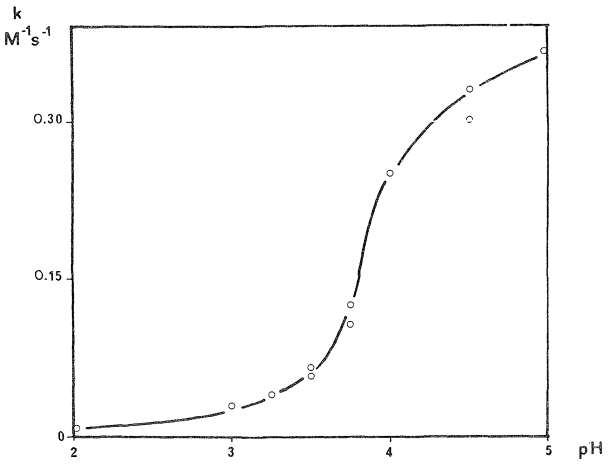

FIG. 4. Variation de la constante de vitesse en fonction du pH. [ENP] = 1×10^{-5} *M*, *T* = 25°C.

l'énergie libre d'interaction électrostatique avec le Cu^{2+}, conduisant à l'augmentation de la constante de vitesse.

De plus, une telle réduction de la charge de la porphyrine, dans le cas des porphyrines substituées en position *méso* (α, β, γ, δ, fig. 1) permet d'accroître la réactivité de la porphyrine en augmentant la densité électronique au centre réactif (24, 26–30). L'effet est probablement moindre dans le cas de la ENP, à cause de la position des groupes chargés sur les chaînes latérales.

(*3*) L'analyse de la fig. 3 a conduit à l'hypothèse de l'existence d'oligomères au pH > 4. La fig. 4 indique la présence de ces oligomères ne diminue pas la réactivité de la porphyrine.

L'évolution des spectres en cours de réaction met également en évidence l'influence de la protonation des chaînes latérales sur l'état des espèces en solution (fig. 5). Dans les deux cas la bande à 380 nm (dimère de la métalloporphyrine (20)) apparaît. A pH = 3.5 (fig. 5*a*) la bande est stable à la fin de la réaction, alors qu'à pH = 4.5 (fig. 5*b*) elle diminue lentement d'intensité et il apparaît éventuellement un précipité dans la cuvette optique. A pH = 3.5, les chaînes latérales protonées maintiennent le dimère en solution, alors qu'à pH = 4.5, les groupes amines commencent à se déprotoner, conduisant à la formation d'oligomères supérieurs qui précipitent éventuellement.

On remarque le même comportement lorsqu'on augmente le pH d'une solution de Cu·ENP formée à pH plus bas.

(b) L'ordre de réaction par rapport à la porphyrine

En supposant un mécanisme simple, l'équation de vitesse s'écrit comme suit:

[2] Vitesse = k[ENP][Cu^{2+}]

Comme dans toutes les réactions effectuées [Cu^{2+}] ≫ [ENP], l'équation se réduit à:

[3] Vitesse = k_{exp}[ENP]

De plus, la vitesse initiale de la réaction varie selon un ordre 1 par rapport à la concentration initiale de porphyrine. Toutefois les graphes de $\ln (A - A_\infty)/(A_0 - A_\infty)$ versus le temps présentent des écarts à la linéarité importants (fig. 6*a*). Il a été vérifié, à l'aide de solutions synthétiques, que ces écarts ne sont pas dus à la méthode expérimentale: l'absorbance mesurée est linéairement reliée au degré d'avancement de la réaction.

Il apparaît donc que seul un "incident" qui se développe au cours même de la réaction puisse être responsable de l'écart à la linéarité, que nous avons attribué à une inhibition par le produit de la réaction.

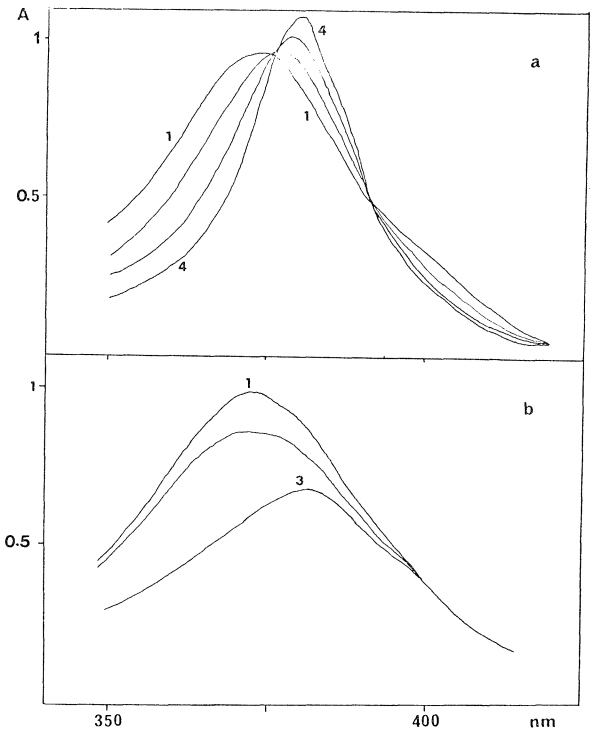

FIG. 5. Evolution des spectres durant la réaction [ENP] = 1×10^{-5} *M*; *T* = 25°C. *a*, pH = 3.5, [Cu(II)] = 2.5×10^{-2} *M*. *b*, pH = 4.5, [Cu(II)] = 5.0×10^{-4} *M*.

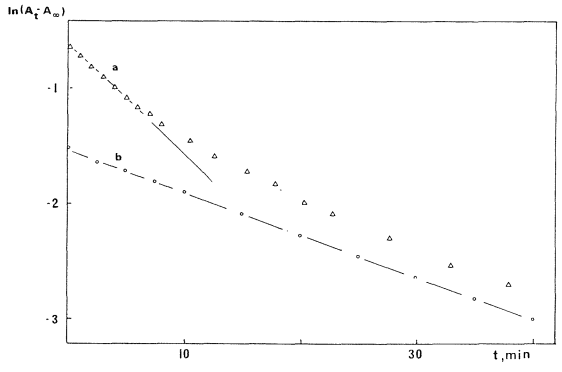

FIG. 6. Courbe d'intégration d'ordre 1. [ENP] = 5×10^{-6} *M*; [Cu(II)] = 5×10^{-2} *M*; pH = 2.0; *T* = 45°C; λ = 408 nm. *a*, [Cu·ENP]$_0$ = 0. *b*, [Cu·ENP]$_0$ = 1.5×10^{-5} *M*.

En effet, l'addition de quantités croissantes du produit entraîne la diminution progressive de la vitesse et, de plus, la courbe cinétique devient alors linéaire (fig. 6*b*). Plus la concentration de Cu·ENP est forte, plus la réaction est ralentie.

Les spectres sont révélateurs de la nature de l'inhibition. L'addition de Cu·ENP à une solution de ENP à pH = 2.0 influence la bande à λ_{max} = 402 nm, i.e. celle de la forme acide de la porphyrine; cet effet est attribué à la formation d'un complexe mixte

ENP–Cu·ENP assez stable pour causer le départ des protons de la forme acide, même à pH = 2.0.

Ce complexe étant moins réactif vis-à-vis l'incorporation du Cu(II), sa formation en fonction du temps entraîne l'allure autoinhibée de la réaction. Lorsque celle-ci est démarrée en présence de Cu·ENP, le complexe mixte est déjà présent en concentration appréciable au départ: la réaction est alors plus lente, mais présente une cinétique d'ordre 1.

C'est la première fois qu'un tel complexe mixte est suggéré, malgré que l'auto-association des porphyrines (1, 2, 23, 24, 31, 32), ainsi que des métalloporphyrines (1, 2, 3, 24, 31, 33, 35) soit bien établie.

Aux autres pH, i.e. 3.5 et 4.5 principalement, l'inhibition par le produit de réaction est aussi présente et elle a été démontrée cinétiquement par la même méthode. Dans ces cas cependant la présence du complexe mixte n'est pas apparente sur les spectres probablement parce que les différences spectrales ne sont pas suffisamment importantes vue l'absence de la forme acide à ces pH.

(c) L'influence de la concentration en Cu(II)

La fig. 7 montre la variation de la constante de vitesse en fonction de [Cu(II)]; le comportement est le même aux divers pH étudiés. Ce type de dépendance est linéaire aux basses concentrations en Cu(II), et semble aussi linéaire, mais de pente différente, aux concentrations plus élevées. Comme la réaction du Zn(II) avec la même porphyrine présente un ordre 1 simple par rapport au Zn(II) (36), les différences constatées avec le Cu(II) sont très probablement liées à la nature de l'ion métallique impliqué.

Il est bien connu que le Cu(II) forme facilement des complexes avec les amines (37). Il est possible que le Cu(II) complexe les groupements diamines des chaînes latérales, ou les chaînes en position 6 et 7 (fig. 1), formant ainsi une espèce complexée moins réactive que la porphyrine seule. Un calcul effectué à partir des constantes d'acidité et de complexation de l'éthylènediamine (*en*) avec le Cu^{2+} indique qu'à pH = 4.5, la proportion de *en* complexée sous forme $Cu{\cdot}en^{2+}$ est de 20 à 30%, avec [Cu(II)] = 2.5×10^{-2} *M*. Or le titrage acide–base de la ENP (fig. 2) a montré que le groupements diamines des chaînes latérales ont des protons plus acides que l'éthylènediamine par un facteur de 10^2–10^3; ils sont donc plus facilement remplacés par Cu^{2+}. De plus, par leur position, les chaînes latérales en position 6 et 7 (fig. 1), permettent la formation d'un tétradentate encore plus stable. Les conditions sont donc favorables à la formation d'un chélate du Cu(II) par les chaînes latérales.

On a alors deux espèces en solution, ENP et

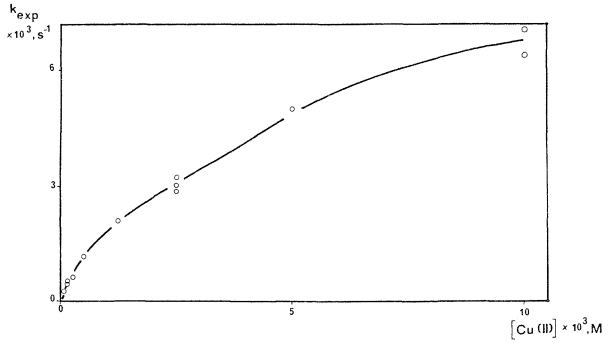

FIG. 7. Influence de la concentration en Cu(II) sur k_{exp} [ENP] = 1×10^{-5} *M*; pH = 3.5; *T* = 45°C.

ENP–Cu. L'équation de vitesse devient ainsi la suivante:

[4] Vitesse = $(k_1[\text{ENP}] + k_2[\text{ENP–Cu}])[\text{Cu(II)}]$

Aux basses concentrations en Cu(II), la concentration en ENP–Cu est faible et le terme correspondant de l'éq. [4] est négligeable devant k_1 ENP; la réaction est alors d'ordre 1 en Cu(II). Aux concentrations plus élevées en Cu(II), le contraire se produit; la vitesse est également d'ordre 1, mais l'espèce complexée ENP–Cu étant moins réactive, la pente de la courbe est plus faible (fig. 7). La courbure représente la transition progressive entre ces deux cas limites.

La réaction du Zn(II) avec ENP montre une cinétique d'ordre 1 par rapport au Zn(II) (36). Or les complexes du Zn(II) avec les polyamines ont des constantes de stabilité plus faibles que ceux du Cu(II) d'un facteur 10^4–10^5 (37). La concentration de l'espèce complexée ENP–Zn est d'autant plus faible, donc négligeable dans ces conditions. Le cas du Zn(II) est ainsi identique à celui du Cu(II) à basses concentrations.

(d) Influence de la présence de ligands du Cu(II)

La présence de faibles concentrations (10^{-4}–10^{-3} *M*) des ligands acétate, pyridine, imadazole et éthylènediamine accélère la réaction d'incorporation du Cu^{2+} à la ENP. La présence des complexes $Cu{\cdot}L^{2+}$, $Cu{\cdot}L_2{}^{2+}$, etc. ouvre de nouvelles voies réactionnelles, selon les équations suivantes:

[5] $Cu^{2+} + \text{ENP} \rightarrow Cu{\cdot}\text{ENP} + 2H^+$ $\quad k_{Cu^{2+}}$

[6] $CuL^{2+} + \text{ENP} \rightarrow Cu{\cdot}\text{ENP} + L + 2H^+$ $\quad k_{CuL^{2+}}$

[7] $CuL_2{}^{2+} + \text{ENP} \rightarrow Cu{\cdot}\text{ENP} + 2L + 2H^+$ $\quad k_{CuL_2{}^{2+}}$

L'équation de vitesse s'écrit alors:

[8] Vitesse = $(k_{Cu^{2+}}[Cu^{2+}] + k_{CuL^{2+}}[CuL^{2+}] + k_{CuL_2{}^{2+}}[CuL_2{}^{2+}])[\text{ENP}]$

A faible concentration en ligand, seules $[Cu^{2+}]$ et

[CuL^{2+}] sont appréciables. Dans ce cas on peut calculer les valeurs de constantes de vitesse individuelles, à 25°C:

$$k_{Cu^{2+}} \simeq 1\ M^{-1}\ s^{-1}$$

$$k_{CuOAc^{+}} \simeq 5\ M^{-1}\ s^{-1}$$

$$k_{Cu.pyr^{2+}} \simeq 16\ M^{-1}\ s^{-1}$$

$$k_{Cu.imz^{2+}} \simeq 6\ M^{-1}\ s^{-1}$$

$$k_{Cu.en^{2+}} \simeq 21\ M^{-1}\ s^{-1}$$

La réactivité accrue des espèces complexées du Cu(II) a déjà été démontrée à quelques reprises (9, 17), de même que pour le Zn(II) (36, 39).

L'analyse cinétiques des réactions à plus fortes concentrations en ligand (10^{-2} à 0.25 *M*) a montré un comportement singulier, inexplicable par les calculs de répartition des espèces du Cu(II) et de constantes de vitesse individuelles. Les spectres enregistrés en cours de réaction (fig. 8) montrent la présence d'un phénomène nouveau à haute concentration. A basse concentration (fig. 8*a*) la transformation du dimère de la base libre (λ_{max} = 372 nm) vers le dimère de la métalloporphyrine (λ_{max} = 382 nm) s'effectue avec une décroissance monotone de

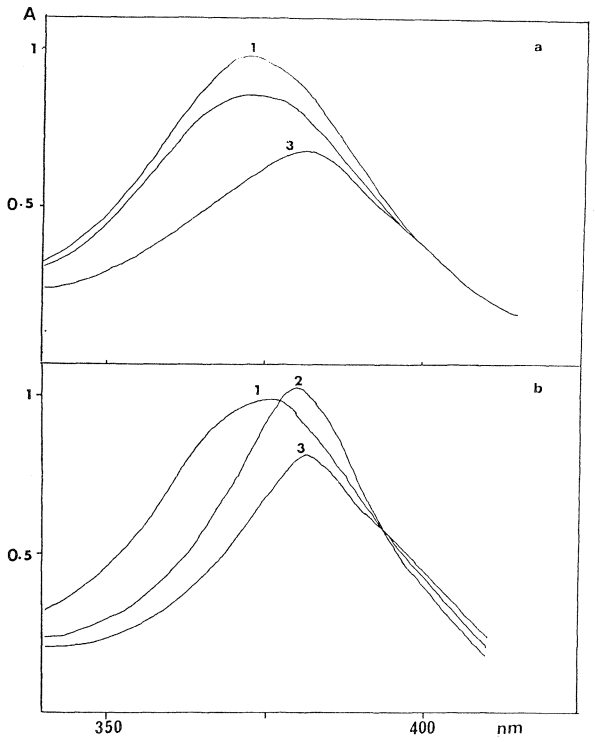

FIG. 8. Evolution des spectres lors de la réaction en présence d'éthylènediamine. [ENP] = 1×10^{-5} *M*; [Cu(II)] = 2.5×10^{-3} *M*; pH = 4.5; *T* = 45°C. *a*, [en] = 5×10^{-4} *M*. *b*, [en] = 5×10^{-2} *M*.

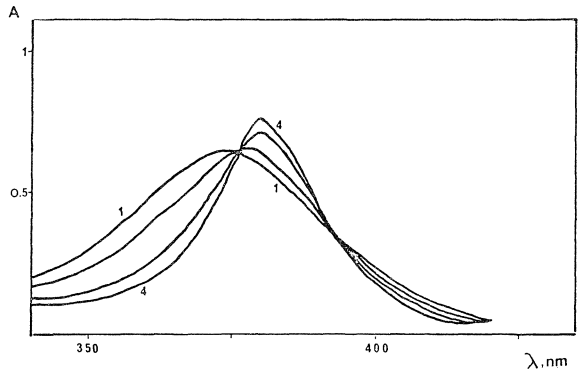

FIG. 9. Evolution des spectres lors de la réaction en présence de forte concentration d'éthylènediamine. [ENP] = 1×10^{-5} *M*; [Cu(II)] = 2.5×10^{-3} *M*; [en] = 2.5×10^{-1} *M*; pH = 4.5, *T* = 25°C, force ionique = 0.75 *M*.

l'intensité. A concentration élevée (fig. 8*b*), il y a d'abord déplacement du maximum vers λ = 382 nm avec augmentation d'intensité; puis l'intensité diminue, quoique moins fortement que dans le premier cas.

On est donc en présence de deux phénomènes consécutifs. On attribue le nouveau phénomène à la complexation, en position axiale, du Cu(II) de la métalloporphyrine par le ligand présent. Les spectres de la réaction en présence de très fortes concentrations de *en* (0.25 *M*) concordent avec cette hypothèse (fig. 9); on y observe uniquement le déplacement de la bande Soret, qui augmente d'intensité. Comme l'élargissement et l'aplatissement du pic à λ_{max} = 382 nm ont été attribués précédemment à la formation d'oligomères supérieurs au dimère, cette bande étroite et plus intense indique l'absence d'oligomères. La Cu·ENP existe donc sous forme de dimère, avec un ligand par métalloporphyrine. C'est essentiellement la même conclusion que celle de MacCragh et coll. qui ont étudié une série de porphyrines du Cu(II) avec des ligands par résonance paramagnétique électronique (38).

Cette idée est confirmée par deux autres faits expérimentaux. D'abord l'addition de fortes concentrations de *en* à une solution de Cu. ENP produit un spectre final semblable à celui de la fig. 9. Deuxièmement, les réactions effectuées en présence de concentrations faibles ou nulle de ligand à ce pH (4.5) montrent un précipité à la fin de la réaction, alors qu'il n'en apparaît pas dans les cas à hautes concentrations, même après plusieurs jours.

Conclusion

La réaction étudiée présente, par rapport aux autres réactions de formation de métalloporphyrines, quelques traits particuliers, dus à la nature des chaînes latérales de la ENP.

La rôle de H^+ y est double: d'une part la protonation des N pyrroliques conduit à des formes acides très peu réactives, ce qui est le cas général; d'autre part, le degré de protonation des chaînes latérales influence les équilibres d'association de la porphyrine et la vitesse d'incorporation du Cu(II).

La formation d'un chélate du Cu(II) par ces mêmes chaînes conduit à une espèce de réactivité moindre que la porphyrine seule.

L'ordre de réaction par rapport à la porphyrine est différent de 1, à cause de la formation d'un complexe mixte ENP–Cu·ENP, peu réactif, au cours de la réaction. C'est la première fois qu'un tel complexe est mis en évidence.

La présence de faibles concentrations de ligands du Cu(II) accélère la réaction d'incorporation du métal, alors qu'à hautes concentrations l'état du produit final est plutôt dimérique qu'oligométrique suite à la complexation du Cu(II) de la métalloporphyrine en position axiale.

Ces particularités du système Cu(II)/ENP soulignent encore une fois la difficulté de proposer un mécanisme vraiment général d'incorporation des ions métalliques aux porphyrines.

Nitrosyl chloride reacted with 1,5-cyclooctadiene and *trans,trans,trans*-1,5,9-cyclododecatriene in methylene chloride by the *cis*-addition to give chloronitroso alkenes with *cis* and *threo* (*trans*) configuration, respectively. These enantiomorphic *C*-nitroso compounds were isolated as a single compound for the former, and a mixture for the latter, of *dl* and (or) *meso* dimers, the presence of which was readily monitored by ^{13}C nmr spectroscopy. The former can assume a conformation to place the π-bonds of the nitroso and olefinic groups in interacting vicinity and undergo an acid catalyzed intramolecular electrophilic cyclization to give bicyclic hydroxylamines which are readily air oxidized to the corresponding nitroxide radicals. Rearrangement in acetic anhydride – methylene chloride afforded good yields of the stable bicyclic hydroxylamine acetates which served as precursors to generate the corresponding nitroxides under mild conditions. Photoaddition of *N*-nitrosopiperidine to 1,5-cyclooctadiene also partly afforded the *cis*-aminonitroso adduct which underwent the intramolecular addition to give hydroxylamines. The *threo*(*trans*)-chloronitroso alkenes failed to cyclize in similar fashion under comparable conditions. Nitrosylchloride added exclusively to the *trans*-double bond of *trans,cis*-1,5-cyclodecadiene without regiospecificity but was believed to follow the stereospecific *cis*-addition; this chloronitroso compound also underwent the acid catalyzed transannular reaction to give similar hydroxylamines that were not isolated in pure states.

YUAN L. CHOW, K. SOMASEKHARAN PILLAY et HERVÉ RICHARD. Can. J. Chem. 57, 2923 (1979).

Par une addition *cis*, le chlorure de nitrosyle dans le chlorure de méthylène se fixe sur le cyclooctadiène-1,5 et le cyclododécatriène-1,5,9 *trans,trans,trans* pour conduire respectivement aux alcènes chloronitrosés *cis* et *thréo* (*trans*). Les composés énantiomorphes *C*-nitrosés sont isolés sous forme de composé unique dans le cas du cyclooctadiène et sous forme d'un mélange de *dl* et/ou de dimères *méso* dans le second cas. La présence de ces derniers a été révélée par l'étude des spectres rmn du ^{13}C. Les composés dérivant du cyclooctadiène-1,5 adoptent une configuration qui place les liaisons π des groupements nitroso et oléfines au voisinage l'un de l'autre. Ceci permet alors une cyclisation électrophile intramoléculaire, catalysée par l'acide, qui conduit aux hydroxylamines bicycliques. Ces derniers s'oxydent facilement à l'air en radicaux nitroso correspondants. La transposition dans un mélange anhydre acétique – chlorure de méthylène fournit avec de bons rendements les acétates d'hydroxylamines bicycliques stables qui dans des conditions douces servent de précurseurs aux nitroxydes correspondants. L'addition photochimique de la *N*-nitroso pipéridine au cyclooctadiène-1,5 fournit aussi en partie l'adduit amino-nitrosé *cis* qui par une addition intramoléculaire conduit aux hydroxylamines. Dans des conditions identiques, les alcènes chloro-nitrosés *thréo* (*trans*) ne se cyclisent pas. Le chlorure de nitrosyle s'additionne exclusivement sur la double liaison *trans* du cyclododécadiène-1,5 *trans,cis*. La réaction n'est pas regiospécifique mais on pense que l'addition se fait stéréospécifiquement de manière *cis*. Ces composés chloronitrosés subissent également une réaction transannulaire catalysée par les acides pour conduire à des hydroxylamines similaires que l'on n'a pas pu isoler à l'état pur.

Introduction

In the photoaddition of nitrosamines to olefins (1, 2), the isolated crude products very often exhibited esr signals in the region of the isotropic *g*-factor 2.006–2.007 suggesting the presence of nitroxide radicals. Yet, attempts to isolate these nitroxides by careful chromatography have never been rewarded despite the fact that nitroxides are generally fairly stable; in most cases oximes derived from the *C*-nitroso compounds, the primary photoadducts, are the major product, although certain exceptions have been observed (3, 4). That *C*-nitroso compounds can efficiently trap alkyl, acyl, and alkoxyl radicals during photolysis of nitrites and *C*-nitroso compounds has been well-established by de Boer and co-workers (5) and other groups (6, 7). A similar spin trapping reaction might be invoked to account for the nitroxide formations in photoaddition of

0008-4042/79/222923-13$01.00/0

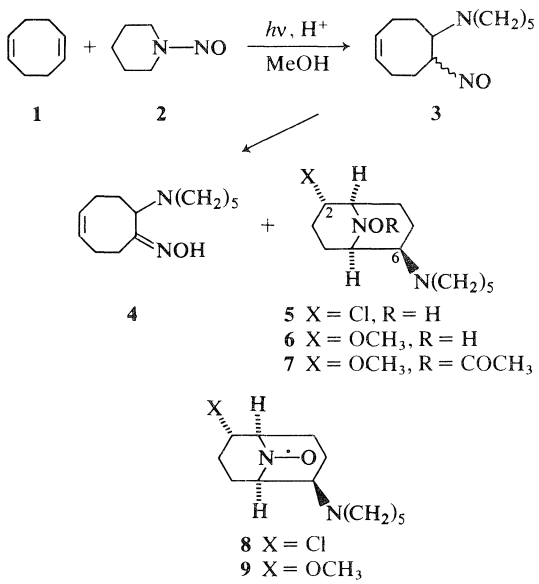
nitrosamines to olefins but the extent must be very small. In cases where tertiary *C*-nitroso compounds are generated, since tautomerization is blocked, a novel intramolecular electrophilic reaction of the nitroso group with a suitably located labile electron pair occurs to give hydroxylamines which are oxidized to nitroxides (3). Such reactions might be regarded as intramolecular "ene" reactions; examples of intermolecular equivalents have been reported (*vide infra*). Subsequently we became interested in electrophilic reaction of nitroso groups with olefinic bonds.

The chemistry of *C*-nitroso compounds has been reviewed (9–12). Characteristically the *C*-nitroso group is readily reduced to hydroxylamines, oxidized to a nitro group, attacked by radicals to give nitroxides and by nucleophiles to give adducts in addition to tautomerization and dimerization (9). The *C*-nitroso group is electrophilic but hardly powerful enough to react with alkenes, dienes, or acetylene unless the nitroso group is activated by a vicinal electron withdrawing moiety, such as nitrosoarenes (13), trifluoronitrosomethane (13), α-halonitrosoalkanes (9), and nitrosylcyanide (14). Such nitroso compounds act as electrophilic dienophiles (9, 13, 14) to give 1,2-oxazines with dienes (13, 14). A 1,2-cycloaddition reaction with simple olefins is rare unless the nitroso group is powerfully electrophilic as in CF_3NO (13). However, recently nitrosoarenes (15–17) and tertiary nitrosoalkanes (18) have been shown to undergo "ene" reaction with olefinic bonds to give hydroxylamine derivatives, though the yields in the latter cases are not specified. In principle, a nitroso group may be protonated to generate a nitrenium ion intermediate which may react with a strategically located π-electron system. On the basis of this assumption, the reactions of some alkenyl nitroso compounds have been investigated.

Results

Photoaddition of *N*-nitrosopiperidine to 1,5-cyclooctadiene (**1**, 1,5-COD) in methanol in the presence of hydrochloric acid or perchloric acid gives the expected amino oxime **4** which was known to arise from tautomerization of the primary 1,2-addition product (1–4), *C*-nitroso compound **3**. In addition, a second product was isolated in fairly high yield in each photoreaction; this second product was shown to possess no carbon–carbon double bond and oximino moiety but the molecular formulae representing the addition of a molecule of hydrochloric acid or, in the latter case, methanol. Crude or analytically pure samples of these two compounds showed poorly resolved ^1H nmr spectra and a broad esr triplet signal of equal intensity with *g*-value 2.006–2.007 and a_N 15–17 G, typical esr parameters of nitroxide radicals (18, 19). Since the observed esr signal is similar to those of the nitroxides of a flexible bicyclo[3.3.1] system and different from those of the relatively rigid bicyclo[4.2.1] system with well-resolved hyperfine splitting from α and β-hydrogens (19), structures **5** and **6** were assigned to these two products; obviously, the esr signals were due to trace amounts of nitroxides **8** and **9** arising from the air oxidation of **5** and **6** (20). Indeed, hydroxylamine **6** was readily oxidized by alkaline hydrogen peroxide to **9**, which was rigorously characterized with elemental analysis and spectroscopy.

Both hydroxylamines **5** and **6** were difficult to purify by sublimation or recrystallization, though **5** could be recrystallized to give a good analysis by working under nitrogen atmosphere as much as possible. Presumably, oxidation occurred constantly during the operation in normal atmosphere to generate trace amounts of nitroxides **8** and **9**. Likewise,



the *O*-acetyl derivatives of hydroxylamines could be prepared only with difficulty, probably for the same reason. By extensive chromatography, hydroxylamine acetate **7** was obtained and showed the typical *N*-acetoxy absorption at 1760 cm^{-1} (3).

Although the ^1H nmr spectra were poorly resolved, it was seen that the C-2 proton in **5** (—C*H*Cl—) had a large coupling constant and that in **6** (—C*H*OCH_3—) had a broad signal; these indicated that the C-6 proton had axial orientation. The narrow signals of the C-6 proton in **5** and **6** indicated the pseudo-equatorial orientation. The configuration will be discussed in detail later.

In the formation of the bicyclic hydroxylamines

shown above, an unisolated nitrosoalkene with a suitable configuration and conformation was assumed to be the precursor. With an aim to clarify the pattern of the transannular reaction the *anti*-dimer of chloronitroso compound **10** was prepared by addition of nitrosyl chloride to 1,5-COD (**1**). The addition gave a good yield of the nitroso dimers. While the purified dimer was very stable, the crude dimeric fractions tautomerized slowly in solution during nmr spectroscopic examinations to give more of oximes **11**, probably catalysed by a trace amount of acids. As the crude or recrystallized dimer showed eight signals in the ^{13}C nmr spectra with the expected chemical shifts, it must be an *anti*-azodioxy compound, either a *meso* (symmetrical) or *dl* (unsymmetrical) dimer (21), arising from a single adduct which was deduced to be the *cis*-adduct, as shown in **10** (*vide infra*). The dimer obviously possessed an *anti*-azodioxy group as shown by uv absorption at 294 nm and strong ir peaks at 1238 and 1208 cm^{-1}. The ^1H nmr spectrum of the dimer exhibited the methine protons at τ 4.57 and 5.48 which were shown to be not coupled to each other. In comparison to a large coupling of the methine protons ($J = 9$ Hz) in *trans*-2-dimethylaminocyclooct-5-ene-1-ol (22), the zero coupling as well as considerations of conformations with Dreiding stereomodels (*vide infra*) suggested that **10** had the *cis*-configuration of the functional groups. The dimer slowly decomposed on storage to give a mixture of *syn*- and *anti*-oximes **11** from which the former, the major product, was isolated. The assignments of the *syn*- and *anti*-configuration were made on the basis of chemical shifts of ^{13}C and the methine protons at the 2-position. The ^{13}C nmr spectrum of the mixture showed two sets of eight signal patterns, one set was relatively more intense than the corresponding signals of the other set. The mixture of oxime **11** was reacted with dimethylamine to give the known *anti*-amino oxime **12** (23).

Decomposition of the dimer of **10** under acidic conditions caused tautomerization to give oximes **11** (and derivatives thereof) and transannular cyclization to hydroxylamines such as **17** and **18**. Generally, in the presence of proton donors the former were formed overwhelmingly, but substantial amounts of the latter were produced in aprotic solvents. Thus, when the dimer was decomposed in a methylene chloride – methanol mixture in the presence of a catalytic amount of perchloric acid, a mixture of *syn*- and *anti*-oxime **11** (70%) and trace amounts of chloro ketone **14** and methoxy ketone **15** were obtained; in addition, by gc–ms, the presence of methoxy oxime **13** was detected. In this reaction, a small amount of hydroxylamine **17** was isolated but could not be crystallized because of the presence of the trace

amount of the corresponding nitroxide **20**, as indicated by the esr triplet at $g = 2.0073$ and $a_N = 17.5$ G. Decomposition of the dimer of **10** in methanol – methylene chloride in the presence of hydrochloric acid or dimethylammonium chloride gave similar results, though the relative amounts of the oximes (**11** and **13**) and the ketones (**14** and **15**) varied considerably. Oxime **12** (5%) was also formed in the latter reaction. In these reactions, similar esr signals were always observed with the crude products and the presence of hydroxylamine **17** or related compounds, e.g., X = Cl or $N(CH_3)_2$, were indicated from the crude fractions of chromatography or gc–ms analysis. Many attempts to purify such crude fractions failed, probably due to air oxidation and other decomposition pathways during the operations.

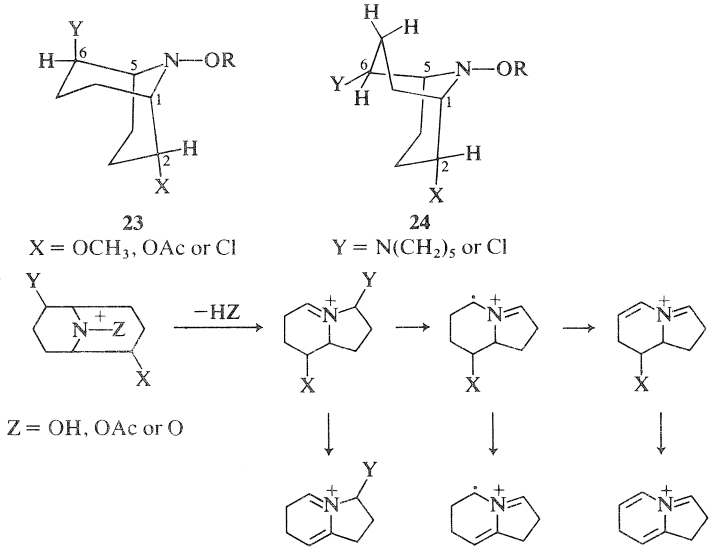
Decomposition of the dimer of *C*-nitroso compound **10** in methylene chloride – acetic anhydride gave hydroxylamine **18** (60%) and oximino acetate **16** (30%), but, in the co-presence of acetic acid or sodium acetate in the same solvent, the yield of **18** was lower and that of **16** increased. Judging from the ten signal pattern of the ^{13}C nmr of oximino acetate **16**, this sample was homogeneous. In view of the chemical shifts of the C-2 at 59.6 ppm and the corresponding methine proton at τ 5.15, this oxime likely possesses the *syn* configuration. The structures of **13**, **14**, and **15** were suggested from their ir, nmr, and mass spectra.

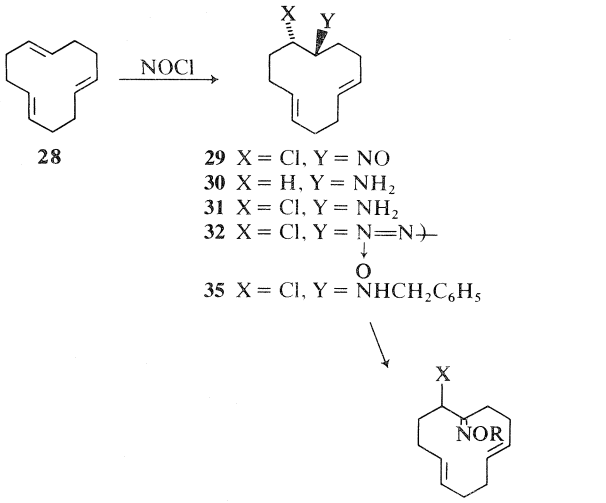
While crude hydroxylamine acetate **18** from chromatography showed an esr triplet due to a trace amount of nitroxide **21** (*vide infra*), the sublimed sample was free of this signal and was characterized rigorously. Both hydroxylamines **17** and **18**, in analogy to hydroxylamines **5** and **6**, exhibited a broad multiplet for the C-2 proton (axial orientation), a narrow one for the C-6 proton (equatorial orientation), and a two proton multiplet for the C-1 and C-5 bridge protons. In particular, the axial orientation of the C-2 proton in **18** was clearly established by the coupling pattern, $J_{2,1} = 5$ Hz, $J_{2,3a} = 11$ Hz and $J_{2,3e} = 7$ Hz, which was obtained by decoupling experiments. From the ^{1}H nmr parameters and considerations based on Dreiding models, **23** and **24** with fairly flattened rings could be the most probable conformations among others for hydroxylamines **5**, **6**, **17**, and **18**. For **17** and **18** and their derivatives, the preferred conformation was most likely **23** because of the narrow signals ($W_{1/2} \approx 10$ Hz) for the protons at C-1 and C-5; it was reported that the corresponding protons in a chair–boat conformation showed much wider signals (≈ 16 Hz) but those in a chair–chair conformation showed narrower signals (9–10 Hz) (24). For a bulky Y = $N(CH_2)_5$ group in **5** and **6**, conformation **24** was more likely since the signal for the corresponding protons was much wider (12–14 Hz).

The mass spectra of these hydroxylamines **5**, **6**, **17**, and **18** indicated the common skeletal features by exhibiting the corresponding mass peaks that might be represented by the ion as shown, among other possibilities. The intensities of these ions varied depending on the group of X, Y, and Z and each compound had other prominent *m/e* peaks than those shown.

Hydroxylamine acetate **18** in methylene chloride showed no esr signal at all but, when shaken in the presence of saturated sodium carbonate solution in the air, it rapidly developed an intense 1:1:1 triplet with *g* value 2.0073 and $a_N = 17.2$ G (line width 4.8 G) within six minutes; the intensity was increased slowly afterward. This signal, as well as those from **5**, **6**, and **17**, persisted for more than a year. Brief reduction of **18** with lithium aluminum hydride gave hydroxylamine **19**, which possessed the expected ms, ^{1}H nmr, and ir spectra and was oxidized with alkaline hydrogen peroxide to give nitroxide **22**, showing a broad esr triplet (1:1:1) with *g* value 2.0078 and $a_N = 17.5$ G (band width 5.4 G).

The structure of hydroxylamine acetate **18** was confirmed by the following chemical transformation. Reduction of **18** with zinc and sodium iodide in acetic acid gave bicyclic amine **25**, which was rigorously characterized by analysis and spectroscopic data. Its ^{1}H nmr spectrum has a very similar pattern to that of **18** in the downfield region; while the C-2 (τ 4.93), C-1, and C-5 (τ 6.90) protons were shifted slightly upfield, the C-6 proton (τ 5.70) remained at the same chemical shift with respect to those of **18**. This suggests that the *N*-acetoxy group orients itself primarily as shown in **23** and **24** exerting long range deshielding effects on protons other than the C-6. The mass spectrum of **25** could be interpreted with a similar fragmentation scheme as shown above. Reduction of **25** with lithium aluminum hydride, followed by tosylation and further reduction with lithium aluminum hydride gave a 6:7 mixture of **26** and **27**; both compounds were identified by their mass spectra from gc–ms analysis. The bicyclic amine **27** was isolated and was tosylated to give known 9-tosyl-9-azabicyclo[3.3.1]nonane (25).

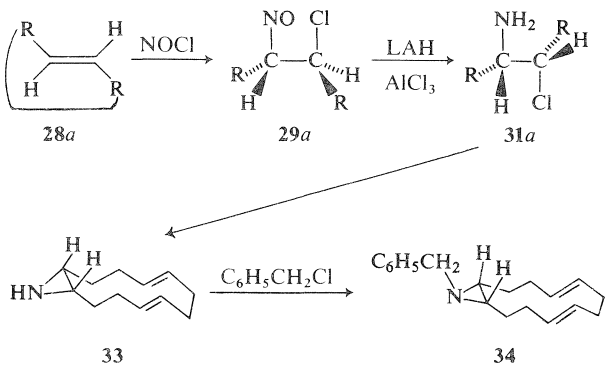




The *anti*-dimer of the chloronitroso compound **29** was obtained in a 94% yield from the addition of nitrosyl chloride to *trans,trans,trans*-1,5,9-cyclododecatriene (**28**, *ttt*CDT) (26, 27); this sample showed one spot on tlc and a sharp melting point. This compound had been prepared previously (26), but its stereochemistry was not reported. Since triene **28** had three-fold axes of symmetry, addition of nitrosyl chloride would not generate regioisomers. The ^{13}C nmr spectrum of the dimer, however, showed 17 lines, some of which were due to superimposed signals. The ^{1}H nmr spectrum of the dimer showed the C-1 (τ 4.16) and C-2 (τ 5.65) protons to be well resolved multiplets; by decoupling of the vicinal protons, the signals were collapsed to two sets of AB quartets. These nmr data indicated that this sample contained two dimers that were shown to be the *dl* and *meso* dimers (21) of *threo* (*trans*) chloronitroso compound **29** by the following transformation. The reduction of this dimeric sample with lithium aluminum hydride gave amine **30** and a minor amount of aziridine **33**, but with a LAH–$AlCl_3$ mixture a single chloro amine **31** in a 65% yield in addition to small amounts of azoxyalkane **32** and amine **30**. Further chloroamine **31** was converted to aziridine **33**.

Azoxyalkane **32** showed a ^{13}C nmr spectrum consisting of two sets of 12 line signals indicating one isomer;[1] it also showed an M^+ ion peak in agreement with the formula. While both amine **30** and chloro amine **31** showed the expected spectral data including ^{13}C nmr spectra containing 12 lines, aziridine **33** exhibited a 6 line ^{13}C nmr spectrum and a simple ^{1}H nmr pattern. This indicated that aziridine **33** must have the *dl*- or *meso*-configuration. Chloro amine **31** exhibited well resolved methine proton signals at τ 5.73 and 7.06 with a coupling constant of 2 Hz. This information did not permit a decision between the *erythro*- or *threo*-configuration. In order to determine the stereochemistry at the C-1 and C-2 positions, aziridine **33** was benzylated to give monobenzylaziridine **34** which could not be bis-benzylated under more vigorous conditions. On treatment with hydrogen chloride, the aziridine ring of **34** was opened up to give monobenzyl chloramine **35**.

The ^{13}C nmr spectrum of monobenzylaziridine **34** exhibited 6 lines for the aziridine portion and 5 lines for the benzyl portion; its ^{1}H nmr spectrum was relatively simple showing a sharp singlet at τ 6.56 for the benzyl protons. These spectroscopic data clearly proved that the aziridines **33** and **34** must possess the plane of symmetry and, therefore, the *meso*-configuration. Should **34** have the *dl*-configuration the aziridine would show 12 line ^{13}C nmr signals and the benzyl protons would be an AB quartet due to their diastereotopic nature. The assignment of the stereochemistry of **33** as *meso* (*cis*)-configuration permits the determination of the stereochemistry of chloronitroso compound **29** as *threo* (*trans*) if the elimination of hydrogen chloride from **31** to give aziridine **33** is assumed to occur by *trans*-elimination as shown below. The stereochemical course of the nitrosyl chloride addition to *ttt*CDT, therefore, must be the *cis*-addition in agreement with that to **1**.



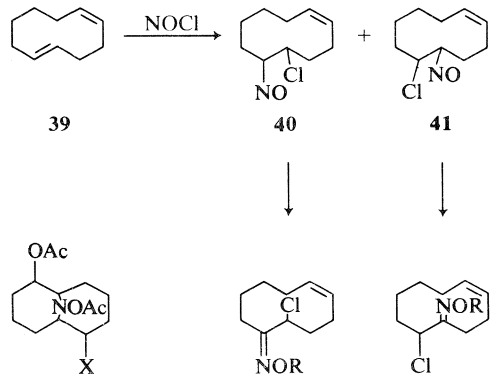
The dimer reacted with pyridine readily to give a nearly quantitative yield of pyridinium chloride **36**, which was further transformed to the known *syn*-dimethylamino oxime **37** (23) on reaction with excess dimethylamine. The treatment of the dimer of **29** with acetic anhydride gave a good yield of oximino acetate **38** and several minor products. Though the minor products could not be obtained, the crude reaction mixture exhibited an esr triplet (1:1:1) with

[1]The isolation of only one azoxyalkane **32** was rather unexpected and may arise by selective reduction of either the *dl* or *meso* isomer of **29** or, alternatively, by stereospecific condensation of one enantiomer of *RR*- or *SS*-**29** with one enantiomer of *RR*- or *SS*-hydroxylamine derived from the reduction of **29**.

$g = 2.0068$ and $a_N = 13.5$ G, typical of a nitroxide. Obviously, if similar transannular electrophilic cyclization as demonstrated with **10** had occurred with **29**, their amounts were fairly small.

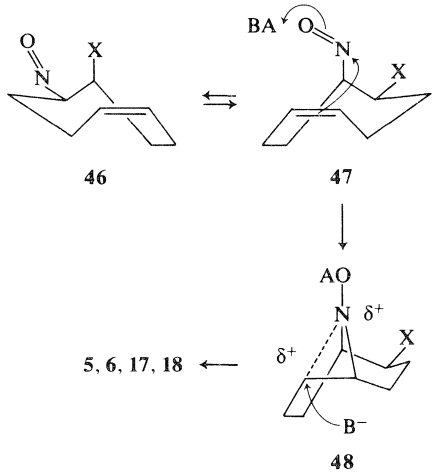
The addition of nitrosyl chloride to *trans,cis*-1,5-cyclodecadiene (**39**, *tc*CDD) is able, in theory, to give isomeric chloronitroso adducts arising from attack at different double bonds, from regioselectivity, and from the *cis*- and *trans*-addition pathway; furthermore, the *C*-nitroso dimers would be a complex mixture of *meso* and *dl* isomers (21) arising from all possible combinations of the above enantiomorphic *C*-nitroso isomers. The crude or recrystallized *C*-nitroso dimer showed a surprisingly sharp melting point and also had uv and ir absorptions compatible with the *anti*-azodioxy linkage. This sample was obviously an isomeric mixture as shown by its ambiguous and diffused ^{13}C and ^1H nmr spectra. However, the ir absorption at 770 cm^{-1} and the result from tautomerization products (*vide infra*) indicated that the chloronitroso compounds were a regioisomeric mixture arising from the attack at the *trans* double bond of **39**, i.e., a mixture of **40** and **41** with unknown configurations.

Decomposition of the dimer of *C*-nitroso compounds **40–41** in the presence of hydrochloric acid



gave a mixture, which showed overlapped esr signals at $g \simeq 2.006$ and two similar nmr signals at τ 5.45 and 5.63, probably due to the C-2 protons of **42** and **43**. As the multiplet at τ 4.7 was changed to broad doublet ($J = 13$ Hz) on irradiation at the τ 8.00 region, the presence of the *cis* double bond was indicated. Chromatography of the mixture afforded one chloro oxime in the pure state and a mixture of cyclized hydroxylamines which could not be purified further. The isolated chloro oxime had pertinent analysis and spectral data for either **42** or **43**. However, structure **42** was favoured for the chloro oxime since decoupling experiments indicated that one C-10 proton at τ 6.93 was coupled with non-allylic protons at τ 8.39. As attempted isomerization of this sample under acidic conditions failed to give the other chloro oxime as shown by nmr monitors, it was concluded that two chloro oximes were positional isomers as in **42** and **43** but not the *syn–anti* isomers of the oxime.

Decomposition of the dimer of **40–41** in the presence of acetic anhydride was slow and gave an oil exhibiting one major esr triplet and two minor ones nearly overlapping in the region $g = 2.007$. The major product was a 1:3 mixture of two oximino acetates (i.e. **44** and **45**) exhibiting two analogous double doublets at τ 5.34 and 5.66 for the C-2 protons; this fraction showed the expected spectral data and analysis, but the assignments of structures to the major and minor components could not be achieved. Two minor compounds obtained in the amount of 8% each were shown to be a chloroacetoxyhydroxylamine acetate, such as **46**, and a diacetoxyhydroxylamine acetate, such as **47**. The spectral data supported the presence of the relevant functional groups in both cases, but their structures could not be confirmed.



Discussion

From the results described above, two aspects of chemical transformations merit discussion, namely, the transannular electrophilic reaction of nitrosoalkenes and the nitrosyl chloride addition to olefins; both of them are intimately related to stereochemistry.

In spite of the report that the addition of nitrosoarenes to olefins occurs by a free radical (one-electron transfer) mechanism (6, 7) the intramolecular reaction of nitrosoalkenes described above must take place by an ionic mechanism on the basis of the following reasons. Firstly, the reaction is catalyzed by an acid and occurs even in the dark to give hydroxyl-

amines, but not nitroxides, as the primary product. Secondly, the transannular reaction affords six-membered heterocycles rather than five-membered ones; it is well documented that cyclization initiated by nitrogen centred radicals generally gives five-membered compounds as the major or exclusive product (29). The overall pattern of the acid catalyzed electrophilic attack of a *C*-nitroso group is the formation of bridged bicyclic hydroxylamines with the attachment of an anion. Such a reaction may be regarded as an allied reaction of the competing acid catalyzed tautomerization in which the electron pair of the α-CH bond participates in the electron reorganization of the nitroso group, if there are no other readily accessible electrons. The stereochemical requirements for the intramolecular reaction of the nitroso and olefinic groups are, therefore, that the π-orbitals of the interacting groups are capable of overlapping through space; this is related to the conformation of the reacting centres and, in turn, to the mode of addition of nitrosyl derivatives to polyenes.

It is indeed fortunate that nitrosyl chloride addition to 1,5-COD occurs stereospecifically to afford a single chloronitroso compound **10** which should have the *cis*-configuration since a proper conformation is available for the transannular reaction. The ^{1}H nmr results show that the *anti*-dimer of the *C*-nitroso compound **10** preferentially assumes the conformation **46** on the basis that the C-1 (CHNO) and C-2 (CHCl) protons are not coupled and, therefore, have ca. 90° dihedral angle, and that the coupling patterns of the C-1 (J = 11.5 and 4 Hz) and C-2 ($W_{1/2}$ = 11 Hz) indicate pseudo-axial and pseudo-equatorial orientations, respectively, for these protons. Studies of Dreiding stereomodels qualitatively show that **46** and **47** are more stable than other conformations for the *cis*-configuration of **10**. While for the dimer the conformation **46** is preferred owing to the bulky azodioxy group, the monomer **10**, having a much smaller bulk of the nitroso group, may be able to invert readily to **47**, from which a transannular interaction of the nitroso and olefinic π-bonds can occur as shown in **47** and **48**. The attack of an anion Y^- from the opposite side of the nitrogen bridge in the intermediate **48** leads to the observed configuration in **17** and **18**. Thus, the stereochemical consequence of the formation of hydroxylamines **17** and **18** necessitates the *cis*-configuration for **10**. An assumption of the *trans*-configuration for **10** does not readily give a conformation to satisfy the ^{1}H nmr parameters from model studies, nor lead to the observed configuration for hydroxylamines **17** and **18**. Preferential tautomerization of **10** to oxime **11** in protic solvents may be rationalized by the fact that the protonation of the nitroso group is accompanied by enlargement of the bulk of this group through solvation; this raises the conformational energy for **48** which, in turn, makes **10** less likely to undergo the transannular reaction.

The unisolated aminonitroso compounds **3** formed in the photoaddition of nitrosopiperidine to 1,5-COD must have *trans*- as well as *cis*-configurations in agreement with the previous findings (1, 4). Because of the bulky protonated piperidino group, the latter should have the conformation **47** preferentially, from which the transannular reaction can occur efficiently even in protic solvents. The stereochemical requirement of this cyclization is very similar to that discussed in the oxidative photoaddition of nitrosamines to 1,5-COD in which the *cis*-1-amino-2-nitrate, but not the *trans*-isomer, can undergo the transannular reaction to give the oxygen bridged bicyclic compound (22).

Whereas the trapping of radicals with *C*-nitroso compounds is a well established route for direct nitroxide formations (5–8), the present cases showed that for certain nitrosoalkenes, such as **10**, acid catalyzed intramolecular electrophilic reaction can also serve as an efficient route to give nitroxides indirectly via hydroxylamines. The intermolecular analogy of such electrophilic reaction undoubtedly can occur to a small extent, and if reactive olefins and *C*-nitroso compounds, e.g., caryophyllene with an endocyclic *trans* double bond (18) or nitrosobenzene (15–17), are used, isolable yields of hydroxylamines can be obtained. Recently, reactions of α-chloronitrosoalkanes with allenes or 2-phenylpropene have been reported to give good yields of analogous compounds (30).

It follows that chloronitroso compounds **40** and **41** are also capable of assuming conformations in which the reacting nitroso and olefinic π-orbitals can be brought to overlapping proximity but probably with a higher activation energy since the yields of the transannular cyclization are low. Such a conformation is obviously not readily available for chloronitroso compound **29**. The similar type of hydroxylamine, if formed at all as judged by the esr signal, is not present in a significant amount.

Reports on the generation of nitroxides and detection by esr studies are numerous but only in a few cases are nitroxides actually isolated and characterized (18–20), probably due to their low yields and (or) instability. Nitroxides are usually non-crystalline and difficult to purify, as shown previously (3) and in this report. On the other hand, hydroxylamine acetates, such as **18**, can be purified and stored, and further, can be easily hydrolysed under mild conditions, e.g., with aqueous sodium carbonate solution, to give hydroxylamines that are readily oxidized in the

air to generate nitroxide radicals (20). These reactions may explain the detection of the nitroxide esr signal with the crude sample of hydroxylamine acetate **18** isolated in rearrangement in acetic anhydride. Therefore, hydroxylamine acetates can serve as stable precursors to generate nitroxides continuously for a considerable period.

In spite of a large number of reports on nitrosyl chloride addition to olefins (28), the stereochemical course of the addition remains relatively vague mainly because of the fact that enantiomorphic adducts dimerize homospecifically to give the *dl* dimers as well as heterospecifically to give the *meso* dimers (21). This situation has recently been nicely demonstrated by Rogić and co-workers (21), when the confusing claims over the *C*-nitroso dimers derived from the addition to cyclohexene (31, 32) were clearly resolved. The clarification of *C*-nitroso monomer **10** with the *cis*-configuration and that of **29** with the *threo* (*trans*)-configuration proves that the nitrosyl chloride additions to 1,5-COD and *ttt*CDT in methylene chloride occur by the *cis* stereochemical course. These are in agreement with the *cis*-addition of nitrosyl chloride to various olefins in low polarity solvents such as methylene chloride and carbon tetrachloride (21, 31, 33) for which the four-centred addition through a molecular complex has been proposed by Meinwald and co-workers (33). A survey of the literature and unpublished results from our laboratory shows that the addition of nitrosyl chloride (31) or formate (34) to olefins in highly polar solvents, such as sulfur dioxide and formic acid, may preferentially give *trans*-addition products; this may occur by a stepwise attack of the nitrosonium ion stabilized by the highly ionizing media.

In this report ^{13}C nmr spectroscopy has been shown to be a superior method to monitor diastereoisomeric mixtures where ^{1}H nmr spectroscopy is of limited usefulness. In particular, owing to a lability to heat, melting points, gc, and tlc are unsatisfactory criteria as measures of homogeneity for the dimers of *C*-nitroso compounds **29** and **40**–**41**. But ^{13}C nmr spectra unambiguously show that the sample of the dimer of **29** is a mixture of *meso* and *dl* compounds and that of *C*-nitroso compound **10** contains only one diastereoisomer, either *meso* or *dl*. In the latter case, the dimerization process is specifically regulated by the conformational factors associated with *cis*-configuration.

Whereas the addition of nitrosyl chloride to *tc*CDD is non-regiospecific as shown by the tautomerization products **42**–**45**, it is established that the *trans* double bond is more reactive than the *cis* one toward nitrosyl chloride, in agreement with the published results (26–28). In analogy to the addition to other olefins as discussed above, the addition to the *tc*CDD *trans* double bond may also occur by stereospecific *cis* geometry. Unfortunately experiments designed to prove this point have not been successful.

Experimental

General Conditions

Unless specified otherwise, the following conditions prevailed. Nuclear magnetic resonance spectra were measured with a Varian A-56/60 or an XL-100 (with or without a Fourier transform attachment) spectrometer in $CDCl_3$ using TMS as the internal standard, and ir spectra were taken in neat or Nujol mulls with a Perkin-Elmer Model 457. Instruments included an Hitachi-Perkin-Elmer Model RMU-6E, a Cary 14, a Varian E-4, and a Varian 1200 vpc apparatus with a flame ionization detector. The gc–ms measurements used a Varian 1400 (20% SE-30 column) coupled with the mass spectrometer. Melting points were reported as determined with a Fisher-Johns hot stage or a Gallenkamp heating block. Elemental analyses were performed by Mr. M. K. Yang with a Perkin-Elmer microanalyser.

Photoaddition of N-*Nitrosopiperidine to 1,5-Cyclooctadiene*

(*1*) A methanol solution (320 mL) containing 1,5-cyclooctadiene (4.32 g), *N*-nitrosopiperidine (5.47 g), and 70% perchloric acid (6.9 g) was irradiated with a 200 W Hanovia lamp under nitrogen through a Nonex filter for 5 h. The photolysate was treated with sodium carbonate (5.5 g) and stirred. The solution was evaporated to ca. 50 mL and filtered. The filtrate was cooled in a refrigerator to give colorless crystals (450 mg). The crystals were recrystallized from methanol to give the perchlorate of hydroxylamine **6**, mp 202–203°C; ir: 3200, 3080, 1110(s), 1050(s), and 620(s) cm^{-1}; ms *m/e* (%): 255 (M^+, 0.8), 254.1998 (1.6; calcd, for $C_{14}H_{26}N_2O_2$: 254.1994), 238(9), 237.1967 (42, calcd. for $C_{14}H_{25}N_2O$: 237.1967), 155(39), 154.1234 (100, calcd. for $C_9H_{16}NO$: 154.1232), 152(35), 140(29), 124.1127 (52, calcd. for $C_8H_{14}N$: 124.1126), 122(20), 98(26), 84.0815 (93, calcd. for $C_5H_{10}N$: 84.0813). *Anal.* calcd. for $C_{14}H_{26}N_2O_2 \cdot HClO_4$: C 47.39, H 7.67, N 7.89; found: C 47.11, H 7.78, N 7.72. The ^{1}H nmr signals were unresolved and showed a singlet at τ 6.73 and a broad signal at τ 6.3. The crystals were taken up in water and neutralized with a sodium hydroxide solution to afford hydroxylamine **6** (*vide infra*).

The mother liquor was evaporated and the residue was diluted with water. Extraction with methylene chloride (50 mL × 5) and the usual workup gave a solid (8.74 g). This solid (4 g) was chromatographed on silicic acid. Elution with 2.5–5% MeOH in CH_2Cl_2 gave oxime **4** (1.42 g) and with 5–10% MeOH in CH_2Cl_2 gave hydroxylamine **6** (1.57 g). Oxime **4** was recrystallized from methanol to give monoclinic crystals: mp 137–138.5°C; ir: 3170(m), 3020(m), 2700(s), 1505(w), 1100(m), 1095(m), 1032(m), 955(s), 948(s), 895(s), 862(m), 770(s), 730(s) cm^{-1}; ^{1}H nmr τ: 1.12 (1H, D_2O exchangeable), 4.39 (m, 2H), 6.92 (m, 2H), 7.32–9.00 (m, 17H); ms *m/e* (%): 222 (M^+, 6), 206(18), 205(100), 204(14), 164(37), 124(32), 122(14), 111(59), 84(60). ^{1}H nmr decoupling experiments showed that, on irradiation of the big signal at 7.32–9.00, the vinyl signal at τ 4.39 changed to an AB quartet (J = 13 Hz) and the signal at τ 6.92 changed pattern. *Anal.* calcd. for $C_{13}H_{22}N_2O$: C 70.23, H 9.97, N 12.60; found: C 70.20, H 9.88, N 12.68. The oxime **4** was hydrogenated in the presence of platinum black in ethanol to give the known *anti*-2-piperidinocyclooctanone oxime; the ir and nmr spectra were superimposable with those of an authentic sample prepared previously; mp and mixed mp 160–162°C (lit. (33) mp 163–165°C).

The fraction containing hydroxylamine **6** showed the fol-

lowing physical constants; ir: 3500–3000 (broad), 1090(s), 955(m), 900(s) cm^{-1}; ms *m/e* (%): 254 (M^+, 2), 252(1), 237(9), 154(100), 152(15), 124(38), 113(15), 112(15), 98(27), 86(29), 84(49); esr in benzene: $g = 2.0051 \pm 0.0003$ G, $a_N = 17.25$ G (line width 4.5 G). The reduction of the solid with lithium aluminum hydride followed by immediate acetylation gave a complex mixture. This solid (150 mg) was treated in water (2 mL) containing 30% H_2O_2 (2 mL) and 2 drops of 1 *N* NaOH for 1 h. The mixture was extracted with methylene chloride, which was worked up to afford a brown paste (100 mg). This crude product was passed through an alumina column to afford nitroxide **9** as a brown semi-solid; ir: 3150 (bw), 1103(s), 1090(s), 898(m) cm^{-1}; esr in benzene: $g = 2.0067$, $a_N = 17.25$ G (line width 5 G); ms *m/e* (%): 253.1917 (M^+, 12, calcd. for $C_{14}H_{25}N_2O_2$: 253.1917), 238(16), 277.1967 (66, calcd. for $C_{14}H_{25}N_2O$: 237.1967), 205.1701 (16, calcd. for $C_{13}H_{21}N_2$: 205.1705), 155(53), 154.1228 (100, calcd. for $C_9H_{16}NO$: 154.1232), 152(53), 125(29), 124.1130 (77, calcd. for $C_8H_{14}N$: 124.1126), 122.0966 (32, calcd. for $C_8H_{12}N$: 122.0970), 120(30), 111(29), 84(44). *Anal.* calcd. for $C_{14}H_{25}N_2O_2$: C 66.37, H 9.95, N 11.06; found: C 66.65, H 10.02, N 11.47. The yields of oxime **4** and hydroxylamine **6** were 37 and 38%, respectively, based on the amount of *N*-nitrosopiperidine.

Hydroxylamine **6** (516 mg) and acetic anhydride (2 mL) in ether were kept at −15°C for 3 h under hydrogen atmosphere. The reaction mixture was poured into ice-water and worked up in the usual manner to give a solid (467 mg) which was crystallized from pentane twice to afford hydroxylamine acetate **7**; mp 91–92°C (started to decompose at 85°C); ir: 1765(s), 1378(s), 1225(s), 1212(s), 1010(s), 950(s), 932(s), 890(s), 845(m), 790(m) cm^{-1}. *Anal.* calcd. for $C_{15}H_{25}N_2O_2Cl$: C 59.89, H 8.38, N 9.31; found: C 60.10, H 8.48, N 9.30.

(*2*) A solution containing *N*-nitrosopiperidine (7.27 g), 1,5-cyclooctadiene (10 mL) and concentrated hydrochloric acid (7 mL) was photolysed under nitrogen for 1.5 h. The solution (4/5) was evaporated; benzene (100 mL) and ethanol (10 mL) were added to the residue and evaporated. The residue was diluted with acetone to give a white precipitate (9.1 g). The mother liquor was evaporated and diluted with water. The aqueous solution, after being evaporated, was washed with ether and neutralized with sodium carbonate solution. The precipitated solid (2.1 g) was filtered to afford a crude hydroxylamine **5** and recrystallized from methanol twice; recrystallization from cyclohexane gave hydroxylamine **5**; mp 166–167°C (dec.); ir: 3200–2600, 3090(m), 1510(w), 982(m), 948(s), 895, 780(s), 730(s) cm^{-1}; ^1H nmr τ: 2.0(O*H*), 5.19 (m of d, $J = 9$ and 4 Hz, 1H), 6.71 (m, 2H), 7.15 (m, 1H), 7.7 (m, 4H), 8.00 (m); ms *m/e* (%): 243(4), 241(11), 207(2), 205(5), 160(36), 158(100), 124(89), 120(35), 111(19), 98(22), 84(29); ^{13}C nmr: 65.5(d), 60.2(d), 56.6(d), 55.8(d), 51.0(t), 30.0(t), 24.8(t), 23.2(t), 22.8(t), 21.6(t), 17.5(t). *Anal.* calcd. for $C_{13}H_{23}N_2OCl$: C 60.33, H 8.96, N 10.82; found: C 60.30, H 9.11, N 10.90. The crude hydroxylamine fraction showed a triplet esr signal (1:1:1) at $g = 2.006$, $a_N = 16.5$ G in carbon tetrachloride. Irradiation at τ 6.71 or at τ 8.00 region changed the coupling pattern of the signal at τ 5.19. Attempted LAH reduction and acetylation yielded a product showing an ir absorption at 1760 cm^{-1} ($NOCOCH_3$) but could not be purified.

The white precipitate (500 mg) was dissolved in water and neutralized. The precipitate (410 mg) was recrystallized from methanol to afford oxime **4**; mp 134–135°C; the ir and nmr spectra were superimposable with those of the previous sample. The mother liquor was combined and evaporated to give a residue. The residue was a mixture of oxime **4** and hydroxylamine **6**, in a ratio of ca. 3:1 as shown by tlc and ir and nmr spectra.

The Preparation of the Dimer of C-*Nitroso Compound* ***10***

(*1*) A methylene chloride solution (20 mL) of nitrosyl chloride (3.26 g, 0.05 mol) was added dropwise in half an hour to a solution of 1,5-cyclooctadiene (10 g, 0.093 mol) in methylene chloride (20 mL) at −10°C. After 0.5 h hexane (100 mL) was added to the reaction mixture, which was evaporated to 40 mL under vacuum. The solution was cooled to deposit a white solid (2.56 g, mp 99–101°C), which was recrystallized from a 1:4 mixture of $CHCl_3$–hexane to afford the *anti*-dimer of *cis*-1-nitroso-2-chloro-5-cyclooctene (**10**); mp 104.5–105°C; uv λ_{max} (CH_2Cl_2): 294 nm (ε_{max}, 6250); ir: 3020(m), 1238(s), 1208(s), 775(m), 752(m), and 736(s) cm^{-1}; ^1H nmr τ: 4.06–4.40 (m, 2H), 4.57 (dd, $J = 11.5$ and 4.0 Hz, 1H), 5.48 (m, $W_{1/2} = 11$ Hz, 1H), 7.1–8.2 (m, 8H); ^{13}C nmr: 131.0(d), 128.5(d), 67.8(d), 61.0(d), 35.7(t), 27.3(t), 21.8(t), and 21.6(t); ms (110°C) *m/e* (%): 176(1.5), 175(2), 174(3), 173(2), 158(4), 156(9), 138(13), 120(10), 107(42), 91(46), 79(100), 67(42), 53(20), 41(33), and 39(29). *Anal.* calcd. for $(C_8H_{12}NOCl)_2$: C 55.34, H 6.97, N 8.07; found: C 55.23, H 6.93, N 8.07. On irradiation at τ 7.89, the multiplet at 5.48 collapsed to a doublet ($J = 8$ Hz) and that at τ 4.57 was modified. On irradiation at τ 7.78, the double doublet at τ 4.57 collapsed to a singlet and the signal at 5.48 changed slightly. Irradiation at τ 5.48 or at τ 4.57 caused no change in the respective signal nor in the olefinic signal at τ 4.2 area.

The blue mother liquor was washed with sodium carbonate solution and water. The organic phase was dried and evaporated. To the residue, *n*-hexane was added to afford an additional dimer of **10** (564 mg, mp 98–102°C.)

(*2*) A methylene chloride solution of nitrosyl chloride (34% by weight, 0.88 g, 4.63×10^{-3} mol) was added in 15 min to a methylene chloride solution (15 mL) containing COD (0.5 g, 4.63×10^{-3} mol). The solution was stirred at −10°C for 30 min and was diluted with *n*-hexane (50 mL). The mixture was evaporated to ca. 30 mL to afford the first crop (196 mg, 24%, mp 98–101°C). Further evaporation to ca. 10 mL afforded the second crop of solid (165 mg, 20%, mp 95–98°C). The mother liquor was evaporated to afford a dark blue oil (222 mg). These samples were examined with ^{13}C nmr spectroscopy and intensity of comparable peaks was used to estimate the % yield of the products. The first crop contained the dimer of **10** and *syn*-oxime **11** in the ratio of 9:1 and the second crop the dimer of **10** and *syn*- and *anti*-oximes **11** in the ratio of 7:2:1. The blue oil consisted of *syn*- and *anti*-oximes **11**, COD, and the dimer in the ratio of 8:4:4:3. The estimated yield of the dimer of **10** was 43%.

Reactions of the Dimer of ***10***

(*1*) The crude dimer (450 mg) was left at room temperature for two months to give an orange oil which was a mixture of *anti*- and *syn*-oxime **11** showing ir: 3280 (broad), 3020(m), 1640(m), 1155(m), 990(s), 900(s), 755(s) and 680(s) cm^{-1}; ^1H nmr: τ 0.95 (OH), 4.33 (m, 2H), 5.40 (dd, $J = 7.0$ and 5.0 Hz, 2/3 H), 5.68 (dd, $J = 8.0$ and 4.0 Hz, 1/3 H), 7.0–8.1 (m, 8H); ^{13}C nmr: *160.2*(s), 158.8(s), 130.6, 130.1, *129.4*(d), *129.3*(d), *60.2*(d), 55.9(d), *36.9*(t), 33.8(t), 31.8(t) *25.9*(t), *22.8*(t), 22.2, *22.1*(t), 20.9(t). The chemical shifts in italics of ^{13}C nmr were relatively more intense than others. A part of the oil was sublimed to afford a colourless oil of *syn*-1-oximino-2-chloro-5-cyclooctene (**11**); one peak at 17.3 min on a 10% SE-30; ir: 3300 (b), 3020(m), 1645(m), 1225(m), 1215(m), 1165(m), 1155(m), 985(s), 900(s), 755(s), and 670(m) cm^{-1}; ^1H nmr τ: 2.26(OH), 4.33 (m, 2H), 5.40 (dd, $J = 7.0$ and 5.0 Hz, 1H), and 7.0–8.1 (m, 8H); ms (100°C) *m/e* (%): 175 (M^+, 3), 173(5), 158(34), 156(88), 138(94), 120(100), 93(56), 84(66), 74(96), and 67(58). *Anal.* calcd. for $C_8H_{12}NOCl$: C 55.34, H 6.97, N 8.07; found: C 55.50, H 6.97, N 8.38. A mixture of oxime **11** was treated with piperidine to give oxime **4**: mp 135–137°C.

(*2*) A suspension of the dimer of **10** (200 mg) in methylene chloride (5 mL) and methanol (20 mL) containing two drops of perchloric acid (70%) was stirred at 40°C for one day, when the dimer disappeared as shown by tlc. The solution was evaporated and water (20 mL) added. Extraction of the solution with methylene chloride (20 mL × 3) gave a colourless oil (170 mg). By the gc peak matching method, chloro oxime **11** (17.3 min) was shown to be present in 70% yield and 2-chloro-5-cyclooctenone (**14**) and 2-methoxy-5-cyclooctenone (**15**) in trace amounts (23). By gc–ms, the oil was shown to contain the above compounds in addition to a mixture of *syn*- and *anti*-methoxy oxime **13** (16.3 min, 15%): ms *m/e* (%): 169 (M^+, 7), 152(87), 137(49), 120(90), 109(55), 94(72), 79(89), 67(100), and 41(78).

The aqueous phase was adjusted to pH 10 and was extracted with methylene chloride to afford solid hydroxylamine **17** (10 mg); ir: 3200(b), 1265(m), 1102(m), 1088(s), 1050(m), 910(s), 840(m), 725(s), 653(m), 630(m) cm^{-1}; ^1H nmr τ: 5.68 (m, $W_{1/2}$ = 8 Hz, 1H), 6.02 (m, $W_{1/2}$ = 22 Hz, 1H), 6.46–6.76 (m, 2H), 6.64 (s, 3H), and 7.5–8.85 (m, 9H); ms (90°C) *m/e* (%): 207 (M^+, 2), 205 (M^+, 6) 190(39), 188(100), 176(6), 174(20), 170(27), 160(7), 158(22), 120(21), 112(28), 71(46), and 41(41); esr (CH_2Cl_2) triplet (1:1:1): g = 2.0073 ± 0.0006, a_N = 17.5 G (line width = 5.5 G).

When the dimer (200 mg) was treated similarly in the presence of dimethylamine hydrochloride, it gave a neutral fraction (185 mg) consisting of chloro oximes **11** as the major product (81%) and hydroxylamine **17** in a 9% yield. This oil showed the same esr signal as above. The oil was treated with zinc (1 g) and acetic anhydride (1 g). The product was worked up and chromatographed to give acetate of chloro oxime **16** (164 mg) and an oil (32 mg) showing the same esr signal. The basic fraction contained oxime **12** (5%) (23).

(*3*) A solution of the dimer (400 mg), acetic anhydride (2.4 g), and acetic acid (28 mg) in methylene chloride (25 mL) was heated at 40°C under nitrogen for 5 h. The reaction mixture was diluted with water and made basic with saturated sodium carbonate solution. Extraction with methylene chloride followed by the usual workup gave a yellow oil (461 mg) which showed two major and one minor spots on tlc. This mixture was taken up in methylene chloride and chromatographed on a silicic acid column. The four fractions eluted with 0.5–1% CH_3OH in CH_2Cl_2 gave a colourless oil (251 mg, 51%) which was sublimed to afford oximino acetate **16**; ir: 3020(m), 1775(vs), 1625(m), 1370(s), 1200(vs), 1002(s), 980(m), 925(s), 770(m), and 750(m) cm^{-1}; ^1H nmr τ: 4.34 (m, 2H), 5.15 (dd, J = 7.0 and 5.0 Hz, 1H), 6.88–8.10 (m, 8H), 7.83 (s, 3H); ^{13}C nmr: 167.3(s) 166.9(s), 129.7(d), 128.3(d), 59.6(d), 36.2(t), 27.1(t), 21.7(t), 21.3(t), 18.8(q) ppm; ms *m/e* (%): 211(6), 209(8), 175(19), 173(52), 138(37), 120(100), 91(73), 79(96), 67(68), and 43(88). *Anal.* calcd. for $C_{10}H_{14}NO_2Cl$: C 55.69, H 6.54, N 6.50; found: C 55.53, H 6.63, N 6.81. On irradiation at τ 7.85, the double doublet at τ 5.15 collapsed to a sharp singlet. On irradiation at τ 7.50, the olefinic signal at τ 4.34 changed to an AB quartet (J = 12 Hz).

The fractions eluted with 2–4% MeOH in CH_2Cl_2 afforded a yellowish solid (145 mg, 18%) which, in chloroform solution, showed a nitroxide esr triplet (1:1:1), g = 2.0068 ± 0.0006, a_N = 17.2 G (line width 5.7 G). The solid was sublimed to afford white crystals of hydroxylamine acetate **18**; mp 79–83°C; ir: 1768(s), 1726(s), 1370(s), 1246(s), 1232(s), 1213(s), 1200(s), 1032(s), 955(m), 900(m), 880(s), 790(m), 738(m) cm^{-1}; ^1H nmr τ: 4.64 (possibly ddd, J = 11, 7.0, and 5.0 Hz, 1H), 5.70 (m, $W_{1/2}$ = 8 Hz, 1H), 6.41 (m, $W_{1/2}$ = 11 Hz, 2H), 7.59–8.46 (m, 8H), 7.87 (s, 3H), 7.93 (s, 3H); ^{13}C nmr: 169.0(s), 168.4(s), 66.7 (d, C2), 59.4 (d, C1 and C6), 55.2 (d, C5), 27.6(t), 23.3(t), 21.6(t), 20.1(q), 19.4(t), 18.8(q) ppm; ms *m/e* (%): 277.0880 and 275.0903 (M^+, 2 and 6%, calcd. for $C_{12}H_{18}NO_4Cl$: 277.0894 and 275.0925), 235.0815 and 233.0800 (27 and 79, calcd. for $C_{10}H_{16}NO_3Cl$: 235.0789 and 233.0819), 218.0782 and 216.0811 (30 and 88, calcd. for $C_{10}H_{15}NO_2Cl$: 218.0761 and 216.0791), 198(44), 176.0646 and 174.0685 (33 and 100, calcd. for $C_8H_{13}NOCl$: 176.0656 and 174.0685), 158(8), 156(20), 138.0930 (46, calcd. for $C_8H_{12}NO$: 138.0919), 120.0809 (24, calcd. for $C_8H_{10}N$: 120.0813), 96.0576 (29, calcd. for C_6H_8O: 96.0576). On irradiation at τ 6.41, the signal at τ 4.64 became a broad double doublet (J = 10 and 7 Hz) and the pattern at τ 5.70 was changed. *Anal.* calcd. for $C_{12}H_{18}NO_4Cl$: C 52.27, H 6.58, N 5.08; found: C 52.57, H 6.61, N 5.17.

The dimer of **10** (100 mg) dissolved in methylene chloride (5 mL) and acetic anhydride (562 mg) was stirred under nitrogen at 50°C for two days. The usual workup gave an oil which was a mixture of oximino acetate **16** (30%) and hydroxylamine acetate **18** (60%) as judged by the ^1H nmr integration of the methine protons at τ 5.15 and 5.70.

Rearrangement of the dimer in acetic anhydride gave oximino acetate **16** and hydroxylamine acetate **18** in 50 and 42% yields. A similar treatment of the dimer (400 mg) in methylene chloride (15 mL) and acetic anhydride (2.25 g) containing fused sodium acetate (800 mg) gave a 3:2 mixture of **16** and **18**. Column chromatography of the mixture gave oxime acetate **16** (260 mg, 52%) and hydroxylamine acetate **18** (217 mg, 34%).

Reactions of Hydroxylamine 18

(*1*) A methylene chloride solution (4 mL) of **18** (0.5 mg) showed no esr signal. To this solution was added saturated sodium carbonate solution (1 mL) and shaken. Immediately the methylene chloride phase showed the esr signal of the 1:1:1 triplet, g = 2.0073 ± 0.0005, a_N = 17.2 G (line width 4.8 G). The signal increased rapidly for the first six minutes and then slowly afterwards and kept the same intensity for one year.

(*2*) Hydroxylamine acetate **18** (50 mg) in ether (5 mL) was treated with lithium aluminum hydride (200 mg) for five hours at room temperature and was worked up in the usual manner to give a solid (29 mg). Sublimation of the solid gave hydroxylamine **19**; mp 126–129°C; ir: 3300 (s, broad), 1255(s), 1095(s), 1060(s), 1035(s), 990(m), 960(m), 930(m), 905(s), 830(m), and 722(s) cm^{-1}; ^1H nmr τ: 5.48 (m, $W_{1/2}$ = 20 Hz, 1H), 5.67 (m, $W_{1/2}$ = 6 Hz, 1H), 6.64 (m, $W_{1/2}$ = 13 Hz, 2H) and 7.3–8.9 (m, 10H); ms *m/e* (%): 193 (M^+, 2), 191(8), 176(35), 174(100), 157(9), 156(15), 155(22), 140(40), 118(22), 112(22), 98(21), 96(26), 82(23), 80(21), and 67(25).

Hydroxylamine **19** (10 mg) was oxidized in aqueous solution containing 30% hydrogen peroxide (1 mL) and two drops of 1 *N* sodium hydroxide, and was worked up in the usual manner to give a yellow solid (5 mg) of **22**; ir: 1260(m), 1020(m), and 800(m) cm^{-1}; esr (CH_2Cl_2), triplet (1:1:1): g = 2.0078 ± 0.0005, a_N = 17.5 G (line width 5.4 G).

(*3*) A mixture of 80% acetic acid (3.5 mL), sodium iodide (175 mg), hydroxylamine acetate **18** (190 mg), and zinc dust (1.05 g) was stirred at room temperature for 36 h and at 40°C for 2 h. The zinc was filtered and the solution was evaporated. Water was added to the residue and the pH adjusted to 10. Extraction with methylene chloride and the usual workup gave an oil (131 mg, 87%) which was distilled to give **25**; ir: 3300(m), 1735(vs), 1370(s), 1240(vs), 1100(m), 1032(s), 922(s), 895(m), 882(m), 798(m), 775(m), 740(s), 700(s), 575(s) cm^{-1}; ^1H nmr τ: 4.93 (broad quintet, J = 10, 5, and 5 Hz, 1H), 5.70 (m, $W_{1/2}$ = 8 Hz, 1H), 6.9 (m, $W_{1/2}$ = 11 Hz, 2H), 7.4(NH), 7.96 (s, 3H), 7.5–8.4 (m, 8H); ^{13}C nmr: 169.6(s), 71.8(d), 61.9(d), 51.6(d), 47.1(d), 29.1(t), 26.6(t), 24.9(t), 20.8(q), 18.9(t); ms *m/e* (%): 219.0836 and 217.0869 (M^+, 2 and 7, calcd. for $C_{10}H_{16}NO_2Cl$: 219.0840 and 217.0869), 182.1180 (52, calcd. for $C_{10}H_{16}NO_2$: 182.1181), 176(28), 174(79),

159(28), 157(82), 122.0969 (100, calcd. for $C_8H_{12}N$: 122.0969), 96(48), 94(38), 82(40), 80(71). On irradiation of the multiplet at τ 6.90, the signal at τ 4.93 changed to a broad double doublet (J = 10.0 and 5.0 Hz) and the signal at τ 5.70 was modified. *Anal.* calcd. for $C_{10}H_{16}NO_2Cl$: C 55.17, H 7.41, N 6.44; found: C 55.29, H 7.48, N 6.72.

Reactions of Bicyclic Amine ***25***

The bicyclic amine **25** (120 mg) was reduced with lithium aluminum hydride (150 mg) in ether (20 mL) at room temperature for 16 h and was worked up to afford a colourless oil (47 mg); ir: 3300, 1055(s), 1035(s); ms *m/e* (%): 177(1), 175(3), 141(17), 140(12), 123(44), 122(30), 96(34), 94(100), 82(57). The oil (40 mg) was treated with *p*-toluenesulfonyl chloride to give a crude product. This crude product was refluxed with lithium aluminum hydride (150 mg) in ether for one day to afford an oil. By gc–ms analysis, this oil was shown to contain bicyclic amines **27** and **26**; **27**, rt 4.9 min, 43%, *m/e* (%): 125 (M^+, 49), 96(87), 83(41), 82(100), 69(28); **26**, rt 7.2 min, 36%, *m/e* (%): 141 (M^+, 1), 123(62), 122(28), 108(18), 95(25), 94(100), 82(19).

This oil was chromatographed on basic alumina and was eluted with 4–8% CH_3OH–CH_2Cl_2 to afford an oil (7 mg) which was treated with *p*-toluenesulfonyl chloride in pyridine to give a crystalline compound of 9-tosyl-9-azabicyclo[3.3.1]-nonane **27** ($NH{=}NSO_2C_6H_4CH_3$); ms *m/e* (%): 279 (M^+, 8), 236(21), 155(49), 124(11), 95(15), 91(80), 82(57); mp 152–155°C (lit. (25) mp 154–156°C).

Preparation of the Dimer of Chloronitroso Compound ***29***

A solution of nitrosyl chloride (8.3 mL, 0.18 mol) in methylene chloride (50 mL) was added to a solution of *trans,trans,-trans*-cyclododecatriene **28** (32.4 g) in methylene chloride (250 mL) dropwise over 20 min at −10°C. The mixture was allowed to warm to room temperature slowly and methanol was added to give a precipitate (39.02 g, 94%). The precipitate was recrystallized from a 4:1 mixture of ether–CH_2Cl_2 to afford white crystals of the *anti*-dimer of *threo*-1-nitroso-2-chloro-*trans,trans*-5,9-cyclododecadiene (**29**); mp 133–134°C (lit. (26) mp 125–125.5°C); uv (ether): 302 nm (ε, 9400); ir: 3020(m), 1260(s), 1220(s), 1180(s), 1130(m), 990(s), 975(s), 965(s), 770(s), 740(s), and 650(s) cm^{-1}; ^1H nmr τ: 4.16 (m, 1H), 4.70 (m, 4H), 5.65 (m, 1H), 7.7–8.3 (m, 12H); ^{13}C nmr: 133.3, 133.1, 133.0(2C), 129.2, 129.0, 128.9, 128.5, 62.7(d), 62.6(d), 57.5(d), 56.7(d), 33.0 (t, 2C), 31.6 (t, 2C), 31.3 (t, 2C), 28.4(t), 28.1 (t, 4C), 27.7(t); ms (130°C) *m/e* (%): 212(1), 210(2), 161(51), 119(32), 91(60), 79(97), 67(100). On irradiation at the τ 7.8–8.12 region, the multiplet at τ 5.65 collapsed to two nearly superimposed doublets ($J \sim$ 5.0 Hz), the multiplet at τ 4.16 to two doublets at τ 4.11 (J = 5.5 Hz) and 4.21 (J = 4.5 Hz), and the multiplet at τ 4.70 changed its pattern. *Anal.* calcd. for $(C_{12}H_{18}NOCl)_2$: C 63.29, H 7.97, N 6.15; found: C 63.36, H 8.19, N 6.25.

Reduction of the Dimer of ***29*** *with Lithium Aluminum Hydride*

(*1*) A mixture of the crude dimer of **29** (10 g) and lithium aluminum hydride (8.5 g) in ether was refluxed for four days and was treated with 10% potassium hydroxide solution. The usual workup gave basic (5.2 g) negative Beilstein test and neutral (1.05 g) fractions; the latter were shown to be starting triene **28**. The solid base fraction (1.8 g) was chromatographed on silicic acid to afford, with 7% CH_3OH in ether, aziridine **33** (130 mg) as white needles; mp 75–77°C; ir: 3170 (s, b), 3025(m), 970(s), 950(m), and 740(m) cm^{-1}; ^1H nmr τ: 4.78 (m, 4H), 7.77–7.84 (m, 4H), 7.90–8.2 (m, 8H), 8.6–8.9 (m, 2H), and 9.08 (D_2O exchangeable); ^{13}C nmr: 133.1(d), 128.4(d), 37.0(d), 31.6(t), 29.8(t), and 27.9(t) ppm; ms (80°C) *m/e* (%): 177.1499 (M^+, 6, calcd. for $C_{12}H_{19}N$: 177.1517), 176.1448 (17, calcd. for $C_{12}H_{18}N$: 176.1439), 162.1269 (14, calcd. for $C_{11}H_{16}N$: 162.1283), 148(16), 134(17), 122(24), 80(39), 69(100). The solid was sublimed to give white needles, mp 78–78.5°C. *Anal.* calcd. for $C_{12}H_{19}N$: C 81.30, H 10.80, N 7.90; found: C 81.71, H 10.66, N 7.91.

Further elution with 10–20% CH_3OH–ether gave amine **30** (1.03 g) as white needles: mp 93–97°C; ir: 3350, 3280, 3030, 1610(w), 1560 (m, b), 975(s), 970(s), 960(s) cm^{-1}; ^1H nmr τ: 4.90 (m, 4H), 7.23 (bt, $J \simeq$ 10 Hz, 1H), 7.74–9.2 (m, 16H); ^{13}C nmr: 131.9, 131.5, 130.5, 130.0, 45.7(d), 36.6(t), 32.0(t), 31.9(t), 30.3(t), 29.8(t), 29.5(t), 22.6(t) ppm; ms *m/e* (%): 179.1672 (M^+, 31, calcd. for $C_{12}H_{21}N$: 179.1673), 150(28), 136(43), 122(46), 110(43), 96(88), 83(94), 82(92), 70(80), 69(83), 56(100). Sublimation of the solid afforded white needles. *Anal.* calcd. for $C_{12}H_{21}N$: C 80.38, H 11.81, N 7.81; found: C 80.11, H 12.03, N 7.53.

The acetyl derivative of amine **30** was recrystallized from ethanol; mp 120–123°C, ir: 3270(sb), 3080(m), 1635(sb), 1560(s) cm^{-1}; ^1H nmr τ: 4.90 (m, 4H), 6.12 (m, 1H), 7.68–9.10 (m, 16H), 8.04 (s, 3H); ^{13}C nmr: 168.9(s), 131.7 (d, 2C), 130(d), 129.3(d), 44.4(d), 33.7(t), 31.7(t), 31.5(t), 29.4(t), 29.1(t), 27.8(t), 22.8(q), and 22.5(t) ppm; ms *m/e* (%): 221 (M^+, 75), 178(26), 162(100), 133(69), 125(66), 79(76). *Anal.* calcd. for $C_{14}H_{23}NO$: C 75.97, H 10.47, N 6.33; found: C 76.10, H 10.66, N 6.02.

(*2*) The dimer of **29** (500 mg, 1.1×10^{-3} mol) was placed in the thimble of a Soxhlet extractor and leached for 11 h by refluxing a mixture of LAH (274 mg, 7.2×10^{-3} mol) and aluminum chloride (960 mg) in ether. The mixture was worked up by the usual method to afford a crude semi-solid (410 mg); gc analysis showed three peaks at 2.4 (azoxy compound **32**), 3.7 (amine **30**), and 4 (chloroamine **31**) min in 15:10:65 ratio. The mixture was sublimed to afford azoxy compound **32** (85 mg) which was recrystallized from ether; mp 111–113°C; uv (CH_3OH): 354 nm (ε, 26), 290 (sh ε, 21); ir: 1490(s), 1440(s), 1265(s), 1120(sb), 990(s), 970(s), 962(s) cm^{-1}; ^1H nmr τ: 4.84 (m, 8H), 5.46 (m, 1H), 5.65 (bt, $J \simeq$ 6 Hz, 2H), 6.40 (m, 1H), 7.65–8.60 (m, 24H); ^{13}C nmr: 133.6, 133.4, 132.7, 132.4, 130.0, 129.4, 128.5, 78.5, 59.0, 58.7, 57.2(2C), 34.1, 33.8, 31.8(3C), 29.7, 29.5, 29.1, 28.7, 28.2, and 24.5 ppm; ms *m/e* (%): 438.2205, 440.2181, 442.2138 (M^+, 4, 2.5, 1, calcd. for $C_{24}H_{36}N_2OCl_2$: 438.2205, 440.2175, 442.2145). 421, 423, 425 (14, 9, 25), 349.2616 (33, calcd. for $C_{24}H_{33}N_2$: 349.2644), 208(25), 178.1357 (84, calcd. for $C_{12}H_{18}O$: 178.1358), 124(50), 123(59), 109(92), 95(58), 67(100).

The remaining solid showed gc peaks for amine **30** and chloroamine **31** in the 1:7 ratio and a ^{13}C nmr spectrum which showed the peaks for chloroamine **31** with weak peaks for amine **30**. Further sublimation afforded white crystals of chloroamine **31**; ir: 3400–3300(wb), 3015(w), 1600(wb), 990(s), 973(s), 962(s), 760 cm^{-1}; ^1H nmr τ: 4.89 (m, 4H), 5.73 (ddd, J = 7.5, 7, and 2.0 Hz, 1H), 7.06 (ddd, J = 6.5, 6.0, and 2 Hz, 1H), 7.70–8.20 (m, 10H), 8.32–8.50 (m, 2H), 8.33 (bs, D_2O exchangeable); ms *m/e* (%): 213.1295, 215.1252 (M^+, 9 and 3, calcd. for $C_{12}H_{20}NCl$: 213.1284, 215.1255), 178.1601 (43, calcd. for $C_{12}H_{20}N$: 178.1596), 132(5), 130(13), 117.0343, 119.0318 (40 and 14, calcd. for C_5H_8NCl: 117.0345, 119.0316), 96(30), 79(15), 67(14), 56(42), 43(100). On irradiation at τ 8.4 or τ 7.99 the ddd at τ 7.06 and 5.73 collapsed to doublets (J = 2.0 Hz). Irradiation of either of the two signals caused the other to collapse to double doublets with J = 6.5 and 6.0 Hz and J = 7.5 and 7.0 Hz, respectively.

The Base Treatment of Chloroamine ***31***

A 5:1 mixture of chloroamine **31** and amine **30** (51 mg) and sodium methoxide (100 mg) in methanol (3 mL) was kept at room temperature for four hours. The solution was brought to pH 9–10 and extracted with ether to give a crude product

(44 mg). The gc analysis of this oil on a 10% SE 30 column gave the peaks corresponding to amine **30** (4.3 min, 17%), chloroamine **31***a* (5.0 min, 16%), aziridine **33** (5.4 min, 10%), and three unknown peaks. The known compounds were further confirmed by a peak matching method.

Benzylation of Aziridine ***33***

Aziridine **33** (35 mg) and benzylchloride (249 mg) in dry benzene (2 mL) were refluxed for six hours. The residue was treated with ether to give the hydrochloride of **33** (19 mg, 46%), mp 193–197°C (dec.); ir: 2725(m), 2680(m), 2500(w), 966(s) cm^{-1}; ^1H nmr: τ 2.36 (bs, 2H), 4.90 (m, 4H), 7.32 (bd, J = 7 Hz, 2H), 7.6–8.6 (m, 12H). The ether filtrate was evaporated to give an oil of *N*-benzylaziridine **34** (29 mg); ir: 3030(m), 1600(w), 1495(m), 1100(s), 1028(s), 968(s), 692(s) cm^{-1}; ^1H nmr: τ 2.78 (s, 5H), 4.88 (m, 4H), 6.56 (s, 2H), 7.7–9.0 (m, 12H). This oil was slightly contaminated with benzylchloride as shown by the ^1H nmr signals at τ 5.50(s) and 2.74. The oil was refluxed in benzene containing benzylchloride (250 mg) for 12 h. The residue was chromatographed on a silicic acid column to give an oil (22 mg, 42%) showing one spot on a tlc plate corresponding to *N*-benzylaziridine, **35**; ^1H nmr τ: 2.78 (m, 5H), 4.88 (m, 4H), 6.56 (sharp s, 2H); ^{13}C nmr: 139.0, 133.1(2C), 128.1(2C), 127.7(2C), 127.5(2C), 126.7, 65.0 (benzyl), 46.4 (2C, CHN), 31.6(2C), 29.9(2C) and 27.1(2C) ppm; ms (40°C) *m/e* (%): 267.1976 (M^+, 32, calcd. for $C_{19}H_{25}N$: 267.1987), 266(28), 200(13), 187(12), 176.1442 (50, calcd. for $C_{12}H_{18}N$: 176.1439), 172(30), 159(90), 134(43), 91(100), and 41(23).

The above oil taken up in ether (5 mL) was treated with dry hydrogen chloride gas repeatedly to give precipitates (25 mg). This solid was added to a saturated sodium carbonate solution which was extracted with ether to give an oil showing two spots on tlc analysis. Preparative tlc of the oil gave *N*-benzylaziridine **34** (4 mg) and compound **35** (12 mg); ir: 3400 (w, vb), 3025(m), 1580(w), 1260(m), 1080(m), 985(s), 970(m), 958(s), 800(m, b), 750(s), and 698(s) cm^{-1}; ^1H nmr τ: 2.80 (m, 5H), 5.12 (m, 4H), 5.88 (m, $W_{1/2}$ = 18 Hz), 6.24 (AB q, J = 13.5 Hz, $\Delta\delta$ = 28 Hz), 7.50 (m, $W_{1/2}$ = 22 Hz), and 7.8–9.2 (m, 12H), 8.84 (1H, D_2O exchangeable); ^{13}C nmr: 140.3, 132.8, 132.0, 130.5, 129.2, 128.6(2C), 128.1 (2C), 126.9, 63.4, 53.5, 50.3, 33.7, 31.9, 29.5, 29.3, and 28.9; ms (40°C) *m/e* (%): 303.1756 and 305.1729 (M^+, 22 and 8, calcd. for $C_{19}H_{26}NCl$: 303.1754 and 305.1724), 268.2067 (24, calcd. for $C_{19}H_{26}N$: 268.2066), 241(8), 146(26), 133(100), 106(7), 91(61), and 41(8).

Reactions of the Dimer of ***29***

(*1*) A mixture of anhydrous sodium acetate (1 g), the dimer (500 mg, 1.1×10^{-3} mol), and acetic anhydride was stirred under nitrogen at 45°C for 3 days. The solution was adjusted to pH 9 and extracted with methylene chloride (60 mL × 3) to give an oil (481 mg) which showed two major spots (one of them corresponding to the starting material) and several minor spots on tlc. The oil also showed a broad esr triplet (1:1:1) at $g = 2.0068 \pm 0.0008$, a_N = 13.5 G (line width = 6.5 G).

The mixture was chromatographed on silica gel (40 g). The middle fraction eluted with methylene chloride afforded a solid (301 mg) which was recrystallized from methanol to give oximino acetate **38**; mp 49–49.5°C; ir: 3030(w), 1775(s), 1635(m), 1370(s), 1202(s), 996(s), 978(s), 960(s), 950(s), 924(s), 878(m), 803(m), 765, and 718(m) cm^{-1}; ^1H nmr τ: 4.82 (m, 4H), 5.17 (bt, J = 6 Hz, 1H), 6.7–7.4 (m, 1H), 7.6–7.9 (m, 11H), and 7.80 (s, 3H); ^{13}C nmr: 167.9(s), 165.5(3), 132.7, 132.5, 129.6, 129.2, 57.6(d), 31.8(t, 2C), 31.7(t), 29.1(t), 29.0(t), 26.1(t), 19.4(q); ms *m/e* (%): 212(11), 210(32), 192(8), 174(99), 79(63), 67(78), 43(100). On irradiation at τ 7.82, the multiplet at τ 5.17 collapsed to a singlet and the multiplet at τ 4.82 became an AB quartet (J = 16 Hz). *Anal.* calcd. for $C_{14}H_{20}NO_2Cl$: C 62.33, H 7.47, N 5.19; found: C 61.99, H 7.51, N 5.22. An attempt to isolate the minor components of the mixture was unsuccessful.

(*2*) A mixture of the dimer (1 g), methylene chloride (10 mL), methanol (20 mL), and pyridine (500 mg) was stirred under nitrogen at 35°C for one day. The residue after evaporation of solvents was washed with ether to afford crystals of pyridinium chloride **36** (1.23 g); mp 190–194°C (dec.); ir: 3120(s, b), 1625(m), 1290(m), 1140(m), 1010(s), 998(s), 980(s), 970(s), 960(s), 895(m), 820(m), 770(s), 725(s), 690(s) cm^{-1}; ^1H nmr (D_2O) τ: 1.0–2.0 (m, 5H), 4.58 (m, 5H), 6.8–7.35 (m, 2H), 7.5–8.6 (m, 10H). The pyridinium hydrochloride (860 mg) was stirred with an excess of aqueous dimethylamine solution and was worked up in the usual manner to afford amino oxime **37** (645 mg, 91%) as an oil; the ir and nmr spectra were superimposable with those of an authentic sample (23).

(*3*) A solution of the dimer (1 g) in methylene chloride (10 mL) and methanol (10 mL) containing 0.1 mL of concentrated hydrochloric acid was heated at 50°C for 3 days. The reaction was worked up in the usual manner to afford an oil (891 mg) which was chromatographed on alumina. The first fraction eluted with methylene chloride gave the methoxyketone corresponding to **38** (X = OCH_3, R = H, 72 mg) as a colourless volatile oil; ir: 3035(w), 1725(s), 1720(s), 1715(sh), 1130(m), 1098(s), 1080(m), and 970(s) cm^{-1}; ^1H nmr τ: 4.82 (m, 4H), 6.40 (dd, J = 6.5 and 4.0 Hz, 1H), 6.65 (s, 3H), 7.5–8.15 (m, 12H); ms *m/e* (%): 208 (M^+, 93), 176(13), 120(46), 111(47), 81(71), 79(76), 68(100), and 67(100). The second fraction eluted with 0–1% MeOH in CH_2Cl_2 afforded the methoxy oxime **38** (X = OCH_3, R = H, 365 mg); ir: 3330(bs), 3030(w), 1640(w), 1120(m), 1085(vs), 965(s) cm^{-1}; ^1H nmr τ: 1.56(OH), 4.80 (m, 4H), 5.84 (t, J = 5 Hz, 1H), 6.72 (s, 3H), 7.35 (m, 1H), and 7.6–8.3 (m, 11H); ^{13}C nmr: 158.7(s), 131.5(2C), 131.0, 130.6, 78.2(d), 54.5(q), 31.9(t), 31.7(t), 29.9(t), 28.5(t), 27.8(t), 25.4(t); ms *m/e* (%): 223 (M^+, 27), 206(100), 174(41), 169(45), 139(78), 79(71), 67(84). On irradiation at τ 8.20 the triplet at τ 5.84 collapsed to a singlet.

Preparation of the Dimer of C*-Nitroso Compound* ***40–41***

The dimer of **35–36** was prepared in a similar manner to that described above and was recrystallized from methylene chloride as white needles: mp 150–151°C; ir: 3008(m), 1258(s), 1212(s), 1200(s), 1192(s), 1183(s), 1155(m), 770(s), 738(m), 720(s) cm^{-1}; ^1H nmr τ: 4.28 (m, 1H), 4.45 (m, 2H), 5.4 (m, 1H), 7.3–8.1 (m, 4H), 8.4 (m, 4H); uv: 299 nm (ε, 7960); ms *m/e* (%): 203(1), 201(2), 186(13), 184(40), 166(60), 135(90), 93(88), 81(75), 79(70), 67(100). Dissolution of the dimer in dimethylformamide caused decomposition and the ^{13}C nmr could not be taken. *Anal.* calcd. for $(C_{10}H_{16}NOCl)_2$: C 59.55, H 8.00, N 6.95; found: C 59.20, H 7.80, N 6.98.

Reactions of the Dimer of C*-Nitroso Compound* ***40–41***

(*1*) The dimer of **40–41** (500 mg) in a 1:2 mixture of methylene chloride and methanol containing one drop of concentrated hydrochloric acid was refluxed for 36 h. Acid–base extraction of the reaction mixture afforded neutral (464 mg) and basic (33 mg) fractions. The neutral fraction in methylene chloride showed overlapping esr triplets in which the major one was that at $g \simeq 2.0061 \pm 0.0010$, $a_N \simeq 15.2$ G. It also showed ^1H nmr signals at τ 5.45 (dd, J = 11 and 5 Hz), 5.63 (dd, J = 10 and 5 Hz), and two equal intensity singlets at τ 6.71 and 6.81 and two major spots and other minor spots on tlc. The oil (290 mg) was chromatographed on silica gel. The fraction eluted with 0.5–1% MeOH–CH_2Cl_2 gave a solid which was sublimed to give oxime **42**; mp 94–95°C; ir: 3250 (broad), 3005(w), 1620(w), 1433(s), 1000(s), 980(s), 970(s), 910(m), 765(m), 715(m), 625(m) cm^{-1}; ^1H nmr τ: 0.99(OH), 4.70 (m, 2H), 5.45 (dd, J = 11 and 4.5 Hz, 1H), 6.93 (m, 1H), 7.41–8.29 (m, 7H), 8.39 (m, 4H); ^{13}C nmr: 160.2(s), 133.4(d), 128.0(d), 55.6(d), 33.0(t), 29.4(t), 25.3(t), 24.9(t), 24.6(t),

22.5(t); ms *m/e* (%): 203 (M^+, 3), 201(8), 186(20), 184(57), 166(100), 148(55), 91.0546 (51, calcd. for C_7H_7: 91.0547), 79(44), 67(49). On irradiation at τ 8.06 the double doublet at τ 5.45 collapsed to a doublet (J = 11.0 Hz) and the multiplet at τ 4.70 became a poorly resolved doublet (J = 13 Hz). On irradiation at τ 8.39, the multiplet at τ 6.93 became an ill-resolved doublet (J = 14 Hz). *Anal.* calcd. for $C_{10}H_{16}NOCl$: C 59.55, H 8.00, N 6.95; found: C 59.71, H 8.14, N 7.05.

The fraction eluted with 2–4% CH_3OH–CH_2Cl_2 gave a colourless oil which showed a weak nmr signal for olefinic protons and several methoxy singlets, among them, those at τ 6.63, 6.72, and 6.78 had a ratio of 2:1:2; ir: 3300(b), 1710(w), 1650(w), 1090(vs), 945(vs), 915(vs); ms *m/e* (%): 197(21) 180(78), 165(88), 148(100), 123(72). This oil showed strong and complex esr signals at the g = 2.006 region.

(*2*) A methylene chloride (20 mL) solution containing acetic anhydride (2 g) and the dimer of **40**–**41** (403 mg) was stirred under nitrogen at 50°C for 3 days. After the usual workup, the residue (517 mg) was taken up in a 1:1 mixture of methylene chloride – ether from which the starting dimer was precipitated (107 mg). The mother liquor was evaporated and the residue showed three overlapping esr triplet (equal intensity) signals (one major and two minor) in which the major triplet had g = 2.007 ± 0.001, a_N = 14.2 G (line width 4 G). This mixture was chromatographed on silica gel. The first fraction eluted with methylene chloride gave an oil (147 mg, 45%) which was distilled to give a 1:3 mixture of oximino acetate **44** and **45**; ir: 3000(m), 1775(vs), 1630(m), 1260(m), 1205(vs), 1175(s), 1000(s), 935(s), 890(s), 842(m), 780(m), 735(s), 710(m) cm^{-1}; ^1H nmr τ: 4.65 (m, 2H), 5.34 (dd, J = 12.0 and 4.5 Hz, 1/4H), 5.66 (dd, J = 11.0 and 5.0 Hz, 3/4H), 7.2–8.10 (m, 11H), 7.74(s) and 7.76(s) in a 1:3 ratio; ^{13}C nmr: 166.2, 166.1, 131.8, 131.7, 127.5, 127.3, 54.2, 51.5, 34.9, 33.6, 31.3, 28.0, 27.8, 26.5, 24.2, 23.8(2C), 23.5(2C), 21.6, 21.3, and 19.4 ppm; ms (70°C) *m/e* (%): 246 (M^+ +1, 4), 244(10), 243 (M^+, 1), 201(66), 184(65), 166(65), 148(100), 135(85), 93(85). *Anal.* calcd. for $C_{12}H_{18}ClNO_2$: C 59.14, H 7.44, N 5.75; found: C 58.89, H 7.55, N 5.60.

Elution with 0.5–2% CH_3OH–CH_2Cl_2 gave a solid (27 mg, 8%) which showed a single spot on tlc and could not be recrystallized. This solid is assumed to be the bicyclic hydroxylamine acetate **46** (or isomer thereof); ir: 1765(s), 1722(s), 1245(s), 1202(s), 1192(s), 1125(m), 1040(m), 1015(m), 950(m), 850(m), 788(m), 755(m), 730(m), 715(m) cm^{-1}; ^1H nmr τ: 4.70 (bt, J = 9 and 1 Hz, 1H), 5.48 (m, 1H), 6.72 (m, 2H), 7.7–8.6 (m, 12H), 7.83 (s, 3H), 7.96 (s, 3H); ms *m/e* (%): 305.1219 and 303.1237 (M^+, 2 and 7, calcd. for $C_{14}H_{22}NO_4Cl$: 305.1208 and 303.1238), 263(3), 261(8), 246(36), 244(100), 226(96), 220(26), 218(77), 208(31), 184(36), 166(31), 148(43).

The fraction eluted with 2% CH_3OH–CH_2Cl_2 gave an oil (30 mg, 8%) which was sublimed to give **47** (or isomers thereof); ir: 3450(bm), 1765(vs), 1735(vs), 1240(vs), 1190(vs), 1025(s), 940(m), 890(m), 860(m), and 810(m) cm^{-1}; ^1H nmr τ: 4.74 (m, 2H), 5.27 (bq, J = 6.5 Hz, 2H), 7.7–8.8 (m, ca. 12H), 7.90 (s, 3H), 7.93 (s, 6H); ms *m/e* (%): 327 (M^+, 2), 285(33), 268(100), 226(36), 208(22), 166(31), 148(28), 96(25), 67(24); esr major triplet (1:1:1) $g \simeq 2.0089$, a_N = 14.3 G and two minor triplets at $g \simeq 2.0063$ and 2.0045.

Photolysis of nitramines in a neutral solvent generated nitrogen dioxide and aminyl radicals which abstracted a hydrogen but did not add to a π-bond. In dilute acidic solution, the aminyl radicals generated from the photolysis were protonated to the corresponding aminium radicals that preferentially added to π-bonds rather than abstracted a hydrogen. However, complex mixtures of addition products were obtained when nitramines were photolysed in the presence of cyclohexene under nitrogen. The plethora of the products is believed to arise from the complex behavior of nitrogen dioxide in solution; for example, (*i*) nitrogen dioxide may react as *O*- or *N*-radical, (*ii*) nitrogen dioxide exists in equilibrium with nitrogen tetraoxide, and (*iii*) both oxides can react as oxidizing or radical trapping agents. Under oxygen, the oxidative addition of nitramines to cyclohexene gave 1-dialkylamino-2-nitratocyclohexenes which could be treated with lithium aluminium hydride to give good yields of the corresponding amino alcohols. The quantum yields of nitramine disappearance indicated that the photolysis followed short chain processes either in neutral or acidic conditions. The decrease in quantum yield at $> 2\ N\ H_2SO_4$ is believed to be due to a reduced reactivity of aminium radicals in a highly acidic environment. The probable mechanisms of these photolytic radical chain processes are discussed.

La photolyse des nitramines dans un solvant neutre produit du bioxyde d'azote et des radicaux aminyles qui enlèvent un atome d'hydrogène sans toutefois s'additionner sur la liaison π. En solution diluée d'acide les radicaux aminyles générés sont, par protonation, transformés en radicaux aminiums correspondants qui eux d'additionnent préférentiellement sur la liaison π au lieu d'arracher un atome d'hydrogène. Par ailleurs la photolyse des nitramines en présence de cyclohexane et sous atmosphère d'azote conduit à un mélange complexe de produits d'addition. On pense que la formation de ces produits est due au comportement du dioxyde de l'azote en solution, par exemple (*i*) le dioxyde d'azote peut réagir comme un radical *O* ou *N*, (*ii*) le dioxyde d'azote existe en équilibre avec le tétraoxyde et (*iii*) les deux oxydes peuvent agir soit comme agents oxydants soit comme pièges à radicaux. L'addition oxydante des nitramines sur le cyclohexène sous atmosphère d'azote conduit aux dialkylamino-1 nitrato-2 cyclohexènes qui traités à l'hydrure double d'aluminium et de lithium donnent avec de bons rendements les aminoalcools correspondants. La disparition des rendements quantiques de nitramines indique que la photolyse en milieu neutre ou acide se fait selon un court procédé en chaîne. On croit que la diminution des rendements quantiques, à des concentrations de $H_2SO_4 > 2\ N$, est due à la réactivité réduite des radicaux aminiums en milieu fortement acide. On discute du mécanisme probable de ces réactions de photolyse radicalaire en chaîne.

Introduction

Dialkylnitramines (R_2NNO_2) react as neutral compounds (1–4) and exhibit a $\pi \rightarrow \pi^*$ transition absorption at about 240 nm (ε, ~5500) without showing a $n \rightarrow \pi^*$ transition absorption (5–7) commonly observed in nitrosamines (8) in protic solvents. The N—N bond distance of *N*-nitrodimethylamine (NNOD) has been measured crystallographically to be relatively short (9*a*)[2] (ca. 1.3 Å) indicating considerable resonance contribution of the polar form $R_2{}^+N{=}NO_2{}^-$ to the structure (4). The photochemistry of nitramines has been sporadically investigated in the past (10–15). Photolysis of *N*-methyl-*N*-nitro-1-naphthylamine with > 360 nm light has been shown to cause rearrangement to the *o*- and *p*-nitro derivatives by a non-radical mechanism (10).

In contrast to the photostability of nitrosamines in neutral solvents (16, 17), dialkylnitramines undergo photodecomposition in hydrocarbons, alcohols, and acetonitrile to give the corresponding nitrosamines as a major product (11–13). However, photolysis of *N*-nitrodibenzylamine gave *N*-benzylidene benzyl-

[1]Part of the results were published in ref. 1 as a communication.

TABLE 1. Photolysis of nitramines under neutral conditions

Conditions[a]				Percent of products			
Nitramines	Solvent	Olefin	Gas	R_2NNO	R_2NH	R_2NCHO	Remarks
NNOP	MeOH	None or *cyclo*-C_6H_{10}	N_2	Trace	13	7	[b]
NNOP	*n*-Hexane	*cyclo*-C_6H_{10}	CO	33	38	—	[c]
NNOD	*n*-Hexane	*cyclo*-C_6H_{10}	CO	7	28	26	[c]
NNOD	CH_3CN	*cyclo*-C_6H_{10}	CO	22	35	2	[c,d,e]
NNOD	*n*-Hexane	*cyclo*-C_6H_{10}	N_2	6	—	14	[c,f]
NNOD	CH_3CN	Norbornene	CO	55	8	3	[c,f]

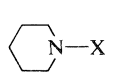
[a]More than one equivalent of the olefins was added and the workup of the photolysate was different in each experiment as shown in the Experimental.
[b]The percentages are calculated from the gc peaks; the yields of the crude products were low due to solubility in water.
[c]The amines (R_2NH) were isolated as the nitrate salts and other products were determined by gc and (or) nmr analyses.
[d]In addition, *N*-methylformamide (15%) and 1,3,5-trimethylhexahydro-1,3,5-triazine (10%) were detected by gc–ms.
[e]In the photolysis, $NaHCO_3$ (2 g) was added.
[f]In the photolysis, Na_2CO_3 (2 g) was added.

amine and dibenzylammonium nitrate (12) in addition to the nitrosamine. Thermal decomposition of *N*-nitrodimethylamine in the gas phase was reported to give *N*-nitrosodimethylamine (18). These reactions are generally assumed to occur by the homolytic scission of the N—N bond (12, 14, 15). Photolysis of a 1:1 mixture of doubly ^{15}N-labelled and unlabelled NNOD in the solid phase (13) gave *N*-nitrosodimethylamine with statistically distributed ^{15}N-label but the recovered NNOD showed no mixing of the ^{15}N-label. Although these results do not unambiguously distinguish between N—N or N—O bond scission as the primary photoreaction, the authors favor the latter (13) presumably leading to the generation of oxygen atoms. Our interests in nitrosamine photochemistry (16) have led us to investigate the photoreaction of *N*-nitropiperidine (NNOP) and *N*-nitrodimethylamine (NNOD) which is described in this report.

Results

Nitramines were prepared by oxidation of nitrosamines with 50% hydrogen peroxide. Since 90% hydrogen peroxide used in the original Emmons' method was not available (19), the oxidation was repeated to obtain a better conversion. The unreacted nitrosamines could be removed by passing gaseous hydrochloric acid through a dry ether solution of the crude product. The hydrochlorides of nitrosamines (20) precipitated leaving the much less basic nitramines in the solution.

The photodecomposition of NNOP (**1***a*) and NNOD (**2***a*) under neutral conditions proceeded efficiently and gave similar results regardless of the presence or the absence of cyclohexene or norbornene, e.g., no addition product to the olefins was obtained. The results are summarized in Table 1. In methanol, NNOP was photolysed under nitrogen to give *N*-formylpiperidine (**1***c*), piperidine (as the nitrate salt), and NNP (**1***b*); no formaldehyde was detected. However, in *n*-hexane under carbon monoxide, formamide **1***c* was not formed, indicating that the formyl group was derived from methanol. Photolysis of NNOD under various conditions gave dimethylformamide (**2***c*), *N*-nitrosodimethylamine (**2***b*), and dimethylammonium nitrate, and in one



1

$(CH_3)_2N—X$

2

b X = NO
c X = CHO

case the trimer of formylidenemethylamine (i.e., 1,3,5-trimethylhexahydro-1,3,5-triazine) and *N*-methylformamide were also obtained. Photolysis of NNOD in acetonitrile in the presence of solid sodium carbonate or bicarbonate yielded considerable amounts (22% and 55%) of nitrosamine **2***b*. Since formamide **2***c* was formed in the absence of methanol, carbon monoxide, or carbonate, the formyl group was not derived from these entities but most probably from the *N*-methyl carbons.

Under dilute acidic conditions the patterns of nitramine photolysis were quite different in the presence or the absence of cyclohexene; in the former case photoaddition of nitramines to the olefin occurred exclusively. In methanol containing hydrochloric acid (ca. 0.05 *N*), NNOP was photolytically decomposed to the piperidinium salt cleanly; formaldehyde was also detected in the distillate. However, under similar conditions but in the presence of cyclohexene, a complex mixture of addition products to cyclohexene was obtained; this mixture consisted of 2-piperidinocyclohexanol (*cis* and *trans*

mixture, **3**, 20%), 2-piperidinocyclohexanone oxime (**9**, 22%), 1-nitro-2-piperidinocyclohexane (**4**, 9%), and two more compounds that were tentatively assigned from gc–ms analysis as piperidinocyclohexene (12%, **11**) and 1-methoxy-2-piperidinocyclohexane (10%, **5**). In a similar manner, NNOD was photolysed in the presence of cyclohexene either under nitrogen or carbon monoxide to give a mixture consisting of dimethylaminocyclohexane (**6**, 15%), 2-dimethylaminocyclohexanol (*cis* and *trans* mixture, **7**, 28%), 2-dimethylaminocyclohexanone oxime (**10**, 24%), and 1-nitro-2-dimethylaminocyclohexane (**8**, 22–24%) in addition to two unknown compounds. In these reactions, piperidine and dimethylamine were also formed but could not be determined quantitatively due to their volatility and solubility. The percentages given above are the relative ones of the gc peaks.

11

Similar photoaddition of nitramines as above, but under oxygen, took place smoothly and gave a crude product which showed strong ir absorptions for nitrate (1620, 1270, 850 cm^{-1}), carbonyl (1710 cm^{-1}), and hydroxyl (3400 and 1100 cm^{-1}) groups (21). The LAH reduction of this crude product from NNOP addition afforded a good yield of an oil which showed two gc peaks corresponding to *cis*- and *trans*-2-piperidinocyclohexanols (**3**) (21) in a 1:2 ratio. The stereoisomers were separated by column chromatography. Similar reduction of the crude product from NNOD photoaddition afforded 64% of a mixture consisting of *cis*- and *trans*-2-dimethylaminocyclohexanol (**7**) (21, 22). A few gc peaks due to side products were also detected but in only minor amounts.

The kinetic disappearance of NNOP in acidic and neutral solutions and under nitrogen or oxygen was shown to follow a zero order in the initial stage of the photolysis. The quantum yields obtained from these studies using the ferric oxalate actinometry (23) are summarized in Table 2. In dilute acidic solutions (<2 *N* H_2SO_4) the quantum yields were higher than those in neutral or in highly acidic (>5 *N* H_2SO_4) solutions, and varied only slightly in the presence or absence of oxygen and (or) olefins in methanol solvent. In acetic acid solutions the quantum yield was slightly higher in the presence of oxygen and noticeably lower in the absence of cyclohexene.

TABLE 2. Quantum yields of *N*-nitropiperidine (0.0077 *M*) photodecomposition[a]

Conditions	ϕ

[a]The photolysis was carried out with a solution containing *N*-nitropiperidine (0.0077 *M*) and cyclohexene (0.02 *M*) under nitrogen unless specified otherwise.
[b]In the absence of cyclohexene.
[c]Under oxygen.

Discussion

In this study, it is shown that the photolyses of dialkylnitramines in neutral solvents form the corresponding dialkylformamides under certain conditions in addition to the reported nitrosamines and ammonium nitrates (11, 12). As already pointed out, the formyl group of formamide **1***c* is derived from methanol and that of formamide **2***c* from the *N*-methyl groups of NNOD. Under dilute acidic methanol solution NNOP is photolytically reduced and methanol is oxidized to formaldehyde. These results can be explained by the homolysis of the N—N bond to form dialkylaminyl radicals and nitrogen dioxide. Under neutral conditions the aminyl radicals abstract hydrogen from methanol or alkenes, or from a dimethylamino moiety if no other suitable H-atom donor is in sight (24). In acidic solutions, aminyl radicals (pK_a 6.5–7.5) (25) are protonated to give the aminium radicals which either add to a π-bond or abstract a hydrogen in the absence of olefins (26). Neither aminyl nor aminium radicals could be trapped by carbon monoxide under our reaction conditions.

The major reaction processes, in a neutral medium, can be summarized by eqs. [1]–[7] and, in acidic methanol, by eqs. [1], [8], [2], [9], and [7]. The disproportionation of the dimethylaminyl radicals to give formylidenemethylamine (eq. [4]) and subsequent trimerization or hydrolysis to formaldehyde

have been proposed previously (24). Under the photolysis conditions the oxidation of $\cdot CH_2OH$ and R_2NCH_2OH (eqs. [3], [6], [9]) can be visualized in a

[1] $R_2NNO_2 \xrightarrow{h\nu} NO_2 + R_2N\cdot$

[2] $2NO_2 \rightarrow N_2O_4$

[3] $R_2N\cdot + CH_3OH \rightarrow R_2NH + \cdot CH_2OH \xrightarrow{ox} CH_2O$

[4] $2(CH_3)_2N\cdot \rightarrow (CH_3)_2NH + CH_3N{=}CH_2 \xrightarrow{H_2O} CH_3NH_2 + CH_2O$ (with $CH_3N{=}CH_2 \rightarrow$ *sym*-triazine)

[5] $R_2NH + N_2O_4 \rightarrow R_2NNO + HNO_3$

[6] $R_2NH + CH_2O \rightarrow R_2NCH_2OH \xrightarrow{ox} R_2NCHO$

[7] $R_2NNO_2 + \cdot CH_2OH \rightarrow R_2N\cdot + ONOCH_2OH \rightarrow HNO_2 + CH_2O$

[8] $R_2N\cdot + H^+ \rightleftarrows R_2NH^+$

[9] $R_2\overset{+\cdot}{N}H + CH_3OH \rightarrow R_2\overset{+}{N}H_2 + \cdot CH_2OH \xrightarrow{ox} CH_2O$

number of ways but may be assumed to use nitrogen dioxide or tetroxide as oxidants (27). *N*-Methylformamide could also be formed from formylidenemethylamine by oxidation. On the basis of the proposed reaction pathways, certain observations can be rationalized. Under acidic conditions, the generated dialkylamines are protonated and, therefore, cannot undergo the hydration and oxidation pathway to form formamides **1***c* and **2***c* as shown in eq. [6]. The formation of high percentages of nitrosamine **2***b* in acetonitrile in the presence of sodium carbonate or bicarbonate suggests a base promoted nitrosation of the amine with nitrogen tetroxide as in eq. [5]. This nitrosation process is a well-known reaction for the preparation of nitrosamines (2). In solution, nitrogen dioxide is expected to be in equilibrium with dinitrogen tetroxide under the reaction conditions; both of them may act as oxidizing agents or radical trapping agents (27). The reactions of nitrogen dioxide with alkanes or alkyl radicals in the gas phase have been shown to follow a complex pattern and also to yield nitric oxide in a late stage from secondary reactions (27). It is possible that nitrosamines might be produced by the combination of the aminyl radicals and nitric oxide. Such a mechanism, even if operative, cannot account for the large percentage yields of nitrosamine **2***b* in the presence of carbonates since it is inconceivable that such bases can catalyse the radical combination.

The quantum yields indicate that nitramine photolysis involves short radical chain processes. The chain transfer step, eq. [7], while difficult to pin down, is also suggested as a possibility in analogy to the nitrosamine photolysis (16, 23). Equation [10] might be another chain transfer step. As in most of free radical chain reactions, the propagation processes in the present case cannot be proven easily. Particularly, in the presence of many radical species in the reaction system, any suggestions of such steps are open to questions.

[10] $R_2NNO_2 + \cdot NO_2 \rightarrow R_2N\cdot + N_2O_4$

In neutral solvents nitrosamines survive as final products because of their photostability under the reaction conditions (16, 17). It might be suggested that, in acidic solution, nitrosamine **1***b* is formed as the primary product by an unknown oxygen transfer mechanism, as suggested to be operative in solid phase photolysis (13), and undergoes photodecomposition. This pathway is not operating since piperidone oxime and the trimer of tetrahydropyridine, the products expected from the nitrosamine photolysis in acidic solution (17, 26), are not obtained. Therefore, while the pattern of photoaddition of nitramines to olefins in acidic solutions is very similar to that of nitrosamines, particularly in the presence of oxygen (*vide infra*), the nitramine photolysis generates the aminium radicals directly in the primary photoprocess and not through the intermediacy of nitrosamines.

The efficient photoaddition of nitramines to cyclohexene under dilute acidic conditions and the failure to do so under neutral conditions clearly demonstrate the reactivity difference between aminium and aminyl radicals. The former shows propensity to attack a π-bond over hydrogen abstraction and the latter undergoes other types of reactions (e.g., dimerization, disproportionation, hydrogen abstraction, etc.) rather than addition. The formation of piperidine and formamide **1***c* in the photolysis of NNOP clearly indicates the pattern of the reactivity of the piperidinyl radicals. We have demonstrated these reactivity patterns by nitrosamine (16) and tetrazene (22, 24) photolyses in recent publications. In the present case, the counter radical in the photoaddition, nitrogen dioxide, can behave as an *O*- as well as an *N*-centered radical to give 2-dialkylaminocyclohexyl nitrites and nitro compounds (21) such as **4** and **8**. It is also conceivable that compounds **4** and **8** are formed by a chain transfer step as shown in eq. [11]. The nitrites may be hydrolysed under the

[11] 
acidic conditions or photolysed (28) to alcohols **3** and **6**, though no effort was made to determine the nature

of these side reactions. It is believed that oximes **9** and **10** are formed via trapping of *C*-radical intermediates by dinitrogen tetroxide as in eq. [12]; tautomeriza-

[12] 
12

tion of *C*-nitroso compounds **12** to oximes is a well-known reaction (16). The other products can be explained by radical mechanisms except the methoxy derivative **5**; its formation may involve an ionic step since there is no precedence for the formation of ether linkages in radical propagation steps involving methanol. While photolysis of nitramines in acidic conditions under an inert gas gave good overall yields of addition products, it gave complex mixtures and cannot be useful for synthetic applications.

The nitramine photolysis in acidic solution under oxygen gives nitrate esters as the primary product and is assumed to proceed via trapping of the *C*-radical intermediates by oxygen as shown in eq. [13],

[13] 
14 **13**

in analogy to nitrosamine photolysis under oxygen (21, 30). Again, dinitrogen tetroxide is assumed to be a nitroso group donor and the NO_3 radical may also combine with the *C*-radical intermediate to form nitrate **14**. The formation of nitroso derivatives during radical reactions of nitrogen dioxide has been known (27), but use of dinitrogen tetroxide as a NO donor has not been proposed previously. The rearrangement of pernitrites to nitrates (e.g., **13** → **14**) has been shown to be spontaneous at about 0°C (29). We have shown that during basic workup nitrate esters can be decomposed to ketones or alcohols (21, 30) which might account for the complexity of the ir spectra of the crude products. An alternative route for the formation of the ketones and alcohols is the decomposition of pernitrite **13** by acid catalysis or photolysis under the reaction conditions. Such reactions are analogous to the decomposition of alkyl hydrogen peroxides (22). However, the treatment of the mixtures with lithium aluminium hydride readily converts them to *cis* and *trans* alcohols **3** and **7** in good yields. The oxidative photoaddition of nitramines to olefins works simply and is an excellent method for preparation of α-aminoalcohols.

It is striking that the quantum yields do not vary significantly within experimental error in the range of 0.1–2 *N* H_2SO_4 either in methanol or acetic acid solution and, also, in the presence or the absence of cyclohexene and oxygen in methanol. This must indicate that the reactivity and concentration of the species propagating the chain processes do not change significantly within this acidity range. Therefore, the drops in the quantum yields above 2 *N* H_2SO_4 could be due to a decrease of the reactivity of the aminium radical at higher acid concentrations as this is known from kinetic esr (31) and flash photolysis studies (32). The causes of the stabilization of aminium radicals at high acidity are not well understood; it may be partly due to screening of the radicals by inert anions, a phenomenon similar to stabilization of carbonium ions in superacid solution (33).

Alternatively, it is tempting to suggest that high acidity might affect the concentration of available nitramines in the solution through protonation and thus also the rates of chain transfer steps such as eqs. [7], [11], and [13]. However, such an acidity effect appears not to be operating since uv spectra of NNOP in methanol are not altered at all in changing acidity from 0–10 *N* H_2SO_4 concentrations. In acetic acid, the optical density difference between λ_{max} 242 nm and λ_{min} 222 nm increases monotonically when the concentration of H_2SO_4 is changed from 0–10 *N*. As there is no abrupt change of the absorption in the vicinity of 2 *N* H_2SO_4 concentration range, the concentration of the nitramine appears to be relatively stable in this acidity range and should not affect the quantum yields.

Experimental

General Conditions and Materials

Unless specified otherwise the following conditions were used. Infrared spectra were recorded with a Perkin-Elmer 457 spectrophotometer using liquid films or Nujol mulls. Ultraviolet spectra were taken with either a Cary 14 or a Unicam SP8000 spectrophotometer. Nuclear magnetic resonance spectra were recorded on a Varian A-56/60 or an XL-100 equipped with a Nicolet 1080 computer in CCl_4 or $CDCl_3$ with Me_4Si as the internal standard. The chemical shifts of ^1H nmr were reported in τ values and those of ^{13}C nmr in parts per million from Me_4Si and coupling constants in hertz (Hz). The decoupling experiments were performed with the XL-100 spectrometer. Mass spectra were recorded with a Hitachi Perkin-Elmer RMU-6E mass spectrometer. High resolution mass spectra were performed at the University of British Columbia, Mass Spectrometric Services. Elemental analyses were carried out by Mr. M. K. Yang using a Perkin-Elmer 240 microanalyzer. Gas chromatographic analyses were performed on a Varian 1200 flame analytical machine using a Varian Aerograph Model 20 recorder equipped with a Model 224 disc

chart integrator. Analyses by gas chromatography – mass spectrometry were performed by Mr. G. Owen to whom we are much indebted. The percentages given in gc analysis were relative ones.

Column chromatography used neutral or basic alumina (Brockman activity 1, 80–200 mesh) or silicic acid (Mallinckrodt, 100 mesh). Acetonitrile (Fisher Scientific) was passed through alumina immediately before use. The commercially available olefins were purified by distillation. Nitrogen supplied in compressed cylinders (Union Carbide of Canada) was purified by passing through a train of a Fieser's solution, concentrated sulfuric acid, and KOH pellets.

The procedure of Emmons (19) was used to oxidize *N*-nitrosodialkylamines to *N*-nitrodialkylamines except that 50% H_2O_2 was used in the place of 90% H_2O_2. The oxidation was repeated to ensure a higher conversion to nitramines. The ether solution of the crude oxidation product was treated with hydrogen chloride to precipitate the unreacted nitrosamines. The ether filtrate was washed with water and dried over magnesium sulfate and evaporated. NNOP distilled at 100–105°C/23 Torr as a clear liquid; ir: 1513, 1388, 1330, 1280, and 1241 cm^{-1}, nmr τ: 6.20 (m, 4H) and 8.33 (m, 6H); uv(MeOH): 249 nm (ε 5500). NNOD was recrystallized from ethanol as white needles (74%); mp 54–55°C (lit. (19) mp 58°C); uv(CH_3OH): 240 nm (ε 6000); ir: 1510(s), 1320(s), 1260(s); nmr τ: 6.56 (t, J = 1.5 Hz); ms *m/e*(%) 91 (M^+, 20), 90(92), 74(8), 44(36), and 42(100); gc retention time on an SE 30 column (150–250°C at 4°/min), 3.6 min.

General Conditions of Photolysis

A solution containing a nitramine and other components in a solvent was placed in a Quartz photolysis apparatus equipped with a Corex filter and was cooled externally with an ice bath. The solution, while purged with a slow stream of a gas, was irradiated with a 200 W Hanovia mercury lamp. The progress of photolysis was followed by recording the absorbancy and the irradiation was terminated when the absorption disappeared. The zero hour sample was kept in the dark to serve as control which showed the absorption peak unchanged. The workup of photolysates varied according to the conditions.

Photolysis of Nitramines Under Neutral or Basic Conditions

N-*Nitropiperidine*

(*a*) NNOP (7.0 g, 0.008 mol) in methanol (200 mL) was photolysed under N_2 for 2.25 h. The solvent was distilled through a Vigreux column and the distillate was trapped (170 mL) in a vessel cooled in Dry Ice. Treatment of the distillate (50 mL) with a 2,4-dinitrophenylhydrazine reagent solution (20 mL) gave no hydrazone. The residue from the photolysate (1.03 g), which exhibited a strong ir band at 1655 cm^{-1} and nmr signals at τ 2.00(s) and 2.90 (m, D_2O exch.), was examined by gc (20% SE30, 130°C) and found to contain two major components and one minor component. Peak matching gc and gc–ms characterized the first component as piperidine (54%; retention time, 1.2 min) and the second component (45%; retention time, 5 min) as *N*-formylpiperidine. The minor component was *N*-nitrosopiperidine. The liquid taken up in ether was extracted with 1 *N* aqueous hydrochloric acid solution. The ether solution was dried and evaporated to afford *N*-formylpiperidine (250 mg); ir: 3400, 1655(s), 1258(w) cm^{-1}; ms *m/e*(%): 113(100), 98(55), 84(57), 70(23), 56(55), and 39(18). The residue from the photolysate exhibited a blue color in the diphenylamine test indicating the presence of nitrate ion.

When the photolysis was carried out under similar conditions but in the presence of one equivalent of cyclohexene, comparable results were obtained in which piperidine and *N*-formylpiperidine were obtained in a 3:2 ratio as shown by gc analysis.

(*b*) A solution of NNOP (1.3 g) and cyclohexene (2.52 g) in *n*-hexane was photolysed under carbon monoxide atmosphere for 16 h. During photolysis, a dark red oil, deposited on the wall, was removed by dissolving it in ethanol every two hours. The combined ethanol solutions were evaporated to give piperidinium nitrate; the ir and nmr spectra were identical with those of an authentic sample. The photolysate was evaporated to give a yellow oil (583 mg) which gave one major gc peak corresponding to *N*-nitrosopiperidine in addition to several weak peaks, none of them corresponding to *N*-formylpiperidine.

N-*Nitrodimethylamine*

(*a*) A mixture of NNOD (1.8 g), cyclohexene (8.4 g), and sodium bicarbonate (2 g) in acetonitrile (200 mL) was photolysed under carbon monoxide for 6 h. The clear photolysate, after filtration, was evaporated and the residue was separated to ether soluble and insoluble parts. The ether solution was evaporated to give a red oil (440 mg) which was shown to contain *N*-nitrosodimethylamine (22%) and *N*,*N*-dimethylformamide (2%) by gc and an nmr estimation; the nmr spectrum showed two pairs of singlets at τ 6.20 and 6.92 and at τ 7.03 and 7.12 in the ratio of 10:1. The ether insoluble oil was stirred with acetonitrile and separated to give a red oil (761 mg, 35%), the ir and nmr spectra were identical with those of dimethylammonium nitrate.

(*b*) A mixture of NNOD (1.8 g), norbornene (18.8 g), and powdered sodium carbonate (2 g) in acetonitrile (190 mL) was irradiated for 6 h. The photolysate was distilled with a Vigreux column and the distillate (170 mL) was treated with dry HCl. The solvent was evaporated to give an oil which was taken up in ether and washed with aqueous sodium carbonate solution and was evaporated, after drying, to afford a yellow oil (423 mg) which exhibited nmr singlets at τ 6.20 and 6.92 in addition to other signals contained in *N*-nitrosodimethylamine (2%) and 2-*endo*-acetamidobicyclo[2.2.1]heptane. The latter was assumed to be formed by an acid catalysed addition of acetonitrile to norbornene and was isolated as white crystals; mp 134–135°C (lit. (34) mp 131–132°C). The photolysate was evaporated to give a residue (1.89 g) which was found to contain the following compounds by the gc peak matching method and estimation from the *N*-methyl singlets of the nmr spectrum: dimethylammonium nitrate (8%), *N*-nitrosodimethylamine (55%), dimethylformamide (3%), and NNOD (6%) in addition to two unidentified minor components.

(*c*) A *n*-hexane solution (200 mL) containing NNOD (0.9 g) and cyclohexene (1.68 g) was photolysed under carbon monoxide for 19 h during which an oil deposited on the wall. The photolysate was evaporated to a residue (153 mg) which showed ir peaks at 1625, 1280, and 870 cm^{-1} for the nitrate group and 1675, 3400, 1065, and 1025 cm^{-1} and weak nmr signals for the cyclohexyl moiety. Since the gc of the residue showed a complex pattern, this was not investigated further. The deposited oil was separated to methylene chloride soluble (340 mg) and insoluble fractions (175 mg). The insoluble fraction was shown to be dimethylammonium nitrate with a small amount of dimethylformamide by its ir and nmr spectra. The soluble fraction was shown to contain *N*-nitrosodimethylamine, dimethylformamide, and dimethylammonium nitrate in the ratio of 1:3:2 by the nmr spectra and gc analysis.

(*d*) A mixture of NNOD (0.9 g, 0.01 mol), cyclohexene (3.36 g, 0.04 mol), and sodium carbonate (2 g) in *n*-hexane (200 mL) was photolysed under nitrogen for 10 h. The photolysate was decanted from the deposited oil and was evaporated to give a yellow oil (322 mg) showing singlets at τ 7.03 and 7.11 for **2***c*, 6.20 and 6.92 for **2***b*, and 6.81 and 7.82 for $(CH_2{=}NCH_3)_3$ (24). Gas chromatographic analysis of the oil

gave the peaks corresponding to **2***b* (6.1 min, 3%) and **2***c* (6.6 min, 30%) and other unidentified peaks.

The insoluble fraction was taken up in methanol and was evaporated to give a dark oil (190 mg); this oil showed a doublet at τ 7.16 (J = 6 Hz, collapsing to a singlet after D_2O exchange) for *N*-methylformamide and singlets at τ 7.03 and 7.11 for **2***c* and 6.20 and 6.92 for **2***b*. The gc analysis of this mixture gave the peaks corresponding to **2***b* (19%), **2***c* (15%), **2***a* (3%), and *N*-methylformamide (58%). The last compound was separated by preparative gc and showed ir, nmr, and ms spectra identical with those of a sample synthesized from methylamine and formic acid.

Photolysis of N-*Nitropiperidine in Acidic Methanol*

NNOP (1.0 g, 0.008 mol) and concentrated HCl (1 mL, 0.06 *N*) in methanol (200 mL) were irradiated under nitrogen for 2 h at which time the reaction mixture was distilled. A mixture of the distillate (50 mL) and 2,4-dinitrophenylhydrazine reagent solution (20 mL) was evaporated to approximately 20 mL and was cooled. The yellow precipitate was recrystallized from methanol to give formaldehyde 2,4-dinitrophenylhydrazone, mp 159–162°C; a mixed melting point with an authentic sample was 161–163°C.

The residue from the photolysate (1.0 g) was dissolved in hot 2-propanol and was cooled to give white crystals (150 mg, mp >200°C) which exhibited identical ir and ms spectra to those of an authentic sample of piperidine hydrochloride; ir: 2520(m), 2420(m), 1590(m), 1160, 1028, 940, and 860(m) cm^{-1}. The mother liquor was evaporated and the residue was diluted with water (50 mL) and worked up in the usual manner. Extraction of the basic fraction with ether gave a crude oil (250 mg) which on gc analysis (20% SE30, 130°C) gave a single peak superimposable with that of piperidine.

In a separate experiment, the photolysate was worked up in the usual manner and the aqueous solution, made basic with sodium carbonate, was extracted with methylene chloride. The methylene chloride solution was dried and evaporated to give an oil (530 mg); ir: 3350(w, br), 2665(w), 2520(w), 2420(w), 1590(w), 1295, 1265, 1160(s), 1130(s), 1035, 862, and 780(m) cm^{-1}; nmr τ: 6.55(m), 7.15(s), 7.57(m), and 8.50(m). Three peaks with retention times of 1.2, 2.4, and 12.7 min were observed when this mixture was examined by gc (20% SE30, 130°C). By peak matching the first and third peaks were shown to be piperidine (37%) and piperidine hydrochloride (21%). The second peak exhibited ms fragments at *m/e* 96(19), 95(100), 94(78), and 67(72) and was characterized as dipiperidinomethane (41%) by comparison with the mass spectrum of an authentic sample prepared from piperidine and methylene chloride.

Photolysis of Nitramines Under Acidic Conditions in the Presence of Cyclohexene

(*a*) A solution of NNOP (1.0 g, 0.008 mol), cyclohexene (0.65 g, 0.008 mol), and concentrated HCl (0.67 mL, 0.04 *N*) in methanol (200 mL) was irradiated under nitrogen for 4.5 h. As the 249 nm band of NNOP in the uv spectra of the photolysate slowly disappeared it was replaced by a new absorption at about 210 nm which subsequently disappeared with further irradiation. The workup gave a neutral fraction (40 mg) and a basic fraction (770 mg); ir: 3300(w), 1550(m), 1155, and 1115(m) cm^{-1}; nmr τ: 4.30(m), 6.70 (d, J = 6 Hz), 7.6(m), and 8.5(m). The complex basic fraction was analyzed by the gc peak matching method and by gc–ms (20% SE30, 110–200°C at 8°/min) and found to be a mixture of eight compounds with the following retention times: 3.0 min, 16%, piperidine; 6.0 min, 5.5%, dipiperidinomethane; 18.3 min, 12%, ms *m/e*: 165(M^+, 42), 164(18), 150(15), 137(100), 124(64), 122(88), 84(50), and 81(48); 20.7 min, 10%, ms *m/e*: 197(M^+, 32), 182(80), 124(100), 98(41), 85(25), and 84(27); 21.2 min, 20%, 2-piperidinocyclohexanol (**3**); 24.6 min, 22%, 2-piperidinocyclohexanone oxime (**9**); 26.1 min, 9%, 1-nitro-2-piperidinocyclohexane (**4**). The above identifications were made by comparison of mass spectra with those of the authentic samples (21, 22, 24). The compounds eluting at 18.3 min and 20.7 min were tentatively identified as a piperidinocyclohexene (**11**) and 1-methoxy-2-piperidinocyclohexane (**5**), respectively, from the mass spectra.

(*b*) A solution of NNOD (0.9 g, 0.01 mol), cyclohexene (1.64 g, 0.02 mol), and concentrated hydrochloric acid (0.9 mL) in methanol (190 mL) was photolysed under nitrogen for 3 h. The photolysate was worked up in the usual manner to give a neutral (160 mg) and basic fraction (790 mg). The basic fraction showed ir peaks at 3350, 1660, 1552, 1160, 1115, and 1048 cm^{-1} and nmr singlets at τ 7.66, 7.70, and 7.80 and was analyzed by gc peak matching and gc–ms (10% SE30, 100–275°C at 6°/min) to give the following compounds: 2.9 min, 15%, dimethylaminocyclohexane (**6**); 4.6 min, 28%, 2-dimethylaminocyclohexanol (**7**); 5.3 min, 8%, unknown, *m/e* (%): 170(22), 142(100), 126(66), 84(68), 71(70), 58(66), 44(38), and 42(44); 6.7 min, 24%, 2-dimethylaminocyclohexanone oxime (**10**), *m/e*(%): 156(M^+, 15), 139(100), 84(80), 71(60), 44(45), and 42(58); 7.5 min, 22%, 1-nitro-2-dimethylaminocyclohexane (**8**); 13.4 min, 3%, unknown, *m/e* (%): 327(2), 222(47), 125(100), 110(75), 84(72), and 58(78).

The neutral fraction showed >30 gc peaks and nmr signals for NNOD at τ 6.6 and for a cyclohexyl moiety at τ 8.00 region. The fraction was not investigated further.

(*c*) The same photoreaction as above was carried out except carbon monoxide instead of nitrogen was used. The photolysate was worked up to give a neutral (176 mg) and basic fraction (680 mg). The basic fraction gave, by gc analysis, **6** (15%), **7** (28.5%), **10** (24.5%), and **8** (24.5%) in addition to the two unknowns. The neutral fraction showed gc and ir spectra similar to that above and was not investigated further.

Oxidative Photoaddition of Nitramine to Cyclohexene in the Presence of Oxygen

(*a*) A solution of NNOP (1 g, 0.008 mol), cyclohexene (0.65 g, 0.008 mol), and concentrated HCl (0.67 mL, 0.04 *N*) in methanol (200 mL) was photolysed under oxygen for 1 h. The photolysate was worked up in the usual manner to yield a small amount of the neutral fraction and the basic extract (1.48 g); ir: 3400(w, br), 1710(w), 1620(s), 1100, and 865(s) cm^{-1}. The basic extract was dissolved in THF (100 mL) and reduced with LAH (1.2 g, 0.03 mol). The usual workup gave an oil (1.01 g, 72%).

The reduced basic extract was chromatographed on alumina (40 g). The first compound (300 mg, 25%) eluted with 0.5% methanol–CH_2Cl_2 gave a solid which was sublimed (25°C/0.5 Torr) to give trans-2-piperidinocyclohexanol (**3**); mp 30.5–32°C (lit. (21) mp 35–36°C); ir (Nujol): 3450(s), 1305, 1195, 1160, 1100(s), 1078(s), 1005, 940, and 870 cm^{-1}; nmr τ: 6.75(m, 1H), 6.75(s, D_2O exch.), 7.80(m, 1H), 7.2–8.2 (unresolved, 5H), 8.50(m, 10H), and 8.80(m, 3H); ms *m/e*(%): 183(13), 166(2), 154(4), 140(6), 125(13), 124(100), 111(16), 98(33), and 84(13). The second compound (150 mg, 12%) was eluted with 1% methanol–CH_2Cl_2 as a crystalline solid which was sublimed twice (25°C/0.5 Torr) to give *cis*-2-piperidinocyclohexanol (**3**); mp 83–85°C; ir (Nujol): 3170(w), 1190, 1105, 985, and 870 cm^{-1}; nmr (CCl_4) τ: 6.10(m, 1H), 7.45(m, 6H), and 7.9–9.0 (unresolved, 14H). Resublimation (25°C/0.5 Torr) gave an analytical sample of the *cis*-alcohol melting at 87–89°C (lit. (21) mp 93–94°C). *Anal.* calcd. for $C_{11}H_{21}NO$: C 72.08, H 11.55, N 7.64; found: C 71.77, H 11.43, N 7.67.

(*b*) A solution of NNOD (0.9 g, 0.01 mol), cyclohexene (1.64 g, 0.02 mol) and concentrated hydrochloric acid in

methanol was irradiated under oxygen for 1.5 h. The photolysate was evaporated and separated to a neutral (105 mg) and a basic fraction (1.52 g); ir: 3420(m), 1715(m), 1625(s), 1275(s), 1040(m), and 870(s) cm^{-1}. The basic fraction was immediately reduced with lithium aluminium hydride (1.5 g) for one day. After usual workup, it gave a 1:3 mixture (1.04 g, 64%) of *cis*- and *trans*-2-dimethylaminocyclohexanols as shown by ir and nmr spectra and gc analysis in comparison with an authentic sample (21, 20).

Quantum Yield Determination

The quantum yields of the photodecomposition of *N*-nitropiperidine under various conditions were determined by the technique described in the previous publications (23). Solutions containing *N*-nitropiperidine (0.01 *M*), cyclohexene (0.02 *M*), and various amounts of acids were placed in quartz tubes and irradiated in a merry-go-round apparatus equipped with a Hanovia 450 W medium pressure mercury lamp. At each five minute interval a tube was removed and frozen in a dark place until making the uv measurements. The decreases of the absorbance of the 245 nm of the nitramine were recorded and plotted against the time. The decreases followed a zero order kinetics up to 30 min irradiation and the slopes gave the amount of nitramine decomposition. After 30 min irradiation, the decreases curved upward indicating that secondary reactions had set in. The zero hour samples were kept in the dark and were found to show no noticeable decrease in the uv absorption. A ferric oxalate actinometry was used and a *correction factor* (23) measuring the light quanta absorbed by the nitramine solution was determined to be 45%. The results are summarized in Table 2.

Kinetic equations for reactions in concentrated aqueous acids based on the concept of "excess acidity"[1]

ROBIN A. COX AND KEITH YATES

Department of Chemistry, University of Toronto, 80 St. George St., Toronto, Ont., Canada M5S 1A1

Received May 14, 1979

ROBIN A. COX and KEITH YATES. Can. J. Chem. 57, 2944 (1979).

Kinetic equations, applicable to A-1, A-S_E2, and A-2 reactions in concentrated aqueous acids, are derived. The variation in reaction rate with varying acid concentration is treated in terms of the "excess acidity" of the medium (X-function), rather than in terms of Hammett-type acidity functions or the water activity. The parameters obtained are the medium-independent rate constant k_0, in the aqueous standard state, as an intercept, and a slope parameter m^*; hydration parameters (r-values) are also obtained, for A-2 reactions. The equations derived are shown to apply to A-1 acetal hydrolyses, A-S_E2 electrophilic aromatic substitutions, and mixed A-2/A-1 ester hydrolyses. In a general discussion of available methods for analyzing rate data in these media, it is shown that the X-function method encompasses most, if not all, of the others, and that classical acidity functions are no longer necessary.

ROBIN A. COX et KEITH YATES. Can. J. Chem. 57, 2944 (1979).

On a déduit les équations cinétiques applicables aux réactions de type A-1, A-S_E2 et A-2 dans des solutions aqueuses concentrées d'acides. La variation de la vitesse de réaction en fonction de la concentration de l'acide est interprétée en fonction d'un excès d'acidité (fonction de X) plutôt que selon des fonctions d'acidité de type de Hammett ou d'activité de l'eau. On a obtenu les paramètres suivants: la constante de vitesse k_0 indépendante du milieu, dans l'état fondamental aqueux en tant qu'intersection et un paramètre de pente m^* ainsi que les paramètres d'hydratation (valeur conventionnelle) trouvées au cours des réactions de type A-2. On a montré que les équations dérivées s'appliquent aux hydrolyses A-1 d'acétales aux substitutions électrophiles en série aromatique A-S_E2 et aux hydrolyses d'esters mixtes A-2/A-1. Dans une discussion générale sur l'ensemble des méthodes disponibles d'analyse de données de vitesse en milieu acide on a montré que la méthode de la fonction de X englobe la plupart si ce n'est pas toutes les autres méthodes, et que les fonctions classiques d'acidité ne sont plus nécessaires.

[Traduit par le journal]

Introduction

Recently excess acidities, or X-functions, have been determined for 0–99.5% aqueous sulfuric acid and 0–78% aqueous perchloric acid (1). These are derived from ionization ratio data for all types of base in these systems, using a concept developed by Marziano, Passerini, and their associates (2). They have been used to evaluate acid dissociation constants, in the aqueous standard state, for a large number of weak bases in these media (1).

For proton transfer to a base B, eq. [1], the

$$[1] \quad B + H^+ \overset{K_{BH^+}}{\rightleftharpoons} BH^+$$

$$[2] \quad \log (C_{BH^+}/C_B) - \log C_{H^+} = \log (f_B f_{H^+}/f_{BH^+}) + pK_{BH^+}$$

general thermodynamic eq. [2] can be written, from the definition of K_{BH^+}, where C is molar concentration, f molar activity coefficient, and K_{BH^+} is the acid ionization constant of the species BH^+. The assumption is then made that the activity coefficient term in eq. [2] is a linear function of a similar term for a "standard base" B*, slope m^*, which is the previously derived X-function (1), eq. [3].

$$[3] \quad \log (f_B f_{H^+}/f_{BH^+}) = m^* \log (f_{B^*} f_{H^+}/f_{B^*H^+}) = m^* X$$

This assumption has now been extensively tested and found to be obeyed for many different types of base in strong acids (2, 3), and for many types of acid in strongly basic solutions (4, 5). Equation [4] can then be used for the evaluation of pK_{BH^+} values

$$[4] \quad \log I - \log C_{H^+} = m^* X + pK_{BH^+}$$

in the aqueous standard state; the term C_{BH^+}/C_B in eq. [2] is the measured ionization ratio I (1).

In this paper these X-functions are used to develop general kinetic equations, applicable to acid-catalyzed reactions in these and other non-ideal strong acid media, and, by a simple extension (4), to base-catalyzed reactions in strongly basic media (6).

The accompanying papers test this analysis for several different reactions (7, 8).

Kinetic Analysis

A-1 Mechanism

$$S + H^+ \overset{K_{SH^+}}{\rightleftharpoons} SH^+$$

[5] $$SH^+ \xrightarrow[\text{slow}]{k_0} A^+ \xrightarrow{\text{fast}} P$$

Equation [5] represents a rate-determining unimolecular reaction, with a medium-independent rate constant k_0, of a protonated substrate SH^+ formed from the substrate S in a fast pre-equilibrium proton transfer (K_{SH^+}). The product P may be formed directly, or after subsequent fast step(s) from an intermediate A^+. The observed rate (pseudo-first-order rate constant k_ψ) is then given by eq. [6],

[6] $$dC_P/dt = -d(C_S + C_{SH^+})/dt = k_\psi(C_S + C_{SH^+}) = k_0 a_{SH^+}/f_\ddagger$$

where the substrate concentration is written as the sum of protonated and unprotonated forms (since the extent of protonation is also medium-dependent); a is activity and $f_\ddagger$ is the activity coefficient of the transition state.

Two cases may be considered; one in which the substrate is predominantly unprotonated in the acidity range under study, and the other in which it is mainly protonated.

For case 1 we may write eq. [7], substitute this into eq. [6], take logs and rearrange to give eq. [8].

[7] $$a_{SH^+} = a_S a_{H^+}/K_{SH^+} = C_S C_{H^+} f_S f_{H^+}/K_{SH^+}$$

[8] $$\log k_\psi - \log C_S/(C_S + C_{SH^+}) - \log C_{H^+} = \log (f_S f_{H^+}/f_\ddagger) + \log (k_0/K_{SH^+})$$

Probably the best assumption that can be made about the activity coefficient ratio term in eq. [8] is that it is a linear function of a similar term describing the equilibrium protonation of S, with slope parameter $m^\ddagger$, eq. [9]

[9] $$\log (f_S f_{H^+}/f_\ddagger) = m^\ddagger \log (f_S f_{H^+}/f_{SH^+}) = m^\ddagger m^* X$$

This is an extension of the Kresge α-coefficient assumption (9, 10). Since the second term in eq. [9] is linear in X (eq. [3] above), the slope parameter can be written as the product, $m^\ddagger m^*$, and eq. [8] becomes eq. [10]. (The Bunnett–Olsen treatment (11), in contrast, uses an *additive* combination of slope parameters.)

[10] $$\log k_\psi - \log C_S/(C_S + C_{SH^+}) - \log C_{H^+} = m^\ddagger m^* X + \log (k_0/K_{SH^+})$$

For case 2, $a_{SH^+} = C_{SH^+} f_{SH^+}$ can be substituted into eq. [6]; taking logs and rearranging produces eq. [11]. Addition of $\log f_{SH^+}$ to each side of eq. [9] gives eq. [12], which on substitution into eq. [11] results in the linear equation [13].

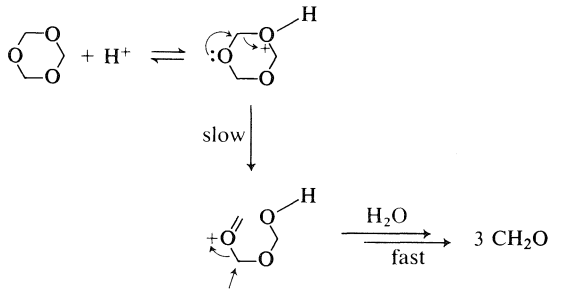
[11] $$\log k_\psi - \log C_{SH^+}/(C_S + C_{SH^+}) = \log (f_{SH^+}/f_\ddagger) + \log k_0$$

[12] $$\log (f_{SH^+}/f_\ddagger) = (m^\ddagger - 1) \log (f_S f_{H^+}/f_{SH^+}) = (m^\ddagger - 1) m^* X$$

[13] $$\log k_\psi - \log C_{SH^+}/(C_S + C_{SH^+}) = (m^\ddagger - 1) m^* X + \log k_0$$

Equations [10] and [13] are the appropriate kinetic equations for an A-1 process; values of log C_{H^+} and X for use with these are available (1, 12). If ionization ratio data for the substrate can be obtained, application of eq. [4] gives pK_{SH^+} and m^*, and the terms which correct for differing extents of protonation (the second terms in eqs. [10] and [13]) can also be evaluated, if necessary. If not, either zero or full protonation can be assumed and eq. [10] or eq. [13] used anyway; now, however, the slope and intercept parameters from the straight line plot will be composites, as indicated.

Some A-1 reactions, as attested by much evidence, acidity function and otherwise, involving unprotonated substrates are illustrated in Fig. 1. These are acetal hydrolyses in sulfuric acid at 25°C of methoxymethyl acetate (13), trioxane (14), and paraldehyde (15). In all of these fast pre-equilibrium proton transfer is followed by slow unimolecular breakup of the protonated species, as illustrated for the depolymerization of trioxane (ref. 16, pp. 148–150; ref. 23, pp. 187–189):



The plots according to eq. [10] show excellent linearity; the data resulting from least-squares analysis are in Table 1. No ionization ratio data for

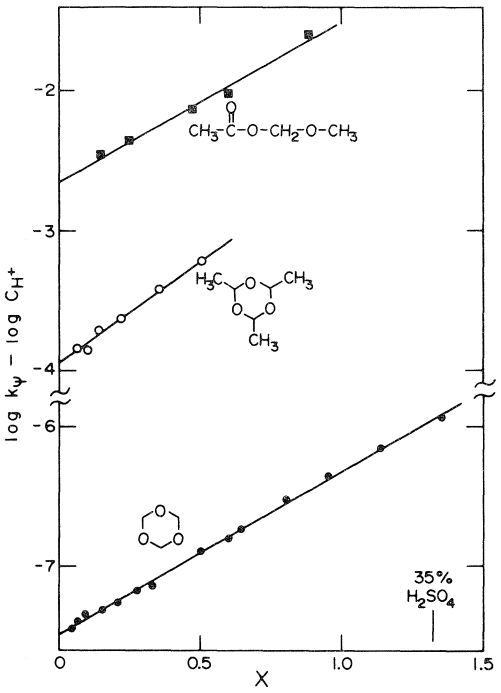


FIG. 1. Some acetal hydrolyses in sulfuric acid at 25°C, plotted according to eq. [10]. Rate data from refs. 13–15; X and log C_{H^+} from ref. 1.

these compounds seem to be available, but it is known that m^* values for typical oxygen protonations are in the range 0.4–0.6 (1), so that $m^{\ddagger}$ is probably in the range 2–3.

A-S_E2 Mechanism

$$[14] \quad S + H^+ \underset{\text{slow}}{\overset{k_0}{\rightarrow}} SH^+ \underset{\text{fast}}{\rightarrow} P$$

Equation [14] represents rate-determining proton transfer to the substrate, with subsequent reaction of SH^+ being fast. The rate is given by eq. [15]; on making the assumptions of eq. [9] and taking logs, eq. [16] results.

$$[15] \quad k_\psi C_S = k_0 a_S a_{H^+}/f_{\ddagger} = k_0 C_S C_{H^+} f_S f_{H^+}/f_{\ddagger}$$

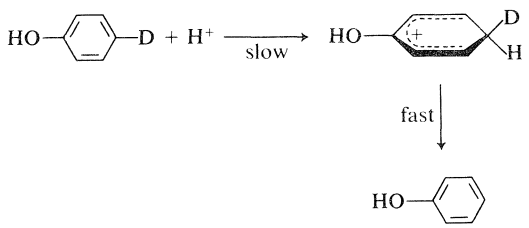
$$[16] \quad \log k_\psi - \log C_{H^+} = m^{\ddagger} m^* X + \log k_0$$

Here the slope parameter $m^{\ddagger}$ is identical to the term α (also called α_A (10)), which has been defined by Kresge *et al.* (9). The value of α is interpretable as the degree of proton transfer at the transition state as shown in eq. [17]; this value varies between zero and one, as the transition state varies between (S + H^+) and SH^+ (9, 10).

$$[17] \quad f_{\ddagger} = (f_S f_{H^+})^{1-\alpha} (f_{SH^+})^{\alpha}$$

Some caution is necessary in using eq. [16] in sulfuric acid and other partially dissociated acids, because in these cases species other than protonated water can act as acid catalysts, in the general acid catalysis mechanism of eq. [14] (17). Kresge and his colleagues have discussed this in connection with aromatic protodetritiation in different acid systems (18), and Cox and Buncel have found catalysis by undissociated H_2SO_4 and protonated $H_3SO_4^+$ for several azoxy rearrangements in strong sulfuric acid (17, 19). In fully dissociated acids such as $HClO_4$ and HCl, these considerations do not apply, however; an equation similar to eq. [16] has been extensively tested by Kresge and co-workers in aqueous $HClO_4$ (10).

Included here are some protodedeuterations (20, 21) and a protodeboronation (22), for substituted benzenes in dilute sulfuric acid, illustrated in Fig. 2. These widely-studied reactions are known to be A-S_E2 (ref. 16, pp. 186–190; ref. 23, pp. 262–274), with the rate-determining step being Wheland intermediate formation:



Excellent linearity according to eq. [16] is obtained; the results of least-squares analysis are given in Table 2.

Again the slope parameters are composites, $m^{\ddagger}m^*$; m^* values for typical carbon protonations are large, in the range 1.2–1.6 (1), so $m^{\ddagger}$ probably has a value between 0.5 and 1.0 for these reactions, which seems reasonable.

A-2 Mechanism

$$[18] \quad S + H^+ \underset{\text{fast}}{\overset{K_{SH^+}}{\rightleftharpoons}} SH^+ \qquad SH^+ + Nu \underset{\text{slow}}{\overset{k_0}{\rightarrow}} P$$

The A-2 mechanism of eq. [18] differs from the A-1 mechanism of eq. [5] in the involvement of additional species with protonated SH^+ in the rate-determining transition state. These species, symbolized Nu in eq. [18], may be nucleophiles or bases. Usually one or more water molecules are involved (16, 23, 24); occasionally bisulfate ions in sulfuric

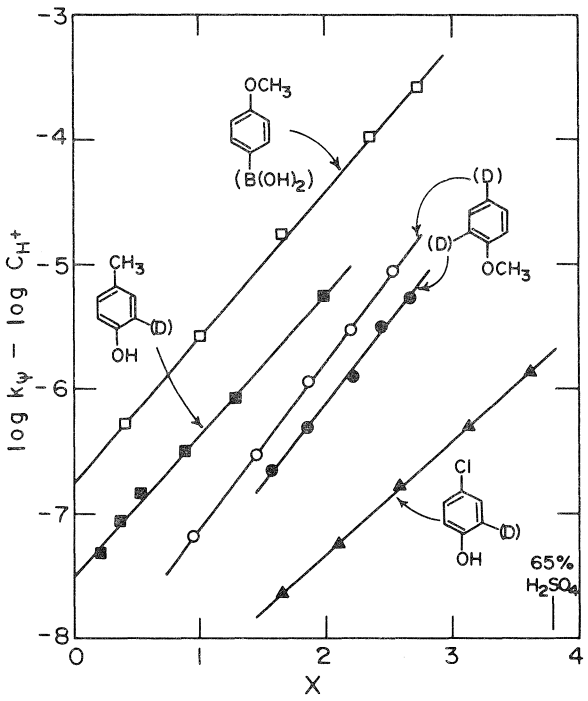

FIG. 2. Some protodedeuterations (20–21) and a protodeboronation (22) of benzene derivatives in sulfuric acid at 25°C. Plotted according to eq. [16], using X and log C_{H^+} from ref. 1.

acid (25, 26), and possibly other species in different acid media (17).

A similar analysis to that for the A-1 case given above results in eq. [19] for mainly unprotonated substrates, and eq. [20] for substrates which exist

$$[19]\quad \log k_\psi - \log C_S/(C_S + C_{SH^+}) - \log C_{H^+} = m^{\ddagger}m^*X + \log a_{Nu} + \log (k_0/K_{SH^+})$$

$$[20]\quad \log k_\psi - \log C_{SH^+}/(C_S + C_{SH^+}) = (m^{\ddagger} - 1)m^*X + \log a_{Nu} + \log k_0$$

predominantly in the protonated form under the reaction conditions. These differ from eqs. [10] and [13] above in the inclusion of an additional nucleophile (or base) activity term. Thus plots of the left-hand side (LHS) of these equations vs. X will curve downward for an A-2 process involving water, the most common case (7). In practice, different log a_{Nu} values can be subtracted from the LHS (one water, two waters, one bisulfate, etc.) until linearity against X is achieved. Alternatively the problem can be treated as a double linear regression with X as one variable and, say, log a_{H_2O} as the other. This procedure gives both $m^{\ddagger}$ and r values, where r is the net number of water molecules involved in forming the transition state (24). This approach is demonstrated in an accompanying paper (7).

For cases in which a mechanism change occurs, as in most ester hydrolyses (24, 27), a non-linear least-squares computer program which fits a combination of (say) eqs. [10] and [19] (i.e., $k_\psi = k_{A-1} + k_{A-2}$) will give all the relevant parameters directly (8).[2] A good illustration of this can be found in the recent work of Edward and Wong (28), who studied the hydrolyses of ethyl benzoate, ethyl thiolbenzoate, and ethyl thionbenzoate in sulfuric acid. They found that all these esters hydrolyzed by an A-2 process in weak acid, with two water molecules involved in the reaction, and switched to an A-1 process in stronger acid, with the position of mechanism change being very substrate-dependent. Detailed mechanisms were given (28), proposed on the basis of the r-parameter (24) and the transition-state activity coefficient (29) criteria. Ample confirmation of these mechanistic proposals can be seen in the excellent agreement of theory with experiment in Fig. 3, where the theoretical curves[2] are calculated assuming that eq. [10] applies to the high acidity A-1 reaction, and eq. [19] to the low acidity A-2 process, with log a_{Nu} taken as 2 log a_{H_2O}. The resulting parameters are given in Table 3. In this case the protonation behaviour is available (1, 28, 30), so $m^{\ddagger}$ and k_0 values can be calculated for the A-2 reactions. The resulting $m^{\ddagger}$ values are closely similar for the three substrates, despite their quite different

[2]A suitable program is given elsewhere (8).

protonation behaviour (as exemplified by the m^* values), suggesting similar transition state structures. The k_0 values all refer to the aqueous standard state, and thus are convenient for rate comparisons under standard conditions.

General Discussion

The X-function treatment described above has at least three distinct advantages over the currently available methods, of which there are several.

Firstly, it includes the best parts of all previous

TABLE 3. Data resulting from the application of eqs. [10] and [19] to some ester hydrolyses in sulfuric acid at 25°C[a]

[f]Data insufficient for reliable estimation (28).

treatments (except the original Zucker–Hammett hypothesis (31), since discredited on various grounds, for instance the unacceptable activity coefficient behaviour required (24)). It includes the α-coefficient treatment (9), eq. [16], in its entirety. The basis is similar to that for the Bunnett–Olsen method (11),[3] and the parameters derived using the two can be interconverted. It gives the r-parameters (superseding the original w-values (32)) of the hydration parameter treatment (24), but only for those cases in which water really is involved in the reaction; the artificiality of plotting log rate constants against log water activity for cases in which water is not involved, is removed. It offers easy calculation of $f^*_{S\ddagger}$ values from eq. [9], if the necessary f_S values are available (see below), giving the advantages of the transition-state activity coefficient (TSAC) method (29).

Secondly, acidity functions, H_0, H_A, H_0''', etc., are not needed; the activity coefficient cancellation assumption, required to derive them, is not made (1). The only assumption made here is that activity coefficient ratios are linear functions of one another as in eqs. [3] and [9]. This assumption can be tested for equilibria, where it works well (1–5); it cannot be tested directly when transition states are involved, but the results suggest it is valid here too. The similarly-based Bunnett–Olsen method (11, 33) requires in addition the use of H_0, and hence the cancellation assumption used in its derivation;[3] also X-functions are derived using a much larger data base than that used for H_0 (1), and thus should offer higher precision. Nevertheless, at least in sulfuric acid (1), the X-function and Bunnett–Olsen methods are compatible (but see ref. 34), and should lead to the same mechanistic conclusions; detailed kinetic equations for the latter have been given (33). The slope parameters given by the two treatments, m^* and $m^{\ddagger}$, and ϕ_e and $\phi_{\ddagger}$ (33), can be interconverted, approximately, via eq. [21].

$$\begin{aligned} & H_0 + \log C_{H^+} \simeq -X \\ & m^* \simeq 1 - \phi_e \\ & m^{\ddagger} \text{ (or } \alpha) \simeq (1 - \phi_{\ddagger})/(1 - \phi_e) \\ & \phi_{\ddagger} \simeq 1 - m^{\ddagger}m^* \end{aligned} \qquad [21]$$

Thirdly, the nucleophilic or basic species actually involved in the transition state of an A-2 reaction can be determined, using eq. [19] or eq. [20]. Only the hydration parameter treatment (24) has successfully provided this information before, and only for those reactions involving water. The involvement of bisulfate ions in sulfuric acid has been inferred (25, 26), using a treatment which essentially ignored the activity coefficient variations; however, these are unlikely to be negligible in most cases. The TSAC method ignores any explicit involvement of additional species in the derivation of $f^*_{S\ddagger}$ (29), which may therefore contain contributions from (e.g.) the water activity for an A-2 process. This was pointed out by Edward and Wong (28), who use a slightly modified treatment in consequence. The treatment described here, with its ability to deal with additional species activity terms and with mixed mechanisms, probably offers the easiest access to this information.

The major difference between the excess acidity method and the Bunnett–Olsen method (11, 33), apart from the already-mentioned use of H_0 in the latter, lies in eq. [9]. In this work, in common with Kresge (9, 10) a *multiplicative* combination of slope parameters is used, whereas Bunnett and Olsen (11) and their followers (33) prefer an *additive* combina-

[3]This point is discussed in detail in ref. 1.

tion; this work could be regarded as an extension of the Kresge method to include A-1 and A-2 reactions. As Professor Bunnett has remarked, "time will tell which approach is more profitable" (11). There are minor differences; for instance the Bunnett–Olsen method as originally formulated (11) does not include the nucleophile/base activity in A-2 reaction equations, and hence predicts linearity in cases where the X-function method predicts curves (eqs. [19] and [20]). This is easily allowed for, however, as Modena and co-workers have recently begun to do (33); as mentioned, the excess acidity and Bunnett–Olsen methods are essentially compatible.

The X-function method, and the TSAC method (29), provide complementary information regarding reaction mechanisms in strong acid media. Equation [9] can be rearranged to give eq. [22].

$$[22]\quad \log f^*_{S\ddagger} = \log f_S - \log C_{H^+} - m^\ddagger m^* X + \log a^*_{H^+}$$

Of the terms on the right, $\log f_S$ must be measured or estimated (35), $\log C_{H^+}$ is available (1, 12), and $m^\ddagger m^* X$ is obtainable as described in this paper, and $\log a^*_{H^+}$ values have been derived for several acid media (36). The latter are proton activities relative to the standard tetraethylammonium ion, TEA^+, which is assumed to be invariant in its activity coefficient behaviour as the medium composition is changed (the Boyd approximation (37)); the $\log f^*_{S\ddagger}$ values obtained will also be relative to this ion (29).

The TSAC method, which relies on an essentially qualitative comparison of curve shapes, comparing the $\log f^*_{S\ddagger}$ curve as a function of acidity with known activity coefficient curves (29, 35), is probably the better method for distinguishing between different mechanistic possibilities. It can distinguish between A-1 and A-S_E2 mechanisms, for instance (38), which is difficult using any of the other methods. It does, however, require additional data not needed by the X-function method; the activity coefficient of the substrate as a function of acidity must be available or measureable (35).

On the other hand, once the mechanism is known or can reasonably be inferred, the X-function method probably provides the best medium-independent rate constants, k_0, for subsequent analysis. Since these are obtained by extrapolation to the standard state, pure water (where the deviation from ideality, X, is zero), they can be directly compared with those obtained, for instance, in aqueous buffer media, without having to be concerned with activity coefficients or differing acidity function behaviour. Comparison of rate constants obtained in non-ideal solutions has always been a problem; for example, should comparison be made at points of equal weight percent acid, equal molarity, equal H_0, equal substrate acidity function value, or equal water activity? Extrapolation to $H_0 = 0$ is commonly used (39), but this is suspect because different substrates often follow different acidity functions (16). In any case, 1 M acid can hardly be regarded as an ideal solution; the deviation from ideality, expressed as X, is 0.17 for H_2SO_4 and 0.20 for $HClO_4$ at this concentration (1). If rate constants obtained in one of these ways are used to calculate $\Delta H^\ddagger$, $\Delta S^\ddagger$, ρ, etc., it becomes difficult to decide what part of the calculated number represents real substrate behaviour and what part represents deviation from ideality of the medium (19). Using standard state k_0 values from the X-function treatment avoids these problems; they can be used with confidence for calculations of activation parameters, and in LFER plots. This is further demonstrated in the accompanying papers (7, 8).

The slope parameters, $m^\ddagger$, should offer mechanistic information; this has been discussed (in terms of $\phi_\ddagger$) by Lucchini *et al.* (33). Writing eq. [9] in the form of eq. [23],

$$[23]\quad \log f_\ddagger = m^\ddagger \log f_{SH^+} + (1 - m^\ddagger) \log f_S f_{H^+}$$

three possible types of behaviour may be visualized. Firstly, if $m^\ddagger \simeq 1$, $\log f_\ddagger \simeq \log f_{SH^+}$. This is suggestive of an A-2 reaction, where the hydration requirements of SH^+ and of an A-2 transition state should be similar (29); here it is known that $\log f^*_{S\ddagger}$ increases steeply with acidity, as does $\log f_{SH^+}$ (29, 35). Secondly, if $m^\ddagger < 1$, both terms on the right in eq. [23] will be positive, leading to a rise of $\log f_\ddagger$ with acidity; this is characteristic of A-S_E2 reactions (38). Finally, if $m^\ddagger > 1$, the two terms in eq. [23] will tend to cancel, increasingly so as $m^\ddagger$ increases; this leads to $\log f_\ddagger$ values which change only slowly with acidity. This is characteristic of an A-1 reaction (29, 38). The above analysis appears to be borne out experimentally (see Tables 1–3 and the earlier Discussion). In addition, it seems reasonable that similar $m^\ddagger$ values in related reactions would reflect similar transition state structures (see Table 3).

In summary, the major uses of the X-function method appear, at present, to be: confirming or rejecting proposed mechanisms, by producing a linear plot according to one of the equations given in this paper; determining what species are present in the transition states of A-2 reactions; and producing reliable intercept k_0 values for subsequent analysis.

The X-function method has been used to evaluate the basicities of six nuclear-substituted acetophenones and acetone, using a combination of new measurements and literature data; the protonation pK_{BH^+} of acetone was found to be -5.37. The same method, which involves the excess medium acidity, when used to analyze the enolization rate constants obtained from the measured bromination rates, shows that most of the acetophenones enolize by an A-2 process involving two water molecules in the rate-determining step. Observed linear free energy relationships for the basicities and the enolization rates imply a relatively early transition state for the enolization. Acetone was found to enolize by a similar mechanism in sulfuric acid solutions more dilute than 81% w/w, but at higher acidities bisulfate ion was the preferred base. The mechanistic behaviour of 4-nitroacetophenone was found to be different, not A-2 but either A-1 or A-S_E2.

ROBIN A. COX, CLINTON R. SMITH et KEITH YATES. Can. J. Chem. **57**, 2952 (1979).

On a utilisé la méthode de l'excès d'acidité (fonction de X) pour évaluer les basicités de six acétophénones substituées et de l'acétone en utilisant une combinaison de nouvelles mesures avec des données de la littérature; on a ainsi trouvé que la protonation pK_{BH^+} de l'acétone est de -5.37. Lorsqu'on utilise la même méthode, qui fait appel à l'excès d'acidité du milieu, pour analyser les constantes de vitesse d'énolisation obtenues à partir des vitesses de bromation, on trouve que la plupart des acétophénones s'énolisent selon un mécanisme A-2 qui implique deux molécules d'eau dans l'étape déterminante de la réaction. Les relations linéaires entre l'énergie libre et les vitesses de basicité et d'énolisation impliquent un état de transition qui se manifeste très tôt au cours de l'énolisation. On a remarqué que le mécanisme d'énolisation de l'acétone ne varie pas dans des solutions d'acide sulfurique à concentration inférieure à 81% (W/W); toutefois à de plus fortes concentrations, l'ion bisulfate est la base préférée. Le mécanisme est différent dans le cas de la nitro-4 acétophénone et n'est pas du type A-2 mais du type A-1 ou A-S_E2.

[Traduit par le journal]

Introduction

Recently an extrapolative technique for obtaining protonation equilibrium constants (pK_{BH^+}) of weak bases has been developed, using ionization ratio (I) measurements in strong acid media (1, 2). Known as the X-function method (1), it involves proton concentrations (C_{H^+}) and the concept of excess medium acidity (X), rather than classical Hammett-type acidity functions, and is summarized as eq. [1] (1).

$$[1] \quad \log I - \log C_{H^+} = m^*X + pK_{BH^+}$$

It has been shown to be both accurate and general (1–3). In this paper the method is used to determine the basicities of six nuclear-substituted acetophenones and acetone.

Excess acidities can also be used in kinetic analysis, as shown in an accompanying paper (4). In that paper rate equations for A-1, A-S_E2, and A-2 processes are derived and tested; these are given here, for reactions involving predominantly unprotonated substrates, as eqs. [2]–[4], respectively,

$$[2] \quad \log k_\psi - \log C_S/(C_S + C_{SH^+}) - \log C_{H^+} = m^{\neq}m^*X + \log (k_0/K_{SH^+})$$

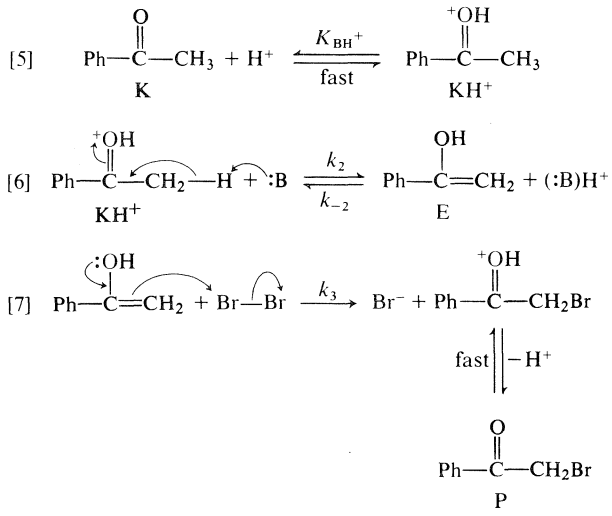
$$[3] \quad \log k_\psi - \log C_{H^+} = m^{\neq}m^*X + \log k_0$$

$$[4] \quad \log k_\psi - \log C_S/(C_S + C_{SH^+}) - \log C_{H^+} = m^{\neq}m^*X + \log a_{Nu} + \log (k_0/K_{SH^+})$$

with symbols as previously defined (4). It is of interest to use this method, eq. [4] in particular, to investigate those A-2 reactions which involve base attack in the rate-determining step, rather than the more commonly studied nucleophilic attack (4–6). This is one of the three possible mechanistic roles for water given by Bunnett, based on the w hydration parameter approach (7). To this end we have studied the enolization of some acetophenones in moderately concentrated sulfuric acid solutions by following their rates of bromination.

The bromination of ketones in acid solution is well known to proceed by the pathway shown in eqs. [5]–[7] (8).

0008-4042/79/222952-08$01.00/0



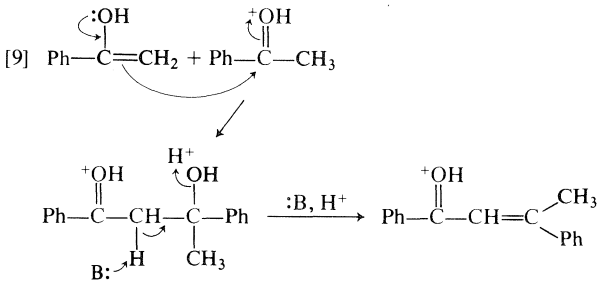
The assumption that the enol is a reactive intermediate, in a steady-state concentration, results in

$$[8] \quad -d[Br_2]/dt = k_3[E][Br_2] = (k_2/K_{BH^+})[K][H^+][B] \times \{1/(1 + k_{-2}[H^+]/k_3[Br_2])\}$$

eq. [8] for the reaction rate, given in terms of the observed variable, the bromine concentration. Provided that the last term in the denominator of eq. [8] is negligible, the observed pseudo-first-order rate constant k_ψ at a given acid concentration (fixed $[H^+]$ and [B]) can be obtained by following the zero-order bromine consumption; the rate-determining step is enolization, eq. [6]. For acetone, k_3 has been shown to be nearly 10^7 (9), so eq. [8] will be well-behaved as long as (*a*) k_{-2} is not large, and (*b*) the bromine concentration is greater than about 10^{-4} *M*. The value of k_{-2} is not expected to be large, since the reverse of eq. [6] involves carbon protonation, known to be comparatively slow (10).

Possible complications to be considered include bromination of the aromatic ring, and polybromination. The latter, troublesome in base-catalyzed enolization (11), is not expected to be a problem because acid-catalyzed bromoketone bromination is known to be slower than reaction of the parent compound (12). Another possible side reaction is condensation, e.g., eq. [9], producing unsaturated compounds which may also consume bromine (13); this has been observed at high ketone concentrations and high acidities (13), but not at uv spectral concentrations (14). It should not be important under the conditions used here.

The compounds involved in this study were 4-methoxy-, 4-methyl-, and 3-methylacetophenone



(**1–3**), acetophenone (**4**), 4-bromo-, 3-bromo-, and 4-nitroacetophenone (**5–7**), and acetone.

Experimental

The acetophenones were commercially available, and were recrystallized or redistilled before use. Sulfuric acid concentrations were determined titrimetrically.

Product analyses were performed by allowing equimolar amounts (~0.01 mol) of the acetophenone and bromine to react in 200 mL of 50% sulfuric acid until the bromine was decolourized (~2 h). Neutralization with sodium hydroxide and ether extraction, followed by drying and solvent evaporation, gave product oils which were examined spectrally.

For the basicity measurements, 10 μL of a stock methanolic ketone solution was diluted to 10 mL with the test acid and the uv–visible spectrum recorded. Determinations were in duplicate for each acid concentration. For **2**, **3**, and **6**, absorbances at the wavelength of the unprotonated form were subtracted from those at the wavelength of the protonated form, on the same spectrum (the Davis–Geissman procedure (15)), and the resulting absorbance differences used; this was sufficient to account for the small medium effect observed. For **7** the medium effect was more noticeable, and characteristic vector analysis (CVA) was necessary (16). After this treatment the protonation behaviour as a function of acidity is contained in the resulting coefficients of the first vector (16), and these were used directly. Extinction data for **2** and **5** have been reported by Flexser and Hammett (17); these were also treated by CVA. For **5** the resulting coefficients were used directly; for **2** they were added to our own data, after correcting for scale differences, and both sets used together. The experimental data used are given in Table 1.[1] Davis–Geissman extinction differences were already available for **1** (18), as were pK_{BH^+} and m^* values for **4** (1, 16). For acetone, a combination of uv extinction (14), proton (19) and ^{13}C (20) nmr data, all relating to the protonation, was normalized to a common scale and analyzed by CVA simultaneously.

The reaction kinetics were followed by monitoring the decreasing visible absorption due to bromine at 425 nm as a function of time, as the bromine reacted with an excess of the substrate, at 25°C. The concentration ranges were 10^{-2} to 10^{-3} *M* for bromine, and 1.5×10^{-2} to 10^{-3} *M* for the ketones, depending on reactant and product solubility; the ketone was kept in excess to minimize possible polybromination.

The pseudo-first-order rate constants k_ψ were evaluated as follows. Enolization is first order in ketone (K):

$$[K]_t = [K]_0 \exp(-k_\psi t)$$

[1] Tables 1, 3, and 4 are on deposit and may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

and bromine consumption is generally faster than enolization (see above):

$$[K]_t = [K]_0 - ([Br_2]_0 - [Br_2]_t)$$

Substituting this into the first equation, converting to bromine absorbance (A) at 425 nm (path length l, extinction coefficient ε), and taking logs, gives

$$\log(\varepsilon l[K]_0 - A_0 + A_t) = \log(\varepsilon l[K]_0) - k_\psi t/2.3026$$

Values of the left-hand side of this equation, plotted as a function of time, were accurately linear (correlation coefficients > 0.999) for sulfuric acid solutions more dilute than about 60% w/w. The necessary extinction coefficient ε was obtained from a previously measured calibration curve; the path length and initial ketone concentrations were known, and the initial bromine absorbance was determined, in the absence of added ketone, immediately prior to reaction. Two or more determinations of each rate constant were made, in general; these are given in Tables 3 and 4,[1] together with errors listed as maximum deviations from the mean.

Results

Reaction Products

The enolization reaction, eq. [6], was studied kinetically by following the bromine consumed, as in eq. [7], so it was necessary to establish that this is the only bromine-consuming process involved. To this end the products of large-scale reactions were isolated; ^{1}Hmr spectra provided both convenient identification ($RCOCH_2Br$ and $RCOCHBr_2$ protons are very distinctive (21)) and product ratios, from the peak areas. Observed in most cases were the expected monobrominated compounds and recovered starting material only; dibrominated products, condensation products, etc., were not found. In the case of 4- and 3-methoxyacetophenone considerable ring bromination was observed, as might be expected (anisoles brominate readily (22)), and these compounds were accordingly not studied further.

Basicities

These were determined from the variation of uv–visible spectrum with acid concentration as described in the Experimental. For the acetophenones, values of pK_{BH^+} and m^*, and ΔA_B and ΔA_{BH^+}, were obtained from the Davis–Geissman absorbance differences (ΔA), or the first characteristic vector coefficients (c_1), directly. A non-linear least-squares computer program (23) was used to fit eq. [10]

$$[10]\quad (\Delta A - \Delta A_B)/(\Delta A_{BH^+} - \Delta A) = \text{antilog}(m^*X + pK_{BH^+} + \log C_{H^+})$$

(derived from eq. [1]), since this procedure uses the available data to best advantage (24). Four coefficients were calculated by the program, $a_1 = \Delta A_B$ (or c_{1-B}), $a_2 = \Delta A_{BH^+}$ (or c_{1-BH^+}), $a_3 = pK_{BH^+}$ and $a_4 = m^*$ (see eq. [10]), using values of X and $\log C_{H^+}$ as a function of $\%H_2SO_4$ w/w from ref. 1. The observed absorbance differences or characteristic vector coefficients are given in Table 1, together with $\log I$ values calculated using ΔA_B and ΔA_{BH^+} given by the program.[1] The latter are in Table 2, along with the m^* and pK_{BH^+} values obtained. Figure 1 compares experimental points

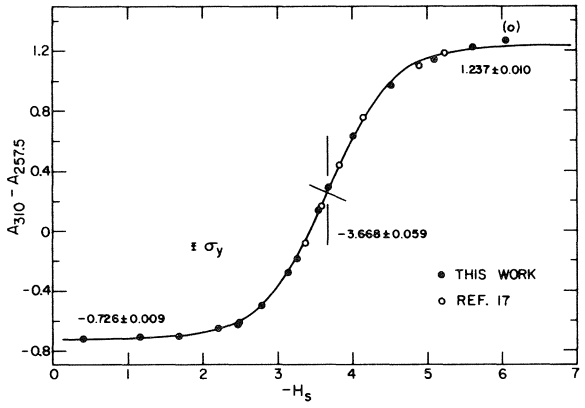

FIG. 1. Absorbance differences for 4-methylacetophenone vs. its substrate acidity function $-H_S$. Points are experimental; the curve is obtained using eq. [10] and the coefficients of Table 2.

with the best regression curve for 4-methylacetophenone (**2**), and Fig. 2 illustrates the excellent log I values obtained for **2**. These two figures use a substrate acidity function (1), $-H_S = m^*X + \log C_{H^+}$, applicable only to **2**, necessitating the exact unit slope shown in Fig. 2.

Acetone is unusual, in that characteristic vector analysis (CVA) produces a second vector (v_2) accounting for some 30% of the observed variability, with the first, v_1, only accounting for about 65%, as against at least 95% in most cases (16). Thus extracting a pK_{BH^+} value for acetone from the data necessitates a more complex analysis.[2]

According to Palm and co-workers (e.g., ref. 25), the protonation of carbonyl compounds, eq. [11], can be regarded as taking place in two stages, eqs. [12] and [13].

$$[11]\quad B + H^+_{aq} \overset{K_{BH^+}}{\rightleftharpoons} BH^+$$

$$[12]\quad B + H^+_{aq} \overset{K_1}{\rightleftharpoons} B\ldots H^+_{aq}$$

$$[13]\quad B\ldots H^+_{aq} \rightleftharpoons BH^+$$

As long as B and B . . . H^+_{aq} do not differ appreciably in their properties (uv spectrum, nmr chemical shift, etc.) the first equilibrium, eq. [12], will not be observable (other than as a slight "medium effect") and the spectral changes observed can be regarded as being due to eq. [11]. This is the case for the acetophenones studied here; even for those requiring CVA v_1 accounted for almost all of the observed systematic (i.e., non-random) variation. However, for a simple compound such as acetone, without a large polarizable phenyl group, association complex formation (eq. [12]) produces a quite noticeable spectral change (14), often mistaken for protonation itself (26), which is reduced here to the observed large variability (30%) due to v_2. In this case we equate v_2 with the eq. [12] process, and v_1 with eq. [13]:

$$I = [BH^+]/[B] \qquad I_1 = [B\ldots H^+_{aq}]/[B]$$

$$I_2 = I/I_1 = [BH^+]/[B\ldots H^+_{aq}]$$

$$\log I - \log C_{H^+} = m^*X + pK_{BH^+}$$

(not directly observable)

$$[14]\quad \log I_1 - \log C_{H^+} = m^*{}_1X + pK_1$$

(observable, v_2)

$$[15]\quad \log I_2 = (m^* - m^*{}_1)X + (pK_{BH^+} - pK_1)$$

(observable, v_1)

[2]The following analysis is based on one due to J. P. Guthrie (personal communication).

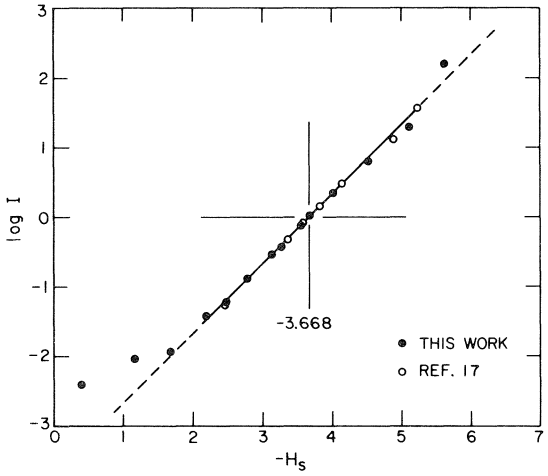

FIG. 2. Log I vs. $-H_S$ for 4-methylacetophenone. The line drawn has the theoretical unit slope.

Equations [14] and [15] were used with the coefficients of the second and first vectors, c_2 and c_1 (rather than ΔA) as described above. *All* of the available data relating to the protonation, uv extinction measurements (14), and proton (19) and ^{13}C (20) nmr chemical shifts, were analyzed simultaneously. For acetone the results obtained were: $pK_1 = -2.02 \pm 0.04$ ($m^*{}_1 = 0.30 \pm 0.01$) for association complex formation, eq. [12]; and $pK_{BH^+} = -5.37 \pm 0.07$ ($m^* = 0.85 \pm 0.02$) for the true protonation equilibrium, eq. [11].

Kinetics

Bromination of the acetophenones **2**, **3**, **4**, **6**, and **7**, as described in the Experimental, resulted in the enolization rate constants given in Tables 3 and 4,[1] and illustrated in Fig. 3. The reactions could not be studied at acidities higher than those cited; above a certain acidity, depending on the substrate basicity, the rates of bromine consumption began to exhibit non-linear behaviour. This is not unexpected; the last term in the denominator of the rate equation used, eq. [8] above, contains a term in $[H^+]$, and above a certain acidity the assumption that this term is negligible will break down. Also possible is the onset of side reactions, such as eq. [9] above.

Except for 4-nitroacetophenone, Fig. 3 shows an initial rate increase, followed by a levelling off. This is similar to the behaviour found for typical A-2 reactions (4–6), and as these are also expected to be A-2 processes (eqs. [5] and [6]), the appropriate kinetic equation to use in analyzing the variation of rate constant with acidity was eq. [4] (4). Required for eq. [4] are values of the protonation correction term, $\log C_S/(C_S + C_{SH^+})$, obtained using eq. [1] and the pK_{BH^+} and m^* values from Table 2; the sub-

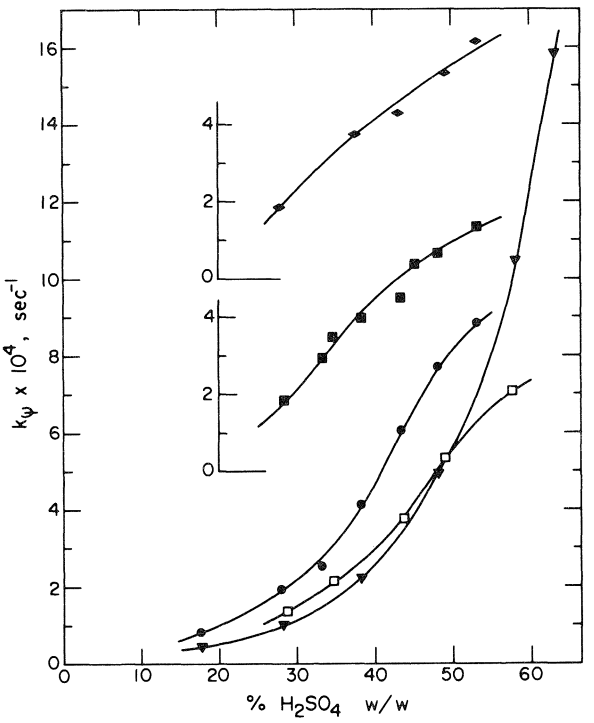

FIG. 3. Observed bromination rate constants vs. percent sulfuric acid, for acetophenone (●), 3-bromoacetophenone (□), 4-nitroacetophenone (▼), 4-methylacetophenone (■), and 3-methylacetophenone (◆). The latter two curves are offset upwards by 5 and 10 scale divisions, respectively, for clarity.

strates (except for acetone) were found to be essentially unprotonated at the acidities studied. The catalyzing base was assumed to be water; water activities in molarity units were calculated using available activities (27) and densities (28).[3] Preliminary studies using double linear regression, with X as one variable and log a_{H_2O} as the other, showed that 1.6–1.7 water molecules were involved on average; i.e., for this reaction $r = 1.6$–1.7 (4, 29). Accordingly 2 log a_{H_2O} was subtracted from the left-hand side of eq. [4] and the result plotted as a function of X. (The value two was used for simplicity; the method can distinguish between 1, 2, and 3 water molecules, but not between 1.5 and 2.5.) An example of the excellent linear plots obtained is shown in Fig. 4, which includes both our results for the enolization of acetophenone obtained by bromination, and Zucker and Hammett's original results (30) obtained by iodination. These two data sets are superimposable and were treated together. Figure 4

[3]Intercept log k_0 values obtained using molarity water activities are true second-order rate constants, i.e., values in 1 M water, allowing convenient comparisons between H_2O and HSO_4^- as bases. Values of log k_0 in pure water, 55.34 M at 25°C, may be obtained from these by adding 2 × 1.743.

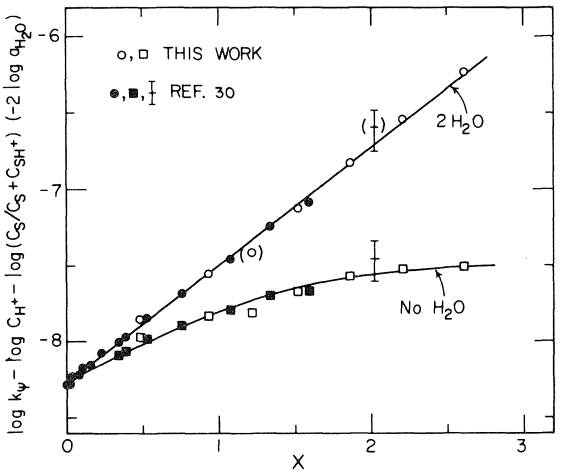

FIG. 4. Plots according to eq. [4] for the enolization of acetophenone in sulfuric acid at 25°C. Assumed are the involvement of two water molecules (circles, line), or none (squares, curve).

also shows the curved plot resulting from the assumption of an A-1 process (eq. [2]) for comparison; plots assuming one or three water molecules, or bisulfate ion, are also curved. The derived $m^{\ddagger}$ and log k_0 data for all the compounds studied are given with the relevant statistical information in Table 5.

The behaviour of 4-nitroacetophenone, as seen in Fig. 3, is clearly different; for this compound, assumption of an A-2 reaction involving two water molecules resulted in a curve, as can be seen from Fig. 5. In fact any A-2 assumption produced a curved plot for this compound, but plots according to either

[g]Data from ref. 31.

eq. [2] (A-1) or eq. [3] (A-S_E2) were linear. The accurately linear A-S_E2 plot (correlation coefficient 0.999) is shown in Fig. 5.

Acetone enolization has been studied over the whole acidity range by Haldna *et al.* (31); their results were treated according to eq. [4], producing the plots shown in Fig. 6. Acetone also enolizes with the involvement of two water molecules, but only in sulfuric acid solutions less concentrated than about 81%. After this point a change in mechanism occurs, shown by the break in the curve; assuming the involvement of one bisulfate ion as a base after this point, rather than two water molecules, produced the good straight line shown in Fig. 6. Bisulfate ion concentrations were used, obtained from published

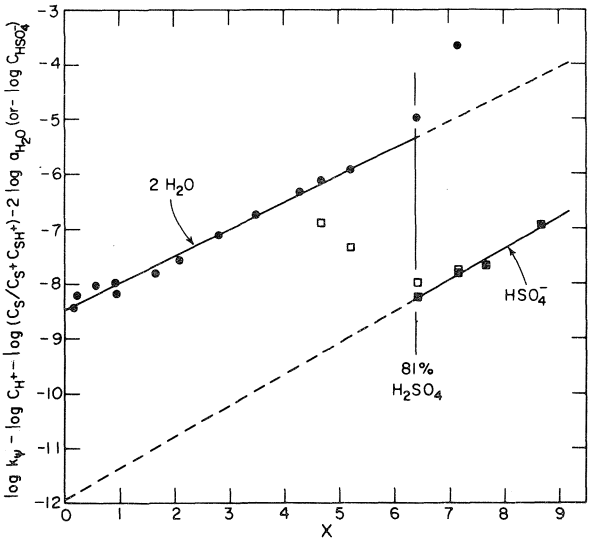

FIG. 6. Plots according to eq. [4] for the enolization of acetone in sulfuric acid at 25°C (31). Circles, assuming the involvement of two water molecules; squares, of one bisulfate ion. Filled squares are points which have been corrected for the reaction involving water.

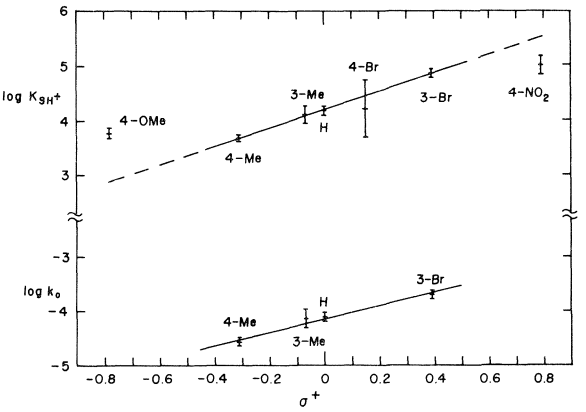

FIG. 7. Linear free-energy relationship plots for acetophenone basicities (upper), and acid-catalyzed enolization rates (lower), both in the aqueous standard state.

sources (32), since the activities were unavailable (33); the rate constants were corrected for the reaction involving water, using $k = k_{H_2O} + k_{HSO_4^-}$.

Linear free energy relationship plots against σ^+ (34), for the pK_{BH^+} values of Table 2 and the log k_0 values of Table 5, are shown in Fig. 7. The resulting ρ values were 1.69 ± 0.13 and 1.24 ± 0.15, respectively.

Discussion

Analysis of equilibrium and rate data obtained in non-ideal strong acid media by the X-function method as described here is capable of providing a considerable amount of mechanistic information.

An advantage of the method is that it enables rate and equilibrium quantities to be compared in the aqueous standard state (i.e. in water) rather than in an arbitrarily chosen acid solution, thus removing medium effects from the comparison (4). Medium effects do occur here; this treatment presents them as values of m^* and $m^{\ddagger}$. Table 2 shows that although

most of the m^* values are around 0.6, normal for carbonyl group protonation (1), methoxy- and nitroacetophenone differ, with values of 0.76 and 0.48, respectively. Slight differences also appear among the $m^{\ddagger}$ values in Table 5.

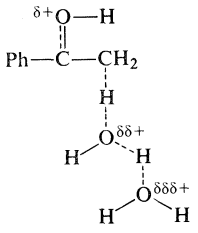
The standard state pK_{BH^+} and log k_0 values are obtained by an extrapolation, to $X = 0$ (1, 4), which is likely to increase the experimental scatter. Figure 7, which shows two of several possible linear free energy relationships, illustrates this. The scatter is noticeable; even so, the equilibrium and rate plots can be seen to be similar, and reasonable conclusions can still be drawn. A decision to employ σ or σ^+ for the correlation could not be made on the basis of the data, although good correlations with σ^+ have been found before (35).

In the equilibrium plot, the points for the 4-methoxy and 4-nitro substituents can be seen to be well above and below the correlation line, respectively. At least for 4-methoxy, the deviation is well outside the experimental error (given on the plot as $\pm$ one standard deviation, in the error bars). These two substituents are also the ones that deviate considerably, and in opposite directions, from the usual carbonyl protonation m^* of 0.6. It may well be that this treatment has separated the "internal" effect of the substituents, due to resonance, induction, etc., from the "external" effect of charge dispersal into the medium by solvation (measured as m^*). The latter will increase in importance in good solvating media, such as the highly aqueous one used here. For instance, if the oxygen lone pairs in the methoxy substituent are partially "tied up" by solvating water molecules, they are less available for resonance donation into the ring, and can delocalize less positive charge from the *para* position, leading to a less enhanced σ^+ value, as would seem to be required here.

For the various $\rho\sigma$ plots tried, the difference in ρ between equilibrium and rate plots was in the range 0.5–0.6; a Brönsted-type plot of the log k_0 values for **2**, **3**, **4**, and **6** (Table 5) against $-pK_{BH^+}$ for the same compounds (Table 2) is accurately linear (correlation coefficient 0.99) with a slope of 0.71 ± 0.08. This can all be interpreted in terms of a transition state with the proton less than half-transferred to the base; between 50% and 70% of the positive charge present in the protonated ketone is still present in the transition state for enolization.

Insertion of the pK_{BH^+} for acetone, -5.37, into the above Brönsted-type plot produces a predicted log k_0 of -3.30 for the reaction involving water; to this must be added a statistical factor of log 2, since there are two equivalent methyl groups in acetone, giving log $k_0 = -2.99$. This is in good agreement with the observed value of -3.10 ± 0.09. The less readily protonated ketones are more reactive, and reactivities can be adequately predicted from basicities. Less basic ketones react more slowly in a given acid solution because of the lower concentration of the protonated ketone intermediate (36).

Between 1.5 and 2 water molecules act as the "base" in the acid-catalyzed enolization, in sulfuric acid solutions more dilute than about 80%; for simplicity we have assumed $r = 2$ here (e.g., see Fig. 4). Distinctions finer than those between whole numbers are probably possible using the X-function method, but much accurate data over a wide acidity range appears to be necessary. There is no whole-number requirement; r-values should reflect the average situation. In a case like this, with an early transition state without much charge dispersal, fewer than two water molecules should disperse what charge there is reasonably well. More than one appears to be necessary, however, and a transition state like **8** can be visualized for the enolization.



8

Values of r reflect the number of water molecules actually involved in the reaction (the "order" of the reaction in water (29)); solvation changes (if any) between reactant and product should appear in the $m^{\ddagger}$ values. For instance, the acetophenones (excluding 4-nitro-) all have $m^* \simeq 0.6$ and $m^{\ddagger} \simeq 1.3$; acetone has $m^* \simeq 0.8$ and $m^{\ddagger} \simeq 0.6$. This may reflect steric hindrance to solvation of the carbonyl group by the phenyl group, present in the acetophenones and their bromoketone products, but absent in acetone.

In more concentrated sulfuric acid, the base changes and bisulfate ion takes over, as can be seen for acetone in Fig. 6 (31); the reaction involving bisulfate, and that involving water, were found to have the same rate in 81% sulfuric acid. This agrees with the earlier observation of Swain and Rosenberg (37), who studied the racemization of D-α-phenylisocaprophenone in strong sulfuric acid. The change in base is to be expected, since the water activity is decreasing very rapidly as compared to the bisulfate ion concentration in this acidity region (33). The very long extrapolation of Fig. 6 suggests that water is a better base than bisulfate ion *in water* by a factor

of 10^3–10^4. The only previous estimate is the factor of 10^2 given by Swain and Rosenberg, in 85–94% sulfuric acid (37).

4-Nitroacetophenone is anomalous. As shown above (e.g., Fig. 5) the rate-determining step for the enolization of this compound is not an A-2 process at all, but is either A-1 or A-S_E2. Based upon the m^* value of 0.6, an A-S_E2 process ($m^* < 1$) seems much more likely than an A-1 one ($m^* > 1$) (4). In any case, it is difficult to visualize a reasonable A-1 process for this compound. One possible A-S_E2 mechanism may be that the initial protonation, eq. [5], is rate-determining; this seems unlikely, though, because a pK_{BH^+} of -5.0 and a log k_1 of -4.9 (Table 5) lead to a k_{-1} for the reverse of eq. [5] of 1.2. Deprotonation from oxygen is likely to be diffusion-controlled, with a rate constant of 10^9 at least. At this time no firm conclusions can be drawn regarding the reaction mechanism for this compound.

Received May 14, 1979

ROBIN A. COX, MALCOLM F. GOLDMAN, and KEITH YATES. Can. J. Chem. 57, 2960 (1979).

The excess acidity method has been used to analyze the observed acid-catalyzed hydrolysis rate constants for methyl benzoate, methyl *para*-toluate, methyl *ortho*-toluate, and methyl 2,6-dimethylbenzoate, over a wide sulfuric acid concentration range, at several different temperatures. Enthalpies and entropies of activation in the aqueous standard state are reported, with slope parameters m^*; also given are the pK_{BH^+} and m^* values found for the protonation of these compounds. The mechanistic changeover from $A_{Ac}2$ to $A_{Ac}1$ hydrolysis occurs at lower acidity with increasing methyl substitution, mainly due to the decrease in activation enthalpy in the transition state for the $A_{Ac}1$ process, caused by release of steric strain and increased mesomeric interaction. The $A_{Ac}2$ hydrolysis involves two water molecules, and is energetically favourable and entropically unfavourable. The $A_{Ac}1$ reaction is difficult energetically, but this is offset by the large positive activation entropies found.

ROBIN A. COX, MALCOLM F. GOLDMAN et KEITH YATES. Can. J. Chem. 57, 2960 (1979).

On a utilisé la méthode de l'excès d'acidité pour analyser les constantes de vitesse observées au cours de l'hydrolyse acide des esters suivants: benzoate de méthyle, *ortho* et *para*-toluate de méthyle et diméthyl-2,6 benzoate de méthyle en faisant varier considérablement la concentration de l'acide sulfurique et la température. On donne les enthalpies et entropies d'activation de l'état fondamental en solution aqueuse, et les paramètres de pente m^*; ainsi que les valeurs de pK_{BH^+} et du m^* trouvées lors de la protonation de ces composés. Le changement du mécanisme de l'hydrolyse de $A_{Ac}2$ à $A_{Ac}1$ se produit à une faible acidité avec l'augmentation des substituants méthyles. Ceci est dû principalement à la diminution de l'enthalpie d'activation dans l'état de transition du mécanisme de type $A_{Ac}1$ provoqué par la décompression stérique et par une augmentation de l'interaction mésomérique. L'hydrolyse du type $A_{Ac}2$ implique deux molécules d'eau et est énergiquement favorisée mais défavorisée du point de vue de l'entropie. Pour la réaction du type $A_{Ac}1$ la grande valeur positive trouvée pour l'entropie compense le fait qu'elle soit énergiquement défavorisée.

[Traduit par le journal]

Introduction

The extrapolative X-function method for the determination of weak base protonation equilibrium constants, eq. [1] (1), can be expanded to provide

$$[1] \quad \log I - \log C_{H^+} = m^*X + pK_{BH^+}$$

$$\Delta G^0 = \Delta H^0 - T\Delta S^0 = -RT \ln K$$

$$= pK_{BH^+}\, RT \ln 10$$

$$[2] \quad \log I - \log C_{H^+} = m^*X + \Delta G^0/RT \ln 10$$

$$= m^*X + \Delta H^0/RT \ln 10 - \Delta S^0/R \ln 10$$

free energies, enthalpies and entropies of ionization, eq. [2], from log ionization ratio (I) measurements as a function of temperature, as long as values for X and log C_{H^+} at the appropriate temperature are available (see Appendix). In this paper this method is used to obtain ΔG^0 values for the substrates, to enable the calculation of pK_{BH^+} values at temperatures other than 25°C.

Excess acidities can also be used in kinetic analysis, as discussed in the previous two papers (2, 3); the appropriate kinetic equations for A-1 and A-2 reactions of predominantly unprotonated substrates are

$$[3] \quad \log k_\psi - \log C_{H^+} - \log C_S/(C_S + C_{SH^+})$$

$$= m^{\ddagger}m^*X + \log (k_0/K_{SH^+})$$

$$[4] \quad \log k_\psi - \log C_{H^+} - \log C_S/(C_S + C_{SH^+})$$

$$= m^{\ddagger}m^*X + \log a_{Nu} + \log (k_0/K_{SH^+})$$

reproduced here as eqs. [3] and [4], with the same nomenclature as that used before (2). If rate measurements at different temperatures are available, values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ in the aqueous standard state can be obtained. Expanding the term log (k_0/K_{SH^+}), which contains the medium-independent rate constant k_0, as above using the absolute rate theory (4),

[1]Presented at the 62nd Chemical Conference of the Chemical Institute of Canada, Vancouver, B.C., June, 1979, No. OR-12.

[2]Taken in part from the Ph.D. Thesis of Malcolm F. Goldman, University of Toronto, 1975.

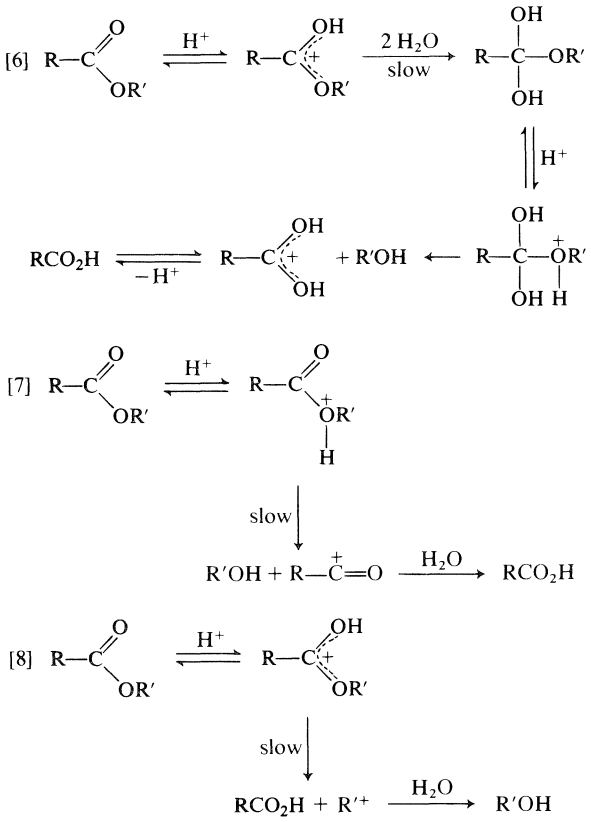
0008-4042/79/222960-07$01.00/0

results in eq. [5], in which the numerical term 10.3188

$$[5] \quad \log (k_0/K_{SH^+}) = (\Delta S^{\ddagger} - \Delta S^0)/R \ln 10 + 10.3188 + \log T - (\Delta H^{\ddagger} - \Delta H^0)/RT \ln 10$$

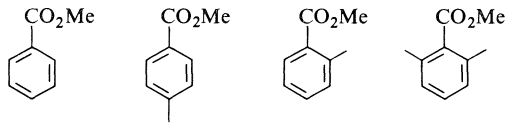
contains the necessary Boltzmann and Planck constants (4). Substitution of eq. [5] into eqs. [3] and [4] gives the rate equations used in this study.

Previous studies on the mechanism of ester hydrolysis in acid solutions (e.g., the summaries in refs. 5–7) have shown that, after pre-equilibrium protonation, most esters hydrolyze by an A_{Ac}-2 mechanism in dilute acid, eq. [6], and that some switch to an A_{Ac}-1 mechanism in more concentrated acid, eq. [7]. Esters which have R′ substituents capable of forming carbonium ions of reasonable stability can hydrolyze by an A_{Al}-1 mechanism, eq. [8]. Structural and electronic effects in the ester



substrate, the medium acidity, and the water activity all help determine which of these mechanisms is followed (5–7).

During the earlier work it was observed that *ortho*-substituted phenyl acetates behaved differently from their *para*-substituted isomers in that the mechanistic changeover from A_{Ac}-2 to A_{Ac}-1 occurred in more dilute acid for the former (8). This appears to be due to a steric effect. Steric effects on acid-catalyzed aromatic ester hydrolyses have received little attention, and in this paper we report on the hydrolyses of the progressively more crowded aromatic esters methyl benzoate (**1**), methyl *para*-toluate (**2**), methyl *ortho*-toluate (**3**), and methyl 2,6-dimethylbenzoate (**4**).



1 **2** **3** **4**

Methyl esters were chosen to minimize A_{Al}-1 hydrolysis, since formation of the unstable carbonium ion CH_3^+ is highly unlikely under conditions in which the more stable acylium species $Ar-\overset{+}{C}=O$ can be formed. The reactions were studied over a wide range of acidities and temperatures in aqueous sulfuric acid, in order to provide accurate acidity dependences and activation parameters, and thus obtain the maximum amount of mechanistic information.

Experimental

Sulfuric acid concentrations were determined from their densities, measured at 25°C using an Anton Paar precision density meter Model No. DMA 02C, by comparison with known densities from the literature (9); these were occasionally checked by titration. Compounds **1**, **2**, and **3** were prepared from the available parent acids and methanol, using a standard acid-catalyzed esterification technique (10); the acylium ion formed by dissolving 2,6-dimethylbenzoic acid in oleum was allowed to react with methanol, according to Newman (11), giving **4**. Upon purification physical properties in agreement with literature values were obtained.

Basicities were obtained from the change in uv spectrum with changing acidity, using a Cary-16 UV spectrophotometer with its cell block thermostatted at 10.0 ± 0.2°C by means of a Neslab PBC-4 bath cooler. The data were analyzed using the Davis–Geissman method (12), and the resulting extinction differences curve-fitted as described previously (3); observed extinction differences and derived log ionization ratios as a function of weight percent sulfuric acid are given in Table 1.[3]

The hydrolysis reaction rates were studied by following uv absorbance changes, using either the sampling method used before (13) for slow reactions, or directly in the thermostatted cell block of a Cary-16, Unicam SP-800, or Unicam SP-1600 UV spectrophotometer, for reactions with half-lives of less than 4–5 hours (14). Pseudo-first-order rate constants were obtained from the slopes of ln $|A_t - A_\infty|$ vs. time plots, or, for very slow reactions, by using the Guggenheim method (14,

15). The observed rate constants, means of 2–6 independent kinetic runs, are given as a function of weight percent sulfuric acid and temperature in Table 4,[3] together with the temperature-corrected values of X, log C_{H^+}, log a_{H_2O}, and log $C_S/(C_S + C_{SH^+})$ needed for eqs. [3]–[5]. The temperature correction for X is discussed in the Appendix; temperature-corrected log water activities are available (13) or can be calculated from listed thermodynamic data (16). They were converted to molarity units (from mole fractions) via the densities (9). Temperature-corrected log C_{H^+} values for aqueous sulfuric acid solutions were estimated from available 25°C data (1), densities (9), and the study by Young *et al.* (17), which gives bisulfate ion concentrations in sulfuric acid at 0°, 25°, and 50°C; this temperature correction is quite small, and could reasonably have been ignored without affecting the results.

The wavelengths at which the kinetics were studied were chosen, by preliminary measurements, as those which maximized the observed absorbance differences between reactant and product. In general these were within 2–3 nm of the quite similar reactant and product λ_{max} positions. Even so, the maximum observed change was often very small (0.1–0.2 absorbance units), particularly in dilute acid, and this occasionally resulted in increased scatter amongst the individual determinations. In the stronger acids decarboxylation and (or) sulfonation processes were sometimes noticeable, although these were much slower than the hydrolysis. Apart from this, the spectra of the reaction products were in reasonable agreement with those of authentic samples of the expected product carboxylic acids in the same media.

Activity coefficients of the neutral substrates at different acidities, required for the transition-state activity coefficient method (18), were determined by distribution measurements (19, 20) and are given in Table 5.[3]

Results and Discussion

Basicities

These were obtained from the variation of uv spectrum with acid concentration, using the Davis–Geissman method (12) and direct curve-fitting as described previously (3). The pK_{BH^+} values found for **1**, **2**, **3**, and **4** at 10°C, and a value measured for methyl benzoate at 25°C, are listed in Table 2, together with the relevant statistical information (3). The measurement temperature was 10°C rather than 25°C because of the fast hydrolysis rates of **3** and **4** in strong acid. The site of protonation is the carbonyl oxygen (21), presumably due to the better charge delocalization available, into the ring and onto the other oxygen. The ether-protonated form has no delocalization possibilities.

So that pK_{BH^+} values at 25°C, and at the temperatures at which the kinetic measurements were performed, could be obtained, the values in Table 2 were converted to free energies of protonation, $\Delta G°$, using eq. [2] above. These are listed in Table 3, together with pK_{BH^+} values calculated from them at 10° and 25°C, and the observed m^* values. In order to check the validity of eq. [2], methyl benzoate, which hydrolyzes slowly, was studied at both 10° and 25°C. Both temperatures gave the same ΔG^0; the agreement between the calculated pK_{BH^+} values in Table 3 and the observed ones in Table 2 is excellent. This means that the entropy contribution to the free energy is small, as expected; it is known that as basicities decrease, the enthalpy term becomes the predominant contributor to the free energy, and the entropy term remains approximately constant at its aqueous value, for instance in primary aromatic amines (22), pyridines (23), and azine *N*-oxides (23).

The protonation correction terms, log $C_S/(C_S + C_{SH^+})$, or $-\log(1 + I)$, needed for eqs. [3] and [4], were calculated using temperature-correct pK_{BH^+} values. This can be quite important; as can be seen from Table 3, the pK_{BH^+} for methyl benzoate over only a 15° temperature range varies by nearly 0.4 pK units. Assuming that the same value applied over the 50° range of the kinetic measurements would not have been appropriate. The observed 25°C value for methyl benzoate, −6.99 ± 0.11, agrees very well with the −6.92 which can be derived from the half-

protonation H_0 of -8.18 and slope vs. $-H_0$ of 0.846 quoted by Lane *et al.* (24), presumably at room temperature. The other esters appear not to have been studied previously.

The pK_{BH^+} values (e.g., Table 3, 25°C) show that a *para*-methyl group is much more efficient at increasing basicity than is an *ortho*-methyl, the pK difference from the unsubstituted case being ~2 units for the former, vs. ~1 unit for the latter. This is probably a manifestation of steric hindrance, making it more difficult to achieve the coplanarity required for full mesomeric (hyperconjugative) delocalization in the *ortho* case (25). Another consequence of "twisting" in the *ortho*-methyl compounds can be seen in the greatly reduced ε_B and ε_{BH^+} values for **3** and **4**, compared to **1** and **2**, in Table 2, as previously observed for hindered azoxybenzenes (25).

Kinetics

Observed pseudo-first-order rate constants, k_ψ, for the substrates **1**–**4** were obtained by following the (sometimes very small) changes in uv absorbance between reactant ester and product carboxylic acid, over an acidity range of 20–90% sulfuric acid, and a temperature range of 50°. These are given in Table 4,[3] and are plotted against X according to eqs. [3] and [4] in Figs. 1–4 (experimental points); for convenience, a percent sulfuric acid concentration scale is also included, at the top of these figures. Methyl benzoate has been previously studied at 25°C by Lane *et al.*, (24); their data and ours are superimposable, and both sets are included in Fig. 1. Other, less comprehensive, studies of the hydrolysis rates of

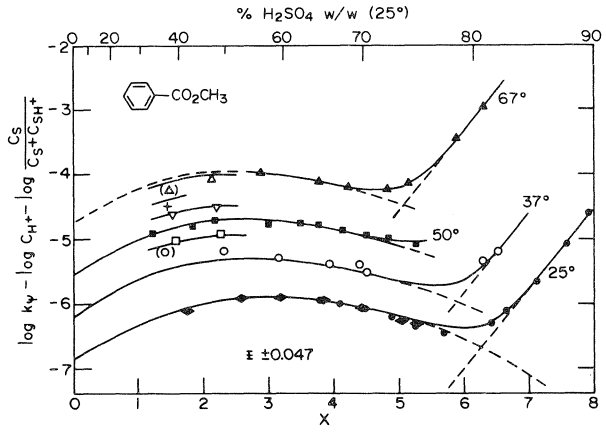

FIG. 1. The hydrolysis of methyl benzoate in aqueous sulfuric acid. Some data at 25°C from ref. 24 (◆); all other data, this work, with the different symbols referring to different temperatures (Table 4).[3] Points are experimental, curves theoretical, assuming an A-2 reaction with two water molecules (eq. [4]) at low acidities, and an A-1 process (eq. [3]) at high acidities. Points not included in the fit are in parentheses.

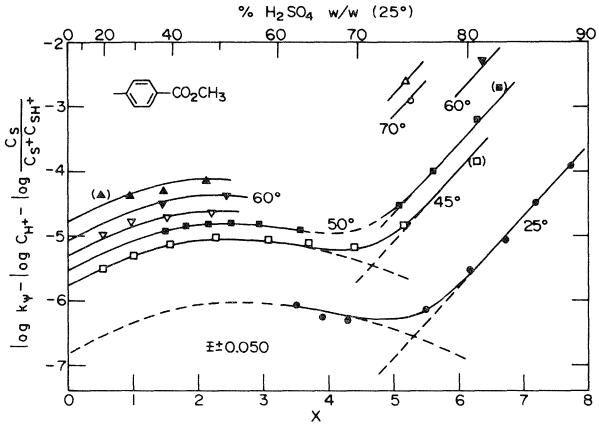

FIG. 2. The hydrolysis of methyl *para*-toluate in aqueous sulfuric acid. See Fig. 1.

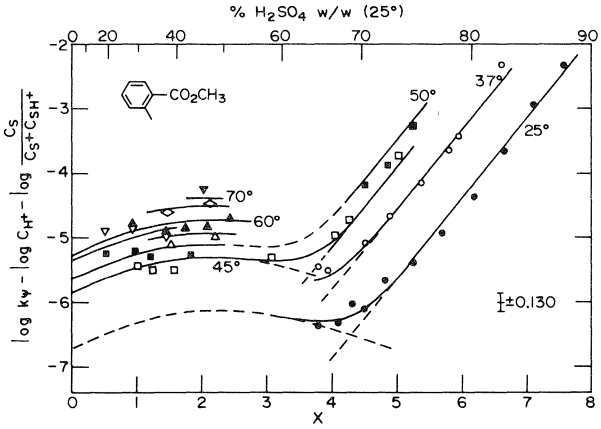

FIG. 3. The hydrolysis of methyl *ortho*-toluate in aqueous sulfuric acid. See Fig. 1.

these compounds are also in adequate agreement (26). All of the data and parameters are fully temperature-corrected.

The graphs for **1**, **2**, and **3** (Figs. 1–3) all exhibit initial downward curvature, typical of an A-2 reaction involving water (2), followed by an upward linear region, typical of an A-1 process (2), like many similar esters (5). Compound **4** (Fig. 4) appears to react almost entirely A-1, but there is noticeable deviation from linearity in the dilute acid region, indicative of a possible A-2 component for this substrate also. Methyl mesitoate (the 2,4,6-trimethyl ester) has been studied previously (27); when treated similarly, exclusive A-1 linear behaviour results for this compound.

The data for **1**–**4**, and that for methyl mesitoate (27), have also been treated using the transition-state activity coefficient (TSAC) method (7, 18). This involves examination of the behaviour of eq. [9] as a

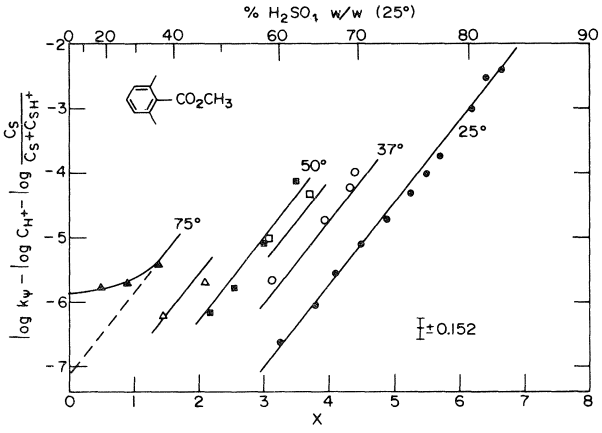

FIG. 4. The hydrolysis of methyl 2,6-dimethylbenzoate in aqueous sulfuric acid. See Fig. 1.

function of acidity; curves of different shapes are

$$[9] \quad \log (f^*_{S^+}/k_0) = \log f_S + \log a^*_{H^+} - \log k_\psi + pK_{SH^+}$$

indicative of different mechanisms (18). The last two terms are given above, and values of $\log a^*_{H^+}$, log proton activities, relative to the activity coefficient of the tetraethylammonium ion, are available (28). The activity coefficients of the neutral substrates **2**, **3**, and **4**, f_S, were measured; activity coefficient data for methyl benzoate and methyl mesitoate are listed (19). The resulting curves have been published (18) and are entirely consistent with the A-2 and A-1 hydrolysis mechanisms, with the changeover A-2 → A-1 taking place in more and more dilute acid as the methyl substitution in the molecule is increased.

With the A-2 → A-1 behaviour established, eqs. [3]–[5] can be used to fit the data, giving activation parameters and slopes. Combining eqs. [4] and [5] yields an equation of the form $y = a + bx_1 + cx_2 + dx_3$, where y consists of the terms on the left in eq. [4], minus $\log T$; the variables are X (x_1), $1/T$ (x_2), and log water activity (x_3), and the constants are $(\Delta S^+ - \Delta S^0)/R \ln 10 + 10.3188$ (a), m^+m^* (b), $(\Delta H^0 - \Delta H^+)/R \ln 10$ (c), and the molecularity of the reaction in water, r (d) (2). Combining eqs. [3] and [5] produces a similar equation (without $r \log a_{H_2O}$) for the A-1 process, and both can be solved using standard multiple linear regression techniques (29). In the overlap region for **1**, **2**, and **3**, however, the observed rate constant k_ψ is given by $k_{A\text{-}2} + k_{A\text{-}1}$, and curve-fitting was necessary, since the k's themselves, not their logarithms, are additive. A standard computer program was used (29); for **4** multiple linear regression could be used directly. It was found that the data did not justify calculating a separate value for r, and so it was assumed to have the fixed value 2, as before (2, 3), this being the average result of preliminary calculations.

The results of this procedure can be seen as the theoretical curves in Figs. 1–4; agreement with experiment is good, as illustrated by the error bars in the figures. The parameters obtained are given in Table 6; these refer to the aqueous standard state, not to any particular acid solution (2).

From the foregoing discussion, the assumption can be made that $\Delta H^0 \simeq \Delta G^0$ and $\Delta S^0 \simeq 0$ for the A-2 reaction, and m^* is available from Table 3, so ΔH^+, ΔS^+, and m^+ can be obtained, as in Table 7. Values of m^+ for a typical A-2 process are around 1.0 (2), as found for **1** and **3**; the m^+ for **2** seems a little high. Since the product m^+m^* values in Table 6 fall in a natural progression, this is probably due to an anomalously low m^*, 0.6, as compared to 0.8 and 0.7 for **1** and **3** (Table 3); a more likely value would be 0.8. The large negative entropies are to be expected from the mechanism (eq. [10]), with the transition state resembling **5**. Steric effects are apparent in the reduced activation energy for the *ortho*-substituted compound **3**, compared to **1** and **2**; delocalization of the positive charge in **5** over the aromatic group R will be more difficult with R twisted out-of-plane, and the carbon will be more electrophilic, lowering ΔH^+. In the protonated substrate, less charge on the ring means more on the two oxygens, with a higher solvation requirement (hence the lowered m^* values for **3** and **4** relative to

[a]As in Table 6.

[10] 
5

1); the resulting increased solvent electrostriction, and the decreased free rotation of R in the crowded transition state **5**, caused by the *o*-methyl, leads to the observed more negative entropy of activation for **3**, compared to **1** and **2**.

$\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$, and $m^{\ddagger}$ cannot be calculated in the same way for the A-1 process, because protonation at the ether oxygen rather than the carbonyl oxygen is involved (eq. [7]), and ΔG^0 for this is not available. Nevertheless, detailed mechanistic information can still be obtained. Two possibilities for the rate-determining step can be visualized, a pre-equilibrium protonation as in eq. [11], or a concerted A-S_E2

[11] 
6

[12] 
process as in eq. [12]. Kinetic analysis as described before (2) leads to two kinetically indistinguishable rate equations for these mechanisms. Both resemble eq. [3], only now $m^{\ddagger}m^*$ and K_{SH^+} refer to ether oxygen protonation.[4] For eq. [12], H^+ and HA are not easily distinguished below about 90% sulfuric acid (30), so $H^+ \equiv$ HA and the kinetic analysis follows that of eq. [16] in ref. 2, with an intercept containing $\log k_0$ only. However, examination of the $m^{\ddagger}m^*$ values in Table 6, all greater than one for the A-1 reaction, rules the latter possibility out. The ether-protonated structure **6**, with its localized charge, should have a high solvation requirement, with $m^* \simeq 0.5$ (1), giving $m^{\ddagger}$ values of around 2.5. This is quite unreasonable for an A-S_E2 but normal for an A-1 process (2), and hence the A-1 mechanism of eq. [11] is followed.

Although ΔH^0 and ΔS^0 for ether oxygen protonation are not available, reasonable assumptions are that $\Delta S^0 \simeq 0$, as discussed above, and that the ΔH^0 values for **1**, **2**, **3**, and **4** are closely similar, since the R group in **6** has little interaction with the positive charge. Thus the trends in Table 6 can be reasonably discussed. The activation enthalpies show a steady decrease **1** → **4**, presumably due to release of steric strain in the transition state, since this increases **1** → **4**, and to the improved hyperconjugative charge delocalization in the product ion provided by the methyl groups. Overall the enthalpies are much higher for the A-1 than for the A-2 hydrolysis, probably because the ether oxygen is much less basic than the carbonyl oxygen, i.e., most of the $(\Delta H^{\ddagger} - \Delta H^0)$ term is contributed by $-\Delta H^0$; it is difficult to see why the rate-determining step in eq. [11] would need a high $\Delta H^{\ddagger}$. These high enthalpies are offset by the large positive entropies of activation, due to the formation of two species from one, and to the release of solvent molecules resulting from delocalization of the highly solvated charge in **6** into the product acylium ion. Experimentally the entropies of activation for **1**–**4** are all the same; changing methyl substitution in the ring is unlikely to affect either of these factors appreciably. The major factor controlling the earlier mechanistic change A-2 → A-1 in going from **1** to **4** is the relative reduction in activation enthalpy for the A-1 reaction.

[4]Both of these rate equations still contain the term $\log (C_S/(C_S + C_{SH^+}))$ that corrects for *carbonyl* protonation; in this case this represents "locking up" of the substrate in an unreactive form, and the reduced concentration of the substrate that results must be accounted for in the kinetic scheme. This is indicated in eqs. [11] and [12].

Appendix

X-Functions at Temperatures other than 25°C

For the general protonation reaction of eq. [A1], the equilibrium constant K_{BH^+} can be divided into

$$[A1]\quad B + H^+ \rightleftharpoons BH^+ \quad (K_{BH^+})$$

$$[A2]\quad K_{BH^+} = a_B a_{H^+}/a_{BH^+} = (C_B C_{H^+}/C_{BH^+}) \times (f_B f_{H^+}/f_{BH^+})$$

concentration and activity terms as in eq. [A2]. Taking logarithms, and making the assumption that the activity coefficient term $\log (f_B f_{H^+}/f_{BH^+})$ is a linear function of a similar term for a "standard base" B*, abbreviated X, leads directly to the basic excess acidity equation, eq. [1] above, as discussed previously (1). Equation [A2] has the form $K_a = K_C K_f$, and so X can also be expressed as a "combined free energy of transfer", as in eq. [A3].

$$[A3]\quad \Delta G^* = -RT \ln K_f^* = -RTX \ln 10 = -5.708X \text{ kJ/mol at } 25°C$$

It has been found experimentally that eq. [1] above applies to a very wide variety of bases, always giving linear behaviour (see ref. 1 and the references cited there). As might be anticipated, ionization ratios obtained at temperatures other than 25°C also exhibit linear behaviour when plotted against X (using, e.g., the data in ref. 31), giving as intercepts pK_{BH^+} values valid at the temperature of measurement (not at 25°C). Since the extrapolation is to $X = 0$, the reference state (water) at the measurement temperature, these intercept values can be used to derive ΔG^0, ΔH^0, ΔS^0, etc., for the base in question, regardless of any variation in X itself with temperature; the latter is manifested as the different *slopes* obtained at different temperatures. This slope variation can be removed, however; because of the form of eq. [A3] above it is apparent that, if eq. [1] applies, the combined free energies of transfer, $-RT \ln (f_B f_{H^+}/f_{BH^+})$, must be linear functions of one another also. Thus the X-function, expressed as a free energy, is easily corrected from 25°C to T°C via eq. [A4]. Temperature-corrected excess acidities lead to tem-

$$[A4]\quad X_T = X \times 298.15/(273.15 + T)$$

perature independent m^* and $m^\ddagger$ slopes; for this reason eq. [A4] was used in this work throughout.

L'étude par rmn du proton des composés du titre nous a permis de proposer pour ceux-ci une conformation en hélice avec des mécanismes particuliers d'interconversion en accord avec des déterminations de structure cristalline et des calculs théoriques. Comme dans la famille voisine de l'anisole, on observe un certain effet mésomère de l'hétéroatome, partiellement inhibé par des interactions stériques.

La rmn du carbone 13 apporte également dans une certaine mesure des arguments en faveur d'une telle conformation. L'effet de l'hétéroatome sur les déplacements chimiques se discute classiquement en termes d'effet mésomère ou inducteur, un effet d'atome lourd devant cependant être invoqué dans le cas des composés tellurés.

GABRIEL LLABRÈS, MARCEL BAIWIR, LÉON CHRISTIAENS, and JEAN-LOUIS PIETTE. Can. J. Chem. **57**, 2967 (1979).

The ^{1}Hmr study of the title compounds has revealed a screw conformation, with defined interconversion processes, in good agreement with crystal structure determinations and theoretical calculations. The mesomeric effect of the heteroatom is smaller than in the anisole series, due to steric inhibitions.

The ^{13}Cmr enhances, to some extent, these conclusions. In the case of Te compounds, a heavy atom effect adds to the classical mesomeric and inductive effects to account for the experimental observations.

Introduction

Les relations structurelles entre l'éther de diphényle et ses dérivés et les hormones thyroïdiennes (1) ne sont certainement pas étrangères à l'intérêt soutenu porté à ces composés depuis quelques années. De nombreuses techniques expérimentales ont été utilisées pour étudier les conformations préférentielles et les mécanismes d'interconversion des différents conformères stables de ces composés. Le résultat le plus remarquable de tous ces travaux est le manque d'homogénéité des conclusions qui en ont été tirées.

On admet généralement que quatre types de conformation peuvent être considérés (fig. 1). La structure A est plane (2). Dans la structure B, les cycles sont perpendiculaires au plan C—X—C (3). La structure de Marino C est caractérisée par l'orthogonalité des deux cycles (4). Enfin la structure en hélice D est caractérisée par l'angle β fait par le plan C—X—C avec les cycles (5).

Une forme A rigide est stériquement impossible, tandis que la forme B présente un minimum de conjugaison entre les cycles et l'hétéroatome. C'est pourquoi on retient les formes C et D pour interpréter les résultats expérimentaux (voir par exemple (6) et les références y citées).

Les structures cristallines de certains composés étudiés ici ont été déterminées (tableau 1). Dans tous les cas, les composés adoptent la conformation en hélice D, l'angle β variant de 29 à 36°. On remarque également que l'angle C—X—C diminue quand la distance C—X augmente:

$$[1] \quad \text{angle (C—X—C)} = -34.5 \text{ dist (C—X)} + 171.5 \quad (R = 0.99)$$

Enfin, la distance C—O observée (1.28 Å) est significativement plus courte que la liaison simple classique (1.43 Å): elle possèderait donc dans l'éther de diphényle un certain caractère de liaison double.

S'il est évident qu'une seule technique ne peut fournir la somme des résultats expérimentaux nécessaires à la résolution complète du problème con-

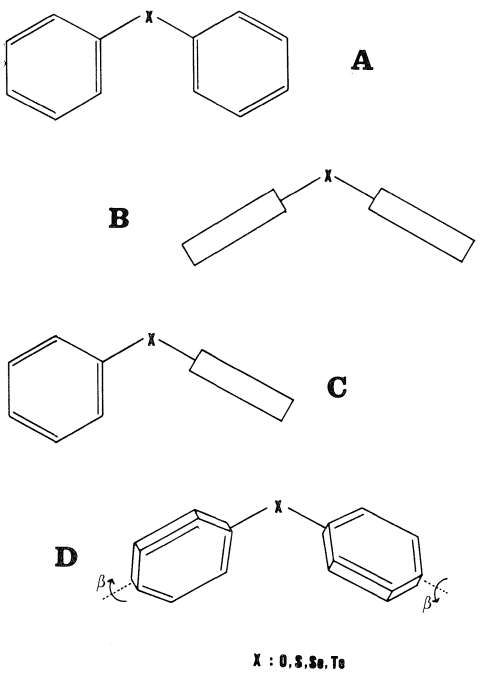

FIG. 1. Les conformations moléculaires de l'éther de diphényle et de ses analogues.

formationnel, nous avons étudié dans quelle mesure la rmn du proton et du carbone 13 fournissait des résultats en accord avec d'autres techniques, et notamment la chimie quantique et l'analyse structurelle par diffraction des rayons X.

Résonance magnétique du proton

On observe pour les quatre composés de la famille de l'éther de diphényle un spectre du type AA'BB'C, ce qui signifie une double équivalence, tant inter- qu'intracyclique. De plus, ce résultat reste qualitativement le même quand on fait varier la température de -80 à $+150$°C.

Les paramètres mesurés sont repris dans le tableau 2.

A cause d'effets stériques et d'anisotropie magnétique entre les cycles, la conformation A est incompatible avec un spectre AA'BB'C. De plus, les paramètres observés devraient différer fortement de ceux de la famille de l'anisole, ce qui n'est manifestement pas le cas (7).

Si de nombreux résultats expérimentaux (8–15) sont en faveur d'une certaine délocalisation de la paire libre de l'hétéroatome, diminuant de l'oxygène au tellure, la rmn du proton n'apporte rien de neuf à ce sujet.

Nous avons utilisé le modèle de Haigh et Mallion (16) pour calculer les effets de l'anisotropie magnétique d'un cycle sur les protons de l'autre. La fig. 2 illustre les résultats de ce calcul dans le cas de l'éther de diphényle. On voit que l'effet calculé peut être assez important, de l'ordre du ppm, pour les deux protons d'un même cycle. C'est pourquoi l'équivalence observée implique un mécanisme particulier d'interconversion, la rotation libre des cycles étant rendue fort improbable par les interactions stériques qu'elle entraînerait.

Galasso *et al.* (17) ont calculé l'énergie de toutes les conformations de Ph—X—Ph (X = O, S et Se). La conformation D est énergétiquement la plus stable, l'interconversion se faisant via la conformation C dans le cas X = O, c'est-à-dire quand l'effet mésomère de l'hétéroatome est le plus important, et via la conformation B dans les autres cas, l'encombrement stérique y étant moindre.

La relation de Penney (18), qui lie l'intégrale de recouvrement de l'hétéroatome et de l'orbitable π du carbone adjacent à l'angle β fait par le cycle avec le plan C—X—C permet de calculer cet angle β à partir des paramètres de rmn observés:

$$[2] \quad I(\beta) = (I(O)/4)(1 + 3\cos 2\beta)$$

Si, comme il paraît raisonnable de le faire, on considère, d'une part, que le déplacement chimique du proton en *para* est proportionnel à l'intégrale $I(\beta)$ et que, d'autre part, l'intégrale $I(\beta)$ est maximum dans la série de l'anisole, où la structure est plane sans effets stériques, [2] se transforme en

$$[3] \quad \cos 2\beta = \frac{1}{3}\left[4\frac{\Delta\delta(\text{Ph—X—Ph})}{\Delta\delta(\text{Ph—X—Me})} - 1\right]$$

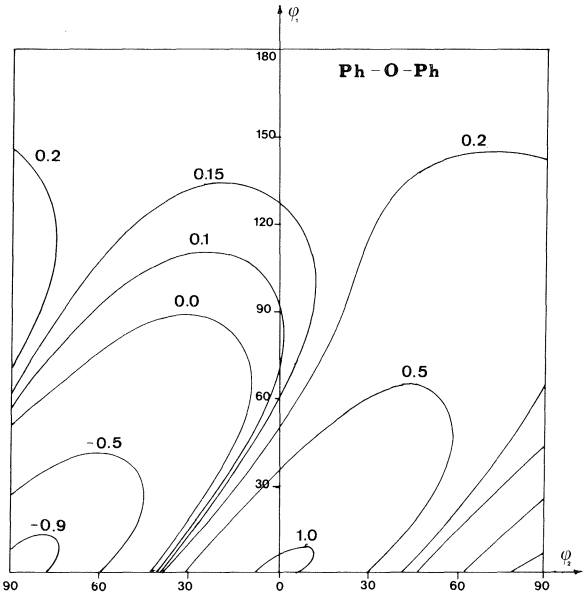

FIG. 2. Contribution de l'anisotropie magnétique d'un cycle sur le déplacement chimique des protons en *ortho* de l'autre cycle. Courbes d'isoécran (ppm). φ_1 = angle de rotation du cycle affecté; φ_2 = angle de rotation du cycle agissant.

L'accord entre les angles β ainsi obtenus et ceux observés expérimentalement est remarquable (tableau 3). Ce résultat justifie *a posteriori* l'hypothèse de planéité de l'anisole et de ses analogues.

Dans les benzènes monosubstitués, il existe d'excellentes relations linéaires entre l'électronégativité du substituant et la constante de couplage J_{23}. Or, bien que l'on accorde généralement au groupement OPh une électronégativité supérieure à celle du groupement OMe, J_{23} a, dans Ph—O—Ph et Ph—S—Ph, des valeurs inférieures à celles mesurées dans Ph—O—Me et Ph—S—Me respectivement.

Cooper (19) a montré que l'effet stérique diminue la constante de couplage d'une fragment —CH=CH—. La fig. 3 montre qu'il existe une bonne

TABLEAU 3. Calcul de l'angle β d'après [3]

	O	S	Se	Te
β calc. (^{1}H)	32.2°	35.8°	35.0°	30.5°

relation linéaire ($R > 0.99$) entre les différentes ΔJ observées entre les familles de l'anisole (sans effets stériques) et de l'éther de diphényle (avec) et la différence Δr entre le contact de van der Waals (3.60 Å) et la distance C—C mesurée.

Dans la famille étudiée ici, un certain effet mésomère existe (20) qui va diminuant de O à Te. Il est inférieur à celui observé dans la famille de l'anisole, la résonance étant partiellement inhibée par des interactions stériques.

Le tableau 4 donne les paramètres mesurés dans quelques composés diparasubstitués. Dans les dérivés méthylés, le déplacement chimique du méthyle augmente de O à Te. L'effet est qualitativement le même que celui mesuré dans la famille de l'anisole, mais moins important (0.15 ppm au lieu de 0.60 ppm). Ce résultat reflète également une certaine inhibition de la résonance par des interactions stériques.

Résonance magnétique du carbone 13

A partir des paramètres du tableau 5, on peut établir d'excellentes relations linéaires ($R > 0.99$) entre les déplacements chimiques des carbones C_1 et C_o des familles de l'éther de diphényle d'une part, et de l'anisole et des halogénobenzènes d'autre part.

Dans ce cas-ci, à nouveau, l'effet déblindant des chalcogènes sur C_1 diminue de O à Se pour devenir blindant pour Te. Pour C_o, l'effet blindant pour O

RMS	0.067	0.028	0.087	—	0.056	0.077	0.084	0.092	0.046

TABLEAU 5. Déplacements chimiques carbone-13

	O	S	Se	Te
C_1	157.2	135.3	130.5	114.8
C_o	118.8	129.0	132.5	137.5
C_m	129.8	130.7	129.3	129.4
C_p	123.3	126.9	127.3	127.6

devient de plus en plus déblindant de S à Te, tandis qu'en C_p, on observe un léger effet blindant qui va en s'atténuant de O à Te.

Par ailleurs, les déplacements chimiques des carbones C_o et C_p sont liés aux déplacements chimiques des protons correspondants par des relations linéaires ($R = 0.99$). Ceci tend à montrer que les effets des chalcogènes sur ces positions seraient de nature essentiellement électronique.

On peut également utiliser la relation de Penney adaptée [3] pour calculer l'angle de rotation β des cycles, à partir des déplacements chimiques de C_p. Le tableau 3 montre que, si l'accord observé est moins bon que celui obtenu avec le proton, il n'en demeure pas moins satisfaisant.

Les résultats obtenus par la résonance magnétique du carbone 13 permettent de conclure à la dualité inducteur–mésomère de l'effet des chalcogènes, la situation se compliquant, dans la cas de Te, d'un effet d'atome lourd (21). Celui-ci explique, en effet, pourquoi l'effet inducteur de O, S et Se sur C_1 devient blindant pour Te. En *ortho*, il ne se manifeste plus et le caractère −I, inférieur au caractère +E pour O, s'impose de plus en plus dans la séquence S, Se, Te. Ce résultat rejoint celui obtenu par Sadekov *et al.* (15). En *para* enfin le caractère mésomère de l'hétéroatome s'exprime légèrement.

Partie expérimentale

Les composés étudiés ici ont été synthétisés dans nos laboratoires suivant une méthode analogue à celle décrite pour la préparation de l'acide phényltelluro-2 benzoïque (22): condensation du diazoïque neutralisé sur le tellurophénolate de sodium obtenu par réduction du noyau de $NaBH_4$ à partir du dimère correspondant.

L'obtention des spectres, le calcul des paramètres de rmn et les conditions expérimentales ont été décrits dans la partie I de la présente série de rapports.

Remerciements

Nous tenons à remercier Messieurs les Professeurs J. Toussaint, M. Renson et A. Van de Vorst pour l'intérêt suivi qu'ils accordent à nos travaux. Nous remercions également le Centre de R.M.N. de l'Université de Liège qui a mis son matériel à notre disposition et, plus spécialement, son Directeur, Monsieur J. Denoel pour son aide technique.

Time-resolved CIDEP in the photoreduction of quinones. A study of the spin lattice relaxation time of semiquinone radicals in solution

JACOBUS W. M. DEBOER, THERESE Y. C. CHAN CHUNG, AND JEFFREY K. S. WAN

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received May 18, 1979

JACOBUS W. M. DEBOER, THERESE Y. C. CHAN CHUNG, and JEFFREY K. S. WAN. Can. J. Chem. **57**, 2971 (1979).

The application of time-resolved CIDEP observations to the measurements of T_1 of transient radicals is examined in detail. The importance of proper treatment of the response time is considered theoretically and demonstrated experimentally. By taking into account the variation of response time at high power, a method is described on how to evaluate B_1. At low power levels when the response time does not vary significantly, the extrapolation to zero power will provide a good estimate of T_1. The method was applied to measure T_1 for both the neutral radical and the radical anions of the benzoquinone, tetrachlorobenzoquinone, and duroquinone. It is confirmed that there is no significant difference in T_1 between the neutral radical and the radical anions. The values of the estimated T_1 are 2.2 μs for semibenzoquinone, 2.7 μs for semitetrachlorobenzoquinone, and 3.2 μs for semiduroquinone, all at 10°C and in a 50% isopropanol/toluene solvent.

JACOBUS W. M. DEBOER, THERESE Y. C. CHAN CHUNG et JEFFREY K. S. WAN. Can. J. Chem. **57**, 2971 (1979).

On examine en détail l'application des observations de CIDEP résolues en fonction du temps aux mesures de T_1 des radicaux temporaires. On considère de façon théorique et on démontre expérimentalement l'importance d'un traitement convenable du temps de réponse. On décrit une méthode d'évaluation de B_1 en tenant compte de la variation du temps de réponse à haute puissance. A de faibles niveaux de puissance, quand le temps de réponse ne varie pas de façon significative, l'extrapolation à la puissance zéro fournit une bonne évaluation de T_1. La méthode est appliquée à la mesure de T_1, pour les radicaux neutres et les anions radicalaires de la benzoquinone, de la tétrachlorobenzoquinone et de la duroquinone. L'absence de différence significative de T_1 entre le radical neutre et les anions radicalaires est confirmée. Les évaluations de T_1 sont de 2.2 μs pour la semibenzoquinone, 2.7 μs pour la semitétrachlorobenzoquinone et 3.2 μs pour la semiduroquinone. Ces évaluations sont faites à 10°C dans une solution à 50% d'alcool isopropylique/toluène comme solvant.

[Traduit par le journal]

Introduction

The technique of chemically induced dynamic electron polarization (CIDEP) is now often applied to elucidate the mechanisms and kinetics of free radical reactions in solution (1–3), transient intermediates in photosynthetic systems (4–6), and excited triplet states of organic molecules in crystals (7–9). Perhaps another unique application of CIDEP is the measurement of spin lattice relaxation time T_1 of transient radicals (10–12). Although the electronic T_1 is an important physical parameter which can provide an insight into molecular motions, relatively few other simple methods are available to obtain accurate T_1 of transient radicals.

Two distinctly different types of esr spectrometers have been used in CIDEP studies (13, 14): (*1*) time resolved spectrometers with total response time $\tau < 1\ \mu s < T_1 \ll$ radical half life $t_{1/2}$ where a pulsed electron beam or pulsed laser (on-time < 1 μs) is used to generate the radicals; (*2*) slow response spectrometers ($T_1 < \tau$ (30–500 μs) $< t_{1/2}$) where the radicals are generated by a modulated light source such that the on-time (0.1–20 ms) is sufficiently long for the signal intensity to reach a steady state amplitude. There are a number of advantages in chemical kinetic CIDEP studies to use a slow response spectrometer for initial polarization observations (14, 15) and in the past few years we have devoted our main effort in establishing a method (16) which utilizes an intermittent light source in conjunction with a 100 kHz esr spectrometer to evaluate relative rate parameters of photochemical reactions from the semi-steady-state CIDEP observations. While the steady-state values of the enhancement factor do not depend upon the microwave power level (15), they do have to be corrected for $t_{1/2}$ and T_1 to give the intrinsic value. The parameter $t_{1/2}$, which is obtained directly from the chemical decay part of the computer trace, compensates for changes in light intensity and also any changes in the viscosity of the media. Unfortunately T_1 has to be measured from separate experiments.

0008-4042/79/222971-07$01.00/0

The obvious choice is to take the value of T_1 from a time-resolved CIDEP study. In this paper we examine in detail the advantages and the limits of the application of time-resolved CIDEP technique to the evaluation of T_1 of anthrasemiquinone and other benzosemiquinone radicals in solution.

The situation involved in the time-resolved CIDEP experiment is one when at $t = 0$ suddenly a macroscopic electron magnetization is created. Before $t = 0$ no unpaired electron spins are present in the esr cavity. The sudden creation of magnetization is such that it is much faster than the spectrometer response time τ or T_2 of the spins created, whichever is the longer time. The creation of magnetization, of particular interest here, is produced by photochemical reactions initiated by a laser pulse less than 10 ns duration. Any magnetic polarization is assumed to arise within 10^{-8} s so that the criterion of sudden spin creation is satisfied even when τ, T_2 were as short as 10^{-7} s. If we define the z-axis to be parallel to the static magnetic field B_0, then the magnetization created will be initially along that axis, i.e. the photochemical process produces no coherence in the x,y-plane. Once the magnetization $\boldsymbol{m}$ is produced, the microwave field of magnitude B_1 will exert a torque on $\boldsymbol{m}$ which pulls $\boldsymbol{m}$ away from the z-axis as accompanied by the absorption or emission of microwave energy. At the same time relaxation tends to destroy m_y and restore m_z to the thermal equilibrium value m^∞. In addition, chemical reactions may destroy the spins created independently, although in many of the systems studied the half life of the radicals is considerably longer than T_1. Nevertheless, the observation of the spin using an esr spectrometer is related to m_y, but the response of the spectrometer may obscure the time evolution profile. It is therefore necessary to critically examine the performance of the spectrometer preamplification stages by measuring experimentally the total spectrometer response time and its effect on the determination of T_1.

Theoretical Considerations

Previous work by McLauchlan and co-workers (10) and by Verma and Fessenden (17) has dealt with the theory and technique of using CIDEP to measure T_1 of polarized radicals in solution. The present treatment is an attempt to understand and to underline the difficulties in the experimental measurements and to formulate a practical approach to simulate the experimental observations by a general theoretical treatment. Here, the following assumptions are made in the considerations of the esr spectrometer response in relation to the laser induced magnetization: (*a*) $\boldsymbol{m}(t) = 0$ and $t < 0$; (*b*) $\boldsymbol{m}(0) = (0, 0, m^0)$; (*c*) m^∞ is the steady-state magnetization in the *absence* of microwave field; (*d*) chemical decay of the radical concentration is slow compared to T_1 and T_2; (*e*) the spectrometer response is truly exponential; i.e. the response to a step function is given by a single exponential; (*f*) the observed signal h is proportional to m_y; (*g*) the kinetics of the spin system can be properly described by the Bloch equations.

The Bloch equations in the reference frame rotating with the microwave frequency ω give

$$[1] \quad \dot{m}_x = \delta\omega m_y - R_2 m_x$$

$$[2] \quad \dot{m}_y = -\delta\omega m_x - \omega_1 m_z - R_2 m_y$$

$$[3] \quad \dot{m}_z = \omega_1 m_y - R_1(m_z - m^\infty)$$

where

$$\delta\omega = \omega_0 - \omega$$

$$\omega_0 = \gamma B_0$$

$$\omega_1 = \gamma B_1$$

$$R_1 = (T_1)^{-1}$$

and

$$R_2 = (T_2)^{-1}$$

We shall consider here the on-resonance case, which is $\delta\omega = 0$ and thus m_x and m_y are decoupled:

$$[4] \quad \dot{m}_x = -R_2 m_x \qquad (\text{with } m_x(0) = m_x(\infty) = 0, m_x(t) = 0)$$

$$[5] \quad \dot{m}_y = \omega_1 m_z - R_2 m_y$$

$$[6] \quad \dot{m}_z = \omega_1 m_y - R_1(m_z - m^\infty)$$

where R_2 represents the effective transversal relaxation rate including the inhomogeneous contributions. The initial polarization is given by m^0/m^∞.

Using the initial conditions $m_z(0) = m^0$ and $m_y(0) = 0$, eqs. [5] and [6] can be solved with the method of Laplace transforms to yield

$$[7] \quad \boldsymbol{M}(x) = \int_0^t m(t)\, e^{-xt}\, dt = \mathscr{L}(\boldsymbol{m}) \qquad \mathscr{L}(\boldsymbol{m}) = x\boldsymbol{M}(x) - \boldsymbol{m}(0)$$

$$[8] \quad (x + R_2)M_y = -\omega_1 M_z$$

$$[9] \quad (x + R_1)M_z = \omega_1 M_y + (R_1 m^\infty/x) + m^0$$

or

$$[10] \quad M_y = \frac{-\omega_1(R_1 m^\infty + m^0 x)}{x[(x + R_1)(x + R_2) + \omega_1^2]}$$

It is convenient to include the spectrometer response time at this point. Let the response function be $g(t)$, then the response $h(t)$ to an input $f(t)$ is

$$[11] \quad h(t) = g^*f = \int_{-\infty}^{t} g(t - t')f(t')\,dt'$$

and $\mathscr{L}(h)$ is simply the product of $\mathscr{L}(g)$ and $\mathscr{L}(f)$:

$$[12] \quad H(x) = G(x)F(x)$$

For a true exponential response, g is given by

$$[13] \quad g(t) = \tau^{-1}e^{-t/\tau}$$

thus

$$[14] \quad G(x) = \tau^{-1}/(x + \tau^{-1})$$

The combination of eqs. [10], [12], and [14] gives

$$[15] \quad H(x) = \frac{-\omega_1(R_1m^\infty + m^0x)}{x(x - \lambda_1)(x - \lambda_2)(x + \tau^{-1})}$$

where

$$\lambda_{1,2} = -R \pm (1/2)\sqrt{(R_2 - R_1)^2 - 4\omega_1^2}$$

and

$$R = (1/2)(R_2 + R_1)$$

If $\lambda_1 \neq \lambda_2$, eq. [15] can be written as

$$[16] \quad H(x) = \frac{b_1}{x} + \frac{b_2}{x - \lambda_1} + \frac{b_3}{x - \lambda_2} + \frac{b_4}{x + \tau^{-1}}$$

and therefore

$$[17] \quad h(t) = b_1 + b_2e^{\lambda_1 t} + b_3e^{\lambda_2 t} + b_4e^{-t/\tau}$$

and the b's are found to be

$$[18] \quad b_1 = -\frac{\omega_1R_1m^\infty}{\lambda_1\lambda_2}$$

$$b_2 = \frac{\omega_1m^0 + \omega_1R_1m^\infty\lambda_1^{-1}}{(\lambda_2 - \lambda_1)(1 + \lambda_1\tau)}$$

$$b_3 = -\frac{\omega_1m^0 + \omega_1R_1m^\infty\lambda_2^{-1}}{(\lambda_2 - \lambda_1)(1 + \lambda_2\tau)}$$

$$b_4 = -\tau\frac{\omega_1m^0 - \omega_1R_1m^\infty\tau}{(1 + \lambda_1\tau)(1 + \lambda_2\tau)}$$

If $\omega_1 < (1/2)(R_2 - R_1)$, $\lambda_{1,2}$ are real and the signal h is a sum of decaying exponentials. However, if $\omega_1 > (1/2)(R_2 - R_1)$, the $\lambda_{1,2}$ are complex which lead to oscillatory components with frequency Ω:

$$[19] \quad \Omega = [\omega_1^2 - (1/4)(R_2 - R_1)^2]^{1/2}$$

$$\lambda_{1,2} = -R \pm i\Omega$$

and eqs. [17] and [18] become

$$[20] \quad h(t) = b_1 + (c_2\cos\Omega t + c_3\sin\Omega t)e^{-Rt} + b_4e^{-t/\tau}$$

$$b_1 = -\frac{\omega_1R_1m^\infty}{R^2 + \Omega^2}$$

$$c_2 = \frac{\omega_1m^0\tau - b_1(1 - 2R\tau)}{D}$$

$$[21] \quad c_3 = \frac{-\omega_1m^0(1 - R\tau) + b_1[R(1 - R\tau) + \Omega^2\tau]}{\Omega D}$$

$$b_4 = \tau\frac{-\omega_1m^0 + \omega_1R_1m^\infty\tau}{D}$$

$$D = (1 - R\tau)^2 + (\Omega\tau)^2$$

Note that eqs. [17] to [21] hold true for any ω_1 (except the only case when $\omega_1 = (1/2)(R_2 - R_1)$), but in general the quantities $\lambda_{1,2}$, Ω, and D are complex. However, for two cases (*i*) when $\omega_1 < (1/2) \times (R_2 - R_1)$, all quantities in eqs. [17] and [18] are *real*, and (*ii*) when $\omega_1 > (1/2)(R_2 - R_1)$, all quantities in eqs. [20] and [21] are *real*.

It is clear from the above treatment that the six parameters (ω_1, T_1, T_2, τ, m^0, m^∞) are not determined uniquely and simultaneously by the shape of the response. Since the *absolute* values of m^0 and m^∞ are not measured, only five independent parameters will enter the shape calculation. These are for case (*i*): λ_1, λ_2, τ, ω_1m^0, and $\omega_1R_1m^\infty$; and for case (*ii*): R, Ω, τ, ω_1m^0, and $\omega_1R_1m^\infty$. These conclusions will be tested in the following experimental investigation of anthrasemiquinone radicals in solution and a more limited method will be developed to apply the time-resolved CIDEP observations to estimate the values of T_1.

Experimental

The laser flash photolysis coupled with esr dc detection was first demonstrated by Kim and Weissman (18) and subsequently developed further for CIDEP studies by Trifunac and co-workers (1), by McLauchlan and co-workers (2), and by McIntosh and Bolton (4). Verma and Fessenden (17) have developed earlier a time-resolved esr spectrometer for CIDEP studies of radicals generated by submicrosecond pulses of 2.8 MeV electrons. The experimental design used by Kim and Weissman (18) was essentially duplicated in our present apparatus, which uses a Molectron UV24 N_2 pulsed laser as the light source. The esr spectrometer used is a Varian E3 old model and the dc signal was taken off after the preamplification and fed through a Hewlett Packard 461A 40 dB wide-band amplifier. Additional amplification when required was accomplished by using a Tektronic T922R scope amplifier. The amplified dc signal was digitized by either a Biomation 610 at 100 ns per point or by a Nicolet Explorer III digital scope at 50 ns per point. Both the laser and the digitizer were triggered by an external signal generated from a Hewlett Packard 3325A

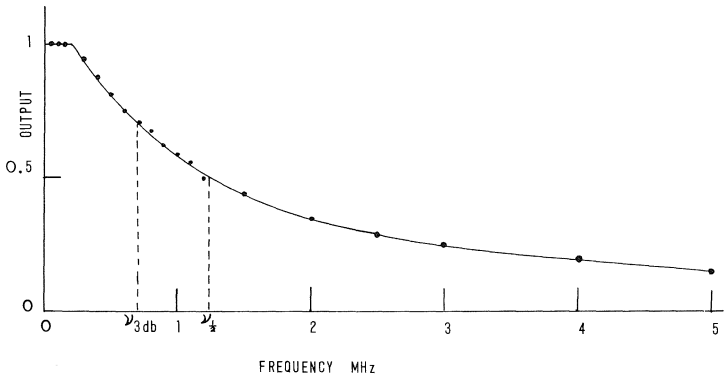

FIG. 1. The frequency response curve of the spectrometer preamplifier.

synthesizer/function generator at 7 Hz. The digitized data were collected and processed by a Nicolet 1180 computer in a synchronous mode.

The microwave cavity of the E3 spectrometer was modified by replacing the front plate with a brass plate having a centered hole of 9 mm diameter for transmission of the laser beam. This modification lowered the cavity Q. However, any further spoiling of Q did not seem to affect the response time.

The initial polarization of the semiquinone radicals studied in this work is so large that the signal-to-noise ratio was excellent even for a single pulse observation. Therefore, it is simple to locate the resonance and its maximum by hand-scanning of the magnetic field slowly while observing the polarization on the scope.

The chemical systems studied were mainly quinones in isopropanol and in the presence of 0.5 *M* phenol. The solution was placed in a 3 mm od Pyrex tube, vacuum degassed, and the tube was then sealed off. In the anthraquinone series, all experiments were done at -7°C with a variation of microwave power between 0.25 and 16 mW. In each experiment observations were monitored both on-resonance and then off-resonance (by shifting the magnetic field about 0.5 kg). In order to eliminate the randomness in the observed signal amplitude 100 scans were collected and time averaged for each measurement, including the off-resonance observation. The reported "time-resolved CIDEP" observation represents the difference between the time averaged on- and off-resonance traces, at a particular power level. In our apparatus some instability in the diode current was observed at a power level of 16 mW or higher.

Results and Discussion

The Measurements of the Spectrometer Response Time

As can be seen from the above theoretical considerations the effect of spectrometer response time is very important unless $\tau^{-1} \gg |\lambda_1|, |\lambda_2|$. When this condition is not met, the shape of the response will depend on the functional form of the spectrometer response function. The total system response in our apparatus is determined by the spectrometer system since the combined response time of the wide-band amplifiers and digitizers is less than 200 ns. We have decided therefore to carry out an independent evaluation of the spectrometer response time by removing the crystal diode and replacing the preamplifier input by a 1 mV signal from the HP3325A synthesizer. In this manner the frequency characteristics of the preamplifier were determined. Figure 1 shows the output voltage as a function of the frequency and Table 1 demonstrates that the actual response is very closely related to a true exponential response.

From the curve in Fig. 1 the response time of the E3 spectrometer preamplifier is estimated to be 230 ns. This is normally short enough for the measurement of T_1 in the microsecond range. However, further experiments (see below) indicate that the total system response time appears to change with microwave power. Moreover, to obtain T_1 directly from the decay curves, B_1 must be small so that $(\gamma B_1)^2 \ll (1/4)(R_2 - R_1)^2$.

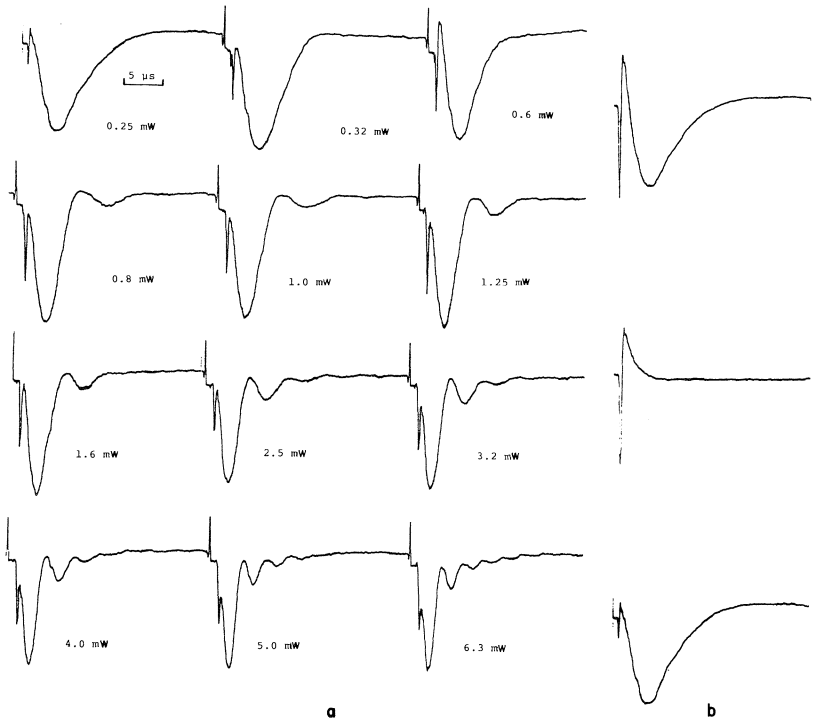

FIG. 2. (*a*) The transient emissive signal decay of the semianthraquinone radicals at −7°C at various microwave power levels. Each curve represents the difference between the on-resonance and off-resonance responses (see *b*). In each trace the first spike represents the laser trigger pulse and the second the laser flash. (*b*) A typical experimental set of observations at 0.25 mW. The upper trace is on-resonance, the middle trace is off-resonance, and the bottom trace is the difference.

anthraquinone/phenol photoreduction are shown in Fig. 2. Each of the traces at a particular power level could be simulated with $m^{\infty} = 0$, $m^{0} < 0$, by using a computer program written for the Nicolet 1180 system. However, it was clear that the simulation of all traces at all different power levels cannot be accomplished by using a unique set of parameters T_1, T_2, and τ, as suggested by the above theoretical considerations. At high power levels a longer response time and a shorter "apparent relaxation time" were required to simulate the experimental shape. The change in τ with power levels seems to be confirmed by a series of off-resonance experiments in which the "pick-up" decayed slower at high power levels. In the determination of T_1 by the method of extrapolation to zero power, it is, therefore, necessary to take into account the change of τ at high power and only data taken at power levels of 1 mW and less should be used for the extrapolation.

On the other hand, experiments carried out at high power levels enable the observation of oscillatory components as defined in eq. [19]. This in turn might be used to measure B_1.

(a) Measurements of B_1

As shown in Fig. 2 oscillatory components began to be visible at power 0.8 mW and higher. However, since the experimental traces at high power cannot be simulated satisfactorily without a detailed correlation to τ, a different approach to determine B_1 was undertaken.

From eq. [19] it is seen that the oscillatory frequency Ω depends upon ω_1 only when $\omega_1 \gg (1/4)(R_2 - R_1)^2$. If we define T to be the oscillation period ($T = 2\pi/\Omega$), then

$$[22] \quad B_1 = 2\pi/\gamma T$$

or

$$B_1\,(\text{mG}) = 356.8/T\,(\mu\text{s})$$

Using this equation the values obtained for B_1 are shown in Fig. 3, and the solid line represents eq. [23]:

$$[23] \quad B_1\,(\text{mG}) = 54 \times (\sqrt{P} - 0.17)$$

where P is the power level read from the spectrometer dial. The B_1 values obtained in this manner give a good fit between the calculated and experimental traces over the entire power range (0.25 to 12.5 mW).

(b) Signal Amplitude at High Power

In many of our experiments the assumption $m^{\infty} = 0$ is valid and the signal amplitude at high

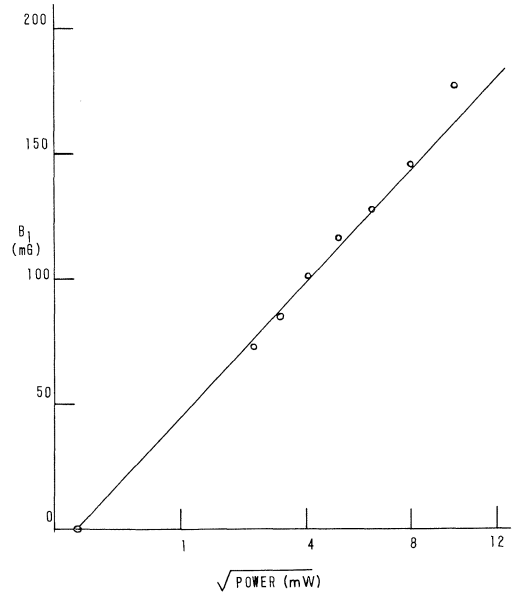

FIG. 3. The plot of B_1 as calculated from the oscillation period versus the square root of microwave power level P as read from the spectrometer dial.

power in eq. [20] can be written as

$$[24]\quad h(t) = [(\omega_1 m^0)/\Omega D][(\Omega\tau \cos \Omega t - (1 - R\tau) \sin \Omega t)e^{-Rt} - \Omega t e^{-t/\tau}]$$

While the shape of [24] is dependent on R_1, Ω, and τ, the signal amplitude is proportional only to ω_1 directly.

The variation of the signal amplitude with B_1 is shown in Fig. 4. Below the saturation point

$$B_1 = (1/\gamma)(1/\sqrt{T_1 T_2})$$

which is indicated by the arrow in Fig. 4, signal amplitude is approximately linear in B_1. As B_1 increases above this point, Ω grows and the maximum signal occurs faster. With a slower response time the signal therefore decreases at higher B_1 since the observation cannot follow the faster oscillation. With a fast response spectrometer the signal will continue to grow but levels off when $\omega_1 \gg R$. Finally in the limit $\tau \ll w_1^{-1} \ll T_1, T_2$, the maximum signal is equal to m^0.

(c) Measurements of T_1

At very low power, i.e. $\omega_1^2 \ll (1/4)(R_2 - R_1)^2$, $\lambda_{1,2}$ are approximately equal to $-R_{1,2} \mp \omega_1^2 \div (R_2 - R_1)$ and the signal decay is dominated by T_1 (for $T_1 > \tau$). Since the Varian E3 is not equipped with a low-power operation configuration, the lowest B_1 usable is about 15 mG and the extrapolation to $B_1 = 0$ only provides *an estimate* of T_1 (10).

To analyze the experimental data we define an

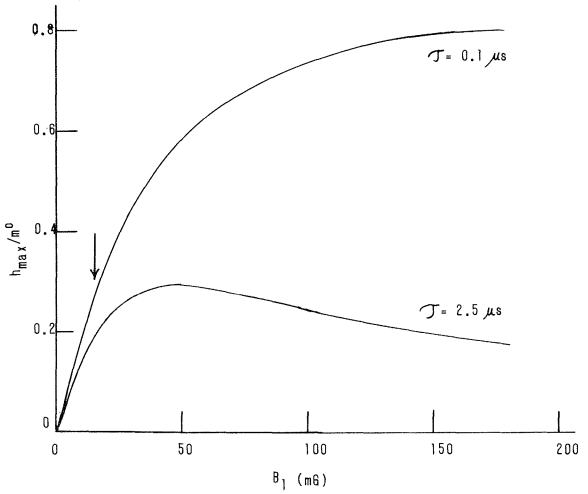

FIG. 4. The signal amplitude expressed as the ratio of h_{max}/m^0 plotted as a function of B_1.

effective decay time T_{eff} as equal to $1/R$ and it is the decay time of the total magnetization. We also define an apparent decay time T_{app} which is obtained from the analysis of the experimental trace assuming it being exponential. The difference between T_{eff} and T_{app} arises from the response time variation and the oscillations. In many of our quinone experiments $T_1 > T_2$. Thus, if $\omega_1 > (1/2)T_2^{-1}$, T_{eff} will be independent of the power but T_{app} will vary with the power. By extrapolation from $B_1 = 15$ mG to $B_1 = 0$, we have in fact reached the limit $T_{eff} = T_{app}$.

Measurements of T_1 *of Semibenzoquinone Radicals and Radical Anions*

(a) The Neutral Semiquinone Radicals

The following semibenzoquinone radicals were generated in the laser flash photolysis of their parent quinones in the presence of 0.5 *M* phenol in a solvent 50% isopropanol in toluene at 10°C: semibenzoquinone, semitetrachlorobenzoquinone, and semiduroquinone. Each radical was studied at various microwave power levels ranging from 0.25 to 1.3 mW, and the apparent decay time T_{app} was obtained from each of the decay traces. The reciprocals of these T_{app} were plotted as a function of the power and extrapolated to zero power to obtain the estimated T_1 (Fig. 5).

(b) The Semiquinone Radical Anions

The same three quinones were photoreduced by 0.5 *M* triethylamine in the same solvent at the same temperature. The CIDEP of each of the radical anions was studied over the same microwave power range and the T_1 was obtained by the same analysis and method as in (*a*). For each of the three different

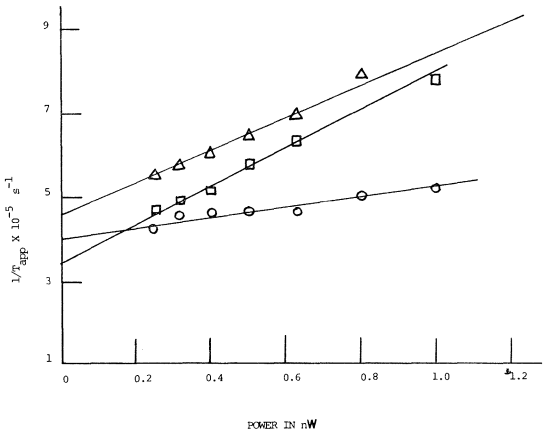

FIG. 5. The plot of $1/T_{app}$ as a function of microwave power. △: Semibenzoquinone radical; ○: semitetrachlorobenzoquinone radical; and □: semiduroquinone radical. The estimated T_1 extrapolated to zero power are 2.2 μs for semibenzoquinone; 2.7 μs for semitetrachlorobenzoquinone; and 3.2 μs for semiduroquinone, all at 10°C and in 50% isopropanol/toluene solvent.

quinones in the same solvent at the same temperature, we found that there is no significant difference outside experimental errors between the T_1 of the neutral radical and the radical anion. In the development of the slow response semi-steady-state CIDEP method using a rotating sector (16), we have made some assumptions by using the literature T_1 values for semibenzoquinone radical anions for the neutral radical systems. The present experiments support such assumptions and the T_1 values of the semiquinone radical anions measured here by the time-resolved CIDEP method agree quite well with those reported in literature using saturation method (19). It also establishes that T_1 has the same value when measured at different hyperfine fields (20).

Conclusions

The importance of proper treatment of the response time in the application of time-resolved CIDEP observations to the measurements of T_1 is demonstrated in detail by comparing the theoretical treatment with the experimental analysis. With spectrometers using either 100 kHz or 2 MHz modulation the intrinsic response time is longer than 800 ns (and much higher with 100 kHz modulation). Any analysis of the time evolution profiles using modulated spectrometers must therefore involve the analysis of the response time in details. Using dc detection method with spectrometers having an intrinsic response time less than 300 ns, T_1 of the transient radicals can be estimated by the extrapolation to zero power method, provided that the response time is known to be approximately constant over the range of power used.

The reaction of ethyl 3,4,6-tri-*O*-acetyl-2-amino-2-deoxy-β-D-glucoside in acetone

BRIAN CAPON, CECILIA LABBÉ, AND DAVID S. RYCROFT
Department of Chemistry, University of Glasgow, Glasgow, G12 8QQ, Scotland, U.K.

Received April 30, 1979

BRIAN CAPON, CECILIA LABBÉ, and DAVID S. RYCROFT. Can. J. Chem. 57, 2978 (1979).

It is shown by ^1H and ^{13}C nmr spectroscopy that ethyl 3,4,6-tri-*O*-acetyl-2-amino-2-deoxy-β-D-glucoside reacts in acetone to yield a Schiff base, not the hemiorthoamide proposed previously.

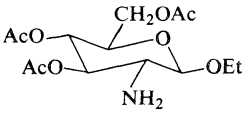
BRIAN CAPON, CECILIA LABBÉ et DAVID S. RYCROFT. Can. J. Chem. 57, 2978 (1979).

On a déterminé par la résonance magnétique du ^1H et du ^{13}C que le tri-*O*-acétyl-3,4,6 amino-2 déoxy-2-β-D-éthylglucoside réagit dans l'acétone pour donner une base de Schiff et non l'hémiorthoamide proposé antérieurement.

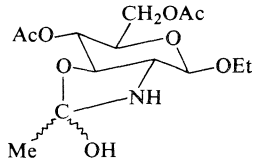
[Traduit par le journal]

It was reported in 1970 (1) that ethyl 3,4,6-tri-*O*-acetyl-2-amino-2-deoxy-β-D-glucoside (**1**) reacts in acetone solution to yield a compound (**2**) with a hemiorthoamide structure. In view of our interest in tetrahedral intermediates (2) and in the expected instability of hemiorthoamides (3, 4) we have re-investigated this reaction. The optical rotation of a solution of ethyl 3,4,6-tri-*O*-acetyl-2-amino-2-deoxy-β-D-glucoside in acetone changed in a similar manner to that reported previously (1, 5) ($[\alpha]_D - 1.67$ (1 min) → $-31.72°$) and on workup as described previously (1) a product with the same ^1H nmr spectrum as reported previously was obtained (cf. Fig. 2, ref. 1). In this spectrum it was proposed (1) that the two signals at δ = ca. 1.90 separated by ca. 2 Hz were the signals of the methyl of the orthoamide group of **2** which was a doublet because of spin–spin coupling with the NH proton. However in our hands the separation of these two signals was approximately 5/3 times greater when the spectrum was run at 100 MHz (4.8 Hz) than when it was run at 60 MHz (2.8 Hz) and approximately 3/2 times greater when it was run at 90 MHz (3.9 Hz). We therefore conclude that the two signals arise from a difference in chemical shift and not from spin–spin splitting. This conclusion is supported by the effect on the spectrum of shaking with deuterium oxide. In our hands this led to a loss of the NH signal (δ = ca. 1.60, variable) without any alteration of the two peaks at δ = ca. 1.90. However, these experiments are not inconsistent with structure **2** since two diastereoisomers, and hence two methyl signals, are possible.

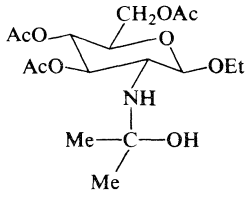
The reaction of **1** was investigated further in acetone-d_6. The optical rotation changed as in acetone ($[\alpha]_D = -3.15$ (1 min) → $-32.5°$) and a similar product was isolated. The ^1H nmr spectrum of this in $CDCl_3$ lacked the upfield peak at δ = ca. 1.90 (1.89) but the downfield peak (δ = 1.94) was



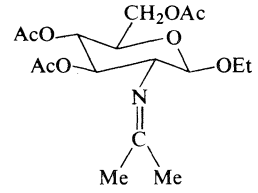
1



2



3



4

unchanged. In addition the peak at δ = 2.01 was of reduced intensity. It was therefore concluded that **1** had reacted with acetone to produce a product in which there were signals at δ = 1.89 and 2.01 which were derived from the acetone. The spectrum of the product from acetone-d_6 also lacked the signal at δ = 2.17 of acetone which was apparent in our spectrum of the product from acetone-h_6 and in Fig. 2 of ref. 1.

Better resolved spectra were obtained with solutions in acetonitrile-d_3. The compound from CH_3COCH_3 showed methyl signals at δ = 1.84, 1.88, 1.91, 1.95, and 2.01. In addition there were small peaks at δ = 2.00 and 1.99 which corresponded to those of the starting material **1** (the third signal of **1** occurs at δ = 1.95 and overlaps with one of those of the product) and at δ 2.08 which corresponded to that of acetone. The product from CD_3COCD_3 lacks the signals at δ = 1.84 and 1.91.

Examination of the ethyl group triplet of the spectra in CD_3CN (or $CDCl_3$) (cf. Fig. 2, ref. 1) indicates that besides the main triplet (δ 1.10,

0008-4042/79/222978-03$01.00/0

CD_3CN; 1.16, $CDCl_3$) there is a second triplet (δ 1.19, CD_3CN; 1.28, $CDCl_3$) of lower intensity which corresponds to the triplet of **1**. Since acetone is also present it is concluded that the product has partially decomposed in both solvents. When D_2O was added to a solution in CD_3CN of the product from **1** and CH_3COCH_3 a spectrum was obtained that corresponded to the sum of the spectra of the starting components. The best spectrum of the product was obtained in CD_3COCD_3 solution after leaving at 35°C for 18 h. This corresponded to ca. 90% conversion but after workup the spectrum taken immediately in $CDCl_3$ indicated that only ca. 80% of the product was present, and on leaving, further decomposition took place. A more stable spectrum was obtained with solutions in CD_3CN.

The two most likely structures were considered to be a carbinolamine **3** or a Schiff base **4**. The latter structure is supported by the fact that the chemical shift of the proton at C2 moves downfield from δ = 2.7 to ca. 3.5 where it overlaps with the protons at C6, C5, and the CH_2 of the ethyl group to form a highly complex multiplet. Further support for the Schiff base structure comes from the ^{13}C nmr spectra (Table 1) and in particular the presence of a signal at δ = 171.7 corresponding to a C=N group (the carbon of the C=N group of Me_2C=NMe has δ = 168(6)). This signal was not observed in the room temperature spectrum of the product from acetone-d_6. However by running spectra at −40°C so that S/N improvement was quicker and decomposition slower a signal from the acetone-d_6 product was seen at δ = 172.16 with ca. 25% of the height of the corresponding signal at δ = 172.29 from the acetone-h_6 product. This loss in height arises partly because of spin-coupling to six deuterium nuclei giving an unresolved 13 line multiplet ($|^2J_{CD}|$ is expected (7) to be ca. 0.5–1 Hz) and partly because of the reduction in the nOe and increase in T_1 attendant on neighbouring deuterium substitution. The geminal deuterium isotope effect on the chemical shift cannot be predicted as such effects have received little study (8) and may be either positive or negative. The effect observed here is very small (−0.13 ppm; cf. +0.32 ppm for acetone-d_6). No signal for a quaternary carbon at δ = 60–80 could be discerned which would be expected if the product had a carbinolamine structure **3**. The signals of the methyl groups derived from the acetone, which occur at δ = 29.4 and 19.5, are also absent in the spectrum of the product from CD_3COCD_3. The large difference in chemical shift that they show is also consistent with the structure **4** (cf. δ = 29.1 and 18.0 for Me_2C=NMe (6)) but would be unexpected for structure **3**. Significant differences in chemical shift in the spectra of **1** and the product were also found for the signals of C1, C2, and C3. Particularly noteworthy is the downfield shift of 8 ppm of the signal of C2.

It is concluded that the change in optical rotation which occurs when **1** is dissolved in acetone arises from formation of the Schiff base **4**, not of the hemiorthoamide **2**.

Experimental

Proton nmr spectra were run at ambient probe temperature on Varian T60 (60MHz), Perkin Elmer R32 (90MHz), and Varian HA100 (100MHz) spectrometers. ^{13}C nmr spectra with a digital resolution of 1.25Hz/data point were run on a Varian XL100 spectrometer at 25.2 MHz in the pulsed FT mode. Off-resonance proton decoupled spectra were used to confirm assignments. Optical rotations were measured on a Perkin Elmer 141 polarimeter.

Ethyl tri-*O*-acetyl-2-amino-2-deoxy-β-D-glucopyranoside (**1**) was allowed to react in acetone as described previously (1) to yield a product with the same ^1H nmr spectrum as reported previously (cf. Fig. 2, ref. 1). In CD_3CN solution the following signals were present: δ = 5.15 (t, *J* = 8.7 Hz, H3 or H4), 4.93 (t, *J* = 8.7 Hz, H4 or H3), 4.56 (d, *J* = 7.3 Hz, H1), 4.4–3.3 (complex multiplet H6, H5, H2, and CH_3CH_2), 2.01, 1.95, 1.91, 1.88, 1.84 (s, CH_3), and 1.10 (t, *J* = 7 Hz, CH_3CH_2). A similar product was obtained from acetone-d_6; the ^1H nmr spectrum was similar to that obtained from CH_3COCH_3 but no signals at δ = 1.84 and 1.91 were present.

Received May 16, 1979

K. REDDA, L. A. CORLETO, and E. E. KNAUS. Can. J. Chem. **57**, 2981 (1979).

Reaction of *N*-(4-pyridylcarbonylamino)-1,2,3,6-tetrahydropyridine (**2***a*) with methyl chloroformate afforded the quaternary salt **3***a* whereas reaction with methyl iodide gave a mixture of **3***b* and **6**. Sodium borohydride reduction of **3***a* using methanol at −65°C gave the *N*-methoxycarbonyl-1,2-dihydropyridine **4***a* whereas reduction using ethanol at 0°C gave the 1,2,3,6-tetrahydropyridine **4***b*. Reduction of **3***b* and **6** gave rise to a mixture of **4***c* and **7**. Catalytic hydrogenation of **4***b* and **4***c* afforded the respective piperidyl derivatives **10** and **11**. The pharmacological activities of the products are presented.

K. REDDA, L. A. CORLETO et E. E. KNAUS. Can. J. Chem. **57**, 2981 (1979).

La réaction de la *N*-(pyridylcarbonylamino-4) tétrahydro-1,2,3,6 pyridine (**2***a*) avec le chloroformate de méthyle fournit le sel quaternaire **3***a* tandis que la réaction avec l'iodure de méthyle fournit un mélange de **3***b* et de **6**. La réduction de **3***a* par le borohydrure de sodium dans le méthanol à −65°C conduit à la *N*-méthoxycarbonyl dihydro-1,2 pyridine **4***a* mais dans l'éthanol à 0°C on obtient le tétrahydro-1,2,3,6 pyridine **4***b*. La réduction de **3***b* et de **6** conduit à un mélange de **4***c* et de **7**. L'hydrogénation catalytique de **4***b* et de **4***c* permet d'obtenir respectivement les dérivés pipéridyles **10** et **11**. On rapporte les propriétés pharmacologiques de ces produits.

[Traduit par le journal]

The sodium borohydride reduction of *N*-carbonyliminopyridinium ylides **1** is a facile procedure for the synthesis of *N*-carbonylamino-1,2,3,6-tetrahydropyridines **2** (1). A broad spectrum pharmacological

a R = 4-Pyridyl
b R = 3-Pyridyl
c R = 2-Pyridyl

screen[2] indicated that **2***a–c* exhibited analgesic and anti-inflammatory activities comparable to Aspirin and Indomethacin respectively (2). It was therefore of interest to determine what effect hydrogenation of the 4-pyridyl ring of **2***a* would have on pharmacological activity. We now wish to describe the syntheses and pharmacological activities of reduced pyridyl analogs of *N*-(4-pyridylcarbonylamino)-1,2,3,6-tetrahydropyridine (**2***a*).

The reaction of **2***a* with methyl chloroformate in methanol at −65°C for 30 min affords the quaternary salt **3***a* which on reduction with sodium borohydride also at −65°C for 3 h gave *N*-[4-(1-methoxycarbonyl-1,2-dihydropyridyl)carbonylamino]-1,2,3,6-tetrahydropyridine (**4***a*, 70.5%) (3). On the other hand the same reaction in ethanol at 0°C gave *N*[4-(1-methoxycarbonyl-1,2,3,6-tetrahydropyridyl)-carbonylamino]-1,2,3,6-tetrahydropyridine (**4***b*, 52.7%). Alternatively, reduction of **4***a* using sodium borohydride in ethanol at 0°C also gave **4***b* (58.4%).

Treatment of **2***a* with methyl iodide in methanol followed by sodium borohydride reduction at −65°C afforded a mixture of **4***c* (23.7%), arising from the reduction of **3***c* and **7** (17.1%). The most plausible

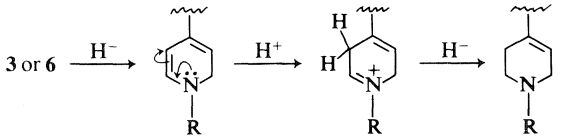
mechanism for the formation of **7** involved methylation of the enolic tautomer **5** to give **6** which on subsequent reduction would yield **7**. A similar O-methylation reaction has been observed for *N*-carbonyliminopyridinium ylides (4).

The mechanism for the reduction of pyridinium salts **3** and **6** likely involves attack by hydride anion at a carbon adjacent to the quaternary nitrogen to give the dienamine **8** which on protonation and subsequent reduction of the immonium species **9** would afford **4** or **7** (5).



Catalytic hydrogenation of **4***b* and **4***c* using palladium on charcoal and hydrogen gas at 40 psi gave the saturated derivatives **10** (82.8%) and **11** (97.6%) respectively.

Reaction of isonipecotic acid hydrazide with 2,4-dinitrophenylpyridinium chloride, using the procedure reported previously (1), gave *N*-(4-piperidylcarbonylimino)pyridinium ylide **12** (10.9%). Reduction of **12** with sodium borohydride in ethanol at 0°C for 4 h afforded *N*-(4-piperidylcarbonylamino)-1,2,3,6-tetrahydropyridine **13** (86%).

The analgesic and anti-inflammatory activities of the *N*-aminocarbonyl-1,2,3,6-tetrahydropyridines were determined.[2]

The compounds were suspended in a solution of physiological saline and Tween 80 (TM) surfactant and administered subcutaneously (S.C.) to Swiss albino mice, before determining their analgesic activity in the phenylquinone writhing test according to the procedure of Collier (6). The analgesic activities of the compounds tested are compared to Aspirin (TM) and Dextropropoxyphene (TM) as illustrated in Table 1. A compound causing a 30–50% reduction is considered to be slightly active whereas one causing a greater than 50% reduction in the number of writhes is an active analgesic agent.

Anti-inflammatory activity was measured using the antagonism of carrageenan induced rat paw edema procedure of Winter (7). The compounds were administered subcutaneously to Sprague–Dawley rats and the anti-inflammatory activities compared to Indomethacin (TM) as shown in Table 2. A compound causing a greater than 30% reduction in edema is considered to be an active anti-inflammatory agent.

Examination of the analgesic test results (Table 1) indicates that elaboration of the 4-pyridyl ring of **2***a* to a 1-methoxycarbonyl-1,2-dihydropyridyl ring **4***a* enhances potency providing a compound with an improved dose-response. Reduction of **2***a* to the *N*-methoxycarbonyl-1,2,3,6-tetrahydropyridyl derivative **4***b* does not change activity whereas the closely

TABLE 1. Analgesic activity of *N*-aminocarbonyl-1,2,3,6-tetrahydropyridines and piperidines tested

Compound	Dose (mg/kg)	Response (% inhibition)

[a]Active.
[b]Slightly active.
[c]Inactive.

related analog **4***c* exhibits some analgesic activity. The O-methyl iminoether **7** was inactive which suggests the aminocarbonyl moiety is essential for analgesic activity. The fully hydrogenated analog **10** of **4***a* and **4***b* exhibited slight activity. Replacement of the 4-pyridyl ring of **2***a* by a 4-piperidyl ring **13** results in a decrease in activity but the compound is still considered to be an active analgesic.

Elaboration of the 4-pyridyl ring of **2***a* to the 1-methoxycarbonyl-1,2-dihydropyridyl derivative **4***a* results in a small reduction in anti-inflammatory activity whereas conversion to the *N*-methoxycarbonyl-1,2,3,6-tetrahydropyridyl derivative **4***b* provides a slightly active anti-inflammatory agent (see Table 2). Replacement of the 4-pyridyl ring of **2***a* by the *N*-methyl-1,2,3,6-tetrahydropyridyl ring present in **4***c* and **7** or the piperidine ring in **13** provides inactive compounds. The observation that **4***c* causes a 34% reduction in inflammation while **7** is totally inactive indicates that the carbonylamino moiety is essential for anti-inflammatory activity. The fully hydrogenated derivative **10** was found to be a slightly active anti-inflammatory agent.

Other broad spectrum pharmacological screening results indicated that **4***c* inhibited passive cutaneous anaphylaxis in the rat and was found to be an active anti-anaphylactic agent according to the procedure of Goose (8). The *N*-methoxycarbonyl-1,2-dihydropyridyl derivative **4***a* provided a partial block of the response to histamine in the isolated Guinea pig ileum (9) and was considered to be a slightly active antihistaminic agent. None of the compounds prepared exhibited antidepressant, cardiovascular, or hypoglycemic activities.

Experimental

Melting points were determined with a Büchi capillary apparatus and are uncorrected. Nuclear magnetic resonance spectra were determined for solutions in deuterochloroform with TMS as internal standard with a Varian EM-360A spectrometer. Infrared spectra (potassium bromide unless otherwise noted) were taken on a Unicam SP-1000 or Perkin Elmer 267 spectrometer. Mass spectra were measured with an AEI-MS-50 mass spectrometer and these exact mass measurements are used in lieu of elemental analyses. All of the products described gave rise to a single spot on tlc using a solvent system less polar and more polar than the specific solvent system described for purification of the reaction mixture. No residue remained after combustion of the products.

N-[*4-(1-Methoxycarbonyl-1,2-dihydropyridyl)carbonylamino*]-*1,2,3,6-tetrahydropyridine* (**4**a)

General Procedure

A solution of methyl chloroformate (0.202 g, 2.15 mmol) in methanol (20 mL) was added dropwise with stirring to a solution of **2***a* (0.218 g, 1.07 mmol) in methanol (20 mL) pre-cooled to −65°C. The reaction was allowed to proceed for 30 min at −65°C with stirring. Sodium borohydride (0.8 g) was added and the reaction was allowed to proceed for an additional 3 h at −65°C. The reaction mixture was then poured onto crushed ice (125 mL) followed by gradual warming to room temperature. Extraction with chloroform (200 mL), drying (sodium sulfate), and removal of solvent *in vacuo* gave a white solid which was purified by elution from a 2.5 cm × 20 cm silica gel column using ether (400 mL) to afford **4***a* (0.199 g, 70.5%); mp 132–134°C; ir: 3200 (m, NH), 1710, and 1670 (s, CO) cm^{-1}; ^1H nmr δ: 7.18 (s, 1H, NH, exchanges with deuterium oxide), 6.84 (d($J_{5,6}$ = 8 Hz), 1H, H-6 (dihydropyridine)), 6.20 (d($J_{2,3}$ = 5 Hz) of d($J_{2',3}$ = 5 Hz) of d($J_{3,5}$ = 2 Hz), 1H, H-3 (dihydropyridine)), 6.00–5.61 (m, 2H, H-4, H-5 (tetrahydropyridine)), 5.45 (d($J_{5,6}$ = 8 Hz) of d($J_{3,5}$ = 2 Hz), 1H, H-5 (dihydropyridine)), 4.51 (d($J_{2,3}$ = 5 Hz), 2H, H-2 (dihydropyridine)), 3.80 (s, 3H, —CH_3), 3.58–3.32 (m, 2H, H-6 (tetrahydropyridine)), 3.08 (t($J_{2,3}$ = 6 Hz), 2H, H-2 (tetrahydropyridine)), 2.52–2.08 (m, 2H, H-3 (tetrahydropyridine)). Exact mass calcd. for $C_{13}H_{17}N_3O_3$: 263.1270; found (high resolution ms): 263.1267.

N-[*4-(1-Methoxycarbonyl-1,2,3,6-tetrahydropyridyl)carbonylamino*]-*1,2,3,6-tetrahydropyridine* (**4**b)

Method A

A solution of methyl chloroformate (0.38 g, 4.02 mmol) was added dropwise to a solution **2***a* (0.40 g, 2.01 mmol) in 95% ethanol (40 mL) pre-cooled to −65°C and the reaction was allowed to proceed for 30 min at −65°C with stirring. Sodium borohydride (0.25 g) was added at once and the reaction allowed to proceed for 4 h at 0°C prior to completion as described under the general procedure. The reaction product was then purified by elution from a 2.5 cm × 17 cm neutral alumina column with ethyl acetate (400 mL) to give **4***b* (0.281 g, 52.7%); mp: 153–155°C; ir: 3180 (m, NH), 1715, and 1675 (s, CO) cm^{-1}; ^1H nmr δ: 7.3–6.88 (m, 1H, H-5 (*N*-tetrahydropyridylcarbonyl)), 6.72 (s, 1H, NH, exchanges with deuterium oxide), 6.0–5.48 (m, 2H, H-4, H-5 (*N*-aminotetrahydropyridine)), 3.80 (s, 3H, —CH_3), 3.80–3.32 (complex m, 4H, H-6 (*N*-tetrahydropyridylcarbonyl), H-6 (*N*-aminotetrahydropyridine)), 3.07 [t($J_{2,3}$ = 6 Hz), 4H, H-2 (*N*-tetrahydropyridylcarbonyl), H-2 (*N*-aminotetrahydropyridine)), 2.50–1.70 (complex m, 4H, H-3 (*N*-tetrahydropyridylcarbonyl), H-3 (*N*-aminotetrahydropyridine)). Exact mass calcd. for $C_{13}H_{19}N_3O_3$: 265.1426; found (high resolution ms): 265.1429. *Anal.* calcd. for $C_{13}H_{19}N_3O_3$: C 58.85, H 7.22, N 15.84; found: C 58.63, H 7.27, N 15.75.

Method B

To a solution of **4***a* (1.172 g, 4.46 mmol) in 95% ethanol (120 mL) pre-cooled to 0°C was added sodium borohydride (0.35 g). The reaction was allowed to proceed for 5 h at 0°C

with continuous stirring and then completed as described under the general procedure. The reaction product was purified by elution from a 2.5 cm × 18 cm neutral alumina column using ethyl acetate (700 mL) to give **4***b* (0.69 g, 58.4%); mp: 153–156°C; identical (ir) to the product prepared under method A.

N-[*4-(1-Methyl-1,2,3,6-tetrahydropyridyl)carbonylamino*]-*1,2,3,6-tetrahydropyridine* (**4***c*) *and* N-[*(1,2,3,6-Tetrahydropyridyl)*]-C-*methoxy*-C-[*4-(1-methyl-1,2,3,6-tetrahydropyridyl)*]*azomethine* (**7**)

Methyl iodide (10 mL) was added to a solution of **2***a* (5.0 g, 24.6 mmol) in dry methylene chloride (120 mL). The reaction was allowed to proceed for 4 h with stirring at 25°C prior to refluxing for an additional 4 h. Removal of the solvent *in vacuo* afforded a hygroscopic intense yellow solid which was dissolved in methanol (120 mL) and the solution cooled to −65°C. Sodium borohydride (1.8 g) was added in one aliquot and the reaction was allowed to proceed for 4 h at −65°C prior to completion as described under the general procedure. The reaction mixture was chromatographed using a 2.5 cm × 18 cm neutral alumina column. Elution with ether–methanol (10:1 v/v) (400 mL) gave **4***c* (1.289 g, 23.7%); mp: 119–122°C, ir: 3200 (m, NH) and 1665 (s, CO) cm^{-1}; ^1H nmr δ: 6.94 (s, 1H, NH, exchanges with deuterium oxide), 6.52 (m, 1H, H-5 (*N*-methyltetrahydropyridine)), 6.00–5.44 (m, 2H, H-4, H-5 (*N*-aminotetrahydropyridine)), 3.72–3.33 (m, 2H, H-6 (*N*-aminotetrahydropyridine)), 3.07 [t($J_{2,3}$ = 6 Hz), 4H, H-2 (*N*-aminotetrahydropyridine), H-6 (*N*-methyltetrahydropyridine)), 2.63–2.08 (complex m, 6H, H-3 (*N*-aminotetrahydropyridine), H-2, H-3 (*N*-methyltetrahydropyridine)), 2.38 (s, 3H, —CH_3). Exact mass calcd. for $C_{12}H_{19}N_3O$: 221.1529; found (high resolution ms): 221.1529.

Further elution with ether–methanol (5:1 v/v) (500 mL) gave a solid which was further purified by preparative tlc using twenty-four 20 cm × 20 cm silica gel GF 254 plates, 0.75 mm in thickness, with ethyl acetate – methanol (1:1 v/v) as development solvent. Extraction with warm methanol (200 mL) of the fraction having R_f 0.30 afforded **7** (0.987 g, 17.1%); mp: 133–136°C; ir: 1655 (s, C=N) cm^{-1}; ^1H nmr δ: 6.55 (m, 1H, H-5 (*N*-methyltetrahydropyridine)), 6.2–5.5 (m, 2H, H-4, H-5 (*N*-aminotetrahydropyridine)), 4.5–4.1 (m, 2H, H-6 (*N*-aminotetrahydropyridine)), 4.10–3.65 (m, 3H, H-6 (*N*-methyltetrahydropyridine)), 3.52 (s, 2H, —OCH_3), 3.11 (t($J_{2,3}$ = 5 Hz), 2H, H-2 (*N*-aminotetrahydropyridine)), 2.78–2.28 (complex m, 6H, H-3 (*N*-aminotetrahydropyridine), H-2, H-3 (*N*-methyltetrahydropyridine)), 2.39 (s, 3H, —N—CH_3). Exact mass calcd. for $C_{13}H_{21}N_3O$: 235.1684; found (high resolution ms): 235.1685.

N-*(1-Methoxycarbonyl-4-piperidylcarbonylamino)piperidine* (**10**)

Catalytic hydrogenation of **4***b* (1.572 g, 5.93 mmol) in methanol (120 mL) was effected using 10% palladium on charcoal (200 mg) and hydrogen gas at 40 psi for 12 h. The charcoal was removed by filtration and the recovered charcoal washed with methanol (30 mL). Removal of the solvent *in vacuo* gave a product which was purified by elution from a 2.5 cm × 20 cm neutral alumina column using ether–methanol (10:1 v/v) (600 mL) to afford **10** (1.321 g, 82.8%); mp: 160–162°C; ir: 3220 (m, NH), 1695, and 1655 (s, CO) cm^{-1}; ^1H nmr δ: 6.6 (s, 1H, NH, exchanges with deuterium oxide), 4.48–4.0 (m, 1H, H-4 (*N*-piperidylcarbonyl)), 3.75 (s, 3H, —OCH_3), 3.35–2.0 (complex m, 8H, H-2, H-6 (*N*-piperidylcarbonyl), H-2, H-6 (*N*-aminopiperidine)), 2.0–1.22 (complex m, 10H, H-3, H-5 (*N*-piperidylcarbonyl), H-3, H-4, H-5 (*N*-aminopiperidine)). Exact mass calcd. for $C_{13}H_{23}N_3O_3$: 269.1740; found (high resolution ms); 269.1744.

N-*(1-Methyl-4-piperidylcarbonylamino)piperidine* (**11**)

Catalytic hydrogenation of **4***c* (0.163 g, 0.738 mmol) in methanol (60 mL) was carried out in the presence of 10% palladium on charcoal (40 mg) and hydrogen gas at 40 psi for 12 h. The charcoal was removed by filtration and the recovered charcoal washed with methanol (30 mL). Removal of the solvent *in vacuo* afforded **11** (0.162 g, 97.6%); mp: (171–174°C; ir: 3215 (m, NH) and 1655 (s, CO) cm^{-1}; ^1H nmr δ: 6.48 (s, 1H, NH, exchanges with deuterium oxide), 3.70 (s, 1H, H-4 (*N*-methylpiperidine)), 3.30–2.37 (complex m, 8H, H-2, H–6 (*N*-methylpiperidine), H-2, H-6 (*N*-aminopiperidine)), 2.27 (s, 3H, —N—CH_3), 2.10–1.15 (complex m, 10H, H-3, H-5 (*N*-methylpiperidine), H-3, H-4, H-5 (*N*-aminopiperidine). Exact mass calcd. for $C_{12}H_{23}N_3O$: 225.1840; found (high resolution ms): 225.1840.

N-*(4-Piperidylcarbonylimino)pyridinium Ylide* (**12**)

To an ice-cooled solution of 2,4-dinitrophenylpyridinium chloride (3.33 g, 11.8 mmol) in methanol (30 mL) was added dropwise isonipecotic acid hydrazide (1.68 g, 11.8 mmol) in methanol (30 mL) and then triethylamine (1.0 mL). The reaction mixture was allowed to stand at room temperature overnight. The solid which precipitated was filtered off and washed in succession with 60 mL each of methanol, water, methanol, and ether. A suspension of the solid obtained above in dioxane–water (4:1) (200 mL) was heated under reflux for 12 h to afford a clear solution. The solvent was removed *in vacuo* below 55°C, water was added to the residue and the insoluble material removed by filtration. The filtrate was concentrated under reduced pressure to give **12**. Chromatography on a neutral alumina column (2.5 cm × 26 cm) using ether–methanol (1:1 v/v) (250 mL) as eluant afforded pure **12** (0.263 g, 10.9%); mp: 65–67°C; ^1H nmr δ: 8.5 (d($J_{2,3}$ = $J_{5,6}$ = 6 Hz) of d($J_{2,4}$ = $J_{4,6}$ = 1.5 Hz), 2H, H-2, H-6 (pyridinium)), 7.72–8.4 (m, 3H, H-3, H-4, H-5 (pyridinium)), 1.4–3.3 (complex m, 9H, piperidyl hydrogens), 3.7 (broad s, 1H, NH, exchanges with deuterium oxide). Exact mass calcd. for $C_{11}H_{15}N_3O$: 205.1136; found (high resolution ms): 205.1134.

N-*(4-Piperidylcarbonylamino)-1,2,3,6-tetrahydropyridine* (**13**)

Sodium borohydride (50 mg) was added to a solution of 95% ethanol (20 mL) pre-cooled to 0°C. A solution of **12** (0.11 g, 0.539 mmol) in 95% ethanol (20 mL) was added dropwise during 20 min. After stirring for 4 h at 0°C the reaction mixture was poured onto crushed ice (75 mL) and allowed to come to room temperature. Extraction with chloroform (4 × 40 mL), drying ($NaSO_4$), and removal of the solvent *in vacuo* gave **13** as a white solid (97 mg, 86.5%); mp: 68–71°C; ir: 3200 (m, NH) and 1665 (s, CO) cm^{-1}; ^1H nmr δ: 5.7 (m, 2H, H-4, H-5 (tetrahydropyridine)), 4.2 (s, 1H, NH, exchanges with deuterium oxide), 1.4–3.8 (complex m, 15H, remaining tetrahydropyridyl and piperidyl hydrogens). Picrate derivative; mp: 82°C. *Anal.* calcd. for $C_{11}H_{19}N_3O$·picrate: C 46.58, H 5.06; found: C 46.36, H 5.02.

Binuclear palladium complexes of 3,5-disubstituted pyrazoles

J. POWELL[1] AND A. KUKSIS

Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received April 25, 1979

J. POWELL and A. KUKSIS. Can. J. Chem. **57**, 2986 (1979).

A series of binuclear palladium 3,5-disubstituted pyrazole complexes of the general formulation $[(CH_{3-n}X_nCO_2)(pzH)Pd(\mu\text{-}pz)]_2$ where pz = 3,5-dimethyl or 3,5-diphenylpyrazole, X = F, Cl, Br, C_6H_5, n = 0–3, were prepared. These complexes are unique in that they contain both bridging pyrazolyl and monodentate pyrazole groups.

J. POWELL et A. KUKSIS. Can. J. Chem. **57**, 2986 (1979).

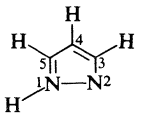
On a préparé une série de complexes binucléaires palladium-pyrazoles disubstitués en position 3 et 5 de formule générale $[(CH_{3-n}X_nCO_2)(pzH)Pd(\mu\text{-}pz)]_2$ où pz = diméthyl-3,5 ou diphényl-3,5 pyrazoles, X = F, Cl, Br, C_6H_5, n = 0–3. Ces complexes sont uniques par le fait qu'ils contiennent à la fois un pyrazole agissant comme pont et un pyrazole monodentate.

[Traduit par le journal]

Introduction

Recently much effort has been devoted to the preparation of soluble transition metal complexes which may serve as models for metal surfaces (1). Bimetallic complexes in which two metals are held rigid and close together by bridging ligands are an obvious starting point for this study.

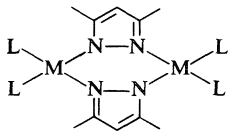
Pyrazole is a thermally and hydrolytically very stable, white crystalline solid. As a ligand it coordinates to metals through the 2-N. When deprotonated, pyrazole becomes the pyrazolide ion which can coordinate through both nitrogens as an exobidentate ligand of C_{2v} symmetry.



Pyrazole

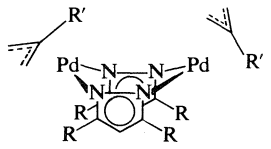
Pyrazolide ion

Coordination of the nitrogens to a single given metal is impossible because of molecular geometry and as a result metallocycles of general structure **I** are formed (2).



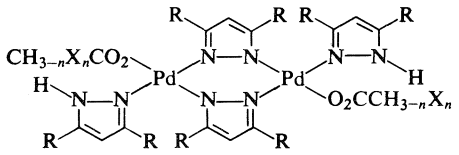
I
M = Rh
L = CO

Since the appearance of Trofimenko's review (3) on the coordination chemistry of pyrazole-derived ligands in 1972, many papers reporting the synthesis of 2-monohaptopyrazole and 1,2-dihaptopyrazolide metal or metalloid complexes have been published. In 1975 Coletta *et al.* (4) reported the synthesis of several compounds of the type $[M(pyrazole)_nX_m]$, where X = univalent anion = Cl, Br, M = Pd or Pt, n = 2, 4, m = 2. In 1971 Trofimenko (2) reported the reaction of 3,5-dimethylpyrazolide ion with $[\pi\text{-}CH_2C(C_6H_5)CH_2PdCl]_2$. A colourless solid was isolated which on the basis of elemental analysis, ^1H nmr spectra, and molecular weight studies was assigned structure **II**. Molecular models indicate the metallocycle ring to be in the puckered boat form rather than planar. Minghetti *et al.* reported the preparation of the trimeric gold(I) pyrazolide, $[Au(\mu\text{-}C_3N_2H_3)]_3$, in 1979 (5).



II
R = CH_3
R′ = C_6H_5

In this paper we report the preparation of a series of binuclear palladium 3,5-disubstituted pyrazole complexes believed to have structure **III**. These complexes are unique in that they contain both bridging pyrazolyl and monodentate pyrazole groups.



III

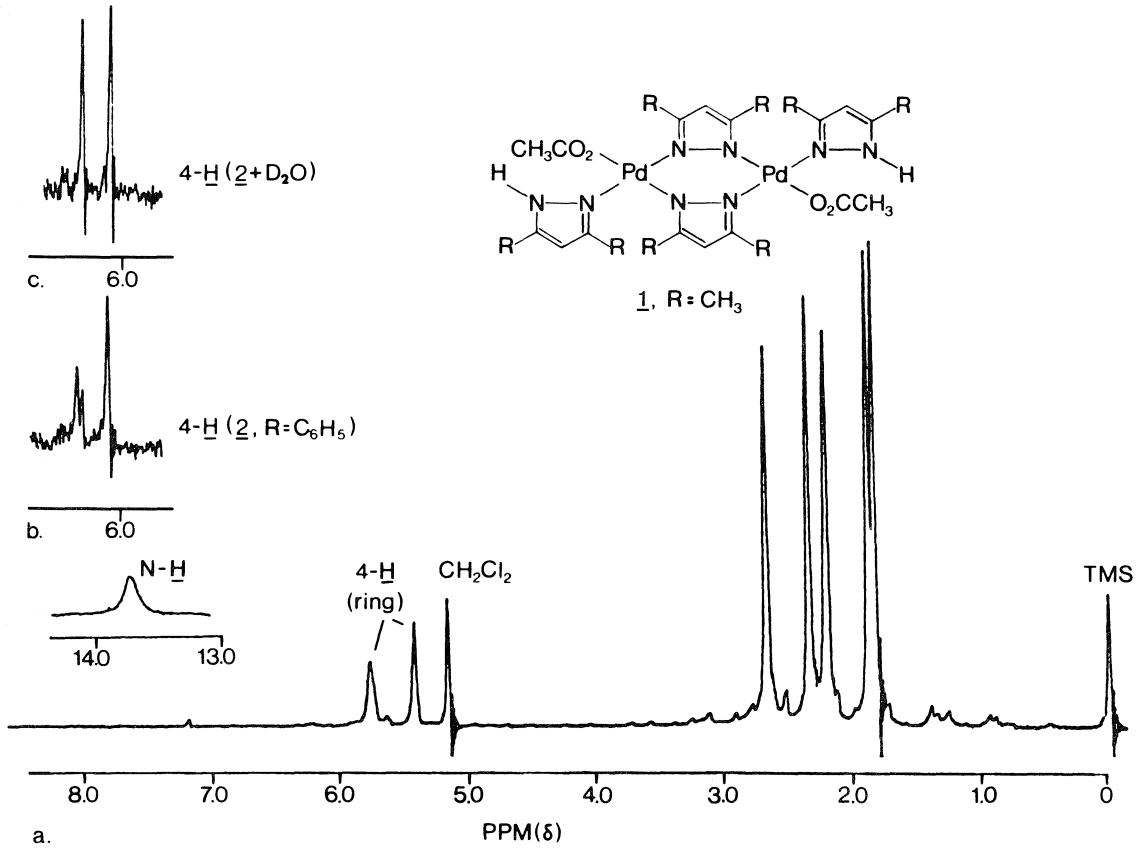

FIG. 1. (*a*) The ^{1}H nmr spectrum of $[(CH_3CO_2)(3,5\text{-dmpH})Pd(\mu\text{-}3,5\text{-dmp})]_2$, **1**, $CDCl_3$ solution. (*b*) The ^{1}H nmr spectrum of $[(CH_3CO_2)(3,5\text{-dppH})Pd(\mu\text{-}3,5\text{-dpp})]_2$, **2**, in the region 6.10–6.35 ppm, $CDCl_3$ solution. The 2:1:1 pattern for the 4-H pyrazole ring protons is more clearly resolved than in the ^{1}H nmr spectrum of **1**. (*c*) Treatment of the $CDCl_3$ solution of **2** with D_2O results in the collapse of the 2:1:1 splitting pattern of the 4-H pyrazole ring protons to two singlets of equal intensity.

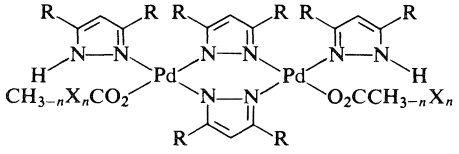
Results and Discussion

Addition of 3,5-dimethylpyrazole (3,5-DMP) to a deep orange dichloromethane solution of palladium(II) acetate

$$Pd(O_2CCH_3)_2 + 2(3,5\text{-DMP}) \xrightarrow{CH_2Cl_2} \underset{\mathbf{1}}{\text{yellow powder}}$$

yielded a yellow solution from which a yellow powder, **1**, was isolated. On the basis of ^{1}H nmr, ir spectra, and elemental analysis, a compound having structure **III** is proposed, where R = CH_3, n = 0, a metallocycle, in which the ring is in the puckered boat form rather than planar and the acetate groups are *trans*. Structure **IV** is however a possible alternative.

Both structures would be expected to show five methyl resonances of equal intensity in their ^{1}H nmr spectra and five sharp singlets in the ratio 1:1:1:1:1 are observed in the region 1.80–2.65 ppm (Fig. 1*a*). Structures **III** and **IV** should be distinguishable on the basis of the number of peaks corresponding to the 4-H on the 3,5-dimethylpyrazole ring. One would expect to see two singlets in the ratio 2:2 in the case of structure **III** and three singlets in the ratio 2:1:1 in the case of structure **IV**. Two distinct peaks are



IV

R = CH_3, X = F, Cl, Br, n = 0–3
R = C_6H_5, X = Cl, n = 0, 1
R = H, n = 0

observed in the region 5.20–5.80 ppm, a sharp singlet of relative intensity 2 at 5.40 ppm and a broader,

slightly split peak of relative intensity 2 at 5.75 ppm. A more clearly resolved 2:1:1 pattern for the 4-H pyrazole ring protons is observed in the ^{1}H nmr spectrum of $[(CH_3CO_2)(3,5\text{-dppH})Pd(\mu\text{-dpp})]_2$, **2**, where 3,5-dpp = 3,5-diphenylpyrazole (Fig. 1*b*). On the basis of these observations structure **IV**, having *cis* acetate groups, may be assigned. However, splitting of the peak at 5.75 ppm may be due to long range coupling between the 4-H and the N—H proton of the terminal pyrazole groups. This type of interaction of the N—H proton with the other ring protons has been found to complicate the ^{1}H nmr spectra of substituted pyrroles (6). The ^{1}H nmr spectrum of a D_2O treated $CDCl_3$ solution of **2** showed only two sharp singlets of equal intensity in the region 6.10–6.35 ppm (Fig. 1*b*). Treatment of a $CDCl_3$ solution of **1** with D_2O resulted in a sharpening of the signal at 5.75 ppm. In both spectra the signals due to the N—H protons had disappeared indicating that deuterium–hydrogen exchange had occurred. These observations demonstrate conclusively that the splitting of the 4-H pyrazole ring protons is due to long range coupling with the N—H proton. On the basis of these results compound **1** is assigned structure **III**, the *trans* orientation is presumably favoured on steric grounds. The signal due to the N—H proton occurs much farther downfield at 13.60 ppm as a broad singlet.

The ir spectrum of compound **1** in a KBr pellet shows two strong, broad bands in the 1570–1630 cm^{-1} and 1360–1470 cm^{-1} regions which are assigned to ν(C═O) and ν(C—O), respectively. These carboxyl stretching frequencies are characteristic of unidentate acetate complexes (7). Due to the broad nature of the N—H stretches, it is not possible to determine from the ir spectra whether hydrogen bonds of different types are present.

Reaction of compound **1** with CCl_3COOH, $CHCl_2COOH$, $CH_2ClCOOH$, CBr_3COOH, CF_3COOH, and $(C_6H_5)COOH$ gave complexes **3**–**8** (see Table 1) as yellow powders. In all cases the methyl resonance at 1.80 ppm in the ^{1}H nmr spectrum disappeared. Except for the appearance of the peaks due to ClH_2C—, Cl_2HC—, C_6H_5— and slight shifts in the position of the N—*H* signal, the remainder of the ^{1}H nmr spectra of **3**–**8** is little changed from that of **1**. ^{1}H nmr and ir spectral data for these compounds are given in Table 1.

Compounds **3**–**8** were the products of simple metathetical reactions in which the acetate groups of compound **1** were replaced with other substituted acetate groups. Compounds **3**–**8** should also be attainable from the reaction of 3,5-dimethylpyrazole with the corresponding palladium(II) carboxylate. Reaction of 3,5-DMP with $Pd(O_2C(C_6H_5))_2$ and $Pd(O_2CCH_2Cl)_2$ gave orange oils as products which were not characterized further. When $Pd(O_2CCH_3)_2$ was reacted with pyrazole an insoluble white solid which analysed as $Pd_2C_{16}H_{20}N_8O_4$, $[(CH_3COO_2)(pzH)Pd(\mu\text{-pz})]_2$, **9**, where pz = pyrazole, was obtained. Reaction of $Pd(O_2CCH_3)_2$ with 3,5-diphenylpyrazole gave complex **2** as a yellow powder, structurally analogous to the product of the reaction with 3,5-dimethylpyrazole (see Fig. 1*b*).

The puckered boat form of the metallocycle ring is suggested as the sterically most favourable structure. Binuclear complexes containing coplanar pyrazolide rings have however been reported. The X-ray crystal structure of $[(\eta^5\text{-}C_5H_5)_2Ti(pz)_2]_2$, where pz = pyrazole, shows the compound to have two coplanar pyrazolide anions bridging the two titanium atoms. The four nitrogens from the pyrazolide groups and the titanium atoms form a six membered ring which is in a chair configuration, the metal atoms lying above and below the plane of the pyrazolide rings. The coplanarity of the pyrazolide groups is apparently enforced by the cyclopentadienyl rings which hinder tilting of the pyrazolide groups relative to their observed positions (8).

The metallocycle ring in these palladium complexes is stereochemically rigid. None of the compounds had temperature dependent ^{1}H nmr spectra. Consistent with a rigid boat conformation of the $Pd_2(\mu\text{-}C_5N_2H_7)_2$ ring, the complex $[Pd_2(\mu\text{-}3,5\text{-}dmp)_2Cl_2(PMe_2Ph)_2]$, where PMe_2Ph = dimethylphenylphosphine, exhibits diastereotopic phosphine methyl groups in its ^{1}H nmr spectrum which do not site exchange at temperatures as high as 190°C (9).

The absence of further polymerisation in these compounds (i.e. formation of complexes of the type $[Pd(pyrazole)_2]_n$) may be attributed to hydrogen bonding between N—H and O—$\overset{\overset{O}{\|}}{C}CH_{3-n}X_n$. Without "endcapping" groups on the metal, 1,2-dihapto-pyrazolides of transition metals usually form a polymeric chain (2).

Experimental

All compounds are air stable. Microanalyses were performed by Microanalyses Lab., Toronto and Canadian Microanalytical Service Ltd. Melting points were determined on a Kofler Hotstage and are uncorrected. 3,5-Dimethylpyrazole was purchased from Aldrich Chemical Co. 3,5-Diphenylpyrazole was prepared by a published method (10). Infrared spectra were obtained as KBr pellets using a Unicam SP 1025 Infrared Spectrophotometer. ^{1}H nmr spectra were recorded on a Varian T60 NMR spectrometer.

Method of Preparation

Bis(1,2-dihapto-3,5-dimethylpyrazolido)bis(acetato)bis(3,5-dimethylpyrazole)dipalladium(II), 1

To 0.84 g (3.74 mmol) palladium(II) acetate dissolved in dichloromethane was added 0.74 g (7.48 mmol) 3,5-dimethylpyrazole. The deep orange solution slowly became yellow. After stirring overnight the solution was diluted with hexane

The photoinitiated isomerization and addition reactions of liquid 2-butenes in the presence of hydrogen sulfide

FRANÇOIS-XAVIER GARNEAU AND IRENEUSZ SZCZEREK

Université du Québec à Chicoutimi, Département des Sciences Pures, Chicoutimi (Qué.), Canada G7H 2B1

Received November 28, 1978[1]

FRANÇOIS-XAVIER GARNEAU and IRENEUSZ SZCZEREK. Can. J. Chem. **57**, 2991 (1979).

The near ultraviolet photolysis ($\lambda > 280$ nm) of liquid *cis*-2-butene in the presence of hydrogen sulfide was shown to result in isomerization and addition reactions. The former was monitored by the formation of *trans*-2-butene as a function of time and hydrogen sulfide concentration. The latter was observed by the presence of *s*-butyl mercaptan and di-*s*-butyl sulfide as products. The total amount of addition products as well as the relative amounts of mercaptan and sulfide were determined as a function of time. Using the foregoing information the extent of the isomerization reaction was shown to be greater than that of the addition reaction during the course of the irradiation at a concentration ratio of H_2S/*cis*-2-butene equal to 0.15.

It was also shown that hydrogen sulfide was a more effective sensitizer than *s*-butyl mercaptan and di-*s*-butyl sulfide but less effective than di-*s*-butyl disulfide in the isomerization of liquid *cis*-2-butene. The extent of isomerization and addition reactions were shown to be greater starting with *cis*-2-butene than with *trans*-2-butene in the presence of hydrogen sulfide.

FRANÇOIS-XAVIER GARNEAU et IRENEUSZ SZCZEREK. Can. J. Chem. **57**, 2991 (1979).

Des réactions d'isomérisation et d'addition ont été observées lors de la photolyse dans le proche uv ($\lambda > 280$ nm) du *cis*-butène-2 avec le sulfure d'hydrogène en phase liquide. L'isomérisation a été suivie par la formation du *trans*-butène-2 en fonction du temps et de la concentration du sulfure d'hydrogène. La formation du mercaptan de butyl-secondaire et du sulfure de di-butyl-secondaire comme produits témoigne d'une réaction d'addition. Les quantités totales des produits d'addition ainsi que leur quantité relative ont été mesurées en fonction du temps. A l'aide de ces données, nous avons montré que l'étendue de la réaction d'isomérisation est plus importante que celle de la réaction d'addition au cours de la photolyse avec un rapport de concentration H_2S/*cis*-butène-2 égal à 0.15.

En outre, le sulfure d'hydrogène s'est avéré un sensibilisateur plus efficace que le mercaptan de butyl-secondaire et le sulfure de di-butyl-secondaire mais moins efficace que le disulfure du dibutyl-secondaire dans l'isomérisation du *cis*-butène-2 liquide. Les réactions d'isomérisation et d'addition sont plus rapides en partant avec le *cis*-butène-2 que le *trans*-butène-2 en présence du sulfure d'hydrogène.

Introduction

The photoinitiated reactions of sulfur compounds with olefins has been the subject of a large number of studies (1). Initially most of the work reported was concerned with the addition reactions of sulfur compounds such as hydrogen sulfide, mercaptans, and disulfides with olefins (2). In these cases fairly high concentrations of the sulfur compounds were used. Subsequently, it was observed that an important isomerization reaction occurred with olefins whose structures permitted the existence of *cis* and *trans* isomers (3). The abstraction of hydrogen atoms by thiyl radicals has also been reported (4).

Collin *et al.* have shown that hydrogen sulfide and mercaptans are indeed very effective sensitizers of isomerization (no addition products were detected) in the far uv gas phase photolysis (5) and, when in low concentrations of hydrogen sulfide, in the liquid phase radiolysis and photolysis of *cis*- and *trans*-2-butene (6). In this paper we report the details of our study on the near uv ($\lambda > 280$ nm) liquid phase photolysis of *cis*- and *trans*-2-butene in the presence of low concentrations of hydrogen sulfide and to a comparison of the extent of isomerization and addition reactions.

Experimental

Chemicals

cis-2-Butene (99.5%), *trans*-2-butene (99.0%), hydrogen sulfide (99.5%), and isobutylene (99.8%) (Matheson of Canada Ltd.) were used as received after being degassed. *cis*-2-Butene contained *trans*-2-butene (0.50%) and 1,3-butadiene ($\simeq$ 110 ppm). *trans*-2-Butene contained *cis*-2-butene (0.35%) and 1,3-butadiene ($\simeq$ 210 ppm). *s*-Butyl mercaptan (bp 84–85°C), di-*s*-butyl sulfide (bp 160–162°C), and di-*s*-butyl disulfide (bp 92–94°C/8 mm) were prepared using the methods described by Vogel (7). Trichloroacetyl isocyanate (Eastman Kodak) was used as received.

Apparatus

The light source was a Hanovia 450 W high pressure mercury-vapor lamp. The samples were prepared in a Pyrex tube fitted with a high-vacuum stopcock using a mechanical – oil

[1]Revision received July 31, 1979.

0008-4042/79/222991-05$01.00/0

diffusion pump system with Teflon stopcocks which was capable of maintaining a vacuum of about 10^{-5} mm mercury. Pressure measurements were made using a metallic membrane manometer (Wallace and Tiernan). The gaseous samples were liquified in the tube using liquid nitrogen. The liquid occupied from 50–75% of the volume of the tube. Only the liquid phase was irradiated.

The irradiations were carried out at room temperature (20°C). Based on the number of moles of *cis*-2-butene and hydrogen sulfide introduced into the tube, the volumes of the liquid and gas phases, and the total pressure of the mixture measured at 20°C, the quantity of hydrogen sulfide in the liquid phase is estimated to be equal to or slightly greater than 90% of the amount added to the tube.

Analysis

The isomerization of *cis*- and *trans*-2-butene was followed by gas chromatography using a 1.5 m × 2.3 mm id *n*-octane/Porasil C "Durapak" column and a hydrogen flame ionization detector.

The presence of hydrogen sulfide after photolysis was detected by the formation of a black precipitate (PbS) with lead acetate and by the formation of sulfur on reaction with a solution of iodine and potassium iodide.

The extent of the addition reaction in the *cis*- and *trans*-2-butenes with hydrogen sulfide system was followed by the disappearance of the hydrogen sulfide. The latter was determined by cooling the reaction mixture in an icebath and allowing the hydrogen sulfide and the 2-butene to pass into a standard acidified iodine – potassium iodide solution (the 2-butene did not react with the KI_3 solution under our conditions). The excess iodine was then titrated with a standard sodium thiosulfate solution.

The two addition products were obtained on evaporation of the gaseous butenes and hydrogen sulfide and were separated from each other by treatment with aqueous sodium hydroxide followed by extraction. They were purified by fractional distillation and were identified by comparison with authentic materials. The structure of the mercaptan was confirmed by the technique of Butler and Mueller (8). A very small amount (~ 0.01% of the addition product mixture) of another substance was detected by gas chromatography and its retention time corresponded to that of di-*s*-butyl disulfide, a possible product in our reaction system.

The variations in the relative amounts of the mercaptan and sulfide formed on irradiation were followed by gas chromatography using 2 m silicone gum 10% UC-W98 column and a hydrogen flame ionization detector.

Results and Discussion

An examination of the reaction mixture resulting from the liquid-phase photolysis ($\lambda > 280$ nm) of *cis*-2-butene and 15% hydrogen sulfide showed the presence of *cis*- and *trans*-2-butenes, *s*-butyl mercaptan, di-*s*-butyl sulfide, and unreacted hydrogen sulfide.

Isomerization Reaction

The isomerization of *cis*-2-butene in the presence of hydrogen sulfide was followed by the variation of the *trans*/(*cis* + *trans*) ratio as a function of time (Fig. 1). The isomerization to *trans*-2-butene occurred rapidly in the initial stages of the photolysis but then decreased in rate as an equilibrium mixture of ca.

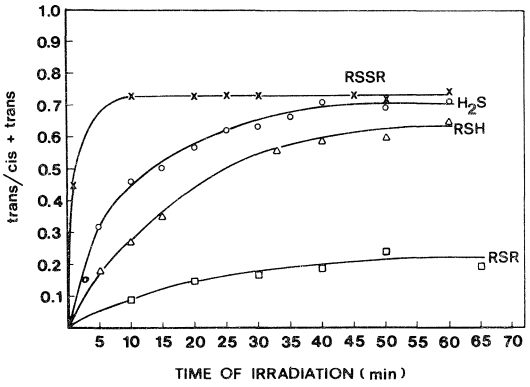

FIG. 1. Photolysis of *cis*-2-butene in the presence of 15% of various sulfur compounds: ×, di-*s*-butyl disulfide; ○, hydrogen sulfide; △, *s*-butyl mercaptan; □, di-*s*-butyl sulfide. The variation of the *trans*/(*cis* + *trans*) ratio vs. the irradiation time. R = *s*-butyl.

70% *trans* and 30% *cis* was approached. An increase in the relative concentration of hydrogen sulfide to *cis*-2-butene was observed to lead to a corresponding increase in the amount of *trans*-2-butene formed (Fig. 2). A concentration ratio of $H_2S/cis\text{-}C_4H_8$ of 0.35 led to the equilibrium mixture in 15 min of irradiation compared to about 40 min with a 0.15 concentration ratio (Fig. 1). That the equilibrium state is reached more rapidly at higher hydrogen sulfide concentrations is clearly shown in Fig. 3 and would be due to an increase of absorption of light by hydrogen sulfide. It is unlikely that the isomerization is due to a photosensitization by the triplet state of hydrogen sulfide for the following reasons: (*1*) hydrogen sulfide is not known to be a good triplet sensitizer of the isomerization *cis–trans* of 2-butenes, (*2*) a mechanism via the triplet state should lead to a photostationary ratio close to 1.0 based on the trends observed in previous studies and the triplet energy of hydrogen sulfide, E_t = 133 kcal/mol (10,

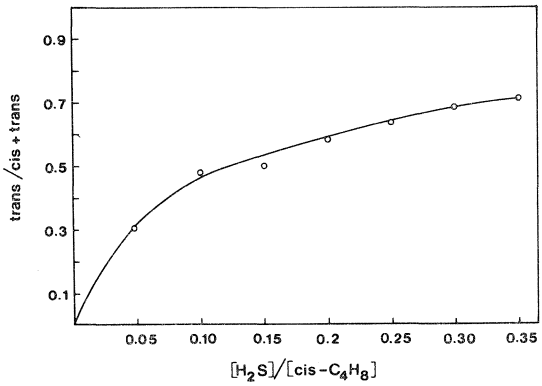

FIG. 2. Photolysis of *cis*-2-butene in the presence of hydrogen sulfide. The variation of the *trans*/(*cis* + *trans*) ratio vs. hydrogen sulfide concentration. Irradiation time 15 min.

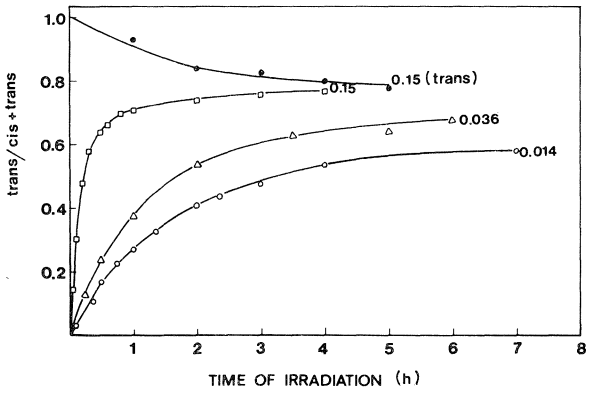

FIG. 3. Photolysis of *cis*- and *trans*-2-butene in the presence of hydrogen sulfide. The variation of the *trans*/(*cis* + *trans*) ratio vs. irradiation time at one concentration ratio (0.15) of hydrogen sulfide (●) in the *trans*-2-butene system and at three concentration ratios of hydrogen sulfide in the *cis*-2-butene system: □, 0.15; △, 0.036; ○, 0.014.

11), and (*3*) even though no actinometry was carried out, the large amount of *trans* isomer formed in our system is indicative of a high quantum yield (> 10) as would be the case in a chain process but would not be the case in a process involving triplet sensitization.

Addition Reaction

The isomerization reaction was accompanied by an addition reaction as shown by the formation of *s*-butyl mercaptan and di-*s*-butyl sulfide as the main products. These two compounds are presumably formed by the addition via thiyl radicals of hydrogen sulfide and mercaptan respectively to the 2-butenes. The extent of the addition reaction was determined by following the disappearance of hydrogen sulfide as a function of time (Fig. 4). As in the isomerization reaction, the addition occurred rapidly in the early stages of the photolysis and then tapered off on continued irradiation and in the presence of decreasing quantities of hydrogen sulfide. After 2 h of irradiation, about 87% of the hydrogen sulfide had disappeared from the reaction system.

The relative quantities of the two main addition products were determined as a function of the time of irradiation for the reaction systems hydrogen sulfide + *cis*-2-butene and *s*-butyl mercaptan + *cis*-2-butene (Fig. 5). The levelling off of the ratio RSH/(RSH + RSR) with increasing time of irradiation indicates that the mercaptan (RSH) can arise at least in part by a secondary pathway. At least two explanations may be suggested for the initial decrease of the *s*-butyl mercaptan (RSH): on the one hand it may absorb the light and decompose to RS + H or R + SH (1), and in addition it may participate in a (some) reaction(s) of the type

[1] $R + RSH \rightarrow RH + RS$

It should be noted that the lower curve (RSH + *cis*-2-butene system) represents experiments where the mercaptan was added to the butene. Thus this lower curve shows its subsequent transformation to sulfide. The upper curve corresponds to experiments where hydrogen sulfide was the added sulfur compound. In this case RSH the mercaptan is a product.

The Radical Nature of the Reactions

The radical nature of the isomerization and addition reactions was shown in the following manner:

(*1*) The absence of isomerization and addition products when a small amount of oxygen, a well-known radical scavenger, was introduced.

(*2*) The increase in the rate of isomerization on addition of acetone (H_2S/acetone: 1/1). After 5 min irradiation, the *trans*/(*cis* + *trans*) ratio was 0.63 and

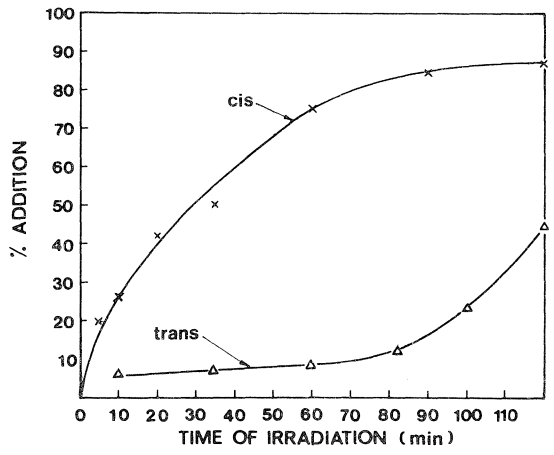

FIG. 4. Photolysis of *cis*- and *trans*-2-butene in the presence of 15% hydrogen sulfide. The variation of the % addition reaction (% hydrogen sulfide reacted) vs. the irradiation time (min).

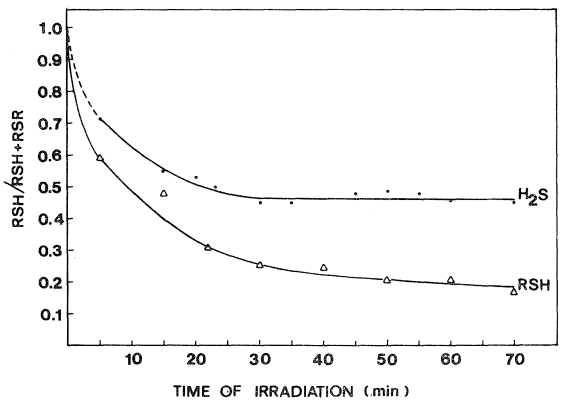

FIG. 5. Photolysis of *cis*-2-butene in the presence of 15% hydrogen sulfide (●) and 15% *s*-butyl mercaptan (△). The variation of the mercaptan/(mercaptan + sulfide) ratio vs. the irradiation time (min). R = *s*-butyl.

TABLE 1. A comparison of the photoinitiated isomerization and addition reactions of hydrogen sulfide with *cis*-2-butene in the liquid phase[a]

Irradiation time (min)	Amount of H_2S reacted (mmol)	% of *trans*-2-butene formed	RSH[b] / RSH + RSR	Amount of butenes remaining (mmol)	Amount of *trans*-2-butene (mmol)	Isomerization / Addition
5	0.20	32	0.70	6.40	2.05	10.25
10	0.26	46	0.64	6.30	2.90	11.15
20	0.42	57	0.50	6.03	3.44	8.19
35	0.51	66	0.45	5.87	3.87	7.59
60	0.75	71	0.45	5.50	3.91	5.21

[a]1 mmol of hydrogen sulfide and 6.66 mmol of *cis*-2-butene.
[b]R = *s*-butyl.

the equilibrium value was reached after 10 min as compared to 40 min in the absence of acetone. This can be explained by the more efficient production of HS radicals due to the greater absorption coefficient of acetone which leads to an increase in the formation of methyl radicals in the following manner:

[2] $CH_3COCH_3 + h\nu \rightarrow CH_3CO + CH_3$

[3] $CH_3 + H_2S \rightarrow CH_4 + HS$

The photostationary ratio of 2.3 observed in our system would militate against acetone triplet sensitization as the only mechanism of isomerization although its partial involvement cannot be excluded (12).

(*3*) The formation of isobutylsulfide (identified by its nmr spectrum) as the only addition product in the photolysis of liquid isobutylene in the presence of hydrogen sulfide under the same conditions. An ionic mechanism would have resulted in the formation of *tert*-butylsulfide, the Markownikoff addition product (1, 2).

Influence of Additives

As the addition products were formed during the course of the isomerization reaction, the influence of the former on the latter was compared to the reaction with hydrogen sulfide (Fig. 1). As expected, considering the dissociation energies of the bonds involved and the absorption coefficients of the compounds (9), the disulfide proved to be the most effective sensitizer for the isomerization reaction under our conditions. *s*-Butyl mercaptan was slightly less effective than H_2S and the sulfide was the poorest sensitizer of the compounds studied.

Comparison of Isomerization and Addition Reactions

The extent of isomerization was compared to that of addition in the reaction system *cis*-2-butene and hydrogen sulfide (Table 1). The extent of the isomerization reaction is slightly more than ten times that of the addition reaction in the early stages of the photolysis and then decreases as the equilibrium mixture of *cis* and *trans* is reached.

Photolysis of trans-*2-Butene*

The isomerization and addition reactions of *trans*-2-butene with hydrogen sulfide were examined as a function of time (Figs. 3 and 4). As in the case of the radiolysis of liquid *trans*-2-butene (6), isomerization occurred at a slower rate than that of *cis*-2-butene. A similar situation was observed in the case of the addition reaction (Fig. 4).

The presence of a larger quantity of 1,3-butadiene as an impurity in the *trans* as compared to the *cis* does not appear to explain the difference in the rate of isomerization as the introduction of maleic anhydride, an often used dienophile in Diels–Alder reactions, to the *trans* + hydrogen sulfide system did not have any significant effect. The rate is either influenced by the rotation barrier of the intermediate formed by the addition of the HS radical to the 2-butene (13) or the limiting step is rather the addition itself of the thiyl radical to the 2-butene (5).

In regard to the addition reaction of *trans*-2-butene with hydrogen sulfide (Fig. 4), an essentially stationary situation was observed to prevail for approximately 1 h after the initial 10 min of irradiation followed by a gradual increase in the extent of addition.

Acid catalysis in the gas phase: dissociative proton transfer to formate and acetate esters

A. C. HOPKINSON, G. I. MACKAY, AND D. K. BOHME

Department of Chemistry, York University, Downsview, Ont., Canada M3J 1P3

Received March 16, 1979

A. C. HOPKINSON, G. I. MACKAY, and D. K. BOHME. Can. J. Chem. **57**, 2996 (1979).

The flowing afterglow and selected ion flow tube techniques are employed in gas-phase measurements of the intrinsic kinetics of protonation of methyl formate, *n*-propyl formate, ethyl acetate, and *n*-propyl acetate and subsequent fragmentation according to

$$AH^+ + RCOOR' \rightarrow RCOO(R')H^+ + A \begin{cases} \rightarrow RCO^+ + R'OH \\ \rightarrow RCOOH + R'^+ \end{cases}$$

with R = H and CH_3, R′ = CH_3, C_2H_5, and $(CH_2)_2CH_3$, and A = H_2, CH_4, CO, and H_2O. Protonation by the acids, AH^+, with relative strengths spanning a range of 65 kcal mol^{-1}, is observed to proceed extremely rapidly with rate constants at 299 ± 2 K encompassing values of 2.9 to 8.5 × 10^{-9} cm^3 $molecule^{-1}$ s^{-1}. Fragmentation is observed for $HCOOCH_3$ only with the strongest acid, H_3^+, to produce $CH_3OH_2^+$. For $HCOO(CH_2)_2CH_3$, fragmentation is observed to produce $C_3H_7^+$ with H_3O^+, and also $HCOOH_2^+$ with H_3^+. Little fragmentation of $CH_3COOC_2H_5$ occurs with H_3O^+ but with H_3^+ the major product is $CH_3COOH_2^+$ with smaller amounts of CH_3CO^+ and $C_2H_5^+$. Proton transfer from H_3O^+ to $CH_3COO(CH_2)_2CH_3$ results in considerable dissociation to form $CH_3COOH_2^+$. The fragmentation of these esters is discussed in terms of known reaction energetics and in terms of mechanisms for unimolecular acyl–oxygen, $A_{Ac}1$, and alkyl–oxygen, $A_{Al}1$, fission often invoked for analogous reactions in solution as well as modifications of these mechanisms which have been proposed in the context of recent gas-phase measurements.

A. C. HOPKINSON, G. I. MACKAY et D. K. BOHME. Can. J. Chem. **57**, 2996 (1979).

On a utilisé les techniques de la lueur d'écoulement et du tube à écoulement d'ions pour mesurer en phase gazeuse, la cinétique intrinsèque de la protonation des formates de méthyle et de *n*-propyle des acétates d'éthyle et de *n*-propyle suivi d'une fragmentation se produisant d'après le schéma suivant:

$$AH^+ + RCOOR' \rightarrow RCOO(R')H^+ + A \begin{cases} \rightarrow RCO^+ + R'OH \\ \rightarrow RCOOH + R'^+ \end{cases}$$

dans lequel R = H et CH_3, R′ = CH_3, C_2H_5 et $(CH_2)_2CH_3$, et A = H_2, CH_4, CO et H_2O. On a observé que la protonation par les acides AH^+ ayant une force relative s'étendant sur une échelle de 65 kcal mol^{-1} est extrêmement rapide avec une constante de vitesse à 299 ± 2 K qui englobe des valeurs allant de 2.9 à 8.5 × 10^{-9} cm^3 $molécule^{-1}$ s^{-1}. On observe la fragmentation du CH_3COOH qu'en présence de l'acide le plus fort, H_3^+, et il se produit des $CH_3OH_2^+$. La fragmentation $CH_3(CH_2)_2COOH$ produit du $C_3H_7^+$ lors de la protonation par H_3O^+ et également du $HCOOH_2$ lors de la protonation par H_3^+. Il ne se produit que peu de fragmentation du $CH_3COOC_2H_5$ si on utilise H_3O^+ toutefois avec H_3^+ le produit principal est $CH_3COOH_2^+$ avec des quantités plus faibles de CH_3CO^+ et de $C_2H_5^+$. Le transfert de proton de H_3O^+ à $CH_3(CH_2)_2COOH$ conduit à une dissociation considérable provoquant la formation de $CH_3COOH_2^+$. On discute de la fragmentation de ces esters en termes des énergies connues des réactions et en termes des mécanismes unimoléculaires de fission oxygène–acyle, $A_{Ac}1$, et oxygène–alkyle $A_{Al}1$ auxquels on fait souvent appel pour les réactions analogues en solutions ainsi qu'à des modifications de mécanismes qui ont été proposés dans le contexte de mesures récentes en phase gazeuse.

[Traduit par le journal]

Introduction

We have recently initiated an experimental program designed to explore, in a systematic manner, the kinetics of the gas-phase fragmentation of protonated molecules, BH^+, which have been activated by proton-transfer reactions of the type

[1] $AH^+ + B \rightarrow [BH^+]^* + A$

The flowing afterglow technique employed in these investigations allows the deliberate alteration of the identity of AH^+ and thus the overall exothermicity of this process (1). The ensuing fragmentation

[1*a*] $[BH^+]^* \rightarrow$ products

may thus be followed as a function of the degree of chemical activation of BH^+, at least to the extent to

0008-4042/79/222996-09$01.00/0

which changes in overall exothermicity alter the excess energy deposited in this ion.[1] In an earlier study (3*a*) we reported the intrinsic kinetics of the protonation of formic and acetic acid and the ensuing formation of acylium ions according to dissociative proton transfer of the type

[2] $AH^+ + RCOOH \rightarrow [RCOOH_2^+]^* + A$

[2*a*] $[RCOOH_2^+]^* \rightarrow RCO^+ + H_2O$

with R = H, CH_3, and acids AH^+ whose relative strengths spanned a range of 65 kcal mol^{-1}. These carboxylic acids are members of a larger group of molecules of the type

[3] 
which, when protonated, may undergo heterolysis in one of two ways commonly invoked to explain their cleavage in concentrated acid solutions (4–6): unimolecular acyl–oxygen fission, $A_{Ac}1$, according to

[4] 
or unimolecular alkyl–oxygen fission, $A_{Al}1$, according to

[5] 
The preferred route of cleavage in solution appears to be sensitive to the nature of R′. In concentrated acid solution the esters of secondary and tertiary alcohols hydrolyse by the $A_{Al}1$ mechanism producing a carboxylic acid and a secondary or tertiary carbonium ion. Esters of primary alcohols would produce the much less stable primary carbonium ions by this mechanism, and consequently cleave by the $A_{Ac}1$ mechanism, except when the carbonium ion is stabilized by an adjacent electron-donating group (e.g. phenyl or methoxy).

The products of both A1 mechanisms have been observed in the gas phase (7, 8). The $A_{Al}1$ mechanism, although the less common in solution reactions, appears to predominate in the gas phase. Two possible explanations of this change in behaviour are (*i*) the $A_{Ac}1$ mechanism requires the energetically less accessible ether-protonated ester as an intermediate (9, 10) and thus, in the absence of solvent, is difficult to obtain or (*ii*) that in the gas phase the internally assisted $A_{Al}1$ mechanism,

[1]For a flowing afterglow study of the fragmentation of $CH_3NO_2H^+$, see ref. 2.

[6] 
employing a six membered cyclic transition state (reaction [6]) established experimentally (7) by use of deuterium on the β-carbon of the ether group, does not require formation of the unstable primary carbonium ion.

The previous gas phase studies (7, 8) have employed protonated hydrocarbons as the acid (CH_5^+, $C_2H_5^+$, t-$C_4H_9^+$) to initiate the dissociative proton transfer of esters. Here we have used the acids $AH^+ = H_3^+$, CH_5^+, HCO^+, and H_3O^+ which have exothermicities varying over a much wider range (65 kcal mol^{-1}) and we have studied, under the more controlled conditions of the flowing afterglow apparatus, the dissociation mechanisms ([7*a*] and [7*b*])

[7] $AH^+ + RCOOR' \rightarrow [RCOOR'H^+]^* + A$

[7*a*] $[RCOOR'H^+]^* \rightarrow RCOOH + R'^+$

[7*b*] $[RCOOR'H^+]^* \rightarrow RCO^+ + R'OH$

of some formate and acetate esters as a function of the excess energy provided in the proton transfer reaction.

Experimental

The majority of the measurements were carried out in a hydrogen buffer using a conventional flowing plasma mass-spectrometer (flowing afterglow) system which has been described previously (1). A few of the measurements were carried out in a helium buffer with the apparatus in the Selected Ion Flow Tube (SIFT) configuration modelled after the original design reported by Adams and Smith (11). In this configuration a differentially pumped quadrupole mass filter was interposed between the ion production and reaction regions. Ions were extracted from the ion production region through a 1 mm diameter orifice into the quadrupole mass filter which communicated with the flow tube through a 5 mm diameter gas entrainment orifice. The ions were injected into the flow tube at ca. 40 eV and allowed to thermalize by collision at 299 ± 2 K before they entered the reaction region 106 cm further downstream. This procedure eliminated ion types other than the reagent ion and the neutral reagent and buffer gas molecules from the reaction region.

The ions were produced in hydrogen carrier gas in the usual manner according to reactions of the type

[8] $H_3^+ + X \rightarrow XH^+ + H_2$

with k = (2.4 ± 0.5), (2.0 ± 0.4), and (4.3 ± 1.1) × 10^{-9} cm^3 $molecule^{-1}$ s^{-1} for X = CH_4, CO, and H_2O, respectively (unpublished results from this laboratory, refs. 13, 14). We have shown elsewhere that the protonation of CO accomplished in this manner establishes the HCO^+ and not the COH^+ isomer (13).

$\rightarrow CH_3COOH_2^+ + C_3H_6$			+25±4

[a]The measured reaction rate constant, k, is given in units of 10^{-9} cm^3 molecule^{-1} s^{-1} along with its estimated accuracy and the number of measurements which is given in parentheses.

[b]The collision rate constant in units of 10^{-9} cm^3 molecule^{-1} s^{-1} calculated using the average-dipole-orientation theory (the $\overline{\cos\theta}$ model) (ref. 16). Permanent dipole moments were taken from ref. 12*a*. Mean polarizabilities of 5.90 Å^3 for $HCOOCH_3$, 8.50 Å^3 for $HCOO(CH_2)_2CH_3$ and $CH_3COOC_2H_5$, and 11.7 Å^3 for $CH_3COO(CH_2)_2CH_3$ were calculated from bond and group polarizabilities taken from ref. 12*b*.

[c]Standard enthalpy change in kcal mol^{-1}, PA(H_2, CH_4, CO, H_2O) = 101 ± 1, 131.5 ± 2.2, 143 ± 1, and 166.4 ± 2.4 kcal mol^{-1}, respectively (ref. 13). PA($HCOOCH_3$, $HCOO(CH_2)_2CH_3$, $CH_3COOC_2H_5$, $CH_3COO(CH_2)_2CH_3$) = 187.8 ± 2, 191.6 ± 2, 195.4 ± 2, and 198 ± 2 kcal mol^{-1} taken from ref. 18*a*. Auxiliary thermodynamic data were taken from ref. 18*b*.

The formates were added into the reaction region as vapors diluted to ca. 10% in helium. The determination of their flows required separate viscosity measurements (15). Reagent and product ions were monitored as a function of addition of the vapor in the range from 5×10^{-5} to 5×10^{-3} mTorr, at total gas pressures, P, between 0.196 and 0.50 Torr, average gas velocities, $\bar{v}$, in the range 7.6 to 8.6×10^3 cm s^{-1}, effective reaction lengths, L, of 48, 59, and 85 cm, and a gas temperature, T, of 299 ± 2 K. Rate constants were determined in the usual manner (1). Branching ratios were obtained by computer fitting and inspection of observed variation in the reactant and product ion signals. This analysis (15) required a knowledge of the mass discrimination, m, between the various ion signals. When a reaction resulted in more than one product ion, m had to be inferred from complementary studies performed under similar experimental conditions. The majority of the uncertainty in the branching ratios (±20%) arose from the error associated with this method of determining the mass discrimination.

The gases used were hydrogen (Linde, Very Dry Grade, 99.95% H_2), methane (Matheson, Ultra High Purity, 99.9% CH_4), helium (Linde, Prepurified Grade, 99.995% He), and carbon monoxide (Matheson, C.P. Grade, 99.5% CO). The vapors were derived from methyl formate and methyl acetate (both from BDH Chemicals), and *n*-propyl formate and *n*-propyl acetate (both from Chem. Service Media). The purities of the esters were checked by conventional gas chromatograph – mass spectrometer assays and, when necessary, redistilled before use.

Results and Discussion

Kinetics of Proton Transfer and Product Distributions

The rate constants measured in this study are listed in Table 1. All of these reactions were observed to be rapid with the rate constant, k, spanning a range in values from 2.8 to 8.5×10^{-9} cm^3 molecule^{-1} s^{-1}. As has been our previous experience with other similar systems, these values are systematically higher by ~50% than the values of the collision rate constants derived from the average-dipole-orientation theory (16) (these are included in Table 1). The implications of such deviations have been discussed elsewhere (16, 17).

For the reactions of H_3O^+, HCO^+, and CH_5^+ with methyl formate only one product ion (m/e = 61) was observed. This ion was identified as protonated methyl formate. There was no measurable evidence for subsequent dissociation. In contrast, the reaction of H_3^+ with methyl formate was observed to produce

predominantly (>90%) $CH_3OH_2^+$ which reacted further by proton transfer to establish $HCOO(CH_3)H^+$ according to the reaction

[9] $CH_3OH_2^+ + HCOOCH_3 \rightarrow HCOO(CH_3)H^+ + CH_3OH$

Figures 1 and 2 provide an indication of the results obtained with *n*-propyl formate. H_3O^+ reacted to produce considerable (~50%) amounts of $C_3H_7^+$ and a small amount (~5%) of $HCOOH_2^+$. Both product ions reacted further with *n*-propyl formate by proton transfer to produce $HCOO((CH_2)_2CH_3)H^+$ in addition to that amount which is produced directly by protonation with H_3O^+. Figure 2 shows that both dissociative channels increased in importance with H_3^+ as the reactant ion, the $C_3H_7^+$ and $HCOOH_2^+$ ions being produced approximately in the ratio of 9:1. The $HCOO((CH_2)_2CH_3)H^+$ appeared to be produced in this case entirely by secondary proton transfer reactions with the weaker

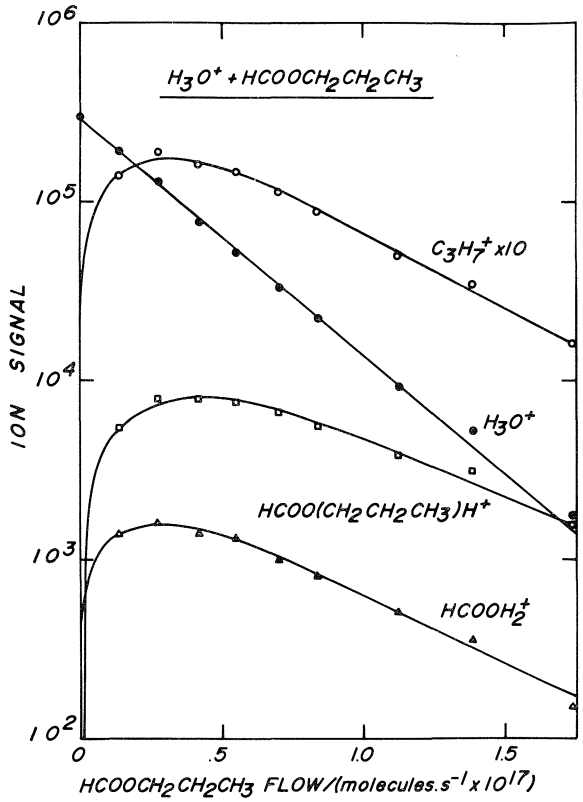

FIG. 1. The variation in major positive ions observed upon the addition of *n*-propyl formate vapour into a flowing H_2O–H_2 plasma in which H_3O^+ is initially the dominant ion. The decay of H_3O^+ provides a rate constant of 4.2×10^{-9} cm^3 molecule^{-1} s^{-1}. $T = 297$ K, $P = 0.363$ Torr, $\bar{v} = 7.8 \times 10^3$ cm s^{-1}, and $L = 45.9$ cm.

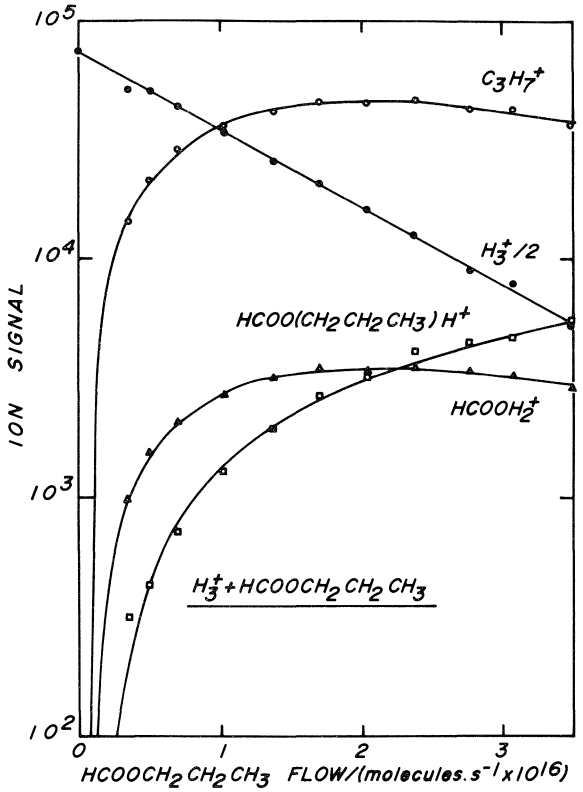

FIG. 2. The variation in major positive ions observed upon the addition of *n*-propyl formate vapour into a flowing H_2 plasma in which H_3^+ is initially the dominant ion. The decay of H_3^+ provides a rate constant of 8.5×10^{-9} cm^3 molecule^{-1} s^{-1}. $T = 299$ K, $P = 0.296$ Torr, $\bar{v} = 8.5 \times 10^3$ cm s^{-1}, and $L = 58.9$ cm.

second-generation acids $C_3H_7^+$ and $HCOOH_2^+$. The subsequent reaction of $HCOO((CH_2)_2CH_3)H^+$ is presumably due to 3-body association with *n*-propyl acetate. The product ion of this association reaction was outside the detection range of the mass spectrometer used in this study.

H_3O^+ was observed to react with ethyl acetate to produce primarily (>90%) an ion ($m/e = 89$) corresponding to protonated ethyl acetate. A concomitant but much smaller (<10%) increase was observed in the signal of an ion at $m/e = 61$, presumably $CH_3COOH_2^+$, which was suggestive of a small dissociative proton transfer channel. In contrast, the results shown in Fig. 3 indicate that dissociative proton transfer predominates in the reaction of H_3^+ with ethyl acetate. $CH_3COOH_2^+$ has become the dominant product (~75%) and two additional products at $m/e = 29$ and 43, identified as $C_2H_5^+$ (~5%) and CH_3CO^+ (~20%), were observed. The shape of the $CH_3COO(C_2H_5)H^+$ signal variation is

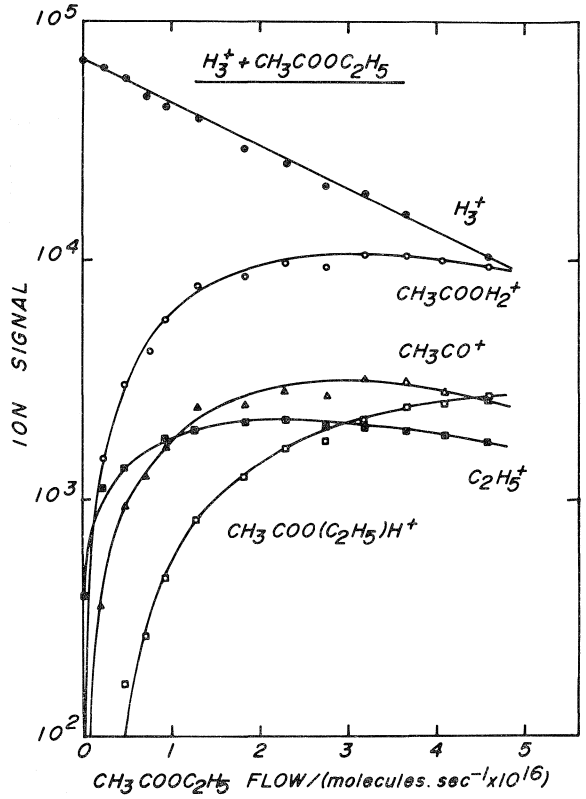

FIG. 3. The variation in the major positive ions observed upon the addition of ethyl acetate vapour into a flowing H_2 plasma in which H_3^+ is initially the dominant ion. The decay of H_3^+ provides a rate constant of 5.0×10^{-9} cm^3 molecule^{-1} s^{-1}. $T = 296$ K, $P = 0.508$ Torr, $\bar{v} = 7.7 \times 10^3$ cm s^{-1}, and $L = 46.9$ cm.

indicative of a secondary product arising entirely from proton transfer reactions with the second-generation acids $CH_3COOH_2^+$, $C_2H_5^+$, and CH_3CO^+.

Finally, H_3O^+ was observed to react with *n*-propyl acetate to form ions corresponding to $CH_3COOH_2^+$ and $CH_3COO((CH_2)_2CH_3)H^+$ in approximately equal amounts. Both ions reacted further, presumably by proton transfer and 3-body association, respectively.

Energetics and Mechanism of Dissociative Proton Transfer

Available thermochemical information enabled us to calculate the relative energies of most of the possible dissociation products of the two protonated formate esters and some of these are shown in Fig. 4. Many combinations of ions and molecules fall within the reaction exothermicities available from the protonation of the esters, particularly by H_3^+, but, in order to simplify the diagram, only products not requiring extensive skeletal rearrangements have been included. For example, the dissociation of $HCOO(CH_3)H^+$ into $CH_3CO^+ + H_2O$, which is only 7 ± 3 kcal mol^{-1} endothermic, has been excluded from Fig. 4.

Methyl Formate

The known energetics indicate that if the majority of the reaction exothermicity from the initial protonation reaction is deposited in $HCOO(CH_3)H^+$ then, in the absence of any barrier to reaction, dissociation of this ion into $CH_3OH_2^+$ and CO should be energetically favorable regardless of which acid (H_3^+, CH_5^+, HCO^+, or H_3O^+) performed the initial protonation.[2] Other plausible reaction products would become accessible with the acids CH_5^+, viz. $HCO^+ + CH_3OH$, and H_3^+, viz. $HCO^+ + CH_3OH$ and $CH_3^+ + HCOOH$. Experimentally, however, only H_3^+ produced measurable dissociation and even with this acid only the most stable products, $CH_3OH_2^+ + CO$, were formed. The absence of $HCO^+ + CH_3OH$ in the dissociation by CH_5^+ and particularly H_3^+ is somewhat surprising, as these species are expected to be formed initially by the $A_{Ac}1$ fission of the C—O bond of the methoxy-protonated tautomer.

[10] 
Also, the work of Pesheck and Buttrill (7) has established that protonated methyl acetate dissociates by the $A_{Ac}1$ mechanism to form the acetyl ion and methanol. Furthermore, previous observations made in this laboratory under similar operating conditions indicated that in the dissociative proton transfer reaction of H_3^+ with HCOOH both $HCO^+ + H_2O$, and $H_3O^+ + CO$ were produced with the former, the *less* stable, predominating by a factor of approximately two (3*a*). In this case the production of $H_3O^+ + CO$ from $HCOOH_2^+$ which is analogous to the production of $CH_3OH_2^+ + CO$ from $HCOO(CH_3)H^+$, was viewed to proceed by $A_{Ac}1$ cleavage accompanied by synchronous or near-synchronous transfer of a proton from the carbon atom to the developing water molecule (3*a*).[3] The

[2]At the pressures employed in these measurements collisional stabilization of the excited product ions formed by the initial protonation reaction may be important. The influence of the H_2 or He bath pressure on the observed product spectrum was not investigated systematically in this study.

[3]Sequential proton (deuteron) transfer within a reaction intermediate also has been invoked recently to account for gas-phase observations of hydrogen–deuterium exchange reactions involving hydrogen-containing anions and weak acids such as H_2O (3*b*, 3*c*).

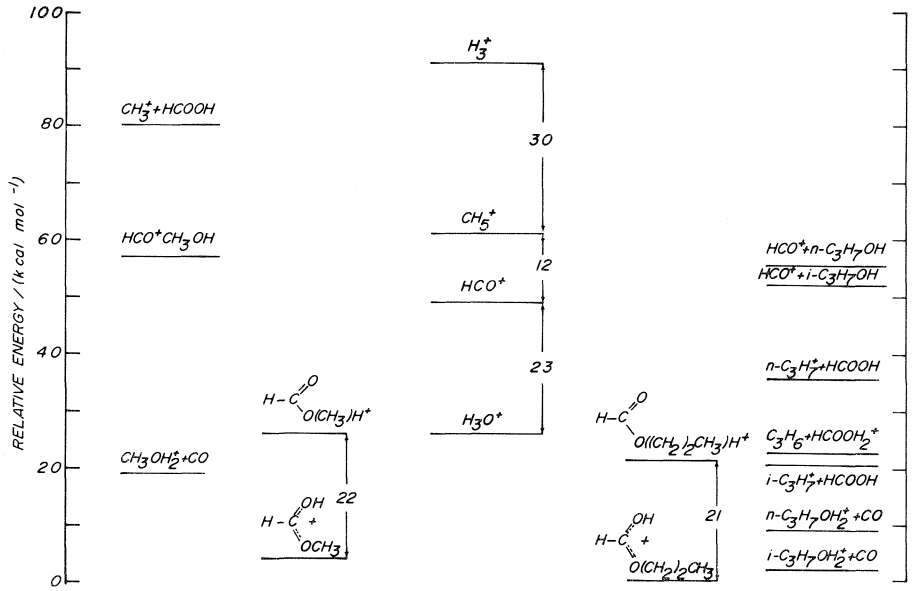

FIG. 4. Relative energies of the acids H_3^+, CH_5^+, HCO^+, and H_3O^+, the two-tautomers of protonated methyl- and *n*-propyl formate, and possible dissociation products of the protonated formates.

analogous route in the decomposition of $HCOO(CH_3)H^+$ would involve proton transfer to the developing methanol molecule according to

[11] 
The failure to observe production of any HCO^+ in this case, then, would imply that this intramolecular proton transfer is essentially quantitative. Methanol has a much higher proton affinity than carbon monoxide ($\Delta PA = 38 \pm 4$ kcal mol^{-1}) (13) and we have previously observed rapid proton transfer from HCO^+ to CH_3OH initially at infinite separation (13). The difference in proton affinity between water and carbon monoxide which is relevant in the analogous decomposition of $HCOOH_2^+$ is considerably smaller ($\Delta PA = 23 \pm 3$ kcal mol^{-1}) (13) while proton transfer between the products of the $A_{Ac}1$ fission in protonated methyl acetate, viz. $CH_3CO^+ + CH_3OH$, is actually *endothermic* by 13 ± 4 kcal mol^{-1} for ground states at infinite separation. Although the extent of intramolecular transfer which proceeds according to this model is likely to be sensitive to the total excess energy deposited by the initial protonation reaction which is expected to be different in each of the three protonated species, the trend in dissociation with ΔPA which has been identified for these three species appears to be consistent with this intramolecular proton transfer mechanism invoked originally for this dissociation of $HCOOH_2^+$. The same overall result can be viewed to be achieved by a 1,2-hydride shift from the carbon to the positive oxygen atom with concomitant cleavage of the C—O bond. Such shifts are invoked in many acid-catalysed reactions in solution (19).

n-*Propyl Formate*

In contrast with methyl formate, *n*-propyl formate underwent extensive dissociation, even when the weakest acid, H_3O^+, was used as the protonating agent. If the dissociation is to be exothermic in the latter case, the product, $C_3H_7^+$, must be the isopropyl cation and not the expected *n*-propyl cation:

[12] 
The $A_{Al}1$ cleavage would result in the *n*-propyl

cation and formic acid and if this mechanism is operative it is necessary to postulate that cleavage of the C—O bond is accompanied by a 1,2-hydride shift in the propyl fragment to achieve the more stable isopropyl cation:

[13] 
Ab initio molecular orbital calculations have established that $n\text{-}C_3H_7^+$ collapses into $i\text{-}C_3H_7^+$ without a barrier (20, 21). Such a mechanism has been invoked by Pesheck and Buttrill (7) to account for what appeared to be an abnormally large production of $C_4H_{10}^+$ from protonated isobutyl acetate. In this case the *s*-butyl group is conceived to rearrange via a 1,2-hydride shift to the more stable *tert*-butyl group.

A modification of this mechanism, again involving fission of the alkyl–oxygen bond but with concomitant migration of a β-hydrogen of the alkyl group to the carbonyl oxygen has been indicated in the dissociation of protonated ethyl acetate (9). The mechanism requires protonation of the energetically less favourable alkoxy oxygen, which is accessible even in protonation by H_3O^+, and proceeds via a 6-membered cyclic transition state:

[14] 
According to this scheme the initial products from protonated *n*-propyl formate are protonated formic acid and propene but proton transfer may again be postulated to occur during the fragmentation to form the isopropyl cation. Propene actually has a slightly higher proton affinity than formic acid ($\Delta PA = 2$ kcal mol^{-1}) (3*a*). Our experimental observations of the dissociative proton transfer with H_3^+ indicated the production of appreciable amounts (~10%) of $HCOOH_2^+$ and this may well be attributed to this internally assisted $A_{Al}1$ mechanism initiated by protonation of the alkoxy oxygen. Protonation at this position by H_3O^+ would require the deposition of at least 80% of the reaction exothermicity as internal energy of the ion so that production of $HCOOH_2^+$ and $C_3H_7^+$ via this mechanism is somewhat less plausible in this case. Production of $C_3H_7^+$ at low reaction exothermicities for the initial protonation may well proceed preferentially by the $A_{Al}1$ cleavage initiated by protonation at the carbonyl oxygen and accompanied by a 1,2-hydride shift. Some support for this viewpoint is provided by recent observations which we have made of the generation of $C_3H_7^+$ from *n*-propanol at exothermicities considerably lower than required for formation of $CH_3CH_2CH_2^+$:

[15] $CH_3CH_2CH_2OH + H_3O^+$

$\rightarrow CH_3CH_2CH_2OH_2^+ + H_2O + 23 \pm 4$

[15*a*] $\rightarrow n\text{-}C_3H_7^+ + H_2O - 33 \pm 4$

[15*b*] $\rightarrow i\text{-}C_3H_7^+ + H_2O - 17 \pm 4$

In this decomposition internal assistance by a carbonyl group of the type suggested for $HCOO(CH_2)_2\text{-}CH_3$ is not available so that C—O cleavage accompanied by a synchronous 1,2-hydride shift is definitely the preferred mechanism in this reaction. This suggests in turn that $C_3H_7^+$ may also not be formed via the 6-membered cyclic transition state in its generation from $HCOO(CH_2)_2CH_3$, at least not at low reaction exothermicities.

Ethyl Acetate

Protonated formic acid does not cleave readily by the $A_{Ac}1$ mechanism to form the acylium ion HCO^+ and it seemed probable that this mechanism should be more competitive with esters of larger carboxylic acids. In fact methyl acetate has been found to react with CH_5^+ mainly by proton transfer but with formation of about 20% CH_3CO^+ and no $CH_3\text{-}COOH_2^+$ (7), indicating that the cleavage of this ester occurs only by the $A_{Ac}1$ mechanism. Ethyl acetate might therefore be expected to form both the acetyl ion, CH_3CO^+, via the $A_{Ac}1$ mechanism and also $CH_3COOH_2^+$ by the internally assisted $A_{Al}1$ mechanism. Experimentally we found that H_3O^+ simply transferred a proton to ethyl acetate and the product of the $A_{Al}1$ mechanism, although slightly exothermic assuming all the reaction exothermicity to be in the protonated ester, occurred only to a small amount (<10%). In the reaction with H_3^+ (Fig. 3), there is sufficient energy to produce dissociation into $CH_3COOH_2^+$ and $C_2H_5^+$, the

products of the internally assisted and unassisted $A_{Al}1$ mechanisms, and also the acetyl ion, the product of the $A_{Ac}1$ mechanism. All three products were observed experimentally, with the relative concentrations in the same order as expected from the exothermicities. The CH_3CO^+ could possibly be generated by secondary dissociation of $CH_3COOH_2^+$ as a result of the excess energy in this ion. However, this interpretation is not substantiated by the results of the reaction of CH_5^+ with ethyl acetate (7) where the ratio of $CH_3COOH_2^+$ to CH_3CO^+ ($\sim 3.5:1$) is approximately the same as with the much stronger acid H_3^+. If the $CH_3COOH_2^+$ were the major primary source of CH_3CO^+ then the amount of dissociation might be expected to be much larger in the reaction initiated by the highly exothermic proton transfer from H_3^+ than in the dissociation initiated by the much weaker acid CH_5^+.

In summary, then, it appears that the dissociation of ethyl acetate, when protonation is accompanied by large exothermicities, can be induced to dissociate by both $A_{Al}1$ and $A_{Ac}1$ mechanisms with the relative frequencies being approximately 4:1.

n-*Propyl Acetate*

Dissociation of *n*-propyl acetate was induced by even the weakest acid, H_3O^+. However, $CH_3COOH_2^+$ was the only dissociation product, in contrast with dissociation of *n*-propyl formate, where $C_3H_7^+$ was the only major product.

$$[16]\quad H_3O^+ + CH_3COO(CH_2)_2CH_3 \rightarrow CH_3COO((CH_2)_2CH_3)H^+ + H_2O + 32 \pm 4$$

$$[16a]\quad \rightarrow CH_3COOH_2^+ + C_3H_6 - 25 \pm 4$$

$$[16b]\quad \rightarrow i\text{-}C_3H_7^+ + CH_3COOH - 32 \pm 4$$

$$[16c]\quad \rightarrow n\text{-}C_3H_7^+ + CH_3COOH - 48 \pm 4$$

$$[16d]\quad \rightarrow CH_3CO^+ + n\text{-}C_3H_6OH - 44 \pm 5$$

Acetic acid has a larger proton affinity than propene ($\Delta PA = 7$ kcal mol^{-1}) and formation of $CH_3COOH_2^+$ is the only dissociative channel requiring less energy than the maximum available from the initial proton transfer between *n*-propyl acetate and H_3O^+. The observed product suggests that only the $A_{Al}1$ mechanism is operative.

The stronger acid, CH_5^+, also yields predominantly the protonated carboxylic acid with *n*-propyl acetate and *n*-propyl propionate but small amounts of further decomposition products were observed for each ester ($\sim 10\%$ of $m/e = 43$, CH_3CO^+ and/or $C_3H_7^+$, for *n*-propyl acetate (7), and 8.8% of $C_7H_5CO^+$ and 1.6% of $C_3H_7^+$ for *n*-propyl propionate (8*b*)). It is not possible to deduce whether the $A_{Ac}1$ mechanism is operative for these two esters, but clearly it is at most a minor pathway for both esters.

Conclusions

Our results, combined with the results of icr and mass spectrometer studies on larger esters, permit certain generalisations about the mechanism of cleavage of esters in the gas phase. For methyl esters the $A_{Ac}1$ mechanism is the only one followed and even this requires high energy to achieve cleavage. For esters containing larger alkyl groups as the ether substituent the $A_{Al}1$ mechanism is dominant and even when the reaction exothermicity is increased and the $A_{Ac}1$ mechanism has become operative for the ethyl and *n*-propyl esters examined here, it never becomes the dominant channel. This behaviour is in marked contrast with the reactions in solution where the $A_{Ac}1$ mechanism is the most common. One possible explanation for this change in behaviour is that the $A_{Ac}1$ mechanism requires protonation on the energetically less accessible ether oxygen and this is more easily achieved in solution where the solvent can assist in accommodating some of the positive charge. In the gas phase the charge on the ether protonated ester is formally localised on the ether oxygen but the hydrogen atoms of the ester group carry considerable positive charge and this can be partly delocalised by forming a hydrogen bond between a hydrogen atom on the β-carbon and the carbonyl oxygen. This "internally solvated" structure then provides the 6-membered ring arrangement which is necessary for the internally assisted $A_{Al}1$ mechanism. Alternatively the normal product of $A_{Al}1$ fission, R^+, may be formed directly from the carbonyl protonated ester, or indirectly by the internally assisted mechanism followed by proton transfer, if this channel is energetically the more favourable.

The allyl and benzyl groups as hydrogen bond acceptors in derivatives of 2-allylphenol and 2-benzylphenol

TED SCHAEFER, RUDY SEBASTIAN, AND TIMOTHY A. WILDMAN

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received May 28, 1979

TED SCHAEFER, RUDY SEBASTIAN, and TIMOTHY A. WILDMAN. Can. J. Chem. **57**, 3005 (1979).

The ^{1}H nmr spectra of 2-allylphenol, 2-allyl-6-methylphenol, 2-allyl-6-chlorophenol, and 2-benzyl-4-chlorophenol are analyzed in some detail. It is shown that, relative to a methyl group, the allyl and benzyl moieties, respectively, favor a *cis* orientation by 1570 ± 250 J/mol and 900 ± 220 J/mol in free energy at 305 K in CCl_4 solution. These numbers appear to be independent of the CCl_4 solvent. Coupling parameters within the allyl group in these molecules and in propene and allylbenzene show some regularities but are probably not reliable indicators of the allyl conformational preference, at least in the absence of a model allowing for hindered rotor state populations.

TED SCHAEFER, RUDY SEBASTIAN et TIMOTHY A. WILDMAN. Can. J. Chem. **57**, 3005 (1979).

On a analysé de façon détaillée les spectres rmn du ^{1}H des allyl-2 phénol, allyl-2 méthyl-6 phénol, allyl-2 chloro-6 phénol et benzyl-2 chloro-4 phénol. On a montré que par rapport au groupe méthyle les groupes allyle et benzyle favorisent une orientation *cis* avec respectivement une énergie libre de 1570 ± 250 J/mol et 900 ± 220 J/mol à 305 K en solution dans le CCl_4. Ces valeurs semblent être indépendantes du CCl_4 utilisé comme solvant. Les paramètres de couplage à l'intérieur des groupes allyles dans ces molécules, dans le propène et les allylbenzènes montrent quelques régularités, mais ce ne sont probablement pas des indicateurs surs d'une préférence conformationnelle du groupe allyle, du moins en l'absence de modèle permettant un rotation des différentes populations encombrées.

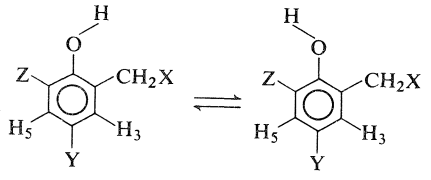
Introduction

A recent direct measurement (1) of the intramolecular equilibrium of the hydroxyl group in 2-methylphenol and in 4-chloro-2-methylphenol shows that the *trans* conformer **2** (X = H, Y = H or



1 **2**

Cl, Z = H) is favored by a free energy of 1600 ± 170 J/mol in CCl_4 solution at 305 K. The measurement depends on the well-established observation (2–5) that $^5J_m^{H,OH}$, the coupling constant over five formal bonds between the hydroxyl proton and the *meta* ring protons, is highly stereospecific. Thus, ^5J_c, the couplings to H-3 in **1** and to H-5 in **2**, approximate to zero; whereas the corresponding ^5J_t couplings over the all-*trans* path are finite. The free energy difference between **1** and **2** follows as $\Delta G^0 = -RT \ln K = -RT \ln {}^5J_3/{}^5J_5$, where it is assumed that in dilute solutions the activity coefficients of **1** and **2** are equal. This procedure has yielded internally selfconsistent results (1–5), as well as agreement with other techniques.

Because the internal barrier to rotation of the hydroxyl group is large compared to thermal energies at ambient temperatures, conformations in which the hydroxyl group deviates from the benzene plane can be ignored to a very good approximation (1). This situation contrasts markedly with that found for the corresponding thiophenol derivatives (5).

In this paper, the conformational preference of the hydroxyl group is investigated for 2-allylphenol, 2-allyl-6-chlorophenol, 2-allyl-6-methylphenol, and 2-benzyl-4-chlorophenol. In addition, all coupling constants for the allyl groups are assessed as indicators of the conformational preferences of the hydrocarbon sidechains in these phenol derivatives, comparing them to propene and allylbenzene as well.

Experimental

Of commercial origin (Aldrich, Parish, and Matheson), the compounds were prepared as dilute solutions (see Tables) and were degassed by the freeze–pump–thaw technique. The samples were flame-sealed into 5 mm od nmr tubes and contained some tetramethylsilane (TMS). The ^{1}H nmr spectra were calibrated in the frequency sweep mode on an HA100 spectrometer at a probe temperature of 305 K. Calibrations of peak positions involved interpolations between frequency markers placed at ca. 5 Hz intervals at sweep rates of 0.2 Hz/s and at a spectral dispersion of 1 Hz/cm of chart paper. The root mean square errors in peak frequencies were typically 0.02 Hz or less. Intermolecular hydroxyl proton exchange was retarded as described (1–5).

Results and Discussion

Spectral Analysis

Performed by means of the computer program LAME (6, 7), the analyses yielded the spectral parameters in Tables 1 to 3. The ^1H nmr spectra of 2-allylphenol, for example, arises from a 10-spin system. However, there is no detectable coupling between the olefinic and ring protons. Accordingly, the ring proton and hydroxyl proton spectra could be analyzed as parts of a 7-spin spectrum and, on the other hand, the olefinic proton spectrum was analyzable as part of a 5-spin system. The methylene protons are coupled to all ring and olefinic protons. The phenyl group ^1H nmr spectrum of the benzyl derivative did not yield to analysis. Figure 1 displays the hydroxyl proton spectra of 2-benzyl-4-chlorophenol in two solvents. Unresolved coupling to the exocyclic phenyl protons causes some broadening; compare spectrum in (1).

Conformational Preference of the Hydroxyl Group

2-Benzyl-4-chlorophenol

According to the assumptions above, it follows that conformation **2** (X = phenyl, Y = Cl, Z = H) has a lower free energy than **1** of $-RT \ln K = -RT \ln {}^5J_3/{}^5J_5 = -RT \ln 0.283/0.368 = 670 \pm 180$ J/mol in CCl_4 solution and 1640 ± 170 J/mol in C_6D_6 solution. The estimated errors assume that the standard deviations in Table 1 are to be multiplied by 4. The greater stability of the *trans* form, **2**, in C_6D_6 has its counterpart in 2-methylphenol (1). Perhaps it arises from intermolecular hydrogen bonding to the π electrons of the solvent molecules, which is more favorable in the *trans* than the *cis* conformations. Preferential solvation near the hydroxyl group is indicated by the large shifts to high field of OH and H-6 resonances relative to the CCl_4 solution (Table 1).

The *trans* form of 2-methyl-4-chlorophenol is more stable than the *cis* form by 1590 ± 250 J/mol in CCl_4 solution. Comparison with 2-benzyl-4-chlorophenol suggests intramolecular hydrogen bonding to the phenyl group in the latter compound accounts for ca. 1 kJ/mol in free energy. The temperature dependence of the stretching band intensities in 2-benzylphenol (8) leads to an enthalpy of 1380 ± 210 J/mol favoring the *cis* form and an entropy difference of -4.4 ± 0.84 J/mol deg so that the free energy difference at 305 K is 40 ± 470 J/mol, *cis* favored. Another infrared investigation implies that the *cis* form is stabilized by a free energy of 450 ± 390 J/mol at 305 K (9). The nmr result of 670 ± 180 J, *trans* favored, is not in striking agreement with the infrared data.

It might be argued that the present data refer to a much more concentrated solution (ca. 0.3 *M*) than do the infrared measurements (ca. 10^{-2} *M*), and that self-association of the solute would favor the *trans* form. This possibility was investigated for 2-methyl-4-chlorophenol (1) and no evidence could be found that self-association drives the intramolecular equilibrium towards the *trans* form, at least for concentrations up to 8 mol% in CCl_4. See also the discussion below on 2-allylphenol and its derivatives. ^{13}C chemical shifts do not throw any light on intramolecular equilibria in benzylphenols (10).

2-Allylphenol, 2-Allyl-6-chlorophenol, and 2-Allyl-6-methylphenol

The chloro derivative exists predominantly as the *trans* form, **2** (X = vinyl, Y = H, Z = Cl), because $^5J_3$ is 0.62_6 Hz and $^5J_5$ <0.03 Hz; 4,6-dichloro-2-methylphenol behaves similarly (footnote 1 in (1)).

Removal of the chlorine substituent to yield 2-allylphenol, gives an equilibrium in which the *trans* form, **2**, is favored by a free energy of 90 ± 190 J/mol; that is, the equilibrium constant is effectively unity. Comparison with 2-methylphenol implies that the allyl group stabilizes the *cis* form, in which the hydroxyl group reputedly hydrogen bonds to the π electrons, by 1500 ± 350 J/mol. The infrared data

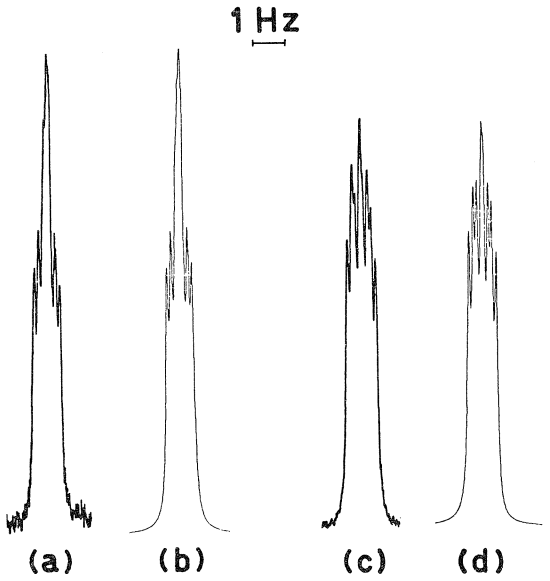

FIG. 1. The hydroxy ^{1}H nmr spectra of 2-benzyl-4-chlorophenol at 100 MHz and 305 K as (*a*) 3 mol% in CCl_4, (*b*) calculated with the parameters in Table 1, (*c*) 5 mol% in C_6D_6, (*d*) calculated with parameters in Table 1. Unresolved coupling to the sidechain protons causes the resolution to be somewhat lower than that in ref. 1, for example.

on enthalpy and entropy yield 760 ± 1100 J/mol as the free energy advantage of the *cis* form of 2-allylphenol (8).

Now, for 2-allyl-6-methylphenol the coupling constants (Table 2) show that **1** (X = vinyl, Y = H, Z = CH_3) has a lower free energy than **2** of 1640 ± 150 J/mol, precisely as would be concluded from a simple comparison of 2-methylphenol and 2-allylphenol. In other words, no solvent or self-association perturbations need be invoked in a comparison of the *cis–trans* equilibria for the latter molecules. In 2-allyl-6-methylphenol, where two *ortho* substituents are present, such associations are expected to be even less significant. Solvent stabilization of those conformers of higher dipole moment is probably not very important in these phenol derivatives (the dipole moments of toluene and allylbenzene differ by less than 0.1 D).

In view of these results, which suggest that a comparison of the *cis–trans* equilibria would yield the same result for the free molecules, a direct comparison with studies of intramolecular photocyclization of the allyl compounds may prove interesting (11). It need not be true that the *cis–trans* equilibria are identical for solvated and free molecules when only one of the *ortho* substituents is present.

A referee has mentioned the possibility of out-of-plane conformations of the hydroxyl group in these compounds. As discussed for phenol itself (12), substantial out-of-plane populations would entail an observable $^6J_p^{H,OH}$. No evidence was found for a $^6J_p^{H,OH}$ of greater than 0.04 Hz in these compounds, indicating that coplanar conformations of the hydroxyl groups are favoured by an energy not significantly less than in phenol, i.e., about 3.5 kcal/mol.

Long-range Coupling Between Methylene Protons and Ring Protons

There exists abundant evidence (13) that coupling between methylene protons and the ring protons depends on the angle of rotation about the sp^2–sp^3 carbon–carbon bond. For example, $^6J_p^{H,CH} \alpha \sin^2\theta$, where θ is the angle by which the C_α—H bond twists out of the benzene plane (13). Of course, unless the barrier to rotation about the exocyclic bond is very large ($\gg$kT), $\sin^2\theta$ must be averaged over the occupied hindered rotor state states (13). The asymmetry of the compounds under consideration here does not allow such a procedure. However, an extensive set of molecular orbital calculations at the PCILO level of approximation suggests that the θ values for the two methylene C—H bonds are 15° and 105° (14), and that such a conformation is stabilized to the extent of 17 kJ/mol. In that event, our previous work (13) predicts $^6J_p^{H,CH}$ as −0.6 Hz, although a further twist of 15°, i.e., to give θ values of 0° and 120°, would yield a ^6J_p of -0.4_6 Hz.

It is interesting that in all of the allyl compounds $^6J_p^{H,CH}$ is −0.41 ± 0.03 Hz and it would be tempting to take this as a rough confirmation of the energy calculations (allowing for small errors in the calculated θ values). In our opinion, however, the only correct approach[1] involves a proper average over all populated states of the hindered sidechain, including the *cis* and *trans* conformers. In the absence of this possibility the magnitudes of $^6J_p^{H,CH}$ for these compounds suggest that the conformational preferences of the allyl and benzyl moieties are very similar.[2]

The Couplings Within the Allyl Group

Their most striking aspect is the small variation from compound to compound in Table 3. Nevertheless, regularities are apparent. In Fig. 2, ^2J_g, and ^3J_t

[1]Such an approach can yield reliable information on preferred conformations and internal rotational barriers for molecules of sufficient symmetry (13).

[2]The decrease in the magnitude of $^6J_p^{H,CH}$ of the allyl group from 0.44 Hz in the 6-chloro derivative (in which the hydroxyl group points away from the allyl group) to 0.38.Hz in the 6-methyl derivative (in which the largest population occurs for the conformer in which the hydroxyl group points towards the allyl group) *is* consistent with reduced freedom of motion of the allyl sidechain for a preferred conformation in which the C_α—C_β bond prefers a plane perpendicular to the benzene plane. The entropy of ionization of 2-allylphenol indicates some restriction of motion of the sidechain in the neutral species (15).

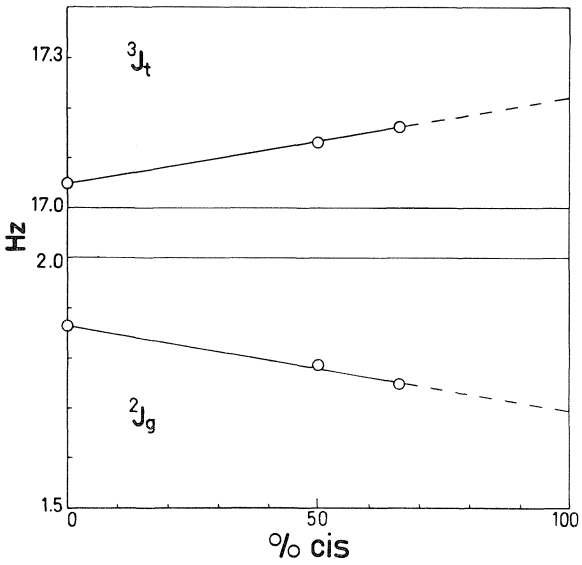

FIG. 2. The coupling constants ^2J_g and ^3J_t in Hz from Table 3 are plotted vs. the population of the conformer in which the hydroxyl group lies *cis* to the allyl group. From left to right, the points refer to 2-allyl-6-chlorophenol, 2-allylphenol, and 2-allyl-6-methylphenol.

are plotted vs. the population of the *cis* conformer, as calculated from $^5J_m^{H,OH}$, for 2-allyl-6-chloro-, 2-allyl-, and 2-allyl-6-methylphenols (four times the standard deviations is ≤ 0.02 Hz for these parameters). In other words, the *cis* conformer of 2-allylphenol has $^3J_t = 17.23 \pm 0.02$ and $^2J_g = 1.69 \pm 0.02$ Hz.

In terms of the Pople and Bothner-By model (16), the decrease of 0.2 Hz in ^2J_g in going from the *trans* to *cis* conformer corresponds to electron withdrawal from antisymmetric orbitals of the $=CH_2$ fragment (hyperconjugative effects), presumably by the polar hydroxyl group. Of course, there occurs a similar drop in ^2J_g between propene and allylbenzene (Table 3), so that conformational changes of the allyl group might also account for the 0.2 Hz decrease.

In principle, the allylic couplings, ^4J_c and ^4J_t, are excellent probes into the conformation of the allyl group in these compounds (17). In practice, the variations are so small (Table 3) that their theoretical values (17) cannot be used to test the calculated (14) high stability of the preferred *cis* conformer of 2-allylphenol. In our opinion, the observed couplings indicate a degree of motional flexibility of the allyl group. A proper treatment would again require a populational average over all the torsional states.

Conclusions

Compared to an *ortho* methyl group, an *ortho* allyl substituent in phenol favours a *cis* orientation of the hydroxyl group by a free energy of 1570 ± 250 J/mol (which is the average of the values obtained from direct comparison and from competition in 2-allyl-6-methylphenol) at 305 K in CCl_4 solution. This value may apply to the gas phase also, probably because *cis* and *trans* conformers have very similar polarities. A similar comparison suggests that the benzyl group favours the *cis* orientation of the hydroxyl group by a free energy of 900 ± 220 J/mol at 305 K in CCl_4.

The coupling parameters within the allyl moiety in propene are rather insensitive to substitution by phenyl or substituted phenyl groups. In our opinion, this means that many hindered rotor (torsion) states are significantly populated at ambient temperatures.

Kinetics of solvent extraction of metal ions with HEDHP. III. The kinetics and mechanism of solvent extraction of Cr(III) from acidic aqueous solutions with bis-(2-ethyl hexyl) phosphoric acid in benzene

MUHAMMAD FAKHRUL ISLAM AND RANJIT KUMAR BISWAS
Department of Applied Chemistry, University of Rajshahi, Rajshahi, Bangladesh

Received January 10, 1979

MUHAMMAD FAKHRUL ISLAM and RANJIT KUMAR BISWAS. Can. J. Chem. **57**, 3011 (1979).

The rate of solvent extraction of chromium(III) from aqueous sulphuric acid solutions (containing 0.05 mol dm^{-3} sulphate ion and 0.25 mol dm^{-3} acetate buffer, ionic strength, $I = 0.40$ mol dm^{-3}) with bis-(2-ethyl hexyl) phosphoric acid (HDEHP or H_2A_2) in benzene has been measured under various conditions. The rate of backward extraction measurement of Cr(III) from organic phase to aqueous phase is not possible due to the inert property of Cr(III)–DEHP chelate. The forward rate is found to be first-order w.r.t. Cr(III) concentration in the aqueous phase and HDEHP concentration in the organic phase. The order w.r.t. H^+ concentration varies from -1 to 1 over the pH range 1.5 to 5.25. The rate is found to decrease with increasing sulphate and nitrate ions concentrations in the aqueous phase. At (30 ± 1)°C, the rate expression, in the presence of sulphate, acetate, and nitrate ions, is found to be represented by:

$$-dC_{Cr}^{A}/dt = 10^{-0.893} C_{Cr}^{A}[H_2A_2]_{(o)}(500[H^+] + 1 + 10^{-4}[H^+]^{-1})^{-1}(1 + 4.17[SO_4^{2-}])^{-1}(1 + 0.5[NO_3^-])^{-1}$$

In the absence of the anions, the formation of $CrHA_2^{2+}$ intermediate complex ($Cr(OH)^{2+} + H_2A_{2(o)} \rightarrow CrHA_2^{2+} + H_2O$) is the rate determining step at all acidities. The effects of the anions on the rate are discussed.

MUHAMMAD FAKHRUL ISLAM et RANJIT KUMAR BISWAS. Can. J. Chem. **57**, 3011 (1979).

On a mesuré la vitesse d'extraction du chrome(III) à partir de solutions aqueuses d'acide sulfurique (contenant des ions sulfates à 0.05 mol dm^{-3}, tampon acétate à 0.25 mol dm^{-3} d'une force ionique $I = 0.40$ mol dm^{-3}) en utilisant comme solvant l'acide bis(éthyl-2 hexyl) phosphorique (HDEHP ou H_2A_2) en solution dans le benzène et en changeant les conditions. Le caractère inerte du chélate Cr(III)–DEHP ne permet pas de mesurer la vitesse d'extraction en retour de la phase organique à la phase aqueuse. On a trouvé que la vitesse d'extraction directe est du premier ordre par rapport à la concentration du Cr(III) dans la phase aqueuse et à celle du HDEHP dans la phase organique. L'ordre par rapport à la concentration en ions H^+ varie de -1 à 1 sur une échelle de pH allant de 1.5 à 5.25. On a trouvé que la vitesse décroît quand on augmente la concentration en ions sulfate et nitrate de la phase aqueuse. On a trouvé que l'expression de la vitesse, à 30 ± 1°C en présence d'ions sulfate, acétate et nitrate, peut être représentée par la formule suivante:

$$-dC_{Cr}^{A}/dt = 10^{-0.893} C_{Cr}^{A}[H_2A_2]_{(o)}(500[H^+] + 1 + 10^{-4}[H^+]^{-1})^{-1}(1 + 4.17[SO_4^{2-}])^{-1}(1 + 0.5[NO_3^-])^{-1}$$

En l'absence d'anions la formation du complexe intermédiaire $CrHA_2^{2+}$ ($Cr(OH)^{2+} + H_2A_{2(o)} \rightarrow CrHA_2^{2+} + H_2O$) est l'étape déterminante à toutes les acidités. On a discuté de l'effet des anions sur la vitesse d'extraction.

In previous papers of this series, the authors have discussed the kinetics and the mechanism of the solvent extractions of Ti(IV) (1) and V(IV) (2) with HDEHP in benzene. In these papers, it has been reported that the rate of extraction and back extraction of Ti(IV) with HDEHP is slow, whereas that of V(IV) is fast. Taube (3) and Basolo and Pearson (4) noted that the rate of most substitution reactions in Cr(III) complexes in the aqueous solutions was quite slow. The slow behaviour of Cr(III) toward solvent extraction with acetyl acetone was reported by McKaveney and Freiser (5), who noted that no extraction of Cr(III) took place from a sulphate medium into a 1:1 chloroform – acetyl acetone mixture in the pH range of 0 to 6.0 after mixing the phases for 30 min, and this failure to extract was attributed to the extremely slow rate of formation of the metal chelates. Morrison and Freiser (6) reported that the reflux of aqueous Cr(III) solution with acetyl acetone at pH 6.0 for 1 h resulted in complete extraction. On these grounds, Hellwege and Schweitzer (7) studied the extraction kinetics of Cr(III) from perchlorate and chloride media into chloroform containing acetyl acetone. In addition, Sambasiva *et al.* (8) reported the kinetics of extraction of Cr(VI) from HCl solutions by di-*n*-pentyl and di-*n*-octyl sulfoxides.

The extraction equilibrium of Cr(III) from HCl solutions with HDEHP in toluene was reported by Kimura (9) along with 50 other elements. In a previous paper, the authors have reported the extraction equilibrium study of Cr(III) from sulphate–acetate media with HDEHP in benzene (10), in which it has been reported that the time required to reach equilibrium is about 15–30 min at the experimental conditions. This paper discusses the kinetics and mechanism of the extraction of Cr(III) from acidic sulphato–acetato media with HDEHP and compares the result with other results from the literature.

Experimental

Reagents

Reagent grade chemicals were used in the investigations: chromic sulphate (M. C. and Bell), benzene (purified, bp 79–81°C, M. C. and Bell), bis-(2-ethyl hexyl) phosphoric acid (Eastman Kodak), sulphuric acid (98%, BDH), sodium nitrate (99%, BDH), acetic acid (99.4%, BDH), sodium acetate (99%, BDH), sodium azid (99%, E. Merck), potassium permanganate (99%, BDH), etc. All the chemicals were used without further purifications. Regenerated benzene was also used.

Procedures

The stock solution of Cr(III) was prepared by dissolving $Cr_2(SO_4)_3 \cdot 18H_2O$ in sulphuric acid and diluting with water. It was then standardized by titrating with standard ferrous ammonium sulphate (11). The acidity of the stock solution was estimated by titrating with standard Na_2CO_3 solutions. The total sulphate content was then calculated. The test solutions were then prepared by diluting the stock so that the resulting solutions always contained 0.05 mol dm^{-3} sulphate ion (added as Na_2SO_4 or H_2SO_4) and 0.25 mol dm^{-3} acetate ion (added as AcNa or AcH), so that ionic strength $I = 0.40$ mol dm^{-3}, except in the sulphate and acetate ions dependence studies. The pH of the solutions were then adjusted by adding anhydrous Na_2CO_3 only if necessary. The solutions so obtained were kept standing at least for 12 h before extraction. HDEHP was diluted with benzene (pre-equilibrated with water) to obtain the desired strengths.

The details of the procedures were essentially the same as those described in the previous papers (1, 2). pH of the solutions were measured by a Corning-5A-model pH meter. The aqueous phase Cr(III) concentrations were kept at 200 mg dm^{-3} initially in almost all the studies, except in determining the order w.r.t. Cr(III) by differential method.

The initial volume of each phase was always 20 mL. Two phases were taken in a stoppered bottle and agitated at the rate of about 500 shakes min^{-1} at (30 ± 1)°C maintained in a thermostatic water bath by an electrically operated shaking machine. The shaking speed was high enough to give the maximum rate (1). After a certain interval (2–15 s), two phases were separated quickly with a pipette. No emulsification was observed. A certain portion of the aqueous phase was pipetted out, oxidised to dichromate by $KMnO_4$–NaN_3 oxidation method, and its absorbance was measured at 370 nm by spectronic-20 (12) to estimate the Cr(III) content in the aqueous phase. The organic phase Cr(III) concentration was obtained by difference.

Treatments of Data

At high shaking speed and constant temperature and ionic strengths, the rate expression may be expressed as (13–17):

$$[1] \quad -dC_{Cr}^{A}/dt = k_f^* C_{Cr}^{Aa}[H_2A_2]_{(0)}^{b}[H^+]^c$$

where C_{Cr}^{A} = concentration of Cr(III) in the aqueous phase (mg dm^{-3}) and k_f^* = forward rate constant at 0.05 mol dm^{-3} sulphate and 0.25 mol dm^{-3} acetate medium. At constant buffered hydrogen ion concentration (h) and extractant concentration (h_a), eq. [1] becomes:

$$[2] \quad -dC_{Cr}^{A}/dt = qC_{Cr}^{Aa}$$

where q = pseudo first order rate constant = $k_f^* h_a^b (h)^c$. Where $a = 1$ (as found by differential method using both single and multiple runs (18)), the parameter q can be estimated from the slope of log C_{Cr}^{A} vs. time (t) plots.

Since the reaction order w.r.t. H^+ concentration is found to vary between -1 at higher acidities to 1 at lower acidities, q may be represented by:

$$[3] \quad q = k_f^* h_a^b (k_h[H^+] + 1 + k_{h-1}[H^+]^{-1})^{-1}$$

(k_h, k_{h-1} = proportionality constants in the pH dependence of rate at higher and lower acidities respectively) so that, at constant extractant concentration (h_a), where $q = q_{H^+}$, the value of k_h and k_{h-1} may be obtained by the curve fitting of the log q_{H^+} vs. log $[H^+]$ plots. Similarly, at constant h, where $q =$

$q_{H_2A_2}$, the value of b may be obtained from the slope of log $q_{H_2A_2}$ vs. log $[H_2A_2]_{(0)}$ plots. Using the known values of b, k_h, and k_{h-1}, the value of k_f* can be evaluated from the intercepts of the above two plots.

The effects of sulphate, acetate, and nitrate ions on the rate can be represented by the following empirical expression:

$$[4] \quad \log q_L = \log K_f' h_a^b [k_h h + 1 + k_{h-1} h^{-1}]^{-1} - \log (1 + k_{f(L)}[L])$$

where $L = Ac^-$, SO_4^{2-}, or NO_3^- and $k_f' = |k_f^*, k_{f'}^{0*}|$ or k_f^* ($k_{f'}^{0*}$ = forward rate constant at 0.25 mol dm^{-3} acetate medium only) owing to the fact that the reaction order w.r.t. SO_4^{2-} and NO_3^- varies between 0 and -1. For Ac^-, $k_{f(L)} = 0$. The value of $k_{f(L)}$ for other systems may be obtained by the curve fitting method.

Results

In the study of the rate of forward extraction, Cr(III) was present in the aqueous phase. The data used for analysis were only those obtained from the experiments in the early stages of extraction and the effect due to the back extraction may be considered negligible.

(i) Reaction Order w.r.t. Cr(III) Concentrations

Figure 1 shows that the slope of log $(-dC_{Cr}^A/dt)$ vs. log C_{Cr}^A plots are approximately unity in both the methods used (single and multiple runs). Hence, the reaction order w.r.t. Cr(III) is unity.

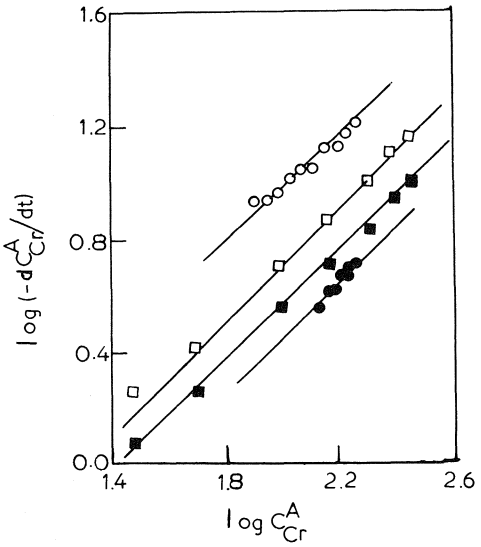

FIG. 1. Determination of the order w.r.t. Cr(III) in the forward extraction. SO_4^{2-} = 0.05 mol dm^{-3}, Ac^- = 0.25 mol dm^{-3}. (○), HDEHP = 0.6 mol dm^{-3}, pH = 4.07, C_{Cr}^A(ini) = 210 mg dm^{-3}, single run. (●), HDEHP = 0.6 mol dm^{-3}, pH = 2.72, C_{Cr}^A(ini) = 200 mg dm^{-3}, single run. (□), HDEHP = 0.6 mol dm^{-3}, pH = 3.5, dt = (5 − 0) s, multiple run. (■), HDEHP = 0.6 mol dm^{-3}, pH = 3.5, dt = (10 − 5) s, multiple run. The slope of all the lines is unity.

(ii) Reaction Order w.r.t. HDEHP Concentrations

The rate has been measured in the HDEHP concentration range of 0.15 to 0.80 mol dm^{-3} and at constant pH values of 2.32, 3.70, and 4.55. The log $q_{H_2A_2}$ vs. log $[H_2A_2]_{(0)}$ plots are given in Fig. 2. Figure 2 shows that the plots are straight lines with a slope of +1, thus, the order w.r.t. HDEHP, i.e. b is 1. From this result, it is concluded that the rate of extraction is proportional to the HDEHP concentrations in the organic phase.

(iii) Reaction Order w.r.t. H^+ Concentrations

The plots of log q_{H^+} vs. log $[H^+]$ are shown in Fig. 3 for constant HDEHP concentrations of 0.2, 0.4, and 0.6 mol dm^{-3} in the pH range 1.5 to 5.25. Figure 3 indicates that the slope of the plot approaches negative unity in the higher log $[H^+]$ region but the value increases with the decrease in log $[H^+]$ until it approaches the value of positive unity. The constants k_h and k_{h-1} in eq. [3] were determined and are listed in Table 1.

(iv) Reaction Order w.r.t. SO_4^{2-} Concentrations

The rates have been measured as a function of sulphate ion concentrations in the aqueous phase containing 0.25 mol dm^{-3} acetate at pH 3.0 (h_a = 0.4 mol dm^{-3}) and 4.5 (h_a = 0.6 mol dm^{-3}). The rate is found to decrease with the increase in the sulphate ion concentrations. Figure 4 represents the log $q_{SO_4^{2-}}$ vs. log $[SO_4^{2-}]$ plots. The experimental points do not fall on straight lines, but curves are obtained which approach a minus unity slope at higher sulphate ion concentrations. The constant $k_{f(L)}$, i.e.

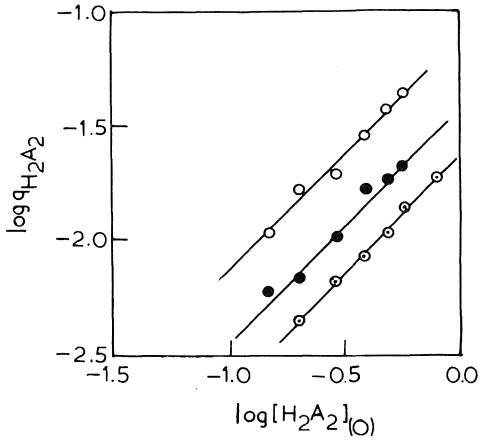

FIG. 2. Determination of the order w.r.t. HDEHP in the forward extraction. SO_4^{2-} = 0.05 mol dm^{-3}, Ac^- = 0.25 mol dm^{-3}. (○), pH = 3.70, slope = 1.00, intercept = −1.14. (●), pH = 2.32, slope = 0.97, intercept = −1.45. (⊙), pH = 4.55, slope = 1.00, intercept = −1.66.

TABLE 1. Value of constants in the rate expression

Rate constant			Other constant			
$\log k_f^*$	$\log k_{f'}{}^{0*}$	$\log k_f{}^{0*}$	k_h	k_{h-1}	$k_{f(SO_4^{2-})}$	$k_{f(NO_3^-)}$
-0.974 ± 0.047	-0.893	-0.893	500	10^{-4}	4.17	0.50

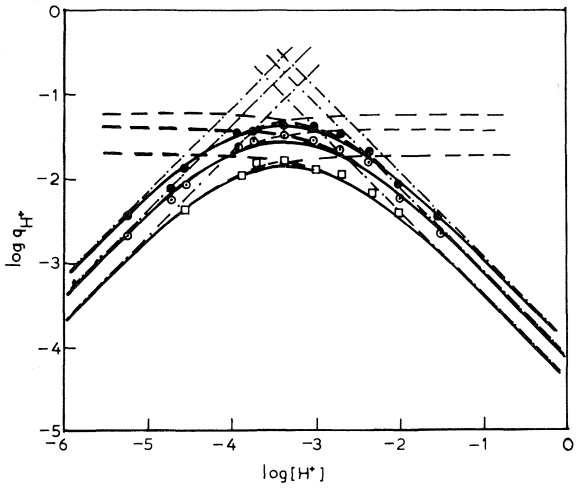

FIG. 3. Determination of the order w.r.t. H^+ in the forward extraction. $SO_4^{2-} = 0.05$ mol dm^{-3}, $Ac^- = 0.25$ mol dm^{-3}. (●), HDEHP = 0.6 mol dm^{-3}; (⊙), HDEHP = 0.4 mol dm^{-3}; (□), HDEHP = 0.2 mol dm^{-3}. The solid thick lines are drawn by: $\log q_{H^+} = \log k_f{}^* h_a{}^b - \log (k_h[H^+] + 1 + k_{h-1}[H^+]^{-1})$, where the value of k_h and k_{h-1} are found to be 500 and 10^{-4} respectively which fit the experimental points best. The thick broken lines are: $\log q_{H^+} = \log k_f{}^* h_a{}^b - \log (1 + k_h[H^+])$ and thin broken lines are: $\log q_{H^+} = \log k_f{}^* h_a{}^b - \log (1 + k_{h-1}[H^+]^{-1})$. The dotted and broken lines represent the asymptotes.

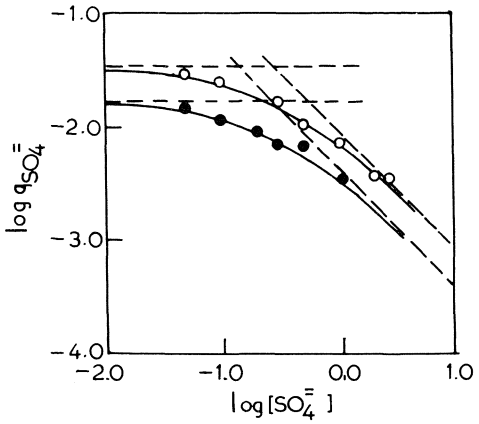

FIG. 4. Determination of the order w.r.t. SO_4^{2-} in the forward extraction. $Ac^- = 0.25$ mol dm^{-3}, (○), pH = 3.0, HDEHP = 0.4 mol dm^{-3}; (●), pH = 4.5, $H_2A_2 = 0.6$ mol dm^{-3}. The solid lines are drawn by $\log q_{SO_4^{2-}} = \log k_{f'}{}^{0*} h_a \times (500h + 1 + 10^{-4}h^{-1})^{-1} - \log (k_{f(SO_4^{2-})}[SO_4^{2-}] + 1)$, where $k_{f(SO_4^{2-})}$ is found to be 4.17, i.e. the value given for $k_{f(SO_4^{2-})}$ that fits the experimental points best is 4.17. The broken lines are two asymptotes: $\log q_{SO_4^{2-}} = \log k_{f'}{}^{0*} \times h_a(500h + 1 + 10^{-4}h^{-1})^{-1} = I$ and $\log q_{SO_4^{2-}} = I - \log k_{f(SO_4^{2-})} - \log [SO_4^{2-}]$.

$k_{f(SO_4^{2-})}$ in eq. [4], for this case, has been determined from the plot by the method of trial, i.e. the value given for $k_{f(SO_4^{2-})}$ that fits the experimental points best and is listed in Table 1. The rate constant $k_{f'}{}^{0*}$ in the presence of 0.25 mol dm^{-3} $[Ac^-]$ is also calculated and listed in the same table.

(v) Reaction Order w.r.t. Ac^- Concentrations

The rate of extraction has been determined when the HDEHP concentration is kept at 0.4 mol dm^{-3} and the acetate ion concentration is changed. The pH of the aqueous phase (containing 0.05 mol dm^{-3} SO_4^{2-}) in these experiments is kept at 3.0. Figure 5 represents the $\log q_{Ac^-}$ vs. $\log [Ac^-]$ plot, where it is found that there is no change of q_{Ac^-} value with the change of $[Ac^-]$, indicating the independence of the acetate ion concentration on the rate of Cr(III) extraction. Acetic acid was found to be partitioned between the benzene and aqueous phase (distribution coefficient, $[AcH]_{(0)}{}^{1/2}/[AcH] = 0.235$ in water/benzene system only and is nearly equal to 0.367 in water/0.2 mol dm^{-3} HDEHP dissolved in benzene). No correction was made for this and in Fig. 5, $[Ac^-]$ indicates the total concentration of acetic acid and sodium acetate, because the rate is found to be independent of acetate ion concentration.

(vi) Reaction Order w.r.t. NO_3^- Concentrations

It is found that the rate of extraction of Cr(III) is decreased to some extent in presence of nitrate ions in the aqueous phase, although the distribution coefficient does not vary with the increase in the nitrate ion concentration (10). For this, the experiments have been conducted from the aqueous solutions containing 0.05 mol dm^{-3} sulphate ion, 0.25 mol dm^{-3} acetate ion and variable amounts of nitrate ions (added as $NaNO_3$). Figure 5 represents the log $q_{NO_3^-}$ vs. log $[NO_3^-]$ plot, which shows that the value of log $q_{NO_3^-}$ decreases with the increase in the nitrate ion concentrations. The experimental points do not fall on a straight line but a curve is obtained which approaches zero slope at lower nitrate ion concentration ranges and -1 slope at higher nitrate ion concentration ranges. The value of the constant $k_{f(NO_3^-)}$ in eq. [4] has been estimated from the plot by the method of trial and error and is listed in Table 1.

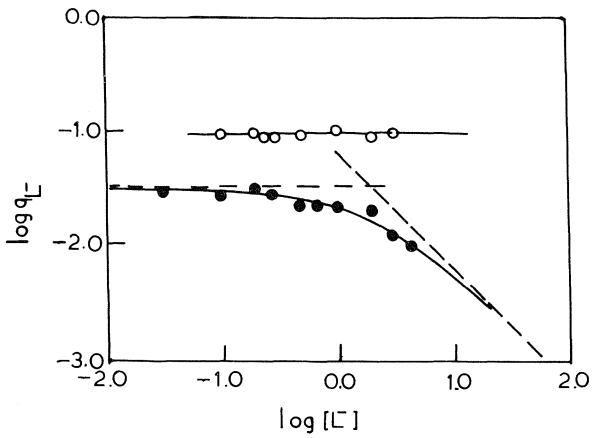

FIG. 5. Determination of the order w.r.t. Ac^- and NO_3^- in the forward extraction. (*a*) (○), [L] = $[Ac^-]$ = $[SO_4^{2-}]$ = 0.05 mol dm^{-3}, pH = 3.0, HDEHP = 0.4 mol dm^{-3}, $k_{f(Ac^-)}$ = 0 (cf. eq. [15]). (*b*) (●), L = $[NO_3^-]$ = $[SO_4^{2-}]$ = 0.05 mol dm^{-3}, pH = 3.0, HDEHP = 0.4 mol dm^{-3}, Ac^- = 0.25 mol dm^{-3}. The solid line is drawn by $\log q_{NO_3^-} = \log k_f^* h_a(500h + 1 + 10^{-4}h^{-1})^{-1} - \log (k_{f(NO_3^-)}[NO_3^-] + 1)$, where $k_{f(NO_3^-)}$ is found to be 0.5. The broken lines are two asymptotes: $\log q_{NO_3^-} = \log k_f^* h_a(500h + 1 + 10^{-4}h^{-1})^{-1} = I$ and $\log q_{NO_3^-} = I - \log (k_{f(NO_3^-)}) - \log [NO_3^-]$.

(vii) Evaluation of the Rate Constants

The forward extraction rate constant, k_f^* at 0.05 mol dm^{-3} sulphate and 0.25 mol dm^{-3} acetate media, has been evaluated from the experimental results. The value of $\log k_f^*$ is quoted in Table 1 with standard deviation.

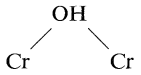
In this case, the rate constant, $\log k_f^{0*}$ (where k_f^{0*} = forward rate constant in absence of sulphate and acetate ions and $\log k_f^{0*}$ is identical with the $\log k_{f'}^{0*}$ as the rate is independent of acetate ion concentrations) has been evaluated by comparing the relation given by eq. [1] containing H^+ term modified as in eq. [3], which is valid for 0.05 mol dm^{-3} sulphate and 0.25 mol dm^{-3} acetate media, with the following relationships

$$-\frac{dC_{Cr}^{A}}{dt} = \frac{k_f^{0*} C_{Cr}^{A}[H_2A_2]_{(0)}[Ac^-]^0}{(500[H^+] + 1 + 10^{-4}[H^+]^{-1})(1 + 4.17[SO_4^{2-}])}$$

and is tabulated in Table 1.

Discussion

It has been reported early that in the lower acidities Cr(III) is present as hydrolysed and polymerised species. At higher acidities (pH < 2), Cr(III) is present as $[Cr(H_2O)_6]^{3+}$ (19, 20). But as the acidity is decreased, there will appear successively the species like $[Cr(OH)]^{2+}$, $[Cr_2(OH)_2]^{4+}$, $[Cr_4(OH)_4]^{8+}$, $[Cr_2(OH)_3]^{3+}$, $[Cr_4(OH)_8]^{4+}$, $[Cr(OH)_2]^{2+}$, etc. until it precipitates out as $Cr(OH)_3$ at pH around 5.5 (co-ordinated water molecules are not shown) (10, 19, 20). Kobayashi *et al.* reported that the polynuclear chromium compounds contain the non-linear



groups (21).

In discussing the results obtained from the rate measurements, i.e. the first order dependence of Cr(III) concentrations on the rate at any pH indicates that the mononuclear Cr(III) species are always involved in the rate determining step. Although there may be present various types of Cr(III) species (mono or polynuclear), only the mononuclear species will be responsible for the rate determinations. The first order dependence of Cr(III) concentration on the rate is in agreement with the general observation that the order w.r.t. the metal ions is found to be unity (2, 7, 13–17, 22, 23), except in the case of extraction of Ti(IV) with HDEHP (1) and of Zn(II) with di-α-naphthyl dithiocarbazone (24). Thus, at lower acidities Cr(III), present as polynuclear form, breaks down rapidly to mononuclear form which then reacts.

The value of the rate constant ($k_f^{0*} = 10^{-0.974}$) obtained for the system may be considered high. It is well known that the substitution reactions in Cr^{3+} species are so slow that it takes a few hours to a few days for completion of the reactions. It is well known that the substitution in $Cr(OH)^{2+}$ is 10–100 times faster than the substitution in Cr^{3+} and the interconversion of Cr^{3+} with $Cr(OH)^{2+}$ is very rapid. As a result, the value of the rate constant suggests that the reactions will proceed via $Cr(OH)^{2+}$ as a primary path instead of via Cr^{3+} in the lower pH ranges at which the experiments were done. At higher pH ranges, the dihydroxypolymerised species may be assumed to be converted rapidly into $Cr(OH)^{2+}$ ions which then react.

The first hydrolysis constant (β_1) for $Cr(OH)^{2+}$ may be given by:

$$[5] \quad [Cr^{3+}] = [Cr(OH)^{2+}][H^+]/\beta_1$$

where β_1 has been estimated to be about 10^{-4} (20, 25), and as a result, the rate expression in absence of sulphate and acetate ion in the low pH range (around pH 2) may be represented by:

$$[6] \quad -dC_{Cr}^{A}/dt = (500\beta_1)^{-1} k_f^{0*}[Cr(OH)^{2+}] \times [H_2A_2]_{(0)}$$

At very low acidities (around pH 4.5, where Cr(III) is supposed to be present entirely as $Cr(OH)_2^+$ or its polymer), the following hydrolysis equilibrium is maintained:

[7] $[Cr(OH)^{2+}] = [Cr(OH)_2{}^{+}][H^+]/\beta_2$

where $\beta_2 = 10^{-6.5}$ (20) and the rate expression becomes:

[8] $-dC_{Cr}{}^{A}/dt = \beta_2 10^4 k_f{}^0 * [Cr(OH)^{2+}][H_2A_2]_{(0)}$

The eqs. [6] and [8] suggest that at both high and low acidities, the step represented by:

[9] $Cr(OH)^{2+} + H_2A_2 \rightarrow CrHA_2{}^{2+} + H_2O$

acts as rate determining in the pH range studied. A similar type of mechanism through the formation of hydroxy species has been suggested for the extraction of Fe(III) with HDEHP by Roddy *et al.* (26).

Similar to the fact that the sulphate ion (10) decreases the distribution ratio of Cr(III), the rate of extraction of Cr(III) is also decreased by the presence of sulphate ion, probably due to the formation of the aqueous Cr^{3+}–$SO_4{}^{2-}$ complex and/or Cr^{3+}–$SO_4{}^{2-}$ ion pairs (27). The sulphate group of such complexes or ion pairs are more slowly replaced by $HA_2{}^{-}$ group or the dissociation of such complexes affects the rate of extraction. Analogous suggestions may be put forward for the effect of nitrate ion on the rate. It is known that Cr(III) also forms complex of the type $[Cr_3O(Ac)_6]^{+}$ with acetate (28). The independence of rate on acetate ion suggests that the complex of Cr(III) with Ac^{-} rapidly breaks down into Cr(III) or such product, in presence of $HA_2{}^{-}$ group which then react with $HA_2{}^{-}$ or no such complex is formed in presence of high sulphate ion concentrations. The exact explanation is not known to us. The acetate independence of Cr(III) on the extraction ratio was also observed and reported (10).

The failure to the backward extraction is expected since a number of metal chelates are known to exhibit refractory character towards the attack by ligands (7, 29). This type of inertness is particularly expected in the case of Cr(III).

Appendix

Elaborated Mathematical Treatment of eq. [3] to Evaluate the Value of k_h and k_{h-1}

At higher acidities, the contribution due to $k_{h-1}[H^+]^{-1}$ term may be disregarded, and the following equation may be considered to fit the experimental points:

[10] $\log q_{H^+} = \log k_f * h_a{}^b - \log (k_h[H^+] + 1)$

The curve represented by eq. [10] has two asymptotes:

[11] $\underset{[H^+]\rightarrow 0}{\text{Lt}} \log q_{H^+} = \log k_f * h_a{}^b$

[12] $\underset{[H^+]\rightarrow \infty}{\text{Lt}} \log q_{H^+} = \log k_f * h_a{}^b - \log k_h - \log [H^+]$

The asymptote represented by eq. [12] has intercept of value $\log k_f * h_a{}^b - \log k_h$ and hence the value of k_h may be obtained as the value of $\log k_f * h_a{}^b$ is known from the asymptote represented by eq. [11].

Similar treatment at the lower acidities, where the term $k_h[H^+]$ may be neglected, gives the value of k_{h-1}.

The oxidation of ascorbic acid and hydroquinone by perhydroxyl radicals. A flash photolysis study

A. D. NADEZHDIN AND H. B. DUNFORD
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received May 25, 1979

A. D. NADEZHDIN and H. B. DUNFORD. Can. J. Chem. **57**, 3017 (1979).

The oxidation of ascorbic acid (AH_2) and hydroquinone (QH_2) by photolytically generated $HO_2^{\bullet}$ radicals was studied over a broad range of pH. The rate constants of the following processes were obtained

$$k(AH + HO_2^{\bullet} \rightarrow A^{-\bullet} + H_2O_2) = (1.25 \pm 0.25) \times 10^6\ M^{-1}\ s^{-1}$$

$$k(AH^- + O_2^{-\bullet} \rightarrow A^{-\bullet} + HO_2^-) = (5.75 \pm 0.35) \times 10^4\ M^{-1}\ s^{-1}$$

and

$$k(QH_2 + HO_2^{\bullet} \rightarrow {}^{\bullet}QH + H_2O_2) = \text{either } (0.85 \pm 0.1) \times 10^4$$

$$\text{or } (1.7 \pm 0.2) \times 10^4\ M^{-1}\ s^{-1}$$

depending upon two different possible mechanistic interpretations.

A. D. NADEZHDIN et H. B. DUNFORD. Can. J. Chem. **57**, 3017 (1979).

On a étudié, sur une large échelle de pH, l'oxydation de l'acide ascorbique (AH_2) et de l'hydroquinone (QH_2) par des radicaux $HO_2^{\bullet}$ générés photochimiquement. On a obtenu les constantes de vitesse pour les réactions suivantes:

$$k(AH + HO_2^{\bullet} \rightarrow A^{-\bullet} + H_2O_2) = (1.25 \pm 0.25) \times 10^6\ M^{-1}\ s^{-1}$$

$$k(AH^- + O_2^{-\bullet} \rightarrow A^{-\bullet} + HO_2^-) = (5.75 \pm 0.35) \times 10^4\ M^{-1}\ s^{-1}$$

et

$$k(QH_2 + HO_2^{\bullet} \rightarrow {}^{\bullet}QH + H_2O_2) = \text{soit } (0.85 \pm 0.1) \times 10^4$$

$$\text{ou } (1.7 \pm 0.2) \times 10^4\ M^{-1}\ s^{-1}$$

dépendant des deux différentes interprétations possibles du mécanisme de la réaction.

[Traduit par le journal]

Introduction

The role of perhydroxyl radicals in different oxidadation processes involving oxygen is widely discussed in the literature especially that of biochemistry (1) during the last decade. A large number of elementary reactions of $O_2^{-\bullet}$ (or its acidic form $HO_2^{\bullet}$) have been studied quantitatively. Although most of the processes reported involve perhydroxyl radical as a reducing agent, there are a few studies describing its oxidative ability. In particular, several reactions of $HO_2^{\bullet}$ with one-electron reductants, such as transition metal ions in low oxidation states, Fe^{2+} (2), Cu^+ (3), Ce^{3+} (4) were studied by different techniques. Oxidation of a number of organic reductants like cysteine (5), ascorbic acid (6), and hydroquinone (7) by $HO_2^{\bullet}$ was indicated in γ radiolysis experiments in which an increase of H_2O_2 yield was observed. More recent kinetic studies provide the values of rate constants (8–12). These papers will be discussed in detail later.

In the case of two-electron reductants such as organic molecules one faces several experimental problems. These include possible reactivity of $HO_2^{\bullet}$ radicals with the products of one-electron transfers (semiquinone radicals), and reactions of semiquinones with molecular oxygen which could lead to a chain process (9). Another important problem is the reductive ability of superoxide anions, so the presence of small amounts of products of the two-electron oxidation of initial reagent can cause $O_2^{-\bullet}$ consumption and semiquinone production (see below). This could be a serious misleading factor, when the reaction is studied by following the increase of semiquinone concentration. Therefore, the observation of the initial reductant consumption has to be considered as more direct and reliable than other methods.

In this work we studied the oxidation of ascorbate (AH_2) and hydroquinone (QH_2) by perhydroxyl radicals generated by the flash photolysis of water solutions containing reductant and H_2O_2. As was explained in detail in our initial paper (12), when the ratio of $[H_2O_2]_0$:[reductant] exceeds 10^3, all primary $^{\bullet}OH$ radicals generated by photolysis of H_2O_2

0008-4042/79/233017-06$01.00/0

(13) are scavenged by hydrogen peroxide producing $HO_2^{\bullet}$ radicals within 1/10 of a millisecond after the flash.

Materials and Methods

All the chemicals were of reagent grade used without further purification except ascorbate, which was recrystallized from spectroscopic grade methanol. Buffer solutions for pH regions 3.8–5.8 and 6.0–7.8 were acetic acid – sodium acetate and potassium dihydrogen phosphate – sodium hydroxide; pH values lower than 3.5 were adjusted by adding concentrated $HClO_4$. Several experiments in the neutral pH region were accomplished without any buffer and no dependence of the results on the presence of buffer or its concentration was observed. In the majority of experiments with buffers the ionic strength value was 0.02 *M*. Approximately 10^{-5} *M* EDTA was added to the ascorbate stock solution to prevent AH_2 oxidation on heavy metal residues. Quintuply distilled water was used for all experiments. Control experiments, where optical absorption of the solution was recorded vs. time in the absence of flash light, showed that the spontaneous oxidation of AH_2 and QH_2 by O_2 or H_2O_2 was a negligibly slow process compared to the reductants consumption under irradiation (14).

The flash photolysis apparatus with spectrophotometric registration has been described (12). The limiting error of absorbance was between 5×10^{-5} and 2×10^{-4} absorbance units depending upon the time interval of the experiment. Consumption of ascorbic acid after each flash was followed in the spectral region 260–265 nm where AH_2 absorbs very strongly as is shown in Fig. 1*a* and where dehydroascorbate does not absorb appreciably. Oxidation of hydroquinone was followed at 290 nm where absorption of hydroquinone is about seven times stronger than that of quinone (Fig. 1*b*). H_2O_2 was present in the solutions in a large excess. However, since its molar absorptivity is relatively low ($\sim 2\ M^{-1}\ cm^{-1}$ at 290 nm and $\sim 12\ M^{-1}\ cm^{-1}$ at 265 nm) compared to that of ascorbate or hydroquinone the absorption changes recorded after each flash are totally accounted for by the consumption of reductant. At the wavelength of the photolyzing light (λ = 330 nm) absorption by the reductants was negligibly small compared to that of H_2O_2 and in control flash experiments in the absence of H_2O_2 no change of AH_2 or QH_2 concentrations was observed. The concentration of perhydroxyl radicals formed per flash was measured by the method described in ref. 12 using the $O_2^{-\bullet}$ scavenger, tetranitromethane. All experiments were carried out at 22°C.

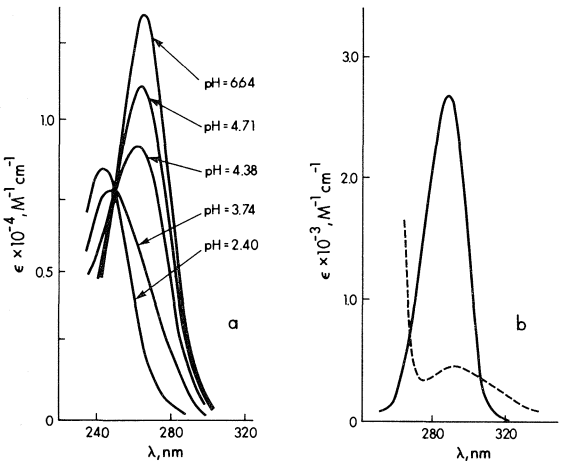

FIG. 1. The ascorbate and hydroquinone absorption spectra. (*a*) Molar absorptivity (ε) of ascorbic acid at different pH values, $\mu = 0.02\ M$, 22°C. (*b*) Solid line: absorption spectrum of hydroquinone at low and neutral pH; broken line represents quinone spectrum.

Results and Discussion

The change of the optical absorption vs. time after each flash in the system $AH_2 + H_2O_2$ obeyed first order kinetics. A typical run is illustrated in Fig. 2. It can be seen from Table 1 that the value of the relaxation time τ_0, is inversely proportional to $[AH_2]$ and did not depend on the initial concentration of perhydroxyl radicals, $[HO_2^{\bullet}]_0$. On the other hand the overall change of AH_2 concentration did not depend on $[AH_2]_0$ and was directly proportional to $[HO_2^{\bullet}]_0$. The stoichiometry of the reaction was $[HO_2^{\bullet}]_0 : \Delta[AH_2] = 2 \pm 0.2$. These facts can be interpreted in terms of two alternative schemes:

Scheme (*a*)

$$[1] \quad HO_2^{\bullet} + AH_2 \rightarrow A^{-\bullet} + H_2O_2 + H^+$$

$$[2] \quad HO_2^{\bullet} + A^{-\bullet} \xrightarrow{H^+} A + H_2O_2$$

or Scheme (*b*)

$$[1] \quad HO_2^{\bullet} + AH_2 \rightarrow A^{-\bullet} + H_2O_2 + H^+$$

$$[3] \quad A^{-\bullet} + A^{-\bullet} \xrightarrow{2H^+} A + AH_2$$

where $A^{-\bullet}$ is the semiquinone radical of ascorbate, studied and chemically characterized in refs. 15–17, and A designates dehydroascorbate.

If reaction [2] is faster in our system than [3] and Scheme (*a*) is valid we can write

$$d[AH_2]/dt = -k_1[AH_2][HO_2^{\bullet}]$$

$$d[HO_2^{\bullet}]/dt = -k_1[AH_2][HO_2^{\bullet}] - k_2[A^{-\bullet}][HO_2^{\bullet}]$$

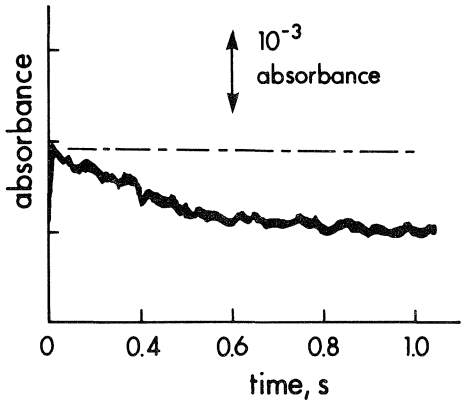

FIG. 2. Absorption change vs. time after flash in the system ascorbate (AH_2) + H_2O_2. $[AH_2]_0 = 1.2 \times 10^{-5}\ M$, $[HO_2^{\bullet}]_0 = 1.2 \times 10^{-7}\ M$, pH = 7.11, $\mu = 0.02\ M$, 22°C.

Using the steady state approximation for the value of $[A^{\cdot}]$ one gets

$$k_1[AH_2][HO_2] = k_2[A^{-\cdot}][HO_2^{\cdot}]$$

and therefore

$$d[HO_2^{\cdot}]/dt = -2k_1[AH_2][HO_2^{\cdot}]$$

Integrating this system of equations and taking into account that $[AH_2] \gg [HO_2^{\cdot}]_0$ we get

$$[4] \quad [AH_2]_0 - [AH_2] = \tfrac{1}{2}[HO_2^{\cdot}]_0\{1 - \exp(-2k_1[AH_2]t)\}$$

Scheme (*b*) after integrating gives

$$[5] \quad [AH_2]_0 - [AH_2] = \tfrac{1}{2}[HO_2^{\cdot}]_0\{1 - \exp(-k_1[AH_2]t)\}$$

Equations [4] and [5] describe the same stoichiometry and kinetic behaviour but the second gives a rate constant two times larger for reaction [1] than the first. Fortunately we were able to distinguish between these two possibilities.

Let us suppose that (*b*) is the correct scheme. According to the steady state approximation for $[A^{-\cdot}]$ relation [6] must be fulfilled:

$$[6] \quad 2k_3[A^{-\cdot}]^2 = k_1[AH_2][HO_2^{\cdot}]$$

The rate constant of the disproportionation of $A^{-\cdot}$ radicals, k_3, is known at different pH values (14). For example at pH = 5 it is $\sim 1.5 \times 10^7$ M^{-1} s^{-1} and at pH 7 it is $\sim 10^6$ M^{-1} s^{-1}. The value of $[A^{-\cdot}]$ in the course of the reaction was estimated by the recording of absorption vs. time at 360 nm where the molar absorptivity of $A^{-\cdot}$ radicals is maximal

and equal to $3 \times 10^3\ M^{-1}\ cm^{-1}$ (15). At least $4 \times 10^{-8}\ M$ of a species with such a molar absorptivity should be easily detected using our registration system. Under typical conditions, $[AH_2]_0 = 10^{-5}\ M$ and $[HO_2^{\cdot}]_0 \simeq 10^{-7}\ M$, we did not observe any change of absorbance at 360 nm in a pH region from 4.2 to 7.5, therefore in the course of AH_2 consumption $[A^{-\cdot}]$ did not exceed $4 \times 10^{-8}\ M$. Using the above mentioned values of k_3 and the experimentally determined k_{app} as k_1 in accordance with Scheme (*b*), one can see that relation [6] is not fulfilled. Therefore reaction [2], Scheme (*a*), must be the main way of $A^{-\cdot}$ radical consumption and k_1 is equal to one half of the k_{app} values in the last column of Table 1.

The dependence of $\log k_1$ vs. pH is shown in Fig. 3. The data can be accounted for quantitatively by considering the acid–base equilibria

[7] $AH_2 \rightleftharpoons AH^- + H^+ \qquad K_7 = [H^+][AH^-]/[AH_2]$

and

[8] $HO_2^{\cdot} \rightleftharpoons O_2^{-\cdot} + H^+ \qquad K_8 = [H^+][O_2^{-\cdot}]/[HO_2^{\cdot}]$

Assuming that the reaction between ascorbate and perhydroxyl radical over the pH region of the study is in fact the sum of two processes

[9] $AH^- + HO_2^{\cdot} \xrightarrow{k_9} A^{-\cdot} + H_2O_2$

[10] $AH^- + O_2^{-\cdot} \xrightarrow{k_{10}} A^{-\cdot} + HO_2^-$

we have

$$[11] \quad \tfrac{1}{2}k_{app} = k_1 = \frac{k_9K_7[H^+] + k_{10}K_7K_8}{([H^+] + K_7)([H^+] + K_8)}$$

Use of a nonlinear least-squares computer program fitting the data to eq. [11] gave the following best fit parameters

$$pK_7 = 4.0 \pm 0.1$$

(compared to the literature value of 4.1 (18))

$$pK_8 = 5.05 \pm 0.1$$

(compared to the literature value 4.9 (19))

$$k_9 = (1.25 \pm 0.15) \times 10^6\ M^{-1}\ s^{-1}$$

and

$$k_{10} = (5.75 \pm 0.35) \times 10^4\ M^{-1}\ s^{-1}$$

The continuous curve in Fig. 3 is numerically simulated using these values. At pH > 7 k_{app} is practically equal to $2k_{10}$, i.e., $1.15 \times 10^5\ M^{-1}\ s^{-1}$. This value is consistent with that obtained by Bielski and Richter (9) ($1.52 \times 10^5\ M^{-1}\ s^{-1}$) and close to the rate constant for $AH_2 + O_2^{-\cdot}$ (8), $2.7 \times 10^5\ M^{-1}\ s^{-1}$ at pH = 7.4. However, the rate constant for the same reaction given in ref. 10, $(0.8 \pm 0.2) \times 10^8\ M^{-1}\ s^{-1}$, is much bigger than our value as well as that listed in refs. 8 and 9.

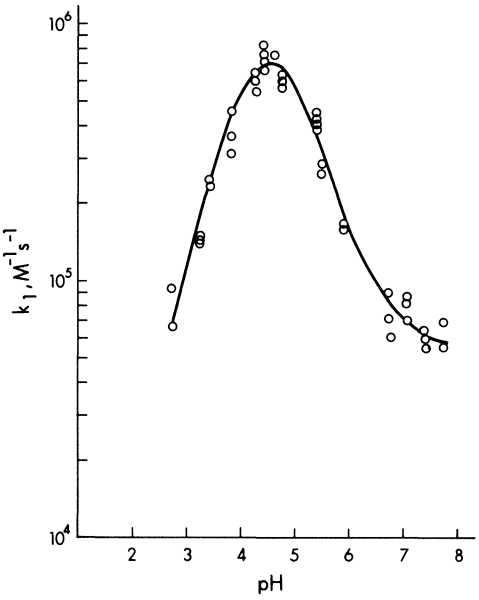

FIG. 3. The pH dependence of k_1. $\mu = 0.02\ M$, 22°C. Points represent experimental data, while the continuous line is numerically simulated using eq. [11] and the best fit parameters.

The results of the flash photolysis study of hydroquinone oxidation are represented in Table 2. We observed the same kind of kinetics as in the $AH_2 + HO_2^{\cdot}$ system and, as it can be seen from Table 2, the value of τ_0 was inversely proportional to $[QH_2]_0$ and did not depend on $[HO_2^{\cdot}]_0$. The overall change of absorption at $\lambda = 290$ nm did not depend on $[QH_2]$ and was proportional to $[HO_2^{\cdot}]_0$, corresponding to the stoichiometry: $[HO_2^{\cdot}]_0 : \Delta[QH_2] = 2 \pm 0.1$. The same two possible mechanisms as in the case of ascorbate oxidation (*a* and *b*) could be suggested for $QH_2 + HO_2^{\cdot}$ interaction, but in the case of hydroquinone we were not able to choose between the two possible ways of semiquinone consumption

[12] $QH^{\cdot} + HO_2^{\cdot} \rightarrow Q + H_2O_2$

or

[13] $QH^{\cdot} + QH^{\cdot} \rightarrow QH_2 + Q$

where $QH^{\cdot}$ is the protonated form of the semiquinone radical ($pK \simeq 4$ (20)) and Q designates *p*-benzoquinone. The rate constant of semiquinone radical disproportionation is extremely high at low pH, $2k_{13} = 1.2 \times 10^9\ M^{-1}\ s^{-1}$ (21) and without knowledge of k_{12} we could not compare the rates of the reactions [12] and [13]. Therefore the elementary rate constant of the reaction

[14] $QH_2 + HO_2^{\cdot} \rightarrow QH^{\cdot} + H_2O_2$

TABLE 2. Reaction between hydroquinone and perhydroxyl radical; $k_{app} = 1/(\tau_0[QH_2]_0)$

3.51	1.50	1.2	0.7	0.45	1.48

could be equal to k_{app} from Table 2 or be one half of its value, i.e. k_{14} is either $(1.7 \pm 0.2) \times 10^4$ M^{-1} s^{-1} or $(0.85 \pm 0.1) \times 10^4$ M^{-1} s^{-1}. It is seen from Table 2 that in the pH region from 0.4 to 3.5 k_{app} does not depend on $[H^+]$. At the pH values from 3.5 to 4 the overall change of absorption caused by the flash decreased drastically and a further increase of pH eliminated that change totally. It is possible that traces of quinone could be present as an impurity or even formed slowly in the dark in the solution containing H_2O_2 and hydroquinone. It could compete with hydroquinone for hydroperoxyl radicals at pH values close to the pK of $HO_2^{\cdot}$, 4.88 (19), because of the very high rate constant of the reaction

[15] $Q + O_2^{-\cdot} \rightarrow Q^{-\cdot} + O_2$

$k_{15} = 9.8 \times 10^8$ M^{-1} s^{-1} (11). According to this suggestion quinone should not interfere with hydroquinone oxidation at lower pH values, since $HO_2^{\cdot}$ could be relatively inert as a reductant of Q, and $[O_2^{-\cdot}]$ is small in acidic solutions. The following experiments served to confirm these speculations. Addition of 2×10^{-5} M quinone to the solution containing 2×10^{-4} M QH_2 and 0.2 M H_2O_2 at pH 2.5 totally subdued the hydroquinone consumption normally observed in the absence of quinone after a flash. However, several drops of concentrated $HClO_4$ added to the solution restored the process of QH_2 oxidation under irradiation; the final pH in the system was 1.05. The latter result is relevant to the problem of the drastic disagreement between our value of the rate constant of $QH_2 + HO_2^{\cdot}$ interaction, 1.7×10^4 M^{-1} s^{-1}, and that of the reaction of QH_2 oxidation by $O_2^{-\cdot}$, 1.6×10^7 M^{-1} s^{-1} given in ref. 11 (in spite of the fact that the $HO_2^{\cdot}$ radical is a stronger oxidant than $O_2^{-\cdot}$). In fact we did not observe QH_2 consumption under flash irradiation at neutral pH. The authors of ref. 11 studied the reaction of hydroquinone with $O_2^{-\cdot}$ by following the semiquinone production in the solution of QH_2 where superoxide anions were generated. Taking into account the extremely high rate constant of reaction [15] (see above), one can see that if about 1% of QH_2 is present as quinone, formation of semiquinone could occur via quinone reduction, rather than hydroquinone oxidation. In conclusion we want to stress the necessity of considering all possible ways of intermediate formation when studying superoxide reactions. It is dangerous to assume that $O_2^{-\cdot}$ is acting as an oxidant because of its very strong reducing ability.

According to our data the reactivity of ascorbate in a one-electron oxidation by $HO_2^{\cdot}$ and $O_2^{-\cdot}$ is greater than that of NADH (12), whereas ascorbate radicals, products of the one-electron oxidation of ascorbic acid, are more inert as reductants than NAD$^{\cdot}$ radicals (22). Thus ascorbate has a greater tendency than NADH to react via one-electron steps, whereas with NADH the hydride ion transfer mechanism can compete successfully with the slower initial one electron transfer.

Magnetic field effect on the fluorescence from γ-irradiated solutions of perfluorocarbons[1]

ROBERT SMITH DIXON AND VINCENT JOHN LOPATA

Atomic Energy of Canada Limited Research Company, Research Chemistry Branch, Whiteshell Nuclear Research Establishment, Pinawa, Man., Canada R0E 1L0

Received May 22, 1979

ROBERT SMITH DIXON and VINCENT JOHN LOPATA. Can. J. Chem. **57**, 3023 (1979).

The effect of an applied magnetic field on the fluorescence from γ-irradiated solutions of perfluorobiphenyl and perfluoronaphthalene has been measured in various solvents. In all the solvents used (cyclohexane, squalane, isooctane) the fluorescence intensity increases with increasing field and tends towards a plateau at high fields (> 0.1 T). At low fields, the fluorescence enhancement is smaller for the perfluorocarbons than for the parent hydrocarbons, due to the larger electron–nuclear hyperfine coupling and broader spread of the hyperfine levels in the radical ions of the perfluorocarbons. At high fields the fluorescence enhancement is also smaller for the perfluorocarbons than for the parent hydrocarbons, indicating a larger relative proportion of prompt (field-independent) fluorescence for the perfluorocarbons than for the parent hydrocarbons.

ROBERT SMITH DIXON et VINCENT JOHN LOPATA. Can. J. Chem. **57**, 3023 (1979).

On a mesuré dans différents solvants l'effet d'un champ magnétique appliqué sur la fluorescence provenant des solutions de perfluorobiphényles et perfluoronaphtalènes irradiées aux rayons γ. Dans tous les solvants utilisés (cyclohexane, squalane, isooctane) l'intensité de la fluorescence augmente avec le champ et tend vers un plateau pour des valeurs élevées du champ (> 0.1 T). Lorsque le champ est faible la fluorescence provenant des perfluorocarbures augmente plus faiblement que celle reliée aux hydrocarbures apparentés. Ceci est dû à un plus grand couplage hyperfin électron–noyau et à un étalement plus vaste des niveaux hyperfins des ions radicalaires des perfluorocarbures. A champs forts l'augmentation de la fluorescence est également plus petite pour les perfluorocarbures que pour les hydrocarbures apparentés indiquant ainsi une plus grande proportion relative de fluorescence rapide (indépendante du champ) dans le cas des perfluorocarbures que dans les cas des hydrocarbures apparentés.

Introduction

Large yields of electrons and cations are produced following absorption of ionizing radiation by a liquid. In nonpolar liquids, the major fraction of the ion pairs produced by γ or electron irradiation does not separate completely but undergoes geminate recombination. This produces electronically excited singlet and triplet states, the relative yields of which have been predicted to change in an applied magnetic field (1–3). Such an effect has now been observed in both pulse (4–6) and γ-irradiated (6–8) solutions of aromatic hydrocarbons in alkane solvents. Recently, experiments using the single photon counting technique have confirmed the effect (9–11).

When a pair of solute radical ions M^+ and M^- recombine geminately, loss of spin correlation, i.e., a change from singlet to triplet, occurs because of the isotropic hyperfine interactions between the unpaired electrons and the hydrogen nuclei of M^+ and M^-. A magnetic field was predicted to decrease the rate of loss of spin correlation leading to an increase in singlet production, the effect being time-dependent (1–3). This was confirmed in pulse-irradiated solutions of hydrocarbons in squalane and cyclohexane (4–6). In continuously γ-irradiated solutions (6–8), a smaller magnetic field effect is observed because the prompt emission, which exhibits no field effect, is superimposed on the emission from slower ion recombinations, which does show a magnetic field effect.

To date, the study of the effects of substitution in the solute molecule has been limited to deuteration. Since the magnetic moment of a deuteron is smaller than that of a proton (12, 13) electron–nuclear hyperfine coupling is smaller in deutero radical ions than in the corresponding protiated ions. Thus the rate of loss of spin correlation was calculated to be lower for deuterated compounds (2, 3), leading to a smaller magnetic field effect at high fields. This has been confirmed experimentally with naphthalene and naphthalene-d_8 (8). However, at low fields, the opposite effect was observed, i.e., the enhancement of the fluorescence intensity was higher for naphthalene-d_8 than for naphthalene. Although this appears contradictory, it does, in fact, provide further support for the theory. In order to be effective in preventing mixing between the singlet and triplet states of the geminate ion pair prior to recombination (resulting

[1]AECL No. 6647.

0008-4042/79/233023-05$01.00/0

in a smaller triplet formation in a magnetic field), the Zeeman splitting due to the field must be greater than the spread of the hyperfine levels. This spread is smaller for naphthalene-d_8 because of the smaller coupling constant, so a smaller field is required to produce an initial enhancement in naphthalene-d_8. This hypothesis may be tested further by examining magnetic field effects on compounds with large coupling constants. Radical ions of fluorinated aromatic hydrocarbons have high coupling constants (e.g., 14–16) and we have therefore compared the magnetic field effect on the fluorescence intensity from γ-irradiated naphthalene-f_8 (PFN) and biphenyl-f_{10} (PFB) with that from the corresponding protiated molecules in various solvents.

Experimental

The experimental arrangement is described in detail elsewhere (6–8). The solutions were irradiated in a Suprasil cell which was part of a flow system for ease of sample changing. The Ir-192 γ-ray source gave a dose rate of $\sim 5 \times 10^{-5}$ J g^{-1} s^{-1}, in the solution, as measured by the Fricke dosimeter. The light emitted during radiolysis was focussed by a lens onto an RCA 1P28 photomultiplier tube and the level displayed on a recorder. The cell was positioned between the poles of a small electromagnet which provided a field up to 0.5 T, as measured by a Hall-type gaussmeter. The small residual field ($\sim 10^{-3}$ T) remaining when the magnetic field was turned off was eliminated by passing a reverse current through the magnet until the magnetic field was a minimum in the direction of the Hall crystal. The field at the minimum was $< 10^{-4}$ T. The magnetic field had no effect on the photomultiplier tube or on the emission intensity from a cell containing solvent only, but it was necessary to correct for the current produced in the photomultiplier tube by the γ-source.

Solutions were de-aerated by bubbling with dry ultrahigh purity argon gas (Matheson). Biphenyl (Hinton) and naphthalene (Aldrich) were zone-refined prior to use. Squalane (Eastman) was passed through a silica gel column until the absorption edge, measured spectrophotometrically, remained constant. Biphenyl-f_{10} (Imperial Smelting), naphthalene-f_8 (PCR Inc.), cyclohexane, isooctane, and benzene (Fisher spectroanalyzed) were used without further purification.

Results

In order to determine the emitting species in irradiated solutions of perfluorocarbons, comparisons were made between the spectra obtained by pulse radiolysis and by spectrofluorimetry. The emission spectra from pulse-irradiated 10^{-2} M perfluorobiphenyl (PFB) and perfluoronaphthalene (PFN) in cyclohexane are shown in Fig. 1. Similar spectra were obtained in benzene and the spectra measured during the pulse and following the pulse were the same, within experimental error. The intensity of the PFN spectrum was about twice that of the PFB spectrum, in accordance with their measured fluorescence yields (17). The spectra of both perfluorinated compounds are substantially red-shifted compared to the protiated compounds

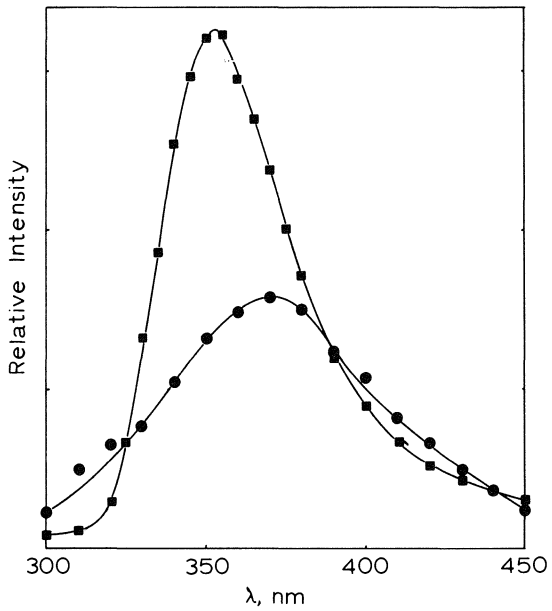

FIG. 1. Fluorescence spectra from pulse-irradiated 10^{-2} M perfluorobiphenyl (○) and perfluoronaphthalene (□) in cyclohexane (corrected for the spectral response of the light detection system).

(18). The maximum of the PFB spectrum occurs at 371 nm, which compared well with spectrofluorimetric measurements of 372 nm in cyclohexane (this laboratory) and 375 nm in petroleum ether (17). The maximum of the PFN spectrum occurs at 353 nm, which is in good agreement with the spectrofluorometric values of 352 nm in cyclohexane, 357 nm in squalane (this laboratory), and 355 nm in petroleum ether (17). However, it is somewhat lower than the values of Singh and Quinn (19) who found a small red shift in λ_{max} with increasing solute concentration. Thus self-absorption, excimer formation, or an impurity effect cannot be excluded completely at high concentrations. Excimer formation appears unlikely since none was seen in photoexcited PFN in methylcyclohexane down to 213 K, though there is evidence for excimer formation in more viscous solvents at low temperatures (20). Nevertheless the similar spectra obtained spectrofluorimetrically and pulse-radiolytically show that the emission from irradiated solutions arises mainly from singlet fluorescence.

The changes in intensity of the fluorescence from γ-irradiated solutions of PFB and PFN (10^{-2} M) in various solvents, viz., cyclohexane, squalane, and isooctane, as a function of magnetic field strength are compared with those of the parent hydrocarbons in Figs. 2 and 3. In all cases the fluorescence intensity increases steadily with increasing magnetic field and tends towards a plateau above ~ 0.1 T, the plateau

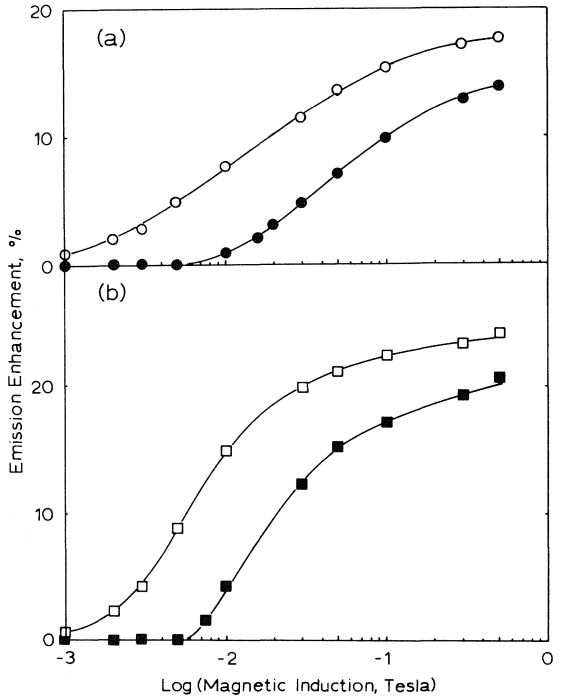

FIG. 2. Increase in fluorescence intensity as a function of applied magnetic field: (*a*) 10^{-2} *M* biphenyl (○) and perfluorobiphenyl (●) in squalane; (*b*) 10^{-2} *M* biphenyl (□) and perfluorobiphenyl (■) in isooctane.

value depending on the solvent. At low fields, the effect of magnetic field on the perfluorinated compounds is much less than on the parent hydrocarbons, and a minimum field of $\gtrsim 0.005$ T is required to produce an initial increase for the perfluorinated compounds. At high fields, the "plateau" value is also smaller for the perfluorinated compounds than the corresponding hydrocarbons in each solvent.

Discussion

In solutions of an aromatic hydrocarbon in an alkane solvent, geminate recombination of solute radical ion pairs is one source of excited states (21–26). For an aromatic hydrocarbon, M, in an alkane solvent, S, the major reactions leading to excited state formation via ion recombination are as follows:

[1] $S \rightsquigarrow S^+ + e^-$

[2] $S^+ + M \rightarrow M^+ + S$

[3] $e^- + M \rightarrow M^-$

[4] $M^+ + e^- \rightarrow M^*$

[5] $S^+ + M^- \rightarrow M^* + S$

[6] $M^+ + M^- \rightarrow M^* + M$

where M* may be an excited singlet or triplet state.

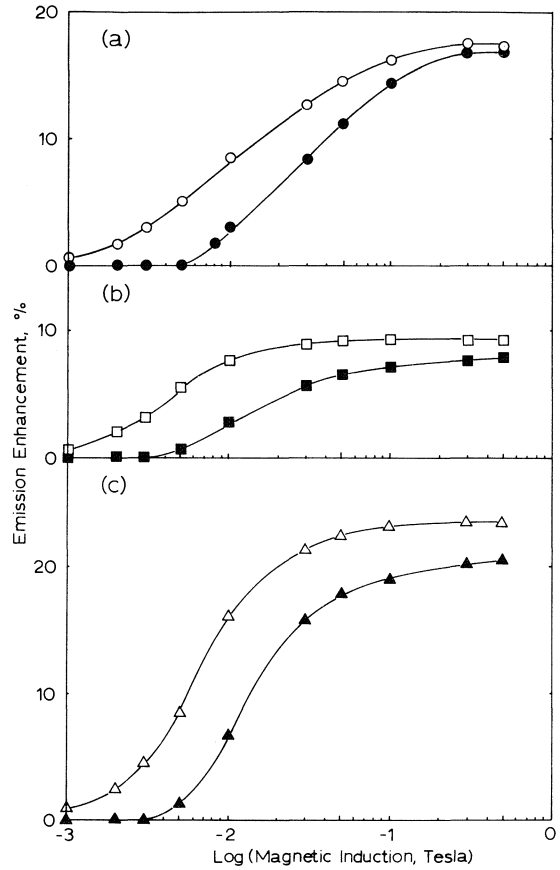

FIG. 3. Increase in fluorescence intensity as a function of applied magnetic field: (*a*) 10^{-2} *M* naphthalene (○) and perfluoronaphthalene (●) in squalane; (*b*) 10^{-2} *M* naphthalene (□) and perfluoronaphthalene (■) in cyclohexane; (*c*) 10^{-2} *M* naphthalene (△) and perfluoronaphthalene (▲) in isooctane.

At high solute concentrations, reaction [6] will probably be the main ion recombination process. Solute excited states may also be formed by energy transfer from excited solvent molecules (21, 22, 24) via reactions [7] and [8].

[7] $S \rightsquigarrow S^*$

[8] $S^* + M \rightarrow M^* + S$

The emission observed in our experiments is the fluorescence from excited singlet PFB and PFN. This may come from direct excitation or from ion recombination of the undissociated solute radical ion pairs (e.g., $PFB^+ + PFB^-$ or, possibly, $S^+ + PFB^-$). PFB appears to attach electrons and a spectrum which is probably that of PFB^- has been observed in acetonitrile and other solvents.[2] The spectrum of PFN^- is not as clearly defined, but addition of PFN to irradiated solutions of PFB in

[2]A. Singh and co-workers, private communication.

acetonitrile reduces the yield of PFB^-.[2] The thermoluminescence seen in frozen solutions of PFB and PFN in polar (27) and non-polar (20) solvents is considered to arise from ion recombination. If the recombining anion were F^- from dissociative electron capture, excited singlets would not be formed (27). Thus, although the extent of dissociative electron capture of PFB or PFN to produce F^- is not known, it appears that the large anions PFB^- and PFN^- have lifetimes long enough to allow their geminate recombination in the non-polar solvents used in the present work.

The increase in fluorescence intensity in a magnetic field was predicted by Brocklehurst (2, 3). The spins of the odd electrons on the recombining ions M^+ and M^- are initially paired in a singlet solvent molecule prior to ionization. If the spins remain correlated, i.e., if their relative orientation and phase do not change, then only singlets will be produced when M^+ and M^- recombine. However, if correlation is lost, triplets may be formed. The theory (2, 3) shows that loss of spin correlation occurs because of the hyperfine interaction between the unpaired electrons and the magnetic nuclei of M^+ and M^-. The loss of correlation is slower in a magnetic field because of the Zeeman effect. At zero field, the degeneracy of the states of the odd electrons in the ion pair, viz., $S = 0$, $M_s = 0$ and $S = 1$, $M_s = 0$, ± 1 (abbreviated to S_0, T_0, T_+, and T_-) allows mixing between the singlet and all three triplet states. At high fields, however, the T_+ and T_- states have different energies because of the Zeeman splitting and appreciable mixing can only take place between the S_0 and T_0 states. This leads to increased singlet formation in a magnetic field. The magnetic field effect is time-dependent (4–6) but is predicted to be zero for ion recombinations which take place in less than ~ 5 ns (2, 3). In pulse-irradiated solutions, the "prompt" emission, which is field-independent, can be separated from the slower ion recombination fluorescence, which is field-dependent. However, in continuously irradiated solutions, the field-independent fluorescence is superimposed on the field-dependent fluorescence, which leads to a smaller overall field effect.

The field effect shown in Figs. 2 and 3 is consistent with the theory (2, 3), and with our earlier results (6–8). The enhancement of the emission intensity increases with increasing magnetic field and approaches a plateau at fields >0.1 T. The high field value varies with solvent in the order cyclohexane < squalane < isooctane for all solutes. The difference between squalane and cyclohexane may be explained in terms of the ion recombination times in the two solvents. In cyclohexane the smaller average ion recombination time will lead to a larger fraction of prompt (field-independent) fluorescence than in squalane, i.e., to a smaller magnetic field effect. The results in isooctane thus indicate a much smaller fraction of prompt fluorescence than in any other solvent which we have studied. The origin of the prompt fluorescence is, however, not unambiguous and the relative contributions of ion recombination and energy transfer to the formation of solute excited states are still being debated (21–26). In cyclohexane, energy transfer from the solvent occurs (24, 25) whereas the lack of fluorescence of isooctane (28) suggests that energy transfer is less likely in this solvent. No data are available to permit an assessment in squalane.

Figures 2 and 3 show that substantially different fields are required to induce the initial effect for the protiated and perfluorinated compounds. For the protiated compounds, a field less than 10^{-3} T is sufficient to cause a small increase in fluorescence intensity, whereas a field greater than $\sim 5 \times 10^{-3}$ T is required to produce an increase with the perfluorinated compounds. This different behaviour provides further support for the theory (2, 3). The rate of loss of spin correlation depends to a large extent on the magnitude of the coupling constant a between the unpaired electrons and the magnetic nuclei of the recombining ions. Fluorination increases the coupling in radical ions of aromatic molecules (14–16) as compared to the parent hydrocarbons (12, 13). Few data are available for the perfluorinated solutes used here, but the cation of PFN has coupling constants of 19 G and 4.78 G, respectively, for the α and β positions (14, 15). These are much higher than the corresponding values of 4.90 and 1.83 G respectively, in naphthalene (29). Coupling constants of anions are generally smaller than those of the corresponding cations, both in hydrocarbons (13) and partly fluorinated hydrocarbons (14). Coupling constants of the anion of PFN are not known; they will presumably be smaller than those of the corresponding cation, but larger than those of the naphthalene radical anion. Thus we expect a larger overall coupling for the PFN ions than for the parent naphthalene ions. Data are unavailable for the radical ions of PFB but comparisons between biphenyl (13) and partly fluorinated biphenyl (14) suggest that the above arguments will also apply to PFB.

The higher electron–nuclear hyperfine coupling in the radical ions of the perfluorocarbons means higher overall spectral widths and a broader spread of the hyperfine levels, and this explains the larger field required to produce an initial effect with the perfluorocarbons (Figs. 2, 3). We have seen earlier that

the magnetic field causes the Zeeman splitting, which prevents mixing between the S_0 and $T_\pm$ states, and this results in higher singlet production. It is clear that, to prevent such S_0–$T_\pm$ mixing and the corresponding singlet increase, the magnetic field must be large enough to prevent overlap of the hyperfine levels, so that mixing of S_0 and $T_\pm$ does not occur. Since the spread of the hyperfine levels is larger for the perfluorinated compounds, a larger field will therefore be required to prevent overlap and to produce an initial singlet increase, as is found. The effect observed at low fields thus provides further support for the theoretical model (2, 3).

At high fields, the magnetic field effect is smaller for the perfluorocarbons than for the hydrocarbons (Figs. 2, 3). Because of the higher coupling constants in the perfluorocarbons, the rate of loss of spin correlation should be higher than for the parent hydrocarbons so that, all other things being equal, the magnetic field effect should be larger for the perfluorocarbons at high fields. The reverse result undoubtedly occurs because of different ratios of field-dependent and field-independent fluorescence in the two sets of compounds. The magnetic field effect in continuously irradiated solutions is an overall effect because the prompt fluorescence (field-independent) is superimposed on the slower ion recombination (field-dependent) fluorescence. Our preliminary results in pulse-irradiated solutions of naphthalene, PFN, biphenyl, and PFB in cyclohexane show that the ratio of in-pulse emission to post-pulse emission is much larger for the perfluoro compounds than for the parent hydrocarbons. This will, in turn, mean a larger fraction of field-independent fluorescence for the perfluoro compounds and a smaller field effect at high magnetic fields, as observed.

Stereochemical analysis of *exo*-methylenebenzocycloalkanes: evidence from carbon-13 nuclear magnetic resonance chemical shifts, ^{13}C–^{13}C nuclear spin couplings, and force field calculations[1]

GERALD W. BUCHANAN, JOCELYN SELWYN, AND BRIAN A. DAWSON
Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received May 25, 1979

GERALD W. BUCHANAN, JOCELYN SELWYN, and BRIAN A. DAWSON. Can. J. Chem. **57**, 3028 (1979).

A series of *exo*-methylenebenzocycloalkanes with ring sizes 5–8 have been prepared, enriched with ^{13}C and also deuterated at the exocyclic position. ^{13}C chemical shifts are found to be influenced by the degree of planarity between the aromatic ring and the exocyclic methylene function. ^{13}C–^{13}C couplings through one, two, and three bonds have been measured. The $^{1}J_{CC}$ values correlate very well with %*S* character calculations. Values of $^{3}J_{CC}$ are found to be influenced by both dihedral angle and valence angle. The relative propensity for these compounds to isomerize to endocyclic material is discussed. Some earlier spectral assignments for the indene derivative are shown to be in error.

GERALD W. BUCHANAN, JOCELYN SELWYN et BRIAN A. DAWSON. Can. J. Chem. **57**, 3028 (1979).

On a préparé une série d'*exo*-méthylènebenzocycloalcanes dont la taille des cycles varie de 5 à 8, enrichis en ^{13}C et également deutérés en position exocyclique. On a trouvé que le degré de planéarité entre le cycle aromatique et la fonction méthylène exocyclique influence les déplacements chimiques du ^{13}C. On a mesuré les constantes de couplage ^{13}C–^{13}C à travers une, deux ou trois liaisons. Les valeurs $^{1}J_{CC}$ correspondent parfaitement aux calculs du % de caractère *S*. On a trouvé que l'angle dièdre et l'angle de valence influencent $^{3}J_{CC}$. On a discuté de la tendance relative qu'ont ces composés à s'isomériser en dérivés endocycliques. On a démontré que certaines interprétations spectrales faites antérieurement pour les dérivés de l'indène sont erronées.

Introduction

The dihedral angle dependence of proton–proton vicinal coupling constants is well known (1) and has been widely used for structure determination. In addition, factors such as bond length, valence angle, substituent electronegativity, and substituent orientation are known to affect the magnitude of $^{3}J_{HH}$ (2).

The widespread application of $^{3}J_{HH}$ to stereochemistry has prompted investigations into possible "Karplus-type" relationships in vicinal ^{13}C–^{13}C couplings as well, using single-site ^{13}C-enriched materials. Among systems recently examined are carboxylic acids (3), aliphatic alcohols (4, 5), ketones (6), and esters (7).

To date, few ^{13}C–^{13}C coupling data have been reported for conjugated networks of the type $C{=}C{-}C{=}{}^{13}C\langle{}^{H}_{H}$. The present study presents data for such pathways, present in *exo*-methylenebenzocycloalkanes. These compounds were chosen for study due to unusual behaviour, possibly of conformational origin, observed in the intramolecular Friedel-Crafts acylation reactions leading to the corresponding ketones.[2] No information regarding the geometries of these materials is available from ^{1}H nmr, due to peak overlap in the region $\delta = 1$–3, and the lack of protons vicinal to the *exo*-CH_2 protons.

In addition to the nmr measurements, force-field calculations of the molecular geometries were carried out using the GEMO program (8, 9). The resulting geometries were employed to study the dihedral angle dependence of $^{3}J_{CC}$ and also were used as input for the INDO MO program (10) to calculate the Fermi contact contributions to ^{13}C–^{13}C couplings through one, two, and three bonds.

The ^{13}C chemical shifts for the *exo*-methylene carbon, C-1, and the quaternary aromatic positions are also discussed in detail with respect to the calculated geometries.

Results and Discussion

Chemical Shifts

The ^{13}C shifts for **1–4** are presented in Table 1.

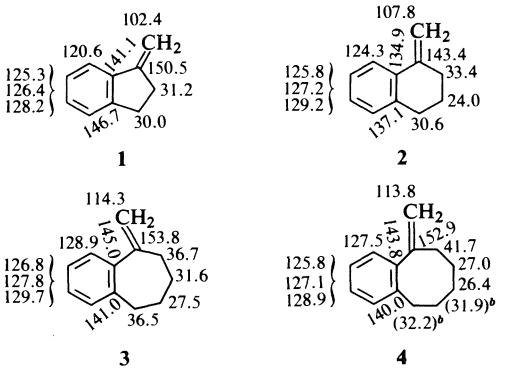
TABLE 1. ^{13}C chemical shifts (δ_C from TMS ± 0.1)[a]



[a]0.1 *M* solutions in $CDCl_3$.
[b]Parentheses denote uncertain assignments.

With the exception of compound **1** (11), no carbon nmr data have been previously reported for these materials. Several techniques were used for peak assignment. Initially, distinction between quaternary, methine, and methylene resonances was made on the basis of their multiplicity in the single frequency off-resonance (SFORD) decoupling experiment. The *exo*-methylene carbons were positively identified by the unambiguous synthesis of the ^{13}C-enriched materials **1***a*–**4***a*. These compounds also permitted clear assignment of the C-1 resonance due to the observation of $^1J_{CC}$ near 70 Hz, a value close to that found in simple disubstituted alkenes (12).

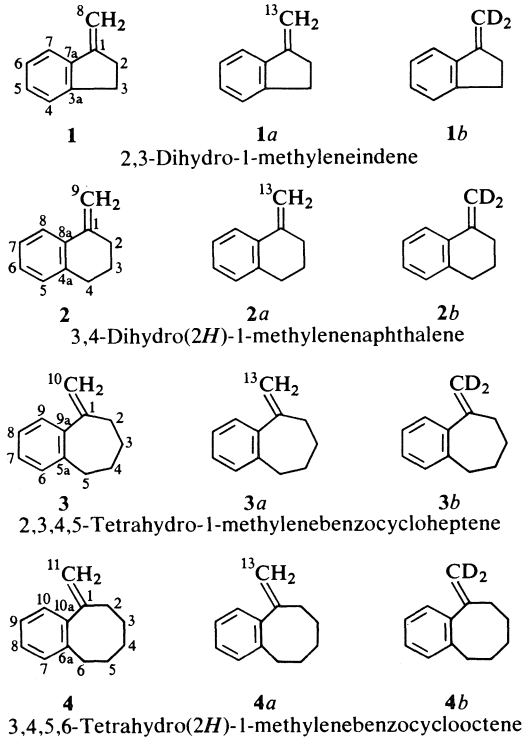


FIG. 1. Structures, IUPAC names, and numbering schemes for materials studied.

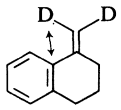
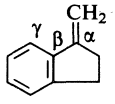
Synthesis of the dideuterated compounds **1***b*–**4***b* allowed unambiguous assignment of the C-2 vs. C-3 resonances in **1**–**4** and distinction between the two quaternary aromatic carbon resonances. The presence of deuterium causes small, but resolvable, coupling between deuterium and the vicinal carbon atom (C-2) ($^3J_{CCCD}$ is ca. 0.6–1.5 Hz) (13–16), thereby permitting distinction between C-2 and C-3. The C-3 carbon, being 4 bonds separated from deuterium, is not measurably spin coupled to it. Similarly, C-7a can be distinguished from C-3a in **1***b*, as can C-8a from C-4a in **2***b* etc. In these cases, the quaternary carbons vicinal to the deuterium also show reduced integrated intensities, compared to their protio analogs, due to the less efficient dipole–dipole relaxation of these carbons by the spatially proximate deuterium atom (below), which results in a reduced nOe and a lengthened T_1.



2*b*

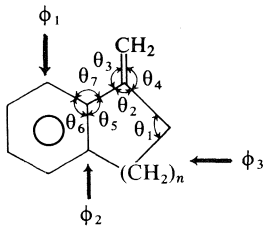
For the remaining methylene carbon assignments, the effect of *exo*-CH_2 addition (17) on the ^{13}C shifts of cycloalkanes was considered, in conjunction with the previously published data for benzocycloalkanes (18). With regard to the aromatic methine resonances only the carbon vicinal to the *exo*-methylene carbon could be clearly assigned. This was done on the basis of its upfield "γ" shift (11) in the nearly planar cases of **1** and **2**, and the observation of $^3J_{CC}$ to this position in **1***a*–**4***a*.



1

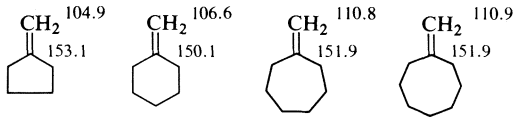
It is interesting to note the influence of benzannelation on the carbon shifts of **1**–**4** relative to the methylenecycloalkanes below (17, 19), particularly at the C-1 and *exo*-methylene positions. Our force-field calculations indicate that for **1** and **2**, the *exo*-methylene carbon is nearly coplanar with the benzene ring (Table 2, data for ϕ_1 and ϕ_2), while compounds **3** and **4** are highly non-planar in this region of the molecule.

TABLE 2. Calculated valence (θ) and torsional[a] (ϕ) angles (±0.1°)



Compound	θ_1	θ_2	θ_3	θ_4	θ_5	θ_6	θ_7	ϕ_1	ϕ_2	ϕ_3
1 (n = 1)	103.2	113.7	123.8	122.5	103.9	121.4	134.5	1.4	178.9	178.2
2 (n = 2)	111.3	119.6	122.8	117.6	119.4	118.3	122.2	1.8	177.1	147.6
3 (n = 3)	114.7	119.4	120.7	119.7	121.0	119.5	119.5	59.0	122.5	109.6
4 (n = 4)	120.1	120.4	120.2	119.4	120.8	119.8	119.4	84.4	96.9	139.5

[a]Defined as the angles which the exocyclic (=CH_2) carbon makes with the carbons denoted by (⟶) as shown on the diagram.



These calculated results are in reasonable agreement with the only experimental data for these materials, those for **1**–**3**, extracted from photoelectron spectra (20).

For the planar cases **1** and **2**, benz-annelation results in substantially increased shielding at C-1, ca. 3–6 ppm. For the non-planar systems **3** and **4**, the C-1 resonance is slightly deshielded relative to the methylenecycloalkane models shown above.

Similarly the *exo*-methylene resonance of **1** is shifted upfield on benz-annelation and those of **3** and **4** experience downfield shifts upon fusion of the aromatic ring. Compound **2** is anomalous in this regard, in that the *exo*-CH_2 resonance is slightly deshielded (ca. 1 ppm) relative to methylenecyclohexane, even though the aromatic ring is nearly coplanar to the $=CH_2$ function.

Our assignments for C-3a and C-7a of **1**, based on deuteration results, are reversed from those reported previously (11). The earlier assignments were made using indane as a model compound and assuming a "β" deshielding effect of the *exo*-methylene group at C-7a. The present work clearly shows that the shifts of the quaternary aromatic carbons cannot be treated on this basis. For **1** and **2**, the shifts of C-7a and C-8a are upfield relative to C-3a and C-4a respectively. In the cases of **3** and **4**, the effect is reversed for the shifts of C-9a and C-10a vs. C-5a and C-6a respectively. Additional support for the present assignments comes from the results of total electron density calculations which are presented in Table 3. The values were calculated from the INDO MO program (10). In each of **1**–**4**, the quaternary aromatic carbon with the higher calculated electron density resonates at higher field, i.e., lower δ_C. We realize that attempts to quantitatively correlate electron densities with chemical shifts are dangerous, but qualitative comparisons are useful.

TABLE 3. Calculated electron densities[a] and ^{13}C shifts (δ_C) for quaternary aromatic carbons

Compound	Carbon	Electron density	$\delta_C \pm 0.1$
1	3a	3.9758	146.6
	7a	3.9883	141.1
2	4a	3.9785	137.1
	8a	3.9857	134.9
3	5a	3.9825	141.0
	9a	3.9795	145.0
4	6a	3.9831	140.0
	10a	3.9715	143.8

[a]Total electron densities in electron units.

Thus, to summarize, the chemical shift trends found at the *exo*-methylene group, C-1, and the quaternary aromatics for **1**–**4** are generally divisible into two categories. The first category is for materials having ϕ_1 and ϕ_2 (Table 2) close to 0° and 180° respectively, i.e., **1** and **2**, while the second category encompasses the non planar materials **3** and **4**, which have ϕ_1 and ϕ_2 values greatly different from 0° and 180° respectively.

^{13}C–^{13}C Couplings

The experimental and INDO MO calculated (10) ^{13}C–^{13}C J values are presented in Table 4. Previously (19), $^1J_{C=CH_2}$ values of 73.2, 72.0, 72.0, and 72.0 Hz were reported for the methylenecycloalkanes of ring sizes 5, 6, 7, and 8 respectively. Data in Table 4 indicate that benz-annelation has little influence on this parameter. The agreement between observed and calculated ^1J values for **1**–**4** is fairly

good, suggesting a dominance of the Fermi contact mechanism for these couplings.[3]

A usual correlation of directly bonded coupling constants is with the product of the *S* character of the bonding orbitals, and the equation below has been proposed (21). In the present work, the % *S* character for the carbons involved was calculated

$$^1J_{C_AC_B} = \frac{7.3(\%S_A)(\%S_B)}{100} - 17 \text{ Hz}$$

from the SCF density matrix, calculated in the coupling constant program. The electron densities in the carbon 2*s*, $2p_x$, and $2p_y$ orbitals were obtained, and from this, the % *S* character can be determined. Using this approach, excellent agreement between observed and calculated $^1J_{CC}$ values was found, the calculated values being 73.7, 73.6, 73.4, and 73.3 Hz for **1**, **2**, **3**, and **4** respectively.

Regarding geminal ^{13}C–^{13}C couplings, no resolvable $^2J_{CC}$ values (i.e. > 0.6 Hz) were observed to the quaternary aromatic carbons 7a, 8a, 9a, and 10a of **1**, **2**, **3**, and **4** respectively. Measurable ^2J values into the aliphatic ring were obtained, however, for **2**, **3**, and **4**. In these instances the calculated couplings exceed the observed by a factor of about five, suggesting that the Fermi contact mechanism is probably not dominant in these interactions.[3] In the previous work on the simple methylenecycloalkanes (19), no $^2J_{CC}$ or $^3J_{CC}$ data were included, perhaps due to the low resolution of the instrument employed.

The vicinal couplings ($^3J_{CC}$) are of particular interest in this work, since for each of **1**–**4**, there are three possible pathways for vicinal coupling, and in every instance, a resolvable $^3J_{CC}$ was obtained experimentally. Agreement between calculated and observed values (Table 4) is considerably better than for geminal couplings, although the calculated couplings are all higher than the observed. Furthermore, it is of interest to attempt to correlate the observed $^3J_{CC}$'s with the calculated torsional (dihedral) angles between the coupled carbons, i.e., ϕ_1, ϕ_2, and ϕ_3 of Table 2. Strictly speaking, it is valid only to examine the dihedral angle dependence of ^3J for couplings occurring via similar types of bonding networks.

If one considers the vicinal couplings to the aromatic carbons, a dihedral angular dependence of $^3J_{CC}$ is obtained as shown in Fig. 2. The single deviation from a "Karplus-type" curve occurs in compound **1** for $^3J_{CC}$ to C-7. In this case, $^3J_{CC}$ is observed

TABLE 4. Experimental and calculated[a] ^{13}C–^{13}C couplings (±0.2 Hz)

[a]In parentheses, from the INDO MO program (10).

[3]A referee has pointed out that the INDO scheme may not include all Fermi-dominated mechanisms. Accordingly, one must view the calculated couplings with some caution, in terms of interpreting the results to imply complete dominance or absence of the Fermi-contact coupling mechanism.

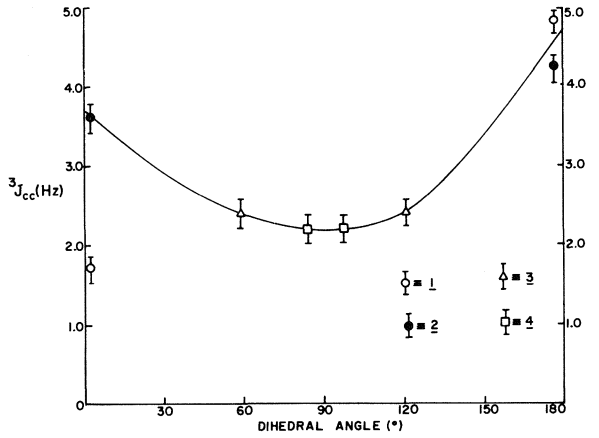

FIG. 2. Dihedral angle dependence of vicinal ^{13}C–^{13}C couplings from the *exo*-methylene carbon to aromatic ring carbons.

to be only 1.7 Hz where the dihedral angle ϕ_1 between the coupled carbons is calculated to be 1.4°. Examination of the other calculated structural data in Table 2, however, shows a marked increase in the *valence* angle θ_7 in **1** compared to **2–4**.

For ^1H–^1H couplings through three bonds, it has been noted (2) that the couplings decrease with increasing C—C  valence angle. This trend is evident in the cyclic alkenes, where $^3J_{HH}$ values for the alkene protons are found to be as follows: cycloheptene (10.8 Hz), cyclohexene (8.8 Hz), cyclopentene (5.1 Hz), cyclobutene (3.0 Hz), and cyclopropene (1.3 Hz). In this series the dihedral angle between the coupled alkene protons is constant. The present findings for **1** suggest that valence angles also influence $^3J_{CC}$. In fact, for the $^3J_{CC}$ to C-3a of **1**, the rather large coupling of 4.8 Hz may be due, in part, to the compressed valence angle θ_5, relative to **2–4**. Clearly, further work is needed to elucidate the valence angle dependence of $^3J_{CC}$ and we are presently synthesizing a series of model compounds to this end.

It is interesting to compare these results with those for 1,3-butadiene (22), enriched with ^{13}C at a terminal methylene position. For this material, $^1J_{CC} = 68.8$, $^2J_{CCC}$ is <1.0, and $^3J_{CCC} = 9.05$ Hz. The latter value, which represents an essentially pure (i.e. >95%) transoid geometry, is considerably larger than any of the ^3J transoid values in Table 4, suggesting that a lower π bond order may be present in **1–4** than in 1,3-butadiene itself.

With respect to the vicinal ^{13}C–^{13}C couplings into the alicyclic ring to C-3, the overall range of $^3J_{CC}$ is small, i.e., 1.9–2.9 Hz. We feel that attempts to correlate such small changes with calculated torsional angles are probably not justified at this stage, since only 4 data points are available. A cursory look at the data, however, suggests that **1** may again be anomalous due to valence angle effects.

Experimental

Spectra

^{13}C spectra were recorded at 25.16 MHz using a Varian XL-100-12 nmr spectrometer equipped with a Nicolet TT-100 Fourier transform data system. For chemical shift measurements on non-labelled compounds, samples were examined as 0.1 *M* solutions in $CDCl_3$ solvent in 5 mm sample tubes. Spectral widths were 5000 Hz.

For measurements of ^{13}C–^{13}C couplings with enriched materials, the sample concentration was 0.04 *M* in $CDCl_3$, and the spectral widths were 500 Hz. A minimum of 8K data points were employed.

Calculations

The initially specified geometries for **1–4**, used as input for the GEMO program (8), were derived from standard parameters (23). Subsequently GEMO carries out a systematic variation of bond lengths, bond angles, and torsional angles to minimize the conformational energy of the molecule. Parameters were iterated until a convergence criterion of 0.01 kcal/mol was met. The barrier to rotation about the bond linking the *exo*-methylene group to the aromatic ring was taken as 2.0 kcal/mol, by analogy with results for styrene (24). Constants for the van der Waals interactions were taken from COMOL, a program written for conformational energy calculations by M. H. J. Koch, Laboratoire de Chimie Physique et de Cristallographie, Université de Louvain, Belgium.

The ^{13}C–^{13}C couplings were calculated using the finite perturbation procedure of Pople *et al.* (10), with a program obtained from Quantum Chemistry Program Exchange #224, Bloomington, IN.

Materials

Compounds **1–4** were synthesized from the corresponding known ketones via Wittig reactions. A typical procedure follows.

Triphenylmethylphosphonium iodide (1.0 g) was placed in a dry 100 mL roundbottom flask fitted with a septum, a gas inlet tube, and a condenser. After flushing with purified nitrogen for 10 min and addition of 25 mL of anhydrous ether, the system was again flushed with nitrogen for 10 min. *N*-Butyllithium (2.0 mL, 1.6 *M* in hexane) was added and the solution was stirred for 20 min. The appropriate ketone (0.003 mol), in 4 mL of anhydrous ether, was added to the reaction flask. After stirring for half an hour 25 mL of water was added and the resulting mixture was vigorously stirred until all the solid particles had dissolved (usually ~1 h). The ether and water layers were separated and the water layer was extracted with ether (4 × 30 mL). The combined ethereal extracts were dried ($MgSO_4$) and the solvent removed under vacuum. The crude product was purified on a neutral aluminum oxide column, eluting with ether. Compound **1**, yield 38%; n_D^{20} 1.5762; ir $\nu_{max}(CDCl_3)$: 1640, 900 cm^{-1}; lit. (25) n_D^{23} 1.5759. Compound **2**, yield 45%; n_D^{20} 1.5558; ir $\nu_{max}(CDCl_3)$: 1642, 900 cm^{-1}; lit. (26) n_D^{20} 1.5560. Compound **3**, yield 40%; n_D^{20} 1.5562; ir $\nu_{max}(CDCl_3)$: 1640, 899 cm^{-1}; lit. (26) n_D^{20} 1.5560. Compound **4**, yield 56%, n_D^{20} 1.5460, ir $\nu_{max}(CDCl_3)$: 1642, 899 cm^{-1}; lit. (26) n_D^{20} 1.5471; ir $\nu_{max}(CCl_4)$: 1642, 899.

Compounds **1–4** also gave ^1H spectra consistent with their structures. It should be noted that **2** undergoes facile isomerization to its endocyclic isomer in $CDCl_3$, a reaction which has

already been followed by ^1H nmr (27). Thus, after the several hours required for a ^{13}C spectrum, **2** had rearranged to approximately a 50:50 mixture of endocyclic and exocyclic material. For **1** and **3**, isomerizations are relatively slow in $CDCl_3$, and **4** does not isomerize, even in the presence of *p*-toluenesulfonic acid (26).

The series of ^{13}C-labelled materials **1***a*–**4***a* and the deuterated compounds **1***b*–**4***b* were prepared in an analogous manner, starting with the appropriately labelled methyl iodide, available from Stohler Isotope Chemicals, Montreal, P.Q.

Received June 5, 1979

SURESH CHANDRA SHARMA and BRIAN MAURICE LYNCH. Can. J. Chem. **57**, 3034 (1979).

Reactions of various 5-aminopyrazoles with ethyl levulinate in acetic acid have been shown to furnish moderate to good yields of the correspondingly substituted 4-methyl-6*H*-pyrazolo-(3,4-b)azepin-7-ones, accompanied by the acetamidopyrazoles. The courses of methylation and of bromination reactions of some of the pyrazoloazepinones have been explored and defined, and conversion of one pyrazoloazepinone into 7-chloropyrazoloazepine and thence by nucleophilic displacements into 7-(substituted amino)pyrazoloazepines has been effected. Structural assignments, tautomeric preferences, and through-space interactions between substituents were established through nuclear magnetic resonance spectroscopy (^{1}H and ^{13}C). Some members of the pyrazoloazepinone series exhibit significant anti-inflammatory and analgesic effects in mice.

SURESH CHANDRA SHARMA et BRIAN MAURICE LYNCH. Can. J. Chem. **57**, 3034 (1979).

Les réactions de différents amino-5 pyrazoles avec le lévulinate d'éthyle dans l'acide acétique fournissent avec des rendements variables les méthyl-4 6*H*-pyrazoloazépine(3,4-b)-ones-7 substituées correspondantes, accompagnés d'acétamidopyrazoles. On a exploré et défini le cours des réactions de méthylation et de bromation de quelques pyrazoloazépinones et on a effectué la transformation d'une pyrazoloazépinone en chloro-7 pyrazoloazépine qui, par des réactions de déplacements nucléophiles conduit aux pyrazoloazépines portant un groupement amino-substitué en position 7. On a établi par la résonance magnétique du proton et du ^{13}C les structures, les préférences tautomériques et les interactions spatiales entre les substituants. Certaines pyrazoloazépinones ont des effets anti-inflammatoire et analgésique significatifs chez les souris.

[Traduit par le journal]

Introduction

3(5)-Aminopyrazoles are useful starting points for syntheses of various pyrazoloazines from sequential condensation and ring-closure reactions involving exocyclic or ring nitrogen atoms and the electron-rich 4-carbon, as exemplified in previous papers from this laboratory (1–3). In view of current interest in the biological activities shown by ring-expanded purines (4–6), we now seek to use the aminopyrazoles as precursors of compounds with analogously fused five and seven membered rings (for example, pyrazoloazepines and pyrazolothiazepines (7)).

Our work involves extension of Makisumi's findings (8) that reactions of 5-amino-1-substituted pyrazoles **1** with ethyl acetoacetate in acetic acid yield 4-hydroxy-6-methyl-1-substituted pyrazolo(3,4-b)pyridines **2**, probably by way of the isolable azomethine/enamine species **3**, **4** (reaction of the parent 1*H*-compound **1***a* furnishes 7-hydroxy-5-methylpyrazolo(1,5-a)pyrimidine **5** in addition to **2***a*). Use of ethyl levulinate rather than ethyl acetoacetate might be expected to yield 1-substituted-7-methyl-5*H*-pyrazolo(3,4-b)azepin-4-ones of general structure **6** if an analogous cyclization pathway is followed, but since Bertho (9) found that reaction of aniline with levulinic acid gave 5-methyl-3*H*-1-benzazepin-2-one **7**, albeit in very low yield, products of general structure **8** (1-substituted-4-methyl-6*H*-pyrazolo(3,4-b)azepin-7-ones) are also possible (see Fig. 1). A further possibility is the independent formation of type **7** and type **8** compounds.

Results and Discussion

We find that reaction of eleven representative aminopyrazoles (**1***a* through **1***m*) with ethyl levulinate in acetic acid furnishes mixtures of the corresponding acetamidopyrazoles and individual molecular species (not pairs of isomers) analysing for types **7** or **8**. Cyclisation competed poorly with simple acetylation where the 1-substituent in the aminopyrazole was strongly electron-attracting (*m*-chlorophenyl, *m*-bromophenyl), but for all other aminopyrazole substrates yields of cyclisation products were higher (see Table 1 for details).

The fine structure of the cyclisation product obtained from 5-amino-1-methylpyrazole **1***b* was established as **8***b* (1,4-dimethyl-6*H*-pyrazolo(3,4-b)-azepin-7-one) through observation of a diagnostic nuclear Overhauser enhancement in the ^{1}H nmr spectrum. The product exhibited a 19% increase in

signal intensity for the pyrazole ring proton signal (δ 7.48) on irradiation of the *C*-methyl proton signal (δ 2.02) as expected from the spatial proximity of these nuclei in **8***b*. The separation between the *C*-methyl protons and the pyrazole ring proton in **7***b* would preclude any nuclear Overhauser effect enhancement. We similarly assign type **8** structures to all the cyclisation products from the 1-substituted 5-aminopyrazoles **1***c* through **1***m*. Assignments are based upon the close correspondences of the key features of the ^{1}H and ^{13}C nmr spectra of all these products to the proven **8***b* (see Tables 2 and 3, and further discussion below), and also upon evidence

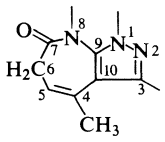

FIG. 1. Ring numbering for 4-methyl-6*H*-pyrazolo(3,4-b)-azepin-7-ones.

of interaction between N-1 and N-8 substituents in the derived type **9** compounds.

For reaction of ethyl levulinate with 1*H*-3(5)-aminopyrazole **1***a*, closure at ring nitrogen to yield either 5-methyl-7*H*-pyrazolo(1,5-a)1,3-diazepin-8-one **10** or 8-methyl-6*H*-pyrazolo(1,5-a)1,3-diazepin-5-one **11** is possible, but these structures for the cyclisation product are excluded by its ^{1}H nmr spectrum, which shows a one-proton *singlet* at δ 7.89 assignable to a pyrazole ring proton. Structures **10** or **11** would give rise to signals for two protons in that spectral region, each split by a vicinal coupling of ca. 2 Hz. In further confirmation, both **10** and **11** have *one* proton bound to nitrogen (and thus expected to exchange rapidly with added deuterium oxide); our product from **1***a* shows *two* low-field one-proton signals (at δ 10.27 and 12.77) disappearing rapidly on addition of deuterium oxide to the perdeuteriated dimethyl sulfoxide solvent. A 4-methyl-6*H*-pyrazolo-(3,4-b)azepin-7-one structure is assigned to the product from aminopyrazole **1***a*, again on the basis of general similarity of the ^{1}H and ^{13}C nmr spectra to those of **8***b* (see Tables 2 and 3), but the tautomeric preference between **8***a* (1*H*,6*H*-4-methyl-pyrazolo(3,4-b)azepin-7-one) and **12***a* (2*H*,6*H*-4-

*This quantity of aminopyrazole was heated under reflux with an equimolar quantity of ethyl levulinate in an amount of acetic acid furnishing a total concentration of 20% w/v, for a period of 18–20 h.

methylpyrazolo(3,4-b)azepin-7-one) is not evident from simple spectroscopic examination of this one species.

However, a study of the products obtained when the various substituted 4-methyl-(6*H*)pyrazolo-(3,4-b)azepin-7-ones were subjected to standard methylation procedures provided evidence concerning the position of equilibrium in the **8***a*–**12***a* system. When the 1-substituted 4-methyl-(6*H*)pyrazolo(3,4-b)-azepin-7-ones **8***b*–**8***f* were reacted, the corresponding 4,8-dimethyl derivatives **9***b*–**9***f* were obtained (see Table 4). However, reaction of the parent compound yielded a trimethyl-6*H*-pyrazolo(3,4-b)azepin-7-one differing from 1,4,8-trimethyl-6*H*-pyrazolo(3,4-b)-azepin-7-one **9***b* in melting point and in its ^1H and ^{13}C nmr spectra (see Tables 2 and 3). The ^{13}C nmr signals from the *N*-methyl carbons fall at δ 35.2 and 37.5 for **9***b*, and at δ 33.6 and 39.4 for the other isomer. By analogy with the pattern observed for the *N*-methyl carbons in 1-methylindazole and in 2-methylindazole (shifts are δ 35.3 and 39.7 respectively (10)), it is proposed that this "other isomer" is 2,4,8-trimethyl-6*H*-pyrazolo(3,4-b)azepin-7-one, **12***b*. The close resemblance of the 3-carbon shift in the parent cyclisation product (δ 127.1) to that for the 2,4,8-trimethyl compound **12***b* (δ 127.3), and the considerable difference from that for the 1,4,8-trimethyl compound **9***b* (δ 135.3) suggests strongly that the preferred tautomeric form of the parent cyclisation product is **12***a*.

There are interesting proximity effects for the methylation products possessing N-1 aryl groups: in these (compounds **9***d*, **9***e*, **9***f*), the N-8 methyl protons are shielded by approximately 0.4 ppm as compared with the 8-methylated species lacking a 1-aryl group. The shielding effect is readily explained if the 1-aryl and pyrazoloazepinone mean ring planes are orthogonal in these 8-methylated species, with the methyl group falling in the diamagnetic zone around the 1-aryl group. Similar, larger shielding effects are observed for the N-8 methyl carbon signals in these species (**9***b*, **9***c* δ 37.5, 37.0; **9***d*, **9***e*, **9***f* δ 35.2, 34.9, 35.1), but these are better rationalised by sterically induced C—H bond polarisations (cf. ref. 11) than anisotropic influences.

Other conversion reactions effected with the azepinone moieties of type **8** and **9** species yielded products of spectroscopic interest or relevant to structure proofs; thus monosubstitution of the compound **9***d* occurred on treatment with bromine. The monosubstitution product has the structure **13** (5-bromo-4,8-dimethyl-1-phenyl-6*H*-pyrazolo(3,4-b)-azepin-7-one), established by the following changes in the ^1H and ^{13}C nmr signal patterns: (*a*) loss of the characteristic H-5 one-proton triplet signal from the δ 5.5 region, (*b*) loss of the J_{5-6} splitting of the two-proton 6-CH_2 signal and an *upfield* shift from δ 3.04 to 2.71, (*c*) a lowered intensity and an upfield shift of the δ 116.6 signal assigned to C-5 to δ 108.0, and (*d*) a downfield shift from δ 36.7 to δ 48.0 for the signal assigned to C-6. The upfield and the downfield shifts in the carbon signals are those to be expected for *ipso*- and vicinally-located bromine (cf. ref. 12), but the upfield shift for the protons attached to C-6 has no precedents, as far as we are aware; a tentative explanation could lie in unfavorable dipole–dipole interactions between the C—Br and C=O bonds in this compound.

*Proton counts and signal multiplicities are shown in parentheses. Envelope dimensions for complex aromatic multiplets are expressed in Hz. J_{56} for all compounds = 7.2 ± 0.2 Hz.

The representative pyrazoloazepinone **8***e* was converted into the unstable, reactive chloro compound **14** on treatment with phosphorus oxychloride. The crude compound was used directly in a series of displacements by nitrogen nucleophiles, providing the 7-(substituted amino) entities **15–17**. The high reactivity of **14** is to be expected from its imidochloride character.

Because our assignments of structure for the pyrazoloazepinones and their derivatives rest almost completely upon pattern resemblances and substituent-induced variations in the ^{1}H and ^{13}C nmr signals for related series of compounds, we wish to provide an account of our reasoning in allocating the nmr signals to specific groups or atoms. We interpreted the features of the ^{1}H nmr spectra assignable to entities present in the uncyclised aminopyrazole (that is, substituents or protons at positions 1, 2, and 3) by direct comparison with the aminopyrazoles, and by general resemblances to other 1- and 1,3-substituted pyrazoles (13–16); the proton signals from the 4-methyl-, 5-methine-, and 6-methylene functions were simply assignable by proton count and by signal multiplicity.

The key compound for signal assignments in the ^{13}C nmr spectra is the species **8***b*, where the nOe

experiment cited above defines the structure. The broadband-decoupled spectrum of this compound gave signals falling into two intensity groupings: δ 20.4, 35.5, 36.2, 112.2, 135.8 (more intense); 113.3, 132.6, 136.7, 170.4 (less intense). Gated decoupling experiments revealed direct $^{13}C—^{1}H$ couplings for all the more intense signals, while the less intense group showed no significant splitting. The δ 20.4 and 35.5 signals were quartets under the gated decoupling conditions, the δ 36.2 signal was a triplet, and the δ 112.2 and 135.8 signals doublets. Since a signal at δ 20.4 ± 0.6 appears in all the pyrazoloazepinones, and a δ ca. 35.5 only for species possessing a 1-methyl substituent (**8***b*, *c*; **9***b*, *c*) it follows that the δ 20.4 signal corresponds to the 4-methyl carbon, and the δ 35.5 to the 1-methyl carbon. The triplet character of the δ 36.2 signal defines it as arising from the 6-methylene carbon. The δ 135.8 doublet signal is assigned to C-3 of the pyrazole ring, by analogy with the chemical shift of C-3 in 1-methylpyrazole (δ 139.4 (17)) and in 5-acetamido-1-methylpyrazole (δ 138.3); the δ 112.2 signal is then assigned by elimination to the methine C-5 (a reasonable analogy for this would be the shift (δ 117.6) for C-3 in 2-methyl-2-butene (18)). Of the family of less intense signals, that at δ 170.4 is immediately assignable as the amide carbonyl, C-7; the δ 132.6 signal, since a signal close to this position appears for all the pyrazoloazepinones, is assigned to C-4 (again, the shift for C-2 (δ 130.1) in 2-methyl-2-butene (18) is an appropriate analogy). Of the two remaining quaternary carbon signals, that at δ 113.3 is assigned to the electron-rich C-10, and the δ 136.7 to C-9. The signal patterns noted in the ^{13}C nmr spectra of compound **8***b* are followed generally for all the type **8** and type **9** compounds, with minor perturbations as a function of the nature of the 1-substituent, and the presence or absence of methyl groups at positions 3 or 8.

Compounds with a *C*-methyl group at the 3 position (**8***c*, *e*, *l*; **9***c*, *e*) exhibit a characteristic signal at around δ 14.5.

Biological Screening Results

The various pyrazoloazepinone derivatives synthesised in this program were evaluated for analgesic activity by monitoring reduction of phenylquinone-induced writhing in mice, using aspirin (50 mg/kg subcutaneous administration) as standard compound (50% reduction is effected by this concentration of aspirin). Compound **8***d* (4-methyl-1-phenyl-6*H*-pyrazolo(3,4-b)azepin-7-one) gave 89% reduction of writhing activity at 32 mg/kg. Compound **12***a* (2*H*,-6*H*-4-methylpyrazolo(3,4-b)azepin-7-one) gave 13% reduction at 128 mg/kg, and also showed anti-inflammatory activity (antagonism of carageenan-induced oedema) at 64 mg/kg in rats.

Conclusions and Comments

The delineated reactions of aminopyrazoles with ethyl levulinate provide a reasonably effective synthetic route to 6*H*-pyrazolo(3,4-b)azepin-7-ones; the yields are far superior to those obtained when aniline is reacted with various γ-keto acids (cf. Bertho (9)). We attribute the increased effectiveness of the cyclisation to the high electron density at the 4-position in the aminopyrazole substrates **1**. The observed cyclisation mode (involving amide formation between ester and amine functions, and electrophilic alkylation at the 4-position) is opposite to that observed in the reactions of aminopyrazoles with ethyl acetoacetate; the preferred reaction course when a ketoester reacts with an aminopyrazole possessing two potential nucleophilic centres (amino-nitrogen and the 4-carbon) is thus not readily predictable Reactions of aminopyrazoles with other γ-dicarbonyl species (such as 2,5-pentanedione (acetonylacetone) or 1,2-diformylhydrazine) were explored briefly as potential routes to other pyrazoloazepines or pyrazolotriazepines, in view of the successful formation of the fused seven-membered ring with ethyl levulinate. However, the products obtained were the unexceptional 5-(2,5-dimethyl-1-pyrrolyl)-1-substituted pyrazoles and 4-(1-substituted-5-pyrazolyl)-1,2,4-triazoles, with preferred cyclisation yielding five-membered rings.

Experimental

General

Melting points were determined using a Fisher-Johns apparatus. Specimens for elemental analysis were dried at 65°C/0.2 Torr for at least 6 h and were analysed using a Hewlett-Packard Model 185 CHN analyser. Most of the ^{1}H nmr measurements were made using a Varian A-60D instrument; the nuclear Overhauser effect experiments used a Varian XL-100. The ^{13}C nmr spectra were obtained using a Bruker WP-80 Fourier transform instrument operating at 20.115 MHz, a 30° pulse of length 3.0 μs, and 16K data points with sweep widths of 5000 Hz. The data assembled in Table 3 were acquired using broadband decoupling, and signal assignments were confirmed using gated decoupling sequences. All chemical shifts are expressed in parts per million from tetramethylsilane (internal reference).

*Standard Synthetic Procedure for Substituted 4-Methyl-6*H*-pyrazolo(3,4-b)azepin-7-ones, **8** and **12***

3(5)-Aminopyrazole **1***a* (4.15 g, 0.05 mol) and ethyl levulinate (7.50 g, 0 05 mol) were heated under reflux in acetic acid (50 mL) for 20 h. The reaction mixture was concentrated under reduced pressure and neutralised with saturated aqueous sodium hydrogen carbonate, yielding a crystalline mixture of 3(5)-acetamidopyrazole and 2*H*,6*H*-4-methylpyrazolo(3,4-b)-azepin-7-one, **12***a*. Separation was effected by preparative thin-layer chromatography on silica using toluene/ethyl acetate/methanol (100:85:15 v/v), yielding the pyrazoloazepinone **12***a*, which was crystallised from ethanol to give 3.67 g (45% yield) of material mp 221–222°C (see Table 1), and 3(5)-acetamidopyrazole, crystallised from ethanol, mp 217–218°C (yield 1.52 g, 29%). ^{1}H nmr (DMSO-d_6) δ: 10.38 (s, 1H, acetamido N*H*), 7.57 (d, 1H, J = 1.6 Hz, H-3(5)), 6.48 (d, 1H, J = 1.6 Hz, H-4), 3.39 (s, 1H, H-1), 2.02 (s, 3H, acetyl H). *Anal.* calcd. for $C_5H_7N_3O$: C 47.99, H 5.64, N 33.58; found: C 48.25, H 5.23, N 33.57.

Similar reactions of other 1-substituted 5-aminopyrazoles **1***b–m* gave mixtures of 1-substituted-4-methyl-6*H*-pyrazolo-(3,4-b)azepin-7-ones **8***b–m* and 1-substituted 5-acetamidopyrazoles, separated as above. Reactant quantities, yields, and analytical data are summarised in Table 1 for the various products of type **8**, and details of the ^{1}H and ^{13}C nmr spectra in Tables 2 and 3. The acetamidopyrazoles were isolated and characterised by ^{1}H and ^{13}C nmr, but were not purified for element analysis. Some of these products contained detectable proportions of the tautomeric 2-acetamido-5-iminopyrazoles.

*Methylations of 4-Methyl-6*H*-pyrazolo(3,4-b)azepin-7-ones*

The following procedure is typical: 1,4-dimethyl-6*H*-pyrazolo(3,4-b)azepin-7-one, **8***b* (4.00 g, 0.0225 mol) was dissolved in 3 *M* aqueous sodium hydroxide and was cooled in ice while a twofold molar proportion of dimethyl sulfate was added dropwise. The reaction mixture was heated to 90°C for 5 min, left to stand at laboratory temperature for 1 h, and extracted with chloroform (3 × 100 mL). The aqueous residue was extracted continuously with a further 200 mL chloroform and the extracts were combined, dried, and evaporated; crystallisation of the residue from ethanol provided 1,4,8-trimethyl-6*H*-pyrazolo(3,4-b)azepin-7-one **9***b*, mp 119–121°C (2.90 g, 67%). Analogous reactions with the compounds **8***c* through **8***f* provided the corresponding 8-methyl derivatives **9***c* through **9***f* (see Table 4).

Methylation of 2*H*,6*H*-4-methylpyrazolo(3,4-b)azepin-7-one **12***a* (0.20 g, 0 0011 mol) under the above conditions provided 0.150 g (70%) of 2,4,8-trimethyl-6*H*-pyrazolo(3,4-b)azepin-7-one **12***b*, mp 92–94°C, differing in ^{1}H and ^{13}C nmr spectra from **9***b* (see Tables 2 and 3).

*Bromination of 4,8-Dimethyl-1-phenyl-6*H*-pyrazolo(3,4-b)-azepin-7-one, **9**d*

The above compound (1.00 g) was dissolved in dichloromethane (3 mL) and treated with bromine (0.70 g) in dichloromethane (1.0 mL) by dropwise addition, and allowed to react at room temperature with continuous stirring for 1 h. Dichlo-

romethane (10 mL) was added, and the resulting solution was washed with saturated aqueous sodium hydrogen carbonate and with water, dried, and concentrated, providing 0.85 g (65%) of 5-bromo-4,8-dimethyl-1-phenyl-6*H*-pyrazolo(3,4-b)-azepin-7-one **13**. An analytical sample, mp 106°C, was obtained by precipitation from dimethyl sulfoxide with water. ^{1}H nmr (DMSO-d_6) δ: 7.84 (s, 1H, H-3), 7.38 (s, 5H, 1-phenyl), 2.71 (s, 5H, 6-CH_2 and 8-CH_3), 2.21 (s, 3H, 4-CH_3). ^{13}C nmr (assignable peaks from overnight accumulation for a 0.2% solution in DMSO-d_6) δ: 165.9 (C-7), 137.9 (C-3), 113.1 (C-10), 107.5 (C-5), 47.8 (C-6), 34.5 (8-CH_3), 20.5 (4-CH_3). *Anal.* calcd. for $C_{15}H_{14}N_3OBr$: C 54.23, H 4.24, N 12.65; found: C 53.84, H 4.16, N 12.91.

*Formation and Nucleophilic Displacements of 7-Chloro-3,4-dimethyl-6*H*-pyrazolo(3,4-b)azepine, **14***

3,4-Dimethyl-1-phenyl-6*H*-pyrazolo(3,4-b)azepin-7-one **8***e* (3.00 g, 0.0125 mol) was heated under reflux in phosphorus oxychloride (10 mL) for 2 h. The reaction mixture was concentrated under reduced pressure, yielding the crude **14**. Attempts at purification resulted in reversion to the starting material. However, successful conversions were effected as follows.

*(a) Into 3,4-Dimethyl-7-methylamino-1-phenyl-6*H*-pyrazolo(3,4-b)azepine **15***

The crude chloro-compound **14** (1.00 g) was dissolved in dichloromethane (10 mL) and cooled in ice. Triethylamine (0.60 g) was added, followed by 40% aqueous methylamine (0.35 g). After stirring for 1 h the solvent was removed under reduced pressure and the residue was crystallised from aqueous methanol, providing 0.85 g (89%) of the methylamino compound **15**, mp 173–174°C. ^{1}H nmr ($CDCl_3$) 430–485 Hz (5H, 1-phenyl), δ: 5.23 (q, 1H, J = 5.0 Hz (disappearing on addition of D_2O), N*H*CH_3), 4.96 (t, J = 7.2 Hz, H-5), 2.76 (d, 3H, J = 5.0 Hz (collapsing to singlet on addition of D_2O), NHCH_3), 2.53 (d, 2H, J = 7.2 Hz, 6-CH_2), 2.47 (s, 3H, 3-CH_3), 2.16 (s, 3H, 4-CH_3). ^{13}C nmr ($CDCl_3$) (phenyl ring signals excluded) δ: 154.3 (C-7), 147.7 (C-9), 140.5 (C-3), 133.2 (C-4), 110.8 (C-5), 109.9 (C-10), 34.0 (C-6), 28.8 (7-NHCH_3), 21.0 (4-CH_3), 15.5 (3-CH_3). *Anal.* calcd. for $C_{16}H_{18}N_4$: C 72.15, H 6.81, N 21.04; found: C 72.25, H 6.73, N 21.00.

*(b) Into 3,4-Dimethyl-7-dimethylamino-1-phenyl-6*H*-pyrazolo(3,4-b)azepine, **16***

The chloro compound **14** (0.50 g) was heated under reflux for 4 h in *N*,*N*-dimethylformamide (5 mL). The reaction mixture was extracted with dichloromethane (3 × 25 mL), washed with water, dried, and concentrated. Separation by preparative thin-layer chromatography gave the 7-dimethylamino derivative **16**, mp 51°C (0.19 g, 36%) and the azepinone **8***e* (0.20 g, 50%). ^{1}H nmr ($CDCl_3$) 440–490 Hz (5H, 1-phenyl), δ: 5.07 (t, 1H, J = 7.2 Hz, H-5), 3.04 (s, 6H, N(CH_3)$_2$), 2.70 (d, 2H, J = 7.2 Hz, 6-CH_2), 2.49 (s, 3H, 3-CH_3), 2.11 (s, 3H, 4-CH_3). *Anal.* calcd. for $C_{17}H_{20}N_4$: C 72.82, H 7.19, N 19.98; found: C 72.59, H 7.01, N 19.56.

*(c) Into 7-Cyclohexylamino-3,4-dimethyl-1-phenyl-6*H*-pyrazolo(3,4-b)azepine, **17***

Cyclohexylamine (0.45 g) was added to the chloro compound **14** (1.00 g). After the exothermic reaction had subsided, benzene (10 mL) was added and the crystalline hydrochloride of **17** was collected by filtration. Yield 1.26 g, 94%, mp 177–178°C. ^{1}H nmr (DMSO-d_6): 440–495 Hz (5H, 1-phenyl), δ: 5.07 (t, 1H, J = 7.2 Hz, H-5), 195–235 Hz (1H, H-1 of cyclohexyl moiety), δ: 2.71 (d, 2H, J = 7.2 Hz, 6-CH_2), 2.35 (s, 3H, 3-CH_3), 2.09 (s, 3H, 4-CH_3). *Anal.* calcd. for $C_{21}H_{27}N_4Cl$: C 68.00, H 7.34, N 15.10; found: C 67.83, H 7.63, N 14.82. Treatment with aqueous sodium hydrogen carbonate gave **17**, mp 81°C. Attempted crystallization from aqueous methanol resulted in reversion to the pyrazoloazepinone **8***e*.

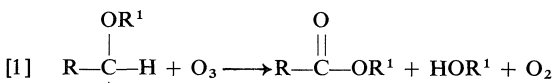
Second order rate constants for the oxidation by ozone of several acyclic acetals of heptaldehyde were determined at several temperatures. An isokinetic relationship is shown to exist for this series of reactions and the isokinetic temperature was found to be below the experimental temperature range, a domain of temperatures where reactivity is dominated by entropy factors. These results are contrasted with those obtained for cyclic acetals of heptaldehyde, where the isokinetic temperature falls above the working temperatures, a domain of temperatures where reactivity depends mainly on enthalpy factors. These results are interpreted in terms of a conformational change before oxidation in the acyclic acetals.

ROLAND J. TAILLEFER, SHIRLEY E. THOMAS, YVES NADEAU et HELMUT BEIERBECK. Can. J. Chem. **57**, 3041 (1979).

Les constantes de vitesse de deuxième ordre pour l'oxydation par l'ozone de plusieurs acétales acycliques du heptaldéhyde ont été déterminées à plusieurs températures. Ceci a permis de mettre en évidence l'existence d'une relation isocinétique pour cette série de réactions. La température isocinétique trouvée est inférieure au domaine de températures expérimentales. Ceci correspond à un domaine de températures où la réactivité dépend essentiellement de $\Delta S^{\ddagger}$. Ces résultats sont en opposition avec ceux de l'oxydation d'acétales cycliques du heptaldéhyde où la température isocinétique est supérieure aux températures expérimentales, donc dans un domaine de températures où la réactivité dépend essentiellement de $\Delta H^{\ddagger}$. Ces résultats sont interprétés en invoquant un changement conformationnel dans les acétales acycliques avant l'étape d'oxydation.

Recently, a new method of oxidation of acetals by ozone (eq. [1]) was discovered (1). The reaction is



[1] $R-C(OR^1)_2-H + O_3 \longrightarrow R-C(=O)-OR^1 + HOR^1 + O_2$

quite general, giving esters in high yield. The rates at which different acetals are oxidized, however, vary considerably and this led to the proposal of a stereoelectronic theory for the oxidation of acetals by ozone (2). Basically, it was proposed that in order for oxidation to proceed, it is required that one nonbonded electron pair on each oxygen atom of the acetal function lies antiperiplanar to the C—H bond of the acetal function (Scheme 1). This theory was supported by the synthesis of rigid models of every possible gauche conformation that an acetal can adopt and it was found that those conformations which had the stereochemical requirements did in fact undergo oxidation, while those that did not were stable towards ozone. This theory of stereoelectronic control of reactivity was later extended to the breakdown of tetrahedral intermediates formed during the hydrolysis of orthoesters (3, 4), imidate salts (3, 5), esters, and amides (3, 6). In view of the fact that stereoelectronic control of reactivity may be important in many other reactions (3), including reaction of phosphate diesters (7), and reactions of biological interest (8), it seemed important to investigate further the mechanism of oxidation of acetals by ozone.

The mechanism of the reaction[4] can be written as described in Scheme 2. This mechanism is supported by the work of Henry (9). The stoichiometry of the reaction is that shown and the reaction is first-order in ozone and first-order in acetal. Furthermore, nmr

SCHEME 3

Experimental

The acetals used in this study were prepared by standard procedures. Their physical properties corresponded to literature values and their spectra were in accord with their structures. Vapor phase chromatographic analyses were carried out on Varian Aerograph instruments, model 2800 with thermal conductivity detector and temperature programming, or model 600D with flame detector. Columns of various loadings (5%, 10%, 15%) and dimensions (5 ft × 1/8 in., 10 ft × 1/4 in., 15 ft × 1/4 in.) were employed with the liquid phases SE-30, Carbowax-20M, and PPE (OS-138). Ozone was produced from a Welsbach Ozonator model T-816. Low temperature baths were either an acetone – Dry ice mixture (−78°C) or a Neslab low temperature bath, model LTE-9 (−70 to 0°C). The ethyl acetate used was of spectroscopic grade (Fisher Scientific Co., Limited).

General Procedures for Kinetic Runs

Ethyl acetate (50–100 mL) was placed in a reactor together with solid sodium bicarbonate (1–2 g) and cooled to an appropriate temperature. An ozone–oxygen stream (3–5% ozone) was then bubbled through the solvent to achieve a saturated solution in ozone. The sample of acetal (100–200 mg, ca. 1.0 mmol/100 mL) and an internal standard (20–60 mg) were dissolved in 5 mL ethyl acetate, cooled, and added to the ozone solution. The ozone stream was maintained throughout the reaction time to ensure a constant ozone concentration. After ≃2 minutes, the first sample was removed (time = 0), cooled to −78°C while the ozone was displaced by nitrogen, after which samples were removed at convenient intervals. The reaction was followed by vapor phase chromatography. Pseudo-first order rate constants were obtained by following the disappearance of the acetal with respect to the internal standard. The internal standard was a heptanoic acid ester, the vpc response of which was calibrated against the acetal response. All peaks in the vpc spectrum were completely resolved.

Competition Experiments

Relative rates of oxidation of acetals **2** (R = H, CH_3) were also determined by a competition method as described by Hammett (11). The mixture of acetals and internal standard (*n*-propylheptanoate) was reacted with ozone in ethyl acetal at an appropriate temperature. Concentrations were determined as above by vpc analysis.

Concentrations of Ozone in Ethyl Acetate

Ethyl acetate was saturated with ozone at several temperatures ranging from 0°C to −78°C. Aliquots of these solutions were treated at −78°C with acidified potassium iodide solution and the liberated iodine was titrated with standard thiosulfate. The variation of the ozone concentration in ethyl acetate with temperature is shown in Fig. 1.

Results

Tables 1 and 2 list the data obtained for the oxidation of acetals **1** and **2**. Pseudo-first order rate constants were found by following the disappearance of starting acetals. All reactions were carried out at least once to three half-lives or more and all showed good linearity. Second order rate constants were obtained by dividing the pseudo-first order rate constant by the ozone concentration, found for a particular temperature, by interpolation from the graph in Fig. 1. The activation parameters found by plotting ln k/T vs. $1/T$, where k is the second order rate constant, are summarized in Table 3. Relative rates of oxidation of acetals **2** at different temperatures as determined by the competition method are listed in Table 4. The result obtained at −78°C (0.64) compares well with that obtained from separate measurements (0.63).

Discussion

Examination of Table 3 reveals first of all that electron donation in the ether portion of the acetal function increases the rate (−78°C). In fact, the pseudo-first order constants (Table 1) for acetals **1** can be correlated with Tafts σ* constants (12) giving a ρ value of −1.31.[5] Also the entropy of activation for these reactions is very high and negative, indicating a highly ordered transition state.

However the most significant entry in Table 3 is the enthalpy of activation: the slowest reacting acetal **1** (R = Me, $k_{-78} = 6.42 \times 10^{-4}$ L mol^{-1} s^{-1}) has the lowest enthalpy of activation ($\Delta H^{\ddagger} = 35.1$ kJ mol^{-1}) while the fastest reacting acetal **1** (R = *i*Pr, $k_{-78} = 1.93 \times 10^{-3}$ L mol^{-1} s^{-1}) has the highest enthalpy of activation (38.4 kJ mol^{-1}). For cyclic acetals **2** on the other hand, we find the normal situation: the faster the reaction (k), the lower $\Delta H^{\ddagger}$.[6] Clearly then the two different types of acetal show different behavior towards oxidation by ozone.

Leffler has shown (13) that often in a reaction series there is a relationship between $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$. This relationship is called the isokinetic relationship (or the compensation effect) and may be written in the form of eq. [2] where β is the isokinetic temper-

$$[2] \quad \Delta H^{\ddagger} = \beta \Delta S^{\ddagger} + h_0$$

ature and h_0 a constant. When such a relationship exists for a particular reaction series, β represents a point of inversion of reactivity.[7] When β is higher than the experimental temperature range, then this represents a domain of temperatures where reactivity depends essentially on $\Delta H^{\ddagger}$. On the other hand, when the isokinetic temperature β is lower than the experimental temperature range, then we have a domain of temperatures where reactivity depends essentially on $\Delta S^{\ddagger}$. When $T = \beta$, then all the compounds in the reaction series react at the same rate.

Proportionality between $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ as determined by plotting eq. [2] however, is not a criterion to prove that an isokinetic relationship holds. Exner (14) and others (15) have criticized the procedure because $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ are determined from the same equation and are therefore necessarily interdependent.

A better way of representing the data, according to Exner (14), is to plot log k against $1/T$ and see if all the lines appear to go through the same point. This is indeed found to be the case for the acyclic acetals **1** (Fig. 2), since the incorporation of the isokinetic constraint left the Arrhenius plot virtually unchanged. The root mean square deviation of fit was found to be 0.0426 when the individual Arrhenius lines were derived in the usual manner. When they were forced through a common point the root mean square deviation increased only insignificantly to 0.0430. The slopes b_i and the coordinates x_0 and y_0 of the isokinetic point were derived by an interactive non-linear least squares minimization (Taylor series expansion) of the function f of the log k values y_{ij} and the inverse temperatures x_{ij} (see for example ref. 16)

$$y_{ij} = b_i(x_{ij} - x_0) + y_0$$

$$f = \sum_i [b_i(x_{ij} - x_0) + y_0 - y_{ij}]^2 = \min$$

$$\partial f/\partial b_i = 0 \qquad i = 1, \ldots, n$$

$$\partial f/\partial x_0 = 0$$

$$\partial f/\partial y_0 = 0$$

The isokinetic temperature, $1/x_0$, found in this way, is 118 K or −155°C. The point of intersection of any two lines varies between −168°C and −92°C, making the error in the isokinetic temperature quite large. Still the limits are below the working temperature range (−78 to −32°C). Therefore, the reactivity in this series of reactions is dominated by *entropy* factors (*vide supra*).

The isokinetic hypothesis cannot be statistically rejected, but considering the large errors in $\Delta H^{\ddagger}$ the hypothesis that the series be isoenthalpic cannot be rejected either. If this were the case however, the reactivity of the series of reactions would still be dominated by *entropy* factors.

The behavior of acyclic acetals **1** can be contrasted with that of cyclic acetals **2**, for which the point of intersection of the two Arrhenius lines falls at a point corresponding to a temperature of −4°C (Fig. 3). Because there are only two lines (hence no statistical test can be made) and the errors in $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ are so large, the value of −4°C for the isokinetic tem-

[5]Log k vs. 2σ* of the R group at −78°C. Correlation coefficient, 0.91.
[6]The errors in the $\Delta H^{\ddagger}$ are rather large and the consequence of that will be discussed later.
[7]For a good lead reference on this subject, see ref. 14.

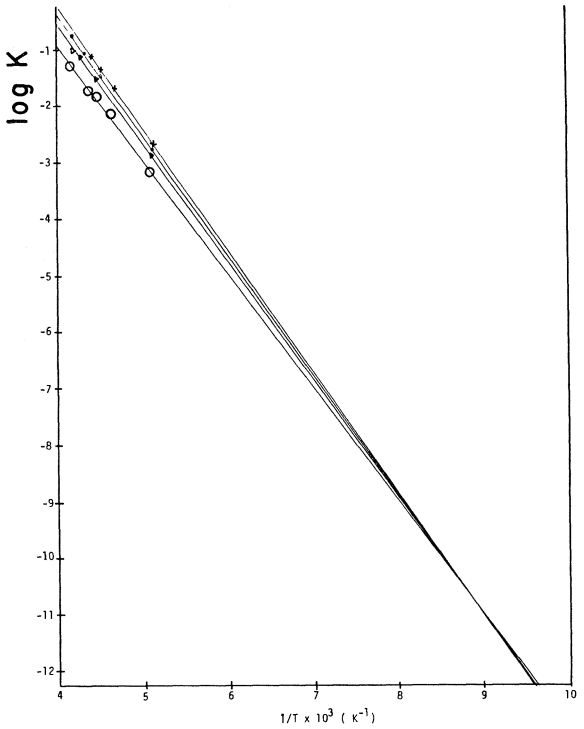

FIG. 2. Arrhenius plots of four acyclic acetals **1**.

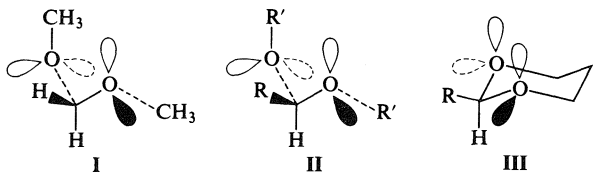
perature cannot be accepted from these data alone. That −4°C is about the right value however is confirmed by the results obtained by the competition experiments (Table 4). These data clearly show the point of intersection (inversion of reactivity) of the two lines to be around 0°C: the relative reactivity at −78°C of the two acetals **2** is reversed at 20°C. At 0°C, the relative rate is about 1. The significant point here is that the isokinetic temperature be *above* the working temperature range, hence a range of temperature where reactivity is dominated by *enthalpy* factors.

It appears then that the two types of acetals behave differently. One way of interpreting the results is to consider the preferred conformation of acyclic acetals. It has been shown (17) that the preferred conformation of dimethoxymethane is that represented by structure **I** (Scheme 4). Evidence has been presented (18) for a similar conformation of other acetals (structure **II**, Scheme 4). However, this conformation



SCHEME 4

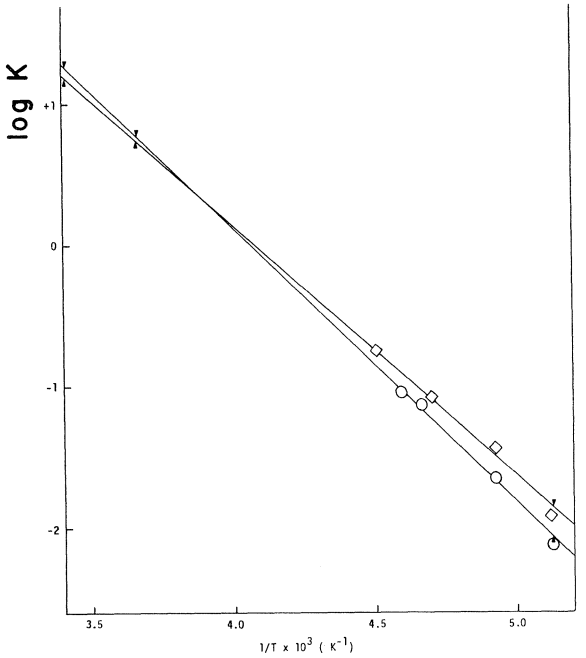


FIG. 3. Arrhenius plots of two cyclic acetals **2**. Log k_{rel} (Table 4) indicated by arrows.

is one which Deslongchamps *et al.* (2, 3) have shown to be unreactive towards ozone. Prior to oxidation, the OR group must rotate (or invert) in order that two non-bonding electron pairs, one on each oxygen atom, lie anti-periplanar to the C—H bond of the acetal function. Thus conformational changes in acyclic acetals are required prior to oxidation by ozone. Since this series of reactions has been shown to be dominated by entropy factors, this suggests that there is a direct relationship between conformational changes and entropy factors. This relationship can be attributed to the reorganization of solvent molecules around the acetal function during the rotation step. Of course, no such conformational changes are required for the cyclic acetals **2** (structure III, Scheme 4) and hence the reactivity of that series of reactions is dominated by enthalpy factors.

Finally, one comment should be added about the fact that the ρ* value found for the oxidation of the acyclic acetals **1**, was −1.31 (−78°C). Previous studies had shown (2, 3, 9) that electron donors accelerate the reaction. However, one consequence of having a reaction series in a domain of temperature where reactivity is dominated by entropy factors, is to reverse the sign of ρ (13). If the rate of a reaction was only a function of $\Delta H^{\ddagger}$, this phenomenon would have been observed. But the variation of $\Delta S^{\ddagger}$ causes the term $T\Delta S^{\ddagger}$ to contribute more than the change in $\Delta H^{\ddagger}$ to the overall $\Delta G^{\ddagger}$ (cf. Table 3).

Kinetic studies on the catalytic reduction of nitrotoluene by hydrazine

N. GOSWAMI AND M. L. RAHMAN[1]

Department of Chemistry, University of Rajshahi, Bangladesh

Received August 9, 1978[2]

N. GOSWAMI and M. L. RAHMAN. Can. J. Chem. **57**, 3047 (1979).

Kinetics of reduction of *p*-nitrotoluene by hydrazine in presence of Raney nickel catalyst have been studied spectrophotometrically. It has been found that the reaction is first order with respect to both hydrazine and nitrotoluene. The influence of solvent, salt, and the amount of catalyst on the reaction rate has been investigated. The rate constant was found to depend on the dielectric constant, the ionic strength, and on the catalyst concentration. The activation energy was estimated to be 103.92 kJ mol^{-1} in 73.58% ethanol in water. This value decreases considerably when the polarity of the solvent increases and when other salts are added. In pure water the value is 32.25 kJ mol^{-1}.

N. GOSWAMI et M. L. RAHMAN. Can. J. Chem. **57**, 3047 (1979).

On a étudié par spectrophotomètrie les cinétiques de réduction du *p*-nitrotoluène par l'hydrazine en présence du nickel de Raney comme catalyseur. On a trouvé que la réaction est d'ordre un par rapport à l'hydrazine et au nitrotoluène. On a étudié l'influence du solvant, du sel, et de la quantité de catalyseur sur la vitesse de réaction. On a trouvé que la constante de vitesse dépend de la constante diélectrique, de la force ionique et de la concentration du catalyseur. On a obtenu une énergie d'activation de 103.92 kJ mol^{-1} pour la réaction dans l'éthanol à 73.58% dans l'eau. Cette valeur décroît considérablement quand la polarité du solvant augmente et quand on ajoute d'autres sels. Dans l'eau pure la valeur est de 32.25 kJ mol^{-1}.

[Traduit par le journal]

Introduction

Hydrazine has been widely used for the reduction of a large number of organic compounds. In the absence of a catalyst the rate of the reaction is very slow and drastic conditions such as heating and refluxing for a long period are required. In the presence of catalysts, however, the reaction rate greatly increases (1–3). The reduction of aromatic nitrocompounds by hydrazine has two advantages. Firstly, as opposed to direct hydrogenation, no pressure apparatus is necessary. Secondly, the catalytic hydrazine reduction method gives yields equal to or better than direct catalytic hydrogenation or other methods (4). Despite the versatility of hydrazine as a reducing agent, most of the work (4) in the field has been aimed at obtaining better yields of the reduction products. Very little seems to have been done on the kinetics and mechanisms of these reactions. The present work has been undertaken to study the kinetics of the reduction of an aromatic nitrocompound (*p*-nitrotoluene) with hydrazine in the presence of a Raney nickel catalyst. This reaction involves two phases, viz. solid and liquid and it would be interesting to study the kinetics of a heterogeneous reaction in solution which, relative to gas phase, has received very little attention.

Experimental

Chemicals

p-Nitrotoluene supplied by the Matheson Coleman and Bell company and hydrazine hydrate by the Merck–Schuchardt company were used without further purification. Rectified spirit was preferred to absolute alcohol as a solvent because the latter might contain traces of benzene. Dioxane was supplied by the Matheson Coleman and Bell company and was used without further purification. Analytical grade potassium chloride and potassium sulphate obtained from Merck AG. Darmstadt were used. When calculating the solvent composition, water from hydrazine hydrate was taken into account.

Raney Nickel

Raney nickel prepared by the method of Mozingo (5) was thoroughly washed with benzene which was removed *in vacuo*. It was heated to about 533 K and then cooled *in vacuo*. The cooled catalyst was stored in xylene. When necessary, an amount of the catalyst was taken in a flask and the xylene was removed *in vacuo*. Heating was then continued to 673 K for 10 h. The degassed catalyst was used within a fortnight of its degasification, which was the period when most reproducible results were obtained. It was observed that catalysts prepared by heating to temperatures lower than 673 K were different in activity and changed their activity rather rapidly.

Kinetic Methods

The reaction vessel was a two-necked round-bottomed flask thermostated to ± 0.1 K. With a definite amount of the catalyst the reactants were thoroughly mixed by an electric stirrer and the aliquots were periodically transferred and filtered off as quickly as possible, the time being recorded by a stop watch. The filtered solutions were analysed for their *p*-nitrotoluene content by measuring the absorbances at 275 nm with the help of a Beckman DB spectrophotometer. For the measurement of the concentration of hydrazine a

colouring agent (6) was added and the absorbances were monitored at 458 nm. It was checked that the substances obeyed the Beer–Lambert law and the solvent in the reference cell contained all the components present in the sample cell except the one whose concentration was being determined.

pH

A Coleman model-39 pH meter was used for measuring the pH.

Results

The main product of the reduction of *p*-nitrotoluene by hydrazine in presence of Raney nickel catalyst was found to be *p*-toluidine. In spite of repeated attempts no intermediates or coupled products could be detected. *p*-Toluidine had its maximum absorption at 236 nm at which *p*-nitrotoluene also absorbed significantly. Since it was inconvenient to calculate the concentration of *p*-toluidine from the overlapped absorbance, the kinetics were studied by measuring the rate of decrease of nitrotoluene. It was also observed that quantitative measurement of *p*-toluidine was difficult in the presence of hydrazine which did not seem to behave as a satisfactory solvent at this low wavelength. Table 1 shows the *p*-nitrotoluene decay runs for ethanol–water system.

By keeping the hydrazine concentration and in large excess, the order of the reaction with respect to nitrotoluene was determined and found to be unity in the initial part of each run, but the order approached zero (Fig. 1) or two (Fig. 6) near the end of the run. The transition from first to zero order was observed only when the proportion of ethanol to water was the highest in the medium (73.58%) and in all other cases it was from first to second order. It is interesting to note that with 73.58% ethanol – water medium the first-order behaviour was observed over only 20% of the reaction and that this rose to the extent of about 60% with higher proportion of water (40% and less ethanol). From the slope of the double logarithmic plot of initial rate vs. initial concentration (i.e. initial absorbance), the true order with respect to *p*-nitrotoluene was calculated and found to be unity.[3]

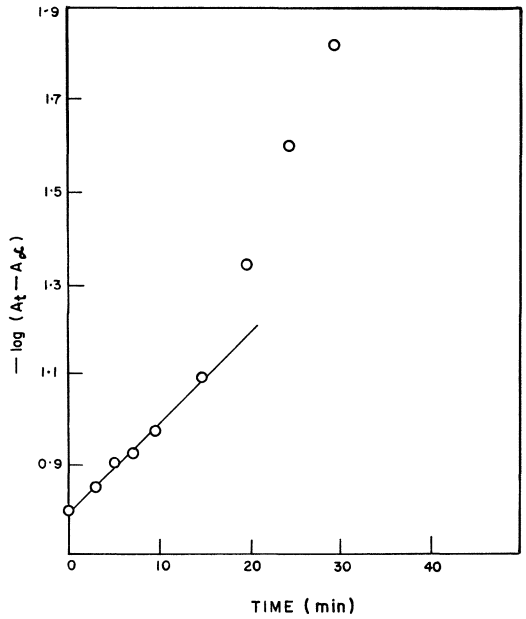

FIG. 1. Variation of $-\log (A_t - A_\infty)$ with time (min); A_t indicates the absorbance at a certain time and A_∞, absorbance at an infinite time; the initial concentration of *p*-nitrotoluene was 5.0×10^5 *M* in 73.58% ethanol in water containing 1 *M* hydrazine; the concentration of the catalyst (Raney nickel) was 5.0 g dm^{-3}; the reaction temperature was 310 K.

Table 1 indicates that the absorbance decreases to

[3]Complete set of data may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

zero in some runs but not in others. The zero final absorbance seems to be favoured by high concentrations of hydrazine ($\sim$ 11 M) in a water-rich medium. With low concentrations ($\sim$ 1.0 M) of hydrazine zero absorbance was never obtained.

Under pseudo-first order conditions, the rate can be written as

$$[1] \quad -\frac{d[B]}{dt} = k[Hy]^{n_1}[B] = k'[B]$$

Here [B] stands for the nitrotoluene concentration and [Hy] for the hydrazine concentration. The pseudo-first order rate constant, k', should thus depend on hydrazine concentration. Figure 2 shows that a plot of k' (the rate constants were calculated from first 50% of the reaction) against [Hy] gives a straight line, indicating that the reaction is also first order with respect to hydrazine.

The reaction rate was found to increase linearly with the amount of catalyst up to a certain point after which the rate of increase became slower.[3]

Addition of water to the reaction medium enhanced the rate. The reaction became faster in presence of acids or bases. Effect of dielectric constant on the reaction rate was studied in the dioxane–water and ethanol–water systems and the plots of log k' (the rate constants were calculated from first 30–50% and about 60% of the reaction for the dioxane–water and water–ethanol systems respectively) versus $1/D$ were found to be linear in both systems (Fig. 3). Values of D corresponding to different mixtures of water and ethanol and of dioxane and water were obtained from literature (7).

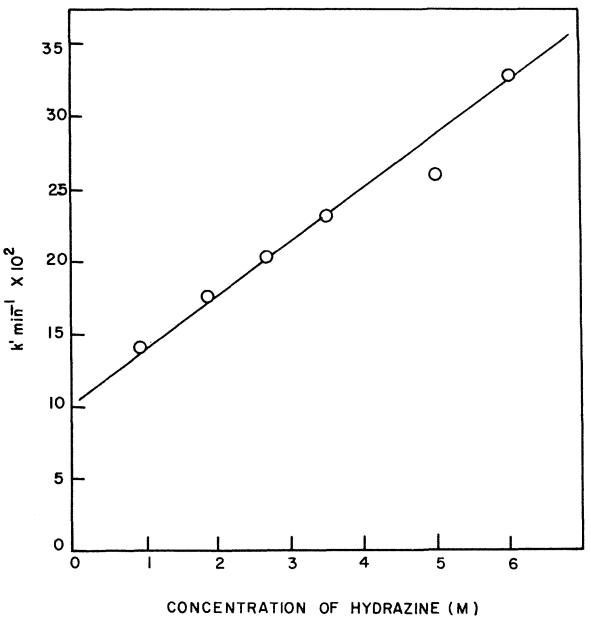

FIG. 2. Variation of rate constant (k' min^{-1}) with the hydrazine concentration (M); the hydrazine concentration was varied keeping the solvent composition constant (50% ethanol in water); the concentration of the catalyst (Raney nickel) was 5.0 g dm^{-3}; the reaction temperature was 313 K. The rate constants were calculated from first 50% of the reaction.

The reaction rate was found to increase with increasing ionic strength of the medium. In the presence of KCl or K_2SO_4, log k' (the rate constants were calculated from first 60–75% of the reaction) was found to vary linearly (Fig. 4) with $\sqrt{\mu}$ (experiments were carried out in 38.23% ethanol – water system).[3] For the calculation of the ionic strength only the concentration of the added electrolyte was taken into account because the concentrations of other ions that might be involved were not known.

The logarithm of the pseudo-first order rate constant was plotted against the reciprocal of temperature when 73.58% alcohol in water was used as the solvent. The result was a straight line (Fig. 5).[3] The slope of the line gave an activation energy of 103.92 kJ mol^{-1}. The activation energy decreased considerably when the proportion of water in the solvent increased and when other salts were added. Table 2 shows the activation energies for various media.

It was thought desirable to compare catalytic reduction by hydrazine with catalytic reduction by

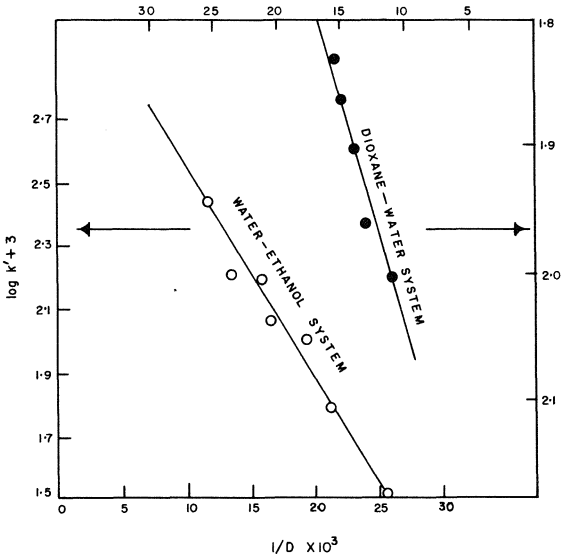

FIG. 3. Variation of logarithm of the rate constant (k' min^{-1}) with the reciprocal of the dielectric constant (D) of the solvent, e.g. ethanol–water system and dioxane–water system containing 1 M hydrazine and 5.0 g dm^{-3} catalyst (Raney nickel); ○, ethanol–water system with the p-nitrotoluene concentration (7.0 × 10^{-5} M) at reaction temperature 298 K; ●, dioxane–water system with the initial p-nitrotoluene concentration (4.0 × 10^{-5} M) at reaction temperature 313 K. The rate constants were calculated from first 30–50% and about 60% of the reaction for the dioxane–water and water–ethanol systems respectively.

0.0	—	5.0×10^{-5}	1.0	5.0	32.25

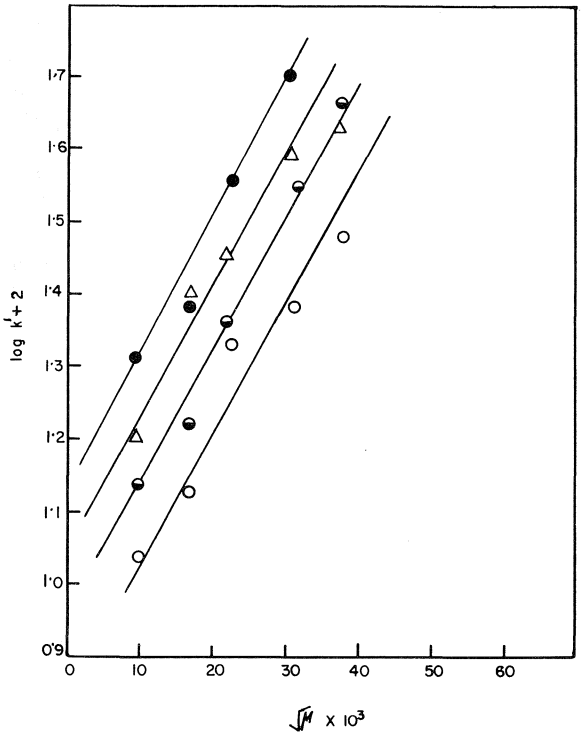

FIG. 4. Variation of logarithm of rate constant (k' min^{-1}) with the square root of the ionic strength ($\sqrt{\mu}$) of KCl and K_2SO_4 in solution with the initial *p*-nitrotoluene concentration 5.0×10^{-5} *M* in 38.23% ethanol – water system containing 1 *M* hydrazine and 5.0 g dm^{-3} catalyst (Raney nickel); ○, in presence of KCl at 298 K; ◒, KCl at 303 K; △, K_2SO_4 at 298 K; ●, K_2SO_4 at 303 K. The rate constants were determined from first 60–75% of the reaction.

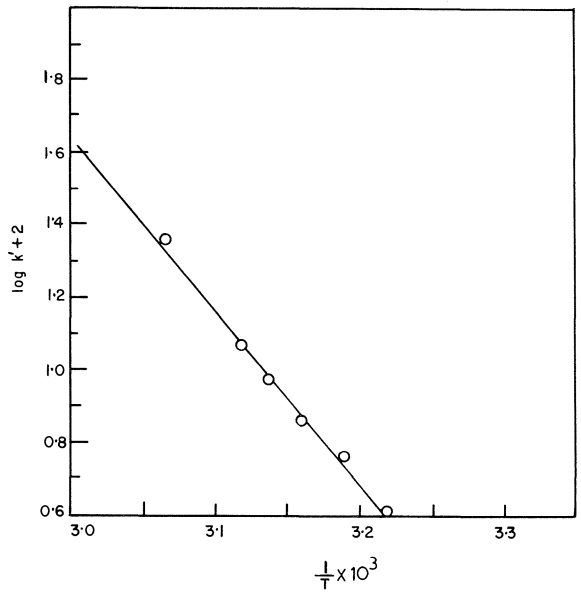

FIG. 5. Variation of logarithm of the rate constant (k' min^{-1}) with the reciprocal of absolute temperature (T); the initial concentration of *p*-nitrotoluene was 5.0×10^{-5} *M* in 73.58% ethanol – water; the hydrazine concentration was 1 *M* and the concentration of the Raney nickel catalyst was 5.0 g dm^{-3}. The rate constants were determined from first 20% of the reaction.

hydrogen. Instead of using hydrogen under pressure, we prepared a type of Raney nickel catalyst that contained a significant amount of adsorbed hydrogen. As mentioned previously, the catalyst in the present work was heated to 673 K to remove hydrogen. This catalyst however was heated only to 533 K and it was able to reduce nitrotoluene at an appreciable rate in absence of hydrazine. The reduction power of this catalyst is clearly due to the adsorbed hydrogen and is therefore similar to catalytic reduction by hydrogen (8). It was found that the rate of reduction was again proportional to the first power of the concentration of nitrotoluene. The effect of dielectric constant and added electrolytes was not so pronounced with this catalyst as in presence of hydrazine and the variation of the rate constant was not very regular.

Discussion

In general a heterogeneous reaction takes place in the following steps: diffusion, adsorption, actual chemical reaction on the surface, desorption, and diffusion again. Of these, diffusion is very fast and is most unlikely to be rate-determining in the present case, because the reaction has a rather high energy of

activation. Besides, an electric stirrer rotating at a constant speed was employed to mix the reactants, thus minimizing the effect of diffusion. The high energy of activation also precludes the possibility of adsorption or desorption being rate-determining. We are thus left with the actual chemical reaction itself on the surface of the catalyst:

[2] S—A + S—B → toluidine + S

Here S stands for surface and A, reducing agent.

The observed kinetics that the reaction is first order with respect to nitrotoluene can be explained according to this scheme if it is assumed that nitrotoluene is sparsely adsorbed on the surface. A very pertinent question in connection with the present reaction is whether hydrazine itself acts as the reducing agent or a product or products of decomposition of hydrazine bring about the reduction. It has been found (9–11) that hydrazine decomposes in the presence of catalysts to give N_2, H_2, and NH_3. Pietra (12), Rottendorf and Sternhell (13) have suggested that the reactivity of hydrazine in the presence of catalysts like Ni, Pd, Pt, Ru, etc. is simply due to the hydrogen liberated. Our observation that the reduction reaction in the presence of Raney nickel alone shows similar behaviour tends to support this hypothesis.

However, it has been observed by repeated experiments that the reaction rate changes considerably if the polarity of the solvent is changed and if foreign electrolytes are added. It is not only the reaction rate that changes, the activation energy also decreases from 103.92 kJ mol^{-1} to about one-third of this value (Table 2). Thus there can be no doubt that the rate-determining step or steps should be ionic in character; we are therefore forced to look for an additional or alternative rate-determining step.

Audrieth and Jolly (11) who worked on the decomposition of hydrazine on Raney nickel found that the reaction was markedly influenced by the presence of water and added salts. Thus there is some parallelism between the present reaction and hydrazine decomposition. Without giving the detailed mechanism of the reaction, the authors mentioned that the products of decomposition were N_2, H_2, and NH_3 and that the kinetics were variable. If, however, one wants to explain the solvent and salt effects, one has to assume that prior to decomposition into the main products hydrazine breaks up into ions. We are thus led to the conclusion that the slow step we are looking for is possibly the breaking up of hydrazine into ions prior to or concurrently with adsorption on the surface.

Addition of salts could have two kinds of effect on such reactions, one of which is called the mass-law effect. This would have an accelerating or a retarding effect on the rate of ionisation, depending on whether the ions formed are being removed or added from outside. The other effect is due to ionic strength. Increase of ionic strength would have an effect analogous to that of making a solvent more polar. In the unimolecular ionisation of a neutral molecule a polar solvent would help stabilise the ions through solvation. Similarly inert salts would provide the ionic atmosphere in which the charged transition-state would be more stable. We have studied the effect of non-common-ion salts. This is not expected to have any mass-action effect and it has been found that the rate constant increases with the ionic strength. However, the ions that are formed from hydrazine may have inhibitory effect on the reaction rate when they have built up to sufficient concentrations. We have observed that after a certain time the rate of reaction decreases and that it no longer remains first order. The phenomenon is even more prominent in the presence of salts (Fig. 6).

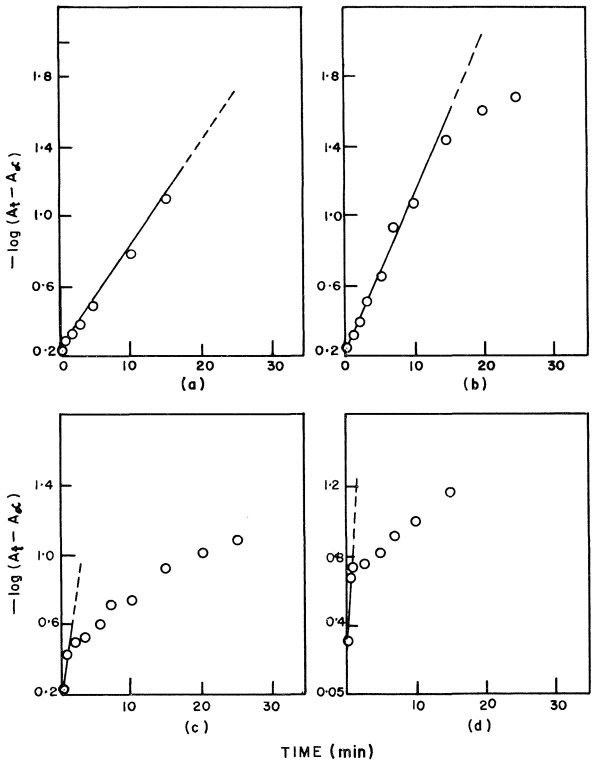

FIG. 6. Variation of $-\log (A_t - A_\infty)$ with time (min) at 298 K; the initial *p*-nitrotoluene concentration was 5.0×10^{-5} *M* in 38.23% ethanol – water containing 1 *M* hydrazine and KCl of different ionic strength; graphs (*a*), (*b*), (*c*), and (*d*) have been obtained with the ionic strengths 1.0×10^{-4}, 5.0×10^{-4}, 30.0×10^{-4}, and 45.0×10^{-4} respectively; the concentration of the catalyst (Raney nickel) was 5.0 g dm^{-3} in each case.

There may be various factors responsible for the decrease in reaction rate some time after the commencement of the reaction. The catalyst may show a poisoning effect and the product or products of reaction may compete for the active sites on the catalyst.

As already mentioned acids and bases have been found to enhance the reaction rate. This also points towards some sort of ionic mechanism. Hydrazine has been reported (4) to exist as hydrazinium positive or hydrazide negative ions depending on the pH of the medium. Addition of a base like $Ba(OH)_2$ is claimed (9) to produce more hydrogen as a decomposition product. A basic medium should, in that case, be more favourable to the reduction reaction. In the present work addition of NaOH has made the reaction faster, but perchloric acid has been found to be even more effective. Acids probably play a dual role in that they produce hydrogen by reaction with the catalyst and may also have catalytic effect.

On montre que la dissociation de la pentafluoroacétone, induite par les champs de radiation infrarouge à haute puissance, se produit selon un mécanisme qui implique des radicaux libres.
[Traduit par le journal]

Introduction

Recently we have shown that the molecule hexafluoroacetone undergoes multiphoton decomposition with great facility when it is excited near its ν_{15} band by pulses of ir radiation (1). We have also found that $CF_3{}^{13}COCF_3$ could be directly dissociated at natural abundance leading to product carbon monoxide with over 85% C-13 content (2). The homogenous gas phase pyrolysis had been studied some time ago by Batey and Trenwith (3) who found Arrhenius parameters for the process

[1] $CF_3COCF_3 \rightarrow C_2F_6 + CO$

to be $k_1 = 10^{9.6} \exp(-50\,900/RT)\ s^{-1}$. These authors favoured a molecular rearrangement process involving an activated complex with a three membered carbon ring. In contrast to this the photochemical decomposition of hexafluoroacetone may be interpreted solely in terms of free radical processes (4):

[2] $CF_3COCF_3 \rightarrow CF_3CO + CF_3 \rightarrow 2CF_3 + CO$

However, many examples of multiphoton decomposition have been discovered in which decomposition proceeds by the least endoergic pathway (5). Thus there is no *a priori* reason to favour either pathway. In early attempts to resolve which pathway predominated we tried radical scavenging experiments with O_2 and NO, these were inconclusive (see below) and thus we have resorted to the expedient of studying the multiphoton decomposition of the structurally similar molecule pentafluoroacetone in which the free radical and molecular pathways would give different product arrays. The results, reported below, favour the free radical pathway.

[2]NRCC summer student, 1978.

Experimental

Samples were photolysed in 18 cm long, 5 cm diameter Pyrex cells with sodium chloride windows. Radiation from a TEA-CO_2 laser (Lumonics model 101) was focused at the centre of the cell by a focal length = 10 cm germanium lens; incident fluence was monitored by a calibrated pyroelectric detector. The temporal distribution of the laser pulse consisted of an initial spike (FWHM = 150 ns) followed by a tail (τ_D = 1 μs); 80% of the energy was in the initial spike.

After irradiation samples were frozen into glass tubes and analysed by glc using a thermal conductivity detector (6 ft Porapak Q, 6 ft silica gel 80–100 mesh, ¼ in. od copper tube, He carrier gas at 90°C). Typical retention times were C_2F_6 3 min, C_2F_4 3.8 min, CF_3H 4.8 min, C_3F_8 13 min, C_2F_3H 8.4 min, and CF_3CF_2H 15 min. The glc response was calibrated with authentic aliquots of fluoroform, tetrafluoroethylene, hexafluoroethane, carbonyl fluoride, and pentafluoroethane. No authentic sample of trifluoroethylene was available, therefore this product was identified by trapping the glc peak and carrying out mass spectrometric analysis.

During the course of the work a complicating reaction was noted. Although the reaction products were stored in sealed glass ampoules prior to analysis and contacted only clean glass surfaces it was observed that the peaks corresponding to the ethylenes were time dependent. Indeed, reaction mixtures stored for longer than 4 h showed no trace of trifluoroethylene, and tetrafluoroethylene itself disappeared given longer times (10 h). This phenomenon is almost certainly a result of reaction with, or catalysed by, hydrogen fluoride or its reaction products. After this effect was noted all ampoules were stored in liquid nitrogen prior to analysis.

Pentafluoroacetone (Hynes Chemical) was purified by distillation at −160 and −78°C, degassed and stored in blackened bulbs. Analysis by glc failed to reveal any impurities. Oxygen was obtained from Matheson (Research Grade). Nitric oxide (Matheson) was purified by distillation from liquid argon to liquid nitrogen.

Results and Discussion

Irradiations were carried out using the R(34) line of the 00°1–10°0 band of CO_2 at 986 cm^{-1}. This line falls on the red edge of an absorption band of pentafluoroacetone. The infrared absorption spectrum of this molecule has neither been published nor analysed

0008-4042/79/233053-03$01.00/0

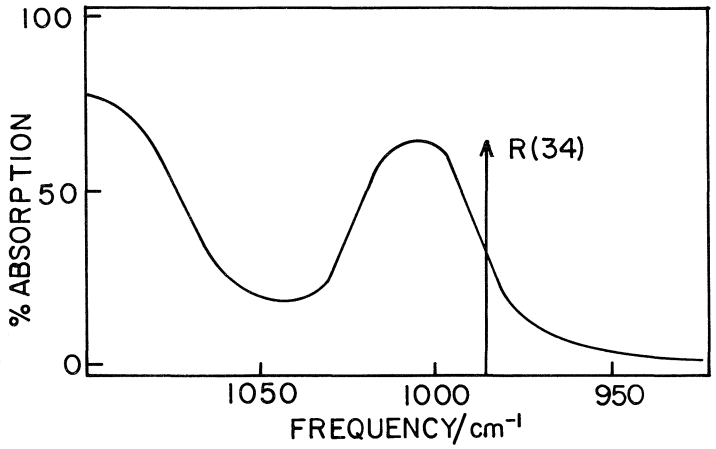

FIG. 1. Low intensity infrared absorption spectrum of pentafluoroacetone; pressure = 46 Torr; pathlength = 10 cm; temperature = 22°C. The arrow indicates the frequency of the CO_2 laser line used.

before, and hence the portion occurring within the gain curve of the CO_2 laser is presented here (Fig. 1). The line used in these experiments probably excited C—C—C skeletal vibrations.

At 0.25 J cm^{-2} incident fluence no decomposition was observed when 0.6 Torr of pentafluoroacetone was photolysed by an unfocused beam. However, decomposition was induced when the beam was focused. Products detected by glc were C_2F_6, C_2F_4, CF_3H, C_2F_3H, C_3F_8, and C_2F_5H. At low conversions all products increased linearly with pulse number. The production rate for the major product detected (C_2F_5H) and the relative production rates for other major products (C_2F_6, C_2F_4, CF_3H, and C_2F_3H) are shown in Fig. 2.

The product array is consistent with the free radical decomposition and recombination mechanism proposed by Pritchard and Perona (6) to explain the one photon photolysis of pentafluoroacetone at 3130 Å; relevant portions are shown below:

[3] $CF_3COCF_2H \xrightarrow{h\nu} CF_3 + CO + CF_2H$

[4] $CF_3 + CF_3 \rightarrow C_2F_6$

[5] $CF_3 + CF_2H \rightarrow CF_3CF_2H^* \rightarrow C_2F_4 + HF$

[6] $CF_3CF_2H^* \xrightarrow{M} C_2F_5H$

[7] $CF_3CF_2H^* \rightarrow CF_2 + CF_3H$

[8] $CF_2H + CF_2H \rightarrow CF_2HCF_2H^* \rightarrow C_2F_3H + HF$

[9] $CF_2HCF_2H^* \xrightarrow{M} C_2F_4H_2$

[10] $CF_2HCF_2H^* \rightarrow CF_2 + CF_2H_2$

[11] $CF_2 + R \rightarrow RCF_2 \xrightarrow{R} RCF_2R$

where R is either CF_2H or CF_3. Free radical attack on pentafluoroacetone to give hydrogen abstraction products has been ignored for the following reasons: (*i*) pentafluoroacetone concentration is low (0.6 Torr), and (*ii*) transient free radical concentrations are high; indeed it is assumed that all pentafluoroacetone molecules within the central focal region are dissociated.

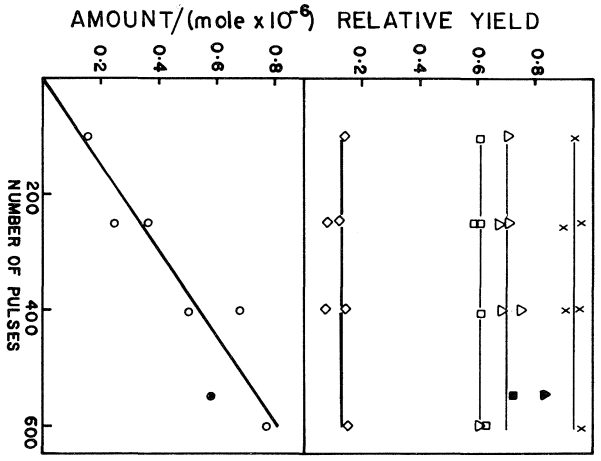

FIG. 2. Product formation in the multiphoton dissociation of pentafluoroacetone as a function of number of pulses. Circles refer to pentafluoroethane. The upper graph displays the relative molar production of other products relative to C_2F_5H: C_2F_4, squares; C_2F_6, triangles; and CF_3H, diamonds. The crosses refer to the peak height ratio C_2F_3H/C_2F_5H from glc. Pressure = 0.6 Torr, cell volume = 330 cm^3; irradiated volume = 14 cm^3; temperature = 23°C; incident fluence = 0.25 J cm^{-2}. The solid symbols are results from irradiation of 0.6 Torr pentafluoroacetone with 0.08 Torr nitric oxide.

We should note at this point that although small amounts of carbon monoxide were not detected by the sampling method its presence was confirmed by pressure measurements above liquid nitrogen and by

mass spectrometry. General support for the proposed mechanism is provided by the value of the ratio of rates of formation

$$\frac{R_f[C_2F_5H] + R_f[C_2F_4] + R_f[CF_3H]}{R_f[C_2F_6]} \approx 2.5$$

A value of 2.0 is expected. Pritchard and Perona (6) find values from 1.80 → 2.40. Furthermore, the ratio of rates of formation is

$$R_f[CF_3H]/(R_f[C_2H_5F] + R_f[C_2F_4]) \approx 0.07$$

which is in good agreement with Pritchard and Perona's estimate for the disproportionation/combination ratio for CF_3 and CF_2H of 0.08. There is, however, one major discrepancy between our results and the one photon study. The earlier workers found $[C_2F_4]/[C_2F_5H] \leq 0.04$, we find values of ~ 0.61. This almost certainly indicates that free radical recombination occurs within a region of high vibrational "temperature"; considering the nature of the excitation this indication is not unexpected. Furthermore, equivalently high yields of C_2F_3H are found. This is not unexpected since the rate of HF elimination from $C_2F_4H_2$* is expected to be at least >20 larger than the rate of elimination from C_2F_5H* (6).

Two experiments with free radical scavengers were performed. In the first 0.6 Torr of pentafluoroacetone was photolysed in the presence of 0.10 Torr of oxygen. The sole product was CF_2O. Clearly vibrationally hot pentafluoroacetone molecules are burned in the presence of oxygen. In the second experiment 0.6 Torr of pentafluoroacetone was photolysed in the presence of 0.08 Torr of NO. No change in either the distribution or the rates of formation of products was observed. Clearly high free radical concentrations and low pressures preclude the effective use of free radical scavengers. We note that the total pressure is limited by dielectric breakdown observed in focused beams.

In conclusion, the product array observed indicates that multiphoton decomposition of pentafluoroacetone proceeds by a free radical mechanism, in which high concentrations of trifluoromethyl and difluoromethyl radicals are formed in a high temperature region. This result makes this molecule relatively unattractive for studies of deuterium atom enrichment in spite of the fact that the molecule contains a single hydrogen atom which may be easily redeuterated by exchange with water through the enol form. Although the free radical mechanism is clearly indicated by the array of products its occurrence could not be proven by classical free radical scavenging experiments. This type of ambiguous behaviour should be general to studies of multiphoton decomposition in focused infrared laser beams in which the decomposition yield is necessarily high and the total pressure is necessarily low.

Entropy changes and structural implications for crystalline phases of pyrazine

ROBERT K. BOYD, JOHN COMPER, AND GEORGE FERGUSON

Guelph–Waterloo Centre for Graduate Work in Chemistry, Guelph Campus, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received May 3, 1979

ROBERT K. BOYD, JOHN COMPER, and GEORGE FERGUSON. Can. J. Chem. **57**, 3056 (1979).

Molar heat capacities of crystalline pyrazine have been measured by adiabatic calorimetry in the range 20–40°C and interpreted to show that in the crystal structures of phases II and III half the molecules must be disordered. Together with previous X-ray studies, this allows possible structures for phase II and phase III to be deduced. Of the eight molecules in the phase III unit cell, four are disordered over two sites so that the point symmetry is effectively *mmm*; the remaining four molecules have 2/*m* symmetry and are not disordered. This structure is consistent with the available spectroscopic evidence. It is likely that the phase II structure is closely related to the phase III structure, for example by the molecules with 2/*m* symmetry adopting a slightly different orientation.

ROBERT K. BOYD, JOHN COMPER et GEORGE FERGUSON. Can. J. Chem. **57**, 3056 (1979).

On a mesuré les capacités calorifiques molaires de la pyrazine cristallisée, à l'aide d'un calorimètre adiabatique dans un intervalle de température de 20–40°C. Les résultats sont interprétés dans le but de montrer que dans les structures cristallines des phases II et III la moitié des molécules doivent être désordonnées. De concert avec les études antérieures de rayons-X, ceci permet de déduire les structures possibles des phases II et III. Des huit molécules dans la maille élémentaire de la phase III, quatre sont désordonnées sur deux sites de telle sorte que le point de symétrie soit effectivement *mmm*. Les quatre molécules restantes ont une symétrie 2/*m* et ne sont pas désordonnées. Cette structure est compatible avec les preuves spectroscopiques disponibles. Il est probable que la structure de la phase II soit reliée de près à celle de la phase III, par exemple par l'intermédiaire des molécules à symétrie 2/*m* adoptant une orientation légèrement différente.

[Traduit par le journal]

The nature of the phase transitions in crystalline pyrazine has been the subject of several investigations incorporating a wide range of techniques; thus, infrared (1) and Raman (2) studies both detected a phase transition at about 29°C. Similarly, an nqr study (3) of the ^{14}N quadrupole coupling constants in pyrazine yielded evidence of a phase transition near 27°C, and also of a second transition near 35°C. Measurements of proton spin–lattice relaxation times (4) (T_1 and T_{1D}) in crystalline pyrazine, on the other hand, resulted in *no* indication of any discontinuity in the appropriate temperature range being detected.

The solid state structure of phase I of pyrazine has been fully defined by X-ray methods at 20°C (5) and at −89°C (6) and more recently (7) an investigation of the phase I–II (28.5°C) and II–III (36.5°C) transitions of pyrazine[1] has been reported in which such techniques as X-ray diffraction, calorimetry, and low-frequency infrared and Raman spectroscopy were used.

In the present work, heat capacities of pyrazine were measured in the range 20–40°C by adiabatic calorimetry; the techniques used have been described previously (8). The pyrazine sample ("Gold Label" brand, Aldrich Chemical Co.) was sublimed from BaO and the heat capacities C_p measured in the 20–40°C range are shown in Fig. 1. The transition centred at about 27.5°C is essentially isothermal and requires an equilibration time of about 1 h if sufficient energy is added to raise the sample temperature from just below the transition to just above it. Two independent measurements of the excess enthalpy of this transition yielded values of 963 J mol^{-1} and 976 J mol^{-1}, in reasonable agreement with the value (954 J mol^{-1}) obtained previously by other means (7). These correspond to values for the excess molar entropy change (ΔS(excess)) for the phase I–II transition of R ln 1.46 to R ln 1.48. The existence of the very weak anomaly (7) centred near 37°C was confirmed in three independent sets of measurements (Fig. 1) in the present work. The excess enthalpy of this transition was 60 ± 10 J mol^{-1}.

The excess entropy of a thermal transition such as that observed for pyrazine near 28°C is frequently interpreted (9) in terms of an order–disorder phe-

[1]The three distinct phases were labelled I, II, III, in order of *increasing* temperature. This is contrary to the usual convention, which uses "Phase I" to describe the highest temperature solid phase. The present work will also use this notation since the possibility of additional transitions between 37°C and the melting point could not be discounted.

0008-4042/79/233056-05$01.00/0

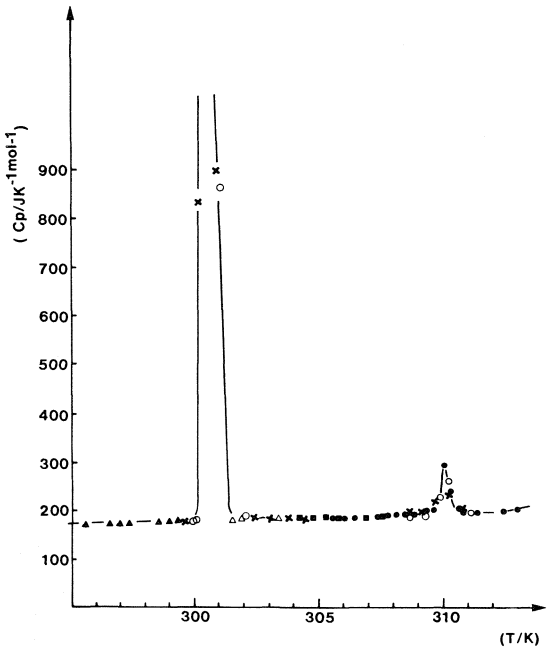

FIG. 1. Heat capacities of pyrazine purified by sublimation. The different symbols used represent independent series of experiments.

nomenon via the equation:

$$\Delta S(\text{excess}) = \Delta S(\text{configuration}) + \Delta S(\text{lattice})$$

where

$$\Delta S(\text{configuration}) = R \ln (W_{II}/W_I)$$

is calculable in terms of the numbers of distinguishable orientations (W) available to molecules in the crystal, above and below the transition. ΔS(lattice) refers to the concomitant change in crystal packing, associated with changes in density, etc. The important point here is that the experimental value of ΔS(excess) is intrinsically an upper limit to ΔS(configuration). Since the baseline heat capacities, above and below the transition, extrapolate reasonably smoothly into one another (Fig. 1), it is expected that ΔS(lattice) should not be large in the present case.

The experimental value of ΔS(excess) (R ln (1.46–1.48)) might correspond to R ln (3/2). However, this would require ΔS(lattice) to be slightly negative. Moreover, the phase I structure is known (5) to be ordered ($W_I = 1$) and it is difficult to understand or interpret a value of $W_{II} = 1.5$. A more reasonable interpretation of the experimental value of ΔS(excess) would involve

$$\Delta S(\text{configuration}) = R \ln (2^{1/2}) = \tfrac{1}{2} R \ln 2 = R \ln (1.414)$$

plus a small positive contribution (approximately 0.3 J K^{-1} mol^{-1}) from ΔS(lattice), as discussed above. This, in turn, implies that the observed transition at 27.5°C corresponds to a process in which an ordered structure ($W_I = 1$) is transformed to a structure in which just *half* of the molecules are disordered over two sites ($W_{II} = 2$). The phase II–III transition (near 37°C) introduces negligible additional excess entropy. Therefore, there can be no gross structural differences between phases II and III, in agreement with previous conclusions (7).

The structural information from the entropy changes, together with the known (5) crystal structure of phase I and the powder and Weissenberg film data (7) for phases II and III, now allow plausible crystal structures for these phases to be deduced.

It is known (7) that the crystal structure of phase III at 38°C is derived from that described (5) for pyrazine phase I at 20°C by a doubling of 9.3 and 5.9 Å unit cell constants, while the third (3.8 Å) was essentially unchanged.[2] The space group of the phase III structure was deduced (7) to be *Cmmm* (D_{2h}^{19}) (the other possible space groups were rejected on the basis of infrared and Raman studies) and while possible symmetry sites of the pyrazine molecules at 38°C were considered (7) no detailed structural model was proposed.

A stereo view of four unit cells of the room temperature phase I structure is shown in Fig. 2. In these cells the molecules are required crystallographically to have 2/*m* symmetry, the two-fold axis coincides with the N· · ·N molecular axis and the molecule lies at an angle of 22.5° to the 5.911 Å axis. The cells are so arranged in Fig. 2 that when all four are considered as a unit, the cell then produced has the approximate dimensions of the phase III structure ($a = 18.57$, $b = 11.31$, $c = 3.85$ Å) (7).

The available evidence (1) indicates that there is no major translational movement of molecules on passing from phases I to II to III. Consequently, the first step in deducing a structure for phase III is to determine if molecules at sites indicated in Fig. 2 could be accommodated into the *Cmmm* space group, and then to decide what different or addi-

[2]The unit cell described (5) for pyrazine has $a = 9.316$, $b = 3.815$, $c = 5.911$ Å in space group *Pmnn*. This is a non-standard setting of *Pnnm* (D_{2h}^{12}. No. 58) which could have $a = 5.911$, $b = 3.815$, $c = 9.316$ Å. Later workers (6, 7) use another non-standard setting of *Pnnm*, which is still correctly labelled *Pmnn* but has the *b* and *c* axes of ref. 5 interchanged. This change produces $a = 9.316$, $b = 5.911$, $c = 3.815$ Å, which allows easy comparison with the *Cmmm* space group of the phase III structure. We also adopt this cell definition in this paper. Non-crystallographers may find these changes from the standard settings confusing.

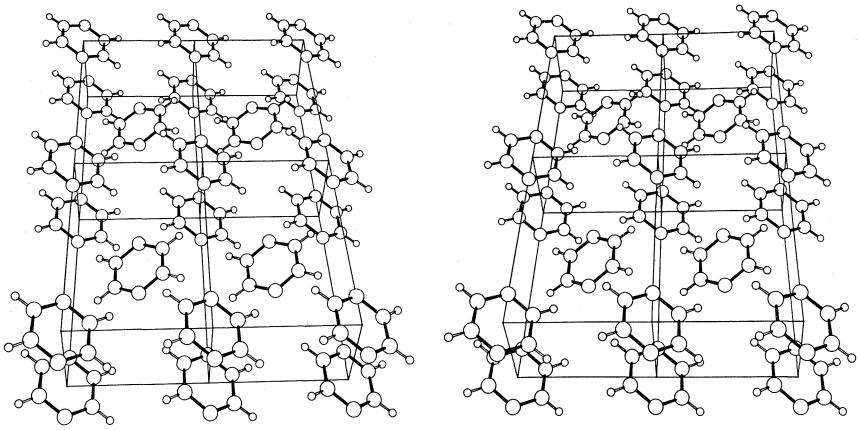

FIG. 2. Stereoview of *four* unit cells of the phase I pyrazine structure (after Wheatley (5)). The 5.9 Å axis is horizontal and the 9.3 Å lies away from the viewer.

tional symmetry requirements are imposed on the molecules by the space group.

Inspection of the symmetry information from International Tables (10) for space group *Cmmm* does indeed show that the molecular centres (as in Fig. 2) could be accommodated in a *Cmmm* lattice.[3] The molecules at the origin (0, 0, 0) of the phase III cell and at ($\frac{1}{2}$, $\frac{1}{2}$, 0) (positions 2*a* in *Cmmm* (10)), and at ($\frac{1}{2}$, 0, 0) and (0, $\frac{1}{2}$, 0) (positions 2*b* in *Cmmm*) are now required to have *mmm* symmetry. The simplest way to achieve this is to require that these molecules be on the mirror planes normal to the 3.8 Å *c*-axis, but this would result in prohibitively short (1.6 Å) H···H intermolecular contacts. The most plausible alternative is to allow the pyrazines at the 2*a* and 2*b* positions to retain the 22.5° orientation found in the phase I structure; the mirror planes normal to the *c*-axis then yield a disordered structure with effective *mirror* symmetry. When *only* this change is made to the four cells of the phase I structure, a structure as shown in Fig. 3 develops.

In Fig. 3 the four molecules situated at ($\frac{1}{4}$, $\frac{1}{4}$, $\frac{1}{2}$), ($\frac{1}{4}$, $\frac{3}{4}$, $\frac{1}{2}$), ($\frac{3}{4}$, $\frac{1}{4}$, $\frac{1}{2}$), and ($\frac{3}{4}$, $\frac{3}{4}$, $\frac{1}{2}$) (originally at ($\frac{1}{2}$, $\frac{1}{2}$, $\frac{1}{2}$) in the smaller phase I cell) have not been moved from, or about, their positions in the phase I cells; the molecular centres are exactly those required for position 4*f* in *Cmmm* (10). These molecules are required by the *Cmmm* space group to have 2/*m* symmetry but in a different manner from that required for phase I. If the molecules are not disordered, the two-fold crystallographic axis which runs parallel to the short 3.8 Å axis will be normal to the ring plane which lies in the crystallographic mirror plane at $z = \frac{1}{2}$. Thus, the only positional uncertainty with these molecules in phase III would be in the precise orientation about the two-fold axis normal to the molecular plane. (An alternative way of obtaining 2/*m* site symmetry is to allow these molecules to retain the orientation found at room temperature and then invoke disorder about the mirror plane at $z = \frac{1}{2}$; the entropy measurements imply that this is not a valid model as it would require *all* those molecules at sites 2*a*, 2*b*, and 4*f* to be disordered.) If the non-disordered molecules in Fig. 3 are simply rotated 22.5° about the N···N molecular axes into the mirror plane at $z = \frac{1}{2}$, the same short (1.6 Å) H···H contacts would be produced as mentioned above for the molecules at the cell corners and edges. Because the entropy data require half the molecules to be non-disordered, the only way to satisfy this and reduce H···H intermolecular interaction in the mirror plane at $z = \frac{1}{2}$ is to rotate the (4*f*) molecules about the crystallographic two-fold axis until such contacts are minimized. A likely orientation is shown in Fig. 4 in which the 4*f* molecules have been rotated 71° about the two-fold axis; this orientation yields H···H intermolecular contacts of approximately 2.4 Å. The atomic coordinates used to produce Fig. 4 were derived from the phase I coordinates by appropriate geometrical manipulations.[4]

This model for the phase III structure is consistent with the results of our entropy studies and available X-ray and spectroscopic data (7). It also has two distinct environments for the nitrogen atoms as required by the nqr results (3).

The arguments presented thus far apply directly to

[3]For details of *Cmmm* (D_{2h}^{19}. No. 65) see p. 154 of ref. 10 and for *Pnnm* (D_{2h}^{12}. No. 58) see p. 146 of ref. 10.

[4]The atomic coordinates are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

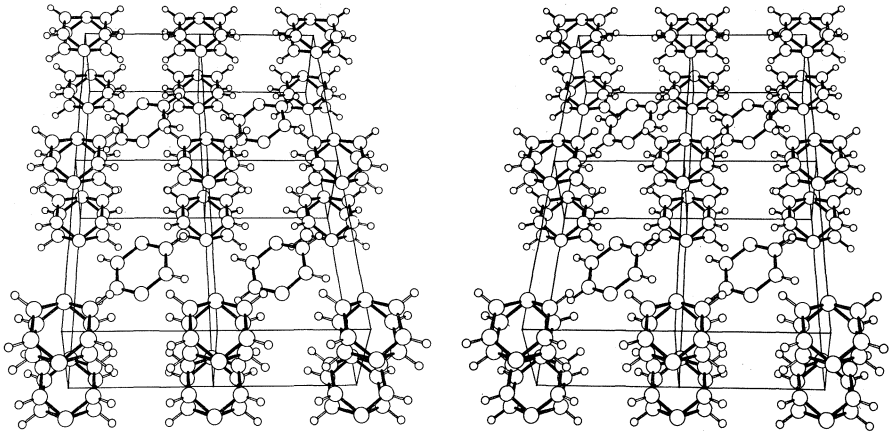

FIG. 3. Stereoview of the same arrangement as in Fig. 2 but with the molecules at the cell edges and corners disordered to yield effective *mmm* site symmetry as would be required in *Cmmm* space group.

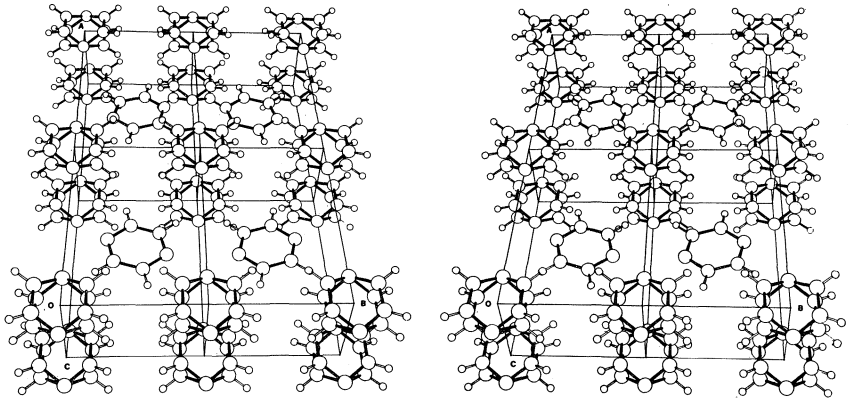

FIG. 4. Stereoview of the postulated phase III structure obtained by modifying the structure shown in Fig. 3. The molecules centred at $(\frac{1}{4}, \frac{1}{4}, \frac{1}{2})$, $(\frac{1}{4}, \frac{3}{4}, \frac{1}{2})$, $(\frac{3}{4}, \frac{1}{4}, \frac{1}{2})$, and $(\frac{3}{4}, \frac{3}{4}, \frac{1}{2})$ now lie in the mirror plane at $z = \frac{1}{2}$ and have been rotated 71° in the plane, about the two-fold symmetry axis to yield an orientation which minimizes intermolecular interactions.

phase III (above 38°C), for which the crystallographic information (7) was more complete than for phase II (28–35°C). However, the thermal transition observed (Fig. 1) (near 38°C) is far too small to correspond to any disordering process or gross change of structure, so that the crystal structures of phases II and III must be very similar. This conclusion is in agreement with all other experimental information (1–7). The most likely process accounting for the II → III transition is a slight change in the orientations of the molecules at the 4*f* sites (2/*m* symmetry). This would be sufficient to account for the accompanying shifts in nqr frequencies (3). In any event, the differences between phases II and III are clearly minor compared to those between phases I and II. The main outstanding problem concerns the nmr data on T_1 and T_{1D} (4), which showed no evidence of either phase transition. The explanation proposed previously (4) is probably still valid in general, viz., the changes in crystal structure are sufficiently subtle as to make only negligible changes in both the dipolar interactions between ^1H nuclei, and in the energy barriers to the molecular reorientations which mediate the spin–lattice relaxation. However, the particular high-temperature structure proposed previously (4) is now known to be wrong, in light of more recent information (7). A more complete understanding of the structure and dynamics of the pyrazine crystal will require accurate crystal structures determined at temperatures above 30°C.

Structure of $Ni[Ag(SCN)_2]_2 \cdot 2diox$ and its derivatives

P. P. SINGH, S. A. KHAN, AND J. P. PANDEY[1]

Department of Chemistry, M.L.K. College, Balrampur-271201 (U.P.), India

Received February 7, 1979

P. P. SINGH, S. A. KHAN, and J. P. PANDEY. Can. J. Chem. **57**, 3061 (1979).

$Ni[Ag(SCN)_2]_2 \cdot 2diox$ and its derivatives have been synthesized. Their structures have been given on the basis of infrared spectral, electronic spectral, magnetic moment, and molar conductance studies. These results demonstrate that $Ni[Ag(SCN)_2]_2$ forms two types of complexes: (*i*) cationic–anionic type of general formula $[NiL_x]^{2+}[Ag(SCN)_2]_2^{2-}$ ($x = 3, 4, 6$) and (*ii*) polymeric bridged type having a chain structure consisting of zig-zag thiocyanate bridges between nickel and silver. The cationic–anionic type of complexes are formed by pyridine, nicotinamide, 4-aminopyridine, aniline, *p*-toluidine, thiourea, ethylene thiourea, bipyridine, phenanthroline, pyrazine-2,3-dicarboxamide, and triphenylphosphine, and the polymeric bridged type by dioxane, acetone, and dimethylformamide. All the ligands have been found to prefer to coordinate to nickel instead of silver.

P. P. SINGH, S. A. KHAN et J. P. PANDEY. Can. J. Chem. **57**, 3061 (1979).

On a synthétisé le complexe $Ni[Ag(SCN)_2]_2 \cdot 2diox$ et ses dérivés et on a établi leur structure en se basant sur l'étude des spectres infrarouges et électroniques et sur l'étude du moment magnétique et de la conductance molaire. Ces résultats démontrent que $Ni[Ag(SCN)_2]_2$ forme deux types de complexes (*i*) un complexe du type ionique de formule générale $[NiL_x]^{2+}[Ag(SCN)_2]_2^{2-}$ ($x = 3, 4, 6$), (*ii*) un complexe du type polymère ponté qui a une structure en chaîne consistant en des ponts thiocyanates en zig zag entre les atomes de nickel et d'argent. Les complexes du type ionique sont formés par la pyridine, la nicotinamide, l'amino-4 pyridine, l'aniline, la toluidine, la thiourée, l'éthylène-thiourée, la bipyridine, la phénantroline, la pyrazinedicarboxamide-2,3 et la triphénylphosphine. Le type polymère ponté est formé par le dioxanne, l'acétone et la diméthylformamide. On a trouvé que tous les ligands manifestent une tendance à se coordiner au nickel plutôt qu'à l'argent.

[Traduit par le journal]

Introduction

In $MM'(NCS)_4$, both M[Co(II), Ni(II), Cu(II)] and M'[Zn(II), Cd(II), Hg(II)] are in their preferred coordination geometry, and the compounds are energetically quite stable (1–7). Bimetallic tetrathiocyanate, in which one metal prefers octahedral coordination geometry and the other a linear, viz., Ag(I), Cu(I), Au(I), has not been reported previously. We have synthesized such compounds and have studied their structures and properties, particularly with a view to investigate differences with $MM'(NCS)_4$ types of compounds.

Experimental

Materials and Manipulations

Reagent grade hydrated nickel(II) nitrate, silver(I) nitrate, and potassium thiocyanate (BDH) were used after recrystallization. Nicotinamide (nia), triphenylphosphine (Ph_3P), bipyridine (bipy), 1,10-phenanthroline (phen), thiourea (tu), ethylene thiourea (etu), 4-aminopyridine (apy), and *p*-toluidine (tol) (Aldrich Chemical) were used after recrystallization from ethanol. Acetone (ace), dioxane (diox), dimethylformamide (dmf), pyridine (py), and aniline (ani) (BDH) were purified by known methods. Pyrazine-2,3-dicarboxamide (pzd) (Aldrich Chemicals) was used as such from fresh bottles.

Synthesis of the Complexes

(*i*) $Ni[Ag(SCN)_2]_2 \cdot 2L$ (L = diox, ace, dmf): 5 mmol of Ni(II) thiocyanate and 10 mmol of Ag(I) thiocyanate were mixed together in 50 mL of each of the above solvents (ligands) separately and stirred for 48 h. Light green complexes were formed, filtered, washed with solvents, and dried in vacuum.

(*ii*) $Ni[Ag(SCN)_2]_2 \cdot xL$ ($x = 3, 4, 6$ and L = py, nia, apy, bipy, phen, ani, tol, tu, etu, pzd, and Ph_3P): homogeneous suspensions of 2.5 mmol of $Ni[Ag(SCN)_2]_2$ in ethanol were stirred in a number of 100 mL flasks. To each suspension ethanolic solutions containing excess of different ligands were added and stirred for 24 h. Solid complexes which formed were filtered, washed with ether, and finally dried in vacuum.

Elemental Analysis

Nickel was estimated as dimethylglyoximate, silver as chloride, and sulphur as sulphate gravimetrically. Nitrogen was estimated by Kjeldahl's method. The analytical data are presented in a table deposited as unpublished material.[2]

Physical Measurements

Molar Conductance Measurements

The molar conductance of the only soluble complex of etu was measured in dimethylformamide with a Philip PR-9500 conductivity bridge.

Infrared Spectra

The infrared spectra in the region 4000–200 cm^{-1} were recorded on a Perkin-Elmer 621 model spectrophotometer.

[1]Present address: Degree College, Pratapgarah (U.P.), India.

[2]The set of data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

0008-4042/79/233061-04$01.00/0

Visible and Near Infrared Absorption Spectra

Electronic spectra were recorded on a Cary-14 spectrophotometer in the region 300–2500 nm.

Magnetic Susceptibility Measurements

The measurements were made by the Gouy method at room temperature using $CoHg(SCN)_4$ as standard. Diamagnetic corrections were made using Pascal's constants.

Results and Discussion

All the complexes are insoluble in solvents suitable for molecular weight determination or for growth of single crystal for X-ray analysis. Because of this, we have confined our studies to infrared spectral, electronic spectral, magnetic moment, and molar conductance measurements only. The complexes have been studied under two groups; one with weak bases like diox, dmf, and ace, and the other with strong or medium strong bases viz., py, apy, nia, bipy, phen, tu, etu, pzd, ani, and tol.

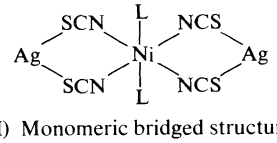
(A) $Ni[Ag(SCN)_2]_2 \cdot 2L$ (L = diox, dmf, ace)

(*i*) The analytical results reveal that two ligands molecules are coordinated to each molecule of $Ni[Ag(SCN)_2]_2$.

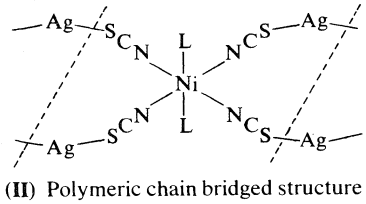
(*ii*) The positions of infrared spectral bands (Table 1) in the ν_{CN}, ν_{CS}, and δ_{NCS} regions which are diagnostic for the nature of thiocyanate bonding, indicate the presence of only bridged thiocyanate groups (4, 5, 8–10).

(*iii*) The positions of electronic spectral bands, spectral parameters, and magnetic moment values as discussed later, indicate that nickel is in octahedral coordination geometry.

Keeping the above facts and the structure of the reported bimetallic tetrathiocyanates (4, 5, 11) in view, the following two structures can be proposed for $Ni[Ag(SCN)_2]_2 \cdot 2L$



(**I**) Monomeric bridged structure



(**II**) Polymeric chain bridged structure

Structure **I** has been proposed on the basis of similarity in the positions of infrared spectral bands in ν_{CN}, ν_{CS}, and δ_{NCS} regions and in electronic spectral band positions with that of $NiHg(SCN)_4 \cdot 2L$ (2, 3, 11). But this structure is energetically unfavourable because Ag(I) prefers a coordination number of two in which it requires linearity along —NCS—Ag—SCN— due to *sp* hybridization. This linearity is not maintained in this structure.

The polymeric chain bridged structure **II** appears to be the most probable structure for $Ni[Ag(SCN)_2]_2 \cdot 2L$ as is supported by the following: (*i*) This structure is based on the crystal structure (12) of AgSCN in which the structural unit is an endless chain formed by the bonds from the silver atom to the S-end of one thiocyanate group and the N-end of another group. The chain has a zig-zag shape and is bent at sulphur (104°) as well as at nitrogen (165°). (*ii*) The preferable coordination number two of Ag(I) is maintained. (*iii*) Octahedral coordination geometry as required by magnetic moment values and electronic spectral studies are also satisfied. (*iv*) The ligands show features of coordination. In the dioxane complex the absorption bands associated with the C—O—C antisymmetric stretch show the expected frequency decrease indicating coordinated dioxane molecules (1, 13). dmf and ace show features of coordination through their carbonyl oxygen as is evidenced by the negative shift in the ν_{CO} mode (14). (*v*) The octahedral coordination geometry of nickel and the presence of a ν_{Ni-L} band in the far infrared region support the linkage of the ligand to nickel. (*vi*) We observed bands due to ν_{Ag-SCN}, ν_{Ni-O}, and ν_{Ni-NCS} modes in the regions 215–220, 370–395, and 235–260 cm^{-1} respectively (3, 15). The presence of bands in these regions indirectly supports our proposed structure.

(B) $Ni[Ag(SCN)_2]_2 \cdot xL$ (x = 3, 4, 6 and L = py, apy, nia, bipy, phen, ani, tol, tu, etu, pzd, and Ph_3P)

(*i*) Analytical data indicate that three molecules of bipy and phen, six molecules of py, apy, nia, ani, tol, pzd, tu, etu, and four molecules of Ph_3P are coordinated to each molecule of $Ni[Ag(SCN)_2]_2$.

(*ii*) The electronic spectral bands, spectral parameters, and magnetic moment values as discussed later show that nickel in all these complexes is in octahedral coordination geometry. The complex of Ph_3P is the only exception; it is diamagnetic indicating the presence of square planar geometry around nickel.

(*iii*) The infrared spectra of these complexes show bands due to ν_{CN}, ν_{CS}, and δ_{NCS} modes in the regions 2060–2130, 710–770, and 430–465 cm^{-1}, respectively. The positions of the bands in these diagnostic regions are indicative of S-bonded thiocyanates (1–3, 6).

(*iv*) The etu complex, whose infrared spectral band positions, magnetic moment values, electronic spectral band positions, values of spectral parameters, mp, etc., are in the range of other complexes of this

class, is soluble in dimethylformamide, whereas the rest are insoluble. The molar conductance of this complex indicates that it is a 1:1 electrolyte. On the basis of its similarity in other data with this class of compounds, it is thought that all the complexes are 1:1 electrolytes.

(*v*) The pyridine derivative ligands show features of coordination through their ring nitrogen as evidenced by the positive shift in the bands due to ring vibrations (1, 5). Both bipyridine and phenanthroline act as bidentate donors. The nitrogen of NH is the donor site in aniline, *p*-toludine, and ethylene thiourea, and sulphur in thiourea as indicated by the negative shifts in ν_{NH} and ν_{CS} modes respectively (1, 16, 17). The 10 *Dq* of the S-bonded thiourea complex is greater by 1 900 cm^{-1} than the N-bonded ethylene thiourea (Table 2). This difference supports linkage through S in thiourea and through N in ethylene thiourea. The X-sensitive absorption bands at 1092, 705, and 437 cm^{-1} are typical of coordinated triphenylphosphine (1).

On the basis of these results, it can be presumed that the complexes are of the cationic–anionic type as described elsewhere (6) and the possible cations and anions are:

$[NiL_6]^{2+}[Ag(SCN)_2]_2^{2-}$ (L = monodentate donor)

$[Ni(LL)_3]^{2+}[Ag(SCN)_2]_2^{2-}$ (LL = bidentate donor)

The coordination of the ligands to nickel and thiocyanate groups through S to silver can be supported on the following grounds: (*i*) The nickel is in octahedral coordination geometry, which is possible only when the ligands are linked to nickel. (*ii*) The presence of the bands in the regions 275–285 cm^{-1} and at 240 cm^{-1} can more favourably be assigned to ν_{Ni-L} (nitrogen donors) and to ν_{Ni-L} (sulphur donor) respectively (6, 17). The presence of the bands in these regions also supports our proposed structures.

In the case of the triphenylphosphine complex, which is diamagnetic, the cation probably has a square planar geometry and the following structure for this complex may be proposed.

$[Ni(Ph_3P)_4]^{2+}[Ag(SCN)_2]_2^{2-}$

Electronic Spectral Discussion

In order to extend support to the stereochemistry around nickel, we have recorded the electronic spectra of some representative complexes as Nujol mulls (Table 2). In all the complexes we observe bands in the region 27 700 – 24 400 cm^{-1} assigned to ν_3 arising from the transition $^3A_{2g} \rightarrow {}^3T_{1g}(P)$, in the region 17 200 – 14 000 cm^{-1}, ν_2 arising from the transition $^3T_{2g} \rightarrow {}^3T_{1g}(F)$ and in the region 10 500 – 8 400 cm^{-1}, ν_1 arising from the transition $^3A_{2g} \rightarrow {}^3T_{2g}(F)$. Besides these bands, certain low energy bands in the region 8 000 – 5 000 cm^{-1} are also observed in the complexes of dioxane, acetone, and dimethylformamide. They are possibly due to transitions to ^3E_g and $^3B_{2g}$ levels in D_{4h} symmetry. The complex spectra of these complexes may be due to low symmetry affects and thus the *Dq*, *B'*, and β values for these complexes have not been calculated. For the rest of the complexes where nickel is thought to be in O_h symmetry, the ν_2 and ν_3 bands have been selected and various ligand field parameters calculated using the matrices of Tanabe and Sugano (18). Magnetic moment values (2.90–3.22 BM), positions of electronic spectral bands, and the values of spectral parameters indicate an octahedral coordination geometry around nickel (19). *Dq* values of the complexes of pyridine derivatives are higher than the other complexes indicating that pyridine derivatives exert a strong ligand field. Values of the Nephelauxetic parameter β indicate approximately the same degree of covalency in all the complexes.

The spin–orbit coupling constant values ($-\lambda'$) are

lower than the free nickel ion value (315 cm^{-1}) showing delocalization of the *d*-orbitals of nickel and orbital overlap to some extent. Orbital overlap is also suggested by the values of Racah parameter B', which is about 73–90% of the free nickel ion value (1056 cm^{-1}).

G. LAUNAY, B. WOJTKOWIAK, and T. M. KRYGOWSKI. Can. J. Chem. **57**, 3065 (1979).

Symmetrical influences of the solvent and the substituent on NH_2-Lewis acidity of six *p*-substituted anilines studied in a series of six solvents were found. The sensitivity parameter (Hammett reaction constant) estimated for various solvents correlated well with basicity of solvents. The sensitivity parameter of the regression of NH_2-acidity vs. basicity parameters of solvents (slope in eq. [5]) correlated with electron attraction or repulsion as measured by substituent constants σ.

G. LAUNAY, B. WOJTKOWIAK et T. M. KRYGOWSKI. Can. J. Chem. **57**, 3065 (1979).

On a trouvé les influences symétriques du solvant et des substituants sur les acidités de Lewis du groupe NH_2 de six anilines *para* substituées en utilisant une série de six solvants. Les paramètres de sensibilité (constante de la réaction de Hammett) évalués pour plusieurs solvants sont en parfaite corrélation avec la basicité de ces derniers. Le paramètre de sensibilité de la régression d'acidité du NH_2 en fonction des paramètres de basicité du solvant (pente de l'équation [5]) est en corrélation avec une attraction ou une répulsion des électrons telle que mesurée par les constantes de substituants σ.

[Traduit par le journal]

Introduction

Recently Kamlet and Taft (1) have introduced a new scale of solvent basicity making use of the magnitudes of enhanced solvatochromic shifts of the longest wave band in the uv–visible spectrum of *p*-nitroaniline relative to that of *N,N*-diethyl-*p*-nitroaniline. In practice $\tilde{\nu}_{max}$-values for *p*-nitroaniline are plotted against $\tilde{\nu}_{max}^{ref}$-values (1) of its *N,N*-diethyl derivative for measurements carried out in nonpolar solvents, leading to the following regression line:

$$[1] \quad \tilde{\nu}_{max} = a_1\tilde{\nu}_{max}^{ref} + b_1$$

Bathochromic shifts $\Delta\tilde{\nu}$ from this line for *p*-nitroaniline are observed when measurements are carried out in solvents interacting as Lewis bases. The shift is given by:

$$[2] \quad \Delta\tilde{\nu} = \tilde{\nu}_{max}(\text{calcd.}) - \tilde{\nu}_{max}(\text{obs.})$$

and its magnitude increases with increase of the solvent's Lewis basicity. This quantity was taken as a measure of the solvent basicity (1).

Principle of the Method

The aim of this paper is to extend this method to the study of substituent effects in other *p*-substituted anilines. In a given solvent the shift of the first primary band is a measure of the Lewis acidity of the NH_2 group and depends on the effect of the substituent X. It must be noted that, at least for strongly donating substituents, the first primary band is not the lowest frequency band, as it is for the NO_2 substituent. *N,N*-dimethylanilines were preferred to *N,N*-diethylanilines because they are more readily available. The following substituted species were studied: X = $N(CH_3)_2$, CH_3, H, COPh, CN, and NO_2.

Experimental

The anilines and *N,N*-dimethylanilines were commercial products purified by standard methods. Spectroscopic grade solvents were used without further purification. Measurements were carried out at 25°C on a Beckman DK2A spectrophotometer. The wave number accuracy is about $\pm$ 40 cm^{-1}.

Results and Discussion

The wave numbers (cm^{-1}) of the first primary band are collected in Table 1 for *p*-substituted anilines and for their *N,N*-dimethyl derivatives. The parameters a_1 and b_1 obtained for non-polar solvents are compiled in Table 2 for each substituent. The correlation coefficients are also reported. Using these parameters, the shifts $\Delta\tilde{\nu}$ (eq. [2]) were calcu-

lated for each polar solvent and for each substituent (Table 3).

The analysis of the data can be carried out in two different ways. First, the substituent effect can be described in terms of the Hammett equation

$$[3] \quad \Delta\tilde{\nu}(X) = \rho\sigma_X$$

where σ_X is the effect of each substituent X, and ρ is the sensitivity to the substituent effect, called usually the reaction constant.

The application of eq. [3] to the data of Table 3 leads to the results collected in Table 4. The correlation coefficients are rather good, and we are therefore allowed to analyse the ρ values of Hammett plots in terms of solvent effect. The reaction constant ρ in eq. [3] has a physical meaning of the degree of differentiation of NH_2–acidity of *p*-substituted anilines in different solvents due to a fixed kind of structure change (substituent effect). This differentiation becomes greater with increase of a solvent's basicity and hence it would seem reasonable to plot ρ vs. DN, a solvent basicity parameter introduced by Gutmann (cf. ref. 2). The following linear regression was obtained:

$$[4] \quad \rho = 51\mathrm{DN} - 220$$

with a correlation coefficient $r = 0.992$ (Fig. 1).

The data can also be analysed in another way, by considering the influence of the solvent on $\Delta\tilde{\nu}$ values of a given compound using the following equation (3):

$$[5] \quad \Delta\tilde{\nu}\ (\text{solvent}) = K \cdot \mathrm{DN}$$

The regression coefficient K represents the sensitivity of the acidity of the NH_2 group to the solvent basicity for a *p*-substituted aniline with a fixed substituent in the series. The application of eq. [5] to the data of Table 3 leads to the results collected in Table 5. Kamlet *et al.* have very recently drawn a similar conclusion (8). However it was not expressed in a quantitative way as in eq. [5].

When $\Delta\tilde{\nu}$ values are plotted against DN values (eq. [5]) the correlations are satisfactory, except for the first two substituents $N(CH_3)_2$ and CH_3. But,

[b]Due to low precision of eq. [1], see Table 1, Δv for CN are not taken into further consideration. See text and footnote 1.

in these cases, the slope is quite low, hence a low value of the correlation coefficient must be expected.

It is clear that for p-substituted anilines with electron donor substituents there is some kind of π-electron saturation (4), and hence the influence of solvent on NH_2-acidity is rather low or nil. The situation becomes different when substituents are more electron attractive. Then the π-electron system becomes more mobile and hence more sensitive to solvent influences, resulting in an increase of the K-values of eq. [5]. Thus, some relationship between K and σ should be observed. In fact, Fig. 2 shows the correlation between the regression coefficients K and the substituent constant σ. Even though the linearity is not so good as between ρ and DN, there is a clear dependence of K on σ. The point corresponding to the CN derivative should be excluded, since the standard regression line (eq. [1]) is not precise enough[1] for this case. The correlation coefficient now becomes satisfactory ($r = 0.937$) with the following regression equation

$$[6] \quad K = 49\sigma + 35$$

for 5 experimental points. The more detailed physical interpretation of slopes of eqs. [4] and [6] may be obtained as follows. Consider measurements of $\Delta\tilde{\nu}$ for substituted and unsubstituted species carried out in the same solvent. Equation [7a] holds:

$$[7a] \quad \Delta\tilde{\nu}_s - \Delta\tilde{\nu}_{un} = \rho\Delta\sigma$$

When measurements are repeated for the same compounds in another solvent one obtains:

$$[7b] \quad \Delta\tilde{\nu}_s' - \Delta\tilde{\nu}_{un}' = \rho'\Delta\sigma$$

Next consider measurements of $\Delta\tilde{\nu}$ for unsubstituted species carried out in two different solvents. Equation [8a] holds:

$$[8a] \quad \Delta\tilde{\nu}_{un} - \Delta\tilde{\nu}_{un}' = K\Delta DN$$

TABLE 4. Statistics of $\Delta\tilde{\nu}$ vs. σ plot (eq. [3])

Solvent	ρ[a]		r	n	Abbreviation
Dioxane	432	(50)	0.980	5	D
Butoxybutane	785	(116)	0.969	5	B
Acetonitrile	502	(53)	0.983	5	A
Trimethylphosphate	1025	(34)	0.998	5	TMP

Hexamethylphosphotriamide	1700	(287)	0.986	3	HMPT

[a]Standard deviation of the estimate in parentheses.

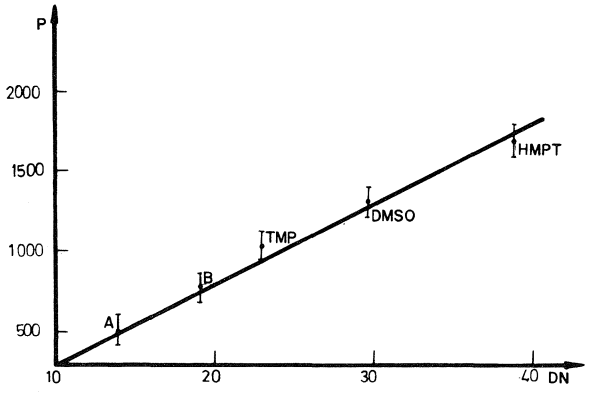

FIG. 1. Plot of ρ of eq. [3] vs. DN.

TABLE 5. Statistics of $\Delta\tilde{\nu}$ vs. DN plot (eq. [5])

Substituent	K[a]	r	n
$N(CH_3)_2$	−14 (6)	0.749	6
CH_3	27 (15)	0.786	4
H	50 (10)	0.962	4
COPh	66 (7)	0.979	6
CN	47 (7)	0.966	5
NO_2	60 (8)	0.974	5

[a]Standard deviation of the estimate in parentheses.

[1]The standard line (eq. [1]) must be estimated with a very high accuracy ($r > 0.99$); otherwise quite erroneous results can be obtained. In this case $r = 0.962$, and hence the point for CN is not taken into account. For details of the problem of the accuracy of a standard line see ref. 5.

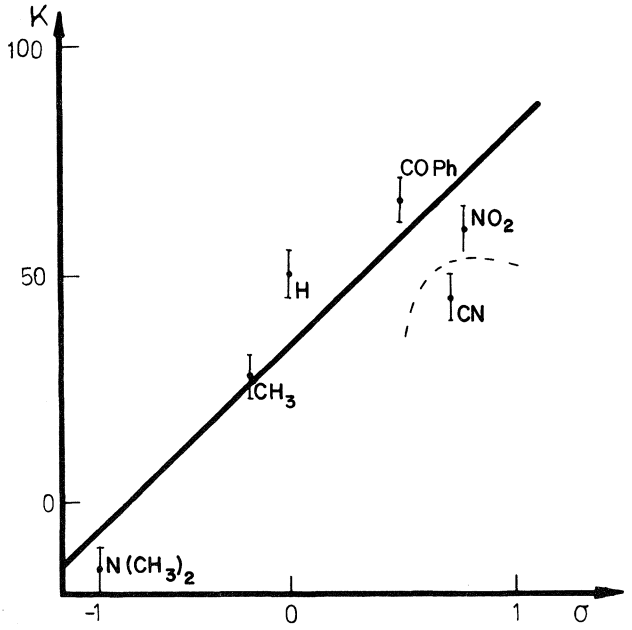

FIG. 2. Plot of K of eq. [5] vs. σ. The line is drawn excluding the point for CN.

When the analogous measurements are carried out for substituted species in the same two solvents one obtains:

[8*b*] $\Delta\tilde{\nu}_s - \Delta\tilde{\nu}_s' = K'\mathrm{DN}$

Combining eq. [7*a*] with eq. [7*b*] and eq. [8*a*] with eq. [8*b*] one obtains eqs. [9] and [10], respectively:

[9] $(\Delta\tilde{\nu}_s - \Delta\tilde{\nu}_{un}) - (\Delta\tilde{\nu}_s' - \Delta\tilde{\nu}_{un}') = \Delta\sigma(\rho - \rho')$

[10] $(\Delta\tilde{\nu}_{un} - \Delta\tilde{\nu}_{un}') - (\Delta\tilde{\nu}_s - \Delta\tilde{\nu}_s') = \Delta\mathrm{DN}(K - K')$

The left sides of eqs. [9] and [10] are set equal, leading to eq. [11].

[11] $\Delta\sigma(\rho - \rho') = \Delta\mathrm{DN}(K - K')$

Further discussion depends upon which slope is to be analysed. For the reaction constant of eq. [3] we obtain, after simple rearrangement, eq. [12]:

[12] $\rho' = \rho + (\Delta K/\Delta\sigma)\mathrm{DN}$

The numerical form of this equation is eq. [4]. The slope of eq. [4] may be interpreted to be $\mathrm{d}K/\mathrm{d}\sigma$, the magnitude describing how the sensitivity of the system to solvent effect depends on the electronegativity of the substituent. On the other hand, if the slope of eq. [6] is to be discussed, after simple rearrangement we obtain eq. [13]:

[13] $K' = K + (\Delta\rho/\Delta\mathrm{DN}) \cdot \sigma$

The numerical form of eq. [13] is eq. [6]. The slope of eq. [6] is assumed to be $\mathrm{d}\rho/\mathrm{dDN}$; the magnitude describing how the sensitivity of the system to the substituent effect depends on the solvent basicity.

Partly similar conclusions were drawn by Kalinowski (6) for the case of solvent effect on ρ for reversible polarographic reduction of substituted nitrobenzenes and azobenzenes, but the complete symmetry of the problems was not discussed there, most probably because of difficulties with liquid-junction potentials. In the case of measurements discussed in this paper no such problem exists.

It can be concluded that solvent and substituent effects on acidity of *p*-substituted anilines are mutually symmetrical; when acidity is correlated with substituent effect, the resulting regression coefficient correlates to solvent basicity.[2] On the other hand, when acidity of NH_2 is correlated with solvent basicity, the regression coefficient now correlates to substituent constant. This property depends on the commutativity of Leffler–Grunwald operators (7), δ_{subst} and δ_{solv}, acting on the measured property $\Delta\tilde{\nu}$. When analysed in columns, the data compiled in Table 2 can be written generally as $\delta_{solv}\Delta\tilde{\nu}$ whereas, when analysed in rows, they can be written as $\delta_{subst}\Delta\tilde{\nu}$. Thus if an element of Table 2 is considered, it can be written as $\delta_{subst}\delta_{solv}\Delta\tilde{\nu}$ or $\delta_{solv}\,\delta_{subst}\Delta\tilde{\nu}$, independent of how it is viewed (row or column).

Finally it seems likely that the symmetrical form of the mutual relation between substituent and solvent effects is quite common even though it has not been systematically investigated. However, due to the complexity of solute–solvent interactions for molecules with different substituents, the above mentioned phenomenon is not often met in a clear form particularly for a longer series of experimental data.

[2]NOTE ADDED IN PROOF: Such mutual relationships are known as iso-parametric relationships (V. A. Palm, private communication to T.M.K. and lecture at the Euchem Conference on Correlation Analysis in Chemistry. Assisi, Italy. Sept. 10–14, 1979).

^{13}C nuclear magnetic resonance spectra of some halosteroids, 6-ketosteroids, and related compounds

HERBERT L. HOLLAND AND EVERTON M. THOMAS

Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received June 14, 1979

HERBERT L. HOLLAND and EVERTON M. THOMAS. Can. J. Chem. **57**, 3069 (1979).

The ^{13}Cmr spectra of 21-haloprogesterones have been assigned, and chemical shifts compared with those of simple α-haloketones. In addition, the ^{13}Cmr spectra of some C-5α and C-6β halosteroids are presented, and long range $^{13}C—^{19}F$ coupling observed between C-19 and the C-6β fluorine in some cases. The spectra of several oxygenated analogues and of a series of 5α-hydroxy-6-ketosteroids are also discussed.

HERBERT L. HOLLAND et EVERTON M. THOMAS. Can. J. Chem. **57**, 3069 (1979).

On a identifié les spectres rmn du ^{13}C des haloprogestérones-21 et on a comparé leurs déplacements chimiques à ceux des α halocétones simples. On présente de plus les spectres rmn du ^{13}C de quelques stéroïdes halogénés en position 5α et 6β, ainsi que les couplages à longue distance $^{13}C—^{19}F$ observés dans certains cas entre le carbone en position C-19 et le fluor en C-6β. On discute également des spectres de plusieurs analogues oxygénés des hydroxy-5α céto-6 stéroïdes.

[Traduit par le journal]

In spite of the widespread use of halosteroids in medicine, there have been few systematic studies of their ^{13}Cmr spectra. In this paper, we report the ^{13}Cmr spectra of some C-5, -6, and -21 fluoro-, chloro-, and bromosteroids. In addition, the spectra of several oxygenated analogues and of a series of 5α-hydroxy-6-ketosteroids are discussed.

Assignments for the 21-haloprogesterones **1***a–c*, together with those of the parent steroid **1***d* (1), are presented in Table 1. Shifts at carbons 17, 20, and 21 are consistent with those of the corresponding carbons of the halo acetones (**7**) and α-halo acetophenones (**8**). The α, β, and γ halogen substituent effects for these compounds and the steroids **1** are listed in Table 1. The magnitudes of these effects are different from those derived for the corresponding alkanes (2), being closer to those reported for α-halocyclohexanones (3). For the latter, interaction between halogen non-bonded orbitals and the π* orbitals of the carbonyl, increasing electron density adjacent to halogen, has been used to explain the observed shifts (3). A similar effect is presumably operating in the simple α-haloketones reported here, and is increased with respect to that in the α-halocyclohexanones by the absence of rigid stereochemistry, allowing maximal orbital overlap to be achieved.

The assignments for a series of C-5α halo and hydroxy substituted androstanes **3** and **4** are listed in Table 2. Carbons of rings C and D of this series are readily assignable by comparison with the spectra of other 17-keto and 17β-hydroxyandrostanes (1). Carbons in rings A and B of the 5α,6β-dichloro

[a]Chemical shifts marked with an asterisk may be interchanged.

The assignment of the rings A and B resonances of **3***c* was again achieved by comparison with the spectra of C-5α and C-6β substituted cholestanes (4). The rings A and B resonances of **3***e*, **6**, and **4***b* were all readily assignable by comparison with the assignments of similarly substituted cholestane derivatives (1). The anticipated upfield γ shift at C-1 caused by the C-5α OH (1, 4) (as in **3***e*, **4***b*, and **6**) is also clearly present with a C-5α chloro substituent (as in **3***f*); it is mitigated in **3***a–c* by the downfield δ shift of the electronegative substituent at C-6β (4).

Chemical shift assignments for the 6-fluorosteroids **3***d*, **4***a*, and **2** (5), and for the 6-chloroan-

[a]Solvent DMSO-d_6.

drostenediones, are presented in Table 3. Assignments of the resonances of **3***d* and **4***a* were made by application of the appropriate C-6β substituent shift parameters (4) to the spectra of **4***b* and **6** (rings A and B only), respectively. The Δ^4-3-ketones **2** were assigned with reference to the spectrum of androst-4-ene-3,17-dione (1, 6). The ^{13}C—^{19}F coupling constants of the fluorosteroids are in Table 4, along with the shift parameters for the 6-halo substituent of **3***d*, **4***a*, and the series **2**. The values of $J(^{13}C—^{19}F)$ for coupling to C-5, -6, -7, and -10 of **3***d* and **4***a* are as expected (4). The couplings to C-4 in **2***a* and **2***c* are due to the presence of the Δ^4-3-keto system; long range $^1H—^1H$ coupling of the C-4 and C-6β hydrogens in Δ^4-3-ketosteroids is well known (7, 8). The coupling to C-8 of **2***c* reflects the presence of an F—C-8 dihedral angle of 180° in this compound.

The striking feature of the spectra of **3***d* and **4***a* is the presence of a significant δ coupling to C-19. The magnitude of this coupling suggests the presence of a through space contribution, an interpretation strengthened by the corresponding value of $^4J \simeq$ zero observed for **2***a* and **2***c*. The internuclear C-19—F distance, estimated from Dreiding models of **3***d* and **4***a* is 2.5 Å; the corresponding distance in **2***a* is 3.0 Å. The former distance is well within the limit established for $^1H—^{19}F$ through space interactions, whereas the latter is close to the limiting value over which such interactions occur (9). A $^4J(^{13}C—^{19}F)$ value of 10 Hz for a 6β-fluorosteroid has been reported, but without comment (4). Long range $^1H—^{19}F$ coupling of the C-19 methyl hydrogens to the C-6 fluorine was observed in **3***d* (J = 4.4 Hz), **4***a* (J = 3.6 Hz), and **2***a* (J = 2.2 Hz) (see ref. 10).

The shift parameters for C-6α and C-6β fluoro and chloro substituents in **2** (Table 4) are indicative of the stereochemistry of substitution at C-6. The axial substituents (as in **2***a* and **2***b*) interact electronically with the π system (7, 8, 11, and references therein), reflected in anomalous shifts, particularly at C-4. Axial (β) substitution also produces the characteristic downfield shifts at C-1 and the upfield shifts at C-8 (4).

Chemical shifts for the last series of compounds to be examined herein, the 6-ketones, are presented in Table 5. The resonances of the Δ^4-3,6,17-trione **2***e* were assigned by application of the shift parameters for a 6-keto function (1) to the spectrum of androst-4-ene-3,17-dione (1, 6), and those of rings A and B of the series **5** by applying the shift parameters for a C-5α OH to the spectrum of 3β-acetyloxy-5α-cholestan-6-one (1). Significant deviation of observed (13.9 ppm) from calculated (16.9 ppm) values occurred only in the case of C-19. The downfield shift (+3.9 ppm) at C-19 normally attributed to the C-5α OH has been fully discussed (12). From our data it is apparent that this shift is absent or severely

mitigated in the presence of a 6-keto function, an observation which supports the electronic origin proposed (12) for the γ antiperiplanar effect.

Experimental

Spectra were recorded and assigned as previously described (13). The following compounds were prepared by published procedures and gave satisfactory physical and analytical data: 21-fluoropregn-4-ene-3,20-dione (**1***a*) (14), 21-chloropregn-4-ene-3,20-dione (**1***b*) (15), 21-bromopregn-4-ene-3,20-dione (**1***c*) (16), 6β-fluoroandrost-4-ene-3,17-dione (**2***a*) (17), 6β-chloroandrost-4-ene-3,17-dione (**2***b*) (18), 6α-fluoroandrost-4-ene-3,17-dione (**2***c*) (17), 6α-chloroandrost-4-ene-3,17-dione (**2***d*) (18), androst-4-ene-3,6,17-trione (**2***e*) (11, 19), 5,6β-dichloro-5α-androstan-3β-ol-17-one (**3***a*) (15), 5,6β-dichloro-5α-androstan-3β-ol-17-one 3-acetate (**3***b*) (15), 5-bromo-5α-androstan-3β,6β-diol-17-one diacetate (**3***c*) (11), 6β-fluoro-5α-androstan-3β,5-diol-17-one (**3***d*) (17), 5α-androstan-3β,5,6β-triol-17-one 3-acetate (**3***e*) (19), 5-chloro-5α-androstan-3β-ol-17-one (**3***f*) (20), 6β-fluoro-5α-androstan-5-ol-3,17-dione (**4***a*) (17), 5-hydroxy-5α-androstan-3,17-dione (**4***b*) (11), 5α-androstan-3β,5-diol-6,17-dione 3-acetate (**5***a*) (21), 5α-androstan-3β,5,17β-triol-6-one 3,17-diacetate (**5***b*) (21), 5α-pregnan-3β,5-diol-6,20-dione 3-acetate (**5***c*) (21), and 5α-androstan-3β,5,17β-triol (**6**) (11). Other compounds used in this study were commercial samples.

Artificial carbohydrate antigens: the synthesis of the tetrasaccharide repeating unit of *Shigella flexneri* O antigen[1]

STAFFAN JOSEPHSON[2] AND DAVID R. BUNDLE

Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received June 5, 1979

STAFFAN JOSEPHSON and DAVID R. BUNDLE. Can. J. Chem. **57**, 3073 (1979).

The synthesis of a tetrasaccharide glycoside, 8-methoxycarbonyloctyl *O*-2-acetamido-2-deoxy-β-D-glucopyranosyl-(1→2)-*O*-α-L-rhamnopyranosyl-(1→2)-*O*-α-L-rhamnopyranosyl-(1→3)-α-L-rhamnopyranoside, representing the repeating unit of the *Shigella flexneri* serogroup Y O antigen is reported, together with that of a component trisaccharide. Both oligosaccharide glycosides are functionalised to permit covalent attachment to immunogenic carriers and solid matrices. A key intermediate used to establish α-1,2-rhamnopyranoside linkages was 2-*O*-acetyl-3,4-di-*O*-benzyl-α-L-rhamnopyranosyl chloride (**1**), which was obtained in quantitative yield from 3,4-di-*O*-benzyl-1,2-*O*-(methoxyethylidene)-β-L-rhamnopyranose. Thus 8-methoxycarbonyloctyl 3,4-di-*O*-benzyl-α-L-rhamnopyranoside (**2**) prepared from the rhamnopyranosyl chloride **1** was used in a second Koenigs–Knorr reaction to provide an α-1,2-linked disaccharide. The disaccharide is in turn glycosylated at the C-2′ position with tri-*O*-acetyl-2-deoxy-2-phthalimido-D-glucopyranosyl bromide to provide the trisaccharide glycoside, 8-methoxycarbonyloctyl *O*-2-acetamido-2-deoxy-β-D-glucopyranosyl-(1→2)-*O*-α-L-rhamnopyranosyl-(1→2)-α-L-rhamnopyranoside. Application of the same reaction sequence to a rhamnopyranoside selectively blocked with benzoate esters at C-2 and C-4 gave the *S. flexneri* tetrasaccharide repeating unit. The success of this strategy was dependent upon the ability to use selective transesterification conditions, which permit removal of O acetate groups whilst leaving benzoate esters intact.

STAFFAN JOSEPHSON et DAVID R. BUNDLE. Can. J. Chem. **57**, 3073 (1979).

On décrit la synthèse du glycoside tétrasaccharide méthoxycarbonyloctyl-8 *O*-acétamido-2 déoxy-2 β-D-glucopyrannosyl-(1→2)-*O*-α-L-rhamnopyrannosyl-(1→2) *O*-α-L-rhamnopyrannosyl-(1→3)-α-L-rhamnopyrannoside représentant le monomère de l'antigène O du sérogroupe Y du *Shigella flexneri*; on rapporte aussi la synthèse d'un trisaccharide. Les deux glycosides oligosaccharides sont fonctionnalisés dans le but de les unir par une liaison covalente à des supports immunogènes et à des supports solides. L'intermédiaire clé utilisé pour établir les liaisons α-rhamnopyrannosides-1,2 est le chlorure de *O*-acétyl-2 di-*O*-benzyl-3,4 α-L-rhamnopyrannosyle (**1**) qui est obtenu quantitativement à partir du di-*O*-benzyl-3,4 *O*-(méthoxyéthylidène)-1,2 β-L-rhamnopyrannose. Ainsi le méthoxycarbonyloctyl-8 di-*O*-benzyl-3,4 α-L-rhamnopyrannoside (**2**), préparé à partir du chlorure de rhamnopyrannosyle **1**, est utilisé dans une seconde réaction de Koenigs–Knorr pour obtenir la liaison α-disaccharide-1,2. Le disaccharide est, à son tour, glycosilé en position C-2′ avec le bromure de tri-*O*-acétyl déoxy-2-phtalimido-2 D-glycopyrannosyle pour conduire au glycoside trisaccharide, méthoxycarbonyl-octyl-8 *O*-acétamido-2 déoxy-2 β-D-glucopyrannosyl(1→2)*O*-α-L-rhamnopyrannosyl-(1→2)-α-L-rhamnopyrannoside. L'utilisation de cette même suite de réactions sur un rhamnopyrannoside bloqué sélectivement en positions C-2 et C-4 avec des esters benzoïques donne le monomère du *S. flexneri* tétrasaccharide. Le succès de cette stratégie dépend de la capacité d'utiliser des conditions sélectives de transestérification qui permettent d'enlever le groupe O acétate sans toucher au groupe benzoate.

[Traduit par le journal]

Introduction

The skeletal structure of the *Shigella flexneri* serogroup Y O antigen is a tetrasaccharide of the following structure:

$$\text{-}[\text{-}3)\text{-}\beta\text{-D-GlcNAc}p\text{-}(1\rightarrow2)\text{-}\alpha\text{-L-Rham}p\text{-}(1\rightarrow2)\text{-}\alpha\text{-L-Rham}p\text{-}(1\rightarrow3)\text{-}\alpha\text{-L-Rham}p\text{-}(1\text{-}]_n$$

(1). Much is known about the general serological features of O antigens, particularly with respect to the genus *Salmonella* (2, 3). One of the important features of O antigens is that the "chemical repeating unit" (that isolated by chemical degradation of the intact O chain) does not necessarily coincide with the biological repeating unit (that intact unit which is built up and transferred to the C_{55}-isoprenoid carrier during biosynthesis) (2, 4). Since the biological repeating unit will be important in serological reactions which involve the most distal regions of the O chains (2) such information is relevant to synthesis

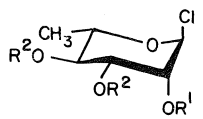
of artificial antigens. The biological repeating unit of *S. flexneri* O chains is not known and we have, therefore, synthesised two of the four possible repeating units of the serogroup Y LPS. Our original interest in *S. flexneri* antigens (5) stemmed from a desire to investigate via artificial antigens the possible existence of so-called "conformational determinants" (3). In order to provide a comprehensive range of haptens for such studies and also to raise antibodies (via artificial antigens) of differing specificities we have synthesised several di-, tri-, and tetra-saccharide haptens (5–8). These structures coupled to solid supports provide immunoabsorbents with which to fractionate immune-sera raised against whole-cell vaccines. In this way the various determinants of *S. flexneri* O antigens may be systematically studied. This paper describes the synthesis both of a tetrasaccharide glycoside, 8-methoxycarbonyloctyl *O*-2-acetamido-2-deoxy-β-D-glucopyranosyl-(1→2)-*O*-α-L-rhamnopyranosyl-(1→2)-*O*-α-L-rhamnopyranosyl-(1→3)-α-L-rhamnopyranoside, which represents the repeating unit of the serogroup Y O antigen, and a component trisaccharide hapten, 8-methoxycarbonyloctyl *O*-2-acetamido-2-deoxy-β-D-glucopyranosyl-(1→2)-*O*-α-L-rhamnopyranosyl-(1→2)-α-L-rhamnopyranoside.

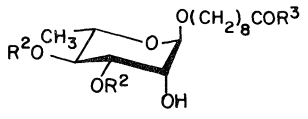
Results and Discussion

In order to establish successive 1,2-linkages use was made of a method developed by Garegg and coworkers (9) and elegantly exploited by Lemieux in a synthetic scheme leading to the type 1 blood group H and Lewis-b determinants (10). This method involves the benzylation of 1,2-orthoesters to provide hexopyranose derivatives with "persistent" blocking groups at all positions except C-1 and C-2. In an earlier synthesis of the rhamnose disaccharide glycoside, 8-methoxycarbonyloctyl 2-*O*-(α-L-rhamnopyranosyl)-α-L-rhamnopyranoside, the essential intermediate, a 3,4-di-*O*-benzyl rhamnopyranoside (**2**) was synthesized via a typical orthoester glycoside synthesis (5). The work reported here uses the same 1,2-orthoester, 3,4-di-*O*-benzyl-1,2-*O*-(methoxyethylidene)-β-L-rhamnopyranose, but we have found it more advantageous to convert this compound to 2-*O*-acetyl-3,4-di-*O*-benzyl-α-L-rhamnopyranosyl chloride (**1**) (7). This was achieved in essentially quantitative yield by reaction of the 1,2-orthoester with trimethylchlorosilane at reflux in dichloromethane for 2 h (11). The glycoside **2** was obtained from **1** in 75% yield by a silver trifluoromethanesulphonate (triflate) promoted Koenigs–Knorr reaction. This contrasts with the orthoester method which gives **2** in 63% yield from the 1,2-orthoester (5). We have also shown that 2-*O*-acetyl-3,4-di-*O*-benzyl-α-L-rhamnopyranosyl chloride (**1**) is an excellent building unit for construction of 1,2-linkages (7, 8). In addition this partially benzylated rhamnopyranosyl chloride is a more effective glycosylating intermediate than either the tri-*O*-acetyl-α-L-rhamnopyranosyl chloride or bromide (8). Thus glycosylation of glycoside **2** with **1** in a silver triflate promoted Koenigs–Knorr reaction (12) gave **3** in 71% yield. Following transesterification of **3**, the selectively blocked disaccharide **4** was reacted with tri-*O*-acetyl-2-deoxy-2-phthalimido-D-glucopyranosyl bromide (13) in the presence of silver triflate and 2,4,6-trimethylpyridine (collidine) to provide the blocked trisaccharide **5** in 70% yield. Removal of the blocking groups was performed in two steps. Transesterification, followed by conversion of the amino-sugar residue to the acetamido derivative, gave the partially benzylated trisaccharide **6**, which was then hydrogenated over palladium to give the de-blocked trisaccharide hapten **7**.

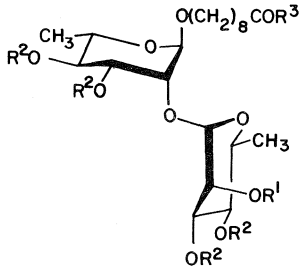
Synthesis of the tetrasaccharide repeating unit of *S. flexneri* lipopolysaccharide was begun with an 8-methoxycarbonyloctyl α-L-rhamnopyranoside selectively blocked at positions C-2 and C-4 (7). The preservation of the ester function of 8-methoxycarbonyloctyl glycosides (which is ultimately used to establish covalent linkage to protein or a solid matrix) is a limiting factor when selecting suitable "temporary" and "persistent" blocking groups for sequential chain extension. In addition the "persistent" blocking groups must be sufficiently stable to withstand the partial de-blocking conditions used to reveal the single hydroxyl group, which is the site of the next glycosylation reaction. Previously (7) we used 8-methoxycarbonyloctyl 2,4-di-*O*-benzoyl-α-L-rhamnopyranoside as the starting point for synthesis of a rhamnose trisaccharide glycoside containing a 1,3-linkage. This derivative was used again here since it was shown that the benzoate esters were sufficiently stable to withstand transesterification (by magnesium methoxide in methanol), conditions which remove 2-acetates from contiguous pyranose rings. Thus sequential Koenigs–Knorr reactions using silver triflate, *N*,*N*-tetramethylurea (12), and the selectively blocked rhamnopyranosyl chloride **1** provide first the disaccharide **10**, and following transesterification to yield **11**, the second chain extension step gives the trisaccharide **12**. Removal of the 2″-acetate from the trisaccharide by treatment with magnesium methoxide gave **13** which was reacted with tri-*O*-acetyl-2-deoxy-2-phthalimido-D-glucopyranosyl bromide (13) in the presence of silver triflate and collidine. The fully blocked tetrasaccharide **14** was obtained chromatographically pure in 85% yield. The de-blocking sequence was similar to



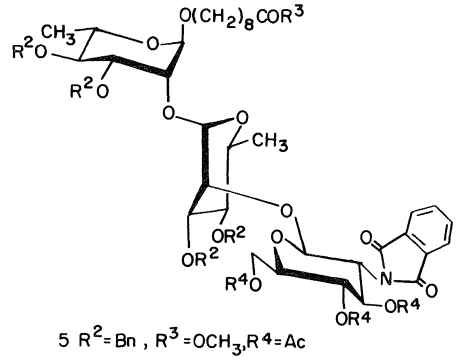
1 R^1 = Ac, R^2 = Bn



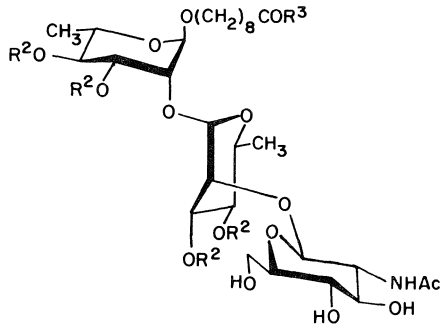
2 R^2 = Bn, R^3 = OCH_3



3 R^1 = Ac, R^2 = Bn, R^3 = OCH_3
4 R^1 = H, R^2 = Bn, R^3 = OCH_3



5 R^2 = Bn, R^3 = OCH_3, R^4 = Ac



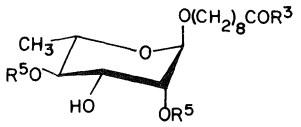
6 R^2 = Bn, R^3 = OCH_3
7 R^2 = H, R^3 = OCH_3
8 R^2 = H, R^3 = $NHNH_2$

Bn = CH_2Ph

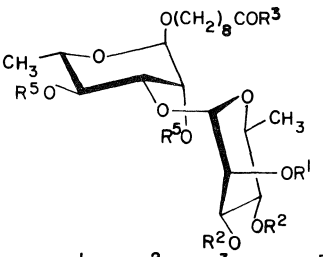
that used for trisaccharide **5** with the exception that following hydrogenolysis of the benzyl ethers, a second transesterification step was necessary to completely de-benzoylate the tetrasaccharide. The yield of analytically and chromatographically pure tetrasaccharide **15** from **14** was 67%. Both haptens, the trisaccharide **7** and tetrasaccharide **15**, were converted to the corresponding acyl hydrazide derivatives **8** and **16**, in which form they are used to prepare artificial antigens and immunoabsorbents according to standard procedures (14, 15).

The anomeric purity of both the tri- and tetrasaccharide glycosides and their blocked precursors was confirmed by ^{13}C and ^{1}H nmr. Consideration of the glycosyl halides (13, 16) and reaction conditions (12, 13, 16) employed to synthesize **7** and **15** lead to an expectation of high anomeric purity. This is indeed the case and ^{13}C nmr data for compounds **3–16** require that the compounds possess the desired anomeric configuration and have the structures indicated. In addition single bond $^{1}J_{^{13}C_1,^{1}H_1}$ coupling constants for all four glycosidic linkages of compound **15** confirm the anomeric configurations. This conclusion derives from the observation (17) that aldopyranoses with H-1 in equatorial orientation have ^{1}J values $\simeq$ 170 Hz whilst those that are axial have $^{1}J \simeq$ 160 Hz. The observed coupling constants for compound **15** are consistent with the desired structure.

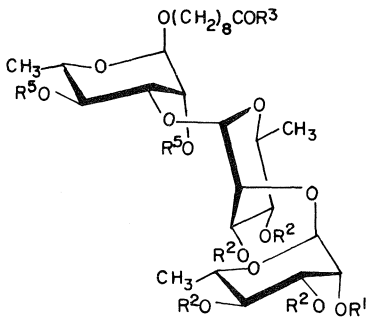
Proton nmr spectra for the trisaccharide glycoside **7** show three distinct anomeric protons whilst the same trisaccharide attached α-1,3 to another α-L-



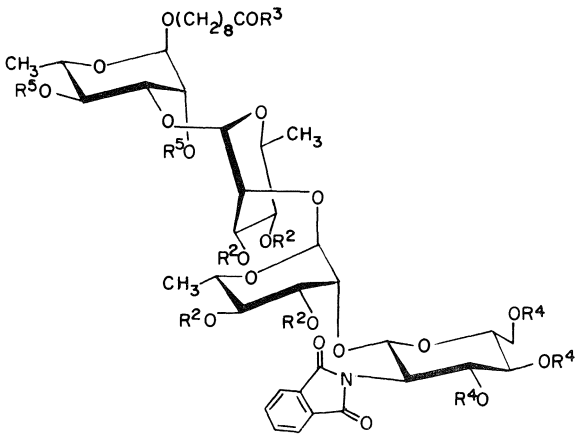
9 R^3=OCH_3, R^5=Bz



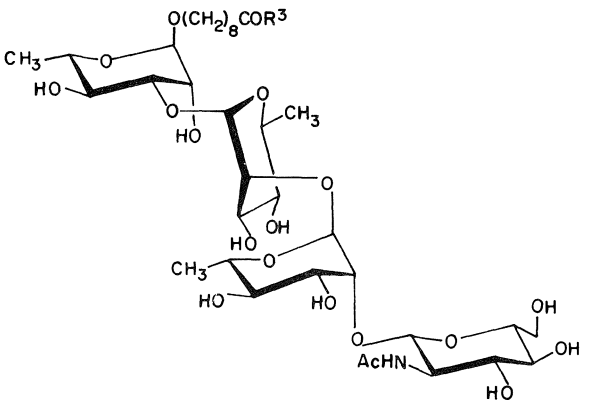
10 R^1=Ac, R^2=Bn, R^3=OCH_3, R^5=Bz
11 R^1=H, R^2=Bn, R^3=OCH_3, R^5=Bz



12 R^1=Ac, R^2=Bn, R^3=OCH_3, R^5=Bz
13 R^1=H, R^2=Bn, R^3=OCH_3, R^5=Bz



14 R^2=Bn, R^3=OCH_3, R^4=OAc, R^5=Bz



15 R^3=OCH_3
16 R^3=$NHNH_2$

rhamnopyranoside, as in compound **15**, shows two sets of overlapping anomeric signals. One α-linked rhamnopyranoside H-1 resonance is coincident with that due to H-1 of the 2-acetamido-2-deoxy-β-D-glucopyranoside residue. This observation is reminiscent of the ^{1}H nmr spectrum of the serogroup Y O antigen (3) and contrasts sharply with the ^{1}H nmr of 8-methoxycarbonyloctyl *O*-α-L-rhamnopyranosyl-(1→2)-*O*-α-L-rhamnopyranosyl-(1→3)-*O*-α-L-rhamnopyranosyl-(1→3)-*O*-2-acetamido-2-deoxy-β-D-glucopyranoside (8) which shows four distinct and well separated anomeric resonances at 80 MHz. The incremental shift differences due to linkage, sequence, and conformation are receiving further study and will be published separately together with anomeric T_1 evidence which indicates preferred conformations in agreement with the requirements of the *exo*-anomeric effect (18).

In conclusion we have clearly demonstrated that sequential addition, to selectively blocked glycosides,

of suitable monosaccharide building units in conjunction with silver triflate promoted Koenigs–Knorr reactions provides an efficient process for preparing artificial antigens at least as large as tetrasaccharide. Such compounds should prove to be of the utmost value in probing and extending existing serological principles pertaining to oligosaccharide determinants.

Experimental

The materials and methods used here are similar to those employed in previous publications (5–8) with the following exceptions. Preparative high pressure liquid chromatography (hplc) was performed on a Waters 500LC system. A column (25 cm × 1.5 cm) of Sephadex LH20 with methanol as solvent was used to purify acyl hydrazide derivatives. Single bond coupling constants $^1J_{^{13}C_1,^1H_1}$ were determined from ^{13}C spectra recorded in the "gated" decoupling mode (19). Assignments of ^{13}C resonances are tentative.

*2-O-Acetyl-3,4-di-O-benzyl-α-L-rhamnopyranosyl Chloride (**1**)*

Trimethylchlorosilane (10 mL) was added to a solution of 3,4-di-*O*-benzyl-1,2-*O*-(methoxyethylidene)-β-L-rhamnopyranose (8.0 g, 20 mmol) (5) in dichloromethane (50 mL). The reaction was refluxed for 2 h, then evaporated and dried under vacuum to yield a light yellow syrup of **1** (8.1 g, ~100% yield). Proton and ^{13}C nmr indicate the syrup to be at least 95% pure. ^1H nmr ($CDCl_3$) δ: 1.35 (d, $J_{5,6}$ = 6.2 Hz, 3H, H-6), 2.15 (s, 3H, CH_3CO), 3.48 (t, $J_{3,4}$ = 9.5 Hz, 1H, H-4), 3.78–4.32 (m, 2H, H-3 and H-5), 4.57 and 4.65 (AB system, J_{AB} = 10.2 Hz, CH_2Ph), 5.46 (dd, $J_{1,2}$ = 1.7 Hz, $J_{2,3}$ = 2.8 Hz, 1H, H-2), 5.96 (d, $J_{1,2}$ = 1.7 Hz, 1H, H-1), 7.20–7.60 (m, 10H, aromatic); ^{13}C nmr ($CDCl_3$) δ: 90.3 (Cl), 79.4, 76.6 (2C, CH_2Ph), 75.5 (C4), 72.1 (C3), 71.4 (C2), 70.9 (C5), 17.7 (C6).

*8-Methoxycarbonyloctyl 3,4-Di-O-benzyl-α-L-rhamnopyranoside (**2**)*

A solution of **1** (8.1 g, 20 mmol) in dichloromethane (50 mL) was added dropwise to a stirred solution of 8-methoxycarbonyloctanol (4.0 g, 21.3 mmol) (12) silver triflate (6.0 g, 23.3 mmol) and *N,N*-tetramethylurea (10 mL, 83.3 mmol) in dichloromethane (100 mL) at −70°C. The reaction was allowed to warm to room temperature overnight and the solution was then filtered. Following extraction with saturated sodium bicarbonate and water, the concentrated syrup was purified by hplc with Skellysolve B – ethyl acetate (3:1) as solvent. The pure syrup was dissolved in methanol (200 mL) containing a catalytic amount of sodium and stirred overnight. De-ionisation with Rexyn 101 (H^+), concentration, and chromatography by hplc with Skellysolve B – ethyl acetate (2:1) gave pure **2** (7.7 g, 75% yield); $[\alpha]_{589}$ −24.2° (*c* 1.0, $CHCl_3$); R_f 0.20 (solvent same as above); ^1H nmr ($CDCl_3$) δ: 0.90–1.75 (m, 15H, H-6 and —$(CH_2)_6$—), 2.30 (t, 2H, —CH_2CO—), 2.50 (d, 1H, OH), 3.62 (s, 3H, CH_3O), 3.23–4.18 (m, 7H, OCH_2 and ring protons), 4.43–5.01 (m, 4H, OCH_2Ph), 7.23–7.27 (m, 10H, aromatic); ^{13}C nmr ($CDCl_3$) δ: 99.1 (C1), 80.2, 80.1 (2C, CH_2Ph), 75.4 (C4), 71.9 (C3), 68.6 (C2), 67.5 (C5), 67.3 (OCH_2), 17.9 (C6). *Anal.* calcd. for $C_{30}H_{42}O_7$: C 70.01, H 8.23; found: C 69.98, H 8.27.

*8-Methoxycarbonyloctyl 2-O-(2-O-Acetyl-3,4-di-O-benzyl-α-L-rhamnopyranosyl)-3,4-di-O-benzyl-α-L-rhamnopyranoside (**3**)*

Glycoside **2** (4.1 g, 8 mmol) was dissolved in dichloromethane (100 mL) containing silver triflate (3.1 g, 12 mmol) and *N,N*-tetramethylurea (5 mL, 42 mmol). The solution was cooled to −70°C and rhamnopyranosyl chloride **1** (4.0 g, 10 mmol) dissolved in dichloromethane (30 mL) was added dropwise with stirring. The reaction was allowed to warm to room temperature overnight and the solution was then filtered. Following extraction with saturated sodium bicarbonate and water, the concentrated syrup was purified by hplc with Skellysolve B – ethyl acetate (3:1) as solvent. Pure disaccharide **3** (5.0 g, yield 71%) was obtained; $[\alpha]_{589}$ −19.4° (*c* 1.0, $CHCl_3$); R_f 0.34 (same solvent as above); ^1H nmr ($CDCl_3$) δ: 1.20–1.60 (m, 18H, H-6, H-6′ and —$(CH_2)_6$—), 2.12 (s, 3H, CH_3CO), 2.31 (t, 2H, —CH_2CO—), 3.66 (s, 3H, CH_3O), 3.10–4.10 (m, 7H, ring protons and —CH_2O—), 4.30–4.80 (m, 8H, CH_2Ph), 4.85 (d, $J_{1,2}$ = 1.0 Hz, 1H, H-1), 4.99 (bs, 1H, H-1′), 5.52, 5.57 (dd, $J_{1,2}$ = 1.9 Hz, $J_{2,3}$ = 3.3 Hz, 1H, H-2′), 7.31 (bs, 20H, aromatic); ^{13}C nmr ($CDCl_3$) δ: 99.4 (C1), 98.8 (C1′), 80.1 (3C, CH_2Ph), 77.8 (CH_2Ph), 75.4 (2C, C2 and C4), 74.9 (C4′), 72.1 (C3), 71.8 (C3′), 69.1 (C2′), 68.3 (C5), 68.0 (C5′), 67.6 (OCH_2), 18.1 (2C, C6 and C6′). *Anal.* calcd. for $C_{52}H_{66}O_{12}$: C 70.73, H 7.53; found: C 70.50, H 7.61.

*8-Methoxycarbonyloctyl 2-O-(3,4-Di-O-benzyl-α-L-rhamnopyranosyl)-3,4-di-O-benzyl-α-L-rhamnopyranoside (**4**)*

Disaccharide **3** (4.0 g, 4.8 mmol) in methanol (100 mL) containing a catalytic amount of sodium methoxide was left overnight at room temperature. The syrup, obtained after removal of sodium ions with Rexyn 101 (H^+) resin, filtration, and evaporation, was purified by hplc with Skellysolve B – ethyl acetate (2:1) as solvent. This gave pure **4** (3.5 g, 92% yield); $[\alpha]_{589}$ −27.0° (*c* 1.1, $CHCl_3$); R_f 0.46 (solvent same as above); ^1H nmr ($CDCl_3$) δ: 1.20–1.70 (m, 18H, H-6, H-6′ and —$(CH_2)_6$—), 2.32 (t, 2H, —CH_2CO), 2.52 (bs, 1H, OH), 3.67 (s, 3H, CH_3O), 3.20–4.20 (m, 8H, ring protons and —CH_2O—), 4.50–5.00 (m, 8H, CH_2Ph), 4.99 (d, $J_{1,2}$ = 1.0 Hz, 1H, H-1), 5.11 (d, $J_{1,2}$ = 1.6 Hz, 1H, H-1′), 7.30–7.50 (m, 20H, aromatic); ^{13}C nmr ($CDCl_3$) δ: 101.0 (C1′), 98.9 (C1), 80.5 (CH_2Ph), 80.2 (2C, CH_2Ph), 79.6 (CH_2Ph), 75.3 (2C, C2 and C4), 74.9 (C4′), 72.3 (C3), 72.1 (C3′), 68.8 (C2′), 68.0 (2C, C5 and C5′), 67.5 (OCH_2), 18.1 (C6), 18.0 (C6′). *Anal.* calcd. for $C_{50}H_{64}O_{11}$: C 71.40, H 7.67; found: C 71.24, H 7.64.

*8-Methoxycarbonyloctyl O-(3,4,6-Tri-O-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranosyl)-(1 → 2)-O-(3,4-di-O-benzyl-α-L-rhamnopyranosyl)-(1 → 2)-3,4-di-O-benzyl-α-L-rhamnopyranoside (**5**)*

The partially protected glycoside **4** (2.2 g, 2.6 mmol) was dissolved in dichloromethane (30 mL) containing silver triflate (1.4 g, 5.5 mmol) and collidine (0.7 g). The solution was cooled to −70°C and 3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-D-glucopyranosyl bromide (2.5 g, 5.0 mmol) (12) dissolved in dichloromethane (15 mL) was added dropwise with stirring. The reaction was allowed to warm to room temperature overnight and the reaction mixture was then filtered. Following extraction with dilute hydrochloric acid (0.1 *M*), sodium bicarbonate, and water, the product after concentration to a syrup was purified on a silica gel column with Skellysolve B – ethyl acetate (1:1). This gave pure **5** (2.3 g, 70% yield); $[\alpha]_{589}$ 6.1° (*c* 1.0, $CHCl_3$); R_f 0.58 (solvent same as above); mp 117–118°C (recrystallized from ethyl acetate – Skellysolve B); ^1H nmr ($CDCl_3$) δ: 1.00–1.70 (m, 18H, H-6, H-6′ and —$(CH_2)_6$—), 1.90 (s, 3H, CH_3CO), 1.98 (s, 3H, CH_3CO), 2.02 (s, 3H, CH_3CO), 2.28 (t, 2H, —CH_2CO—), 3.65 (s, 3H, CH_3O), 5.32 (d, $J_{1,2}$ = 8.5 Hz, 1H, H-1″), 5.93, 6.06 (dd, $J_{2,3}$ = 10.7 Hz, $J_{3,4}$ = 9.1 Hz, 1H, H-3″), 6.90–7.90 (m, 24H, aromatic), 3.00–5.30 (m, 25H, ring protons and —CH_2Ph); ^{13}C nmr ($CDCl_3$) δ: 101.3 (C′), 100.0 (C1″), 98.7 (C1), 80.7 (CH_2Ph), 79.2 (2C, CH_2Ph), 79.1 (CH_2Ph), 77.8 (C2′), 76.6 (C2), 75.4 (C4), 75.0 (C5″), 72.6 (C4′), 71.4 (2C, C3 and C3′), 70.2 (C4″), 68.9 (C3″), 68.5 (C5), 67.5 (2C, C5′ and

OCH_2), 61.5 (C6″), 54.7 (C2″), 18.1 (C6), 17.7 (C6′). *Anal.* calcd. for $C_{70}H_{83}NO_{20}$: C 66.81, H 6.65, N 1.11; found: C 66.58, H 6.58, N 1.14.

8-Methoxycarbonyloctyl O-*(2-Acetamido-2-deoxy-*β-D-*glucopyranosyl)-(1 → 2)-*O-*(3,4-di-*O-*benzyl-*α-L-*rhamnopyranosyl)-(1 → 2)-3,4-di-*O-*benzyl-*α-L-*rhamnopyranoside (**6**)*

The trisaccharide **5** (1.6 g, 1.3 mmol) was dissolved in methanol (150 mL) containing a catalytic amount of sodium methoxide and was left for 5 h at room temperature. The syrup, obtained after removal of sodium ions with Rexyn 101 (H^+) resin, filtration, and evaporation was dissolved in ethanol (40 mL). Hydrazine hydrate (0.36 g, 85% solution, 6.1 mmol) was added to this solution and the solution was boiled for 2 h. The solution was evaporated and dried under high vacuum to remove traces of hydrazine. The product was then dissolved in methanol–water (3:1, 10 mL), acetic anhydride (3 mL) was added, and the solution was stirred at room temperature overnight. Concentration followed by purification on silica gel with chloroform–methanol (7:1) gave pure trisaccharide **6** (0.95 g, 70% yield); $[\alpha]_{589}$ −5.3° (*c* 1.2, methanol); R_f 0.54 (same solvent as above); ^{1}H nmr (acetone-d_6) δ: 1.00–1.70 (m, 18H, H-6, H-6′ and —$(CH_2)_6$—), 1.70 (s, 3H, CH_3CONH), 2.29 (t, 2H, —CH_2CO—), 3.61 (s, 3H, CH_3O), 7.20–7.60 (m, 20H, aromatic), 3.10–5.30 (ring protons); ^{13}C nmr (CD_3OD) δ: 104.1 (C1″), 102.1 (C1′), 99.7 (C1), 81.3 (CH_2Ph), 79.8 (CH_2Ph), 78.9 (2C, CH_2Ph), 78.2 (C2′), 77.1 (C5″), 76.4 (C2), 76.0 (C4), 75.9 (C4′), 75.5 (C3″), 73.1 (C3), 72.3 (C3′), 71.5 (C4″), 69.4 (C5), 68.6 (C5′), 68.3 (OCH_2), 62.3 (C6″), 57.7 (C2″), 18.4 (C6), 18.1 (C6′). *Anal.* calcd. for $C_{58}H_{77}NO_{16}$: C 66.71, H 7.43, N 1.34; found: C 66.49, H 7.33, N 1.48.

8-Methoxycarbonyloctyl O-*2-Acetamido-2-deoxy-*β-D-*gluco-pyranosyl-(1 → 2)-*O-α-L-*rhamnopyranosyl-(1 → 2)-*α-L-*rhamnopyranoside (7)*

The trisaccharide **6** (900 mg, 0.86 mmol) was dissolved in acetic acid (40 mL) and hydrogenated over 10% palladium on charcoal (0.5 g) at 505 kPa for 3 h. Filtration and evaporation provided a residue which was purified on a silica gel column with ethyl acetate – methanol – water (7:2:1) to give pure **7** (460 mg, 84% yield); $[\alpha]_{589}$ −36.4° (*c* 1.1, methanol); R_f 0.40 (solvent same as above); ^{1}H nmr (D_2O, 85°C) δ: 1.20–1.90 (m, 18H, H-6, H-6′ and —$(CH_2)_6$—), 2.07 (s, 3H, CH_3CONH), 2.37 (t, 2H, —CH_2CO—), 3.71 (s, 3H, CH_3O), 4.74 (d, $J_{1,2}$ = 8.1 Hz, 1H, H-1″), 4.84 (d, $J_{1,2}$ = 0.8 Hz, 1H, H-1), 5.16 (d, $J_{1,2}$ = 1.8 Hz, 1H, H-1′); ^{13}C nmr (D_2O) δ: 103.9 (C1″), 102.3 (C1′), 99.8 (C1), 80.1 (C2), 79.9 (C2′), 77.0 (C5″), 74.9 (C3″), 73.5 (2C, C4 and C4′), 71.5 (C4″), 71.1 (2C, C3 and C3′), 70.4 (C5′), 69.9 (C5), 68.9 (OCH_2), 62.0 (C6″), 57.1 (C2″), 18.1 (2C, C6 and C6′). *Anal.* calcd. for $C_{30}H_{53}NO_{16}$: C 52.70, H 7.81, N 2.05; found: C 52.50, H 7.91, N 2.13.

8-Hydrazinocarbonyloctyl O-*2-Acetamido-2-deoxy-*β-D-*glucopyranosyl-(1 → 2)-*O-α-L-*rhamnopyranosyl-(1 → 2)-*α-L-*rhamnopyranoside (8)*

The de-blocked trisaccharide **7** (53.5 mg, 0.08 mmol) was dissolved in ethanol (3 mL) to which 85% hydrazine hydrate (1.0 g) was added. The solution was stirred for 72 h, then evaporated and dried under high vacuum. Purification on a Sephadex LH20 column with methanol as solvent gave pure hydrazide **8** (49.7 mg, 93% yield); $[\alpha]_{589}$ −35.2° (*c* 1.0, methanol); R_f 0.26 (ethyl acetate – methanol – water 6:3:1); ^{1}H nmr (D_2O, 85°C) δ: 1.10–1.70 (m, 18H, H-6, H-6′ and —$(CH_2)_6$—), 2.10 (s, 3H, CH_3CONH), 2.26 (t, 2H, —CH_2CO—), 4.77 (d, $J_{1,2}$ = 7.8 Hz, 1H, H-1″), 4.87 (bs, 1H, H-1), 5.19 (d, $J_{1,2}$ = 1.7 Hz, 1H, H-1′), 2.10–4.25 (ring protons); ^{13}C nmr (D_2O) δ: 103.9 (C1″), 102.2 (C1′), 99.4 (C1), 80.0 (2C, C2 and C2′), 77.0 (C5″), 74.8 (C3″), 73.4 (2C, C4 and C4′), 71.3 (C4″), 71.0 (2C, C3 and C3′), 70.4 (C5′), 69.9 (C5), 69.2 (OCH_2), 61.8 (C6″), 57.0 (C2″), 17.8 (2C, C6 and C6′). *Anal.* calcd. for $C_{29}H_{53}N_3O_{15}$: C 50.94, H 7.81, N 6.15; found: C 50.90, H 7.98, N 6.30.

8-Methoxycarbonyloctyl O-*(3,4-Di-*O-*benzyl-*α-L-*rhamno-pyranosyl)-(1 → 2)-*O-*(3,4-di-*O-*benzyl-*α-L-*rhamno-pyranosyl)-(1 → 3)-2,4-benzoyl-*α-L-*rhamnopyranoside (13)*

Glycoside **11** (2.2 g, 2.5 mmol) (7) was dissolved in dichloromethane (40 mL) containing silver triflate (1.3 g, 5.2 mmol) and *N,N*-tetramethylurea (2 mL). The solution was cooled to −70°C and the rhamnosyl chloride **1** (2.0 g, 4.9 mmol) dissolved in dichloromethane (15 mL) was added dropwise with stirring. The reaction was allowed to warm to room temperature overnight and was then filtered. Following extraction of the filtrate with saturated sodium bicarbonate and water, the concentrated syrup was purified on a silica gel column with Skellysolve B – ethyl acetate (3:1) as solvent. This gave trisaccharide **12** contaminated with a little disaccharide **11**, both having a R_f 0.32. The syrup was dissolved in a methanol (30 mL)–tetrahydrofuran (10 mL) mixture which was cooled to 0°C and a freshly prepared solution of magnesium methoxide in methanol (15 mL of a 1% solution) was added. The reaction was then stirred for 48 h at 0°C. After removal of magnesium ions with Rexyn 101 (H^+) resin, filtration, and evaporation, the syrup obtained was purified on a silica gel column with the solvent Skellysolve B – ethyl acetate (2:1). This gave pure **13** (1.7 g, 56% yield); $[\alpha]_{589}$ +26.6° (*c* 1.0, chloroform); R_f 0.38 (solvent as above); ^{1}H nmr ($CDCl_3$) δ: 1.03 (d, $J_{5,6}$ = 5.8 Hz, 3H, H-6″), 1.06 (d, $J_{5,6}$ = 5.9 Hz, 3H, H-6′), 1.10–1.80 (m, 15H, H-6 and —$(CH_2)_6$—), 2.10–2.35 (m, 4H, —OH and —CH_2CO—), 3.66 (s, 3H, CH_3O—), 6.85–7.50 (m, 26H, aromatic), 7.80–8.10 (m, 4H, aromatic), 3.00–5.50 (ring protons); ^{13}C nmr ($CDCl_3$) δ: 101.0 (C1′), 100.5 (C1″), 97.4 (C1), 80.1 (CH_2Ph), 79.5 (3C, CH_2Ph), 76.0 (C2′), 75.3 (C3), 74.5 (C4′), 74.1 (C3′), 73.5 (C4″), 72.6 (C2), 72.1 (C4), 71.9 (C3″), 69.0 (C2″), 68.6 (C5′), 68.4 (C5″), 67.9 (C5), 66.7 (OCH_2), 17.8 (3C, C6, C6′ and C6″). *Anal.* calcd. for $C_{70}H_{82}O_{17}$: C 70.33, H 6.91; found: C 70.14, H 6.91.

8-Methoxycarbonyloctyl O-*(3,4,6-Tri-*O-*acetyl-2-deoxy-2-phthalimido-*β-D-*glucopyranosyl)-(1 → 2)-*O-*(3,4-di-*O-*benzyl-*α-L-*rhamnopyranosyl)-(1 → 2)-*O-*(3,4-di-*O-*benzyl-*α-L-*rhamnopyranosyl)-(1 → 3)-2,4-di-*O-*benzoyl-*α-L-*rhamnopyranoside (14)*

The partially blocked trisaccharide **13** (1.3 g, 1.1 mmol) was dissolved in dichloromethane (30 mL) together with collidine (0.35 g, 2.9 mmol) and silver triflate (0.75 g, 2.9 mmol). The solution was cooled to −70°C and the 3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-D-glucopyranosyl bromide (1.3 g, 2.6 mmol) (10) dissolved in dichloromethane (15 mL) was added dropwise with stirring. The reaction was allowed to warm to room temperature overnight and was then filtered. Following extraction of the filtrate with 3% hydrochloric acid, saturated sodium bicarbonate, and water, the concentrated syrup was purified on a silica gel column with Skellysolve B – ethyl acetate (1:1) as solvent. This gave pure tetrasaccharide **14** (1.5 g, 85% yield); $[\alpha]_D$ +48.4° (*c* 1.2, chloroform); R_f 0.56 (same solvent as above); ^{1}H nmr ($CDCl_3$) δ: 0.93 (d, $J_{5,6}$ = 5.9 Hz, 3H, H-6″), 0.99 (d, $J_{5,6}$ = 5.7 Hz, 3H, H-6′), 1.10–1.75 (m, 15H, H-6 and —$(CH_2)_6$—), 1.89 (s, 3H, CH_3CO—), 1.93 (s, 3H, CH_3CO—), 2.01 (s, 3H, CH_3CO—), 3.65 (s, 3H, CH_3O—), 5.90, 6.05 (dd, $J_{2,3}$ = 9.1 Hz, $J_{3,4}$ = 10.8 Hz, 1H, H-3‴), 6.80–8.30 (m, 34H, aromatic); ^{13}C nmr ($CDCl_3$) δ: 100.9 (2C, C1′ and C1‴), 99.8 (C1″), 97.3 (C1), 80.6 (CH_2Ph), 79.8 (CH_2Ph),

*8-Methoxycarbonyloctyl 2-Acetamido-2-deoxy-*β-D-*gluco-pyranosyl-(1 → 2)-*O-α-L-*rhamnopyranosyl-(1 → 2)-*O-α-L-*rhamnopyranosyl-(1 → 3)-*α-L-*rhamnopyranoside (**15**)*

The tetrasaccharide **14** (1.3 g, 0.81 mmol) was dissolved in methanol (100 mL) containing a catalytic amount of sodium and the reaction was stirred overnight. The syrup obtained after removal of sodium ions with Rexyn 101 (H^+) resin, filtration, and evaporation was dissolved in ethanol (40 mL). Hydrazine hydrate (0.30 g, 85% solution, 5.1 mmol) was added to this solution and the solution was boiled for 2 h. The solution was evaporated and dried under high vacuum to remove traces of hydrazine. The product was then dissolved in methanol (20 mL), acetic anhydride (2 mL) was added, and the solution was stirred at room temperature overnight. Concentration gave a syrup which on tlc showed several spots (this due to incomplete de-benzoylation), so no purification was done at this point. The syrup was instead dissolved in acetic acid (40 mL) and hydrogenated over 10% palladium on charcoal (0.5 g) at 505 kPa for 3 h. Filtration and evaporation gave a foam which was again dissolved in methanol (100 mL) containing freshly prepared sodium methoxide. The reaction was then stirred for 48 h. The syrup, obtained after removal of sodium ions with Rexyn 101 (H^+) resin, filtration, and evaporation, was purified on a silica gel column with ethyl acetate – methanol – water (7:2:1) to give pure tetrasaccharide **15** (450 mg, 67% yield); $[\alpha]_{589}$ −54.0° (*c* 1.1, CH_3OH); R_f 0.28 (solvent as above); ^1H nmr (D_2O, 85°C) δ: 1.10–1.85 (m, 21H, H-6, H-6′, H-6″ and —$(CH_2)_6$—), 2.10 (s, 3H, CH_3CONH), 2.32 (t, 2H, —CH_2CO—), 3.71 (s, 3H, CH_3O), 4.75 (d, $J_{1,2}$ = 1.3 Hz, 1H, H-1), 4.76 (d, $J_{1,2}$ = 7.9 Hz, 1H, H-1‴), 5.19 (bd, 2H, H-1′ and H-1″), 3.25–4.25 (ring protons); ^{13}C nmr (D_2O) δ: 103.9 (C1‴, $^1J_{^{13}C_1,^1H_1}$ = 162.8 Hz), 102.3 (C1″, $^1J_{^{13}C_1,^1H_1}$ = 171.0 Hz), 102.0 (C1′, $^1J_{^{13}C_1,^1H_1}$ = 171.0 Hz), 101.1 (C1, $^1J_{^{13}C_1,^1H_1}$ = 168.0 Hz), 80.1 (C2″), 79.7 (C2′), 78.4 (C3), 77.0 (C5‴), 74.9 (C3‴), 73.5 (3C, C4, C4′ and C4″), 71.1 (4C, C2, C3′, C3″, C4‴), 70.4 (C5″), 70.1 (2C, C5 and C5′), 68.9 (OCH_2), 61.9 (C6‴), 57.1 (C2‴), 18.1 (3C, C6, C6′ and C6″). *Anal.* calcd. for $C_{36}H_{63}NO_{20}$: C 52.10, H 7.65, N 1.69; found: C 51.95, H 7.80, N 1.85.

The crystal and molecular structure of *syn*-2,11-dithia[3,3]metacyclophane

WILLEM ANKER, GORDON W. BUSHNELL,[1] AND REGINALD H. MITCHELL[2]

Chemistry Department, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received June 6, 1979

WILLEM ANKER, GORDON W. BUSHNELL, and REGINALD H. MITCHELL. Can. J. Chem. **57**, 3080 (1979).

The crystal structure of *syn*-2,11-dithia[3,3]metacyclophane, $C_{16}H_{16}S_2$, has been determined by single crystal X-ray diffraction and refined to an *R*-value of 0.049. The crystal is monoclinic with cell dimensions a = 1898.2(5), b = 795.7(3), c = 924.1(4) pm, β = 100.03°(4). The space group is $P2_1/n$ with 4 molecules per cell, D_m = 1.34 g cm^{-3}, D_c = 1.317 g cm^{-3}. Of several possible *syn* conformations, the molecule is found in that with the largest S—S distance of 697.4 pm. The benzenoid rings form a dihedral angle of 20.6°. The distance between the pair of aromatic H atoms which are *ortho* to two methylene groups is 273.0 pm, with 305.2 pm between the carbon atoms to which they are attached. Small angular distortions are observed at these carbon atoms. Mean bond lengths are: C—S 181.0(12), C—C (aromatic) 138.5(8), C—C (bridge) 151.0(11) pm. Mean bond angles are: C—S—C 104°(1), S—C—C 115.4°(9). The C—C—C angles are in the range 117.9–122.7°. The molecule possesses an approximate (non-crystallographic) 2-fold axis of symmetry passing through the midpoints of C(8)—C(18) and C(4)—C(14). The aromatic rings are planar, with the methylene carbons 5–11 pm out of plane on the sulphur side. The S(1) is 171.8(2) pm from plane *1* and 136.8(2) pm from plane *2*, while for S(2) the corresponding values are 136.0(2) and 175.3(2) respectively.

^{1}Hmr data have been re-examined and compared with those obtained for other cyclophanes, together with ^{13}Cmr data and are consistent with the fact that in solution 2,11-dithia[3,3]metacyclophane, **1**, exists as the *syn*-conformer with no appreciable participation of the *anti*-conformer. All related dithia[3,3]metacyclophanes which have internal aryl hydrogens (i.e., no internal substituents) likewise appear to be *syn* from ^{1}Hmr data.

WILLEM ANKER, GORDON W. BUSHNELL et REGINALD H. MITCHELL. Can. J. Chem. **57**, 3080 (1979).

On a déterminé la structure cristalline du dithia-2,11 méta[3,3] cyclophane *syn*, $C_{16}H_{16}S_2$, par diffraction de rayons-X sur un cristal unique et on l'a affinée jusqu'à une valeur conventionnelle de 0.049. Le cristal est monoclinique avec une dimension de maille de a = 1898.2(5), b = 795.7(3), c = 924.1(4) pm, β = 100.03°(4). Le groupe d'espace est $P2_1/n$ avec 4 molécules par maille, D_m = 1.34 g cm^{-3}, D_c = 1.317 g cm^{-3}. Entre plusieurs conformations *syn* possibles, la molécule se classe parmi celles qui ont la plus grande distance S—S soit 697.4 pm. Les cycles aromatiques forment un angle dièdre de 20.6°. Les deux atomes d'hydrogène aromatique en *ortho* des deux groupés méthyléniques sont distants entre eux de 273.0 pm et les atomes de carbone auxquels ils sont attachés sont distants de 305.2 pm. On a observé des petites distorsions angulaires au niveau de ces atomes de carbone. Les longueurs moyennes de liaison sont de: C—S 181.0(2), C—C (aromatique) 138.5(8), C—C (pont) 151.0(11) pm. Les angles moyens de liaison sont de: C—S—C 104°(1), S—C—C 115.4°(9). Les angles C—C—C sont de l'ordre de 117.9–122.7°. La molécule possède approximativement un axe binaire de symétrie (non cristallographique) passant par le point milieu de C(8)—C(18) et C(4)—C(14). Les cycles aromatiques sont plans avec les carbones méthyléniques à 5–11 pm hors du plan du côté du soufre. Le S(1) est à 171.8(2) pm du plan *1* et à 136.8(2) du plan *2* alors que les valeurs correspondantes de S(2) sont respectivement de: 136.0(2) et 175.3(2).

On a réexaminé les données de la rmn du proton et on les a comparées à celles obtenues pour d'autres cyclophanes. Ces données ainsi que celles de la rmn du ^{13}C sont en accord avec le fait que le dithia-2,11 méta[3,3] cyclophane **1** existe en solution sous forme de conformère *syn* sans participation appréciable du conformère *anti*. Les spectres de résonance magnétique du proton révèlent de façon similaire que tous les composés dithia méta[3,3] cyclophanes qui ont des hydrogènes aromatiques internes (i.e. pas de substituants internes) sont sous forme des conformères *syn*.

[Traduit par le journal]

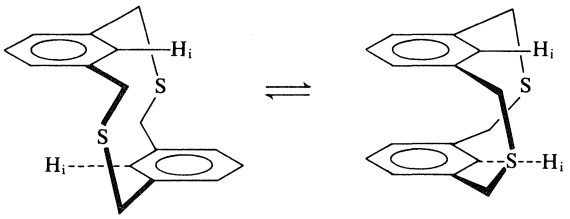
Introduction

2,11-Dithia[3,3]metacyclophane, **1**, was originally prepared in 1968 by two independent groups (1, 2) and was stated to be rapidly equilibrating between various *syn*- and *anti*-conformers. This conclusion was based primarily on the fact that the ^{1}Hmr

[1]Author to whom correspondence concerning X-ray data should be addressed.

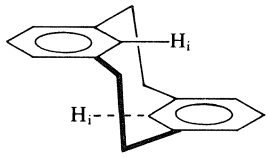
[2]Author to whom correspondence concerning nmr data should be addressed.

0008-4042/79/233080-08$01.00/0



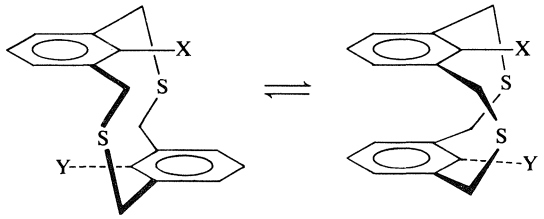
anti-**1** *syn*-**1**

spectrum of **1** showed a single peak at ca. δ 6.6 for the internal aryl hydrogens (H_i) which did not change on cooling. This observed position for H_i was assumed to be an average chemical shift for all contributing conformers, though it was quite clear from these and subsequent papers (3–6) that the *anti*-conformer of **1** was generally thought to be preponderant. This was not unreasonable at that time, since it was known that from ^{1}Hmr (7) and X-ray (8) data that [2,2]metacyclophane only existed in the *anti*-form **2**, and also it was observed (5) that in the



2

coupling reaction of 2,6-bis(bromomethyl)toluene with sodium sulphide, the *anti*-conformer of **3***a* was formed in seven times the amount of *syn*-**3***a*.



anti-**3** *syn*-**3**

a X = Y = CH_3
b X = H; Y = CH_3
c X = H; Y = NO_2
d X = H; Y = NH_2

As a result of an investigation to attempt to resolve an apparent anomaly (9) of melting points of **1**, we undertook an X-ray crystallographic structure determination of **1**. This paper shows that in the crystalline state **1** exists as the *syn*-conformer, and that this is in fact consistent with the structure of **1** in solution.

Experimental

X-ray Measurements

Approximate cell dimensions from Weissenberg and precession photographs were obtained using CuK_α radiation. The space group $P2_1/n$ was established unequivocally from the systematic absences. The equivalent positions in the second setting are : x, y, z; $\frac{1}{2}+x, \frac{1}{2}-y, \frac{1}{2}+z$; $-x, -y, -z$; $\frac{1}{2}-x, \frac{1}{2}+y, \frac{1}{2}-z$. The cell parameters were refined by least squares using 20 pairs of $\pm 2\theta$ measurements taken on a Picker 4-circle diffractometer using automatic centering routines. Zr filtered MoK_α radiation (λ = 71.069 pm) was used for all diffractometer measurements. The crystal was mounted approximately along the *b*-axis and had a shape and size specified by: 0,0,±1, 0.155 mm; ±1,0,0, 0.085 mm; 0,−1,0, 0.390 mm; 0,1,1, 0.245 mm; 0,1,−1, 0.325 mm. The crystal parameters at 23° are a = 1898.2(5), b = 795.7(3), c = 924.1(4) pm, β = 100.03°(4), molecular formula $C_{16}H_{16}S_2$, mol. wt. = 272.42, cell volume 1.374(1) nm^3, density 1.317 g cm^{-3} calculated, 1.34 g cm^{-3} measured (flotation), Z = 4, absorption coefficient ($MoK_{\bar{\alpha}}$) = 3.57 cm^{-1}, I/I_0 0.94 (max) and 0.90 (min) making absorption corrections unnecessary for conformation determination purposes. The intensity measurements were done automatically up to 2θ = 55° in the octants with k and $l \geq 0$, using a $\theta/2\theta$ scan (ω = 0, bisecting position) with 50 steps of 0.04° in 2θ, counting for 1 s per step. Background measurements were for 25 s before and after the step scan. Three standards 8,0,0; 6,2,0; and 0,0,4 were measured after each set of 50 reflections. Duplicate measurement of the two octants was carried out to improve the counting statistics. The sum of the standards had declined by approximately 8% at the finish, but there was no visual evidence of decomposition. Reflections for which $I < 3\sigma(I)$ were not written out by the diffractometer. The intensities were corrected for Lorentz and polarisation effects, and after the merging process there were 1187 independent reflections in the dataset.

Structure Determination

The structure was solved using the Patterson function. A set of programs supplied by Penfold (10) based on ORFLS, FORDAP, ORTEP, and ORFFE was used throughout. Atomic scattering curves were taken from the International Tables (11). All atoms were assumed to be uncharged and the S atoms were treated as anomalous scatterers (12). The refinement was by full matrix least squares minimization of $\sum w(|F_o| - |F_c|)^2$. The sulphur and carbon atoms were given anisotropic temperature parameters. The hydrogen atom positions were calculated from the carbon coordinates using a C—H length of 97 pm. The hydrogen atoms rode on the C skeleton in the final stages of refinement and were all assigned U_{iso} = 380 pm^2. The final weighting scheme, giving no systematic variation of $w\Delta^2$, was $w = (A + Bx + Cx^2 + Dx^3)^{-1}$ where $x = |F_o|$, A = 2.1134, $B = 4.03 \times 10^{-3}$, $C = 1.028 \times 10^{-2}$, $D = -4.9 \times 10^{-5}$. The final agreement factors were R = 0.049 and R_w = 0.069, where $R_w = (\sum w\Delta^2/\sum w|F_o|^2)^{1/2}$. The final difference map had a maximum of 0.53×10^{-6} e pm^{-3} and a minimum of -0.26×10^{-6} e pm^{-3}. The fractional atomic coordinates for the S and C atoms are given in Table 1. The anisotropic temperature parameters, the calculated hydrogen atom positions, and the structure factor tables have been deposited.[3]

Crystal Structure Description

The packing diagram given in Fig. 1 shows that the crystal structure contains four separate molecules

per unit cell. Figures 2 and 3 show the molecular structure and atomic labelling scheme. The molecule has an approximate (non-crystallographic) 2-fold axis of symmetry passing through the midpoints of C(8)—C(18) and C(4)—C(14). The bond lengths are given in Table 2. The mean lengths are: S—C, 181.1 pm; exocyclic C—C, 151.0 pm; and aromatic C—C 138.5 pm. There are no very significant deviations from these means and the values are normal. The bond angles are presented in Table 3. The mean angles C—S—C = 103.9°, and S—C—C = 115.4°.

The angles of the first ring in column 1 agree with the corresponding angles of the second ring in column 2 to an extent expected from the standard deviations, assuming the rings to be identical. Deviations from 120° are collectively greater and the angles at C(8) and C(18) are particularly large. Table 4 gives the results of the mean plane calculations. The aromatic rings are planar and the angle between them is 20.6°. Each methylene carbon atom is significantly out (on the S side) of the least squares plane of the ring to which it is attached. The molecular two-fold axis relates the C(1), C(17) displacements 8.9(7), 10.7(6) pm and the C(11), C(7) displacements 6.9(6), 5.2(6) pm, respectively. Similarly the perpendicular distances S(1)—plane *1*, S(2)—plane *2*, S(1)—plane *2*, and S(2)—plane *1* are 171.8(2), 175.3(2), 136.8(2), and 136.0(2) pm, respectively. Figure 2 illustrates the latter point, and Fig. 3 which is projected along the C(8)—C(18) direction shows that the benzene rings do not lie directly one upon the other, but are 7° apart approximately.

Our primary result is the *syn* geometry of the title compound. However, most of the background literature on metacyclophanes is concerned with ring

	C(8)	393.7(7)		

*The orthogonal system of axes used has *x* along *a*, *y* in the (*a*, *b*) plane, and *z* along the *c** axis. χ^2 is defined as $\Sigma_i(P_i^2/\sigma^2(P_i))$ where the summation is over all atoms, *i*, in the plane. The perpendicular distance of atom *i* from the plane is P_i.

strain. Comparison of our crystal structure with *syn*-**3***a* (13) shows interesting structural changes caused by repulsion between the methyl groups of the latter compound. The crystal structure of *syn*-**3***a* is disordered in the position of one of its sulfur atoms with an 80–20% distribution of conformers in the crystal structure. The most populated conformation of *syn*-**3***a* is quite similar to the conformation of *syn*-**1**, both having the sulfur atoms folded away from the internal aryl positions. The S—S distances are thus at a maximum: *syn*-**1** 697.4 pm and *syn*-**3***a* 695.0 pm. The molecular mechanics of both compounds can be likened to a spring clothes peg, with the $—CH_2—S—CH_2$ bridges acting as pivots for the relatively rigid phenyl groups. *Syn*-**1** has a dihedral angle of 20.6° between the phenyl ring planes, and the distance between the calculated internal hydrogen positions is 273.0 pm, more than twice the van der Waals radius of hydrogen (2 × 120 pm). The π-electron repulsion between C(8) and C(18), 305.2 pm apart, is probably more important than the repulsion between hydrogen atoms. *Syn*-**3***a* has a smaller dihedral angle of 10.3° and is evidence of interaction between the methyl groups which lie 26 and 30 pm from their respective phenyl ring planes on the outer sides. The intramolecular distance between the methyl carbon atoms is 352(1) pm. As expected, *syn*-**3***a* is more strained than *syn*-**1** in its 12-membered ring. The methylene carbon atoms are displaced inwards from the phenyl ring planes by 19 pm in *syn*-**3***a* and 8 pm in *syn*-**1** (averaged values). The $S—CH_2—C$ (aryl) angles average 117.5° in *syn*-**3***a* and 115.4° in *syn*-**1**. The two phenyl rings are not directly above one another in either compound.

Nuclear Magnetic Resonance Spectra

^{1}Hmr spectra were determined as solutions (20 mg of **1** in 0.4 mL solvent) in DMSO-d_6, toluene-d_8, $CDCl_3$, hexachlorobutadiene (HCBD), hexafluorobenzene (HFB), cyclohexane, and CS_2 over a temperature range of −70°C to +150°C on a Perkin-Elmer R32 (90MHz) spectrometer using Me_4Si as internal standard. The results for the internal aryl hydrogens (H_i) are shown in Fig. 4 and full data have been deposited[3] in Table S4. ^{13}Cmr spectra were determined in CD_2Cl_2, DMSO-d_6, THF-d_8, and CS_2 on a Nicolet TT-14 Fourier transform spectrometer operating at 15.1 MHz, and are deposited[3] in Table S5. All chemical shifts are measured in parts per million downfield from Me_4Si.

Discussion

When **1** was first described (1, 2) no other dithiametacyclophanes **3** having defined stereochemistry were known. Mitchell and Boekelheide (5, 14) were

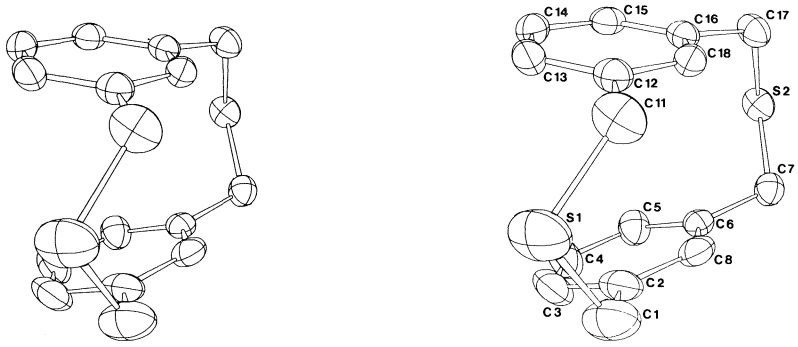

FIG. 2. A stereoscopic view of a single molecule, with the atom labelling scheme and the anisotropic thermal motion shown.

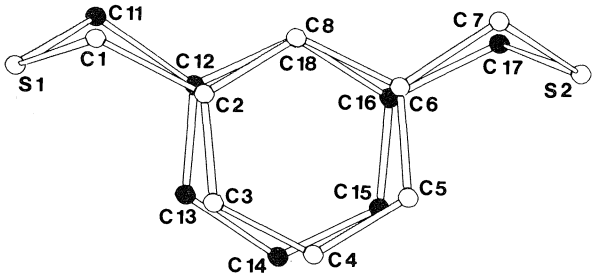

FIG. 3. A single molecule with atom labels, and the carbon atoms of the lower ring blackened.

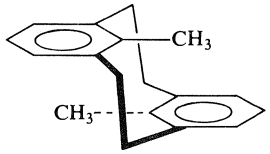
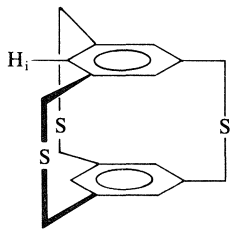
the first to report the preparation of **3***a* in both *syn* and *anti* forms. *Anti*-**3***a* showed in its ^{1}Hmr spectra the internal —CH_3 hydrogens at δ 1.30, shielded by the adjacent benzene ring, whereas the aryl hydrogens were normal at δ 7.0–7.4. *Syn*-**3***a* showed the aryl hydrogens shielded by the adjacent ring at δ 6.66 and the —CH_3 hydrogens normal for a toluene at δ 2.54. This assignment has been confirmed by X-ray data (13). Since *anti*-**3***a* was obtained in the highest yield (5) it was assumed to be the more stable. For the analogous parent compounds **1** (**3**, X = Y = H) no suitable models existed. The internal aryl hydrogens of [2,2]metacyclophane itself, **2**, appeared (7, 15) at δ 4.25, very highly shielded by the opposite benzene rings. Examination of molecular models would predict that H_i in *anti*-**1** would probably not be shielded as much, since they should not be thrust so far into the opposite benzene ring as those in **2**.

Comparison of **4***a* in which the internal —CH_3 hydrogens appear (16) at δ 0.56, with those of *anti*-**3***a* at δ 1.30 (Δδ = 0.74), might crudely suggest that H_i for *anti*-**1** would appear at ca. δ 5.0. Correspondingly H_i for *syn*-**1** might have been expected to be fairly normal and close to δ 7 (as they were in the higher oligomers (5)). Since H_i for **1** actually appear at δ 6.82 ($CDCl_3$, 10°C) with hindsight, the contribution of the *anti*-conformer might have been calculated as small (<10%).



4*a*

Now, however, more suitable models are available for comparison. The *syn*-tris-bridged cyclophane **5**



5

has now been reported and for this H_i appeared at δ 6.90 (17) and δ 6.91 (18). This provides an excellent model for H_i of *syn*-**1**. A good model for *anti*-**1** is *anti*-**3***b* (X = H, Y = CH_3) in which H_i appeared at δ 5.50 (19) and δ 5.59 (20). Clearly H_i for **1** are almost identical in chemical shift to those of **5**. Further the remaining aryl hydrogens of **1** at δ 6.91 are clearly shielded from normal benzene hydrogens, consistent with a *syn* structure for **1**. More recently Vögtle *et al.* (21) have reported the ^{1}Hmr spectra of **3***c* (X = H, Y = NO_2) where H_i appears at δ 7.3 and the remaining aryl hydrogens at δ 6.9 consistent with a *syn* structure for **3***c*. On the other hand **3***d* (X = H, Y = NH_2) exists as the *anti*-conformer since H_i appears at δ 5.0 and the remaining aryl hydrogens at ca. δ 7. Finally, Mitchell (22) has reported the variable temperature ^{1}Hmr spectrum of 2,11-diselena[3,3]metacyclophane **6** in which H_i appear (20°C) at δ 6.46. On cooling to −110°C an *anti*-conformer is formed in which H_i appear at δ 4.50.

Taken collectively this evidence points to the fact that at room temperature 2,11-dithia[3,3]metacyclophane **1** exists in solution, as in the crystalline state, as the *syn*-conformer. We can find no evidence for participation of the *anti*-conformer. On cooling no change in shape of any of the ^{1}Hmr peaks occurs down to $-90°C$ (this work and ref. 3). From Fig. 4 it can be seen that in CS_2 the chemical shift of H_i remains invariant with temperature (as does the shift of the other hydrogens (Table S4)). The behaviour in other solvents is normal (23) and does not indicate a change from one conformer to the other. Consistent with results on other aromatic compounds (24), H_i appear at higher field in toluene (δ 6.50) where stronger π–π interactions occur than in more polar solvents such as DMSO (δ 6.98), see Fig. 4.

Since frequency separations observed from ^{13}Cmr spectra are generally much larger than for ^{1}Hmr, and the Gutowsky–Holm equation (25) which is frequently applied to cyclophanes (see for example refs. 1–3, 22, 36) gives the rate of exchange at coalescence as $k' = \pi\Delta\nu/\sqrt{2}$, we hoped that a low temperature ^{13}Cmr spectrum of **1** might provide further information. Somewhat surprisingly the ^{13}Cmr spectra of the simple dithia[3,3]metacyclophanes have not been reported; however, they are relatively easy to assign in comparison to that published (15) for **2** and measured[4] for **5**, and are shown below in Table 5. (Full data in other solvents are given[3] in Table S5.)

For [2,2](2,7)naphthalenophane **7**, both the *syn*- and *anti*-conformers are known (27). By analogy, the chemical shift difference between the internal aryl carbons for *syn*- and *anti*-**1** is thus predicted to be of the order of 3 ppm (~45Hz). Unfortunately this shift is likely to be somewhat smaller than the corresponding predicted proton shift of 1.5 ppm (~135 Hz) and casts doubt on the ability of ^{13}Cmr data for the ring carbons to provide any more information than ^{1}Hmr. However, for **7**, the difference between the ^{13}C shifts for the bridging methylenes is much larger than for the corresponding ^{1}H shifts. We have also verified this to be true in some of our previously (28) prepared thiacyclophanes which have internal methyl substituents and hence where both *syn*- and *anti*-conformers are known. In the event, the ^{13}Cmr signal due to the bridging methylenes of **1** does collapse at ca. $-100°C$ in CD_2Cl_2. Unfortunately, however, we were not able to find a solvent in which **1** retained some solubility at lower temperatures, and hence could not determine whether a freezing out was occurring of either the possible *syn*-**1** ⇄ *anti*-**1** process, or of the wobbling of bridges (shown below) (3, 17), or scissoring of the rings.

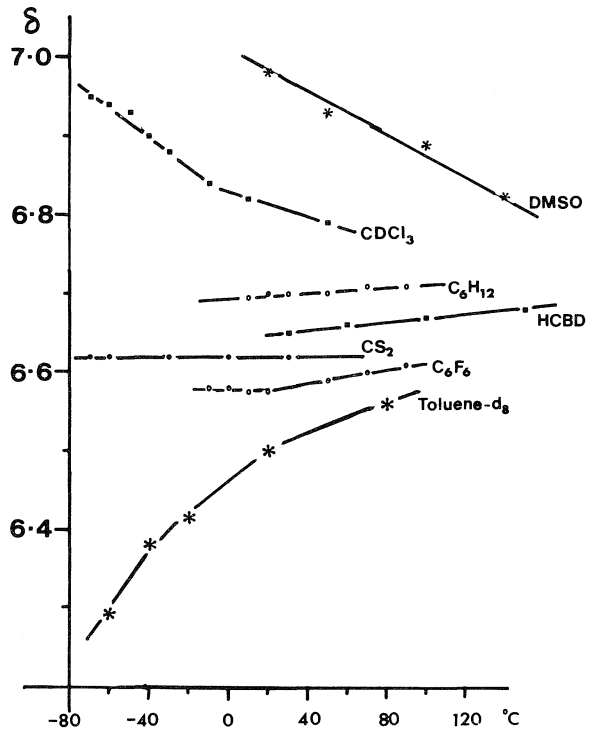


FIG. 4. Chemical shift (δ, ppm) values for H_i of **1** at different temperatures in various solvents.

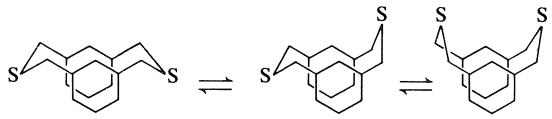
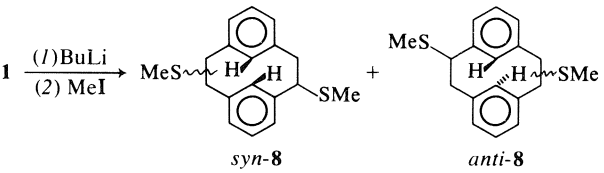


Chemical Reactions of 1

One of the reasons that **1** has been assumed to exist as *syn* ⇄ *anti* conformers is that on Wittig (or Stevens) rearrangement, **1** forms a 4:1, *anti*:*syn* mixture of product isomers **8** (5). It is, in fact, not



syn-**8** *anti*-**8**

necessary that *anti*-**8** has derived from *anti*-**1**, since it is documented (5) that pure *syn*-**3***a* on Wittig or Stevens rearrangement gives *anti* products. Since to our knowledge (see also ref. 20) *syn*-**3***a* is not convertible to *anti*-**3***a*, it is more likely that an intermediate (possibly open, see ref. 5) is isomerised during the course of the reaction.

[4]We thank Prof. Virgil Boekelheide for kindly supplying us with a sample of **5**.

Syn-**7**		$CDCl_3$	127.2	137.8	35.8			(27)

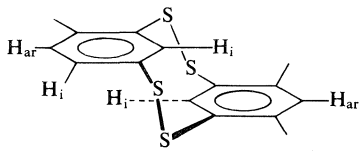
TABLE 6. ^{1}Hmr data (δ) for selected derivatives of **1**

	H_i	H_{ar}	Ref.
	6.58	6.66	29
	6.50	6.58	3
	7.13		4
	6.73 (H_i':6.95)		This work, 30
	6.95		This work, 29
	6.95		This work, 29

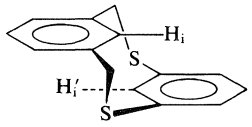
Other Derivatives of 1

There are several derivatives of **1** in the literature which by ^{1}Hmr comparison to **1** should now *all* be assigned as *syn*-conformers. These are presented in Table 6.

There is one [2,2]cyclophane, **9**, which has recently been assigned (31) to be the *anti*-conformer shown. However, in its ^{1}Hmr spectrum, H_i appear at δ 7.88 and H_{ar} at δ 7.01. Given that S—S (203 pm) and C—S (182 pm) bond lengths are longer than C—C (154 pm), and the fact (32) that in **10**, H_i is only deshielded to δ 5.42 from H_i' at δ 4.41, it seems to us most likely that **9** also exists as the *syn*-conformer.



9



10

Conclusions

In the solid state **1** exists as the *syn*-conformer. In solution, ^{1}Hmr data indicate that **1** and a number of its derivatives also exist as the *syn*-conformer, with no appreciable participation of *anti*-**1** either at room temperature, or on cooling to −90°C.

Comment: 7α-Acetoxydihydronomilin and mexicanolide: limonoids from *Xylocarpus granatum* (Koenig)

ANG S. NG
Department of Chemistry, Nanyang University, Singapore 22
AND
ALEX G. FALLIS
Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received September 7, 1979

ANG S. NG and ALEX G. FALLIS. Can. J. Chem. **57**, 3088 (1979).

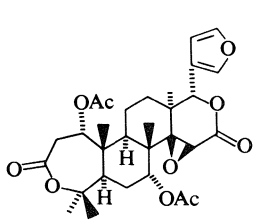
A recent report by the present authors (Can. J. Chem. **56**, 1020 (1978)) of the isolation of 7α-acetoxydihydronomilin from the seeds of *Uncaria gambia* (Roxb.) contains a taxonomic error. The seeds were in fact from *Xylocarpus granatum* (Koenig).

ANG S. NG et ALEX G. FALLIS. Can. J. Chem. **57**, 3088 (1979).

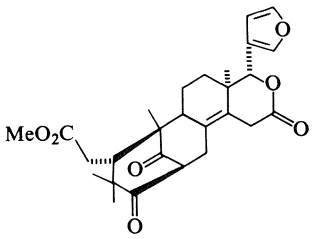
Une erreur taxonomique s'est glissée dans notre récente publication concernant l'isolation de la 7α-acétoxydihydronomiline (Can. J. Chem. **56**, 1020 (1978)). Le produit est extrait de semence de *Xylocarpus granatum* (Koenig) et non de semence de *Uncaria gambia* (Roxb.).
[Traduit par le journal]

In Malaysia extracts of at least two different plant species are used as tanning agents called Gambir. We recently reported (1*a*, see also ref. 1*b*) the isolation and structure elucidation of 7α-acetoxydihydronomilin (**1**) from the seeds of one such species *Uncaria gambia* (Roxb.), a member of the Rubiaceae family.[1] This appeared to be the first example of a limonoid from Rubiaceae and as such, was unexpected as previously limonoids had only been found in the related families Rutaceae, Meliaceae, and Cneoraceae.

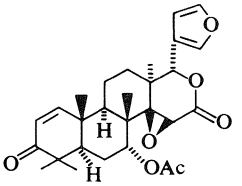
We wish to point out that the seeds we extracted were misidentified and are in fact from *Xylocarpus granatum* (Koenig), a mangrove of the Meliaceae family,[2] an assignment in keeping with their terpene content. In addition to **1** we have isolated (2) the known limonoid mexicanolide (**2**) (3) from these seeds. Earlier Okorie and Taylor (4) identified the structurally related compounds gedunin (**3**), xylocarpin (**4**), and the corresponding Δ^8 olefin from the petroleum ether extracts of *Xylocarpus granatum* (Koenig) seed. Subsequently, examination of unripe seed (originally reported (5) to be *Xylocarpus molluscensis* but established since (6) as *Xylocarpus granatum* (Koenig)) afforded the bitter principle xylomollin as unusual monoterpenoid secoiridoid possessing hemiacetal and acetal functions.



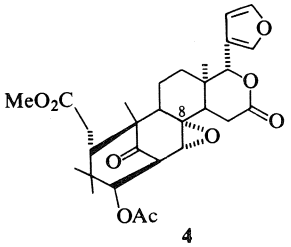
1



2



3



4

[1]7α-Acetoxydihydronomilin has also been isolated from *Cneorum tricoccon* (Linne).

[2]The fruit of *X. granatum* are large, round, and often referred to as "cannon balls." In our sample the largest was similar in size to a soccer ball. One or more tightly packed seeds are contained within this shell or husk. These seeds are easily crushed when fresh but harden and darken upon standing. The dry seeds have a wrinkled appearance and resemble dried prunes in size.

Acknowledgements

We are grateful to Professor D. A. H. Taylor for drawing this taxonomic error to our attention and for a fruitful exchange of correspondence. In addition the National Research Council of Canada is thanked for financial support.

Neutral pyrazolyl-bridged nickel nitrosyl complexes. Synthesis, structure, and reactivity

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR, AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2075 Wesbrook Mall, Vancouver, B.C., Canada V6T 1W5

Received June 28, 1979

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **57**, 3090 (1979).

A series of neutral pyrazolyl-bridged nickel nitrosyl complexes, $[LNi(NO)]_2$ (where L = pyrazolyl, $N_2C_3H_3$; 3,5-dimethylpyrazolyl, $N_2C_5H_7$; or 3,5-di-*tert*-butylpyrazolyl, $N_2C_{11}H_{19}$), is described. The nickel atoms are susceptible to nucleophilic attack and the reactivity of the dimers with neutral donor ligands is reported. In addition to the dimeric molecules a novel trimetallic nickel compound $[(ON)Ni(N_2C_5H_7)_2]_2Ni$ has also been isolated. Crystals of $[Ni(NO)(N_2C_5H_7)]_2$ are monoclinic, $a = 18.925(2)$, $b = 11.012(1)$, $c = 7.037(2)$ Å, $\beta = 100.93(1)°$, $Z = 4$, space group $C2/c$ and crystals of $[(ON)Ni(N_2C_5H_7)_2]_2Ni$ are triclinic, $a = 7.4041(7)$, $b = 9.6331(7)$, $c = 9.7595(8)$ Å, $\alpha = 85.698(9)$, $\beta = 73.174(8)$, $\gamma = 76.109(8)°$, $Z = 1$, space group $P\bar{1}$. Both structures were solved by Patterson and Fourier syntheses and were refined by full-matrix least-squares procedures to $R = 0.035$ and 0.028 for 832 and 2128 reflections with $I \geq 3\sigma(I)$ respectively. Nearly planar centrosymmetric molecules of $[Ni(NO)(N_2C_5H_7)]_2$ contain trigonal planar nickel atoms with Ni—N(pyrazolyl) = 1.880(3) and 1.922(3), Ni—NO = 1.616(4), and N—O = 1.158(4) Å, Ni—N—O = 178.9(4)°. This structure also contains an unusually long N—N bond in the pyrazolyl ring (1.463(4) Å). Centrosymmetric molecules of $[(ON)Ni(N_2C_5H_7)_2]_2Ni$ contain a central square-planar Ni(II) atom bonded to four pyrazolyl nitrogen atoms (mean Ni—N = 1.905(1) Å) and two trigonal planar outer nickel atoms coordinated to two pyrazolyl nitrogen atoms (mean Ni—N = 1.922(3) Å) and to a somewhat bent nitrosyl group (Ni—N = 1.625(3), N—O = 1.153(4) Å, Ni—N—O = 168.9(3)°).

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **57**, 3090 (1979).

On décrit une série de complexes neutres de nitrosyle nickel avec le nickel en position de pont par rapport au pyrazolyle $[LNi(NO)]_2$ (où L = pyrazolyle, $N_2C_3H_3$; diméthyl-3,5 pyrazolyle, $N_2C_5H_7$; ou di-*tert*-butyl-3,5 pyrazolyle, $N_2C_{11}H_{19}$. Les atomes de nickel sont sensibles à une attaque nucléophile et on rapporte la réactivité des dérivés vis-à-vis les ligands donneurs neutres. En plus des molécules dimères, on a également isolé un nouveau composé de nickel trimétallique $[(ON)Ni(N_2C_5H_7)_2]Ni$. Les cristaux de $[Ni(NO)(N_2C_5H_7)]_2$ sont monocliniques: $a = 18.925(2)$, $b = 11.012(1)$, $c = 7.037(2)$ Å, $\beta = 100.93(1)°$, $Z = 4$, groupe d'espace $C2/c$ et les cristaux de $[(ON)Ni(N_2C_5H_7)_2]_2Ni$ sont tricliniques: $a = 7.4041(7)$, $b = 9.6331(7)$, $c = 9.7595(8)$ Å, $\alpha = 85.698(9)$, $\beta = 73.174(8)$, $\gamma = 76.109(8)°$, $Z = 1$, groupe d'espace $P\bar{1}$. On a résolu les deux structures à l'aide de synthèses de Patterson et de Fourier et on les a affinées par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs respectives de $R = 0.035$ et 0.028 pour 832 et 2128 réflexions avec $I \geq 3\sigma(I)$. Les molécules de $[Ni(NO)(N_2C_5H_7)]_2$, sensiblement planes et centrosymétriques, contiennent des atomes de nickel trigonaux plans avec des longueurs de liaisons: Ni—N(pyrazolyle) = 1.880(3) et 1.922(3), Ni—NO = 1.616(4) et N—O = 1.158(4) Å et un angle Ni—N—O = 178.9(4)°. Cette structure contient également une longue liaison N—N dans le cycle pyrazolyle (1.463(4) Å). Les molécules centrosymétriques de $[(ON)Ni(N_2C_5H_7)_2]_2Ni$ contiennent un nickel(II) central quadratique lié aux 4 atomes d'azote du cycle pyrazolyle (i.e. Ni—N = 1.905(1) Å et deux atomes de nickel(II) à l'extérieur trigonaux-plans coordonnés à deux atomes d'azote du cycle pyrazolyle (i.e., Ni—N = 1.922(3) Å et à un groupe nitrosyle légèrement courbé Ni—N = 1.625(3), N—O = 1.153(4) Å, Ni—N—O = 168.9(3)°).

[Traduit par le journal]

Introduction

In our continuing study of pyrazolyl-based ligands (1, 2) our attention has recently been focused on a series of pyrazolyl metal nitrosyl compounds containing bridging bidentate pyrazolyl moieties. The ligating properties of bridging pyrazolyl groups have been reviewed by Trofimenko (3) and recent reports reflecting the current interest in this type of bridging system have included novel η^5-cyclopentadienyl compounds of titanium (4, 5) and nickel (6), binuclear complexes involving palladium and platinum (7), and mono-, bi-, and trinuclear gold derivatives (8). The present paper describes the synthesis of a series of "16-electron" nickel nitrosyl complexes and details their selective acceptor properties towards electron donor molecules. X-ray crystal structures are de-

0008-4042/79/233090-09$01.00/0

scribed for a representative example of the bimetallic complexes prepared and also for the trimetallic compound isolated.

Experimental

Starting Materials

Air-sensitive materials were handled in a glove box under an atmosphere of oxygen-free, dry nitrogen or in a nitrogen-blanketed apparatus. Tetrahydrofuran (THF) was dried by refluxing over sodium/benzophenone and was used immediately following distillation. Benzene was dried by refluxing over molten potassium followed by distillation. Pyrazole and 3,5-dimethylpyrazole (K and K Laboratories) and sodium hydride (Alfa Inorganic) were used as supplied. 3,5-Di-*tert*-butylpyrazole was prepared by a standard route (9). The sodium salts of the three "pyrazole" compounds were prepared by reacting 1:1 mole ratios of sodium hydride and the appropriate pyrazole in THF solution. The solvent was removed and the salts washed with benzene and vacuum dried. Nickel nitrosyl iodide Ni(NO)I was prepared by the method of Haymore and Feltham (10).

Preparation of $[Ni(NO)(N_2C_5H_7)]_2$ *and* $[(ON)Ni(N_2C_5H_7)_2]_2Ni$

Ni(NO)I (2.156 g; 10.0 mmol) and $Na^+N_2C_5H_7^-$ (1.18 g; 10.0 mmol) were mixed together as THF solutions. The resulting blue solution[1] was stirred for 1 h and then the solvent was removed under vacuum. A green solid was isolated and this was soxhlet extracted with benzene solvent for 22 h. The resulting green solution, on cooling, deposited a green crystalline material, $[(ON)Ni(N_2C_5H_7)_2]_2Ni$ (0.05 g; 3.2% yield), which was isolated by filtration and washed with benzene. The filtrate and washings, on removal of solvent by slow evaporation, gave dark green needles of $[Ni(NO)(N_2C_5H_7)]_2$ (1.01 g; 55%).

The $[Ni(NO)(N_2C_3H_3)]_2$ and $[(N_2C_{11}H_{19})Ni(NO)]_2$ dimers were prepared by a similar route using the appropriate sodium "pyrazolide" salt and Ni(NO)I. The yields of these two dimers were 65% and 55% respectively. In these two reactions there was no evidence for the formation of the trimetallic nickel derivatives analogous to the one described above.

Preparation of $[(N_2C_5H_7)Ni(NO)(PPh_3)]_2$

$[Ni(NO)(N_2C_5H_7)]_2$ (0.184 g; 0.5 mmol) was dissolved in THF and solid PPh_3 (0.262 g; 1 mmol) added to the solution. The initial dark green color of the solution gradually changed to a dark blue color. After stirring the reaction mixture overnight the solvent was removed *in vacuo*. The resulting solid was extracted with benzene and the crude material obtained from the benzene solution was recrystallized from benzene/THF to give very dark blue crystals of pure product (0.373 g; 84%).

The $AsPh_3$ complex, $[(N_2C_5H_7)Ni(NO)(AsPh_3)]_2$, was prepared similarly and was isolated as blue–green crystals from benzene solvent in 87% yield. The corresponding compounds containing unsubstituted pyrazolyl bridging moieties, viz. $[(N_2C_3H_3)Ni(NO)(PPh_3)]_2$ and $[(N_2C_3H_3)Ni(NO)(AsPh_3)]_2$, were prepared by analogous reactions and were isolated as purple–blue crystals (yield 47%) and dark blue crystals (yield 52%) respectively.

[1]The blue color at this stage is probably due to the iodide bridged anion $[(ON)Ni(N_2C_5H_7)_2(I)Ni(NO)]^-$ discussed in the following paper.

Preparation of $[Ni(NO)(N_2C_5H_7)]_2 \cdot Ph_2PCH_2CH_2PPh_2$

$[Ni(NO)(N_2C_5H_7)]_2$ dimer (0.202 g; 0.55 mmol) was dissolved in THF and diphos (0.220 g; 0.55 mmol) in the same solvent added to the solution. The dark green solution of the dimer immediately became dark blue. After stirring for about 1 h the solvent was removed *in vacuo*. The dark blue solid obtained was recrystallized from THF/benzene to give the pure product, a blue crystalline material, in high yield.

Reactions of $[Ni(NO)(N_2C_5H_7)]_2$ *with Nitrogen Donor Species*

(a) $N_2C_5H_8$, *3,5-Dimethylpyrazole*

The dimer (0.184 g; 0.50 mmol) reacted with 3,5-dimethylpyrazole (0.096 g; 1.00 mmol) in THF solution to give a blue solution which on work-up gave a blue crystalline solid (0.186 g; 67%). This solid product, $[(N_2C_5H_7)Ni(NO)(N_2C_5H_8)]_2$, appeared indefinitely air-stable at room temperature and solutions, kept under a nitrogen atmosphere, remained blue.

(b) Pyridine, py

A solution (green color) of the dimer, $[Ni(NO)(N_2C_5H_7)]_2$, was treated with an excess of pyridine. The solution turned blue and on removal of solvent and excess ligand a blue solid was obtained. Attempted recrystallization by evaporation of benzene solution gave only the green dimer starting material. Even the crude blue solid out of THF slowly turned green, indicating ready loss of the pyridine ligand. Benzene (^1H nmr) and cyclohexane (ir) solutions of the crude product changed color from blue to green on standing, even under an atmosphere of nitrogen. The ir spectrum of a Nujol mull sample of the "blue solid" showed the presence of coordinated pyridine with characteristic bands at 1600, 635, and 436 cm^{-1} (11–13). The ν_{NO} region showed two bands, a medium shoulder at $\sim$1800 cm^{-1} and a strong main band at 1740 cm^{-1}. The band at 1800 cm^{-1} could well be due to the presence of free dimer in the sample caused by loss of pyridine before and during sample preparation. The ^1H nmr in C_6D_6 showed one signal for the 3,5 Me groups attached to the pyrazolyl moieties but the presence of "free" dimer is again evident from an integration of the various signals. The ready loss of pyridine from the blue solid adduct hampered all attempts to obtain a reasonable analytical analysis for the compound.

(c) Trimethylamine, Me_3N

The $[Ni(NO)(N_2C_5H_7)]_2$ dimer in THF solution displayed a color change from green to blue on treatment with Me_3N at low temperature ($\sim -78°C$). At room temperature the solution turned green and on removal of solvents and volatiles the starting material was recovered. These observations indicate a possible weak coordination of the amine at low temperature in solution.

Attempted Reactions of $[Ni(NO)(N_2C_5H_7)]_2$ *with Other Donors*

Attempted coordination of carbon monoxide or diphenylacetylene to the dimer species did not lead to indicative color changes in THF solutions of the dimer. On removal of solvent and unreacted "ligands" the dimer was quantitatively recovered in both experiments.

Spectra

Mass spectra were recorded on a Varian MAT CH4 mass spectrometer at 70 eV with an ion source temperature of 100–180°C. Infrared spectra were recorded on a Perkin-Elmer 457 spectrophotometer and ^1H nmr spectra on a Varian XL-100 spectrometer. For complexes of low solubility ^1H nmr spectra were obtained using FT techniques. Analytical and spectral data appear in Table 1.

X-ray Crystallographic Analyses

Bis(μ-3,5-dimethylpyrazolyl(N,N′))bis(nitrosylnickel(I))

The crystal chosen was mounted in a general orientation and had dimensions of ca. 0.068 × 0.150 × 0.625 mm. Unit-cell parameters were refined by least squares on 2 sin θ/λ values for 48 reflections measured on a diffractometer with Mo K_α radiation (λ = 0.71073 Å). Crystal data (at 22°C) are:

$C_{10}H_{14}N_6Ni_2O_2$ fw = 367.68

Monoclinic, a = 18.925(2), b = 11.012(1), c = 7.037(2) Å, β = 100.93(1)°, V = 1439.9(4) Å^3, Z = 4, ρ_c = 1.696 g cm^{-3}, $F(000)$ = 752, μ(Mo K_α) = 25.4 cm^{-1}. Absent reflections: hkl, $h + k \neq 2n$, $h0l$, $l \neq 2n$. Space group $C2/c$ (C_{2h}^6, No. 15) from structure analysis.

Intensities were measured with graphite monochromatized Mo K_α radiation on an Enraf-Nonius CAD4-F diffractometer. An ω scan at 0.91–5.03° min^{-1} over a range of (0.65 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of 3 check reflections, measured every 3600 s throughout the data collection, remained constant to within ±2.5%. After data reduction, an absorption correction was applied using the Gaussian integration method (14, 15). Transmission factors ranged from 0.634 to 0.852. Of the 1632 independent reflections measured, 852 (52%) had intensities greater than 3σ(I) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = background count.

Analysis was initiated in the centrosymmetric space group $C2/c$ on the basis of the E-statistics. The coordinates of the Ni atom were determined from the three-dimensional Patterson function and those of the other non-hydrogen atoms from a subsequent difference map. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to R = 0.046, a difference map gave positions for all seven hydrogen atoms which were included in subsequent cycles of refinement with isotropic thermal parameters. The scattering factors of ref. 16 were used for non-hydrogen atoms and those of ref. 17 for hydrogen atoms. Anomalous scattering factors from ref. 18 were used for the Ni atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. Convergence was reached at R = 0.035 and R_w = 0.043 for 852 reflections with $I \geq 3\sigma(I)$. For all 1632 reflections R = 0.095 and R_w = 0.052.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.02 and 0.20σ, respectively. The mean error in an observation of unit weight was 1.1556. The final positional and thermal parameters appear in Tables 2 and 3[2] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

Bis[bis(3,5-dimethylpyrazolyl)nitrosylniccolate(I)(N′,N′)]-nickel(II)

Details of the structure analysis are the same as for $[Ni(NO)(N_2C_5H_7)]_2$ except where noted. Crystal dimensions were 0.173 × 0.233 × 0.140 mm. Forty-nine reflections were used in the refinement of the unit-cell parameters. Crystal data are:

$C_{20}H_{28}N_{10}Ni_3O_2$ fw = 616.64
Triclinic, a = 7.4041(7), b = 9.6331(7), c = 9.7595(8) Å, α = 85.698(9), β = 73.174(8), γ = 76.109(8)°, V = 646.8(1) Å^3, Z = 1, ρ_c = 1.583 g cm^{-3}, $F(000)$ = 318, μ(Mo K_α) = 21.9 cm^{-1}. Absent reflections: none. Space group $P\bar{1}$ (C_i^1, No. 2) from structure analysis.

An ω–θ scan at 0.91–5.03 min^{-1} over a range of (0.60 + 0.35 tan θ°) in ω was employed. Of 2925 independent reflections measured (to 2θ = 55°), 2128 (73%) had intensities greater than 3σ(I) above background. The intensities of the check reflections remained constant to within ±1%. An absorption correction was applied, transmission factors ranging from 0.580 to 0.750.

The coordinates of the Ni atoms were determined from the three-dimensional Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference map. Refinement of the non-hydrogen atoms with anisotropic thermal parameters gave R = 0.038. All 14 hydrogen atoms were located from a difference map calculated at this point and were included in subsequent cycles of refinement with isotropic thermal parameters. Convergence was reached at R = 0.028 and R_w = 0.036 for 2128 reflections with $I \geq 3\sigma(I)$. For all 2925 reflections R = 0.051 and R_w = 0.040. The mean and maximum parameter shifts on the final cycle of refinement corresponded to 0.13 and 1.67σ, respectively. The mean error in an observation of unit weight was 1.1405. Final difference maps for both structures were essentially featureless, showing maximum deviations of ±0.3 e Å^{-3}.

The thermal motions of both molecules have been analysed in terms of the rigid-body modes of translation, libration, and screw motion (19) using the computer program MGTLS. For both molecules (rms σU_{ij} = 0.0025 and 0.0013 Å^2 respectively) analysis of all non-hydrogen atoms except the nitrosyl oxygen atoms gave rms ΔU_{ij} = 0.0059 and 0.0045 Å^2 respectively and physically reasonable rigid-body parameters. For $[(ON)Ni(N_2C_5H_7)_2]_2Ni$ some independent motion was noted for the nitrosyl nitrogen and methyl carbon atoms. The appropriate bond distances have been corrected for libration (20), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths for both molecules appear along with the uncorrected values in Table 4. Corrected bond angles do not differ by more than 1σ from the uncorrected values in Table 5. Torsion angles in the six-membered Ni_2N_4 chelate rings are given in Table 6.

Results and Discussion

In contrast to nickel nitrosyl iodide, an air-sensitive solid (10), the green crystalline pyrazolyl bridged nickel nitrosyl dimers, the trimetallic nickel complex, and the majority of their adducts formed with neutral donor ligands, are all air-stable solids. However, solutions of both the parent compounds and their adducts are very air-sensitive and rapidly

[2]The structure factor table and Table 3 (thermal parameters) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

lose their color on exposure to the atmosphere with concomitant loss of the ν_{NO} band in their ir spectra and deposition of a white solid.

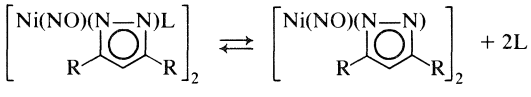
It is evident from the ^1H nmr results (Table 1) that the dimeric compounds have either a planar central, Ni—(N—N)$_2$—Ni, six-membered ring, or this ring is in a boat conformation. Either arrangement would allow delocalization of six π-electrons in both pyrazolyl groups in the molecule. A planar Ni_2N_4 arrangement has been established for the $[Ni(NO)(N_2C_5H_7)]_2$ dimer in the solid state through a crystal structure analysis (see below).

Infrared Spectra

The ν_{NO} bands for the compounds studied are listed in Table 1. The parent dimers (cyclohexane and Nujol) and the trimetallic compound (Nujol) display one ν_{NO} band in their spectra. With increasing steric crowding on the "pyrazolyl" fragment there is a significant shift in ν_{NO} values to lower wave numbers. This shift could result from increased back-bonding from the Ni atoms to the NO groups as a result of a charge build-up on the Ni atoms caused by an inductive effect from the 3,5 substituents on the "pyrazolyl" moieties.

The adducts display one ν_{NO} band in their Nujol mull spectra but two clearly resolved bands in their ir spectra in cyclohexane solution. This may indicate that the two ligands are occupying a *cis* arrangement in the complexes since a *trans* arrangement would be expected to give one ν_{NO} band in the ir (21, 22). In this case, the most likely arrangement for these adducts is one in which the central Ni_2N_4 ring remains planar, with the two NO groups below this plane and the two donor molecules above this plane. Each Ni atom would then acquire pseudo-tetrahedral geometry.

An alternate explanation is that the adducts dissociate in solution and that the two bands in solution arise from the parent and the adduct.



In this case, the adducts would be expected to occupy a *trans* arrangement (one ν_{NO} band due to the ad-

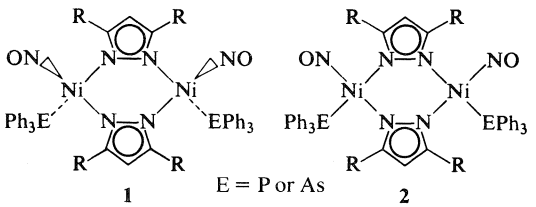
duct). The one exception is the diphos complex which is sterically forced to adopt a *cis* arrangement.

^1H Nuclear Magnetic Resonance Spectra

The spectra (Table 1) for the dimers are consistent with a planar Ni_2N_4 ring for these complexes in C_6D_6 solution. The bis-adduct compounds with PPh_3 and $AsPh_3$ gave simple spectra suggestive of very symmetrical structures in solution. A pseudo-tetrahedral arrangement about the nickel atoms **1** rather than a square-planar one **2** is imperative since the latter arrangement, whether *cis* or *trans*, would lead to two signals for the 3,5 substituents on the pyrazolyl groups. On the other hand, a tetrahedral arrangement about the Ni atoms, as in **1**, satisfactorily accounts for the observed spectra, whatever the arrangement of the NO and EPh_3 groups. Thus if the NO groups are *cis* (as suggested by the ir spectra in cyclohexane solution) the spectra could be explained if the central six-membered ring were planar or in a boat conformation which was either static or rapidly inverting on the nmr time scale. If the NO groups are *trans* then again the central Ni_2N_4 ring may be planar or in a boat conformation but, if the latter, then a rapid inversion process on the nmr time scale is a premise necessary to explain the observed spectra.



1 E = P or As 2

The ^1H nmr spectrum of the diphos derivative (diphos = $(Ph_2PCH_2)_2$) displays one signal for the 3,5 Me substituents on the pyrazolyl rings, consistent with a very symmetrical structure with a bridging diphos ligand between the two Ni atoms.

The ^1H nmr spectrum of the $[(N_2C_5H_7)Ni(NO)(N_2C_5H_8)]_2$ adduct shows, as expected, one signal for the 3,5 Me substituents on the bridging pyra-

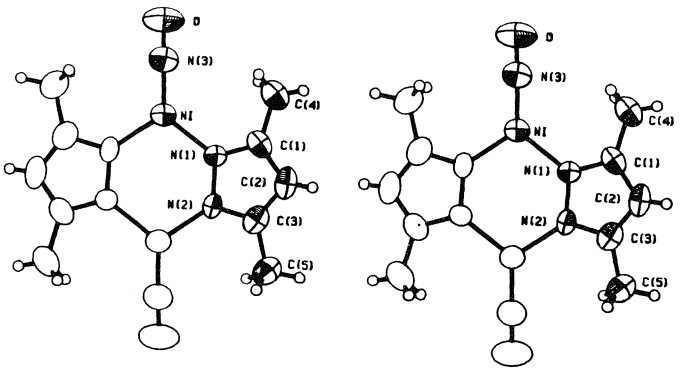


FIG. 1. Stereo view of the bis(μ-3,5-dimethylpyrazolyl(*N*,*N*′))bis(nitrosylnickel(I)) molecule, 50% ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been assigned artificially small thermal parameters for the sake of clarity.

zolyl moieties and two separate signals for the 3,5 Me groups on the donor $N_2C_5H_8$ molecules.

Mass Spectra

The parent dimer complexes all showed strong parent-ion peaks in their mass spectra at about 20% the intensity of the strongest peak due to the parent ion minus two NO groups. The parent ion minus one NO group also gave a prominent signal (35%). The bis-adduct complexes did not display parent ion signals but, rather, gave spectra similar to the parent dimer molecules plus additional signals due to the ligands. Evidently the adducts are not sufficiently thermally stable to withstand the necessary probe temperatures employed (120°C).

The trimetallic compound displayed in its mass spectrum strong signals due to the trimetallic parent ion, parent ion minus one NO group, and parent ion minus two NO groups (strongest signal). In addition a signal corresponding to the doubly charged parent ion minus two NO groups was observed. Noteworthy in this spectrum was the presence of weak signals due to ions from the $[Ni(NO)(N_2C_5H_7)]_2$ dimer. The presence of this dimer must arise from a rearrangement process in the mass spectrometer as there is no evidence for the presence of this compound in the analytically pure trimetallic starting material.

In all the mass spectra the relative intensities of the individual peaks in multi-line signals corresponded closely to those predicted on the basis of the natural isotope composition of elemental nickel.

Crystal Structures of $[Ni(NO)(N_2C_5H_7)]_2$ *and* $[(ON)Ni(N_2C_5H_7)_2]_2Ni$

Both structures provide rare examples of three-coordinate nickel and are the first trigonally coordinated metal nitrosyl complexes to be structurally characterized. The nickel π-complexes $Ni[(CH_3)_3CN{=}C{=}C(CN)_2][(CH_3)_3CNC]_2$ (23), $Ni[P(C_6H_4CH_3)_3]_2(C_6H_5N{=}NC_6H_5)$ (24), and $Ni[P(C_6H_4CH_3)_3]_2(C_6H_5(H)C{=}CHC_6H_5)$(25) have trigonal coordination if the π-donating ligand is considered as being monodentate.

$[Ni(NO)(N_2C_5H_7)]_2$

The crystal structure of $[Ni(NO)(N_2C_5H_7)]_2$ consists of discrete centrosymmetric molecules (Fig. 1) separated by normal van der Waals distances. With the exception of the methyl hydrogen atoms, the molecule is planar within ±0.04 Å and has a Ni. . .Ni′ separation of 3.673(1) Å. Both the central Ni_2N_4 and pyrazolyl rings are slightly, but significantly, non-planar (χ^2 = 8.1 and 20.6, maximum deviations = 0.005(3) and 0.012(4) Å respectively).

The coordination geometry about the nickel is distorted trigonal planar with N—Ni—NO angles of 128.3(2) and 123.3(2)° and an N(1)—Ni—N(2)′ angle of 108.4(1)°. The Ni atom is displaced 0.0061(6) Å from the plane of its substituents. The two Ni—N(pyrazolyl) distances (1.922(3) and 1.880(3) Å) differ by 10σ. Such differences between chemically equivalent bond distances and angles have been noted in other electronically similar tetrahedral $\{NiNO\}^{10}$ complexes (26–28). The nitrosyl group is linearly coordinated (Ni—N—O = 178.9(4)°) and the Ni—NO distance of 1.616(4) Å is intermediate between the values of 1.581(12) Å for the linearly coordinated nitrosyl in the tetrahedral cationic species $Ni(NO)[P(OCH_2)_3CCH_3]^+$ (29) and values of 1.648(5) and 1.686(7) Å for the bent nitrosyls in the tetrahedral complexes $Ni(X)(NO)[P(C_6H_5)_3]_2$ where X = NCS^- (26) and N_3^- (27).

Another unusual feature of the structure of $[Ni(NO)(N_2C_5H_7)]_2$ is the N(1)—N(2) bond length which, at 1.463(4) Å, is considerably longer than the values of 1.33–1.39 Å usually observed for such bonds (refs. 1, 30 and references therein). This may be due to the near planarity of the molecule which allows a *pπ–dπ* interaction between the pyrazolyl π

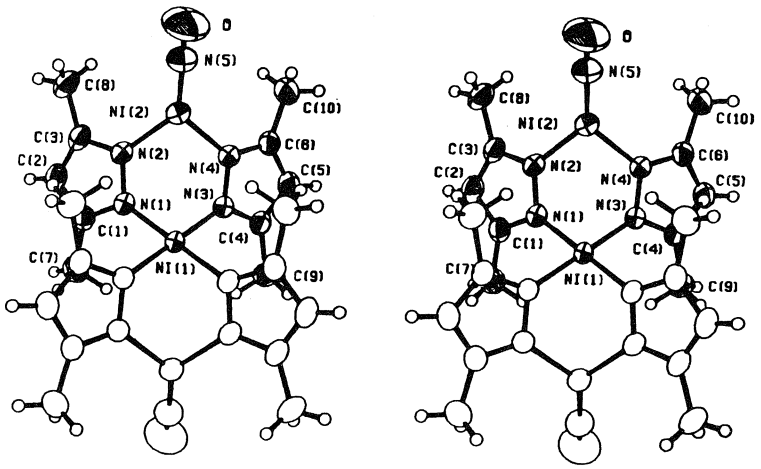

FIG. 2. Stereo view of the bis[bis(3,5-dimethylpyrazolyl)nitrosylniccolate(I)(*N',N'*)]nickel(II) molecule, 50% ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been assigned artificially small thermal parameters for the sake of clarity.

system and filled *d* orbitals on Ni. Back-donation into antibonding π^* orbitals of the pyrazolyl system may be responsible for the observed lengthening of the N—N bond. Other bond lengths in the molecule are normal.

[(ON)Ni($N_2C_5H_7$)$_2$]$_2$Ni

The crystal structure of [(ON)Ni($N_2C_5H_7$)$_2$]$_2$Ni consists of discrete centrosymmetric trinuclear molecules (Fig. 2) separated by normal van der Waals distances. Each molecule contains a central square-planar nickel(II) coordinated to four pyrazolyl nitrogen atoms, and two approximately trigonal planar outer nickel(I) centres coordinated by a nitrosyl group and two pyrazolyl nitrogen atoms. The distorted boat conformation observed for the Ni_2N_4 chelate rings (see Table 6 for torsion angles) and the overall molecular shape is similar to that observed in the complexes [$Me_2Ga(N_2C_3H_3)_2]_2M$, where M = Ni (31) and Cu (32). Attempts to isolate [$Me_2Ga(N_2C_5H_7)_2]_2$Ni failed but a tetrahedral Cu derivative was isolated and its structure has been determined (32). The difference between [(ON)Ni-($N_2C_5H_7$)$_2$]$_2$Ni and the [$Me_2Ga(N_2C_5H_7)_2]_2M$ complexes is the much less restrictive steric requirement of the trigonally coordinated outer Ni atoms as compared to the tetrahedral "$GaMe_2$" groups of the earlier complexes. Thus a square-planar central atom is accommodated in the present structure, with the NO groups extending well away from the central nickel atom and the pyrazolyl methyl groups. Such an arrangement is evidently much less favorable with tetrahedrally coordinated outer atoms as interference with these methyl groups is inevitable.

The central Ni(1) atom has nearly ideal square-planar coordination geometry with unique N—Ni—N angles of 89.70(8) and 90.30(8)°. The mean Ni(1)—N distance of 1.905(1) Å is similar to the value of 1.895(4) Å in [$Me_2Ga(N_2C_3H_3)_2]_2$Ni (31). Trigonally coordinated Ni(2) is displaced 0.0355(3) Å from the plane of its substituents (away from Ni(1)) and has N—Ni—NO angles of 131.1(1) and 131.7(1)° and an N(2)—Ni(2)—N(4) angle of 97.09(8)°. The mean Ni(2)—N(pyrazolyl) bond length of 1.922(3) Å is the same as the longer of the two such bonds in [Ni(NO)($N_2C_5H_7$)]$_2$. The Ni(2)—NO distance of 1.625(3) Å is slightly, but not significantly, longer than the corresponding distance in [Ni(NO)(N_2-C_5H_7)]$_2$ and the nitrosyl grouping is bent (Ni—N—O = 168.9(3)°). The large differences between chemically equivalent bond lengths and angles at the three-coordinate nickel noted for [Ni(NO)(N_2-C_5H_7)]$_2$ are not found in [(ON)Ni($N_2C_5H_7$)$_2$]$_2$Ni. The transition from a nearly planar Ni_2N_4 ring in [Ni(NO)($N_2C_5H_7$)]$_2$ to the distorted boat conformation in [(ON)Ni($N_2C_5H_7$)$_2$]$_2$Ni results in a closer approach of the Ni atoms (Ni(1). . .Ni(2) = 3.3770(3) Å) and a decrease in the intra-annular bond angle at the three-coordinate nickel (from 108.4(1) to 97.09(8)°).

The pyrazolyl ring containing N(1) is planar within experimental error (χ^2 = 2.2) while the second such ring is slightly, but significantly, non-planar (χ^2 = 18.6, maximum deviation = 0.007(3) Å). The Ni atoms are significantly displaced from both pyrazolyl mean planes (Ni(1) by 0.3123(4) and −0.2974(3), Ni(2) by −0.2359(4) and 0.2258(3) Å). The pyrazolyl N—N bonds (mean 1.380(2) Å) are normal and the pyrazolyl planes make angles of 38° with the mean plane of the three-coordinate nickel atom,

effectively eliminating the possibility of $d\pi \rightarrow p\pi$-(pyrazolyl) back donation which may be responsible for the unusually long N—N bond in $[Ni(NO)(N_2C_5H_7)]_2$.

Anionic pyrazolyl-bridged nickel nitrosyl complexes. Synthesis, structure, and reactivity

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR, AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2075 Wesbrook Mall, Vancouver, B.C., Canada V6T 1W5

Received June 28, 1979

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **57**, 3099 (1979).

A series of anionic pyrazolyl-bridged nickel nitrosyl complexes, $M^+[(ON)Ni(\mu\text{-}L_2)(\mu\text{-}X)Ni(NO)]^-$ (where L = pyrazolyl, $N_2C_3H_3$, or 3,5-dimethylpyrazolyl, $N_2C_5H_7$; X = Cl, Br, I, or $N_2C_5H_7$; and M = Na, $(CH_3)_4N$, or $(C_2H_5)_4N$) is described. Crystallographic analyses have been carried out on two of these complexes. Crystals of $[(C_2H_5)_4N]^+[(ON)Ni(\mu\text{-}I)(\mu\text{-}N_2C_5H_7)_2Ni(NO)]^-$ are orthorhombic, $a = 19.910(1)$, $b = 14.0330(7)$, $c = 9.3195(9)$ Å, $Z = 4$, space group $Pn2_1a$ and crystals of $[(C_4H_8O)_2Na][(ON)Ni(\mu\text{-}N_2C_5H_7)_3Ni(NO)]$ are orthorhombic, $a = 19.897(2)$, $b = 19.529(3)$, $c = 15.894(2)$ Å, $Z = 8$, space group $Pbca$. Both structures were solved by Patterson and Fourier syntheses and were refined by full-matrix least-squares procedures to $R = 0.027$ and 0.057 for 2572 and 2168 reflections with $I \geq 3\sigma(I)$ respectively. The structure of $[(C_2H_5)_4N]^+[(ON)Ni(\mu\text{-}I)(\mu\text{-}N_2C_5H_7)_2Ni(NO)]^-$ consists of discrete cations and binuclear anions which have approximate C_{2v} symmetry. The nickel atoms have distorted tetrahedral coordination geometry. Important mean molecular dimensions (distances corrected for libration) are: Ni—I—Ni, 73.67(2)°, Ni—I, 2.765(3), Ni—NO, 1.649(5), Ni—N(pyrazolyl), 1.980(14) Å, and Ni—N—O, 172.5(18)°. The structure of $[(C_4H_8O)_2Na][(ON)Ni(\mu\text{-}N_2C_5H_7)_3Ni(NO)]$ consists of discrete ion-pair units in which the two NiNO moieties are bridged by three $N_2C_5H_7$ ligands, two of which are coordinated to the sodium ion via a novel $\eta^2(N,N)$ π-interaction (mean Na—N = 2.61(3) Å). The sodium is also coordinated to two tetrahydrofuran oxygen atoms to give a distorted tetrahedral coordination geometry about the sodium (Na—O = 2.301(6) and 2.266(5) Å). Except for disordered tetrahydrofuran carbon atoms, the molecular unit has approximate C_{2v} symmetry. The nickel atoms have distorted tetrahedral coordination geometry, the mean distances being Ni—NO, 1.591(6), Ni—N(pyrazolyl), 1.985(2) for the unique pyrazolyl group and 2.016(5) Å for the pyrazolyl nitrogen atoms coordinated to Na. The mean Ni—N—O angle is 176.9(11)°.

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **57**, 3099 (1979).

On décrit une série de complexes anioniques de nickel nitrosyle pyrazolyle avec le Ni en position de pont $M^+[(ON)Ni(\mu\text{-}L_2)(\mu\text{-}X)Ni(NO)]^-$ (où L = pyrazolyle $N_2C_3H_3$ ou diméthyl-3,5 pyrazolyle $N_2C_5H_7$; X = Cl^-, Br, I ou $N_2C_5H_7$ et M = Na, $(CH_3)_4N$ ou $(C_2H_5)_4N$. On a fait des analyses cristallographiques de deux de ces complexes. Les cristaux de $[(C_2H_5)_4N]^+[(ON)Ni(\mu\text{-}I)(\mu\text{-}N_2C_5H_7)_2Ni(NO)]^-$ sont orthorhombiques: $a = 19.910(1)$, $b = 14.0330(7)$, $c = 9.3195(9)$ Å, $Z = 4$, groupe d'espace $Pn2_1a$ et les cristaux de $[(C_4H_8O)_2Na][(ON)Ni(\mu\text{-}N_2C_5H_7)_3Ni(NO)]$ sont orthorhombiques: $a = 19.897(2)$, $b = 19.529(3)$, $c = 15.894(2)$ Å, $Z = 8$, groupe d'espace $Pbca$. On a résolu les deux structures à l'aide des synthèses de Patterson et de Fourier et on les a affinées par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs respectives de $R = 0.027$ et 0.057 pour 2572 et 2168 réflexions avec $I \geq 3\sigma(I)$. La structure de $[(C_2H_5)_4N]^+[(ON)Ni(\mu\text{-}I)(\mu\text{-}N_2C_5H_7)_2Ni(NO)]^-$ consiste en des cations individuelles et des anions binucléaires qui ont une symétrie approximative C_{2v}. La géométrie de coordination des atomes de nickel est de type tétraèdre déformé. Les principales dimensions moléculaires importantes (distances corrigés pour la libration) sont: Ni—I—Ni, 73.67(2)°, Ni—I, 2.765(3), Ni—NO, 1.649(5), Ni—N(pyrazolyle) 1.980(14) Å et Ni—N—O, 172.5(18)°. La structure de $[(C_4H_8O)_2Na][(ON)Ni(\mu\text{-}N_2C_5H_7)_3Ni(NO)]$ consiste en des unités individuelles de paire d'ions dans lesquelles deux fragments NiNO sont en position de pont entre trois ligands ($N_2C_5H_7$). Deux d'entre-eux sont coordonnés à l'ion sodium par l'intermédiaire d'une nouvelle interaction π $\eta^2(N,N)$ (i.e. Na—N = 2.61(3) Å). L'atome de sodium est également coordonné à deux atomes d'oxygène du tétrahydrofuranne pour donner un complexe de coordination de type tétraèdre déformé; au niveau du sodium (Na—O = 2.301(6) et 2.266(5) Å). A l'exception des atomes de carbone désordonnés du tétrahydrofuranne l'unité moléculaire a approximativement une symétrie C_{2v}. Les atomes de nickel ont une coordination tétraédrique déformée. Les distances principales sont: Ni—NO, 1.591(6), Ni—N(pyrazolyle), 1.985(2) pour l'unique groupe pyrazolyle et 2.016(5) Å pour les atomes d'azote coordonnés au sodium. L'angle principal Ni—N—O est de 176.9(11)°.

Introduction

The preceding paper (1) detailed the synthesis of a series of pyrazolyl-bridged nickel nitrosyl dimers and their reactivity towards various types of neutral donor ligands. This account describes the reactivity of these dimeric "16-electron" nickel complexes towards a number of uninegative anions. These anions act as bidentate four-electron bridging ligands and yield stable salts as products. Crystal structure determinations of two of these salts are presented, viz., $[(C_2H_5)_4N]^+[(ON)Ni(\mu\text{-}I)(\mu\text{-}N_2C_5H_7)_2Ni(NO)]^-$ and $[(C_4H_8O)_2Na][(ON)Ni(\mu\text{-}N_2C_5H_7)_3Ni(NO)]$. In the former structure the anion and cation are well-separated entities in the crystal lattice whereas in the latter structure the sodium ion is intimately attached to the anionic part of the salt.

Experimental

The preceding paper detailed the preparation of the pyrazolyl-bridged nickel nitrosyl dimers which were employed as starting materials in this study (1). Their reactivity towards anionic donor species is detailed below.

Preparation of $[(C_2H_5)_4N]^+[(ON)Ni(\mu\text{-}I)(\mu\text{-}N_2C_5H_7)_2Ni(NO)]^-$

A THF solution of $Na^+N_2C_5H_7^-$ (0.236 g; 2.0 mmol) was added to a stirred THF solution of Ni(NO)I (0.431 g; 2.0 mmol). Solid Et_4NCl (0.165 g; 1.0 mmol) was added to the resulting blue solution and the mixture stirred for 24 h. The solution was filtered and the solvent removed *in vacuo*. Extraction with CH_2Cl_2, filtration, followed by evaporation of solvent gave blue crystals of product. These were washed with methanol followed by ether. The yield of pure product was 61%. Elemental analyses and other analytical data for all compounds prepared are presented in Table 1.

Preparation of $Et_4N^+[(ON)Ni(N_2C_5H_7)_2(Cl)Ni(NO)]^-$

The dimer, $[(N_2C_5H_7)Ni(NO)]_2$, (0.184 g; 0.5 mmol) was dissolved in THF and a methanol solution of $Et_4N^+Cl^-$ (0.083 g; 0.5 mmol) added. The green dimer solution immediately turned blue. Evaporation of the solvent gave blue crystals which were washed successively with methanol and ether.

The analogous bromo compound was prepared similarly from the dimer and $Et_4N^+Br^-$. The pyrazolyl $N_2C_3H_3$ bridged halogen derivatives were synthesized utilizing the $[(N_2C_3H_3)Ni(NO)]_2$ dimer as starting material.

Preparation of $Na^+[(ON)Ni(N_2C_5H_7)_3Ni(NO)]^-$

A THF solution of $Na^+(N_2C_5H_7)^-$ (0.354 g; 3.00 mmol) was added to a stirred solution of Ni(NO)I (0.431 g; 2.0 mmol). Solvent was removed *in vacuo* and the oily residue extracted with benzene and filtered immediately. On evaporation of solvent from the resulting solution, lustrous blue crystals of the product formed.

Spectra

Infrared spectra were recorded on a Perkin-Elmer 457 spectrometer and ^1H nmr spectra on a Varian XL-100 spectrometer. For complexes of low solubility ^1H nmr spectra were obtained using FT techniques.

X-ray Crystallographic Analyses

Tetraethylammonium μ-*Iodo-bis(*μ-*3,5-dimethylpyrazolyl-(N,N′))bis(nitrosylniccolate(I))*

The crystal chosen was mounted in a general orientation and had dimensions of ca. 0.20 × 0.66 × 0.43 mm. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 46 reflections measured on a diffractometer with Mo K_α radiation (λ = 0.71073 Å). Crystal data (at 22°C) are:

$C_{18}H_{34}IN_7Ni_2O_2$ fw = 624.84

Orthorhombic, $a = 19.910(1)$, $b = 14.0330(7)$, $c = 9.3195(9)$ Å, $V = 2603.8(3)$ Å^3, $Z = 4$, $\rho_c = 1.594$ g cm^{-3}, $F(000) = 1264$, $\mu(Mo\ K_\alpha) = 25.2$ cm^{-1}. Absent reflections: $0kl$, $k + l \neq 2n$; $hk0$, $h \neq 2n$; and $0k0$, $k \neq 2n$. Space group $Pn2_1a$ (non-standard setting of $Pna2_1$, C_{2v}^9, No. 33) from structure analysis.

Intensities were measured with graphite monochromatized Mo K_α radiation on an Enraf-Nonius CAD4-F diffractometer. An $\omega - 1.67\theta$ scan at 0.91–6.71° min^{-1} over a range of (0.55 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to $2\theta = 60°$. The intensities of 3 check reflections, measured every 3600 s throughout the data collection, remained constant to within ±3.5%.

After data reduction, an absorption correction was applied using the Gaussian integration method (2, 3). Transmission factors ranged from 0.424 to 0.702. Of the 3923 independent reflections measured, 2572 (65%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = background count.

Systematic absences allow space groups $Pnma$ or $Pn2_1a$, analysis being initiated in the latter on the basis of the E-statistics. The positions of the three heavy atoms were determined from the three-dimensional Patterson function and those of O, N, and C atoms from a subsequent difference map. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to $R = 0.037$, a difference map revealed the positions of 28 of the 34 hydrogen atoms. Ideal positions ($C(sp^2)$—H = 0.95, $C(sp^3)$—H = 0.98 Å) were calculated for all hydrogen atoms, which were assigned isotropic U values 1.1 greater than that of the atom to which they are bonded. Hydrogen atom parameters were kept fixed but their contributions were included in the structure factor calculations. The scattering factors of ref. 4 were used for non-hydrogen atoms and those of ref. 5 for hydrogen atoms. Anomalous scattering factors from ref. 6 were used for the I and Ni atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. An isotropic Type I extinction correction (Thornley–Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (7–9). The final value of q was $3.7(2) \times 10^4$. Convergence was reached at $R = 0.027$ and $R_w = 0.033$ for 2572 reflections with $I \geq 3\sigma(I)$. For all 3923 reflections $R = 0.061$ and $R_w = 0.036$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.09 and 0.64σ, respectively. The mean error in an observation of unit weight was 0.9374. A final difference map showed maximum fluctuations of ±1.5 e Å^{-3} near I and ±0.20 e Å^{-3} in regions away from the heavy atoms. The final positional and thermal parameters appear in Tables 2 and 3[1] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

μ-*(3,5-Dimethylpyrazolyl)*-μ-*[bis(tetrahydrofuran)bis-(*η^2*(N,N)-3,5-dimethylpyrazolyl)sodium(N,N,N′,N′)]bis-(nitrosylnickel(I))*

Details of the structure determination are the same as

[1]The structure factor table and Table 3 (thermal parameters) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

for $[(C_2H_5)_4N]^+[(ON)Ni(\mu\text{-}I)(\mu\text{-}N_2C_5H_7)_2Ni(NO)]^-$ except where noted. Crystal dimensions were 0.4 × 0.4 × 0.5 mm. Twenty-five reflections were used in the refinement of the unit-cell parameters. Crystal data are:

$C_{23}H_{37}N_8NaNi_2O_4$ fw = 690.07
Orthorhombic, a = 19.897(2), b = 19.529(3), c = 15.894(2) Å, V = 6176.0(8) Å^3, Z = 8, ρ_c = 1.484 g cm^{-3}, $F(000)$ = 2640, μ(Mo K_α) = 12.7 cm^{-1}. Absent reflections: $0kl$, $k \neq 2n$; $h0l$, $l \neq 2n$; and $hk0$, $h \neq 2n$ define uniquely the space group $Pbca$ (D_{2h}^{15}, No. 61).

An $\omega - 1.33\theta$ scan at 0.87–6.71° min^{-1} over a range of 0.55 + 0.35 tan θ° in ω was employed. Of 5442 independent reflections measured (to 2θ = 50°), 2168 (39.8%) had intensities greater than $3\sigma(I)$ above background. No absorption correction was made due to irregularity of the crystal surface but in view of the low value of μ, no serious errors should arise.

The coordinates of the nickel atoms were determined from the three-dimensional Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference map. It was apparent that conformational and orientational disorder of the THF carbon atoms was present. The occupancy factors for the disordered carbon atoms were initially estimated from the relative peak heights on a difference Fourier and were later adjusted to give nearly equal isotropic U values. The disordered carbon atoms were refined with isotropic thermal parameters and the remaining non-hydrogen atoms with anisotropic thermal parameters. In view of the paucity of data, no attempt was made to locate hydrogen atoms. Anomalous scattering factors from ref. 6 were used for the Ni atoms. Convergence was reached at R = 0.057 and R_w = 0.074 for 2168 reflections with $I \geq 3\sigma(I)$. For all 5442 reflections R = 0.158 and R_w = 0.084. The mean and maximum parameter shifts on the final cycle of refinement corresponded to 0.22 and 2.2σ respectively and the mean error in an observation of unit weight was 1.6045. A final difference map showed maximum fluctuations of ±0.50 e Å^{-3} in the vicinity of the Ni atoms and ±0.33 e Å^{-3} elsewhere.

The thermal motion in both structures has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (10) using the computer program MGTLS. For $[(C_2H_5)_4N]^+[(ON)Ni(\mu\text{-}I)(\mu\text{-}N_2C_5H_7)_2Ni(NO)]^-$ (rms σU_{ij} = 0.0038 Å^2) analyses of the cation and of the anion less nitrosyl oxygen atoms (rms ΔU_{ij} = 0.0067 and 0.0042 Å^2 respectively) gave reasonable rigid-body parameters. For $[(C_4H_8O)_2Na][(ON)Ni(\mu\text{-}N_2C_5H_7)_3Ni(NO)]$ (rms σU_{ij} = 0.0057 Å^2 for the ordered atoms) analysis of the entire ordered part of the molecule excluding nitrosyl oxygen and methyl carbon atoms gave rms ΔU_{ij} = 0.0146 Å^2 and physically reasonable results. The appropriate bond distances have been corrected for libration (11), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 4 along with the uncorrected values. Corrected bond angles are all within 1σ of the uncorrected values in Table 5.

Results and Discussion

The susceptibility of the nickel dimers towards nucleophilic attack is well illustrated by the ease of

formation of anionic complexes with uninegative nucleophiles. In these reactions the formally "16-electron" nickel atoms acquire an 18-electron configuration. However, as reported in the preceding paper (1) for neutral 18-electron complexes formed by reaction of the nickel dimers with suitable donor molecules, the present anionic complexes, although air-stable as solids, are susceptible to atmospheric attack when in solution. The blue color of the (acetone or methylene chloride) solutions is gradually discharged on exposure of the solutions to air, with concomitant loss of the ν_{NO} band in the ir spectrum, and deposition of a white solid.

The order of stability of the anionic complexes with respect to displacement of one bridging moiety by another in the presence of R_4N^+ cations follows the sequence: I > Br > Cl > $(N_2C_5H_7)$. Thus if I^- is available in the reaction mixture this ion displaces any of the others listed to become the third bridging group accompanying the two pyrazolyl moieties already present in the dinuclear anionic complex ion.

Infrared Spectra

Comparison of the ν_{NO} values (Table 1) for the I, Br, and Cl complexes shows a trend which is opposite to that predicted on simple electronegativity arguments. Thus, on electronegativity grounds the Cl compounds should display the highest ν_{NO} values since shift of electron density from the nickel atoms towards Cl should reduce the $d\pi$–π^* back-bonding from Ni to the NO ligand. The reverse trend observed here has also been noted in related series of compounds (12, 13) and may be attributed to the greater π-acceptor ability of the heavier halogen

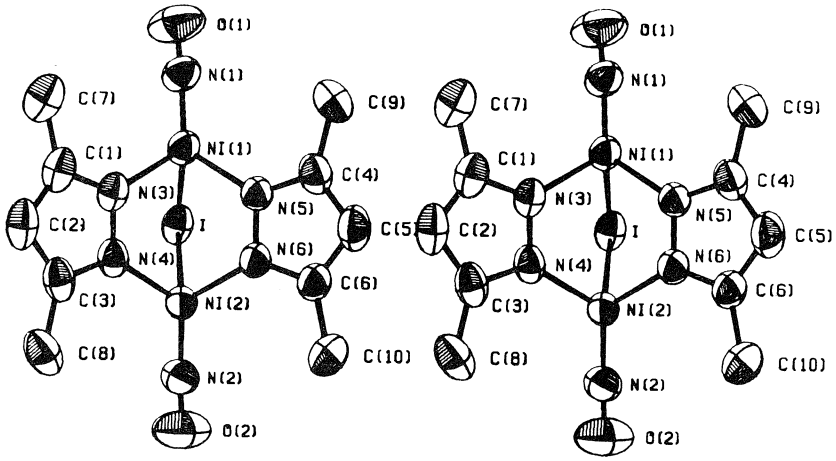

FIG. 1. Stereo view of the $[(ON)Ni(\mu\text{-}I)(\mu\text{-}N_2C_5H_7)_2Ni(NO)]^-$ anion; 50% ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been omitted for the sake of clarity.

ligands, an effect which evidently outweighs the electronegativity effect. There is a noticeable decrease in the ν_{NO} values in going to the 3,5-dimethylpyrazolyl derivatives from the unsubstituted pyrazolyl compounds, presumably caused by an inductive effect of the methyl substituents in the former series of complexes.

^1H Nuclear Magnetic Resonance Spectra

The ^1H nmr spectra of the ionic complexes were recorded in acetone-d^6 solutions. The spectra are entirely in accord with a symmetrically bridged bimetallic anion in solution. Thus the R substituents on the bridging "pyrazolyl" moieties give one sharp signal in the spectra (Table 1). The Et_4N^+ cations give characteristic multiplets with ^{14}N coupling apparent in the CH_3— triplet part of the spectrum but not in the —CH_2— quartet signal.

X-ray Crystallographic Analyses

Tetraethylammonium μ-Iodo-bis(μ-3,5-dimethylpyrazolyl(N,N′))bis(nitrosylniccolate(I))

The crystal structure of $[(C_2H_5)_4N]^+[(ON)Ni(\mu\text{-}I)(\mu\text{-}N_2C_5H_7)_2Ni(NO)]^-$ consists of discrete $(C_2H_5)_4N^+$ cations and binuclear anions (Fig. 1) separated by normal van der Waals distances. The anion contains two NiNO moieties bridged by an iodide and two 3,5-dimethylpyrazolyl ligands and has approximate C_{2v} symmetry. Deviations from ideal C_{2v} symmetry, some of which are significant, are believed to arise primarily from packing forces.

The Ni atoms have distorted tetrahedral coordination geometry, mean[2] angles at Ni (averaged assuming C_{2v} symmetry) being: I—Ni—NO, 116.9(5), I—Ni—N(pz), 93.5(5), N(pz)—Ni—NO, 124.1(8), and N(pz)—Ni—N(pz), 97.1(1)°. The two Ni—I distances of 2.762(1) and 2.767(1) Å are slightly but significantly different and the Ni—I—Ni angle is 73.67(2)°. The Ni---Ni separation is 3.307(1) Å. The four chemically equivalent Ni—N(pz) distances (1.964–1.997(4–5), mean 1.980(14) Å) are significantly different. Such differences between chemically equivalent bonds have been noted in the structures of several other $\{NiNO\}^{10}$ complexes, with both tetrahedral (14, 15 and references therein) and trigonal-planar (1) coordination at Ni. In view of the common observation of this phenomenon, the differences are almost certainly real but, apart from steric factors, no reasonable explanation for this can be given. The mean parameters of the nitrosyl coordination, Ni—N—O = 172.5(18)°, Ni—N = 1.649(5) and N—O = 1.13(1) Å, are near the middle of the observed ranges for these parameters in tetrahedral $\{NiNO\}^{10}$ complexes (14, 15).

Both of the pyrazolyl rings are planar within experimental error (χ^2 = 3.4 and 2.0 for N_2C_3 rings containing N(3) and N(5) respectively) but the nickel and methyl carbon atoms are significantly displaced from both mean planes (N(3) plane: Ni(1), 0.0347(9), Ni(2), −0.0711(8), C(7), −0.031(8), and C(8), 0.016(7) Å; N(5) plane: Ni(1), −0.0706(8), Ni(2), −0.0670(8), C(9), −0.034(8), and C(10), 0.034(8) Å). Other bond lengths and angles are as expected.

μ-(3,5-Dimethylpyrazolyl)-μ-[bis(tetrahydrofuran)-bis(η²(N,N)-3,5-dimethylpyrazolyl)sodium-(N,N,N′,N′)]bis(nitrosylnickel(I))

The structure of $[(C_4H_8O)_2Na][(ON)Ni(\mu\text{-}N_2C_5H_7)_3Ni(NO)]$ consists of discrete ion-pair molecular units (Fig. 2) separated by normal van der Waals distances. If the disordered THF carbon atoms are ignored, the molecule has approximate C_{2v}

[2]Here and elsewhere in this report mean values refer to weighted means with rms deviations from the mean in parentheses.

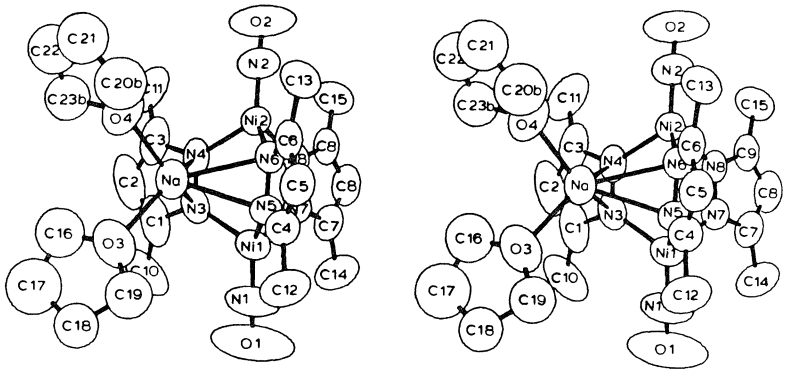

FIG. 2. Stereo view of the μ-(3,5-dimethylpyrazolyl)μ-[bis(tetrahydrofuran)bis(η^2(*N*,*N*)-3,5-dimethylpyrazolyl)sodium-(*N*,*N*,*N*′,*N*′)]-bis(nitrosylnickel(I)) molecule; 50% ellipsoids are shown for the non-hydrogen atoms.

symmetry. The two NiNO moieties are bridged by three 3,5-dimethylpyrazolyl ligands, two of which are also coordinated to sodium via a novel $\eta^2(N,N)$ π-interaction (mean Na—N = 2.61(3), Na—X(1) = 2.531, and Na—X(2) = 2.502 Å, where X(1) and X(2) are the midpoints of the N(3)—N(4) and N(5)—N(6) bonds). Distorted tetrahedral coordination geometry about the sodium is completed by two THF oxygen atoms (Na—O = 2.301(6) and 2.266(5) Å). The shortest Na---C(pz) distance is 3.19(2) Å.

Replacement of the single atom iodide bridge in $[(C_2H_5)_4N]^+[(ON)Ni(\mu\text{-}I)(\mu\text{-}N_2C_5H_7)_2Ni(NO)]^-$ by the two-atom pyrazolyl bridge results in an increase in the Ni---Ni separation from 3.307(1) to 3.439(1) Å in $[(C_4H_8O)_2Na][(ON)Ni(\mu\text{-}N_2C_5H_7)_3Ni(NO)]$. The Ni---Na distances are 3.393(3) and 3.364(3) Å for Ni(1) and Ni(2) respectively. The nickel atoms have distorted tetrahedral coordination geometry with mean angles N(pz)—Ni—NO and N(pz)—Ni—N(pz) of 121(1) and 95.6(9)°. The mean Ni—N(pz) distance involving the pyrazolyl nitrogen atoms coordinated to Na (2.016(5) Å) is significantly longer than the value of 1.985(2) for the other two pyrazolyl nitrogen atoms. The latter distance is in good agreement with the mean Ni—N(pz) distance of 1.980(14) Å in the $[(ON)Ni(I)(N_2C_5H_7)_2Ni(NO)]^-$ anion. The mean parameters of the NiNO group are Ni—N—O = 176.9(11)°, Ni—N = 1.591(6) and N—O = 1.183(8) Å. The short Ni—NO distance is similar to the value of 1.581(12) Å in the $Ni(NO)[P(OCH_2)_3CCH_3]_3^+$ cation (16), which has Ni—N—O = 176.8(2)°.

All three pyrazolyl rings are planar within experimental error (χ^2 = 3.3, 7.3, and 0.2 for N_2C_3 rings containing N(3), N(5), and N(7) respectively). The Ni atoms deviate significantly from all three planes (N(3) plane; Ni(1), 0.0825(8), Ni(2), 0.1273(8); N(5) plane; Ni(1), 0.3042(8), Ni(2) 0.1360(7); N(7) plane; Ni(1), 0.1316(8), Ni(2), −0.0807(7) Å), and the methyl carbon atoms from those planes which interact with the Na (N(3) plane; C(10), 0.04(1), C(11), 0.08(1); N(5) plane; C(12), 0.040(9), C(13), 0.054(7) Å). The deviations of Ni and methyl carbon atoms from the N(3) and N(5) rings are all away from the sodium. Other bond lengths and angles in this structure are as expected.

Acknowledgments

We thank the Natural Sciences and Engineering Council Canada for financial support and the University of British Columbia Computing Centre for assistance. We are grateful to Mr. P. Borda for C, H, N analyses and to Dr. S. Chan for nmr spectra.

Received July 3, 1979

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **57**, 3107 (1979).

Ni(NO)I reacts readily with pyrazolyl gallate ligands Na^+L^- (where L = $MeGa(N_2C_3H_3)_3$, $MeGa(N_2C_5H_7)_3$, and $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]$) to yield four-coordinate nickel nitrosyl complexes, LNi(NO). In addition, the compound $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Ni(N_2C_5H_7)_2Ni(NO)$ has been isolated from one reaction sequence. ^1H nmr data show $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Ni(NO)$ to be stereochemically non-rigid at room temperature in solution. Crystals of [dimethyl(*N*,*N*-dimethylethanolamino)(3,5-dimethylpyrazolyl)gallato(*N*(2),*N*(3),*O*)]nitrosylnickel(I) are monoclinic, a = 9.119(1), b = 13.900(2), c = 14.284(2) Å, β = 107.96(1)°, Z = 4, space group $P2_1/c$. The structure was solved by Patterson and Fourier syntheses and was refined by full-matrix least-squares procedures to R = 0.025 and R_w = 0.032 for 1828 reflections with $I \geq 3\sigma(I)$. The coordination about the nickel atom is severely distorted tetrahedral with angles at nickel ranging from 84.4(1) to 133.5(1)°. The nitrosyl group is coordinated in a non-linear fashion with Ni—N—O = 162.3(4)°, Ni—N = 1.632(4) and N—O = 1.147(4) Å. Other important bond lengths (corrected for libration) are: Ni—O, 2.045(2), Ni—N(pyrazolyl), 1.989(3), Ni—N(amino), 2.071(3), Ga—O, 1.922(2), Ga—N, 1.998(3), and Ga—C, two at 1.971(6) Å.

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **57**, 3107 (1979).

Le Ni(NO)I réagit facilement avec les ligands du type gallate de pyrazolyle Na^+L^- (ou L = $MeGa(N_2C_3H_3)_3$, $MeGa(N_2C_3H_7)_3$ et $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]$) pour donner quatre complexes nitrosylés du nickel tétracoordonnés LNi(NO). On a isolé également le composé $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Ni(N_2C_5H_7)_2Ni(NO)$. Les données de la rmn du ^1H montrent que $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2]Ni(NO)$ est stéréochimiquement non rigide en solution. Les cristaux de [diméthyl(*N*,*N*-diméthyléthanolamino)(diméthyl-3,5 pyrazolyl)gallato(*N*(2),*N*(3),*O*) nitrosyle nickel sont monocliniques: a = 9.119(1), b = 13.900(2), c = 14.284(2) Å, β = 107.96(1)°, Z = 4, groupe d'espace $P2_1/c$. On a résolu la structure par les synthèses de Patterson et de Fourier et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur de R = 0.025 et R_w = 0.032 pour 1828 réflexions avec $I \geq 3\sigma(I)$. La coordination autour de l'atome de nickel est distordue grandement en un tétraèdre avec des angles de 84.4(1) à 133.5(1)°. Le groupe nitrosyle est coordonné de façon non linéaire avec Ni—N—O = 162.3(4)°, Ni—N = 1.632(4) et N—O = 1.147(4) Å. D'autres longueurs importantes de liaison (corrigée pour libration) sont: Ni—O, 2.045(2), Ni—N(pyrazolyl), 1.989(3), Ni—N(amino), 2.071(3), Ga—O, 1.922(2), Ga—N, 1.998(3) et Ga—C, deux à 1.971(6) Å.

[Traduit par le journal]

Introduction

Numerous reports (1–4) have described the synthesis and coordination chemistry of bidentate anionic ligands of the type $Me_2Ga(N_2C_3H_3)_2^-$. More recent publications have discussed the preparations and coordinating properties of the tridentate anionic ligands $MeGa(N_2C_3H_3)_3^-$ (5, 6) and $MeGa(N_2C_5H_7)_3^-$ (7). The coordinating abilities of both the bidentate and tridentate ligands, and the properties of their various transition metal complexes, have been compared with similar boron species described earlier by Trofimenko (8). A significant divergence from the pyrazolyl borate type ligands came with the introduction of unsymmetrical tridentate anionic gallate ligands of the type $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]^-$ (9). These ligands have, as yet, no counterparts in boron chemistry and display unique coordinating properties, very much dependent on the substituents on the pyrazolyl ring and on the amino nitrogen of the ligand (10–12). The present account details our studies on the reactions of Ni(NO)I with the tridentate anionic pyrazolyl gallate ligands $MeGa(N_2C_3H_3)_3^-$, $MeGa(N_2C_5H_7)_3^-$, and $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]^-$. The solid state structure of $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Ni(NO)$ is pre-

0008-4042/79/233107-06$01.00/0

sented and contrasted with the structure of this compound suggested by its room temperature ^1H nmr spectrum in C_6D_6 solution.

Experimental

Starting Materials

Air-sensitive materials were handled in a glove box under an atmosphere of oxygen-free, dry nitrogen or in a nitrogen-blanketed apparatus. Tetrahydrofuran (THF) was dried by refluxing over sodium/benzophenone and was used immediately following distillation. Benzene was dried by refluxing over molten potassium followed by distillation. Ni(NO)I was prepared by the method of Haymore and Feltham (13) and the gallium ligands, Na^+L^-, were prepared as described earlier, L = $MeGa(N_2C_3H_3)_3$ (5), L = $MeGa(N_2C_5H_7)_3$ (7), and L = $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]$ (9, 10).

Preparation of $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Ni(NO)$

Ni(NO)I (0.324 g; 1.5 mmol) was dissolved in THF and a THF solution of $Na^+[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]^-$ (1.63 mmol) was added. The reaction mixture was stirred overnight and the solvent then removed under vacuum. The dark blue residue was extracted with benzene and the mixture filtered. Slow evaporation of the filtrate gave dark blue crystals of the product (0.39 g; 70% yield). An alternate method of purification of this compound was vacuum sublimation at ~80°C. *Anal.* calcd. for $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Ni(NO)$: C 35.5, H 6.2, N 15.1; found: C 35.7, H 6.3, N 14.8. ν_{NO} 1770 cm^{-1} (cyclohexane), 1750 br (Nujol), ^1H nmr (C_6D_6): τ = 3.94s (^4H—pz), 6.53t (CH_2, J = 5 Hz), 7.17s (Me—pz), 7.78s (NMe_2), 7.90s (Me—pz), 8.65t (CH_2, J = 5 Hz), 9.88s ($GaMe_2$) (all τ values refer to $\tau_{C_6H_6}$ = 2.84 ppm, pz = pyrazolyl).

Preparation of $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Ni(N_2C_5H_7)_2Ni(NO)$

Ni(NO)I (0.324 g; 1.5 mmol) was dissolved in THF and a THF solution of the ligand $Na^+[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]^-$ (1.63 mmol) was added. The reaction mixture was stirred for about 10 min and then approximately 1 mL of water was added. The resultant mixture was heated to reflux and oxygen (air) was admitted periodically until a green tinge appeared in the blue solution. After cooling the mixture to room temperature the solvent was removed *in vacuo*. The blue green residue was extracted with benzene and filtered. After several recrystallizations from benzene/heptane mixtures, dark green air-sensitive crystals were isolated in about 20% yield. *Anal.* calcd. for $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Ni(N_2C_5H_7)_2Ni(NO)$: C 40.6, H 6.0, N 18.0; found: C 40.7, H 6.0, N 17.7. ν_{NO} 1790 cm^{-1} (Nujol).

Preparation of $MeGa(N_2C_5H_7)_3Ni(NO)$

Ni(NO)I (0.311 g; 1.44 mmol) was dissolved in THF and an aliquot of $Na^+MeGa(N_2C_5H_7)_3^-$ in THF (1.45 mmol) added with stirring. The mixture was stirred overnight and the solvent then removed *in vacuo*. The blue solid was recrystallized from benzene to give a well formed blue crystalline product (yield ~60%). *Anal.* calcd. for $MeGa(N_2C_5H_7)_3Ni(NO)$: C 41.9, H 5.2, N 21.4; found: C 41.6, H 5.3, N 20.7. ν_{NO} 1785 cm^{-1} (cyclohexane), 1765 cm^{-1} (Nujol), ^1H nmr (C_6D_6) τ = 4.09s (^4H—pz), 7.43s (Me—pz), 8.14s (Me—pz), 9.97s (GaMe).

Preparation of $MeGa(N_2C_3H_3)_3Ni(NO)$

A solution of $Na^+MeGa(N_2C_3H_3)_3^-$ (1.6 mmol) in THF was added dropwise to a stirred solution of Ni(NO)I (0.345 g; 1.6 mmol) in THF at −78°C. After allowing the reaction mixture to warm slowly to room temperature, solvent was removed under vacuum. The solid remaining was extracted with benzene and filtered. Slow evaporation gave blue crystals together with a small amount of orange material. The blue product was separated by vacuum sublimation at 60°C (yield ~60%). *Anal.* calcd. for $MeGa(N_2C_3H_3)_3Ni(NO)$: C 32.1, H 3.2, N 26.29; found: C 32.4, H 3.3, N 23.2. ν_{NO} 1786 cm^{-1} (cyclohexane), 1815 cm^{-1} (Nujol), ^1H nmr (C_6D_6) τ = 1.43d (J = 2 Hz, ^3H—pz), 2.90d (J = 2 Hz, ^5H—pz), 3.77t (J = 2 Hz, ^4H—pz), 10.22s (GaMe).

Mass Spectra

The two compounds $[MeGa(N_2C_3H_3)_3]Ni(NO)$ and $[MeGa(N_2C_5H_7)_3]Ni(NO)$ gave very similar mass spectra. The strongest signal in each spectrum was due to the parent ion minus the nitrosyl group, P—NO^+. All other signals in these two spectra were much weaker (10% or less of the intensity of the P − NO^+ signal) but the P^+ ion and ions due to loss of the methyl group, P − Me^+, and other ions due to loss of "pyrazolyl" moieties were in evidence.

The mass spectrum of the $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Ni(NO)$ complex displayed a weak parent ion signal but the strongest signals corresponded to the P − NO^+ and P − NO − Me^+ ions, with the latter giving the slightly stronger signal. The trimetallic complex $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Ni(N_2C_5H_7)_2Ni(NO)$ again displayed a weak parent ion signal in its mass spectrum. The strongest signal was due to the P − NO − Me^+ ion with a further strong signal arising from the P − NO^+ ion.

In all four spectra the relative intensities of the individual peaks in multi-line signals corresponded closely to those predicted on the basis of the natural isotope compositions of the contributing metal atoms.

Spectra

Infrared spectra were recorded on a Perkin-Elmer 457 spectrometer and ^1H nmr spectra on a Varian XL-100 spectrometer utilizing FT techniques. Mass spectra were obtained on a Varian MAT CH4 spectrometer at 70 eV with an ion source temperature of 100–180°C.

X-ray Crystallographic Analysis of $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Ni(NO)$

The crystal chosen was mounted in a general orientation and had dimensions of ca. 0.12 × 0.29 × 0.39 mm. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 43 reflections measured on a diffractometer with Mo K_α radiation (λ = 0.71073 Å). Crystal data (at 22°C) are:

$C_{11}H_{23}GaN_4NiO_2$ fw = 371.76

Monoclinic, a = 9.119(1), b = 13.900(2), c = 14.284(2) Å, β = 107.96(1)°, V = 1722.3(4) Å^3, Z = 4, ρ_c = 1.434 g cm^{-3}, $F(000)$ = 768, μ(Mo K_α) = 25.8 cm^{-1}. Absent reflections: $0k0$, $k \neq 2n$ and $h0l$, $l \neq 2n$ define uniquely the space group $P2_1/c$ (C_{2h}^5, No. 14).

Intensities were measured with graphite monochromatized Mo K_α radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–θ scan at 0.91–5.03° min^{-1} over a range of (0.60 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 50°. The intensities of 3 check reflections, measured every 3600 s throughout the data collection, decreased linearly by 4% during the data collection. After data reduction, an absorption correction was applied using the Gaussian integration method (14, 15). Transmission factors ranged from 0.518 to 0.742. Of the 3001 independent reflections measured, 1828 (60.9%) had intensities greater than 3σ(I) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = background count.

The positions of the Ga and Ni atoms were determined from the three-dimensional Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference map. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to $R = 0.040$, a difference map gave positions for all 23 hydrogen atoms. Hydrogen positions and isotropic thermal parameters were included in the final stages of the refinement. The scattering factors of ref. 16 were used for non-hydrogen atoms and those of ref. 17 for hydrogen atoms. Anomalous scattering factors from ref. 18 were used for the Ga and Ni atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. Convergence was reached at $R = 0.025$ and $R_w = 0.032$ for 1828 reflections with $I \geq 3\sigma(I)$. For all 3001 reflections $R = 0.066$ and $R_w = 0.039$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.08 and 0.75σ respectively. The mean error in an observation of unit weight was 0.9911. A final difference map showed maximum fluctuations of ± 0.6 e Å^{-3} near Ga and Ni and ± 0.2 e Å^{-3} elsewhere. The final positional and thermal parameters appear in Tables 1 and 2[1] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (19) using the computer program MGTLS. The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0030 Å^2. Two successful analyses were carried out, one rigid-group included all non-hydrogen atoms except the nitrosyl oxygen and the six methyl carbon atoms and the other was a five-atom group consisting of Ga and the four atoms bonded to it (rms $\Delta U_{ij} = 0.0064$ and 0.0022 Å^2, respectively). The appropriate bond distances have been corrected for libration (20), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond distances appear along with the uncorrected values in Table 3. Corrected bond angles are all within 1σ of the uncorrected values given in Table 4. Intra-annular torsion angles defining the conformations of the two five-membered chelate rings appear in Table 5.

Results and Discussion

The reactions of nickel nitrosyl iodide with sodium pyrazolide and substituted sodium pyrazolide salts have been reported recently (21). A series of green crystalline pyrazolyl-bridged, "16-electron", nickel nitrosyl dimers was produced which readily interacted with donor species to form blue crystalline adducts in which the nickel atoms attained an 18-electron configuration (21, 22). The present account is concerned with the synthesis of LNi(NO) species in which L is a tridentate chelating ligand (L = $MeGa(N_2C_3H_3)_3$, $MeGa(N_2C_5H_7)_3$, or $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]$). In the first two complexes a pseudotetrahedral geometry is required as the ligand L cannot occupy a planar set of coordination sites. With L = $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]$ there is the possibility of a square-planar arrangement of the four donor atoms about the nickel in LNi(NO). The solid state structure of this complex (see below) displays the nickel atom in a distorted tetrahedral environment, but the ^{1}H nmr spectrum, for the compound in C_6D_6 at room temperature, suggests a square-planar geometry in solution. In this spectrum both the —NMe_2 and —$GaMe_2$ moieties display but one sharp signal for their two methyl groups. A tetrahedral structure for the LNi(NO) complex in solution would display two signals for each of the NMe_2 and —$GaMe_2$

[1]The structure factor table and Table 2 (thermal parameters) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

groups. A square-planar arrangement, however, could satisfactorily explain the spectrum. A variable temperature ^{1}H nmr spectrum in toluene-d^8 demonstrated that the room temperature spectrum is due to a rapidly fluxional species, in all probability giving an "average" square-planar environment about the Ni atom. In this experiment the sharp —$GaMe_2$ signal was monitored. On cooling the solution the —$GaMe_2$ signal gradually broadened until at −70°C it became a broad hump and at −80°C (the lowest temperature attainable) the appearance of two signals, one to either side of the position of the original signal, was just discernable. Evidently at these lower temperatures the tetrahedral conformation, observed in the solid state, is becoming established in solution. It is noteworthy that of the two "—CH_2—" "triplets" the upfield one loses resolution first (0°C) and not until −40°C does the resolution in the corresponding low field —CH_2— "triplet" start to collapse. At −80°C both —CH_2— "triplets" have broadened out to the point of disappearing into the background of the spectrum.

In the presence of oxygen, solutions of all three of the Ni(I) complexes lose NO and form Ni(II) derivatives. In the case of the complex [$Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)$]Ni(NO) it was found possible to effect partial oxidation to give the novel

N(1)—Ga	−16.7(2)	N(3)—Ni	−24.8(2)

trimetallic complex $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Ni(N_2C_5H_7)_2Ni(NO)$ which contains, formally, both a Ni(I) centre and a Ni(II) centre. Full oxidation of this complex, however, leads to the five-coordinate Ni(II) compound $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Ni[(N_2C_5H_7)_2GaMe_2]$, a compound which has been prepared by a more conventional route and structurally characterized (23).

Of the two complexes $MeGa(N_2C_5H_7)_3Ni(NO)$ and $MeGa(N_2C_3H_3)_3Ni(NO)$, the former is the more readily prepared and is more stable to NO loss in solution. The latter complex readily loses NO in solution, and its preparation is hampered by the tendency to form $[MeGa(N_2C_3H_3)_3]_2Ni$ (5) and even $[Me_2Ga(N_2C_3H_3)_2]_2Ni$ (4) in the reaction mixture. Both of these compounds are very stable to aerial oxidation and moisture (4, 5). The low temperature synthesis led to much improved yields of the desired $[MeGa(N_2C_3H_3)_3]Ni(NO)$ material. However, facile loss of NO from this compound in the analytical instrument resulted in a low analysis for nitrogen.

The stability of the four complexes reported here should be compared with the stability of the analogous (η^5-C_5H_5)Ni(NO) complex reported some years ago (24, 25). This compound, reportedly highly toxic (26), is a dark red liquid, stable in the pure state and in solution and only slightly decomposed upon distillation. Electron diffraction studies show the Ni—N—O grouping to be linear with a Ni—N distance of 1.58 Å (27). The ν_{NO} value is 1833 cm^{-1} (26).

Crystal Structure of [*Dimethyl(*N,N-*dimethylethanolamino)(3,5-dimethylpyrazolyl)gallato-(*N*(2),*N*(3),*O*)]nitrosylnickel(I)*

The crystal structure of $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Ni(NO)$ consists of discrete molecular units, each linked with one other molecule across the centres of symmetry at 1/2, 0, 0 and 1/2, 1/2, 1/2 by C—H---O interactions (O(1)---H(7a) $(1 - x, -y, -z) = 2.33(5)$, O---C = 3.591(6) Å, and O---H—C = 171(3)°) to form weakly associated dimers. All other intermolecular contacts correspond to normal van der Waals interactions.

The molecule (Fig. 1) contains a system of three fused five-membered rings with the central GaONiNN ring being roughly coplanar with the pyrazolyl

ring and perpendicular to the NiOCCN chelate ring. This arrangement of the tridentate gallate ligand is similar to that observed in the octahedral complexes *fac*-$[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NH_2)]_2Ni$ (10) and $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NH_2)]Mo(CO)_2(\eta^3\text{-}C_4H_7)$ (12). The pyrazolyl ring is planar within experimental error ($\chi^2 = 5.9$, maximum deviation = 0.006(4) Å for N_2C_3) with the metal atoms significantly displaced from the N_2C_3 plane (Ga by 0.1354(4) and Ni by 0.1625(4) Å). The two five-membered chelate rings have "envelope" conformations in which one of the five atoms is displaced from the plane of the other four (O(1) and C(7) from the GaNiNN and NiOCN planes respectively, see torsion angles in Table 5).

The gallium atom has distorted tetrahedral coordination geometry with angles ranging from 93.2(1) to 124.7(3)°. The bond distances and angles in the gallate ligand are in good agreement with those reported for similar structures (1, 3–7, 9, 10, 12, 23).

The coordination about the nickel atom is severely distorted tetrahedral with angles ranging from 84.4(1)° for O(1)—Ni—N(3) to 133.5(1)° for O(1)—Ni—N(4). The nitrosyl group is coordinated in a non-linear fashion with Ni—N—O = 162.3(4)°, Ni—N = 1.632(4) and N—O = 1.147(4) Å. Enemark *et al.* have recently discussed the geometries of a number of four-coordinate nickel nitrosyl compounds (28, 29) and have pointed out that as the stereochemistry of a $\{MNO\}^{10}$ complex changes from tetrahedral towards square-planar, the M—N—O angle decreases from 180° towards the square-planar limit of ~120° with a concomitant increase in the M—N distance. The observed $\{NiNO\}^{10}$ geometry in the present complex is consistent with that observed for other four-coordinate $\{NiNO\}^{10}$ structures which have Ni—N—O = 180(0) → 152.7(7)° and Ni—N = 1.581(12) → 1.686(7) Å (refs. 22, 28, 29 and references therein). The Ni—O(1), Ni—N(2), and Ni—N(3) bond lengths of 2.045(2), 1.989(3), and 2.071(3) Å may be compared to corresponding values of 2.090(3), 2.085(3), and 2.112(3) Å in the octahedral Ni(II) complex *fac*-$[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NH_2)]_2Ni$ (10) which has a similar ligand geometry. The longer distances in the Ni(II) complex probably result from considerably greater steric crowding in the octahedral complex.

Novel neutral monomeric five-coordinate manganese and iron dinitrosyl compounds incorporating asymmetric tridentate anionic gallate ligands are described. The crystal structure of the formally "19-electron" iron complex $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Fe(NO)_2$ has been determined. Crystals of [dimethyl(*N*,*N*-dimethylethanolamino)(3,5-dimethylpyrazolyl)gallato(*N*(2),*N*(3),*O*)]dinitrosyliron(I) are monoclinic, $a = 7.3079(6)$, $b = 14.274(1)$, $c = 17.076(1)$ Å, $\beta = 91.709(4)°$, $Z = 4$, space group $P2_1/c$. The structure was solved by Patterson and Fourier syntheses and was refined by full-matrix least-squares procedures to $R = 0.034$ and $R_w = 0.046$ for 2848 reflections with $I \geq 3\sigma(I)$. The crystal structure consists of discrete monomeric units. The coordination geometry about the iron atom is distorted trigonal-bipyramidal with the tridentate gallate ligand acting in a meridional fashion, occupying one equatorial and both axial positions. The two nitrosyl groups occupy the other two equatorial sites and both Fe—N—O groupings are considerably bent toward one another in the equatorial plane. Important mean molecular dimensions (distances corrected for libration) are: Fe—O, 2.037(3), Fe—N(pyrazolyl), 2.112(3), Fe—N(amino), 2.279(3), Fe—NO, 1.710(3), N—O, 1.153(5), Ga—O, 1.916(3), Ga—N, 1.975(3), Ga—C, 1.972(6) Å, and Fe—N—O, 158.6(7)°.

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **57**, 3113 (1979).

On décrit un nouveau complexe monomère neutre du manganèse pentacoordonné et des composés du fer dinitrosylé incorporant des ligands anioniques tridentates asymétriques du type gallate. On a déterminé la structure cristalline du complexe de fer comportant formellement "19 électrons" $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Fe(NO)_2$. Les cristaux de diméthyle(*N*,*N*-diméthyléthanolamino)(diméthyl-3,5 pyrazolyl) gallato(*N*(2),*N*(3),*O*)dinitrosyle fer(I) sont monocliniques $a = 7.3079(6)$, $b = 14.274(1)$, $c = 17.076(1)$ Å, $\beta = 91.709(4)°$, $Z = 4$, groupe d'espace $P2_1/c$. On a résolu la structure à l'aide des synthèses de Patterson et de Fourier et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs de $R = 0.034$ et $R_w = 0.046$ pour 2848 réflexions avec $I > 3\sigma(I)$. La structure cristalline consiste en unités monomères individuelles. La géométrie de coordination autour de l'atome de fer est de type trigonal bipyramidal déformé avec le ligand gallate tridentate agissant de manière méridionale, occupant une position équatoriale et les deux positions axiales. Les deux groupes nitrosyles occupent les deux autres positions équatoriales et les deux groupes Fe—N—C sont considérablement courbés l'un vers l'autre dans le plan équatorial. Les principales dimensions moléculaires importantes (corrigés pour la libration) sont: Fe—O, 2.037(3), Fe—N(pyrazolyl), 2.112(3), Fe—N(amino), 2.279(3), Fe—NO, 1.710(3), N—O, 1.153(5), Ga—O, 1.916(3), Ga—N, 1.975(3), Ga—C, 1.972(6) Å et Fe—N—O, 158.6(7)°.

[Traduit par le journal]

Introduction

Asymmetric tridentate gallate ligands incorporating pyrazolyl and ethanolamino moieties have been the subject of recent publications (1–4). The versatility of these ligands, the stability of their complexes, and their ability to display unique coordination geometries not possible with the related six-electron ligands η^5-$C_5H_5^-$ and $RE(N_2C_3H_3)_3^-$ (where R = H or alkyl and E = B or Ga) has prompted a further expansion of our studies in this area. The present account describes the synthesis and characterization of a series of metal dinitrosyl compounds $LM(NO)_2$ (where M = Mn or Fe and L = $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]$ or $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]$) and details the X-ray structural results for the iron complex $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Fe(NO)_2$.

Experimental

Starting Materials

Air-sensitive materials were handled in a glove box under an atmosphere of oxygen-free dry nitrogen or in a nitrogen-blanketed apparatus. Tetrahydrofuran (THF) was dried by refluxing over sodium/benzophenone and was used immediately following distillation. Benzene was dried by re-

0008-4042/79/233113-06$01.00/0

fluxing over molten potassium followed by distillation. $Fe(NO)_2I$ was prepared by the method of Haymore and Feltham (5) and $Mn[P(OMe)_3]_2(NO)_2Br$ by the method of Reimann and Singleton (6). The gallium ligands Na^+L^- (where L = $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]$ or $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]$) were prepared as described earlier (1, 2).

Preparation of $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]$-$Fe(NO)_2$

$Fe(NO)_2I$ (0.22 g; 0.91 mmol) was dissolved in THF (20 mL) and $Na^+[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]^-$ (1.0 mmol) in THF (10 mL) added to the resulting solution. After stirring the mixture for 1 h the solvent was removed under vacuum. The solid residue was extracted with several portions of benzene. Following filtration the resulting benzene solution of the product was allowed to evaporate slowly. Shiny black crystals of the product were collected (0.29 g; 81%). *Anal.* calcd. for $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]$-$Fe(NO)_2$: C 33.1, H 5.8, N 17.5; found: C 33.5, H 6.0, N 17.3. ν_{NO} 1750, 1673 cm^{-1} (cyclohexane), 1740 br, 1668 br cm^{-1} (Nujol).

The corresponding $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]$-$Fe(NO)_2$ complex was prepared similarly (yield 56%). *Anal.* calcd.: C 29.2, H 5.2, N 18.9; found: C 29.1, H 5.1, N 18.5. ν_{NO} 1750, 1671 cm^{-1} (cyclohexane) 1724 br, 1630 br cm^{-1} (Nujol).

Preparation of $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]$-$Mn(NO)_2$

$Mn[P(OMe)_3]_2(NO)_2Br$ (0.32 g; 0.72 mmol) was dissolved in THF and solid $AgPF_6$ (0.20 g; 0.80 mmol) added to the resulting solution. The original orange solution immediately turned yellow and a white solid formed. $Na^+[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]^-$ (0.78 mmol) in THF was added and the mixture stirred for 3 h. The dark green solution was filtered and the filtrate evaporated to give a green oil and orange solid. The mixture was washed with MeOH and filtered. The orange solid collected was recrystallized from THF/benzene to give dark red crystals of product (yield 0.093 g, 32%). *Anal.* calcd. for $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]$-$Mn(NO)_2$: C 33.2, H 5.8, N 17.6; found: C 33.3, H 5.7, N 17.4%. ν_{NO} 1709, 1643 cm^{-1} (cyclohexane), 1705 br, 1648 br cm^{-1} (Nujol). ^1H nmr (C_6D_6) τ = 4.31 s (pz—H^4), 6.27 t (J = 6 Hz, —CH_2—), 7.53 s (pz—Me), 7.92 s (pz—Me), 8.16 t (J = 6 Hz, —CH_2—), 8.20 s (NMe_2), 9.94 s ($GaMe_2$) (τ values refer to $\tau_{C_6H_6}$ = 2.84 ppm, pz = pyrazolyl).

Mass Spectra

The mass spectra of the three complexes were very similar and those of the $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]$-$M(NO)_2$ (where M = Mn and Fe) compounds were essentially identical. The parent ion in each case was not observed, the highest mass signal arising from the P − Me^+ ion (3%) (P = parent). The strongest signal corresponded to the P − $2NO^+$ ion (100%) with other strong signals arising from the P − NO^+ (40%) and the doubly charged P − 2NO − Me^{2+} ions (20%). The absence of parent ion signals in the mass spectra of organo-gallium complexes, particularly those containing the —$GaMe_2$ moiety, is well documented (7–10).

Spectra

Mass spectra were collected on a Varian MAT CH4 spectrometer at 70 eV with an ion source temperature of 100–180°C. Infrared spectra were recorded on a Perkin-Elmer 457 spectrometer and ^1H nmr spectra on a Varian XL-100 spectrometer using FT techniques.

X-ray Crystallographic Analysis of [*Dimethyl(*N,N*-dimethylethanolamino)(3,5-dimethylpyrazolyl)gallato(*N*(2),*N*(3),*O*)*]*dinitrosyliron(I)*

The crystal chosen was mounted in a general orientation and had dimensions of ca. 0.5 × 0.6 × 0.7 mm. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections measured on a diffractometer with Mo K_α radiation (λ = 0.71073 Å). Crystal data (at 22°C) are:

$C_{11}H_{23}FeGaN_5O_3$ fw = 398.91

Monoclinic, a = 7.3079(6), b = 14.274(1), c = 17.076(1) Å, β = 91.709(4)°, V = 1780.4(2) Å^3, Z = 4, ρ_c = 1.488 g cm^{-3}, $F(000)$ = 820, μ(Mo K_α) = 22.5 cm^{-1}. Absent reflections: $h0l$, $l \neq 2n$ and $0k0$, $k \neq 2n$ define uniquely the space group $P2_1/c$ (C_{2h}^5, No. 14).

Intensities were measured with graphite monochromatized Mo K_α radiation on an Enraf-Nonius CAD4-F diffractometer. An ω − 2θ scan at 1.26–10.06° min^{-1} over a range of (0.60 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of 3 check reflections, measured every 3600 s throughout the data collection, remained constant to within ±2%.

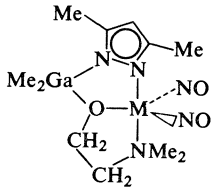
After data reduction, an absorption correction was applied using the Gaussian integration method (11, 12). Transmission factors ranged from 0.331 to 0.408. Of the 4068 independent reflections measured, 2848 (70%) had intensities greater than 3σ(I) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = background count.

The positions of the gallium and iron atoms were determined from the three-dimensional Patterson function and those of the remaining non-hydrogen atoms from subsequent difference maps. The "ethanolamine" carbon atoms were found to be twofold disordered; site occupancies were estimated from peak heights on a Fourier map to be 0.67 for "*a*" sites and 0.33 for "*b*" sites. Isotropic refinement of the disordered carbons with the occupancy factors fixed gave nearly equal thermal parameters for all of the disordered carbon atoms, thus the site occupancies were kept fixed throughout the refinement. All of the ordered non-hydrogen atoms and the four predominant disordered carbon atoms were refined with anisotropic thermal parameters and the remaining four carbon atoms with isotropic thermal parameters to R = 0.054. A difference map at this point revealed positions for all of the ordered hydrogen atoms which were subsequently refined with isotropic thermal parameters. Ideal positions were calculated for the disordered hydrogen atoms (C—H = 0.98 Å, $U = U_c + 1.1$) which were included as fixed atoms in the final stages of refinement. The scattering factors of ref. 13 were used for non-hydrogen atoms and those of ref. 14 for hydrogen atoms. Anomalous scattering factors from ref. 15 were used for the Ga and Fe atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. An isotropic Type I extinction correction (Thornley-Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (16–18). The final value of g was 2.1(2) × 10^4. Convergence was reached at R = 0.034 and R_w = 0.046 for 2848 reflections with $I \geq 3\sigma(I)$. For all 4068 reflections R = 0.061 and R_w = 0.048.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.24 and 3.9σ (oscillating thermal parameter for H(1b)) respectively. The mean error in an observation of unit weight was 1.5830. A final difference map showed maximum fluctuations of ±0.87 e Å^{-3} near the

heavy atoms and ± 0.22 e Å^{-3} elsewhere. The final positional and thermal parameters appear in Tables 1 and 2[1] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (19) using the computer program MGTLS. The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0034 Å^2. Three successful analyses were carried out, two five-atoms groups [Ga,O(1),N(1),C(1),C(2) and Fe,N(3),C(7a),C(10a), C(11a)] and a 14-atom group consisting of all non-hydrogen atoms except nitrosyl oxygens, N(3) and Ga methyl carbons and O(1) (which has anomalous thermal parameters as a result of the disorder) gave physically reasonable rigid-body parameters and ΔU_{ij} values of 29, 13, and 57 $\times 10^{-4}$ Å^2 respectively. The appropriate bond distances have been corrected for libration (20), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear along with the uncorrected values in Table 3. Corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 4. Intra-annular torsion angles defining the conformations of the five-membered chelate rings are listed in Table 5.



Results and Discussion

The neutral monomeric five-coordinate dinitrosyl complexes $LM(NO)_2$, **1**, (where M = Mn or Fe and L = $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]$) are the first of their type to be reported. A distorted trigonal bipyramidal arrangement about the "19-electron" iron centre has been proven conclusively through the X-ray crystallographic analysis of the $LFe(NO)_2$ complex. A similar molecular structure is predicted for the manganese derivative, first from the similarity of its mass spectrum and ir spectrum to those of the iron complex, and secondly from its ^{1}H nmr spectrum. The ^{1}H nmr spectrum (see Experimental section) of the manganese complex $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Mn(NO)_2$ displays one sharp signal for the —$GaMe_2$ moiety and one sharp signal for the —NMe_2 moiety. A trigonal-bipyramidal structure for the complex in solution with equatorial NO groups and a meridional gallate ligand (see **1**), similar to the solid state structure of the analogous iron compound (see below), satisfactorily explains this spectrum. Attempts to obtain the ^{1}H

[1]The structure factor table and Table 2 (thermal parameters) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

nmr of the iron compounds were thwarted by their predicted paramagnetic character.

It is interesting to compare analogous uninegative six-electron ligands in this area of chemistry. A very early attempt to prepare the analogous $(\eta^5\text{-}C_5H_5)$-$Mn(NO)_2$ compound by King (21) resulted in an associated material, of the correct empirical formulation, containing both bridging and terminal ν_{NO} bands in its ir spectrum. Various reasons were advanced at that time to explain the absence of the monomeric species. The analogous $(\eta^5\text{-}C_5H_5)Fe$-$(NO)_2$ compound has not been reported. A dimeric complex $[(\eta^5\text{-}C_5H_5)Fe(NO)]_2$ has been described however in which an Fe=Fe double bond and bridging NO groups were postulated to link the monomer units (22). In the case where L = $[RB(N_2C_3H_3)_3]$ (where R = H or alkyl) no compounds of the type $LM(NO)_2$ (where M = Mn or Fe) have been reported and our attempts to prepare such complexes where L = $[MeGa(N_2C_3H_3)_3]$ have so far proven unsuccessful. The previously characterized (23) $[MeGa(N_2C_3H_3)_3]_2Fe$ complex was isolated in attempts to prepare $[MeGa(N_2C_3H_3)_3]$-$Fe(NO)_2$.

A likely explanation for the above observations is the ability of the asymmetrical gallate ligands herein described to occupy a set of three meridional coordination sites about the transition metal atom, an arrangement which appears necessary to stabilize these monomeric species and which is impossible for the ligands $\eta^5\text{-}C_5H_5$ and $[RE(N_2C_3H_3)_3]$ (where E = B or Ga). This is further substantiated in the synthesis of two manganese dinitrosyl derivatives, $[Mn(NO)_2(PPh_3)_2Br]$ (24) and $[Mn(NO)_2\{P(OMe)_2$-$Ph\}_2Cl]$ (25), where unidentate ligands are involved and in the latter compound the halogen atom and phosphine ligands have been shown to occupy meridional coordination sites in the trigonal-bipyramidal molecule, with the two nitrosyl groups equatorial (25–27). The general paucity of

structural data on five-coordinate metal dinitrosyl derivatives is evident from the review by Enemark and Feltham (28) in which two such structures were discussed, both square-pyramidal cationic complexes with one linear and one bent nitrosyl group. The above Mn derivative (25–27) is the third such example of a five-coordinate metal dinitrosyl structure but the first where the molecular arrangement is that of a trigonal-bipyramid with equatorial nitrosyl groups and axial phosphine ligands. Enemark and Feltham in their review (28) predicted that the two NO groups in five-coordinate metal dinitrosyls should be *cis* (an arrangement found in all such structures to date) and also that a most favorable arrangement would be a trigonal-bipyramidal arrangement with equatorial NO groups.

The crystal structure of $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Fe(NO)_2$ consists of discrete molecules separated by normal van der Waals distances. The molecule (Fig. 1) contains a system of three roughly coplanar fused five-membered rings. This arrangement is typical of meridionally coordinated ethanolamino(pyrazolyl)gallate ligands such as those observed in the square-pyramidal copper complex $(\mu\text{-}N_2C_3H_3)_2[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)\text{-}Cu]_2$ (1) and in the octahedral nickel complex *mer*-$[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NH_2)]_2Ni$ in which the ethanolamine chelate ring was also found to be twofold disordered (2). The pyrazolyl group is planar within experimental error ($\chi^2 = 1.0$ for N_2C_5) and both metal atoms deviate slightly but significantly from the N_2C_5 plane (Ga by 0.0545(5) and Fe by 0.0127(6) Å). The central GaOFeNN ring has an "envelope" conformation in which O(1) is displaced from the approximate plane defined by the other four atoms. The Ga- - -Fe separation

is 3.4567(7) Å. As a result of the disorder, there are two conformations for the FeOCCN chelate ring, both of which are puckered (see torsion angles in Table 5). In general the central chelate rings (GaOMNN where M = Ni, Cu, or Fe) are more nearly planar and the deviations of the metal atoms from the pyrazolyl mean planes smaller when this type of ligand is meridionally, rather than facially coordinated (1, 2, 4).

The coordination geometry about the gallium atom is distorted tetrahedral with bond angles at gallium ranging from 90.1(1) to 122.3(4)°. The overall geometry of the ligand is very similar to that reported for related compounds (1, 2).

The structure of $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Fe(NO)_2$ is only the second trigonal-bipyramidal metal dinitrosyl structure to be reported (as mentioned earlier) and is the first incorporating a uninegative tridentate chelating ligand. The oxygen and two nitrogen atoms of the $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]^-$ ligand occupy one equatorial and the two axial coordination sites respectively with the two nitrosyl groups occupying the two remaining equatorial positions. The trigonal-bipyramid is distorted as a result of steric requirements imposed by the gallate ligand. The iron atom is displaced 0.0752(6) Å (towards N(2)) from the plane of the equatorial substituents and the angle between the axial ligands is 159.4(1)°. The equatorial Fe—O distance is 2.037(3) Å and axial Fe—N distances are 2.112(3) (pyrazolyl) and 2.279(3) Å (amino). The difference in the axial bond lengths is considerably greater than that expected on the basis of hybridization differences at nitrogen alone and is probably due to the greater steric hindrance imposed by the amino methyl groups which are nearly eclipsed with the two nitrosyl groups in either of the two disordered sites.

The geometry of the C_{2v} $\{Fe(NO)_2\}^9$ system is of great interest, being the first such system to be structurally characterized. The only comparable structure is that of the $\{Mn(NO)_2\}^8$ complex mentioned earlier in which both nitrosyl groups are bent (Mn—N—O = 165°) towards each other in the equatorial plane. The Mn—N distances are 1.633–1.665(10) Å and the ON—Mn—NO angles are 111.5–113.5(5)° (for two crystal forms, three crystallographically independent molecules). This arrangement for a C_{2v} $\{M(NO)_2\}^8$ system was predicted by Enemark and Feltham (28). The present $\{M(NO)_2\}^9$ system is similar but the extra electron induces some significant changes. The in-plane bending of the nitrosyl groups is more pronounced (mean Fe—N—O = 158.6(7)°) and the angle between the nitrosyl groups decreases to 108.1(2)°. The M—N distance increases to a mean Fe—N of 1.710(3) Å, a sizeable increase considering that for isoelectronic and isostructural Mn and Fe species the M—NO distance is shorter for the iron analog (28).

Synthesis and structure of 3,5-dimethylpyrazolyl iron and cobalt dinitrosyl dimers

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR, AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2075 Wesbrook Mall, Vancouver, B.C., Canada V6T 1W5

Received July 23, 1979

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **57**, 3119 (1979).

The synthesis and characterization of two 3,5-dimethylpyrazolyl metal dinitrosyl dimers $[(N_2C_5H_7)M(NO)_2]_2$ (where M = Fe or Co) are described and their X-ray crystal structures detailed. Both complexes crystallize in the monoclinic space group $C2/c$, a = 23.848(2), 23.722(4), b = 10.7775(7), 10.6888(6), c = 14.764(1), 14.712(2) Å, β = 117.366(6), 117.094(7)°, Z = 8 (for the iron and cobalt complexes respectively). The structure of the iron complex was solved by Patterson and Fourier syntheses. The cobalt complex is isomorphous with the iron analog. Both structures were refined by full-matrix least-squares procedures to R = 0.028 and 0.035 for 4251 and 3376 reflections with $I \geq 3\sigma(I)$ respectively. Both complexes adopt a boat conformation for the central M—(N—N)$_2$—M ring and display significantly non-linear M—N—O groups. The coordination geometry about the metal atoms is distorted tetrahedral. Important molecular dimensions (distances corrected for libration) are: mean Fe—N(pyrazolyl), 2.009(5), mean Fe—NO, 1.696(2) Å, Fe—N—O, 158.5(3)–168.2(2)°, mean Co—N(pyrazolyl), 1.992(7), Co—NO, 1.646(3)–1.680(3) Å, and Co—N—O, 161.6(3)–173.5(3)°. The iron complex is paramagnetic with formally "17-electron" iron atoms. Both structures are compared with similar four-coordinate metal dinitrosyl compounds.

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **57**, 3119 (1979).

On décrit la synthèse et la caractérisation de deux diméthyl-3,5 pyrazolyl métal dinitrosyle $[(N_2C_5H_7)M(NO_2)]_2$ dimères où M = Fe ou Co et on a détaillé leur structure cristalline. Pour les deux complexes les cristaux sont monocliniques, groupe d'espace $C2/c$, a = 23.848(2), 23.722(4), b = 10.7775(7), 10.6888(6), c = 14.764(1), 14.712(2) Å, β = 117.366(6), 117.094(7)°, Z = 8 (pour les complexes de fer et de cobalt respectivement). La structure du complexe de fer est résolue par les synthèses de Patterson et de Fourier. Le complexe de cobalt et l'analogue de fer sont isomorphes. Les deux structures sont affinées par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs de R = 0.028 et 0.035 pour 4251 et 3376 réflexions avec $I \geq 3\sigma(I)$ respectivement. Les deux complexes adoptent une conformation bateau au niveau du cycle central M—(N—N)$_2$—M et montrent de façon significative des groupes M—N—O non linéaires. La géométrie de coordination autour de l'atome de métal est déformée en un tétraèdre. Les dimensions moléculaires importantes (distances corrigées pour la libration) sont: Fe—N(pyrazolyl), 2.009(5), moyen Fe—NO, 1.696(2) Å, Fe—N—O, 158.5(3)–168.2(2)°, moyen Co—N(pyrazolyl), 1.992(7), Co—NO, 1.646(3)–1.680(3) Å et Co—N—O, 161.6(3)–173.5(3)°. Le complexe de fer est paramagnétique avec un atome de fer portant formellement "17 électrons". On compare les deux structures à celles de composés similaires tétracoordonnés de métal dinitrosyle.

[Traduit par le journal]

Introduction

The reactions of Ni(NO)I with sodium pyrazolide and substituted sodium pyrazolide salts have been reported recently (1). Novel "pyrazolyl" bridged dimers were produced and structurally characterized and their reactivity towards electron-donor species examined (1, 2). An extension of our investigations in this area has resulted in the formation of the dimeric complexes $[(N_2C_5H_7)M(NO)_2]_2$ (where M = Fe or Co) in which the transition metal atoms are bridged by 3,5-dimethylpyrazolyl moieties and assume pseudotetrahedral geometry. Considerable attention has been given recently to four-coordinate metal dinitrosyl complexes (3–5) with particular interest being attached to the extent and direction of bending of the M—N—O groupings, and also to possible catalytic activity (6–11). The two structures reported here add further to the structural parameters already available on four-coordinate metal dinitrosyls and also supply some unique features in the area of binuclear complexes.

Experimental

Starting Materials

Air-sensitive materials were handled in a glove box under an atmosphere of oxygen-free dry nitrogen or in a nitrogen-blanketed apparatus. Tetrahydrofuran (THF) was dried by refluxing over sodium/benzophenone and was used immediately following distillation. Benzene was dried by refluxing over molten potassium followed by distillation. $Fe(NO)_2I$ and $Co(NO)_2I$ were prepared by the method of Haymore and Feltham (12). Sodium dimethylpyrazolide $Na^+N_2C_5H_7^-$ was

0008-4042/79/233119-07$01.00/0

prepared from sodium hydride and 3,5-dimethylpyrazole in THF.

Preparation of $[(N_2C_5H_7)Co(NO)_2]_2$

$Co(NO)_2I$ (0.492 g; 2.0 mmol) was dissolved in THF and a solution of $Na^+N_2C_5H_7^-$ (0.236 g; 2.0 mmol) in the same solvent added. After stirring the mixture for 1 h the solvent was removed *in vacuo*. The solid residue was extracted with several portions of benzene and filtered. Evaporation of the benzene solution gave large black crystals which were washed sparingly with heptane (yield 0.2 g; 46%). *Anal.* calcd. for $[(N_2C_5H_7)Co(NO)_2]_2$: C 28.0, H 3.3, N 26.2; found: C 28.2, H 3.3, N 26.0. ν_{NO} 1822 br, 1750 br cm^{-1} (cyclohexane). ^1H nmr (C_6D_6) τ = 4.04 s (^4H—pz), 8.00 s (pz—Me) (τ values refer to $\tau_{C_6H_6}$ = 2.84 ppm, pz = pyrazolyl).

Preparation of $[(N_2C_5H_7)Fe(NO)_2]_2$

This complex was prepared from $Fe(NO)_2I$ and $Na^+N_2C_5H_7^-$ using a similar procedure to that described above for the analogous cobalt complex. Black crystals were again obtained but in this preparation the yield was about 75%. *Anal.* calcd. for $[(N_2C_5H_7)Fe(NO)_2]_2$: C 28.5, H 3.3, N 26.5; found: C 28.5, H 3.3, N 25.8. ν_{NO} 1800, 1785, 1735, 1720 cm^{-1} (cyclohexane); 1802, 1780, 1750, 1710 cm^{-1} (Nujol).

Spectra

Mass spectra were collected on a Varian MAT CH4 spectrometer at 70 eV with an ion source temperature of 100–180°C. Selected mass spectral data for the two complexes are summarized in Table 1. Infrared spectra were recorded on a Perkin-Elmer 457 spectrometer and the ^1H nmr spectrum on a Varian XL-100 spectrometer using FT techniques. The magnetic susceptibility measurement was made on a Faraday magnetic balance.

X-ray Crystallographic Analyses

Bis(μ-3,5-dimethylpyrazolyl)bis(dinitrosyliron(I))

The crystal chosen was mounted in a general orientation and had dimensions of ca. 0.56 × 0.70 × 0.65 mm. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 48 reflections measured on a diffractometer with Mo K_α radiation (λ = 0.71073 Å). Crystal data (at 22°C) are:

$C_{10}H_{14}Fe_2N_8O_4$ fw = 421.97

Monoclinic, a = 23.848(2), b = 10.7775(7), c = 14.764(1) Å, β = 117.366(6)°, V = 3369.9(5) Å^3, Z = 8, ρ_c = 1.664 g cm^{-3}, $F(000)$ = 1712, μ(Mo K_α) = 16.8 cm^{-1}. Absent reflections: hkl, $h + k \neq 2n$ and $h0l$, $l \neq 2n$. Space group $C2/c$ (C_{2h}^6, No. 15) from structure analysis.

Intensities were measured with graphite monochromatized Mo K_α radiation on an Enraf-Nonius CAD4-F diffractometer. An ω – 1.67θ scan at 1.34–10.06° min^{-1} over a range of (0.70 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 65°. The intensities of 3 check reflections, measured every 3600 s throughout the data collection, remained constant to within ±3.0%. After data reduction, an absorption correction was applied using the Gaussian integration method (13, 14). Transmission factors ranged from 0.365 to 0.464. Of the 6057 independent reflections measured, 4251 (70.2%) had intensities greater than 3σ(I) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = background count.

Systematic absences allow space groups Cc or $C2/c$, analysis being initiated in the latter on the basis of the E-statistics and the number of molecules in the unit-cell. The positions of the iron atoms were determined from the three-dimensional Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference Fourier. After full-matrix least-squares refinement of all non-hydrogen atoms with anisotropic thermal parameters to R = 0.039, a difference map gave positions for all 14 hydrogen atoms which were included in all subsequent cycles of refinement with isotropic thermal parameters. The scattering factors of ref. 15 were used for non-hydrogen atoms and those of ref. 16 for hydrogen atoms. Anomalous scattering factors from ref. 17 were used for the Fe atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. An isotropic Type I extinction correction (Thornley–Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (18–20). The final value of g was 1.1(1) × 10^4. Convergence was reached at R = 0.028 and R_w = 0.038 for 4251 reflections with $I \geq 3\sigma(I)$. For all 6057 reflections R = 0.051 and R_w = 0.042.

TABLE 1. Mass spectral data for $[(N_2C_5H_7)M(NO)_2]_2$

	M = ^{56}Fe		M = ^{59}Co	
Assignment	Intensity	m/e	Intensity	m/e
$M_2(N_2C_5H_7)_2(NO)_4^+$	2	422	12	428
$M_2(N_2C_5H_7)_2(NO)_3^+$	63	392	37	398
$M_2(N_2C_5H_7)_2(NO)_2^+$	30	362	18	368
$M_2(N_2C_5H_7)_2(NO)^+$	53	332	34	338
$M_2(N_2C_5H_7)_2^+$	100	302	100	308
$M(N_2C_5H_7)(NO)_2^+$	0	—	3	214
$M(N_2C_5H_7)(NO)^+$	5	181	6	184
$M(N_2C_5H_7)^+$	27	151	21	154
M_2^+	11	112	11	118

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.10 and 1.9σ respectively. The mean error in an observation of unit weight was 1.1719. A final difference map showed maximum fluctuations of ±0.40 e Å^{-3} near the metal atoms and ±0.17 e Å^{-3} elsewhere. The final positional and thermal parameters appear in Tables 2 and 3 respectively.[1] Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

Bis(μ-3,5-dimethylpyrazolyl)bis(dinitrosylcobalt(I))

Details of the structure analysis are the same as for $[(N_2C_5H_7)Fe(NO)_2]_2$ except where noted. Crystal dimensions were 0.21 × 0.52 × 0.58 mm and 25 reflections were used in the refinement of the unit-cell parameters. Crystal data are:

$C_{10}H_{14}Co_2N_8O_4$ fw = 428.14

Monoclinic, a = 23.722(4), b = 10.6888(6), c = 14.712(2) Å, β = 117.094(7)°, V = 3321.0(8) Å^3, Z = 8, ρ_c = 1.713 g cm^{-3}, $F(000)$ = 1728, μ(Mo K_α) = 19.4 cm^{-1}. Space group $C2/c$.

An ω–2θ scan at 1.06–6.71° min^{-1} over a range of (0.65 + 0.35 tan θ)° in ω was employed. Of 5994 independent reflections measured (to 2θ = 65°), 3376 (56.3%) had intensities greater than 3σ(I) above background. An absorption correction was applied, transmission factors range from 0.365 to 0.684.

The refinement was initiated using the coordinates of all non-hydrogen atoms taken from the isomorphous iron complex. Refinement with isotropic and then with anisotropic thermal parameters gave R = 0.041. The coordinates of all 14 hydrogen atoms were taken from a difference map calculated at this point. Anomalous scattering factors from ref. 17 were used for the cobalt atoms. Convergence was reached at R = 0.035 and R_w = 0.043 for 3376 reflections with $I \geq 3\sigma(I)$. For all

[1]The structure factor table and Table 3 (thermal parameters) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

5994 reflections $R = 0.090$ and $R_w = 0.048$. The mean and maximum parameter shifts on the final cycle of refinement corresponded to 0.13 and 1.4σ respectively and the mean error in an observation of unit weight was 1.0536. A final difference map showed maximum fluctuations of ± 0.65 e Å^{-3} near the cobalt atoms and ± 0.25 e Å^{-3} elsewhere. The final value of the isotropic extinction parameter g was $0.34(11) \times 10^4$.

The thermal motion in both molecules has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (21) using the computer program MGTLS. For both molecules (rms $\sigma U_{ij} = 0.0009$ and 0.0014 Å^2 for the Fe and Co complexes respectively) analysis of all non-hydrogen atoms except nitrosyl oxygen atoms gave rms $\Delta U_{ij} = 0.0036$ Å^2 (for both complexes) and physically reasonable results. The appropriate bond distances have been corrected for libration (22), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 4 along with the uncorrected values and corrected bond angles are all within 1σ of the uncorrected values given in Table 5. Intra-annular torsion angles defining the conformations of the central six-membered chelate rings are listed in Table 6.

Results and Discussion

The solid state structures of dinitrosyl iron iodide and dinitrosyl cobalt iodide have been reported (23). The former structure consists of diamagnetic dimeric molecules in which the two $Fe(NO)_2$ moieties are linked by bridging iodine atoms and also by a long (3.05 Å) Fe—Fe bond. The cobalt compound is polymeric with an infinite chain structure with a Co---Co non-bonded distance of 3.864 Å. In both structures the metal atoms are in a pseudotetrahedral environment and both M—N—O groupings are non-linear. A related dimeric iron complex $[Fe(NO)_2(SEt)]_2$ is also diamagnetic with an Fe—Fe single bond (2.72 Å) and bridging SEt groups linking the two $Fe(NO)_2$ moieties (24). In this complex the Fe—N—O groups are again non-linear.

The present structures offer a unique extension to the structural parameters presently available for four-coordinate metal dinitrosyl compounds, particularly

in the area of binuclear complexes. The dimeric iron complex $[(N_2C_5H_7)Fe(NO)_2]_2$ contains, formally, 17-electron Fe centres, and indeed our inability to obtain a proton nmr spectrum for this complex in solution attested to its paramagnetism. A field-independent μ_{eff} value of 1.83 BM per iron atom at 293 K (correction for ligand and metal diamagnetism = 184×10^{-6} cm^3 mol^{-1}) confirmed the absence of any detectable iron–iron interaction in the solid state. An Fe—Fe bond in the complex, similar to that suggested for the $[Fe(NO)_2I]_2$ and $[Fe(NO)_2(SEt)]_2$ dimers, would of course yield a closed-shell configuration about each iron atom. Evidently the distance between the two iron atoms (3.3359(3) Å) in our complex is too large for such an interaction. It is, however, interesting to compare the isoelectronic complex $[Fe(N_2C_5H_7)(CO)_3]_2$ (25, 26). This compound is predicted to have an Fe—Fe single bond in addition to bridging "pyrazolyl" groups on the basis of its diamagnetism indicated by its proton nmr spectrum. No structural details have as yet been reported for this complex, however, and it is difficult to conceive a metal–metal distance close enough to give such a strong interaction. A planar Fe—$(N—N)_2$—Fe ring in this complex might lead to a superexchange phenomenon involving an electron pair coupling of the iron centres via the bridging pyrazolyl moieties.

The crystal structures of $[(N_2C_5H_7)M(NO)_2]_2$ (M = Fe and Co) are isomorphous and both consist of discrete binuclear molecules separated by normal

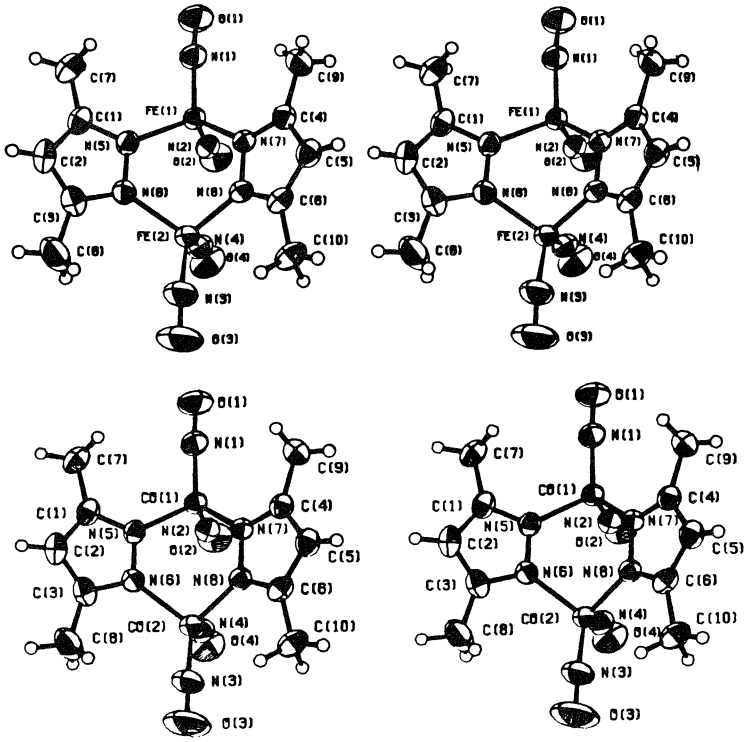

FIG. 1. Stereo view of the bis(μ-3,5-dimethylpyrazolyl)bis(dinitrosyliron(I)) (top) and bis(μ-3,5-dimethylpyrazolyl)-bis(dinitrosylcobalt(I)) (bottom) molecules, 50% ellipsoids are shown for the non-hydrogen atoms.

van der Waals distances. Molecules of both complexes have approximate C_{2v} symmetry (Fig. 1) but packing forces are probably the cause of some small but significant deviations from "ideal" geometry, particularly evident in the differences between corresponding bond angles at the two metal atoms.

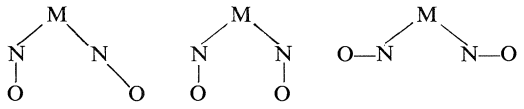
The central six-membered M—(N—N)$_2$—M rings in both structures have slightly distorted boat conformations with similar torsion angles (Table 6), the mean magnitude of the torsion angles being 1.0° greater for the cobalt complex. In spite of the similarity of the torsion angles in the central rings, there are some important differences between the fused-ring systems in the two molecules. The cross-ring distances, N(5)---N(7) and N(6)---N(8), are significantly different from one another in both molecules (the latter being shorter) and those in the iron complex (3.142(2) and 3.102(2) Å) are considerably longer than those in the cobalt complex (2.920(3) and 2.890(3) Å). This is closely related to several other notable structural differences between the iron and cobalt complexes. The greater cross-ring distances in the iron analog allow for a closer approach of the metal atoms (Fe---Fe = 3.3359(3), Co---Co = 3.4717(4) Å) even though the M—N(pz) and N—N(pz) bond distances are shorter by an average of 0.01 Å in the cobalt complex. This may indicate some tendency towards an Fe—Fe interaction in the formally electron-deficient complex $[(N_2C_5H_7)Fe(NO)_2]_2$, whereas in $[(N_2C_5H_7)Co(NO)_2]_2$ the cobalt atoms acquire a closed-shell configuration without the necessity of a metal–metal bond.

TABLE 6. Intra-annular torsion angles (deg) for central M—(N—N)$_2$—M rings

Bond	Angle (deg)	
	M = Fe	M = Co
M(1)—N(5)	−43.8(1)	−46.9(1)
N(5)—N(6)	−3.3(1)	−2.1(2)
N(6)—M(2)	48.6(1)	49.6(1)
M(2)—N(8)	−47.1(1)	−48.1(1)
N(8)—N(7)	0.9(1)	−0.1(2)
N(7)—M(1)	45.2(1)	48.1(1)

In the iron complex both pyrazolyl rings are planar within experimental error (χ^2 = 1.4 and 1.2 for N_2C_3 rings containing N(5) and N(7) respectively) while those in the cobalt complex are both slightly, but significantly, non-planar (χ^2 = 8.4 and 10.7, maximum deviations = 0.005(3) and 0.007(3) Å for the N(5) and N(7) rings respectively). The angles between normals to the pyrazolyl mean planes are 57.9(2) and 54.1(2)° for the iron and cobalt structures respectively. The metal atoms are displaced by small but

significant distances from the pyrazolyl mean planes in both structures but these displacements in the cobalt complex are generally of greater magnitude and are all in the opposite direction to those in the iron complex (Fe(1), −0.0993(2), −0.0881(2), Fe(2), −0.0030(3), −0.0594(3), Co(1), 0.0850(3), 0.1310(4), Co(2), 0.0994(3), 0.0975(4) Å from the N(5) and N(7) pyrazolyl mean planes respectively). The methyl carbon atoms are in general slightly but significantly displaced from the pyrazolyl mean planes as well, and since these deviations result from intermolecular steric forces, both the directions and magnitudes of the displacements are essentially the same in both structures (C(7), −0.018(3), −0.005(4), C(8), −0.019(3), −0.018(4), C(9), 0.048(3), 0.061(4), and C(10), 0.051(2), 0.063(3) Å from the appropriate N_2C_3 plane for the iron and cobalt complexes respectively). The geometry of the pyrazolyl groups is as expected with excellent agreement between independent but chemically equivalent parameters.



1 **2** **3**

The boat conformation adopted by the central M—(N—N)$_2$—M ring in both structures forces the pseudo-axial NO groups close together such that in both complexes the N(2)---N(4) distances are much shorter than the M---M distances and correspond to van der Waals contacts. The N(2)---N(4) distances in the two complexes are equal within experimental error (2.984(2) and 2.990(3) Å in the iron and cobalt complexes respectively) in spite of the significant difference between the M---M distances. This arrangement leads to the asymmetric type of M(NO) grouping **1** in both complexes in which the two M—N—O moieties are bent toward each other in the MN_2 plane but to significantly different extents. Several four-coordinate $\{M(NO)_2\}^{10}$ complexes have been structurally characterized and usually both M—N—O groupings are bent symmetrically to give what have been termed "attracto", **2**, or "repulso", **3**, conformers (3–5). The attracto conformer is favored for metals of the first transition series and ligands which are good π-acceptors and the repulso conformer for metals of the third transition series and ligands which are poor π-acceptors (3). The exact geometry of this type of complex depends on the relative contributions of the d_{xz} and π^*b_1(NO) orbitals to the $1b_1$ molecular orbital (the highest occupied molecular orbital in the $\{M(NO)_2\}^n$ (n = 9, 10) systems) and is therefore sensitive to the nature of the other ligands as well as to the identity of the central metal (3).

The iron complex $[(N_2C_5H_7)Fe(NO)_2]_2$ is the first $\{M(NO)_2\}^9$ system to be structurally characterized and the geometry of the $M(NO)_2$ grouping shows some significant differences with respect to that observed for the $\{M(NO)_2\}^{10}$ complex $[(N_2C_5H_7)Co(NO)_2]_2$. In the iron complex all four independent Fe—NO distances are equal within experimental error (mean Fe—N = 1.696(2) Å) and all four nitrosyl groups are bent, the pseudo-axial nitrosyl groups being bent significantly less than the pseudo-equatorial nitrosyls (168.2(2) and 167.0(2)° for axial, 163.4(2) and 158.5(3)° for equatorial Fe—N—O). The nitrosyl groups are bent toward one another approximately in the FeN_2 plane with ON—Fe—NO and O---Fe---O angles of 112.26(8) and 100.7(1)° at Fe(1) and 109.0(1) and 95.0(1)° at Fe(2). The N—O distances (mean 1.159(4) Å) are equal within experimental error although the axial N—O distances are slightly longer than the other two (see Table 4). The mean Fe—N(pz) distance is 2.009(5) Å but there are some small but significant differences between individual values, probably a result of hybridization differences at the iron atoms. The coordination geometry about the iron atoms is slightly distorted tetrahedral with all bond angles in the range 101.48(6)–113.00(9)°. In the cobalt complex $[(N_2C_5H_7)Co(NO)_2]_2$ there is considerable variation in the Co—NO distances, the "equatorial" Co—N distances (1.659(2) and 1.646(3) Å) being significantly shorter than the "axial" Co—N distances (1.672(2) and 1.680(3) Å). As in the iron complex all four nitrosyl groups are bent, the pseudo-axial nitrosyl groups being bent significantly more than the pseudo-equatorial nitrosyl groups ((165.1(2) and 161.3(3) for axial vs. 173.5(3) and 173.0(4)° for equatorial), opposite to that observed in the iron complex. The bending is again in the MN_2 plane with ON—Co—NO and O---Co---O angles of 113.9(1) and 105.3(1)° at Co(1), 110.4(1) and 100.2(1)° at Co(2). The N—O distances (mean 1.143(5) Å) are not significantly different but the "axial" N—O distances are slightly shorter than the others, again opposite to that observed for the iron complex. The mean Co—N(pz) distance is 1.992(7) Å and the individual values vary more than in the iron complex. The tetrahedral coordination about the cobalt atoms is somewhat more distorted from "ideal" geometry than in the iron complex, bond angles at Co ranging from 93.51(8) to 116.0(1)°. The observed geometry of the $\{Co(NO)_2\}^{10}$ system in $[(N_2C_5H_7)Co(NO)_2]_2$ is quite similar to that observed in several other such systems (3–5). Two previous examples of significantly different M—N—O bending in four-coordinate $\{M(NO)_2\}^{10}$ complexes are the compounds $[M(NO)_2(PPh_3)_2]$ (where M = Ru (27, 28) and M = Os (29)).

Infrared Spectra

The infrared spectrum of the iron dimer displays four sharp ν_{NO} bands both in the cyclohexane solution spectrum and in the Nujol mull spectrum (see Experimental section). The bands are of roughly equal intensity and must reflect an interaction between the two $Fe(NO)_2$ moieties in the binuclear molecule. Two of the four bands may be due to symmetric and asymmetric vibrations of the pseudo-axial NO groups whilst the remaining two may be assigned to similar vibrations of the pseudo-equatorial NO groups. The ir spectrum of the cobalt dimer $[(N_2C_5H_7)Co(NO)_2]_2$ displayed two broad (unresolved?) ν_{NO} bands in cyclohexane solution and a very broad absorption envelope in the Nujol mull spectrum. The extent of the interaction, if any, between equivalent sets of ligands attached to different metal atoms in polynuclear complexes is difficult to predict (30). Such an interaction might be unexpected in the present complexes, however, particularly in the iron compound since the related complex $[Fe(NO)_2I]_2$ displays but two ν_{NO} bands in its solution ir spectrum (23, 31). In this iodide bridged compound a strong Fe—Fe interaction is indicated (23) and the two NO groups on each Fe atom are inequivalent in the same sense as those in the "pyrazolyl" bridged species $[(N_2C_5H_7)Fe(NO)_2]_2$.

Mass Spectra

Selected mass spectral data are summarized in Table 1. In addition to the data listed other signals due to loss of MeCN and Me groups from the $M_2(N_2C_5H_7)_2^+$ ions were observed. A similar loss of MeCN molecules from the ion $Fe_2(N_2C_5H_7)_2^+$ in the mass spectrum of the related complex $[Fe(N_2C_5H_7)(CO)_3]_2$ has been reported (25). The presence of Fe_2^+ ions in the mass spectrum of this carbonyl complex was taken as partial evidence for the presence of an Fe—Fe bond in the compound. It is interesting therefore that the nitrosyl complexes reported herein also display M_2^+ signals in their mass spectra even though they are not predicted to have M—M bonds. Presumably these ions arise from M—M bonded species formed during fragmentation of the original dimeric species. It is instructive to compare these findings with the mass spectral data discussed earlier for halogen- and sulphur-bridged iron and cobalt dinitrosyl dimers (23, 32).

Theoretical study of isotropic hyperfine coupling constants in small radicals by MINDO/3 method

PRABHAT K. K. PANDEY AND P. CHANDRA[1]

Department of Chemistry, Banaras Hindu University, Varanasi-221005, India

Received December 11, 1978[2]

PRABHAT K. K. PANDEY and P. CHANDRA. Can. J. Chem. **57**, 3126 (1979).

Isotropic hyperfine coupling constants for ^{1}H, ^{13}C, ^{14}N, ^{17}O, and ^{19}F nuclei in a large number of small radicals as obtained by the SCF-MO-LCAO-UHF-MINDO/3 scheme are presented. It is seen that whereas calculated ^{1}H, ^{13}C, and ^{14}N hyperfine couplings agree fairly well with experiment, the agreement is not so satisfactory for ^{17}O and ^{19}F couplings.

PRABHAT K. K. PANDEY et P. CHANDRA. Can. J. Chem. **57**, 3126 (1979).

On présente les constantes de couplage hyperfin isotropiques des noyaux de ^{1}H, ^{13}C, ^{14}N, ^{17}O et ^{19}F d'un grand nombre de petits radicaux tels qu'obtenus par la combinaison: SCF MO-LCAO-UHF-MINDO/3. On constate que les constantes de couplage hyperfin calculées dans le cas de ^{1}H, ^{13}C et ^{14}N concordent parfaitement avec les valeurs expérimentales, mais la concordance n'est pas aussi satisfaisante dans le cas des couplages du ^{17}O et de ^{19}F.

[Traduit par le journal]

Introduction

A great deal of experimental data is now available on hyperfine coupling constants of various nuclei in free radicals and radical anions (1, 2). The isotropic hyperfine coupling constant, a_N, which is a measure of the extent of the magnetic interaction between the nuclear spin, I, of the nucleus under consideration and the electron spin, S, of the system being investigated, is obtained through the analysis of esr spectra of fluids. These constants are related to the electron spin density distribution in s-orbitals in the radical and consequently serve as a probe for testing various approximate methods used in the theoretical calculation of spin densities.

Most of the earlier calculations (1–4) in this direction employed either VB (valence bond) or MO (molecular orbital) approaches and were limited to π electron systems. In recent years MO theory has been used for both σ and π radicals at *ab initio* (5–13) as well as at semiempirical levels (such as CNDO and INDO (14–19), CNDO/SP (20), NDDO (21)) to calculate spin densities. Bishcof (22) has used the MINDO/3 approximation (23) to calculate proton hyperfine couplings in a few systems employing optimized geometries. In this paper, we have employed the MINDO/3 scheme (23), within the unrestricted Hartree–Fock (UHF) formalism (24), to calculate ^{1}H, ^{13}C, ^{14}N, ^{17}O, and ^{19}F hyperfine couplings in a large number of radicals. This study is a part of our plan to calculate various molecular properties (25) such as dipole moment derivatives (26), magnetic susceptibilities (unpublished results), and nuclear spin–spin coupling constants (27) using the MINDO/3 approximation.

Theory

The relation between the experimentally observed isotropic hyperfine coupling constant, a_N, of a magnetic nucleus N in a paramagnetic system and the theoretically calculated spin density, $\rho(r_N)$, at the site of the nucleus is given by

$$[1] \quad a_N = (4\pi/3)g\beta\gamma_N\hbar\langle S_z\rangle^{-1}\rho(r_N)$$

where the symbols have their usual meanings. The spin density can be obtained from the molecular ground state wavefunction, Ψ

$$[2] \quad \rho(r_N) = \left\langle \Psi \left| \sum_{k}^{\text{electrons}} 2S_{kz}\delta(r_{kN}) \right| \Psi \right\rangle$$

Ψ was obtained as an antisymmetrized product of UHF molecular orbitals which, in turn, were obtained by employing a valence basis set, ϕ, of Slater type orbitals (STO's). In the MINDO/3 scheme, the matrix elements of the Fock matrix (for α electrons) are given by

$$[3] \quad F_{rr}^{\alpha} = U_{rr} + \sum_{t}^{N}(P_{tt}g_{rt} - P_{tt}h_{rt}) + \sum_{N=M}(P_{MM} - Z_M)g_{MM} \qquad \phi_r \text{ on atom } N$$

$$[4] \quad F_{rs}^{\alpha} = (2P_{rs} - P_{rs}^{\alpha})h_{rs} - P_{rs}^{\alpha}g_{rs} \qquad \phi_r \text{ and } \phi_s \text{ both on atom } N$$

[1]To whom all correspondence should be addressed.

[2]Revision received June 11, 1979.

0008-4042/79/233126-09$01.00/0

[5] $F_{rs}^{\alpha} = (I_r + I_s)S_{rs}B_{NM} - P_{rs}^{\alpha}g_{NM}$

ϕ_r on atom N and ϕ_s on atom M

with similar expressions for the β electrons; where U_{rr} is the core integral; g_{rt} and h_{rt} are the coulomb and the exchange integrals between orbitals ϕ_r and ϕ_t, respectively; Z_M is the core charge of the atom M; g_{NM} is the average coulomb integral between orbitals of atom N and atom M; I_r is the valence state ionization potential of orbital ϕ_r; S_{rs} is the overlap integral between orbitals ϕ_r and ϕ_s, and B_{NM} is an empirical parameter for the pair of atoms N and M. The density matrices obtained from eigenvectors (C^{α}) of F^{α} are

[6] $$P_{rs}^{\alpha} = \sum_{i}^{\text{occ}} C_{ri}^{\alpha}C_{si}^{\alpha}; \qquad P_{rs} = P_{rs}^{\alpha} + P_{rs}^{\beta};$$

$$\rho_{rs} = P_{rs}^{\alpha} - P_{rs}^{\beta}$$

and

[7] $$P_{MM} = \sum_{t}^{M} P_{tt}$$

The parameters employed and the procedure used to evaluate various integrals in these equations are given by Bingham, Dewar, and Lo (23). The spin density, $\rho(r_N)$, in terms of atomic spin density matrix, ρ_{rs} at the nucleus N is given by

[8] $$\rho(r_N) = \sum_{rs} \rho_{rs}\phi_r(r)\phi_s(r)$$

It is assumed in eq. [8] that all contributions to summation are negligible unless both ϕ_r and ϕ_s are on the same atom. Since an *s–p* basis is used in the present calculations only *s* orbitals have nonvanishing densities at the respective nuclei and contribute to isotropic hyperfine couplings. With these simplifications, the expression for hyperfine couplings at nucleus N becomes

[9] $$a_N = [(4\pi/3)g\beta\gamma_N\hbar\langle S_z\rangle^{-1}|\phi_{s_N}(r_N)|^2]\rho_{s_Ns_N}$$

where the subscript s_N denotes the *s*-orbital of atom N. The quantity in the angular brackets has been treated as an adjustable parameter between calculated spin densities and experimental coupling constants in a least-squares sense. The single determinantal UHF wavefunction, however, is not an eigenfunction of the S^2 operator and contains contaminating contributions from higher multiplicities. The annihilation of the largest contaminant leads to a good approximation to a pure spin state and this has been done here by a procedure suggested by Amos and Hall (28). In the parameter fitting in expression [9], annihilated spin densities have been used. The values for these parameters (hereafter called Hyperfine Magnetic Nucleus Constant 'HMNC') for different magnetic nuclei are presented in Table 1 along with corresponding INDO values for comparison.

Results and Discussion

In all 29 radicals have been studied and the experimental geometry was employed wherever available (29–32). In other cases the geometry used in earlier calculations, either from *ab initio* or semi-empirical methods, has been employed (5, 6, 9, 10, 14, 15, 17, 19, 33–36).

Columns 2 and 3 of Table 2 list $\langle S^2\rangle_{sd}$ and $\langle S^2\rangle_{asa}$, the unannihilated and annihilated $\langle S^2\rangle$ values for various systems studied (column 1). In columns 5 and 6 we list annihilated spin densities and calculated hyperfine couplings, respectively, for nuclei given in column 4. The last column of this table contains experimental data (37–56).

It is seen from this table that $\langle S^2\rangle_{sd}$ is invariably much higher than 0.75, the expected value for a doublet radical. We have, therefore, used annihilated spin densities in the least-squares fitting between experimental couplings and spin densities to obtain the HMNC value (listed in Table 1), for $\langle S^2\rangle_{asa}$ is almost always seen to be very close to 0.75, the exact value for a doublet radical. In the following we discuss the calculated MINDO/3 couplings for each nucleus separately and compare the results with those of other calculations.

Proton Hyperfine Couplings

An examination of Table 2 reveals that MINDO/3 proton hyperfine couplings are in fair agreement with the experimental data. In order to understand the details of hyperfine coupling mechanisms we have studied the spin density distributions in a few radicals. Table 3 gives the annihilated spin densities in the different atomic orbitals of π-radicals CH_3 and NH_3^+.

It is interesting to note that the π-orbital ($2p_z$ atomic orbital) has a spin density of 1.0 in both these systems and there is finite, though small, spin density

*All radicals were not used in parametrization. Actual oxygen and fluorine spin densities are obtained by multiplying the figures reported here by 10^{-1} and 10^{-2}, respectively.

transmitted to the σ framework. These spin densities successfully reproduce both the magnitude and the sign of the observed α-proton hyperfine couplings. Thus, like INDO and *ab initio* methods, MINDO/3 can also accommodate the exchange polarization effects which are invoked to account for α-proton hyperfine couplings. Similar arguments can be put forward for CH and OH π-radicals where the calculated values agree fairly well with experimental values.

The observed large proton hyperfine couplings in σ-radicals are also well accounted for by MINDO/3 calculations. Table 4 lists the annihilated spin density distributions in HCN, HCO, H_2CN, and vinyl radicals. From this table it is seen that the spin density in the π-orbitals of HCN, HCO, and H_2CN is very small (π-orbitals are linear combinations of $2p_z$ atomic orbitals where the z axis is perpendicular to the molecular plane). The excess spin density is shifted to the σ framework in these systems. In H_2CN, the highest occupied molecular orbital is of b_2 symmetry and most of the spin density is localized in the $2p_y$ orbital of nitrogen in the molecular plane, which has the same symmetry as the group orbital $(1s_{H_1}-1s_{H_2})$. Thus, in this molecule protons acquire a large spin density due to hyperconjugation. This is supported by *ab initio* calculation (9). The spin density results of HCN^- and HCO are also similar to that of the *ab initio* calculation due to Claxton (9) and the large proton hyperfine couplings in these systems can be accounted for by following his explanations. In these molecules, the ^{13}C, ^{14}N, and ^{17}O couplings also agree fairly well with *ab initio* and experimental data, and indeed in all these cases MINDO/3 results are better than the INDO results of Thomson (18) who employed the INDO optimized geometries in his calculations.

The MINDO/3 calculated proton hyperfine couplings in the vinyl radical agree fairly well with the experimental data, but the ordering of MO's does not agree with that of *ab initio* calculations (9). If we imagine the formation of vinyl radical as a result of removal of one hydrogen atom from ethylene, the resulting free radical is expected to be a σ radical, since the odd electron is most likely to be in one of the sp^2 hybrids at the carbon (or in a rehybridized orbital in the radical plane). This conclusion is supported by *ab initio* calculations where the highest occupied MO is seen to be of σ type and most of the spin density is in atomic orbitals in the radical plane. Although the

*The z axis is perpendicular to the plane of the radical.

MINDO/3 calculations show a total spin density in the π framework of the radical to be zero, the highest occupied and next to highest occupied MO's (Table 5) are seen to be of π symmetry (orbital energies −0.362 and −0.373 au respectively). The highest occupied MO of σ symmetry has an energy of −0.378 au. These MO's are fairly close in energy and the calculations indicate that when this is the case, the assumption that the occupation of MO's is in order of their increasing orbital energies breaks down. The total energy of the radical is given by

$$[10] \quad E = \frac{1}{2}\sum_{i=1}^{occ} E_i^{\alpha} + \frac{1}{2}\sum_{i=1}^{occ} E_i^{\beta}$$

where

$$E_i^{\alpha} = H_{ii}^{\alpha} + \varepsilon_i^{\alpha}$$

$$H_{ii}^{\alpha} = \int \Psi_{i\alpha}^{*}(1) H^{core}(1) \Psi_{i\alpha}(1)\, d\tau$$

$\Psi_{i\alpha}$ being the ith molecular orbital for α electrons with orbital energy ε_i^{α}. Thus each electron of the radical contributes an amount $\frac{1}{2}E_i$ to total energy. The values of E_i for $5\sigma_\alpha$, $1\pi_\alpha$, and $1\pi_\beta$ orbitals of vinyl radical are calculated to be −3.633, −3.765, and −3.798 au respectively. Based on these values, the occupation of MO's should occur in the order $1\pi_\beta$, $1\pi_\alpha$, $5\sigma_\alpha$, thus giving it a configuration (. . . . $1\pi_\beta 1\pi_\alpha 5\sigma_\alpha$) (rather than the configuration ($5\sigma_\alpha 1\pi_\alpha 1\pi_\beta$) based on orbital energies) and consequently predicting the most loosely bound electron of vinyl radical to be in a σ-molecular orbital, in conformity with the experimental as well as the spin density data.

It is seen from Table 5 that whenever the energy separation of the highest occupied and next to the highest occupied molecular orbitals is large, the MINDO/3 procedure predicts both the symmetry of highest occupied molecular orbital, as well as the

hyperfine coupling correctly. The predicted symmetries of the highest occupied molecular orbitals, based on orbital energies are wrong, whenever the orbital energies of highest and next to highest molecular orbitals are very close (~1 eV). In such situations configuration based on E_i values are generally in agreement with experimental as well as the spin density data. Such is the situation in NH_2 and FOO radicals, which (Table 5) have orbital energies of highest occupied molecular orbitals very close. Thus, the π-radicals NH_2 and FOO based on orbital energy data are seen to have the highest occupied MO's of σ-symmetry, contrary to expectation (configurations $(1\pi_\alpha 3\sigma_\alpha 3\sigma_\beta)$ and $(\ldots 4\sigma_\alpha 4\sigma_\beta 5\sigma_\alpha 5\sigma_\beta 2\pi_\alpha 2\pi_\beta 6\sigma_\alpha 6\sigma_\beta 7\sigma_\alpha 7\sigma_\beta 3\pi_\alpha)$ respectively). Employing the E_i values, we get the configurations $(\ldots 3\sigma_\alpha 3\sigma_\beta 1\pi_\alpha)$ and $(\ldots 4\sigma_\alpha 5\sigma_\alpha 5\sigma_\beta 6\sigma_\alpha 2\pi_\beta 2\pi_\alpha 6\sigma_\beta 4\sigma_\beta 7\sigma_\alpha 7\sigma_\beta 3\pi_\alpha)$ for the NH_2 and FOO radicals where the highest occupied molecular orbital is of π-symmetry as expected.

The HOO and HNF radicals from Table 5 are seen to have very similar orbital energies and both ε_i and E_i values predict the wrong symmetry for the highest occupied molecular orbital. In these cases, the use of MINDO/3 optimized geometries and imposition of symmetry in construction of the ground state eigenfunction might yield a lower value of total energy for the configuration, with the highest occupied molecular orbitals of right symmetry, but we have not attempted it. In any case, the orbital energies are so close, that the new calculation is not likely to alter the spin densities significantly.

In the case of the HCC radical, the calculated couplings do not agree with the available experimental data (41) or *ab initio* results (11, 13). In this system the odd electron is found to be in a pair of degenerate orbitals (energy = −0.387 au), thus correctly predicting that the radical is of σ type (total spin density in π_x and π_y being zero). The lack of agreement between calculated and experimental

couplings is probably due to the poor geometry (13) employed by us which may account for the slow convergence of the calculated energy in our computations.

The nonplanar radicals in which proton couplings have been studied are H_2NO, H_2CF, HCF_2, and C_2H_5. In H_2NO, the calculated proton couplings (8.44 G) are in fair agreement with experimental result (11.9 G). The highest occupied MO of this radical belongs to the a' irreducible representation of the C_s point group. The small spin density at the protons comes from $2p_z$ orbitals of nitrogen and oxygen through exchange polarization. Since the next highest occupied MO (a'') is much lower in energy, no spin density is transferred to protons through hyperconjugation. Small proton hyperfine couplings in H_2CF also follow the same pattern. However, the proton couplings in HCF_2 are not reproduced satisfactorily and the failure may be attributed to inappropriate MINDO/3 parametrization for fluorine.

For the ethyl radical, the computations were performed in two conformations (14) and the resultant average values of the couplings for methyl and methylene protons and also for the carbons agree fairly well with experiment. It is found that the odd electron is almost completely localized in the $2p\pi$ orbital (perpendicular to methylene group) of methylene carbon. The methylene protons which are in the nodal plane of this orbital acquire a small spin density because of exchange polarization. The positive spin density at the methyl protons arises through a combination of exchange polarization and hyperconjugation mechanisms.

Following the procedure of Pople and Beveridge (14) and using MINDO/3 spin densities, we estimate the relative importance of hyperconjugation and exchange polarization to be 93% and 7% in transferring the spin density to methyl protons in ethyl radical. Incidentally the same figures were arrived at by Pople and Beveridge who employed INDO spin densities.

The notable success of the annihilated MINDO/3 spin densities is that the π and the σ radicals do not need separate treatments, e.g. the same set of parameters give hyperfine couplings which are close to experimental values both in CH_3 (π radical) and HCO (σ radical). In most other semiempirical schemes, it is seen that a set of parameters which is good for π systems fails for σ systems and vice versa. In general MINDO/3 proton hyperfine couplings are comparable to INDO (14–19) and CNDO/SP (20) values.

^{13}C *Hyperfine Couplings*

A glance at Table 2 shows that the overall trend of MINDO/3 calculated ^{13}C hyperfine couplings is fairly satisfactory, both π and σ radicals being well accounted for. Particularly for CH_3 and HCO, MINDO/3 results are better than either INDO (43.08 G, 146.7 G) (18) or *ab initio* (52 G, 148.4 G) (12) results. In FCO, the MINDO/3 value (218.3 G), though poorer than the *ab initio* value of 290.3 G (10), is better than the corresponding INDO figure of 199.6 G (20). The geometry of FCO which we employed was due to Thomson and Brotchie (10*a*) and is in excellent agreement with UHF optimized geometry of Bleicher and Botschwina (10*b*). The slight disagreement between the calculated and experimental couplings might be attributed to fluorine parameters. The CO_2^- radical is bent in the ground state (35) and ^{13}C coupling is expected to be positive. MINDO/3 predicts a value of 136.4 G whereas the experimental value is 166.7 G. The value for the carbon coupling in HCN is not so good but is far better than the corresponding INDO value (156.1 G) (18). In H_2CN, only proton and nitrogen couplings are known experimentally (50) but Brivati *et al.* (57) have indicated a negative value for carbon coupling in this case. MINDO/3 calculations support this idea with magnitude fairly close to the *ab initio* value of 18.73 G (9). Experimental couplings at carbons in the vinyl radical are considerably different both in sign and magnitude. MINDO/3 accommodates both the sign and the relative magnitude although the absolute magnitudes of couplings are larger than their experimental counterparts. In the ethyl radical too, the magnitude and the sign are well accounted for at both carbons which has already been discussed.

Fluorination of the methyl radical considerably increases the *s*-character of the carbon orbitals which is reflected in increase of couplings on carbon atoms in these radicals. For example, the experimental values of hyperfine couplings in CH_3 and CF_3 are 38.5 G and 271.6 G, respectively. Calculated couplings reflect this feature in the same order (including H_2CF and HCF_2 as intermediate radicals). The magnitudes of individual couplings are not so satisfactory. We have used the INDO optimized geometry (14), which gives an increased pyramidal structure at carbon atom with increase in the number of fluorines in the radical. The less satisfactory aspect of couplings (magnitude) in these systems can be attributed to both geometry and fluorine parameters. Perhaps MINDO/3 optimized geometry might yield better results but we did not attempt it. The values of carbon couplings in CN and HCC radicals are rather poor.

^{14}N *Hyperfine Couplings*

The results of the application of the theory to the

nitrogen couplings are also given in Table 2 for a set of ten radicals. Except for CN and H_2NO, the present calculated couplings are better than any other calculations either *ab initio* or semiempirical. It is particularly interesting to note that in the NH_2, NH_3^+, and NO_2 radicals almost identical (compared to experiment) results are obtained. Despite employing *ab initio* geometrical model (9) in HCN and INDO model (17) in H_2CN the theory predicts very satisfactory ^{14}N coupling constants. The H_2NO case is interesting. It is generally agreed in experimental studies (58) that the spin density of X (X = N, O) is almost entirely localized in the π orbitals of nitrogen or oxygen atoms. However, there is no agreement concerning the spin density distribution between nitrogen and oxygen atoms. The reported values of nitrogen $2p$ spin densities range from 0.23 (59) to 0.9 (60). The calculated (annihilated) spin densities in the $2p\pi$ orbitals of nitrogen and oxygen are 0.3542 and 0.3540, respectively. As have been mentioned earlier, the spin density increases with the increase of s character at particular nucleus, so the pyramidal model employed here might not be very appropriate and MINDO/3 optimized geometry might yield better results.

^{17}O and ^{19}F Hyperfine Couplings

The ^{17}O couplings given in Table 2 are without any least-squares fitting. The HMNC value for ^{17}O is the INDO value due to Pople and Beveridge (14). The fitting was not done because the experimental couplings are not known for most of the systems studied here. Unlike the proton, carbon, and nitrogen couplings the calculated oxygen couplings are seen to be rather poor and do not exhibit any well defined trend. For example, in the case of CO_2^- and NO_2 where the calculated carbon and nitrogen coupling values are satisfactory, the ^{17}O couplings are too small. On the other hand, in H_2NO the calculated coupling is much larger than the experimental value. Peroxy radicals (ROO), which are intermediates in many reactions including those of biochemical interest, have been subjected to many theoretical as well as experimental studies (19, 47, 52, 61, 62). INDO (19) studies have shown that most of the spin density resides in $2p\pi$ orbitals of oxygens (79% on terminal and 21% on central) and is independent of the nature of the substituent R. Present calculations do not show such sharp difference between terminal and central oxygen atom $2p\pi$ spin densities. In HO^1O^2 the $\rho_{2p\pi_{12}}(O^1)$ and $\rho_{2p\pi}(O^2)$ are 0.3833 and 0.6167, respectively; in FOO, $\theta_{2p\pi}$ for O^1 and O^2 and F are 0.4902, 0.4486, and 0.0613, respectively. Table 5 shows in both of these two cases the energy difference between the highest and next highest occupied MO's is very small and reversal of MO's takes place, and consequently interpretation of couplings cannot be based upon MINDO/3 wavefunctions. From the point of view of the sign of spin densities in these systems, MINDO/3 and INDO results agree.

The ^{19}F hyperfine couplings have been studied in a set of 9 systems and are given in Table 2. The calculated couplings are not as satisfactory as the ^1H, ^{13}C, and ^{14}N couplings but are much better than ^{17}O couplings. In FCO, the MINDO/3 gives better matching with experiment (51) than the *ab initio* value of 196.8 G (10*a*). It is also noteworthy that as the number of fluorines in a radical increases, the calculated couplings start getting worse, e.g., in the H_2CF, HCF_2, and CF_3 radicals, whereas experiment shows ^{19}F couplings are smallest in H_2CF and largest in CF_3, the MINDO/3 predicts the largest value for HCF_2. A similar worsening of ^1H and ^{13}C hyperfine couplings with increase of number of fluorines can be seen from Table 2 in several radicals. This worsening of the calculated hyperfine couplings with increasing number of fluorines could be attributed to the fact that the spatial interactions due to fluorine lone pairs are likely to be fairly important and thus sensitive to the assumed geometry of the radical and MINDO/3 optimized geometries might improve the results, but we have not attempted these yet.

Conclusions

In conclusion, it is worthwhile to comment on the use of annihilated spin densities in our calculations. Our calculations indicate, just as those of some other workers (5–10, 17, 18), that annihilation of contaminants improves the results considerably, contrary to the observation of Pople and Beveridge (14). In fact it has been shown by separating UHF spin densities, as suggested by Yonezawa *et al.* (63), into spin delocalization and spin polarization parts that whereas spin polarization contributions are reduced to one-third by annihilation (63, 64), the delocalization contribution remains unaffected (63). The use of a mixture of annihilated and unannihilated spin densities in the ratio of 3:1 has been suggested by Amos and Burrows (65) which again shows a preference for annihilated spin densities.

In the preceding sections results and discussions of isotropic hyperfine couplings for ^1H, ^{13}C, ^{14}N, ^{17}O, and ^{19}F isotopes have been presented for various radicals. We conclude that MINDO/3 coupling constants as obtained by annihilated spin densities are fairly satisfactory in most of the radicals for ^1H, ^{13}C, and ^{14}N. This is also borne out by the correlation coefficients between calculated and experimental couplings of 0.9279, 0.7859, and 0.9988, for these nuclei respectively. Nothing can be said with certainty about ^{17}O results but the ^{19}F couplings seem to be less satisfactory.

Thermodynamic properties of binary mixtures containing thiaalkanes. II. Thermal pressure coefficients of pure compounds at 298.15 K

R. PHILIPPE, Z. FERHAT-HAMIDA, AND J. C. MERLIN

Université de Lyon I, Laboratoire de Chimie Analytique I, 43 boulevard du 11 Novembre 1918, 69621 Villeurbanne, France

Received May 16, 1979

R. PHILIPPE, Z. FERHAT-HAMIDA, and J. C. MERLIN. Can. J. Chem. **57**, 3135 (1979).

An apparatus for the measurement of thermal pressure coefficients of pure compounds is described. The thermal pressure coefficient β of *n*-thiaalkanes R_2S (R = CH_3, C_2H_5, *n*-C_3H_7, *n*-C_4H_9, *n*-C_7H_{15}) and of dithiaalkanes R_2S_2 (R = CH_3, C_2H_5, iso-C_3H_7) were measured at 298.15 K and at zero pressure. These experimental results in conjunction with data from literature for other compounds are compared using the reduced parameter of pressure P^* proposed by Flory. The P^* do not have regular values for the lower members of thiaalkanes series. One explanation of these irregularities is the different size of the molecules.

R. PHILIPPE, Z. FERHAT-HAMIDA et J. C. MERLIN. Can. J. Chem. **57**, 3135 (1979).

Nous décrivons un appareil utilisé pour la mesure des coefficients de pression thermique. Nous avons mesuré, à 298.15 K et à pression nulle, le coefficient de pression thermique β de *n*-thiaalcanes R_2S (R = CH_3, C_2H_5, *n*-C_3H_7, *n*-C_4H_9 et *n*-C_7H_{15}) et de dithiaalcanes R_2S_2 (R = CH_3, C_2H_5 et iso-C_3H_7). Ces résultats expérimentaux sont comparés avec d'autres résultats de la littérature en utilisant le paramètre de réduction de la pression P^* proposé par Flory. Les valeurs de P^* pour les premiers membres de la série des thiaalcanes n'ont pas des valeurs régulières. Ces irrégularités peuvent s'expliquer par la différence de taille deces molécules.

Introduction

The present work is a part of a research programme aimed at the correlation of H^E and V^E for different binary mixtures, and it is a continuation of research on thermodynamic properties of thiaalkanes + alkanes mixtures (1, 2). The knowledge of thermal pressure coefficient of pure components is required for comparison of the excess function of the mixtures with the predictions of various theories (3, 4) and provide useful information about the nature of liquid and about the forces between molecules. Many accurate measurements have been made on alkanes (5, 6) and branched alkanes (7), cycloalkanes (8), aromatic and polar compounds (9), polymers (10), and differently sterically hindered (DSH) compounds (11) but, apparently, no measurements have been done on the thiaalkanes series. Here we present measurements on pure compounds at 298.15 K: the thermal pressure coefficient of five *n*-thiaalkanes and the thermal expansivity and thermal pressure coefficient of three dithiaalkanes.

The thermal expansivity α defined by

$$[1] \quad \alpha = V^{-1}(\partial V/\partial T)_p$$

was measured from density ρ according to the relation

$$[2] \quad \alpha_T = \rho_T{}^{-1}[\rho_1(T_1) - \rho_2(T_2)/(T_2 - T_1)]$$

where the temperature T is defined by $T = (T_1 + T_2)/2$ and the thermal pressure coefficient β, defined by

$$[3] \quad \beta = (\partial P/\partial T)_V$$

was measured directly by static method.

Experimental

Solvents

Cyclohexane was a Fisher product (purity > 99 mol%) and *n*-hexadecane was a Merck product (purity > 99 mol%) and were used without further purification.

The thiaalkanes were "chemically pure" products (all obtained from S.N.P.A., Paris, except 2-thiapropane which was a Prolabo product) and were used without further purification. Their densities were used as criteria of purity; the values found for the lower homologues agree with accepted literatures values (Table 1). No reliable data are available for the higher homologues.

Thermal Expansion Coefficients

The thermal expansion coefficient α was determined according to the formula [2] from the densities ρ measured at three temperatures: T_1 = 297.15 K, T_2 = 299.15 K, and $(T_1 + T_2)/2$. The densities ρ were determined by the pycnometric technique by the same method as described before (1). The pycnometers were made of Pyrex glass and had an internal volume of about 22 cm^3. The temperature was measured with a Leeds and Northrup calibrated strain-free platinum resistance thermometer (8163 B type) associated wth a Leeds and Northrup high precision resistance Mueller bridge (G2 type). The calibration of thermometer was checked at the triple point temperature of water. The magnitude of $T_2 - T_1$ (about 2 K), close to 298.15 K, allows a linear interpolation to determine α.

4-Thiaheptane	832.6	833.12	12
5-Thianonane	834.5	—	
8-Thiapentadecane	839.4	—	
2,3-Dithiabutane	1054.7	1056.9	12
3,4-Dithiahexane	988.4	988.1	12
2,5-Dimethyl-3,4-dithiahexane	937.9	938.1	13

Thermal Pressure Coefficients

Thermal pressure coefficients were determined according to the procedure of Westwater *et al.* (14). The apparatus is similar to that previously described (11) and the schematic diagram of this is presented in Fig. 1. The thermal pressure cell containing the sample is a slightly modified version of that described in literature (6, 7), the volume was within 8 cm^3 and a platinum wire with a sharpened tip was centered in the 0.8 mm capillary. The pressure vessel built by the Prolabo Co. (Paris) was made of stainless steel with a 1 L capacity and could withstand a pressure within 4 MPa at 335.15 K. The hydraulic pressure generator is of screw-capstan type from Hight Pressure Equipment (Erie, U.S.A.). It displaces 60 cm^3 up to a pressure of 35 MPa. Pressure measurements are performed with a strain gauge supplied by Schaevitz Em Ltd. (P 703.0001 type) giving a 0.001 MPa resolution and an accuracy of 0.38% of the full range output. The temperature was measured with a 50 Ω platinum resistance thermometer (Thermo Est S.A.) and a Mueller bridge from Leeds and Northrup Co. (8163 B type, No. 161939). The resistance element section of the thermometer was located close to the bulb of thermal pressure cell and was enclosed in a stainless steel cylinder. The thermometer was calibrated by means of a water triple-point cell. The overall precision of temperature measurement was found to be within ±1 mK. We believe the temperatures measured were within 2 mK. The pressure vessel was immersed in a water thermostat (Lauda, NBS type) and the temperature of water was controlled to within ±0.01 K. Let us notice that the large mass of the pressure vessel minimizes temperature fluctuations of the thermoregulated bath, and at the equilibrium the temperature in the pressure vessel is regulated within ±0.5 mK.

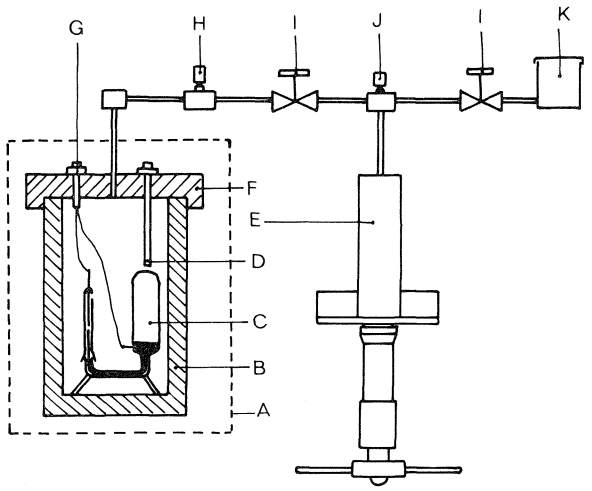

FIG. 1. Schematic diagram of the equipment used in the measurement of thermal pressure coefficient: *A* thermoregulated water bath, *B* pressure vessel, *C* Pyrex glass cell, *D* temperature probe, *E* pressure generator, *F* pressure vessel cap, *G* leads for the constant volume checking circuit, *H* strain pressure gauge, *I* high pressure valve, *J* safety head assembly, *K* reservoir for pressure fluid.

The liquid sample, about 7 cm^3, is placed in the Pyrex glass cell and degassed by repeated freezing with liquid nitrogen and melting under vacuum. The cell was then removed from vacuum line, inverted rapidly over degassed mercury, and the mercury level adjusted at the extremity of the platinum wire for the desired temperature. After positioning in the pressure vessel the whole apparatus is then connected to the pressure line and placed in the water thermostat. The temperature is increased and the pressure adjusted to restore the liquid to its initial volume indicated by the pilot light connected in series with the mercury and the platinum wire. Pressure over 0.5 MPa was used and at equilibrium the contact was sensitive to an increment of 0.001 MPa. The total temperature interval for one run is not larger than 2 K.

The plot of applied pressure against temperature was always linear within experimental error and the slope of this line, computed by a least-squares fitting procedure, gave β_{obs} and the temperature at zero pressure.

A correction is necessitated by the fact that the volume of the glass vessel is not strictly constant. During the experimental process, when the temperature is increased by ΔT and the pressure by ΔP_{obs}, the change in internal volume of the glass is:

$$[4] \quad \Delta V_g = V_g \alpha_g \Delta T - V_g K_g \Delta P_{obs}$$

where α_g is the thermal coefficient of expansion of the Pyrex (9.9×10^{-6} K^{-1} (6)), K_g is the isothermal compressibility of Pyrex ($2.96\ 10^{-7}$ MPa^{-1} (5*b*)) and $V_g = V_l + V_{Hg}$ is the volume of the cell. The volume of liquid sample (V_l) and mercury (V_{Hg}) in the cell were computed from their respective weights.

Similarly the change in volume of mercury is:

$$[5] \quad \Delta V_{Hg} = V_{Hg} \alpha_{Hg} \Delta T - V_{Hg} K_{Hg} \Delta P_{obs}$$

where α_{Hg} is the thermal coefficient of expansion of mercury (1.81×10^{-4} K^{-1} (6)) and K_{Hg} the isothermal compressibility of mercury, represented as a function of the temperature by the equation (23):

$$[6] \quad K_{Hg} = 3.921 \times 10^{-7} + 4.7 \times 10^{-10} (T - 273.15) + 3.5 \times 10^{-15} (T - 273.15)^3 \text{ MPa}^{-1}$$

The change in volume of liquide ΔV_l corresponds with an extra pressure ΔP such as

$$[7] \quad \Delta V_l = (\Delta P - \Delta P_{obs}) V_l K_l$$

where $K_l = \alpha_l/\beta_l$ is the isothermal compressibility of the liquid. Taking relations [4], [5], and [7] into account and dividing through by ΔT, one obtains

$$[8] \quad \beta = \beta_{obs} \frac{\alpha_l V_l}{\alpha_l V_l + (\alpha_{Hg} - \beta_{obs} K_{Hg}) V_{Hg} - (\alpha_g - \beta_{obs} K_g) V_g}$$

The overall performance of the apparatus was checked by measurement of the thermal pressure coefficient of cyclohexane and *n*-hexadecane. The results are shown in Table 2 where they are compared with literature values. As these data have not been obtained by the same method, our results are in excellent agreement with the data obtained by the direct method.

Results and Discussion

In the course of some experiments a slow reaction was found to occur between thiaalkanes and mercury, as shown by a film of black solid material which formed on mercury–liquid interface in the cell and causing a change in the cell volume of about 5×10^{-6} cm^3 found by dilatometric measurements. It therefore appears that any reaction with mercury was insufficient to introduce any significant errors into the data obtained. After 12 h, indeed, no change in internal volume of the cell was detected, and two consecutive sets of measurements on the same sample agree within our estimated experimental uncertainties.

The experimental thermal pressure coefficient β of thiaalkanes is given in Table 3 together with the thermal expansivity α, the pressure reduction parameter P^*, the dipole moment μ, and the molecular surface/volume ratio *s*.

As pointed out previously (11), discussion of these results will be made with the values of pressure reduction parameter P^* representative of cohesive energy of the compounds rather than on β, since β also reflects the state of expansion which varies considerably along the series. The parameter P^* is obtained from the Flory model (3) with experimental values of α and β by the equation:

$$[9] \quad P^* = \beta \tilde{v}^2 T$$

where the reduced volume $\tilde{v}$ is calculated by:

$$[10] \quad \tilde{v}^{1/3} = [(4/3)\alpha T + 1]/(\alpha T + 1)$$

These values are reported on Fig. 2 together with

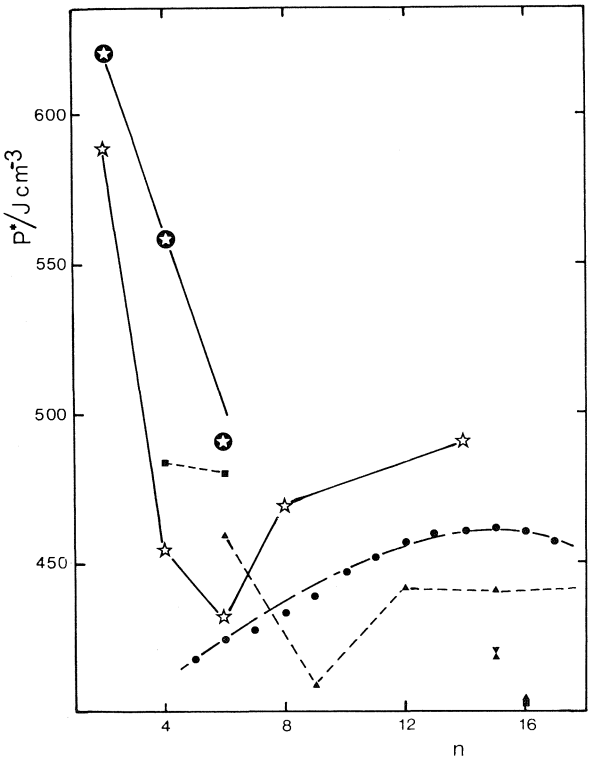

FIG. 2. Pressure reduction parameter P^* plotted versus n the total number of carbon atoms for dithiaalkanes (✪), n-thiaalkanes (☆), n-ethers (■), trialkylamines (▲), n-alkanes (●), diisopentylamine (⧗), and 2,2,4,4,6,8,8-heptamethylnonane (⬟).

the values obtained for other series of compounds (7, 11) for comparison.

These values are higher than those of other series. As for n-trialkylamine series, the P^* values for the lower members of the n-thiaalkanes series do not vary smoothly with molecular weight, and a minimum is found for 4-thiaheptane. The influence of chain length is less perceptible but it seems that the P^* values tend towards a limiting value when the molecular weight increases. The limiting value for this series is higher than for the "DSH" series (11) and the order appears to be $R_2S > n\text{-}Cn > R_3N > R_4Sn > (OR)_4Si$.

For dithiaalkane series, the number of compounds studied is not sufficient to obtain comprehensive conclusions. Nevertheless, by comparison with the n-thiaalkane series, it is quite possible that the larger values found for 2,3-dithiabutane and 3,4-dithiahexane are related to the polarity of these compounds, and by comparison with the branched alkanes and the branched amines (11), the branched dithiaalkane (2,5-dimethyl-3,4-dithiahexane) seems to have slightly lower value of P^*. We do not think that the high values found for the lower members of n-thiaalkanes and dithiaalkanes series can be explained solely by the more polar character of these molecules. Table 3, indeed, shows that molecules of same shape, the aliphatic ethers, have a dipole moment lower than the homomorphic n-thiaalkanes and have a higher P^* value. The size effect prevails over this polarity effect as it can be seen on molar volume:

Compound	V_m (298.15 K) (10^{-6} m^3 mol^{-1})
$(C_2H_5)_2S$	108.5
$(C_2H_5)_2O$	104.7
$(C_3H_7)_2S$	141.7
$(C_3H_7)_2O$	137.7

As interactions of molecules take place between molecular surfaces, we think that the comparison of energies by unit surface is more meaningful than those of energies by unit volume P^*. Energy by unit surface may be determined from the ratio P^*/s where s is the molecular surface/volume ratio. The s values depend on the shape of the molecule and were computed assuming the thiaalkanes to be right cylinders of core volume V^* as n-alkanes (21). This assumption is proved by the fact that the Van der Waals volumes (22) of S atom (10.8×10^{-6} m^3 mol^{-1}) and CH_2 group (10.2×10^{-6} m^3 mol^{-1}) are fairly close. Accordingly s is given by:

$$[11] \quad s = \frac{4}{D} + \frac{\pi D^2 N_A}{2 \times 10^{23} V^*}$$

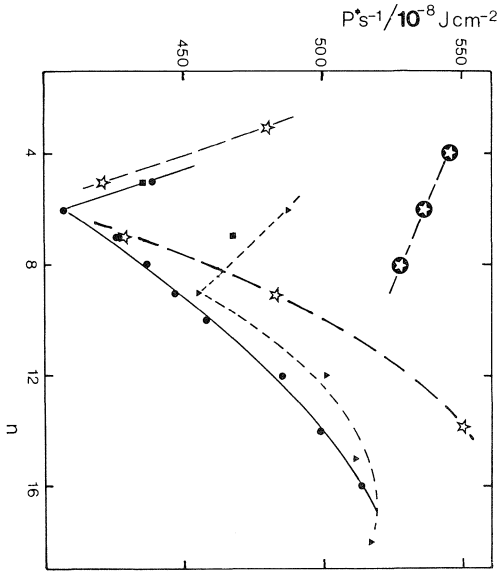

FIG. 3. P^*s^{-1} plotted versus n the total number of atoms of the compounds for dithiaalkanes (✪), n-thiaalkanes (☆), n-ethers (■), triaalkylamines (▲), and n-alkanes (●).

where D is the cylinder diameter equal to 4.98×10^{-10} m (21*b*) for linear alkane chain and 6.96×10^{-10} m (21*a*) for branched alkane chain to that of the 2,5-dimethyl, 3,4-dithiahexane, and $N_A = 6.02 \times 10^{23}$ is the Avogadro constant.

The s values are reported in Table 3 and the P^*s^{-1} values are plotted on Fig. 3 (versus n, the total number of atoms of the compounds because S atom has been considered equivalent to a carbon atom). Figure 3 shows that the P^*s^{-1} values of the n-thiaalkanes are quite comparable to those of n-alkanes. Nevertheless, for dithiaalkanes the P^*s^{-1} values are somewhat higher than those of the n-alkanes or n-thiaalkanes and it is not possible to decide the proportion of increased polarity (Table 3) and that of molecular model in these higher values.

These results will be used for a detailed theoretical interpretation of excess thermodynamic properties (H^E, V^E) of binary mixtures of thiaalkanes with n-alkanes in a later paper.

Acknowledgements

We would like to thank the Franco-Algerian Scientific Corporation Service for a research fellowship to one of us (Z.F.H.). The donation of samples of thiaalkanes from S.N.P.A. is acknowledged.

The synthesis of oligoribonucleotides V.[1] The stepwise synthesis of the 3′-terminal heptanucleotide sequence of $tRNA^{fMet}$ from *E. coli*

KELVIN K. OGILVIE AND NICOLE Y. THERIAULT

Department of Chemistry, McGill University, 801 Sherbrooke St. W., Montreal, P.Q., Canada H3A 2K6

Received June 6, 1979

KELVIN K. OGILVIE and NICOLE Y. THERIAULT. Can. J. Chem. **57**, 3140 (1979).

The stepwise synthesis of a heptaribonucleotide GpCpApApCpCpA corresponding to the 3′-terminus of $tRNA^{fMet}$ from *E. coli* is described. The procedure takes advantage of the ease of obtaining ribonucleoside units bearing a *tert*-butyldimethylsilyl group on the 2′-position. These units, bearing a 5′-methoxytrityl group are phosphorylated at the 3′-position and coupled to the free 5′-position of the growing nucleotide chain using the chlorophosphite coupling procedure. Yields varied from 87 to 50% over the entire sequence.

KELVIN K. OGILVIE et NICOLE Y. THERIAULT. Can. J. Chem. **57**, 3140 (1979).

On décrit la synthèse par étapes de l'heptaribonucléotide GpCpApApCpCpA correspondant à l'extrémité 3′ de l'ARN de transfert (FMet) provenant du *E. coli*. Cette méthode profite de l'obtention facile des unités ribonucléosides ayant un groupement *tert*-butyldiméthylsilyle en position 2′. Les unités portant un groupement méthoxytrityle-5′ sont phosphorylées en position 3′ et couplés à la position 5′ libre de la chaîne nucléotide en croissance en utilisant le procédé de couplage au chlorophosphite. Les rendements pour la séquence complète varient de 87 à 50%.

[Traduit par le journal]

The chemical synthesis of oligonucleotides involves two principal problems: the availability of suitably protected nucleosides and methods to condense these units to form nucleotides. In the deoxynucleotide area adequate protecting groups have long been available and most attention has been applied to the question of phosphorylation procedures (1–9). In the ribonucleotide area developments have lagged well behind the deoxy series largely because of the difficulties of finding suitable procedures for protecting the 2′-hydroxyl group.

Reese extensively explored the problem of protection of ribonucleosides (for review see ref. 10) and essentially settled on tetrahydropyranyl-type protection for the 2′-position. Khorana and co-workers also investigated this area (11) and Smrt and co-workers made important contributions (12, 13) to the protecting groups for ribonucleosides. Neilson was the first to combine the tetrahydropyranyl protecting groups with the triester technology to make important ribonucleotide chains of significant length. In 1974 Neilson and Werstiuk (14), using a block-condensation triester approach, synthesized a nonanucleotide corresponding to the anticodon loop from the fMet tRNA from *E. coli*. They later improved on the synthesis of this same sequence (15). Neilson and England also prepared two tetranucleotides and a pentanucleotide using a single addition (stepwise) procedure (16). The latter is, until now, the longest reported ribonucleotide prepared by a stepwise triester approach. Ikehara and co-workers assembled a pentanucleotide (17) using a stepwise diester approach. They have been experimenting with photochemical protecting groups (18), enzymatic coupling (19), and have recently reported a chemical block – triester synthesis of a heptanucleotide corresponding to units 53–59 from fMet tRNA from *E. coli* (20). Van Boom *et al.* have made the tetradecaribonucleotide $(UA)_7$ by a block-assembly triester procedure (21*a*). They have also prepared hexanucleotides corresponding to naturally occurring sequences by block-condensations (21*b*). Wiewiorowski and co-workers (22) have also used a block-condensation triester approach to prepare a heptanucleotide sequence from the anticodon loop of an initiator tRNA.

We wish to describe in this report the synthesis of the heptaribonucleotide GCAACCA corresponding to the 3′-terminus of fMet tRNA from *E. coli*. The chain was assembled in a stepwise fashion to prove the efficiency of the silyl protecting groups combined with the dichlorophosphite condensation procedure for the synthesis of oligoribonucleotides. The synthesis of all of the protected ribonucleosides has been previously described (23, 24). The present synthesis is outlined schematically in Scheme 1.

The questions which arise most naturally in connection with any new proposal for nucleotide syn-

SCHEME 1

thesis include: (*a*) Do yields fall off significantly with increasing chain length and/or is it necessary to go to higher and higher ratios of reagents to ensure adequate yields? (*b*) Is it necessary to extend the time for condensation as the chain length increases? A positive answer to either or both of these questions can severely limit the practicality of a procedure.

In the early diester work on deoxynucleotides it was often necessary to use high ratios of one reagent to another. For example in the condensation (25) of Tr-(Tp)$_4$T with pT-OAc to form a hexanucleotide a 15-fold excess of pT-OAc was necessary to insure a 60% yield after 3 days of condensation. However, in Neilson's stepwise synthesis of the pentanucleotide ApCpCpUpC (16) the ratio of monomer to growing chain varied slightly from about 1.4 to 1 at the dinucleotide level to 2 to 1 at the pentanucleotide level while the yields decreased moderately from 73 to 45%. However, even though Neilson's work employed mesitylenesulfonyl triazole, considered to be a rapid condensing agent (6), the time of reaction varied from 3 days at the dinucleotide level to 10 days to form the penta. In Ikehara and co-workers' stepwise synthesis of UpAp^{m2}GpCpC (17) using a diester approach, ratios of reacting nucleotide units varied from 1 to 1 at the trinucleotide to 1 to 4 at the pentanucleotide stage. Yields ranged from 38 to 21% over this sequence and all condensation steps required 5 days. It is of course important to note that these procedures did indeed work and the desired nucleotide products were formed.

In Table 1 we have summarized the important observations in connection with the synthesis of the heptanucleotide GpCpApApCpCpA. Three points are worth noting. (*1*) The total reaction time remained constant at 2 h and 45 min over the entire sequence. (*2*) Yields decreased moderately from 87% at the dinucleotide to 50% at the heptanucleotide stage. (*3*) The ratio of monomer to oligomer increased from 1.7 to 1 at the trinucleotide stage to 3.3 to 1 at the heptanucleotide stage. Most of the shorter chains were synthesized several times and the yield ranges are also indicated in Table 1.

All of the nucleotides produced in this work were obtained after thick layer chromatography of the reaction products. The important by-products include the 3′–3′-linked dimers produced during the initial phosphorylation of compounds **1**. Since these

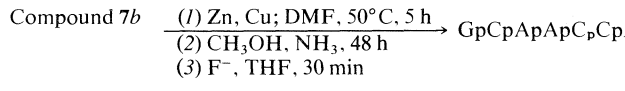
dimers contain two methoxytrityl groups they nearly always have higher R_f values than the desired reaction product and are easily separated. Problems occasionally arise when the tritylated oligomer $n + 1$ has similar chromatographic mobility to the untritylated starting oligomer n. This problem seems to occur largely when the monomer that is being added does not contain a protecting group on the amino function of the base. For example, the tetranucleotide mmt-A^{Si}_{p}(TCE)C^{BzSi}_{p}(TCE)C^{BzSi}_{p}(TCE)A^{Si}_{Si} (**4***a*) had only slightly different chromatographic properties from the starting trimer C^{BzSi}_{p}(TCE)C^{BzSi}_{p}(TCE)A^{Si}_{Si} (**3***b*). This problem is easily overcome since on treating a mixture of **4***a* and **3***b* with 80% acetic acid, compound **4***a* loses a trityl group to produce **4***b* which has chromatographic properties different from **3***b* (Table 2) and separation is easily obtained in this fashion. The yields reported in Table 1 are from reactions where none of the *b*-oligomers (e.g. **3***b*) remained at the end of the reaction. In any event the similarity of desired product and *b*-series starting material occurred for **2***a*, **4***a*, and **5***a* where purity of product was easily verified by detritylation as described. All of the *a*-series compounds (**2***a*–**7***a*) were detritylated with 80% acetic acid at room temperature for 20 h. Isolated yields are reported in Table 1.

Several of the protected nucleotide products were completely deprotected to the free nucleotides for identification. Thus **2***b*, **3***b*, **4***b*, **5***b*, and **7***b* were treated successively with (*1*) Zn–Cu couple in DMF at 55°C for an average of 5 h; (*2*) half-saturated methanolic ammonia at room temperature for two days, and finally (*3*) tetrabutylammonium fluoride (TBAF) for 30 min (Scheme 2).

The properties of the deprotected oligonucleotides are recorded in Table 3. The di- through pentanucleotides were all completely degraded by phosphodiesterases to give the monomer units in the correct ratios. The heptanucleotide GpCpApApCpCpA was degraded first by ribonuclease A to give GpCp, ApApCp, Cp, and A. The GpCp unit was then degraded by ribonuclease T_1 to give Gp and Cp.

The work described in this manuscript clearly



SCHEME 2

demonstrates that the silyl protecting groups combined with the chlorophosphite condensation procedure presents a very effective method for the synthesis of oligoribonucleotides. The protected nucleosides are obtained by rapid and practical synthetic procedures. The chlorophosphite condensation procedure is short ($2\frac{3}{4}$ h). The products are isolated by silica gel chromatography. The synthesis of a heptaribonucleotide by a stepwise procedure clearly demonstrates the facility of the method. We will soon describe the use of these basic procedures along with block condensations in the chemical synthesis of the sequence corresponding to the $tRNA^{fMet}$ from *E. coli*.

Experimental

General Methods

All general procedures including the preparation of all starting materials have been previously described (23, 24). The procedures used for the synthesis of oligonucleotides are as previously described (23, 24) and the ratio of reactants used are summarized in Table 1. The solvents used to isolate the nucleotides **2***a*–**7***a* are listed in Table 4. The procedures used for completely deprotecting the nucleotides **2***a*–**7***a* have also been previously described along with the enzymatic procedures used to characterize the free oligonucleotides (23, 24). Yields (determined spectrophotometrically) for complete deprotection of oligonucleotides are generally in the 30–60% range. The only change in enzymatic procedures was that the products of enzyme degradation were characterized and quantitated on a Spectrophysics Model SP8000 Microprocessor-based HPLC unit. The column used was a Lichrosorb H2-10A (aminobonded phase) column. The solvent consisted of 10% 0.2 *M* $NH_4H_2PO_4$ (pH 3.3) and 90% H_2O. The column was maintained at 30°C with a flow rate of 2 mL/min.

The chemistry of thujone. II.[1] Insect juvenile hormone analogues via acid dianion coupling. The β lactone route

JAMES P. KUTNEY, MICHAEL J. MCGRATH, ROBERT N. YOUNG, AND BRIAN R. WORTH
Department of Chemistry, University of British Columbia, 2075 Wesbrook Place, Vancouver, B.C., Canada V6T 1W5

Received May 25, 1979

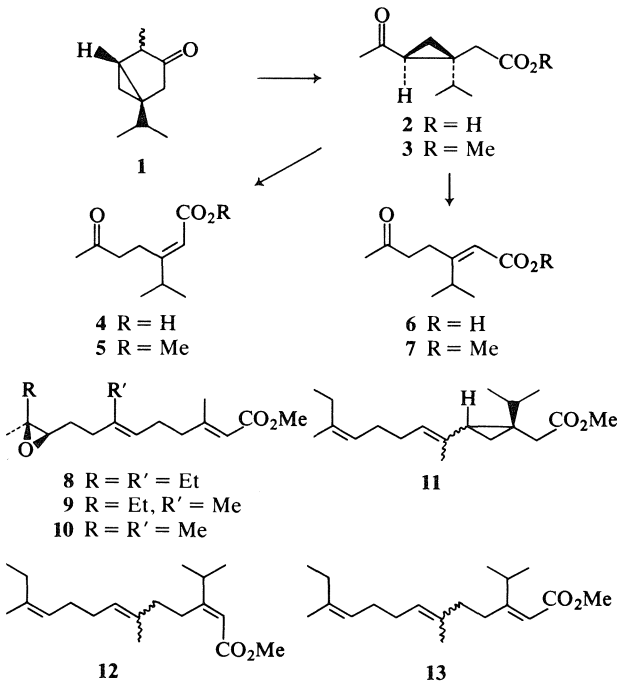
JAMES P. KUTNEY, MICHAEL J. MCGRATH, ROBERT N. YOUNG, and BRIAN R. WORTH. Can. J. Chem. **57**, 3145 (1979).

Several stereoselective syntheses of (*E*)-2-ethyl-6-methyl-5-octenoic acid (**17**) are described. The dianion of pure **17** was subsequently coupled with (*E*)-β-thujaketonic acid methyl ester (**5**), derived from thujone (**1**), to give the β-lactones **45** and **46** which were then epoxidized and pyrolyzed exemplifying a route to juvenile hormone analogues such as **51** and **54**.

JAMES P. KUTNEY, MICHAEL J. MCGRATH, ROBERT N. YOUNG et BRIAN R. WORTH. Can. J. Chem. **57**, 3145 (1979).

On décrit plusieurs synthèses stéréosélectives de l'acide (*E*)-éthyl-2 méthyl-6 octène-5 oïque. Le dianion pur de **17** couplé à l'ester méthylique de l'acide (*E*)-β-thujacétonique (**5**) provenant de la thujone (**1**) conduit aux β lactones **45** et **46**. Ces derniers sont alors transformés en époxyde qui, par pyrolyse, permettent d'accéder aux analogues **51** et **54** de l'hormone juvénile.
[Traduit par le journal]

The steam distillate from the slash (waste) of the western red cedar is an excellent source of the monoterpenoid ketone, thujone (**1**) (1, 2). In an effort to further exploit the ready availability and interesting functionality of **1**, its utility in a general route to a series of insect juvenile hormone (JH) analogues was investigated. Permanganate oxidation (2) of thujone[2] had provided α-thujaketonic acid (**2**) which could be ring opened, thermally to give (*E*)-β-thujaketonic acid (**4**), or via base catalysed cleavage of the ester (**3**) to give (*Z*)-β-thujaketonic acid methyl ester (**7**) (1). The gross structural similarities between the synthetic units, **3**, **5**, and **7** and the "right hand" portion of the juvenile hormones **I**, **II**, and **III** (**8**–**10**) pointed to a potential usage of thujone derived intermediates. In fact an earlier report (1) described the coupling of these keto-acids and esters with C8-units, via Wittig olefination, to give analogues such as **11**, **12**, and **13**. This method was, however, limited to the preparation of derivatives with a trisubstituted internal double bond, thus limiting the series of analogues available for biological screening. A further detriment to this route lay in the difficulty experienced in separating the *E*- and *Z*-isomers (at C6) formed during the coupling.



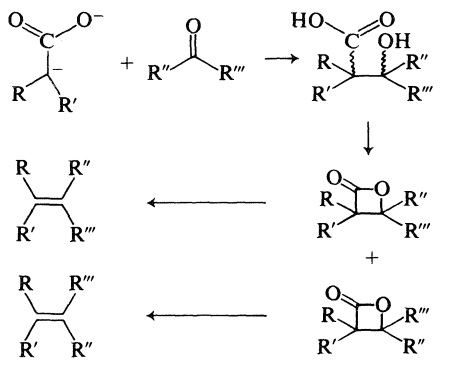
SCHEME 1

Thus, in order to circumvent these difficulties it was necessary to devise an alternative route which, ideally, would fulfill four important requirements: (*i*) the ability to generate tri- and tetrasubstituted internal unsaturations, (*ii*) a mode of coupling that would allow at least selective *trans*-isomer formation, (*iii*) facile separation of the isomeric alkenes, (*iv*) specific protection of the internal double bond so as to allow specific epoxidation at C10(11). Of the various methods available (3–10), that involving coupling between a carboxylic acid dianion and a ketone to give a β-hydroxy acid, generation of di-

[1]For Part I, see ref. 1.

[2]Although thujone exists in two epimeric forms at C4, oxidative cleavage to **2** destroys this chiral centre thus allowing crude thujone to be used for this work.

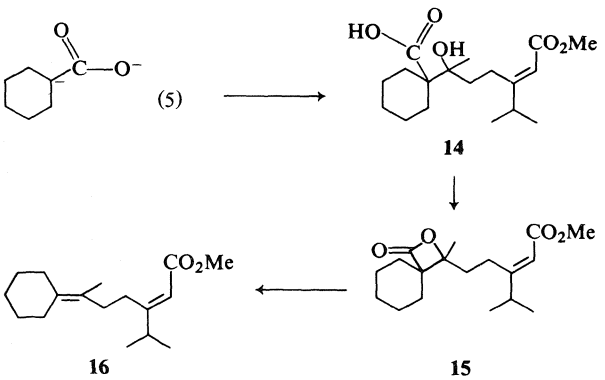
0008-4042/79/233145-10$01.00/0



SCHEME 2

astereomeric β-lactones, and subsequent thermal elimination of carbon dioxide (Scheme 2) seemed the most suitable (4, 11, 12).

To determine the suitability of the thujone-derived ketoesters for the proposed route, the dianion from cyclohexane carboxylic acid was reacted with (*E*)-β-thujaketonic acid methyl ester (**5**). The required adduct **14** was formed in 60% yield. Subsequent reaction with benzenesulphonyl chloride in pyridine provided the β-lactone **15** as evidenced by characteristic infrared absorption at 1810 cm^{-1}. Pyrolysis of **15** at 140°C gave a 68% yield of the expected tetrasubstituted alkene **16**.



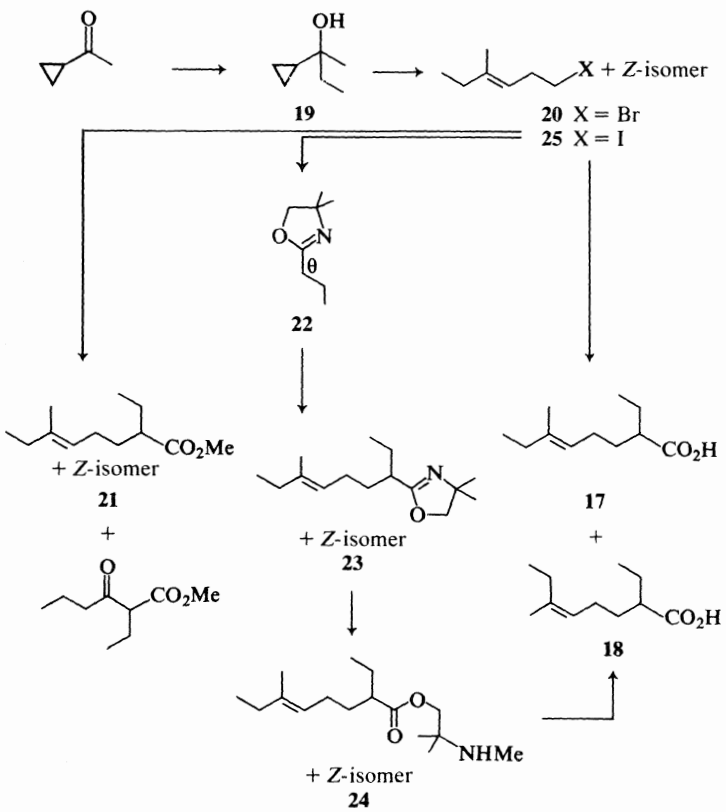
SCHEME 3

With the success of the model sequence, the preparation of prerequisite acid units representing the "left hand" portion of juvenile hormones **8**–**10** was necessary. Initially, the more troublesome targets **17** and **18**, related to the C18 cecropia juvenile hormones (**8** and **9**), were chosen since successful application of the proposed scheme with these units would effectively guarantee a route to the analogue related to **10**.

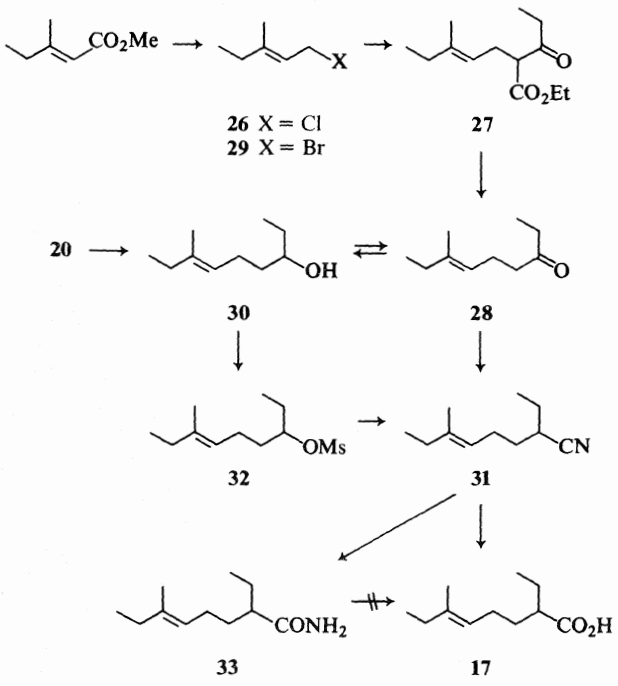
An efficient synthesis of a mixture of the *E*- and *Z*-octenoic acids **17** and **18** was available, based on the known cyclopropylcarbinol–homoallyl rearrangement (13–16), as shown in Scheme 4. Grignard reaction on methyl cyclopropyl ketone afforded the known carbinol **19** (13) which on reaction with magnesium bromide (17, 18) in ether gave a mixture of the *E*- and *Z*-homoallylic bromides **20**. Initially this mixture was used to alkylate (19) the α-anion of methylbutanoate giving only a low yield of the esters **21** admixed with the Claisen product (20), methyl-2-ethyl-3-oxohexanoate. Similar alkylation of the anion **22**, of the oxazoline (21, 22) formed by reaction between butanoic acid and 2-amino-2-methyl-1-propanol, gave only a 44% yield of the adducts **23**. Direct, acid catalysed hydrolysis of **23** was not successful; however, methylation using iodomethane and subsequent aqueous base catalysed hydrolysis gave the esters **24**. Reaction of **24** in aqueous ethanolic sodium hydroxide solution at 50°C did provide a route, albeit inefficient, to the required acids. Reaction of the dianion of butanoic acid (23) with the bromides **20** in a mixture of tetrahydrofuran (THF) and hexamethylphosphortriamide (HMPA) provided the *E*- and *Z*-acids **17** and **18** directly. Best results were obtained by analogous alkylation with the relatively unstable iodides **25**, formed by reaction of the mixture **20** with sodium iodide in acetone or more efficiently by ring opening of **19** with magnesium iodide in ether (17, 18). In this manner an 80% yield (from **19**) of the acids **17** and **18** was obtained. Separation of the isomeric acids **17** and **18** was not possible by glc or by tlc methods. Accurate determination of the ratio of these products was however possible from areas of the resonances due to C5 in the ^{13}Cmr spectrum (24). In this manner, the composition was determined as 80% *E*- (**17**), 20% *Z*- (**18**).

Although this route provided a fast and efficient means of obtaining the octenoic acids for developing the efficiency of subsequent reactions, in order to ensure the integrity of juvenile hormone analogues for biological screening a stereospecific route to **17** or **18** was necessary.

Initially, the synthesis outlined in Scheme 5 was investigated. Horner reaction between 2-butanone and the sodium salt of trimethylphosphonoacetate afforded *E*- and *Z*-methyl-3-methyl-2-pentenoates which were separated by spinning band distillation as described earlier (1, 25). The major, *E*-isomer was elaborated by standard means to the pure *E*-allylic chloride **26** (1). Alkylation of ethyl-3-oxopentanoate (26) with **26** in 1,2-dimethoxyethane (DME) gave pure *E*-β-ketoester **27**. For each intermediate in this route (Scheme 5) the respective *E*- and *Z*-isomers were not separable by either tlc or conventional glc systems. Therefore *E*-, *Z*- mixtures of the intermediates up to and including **27** were initially prepared as described above from a mixture (ca. 2:1) of *E*- and *Z*-methyl-3-methyl-2-pentenoates. In each case the differences in chemical shift for the vinylic methyl signals in 270 MHz ^{1}Hmr proved satisfactory



SCHEME 4

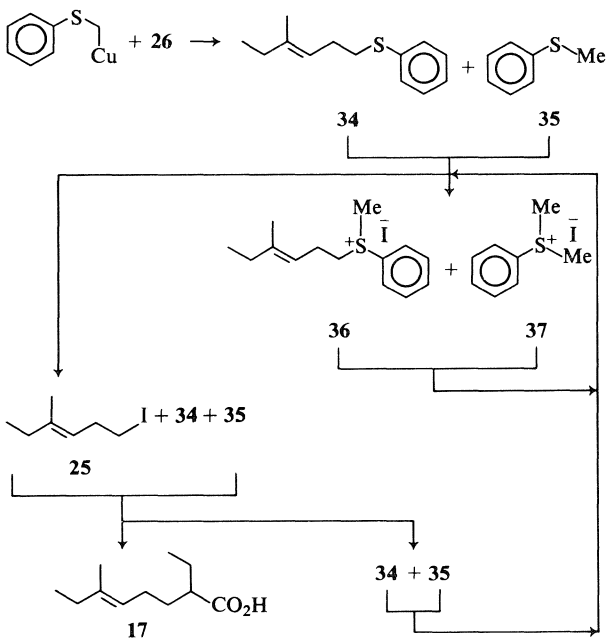


SCHEME 5

for the determination of isomer ratios. These chemical shift values were then used to determine the integrity of subsequent purity of compounds within the *E* series. Examination of **27** (derived from pure *E*-methyl-3-methyl-2-pentenoate) by 270 MHz ^{1}Hmr spectroscopy did not show detectable *Z*-isomer (1). An *E*-, *Z*- mixture of the ketone **28** was prepared from a mixture of isomeric bromides **20** via reaction of the derived Grignard reagent with propanal and oxidation of the alcohol **30** with pyridinium chlorochromate. The ^{1}Hmr spectrum of this mixture of ketones was used to determine the isomeric purity of subsequent batches of the ketone **28**, and to optimize conditions for further transformations. Optimum conditions for the conversion of pure **27** to pure *E*-γ,δ-unsaturated ketone **28** were attained using barium hydroxide in aqueous ethanol under reflux. Thus a 75% yield of **28**, of >98% isomeric purity, was obtained (1). Homologation of **28** was accomplished via the nitrile **31** for which two routes were investigated. Firstly reduction of **28** (>98% *E*) with sodium borohydride in methanol gave **30** which was readily converted to the mesylate **32**. Reaction of the latter with sodium cyanide in HMPA gave a 60%

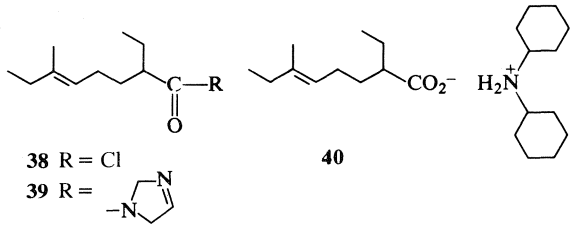
overall yield of **31** contaminated with ca. 9% *Z*-isomer as determined from the 270 MHz ^{1}Hmr spectrum. The obvious isomerization of *E* to *Z* in the sequence **28** → **30** → **32** → **31** dictated an alternative method of preparation of **31**. Success was achieved when **28** (>98% *E*) was reacted with potassium hydride and tosylmethylisocyanide (TOSMIC) (27–29) in DME. The nitrile **31** of ca 98% isomeric purity was isolated in 75% yield. Analogous reaction using potassium *tert*-butoxide in *tert*-butanol and DME gave nitrile of 95% isomeric purity. Hydrolysis of **31** (98% *E*) required heating to 180°C in a sealed tube with potassium hydroxide in aqueous methanol, and under these conditions acid **17** of ca. 87% isomeric purity (determined as above using ^{13}Cmr spectroscopy) was obtained in 74% yield. Treatment of **31** with powdered potassium hydroxide in refluxing dry *tert*-butanol (30) gave a 62% yield of the crystalline primary amide **33** (ca. 93% *E*, 7% *Z*). Although recrystallization of **33** may have improved the isomeric purity, attempts to convert **33** to the acid **17** under mild conditions (aqueous sodium peroxide (31)) were unsuccessful. Thus although this route (Scheme 5) provided the required acid **17**, the subsequent conversion of a substrate of ca. 93% isomeric purity to juvenile hormone analogues was considered unsatisfactory.

An alternative route to the *E*-acid **17** is outlined in Scheme 6. In this regard, pure *E*-allylic chloride (1) **26** was reacted with phenylthiomethylcopper (32–35) in THF to give a mixture of the thioether **34** (75% by glc) and thioanisole **35** (20% by glc). This mixture was generally used as such for subsequent conversions. An analytical sample of **34** (94% *E* by 270 MHz ^{1}Hmr) was obtained by preparative glc. Another sample obtained by fractional distillation of the mixture, however, was similarly shown to be 98% *E*-isomer. Reaction of the mixture of **34** and **35** with iodomethane and sodium iodide in dimethylformamide (DMF) in the presence of metallic mercury and calcium carbonate (35) at 70°C gave, after dilution with ether, the precipitated salts **36** and **37** together with an ethereal solution of the unstable iodide **25**, thioanisole **35**, and the thioether **34** in the ratio 38:50:12 (as determined by glc). Separation of the iodide from the above mixture either by distillation or by preparative glc was not possible. Therefore the mixture was treated, as such, with the dianion from *n*-butanoic acid in THF and HMPA to give the acid **17** and a mixture of **34** and **35**. The separated neutral fraction was combined with the salts from the previous reaction and the cycle repeated. The ^{13}Cmr spectrum of **17** obtained via this route indicated 95% *E*-, 5% *Z*-isomer (24).



SCHEME 6

Although this synthesis had allowed generation of the acid **17** with high stereoselectivity, it was decided that for the purposes of biological screening of subsequently derived JH analogues, a higher isomer integrity was desirable. Therefore various methods of purification of **17** were investigated. A derivative of the acid was sought such that purification would enable separation of pure *E*-isomer and such that efficient regeneration of acid could be accomplished without concomitant alkene isomerisation. The crystalline amide **33** was also available via the acid chloride **38** but, as mentioned above, regeneration of **17** under mild conditions was not possible. The methyl ester was a liquid, as expected, and separation of the *E*- and *Z*-isomers using glc or conventional chromatographic methods (including silver nitrate impregnated silica gel (36)) was not accomplished. Imidizolides were reported (37) to generally exhibit good crystalline properties; however, the derivative **39** derived from **17** was a liquid. Both the ammonium and dimethylammonium salts were crystalline but relatively unstable, each liberating the acid **17** and the respective amine on standing. The crystalline diisopropylammonium salt was stable but recrystallization even from *n*-hexane at −78°C was quite inefficient. The derivative of choice proved to be the dicyclohexylammonium salt **40**, which could be readily formed and which quantitatively liberated the acid **17** on treatment with cold, dilute hydrochloric acid in methanol solution without



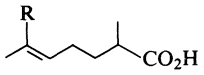
38 R = Cl
39 R =

40

observable *E*-/*Z*- isomerisation. This salt was obtained in stable crystalline form and could be recrystallised from ethyl acetate, 2-butanone, or, more efficiently, from acetone.

A sample of **17** (95% *E*, 5% *Z*) prepared via the route depicted in Scheme 6 was converted to the salt **40** and this derivative recrystallized four times from acetone to give a sample of mp 81.5–82°C. Regeneration of the acid **17** (48% recovery overall) gave a sample of 98% isomeric purity (as determined by ^{13}Cmr). A sample of acid **17** (80% *E*, 20% *Z*), derived as indicated in Scheme 4, was purified as described above, with seven recrystallizations of the intermediate salt, to give a sample of 95% *E* purity. Severe losses of material in this procedure precluded the use of this latter route to the *E*-acid **17**.

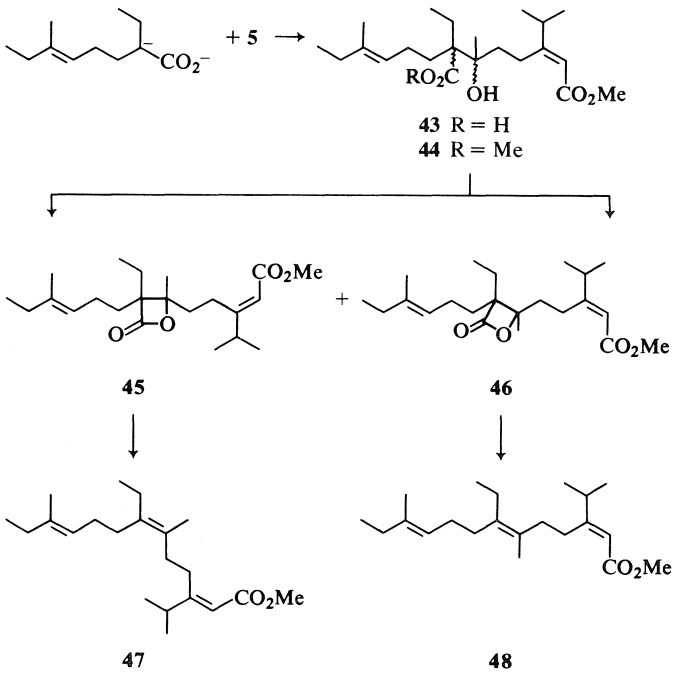
Of the methods examined, that involving the thioether **34** seemed to offer the best route to large quantities of **17** of suitable isomeric purity. Now with the chemistry to pure *E*-acid **17** in hand, its application to the corresponding *Z*-isomer **18** and to the acids **41** and **42**, related to the hormones **8**, **9** and **10**, is assured.



41 R = Et
42 R = Me

Prior to attempting the coupling reaction, several experiments were carried out to determine optimum conditions for formation of the acid dianion. Two bases were examined, lithium diisopropylamide (LDA) and lithium 2,2,6,6-tetramethylpiperidide (LTMP) (38). The extent of α-anion formation was determined by quenching with D_2O and measuring the decrease in area related to the α-H resonance at δ 2.31 in the 270 MHz ^{1}Hmr spectrum of **17**. ^{13}Cmr spectroscopy was used to evaluate any concomitant *E*-/*Z*- isomerisation. In this manner optimum conditions were found (up to 79% dianion formation without detectable stereoisomerisation) using LDA in THF at 50°C for four hours, followed by quenching at 0°C. These conditions were subsequently used for the coupling reaction.

In the event, coupling of pure *E*-acid **17** with the more readily available (*E*)-β-thujaketonic acid methyl ester (**5**) gave a mixture of diastereomeric β-hydroxyacids **43** which was characterized as the methyl esters



43 R = H
44 R = Me

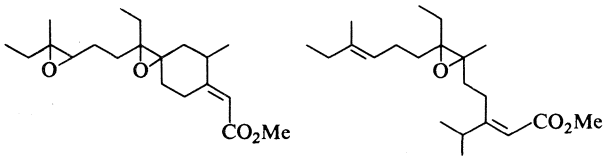
45 **46**

47 **48**

SCHEME 7

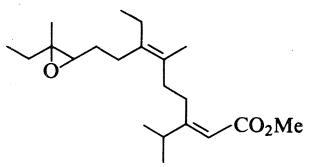
44 obtained by reaction with diazomethane in ether at 0°C. Alternatively reaction of the crude hydroxy-acids with benzenesulphonyl chloride at 0°C in pyridine gave a mixture of the two diastereomeric β-lactones **45** and **46** in the ratio 45:55 (i.e., ratio of the corresponding trienes **47** and **48** formed by pyrolytic cleavage during glc examination). Chromatographic separation on silica gel afforded the individual isomeric lactones. Subsequent pyrolysis of **45** in refluxing methylcellusolve gave the less polar triene-ester **47**. Similarly **46** was efficiently converted to **48**. The coupling reaction was then repeated on a mixture of *E*- and *Z*-acids **17** and **18** (ratio 80:20) and the product converted to a mixture of the isomeric β-lactones. Analysis of this four component mixture both by tlc and glc showed only two components (viz. **45** and **46**) thus confirming the necessity for pure *E*- (or *Z*-) acid as substrate.

Although a variety of methods have appeared for the selective epoxidation (39–47) of trisubstituted alkenes near the terminus of a polyene chain, here the extra activity of an internal tetrasubstituted double bond was expected to preclude any such selection. These suspicions were justified as shown by a trial epoxidation of the triene-ester **47**. Reaction of **47** with one equivalent of *meta*-chloroperbenzoic acid (*m*CPBA) at 0°C gave a mixture of **47**, the bis-epoxide **49**, and a mixture (70:30) of the mono-epoxides **50** and **51**.



49

50



51

The dividends from the choice of the acid dianion coupling mode were now apparent as similar epoxidation of the separated β-lactones **45** and **46** gave a high yield of epoxy-lactones **52** and **53** respectively. Pyrolysis of **52** in refluxing methylcellusolve gave **51**. Similarly **53** gave the juvenile hormone analogue **54** in high yield.

Experimental

Uncorrected melting points were determined on a Reichert micro hot stage. Boiling points are uncorrected. Infrared spectra were recorded on either a Perkin–Elmer 710 or 457 spectrophotometer. ^{1}Hmr spectra were recorded on a Varian T-60, HA-100, or XL-100, or a 270-MHz spectrometer in $CDCl_3$ solution, with tetramethylsilane as internal standard. Isomer ratios were determined by weighing respective peaks of an expanded spectrum run at 270 MHz. Mass spectra were recorded on an Atlas CH-4B or AEI MS-902 instrument. Microanalyses were carried out by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia. ^{13}Cmr spectra were measured on a Varian CFT-20 instrument. Analytical glc separations were carried out on a Hewlett Packard 5830A gas chromatograph. Preparative glc separations utilized a Varian model 90-P gas chromatograph. Column chromatography utilized Merck silica gel 60 (70–230 mesh) or Merck aluminum oxide 90 (neutral). Preparative and thin layer chromatography utilized Merck silica gel GF_{254}.

As a matter of routine, all reagents and solvents were recrystallized or distilled prior to use.

The Hydroxyacid ***14***

A solution of cyclohexane carboxylic acid (93 mg) in dry tetrahydrofuran (5 mL) was added at −78°C to a solution of lithium diisopropylamide (2 equiv.) in dry tetrahydrofuran (2 mL) and the mixture warmed to 50°C for 1.5 h under an atmosphere of dry nitrogen. The solution was cooled to ca. 20°C and then added slowly to a solution of (*E*)-β-thujaketonic acid methyl ester (**5**) (150 mg) in dry tetrahydrofuran at −78°C. The solution was stirred at this temperature for 30 min, warmed to ca. 20°C and neutralized with methanolic hydrochloric acid. The mixture was diluted with water and extracted with dichloromethane. The extract was washed with 5% sodium bicarbonate solution, the washings acidified and extracted with dichloromethane. This extract was dried ($MgSO_4$) and evaporated to give the hydroxy acid **14** (150 mg, 64%) as a colourless oil; ir ν_{max}: 3350, 3300–2400, 1700, 1640; ^{1}H nmr δ: 8.3 (2H, broad envelope, D_2O exchangeable, —CO_2H and —OH), 5.66 (1H, s, —C=C$H$$CO_2CH_3$), 3.70 (3H, s, —$CO_2CH_3$), 1.25 (3H, s, —C(OH)C$H_3$), 1.10 (6H, d, J = 7 Hz, —CH(CH_3)$_2$); ms *m/e*: 311 (M^+ − CH_3), 283, 199, 167, 139.

The β*-Lactone* ***15***

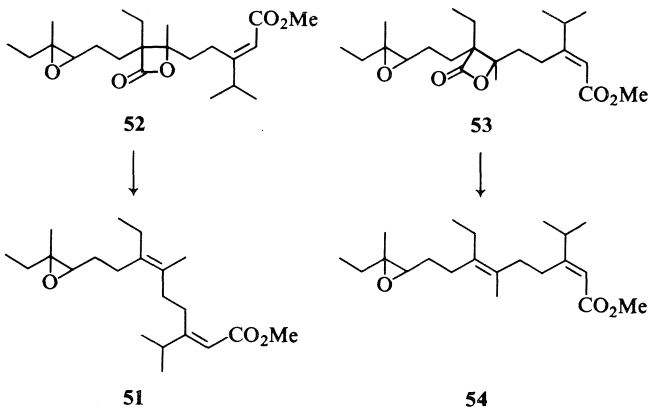
Benzenesulphonyl chloride (200 mg) was added to a solution of the hydroxyacid **14** (110 mg) in dry pyridine (5 mL) at −5°C. The mixture was allowed to stand at ca. 0°C overnight, poured into ice-water and extracted with ether. The extract was washed with 5% sodium bicarbonate solution, dried ($MgSO_4$), and evaporated. Chromatography of the residue on silica gel gave the β-lactone **15** (65 mg, 65%) as a colourless oil; ir ν_{max}: 1810, 1710, 1650; ^{1}H nmr δ: 5.70 (1H, s, —C=C$H$$CO_2CH_3$), 3.70 (3H, s, —$CO_2CH_3$), 1.78 (3H, s, —C(OR)C$H_3$), 1.10 (6H, d, J = 7 Hz, —CH(CH_3)$_2$); ms *m/e*: 264 (M^+ −CO_2), 233, 221, 142.

The Ester ***16***

The β-lactone **15** (60 mg) was heated to 140°C for 1.5 h in a nitrogen atmosphere. Chromatography on silica gel gave the olefin **16** (35 mg, 68%) as a colourless oil; ir ν_{max}: 1710, 1640; ^{1}H nmr δ: 5.70 (1H, s, —C=C$H$$CO_2CH_3$), 3.70 (3H, s, —O$CH_3$), 1.75 (3H, s, —$CH_3$), 1.10 (6H, d, J = 7 Hz, —CH-(CH_3)$_2$); ms *m/e*: 264 (M^+), 233, 221, 142, 123.

The Alcohol ***19***

Ethyl bromide (26 g) in dry ether (25 mL) was added to magnesium turnings (7.51 g) in dry ether (75 mL) under dry nitrogen, and the mixture refluxed for 1.5 h. The solution was cooled to ca. 0°C and cyclopropyl methyl ketone (17 g) added during 30 min. The mixture was stirred at ambient temperature for 16 h, diluted with cold, saturated ammonium chloride solution, and extracted with ether. The extract was washed with brine, dried (K_2CO_3), and concentrated at atmospheric pressure. The crude product was distilled between 43 and 67°C at 60 Torr to give pure (glc, 7% Carbowax 1500 on 90–100 mesh Anakrom ABS) carbinol **19** (18.34 g, 80%); ir (film) ν_{max}:



SCHEME 8

3400, 3080; ^{1}Hmr δ: 1.57 (2H, q, J = 7.4 Hz, —CH_2CH$_3$), 1.09 (3H, s, —CH$_3$), 0.98 (3H, t, J = 7.4 Hz, —CH$_2$CH_3), 0.35 (m, cyclopropyl —H); ms m/e: 99 (M − 15), 85.

(E)- *and* (Z)-*6-Bromo-3-methyl-3-hexene (**20**)*

A solution of 1,2-dibromoethane (18.2 mL) in dry ether was added slowly, at 0°C, to magnesium turnings (5.63 g) in ether (100 mL). After complete addition (1.5 h) the mixture was heated to reflux for 1 h, then stirred at ambient temperature for 16 h. A solution of the alcohol **19** (6.16 g) in dry ether (25 mL) was added and the mixture refluxed for 1.5 h, then stirred at ambient temperature for 6 h. The mixture was cooled and carefully washed with brine. The ethereal layer was dried (Na_2SO_4) and evaporated to give an oil (9.46, g, 98%) which appeared homogeneous by tlc and by glc. This product was distilled at 75°C, 10 Torr to give *E*- and *Z* homoallylic bromides **20**; ir ν_{max}: 2970, 2930, 2880, 1670, 1460, 1380, 1275; ^{1}Hmr ($CDCl_3$) δ: 5.16 (1H, complex multiplet, C4-H), 3.36 (2H, t, J = 7 Hz, —CH_2Br), 2.58 (2H, q, J = 7 Hz, C5-H2), 2.04 (2H, q, J = 7 Hz, C2-H2), 1.64 (3H, bs, C3-CH$_3$), 1.00 (3H, t, J = 7 Hz, —CH$_2$CH_3). An *E*/*Z* ratio of 3:1 was determined from the areas under the vinylic methyl signals for the *E*- (δ 1.64) and *Z*- (δ 1.72) isomers.

*The Esters **21***

n-Butyllithium (0.6 mL of a 2.83 M solution in pentane) was added to a solution of diisopropylamine (0.17 g, 0.24 mL) in dry THF (1.7 mL) at 4°C. The solution was stirred at this temperature for 15 min and then cooled to −78°C. Methyl butanoate (0.173 g) was added and the mixture stirred for 40 min at −78°C. A solution of the bromides **20** (0.36 g) in HMPA (0.15 mL) was added and the mixture stirred at −78°C for 30 min, then at ambient temperature for 1.5 h, poured onto ice cold 1 M HCl and extracted with ether. The ethereal extract was dried (Na_2SO_4) and evaporated. Chromatography on alumina gave the esters **21** (0.08 g, 20%); ir ν_{max}: 1720; ^{1}Hmr ($CDCl_3$) δ: 5.10 (1H, bm, C5-H), 3.72 (3H, s, —OCH$_3$).

*The Oxazolines **23***

n-Butyllithium (0.48 mL of 2.7 M solution in *n*-pentane) was added slowly to a solution of the propyloxazoline **22** (172 mg) in dry THF at −78°C. The yellow solution was stirred at this temperature under a nitrogen atmosphere for 30 min and then treated with the bromides **20** (255 mg). The mixture was kept at −78°C for 30 min and then allowed to attain ambient temperature. The mixture was partitioned between brine and ether, the ethereal layer dried (Na_2SO_4), and evaporated. The residue was distilled at 70°C, 0.1 Torr to give the oxazolines **23** (322 mg, 94%); ^{1}Hmr ($CDCl_3$) δ: 5.17 (1H, bm, vinylic —H), 3.94 (2H, bs, —O—CH$_2$—), 1.64 (3H, bs, vinylic —CH$_3$), 1.33 (6H, bs, >C(CH$_3$)$_2$), 1.03 (3H, t, J = 7 Hz, —CH$_2$CH_3), 0.97 (3H, t, J = 7 Hz, —CH$_2$CH_3), plus small signals attributable to the *Z*-isomer; ms m/e: 237 (M$^+$), 222, 181, 154, 142, 126.

*The Aminoester **24***

A mixture of the oxazolines **23** (70 mg) and iodomethane (1 mL) was allowed to stand at ambient temperature for 20 h, the solvent was removed *in vacuo*, and the residue triturated with ether to afford the methiodide salt. This solid was dissolved in 1 M NaOH (5 mL) and the solution stirred at ambient temperature for 20 h. The mixture was diluted with water and extracted with petroleum ether. The organic layer was dried and concentrated to give **24** (60 mg); ir ν_{max}: 3300, 1725; ^{1}Hmr ($CDCl_3$) δ: 5.00 (1H, bm, vinylic —H), 3.82 (2H, s, —OCH$_2$—), 2.31 (3H, s, —NCH$_3$), 1.51 (3H, bs, vinylic —CH$_3$), 1.08 (6H, s, —C(CH$_3$)$_2$).

*The Acids **17** and **18***

*From **24***

The ester **24** was heated to 50°C for 17 h in a mixture of 6 M NaOH and ethanol. The mixture was acidified with 1 M HCl and extracted with ether to give (48%) the acids **17** and **18** (see below).

*From **20***

n-Butyllithium (2.0 mL of 2.82 M solution in pentane) was added to a cold (−15°C) solution of diisopropylamine (0.8 mL, 0.58 g) in dry THF (4.5 mL) and the mixture stirred for 15 min. Dry *n*-butyric acid (0.25 mL, 0.24 g) was added and the mixture stirred at ca. 0°C for 20 min. The *E*/*Z*-bromides **20** (0.5 g) in dry HMPA (1 mL) were added and the solution stirred at 0°C for 10 min, then at ambient temperature for 30 min. The mixture was carefully acidified and partitioned between ether and brine. The ether extracts were washed with brine (×2), dried and concentrated. Distillation of the residue (115°C, 0.3 Torr) gave the acids **17** and **18** (0.25 g, 48%), (see below).

*The Iodides **25***

*From **20***

The bromides **20** (0.366 g) and dry sodium iodide (0.150 g) in dry acetone (1 mL) were heated to reflux in the presence of $CaCO_3$ and mercury (35). After 30 min the mixture was cooled, filtered, and concentrated *in vacuo*. Distillation of the residue at 30°C/0.1 Torr gave the iodides **25** (0.254 g, 55%).

*From **19** (17, 18)*

The carbinol **19** (11.8 g) in dry ether (200 mL) was added slowly to a solution of magnesium iodide (4 equiv.) in dry ether and the mixture refluxed for 5 h under a nitrogen atmosphere. After a further 16 h at ambient temperature, the reaction was carefully quenched with cold water and then extracted

with petroleum ether (30–60°C). The organic extract was washed with brine. dried (Na_2SO_4), and concentrated *in vacuo* to give the *E*-/*Z*-iodides **25** (23 g, 100%) homogeneous by glc (5% OV 17), bp 40°C/0.1 Torr; ^{1}Hmr ($CDCl_3$) δ: 0.97 (3H, t, J = 7.5 Hz, —CH_2CH_3 *Z*-isomer), 0.99 (3H, t, J = 7.5 Hz, —CH_2CH_3 *E*-isomer), 1.60 (3H, s, —CH_3 *E*-isomer), 1.68 (3H, d, J = 1.1 Hz, —CH_3 *Z*-isomer), 2.0 (2H, m, —CH_2CH_3), 2.57 (2H, m, —CH_2CH_2I), 3.09 (2H, m, —CH_2I), 5.08 (1H, m, vinylic —H). Ratio by ^{1}Hmr (methyl group resonances) *E*/*Z* ca. 3:1.

*The Acids **17** and **18** from **25***

A solution of *n*-butyllithium in hexane (75.2 mL of 1.72 *M*) was added to a mixture of anhydrous diisopropylamine (11.9 g) and dry THF (96 mL) at −78°C under a nitrogen atmosphere. The mixture was stirred at −78°C for 30 min and then warmed to −23°C. At this temperature, *n*-butyric acid (4.71 g) was added and the mixture stirred for 30 min. The temperature was raised to 0°C and dry HMPA (10.5 g) added. After 40 min, the iodides **25** (6.1 g) were added and the solution stirred for 20 h at ambient temperature. The mixture was acidified with cold 1 *N* HCl and extracted with petroleum ether (30–60°C). The organic layer was then extracted with ice cold 1 *N* NaOH, the alkaline layer neutralised with 1 *N* HCl, and extracted with petroleum ether. This organic extract was washed with brine, dried (Na_2SO_4), and concentrated *in vacuo*. Distillation of the residue at 90°C/0.1 Torr gave the isomeric acids **17** and **18** (3.88 g, 79%), homogeneous by glc (5% OV 17); ir ν_{max}: 3400–2400, 1705; ^{1}Hmr ($CDCl_3$) δ: 5.09 (1H, m, C5-H), 2.31 (1H, m, C2-H), 2.00 (4H, m, C7-H2 and C4-H2), 1.60 (4H, m, C3-H2 and C2-CH_2CH_3), 1.66 (3H, s, vinylic —CH_3, *Z*-isomer), 1.58 (3H, s, vinylic —CH_3, *E*-isomer), *E*/*Z* ratio by vinylic —CH_3 signals ca. 3:1; ^{13}Cmr (^{1}H, noise decoupled) ($CDCl_3$) δ: 182.9 (C1), 138.1 (C6, *Z*-isomer), 137.9 (C6, *E*-isomer), 123.3 (C5, *Z*-isomer), 122.0 (C5, *E*-isomer), *E*/*Z* ratio by C5 signal = 4:1; ms *m*/*e*: 184.1454 (M^+, $C_{11}H_{20}O_2$ requires 184.1463), 183, 166, 155, 138, 109. *Anal.* calcd. for $C_{11}H_{20}O_2$: C 71.70, H 10.94; found: C 71.92, H 10.86. NB the discrepancy in the ratios derived by ^{13}C and ^{1}Hmr was apparently due to overlap of the vinylic —CH_3 signals with a broad multiplet. The ratio derived from the ^{13}Cmr spectrum utilised signals with clean, baseline separation.

*The Alcohol **30***

The bromides **20** (3.19 g) and magnesium turnings (0.46 g) were allowed to stir in dry ether (2 mL) for 5 h. Propanal (0.966 g) was added and the stirring continued for 12 h at ambient temperature. The mixture was carefully quenched with water, dried (Na_2SO_4), and concentrated *in vacuo* to give **30** (2.16 g, 83%), identical (by glc) with an authentic sample (1).

*The Ketone **28** from **30***

Oxidation of **30** according to the literature (48) procedure gave the ketone **28** (71%) identical with an authentic sample (1).

*The Mesylate **32***

The alcohol **30** (200 mg) and methanesulphonyl chloride (900 mg) were stirred in dry pyridine (2 mL) at 0°C for 18 h. The mixture was poured into ice-water and extracted with dichloromethane. The extract was washed with brine, dried ($MgSO_4$), and evaporated to give the crude mesylate **32** (450 mg); ir ν_{max}: 1350, 1170; which was used without further purification.

*The Nitrile **31***

*From **32***

The crude mesylate **32** (450 mg) and sodium cyanide (300 mg) were stirred in dry hexamethylphosphortriamide (1 mL) under a nitrogen atmosphere for 15 h. The mixture was diluted with water and extracted with ether. The extract was washed with 1 *N* hydrochloric acid, water and brine, dried ($MgSO_4$), and evaporated. Chromatography on silica gel afforded the nitrile **31** (210 mg, 60% from **30**); ir (film) ν_{max}: 2230, 1668; ms *m*/*e*: 165 (M^+), 150, 137, 122. High resolution molecular weight determination calcd. for $C_{11}H_{19}N$: 165.1517; found: 165.1525. *Anal.* calcd. for $C_{11}H_{19}N$: C 79.94, H 11.59; found: C 80.20, H 11.52.

*From **28***

TOSMIC (29) (0.377 g) in dry DME (4 mL) was added to potassium hydride/mineral oil suspension (0.39 g, 4.99 mmol KH/g of suspension) in dry DME (4 mL) at −46°C under a nitrogen atmosphere. The mixture was stirred at this temperature for 10 min, then at 0°C for 10 min to give a bright yellow solution. Pure *E*-enone **28** (1) (0.175 g) in DME (4 mL) was added at 0°C and the solution stirred for 45 min. Anhydrous methanol (0.079 mL) was added and stirring continued for 1 h (0–5°C). The solution was then allowed to attain ambient temperature and methanol (0.21 mL) added. Stirring was continued for a further 88 h. The mixture was then diluted with water and extracted with *n*-pentane. The extract was washed with brine, dried (Na_2SO_4), and the solvents removed *in vacuo*. Chromatography of the residue on silica gel gave the *E*-cyanide **31** (0.14 g, 75%); bp 67–73°C/0.1 Torr; ^{1}Hmr ($CDCl_3$) δ: 5.08 (1H, t, J = 7.6 Hz, vinylic —H) 2.48 (1H, m, —CHCN i.e., C2-H), 1.63 (3H, s, vinylic —CH_3): ^{13}Cmr ($CDCl_3$) δ: 139.2 (C6), 122.25 (C1), 120.8 (C5). The *E*/*Z* ratio was 98:2 from signals due to the vinylic methyl groups in the 270 MHz ^{1}Hmr spectrum and by signals due to C5 in the ^{13}Cmr spectrum as before. A sample of **31** prepared similarly from the ketones (*E*/*Z* ratio 19:6) was likewise shown to contain the *E*- and *Z*-isomers in the ratio ca. 19:6 indicating no observable double bond isomerisation during this step.

*The Acids **17** and **18** from **31***

A sample of the nitrile **31** (0.054 g, 98% *E*-) and potassium hydroxide (0.09 g) in methanol (1 mL) and water (0.3 mL) were heated at 180°C (sealed tube) for 48 h. Usual work-up gave the acids **17** and **18** (0.042 g, 74%) in the ratio 87:13 determined as above by ^{13}Cmr spectroscopy.

*The Amide **33***

The nitrile **31** (98% *E*-, 0.05 g) and powdered, dry potassium hydroxide (0.06 g) were heated in refluxing, dry *tert*-butanol (0.5 mL) for 10 h. The usual work-up procedure gave the amide **33** (0.034 g, 62%); ^{1}Hmr ($CDCl_3$) δ: 6.22 (1H, s, —NH), 5.60 (1H, s, —NH), 1.66 (3H, s, vinylic —CH_3, *Z*-isomer), 1.58 (3H, s, vinylic —CH_3, *E*-isomer). *E*/*Z* ratio from vinylic methyl signals was 93:7.

*The Sulphide **34***

Pure *E*-chloride **26** (1) (3.6 g) was added to a solution of phenylthiomethylcopper (from 3.7 g of thioanisole) (32–34) in dry THF (28 mL) at −50°C under an atmosphere of nitrogen. The mixture was stirred at −50°C for 30 min, at −23°C for 3 h, then at ambient temperature for 60 h. The solution was diluted with water and extracted with petroleum ether (30–60°C). The extract was washed with brine, dried (Na_2SO_4), and concentrated *in vacuo*. The crude product (4.62 g) was shown (glc, 5% OV17) to comprise thioanisole (20%) and product (75%). An analytical sample of **34** was obtained by preparative glc; ir ν_{max}: 3060, 3045, 1660, 1580, 735, 688; ^{1}Hmr ($CDCl_3$) δ: 7.22 (5H, m, Ar —H), 5.16 (1H, m, vinylic —H), 2.90 (2H, t, J = 6.5 Hz, —$CH_2SC_6H_5$), 1.68 (3H, s, vinylic —CH_3, *Z*-isomer), 1.57 (3H, s, vinylic —CH_3, *E*-isomer), *E*/*Z* ratio: 47:3; ms *m*/*e*: 206.1124 (M^+, $C_{13}H_{18}S$ requires 206.1129), 136, 123. *Anal.* calcd. for $C_{13}H_{18}S$: C 75.69, H 8.80; found: C 75.86, H 8.70.

A small sample obtained by distillation (85°C/0.1 Torr) was similarly shown to have an *E*/*Z* ratio of 49:1.

*The Iodide **25** from **34***

The crude thioether **34** (containing thioanisole, 4.1 g), dry

sodium iodide (10.7 g), calcium carbonate (0.156 g), and mercury (1 drop) were mixed in dry DMF (42 mL). Iodomethane (32.3 mL) was added and the mixture heated at 60–75°C for 28 h under an atmosphere of dry argon. The mixture was then cooled to ca. 20°C, diluted with ether, and cooled to ca. 0°C. The crystalline material was removed by filtration, dried, and reserved for recycling. The filtrate was washed with brine, dried (Na_2SO_4), and the solvents removed by distillation at atmospheric pressure (60–70°C). Gas–liquid chromatographic analysis (5% OV17) of the residue (0.68 g) indicated iodide **25** (38%), thioanisole (49%), and thioether **34** (12%). The iodide thus obtained was not purified but used as such for the next step.

*The Acid **17** from **25***

The dianion of *n*-butyric acid (1.4 g) was alkylated, as described earlier, with the crude **25** (1.8 g) to give (**17**) (0.924 g). The *E*/*Z* ratio in this product was found to be 95:5 by ^{13}Cmr as before. The neutral fraction (2.7 g) from the work-up of this reaction, shown by glc to contain thioanisole (56%) and the thioether (42%), was reserved for recycling.

*Purification of **17** via **40***

Dicyclohexylamine (2.98 g, 3.28 mL) was added to a solution of the acid **17** (95% *E*-, 2.88 g) in *n*-hexane. The mixture was cooled to −78°C and the crystalline product **40** collected by filtration. The salt was recrystallized (× 5) from acetone to give material with mp 81.5–82°C.

The salt **40** was then dissolved in methanol containing ca. 10% HCl at 0°C. The mixture was stirred for 5 min, diluted with ice cold water, and extracted with petroleum ether (30–60°C). The extract was washed with brine, dried (Na_2SO_4), and concentrated *in vacuo*. Distillation of the residue gave **17** (1.38 g). The *E*/*Z* ratio was determined as 49:1 by ^{13}Cmr spectroscopy.

*The Hydroxyacid **43***

n-Butyllithium (5.9 mL, 1.70 *M*) was added to a solution of diisopropylamine (0.922 g, 1.28 mL) in dry THF (6.3 mL) at −78°C under a nitrogen atmosphere, and the mixture stirred for 1 h at this temperature, then at −23°C for 20 min. A solution of the *E*-acid **17** (0.763 g) in dry THF (1 mL) was added and the solution stirred at −23°C for 30 min, then at 0°C for 10 min. The mixture was heated to 50°C for 4 h, and then cooled to −78°C. A solution of the ketoester **5** (0.827 g) in dry THF (1 mL) was added slowly, and the mixture warmed (over 2 h) to 0°C, poured into ice-water, and extracted with petroleum ether (30–60°C). The extract was dried and concentrated to give **5** (0.293 g). The aqueous layer was adjusted to pH 1 with ice cold 1 *N* HCl and then extracted with petroleum ether (30–60°C). This extract was washed with brine, dried, and concentrated to give the hydroxyacid **43** (1.37 g); ir ν_{max}: 3450–2600, 1710, 1700, 1640; ^{1}Hmr ($CDCl_3$) δ: 8.0 (2H, bs, —OH and —CO_2H), 5.60 (1H, s, C=C*H*CO_2Me), 5.05 (1H, bt, vinylic —H), 3.65 (3H, s, —OCH_3), 1.6 (3H, s, vinylic —CH_3), 1.3 (3H, s, —CH_3); ms *m*/*e*: 382.2717 (M^+, $C_{22}H_{38}O_5$ requires 382.2719), 381, 269, 251, 219, 199, 184, 167, 96.

*The Ester **44***

A sample of the crude **43** (60 mg) was esterified with diazomethane in ether to give, after chromatography on silica gel, the ester **44** (27 mg, 44%); ir ν_{max}: 3470, 1715, 1640, 1170; ^{1}Hmr ($CDCl_3$) δ: 5.60 (1H, s, C=C*H*CO_2Me), 5.06 (1H, bt, vinylic —H), 3.63 (3H, s, —OCH_3), 3.60 (3H, s, —OCH_3), 3.50 (1H, bs, —OH), 1.60 (3H, s, vinylic —CH_3), 1.23 (3H, s, —CH_3), 1.08 (6H, d, J = 7 Hz, —CH(CH_3)$_2$); ms *m*/*e*: 396 (M^+), 381, 315, 283, 251, 218, 167, 166. *Anal.* calcd. for $C_{23}H_{40}O_5$: C 69.66, H 10.17; found: C 69.93, H 10.33.

*The β-Lactones **45** and **46***

The crude hydroxyacid **43** (1.37 g) and benzenesulphonyl chloride (0.27 g) were stirred in dry pyridine (3 mL) at 0–5°C for 18 h. The mixture was poured into ice-water and extracted with dichloromethane. The extract was washed with sodium bicarbonate solution, brine, dried (Na_2SO_4), and concentrated *in vacuo*. Chromatography on silica gel at ca. 5°C gave the lactone **46** (0.51 g, 39%); ir ν_{max}: 1810, 1715, 1640, 1170; ^{1}Hmr ($CDCl_3$) δ: 5.68 (1H, s, —C=C*H*CO_2CH_3), 5.09 (1H, bt, vinylic —H), 3.64 (3H, s, —OCH_3), 1.59 (6H, s, 2 × —CH_3), 1.07 (6H, d, J = 7 Hz, —CH(CH_3)$_2$); and the lactone **45** (0.49 g, 38%); ir ν_{max}: 1810, 1715, 1640, 1170; ^{1}Hmr ($CDCl_3$) δ: 5.67 (1H, s), 5.07 (1H, bt), 3.63 (3H, s), 1.57 (6H, s), 1.07 (6H, d, J = 7 Hz). Each isomer was homogeneous by glc (OV17).

*The Triene **47***

The lactone **45** (0.49 g) was heated in refluxing 2-methoxyethanol (20 mL) for 1 h under a nitrogen atmosphere. The solvent was removed *in vacuo* to give, after distillation at 120°C/0.1 Torr, the triene ester **47** (0.39 g, 91%); ir ν_{max}: 1720, 1640, 1175; ^{1}Hmr ($CDCl_3$) δ: 5.66 (1H, s, —C=C*H*CO_2CH), 5.16 (1H, bs, vinylic —H), 3.70 (3H, s, —OCH_3), 1.73 (3H, s, —CH_3), 1.57 (3H, s, —CH_3), 1.10 (6H, d, J = 7 Hz, —CH(CH_3)$_2$); ^{13}Cmr ($CDCl_3$) δ: 170.3 (C1), 167.2 (C3), 136.7 (C11), 135.3 (C7), 127.9 (C6), 123.2 (C10), 112.8 (C2), 50.8 (—O*C*H_3); ms *m*/*e*: 320.2708 (M^+, $C_{21}H_{36}O_2$ requires: 320.2715); *Anal.* calcd. for $C_{21}H_{36}O_2$: C 78.69, H 11.32; found: C 78.97, H 11.06.

*The Triene **48***

Similarly, the lactone **46** gave **48** (90%); ir ν_{max}: 1720, 1640, 1175; ^{1}Hmr ($CDCl_3$) δ: 5.62 (1H, s, —C=C*H*CO_2CH_3), 5.11 (1H, bs, vinylic —H), 3.65 (3H, s, —OCH_3), 1.71 (3H, s, —CH_3), 1.59 (3H, s, —CH_3), 1.07 (6H, d, J = 7 Hz, —CH(CH_3)$_2$); ^{13}Cmr ($CDCl_3$) δ: 170.2 (C1), 167.3 (C3), 136.8 (C11), 135.3 (C7), 127.9 (C6), 123.1 (C10), 112.8 (C2), 50.8 (—O*C*H_3); *Anal.* calcd. for $C_{21}H_{36}O_2$: C 78.69, H 11.32; found: C 78.79, H 11.40.

In the ^{13}Cmr spectra of the trienes **47** and **48** signals for C10 of the 10(11) *Z*-isomers (δ 124.3) were not observable. Furthermore each was homogeneous by glc (5% OV17, 180°C) analysis.

*The Epoxides **49**, **50**, and **51** from **47***

The triene ester **47** (0.05 g) and *m*CPBA (0.027 g) were stirred in chloroform (3 mL) at 0°C for 5 h. Chromatography on silica gel gave triene ester **47** (0.019 g) and a mixture (0.014 g) of **50** and **51**; ir ν_{max}: 1710, 1640; ^{1}Hmr ($CDCl_3$) δ: 5.65 (1H, s, —C=C*H*CO_2CH_3), 5.12 (1H, bt, vinylic —H for **50**), 3.68 (3H, s, —OCH_3), 1.60 (3H, s, vinylic —CH_3 for **50**), 1.41 (3H, s, —CH_3 for **50**), 1.09 (6H, d, J = 7.5 Hz, —CH(CH_3)$_2$ for **51**), 1.12 (6H, d, J = 7.5 Hz, —CH(CH_3)$_2$ for **50**); ratio of **50**/**51** ca. 7:3 from signals at δ 1.12 and 1.09 ppm; ms *m*/*e* 336.2641 (M^+, $C_{21}H_{36}O_3$ requires: 336.2664); and the bisepoxide **49** (0.016 g); ir ν_{max}: 1720, 1640; ^{1}Hmr ($CDCl_3$) δ: 5.65 (1H, s, —C=C*H*CO_2CH_3), 3.67 (3H, s, —OCH_3), 1.41 (3H, s, C6-CH_3), 1.24 (3H, s, C11-CH_3), 1.07 (6H, d, J = 7 Hz, —CH(CH_3)$_2$); ms *m*/*e* 352.2615 (M^+, $C_{21}H_{36}O_4$ requires: 352.2614).

*The Lactone **52***

Reaction of **45** with *m*CPBA (1.5 equiv.) in dichloromethane below 0°C gave, after chromatography on silica gel, the epoxide **52** in 92% yield; ir ν_{max}: 1810, 1710, 1640; ^{1}Hmr ($CDCl_3$) δ: 5.72 (1H, s, C2-H), 3.69 (3H, s, —OCH_3), 1.62 (3H, bs, C6-CH_3), 1.24 (3H, bs, C11-CH_3), 1.09 (6H, d, J = 7.5 Hz, C3-CH(CH_3)$_2$), 0.95 (6H, two overlapping triplets, —CH_2CH_3); homogeneous by glc (5% OV17, 180°C).

*The Lactone **53***

Similarly, **46** gave (91%) the lactone **53**; ir ν_{max}: 1810, 1710, 1640; ^{1}Hmr ($CDCl_3$) δ: 5.73 (1H, s, C2-H), 3.71 (3H, s,

—OCH_3), 1.64 (3H, s, C6-CH_3), 1.27 (3H, s, C11-CH_3), 1.10 (6H, d, J = 7.5 Hz, C3-CH(CH_3)$_2$), 0.97 (6H, two overlapping triplets, —CH_2CH_3); homogeneous by glc (5% OV17, 180°C).

The Epoxide 51

The lactone **52** was heated in refluxing 2-methoxyethanol under a nitrogen atmosphere for 2 h. The solvent was evaporated *in vacuo* and the residue purified by molecular distillation at 130°C, 0.5 Torr to give a quantitative yield of the epoxide **51**; ir ν_{max}: 1710, 1640; ^{1}Hmr ($CDCl_3$) δ: 5.64 (1H, s, C2-H), 3.68 (3H, s, —OCH_3), 2.74 (1H, t, J = 6 Hz, C10-H), 2.40 (1H, quintet, J = 7.5 Hz, —$CH(CH_3)_2$), 1.73 (3H, s, C6-CH_3), 1.22 (3H, s, C11-CH_3), 1.09 (6H, d, J = 7.5 Hz, —CH(CH_3)$_2$), 0.95 (3H, t, J = 7.5 Hz, —CH_2CH_3), 0.94 (3H, t, J = 7.5 Hz, —CH_2CH_3); ms *m/e* 336 (M^+), 318, 304, 289, 218, 202, 177, 121, 109. High resolution molecular weight determination, calcd. for $C_{12}H_{36}O_3$: 336.2664; found: 336.2660. *Anal.* calcd. for $C_{21}H_{36}O_3$: C 74.95, H 10.78; found: C 75.10, H 10.81.

The Epoxide 54

Similarly, **53** gave the epoxide **54**; ir ν_{max}: 1710, 1640; ^{1}Hmr ($CDCl_3$) δ: 5.64 (1H, s, C2-H), 3.68 (3H, s, —OCH_3), 2.72 (1H, t, J = 6 Hz, C10-H), 2.39 (1H, quintet, J = 7.5 Hz, —$CH(CH_3)_2$), 1.74 (3H, s, C6-CH_3), 1.24 (3H, s, C11-CH_3), 1.08 (6H, d, J = 7.5 Hz, —CH(CH_3)$_2$), 0.98 (3H, t, J = 7.5 Hz, —CH_2CH_3), 0.94 (3H, t, J = 7.5 Hz, —CH_2CH_3); ms *m/e* 336 (M^+), 318, 304, 289, 275, 218, 203, 177, 121, 109, 57. High resolution molecular weight determination, calcd. for $C_{21}H_{36}O_3$: 336.2664; found: 336.2676. *Anal.* calcd. for $C_{21}H_{36}O_3$: C 74.95, H 10.78; found: C 74.74, H 10.64.

Ring forming reactions of some amineimides with a note on electrophilic bromination

IAN D. BRINDLE AND MARTIN S. GIBSON

Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received June 28, 1979

IAN D. BRINDLE and MARTIN S. GIBSON. Can. J. Chem. **57**, 3155 (1979).

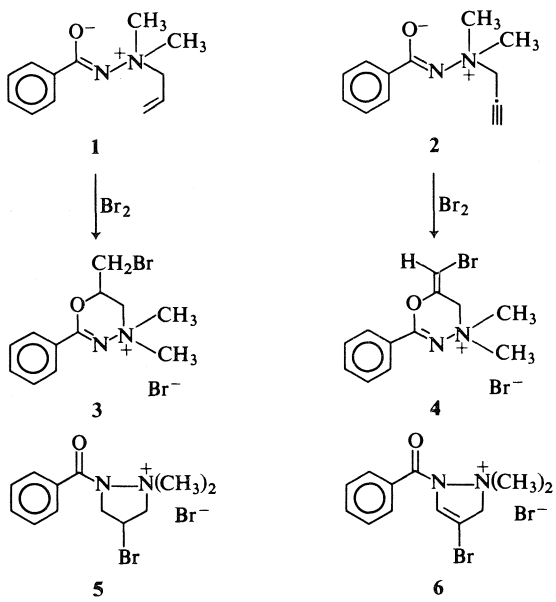
Allylic and propargylic amineimides react with bromine to form 4*H*-1,3,4-oxadiazinium salts in accord with recent studies of electrophilic brominations. A novel synthesis of 5,6-dihydro-4,4-dimethyl-6-hydroxymethyl-2-phenyl-4*H*-1,3,4-oxadiazinium bromide by the reaction of *N'N'*-dimethylbenzohydrazide and epibromohydrin is reported.

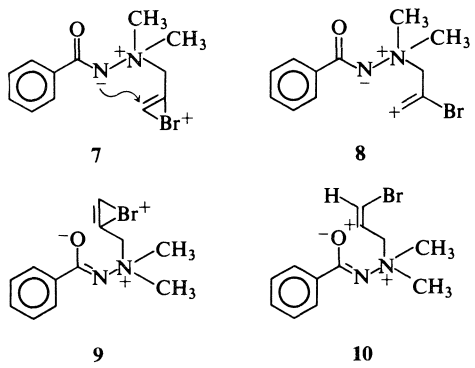
IAN D. BRINDLE et MARTIN S. GIBSON. Can. J. Chem. **57**, 3155 (1979).

Les amineimides allyliques et propargyliques réagissent avec le brome pour former les sels de 4*H* oxadiazinium-1,3,4 en accord avec les récentes études sur les bromations électrophiliques. On rapporte une nouvelle synthèse du bromure de dihydro-5,6 diméthyl-4,4 hydroxyméthyl-6 phényl-2 4*H* oxadiazinium-1,3,4 obtenue par la réaction de la *N'N'*-diméthylbenzohydrazine avec l'épibromohydrine.

[Traduit par le journal]

During the course of a study of the thermolysis of allyldimethylamine-benzimide **1** (1), we noted that both this compound and the related propargyldimethylamine-benzimide **2** underwent ring closure on the addition of bromine to give salts. The ambident nature of the imido group in such amine-imides has been well documented by Wawzonek and Yeakey who noted that methylation occurs at the imide oxygen in 1,1-dimethyl-1-*p*-nitrobenzylamine-acetimide (2) and by Brindle and Gibson who showed that allylic migration occurs to the imide nitrogen on thermolysis under conditions which preclude a prior rearrangement to oxygen (1). Alternative formulations have thus to be considered for the salts derived from bromination of **1** and **2**; that from **1** might be **3** or **5** whilst that from **2** might be **4** or **6**.

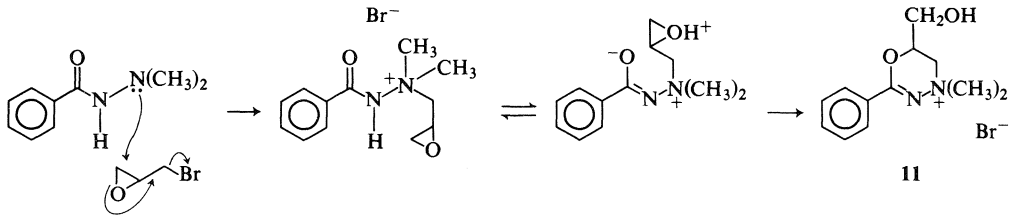




Initially we were disposed to formulae **5** and **6** respectively (3) by analogy with such reactions as the conversion of *N*-2-bromomethyl-*N'*-phenylurea to 1-phenyl-2-imidazolone by ethoxide ion, in which nitrogen rather than oxygen is the nucleophilic centre (4, 5). However the only band in the ir spectrum near the carbonyl region was in each case at 1625 cm^{-1} which seemed more in line with a C=N stretching mode. This matter has now been resolved by a single crystal X-ray study on the salt from bromination of **2** which verifies the structure as the oxadiazinium salt **4** (see following paper); by extension, **3** is the structure assigned to the bromination product of **1**.

These conclusions are consistent with the results of recent studies of electrophilic halogenation by McManus *et al.* (6). Thus formation of salt **6** would involve either the *fused* (*endo*) mode of attack on the halonium intermediate **7** or the even more unlikely prior formation of the carbocation **8**. However,

0008-4042/79/233155-02$01.00/0



SCHEME 1

oxygen attack is actually observed, presumably via the preferred *spiro* (*exo*) configuration **9** or possibly via the more stable carbocation **10**; spiro attack by nitrogen (leading to a four membered ring) was considered unlikely and was not observed.

We have extended the argument to a related system in which a protonated epoxide is the likely intermediate. The reaction of *N'N'*-dimethylbenzohydrazide with epibromohydrin yields the hydroxymethyl 4*H*-1,3,4-oxadiazinium salt **11**. We view this process (Scheme 1) as also involving attack in the *spiro* mode.

Experimental

(E)-6-(Bromomethylene)-5,6-dihydro-4,4-dimethyl-2-phenyl-4H-1,3,4-oxadiazinium Bromide ***4***

Bromine (3.2 g, 0.02 mol) in chloroform was added during 30 min to a solution of compound **2** (1) (4.0 g, 0.02 mol) in chloroform (25 mL). Evaporation and crystallization from 2-propanol gave the *salt* **4** (4.2 g, 58%), mp 173–174°C (dec., sample inserted at 165°C); ν_{max}: 1625 cm^{-1}. *Anal.* calcd. for $C_{12}H_{14}Br_2N_2O$: C 39.78, H 3.87, Br 44.20; found: C 39.99, H 3.93, Br 44.28.

6-(Bromomethyl)-5,6-dihydro-4,4-dimethyl-2-phenyl-4H-1,3,4-oxadiazinium Bromide ***3***

Compound **1** (3.0 g, 0.015 mol) was treated with bromine in chloroform in the same way as **2** above. The crude product solidified on trituration with hexane and crystallized from 2-propanol to give the *salt* **3** (4.1 g, 76%), mp 200–202°C (dec.); ν_{max}: 1625 cm^{-1}. *Anal.* calcd. for $C_{12}H_{16}Br_2N_2O$: C 39.56, H 4.40, Br 43.96; found: C 39.53, H 4.50, Br 44.01.

5,6-Dihydro-4,4-dimethyl-6-hydroxymethyl-2-phenyl-4H-1,3,4-oxadiazinium Bromide ***11***

A solution of *N'N'*-dimethylbenzohydrazide (1.64 g, 0.01 mol) and epibromohydrin (5.0 g, 0.036 mol) in chloroform (10 mL) deposited the *bromide* **11** (0.45 g, 15%) after standing for 2 days at room temperature, followed by trituration with a small amount of methanol. Crystallization from 2-propanol gave hygroscopic microcrystals, mp 182–184°C; ν_{max}: 1610 cm^{-1}. *Anal.* calcd. for $C_{12}H_{17}BrN_2O_2$: C 47.85, H 5.69, Br 26.53; found: C 47.93, H 5.69, Br 26.40.

The crystal and molecular structure of a compound containing a novel ring system: (*E*)-6-(bromomethylene)-5,6-dihydro-4,4-dimethyl-2-phenyl-4*H*-1,3,4-oxadiazinium bromide

DORIS MARGARET THOMPSON,[1] IAN DAVID BRINDLE, AND MARY FRANCES RICHARDSON[2]

Chemistry Department, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received June 28, 1979

DORIS MARGARET THOMPSON, IAN DAVID BRINDLE, and MARY FRANCES RICHARDSON. Can. J. Chem. **57**, 3157 (1979).

The crystal structure of (*E*)-6-(bromomethylene)-5,6-dihydro-4,4-dimethyl-2-phenyl-4*H*-1,3,4-oxadiazinium bromide has been determined by single crystal X-ray diffraction methods. The crystals are monoclinic, space group $P2_1/c$, with $a = 12.002(5)$, $b = 6.414(4)$, $c = 17.881(7)$ Å, $\beta = 101.42(7)°$, and $Z = 4$ formula units of $C_{12}H_{14}N_2OBr_2$. The structure was refined by full-matrix least-squares analysis to a conventional *R*-factor of 0.0491 for 1019 observed reflections.

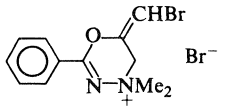
The oxadiazinium ring is in the half-chair form, with the methylene group out of the plane defined by the other five atoms. The C—O bond distances in the ring are somewhat shorter than the distance observed for a carbon–oxygen single bond, suggesting that some delocalization of electron density occurs over part of the ring.

DORIS MARGARET THOMPSON, IAN DAVID BRINDLE et MARY FRANCIS RICHARDSON. Can. J. Chem. **57**, 3157 (1979).

On a déterminé la structure cristalline du bromure de (*E*) (bromométhylène)-6 dihydro-5,6 diméthyl-4,4 phényl-2 4*H* oxadiazinium-1,3,4 en utilisant les méthodes de diffraction de rayons X sur un cristal unique. Les cristaux sont monocliniques, groupe d'espace $P2_1/c$ avec $a = 12.002(5)$, $b = 6.414(4)$, $c = 17.881(7)$ Å, $\beta = 101.42(7)°$ et $Z = 4$ unités de formule $C_{12}H_{14}N_2OBr_2$. On a affiné la structure par une analyse des moindres carrés (matrice complète) jusqu'à un facteur conventionnel *R* de 0.0491 pour 1019 réflexions observées. Le cycle oxadiazinium a une forme de demi-chaise avec le groupe méthylène hors du plan défini par les cinq autres atomes. Les longueurs de liaison C—O sont un peu plus courtes que celles observées pour la simple liaison carbone–oxygène. Ceci suggère qu'une certaine délocalisation de densité électronique se produit sur une partie du cycle.

[Traduit par le journal]

The addition of bromine to propargyl-dimethylaminebenzimide results in a product whose structure is not readily determined by ir and nmr spectroscopy (1). This crystal structure determination has established that an oxadiazinium salt **1** is produced, and contains the first detailed report on the structural parameters of an oxadiazinium ring.



1

Experimental

The compound was prepared as described previously (1), and a single crystal 0.10 × 0.15 × 0.75 mm was mounted on a glass fibre with epoxy glue. Oscillation and Weissenberg photographs showed systematic absences consistent with space group $P2_1/c$. The crystal was transferred to a Picker manual four-circle diffractometer and accurate cell dimensions were obtained from scans of the axial and selected $h\,0\,l$ reflections out to 2θ values of 60°. Crystal data are as follows:

$C_{12}H_{14}N_2OBr_2$ fw = 362.07
Monoclinic, $P2_1/c$, $a = 12.002(5)$, $b = 6.414(4)$, $c = 17.881(7)$ Å, $\beta = 101.42(7)°$, $V = 1349.2$ Å^3, $\rho_c = 1.782$ g cm^{-3}, $Z = 4$, μ(MoKα) = 63.4 cm^{-1}, λ(MoKα) = 0.7107 Å.

Data were measured by the θ–2θ scan technique at a scan speed of 2°/min and a scan range of 2°, to a maximum 2θ of 40°. The background was measured for 10 s at both ends of the scan. A standard reflection was monitored after every 25–50 reflections; its value decreased steadily throughout the course of the data collection, reaching a value of ~80% of the original intensity by the time the data collection was finished. The crystal had become yellow and slightly opaque by the time data collection was completed.

The data were corrected for the declining intensity of the standard, as well as for Lorentz and polarization effects. No absorption correction was made. Of 1258 reflections measured in the independent quadrant, 1019 had $F_o \geq 3\sigma(F_o)$ and were classified as observed. The SHELX-76 set of computer programs was used in structure determination and refinement (2).

The Patterson map yielded the locations of the bromine atoms and subsequent electron-density difference maps revealed the remaining atoms, including hydrogens. Refinement

0008-4042/79/233157-03$01.00/0

was carried out by full-matrix least-squares analysis. The function minimized was $\sum w(|F_o| - |F_c|)^2$, where F_o and F_c are the observed and calculated structure factors, respectively, $w = k/(\sigma^2(F) + gF^2)$, $\sigma(F)$ is based on counting statistics, and k and g are refinable parameters in the least-squares analysis. The final values of k and g were 2.14 and 8.58×10^{-4}, respectively.

The scattering factors of the neutral C, H, N, O, and Br atoms were taken from the International tables for X-ray crystallography (3). Individual hydrogen atom parameters were not refined. The methyl groups were treated as rigid rotors. The positions of the remaining eight hydrogen atoms were calculated, and these atoms were included as fixed contributions to F_c. The thermal parameters of the hydrogen atoms were fixed at values 20% greater than those of the carbon atoms to which they were bonded.

Several cycles of refinement were carried out on 85 parameters (scale factor, positional parameters of all non-hydrogen atoms, anisotropic thermal parameters for bromine, isotropic thermal parameters for the remaining non-hydrogen atoms, and three parameters for each methyl group). For the 1019 observed reflections the final conventional $R = \sum ||F_o| - |F_c||/\sum |F_o| = 0.049$; the weighted $R_w = [\sum w(|F_o| - |F_c|)^2/w|F_o|^2]^{1/2} = 0.052$. The corresponding R and R_w for all reflections were 0.068 and 0.057.

A final difference map revealed scattered small peaks near the bromine atoms but no other significant peaks. A table of observed and calculated structure factors is available.[3]

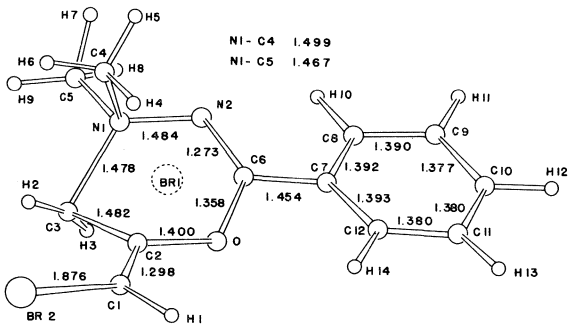

FIG. 1. Perspective view and bond distances for $C_{12}H_{14}N_2OBr_2$. The Br(1) ion lies below the oxadiazinium ring. Standard deviations range from 0.010 Å to 0.014 Å.

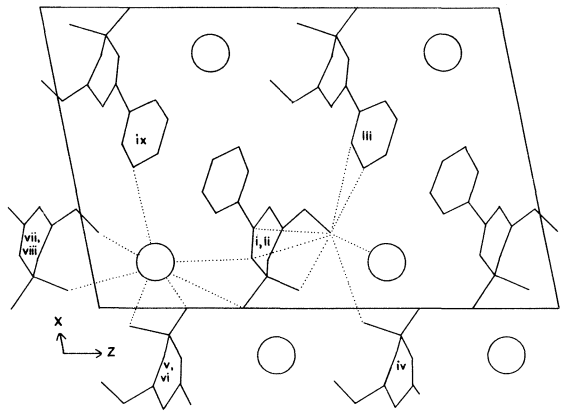

FIG. 2. Molecular packing of $C_{12}H_{14}N_2OBr_2$ as viewed down the y-axis. The large circles represent Br(1) ions. The dotted lines show contacts about Br(1) and Br(2) which are less than 4.0 Å. The Roman numerals are keyed to the symmetry transformations in the table of short contact distances (see footnote 3).

Results and Discussion

Table 1 lists the refined atomic parameters.[3] Figure 1 shows a view of the molecule and the associated bond lengths; the bond angles may be found in Table 2.

The oxadiazinium ring exists in the half-chair form. Five of the six atoms in the ring lie in the same plane (Table 3), whereas the methylene group (C(3)) lies below this plane. The phenyl, alkene, and imide moieties are also planar (Table 3). The *exo*-bromomethylene group is twisted about the C(1)—C(2) bond so that Br(2) lies above the oxadiazinium ring. This feature would appear to be due to steric crowding between Br(2) and the C(3) methylene group, an interpretation which is supported by the expanded C(1)—C(2)—C(3) angle of 131.3(9)° and an H(2)—Br(2) contact (2.86 Å) which is ~0.2 Å shorter than the sum of the van der Waals radii (4).

Most of the bond distances (Fig. 1) are close to

[3]Lists of structure factors, hydrogen positions, and short contact distances in the structure are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[a]The equation of the plane has the form $AX + BY + CZ = D$, where X, Y, and Z are orthogonal coordinates (in Å) of the atoms in a system where the x, y, and z axes are parallel to the a^*, b, and c axes of the unit cell, respectively.
[b]Not used in the plane calculation.

accepted values (5–8). The shortness of the C(6)—O and C(6)—C(7) bonds and the C(2)—O—C(6) angle of 117.5° suggest that there is some electron delocalization between the oxadiazinium and phenyl moieties. The planes of the oxadiazinium and phenyl rings intersect at an angle of 20°.

The molecular packing diagram is shown in Fig. 2. The bromide ions (Br(1)) alternate with oxadiazinium cations. The packing is governed by contacts with Br(1) and Br(2), there being several contacts to these atoms on the order of 3.75 Å. The only other intermolecular distance less than 4.0 Å (other than those involving some of the hydrogen atoms) is from C(3) to C(8) at $(x, 1 + y, z)$; the distance is 3.47(1) Å.

Isotopically-enriched carbohydrates: The preparation of [^{2}H]-enriched aldoses by catalytic hydrogenolysis of cyanohydrins with $^2H_2$[1]

ANTHONY STEPHEN SERIANNI AND ROBERT BARKER[2]

Department of Biochemistry, Michigan State University, East Lansing, MI 48824, U.S.A.

Received June 5, 1979

ANTHONY STEPHEN SERIANNI and ROBERT BARKER. Can. J. Chem. **57**, 3160 (1979).

A procedure is described for the preparation of aldoses and aldose phosphates enriched with ^{2}H by hydrogenolysis of aldononitriles and aldononitrile phosphates over palladium using $^2H_2$. Aldoses, aldose phosphates, and derivatives prepared with ^{13}C and (or) ^{2}H enrichment and characterized by ^{1}H and ^{13}C nmr were: DL-[1-^{14}C, ^{2}H]glyceraldehyde, D-[1-^{13}C, ^{2}H]-erythrose, D-[1-^{13}C, ^{2}H]threose, D-[2-^{13}C, ^{2}H]ribose, D-[2-^{13}C, ^{2}H]arabinose, methyl α-D-[2-^{13}C, ^{2}H]ribofuranoside, methyl β-D-[2-^{13}C, ^{2}H]ribofuranoside, DL-[3-^{2}H]erythrose, DL-[3-^{2}H]threose, DL-[1-^{13}C, ^{2}H]glyceraldehyde 3-phosphate, and D-[1-^{13}C, ^{2}H]ribose 5-phosphate. ^{13}C isotope shifts, ^{1}H and ^{13}C chemical shifts, and homo- and heteronuclear coupling constants are reported.

ANTHONY STEPHEN SERIANNI et ROBERT BARKER. Can. J. Chem. **57**, 3160 (1979).

On décrit une méthode de préparation des aldoses et des phosphates d'aldose enrichis en ^{2}H par hydrogénolyse, à l'aide de ^{2}H/Pd, des aldonitriles et des phosphates d'aldonitrile. On a caractérisé par la rmn du ^{13}C et du ^{2}H les aldoses, les phosphates d'aldoses et les autres dérivés suivants: DL-[^{14}C-1-^{2}H] glycéraldéhyde, D-[^{13}C-1-^{2}H] érythrose, D-[^{13}C-1-^{2}H] thréose, D-[^{13}C-2-^{2}H] ribose, D-[^{13}C-2-^{2}H] arabinose, α-D-[^{13}C-2-^{2}H] ribofurannoside de méthyle, β-D-[^{13}C-2-^{2}H] ribofurannoside de méthyle, DL-[^{2}H-3] érythrose, DL-[^{2}H-3] thréose, phosphate-3 de DL-[^{13}C-1-^{2}H] glycéraldéhyde et phosphate-5 de D-[^{13}C-1-^{2}H] ribose. On a rapporté les déplacements isotopiques du ^{13}C, les déplacements chimiques du ^{1}H et du ^{13}C ainsi que les constantes de couplage homo- et hétéronucléaires.

[Traduit par le journal]

Introduction

Configurational and conformational analysis of carbohydrates and their derivatives in solution by nuclear magnetic resonance spectroscopy is greatly facilitated by the use of isotopically enriched compounds. Assignments of ^{13}C chemical shifts have been made using [^{2}H]-enriched carbohydrates based on the disappearance of the resonance arising from the carbon directly bound to the deuteron and on the upfield shifts experienced by carbon nuclei β and γ to the deuteron (1–4). The interpretation of complex ^{1}Hmr spectra can also be aided by deuteration (5, 6). The use of [^{13}C]-enriched aldoses, aminoaldoses, and aldose phosphates permitted the unequivocal assignment of carbon chemical shifts, determination of ^{13}C–H and ^{13}C–^{13}C coupling constants, and the *in vitro* monitoring of enzyme-catalyzed conversions (7–12). In certain circumstances, the use of [^{13}C, ^{2}H]-enriched aldoses and their biologically-important phosphate esters would permit the examination of chemical and biochemical proton exchange – transfer reactions (isomerizations, epimerizations) by ^{13}C and ^{1}Hmr. A simple method of ^{2}H-enrichment is described in this paper and is applied to the preparation of doubly-enriched [^{13}C, ^{2}H] compounds.

The preparation of [^{2}H]-enriched carbohydrates is most often accomplished by reduction of carbonyl derivatives with NaB^2H_4 (4, 5). This approach is limited by the availability of the appropriate carbonyl. Balza *et al.* (13) have prepared deuterated glycosides by ^{1}H–^{2}H exchange in ^2H_2O on a Raney nickel catalyst. In this paper, we describe a simple method for the incorporation of ^{2}H into the simple aldoses and aldose phosphates in 70–80% yields. An aldose is condensed with cyanide at pH 8.0 ± 0.5 to produce the 2-epimeric cyanohydrins, which are stabilized by lowering the pH to 4.0. The cyanohydrins are hydrogenolyzed in ^2H_2O solution with $^2H_2$ over palladium to yield the [1-^{2}H]-enriched 2-epimeric aldoses having one more carbon than the parent compound. The aldoses can be separated as described previously (14, 15). [^{2}H]-enriched aldose phosphates can be prepared from aldononitrile phosphates in a similar fashion.

The utility of this method lies in the ease with which isotopes of carbon, hydrogen, and oxygen (16)

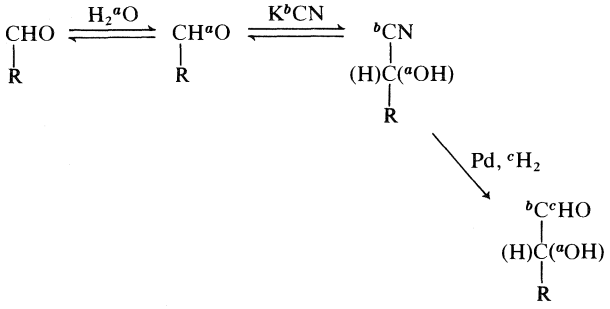

SCHEME 1

can be incorporated either independently or simultaneously into the carbohydrate molecule, as shown in Scheme 1.

We have prepared several singly and multiply-enriched aldoses, aldose phosphates, and derivatives, and characterized them by ^{1}H and ^{13}Cmr. ^{1}Hmr parameters were confirmed and refined by computer simulation of the spectra. ^{13}C isotope shifts, ^{1}H and ^{13}C chemical shifts, and homo- and heteronuclear coupling constants are reported.

Results and Discussion

Carbohydrates via the Catalytic Hydrogenolysis of Cyanohydrins

The synthetic route described in this and earlier reports (9–11) utilizes the condensation of cyanide with an aldose or aldose derivative, as first described by Kiliani (17). In this classical reaction, a cyanide salt and aldose are mixed in aqueous solution at high pH to produce cyanohydrins which, in the alkaline solution, hydrolyze to aldonic acid salts (18). We have observed (19), however, that cyanohydrins can be formed rapidly and essentially quantitatively at pH 8.0 $\pm$ 0.5 with minimal hydrolysis, and that they are stable at pH 4.0. As described by Kuhn and Bister (20) for the preparation of 2-amino-2-deoxy-aldoses from 2-benzylamino-2-deoxyaldononitriles, we find that aldononitriles can be hydrogenolyzed to aldoses in 70–80% yield. Furthermore, condensation with $K^{13}CN$ provides a convenient route for the preparation of [^{13}C]-enriched derivatives of all the aldoses (9, 10) and of the C_3 to C_5 aldose phosphates (11). The mixed aldononitrile epimers produced from cyanide condensation are reduced without purification and the product epimeric aldoses purified by chromatography (14, 15). Aldononitrile phosphate epimers can be separated prior to reduction by chromatography at pH 3.9 (11), illustrating the stability of cyanohydrins and the absence of cyanide exchange at low pH values.

Hydrogen pressure, pH, and the structure of the nitrile all affect the ease of hydrogenolysis of cyanohydrins (9–11). Hydrogenolysis occurs smoothly in the absence of excess cyanide, which appears to poison the catalyst. In the course of this study it was observed that chloride ion promotes "over-reduction" to aminoalditols. Sulfuric acid rather than HCl is preferred since sulfate ion does not inhibit hydrogenolysis, gives higher yields of aldose, and can be removed more easily than chloride ion. Iodate ion, at low concentrations, inhibits reduction completely (11).

In addition to the introduction of carbon isotopes, the catalytic hydrogenolysis of cyanohydrins provides a route to carbohydrates enriched with hydrogen and oxygen isotopes. The technique permits the separate or simultaneous incorporation of carbon and hydrogen isotopes at C-1 and H-1, respectively, and oxygen isotopes at O-2 for each cycle of cyanide addition and catalytic reduction (Scheme 1). Successive application of condensation and reduction permits the synthesis of derivatives enriched at sites other than C-1 and C-2. A wide variety of selectively-enriched carbohydrates and their derivatives, which were difficult to prepare previously, are now accessible.

For the incorporation of ^{2}H, cyanide condensation and hydrogenolysis are carried out in $^{2}H_2O$ instead of H_2O solutions to avoid exchange of ^{1}H for ^{2}H on the catalytic surface. This exchange decreases the incorporation of ^{2}H at H-1. Under the conditions used for hydrogenolysis, ^{1}H–^{2}H exchange did not occur at other positions, as determined by ^{1}Hmr. In several cases, nitrile (~15%) remained in the reduction mixtures after 10 h of hydrogenolysis. Complete conversion to products was achieved by adding new catalyst and continuing the reduction.

Nuclear Magnetic Resonance Parameters

^{13}C nmr Spectra

Substitution of ^{2}H for ^{1}H permits the assignment of ^{13}C resonances of the directly-bound and nearby carbons due to decreased nuclear Overhauser effects and characteristic isotope shifts. In addition ^{13}C–^{2}H coupling can be measured. The effect of ^{2}H substitution for ^{1}H on the ^{13}C chemical shift of the derivatized carbon is shown in Table 1 for several carbohydrates. The values observed are similar to those observed by Gorin (1) and Gorin and Mazurek (4). The use of [^{13}C, ^{2}H]-enriched compounds facilitates the observation of the deuterated carbon and the evaluation of $^{1}J_{^{13}C,^{2}H}$ (Fig. 1). The ^{13}Cmr spectrum of D-[1-^{13}C] threose in aqueous solution shows the presence of three major tautomeric forms, namely, the α- and β-furanoses, and a linear *gem*-diol (hydrate) (Fig. 1A). The proton-decoupled ^{13}Cmr spectrum of D-[1-^{13}C, ^{2}H]threose (Fig. 1B) shows four lines for

[a]Chemical shifts are given relative to external Me_4Si and are accurate to ± ppm. Carbon spectra were obtained with broad-band proton decoupling at 30°C.
[b]$^{1}J_{C,^{1}H}$ couplings for unphosphorylated and phosphorylated aldoses were taken from refs. 10 and 11, respectively, and are accurate to ±0.7 Hz.
[c]Coupling constants are accurate to ±0.7 Hz.
[d]$\Delta\nu = \nu_{(^{1}H)} - \nu_{(^{2}H)}$, where $\nu_{(^{1}H)}$ and $\nu_{(^{2}H)}$ are equal to the resonance frequencies of the protonated and deuterated carbons, respectively. $\Delta\nu$ is positive since the observed isotope shifts upon deuteration are upfield from the protonated homologue.
[e]$\Delta J = {}^{1}J_{^{13}C,^{1}H} - \gamma_{^{1}H}\,{}^{1}J_{^{13}C,^{2}H}/\gamma_{^{2}H}$, where $\gamma_{^{1}H}$ and $\gamma_{^{2}H}$ are the magnetogyric ratios for ^{1}H and ^{2}H, respectively.

each tautomeric form, three arising from ^{13}C–^{2}H coupling, and one from the residual protonated carbon. The ^{13}C–^{2}H isotope shift can be estimated from the difference in resonance position between the protonated carbon and the center of gravity of the deuterated carbon triplet. The percent isotopic incorporation is not reflected in peak areas since nuclear Overhauser enhancement is smaller for deuterated than for protonated methine carbons (21). For example, the ^{1}Hmr spectrum of the same preparation of D-[1-^{13}C, ^{2}H]threose shows no resonance for H-1, indicating deuterium enrichment of at least 97%, whereas the proton-decoupled ^{13}Cmr spectrum (Fig. 1B) gives the appearance of a significant proportion of ^{1}H at H-1.

In Table 1, $^{1}J_{^{13}C,^{2}H}$ coupling constants are listed for several carbohydrates and derivatives. The data indicate that $^{1}J_{^{13}Cl-^{2}H1}$ is larger when OH-1 and OH-2 are *cis* in the furanose ring, and that this coupling is larger in the ring forms than in the acyclic hydrates. The same relationships were observed for $^{1}J_{^{13}C,^{1}H}$ (11) (Table 1). Colli *et al.* (22) have shown for several non-carbohydrate compounds that the ratio $^{1}J_{^{13}C,^{1}H}:{}^{1}J_{^{13}C,^{2}H}$ is very close to the value predicted from the magnetogyric ratios for ^{1}H and ^{2}H. The value of ΔJ indicates the extent of variation between observed and predicted values of $^{1}J_{^{13}C,^{2}H}$ and is zero for perfect agreement. As shown in Table 1, values for ΔJ are within the error of the determinations.

^{1}H nmr Spectra

Replacement of ^{1}H with ^{2}H often simplifies ^{1}H spectra, facilitating the assignment of chemical shifts and coupling constants. For example, whereas the 180 MHz ^{1}Hmr spectrum of D-erythrose is essentially first-order, that of D-threose is complex (Fig. 2A). The complexity was eliminated in the spectrum of DL-[3-^{2}H]threose and it was shown that in D-threose the ^{1}Hmr spectrum is complicated by the near magnetic equivalence of H-3α and H-4α which perturbs the resonances of these nuclei and produces a complex multiplet for H-4′α.

Substituting ^{2}H for ^{1}H at H-3 in threose removes three vicinal ^{1}H–^{1}H couplings and the resonances due to H-3 from the spectrum, greatly simplifying assignment and analysis. D-Threose exists primarily as three tautomeric forms in aqueous solution in the ratio α-furanose/β-furanose/hydrate of 4.2 : 3.1 : 1 (10) (Fig. 1A). Although H-2 can be identified by selective homonuclear decoupling of H-1 or by ^{13}C-enrichment at C-2, neither technique permits the unequivocal assignment of H-3, H-4, and H-4′ for each tautomer. Figure 2B shows the H2-H4 region of the 180 MHz ^{1}Hmr spectrum of DL-[3-^{2}H]threose. The H-2, H-4, and H-4′ resonances are easily identified for the furanose forms on the basis of their proportions in solution. In addition, the spectrum is essentially first-order, permitting direct determination of several geminal and vicinal ^{1}H–^{1}H coupling constants. The H-2 resonance of the hydrate is at 3.46 ppm, but resonances due to H-3, H-4, and H-4′ for this form are not readily assigned. However, from the ^{1}Hmr spectrum of the 3-^{2}H derivative (Fig. 2B), it is clear that H-4 and H-4′ for the linear hydrate lie in the same region as H-4′ for the β-furanose, per-

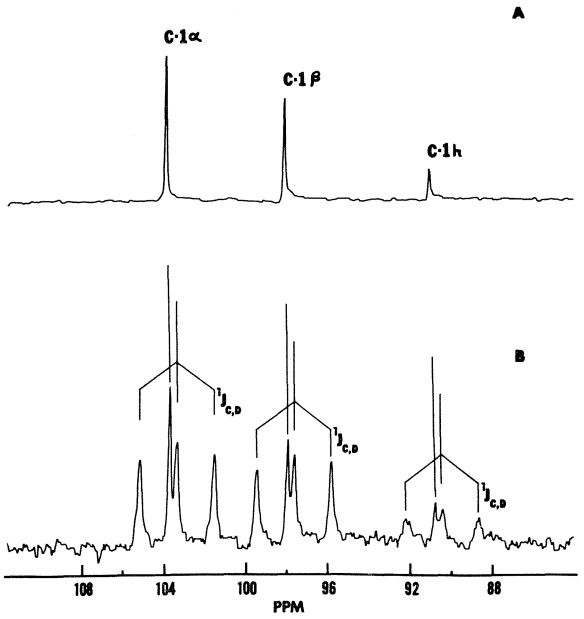

FIG. 1. ^{13}C–^2H coupling and isotope shift in a [^{13}C, ^2H]-enriched carbohydrate. (A) The 15.08 MHz proton-decoupled ^{13}Cmr spectrum of the enriched region of D-[1-^{13}C]threose. The three predominant tautomeric forms in aqueous solution are α- and β-furanose (103.4 and 97.9 ppm, respectively) and acyclic hydrate (91.1 ppm) (10). (B) The 15.08 MHz proton-decoupled ^{13}Cmr spectrum of the enriched region of D-[1-^{13}C, ^2H]threose, showing the splitting of C-1 of each form by the directly-bound deuteron. Isotope shift is shown for each species as the difference in the positions between the protonated C-1 and the center of gravity of the triplet arising from the deuterated C-1.

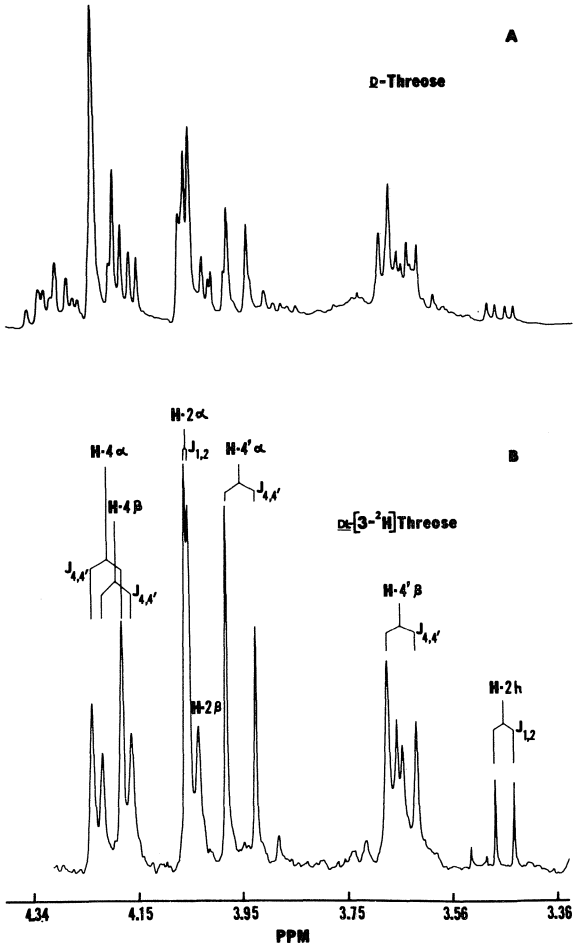

FIG. 2. (A) The 180.04 MHz ^1Hmr spectrum of the H2-H4 region of D-threose. (B) The 180.04 MHz ^1Hmr spectrum of the same region of DL-[3-^2H]threose. Deuteration at C-3 simplifies the spectrum so that assignment of resonances can be made as shown. The upfield half of the doublet from H-2β (due to coupling to H-1β) is observed, with the other half hidden by the H-2α doublet. The magnitude of this coupling is confirmed by observation of H-1β (not shown). The chemical shifts of H-3α and H-3β ,determined by computer simulation, are 4.20 ppm and 4.30 ppm, respectively. Lines between the resonances due to H-4′β appear to arise from H-4 and H-4′ of the acyclic hydrate. H-4′ was arbitrarily designated as the more shielded H-4 of each form.

mitting the position of these resonances to be estimated by computer simulation. Chemical shifts for H-3 for the cyclic forms of D-threose were estimated by comparison of the normal and deuterated compounds and refined by computer simulation. Apparent and intrinsic proton chemical shifts and ^1H–^1H coupling constants for the tetroses are given in Tables 2 and 3.

In both tetroses, H-1 of the hydrate is more shielded than H-1 for the furanoses, while H-2 of the hydrate is the most shielded nucleus.

Heteronuclear ^2H–^1H coupling has been observed in both high resolution ^1H and ^2Hmr spectra (22, 23). However, the ^1Hmr spectra of DL-[3-^2H]threose (Fig. 2B) and DL-[3-^2H]erythrose at 180 MHz do not exhibit ^2H–^1H couplings. Only vicinal or long range ^1H–^2H coupling pathways would be expected in these compounds. Since ^1H–^2H coupling constants are about 15% (1/6.5144) of their ^1H–^1H analogs, the triplets with $^3J_{^1H,^2H}$ values of 0.15–0.77 Hz would be difficult to resolve. As discussed by Mantsch *et al.* (24), ^1H spectra often exhibit an average ^1H–^2H coupling because the remaining ^1H–^1H couplings are considerably larger than the ^1H–^2H couplings or the ^2H-induced isotope shifts in the ^1H spectrum, and the ^1H spectrum is consequently deceptively simple (25). Line broadening (~0.7 Hz) due to pseudorotation of the furanose ring also hinders observation of the smaller ^1H–^2H couplings.

Specific deuteration has been useful in establishing long-range ^1H–^1H coupling in the furanose ring. For example, deuteration of D-erythrose at either H-1 or

TABLE 2. Apparent and intrinsic ^1H chemical shifts for the tetroses and some methyl pentofuranosides in ^2H_2O

Compound	Chemical shifts (ppm)[a]

	(4.3)	(6.2)	(3.3)			(3.1)	(4.8)	(−12.4)
Methyl β-D-ribofuranoside	1.2	4.7	6.8			3.7	6.4	−12.3
	(1.2)	(4.6)	(6.9)			(3.1)	(6.6)	(−12.2)
Methyl α-D-arabinofuranoside	1.7	3.3	5.8			3.4	5.6	−12.2
	(1.7)	(3.3)	(5.9)			(3.1)	(6.1)	(−12.2)
Methyl β-D-arabinofuranoside	4.5	7.9	6.7			3.4	6.7	−12.1
	(4.6)	(8.0)	(7.1)			(3.2)	(7.4)	(−12.0)

[a]Coupling constants are accurate to ±0.15 Hz. Values found in parentheses are intrinsic coupling constants (±0.2 Hz) determined by computer simulation. Assignments of H4, H4′ and H5, H5′ are arbitrary.
[b]Values are accurate to within ±0.3 Hz.

H-3 simplifies the H-3 or H-1 multiplets, respectively, for the β-anomer, indicating that a small (~0.6 Hz) coupling exists between these nuclei. The α-anomer shows no such coupling. Interestingly, methyl α-D-arabinofuranoside has $^4J_{H1,H3} = 0.5$ Hz, whereas the β-anomer shows no coupling (26).

Heteronuclear spin–spin coupling between ^{13}C and ^1H is valuable in examining conformations of carbohydrates in solution. Generally, two- and three-bond ^{13}C–H coupling constants are difficult to obtain from ^1H-coupled ^{13}Cmr spectra, even when [^{13}C]-enriched compounds are used. These studies are greatly facilitated at high fields (67.89 MHz for carbon) as demonstrated recently (27), but, even in this case, deuterated analogues and heteronuclear selective ^1H decoupling were used to confirm assignments. An alter-

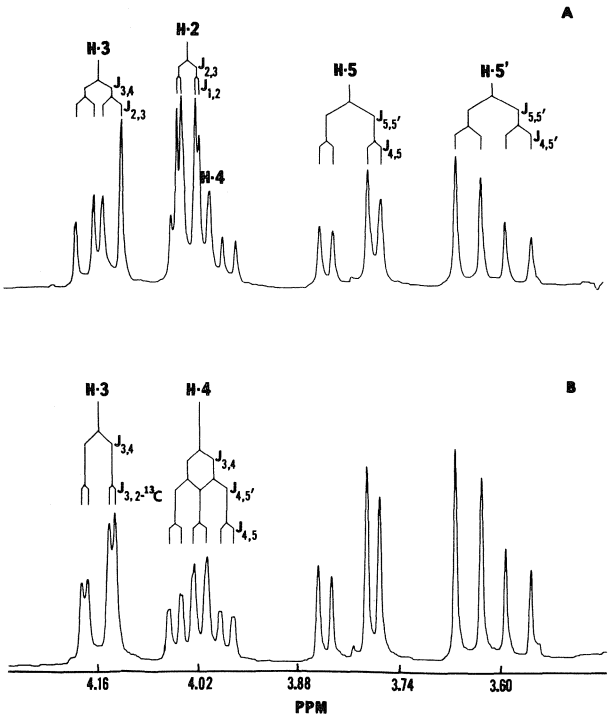

FIG. 3. (A) The 180.04 MHz ^{1}Hmr spectrum of the H-2 to H-5 region of methyl β-D-ribofuranoside, showing the assignment of multiplets. H-5′ was arbitrarily designated as the more shielded H-5. (B) The 180.04 MHz ^{1}Hmr spectrum of the same region of methyl β-D-[2-^{13}C, ^{2}H]ribofuranoside, showing the loss of the H-2 multiplet and coupling of H-3 to ^{13}C-2. The H-4 multiplet is broadened while H-5 and H-5′ are unchanged. Residual [2-^{13}C, ^{1}H] compound would produce two H-2 multiplets split by $^1J_{C2,H2} \simeq 154$ Hz (11). One of these multiplets would appear at approximately 3.59 ppm in this spectrum. It is not observed.

native approach has been to analyze ^{13}C-enriched compounds by ^{1}Hmr (28–34). In cases where ^{1}Hmr spectra are complex, the synthesis of compounds with ^{2}H- and (or) ^{13}C-enrichment may aid interpretation. For example, Fig. 3A shows the 180 MHz ^{1}Hmr spectrum of the H2 to H5 region of methyl β-D-ribofuranoside. The spectrum of the [2-^{13}C, ^{2}H]-enriched derivative (Fig. 3B) is simplified by the loss of a quartet at 4.02 ppm due to H-2. The multiplet centered at 4.14 ppm is altered. In Fig. 3A, $^3J_{H3,H4}$ and $^3J_{H2,H3}$ can be assigned. Inspection of the coupling patterns for H-1 (not shown) and H-2 confirms the assignment of the multiplet at 4.14 ppm to H-3. In Fig. 3B, the H-3 multiplet contains $^3J_{H3,H4}$ and a new coupling, $^2J_{C2,H3} = 1.6$ Hz. Loss of the H-2 multiplet in this spectrum permits H-4 to be assigned and $^3J_{H4,H5}$ and $^3J_{H4,H5'}$ to be evaluated from the H-4 multiplet. Note that H-4 is slightly broadened in the [^{13}C]-enriched compound, suggesting a small three-bond coupling of this nucleus to C-2. This broadening probably does not arise from ^{1}H–^{2}H coupling (see above). Resonances due to H-5 and H-5′ are quartets centered at 3.79 and 3.59 ppm, respectively. In [2-^{13}C, ^{2}H] methyl α-D-ribofuranoside, $^2J_{C2,H3}$ is small, producing a broadening of the H-3 doublet.

The apparent and intrinsic ^{1}H chemical shifts and ^{1}H–^{1}H coupling constants for methyl *ribo* and *arabino* furanosides determined from the experimental and computer-simulated data, respectively, are listed in Tables 2 and 3. Although in several instances the use of [^{2}H]-enriched compounds was not required to make these assignments, there is no doubt of the value of multiply-enriched derivatives for use in more complex instances.

Experimental

Materials and Instrumentation

D-Glyceraldehyde was prepared from D-fructose by oxidation with lead tetraacetate (35) and quantitated with Nelson's reagent (36) using DL-glyceraldehyde (Sigma Chemical Co) as a standard. D-Erythrose and D-threose were prepared as described by Perlin (37) and Ball (38), respectively. Potassium [^{13}C] cyanide (K^{13}CN) was supplied by the Los Alamos Scientific Laboratory, University of California, Los Alamos, NM, with 99.64% purity and 90.7 atom% ^{13}C enrichment. Potassium [^{14}C] cyanide (K^{14}CN) was purchased from New England Nuclear with a specific activity of 46 mCi/mmol. Palladium barium sulfate (5%) and deuterium oxide (^2H_2O) (99.8 atom%) were purchased from Sigma Chemical Co. Lead tetraacetate, deuterium chloride (^{2}HCl) (20%,99 atom%), and sodium deuteroxide (NaO^{2}H) (30%, 99 atom%) were obtained from Aldrich Chemical Co. Acetic acid-$^2H_4$ (99.5 atom%) and deuterium gas ($^2H_2$) (99.5 atom%) were obtained from Merck Sharpe and Dohme Canada Limited.

Dowex 1-X2 (200–400 mesh) was obtained from Sigma Chemical Co. and converted to the hydroxide form with 2 *M* NaOH.

^{13}Cmr spectra were obtained using a Bruker WP-60 15.08-MHz Fourier transform spectrometer equipped with quadrature detection. Spectra were obtained at 30°C with 4K spectral points and the spectrometer was locked to the resonance of ^2H_2O in a capillary. Chemical shifts are given relative to external tetramethylsilane (Me_4Si) and are accurate to ±0.1 ppm.

^{1}Hmr spectra were obtained at 30°C in ^2H_2O on a Bruker WH-180 equipped for Fourier transform operation using a 400 Hz sweep width and 8K spectral points. Chemical shifts are reported in ppm downfield from internal sodium 3-(trimethylsilyl)-1-propanesulfonate and are accurate to ±0.01 ppm. Complex spectra were analyzed by computer simulation as described previously (11,39). The rms error between a simulated and experimental spectrum was typically 0.15 Hz. ^2H_2O solutions were treated with ^2H_2O-washed Chelex resin (Sigma Chemical Co) to remove paramagnetic species (40) prior to analysis by ^{1}Hmr.

pH Measurements in ^2H_2O solutions were corrected using the equation pH = pD − 0.4 (41). Phosphate assays were carried out according to Leloir and Cardini (42) and radioactivity (^{14}C) was assayed as described previously (9).

General Method For the Preparation of Deuterated Carbohydrates. Preparation of D-[*1-*^{13}*C,* ^{14}*C,* ^{2}*H*]-*Erythrose and Threose*

A solution of K^{13}CN (2 mmol, 13 mL ^2H_2O) at 20°C con-

taining $K^{14}CN$ (10^7 cpm) was added to a 25 mL sealed flask (9) and adjusted to pH 8.0 ± 0.1 with 0.7 *M* acetic acid-$^2H_4$. D-Glyceraldehyde (2 mmol) was concentrated from 3 mL of ^2H_2O several times at 30°C *in vacuo*. The residual gum was dissolved in 4–5 mL ^2H_2O and added to the solution of $K^{13}CN$. The pH of the reaction mixture was maintained between 8.0 and 8.3 with additions of 0.7 *M* acetic acid-$^2H_4$ and (or) 1.0 *M* NaO^2H. After 20–25 min, the pH was lowered to 4.0 ± 0.2 with 17 *M* acetic acid-$^2H_4$. A further adjustment of pH to 1.7 ± 0.2 was made with 3 *M* ^2HCl.

Palladium-barium sulfate (5%, 62 mg per mmol of nitrile) was weighed into a 50 mL side-arm flask, 5 mL ^2H_2O was added, and the system was evacuated and charged three times with N_2. After the last evacuation, the system was charged with $^2H_2$ and the catalyst reduced for 15–20 min at atmospheric pressure and 25°C with efficient stirring. The ballast containing $^2H_2$ was filled with light mineral oil to prevent entry of H_2O into the reduction apparatus (10). The [^{13}C]-enriched aldononitriles were then added and the reduction was continued for 10 h, or until the nitriles were completely reduced as determined by gas-chromatography (10). The product epimeric aldoses were deionized and separated as described previously (10). Products were characterized by ^{1}H and ^{13}Cmr yield: 70% based on product weight as gums and on the recovery of radioactivity after separation.

Preparation of D-[2-^{13}C, ^{14}C, ^2H]*Ribose and Arabinose*

D-[2-^{13}C, ^{14}C, ^{2}H]ribose and arabinose were prepared from D-[1-^{13}C, ^{14}C, ^{2}H]erythrose according to a modified procedure described for the preparation of the [1-^{13}C] compounds (9). The condensation reaction with KCN in H_2O was carried out at pH 7.8–8.0 for 9 min. The solution was adjusted to pH 4.0 with acetic acid and then to pH 3.0 ± 0.1 with HCl. The epimeric nitriles were reduced with Pd/H_2 at 20 psi and 25°C in a Parr apparatus, and the product aldoses were purified and analyzed by ^{13}C and ^{1}Hmr. Yield as dry gums: 78% after separation.

Preparation of Methyl α-D-[2-^{13}C, ^{14}C, ^2H]*Ribofuranoside and Methyl* β-D-[2-^{13}C, ^{14}C, ^2H]*Ribofuranoside*

D-[2-^{13}C, ^{14}C, ^{2}H]ribose was converted to the methyl furanosides by the procedure of Barker and Fletcher (43). The reaction mixture was neutralized by passage through a 1.2 cm × 5 cm column of Dowex 1-X8 (200–400 mesh) in the acetate form and elution with deionized water. The resulting solution was concentrated at 30°C *in vacuo* and applied to a 1.5 cm × 23 cm column of Dowex 1-X8 (200–400 mesh) in the hydroxide form (44) and developed with decarbonated distilled H_2O with a flow rate of 0.25 mL/min. Fractions (3 mL) were collected and assayed with phenol–sulfuric acid (45.) The α-anomer eluted between fractions 25–35 and the β-anomer eluted between fractions 60–80. Fractions were pooled, concentrated at 30°C *in vacuo*, and analyzed by ^{13}C and ^{1}Hmr. Anomers were identified by comparison of ^{13}C chemical shifts for C-2 with those reported previously (46).

Methyl-D-arabinofuranosides were prepared by the procedure of Augestad and Berner (47) and the α- and β-anomers were separated by the method of Austin *et al.* (44). Anomers were identified by ^{13}Cmr using chemical shifts reported previously (46).

DL-[2-^{14}C, 3-^{2}H]erythrose and threose were prepared from [1-^{2}H]glycolaldehyde by successive condensations of the C_2 and C_3 deuterated aldoses with KCN ($K^{14}CN$) and reduction with Pd/H_2 (10). The two condensations with KCN were modified by using H_2SO_4 rather than HCl to adjust the pH of the reaction mixtures from 4.0 to 1.7 ± 0.1 prior to reduction. Catalyst was removed by filtration through sintered glass and the reduction products were deionized with $BaCO_3$. The solution was filtered through Celite to remove the $BaSO_4$ precipitate and residual $BaCO_3$, the filter pad was washed well with H_2O, and the filtrate and washings were treated batchwise with Dowex 1 × 8 (OAc^-) and Dowex 50 × 8 (H^+) sucessively. The clear, colorless solution was concentrated to 2 mL at 30°C *in vacuo* and the mixture separated as described previously on Dowex 50 × 8 (200–400) (Ba^{++}) (10).

DL-[1-^{14}C, ^{2}H]glyceraldehyde was prepared from DL-[1-^{14}C,]-glyceronitrile by reduction with $^2H_2$ and purified as described previously (10). Yield after purification, 82%. ^{13}Cmr: 75.5 ppm (C-2, hydrate) and 63.4 ppm (C-3, hydrate).

D-[1-^{14}C]erythrose 4-phosphate (E4P) was prepared from D-[1-^{14}C]erythrononitrile 4-phosphate by reduction with H_2 (11). D-[1-^{14}C] E4P was converted to D-[1-^{13}C, ^{2}H, 2-^{14}C]-ribose 5-phosphate by reduction with $Pd/^2H_2$. DL-[1-^{13}C, ^{14}C, ^{2}H]glyceraldehyde 3-phosphate was prepared from DL-[1-^{13}C, ^{14}C]glyceronitrile 3-phosphate and purified as described previously (11). Yield based on recovery of phosphate and radioactivity after chromatography, 69% with 5% inorganic phosphate.

Carbon-13 nuclear magnetic resonance spectra of oxazoles

HENK HIEMSTRA, HENDRIK A. HOUWING, OKKO POSSEL, AND ALBERT M. VAN LEUSEN
Department of Organic Chemistry, Groningen University, Nijenborgh 16, 9747 AG Groningen, The Netherlands

Received June 14, 1979

HENK HIEMSTRA, HENDRIK A. HOUWING, OKKO POSSEL, and ALBERT M. VAN LEUSEN. Can. J. Chem. **57**, 3168 (1979).

The ^{13}C nmr spectra of oxazole and eight mono- and disubstituted derivatives have been analyzed with regard to the chemical shifts and the various carbon–proton coupling constants of the ring carbons. The data of the parent oxazole are compared with thiazole and 1-methylimidazole.

HENK HIEMSTRA, HENDRIK A. HOUWING, OKKO POSSEL et ALBERT M. VAN LEUSEN. Can. J. Chem. **57**, 3168 (1979).

On a analysé les spectres rmn du ^{13}C de l'oxazole et de huit dérivés mono ou bisubstitués du point de vue des déplacements chimiques et des différentes constantes de couplage C—H des atomes de carbone du cycle. Les données relatives à l'oxazole parente sont comparées à celles du thiazole et du méthyl-1 imidazole.

[Traduit par le journal]

In the course of our work on a new synthesis of azoles (1) we were confronted with a lack of ^{13}C nmr data of oxazoles. Thus far, only the spectrum of benzoxazole (2) and the ^1J (C, H) coupling constants of 4-methyloxazole (3) have been reported.[1] It became, therefore, worthwhile to carry out a ^{13}C nmr analysis of the oxazole ring system.

We here present the data of a series of nine oxazoles, i.e., the chemical shifts of the ring carbons (Table 1) and coupling constants (Table 3). Furthermore, these data of the parent oxazole are compared with thiazole and 1-methylimidazole (Tables 2 and 3).

Experimental

The oxazoles **4**, **6**, **7**, and **8** (Table 1) were recently prepared in our laboratory by reaction of tosylmethyl isocyanide (TosMIC) or derivatives thereof, and aromatic aldehydes (1). Samples of the oxazoles **1**, **2**, **3**, and **5** were prepared according to the literature referred to in Table 1.

The ^{13}C nmr spectra were measured in $CDCl_3$ solution at 35°C on a Varian XL 100 apparatus using the FT technique and an internal deuterium lock. The $CDCl_3$ absorptions were used as internal reference; chemical shifts were corrected to δ_{TMS} with $\delta_{TMS} = \delta_{CDCl_3} + 77.0$ ppm. Coupled spectra were recorded using the gated noise decoupling technique.

In the measurements in which the methyl protons were selectively decoupled, the low power decoupling transmitter was employed in the hetero mode. To that end the proton spectrum of the sample was recorded first (also with ^2H lock and in the CW mode) to determine the exact setting of the decoupler offset, i.e., the setting that gives a zero beat at the position of the singlet of the methyl protons.

Results and Discussion

^{13}C Chemical Shifts

Chemical shift data of the parent oxazole (**1**), three monosubstituted derivatives (**2**–**4**), and five disubstituted ones (**5**–**9**) are given in Table 1. The chemical shifts of the ring carbons have been assigned by making use of the (absence of) one-bond C—H coupling constants (^1J), and known substituent effects of aryl, methyl, methoxy, and tosyl (1*g*, 4, 5).

From this assignment the following generalizations can be made. (*1*) In all cases C(2), located between two electronegative hetero atoms, resonates at the lowest field; at ca. 150 ppm when unsubstituted, and about 10 ppm lower when substituted with methyl, methoxy, or phenyl. (*2*) The chemical shifts of C(4) and C(5), at ca. 126 and 138 ppm, respectively, when both carbons are unsubstituted, show a downfield shift of 10–15 ppm upon substitution with one aryl group and, simultaneously, an upfield shift of about 5 ppm for the other (unsubstituted) carbon.

In Table 2 the chemical shifts of the ring carbons of oxazole (**1**) are compared with thiazole **10** (5) and *N*-methylimidazole **11** (6). The highest field absorption of **1** belongs to C(4) rather than to C(5) as in **10** and **11**, which may be a reflection of the higher electronegativity of oxygen. In **10** the C(4) absorption is shifted ca. 18 ppm to lower field as compared with **1** and **11**; an almost identical difference is observed for the C(β) of thiophene with respect to furan and pyrrole (11).

Coupling Constants

All one-bond coupling constants (^1J) and most of the long range coupling constants (^2J, ^3J) of the oxazole ring atoms were easily obtained from the coupled ^{13}C spectra[2] (see Table 3). The oxazoles

[1] After this paper was submitted for publication, ^{13}C nmr spectra of a large number of benzoxazoles and oxazole were published (12). The spectral data of oxazole were almost identical to our results.

[2] The splitting patterns of the oxazole ring atoms were first order both in ^1H and ^{13}C nmr.

Compound	C(2)	C(4)	C(5)	CH_3
1	150.6	125.4	138.1	—
10[a]	153.6	143.3	119.6	—
11	135.8	126.7	118.3	30.7

[a]Data obtained from ref. 5.

5, **6**, **8**, and 1-methylimidazole (**11**) gave more complex signals because of additional long range coupling with the methyl hydrogens. The additional coupling could be eliminated, however, by selective irradiation of the methyl protons. For the oxazoles **5**, **6**, and **8** this decoupling did not affect the other coupling constants; only 1-methylimidazole (**11**) showed a slight reduction of the coupling constants. The ^2J and ^3J coupling constants of **11** listed in Table 3 were obtained by multiplying the measured coupling constant (J reduced) with a factor derived from the ^1J's of the selectively decoupled and the gated noise decoupled spectra of **11**, assuming a constant ratio J reduced/J for each proton.[3]

$^1J(C,H)$

In all oxazoles (**1–9**) the various ^1J's have about the same values: 230 Hz for C(2)—H(2), 194 Hz for C(4)—H(4), and 210 Hz for C(5)—H(5). This leads to the following sequence for oxazoles ^1J C(2),-H(2) > ^1J C(5),H(5) > ^1J C(4),H(4), whereas for thiazole (**10**) and 1-methylimidazole (**11**) was found ^1J C(2),H(2) > ^1J C(5),H(5) ≃ ^1J C(4),H(4). The

[e]Assignment might be the reverse.
[f]Values are in close analogy to data in ref. 6.

[3]See ref. 4, p. 66 ff.

greater electronegativity of oxygen causes a larger difference between the ^1J's of the oxazoles.

^{2}J (C, H)

The two-bond coupling constants of the oxazoles ^2J C(4),H(5) and ^2J C(5),H(4) have values of about 16 Hz and 18 Hz, respectively. Comparison with **10** and **11** shows that ^2J C(5),H(4) is almost independent of the nature of ring atom 1 (O, S, or N), whereas ^2J C(4),H(5) appears to increase with a larger electronegativity of atom 1 (5).

^{3}J (C, H)

In oxazoles the three-bond coupling constants are smaller than the ^2J's. The sequence in magnitude of the ^3J's for the three ring systems is for oxazole ^3J C(2),H(4) > ^3J C(4),H(2) $\simeq$ ^3J C(2),H(5) > ^3J C(5),H(2), and for thiazole and imidazole: ^3J C(2),H(4) $\simeq$ ^3J C(4),H(2) > ^3J C(2),H(5) > ^3J C(5),H(2).

The data in Table 3 show that the magnitude of the coupling constants of the oxazole nucleus is only slightly affected by substituents. This observation can be of use in structural assignments in oxazole chemistry.

Received September 6, 1979

JOSEF BOJES, TRISTRAM CHIVERS, GREG MACLEAN, RICHARD T. OAKLEY, and A. WALLACE CORDES. Can. J. Chem. **57**, 3171 (1979).

Two novel products, $(Ph_3P{=}N)_2S_4N_4$ and $(Ph_3P{=}N)_3S^+S_4N_5^-$, have been isolated from the reaction of triphenylphosphine with S_4N_4; an X-ray structural determination of $(Ph_3P{=}N)_2S_4N_4$ shows it to consist of a 1,5-disubstituted S_4N_4 ring with the exocyclic substituents in an *axial, equatorial* configuration.

JOSEF BOJES, TRISTRAM CHIVERS, GREG MACLEAN, RICHARD T. OAKLEY et A. WALLACE CORDES. Can. J. Chem. **57**, 3171 (1979).

On a isolé deux nouveaux produits de la réaction de la triphénylphosphine avec S_4N_4: $(Ph_3P{=}N)_2S_4N_4$ et $(Ph_3P{=}N)_3S^+S_4N_5^-$. La détermination de la structure de $(Ph_3P{=}N)_2S_4N_4$ à l'aide de rayons-X montre que ce composé est formé d'un cycle S_4N_4 disubstitué en positions 1 et 5 avec des substituants exocycliques ayant une configuration *axiale équatoriale*.
[Traduit par le journal]

The formation (1, 2) and structure (3) of $Ph_3P{=}N{-}S_3N_3$ have been known for some time. As a part of our studies on the nucleophilic degradation of S_4N_4 (4) we have reinvestigated the reaction of S_4N_4 with triphenylphosphine, the original method used to prepare $Ph_3P{=}N{-}S_3N_3$ (1). Consistent with our earlier results (4), we find that the $S_4N_5^-$ ion is also formed in this reaction, as a salt of the novel sulphonium ion, $(Ph_3P{=}N)_3S^+$. More significant, however, is the formation of $(Ph_3P{=}N)_2S_4N_4$ (**1**) as the major product when the reaction is carried out in acetonitrile. In this Communication we describe the formation and structure of **1**, the first example of a 1,5-disubstituted S_4N_4 ring, and the isolation and characterization of $(Ph_3P{=}N)_3S^+S_4N_5^-$ (**2**).

Reaction of triphenylphosphine (2.85 g, 10.0 mmol) and S_4N_4 (1.00 g, 5.43 mmol) in acetonitrile (60 mL) at 23°C produces a salmon-pink precipitate. After washing this precipitate with diethyl ether (to remove Ph_3PS), extraction with acetonitrile (5 × 100 mL) yields, upon evaporation of the solvent, pale yellow needles of $(Ph_3P{=}N)_3S^+S_4N_5^-$ (**2**) (0.47 g), which exhibit uv–visible (in CH_2Cl_2, λ_{max}: 345 nm(sh), $\varepsilon \sim 3.3 \times 10^3$ L mol^{-1} cm^{-1}, and ~290 nm) and ir (in Nujol, excluding cation bands: 956 s, 916 m, 665 vw, 647 w, 600 w, 438 m, and 300 w cm^{-1}) bands characteristic of the $S_4N_5^-$ ion (4, 5).[2] We found that **2** is also produced in 23% yield from triphenylphosphine and S_4N_4 in benzene at 23°C; it is surprising that no mention of this compound has been made before (1, 2).

We believe the formation of **2** involves $Ph_3P{=}N{-}S{-}N{=}PPh_3$ as an intermediate which immediately disproportionates to $[(Ph_3P{=}N)_3S^+]_2S^{2-}$. The subsequent reaction of sulphide ion with S_4N_4 is known to produce $S_4N_5^-$ (4*b*). In support of this belief we showed that the reaction of $Ph_3P{=}N{-}SiMe_3$ with SCl_2 yields $(Ph_3P{=}N)_3S^+Cl^-$ (85%) (6).[3] Final confirmation of the identity of **2** was obtained by cation exchange between $(Ph_3P{=}N)_3S^+Cl^-$ and *n*-$Bu_4N^+S_4N_5^-$ (4*a*, 5*a*) in acetonitrile.

[1]Author to whom correspondence may be addressed.

[2]The identity of the new sulphonium ion, $(Ph_3P{=}N)_3S^+$, has been confirmed by an X-ray crystal structure determination of **2** performed by Dr. M. Extine, Molecular Structure Corporation, Texas. The important structural parameters are as follows: d(S—N) = 1.635(4), d(P—N) = 1.597(4) Å; NSN = 102.1(2)°, SNP = 119.2(3)°.

[3]A related compound $[(Ph_3P{=}N)_3S^{3+}][3Cl^-]$ (based on analytical data), with a red color, was previously claimed to be one of the products of the reaction of triphenylphosphine with S_4N_3Cl.

0008-4042/79/233171-02$01.00/0

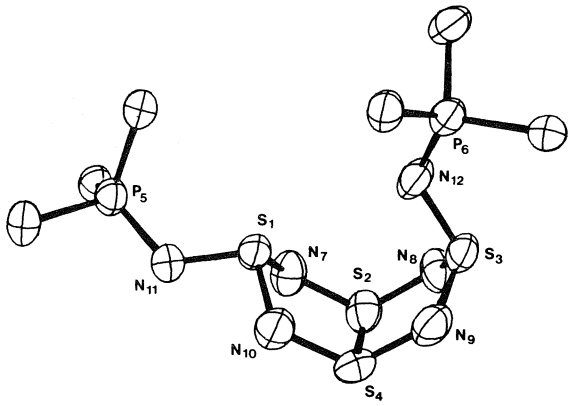

FIG. 1. ORTEP drawing of the $(Ph_3P{=}N)_2S_4N_4$ structure (the phenyl rings are omitted for clarity). Principal structural parameters are (e.s.d's in parentheses): S(1)—N(7), 1.675(4); S(1)—N(10), 1.666(4); S(3)—N(8), 1.630(4); S(3)—N(9), 1.632(4); S(2)—N(7), 1.588(4); S(2)—N(8), 1.605(4); S(4)—N(9), 1.613(4); S(4)—N(10), 1.583(4), S(1)—N(11), 1.599(4); S(3)—N(12), 1.621(4); S(1)—S(3), 3.727(2); S(2)—S(4), 2.452(2); P(5)—N(11) and P(6)—N(12), 1.592(4) Å. N(7)—S(1)—N(10), 101.0(2); N(8)—S(3)—N(9), 104.0(2); N(7)—S(2)—N(8), 120.6(2), N(9)—S(4)—N(10), 120.2(2), S(1)—N(7)—S(2), 118.8(1); S(1)—N(10)—S(4), 118.6(1); S(2)—N(8)—S(3), 120.9(2); S(3)—N(9)—S(4), 120.5(2)°.

The acetonitrile-insoluble solid from the Ph_3P/S_4N_4 reaction (1.09 g) can be recrystallized from CH_2Cl_2/CH_3CN to give pale yellow blocks of $(Ph_3P{=}N)_2S_4N_4$ (**1**) (dec. > 120°C). The structure of **1** has been determined by X-ray diffraction methods. Crystal data are as follows:

$(Ph_3P{=}N)_2S_4N_4$ mw = 736.86
Monoclinic, space group $P2_1/c$, a = 10.306(1), b = 19.473(5), c = 17.804(1) Å, β = 94.03(1)°, V = 3564 Å^3, Z = 4, ρ_c = 1.373 g cm^{-3}.

A total of 3303 reflections [$I \geq 3\sigma(I)$] were collected with a manual GE XRD-5 diffractometer using θ-2θ scans and Cu-K_α radiation. The structure was solved by direct methods and the final full-matrix least-squares refinement, which included anisotropic thermal parameters for all non-hydrogen atoms, gave an unweighted R-factor of 0.043.

The structure of **1** (see Fig. 1) consists of a ruptured S_4N_4 cage in which one cross-ring S—S interaction is replaced by bonds to two exocyclic triphenylphosphinimino ligands. The presence of the two exocyclic groups and the different orientation of the *exo*-S—N bonds (axial and equatorial) cause the endocyclic S—N bond distances to range from 1.583 to 1.675 Å. Nonetheless, the mean SN bond distance (1.62 Å) is similar to that found in S_5N_6 (1.61 Å) (7) and S_4N_4 (1.62 Å) itself (8). The S—S distance between the S atoms bonded to exocyclic groups is opened up to 3.727 Å and the remaining S—S interaction is considerably contracted (2.452 Å), as in S_5N_6 (2.43 Å) (7), in comparison to the two S—S distances of 2.59 Å found in S_4N_4 (8). The mean exocyclic S—N distance (1.61 Å) is similar to that found in $Ph_3P{=}N{-}S_3N_3$ (3), but the mean P=N distance (1.59 Å) is significantly shorter (1.65 Å in $Ph_3P{=}N{-}S_3N_3$).

The only known disubstituted derivatives of S_4N_4 are $S_4N_4O_2$ (9), in which both exocyclic oxygens are attached to the same sulphur atom, and the recently isolated $S_4N_4Cl_2$ (10) of undetermined structure. Thus the X-ray crystallographic study of $(Ph_3P{=}N)_2S_4N_4$ represents the first structural determination of a 1,5-disubstituted S_4N_4 ring. The structure of $S_4N_4Cl_2$, an important intermediate in the chlorination of S_4N_4 may well be related to that of **1**.

The infrared multiphoton chemistry of CF_3D has been investigated in the ν_2 and ν_5 bands. The primary dissociation step forms DF and CF_2. The major sink for the biradical is dimerization to form C_2F_4; this process preserves the $^{13}C/^{12}C$ isotopic selectivity which is reasonably high ($\alpha \approx 20$). The isotopic selectivity for $^2H/^1H$ is impaired by some scrambling reaction involving excited substrate. The possible nature of this scrambling reaction is discussed. In comparison with other CF_3X systems (X = I, Br, Cl), CF_3D is difficult to decompose, having low dissociation probability, and appears to decompose only after collisional activation.

M. GAUTHIER, R. PILON, P. A. HACKETT et C. WILLIS. Can. J. Chem. **57**, 3173 (1979).

On a étudié la chimie multiphoton dans l'infrarouge du CF_3D dans la région des bandes ν_2 et ν_5. La première étape de la dissociation conduit à DF et CF_2. Le principal affaiblissement du diradical est dû à une réaction de dimérisation qui donne du C_2F_4; cette réaction protège la sélectivité isotopique $^{13}C/^{12}C$ qui est raisonnablement grande ($\alpha \approx 20$). La sélectivité isotopique $^2H/^1H$ est affaiblie par une réaction désordonnée qui implique un substrat activé. On discute de la nature possible de cette réaction. Par comparaison aux autres systèmes du type CF_3X (X = Br, I, Cl), CF_3D est difficile à décomposer; il a une faible probabilité de dissociation et semble se décomposer seulement après une activation par collisions.

[Traduit par le journal]

Introduction

In earlier papers (1–3), we have reported details of the infrared multiphoton chemistry of the trifluoromethyl halides, CF_3I, CF_3Br, and CF_3Cl. The present work was undertaken in order to extend the CF_3X series to include CF_3D for two reasons. In the first case, the $^2H/^1H$ isotope shift is large for the ν_5 band of fluoroform (4) which should assure facile selective excitation of CF_3D molecules, a process of obvious practical importance. Secondly, the substitution of halogen by deuterium significantly increases the vibrational frequencies of the molecules, this increase results in a concomitant decrease in the density of vibrational states at any particular internal energy and should lead to a decrease in the efficiency of the multiphoton absorption process (5).

In the halides the primary dissociation step observed is the bond scission, reaction [1]

[1] $CF_3X \rightarrow CF_3 + X$

This reaction is favoured on thermodynamic grounds (6) being some 30 kcal mol^{-1} lower than the molecular elimination, reaction [2]

[2] $CF_3X \rightarrow CF_2 + FX$

However, for CF_3D the situation is reversed. The endothermicity for the molecular elimination, reaction [3]

[3] $CF_3D \rightarrow CF_2 + DF$

is +64.8 kcal mol^{-1} (6) which is over 30 kcal mol^{-1} lower than that for the carbon–deuterium bond scission. Furthermore, the observed activation energy for CF_2 production in the pyrolysis of CF_3H is +69 kcal mol^{-1} (7).

Experimental

All irradiations were performed with a line tunable TEA CO_2 laser (Lumonics Research Ltd., model 103). The temporal distribution of the laser pulse was monitored by a

[1]NRCC No. 17783.

0008-4042/79/243173-05$01.00/0

photon drag detector (Rofin, model 7415). The distribution was bimodal; a short "spike" (FWHM = 80 ns) was followed by a long tail (FWHM = 600 ns). About 70% of the incident energy was contained in the initial "spike". Samples of CF_3D (97%D, 3%H; Merke, Sharpe and Dohme), purified by distillation at −160°C, were irradiated in a Pyrex cell (18 cm long, 5 cm diameter) equipped with sodium chloride windows (Harshaw, laser grade). The laser beam passed through a 1.8 cm aperture and was focussed at the centre of the cell by a $f = 10$ cm germanium lens.

Analysis of all products determined was achieved directly by mass spectrometry. This method is unsatisfactory by comparison with others but was necessitated by (*a*) the inefficiency of the decomposition, *vide infra*, and (*b*) the low sensitivity of available gas chromatographs to the highly fluorinated compounds present. However, many calibrations of both single compounds and binary mixtures were performed in order to check the precision of the method. Moreover, possible interfering compounds were tested in order to improve the reliability of the assignment of *m/e* peaks to constituents of the photolysed mixture. C_2F_4 was determined from peaks at 81, 82, and 83, CF_3D from peak 52, and CF_3H from peak 51. Isotopic selectivities for carbon-13 were determined from the C_2F_4 product peaks and are reported as α values:

$$\alpha = \frac{^{13}C/^{12}C \text{ (product } C_2F_4)}{^{13}C/^{12}C \text{ (substrate } CF_3D)}$$

Results and Discussion

(a) Kinetics

The kinetics of the multiphoton chemistry of CF_3D can be described in terms of the following set of reactions

$$[3]\quad CF_3D \xrightarrow[M]{nh\nu} CF_2 + DF$$

$$[4]\quad CF_2 + CF_2 \rightarrow C_2F_4$$

$$k_4 = 2.5 \times 10^8 T^{1/2} \exp(-200/T) \text{ L mol}^{-1} \text{ s}^{-1} \quad \text{(refs. 8, 9)}$$

$$[5]\quad CF_2 + C_2F_4 \rightarrow c\text{-}C_3F_6$$

$$k_5 = 8.7 \times 10^4 T^{1/2} \exp(-3200/T) \text{ L mol}^{-1} \text{ s}^{-1} \quad \text{(refs. 7, 9)}$$

$$[6]\quad CF_2 + DF \rightarrow CF_3D$$

The only product observed at low conversions, at all pressures, temperatures, and irradiation wavelengths studied was C_2F_4, which is presumably formed with an equivalent amount of DF which did not survive through to analysis in our experiments. However, SiF_4 was detected in experiments carried to higher conversions.

However, it is not clear that the only fate of CF_2 is dimerization to form C_2F_4. Secondary reactions, of the type of reaction [5], are unlikely to be significant, even allowing for reaction at the potentially higher temperatures of the focal region. Indeed no higher products were observed. The importance of reaction [6], the back reaction, is difficult to assess in the absence of appropriate rate data. Smail and Rowland (10) have studied the equivalent reactions involving HI, HBr, and HCl. They report $k_{6(HI)} = 70 \times k_{6(HBr)} = 3500 \times k_{6(HCl)}$. More recent work suggests this trend continues to include HF (11). Accepting this trend and placing $k_{6(HI)}$ at close to the collisional limit gives an upper limit of $k_6 \leq 5 \times 10^4$ L mol^{-1} s^{-1}. For the conversions used in the present series of experiments, even allowing that DF survives as a free gas phase product, one can safely neglect reaction [6] on the grounds that its rate is too low. Further support of this conclusion was gained by irradiating a mixture of 0.5 Torr CF_3D and 0.10 Torr HBr. The observed yields of C_2F_4 and CF_2HBr were approximately equal. A simple analysis of the pulsed kinetics yields $k_{6(HBr)} = 5 \times 10^7$ L mol^{-1} s^{-1} which is in reasonable agreement with the estimate used above.

The above analysis indicates that measurement of C_2F_4 serves as an acceptable surrogate for the yield of primary dissociations as there appear to be no back reactions. Figure 1 shows the pressure dependence of this parameter. It is seen that the dissociation probability is proportional to pressure. There are many explanations for this behaviour; collisions may increase the rate of multiphoton absorption by removing "rotational bottlenecks" (12); the primary dissociation may be the result of bimolecular "energy pooling" reactions of two vibrationally activated molecules (13); or the observed dissociation may be a bulk pyrolysis of the irradiated gas, increased pressure would decrease the rate of cooling of the irradiated volume increasing the yield of dissociation (14). The latter explanation may be rejected on the grounds that the process is isotopically selective for carbon isotopes. Experiments to distinguish between the two remaining possibilities are in progress.

No evidence was found for reaction products arising from carbon–deuterium bond scission. This result confirms the conclusions of an earlier study of multiphoton decomposition of pentafluoroethane (15). That is that for "small" molecules only the lowest thermodynamic exit channel will be observed whereas as the volume of vibrational phase space increases the spontaneous dissociation rate of unimolecular dissociation decreases so that large molecules should show evidence for multichannel dissociation. A simple RRK calculation (16) reveals that the spontaneous dissociation rate for CF_3D reaches 2×10^8 s^{-1} at internal energies 14 kcal mol^{-1} above the threshold for molecular elimination which is well below the threshold for the free radical process. Hence for the methane it is unlikely that

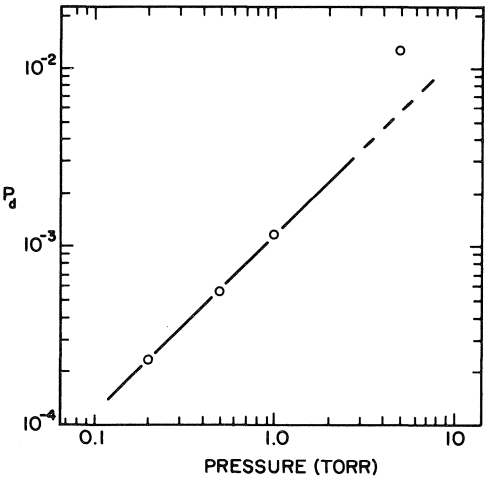

FIG. 1. Pressure dependence of dissociation probability. P_d, the probability that an irradiated molecule will decompose, is plotted against CF_3D pressure. Irradiation wavelength 9797 cm^{-1}; incident fluence (energy density) = 1.04 J cm^{-2}; temperature = 22°C.

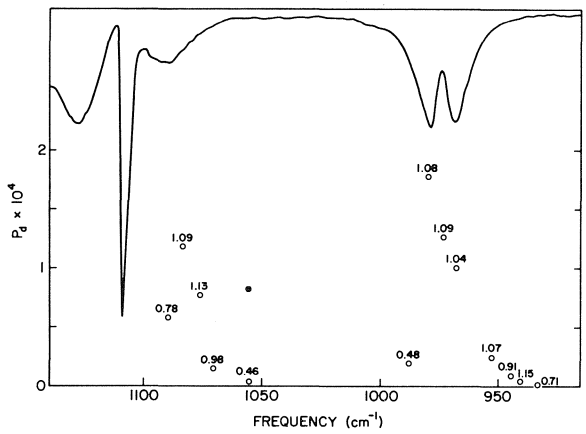

FIG. 2. Excitation frequency dependence of reaction dissociation probability. The parameter above each point refers to the incident fluence in J cm^{-2}. CF_3D pressure = 0.5 Torr, temperature = 22°C. Open circles refer to $^{12}CF_3D$ and the filled ones to $^{13}CF_3D$. The one photon absorption spectrum is shown for reference (solid line).

internal energies greater than 83 kcal mol^{-1} will be reached whereas for the ethane internal energies of 130 kcal mol^{-1} are surpassed in similar radiation fields.

It is obvious from the preceding discussion that fluoroform does not undergo multiphoton decomposition with great facility, indeed it is apparent that collisions are essential. The spectral dependence of the probability of dissociation was investigated at a pressure of 0.5 Torr. The results are shown in Fig. 2 together with the incident fluence used in each irradiation, the threshold fluence convention (14) was not used as the dissociation yield is not pressure independent. This "action spectrum" shows the normal features of multiphoton excitation in focussed beams; that is the multiphoton action spectrum is red shifted from and broader than the one photon absorption spectrum. These are consequences of molecular anharmonicity and the large Rabi frequencies required to overcome that anharmonicity. As noted in the Introduction one expects this problem to be more significant in CF_3D than in CF_3Cl, CF_3Br, and CF_3I, a consequence of the lower density of vibrational states at any particular internal energy. More directly the "quasicontinuum", region II (6), will lie at higher levels for CF_3D than for the halides. The effect of this can be seen from Table 1 which compares dissociation probabilities measured at the centre of the action spectrum for multiphoton decomposition of the four compounds in similar radiation fields. It can be seen that neither the threshold dissociation energies nor the integrated oscillator strengths of the one photon transitions provide sufficient means to correlate the observed dissociation probabilities, without invoking anharmonicity and the quasi continuum relaxation. It is beyond the scope of this work and all current theories of multiphoton absorption to provide an intimate description of the sequential absorption process but the general conclusions of Table 1 provide a useful insight into this area.

(b) Isotopically Selective Excitation and Dissociation

The one photon infrared absorption spectrum of fluoroform has been well studied (4, 17, 18). The bands which fall within the 9–11 μm region where the CO_2 laser has strong output are the $\nu_2(a_1)$ band and the $\nu_5(e)$ band. The former corresponds to a C—F stretch and the latter to a D—C—F bend. In $^{12}CF_3D$ the vibrational frequencies are ν_2 = 1111 cm^{-1}, ν_5 = 975 cm^{-1} (17). The ν_2 band shows well developed PQR structure but restrictions of available laser output allow photolysis only on the tail of the P branch below 1100 cm^{-1}.

In $^{12}CF_3H$ the vibrational frequencies are ν_2 = 1141 cm^{-1} and ν_5 = 1157 cm^{-1} (17), for $^{13}CF_3H$ ν_2 = 1116 cm^{-1} and ν_5 = 1132 cm^{-1} (18). Thus the isotope shift for carbon-13 substitution in CF_3D is expected to be of the order of 35 cm^{-1} for both vibrational bands studied. Fluoroform-*d* may be selectively excited in the ν_5 band at 975 cm^{-1}, 100 cm^{-1} away from any absorption transition in fluoroform-*h*.

Isotopically selective chemistry was verified for carbon-13 by selectively dissociating $^{13}CF_3D$ at

TABLE 1. Multiphoton dissociation of CF_3X species[a]

Compound	Threshold energy[i] (kcal/mol)	Normalised band intensity[b]	Dissociation probability[c] (P_d)
CF_3D	64.8	1.0	1.78×10^{-4}[d]
CF_3D	64.8	Complex band	1.19×10^{-4}[e]
CF_3Cl	81.0	8.4	$>5.1 \times 10^{-4}$[f]
CF_3Br	66.2	8.3	$>2.0 \times 10^{-3}$[g]
CF_3I	49.4	10.5	$>8.8 \times 10^{-2}$[h]

[a]All results are from experimental setup reported in this paper; temperature = 22°C; pressure = 0.5 Torr, irradiation near maximum of "action spectrum".
[b]Integrated band intensity normalised to CF_3D ν_5 band; obtained from infrared absorption spectra measured under standard conditions.
[c]P_d = (number of molecules dissociated)/(number of molecules irradiated).
[d]Irradiation frequency = 979.7 cm^{-1}; incident fluence = 1.08 J cm^{-2}; this work.
[e]1083.5 cm^{-1}; 1.09 J cm^{-2}; this work.
[f]For the three halides the P_d values are lower limits since work in ref. 3 concentrated on ^{13}C decomposition: 1081.1 cm^{-1}; 1.12 J cm^{-2}; ref. 3.
[g]1057.3 cm^{-1}; 1.0 J cm^{-2}; ref. 3.
[h]1053.9 cm^{-1}; 0.68 J cm^{-2}; ref. 3.
[i]Reference 6.

natural abundance in the ν_2 band at 0.46 J cm^{-2} incident fluence of 1055.6 cm^{-1} radiation. The fluoroform-*d* pressure was 0.5 Torr and the cell was at ambient temperature. An α value of 25 was obtained.

The problem of hydrogen isotope selectivity is more complex, however. The hydrogen product is carried as DF which rapidly exchanges with cell walls, therefore only depletion experiments were possible. Such experiments are inherently less sensitive and must be carried to higher conversions. Mixtures of CF_3D and CF_3H in ratios of 32:1 and 1:1 were photolysed in the ν_5 band at 0.5 Torr initial pressure. CF_3D and CF_3H concentrations were monitored from peaks at $m/e = 52$ and 51. However, although CF_3D decreased and C_2F_4 increased with time it was observed that m/e 51 and presumably $[CF_3H]$ increased with time. It was verified that this peak did not arise from other chemical products, e.g., C_2F_6, C_2F_5H, $C_2F_4H_2$, none of which could be detected. Furthermore, the possibility of a contribution of $^{13}CF_2$ from C_2F_4 was discounted by examining m/e peaks at 81, 82, and 83. Hence, we have to conclude that an exchange reaction between CF_3D and HF is induced by the radiation field. The exchange reaction was equally prevalent when the cell walls were held at −90°C and appears to proceed at a rate equal to the rate of C_2F_4 production in our experiments. Quantitative analysis of the peak height time dependence showed that a carbon atom balance was maintained throughout the experiments but offered no positive indication to the nature of the exchange reaction. The problem of selective dissociation of deuterium bearing fluoroform is therefore intractable in the present cell and with the presently available irradiation fluences.

In conclusion, the present study has demonstrated the importance of molecular complexity and vibrational state density in determining the rate and level of multiphoton absorption. CF_3D seems to fit into place with predictions based on studies of other systems. Selective dissociation of carbon-13 at natural abundance has been demonstrated, but the demonstration of selective dissociation of deuterium bearing molecules awaits the control of complicating exchange reactions.

We note that other authors have recently reported the infrared multiple dissociation with application to deuterium enrichment (19). No mention of the complicating side reaction was made. If by suitable cell design the side reaction may be overcome then fluoroform-*d* may become a viable substrate for deuterium enrichment. Furthermore, the side reaction may offer a useful laser based redeuteration pathway.

Pyrolysis of triethylgallium by the toluene carrier technique

MICHELLENE C. PAPUTA AND STANLEY JAMES W. PRICE[1]

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received June 4, 1979

MICHELLENE C. PAPUTA and STANLEY JAMES W. PRICE. Can. J. Chem. **57**, 3178 (1979).

The pyrolysis of triethylgallium has been studied in a toluene carrier gas system in the temperature range of 464.7 to 700.7 K and a pressure range of 0.82 to 3.73 kPa. From the data obtained from this work, the following mechanism for the thermal decomposition of the metal alkyl is proposed:

[1] $Ga(C_2H_5)_3 \rightarrow Ga(C_2H_5)_2 + C_2H_5$

[2] $Ga(C_2H_5)_2 \rightarrow Ga(C_2H_5)H + C_2H_4$

[3] $Ga(C_2H_5)H \rightarrow GaH_2 + C_2H_4$

[4] $nGaH_2 \rightarrow \frac{n}{2}H_2 + (GaH)_n$

[5] $(GaH)_n \rightarrow Ga + \frac{n}{2}H_2$

where [1] is the rate determining step. After runs below 606 K were corrected for the contribution of a concurrent residual reaction, a least-squares analysis of experimental results from 567 to 651 K based on both product and residual alkyl analysis gave

$$\log k_1 = 15.7 - (194\,600/2.303RT)$$

at 1.60 kPa.

The rate constant, k_1, is very slightly pressure-dependent as revealed by tests at 648.0 K (80% and 45% decomposition). Studies indicate there is no detectable surface catalysis effect. Similarly, no effect was observed for changes in concentration or contact time.

The mechanism for the formation of polymeric gallium hydride in reaction [4] is not clearly defined and may consist of more than one step. Reaction [5] is slow but based on the C_2H_4:H_2 ratio must occur to a significant extent (40–80%) during a run. Further decomposition occurs between runs, causing a build-up of H_2 in the reaction vessel.

Experimental data for the hydrogen abstraction by ethyl radicals from toluene

$$C_2H_5^{\cdot} + C_6H_5CH_3 \rightarrow C_2H_6 + C_6H_5CH_2^{\cdot}$$

yield the equation

$$\log k_9 = 11.08 - (40\,200/2.303RT)$$

MICHELLENE C. PAPUTA et STANLEY JAMES W. PRICE. Can. J. Chem. **57**, 3178 (1979).

On a étudié la pyrolyse du triéthyle gallium dans un système utilisant le toluène comme gaz porteur, à des températures allant de 464.7 à 700.7 K et à des pressions variant de 0.82 à 3.73 kPa. A partir des résultats obtenus on propose, pour la décomposition thermique du métal alkylé, le mécanisme suivant:

[1] $Ga(C_2H_5)_3 \rightarrow Ga(C_2H_5)_2 + C_2H_5$

[2] $Ga(C_2H_5)_2 \rightarrow Ga(C_2H_5)H + C_2H_4$

[3] $Ga(C_2H_5)H \rightarrow GaH_2 + C_2H_4$

[4] $nGaH_2 \rightarrow \frac{n}{2}H_2 + (GaH)_n$

[5] $(GaH)_n \rightarrow Ga + \frac{n}{2}H_2$

où [1] est l'étape déterminante. Après avoir corrigé les essais faits en dessous de 606 K pour tenir compte de la contribution d'une réaction résiduelle concourante, une analyse, par la méthode des moindres carrés, des résultats expérimentaux entre 567 et 651 K basés sur les produits de la réaction et sur le métal alkylé résiduel donne l'équation:

$$\log k_1 = 15.7 - (194\,600/2.303RT)$$

à 1.60 kPa.

La constante de vitesse k_1 varie très légèrement avec la pression comme le révèlent les essais

[1]To whom all correspondence should be addressed.

0008-4042/79/243178-04$01.00/0

à 648 K (80% et 45% de décomposition). Les études indiquent qu'il n'y a pas d'effet détectable de la surface du catalyseur. De même, on n'observe pas d'effets dus au changement de concentration ou du temps de contact. Le mécanisme de formation de l'hydrure de gallium polymère dans la réaction [4] n'est pas clairement défini et peut comprendre plus d'une étape. La réaction [5] est lente, mais si on se base sur le rapport $C_2H_4:H_2$, elle peut se produire d'une façon importante (40–80%) au cours d'une réaction. Une décomposition plus poussée se produit entre les essais provoquant un dégagement d'hydrogène dans le vase réactionnel. Les données expérimentales concernant la réaction d'enlèvement d'un hydrogène du toluène par le radical éthyle

$$C_2H_5^{\cdot} + C_6H_5CH_3 \rightarrow C_2H_6 + C_6H_5CH_2^{\cdot}$$

conduisent à l'équation

$$\log k_9 = 11.08 - (40\,200/2.303RT)$$

[Traduit par le journal]

Introduction

The present paper is the fourth in a series in the pyrolysis of ethyl metallic alkyls by the toluene carrier method and is related to previous studies on methyl metallic alkyls. The toluene carrier study of diethylmercury (1) gave $\log A\ (s^{-1}) = 15.4$ and $E = 191.2$ kJ mol^{-1}, in excellent agreement with values proposed by Benson and O'Neal (2). Three previous studies of this compound (3–5) all gave slightly lower $\log A$ and E values but all four studies showed a reasonable degree of agreement when rate constants were compared. The toluene carrier work on diethylzinc (6) showed marked catalysis by zinc oxide. In the absence of zinc oxide $\log A\ (s^{-1}) = 14.3$ and $E = 205.0$ kJ mol^{-1}. These are the only Arrhenius parameters for this compound. Similarly, for tetraethyltin $\log A\ (s^{-1}) = 16.0$ and $E = 248.3$ kJ mol^{-1} (7).

From a mechanistic viewpoint the previous study of trimethylgallium is of considerable importance (8). This study indicated that the A factor of the second step in the decomposition

$$Ga(CH_3)_2 \rightarrow GaCH_3 + CH_3$$

was limited by the time required for the return of $4p$ electron to the $4s$ state. In the case of triethylgallium it was expected that either a similar effect would be observed or that an alternate mode of decomposition would be followed.

Previous studies of $Ga(C_2H_5)_3$ by differential thermal analysis (9) and in a hydrogen carrier system (10) showed first traces of decomposition at approximately 473 K. In the DTA studies ethane and ethylene were produced in roughly equal quantities at 523 K but at 773 K ethylene was the major product. The hydrogen study used the infrared band at 2940 cm^{-1} to monitor the concentration of $Ga(C_2H_5)_3$ as a function of temperature. Bands at 948 cm^{-1} and 2995 cm^{-1} were monitored to follow ethylene and ethane production respectively. The main region of decomposition occurred between 623 K and 723 K. Ethylene was the major product and from the spectra given a very approximate activation energy of 175 kJ mol^{-1} can be estimated.

In conjunction with the development of semiconductor films, two studies of the heat of formation of $Ga(C_2H_5)_3$ have also been carried out (11, 12). These studies gave $\Delta H_{f298}^{0}(Ga(C_2H_5)_3, g) = -60.3$ kJ mol^{-1} and -75.3 kJ mol^{-1}, respectively. This corresponds to a mean Ga—C bond dissociation energy of 217–222 kJ mol^{-1}.

Experimental

Materials

(i) Toluene

The toluene employed was toluene from sulfonic acid, number X325 as supplied by Eastman Organic Chemicals. It was dried by refluxing under vacuum at least 24 h over freshly pressed sodium ribbon and then degassed by bulb-to-bulb distillation.

(ii) Triethylgallium

This was prepared by slowly adding triethylaluminum (25% hexane solution) to freshly prepared gallium tribromide (13). Hexane was distilled off and the fraction boiling at 68–70°C at 8.0 kPa was collected. A 91.2% yield was obtained.

Apparatus and Procedure

The experiments were carried out in a system similar to that used in previous work (14). The reaction vessel had a volume of 160 cm^3. To test for surface effects a vessel was packed with small quartz tubes. This vessel had a volume of 101 cm^3 and a surface-to-volume ratio twenty times that of the unpacked vessel. Both vessels were treated with hot concentrated nitric acid before use. The residual acid was baked out under vacuum after the vessels were installed in the reaction system.

The gaseous products were analyzed using a Perkin-Elmer model 154 gas chromatograph equipped with a 6 mm × 2 m silica gel column. The column was maintained at 80°C, and a helium flow rate of 20 cm^3 per min was used. For hydrogen analysis nitrogen was used in place of helium.

The liquid products were analyzed on a Perkin-Elmer model 900 gas chromatograph equipped with flame ionization detectors. The analyses were done on a 2 mm id × 2 m column packed with 80–100 mesh *n*-octane/porasil C (chemically bonded Durapak). The column and injection port temperatures were 120 and 150°C, respectively. A digital integrator was used and all analyses and standardizations were based on peak areas.

The preparation of gas chromatographic standards and the

method of analysis for butane dissolved in toluene have been previously described (6).

Analysis for residual $Ga(C_2H_5)_3$ was performed by atomic flame emission spectroscopy. An Instrument Laboratory Atomic Absorption/Emission Spectrometer, Model IL 251, was operated in the Flame Emission mode at 417.2 nm and a slit width of 160 μm.

Results and Discussion

Selected experimental results are given in Table 1. They may be discussed in terms of the following mechanism.

[1] $Ga(C_2H_5)_3 \rightarrow Ga(C_2H_5)_2 + C_2H_5$

[2] $Ga(C_2H_5)_2 \rightarrow Ga(C_2H_5)H + C_2H_4$

[3] $Ga(C_2H_5)H \rightarrow GaH_2 + C_2H_4$

[4] $nGaH_2 \rightarrow \frac{n}{2}H_2 + (GaH)_n$

[5] $(GaH)_n \rightarrow Ga + \frac{n}{2}H_2$

[6] $2C_2H_5 \rightarrow C_2H_4 + C_2H_6$

[7] $2C_2H_5 \rightarrow C_4H_{10}$

[8] $C_2H_5 \rightarrow C_2H_4 + H$

[9] $C_2H_5 + C_6H_5CH_3 \rightarrow C_2H_6 + C_6H_5CH_2$

[10] $C_2H_5 + C_6H_5CH_2 \rightarrow C_6H_5CH_2CH_2CH_3$

[11] $H + C_6H_5CH_3 \rightarrow H_2 + C_6H_5CH_2$

[12] $H + C_6H_5CH_3 \rightarrow CH_3 + C_6H_6$

[13] $CH_3 + C_6H_5CH_3 \rightarrow CH_4 + C_6H_5CH_2$

The analytical data given in Table 1 indicate that each time reaction [1] occurs it is rapidly followed by reactions [2] and [3] or some other processes that release the remaining two C_2 groups as ethylene. Reaction [2] rather than reaction [2*a*]

[2*a*] $Ga(C_2H_5)_2 \rightarrow GaC_2H_5 + C_2H_5$

is expected because of the limiting effect of the $4p \rightarrow 4s$ electron pairing that would be concurrent with reaction [2*a*] (8).

Reactions [4] and [5] are suggested overall reactions. Reaction [4] is sufficiently fast that all gallium other than that in undecomposed $Ga(C_2H_5)_3$ is found in the reaction zone.

Taking reactions [2], [3], [4], [6], [7], and [8] the expected $[C_2H_4]/[H_2]$ ratio is about 3.5. The ratio found experimentally, approximately 2.1–3.0, indicates that although reaction [5] does not go to completion during the course of a run, it does occur

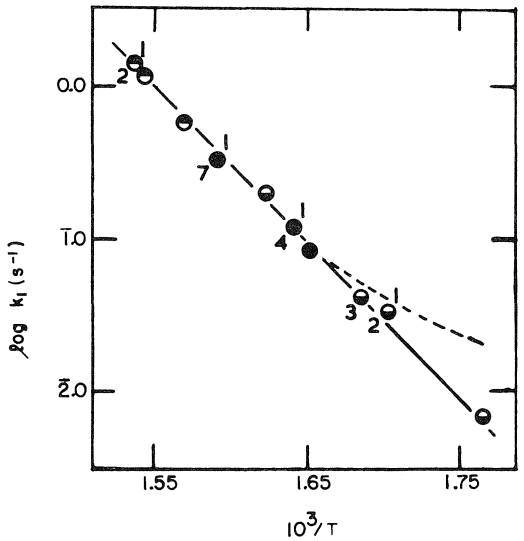

FIG. 1. Arrhenius plot for the decomposition of triethylgallium: ◓, k_m based on analysis for undecomposed $Ga(C_2H_5)_3$; ◒, k_g based on product analysis; ●, k_m and k_g. 610	4.8	0.148
610	1.8	0.148

to a significant extent. The remaining $(GaH)_n$ continues to decompose between runs leading to the observed build-up of H_2 in the reaction vessel.

The values of k_1 used to plot Fig. 1 were calculated from the usual first order equation. The values in Table 2 indicate that the assumption of first order seems valid within the limits of experimental error. Of the 33 values of k_1 used in Fig. 1, 14 are based on atomic emission analysis of residual alkyl, 19 on product analysis, and nine on both methods. No detectable heterogeneous contribution to k_1 was noted and only a very slight dependence on total pressure was observed. Below 606 K the Arrhenius plot showed a distinct curvature. Below 540 K this plot again became linear with an apparent activation energy of about 32 kJ mol^{-1}. The values of k_1 were corrected for this residual reaction before Fig. 1 was constructed.

A weighted linear least-squares analysis of the points in Fig. 1 gives

$$\log k_1\ (s^{-1}) = 15.7 \pm 0.2 - (194\,600 \pm 2\,400/2.303RT) \text{ at } 1.60 \text{ kPa}$$

The errors quoted are twice the standard deviation. The weighting scheme used was related to the expected effect of the accuracy of the analytical procedures on the values of k_1. Points based on residual alkyl analysis were given weightings from 4 to 0 from high decomposition to low decomposition. Points based on product analysis were correspondingly weighed from 0 to 3. The low weighting for values based on product analysis at high decomposition is largely due to the difficulty of recovering the butane dissolved in the toluene for reliable quantitative analysis.

The A factor is very close to that observed for the decomposition of $Ga(CH_3)_3$. Accepting the activation energy as a reasonable measure of $D[(C_2H_5)_2Ga—C_2H_5]$ gives

$$D[C_2H_5Ga—C_2H_5] + D[Ga—C_2H_5] = 465 \pm 15 \text{ kJ mol}^{-1}$$

By analogy with $Ga(CH_3)_3$ then $D[C_2H_5Ga—C_2H_5]$ would be expected to be approximately 160 kJ mol^{-1} and log A_{2a} about 8. At the maximum temperature used in the present work (700 K) this leads to an estimated $\log k_{2a} = -4$ and indicates clearly that reaction [2a] should not be significant in the present study.

It is also possible from the present data to obtain rate constants for the abstraction of hydrogen from toluene by the C_2H_5 radicals released in reaction [1]. The method of calculation has been published previously (6). The Arrhenius equation obtained

$$\log k_9\ (\text{cm}^3\ \text{mol}^{-1}\ \text{s}^{-1}) = 11.08 - (40\,200 \pm 5\,000/2.30RT)$$

is in good agreement with previous results (1, 6, 7).

It is also possible to estimate very approximately the rate of ethyl radical decomposition from the expression

$$d[C_2H_4{}^t - 2(\text{mol } Ga(C_2H_5)_3 \text{ decomposed}) - C_2H_4{}^*]/dt = k_8[C_2H_5]$$

where $C_2H_4{}^t$ = total C_2H_4 and $C_2H_4{}^*$ is the C_2H_4 from disproportionation. The rate constants obtained are somewhat scattered but are in the general range 2–20 s^{-1} and give an activation energy of 134 kJ mol^{-1} at 1.6 kPa in general agreement with previous toluene carrier work (6).

Received May 24, 1979

S. D. PEYERIMHOFF and R. J. BUENKER. Can. J. Chem. **57**, 3182 (1979).

The angular potential energy curves of the X^2B_1, A^2A_1, B^2B_2 valence-shell and $^4\Sigma_g^-$, $^2\Sigma_g^-$ (2^2B_1), $^2\Delta_g$ (2^2A_1, 3^2B_1), and $^2\Sigma_g^+$ Rydberg states arising from $\pi_u{}^2$ $3s$ configurations are calculated by configuration interaction techniques. The data obtained reproduce very satisfactorily all X^2B_1 and A^2A_1 characteristics deduced from experiments; they support the previous theoretical prediction of a small-angle $^2B_2$ state but find a very low $|R_{e'e''}|^2$ value for the $^2B_2$–A^2A_1 transition. The $^4\Sigma_g^-$ as well as three of the above four doublet Rydberg multiplets are found to prefer linear (or nearly linear) geometry and larger NH separations (in the symmetric structure) than NH_2 in its ground state. A relatively large electronic transition moment for combination with both X^2B_1 and A^2A_1 is calculated for the lowest Rydberg multiplet which lies roughly 5.3 eV above the A^2A_1 state, while the intensity of transitions of the higher $3s$ states is found to be considerably smaller. Finally it is pointed out that the former Rydberg transition fits in well with recent emission experiments in this wavelength region recently reported by Herzberg.

S. D. PEYERIMHOFF et R. J. BUENKER. Can. J. Chem. **57**, 3182 (1979).

On a calculé par les techniques d'interaction de configuration les courbes d'énergie potentielle angulaire des électrons de valence X^2B_1, A^2A_1, B^2B_2 et $^4\Sigma_g^-$, $^2\Sigma_g^-$ (2^2B_1), $^2\Delta_g$ (2^2A_1, 3^2B_1) et des états de Rydberg $^2\Sigma_g^+$ provenant des configurations $\pi_u{}^2$ $3s$. Les données recueillies reproduisent de façon très satisfaisante toutes les caractéristiques X^2B_1 et A^2A_1 déduites expérimentalement. Ces données confirment les prédictions théoriques faites antérieurement au sujet du petit angle de l'état $^2B_2$ mais elles fournissent une très faible valeur $|R_{e'e''}|^2$ pour la transition $^2B_2$–A^2A_1. On a trouvé que le $^4\Sigma_g^-$ aussi bien que trois des 4 doublets précédents des multiplets de Rydberg préfèrent une géométrie linéaire (ou presque linéaire) et de plus grandes séparations du NH (dans la structure symétrique) que celles du NH_2 dans l'état fondamental. Pour le plus petit multiplet de Rydberg on a calculé un moment de transition électronique relativement grand pour la combinaison avec X^2B_1 et A^2A_1 qui se situe grossièrement à 5.3 eV au dessus de l'état A^2A_1 alors que l'intensité des transitions des états les plus élevés $3s$ sont considérablement plus petits. Finalement on a montré que la première transition de Rydberg s'accorde avec les récentes expériences d'émission dans cette région de longueur d'onde récemment mentionnée par Herzberg.

[Traduit par le journal]

Introduction

The first two electronic states X^2B_1 and A^2A_1 of NH_2 have been studied quite extensively over a number of years by various experimental and theoretical techniques (1); these states are degenerate ($^2\Pi_u$) in the linear arrangement of nuclei and thus the Renner–Teller interaction produces a number of interesting perturbations in the fine structure of the associated A^2A_1–X^2B_1 spectrum. The equilibrium angles have been determined (1) as 103.3° (X^2B_1) and 144° (A^2A_1), while a third NH_2 valence-shell state B^2B_2 has recently been predicted by *ab initio* SCF and CI studies (2) with an energy minimum occurring at the very small bond angle of 47.5°.

To our knowledge no study has been undertaken thus far in order to identify the Rydberg states of NH_2. The lowest-energy configuration of Rydberg type $\pi_u{}^2 3s$ leads to three doublet states $^2\Sigma_g^-$, $^2\Delta_g$, and $^2\Sigma_g^+$ which all are allowed to combine with the $^2\Pi_u$ (X^2B_1, A^2A_1) states according to the dipole selection rules. If the standard guidelines (3) are applied which place the $3s$ member roughly 29 000 cm^{-1} below its corresponding IP, the lowest vertical Rydberg feature in the NH_2 absorption spectrum is expected to lie quite high (in the 7.5–8 eV region given the fact that the first IP is at 11.4 eV (4)), so that Rydberg states seem to be ruled out as being of importance in the lower-energy part of the NH_2 spectrum. On the other hand, recent *ab initio* CI calculations on the NH_2^+ ion (5) show the lowest states $^3\Sigma_g^-$, $^1\Delta_g$ ($^1B_1$

0008-4042/79/243182-08$01.00/0

component), and $^1\Sigma_g^+$ all to be linear or nearly linear, so that a substantial difference of 0.7 eV is calculated between the first vertical and adiabatic IP, and it is expected that such a difference is carried over to the NH_2 Rydberg states, which are expected to possess potential energy surfaces which run nearly parallel to those of the ionic species. Furthermore if emission from a linear (or nearly linear) Rydberg state to the weakly bent A^2A_1 component of the lower $^2\Pi_u$ species (favored by the Franck–Condon principle) would be a possibility, the Rydberg states might already appear in the NH_2 emission spectrum below 6 eV, and on this basis the features seen between 5 and 6 eV (6) which are indicative of a linear transition, whereby the carrier seems likely to be either NH_2 or NH_2^+, might conceivably involve NH_2 Rydberg transitions.

It is thus the goal of the present work to determine the location as well as the geometrical characteristics of the $\pi_u^2 3s$ Rydberg states of NH_2. At the same time the three known NH_2 valence-shell states will be treated, and intensities for transitions between the various valence-shell and Rydberg species will be calculated in order to aid in the experimental assignment of the NH_2 spectrum in the region above that of the well-known A^2A_1–X^2B_1 band. The theoretical treatment will be quite analogous to that employed in the earlier study (5) of the NH_2^+ system in order to allow for a direct comparison with the results of these calculations as well.

Details of the Calculations

The AO basis set employed in the present work comprises 56 contracted cartesian gaussian functions. It is basically the same as that used in the prior study of NH_2^+ (5) but it has been extended to include one Rydberg-type s ($\alpha = 0.02$) and a set of Rydberg p ($\alpha = 0.02$) functions. Thus it consists of a $(6s,4p,2d)$ set on nitrogen, a $(2s,1p)$ set on each hydrogen, and two s and two p functions in both of the NH bonds; details concerning the values of exponents and contraction coefficients may be found in ref. 5.

The configuration interaction treatment is of the general MRD-CI type (7, 8), with configuration selection and energy extrapolation (8). A core of one orbital corresponding to the $1s$ inner shell is kept doubly occupied in all configurations and one MO representing the inner-shell complement is disregarded entirely in the treatment; all other 54 orbitals in the basis are allowed variable electron occupation according to the MRD-CI procedure. The SCF solutions are obtained for the X^2B_1, A^2A_1, B^2B_2, $^2A_1$, and $^4B_1$ states indicated in Table 1 and these MO's are then employed as the basis for the CI calculations; additional SCF wavefunctions corresponding to $3p$ Rydberg states are also obtained (Table 1) at the X^2B_1 ground state equilibrium geometry. Details of the CI treatment employed, i.e. MO orbital basis, number of reference configurations from which single and double excitations are generated, number of roots according to which selection is carried out, orders of secular equations actually solved (selected configurations) and size of configuration space for which the CI energy has been extrapolated, are collected in Table 2. All configurations which contribute more than 0.25% (on a c^2 basis) are thereby included in the reference set. Finally, an estimate of the full CI energy in the AO basis employed is undertaken (5) according to a generalization of the formula given by Davidson (9) for the contribution of higher than double-excitation configurations. In all cases the sum of the squares of the expansion coefficients for the reference configurations is found to lie between 92% and 96%.

The electronic transition moments $\boldsymbol{R}_{e'e''}$ between two states $\Psi_{e'}$ and $\Psi_{e''}$ are always evaluated in an orthogonal MO basis. Hence in these cases additional CI calculations (listed in the lower part of Table 2) are carried out for the lower-energy species $\Psi_{e''}$ employing the same MO's as are used for the upper state $\Psi_{e'}$; in order to maintain the same accuracy as in the standard treatment this procedure sometimes requires inclusion of additional reference configurations for the lower state in the less suitable MO basis (Table 2).

Results and Discussion

The calculated potential energy curves as a function of the internuclear angle are given in Fig. 1 for the three valence states and the various Rydberg species of NH_2 arising from the $\pi_u^2 3s$ electronic configuration; the NH distance is thereby held fixed at the ground state equilibrium value (10, 11) of $R_0 = 1.935a_0$ (1.024 Å).

The $^2\Pi - X^2B_1$, A^2A_1 *States*

The two lowest states are obtained for 11 different internuclear angles between 180° and 45°. A polynomial fit to these data points gives an angle of 103.0° and 141.4° for the X^2B_1 and A^2A_1 minima respectively, in excellent agreement with the experimentally derived values of 103.3° (11, 12) and 144 ± 5° (13). The SCF and MRD-CI energies are −55.58063 and −55.77367 hartrees, respectively, at the experimental ground state equilibrium (103.3°, 1.024 Å), while the corresponding estimate for the full CI limit in the present AO basis lies at −55.78432 hartree. These values are similar to those obtained by Bell and Schaefer (2) in an earlier SCF and CI treat-

[a]Numbering refers to SCF calculation of Table 1.
[b]The notation mM/nR refers to m main (or reference) configurations and an n-root selection process.

ment employing a double-ζ basis with one d polarization function; they obtain -55.573448 hartree for the SCF solution (103.3°, 1.024 Å) and -55.734014 hartree for their CI value, i.e. an energy lowering of 0.16057 hartree (compared to the 0.19304 hartree value in the present work) as a result of using a smaller number of configurations (991) and a somewhat smaller AO set than in the present work.

A variational treatment (14) for the vibrational part of the Schrödinger equation (based on 30 Hermite polynomials and the angular CI potential) yields a zero-point (bending) energy for the X^2B_1 ground state of 773 cm^{-1} corresponding to $\bar{\nu}_0 = 1546$ cm^{-1}, i.e. roughly 50 cm^{-1} higher than the spectroscopic value of 1497.3 cm^{-1} (1, 11, 15) obtained for this quantity. This discrepancy seems to remain (16) even if the CI treatment is upgraded (to correlate all electrons and not only the valence shells) or if the AO basis set is extended even further (to include f functions) with a reduction ensuing only when the effects of bond length variation with bending are taken into account (16). An even larger change has been found in N_2H_2, for example (17), in comparing results from a direct coupling of all three symmetric vibrational modes ν_1(NH), $\nu_2(\theta)$, and ν_3(NN) with those of the corresponding uncoupled one-dimensional treatments. The calculated zero-point bending energy for the A^2A_1 state (again on the basis of the angular CI potential at fixed $R = 1.024$ Å) is 451 cm^{-1}, but this value cannot be compared directly (16) to the experimental frequency $\bar{\nu}_0$ which is based on an extrapolation to $v = 0$ from higher vibrational quantum numbers.

The calculated ΔE_e value between the two states is 12 148 cm^{-1} (at fixed $R = 1.024$ Å), but this is lowered by approximately 1100 cm^{-1} if the proper distance of $1.855a_0$ for the upper state is employed (see Fig. 2); usage of the calculated zero-point frequencies places the present T_0 value (under the assumption of equal frequencies for the two NH stretching modes) just slightly below the corresponding experimental result of 11 140 cm^{-1} (1). Since, however, the main emphasis in the present work is not placed on obtaining a potential energy surface as accurate as possible for the two $^2\Pi$ components no further geometry optimizations are undertaken. This topic will be taken up in another study employing an even larger AO basis and a more extensive CI treatment in order to obtain an accurate *ab initio* description of the vibrational–rotational structure of the

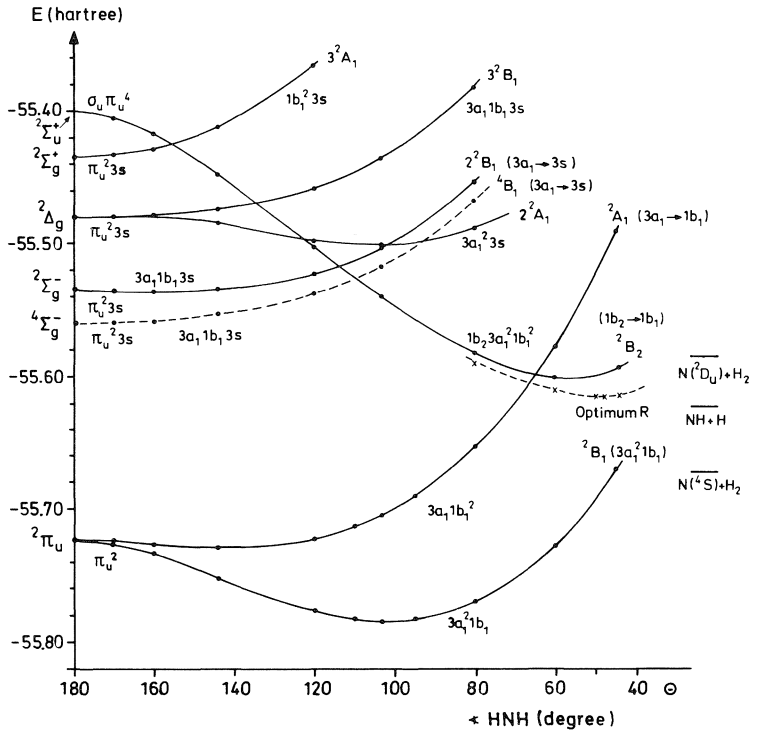

FIG. 1. Calculated CI angular potential energy curves for NH_2 in ground and various excited states (R = 1.024 Å); plotted are the estimates for the full CI energy in the AO basis employed. The corresponding energies for the separated fragments N + H_2 and NH + H are also indicated, whereby the value for $N(^4S)$ + H_2 is calculated while the two other levels are determined from experimental data. The dotted line below the solid $^2B_2$ curve refers to the structure at optimum NH distance.

X^2B_1–A^2A_1 band (16). The calculated $^2A_1$ barrier to linearity is considerably larger (1178 cm^{-1} at the estimated full CI level, R = 1.024 Å) than the value of 777 ± 100 cm^{-1} deduced by Dixon (13) or the more recent value of 730 cm^{-1} calculated by Jungen *et al.* (18) to fit the experimental spectrum; in accordance with the work of Bell and Schaefer (2) it is found that correlation energy effects are quite important for the barrier description since the corresponding SCF barrier is found to be as high as 1442 cm^{-1}. Finally the present calculations confirm the experimental finding that only a single vibrational bending level is found below the barrier maximum.

In summary then the present calculations are seen to represent the geometrical characteristics of the two lowest NH_2 states as well as their relative energy spacing to high accuracy; from this information it is concluded that the other NH_2 states, not yet characterized spectroscopically, should be predicted at approximately the same level of reliability, since the theoretical treatment employed for these species is fully equivalent to that of the X^2B_1 and A^2A_1 states.

The $^2B_2$ *State*

The $^2B_2$ state of NH_2 has been predicted (2) to possess a very small bond angle of 47.5° and the present calculations (Fig. 1) support this finding. In order to ascertain whether the small-angle structure is a real minimum the energy has been obtained for a number of C_{2v} grid points (θ and NH distances) as shown in Fig. 3. It is seen that although there is a strong interdependence between bond angle and bond distance (for smaller distances the larger-angle structure is preferred and for a structure of 180° (Fig. 2) the optimal bond separation is only $2.035a_0$ according to the SCF treatment), the calculations do find a genuine minimum for the symmetric NH_2 structure, just as has been predicted in the previous theoretical work (2). The optimum structure according to the present calculations is θ = 50° and NH = $2.135a_0$ (MRD–CI energy of −55.60267 hartree), although it should be noted that the energy at the neighboring points θ = 50°, NH = $2.195a_0$ and θ = 47.5°, NH = $2.195a_0$ is only higher by 0.0002 hartree and 0.00014 hartree at the MRD-CI level;[1] the optimized structure of ref. 2 is θ = 47.5° and NH = $2.196a_0$. The present energy minimum is

[1]The optimization yields the lowest energy (−55.615230 hartree) at θ = 50° and NH = $2.195a_0$ if the full CI estimate is taken, whereby the increase in energy to θ = 47.5° at the same bond length is 0.00002 hartree while that to NH = $2.135a_0$ for θ = 50° is 0.00018 hartree.

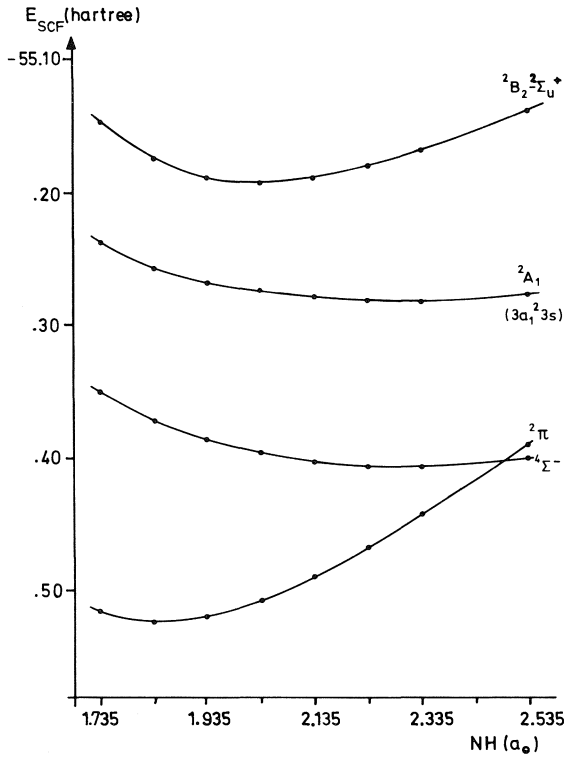

FIG. 2. Calculated SCF energies as a function of the NH distance (assuming C_{2v} symmetry) for various states at $\theta = 180°$.

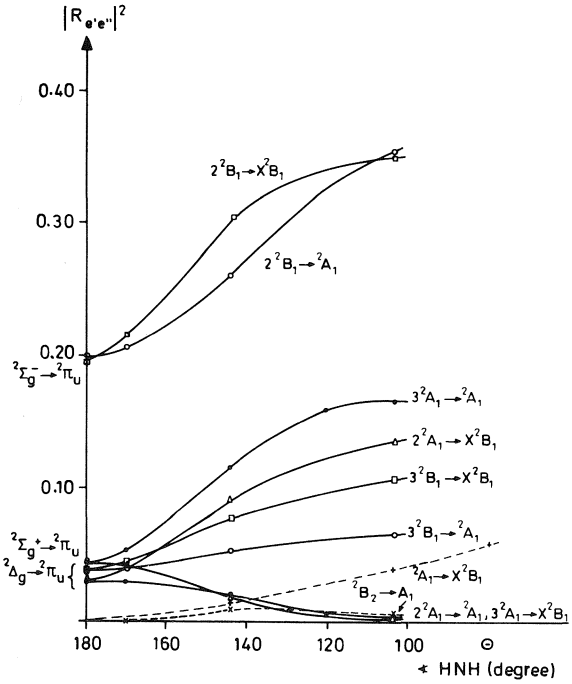

FIG. 3. Calculated CI potential energy curves (full CI estimate) for the $^2B_2$ state showing the relatively large coupling of the geometrical variables ∠HNH and NH distance.

found to lie 4.60 eV (full CI level, or 4.66 eV in the MRD-CI treatment) above that of the X^2B_1 ground state equilibrium structure, in close agreement with the 4.79 eV value predicted earlier for this quantity (2).

In order to have a comparison between the stability of this small-angle structure and the separated species N + H_2 additional CI calculations are carried out for the system (N—H_2) separated at $10a_0$, whereby the equilibrium H_2 bond length of $1.4a_0$ is employed to best represent the N(^4S) + $H_2(^1\Sigma_g^+)$ products. The energy obtained is −55.66536 hartree (MRD-CI) or −55.67200 hartree (full CI estimate), which result lies 39.3 kcal (or 35.6 kcal) *below* that of the $^2B_2$ state. Similarly the energy for the system NH + H is also somewhat below that of the $^2B_2$ minimum based on the difference in binding energies (H_2 = 4.747 eV and NH = 3.40 eV) of 31 kcal/mol between H_2 and NH. A direct fragmentation of $^2B_2$ into N(^4S) + $H_2(^1\Sigma_g^+)$ is not possible, however, so that the lowest C_{2v} products would be N(^2D_u) + $H_2(^1\Sigma_g^+)$, whereby N(^2D_u) is known to lie 2.38 eV (55 kcal) above the lowest ^4S nitrogen state. If all this information is taken together the depth of the minimum in the C_{2v} structure should be in the order of 15–20 kcal, while the NH + H dissociation limit should be approximately 5–10 kcal below the present calculated C_{2v} minimum. According to the present calculations it also seems clear that perturbation in the A^2A_1 state because of the presence of the B^2B_2 state will occur only for very high vibrational energy levels since the calculated adiabatic crossing of states occurs 3.3 eV above the energy of the A^2A_1 minimum.

The $\pi_u{}^2 3s$ Rydberg States

Excitation from the ground state $\pi_u{}^3$ configuration to the first member of the Rydberg *s* series gives rise to one quartet $^4\Sigma_g^-$ ($^4B_1$) and three states $^2\Sigma_g^-$ ($^2B_1$), $^2\Delta_g$ ($^2A_1$, $^1B_1$), and $^2\Sigma_g^+$ ($^2A_1$) of doublet multiplicity. A proper SCF treatment has not been carried through for each of these states (Table 1), however, but rather MO's of the quartet state are employed exclusively in the ensuing MRD-CI calculations for all such Rydberg species (Table 2).

The geometrical characteristics of the various Rydberg states (Fig. 1) are wholly parallel to those of their ionic counterparts investigated earlier (5), for which internuclear angles of 150° ($^3B_1$–$^3\Sigma_g^-$), 107.6° and 155.2° ($^1A_1$, $^1B_1$–$^1\Delta_g$), and 180° ($^1\Sigma_g^+$–$^1A_1$) have been obtained from analogous MRD-CI calculations. Thus the present study finds that three of the four possible Rydberg 3*s* members prefer the linear (or almost linear) geometry (Fig. 1 and Table 3) while only the 2^2A_1 component of the $^2\Delta_g$ state is most stable in a decidedly bent nuclear arrangement.

TABLE 3. Energies (in eV) of the various states contained in Fig. 1 at $\theta = 180°$, $\theta = 103.3°$, and their respective optimum angle ($R = 1.024$ Å throughout)

State	Energy		
	$\theta = 180°$	$\theta = 103.3°$	θ = opt.
$^2\Pi_u \begin{cases} X^2B_1 \\ A^2A_1 \end{cases}$	1.652	0.0[a]	0.0[a] (103.3°)
		2.161	1.506 (141.4°)
$^4\Sigma_g^- - ^4B_1$	6.108	7.241	6.108 (180°)
$^2\Sigma_g^- - 2^2B_1$	6.800	7.633	6.764 (154°)
$^2\Delta_g \begin{cases} 2^2A_1 \\ 3^2B_1 \end{cases}$	8.272	7.690	8.272 (180°)
		9.456	7.68 (≈100°)
$^2\Sigma_g^+ - 3^2A_1$	9.512	12.57	9.512 (180°)
$^2\Sigma_u^+ - B^2B_2$	10.42	6.639	4.93 (55°)
			4.60 (50°, $R = 2.135a_0$)

[a]All energies are given relative to X^2B_1. The MRD-CI energy of this state is −55.77367 hartree, while the energy estimate corresponding to a full CI treatment in the present AO basis is −55.78432 hartree.

In a similar manner the relative splitting between the various components of the $\pi_u{}^2 3s$ configuration is nearly identical to that found for the NH_2^+ ion, for which splittings between $^3\Sigma_g^-$ and the two other components $^1\Delta_g$ and $^1\Sigma_g^+$ of 2.03 eV and 3.45 eV respectively (at $\theta = 180°$ and NH = 1.027 Å) have been calculated (5). On the other hand the preferred bond lengths seem to be larger in the Rydberg states (Fig. 2) than in the ion (approximately $1.934a_0$ (5)), an observation which is consistent with a general tendency for the Rydberg species to dissociate into the lower-energy fragments NH + H (Fig. 1). A further study of this effect might also be of interest in connection with the photodecomposition of NH_3, which process yields (in addition to NH_2 in its X^2B_1 and A^2A_1 states) NH species in various electronic states at relatively high incident energies, whereby it is not yet clear whether such products occur from primary or secondary reaction steps (19, 20).

The lowest members of the Rydberg p series are forbidden to combine directly with the $^2\Pi_u$ ground state (at least in linear symmetry, which should be preferred by most of these states as well as by the corresponding $3s$ members) and have thus not been treated directly in the present work. A few SCF calculations have been carried out ($\theta = 144°$), however, and these place the $^4\Pi_u$ and $^4\Sigma_u^-$ states 1.85 eV and 1.48 eV respectively above the corresponding $^4\Sigma_u^-$ $3s$ species of otherwise identical electronic configuration (Table 1). Splittings of this magnitude are seen to be quite in line with standard Rydberg $3s$–$3p$ energy separations (3).

Calculated Intensities

The square of the electronic transition moments involving the various states treated so far are collected in Fig. 4 as a function of the internuclear angle; transitions to both components of the $^2\Pi_u$ state are considered thereby.

The A^2A_1–X^2B_1 transition is not allowed in the linear arrangement of nuclei but the corresponding $|R_{e'e''}|^2$ value climbs fairly rapidly with bending to a calculated value of 0.039 at 103°, and increases still further for smaller internuclear angles. Apparently the only experimental information which is available for comparison comes from the measurement of Halpern *et al.* (21), who obtain a radiative life-time of 10 μs for the Σ (0, 9, 0) level of the A^2A_1 state. Under the simple assumption that the life-time can be obtained from

$$\tau_{1/e} = 1.5/\bar{\nu}^2 f_e q_{v'v''}$$

(whereby the present calculations give $f_e = 0.00196$),[2] a value for τ of 5.4 μs results if the Franck–Condon factor $q_{v'v''}$ is taken to be 0.5 for this vibrational transition of peak intensity in the band. The latter assumption is not unreasonable, so that the correlation between the theoretical and experimental data seems to be quite adequate. In order to obtain a more direct comparison vibrational wavefunctions χ_v would need to be generated and the integral $|\langle\chi_{v'}|R_{e'e''}(\theta)|\chi_{v''}\rangle|^2$ would have to be evaluated directly rather than simply employing the Franck–Condon approximation.

The $^2\Sigma_u^+$–$^2\Pi_u$ transition is also forbidden in $D_{\infty h}$ symmetry and only the $^2B_2$–$^2A_1$ component becomes dipole-allowed in the bent nuclear arrangement. In contrast to the $^2A_1$–$^2B_1$ electronic transition moment, however, this quantity remains rather small (0.006 at 103°) for the $^2B_2$–$^2A_1$ transition (Fig. 4) so that the unfavorable Franck–Condon region together with the smallness of the $|R_{e'e''}|^2$ value leads one to expect the $^2B_2$–$^2A_1$ bands to be of very low intensity. Asymmetric vibrations will remove the forbidden-

[2]The oscillator strengths are obtained as $f_e = (2/3)|R_{e'e''}|^2 \Delta E$, whereby ΔE is in atomic units; ΔE is 2.161 eV (Table 3) in the calculations, i.e. a value which is quite close to the measured results of 16725 cm^{-1} = 2.0735 eV (21).

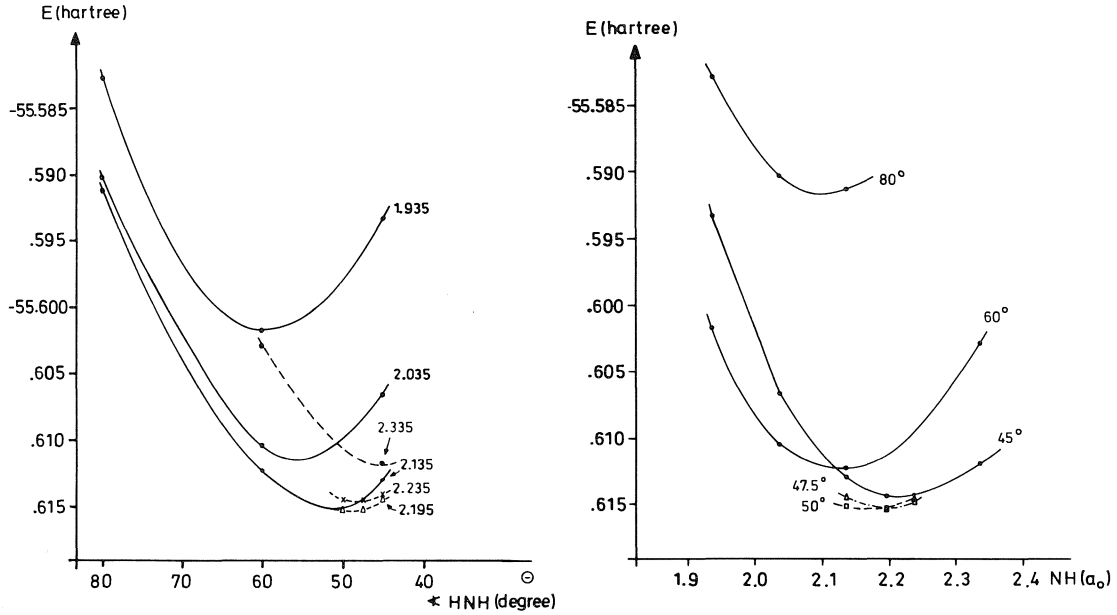

FIG. 4. Calculated transition moments $|R_{e'e''}|^2$ (in au^2) between various electronic states of NH_2 (R = 1.024 Å).

ness to the lower X^2B_1, but even then strong transitions would not appear likely. All these facts taken together then suggest that the $^2B_2$ state will not be easily accessible for direct spectroscopic investigation.

By contrast transitions from the first allowed Rydberg state $^2\Sigma_g^-$–$^2B_1$ to both $^2\Pi_u$ components are calculated to be relatively strong (Fig. 4). For example, a value of $f_e = 0.034$ is deduced for the 2^2B_1–A^2A_1 transition ($|R_{e'e''}|^2 = 0.26$, $\Delta E = 5.29$ eV, $\theta = 144°$), whereby the greatest portion of this intensity should appear in the favored Franck–Condon region, i.e. at linear or near-linear geometries corresponding to a transition energy of roughly 5.30 eV. The pattern in the vibrational structure for the corresponding transition favoring the small-angle $^2B_1$ ground state region might be somewhat complicated by the fact that in this range of internuclear angle ($\sim$103°) and energy the influence of the 2^2A_1 species should also be important (Fig. 1). Intensities of transitions from the Rydberg 3s states to the two $^2\Pi_u$ components are of intermediate strength between that of the well-characterized A^2A_1–X^2B_1 system and what is predicted in the present calculations for the first Rydberg band. Finally additional overlapping features might appear in the corresponding energy range because of the presence of the lower multiplets of the 4s (and some 4p) members not treated in the present work.

Summary and Conclusion

The present study has attempted to describe the NH_2 molecule in a variety of its low-lying electronic states while maintaining C_{2v} symmetry. Very good agreement has been found between the calculated data and the measured characteristics of the first two (X^2B_1 and A^2A_1) states, including details regarding geometrical structure, relative energetics, and transition intensity. A third valence state (B^2B_2), which has been predicted by earlier theoretical work (2), has been confirmed to be a very small-angle species, but computed electronic transition moments indicate very low intensity for a $^2B_2$–$^2A_1$ combination (with the corresponding $^2B_2$–$^2B_1$ species being dipole-forbidden). The calculations thus suggest a relatively long life-time for this species once it is formed, provided radiationless conversion (via an asymmetric vibration) to the $^2A_1$ state is not a much more favored route of deexcitation in this case.

The geometrical behavior of the various multiplets of the 3s Rydberg members parallels very closely that of the respective ionic states, as is to be expected. The calculations predict appreciable (an order of magnitude larger than that of the A^2A_1–X^2B_1 band) intensity for transitions between the first doublet state $^2\Sigma_g^-$–2^2B_1 of this nature and each of the A^2A_1 and X^2B_1 lower states. In particular they indicate that a rather strong $^2\Sigma_g^-$ (2^2B_1)–A^2A_1 band will be found in the 5.0–5.3 eV spectral region, provided appreciable population of one of the states involved is possible, thereby providing a possible assignment for a band system recently observed by Herzberg (6) which has been thought to have either NH_2 or its positive ion as its carrier. The vertical transition

between the X^2B_1 ground state and the first Rydberg member is found to occur around 7.6 eV and it is concluded that observation of such a band system in this energy region might well be hindered because of the presence of overlapping bands involving other $3s$ multiplets and/or those of the lowest $4s$ Rydberg species. Finally preliminary calculations find rather large NH separations in the above Rydberg states, which finding is thought to be an indication for the occurrence of dissociation processes involving fragments such as NH + H which are energetically more stable than is NH_2 in any state lying above its first two ($^2A_1$ and X^2B_1) valence-shell species.

Acknowledgments

The authors wish to thank Professor G. Herzberg for valuable discussions in initiating this work. The services and computer time made available by the University of Bonn Computer Center (RHRZ) have been essential to the present study and are gratefully acknowledged.

Solvent extraction of monothioacetylacetone chelates of zinc(II) and nickel(II)[1]

MARZIO LEBAN, DAVID JEFFRIES, AND JAMES FRESCO
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received July 12, 1979

MARZIO LEBAN, DAVID JEFFRIES, and JAMES FRESCO. Can. J. Chem. **57**, 3190 (1979).

The formation constants of nickel(II) and zinc(II) monothioacetylacetonates have been determined as 2.95×10^{12} and 6.46×10^{10} respectively. These are about 700 times more stable than the corresponding acetylacetonates. Both monothioacetylacetonates were more than 99% extracted into chloroform and ligand hydrolysis was not significant before completion of metal ion extraction.

MARZIO LEBAN, DAVID JEFFRIES et JAMES FRESCO. Can. J. Chem. **57**, 3190 (1979).

On a déterminé les constantes de formation des monothioacétylacétonates de Ni(II) et de Zn(II); leurs valeurs sont de 2.95×10^{12} et 6.46×10^{10} respectivement. Ces composés sont environ 700 fois plus stables que les acétylacétonates correspondants. L'extraction des deux monothioacétylacétonates dans le chloroforme était complète à plus de 99% l'hydrolyse de la ligande n'etait pas significative avant la fin de l'extraction de l'ion métallique.

Introduction

In contrast to results obtained in earlier studies of monothiobenzoylacetone and monothiodibenzoylmethane (1, 2, 3), more recent studies (4, 5) of β-mercaptocinnamamides and monothiodibenzoylmethane have shown the stability of zinc chelates is greater than nickel chelates. This is in accord with the observation (6) that ligands with both oxygen and sulphur basic centres show a reversal of the Irving–Williams order with respect to these two metals.

Data to be presented for monothioacetylacetone show the zinc chelate is less stable than the nickel chelate. Conformity to the Irving–Williams order has been assigned previously to exceptional structural differences between the zinc and nickel chelates of certain sulphur-containing ligands (7).

Disregard of the instability of monothio-β-diketone solutions was suggested (8) as a probable source of error in early measurements. Leban's investigation (9) of the kinetics of decomposition of aqueous solutions of monothioacetylacetone and related compounds was verified subsequently for mixed aqueous solutions (10). Results reported here have been corrected on the basis of these studies.

Experimental

Materials

2-Mercapto-pent-2-en-4-one (**1**) was prepared by a base-catalysed reaction of acetylacetone with hydrogen sulfide (11). The sodium salt (**2**) was then prepared by reacting **1** with alcoholic sodium followed by addition of anhydrous ether to precipitate **2**. The crystals were purified by recrystallization. *Anal.* calcd. for C_5H_7OSNa: C 43.47, H 5.11, S 23.20, equiv. wt. 137.9; found: C 42.28, H 5.10, S 23.31, equiv. wt. 138.2.

1,1,1-Trifluoro-4-mercapto-pent-3-en-2-one (**3**) was prepared according to the procedure described by Ho, Livingstone, and Lockyer (12). Prior to isolation of **3** the reaction mixture was allowed to reach room temperature and the sodium salt (**4**) prepared by reaction with alcoholic sodium and precipitation by addition of petroleum ether. The salt purified by recrystallization from anhydrous ether solution by addition of petroleum ether.

Zinc-65 and nickel-63 were obtained from Amersham-Searle as the dichlorides in dilute HCl solution and were diluted prior to use. The concentration of the zinc-65 stock solution was $< 3 \times 10^{-5}$ *M* (below the detection limit by EDTA titration). The concentration of the nickel-63 stock solution was determined gravimetrically with dimethylglyoxime, to be $3.28\ (\pm 0.02) \times 10^{-2}$ *M*. Radiochemical purity was checked by γ-ray spectroscopy and decay measurements. All other chemicals used were of reagent grade.

Extraction of Monothio-β-diketones

Stock solutions of the monothio-β-diketones were basic in sodium hydroxide. Aliquots of 5 mL stock solution were transferred to separatory funnels containing 25 mL chloroform and 20 mL of buffer solution at ionic strength 0.1 *M*. For **1**, extractions were carried out over the pH range 2 to 9 and for **3** extractions were performed over the pH range 0.6 to 8. To minimize the effect of decomposition of the ligands in the most acidic aqueous phases the time of attainment of extraction equilibrium was crucial. For **1** and **3** it was less than 2 min and 30 s respectively Aliquots of equilibrated aqueous phases were immediately made basic by addition of 5 mL 2 *M* NaOH.

The concentration of monothio-β-diketone in the aqueous phase was recorded using a Beckman DB spectrophotometer. In the case of **3** it was necessary to correct for decomposition in the samples at pH < 4. This was accomplished by measuring the elapsed time from addition of the stock solution of **4** to the separatory funnel to the addition of the 5 mL of 2 *M* NaOH after sampling the equilibrated aqueous phase. This time, together with the first order rate constant reported previously (9), was the basis for decomposition corrections.

Extraction of Metal Chelates

All solutions were thermostatted at 25.0°C. Aliquots of the metal stock solutions were added to buffer solutions previously delivered to separatory funnels. Ionic strength of the aqueous phase was kept constant at 0.1 *M*. Ligand was intro-

[1]Taken in part from the M.Sc. thesis of Marzio Leban, McGill University, Montreal, P.Q. 1970.

0008-4042/79/243190-03$01.00/0

duced just prior to extraction and achievement of equilibrium was verified by parallel experiments.

Values for metal distribution ratios were determined by comparison of the counting rates of aqueous phase aliquots with that of a standard. The zinc-65 activity was measured using a Nuclear Supplies EA-14 gamma well scintillation counter coupled with a Nuclear Supplies SA-250 scaler. For nickel-63 counting a Nuclear-Chicago Type 79180 1.4 mg/cm^2 mica end window Geiger tube connected to a Nuclear-Chicago Type 8770 scaler was used.

The pH values of the equilibrated aqueous phases were measured with a Metrohm pH meter calibrated with Fisher standard buffers at pH 4.00 and 7.00.

Results and Discussion

Ligand Partition Coefficients and Acid Dissociation Constants

The pH dependence of monothioacetylacetone extraction was consistent with the extraction of a weak acid. The data were fitted to a line drawn according to the formula $\log D = \log K_{D_R} - \text{pH} - \log([H^+] + K_a)$. Here D, K_{D_R}, and K_a represent the distribution ratio, partition coefficient, and dissociation constant, respectively. The value of $\log K_{D_R} = 2.52 \pm 0.03$ was obtained by averaging the values of $\log D$ at low pH values. The value of $pK_a = 6.47 \pm 0.06$ was determined from a least squares analysis of the data in the high pH region.

The solvent extraction behaviour of trifluoromonothioacetylacetone was similar to that of the previous species. The values of $\log K_{D_R}$ and pK_a were determined as 2.29 ± 0.01 and 5.04 ± 0.05 respectively. Since fluoromethylacetylacetones are strongly hydrated (13), a lower value of K_{D_R} for **3** with respect to **1** could be expected. Both **1** and **3** have K_{D_R} values one order of magnitude larger than that of acetylacetone ($\log K_{D_R} = 1.37$) (14). This effect may possibly be associated with the replacement of oxygen by sulfur and a resultant decrease in hydrogen bonding sites.

The pK_a value obtained for **1** in this study is in agreement with a value, $pK_a = 6.40 \pm 0.02$, found by potentiometric titration of **2** with HCl.[2] The lower value of pK_a for **1** relative to that of acetylacetone, $pK_a = 8.8$ (14), would be in accord with the sulfur–oxygen electronegativity difference. Thiols are usually stronger acids than the corresponding alcohols and phenols. The increased acidity of **3** as compared to **1** is consistent with the electron withdrawing effect of the —CF_3 group.

Metal Chelate Stability Constants and Partition Coefficients

The extraction of nickel(II) and zinc(II) into chloroform as a function of monothioacetylacetonate concentration showed an initial rapid rise followed by approach to a constant value. The relationship between the distribution ratio of a divalent metal chelate and aqueous free ligand concentration, $[A^-]$, can be shown to be

$$[1]\quad \frac{1}{D} = \frac{1}{K_{D_C}} + \frac{1}{K_{D_C}K_2}\left(\frac{1}{[A^-]}\right) + \frac{1}{K_{D_C}K_1K_2}\left(\frac{1}{[A^-]}\right)^2$$

where K_{D_C}, K_1, and K_2 are the chelate partition coefficient and first and second step-wise formation constants, respectively.

The free ligand concentration is obtained from the initial concentrations of ligand, $[A^-]_i$ and metal ion, $[M]_i$ according to

$$[2]\quad [A^-] = ([A^-]_i - 2[M]_i)K_a/\{[H^+](K_{D_R} + 1) + K_a\}$$

For the case of Zn(II) where $[M]_i \ll [A^-]_i$ eq. [2] may be simplified to

$$[3]\quad [A^-] = [A^-]_iK_a/\{[H^+](K_{D_R} + 1) + K_a\}$$

The calculated value for the free ligand concentration was then substituted in eq. [1] for each extraction and the resulting data matrix solved for the coefficients $1/K_{D_C}$, $1/K_{D_C}K_2$ and $1/K_{D_C}K_1K_2$ using a computer programme which evaluated the coefficients by von Holdt's Matrix Method for Least Squares (15). These values for nickel were $1/K_{D_C} = (9.03 \pm 0.61) \times 10^{-4}$, $1/K_{D_C}K_2 = (1.23 \pm 0.35) \times 10^{-9}$, and $1/K_{D_C}K_1K_2 = (3.08 \pm 0.98) \times 10^{-16}$. For zinc the values were $1/K_{D_C} = (8.82 \pm 0.87) \times 10^{-3}$ and $1/K_{D_C}K_1K_2 = (1.37 \pm 0.05) \times 10^{-13}$. The chelate partition coefficients and stability constants obtained from these appear in Table 1. Successive stability constants could not be resolved from the zinc results.

The stability constants for nickel and zinc acetylacetonates determined under comparable solution conditions (16) are smaller by 2.81 and 2.89 log units respectively than the corresponding monothioacetylacetonates. The greater stability of nickel

TABLE 1. Stability constants and partition coefficients for monothioacetylacetonate chelates of Ni(II) and Zn(II) at 25°C

Metal	$\log K_1$	$\log K_2$	$\log \beta_2$	$\log K_{D_C}$
Ni	$6.60^{+0.19}_{-0.20}$	$5.86^{+0.24}_{-0.27}$	$12.47^{+0.17}_{-0.12}$	$3.04^{+0.03}_{-0.02}$
Zn			$10.81^{+0.01}_{-0.02}$	$2.05^{+0.05}_{-0.04}$

[2]O. Siimann. Unpublished results. McGill University.

monothioacetylacetonate is supported by comparing the shorter nickel–oxygen bond distances of this chelate (17) with those reported for nickel acetylacetonate (18, 19).

Data obtained for the extraction of the zinc chelate of **3** show the stability of the chelate is less than that of the corresponding zinc monothioacetylacetonate. In the presence of pyridine the extraction of the zinc chelate of **3** is enhanced and the formation of a 1:1 pyridine adduct was demonstrated from the extraction data.

The difference between K_{D_C} values for the nickel and zinc monothioacetylacetonates suggests that adduct formation with monothioacetylacetone could have occurred more favorably with the nickel chelate. Also in Table 1 it may be noted that the nickel chelate is 40 times more stable than the zinc chelate and is in conformity with the Irving–Williams order.

In marked contrast with the slow attainment of extraction equilibrium and final incomplete extraction of nickel acetylacetonate (20) the corresponding monothioacetylacetonate extraction achieved equilibrium within 2 min and was virtually quantitative in the region of pH independence.

Sulfides as precursors for sulfonyl chloride synthesis

RICHARD FRANCIS LANGLER,[1] ZOPITO ALESSIO MARINI, AND EDWARD SOMMERS SPALDING

Chemistry Department, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received April 16, 1979

RICHARD FRANCIS LANGLER, ZOPITO ALESSIO MARINI, and EDWARD SOMMERS SPALDING. Can. J. Chem. **57**, 3193 (1979).

Sulfides are advanced as sulfonyl chloride precursors. S_N2 cleavage of the intermediate sulfonium ions is discussed in conjunction with both the sulfohaloform pathway and our previous hypothesis that asymmetric chlorosulfonium chloride salts undergo Pummerer rearrangements which exhibit regioselectivity that can be anticipated on the basis of substituent electronegativity difference (ΔX_p). Thioglycolic acid is developed as a new sulfur transfer agent for sulfonyl chloride synthesis.

RICHARD FRANCIS LANGLER, ZOPITO ALESSIO MARINI et EDWARD SOMMERS SPALDING. Can. J. Chem. **57**, 3193 (1979).

On propose les sulfures comme précurseurs des chlorures de sulfonyles. On discute du clivage des ions sulfoniums intermédiaires selon un mécanisme S_N2 conjointement avec le cheminement du sulfohaloforme et de notre hypothèse antérieure. Cette dernière stipule que les chlorhydrates de chlorosulfonium asymétriques subissent des transpositions de Pummerer qui montrent une régiosélectivité et qui peuvent être prévus à partir de la différence d'électronégativité des substituants (ΔX_p). On a mis en évidence l'acide thioglycolique comme un nouvel agent de transfert de soufre dans la synthèse du chlorure de sulfonyle.

[Traduit par le journal]

Introduction

Our previous studies of the chlorinolysis of sulfur compounds (1–8) have been directed toward the development of new synthetic methods for the preparation of sulfonyl chlorides (2, 4, 5). Sulfonyl chlorides can furnish a variety of functionalities (9–17) and may be prepared with well established methods (2, 9, 18, 19). A widely employed approach involves the aqueous chlorinolysis of sulfur-containing substrates viz. sulfenyl chlorides (20, 21), mercaptans, disulfides, thiolesters, Bunte salts (22), isothioureas (23), thiocyanates (24), sulfinyl chlorides (25), thiolsulfonates (26), and sulfinic acids (2, 27). We have been developing the aqueous chlorinolysis of sulfides as an approach to the preparation of sulfonyl chlorides (4, 5, 7).

An excellent review of methods for the preparation of sulfides has recently become available (28). The most general approach to sulfide synthesis involves nucleophilic substitution by mercaptide anions on carbon bearing a suitable leaving group. This reaction has been extended to include simple aromatic substrates with a leaving group attached directly to a phenyl ring (29). A simple general scheme for sulfonyl chloride synthesis is shown in eq. [1].

$$[1]\quad R'SH + X{-}R'' \xrightarrow{\bar{\bar{B}}} R'SR'' \xrightarrow[HOAc]{Cl_2/H_2O} R''SO_2Cl$$

[1]Enquiries should be directed to Dr. R. F. Langler, Chemistry Department, Mount Allison University, Sackville, N.B., Canada E0A 3C0.

The conversion of sulfides into sulfonyl chlorides requires a cleavage step in the chlorinolysis reaction. These reactions proceed, in general, by chlorosulfonium cation intermediacy so that cleavage[2] may occur in either S_N1 or S_N2 fashion as shown in Scheme 1. We have previously reported the application of benzylic sulfides to the synthesis of sulfonyl chlorides (5). We believe that the cleavage step in these reactions involves an S_N1 mechanism.

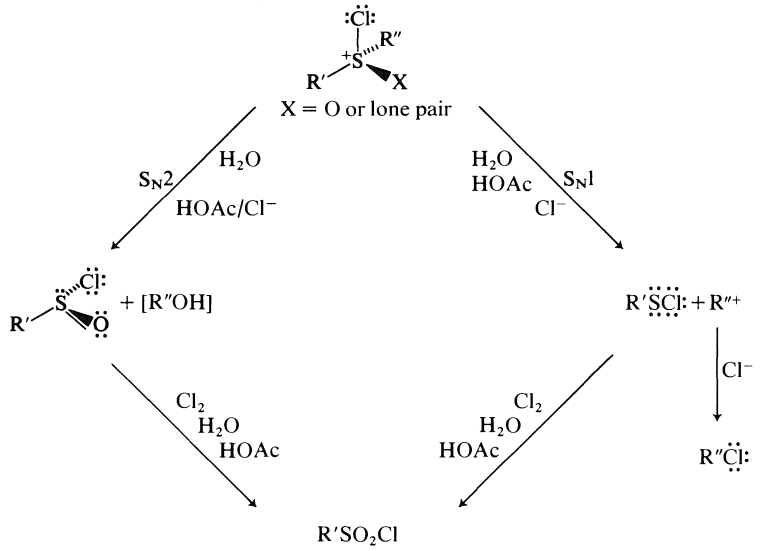
Extensions of the approach which utilizes sulfides in which one substituent attached to sulfur will form a carbocation during chlorinolysis are readily envisioned. In particular, in cases where the desired sulfonyl chloride requires a carbon substituent which would itself form a stable carbocation, one would choose a sulfide in which the group to be lost would give rise to a carbocation of superior stability to that expected for the group to be retained. Unfortunately, extensions of this approach have very little utility since sulfonyl chlorides in which the carbon substituent can form a particularly stable carbocation are themselves unstable[3] and cannot be prepared (12, 15, 30); e.g., aqueous chlorinolysis of 1-naphthylmethyl mercaptan affords 1-chloromethyl naphthalene and not the expected sulfonyl chloride (15).

The detailed pathway by which alkyl sulfides are

[2]Evidence that these reactions are ionic and not free radical has been presented previously (4).

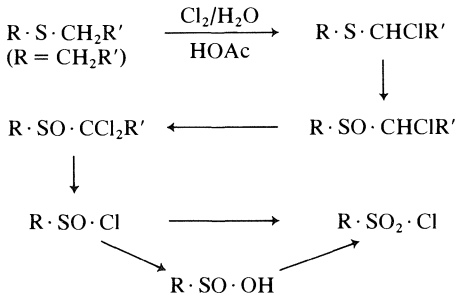
[3]We have suggested that the mode of decomposition is a unimolecular ionic process (15) whereas Kice has suggested a radical mechanism (12) or a cyclic transition state formed by attack of chlorine on the α carbon as it leaves from sulfur.

0008-4042/79/243193-07$01.00/0



SCHEME 1

transformed into sulfonyl chlorides without the intermediacy of carbocations in the cleavage step (the sulfohaloform reaction) has been reported recently (4). (See Scheme 2.)



SCHEME 2. The sulfohaloform reaction

The cleavage step in the sulfohaloform reaction appears to proceed by an S_N2 mechanism (4). Several recognized complications may arise which interfere with the cleavage step: (*i*) steric crowding may preclude the existence of the desired product,[4] (*ii*) steric crowding in the intermediate α-polychloro-oxochlorosulfonium chloride can shift preferred nucleophilic attack by H_2O (4) to chloride ions with a consequent reduction in overall reaction rate and some concomitant shift in the electrophilic site attacked (1*a*), and (*iii*) carbocation formation prior to formation of the requisite α-polychlorosulfoxide intermediate can give rise to a sulfonyl chloride in which the carbon α to the sulfonyl group bears chlorine atoms (6).

Application of the sulfohaloform pathway to the analysis of asymmetric sulfide chlorinations requires that one be able to predict which of the first formed α-chlorosulfides will predominate. The substituent which incorporates the first chlorine atom is the one which will be ultimately cleaved. We have previously (1*a*) reported that asymmetric sulfide chlorinations in aprotic media introduce chlorine more readily on the α-carbon bearing the more electronegative substituent. If this postulate holds in protic media, the major sulfonyl chloride formed will be the one which retains the sulfide substituent having the α-carbon atom with the less electronegative group(s). Mercaptans could then be assessed as sulfur transfer agents for sulfonyl chloride synthesis by choosing R′ (in eq. [1]) so that $X_p(R') > X_p(R'')$.

Results and Discussion

In order to test these proposals, a simple series of sulfides was subjected to exhaustive chlorination in aqueous acetic acid. The appropriate substituent electronegativities are shown in Table 1. Results of the chlorinations with appropriate ΔX_p values are presented in Table 2. These results are consistent with the outcomes expected on the basis of ΔX_p and sulfohaloform reaction arguments as presented above.

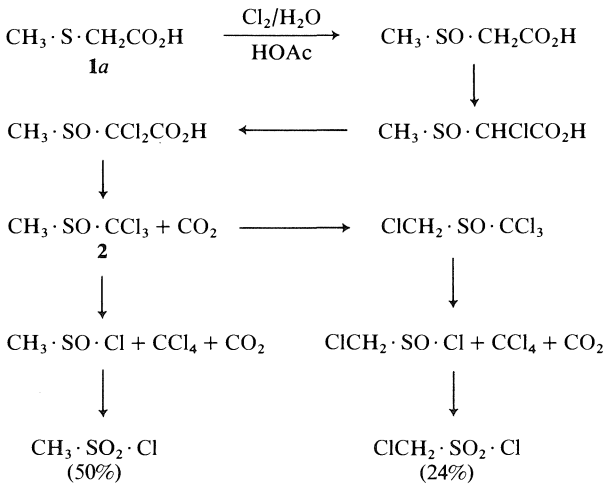
Inspection of the substituent electronegativities tabulated by Huheey (32, 33) led to the conclusion that thioglycolic acid would be an excellent sulfur transfer agent for sulfonyl chloride synthesis as depicted in eq. [1]. We have prepared a series of sulfides from a variety of halides and thioglycolic acid as shown in eq. [2].

$$[2]\quad R{-}X + HSCH_2CO_2H \xrightarrow[CH_3ONa]{CH_3OH} RSCH_2CO_2H \quad \mathbf{1}$$

The first problem is that of delineating the pathway by which the sulfide acids **1** are transformed into sulfonyl chlorides upon exhaustive chlorination in aqueous acetic acid. The pathway study was carried out on the sulfide acid **1***a* (R = CH_3).

Chlorinolysis of **1***a* in aqueous acetic acid for a short time furnished 1,1,1-trichloro-2-thiapropane-2-oxide (**2**) in 75% yield. Since we have previously established (4) that 1,1-dichloro-2-thiapropane-2-oxide reacts[5] under these conditions to furnish methanesulfonyl chloride in 60% yield without proceeding through the trichlorosulfoxide, it follows that the dichlorodimethyl sulfoxide is not the principal intermediate giving rise to **2**. Furthermore, we have shown (1*a*, 4) that sulfides with strongly electron-withdrawing groups on a carbon α to the sulfur atom furnish chlorosulfonium chloride salts which hydrolyze to furnish the corresponding sulfoxides rather than Pummerer rearranging to the corresponding α-chlorosulfides. Therefore the sulfide acid **1***a* must react as shown in Scheme 3. Details for the mechanisms have been given previously (1*a*, 3, 4).

The pathway elaborated for the transformation of the sulfide acid **1***a* into a sulfonyl chloride mixture presents a problem. Namely, there is no Pummerer rearrangement of a chlorosulfonium chloride salt anywhere in the pathway. Since the first step very likely produces a sulfoxide, all Pummerer rearrangements are occurring from oxochlorosulfonium chloride salts. In order that substituent electronegativity be a useful basis for evaluating mercaptans as sulfur transfer agents vis-à-vis sulfonyl chloride synthesis, sulfoxide chlorinations must also exhibit regioselectivity which correlates with substituent electronegativity difference (ΔX_p). Table 3 presents the asymmetric sulfoxide chlorinations which are presently known. The data in Table 3 suggest that ΔX_p may very well continue as a useful basis for



SCHEME 3

[5]The dichlorosulfoxide is converted to the trichlorosulfoxide in 16% yield under these conditions (4).

TABLE 3. Regioisomeric chlorosulfoxides from sulfoxide chlorinations

*Yields are reported for sulfonyl chlorides after purification by distillation or recrystallization.

assessing mercaptans as sulfur transfer agents whether chlorinolyses of the sulfide intermediates follow the sulfohaloform pathway or the closely related pathway shown in Scheme 3.

We have chlorinated a series of sulfide acids **1** which furnished the expected sulfonyl chlorides in good yields as shown in Table 4. The sulfonyl chlorides **3***a* and **3***b* were prepared as examples of more interesting substrates which can be accessed with this new method. The complete route for the preparation of their precursors **7***a* and **7***b* appears in Scheme 4.

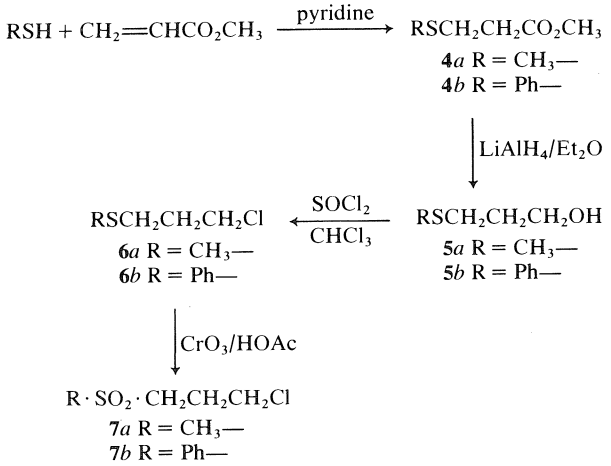
All of the substrates examined for the development of both the present method and our previously published method (5) for the synthesis of sulfonyl chlorides have substituents attached to sulfur via primary carbon atoms. Consequently we have examined a secondary system in order to compare the two methods. The results are shown in eqs. [3] and [4].

$$[3]\quad \underset{\mathbf{1}b}{(CH_3)_2CHSCH_2CO_2H} \xrightarrow[HOAc]{Cl_2/H_2O} \underset{46\%}{(CH_3)_2CHOAc} + \underset{54\%}{(CH_3)_2CHSO_2Cl} + \underset{46\%}{Cl_2CHSO_2Cl}$$

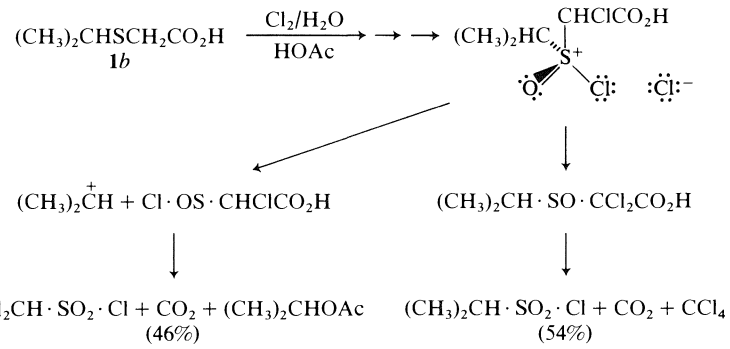
$$[4]\quad (CH_3)_2CHSCH_2Ph \xrightarrow[HOAc]{Cl_2/H_2O} (CH_3)_2CHSO_2Cl + PhCH_2Cl$$

The results shown in eq. [3] indicate that chlorinolyses of the sulfide acids **1** are subject to complication by S_N1 dissociation prior to formation of the α-polychlorosulfoxide intermediates necessary to obtain S_N2 cleavage. However, as shown in eq. [4], benzylic sulfides are not susceptible to such a complication since S_N1 cleavage of the benzyl group occurs very early in the reaction pathway (5). The pathway for the chlorinolysis of **1***b* appears in Scheme 5.

We have now successfully developed two sulfur transfer agents for sulfonyl chloride synthesis i.e. phenylmethanethiol (5) and thioglycolic acid. While yields are generally higher and reaction times shorter for chlorinolyses of benzylic sulfides, there is a drawback in their application to the synthesis of smaller sulfonyl chlorides. When benzylic sulfides are exhaustively chlorinated in aqueous media the



SCHEME 4



SCHEME 5

sulfonyl chloride product is contaminated with approximately one equivalent of benzyl chloride and a small amount of benzyl acetate (5). When the desired sulfonyl chloride has a volatility comparable to that of benzyl chloride, purification is tedious and time consuming. In contrast, the chlorinolysis of sulfide acids **1** produces the desired sulfonyl chlorides carbon dioxide and carbon tetrachloride and the sulfonyl chlorides are therefore isolated in good purity directly from the reaction mixtures. Thus thioglycolic acid is a superior sulfur transfer agent for the preparation of small sulfonyl chlorides where the carbon bearing the chlorosulfonyl group in the product will not be a suitable carbocationic centre. Phenylmethanethiol is a superior transfer agent for the preparation of crystalline or non-volatile sulfonyl chlorides or systems in which the carbon bearing the chlorosulfonyl group can bear positive charge with some facility.

In conclusion, we have developed thioglycolic acid as a new sulfur transfer reagent for sulfonyl chloride synthesis. Sulfonyl chloride synthesis requires substrate analysis in terms of (*i*) stability of carbocations which could be formed by S_N1 dissociation of intermediate chlorosulfonium and oxochlorosulfonium cations, (*ii*) ΔX_p for asymmetric sulfides for which neither carbon attached to sulfur is a potential carbocationic centre, and (*iii*) steric factors which may complicate the cleavage of α-polychloro-oxochlorosulfonium chloride intermediates.

Experimental

General

The ir spectra were recorded on a Perkin-Elmer 237B spectrophotometer. The nmr spectra were obtained on a Varian T-60 instrument using TMS as the internal standard. The mass spectra were recorded on a Dupont-CEC model 21-104 mass spectrometer. The samples were directly introduced using an all glass probe and the spectra run at 30 eV with a source temperature of 150°C. Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected.

Exhaustive Chlorinations In Aqueous Medium

The sulfide substrate was dissolved in glacial acetic acid (25 mL) and water (3 mL). Chlorine (ca. 200 mL/min) was bubbled into the reaction mixture for 2.5 h with ice/water cooling as necessary to maintain the temperature of the reaction mixture between 20 and 30°C. Water (50 mL) was added and the resultant mixture washed with methylene chloride (100 mL). The organic layer was washed with 2.5% w/v NaOH (two 50 mL aliquots), dried ($MgSO_4$), filtered, and the solvent evaporated. The residue was distilled or recrystallized before yield was determined.

Preparation of $PhCH_2CH_2SCH_3$

Sodium metal (0.851 g) was dissolved in absolute ethanol (100 mL). Methanethiol (5 mL) was slowly distilled into the cooled ethoxide solution. 2-Phenyl-1-chloroethane (5.021 g) in ethanol (10 mL) was added dropwise over 15 min and the reaction mixture stirred at ambient temperature for 48 h. Water (100 mL) was added and the resultant mixture washed with chloroform (three 100 mL aliquots). The combined organic layers were dried and concentrated. The crude concentrate was rectified at reduced pressure affording the sulfide (4.572 g, bp 96°C/5 Torr), nmr ($CDCl_3$) δ: 7.70 (5H, s), 3.00 (4H, m), and 2.10 (3H, s); ms *m/e*: 152 ($M^{\ddagger}$, 28%), 91 (53%), and 61 (100%).

Preparation of $CH_3SCH_2CH_2C(=O)OCH_3$ **4**a

Sodium metal (4.210 g) was dissolved in methanol (200 mL) and the solution cooled. Methanethiol (10 mL) was distilled into the reaction mixture and methyl acrylate (15.691 g) added. The reaction mixture was refluxed 1 h. Water (250 mL) was added and the resultant mixture washed with chloroform (four 200 mL aliquots). The combined organic layers were dried and concentrated. The residue was distilled at reduced pressure yielding the sulfide ester (8.586 g, bp 106–108°C/100 Torr), ir ($CHCl_3$): 1740 cm^{-1}; nmr ($CDCl_3$) δ: 3.76 (3H, s), 2.73 (4H, m), and 2.13 (3H, s); ms *m/e*: 134 ($M^{\ddagger}$, 64%), 74 (98%), and 61 (100%).

Chlorination of Asymmetric Sulfides

A series of asymmetric sulfides were subjected to aqueous chlorinolysis as described under "Exhaustive Chlorinations". The relative yields were determined by integration of the nmr spectrum of the crude product. Results are shown in Table 2.

Preparation of $CH_3SCH_2CH_2CH_2OH$ **5**a

Lithium aluminum hydride (1.701 g) was covered with THF (15 mL) and the mixture refluxed for 0.5 h. The mixture was cooled to room temperature and a solution of CH_3S-

$(CH_2)_2CO_2CH_3$ (6.000 g) in THF (10 mL) added dropwise over 10 min. The reaction mixture was refluxed for 0.5 h. Upon completion of the reflux ethyl acetate (2.5 mL) was added dropwise; 10% HCl (30 mL) was added dropwise, the layers separated, and the organic layer dried and concentrated. The residue was fractionated at reduced pressure furnishing the sulfide alcohol (4.238 g, bp 136°C/100 Torr), ir ($CHCl_3$): 3620 and 3450 cm^{-1}; nmr ($CDCl_3$) δ: 3.76 (2H, t), 2.60 (2H, t), 2.33 (1H, s), 2.13 (3H, s), and 1.90 (2H, m); ms *m/e*: 106 (M^+, 100%), 88 (67%), and 73 (40%).

Preparation of $PhS(CH_2)_3Cl$ ***6***b *and $CH_3S(CH_2)_3Cl$* ***6***a

$CH_3S(CH_2)_3OH$ or $PhS(CH_2)_3OH$ (15) (10 g) was dissolved in chloroform (40 mL) and the solution brought to gentle reflux. Thionyl chloride (1 equiv.) in chloroform (20 mL) was added dropwise to the reaction mixture over 10 min. Upon completion of the addition the reaction mixture was refluxed.

After 4.5 h reflux the solvent was removed and the residue distilled affording $PhS(CH_2)_3Cl$ (4.876 g, bp 130°C/2.2 Torr), nmr ($CDCl_3$) δ: 7.20 (5H, s), 3.60 (2H, t), 3.03 (2H, t), and 2.00 (2H, m); ms *m/e*: 188 (19%), 186 (M^+, 57%), 123 (100%), and 110 (82%).

After 24 h reflux the solvent was removed and the residue rectified yielding $CH_3S(CH_2)_3Cl$ (8.309 g, bp 114–116°C/100 Torr), nmr ($CDCl_3$) δ: 3.70 (2H, t), 2.70 (2H, t), 2.13 (5H, m); ms *m/e*: 126 (4.4%), 124 (M^+, 13.3%), 88 (42%), and 61 (100%).

Preparation of $PhSO_2(CH_2)_3Cl$ ***7***b *and $CH_3SO_2(CH_2)_3Cl$* ***7***a

Chromium trioxide (2.5 equiv.) was covered with glacial acetic acid (140 mL) and a solution of the appropriate chlorosulfide (5.00 g) in glacial acetic acid (10 mL) added. The reaction mixture was *vigorously stirred* and the temperature maintained at 90–100°C for 0.5 h. Water (150 mL) was added and the resultant mixture washed with methylene chloride (four 100 mL aliquots). The combined organic layers were washed with 5% NaOH (100 mL aliquots) until the aqueous layer remained basic. The organic layer was dried, concentrated, and the residue distilled.

$CH_3SO_2(CH_2)_3Cl$ (3.816 g, bp 168–170°C/4 Torr) had ir ($CHCl_3$): 1325 and 1145 cm^{-1}; nmr ($CDCl_3$) δ: 3.80 (2H, t), 3.26 (2H, t), 3.00 (3H, s), and 2.20 (2H, m); ms *m/e*: 158 (3.1%), 156 (M^+, 9.3%), 94 (60%), and 41 (100%).

$PhSO_2(CH_2)_3Cl$ (3.139 g, bp 180–182°C/1.9 Torr) had ir ($CHCl_3$): 1325 and 1150 cm^{-1}; nmr ($CDCl_3$) δ: 7.80 (5H, m), 3.60 (2H, t), 3.30 (2H, t), and 2.20 (2H, m); ms *m/e*: 220 (2.7%), 218 (M^+, 8.1%), 77 (100%), and 41 (57%).

Preparation of Sulfide Acids ***1***

The preparations of the sulfide acids were all carried out in the same manner as illustrated for the preparation of the methyl system **1***a*. The crude samples were checked to confirm that the expected product had formed. Sodium metal (0.407 g) was dissolved in methanol (25 mL) and thioglycolic acid (0.807 g) added. A solution of methyl iodide (1.216 g) in methanol (10 mL) was added dropwise and the reaction mixture stirred at ambient temperature for 24 h. The solvent was evaporated and the residue *thoroughly dried*. Water (5 mL) was added, followed by concentrated HCl (1 mL). Chloroform (250 mL) was added, the solution dried ($MgSO_4$), filtered, and concentrated affording crude sulfide acid.

Preparation of $CH_3CH_2SCH_2CO_2CH_3$

Crude sulfide acid was prepared from ethyl bromide (4.264 g), thioglycolic acid (3.614 g), and sodium metal (1.866 g) in methanol (60 mL) as described for the sulfide acids **1**.

The crude acid was covered with methanol (5 mL) and concentrated HCl (6 mL). The reaction mixture was stirred at ambient temperature for 5 min. Chloroform (250 mL) was added and the mixture dried ($MgSO_4$), filtered, and concentrated. The residue was rectified at reduced pressure affording the sulfide acid methyl ester (1.820 g, bp 106–108°C/100 Torr); ir ($CHCl_3$): 1730 cm^{-1}; nmr ($CDCl_3$) δ: 3.73 (3H, s), 3.23 (2H, s), 2.66 (2H, q), and 1.26 (3H, t); ms *m/e*: 134 (M^+, 38.0%), 75 (100%), and 74 (60%). *Anal.* calcd. for $C_5H_{10}O_2S$: C 44.75, H 7.51; found: C 44.25, H 7.73.

$CH_3SCH_2CO_2H$ **1***a* had ir ($CHCl_3$): 3000 and 1720 cm^{-1}; nmr ($CDCl_3$) δ: 11.53 (1H, s), 3.23 (2H, s), and 2.26 (3H, s); ms *m/e*: 106 (M^+, 44%) and 61 (100%).

$CH_3CH_2SCH_2CO_2H$ had ir ($CHCl_3$): 3000 and 1720 cm^{-1}; nmr ($CDCl_3$) δ: 11.50 (1H, s), 3.26 (2H, s), 2.70 (2H, q), and 1.26 (3H, t).

$CH_3(CH_2)_2SCH_2CO_2H$ had ir ($CHCl_3$): 2990 and 1720 cm^{-1}; nmr ($CDCl_3$) δ: 11.09 (1H, s), 3.26 (2H, s), 2.66 (2H, t), 1.73 (2H, m), and 1.00 (3H, t); ms *m/e*: 134 (M^+, 50%), 75 (100%), and 47 (86%).

$CH_3(CH_2)_3SCH_2CO_2H$ had ir ($CHCl_3$): 3000 and 1720 cm^{-1}; nmr ($CDCl_3$) δ: 11.10 (1H, s), 3.50 (2H, s), 2.70 (2H, t), 1.60 (4H, m), and 1.00 (3H, t); ms *m/e*: 148 (M^+, 51%), 89 (78%), 61 (51%), and 47 (100%).

$CH_3(CH_2)_4SCH_2CO_2H$ had ir ($CHCl_3$): 3000 and 1720 cm^{-1}; nmr ($CDCl_3$) δ: 11.23 (1H, s), 3.23 (2H, s), 2.66 (2H, t), 1.40 (6H, m), and 0.90 (3H, t); ms *m/e*: 162 (M^+, 37%), 103 (80%), and 69 (100%).

$CH_3(CH_2)_5SCH_2CO_2H$ had ir ($CHCl_3$): 3000 and 1720 cm^{-1}; nmr ($CDCl_3$) δ: 11.37 (1H, s), 3.23 (2H, s), 2.66 (2H, t), 1.40 (8H, m), and 0.90 (3H, t); ms *m/e*: 176 (M^+, 34%), 117 (100%), and 83 (64%).

$CH_3SO_2(CH_2)_3SCH_2CO_2H$ had ir ($CHCl_3$): 3000 and 1720 cm^{-1}; nmr ($CDCl_3$) δ: 11.30 (1H, s), 3.30 (2H, s), 2.96 (7H, m), and 2.16 (2H, m); ms *m/e*: 195 (27%), 121 (27%), and 73 (100%).

$PhSO_2(CH_2)_3SCH_2CO_2H$ had ir ($CHCl_3$): 3000 and 1720 cm^{-1}; nmr ($CDCl_3$) δ: 11.45 (1H, s), 7.90 (5H, m), 3.26 (4H, m), 2.83 (2H, t), and 2.13 (2H, m); ms *m/e*: 256 (50%), 143 (82%), and 77 (100%).

$(CH_3)_2CHSCH_2CO_2H$ **1***b* had ir ($CHCl_3$): 3000 and 1720 cm^{-1}; nmr ($CDCl_3$) δ: 11.25 (1H, s), 3.33 (3H, m), and 1.30 (6H, d); ms *m/e*: 134 (M^+, 55%), 92 (42%), and 75 (100%).

Chlorinolysis of ***1***a

Crude sulfide acid **1***a* (0.93 g) was chlorinated for 10 min employing the procedure outlined under "Exhaustive Chlorinations". Trichloromethyl methyl sulfoxide (1.212 g) was obtained. After purification by column chromatography employing silica gel and chloroform elution, the product was shown to be identical to authentic material by nmr, ir, and tlc.

Chlorination of Sulfide Acids

The desired alkyl sulfide acid (5 g) was chlorinated as described under "Exhaustive Chlorinations" and the alkane sulfonyl chloride products distilled. In each case the product had the known ir, nmr, and bp. Overall yields for conversion of the alkyl halides into the corresponding sulfonyl chlorides are given in Table 4.

$CH_3SO_2(CH_2)_3SO_2Cl$ **3***a* was recrystallized from chloroform and had mp 62–65°C; ir ($CDCl_3$): 1380, 1310, 1170, and 1145 cm^{-1}; nmr ($CDCl_3$) δ: 3.96 (2H, t), 3.26 (2H, t), 2.96 (3H, s), and 2.56 (2H, t); ms *m/e*: 143 (6.8%), 141 (20.4%), 79 (13.3%), and 41 (100%). *Anal.* calcd. for $C_4H_9ClO_4S_2$: C 21.76, H 4.11; found: C 21.35, H 4.18.

$PhSO_2(CH_2)_3SO_2Cl$ **3***b* was recrystallized from chloroform and shown to be identical to previously prepared material (15) by ir, nmr, mp, and mixture mp.

Chlorination of $(CH_3)_2CHSCH_2CO_2H$ ***1***b

The sulfide acid (4.71 g) was subjected to the procedure outlined under "Exhaustive Chlorinations". The crude product contained 2-acetoxypropane (1.499 g), 2-propanesulfonyl chloride (2.284 g), and dichloromethanesulfonyl chloride (2.509 g) as determined by a method described previously (4). The identity of the constituents in the mixture was confirmed by the addition of authentic samples of each compound which resulted in the change of the intensities of the appropriate signals in the nmr spectrum of the mixture.

Chlorination of $(CH_3)_2CHSCH_2Ph$

The benzylic sulfide (5.84 g) was subjected to the procedure outlined under "Exhaustive Chlorinations". The crude product contained 2-propanesulfonyl chloride (4.281 g). The identity of the sulfonyl chloride and benzyl chloride were confirmed by the addition of authentic samples to the crude which resulted in the change in intensities of the appropriate signals in the nmr spectrum of the mixture. No isopropyl acetate was present in the crude.

Acknowledgements

The authors are indebted to Mr. T. P. Ahern for some technical assistance and to Dr. J. H. Kim for running the mass spectra. We are grateful to Dalhousie University for financial support in the form of a grant from the Research Development Fund.

Carbon-13 nuclear magnetic resonance spectroscopy of caerulomycin A (**1**) produced by cultures of *Streptomyces caeruleus* has shown that [1-^{13}C]acetate labels C-2, C-4, and C-4′, whilst [1,2-^{13}C]acetate enriches these carbons plus C-2′, C-3, C-3′, C-5′, and C-6′. The results establish that acetate is incorporated with little dilution at C-3 and C-4 in the substituted ring of **1**, whereas C-2, and C-2′ to C-6′ of the unsubstituted ring, are assembled from lysine via the symmetrical intermediate 2*S*,6*S*-diaminopimelic acid. The methoxyl carbon incorporates label from DL-[3-^{13}C]serine, but this precursor does not enrich C-5, C-6, or C-7 of the substituted ring, and the origins of these carbons remain undetermined.

A. GAVIN MCINNES, DONALD G. SMITH, JOHN A. WALTER, LEO C. VINING et JEFFREY L. C. WRIGHT. Can. J. Chem. **57**, 3200 (1979).

La résonance magnétique nucléaire du ^{13}C de la caerulomycine A (**1**) produit par les cultures de la *Streptomyces caeruleus* a montré que l'acétate [^{13}C-1] marque les carbones en positions 2,4 et 4′ tandis que l'acétate [^{13}C-1,2] enrichi ces même carbones avec en plus ceux en positions 2′, 3, 3′, 5′ et 6′. Ces résultats indiquent que l'acétate est incorporé avec très peu de dilution en positions C-3 et C-4 du cycle substitué de **1** tandis que les carbones C-2 et C-2′ à C-6′ du cycle non substitué proviennent de la lysine via un intermédiaire symétrique l'acide diaminopimélique 2*S*,6*S*. Le carbone du métoxy est marqué à partir de la DL[^{13}C-3] serine, mais ce précurseur n'enrichit par les carbones 5, 6 ou 7 du cycle substitué dont l'origine rest indéterminé.

[Traduit par le journal]

Introduction

Streptomyces caeruleus produces a unique group of metabolites containing the 2,2′-dipyridyl ring system (1–4). Caerulomycin A (**1**), the first of these compounds to be isolated (1), is an antibiotic and is the main component of the mixture produced under the usual conditions of culture. We have investigated its biosynthesis by measuring the incorporation of isotope from potential ^{13}C- and ^{14}C-labeled precursors.

Experimental

Culture

Streptomyces caeruleus Baldacci HLX 877 was supplied by Dr. P. V. Divekar, Hoechst Pharmaceuticals Ltd., Bombay. Slants prepared from it showed variations in morphology, and successive subculture on agar medium led to a marked decrease in caerulomycin production. Single-colony isolates of the parent strain varied in pigmentation, sporulation, and ability to produce caerulomycin; a non-pigmented sporulating isolate, strain 4/2, was selected for this work. Stock cultures were lyophilized and stored at −20°C; slant cultures were maintained on modified Czapek agar with the following composition (g/L): soluble starch (20), nutrient agar (20), $NaNO_3$ (2.0), $CaCO_3$ (2.0), K_2HPO_4 (1.0), yeast extract (1.0), $MgSO_4 \cdot 7H_2O$ (0.5), KCl (0.5). The pH was adjusted to 8.9 with NaOH before autoclaving. This medium, without nutrient agar, was also used to prepare a vegetative inoculum for cultures producing caerulomycin. The inoculum was grown in two stages. In the first, spores and surface growth from a slant were dispersed in 10 mL of medium and transferred to an additional 40 mL of medium in a 250-mL Erlenmeyer flask. The culture was incubated for 10–12 days at 26°C on a rotary shaker (220 rpm, 3.8 cm eccentricity), then blended, and 4 mL was used to inoculate a second flask containing 50 mL of inoculum medium. The secondary inoculum culture was incubated as before for 4 days.

Cultures for producing caerulomycin A were grown in 250-mL Erlenmeyer flasks containing 50 mL of nutrient medium. In most of the experiments where ^{14}C-labeled compounds were added to the cultures, medium 1 was used. It contained (g/L): soluble starch (20), $NaNO_3$ (2.0), $CaCO_3$ (2.0), K_2HPO_4 (1.0), KCl (0.5), and $MgSO_4 \cdot 7H_2O$ (0.5). The pH value was adjusted to 8.9 with NaOH before autoclaving. In the remaining experiments with ^{14}C-labeled compounds, and where ^{13}C-labeled supplements were added to cultures, medium 2 was used. It contained (g/L): sorbitol (25), KNO_3 (2.0), $CaCO_3$ (2.0), K_2HPO_4 (1.0), $MgSO_4 \cdot 7H_2O$ (0.5), and NaCl (0.5). The pH was adjusted to 8.9 with KOH before autoclaving. Each flask received 2 mL of secondary inoculum and was incubated under the same conditions as the inoculum

cultures. Harvest times and the medium used are given with the results of each experiment.

Labeled Supplements

Radioactive compounds were obtained from New England Nuclear Corporation, Boston, MA; DL-[3-^{13}C]serine as well as sodium [1-^{13}C]- and sodium [1,2-^{13}C]acetate, all 90% enriched, were obtained from Merck Sharp and Dohme, Pointe Claire, P.Q. Supplements were prepared as aqueous solutions; those containing sodium acetate were sterilized by autoclaving; all other solutions were filtered through a 0.45 μm pore size membrane. Where the supplement was added in portions to a culture, it was subdivided equally. Times of addition varied; for radioactive supplements they are noted in Table 1. Carbon-13 labeled supplements were added on the 1st, 4th, 7th, and 10th days after inoculation. Radioactive supplements were added in cumulative amounts corresponding to 1 mmol per liter of culture. Sodium [1-^{13}C]acetate (total 934 mg; 11.3 mmol), sodium [1,2-^{13}C]acetate (882 mg; 10.5 mmol) and DL-[3-^{13}C]serine (108 mg; 1.02 mmol) were each added to 1 liter of culture. Cultures were harvested on the 14th day, except those receiving sodium [1,2-^{13}C]acetate which were harvested on the 15th day and yielded 61 mg of enriched metabolite.

Isolation of Caerulomycin A

Cultures were harvested by filtration and the filtrate, adjusted to pH 7 if acidic, was extracted with three half-volumes of ether. Basic products were then transferred from the ether to *N* HCl and recovered by neutralizing with excess $NaHCO_3$, then reextracting into ether. The product from 1-liter cultures, after removal of solvent, was chromatographed on a column (2.6 cm × 90 cm) of cross-linked dextran (Sephadex G-25 fine, Pharmacia Limited, Uppsala), equilibrated with the solvent system benzene – ethyl acetate – acetic acid – water (1:12:4:12). Caerulomycin A was collected at an elution volume of 340–450 mL during development with the organic phase. It was crystallized from ethanol and sublimed in high vacuum at 120–150°C as colourless needles, mp 175–176°C. The purity of the sample was checked by thin-layer chromatography (3) and by scanning the chromatogram for radioactivity where appropriate.

Instrumentation

Radioactivity was measured in a liquid scintillation counter. On thin-layer chromatograms it was detected with a gas-flow Geiger-Mueller detector.

^{13}C nmr spectra were recorded with Varian XL-100/15 and Varian FT-80A Fourier-transform spectrometers. Conditions were: XL-100/15 (FT-80A): frequency 25.16 MHz (20.0 MHz), spectral width 5120 Hz (4132 Hz), acquisition time 3.2 or 0.8 s (0.99 s), delay between acquisitions 2.2 s for high-resolution spectrum, 1.0 s for suppression of nuclear Overhauser enhancement when chromium acetylacetonate ($Cr(acac)_3$) was used as a relaxation reagent, flip angle 33°, 40° (40°), 90°, pulse length 40 μs (11 μs), time constant for exponential weighting of free induction decay −0.4 s or −1.0 s (−0.4 s), strength of ^{1}H-decoupling field $\gamma H_2/2\pi$ ca. 3800 Hz (ca. 4000 Hz), broad-band decoupling by 0°–180° phase modulation effective over 1000 Hz bandwidth, sample concentration ca. 140 mg/mL, solvent DMSO-d_6, solution volume 0.25 to 0.4 mL, $Cr(acac)_3$ concentration (when used) 10 mg/mL, 5 mm diameter sample tubes, internal lock to ^{2}H in solvent, reference to internal $(CH_3)_4Si$.

Enrichments from singly ^{13}C-labeled precursors were calculated as described previously (5) from spectra of the ^{13}C-enriched and natural-abundance material recorded under identical conditions. In the case of enrichment with [3-^{13}C]-serine, $Cr(acac)_3$ was added to the caerulomycin A solutions and the nmr measurements repeated, with suppression of the nuclear Overhauser enhancement (nOe) by switching off the ^{1}H-decoupling field between data acquisition periods. This technique and method of calculation was also used to obtain absolute ^{13}C enrichments from the sample labeled by [1,2-^{13}C]acetate. In this latter product many resonances consisted of doublet (intensity I_d) and multiplet (I_m; usually quartet) components due to the presence of ^{13}C—^{13}C and ^{13}C—^{13}C—^{13}C or ^{13}C—^{13}C—^{13}C—^{13}C units, superimposed on a central singlet (I_c) resonance arising from ^{13}C not directly bonded to other ^{13}C atoms. The relative intensities I_c, I_d, I_m should be proportional to the amounts of ^{13}C nuclei in each of the above situations, since ^{13}C—^{13}C contributions to spin–lattice relaxation have a negligible effect when a relaxation reagent is used in conjunction with a suppressed nOe technique.

Results

^{14}C-Labeled Substrates

The incorporation of radioactivity into caerulomycin A from a variety of ^{14}C-labeled compounds is summarized in Table 1. Labeled compounds were fed to *S. caeruleus* in two groups, with different growth and feeding conditions being used for each group. L-[U-^{14}C]alanine was included in each group as a reference compound. The results show that tryptophan and glycine are ineffective as precursors and that, although the antibiotic contains a methoxyl group, formate does not contribute to the one-carbon pool from which this part of the caerulomycin A structure is drawn. On the other hand, radioactivity was incorporated efficiently from L-[U-^{14}C]lysine and DL-[3-^{14}C]serine. The direct comparison between L-[U-^{14}C]alanine, sodium [1-^{14}C]acetate, D-[U-^{14}C]glucose, DL-[1-^{14}C]aspartate, and DL-[4-^{14}C]aspartate shows acetate to be the most readily incorporated whereas [1-^{14}C]aspartate is a relatively poor precursor. Higher yields of product and lower dilutions of isotope were obtained when the culture developed slowly, with sorbitol as a carbon source, and with successive small supplements of the precursor during the prolonged period of antibiotic production (see Table 1, cultures grown in medium 2). These conditions were chosen for studies with ^{13}C-labeled compounds.

^{13}C-Labeled Substrates

The ^{13}C nmr spectrum of caerulomycin A has been assigned previously (3). The spectrum of material labeled from [1-^{13}C]acetate showed enrichments of $<0.2\%$ at all positions except C-2 ($6.7 \pm 0.9\%$), C-4 ($19.6 \pm 2.5\%$), and C-4′ ($12.5 \pm 1.6\%$).

Similar feeding conditions were used to examine the incorporation of sodium [1,2-^{13}C]acetate. Values of $^1J_{CC}$ and the following quantities, calculable for

*$x = (p_A - 0.0111)/(B - 0.0111)$, $p_{NA} = 0.0111(1 - x)$, $p_p = Sp_A/B$, $p_s = p_A - p_{NA} - p_p$, $S = (I_d + I_m)/(I_c + I_d + I_m)$ and $T = I_m/(I_d + I_m)$ where $(1 - x)$ is the mole fraction of natural abundance ^{13}C, B(= 0.9) is the ^{13}C probability at sites in [1,2-^{13}C] acetate, and I_c, I_d, and I_m are the integrated intensities of singlet, doublet, and multiplet resonances for individual carbons, respectively.
†$^1J_{CC}$ values were also obtained from the spectrum of the metabolite enriched with [1-^{13}C]acetate, where high ^{13}C enrichments at C-4 and C-4′ allowed the following measurements: C-3, C-4, 65.1±1.0 Hz; C-4, C-5, 66.5±1.0 Hz; C-3′, C-4′, 54.0±1.0 Hz; C-4′, C-5′, 53.4±1.0 Hz.
‡Intensity of broad multiplet not measurable.

each labeled site from the intensities of resonance components in the ^{13}C nmr spectrum of caerulomycin A obtained in this experiment, are given in Table 2: p_A (^{13}C probability), x (mole fraction of ^{13}C originating from labeled precursor), S (probability that the ^{13}C atom is directly bonded to one or more ^{13}C atoms), T (probability of incorporation of a third ^{13}C atom adjacent to a ^{13}C—^{13}C unit). Pairs of coupled carbons were matched from one-bond ^{13}C—^{13}C spin–spin couplings. Table 2 shows that C-2′ through C-6′ plus C-2, C-3, and C-4 are enriched by doubly labeled acetate. Since only C-2, C-4, and C-4′ are enriched by [1-^{13}C]acetate it follows that C-2′, C-3, C-3′, C-5′, and C-6′ originate from the methyl group of acetate. The enrichments ($100(p_A - 0.0111)$) in the [1,2-^{13}C]acetate experiment are not uniform (C-3, C-4 ≈ 15 ± 3%; C-2, C-2′, C-3′, C-5′, C-6′ ≈ 5 ± 1%; C-4′ ≈ 12 ± 2%) but for C-2, C-4, and C-4′ are consistent with those obtained with [1-^{13}C]acetate.

The $^1J_{CC}$ values, enrichments, and the intensity distribution of resonance components for the individual carbons establish unequivocally that pairs of carbons are incorporated as $^{13}C—^{13}C$ units from doubly labeled acetate at the following positions: C-3, C-4; C-2, C-2′; C-3′, C-4′; C-4′, C-5′. It is apparent from both the overlap of pairs and from the positions labeled by each acetate carbon that C-3′, C-5′, and C-6′ are derived from the methyl group of the precursor, preceded or accompanied by scission of the $^{13}C—^{13}C$ bond. This is borne out by an examination of singlet, doublet, and multiplet resonance intensities for individual carbons. Substantially higher enrichment at C-3 and C-4 (see p_A and x values Table 2) indicates that these two carbons are incorporated from acetate as a separate biogenetic unit. It is also apparent (Table 2) that x is the same (0.056 ± 0.005) for C-2, C-2′, C-3′, C-5′, and C-6′. The value of x is about half that for C-4′ (0.138 ± 0.025). The higher enrichment at C-4′ is explained by the contribution from two different $^{13}C—^{13}C$ units, one at C-3′, C-4′ and the other at C-4′, C-5′. The S-values for C-2 and C-2′ through C-5′ are uniform (0.52 ± 0.05) and C-2′ through C-6′ are symmetrically labeled, both in origin and amount about an axis through N-1′ and C-4′. Furthermore the S-value for C-6′ and the T-value for C-3′ and C-5′ coincide (0.23 ± 0.02) indicating that they represent the probability of ^{13}C being present in the precursor pool during assembly of C-2 and C-2′ through C-6′. Subsequent dilution with natural abundance material has reduced p_A for these carbons to 0.062 ± 0.005. Satellites accompanying the C-6′ resonances are, therefore, due to random incorporation of ^{13}C at C-6′ when the ^{13}C probability for C-5′ was about 0.23. They are not due to an intact $^{13}C—^{13}C$ unit at C-5′, C-6′ derived from doubly labeled acetate. The combined evidence at this stage is consistent with C-2 plus C-2′ through C-6′ being derived from the symmetrical intermediate 2*S*,6*S*-diaminopimelic acid as illustrated in Fig. 1.

The value $T = 0.04$ for the C-4′ resonance shows that when this carbon is part of the $^{13}C—^{13}C$ unit C-4′, C-5′ (or C-4′, C-3′), the probability (0.04) of incorporating a single ^{13}C label at the adjacent C-3′ (or C-5′), is about 1/6th the probability (0.23) of incorporating ^{13}C at C-2′ (or C-6′) adjacent to the unit C-3′, C-4′ (or C-4′, C-5′). This is consistent with the single labels at C-3′ and C-5′ originating from the acetate–methyl group via pyruvate (see Fig. 1) and undergoing dilution of ^{13}C to 1/6th the level in the $^{13}C—^{13}C$ pairs derived via oxalacetate and aspartate.

It is also noteworthy that the value $T = 0.06$ for the C-3 resonance is equal to p_A for C-2. Consequently C-2 and C-3 are linked after the monosubstituted pyridine ring, comprising C-2 and C-2′ through C-6′, has been constructed and diluted with natural abundance material.

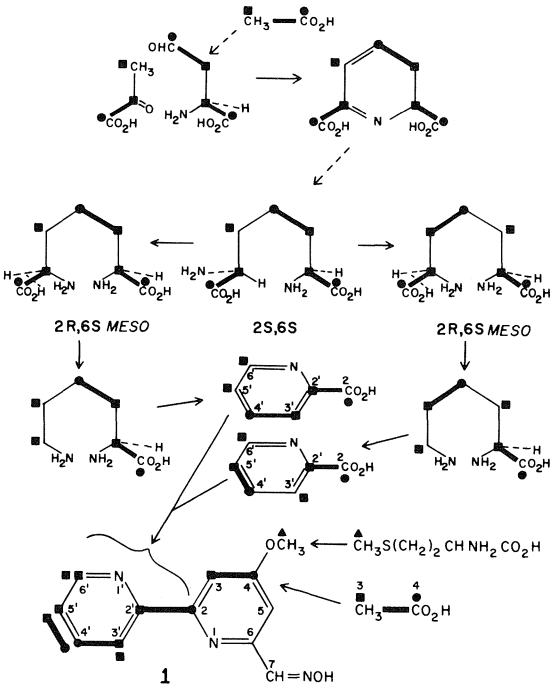

FIG. 1. The portion of the biosynthetic pathway to caerulomycin A involving 2*S*,6*S* diaminopimelic acid and acetate.

Some scrambling of the labels in doubly labeled acetate has occurred prior to incorporation and this has increased the proportion of single label at each site in enriched caerulomycin A. As expected, sites originating from the carboxyl group of acetate were affected to a greater extent than those derived from the methyl group (6).

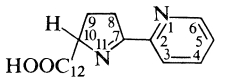
^{13}C nmr analysis of caerulomycin A labeled from DL-[3-^{13}C]serine showed enrichment of the methoxyl carbon ($2.6 \pm 0.6\%$), confirming the expected origin of this substituent from the one-carbon pool of the organism, derived via the serine–glycine conversion (7). Lesser enrichment ($1.0 \pm 0.4\%$) was observed at C-3′ and C-5′. This is accounted for by conversion of serine to pyruvate through the action of serine dehydratase (7), and is supporting evidence for the participation of pyruvate in forming the unsubstituted pyridine ring of caerulomycin A.

None of the precursors discussed above labeled C-5, C-6, or C-7.

Discussion

The pattern of ^{13}C incorporation from [1-^{13}C]- and [1,2-^{13}C]acetate indicates that the unsubstituted pyridyl ring of caerulomycin A is derived from three-

and four-carbon precursors assembled in the manner characteristic of lysine biosynthesis in bacteria. The pathway must include at least one symmetrical intermediate such as 2*S*,6*S*-diaminopimelic acid. Since L-[U-^{14}C]lysine was incorporated with high efficiency and its formation from diaminopimelic acid is virtually irreversible (8), we conclude that lysine is a direct precursor of the antibiotic. Lysine is also a precursor of the pyridine ring in proferrorosamine A (**2**), an iron-complexing metabolite produced by



2

Pseudomonas roseus fluorescens (9). Picolinic acid was also found to be efficiently incorporated into proferrorosamine and it is tempting to suggest that it is also an intermediate in the biosynthesis of caerulomycin A.

While C-2 of the substituted pyridyl ring is contributed by lysine and carbons 3 and 4 enter from acetate by a route which, to judge from the relatively low dilution, is a fairly direct one, the source of the three remaining carbons is uncertain. Serine has been eliminated by direct test, and the possibility that they might come from alanine or pyruvate can be discounted because C-5, C-6, and C-7 should then have been labeled from acetate or serine to an extent similar to that observed for the positions contributed by the three-carbon precursor of lysine. None of the ring carbons was labeled by one-carbon donors and since [1-^{14}C]glycine was a very poor precursor of the antibiotic, a $C_2 + C_1$ unit derivation is unlikely. The most plausible explanation is that a three-carbon glycolytic pathway intermediate, such as dihydroxy acetone phosphate, reacts, either directly or after conversion to methylglyoxal, with a picolinyl-C_2 intermediate to supply the balance of the structure. Helbling and Viscontini (10) have reported that cultivation of *P. roseus fluorescens* on asparagine and [1-^{14}C]glycerol (which would be expected to form [1,3-^{14}C]dihydroxyacetone phosphate) yielded proferrorosamine A in which 75% of the radioactivity was distributed between C-8, C-9, C-10, and C-12. About one-third was located at C-12.

Received June 27, 1979

W. R. DAVIDSON, S. MEZA-HÖJER, and P. KEBARLE. Can. J. Chem. **57**, 3205 (1979).

The equilibria [2]: $RCO^+ + OH_2 \rightleftharpoons RC(OH)_2^+$ for R = CH_3, C_2H_5, and C_6H_5 were studied in a pulsed electron beam high ion source pressure mass spectrometer. van't Hoff plots led to ΔH_2 values: (CH_3), 24.6; (C_2H_5), 22.7; (C_6H_5), 21.9 kcal/mol. $\Delta H_f(RC(OH)_2^+)$ were obtained from gas phase basicity ladders combined with the new $\Delta H_f(t\text{-butyl}^+)$ = 163 kcal/mol (Beauchamp). The $\Delta H_f(RC(OH)_2^+)$ were: (CH_3), 71.3; (C_2H_5), 63.6; (C_6H_5), 95.5 kcal/mol. Combination of ΔH_2 with $\Delta H_f(RC(OH)_2^+)$ leads to $\Delta H_f(RCO^+)$: (CH_3), 153.7; (C_2H_5), 144; (C_6H_5), 174.6 kcal/mol. These results are in agreement with selected data from appearance potentials. The energies and structures of the participants in reaction [2] were calculated by MINDO/3 and STO-3G. MINDO/3 gave good agreement with ΔH_2. The establishment of the equilibria [2] was unusually slow. A study of the kinetics revealed that k_{2f} is approximately third order, unusually small, and has an unusually large negative temperature coefficient. Furthermore, reaction [2] was found to be catalyzed by RCOOH. An explanation of these observations is given by assuming that the proton shift $RCO(OH_2)^+ \rightarrow RC(OH)_2^+$ has a large activation energy barrier in the gas phase. This barrier is removed by formation of a hydrogen bonded complex with RCOOH.

W. R. DAVIDSON, S. MEZA-HÖJER et P. KEBARLE. Can. J. Chem. **57**, 3205 (1979).

On a étudié l'équilibre 2: $RCO^+ + OH_2 = RC(OH)_2^+$ où R = CH_3, C_2H_5 et C_6H_6 à l'aide d'un spectromètre de masse utilisant comme source d'ions à haute pression un faisceau d'électrons produit par pulsations. Les courbes de van't Hoff conduisent à des valeurs de ΔH_2: (CH_3) 24.6, (C_2H_5) 22.7, (C_6H_5) 21.9 kcal/mol. On a obtenu les valeurs de $\Delta H_f(RC(OH)_2^+)$ à partir des échelles de basicité de la phase gazeuse combinées avec la nouvelle valeur pour $\Delta H_f(tert\text{-butyl}^+)$ de 163 kcal/mol (Beauchamp). Les valeurs sont les suivantes: (CH_3) 71.3, (C_2H_5) 63.6 et (C_6H_5) 95.5 kcal/mol. La combinaison de ΔH_2 avec $\Delta H_f(RC(OH)_2^+)$ conduit aux valeurs suivantes de $\Delta H_f(RCO^+)$ (CH_3) 153.7, (C_2H_5) 144, (C_6H_5) 174.6 kcal/mol. Les résultats sont en accord avec des données choisies à partir des potentiels d'apparition. Les énergies et les structures des substances participant à la réaction 2 sont calculées par MINDO/3 et STO-3G. Les calculs faits par MINDO/3 donnent des résultats qui s'accordent bien avec les valeurs de ΔH_2. La réaction [2] atteint l'équilibre lentement ce qui est inhabituel. Une étude des cinétiques révèle que k_{2f} est approximativement du troisième ordre, qu'elle est anormalement faible et qu'elle est dôtée d'un coefficient de température anormalement grand. On a trouvé de plus que la réaction [2] est catalysée par RCOOH. On donne une explication de ces observations en faisant l'hypothèse que le déplacement du proton $RCO(OH_2)^+ \rightarrow RC(OH)_2^+$ a une barrière d énergie d'activation dans la phase gazeuse. Cette barrière est supprimée par la formation d'un complexe d'hydrogène lié à RCOOH.

[Traduit par le journal]

Introduction

Recent reports from this laboratory (1–5) described studies of gas phase equilibria [1] involving the reactions of carbo cations A^+ ($C_2H_5^+$, $C_3H_7^+$, $t\text{-}C_4H_9^+$) with the compounds B:

[1] $A^+ + B \rightleftharpoons AB^+$

where B = H_2 (1), CH_4 (1), OH_2 (2), CO (3), ClR′ (4). Process [1] may be considered as a Lewis acid–base reaction between the Lewis acid A^+ and the $\sigma(H_2, CH_4)$, $\pi(CO)$, and $n(OH_2, ClR')$ donor bases B.

The present work deals with equilibria [2] in which the Lewis acids are the acylium ions RCO^+ and the base is water. Earlier work (3) showed that the product of the addition of water to the acylium ions in the gas phase is the protonated acid $RC(OH)_2^+$.

[2] $RCO^+ + OH_2 \underset{r}{\overset{f}{\rightleftharpoons}} RC(OH)_2^+$

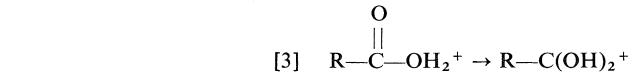
Since RCO^+ can be produced by carbonylation of R^+ by CO (3) these gas phase reactions are analogous to the Koch–Haaf (6) synthesis of acids in con-

[1]Visiting professor 1977–1978 from Chemistry Department, National University of Mexico, Mexico City, Mexico.

[2]To whom all correspondence should be addressed.

0008-4042/79/243205-11$01.00/0

densed media. The gas phase reaction [2] is in principle similar to the Lewis acid–base additions [1]. However, to obtain the final product, the proton shift [3] is required.



[3] $R-\overset{\overset{O}{\|}}{C}-OH_2^+ \rightarrow R-C(OH)_2^+$

The structure on the left is the hydroxyl protonated acid, while that on the right is the more stable carbonyl protonated acid. The necessity for the 1,3 proton shift [3] introduces some complications in the gas phase kinetics of the equilibria [2]. As will be seen these complications are of considerable interest.

In the present work, measurements of the equilibria with R = C_2H_5 and C_6H_5 could be made. van't Hoff plots of the equilibrium constants K_2 lead to ΔH_2^0 and ΔS_2^0. The enthalpies of formation of $RC(OH)_2^+$ can be obtained from the known proton affinities of the acids RCOOH. Therefore one can calculate $\Delta H_f(RCO^+)$ from ΔH_2 and $\Delta H_f(RC(OH)_2^+)$ since the enthalpies of formation of the neutrals involved in [2] are known. The present results combined with earlier data for R = CH_3 (5) and R = H provide ΔH_f values for HCO^+, CH_3CO^+, $C_2H_5CO^+$, and $C_6H_5CO^+$.

It was considered of interest to compare the experimentally determined ΔH_2 with theoretically calculated ΔE_2. Accordingly the electronic energies of the reactants entering process [2] were calculated using MINDO/3 and STO-3G for R (H, CH_3, C_2H_5, and C_6H_5). The theoretical results are also of interest because they provide information on the geometries of RCO^+ and $RC(OH_2)_2^+$. Information is also obtained on the energetics of the proton shift [3], i.e. the energy difference between the hydroxy and carbonyl protonated acids, and the activation energy barrier between these two structures.

Experimental

The kinetics and the equilibria of reaction [2] were studied with a pulsed electron beam high ion source pressure mass spectrometer of design similar to that commonly used in our laboratory (7). However, in the present instrument the electron gun was mounted on the ion source as described earlier, see Fig. 1 (8). The reactant gas mixture at a known pressure between 1.5–4 Torr is passed in slow flow through the thermostated ion source. In the present work equilibria [2] were measured with water vapor as the major gas. The water vapor carried small amounts (~0.1%) of the acid RCOOH. Some of the kinetic measurements were made with methane or isobutane as major gas. The major gas carried small amounts (~0.1%) of the acid RCOOH. The gas mixtures were prepared at 1 atm total pressure in a 5 L storage bulb kept at 170°C. The flow through the ion source was obtained by bleeding the reaction mixture from the storage bulb into the flow system.

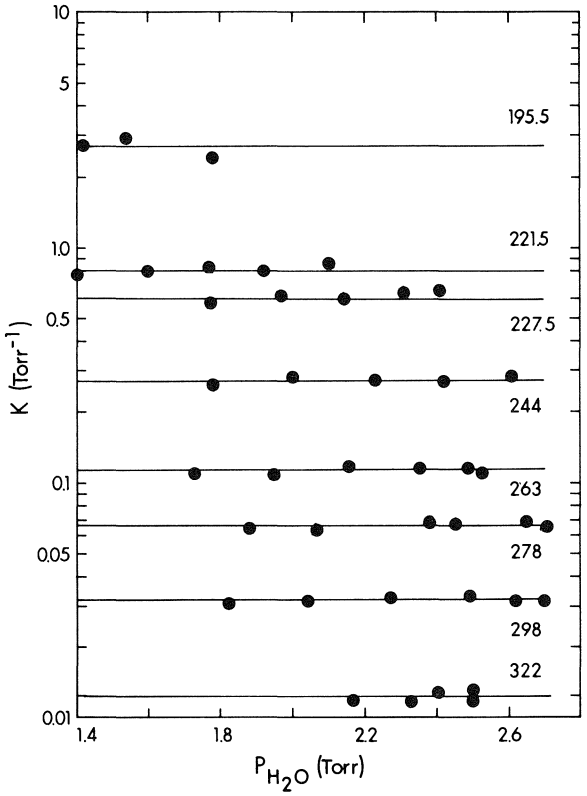


FIG. 1. Plot of equilibrium constants K for reaction $C_2H_5CO^+ + OH_2 \rightleftharpoons C_2H_5C(OH)_2^+$, obtained at different temperatures (°C) versus water pressure.

Results and Discussion

(a) Kinetics and Equilibria of $RCO^+ + OH_2 \rightleftharpoons RC(OH)_2^+$

Equilibrium [2] was measured in experiments where the major gas passed through the ion source was water (1.5–3 Torr). The water vapor contained some 0.1% RCOOH. The positive ions produced by electron impact and subsequent ion–molecule reactions in water vapor are (7) the protonated water clusters $H^+(H_2O)_n$.

[4] $H^+(H_2O)_n + RCOOH \rightleftharpoons RC(OH)_2^+(OH_2)_k + (n-k)H_2O$

In the present system, as expected, the initial ions observed where $H^+(H_2O)_n$, which disappeared within microseconds while ions of mass corresponding to $RC(OH)_2^+$, were formed. The proton transfer [4] is exothermic (9) and fast. At lower temperatures the hydrated protonated acid resulting from [4] added more water molecules, thus rapidly reaching equilibrium. When the ion source temperature was raised, the equilibrium hydrates of the protonated acid con-

tained less and less water molecules. Above a given temperature, the bare protonated acid formed by [4], with $k = 0$, could be observed to decompose via reaction [2r]

[2r] $RC(OH)_2^+ \rightarrow RCO^+ + OH_2$

In a given temperature interval the ions RCO^+ and $RC(OH)_2^+$ were observed to reach stationary concentrations after several hundreds of microseconds. The constant ion intensity ratio at long reaction times was assumed to be the equilibrium concentration ratio for reaction [2] and was used for the evaluation of the equilibrium constant K_2. Plots of K_2 versus water pressure are shown in Figs. 1 and 2 for $R = C_2H_5$ and $R = C_6H_5$. These figures show the pressure range covered and the extent to which K_2 was invariant with water pressure. The equilibrium constants K_2 were also found to be independent of the concentration of the RCOOH. van't Hoff plots of the K_2 from Figs. 1 and 2 are shown in Fig. 3. This figure also includes the van't Hoff plot of reaction [2] with $R = CH_3$ obtained earlier in this laboratory (5). The ΔH_2^0 and ΔS_2^0 obtained from the van't Hoff plots are given in Table 1. The thermochemical significance of the data obtained from the van't Hoff plots will be considered in the next section. The observation that equilibrium [2] required several hundred microseconds to establish, even when pure water at a few Torr pressure was used, is unusual. For example, the clustering equilibria

$$H^+(H_2O)_{n-1} + H_2O \rightleftharpoons H^+(H_2O)_n$$

establish only after some 10 μs under the same temperature and pressure conditions (7).

Rate measurements were made with the hope that they might lead to an understanding as to why equilibrium [2] is so slow. All kinetic runs were done with benzoic acid, i.e. R = Ph. First the time dependence of $PhC(OH)_2^+$ and $PhCO^+$ was examined with water as major gas at pressures between 1.5 to 3 Torr in the temperature range 194–260°C. Addition reactions like [2f] are generally third order, which means that the reverse reaction [2r] must be second order (7, 10, 11). The order of [2r] was examined and found consistent with second order dependence; however, the experimentally accessible pressure change, by a factor of 2, was not really sufficient to prove the order conclusively. As expected, the rate constants were found to be very small. Thus, $k_{2f} \approx 7.5 \times 10^{-31}$ cm^6 molecules^{-2} s^{-1} and $k_{2r} \approx 4.4 \times 10^{-14}$ cm^3 molecule^{-1} s^{-1} (205°C, benzoic acid, third body water vapor). The temperature dependence of k_{2r} and k_{2f} was also examined. It was found that k_{2f} had an extremely large negative temperature coefficient: $k_{2f} = cT^{-n}$ where $n > 13$. The conditions for kinetic studies, with water as

third gas, were not very favorable since the proton transfer reaction [4] at lower temperatures led to hydrates of the protonated acid, which complicated the initial kinetic stage. Therefore an investigation was conducted using methane or isobutane as the major gas. The ions produced by electron impact and subsequent ion molecule reactions in methane are CH_5^+ and $C_2H_5^+$ while in isobutane the final ion is $t\text{-}C_4H_9^+$ (12, 13). When benzoic acid is present these ions engage in rapid proton transfer. For example $t\text{-}C_4H_9^+$ leads to the fast reaction [5].

[5] $t\text{-}C_4H_9^+ + PhCOOH \rightleftharpoons i\text{-}C_4H_8 + PhC(OH)_2^+$

At suitably elevated temperatures one can observe that the protonated benzoic acid formed by [5], subsequently decomposes by [2r]. The time dependence of the ions in such a run with CH_4 as major gas is shown in Fig. 4. The $PhC(OH)_2^+$ is seen to decompose forming $PhCO^+$. The side reaction [6] involving formation of the proton held dimer from the protonated acid is also observed.

[6] $PhC(OH)_2^+ + PhCOOH \rightleftharpoons (PhCOOH)_2H^+$

The ion ratio $[A^+]/[C^+]$, where A^+ is $PhC(OH)_2^+$ and C^+ is $(PhCOOH)_2H^+$ is seen to become constant after about 150 μs. This must mean that the forward and reverse rates of [6] are relatively faster than [2r] such that A^+ and C^+ reach equilibrium in spite of the reactant drain caused by [2r]. It is easy to show that when A^+ and C^+ are in equilibrium $d[A^+]/dT = -\nu_{2r}[A^+]$, where ν_{2r} is the reaction frequency, i.e., pseudo first order rate constant for reaction [2r].

Plots of $\log [A^+]$ versus t for $t > 200$ μs, where the proton transfer [5] was complete, gave good straight lines whose slopes provided values for ν_{2r}. Experiments at different major gas pressures showed that ν_{2r} was pressure dependent. One such plot is given in Fig. 5*A*. It is seen that ν_{2r} is proportional to the pressure of the major gas M. This means: $\nu_{2r} \approx k_{2r}[M]$, i.e., the rate constant k_{2r} is second order and consequently k_{2f} is third order. The pressure dependence of [2r] with methane as third gas was also examined. It was found that methane is three times less efficient as third body than isobutane.

Interestingly k_{2r} was found to be also approximately proportional to the pressure of benzoic acid. For example, changing the benzoic acid from 1.2 to 2.4 mTorr increased k_{2r} from 1.2×10^{-13} to 2×10^{-13} cm^3 $molecule^{-1}$ s^{-1} (isobutane major gas, 260°C). Considering the very low benzoic acid pressure, this is a very large effect. This must mean that benzoic acid does not act as a very efficient third body but as a homogeneous catalyst. This important point

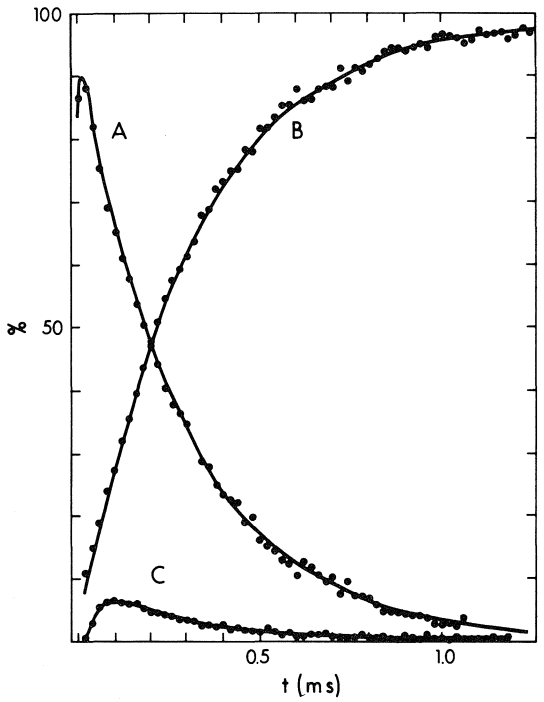

FIG. 4. Dissociation of protonated benzoic acid A = $PhC(OH)_2^+$ to B = $PhCO^+$, by reaction $PhC(OH)_2^+ \rightleftharpoons PhCO^+ + OH_2$. Formation of proton held dimer C = $(PhCOOH)_2H^+$ is also observed. After some 100 μs intensity ratio A/C is constant which means equilibrium A = C is rapid in comparison to decomposition of A to B. $p(CH_4) = 3.5$ Torr, $p(PhCOOH) \approx 3 \times 10^{-3}$ Torr, $T = 266°C$.

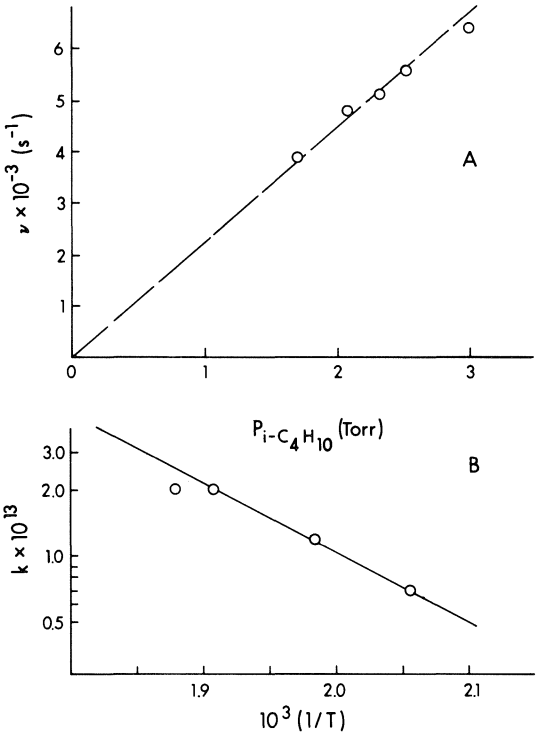

FIG. 5. (*A*) Plot of the reaction frequency ν_{2r} (s^{-1}) versus pressure of the major gas, M = *i*-C_4H_{10}. Increase of ν_{2r} (pseudo first order rate constant) with isobutane pressure shows that decomposition: $PhC(OH)_2^+ \rightleftharpoons PhCO^+ + OH_2$ is approximately second order, i.e. $k_{2r} \approx \nu_{2r}[M]$. All runs at 260°C and $P(PhCOOH)/P(i\text{-}C_4H_{10}) \approx 6 \times 10^{-4}$. (*B*) Arrhenius plot of k_{2r} (cm^3 $molecule^{-1}$ s^{-1}), major gas *i*-butane containing 0.1% benzoic acid. Line obtained gives $k_{2r} = A \exp(-E_A/RT)$ with $A \approx 10^{-6.5}$ cm^3 $molecule^{-1}$ s^{-1} and $E_A = 14.5$ kcal/mol.

will be examined later (see section *c*) in connection with the activation barrier for the proton shift [3].

The temperature dependence of k_{2r} was examined in several runs in which the pressure of the major gas and of the benzoic acid was kept constant. An Arrhenius plot of k_{2r} is shown in Fig. 5*B*. The line obtained provides the equation $k_{2r} \approx A \exp(-E_A/RT)$ with $A \approx 10^{-6.5}$ (cm^3 $molecule^{-1}$ s^{-1}) and $E_A \approx 14.5$ kcal/mol. Unfortunately the temperature range covered is rather short and the data points not quite sufficient. Therefore it is hard to estimate the error in the activation energy. Since catalysis by benzoic acid is also present, the value of the activation energy cannot be directly associated with the endothermicity of reaction [2r].

Combining the k_{2r} obtained above with the equilibrium constants K_2, for benzoic acid (see Fig. 3), one obtains k_{2f}, from $K = k_{2f}/k_{2r}$. For example $k_{2r} = 7 \times 10^{-14}$ (cm^3 $molecule^{-1}$ s^{-1}) (for $T = 486.5$ K, major gas isobutane, see Fig. 5*B*) can be combined with $K_2 = 0.2$ ($Torr^{-1}$) or $= 1 \times 10^{-17}$ (cm^3 $molecule^{-1}$) (for $T = 486.5$ K, see Fig. 3) to obtain $k_{2f} = K_2 k_{2r} = 7 \times 10^{-31}$ cm^6 $molecule^{-2}$ s^{-1}. The third order rate constant k_{2f} is indeed very small, when compared to the value for the forward clustering reaction $H_3O^+ + H_2O + CH_4 \rightleftharpoons H^+(H_2O)_2 + CH_4$ at the same temperature which is 5×10^{-28} cm^6 $molecule^{-1}$ s^{-1}, i.e. three orders of magnitude larger. From $\Delta H_2^0 = -25.8$ kcal/mol and the activation energy $E_{A2r} = 14.5$ kcal/mol one obtains a negative "activation energy" of about 11 kcal/mol for reaction [2f]. Converting this "negative activation energy" to the form $k_{2f} = CT^{-n}$ one obtains the relationship $k_{2f} \approx 6 \times 10^{14} T^{-10.4}$ cm^6 $molecule^{-2}$ s^{-1} (experimental temperature range 485–586 K, third body isobutane). We notice that the negative temperature exponent *n* is very large although not quite as large as the *n* for the same reaction but with water as third body, quoted above. While third body dependent reactions usually have negative temperature coefficients, the value of *n* is usually (7, 10, 11) small, i.e., in the range 1 to 3. A discussion of the mechanism and the possible causes for the unusual behavior of reaction [2f] and [2r] will be given in section *c*.

(b) Thermochemical Information from Equilibria [2]: $RCO^+ + OH_2 \rightleftharpoons RC(OH)_2^+$ and Theoretical Calculations of Energies and Geometries of Compounds Entering Reaction [2]

The ΔG_2^0 values for reaction [2] in the experimentally accessible temperature range can be obtained from the van't Hoff plots in Fig. 3. From the position of the van't Hoff lines, at a given constant temperature, the order for the $-\Delta G_2^0$ is $CH_3CO > C_2H_5CO > C_6H_5CO$. The $-\Delta G_2^0$ at 525 K are given as an example in Table 1. The above order shows that the stabilization of the acyl cation RCO^+ increases in the order R: $CH_3 < C_2H_5 < C_6H_5$. This is the expected order on the basis of increasing polarizability in CH_3, C_2H_5, and C_6H_5, and the stabilization by π donation in $C_6H_5CO^+$. Since the stabilization by R is an electronic effect, the order observed for the ΔG_2^0 changes can be expected to hold also for the ΔH_2^0 changes, obtained from the slopes of the van't Hoff plots. Unfortunately, this is not the case, the $-\Delta H_2^0$ values change little and in an irregular manner (see Table 1). The regular change of the ΔG_2^0 values is reflected not in the ΔH_2^0 results but in the ΔS_2^0 results, which are seen to increase regularly in the order: methyl, ethyl, phenyl: 33, 35, 43 cal/deg. There seems to be no meaningful physical reason for this large entropy increase. The entropy situation may be examined on the basis of reaction [7].

[7] $$CH_3CO^+ + C_6H_5C(OH)_2^+ \rightleftharpoons CH_3C(OH)_2^+ + C_6H_5CO^+$$

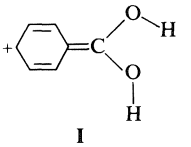
$$A + B \rightleftharpoons C + D$$

From the above quoted ΔS_2^0 values, one can evaluate $\Delta S_7^0 = 43 - 33 = 10$ cal/deg. The translational and rotational symmetry entropy changes are easily evaluated from the well known eq. [8].

[8] $$\Delta S_7(\text{trans}) = R \ln M_C M_D / M_A M_B = 0.6 \text{ cal/deg}$$

$$\Delta S_7(\text{rot. sym}) = R \ln \sigma_A \sigma_B / \sigma_C \sigma_D = R \ln \tfrac{3}{2} = 0.8 \text{ cal/deg}$$

The symmetry numbers σ are based on the geometries of the cations given in Fig. 6. The combined contribution of these entropy changes is 1.4 kcal/deg. The only other significant contribution to ΔS_7^0 can come from a change of internal rotations. The acyl cations, being linear, are devoid of internal rotations. The protonated acids have three internal rotations, two around the C—OH bonds and one for the $C—C(OH)_2^+$ bond. The C—OH rotations may be expected to be similar for the two protonated acids, however, the $C—C(OH)_2^+$ rotation in benzoic acid may be more hindered than that in acetic acid since one expects some stabilization of the protonated benzoic acid by the resonance structure **I** and the corresponding ortho resonance structures.



I

Assuming a barrier of 10 kcal/mol (14) for the C—C internal rotation in the protonated benzoic acid and no barrier for the protonated acetic acid, one can estimate (14) the entropy change for the internal rotations $\Delta S_7(\text{int. rot}) \approx 1$ cal/deg. The reduced moments of inertia required for the calculation (14) were obtained from the structures given in Fig. 6. Combining the above contributions to ΔS_7^0 one obtains $\Delta S_7^0 \approx 2.4$ cal/deg which is considerably smaller than the experimental result $\Delta S_7^0 \approx 10$ cal/deg. We believe that the error lies in the experimental entropies. A similar estimation of ΔS for

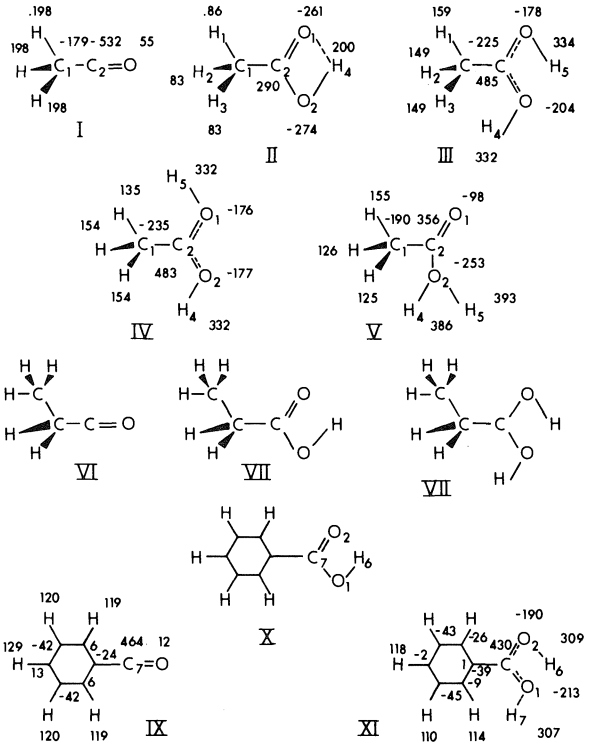


FIG. 6. Structures from STO-3G calculations, bond distances, and bond angles which were optimized in Table 2. Energies from STO-3G and MINDO/3 are also given in Table 2. Numbers besides atoms shown above correspond to STO-3G net atomic charges from Mulliken population analysis given in thousands of an elementary positive charge. Structures **II**, **VII**, **X** are the acids, which are uncharged. All other structures are singly charged positive ions.

reaction [7] but involving propionic rather than benzoic acid leads to a $\Delta S_7^0 \approx 0$ since in this case the properties of the reactants are even more similar.

As discussed in the preceding section, equilibrium [2] is unusually slow. For example the time required to approach 90% of the equilibrium concentrations could be as long as 1 ms. The slowness is deleterious to the accuracy of the equilibrium measurements since other processes affecting the concentrations of the ions RCO^+ and $RC(OH)_2^+$, like diffusion to the wall, and slow side reactions, can be neglected only when they are relatively slow compared to the equilibrium forward and reverse rates. This condition is not fully present in the above measurements. We believe that a set of improved ΔH_2 values can be obtained by using the calculated ΔS_7^0 obtained above. In the earlier publication (5) dealing with equilibrium [2] for R = CH_3, the van't Hoff derived $\Delta H_2 = -24.6$ kcal/mol was found to be in good agreement with the ΔH_2 value calculated from the thermodynamic cycle shown below.

$$\Delta H_2 = \Delta H_f(CH_3COOH) - \Delta H_f(H_2O) - \Delta H_f(CH_2CO) + PA(CH_2CO) - PA(CH_3COOH) = 25.6 \text{ kcal/mol}$$

Assuming that $\Delta H_2 = -24.6$ kcal/mol is correct for R = CH_3 we calculate ΔH_2 for R = C_2H_5 and C_6H_5 by using the ΔG_2^0 at 525 K (Fig. 3 and Table 1) which falls in the middle of the experimental range. Setting $\Delta S_2^0(C_2H_5) = \Delta S_2^0(CH_3)$ and $\Delta S_2^0(C_6H_5) = \Delta S_2^0(CH_3) + 2.4$ cal/deg in accordance with the evaluated ΔS_7^0 one obtains from $\Delta H = \Delta G + T\Delta S$ the improved ΔH_2 values shown in Table 1 as ΔH_2(imp). Related thermochemical literature data (15–24) are also given in Table 1.

It is of some interest to compare the ΔH_2 values with results from theoretical calculations. For this purpose calculations were made with STO-3G and MINDO/3. The electronic energies of all compounds entering reaction [2] with R = H, CH_3, C_2H_5, C_6H_5 were calculated using the Gaussian 70 (STO-3G) program (25). The structures obtained are shown in Fig. 6. The bonds and angles of the ions $RC(OH)_2^+$ and RCO^+ that were optimized are shown in Table 2. The same type bonds and angles were optimized for the corresponding neutrals. The remaining geometry was taken from the standard geometries outlined by Pople and Gordon (26). The electronic energies obtained are shown in Table 2. The MINDO/3 calculations used, for the neutral compounds, distances and angles from Dewar's (27) work when those were available (HCOOH, CH_3-COOH). For the other neutral compounds suitable distances and angles were selected from Dewar's compilation (27) and then some geometry optimization was performed (see Table 2). The geometries of the ions were based on the geometries of the corresponding neutrals plus the geometry optimizations given in Table 2.

The most stable structures predicted by STO-3G and MINDO/3 were the same. Both STO-3G and MINDO/3 predicted for the acids and protonated acids the internally hydrogen bonded structures as being the most stable (see Fig. 6 structure **II** for acetic acid and structure **III** for protonated acetic acid). The hydrogen bonded cisoid structure **III** of $CH_3C(OH)_2^+$ was predicted by STO-3G and MINDO/3 to be more stable by $\sim$8 kcal/mol than the transoid structure **IV** (see Fig. 6 and Table 2). This rotational barrier occurring in all the protonated acids may be responsible for the somewhat larger ΔS_2 of $\sim$33 cal/deg observed for reaction [2] involving the protonated acids as compared to other association reactions: $R^+ + B \rightleftharpoons RB^+$. The carbonyl protonated acid $CH_3C(OH)_2^+$ was predicted by STO-3G to be more stable than the hydroxy protonated isomer $CH_3COOH_2^+$ (see structures **III** and **V** Fig. 6 and Table 2) by 20.6 kcal/mol, MINDO/3 gave a very similar result: 18.8 kcal/mol (see fully optimized structures in Table 2). It is interesting to note that Benoit and Harrison (28), on the basis of a correlation of proton affinities with oxygen 1*s* ionization energies, have estimated a difference of about 24 kcal/mol for the proton affinities for carbonyl and hydroxyl protonation of acetic acid. Since the theoretical calculations are of limited accuracy and the correlation of the oxygen 1*s* ionization energies with the proton affinities is also only approximate, the agreement between the two results must be considered quite good.

The energy changes for reaction [2] can be calculated from the energies of the reactants E(STO-3G) or the ΔH_f(MINDO/3) of the reactants are given in Table 1. The results from MINDO/3 are seen to be very close to the ΔH_2(imp) also given in Table 1. On the other hand, ΔE_2(STO-3G) are found to be roughly two times larger than the ΔH_2(imp). Process [2] is a reaction in which an electron pair bond is formed. STO-3G does not give good results for the energy change in such situations, because of the very limited basis set used (29). Also included in Table 1 is an experimental value for ΔH_2 with R = H, i.e., the formation of protonated formic acid from the formyl cation and water. This result is not based on equilibrium measurements of reaction [2] but was calculated from the proton affinity of CO (21, 22) which leads to $\Delta H_f(HCO^+) = 200.3$ kcal/mol (see Table 1). The proton affinity of HCOOH (16, 17) leads to $\Delta H_f(HC(OH)_2^+)$ and a

[a]Roman numeral beside structure refers to structure shown in Fig. 6.
[b]Bond angles in degrees, bond distances in Å given only for ionic species. Results from STO-3G without parentheses, from MINDO/3 with parentheses.
[c]Numbers in parentheses are the accurately known experimental enthalpies of formation of the neutral molecules (15).
[d]Energies given correspond to fully geometry optimized structures.

combination of the values provides $\Delta H_2 = -49.3$ kcal/mol. An older value $\Delta H_f(HCO^+) = 195$ kcal/mol (19) based on appearance potentials when combined with $\Delta H_f(HC(OH)_2)^+$ leads to $\Delta H_2 = -44.0$ kcal/mol. The MINDO/3 calculation gives $\Delta H_2 = -46$ kcal/mol which is in between the two experimental values and thus is a good theoretical prediction.

A comparison of the enthalpies of formation of RCO^+ obtained from the present ΔH_2(imp) with $\Delta H_f(RCO^+)$ from appearance potentials is shown in the lower half of Table 1. The evaluation of $\Delta H_f(RCO^+)$ from ΔH_2 also requires $\Delta H_f(RC(OH)_2^+)$ which was obtained from gas phase basicity ladders (16, 17). The gas phase basicity ladder was put on an absolute basis by using the new value of $\Delta H_f(t\text{-butyl}^+) = 163$ kcal/mol, due to a redetermination of the ionization potential of the *t*-butyl radical by Houle and Beauchamp (18). This change brings $\Delta H_f(RCO^+)$ obtained from ΔH_2 and $\Delta H_f(RC(OH)_2^+)$ in better agreement with results for $\Delta H_f(RCO^+)$ from appearance potentials. For example: $\Delta H_f(CH_3CO^+) = 153.7$ kcal/mol (from ΔH_2 and $\Delta H_f(CH_3C(OH)_2^+)$ while $\Delta H_f(CH_3CO^+) = 152.3$ kcal/mol from the appearance potential of CH_3CO^+ from CH_3COCH_3 (23, 24). In our earlier

publication (5) dealing with the same ΔH_2 (R = CH_3) agreement with the above appearance potential $\Delta H_f(CH_3CO^+)$ was not obtained. The gas phase basicity of ketene recalculated to the new heat of formation of t-$C_4H_9^+$ leads to a $\Delta H_f(CH_3CO^+)$ = 154.7 kcal/mol (5, 17) or 153.4 kcal/mol (20), both values being in agreement with the appearance potential result.

The relatively good agreement of the $\Delta H_f(C_2H_5CO^+)$ and $\Delta H_f(C_6H_5CO^+)$ results based on ΔH_2 and $\Delta H_f(RC(OH)_2^+)$ with the appearance potential results (see Table 1) is encouraging although the appearance potential data (19) come, in this case, from the more questionable determinations. On the whole, one can conclude that the present results lend support to the new $\Delta H_f(t\text{-}C_4H_9^+)$ = 163 kcal/mol and the corresponding new PA(NH_3) = 208 kcal/mol (18).

(c) Homogeneous Gas Phase Catalysis of the 1,3 Proton Shift $RCO(OH_2)^+ \rightarrow RC(OH)_2^+$

The kinetics of reaction [2] were described in section (*a*), where the following salient features emerged. The third body dependent rate constant in the forward direction was unusually small. The negative temperature coefficient of the same reaction was extremely large, the reaction was catalyzed by the presence of acid RCOOH. These unusual features can be explained if one assumes that the 1,3 proton shift from the hydroxy protonated acid $RCO(OH_2)^+$ to the carbonyl protonated and $RC(OH_2)_2^+$, i.e. reaction [3], has an appreciable *potential energy barrier*. This situation is represented in Fig. 7. In the preceding section results of STO-3G and MINDO/3 calculations showed that $CH_3CO(OH_2)^+$ (structure **V**, Fig. 6) had an energy of ~20 kcal/mol higher than that of $CH_3C(OH)_2^+$ (structure **III**, Fig. 6), a similar result had been predicted by Benoit and Harrison (28) on the basis of a correlation 1*s* oxygen core electron energies with proton affinities. These data, together with the total endothermicity of the dissociation: $CH_3C(OH_2)^+ \rightarrow CH_3CO^+ + OH_2$ ($-\Delta H_2$ = 24.5 kcal/mol, Table 1), were used in the approximate potential energy diagram shown in Fig. 7. In order to explore the approximate size of the barrier for the 1,3 proton shift leading from $CH_3CO(OH_2)^+$ (**III**) to $CH_3C(OH)_2^+$ (**V**), we performed STO-3G calculations of some 20 structures with geometries intermediate between **III** and **V**. Unfortunately these were not sufficient to provide the path requiring the minimum energy, i.e., the reaction coordinate. They did, however, indicate that the barrier is substantial. This result is in agreement with recent work by Middlemiss and Harrison (30). These authors, by measuring the kinetic energy of

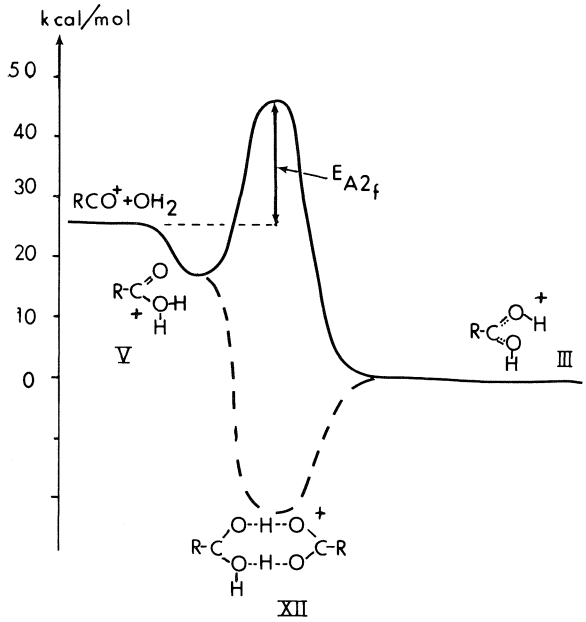

FIG. 7. Schematic potential energy diagram of reaction coordinate of reaction: $RCO^+ + OH_2 \rightleftharpoons RC(OH)_2^+$. $RC(OH)_2^+$ corresponds to carbonyl protonated acid, while $RCO(OH_2)^+$ to hydroxy protonated acid. Energy values are given in diagram from experiment and calculation (see text). Dashed line gives potential energy for catalyzed proton shift: $RCO(OH_2)^+ \rightarrow RC(OH)_2^+$ by formation of an intermediate complex with the acid RCOOH.

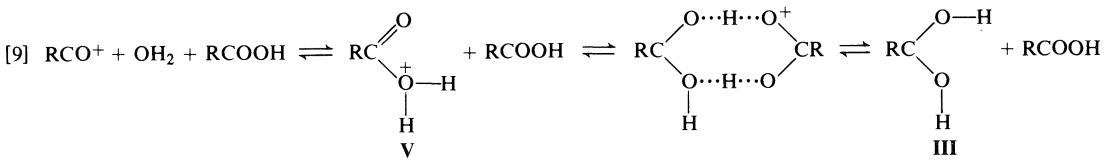
RCO^+ produced by dissociation of internally excited protonated acids, deduced that there are two different protonated acid species which they assumed to be $RC(OH)_2^+$ and $RCO(OH_2)^+$. The structure of lower energy, presumably $RC(OH)_2^+$, dissociated to $RCO^+ + OH_2$ with kinetic energy release. As pointed out by Middlemiss and Harrison, this kinetic energy probably originates from the presence of an energy barrier of the type illustrated in Fig. 7. From the amount of kinetic energy present in RCO^+, the authors estimated that the barrier indicated by E_{A2f} in Fig. 7 is approximately 20 kcal/mol. The barrier E_{A2f} in Fig. 7 was drawn to scale, assuming this value to be correct.

Assuming that Fig. 7 represents at least approximately the true situation, it becomes clear that the equilibrium [7] could not have been measured at the conditions of our experiments in the absence of catalysis. For example, the activation energy barrier $E_{A2r} \approx 40$ kcal/mol for the dissociation of $RC(OH)_2^+$ to $RCO^+ + OH_2$ could not have been overcome at the low temperatures employed. Also in the absence of catalysis k_{2f} would have had a positive temperature coefficient due to the presence of E_{A2f}. The catalytic effect of the acid RCOOH observed in section *a* can be explained by reaction [9].



Here the proton is not "transferred" by a 1,3 shift but the catalyst supplies one proton to position 3 and takes one away from position 1. The likely potential energy diagram for this process is indicated in Fig. 7. The observed very large negative temperature coefficient for k_{2f} can be explained on the basis of the mechanism given in [9]. **V** is much more weakly bonded than **III**. The temperatures used are high enough to cause dissociation of **III**. For these conditions **V** will be nearly completely dissociated to $RCO^+ + OH_2$. One expects a rapid equilibrium $RCO^+ + OH_2 \rightleftharpoons$ **V**, shifted very much to the left side. The concentration of **V** should then be given by eq. [10] where $\Delta H(\mathbf{V})$ and $\Delta S(\mathbf{V})$ represent the enthalpy and entropy changes for: $\mathbf{V} \rightleftharpoons RCO^+ + OH_2$. The MINDO/3 result indicates $\Delta H(\mathbf{V}) \approx 7$ kcal/mol (see Table 2). Therefore one may expect the concentration of **V** to decrease with temperature with the exponential factor exp (7 (kcal/mol)/RT).

$$[10] \quad [\mathbf{V}] = \frac{\exp[-\Delta S(\mathbf{V})/R] \exp[\Delta H(\mathbf{V})/RT]}{[RCO^+][H_2O]}$$

The conversion of **V** to **III**, which occurs via **XII**, will also have a negative temperature coefficient. The very special geometry of **XII** means that **XII** is a low entropy species, i.e. a tight complex. Therefore species **V**, when colliding with the catalyst RCOOH, will form **XII** more frequently at low temperatures, while at high temperatures back dissociation to **V** and RCOOH will be favored. The addition of this negative temperature coefficient to the term exp ($\Delta H(\mathbf{V})/RT$) predicts for k_{2f} a negative temperature coefficient, which when expressed as negative "activation energy" will have a value larger than ~7 kcal/mol. It will be recalled that the negative "activation energy" measured in section *a* (for $R = C_6H_5$) was approximately 11 kcal/mol. Thus mechanism [9] and Fig. 7 do provide a semiquantitative prediction of very large negative temperature coefficient for the rate constant k_{2f} as observed.

It is interesting to note that in protic solvents the 1,3 proton shift required for reaction [2] will be easily catalyzed by the solvent molecules in a manner similar to that indicated by eq. [9], i.e., one given solvent molecule removes the proton from **V** while a second solvent molecule provides a new proton to the carbonyl oxygen of **V**.

Acknowledgements

We are thankful to Professor A. G. Harrison who graciously supplied us with a preprint of his work (30). The STO-3G calculations for the intermediates between $CH_3CO(OH_2)^+$ and $CH_3C(OH)_2^+$ were performed by Dr. P. P. S. Saluja.

Reçu le 7 juin 1979

JEAN-MARIE VARLET, NOËL COLLIGNON et PHILIPPE SAVIGNAC. Can. J. Chem. **57**, 3216 (1979).

La réaction des α-cupro(I)alkanephosphonates avec les chlorures de méthoxalyle et d'éthoxalyle conduit aux phosphonopyruvates de dialkyle qui soumis à l'amination réductrice dans l'éthanol à pH 6–7 en présence de $NaBH_3CN$, d'acétate d'ammonium ou d'amines primaires fournissent les aminoesters phosphoniques; leur hydrolyse par l'acide chlorhydrique dilué conduit aux aminoacides phosphoniques (phosphonoalanine). L'ensemble de ces trois réactions constitue une méthode générale d'accès à la phosphonoalanine et aux structures apparentées.

JEAN-MARIE VARLET, NOËL COLLIGNON, and PHILIPPE SAVIGNAC. Can. J. Chem. **57**, 3216 (1979).

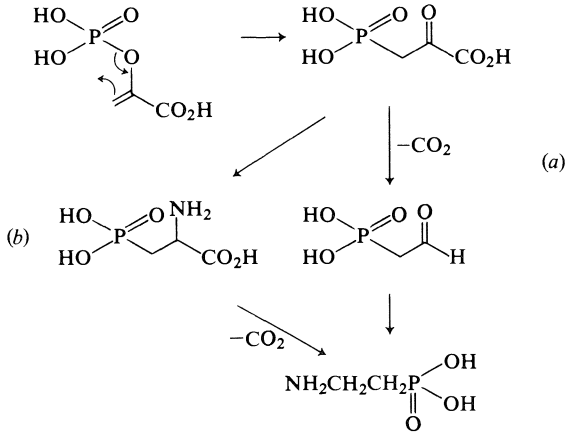
The reaction of α-copper(I)alkanephosphonates with methyl and ethyl oxalyl chlorides gives methyl or ethyl dialkylphosphonopyruvates which, submitted to reductive amination in ethanol at pH 6–7 with sodium cyanohydridoborate ($NaBH_3CN$) and ammonia, or primary amines, lead to phosphonic amino esters; hydrolysis with diluted HCl gives phosphonic amino acids. These three reactions constitute a general way to β-phosphonoalanine and β-alkyl β-phosphonoalanine.

Introduction

Bien qu'il soit l'acide phosphonique le plus répandu, l'acide amino-2 éthylphosphonique (AEPA ou ciliatine) n'est cependant pas le seul phosphonate naturel; d'autres phosphonates de structure apparentée ont été identifiés tel l'acide amino-2 carboxy-2 éthylphosphonique ou phosphonoalanine qui fut isolé par Kittredge et coll. (1) en 1964 et synthétisé par Chambers et Isbell la même année (2).

L'intervention de la phosphonoalanine au cours de la biosynthèse de l'AEPA postulée par Kittredge et coll. (1) a été démontrée par Horiguchi et Rosenberg (3) qui distingue deux voies métaboliques à partir de l'acide phosphonopyruvique provenant du réarrangement intramoléculaire du phosphoénol pyruvate (4). Dans la première (*a*) l'acide phosphonopyruvique après décarboxylation conduit au phosphonoacétaldéhyde converti par transamination en AEPA; dans la seconde (*b*) la transamination de l'acide phosphonopyruvique donne la phosphonoalanine dont la décarboxylation conduit à l'AEPA.

Nous avons montré dans une précédente étude (5) qu'il était possible synthétiquement de réaliser l'amination réductrice du phosphonoacétaldéhyde et des oxo-2 alkanephosphonates en général dans de bonnes conditions (milieu protique, pH 6–7) avec des rendements élevés.



La réalisation à l'échelle préparative de la seconde voie était plus délicate; elle nécessitait l'obtention de dialkylphosphonopyruvates, composés non connus, dont l'amination réductrice constituait un cas intéressant puisque les produits de réaction sont des aminoesters phosphoniques précurseurs d'aminoacides phosphoniques naturels. La séquence réactionnelle suivie ainsi que l'ensemble des structures préparées sont décrites dans la fig. 1.

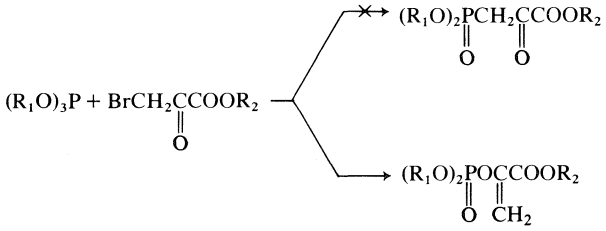
sont pas applicables aux phosphonopyruvates. L'isomérisation de Michaelis–Arbuzov entre un trialkylphosphite et l'α-bromopyruvate conduit exclusivement au phosphoénol pyruvate (réaction de Perkow), dont le réarrangement intramoléculaire en phosphonopyruvate a été postulé mais non démontré.



La mobilité des hydrogènes de l'α-bromopyruvate ne permet pas davantage d'envisager sa réaction avec un phosphite sodé (réaction de Michaelis–Becker), la réaction d'un α-lithioalkanephosphonate (6) sur l'oxalate d'éthyle est également à écarter pour des raisons analogues.

Devant l'échec de ces procédés, nous avons développé une réaction originale qui est la phosphonoalkylation des chlorures de méthoxalyle et d'éthoxalyle. Cette réaction qui utilise le couplage d'un α-cuproalkanephosphonate et d'un chlorure d'acide (7) est très souple et permet d'accéder à une grande variété de structures ainsi qu'en témoigne le Tableau 1.

Les phosphonopyruvates sont sensibles à la basicité du milieu; il est indispensable d'employer la quantité stoéchiométrique de butyllithium préalablement dosé et exempt de lithine; le temps de réaction est limité à cinq heures à −30°C. Les substituants liés au phosphore ni le remplacement de l'oxygène par le soufre n'ont d'effets importants. L'introduction sur le carbone en position α de substituants (Me, Et) perturbe la formation du carbanion phosphonate α-lithié dont l'échange et la condensation sont incomplets; dans ces essais les rendements n'excèdent pas 55%. Il est à remarquer également que le chlorure de méthoxalyle, étant donné sa fragilité, donne toujours des résultats inférieurs.

Les phosphonopyruvates sont des composés fragiles qui se dégradent partiellement à la distillation et lentement à température ambiante. Les dérivés soufrés sont plus stables que les dérivés oxygénés.

Les dérivés oxygénés non substitués sur la position α présentent un pourcentage (20%) de forme énolique décelable en rmn du ^1H et du ^{13}C (voir partie expérimentale).

Amination réductrice des phosphonopyruvates 1 → 2

L'agent aminant est l'acétate d'ammonium ou une amine primaire, l'agent réducteur est le cyanoborohydrure de sodium commercial dans l'éthanol (pH 6–7) à 25°C (8, 9). L'ensemble des résultats est réuni dans le Tableau 2. La réduction a d'abord été étudiée sur les phosphonopyruvates oxygénés ou soufrés non substitués sur la position α (essais **2***c–l*). La fonction carbonyle dans ces structures présente une réactivité inférieure à celle des β-cétophosphonates. Dans des conditions expérimentales équivalentes, le pourcentage d'aminoester pur, contrôlé par rmn et ir n'excède jamais 55%. Une telle désactivation de la molécule attribuable à la présence du groupe ester a été constatée par

TABLEAU 1. Phosphonopyruvates **1**

Essais	pé/Torr (°C)	Rdt (%)
1*a*	100–105/1	10
1*b*	121–125/0.9	52
1*c*	115–120/1	33
1*d*	127–131/0.6	72
1*e*	115–120/0.5	64
1*f*	117–121/0.8	54
1*g*	113–117/0.3	56

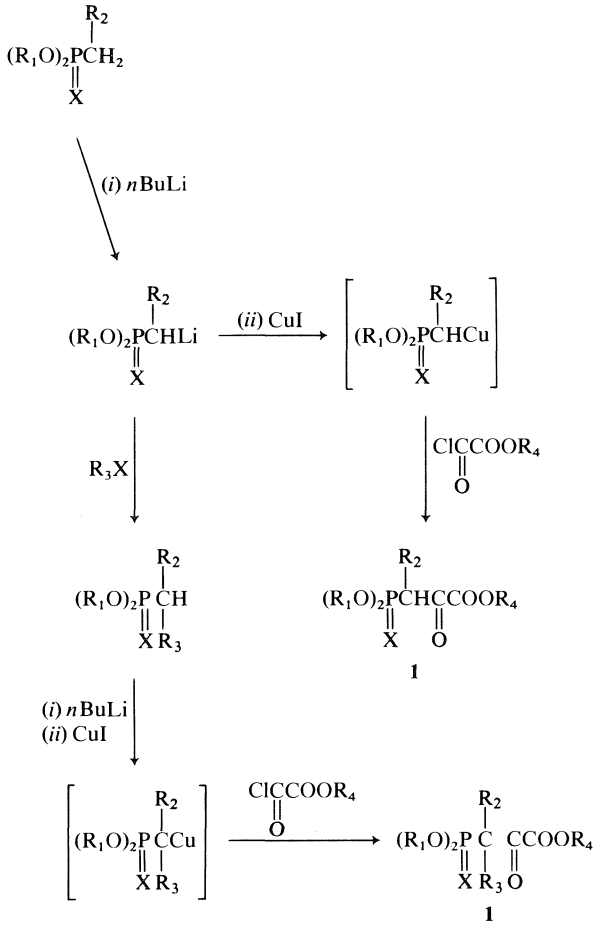
1*l*	131–135/1	67



Borch *et al.* qui n'obtiennent que 21% d'amination réductrice avec la cyclohexanone substituée en 2 par le carboxylate d'éthyle, 50% avec l'acide pyruvique et 47% avec l'acide phénylpyruvique (8). L'emploi de bromure d'ammonium, au lieu d'acétate (essai **2***d'*) n'apporte pas d'amélioration; dans cet essai, on isole parallèlement l'aminoester (ν: 1735 (CO) cm^{-1}) et l'aminoamide (ν: 1675 (CO) cm^{-1}).

$(EtO)_2PCH_2CHCOOEt$ (NH$_2$) $\qquad$ $(EtO)_2PCH_2CHCONH_2$ (NH$_2$)

Les substituants R_1 liés au phosphore n'ont pas d'influence, par contre, le remplacement de l'oxygène par le soufre provoque une chute nette du rendement attribuable très certainement à une gêne stérique, l'aminoréduction des cétones décroissant régulièrement avec leur encombrement (5, 8).

L'importance du facteur stérique est confirmé par les essais réalisés avec des phosphonopyruvates substitués sur la position α. Le rendement de l'amination décroît régulièrement à mesure que croît le degré de substitution ou que grossit le substituant (essais **2***f*, **2***g*, **2***h*).

L'extension de la réaction aux amines primaires (méthylamine, éthylamine) fait l'objet des essais **2***i* et **2***j*. Les résultats sont tout à fait comparables aux précédents. Cependant dans ces deux cas on isole toujours un mélange d'aminoester phosphonique et d'aminoamide décelé en ir et confirmé par rmn ^1H.

L'emploi de la diméthylamine a été un échec; il confirme une observation précédemment signalée lors de l'amination réductrice de l'oxo-2 propylphosphonate de diéthyle (5) pour lequel nous avions constaté la séquence réactionnelle suivante $NH_3 > R_1NH_2 > R_1R_2NH$.

Pour tous les exemples du Tableau 2, les aminoesters phosphoniques sont isolés en milieu acide après double extraction; la fraction recueillie dans la phase éthérée est constituée par l'α-hydroxyéther phosphonique provenant de la réduction des phosphonopyruvates. Cette réaction est confirmée par la réduction directe du phosphonopyruvate **1***d* par le cyanoborohydrure seul dans l'éthanol en présence d'agent protonant. L'α-hydroxyester phosphonique est obtenu avec un rendement de 59%; sa structure est vérifiée par rmn de ^1H et spectrométrie de masse.

$(EtO)_2PCH_2CCOOEt$ (O, O) $\xrightarrow[HCOOH/EtOH]{NaBH_3CN}$ $(EtO)_2PCH_2CHCOOEt$ (O, OH) 59%

Hydrolyse des aminoesters phosphoniques 2 → 3

La libération des fonctions acides carboxyliques et phosphoniques est réalisée par l'acide chlorhydrique 6 *N* porté au reflux pendant une nuit. Les résultats sont rassemblés dans le Tableau 3. Tous les composés sont hydrolysés sans signe apparent de dégradation. Les rendements maximum sont atteints

pour les composés non substitués en α porteurs d'une fonction amine primaire ou secondaire; les rendements minimum sont obtenus pour les composés substitués en α. Nous avons déjà constaté dans une précédente étude l'effet protecteur des substituants en α du phosphore qui contrarient l'attaque nucléophile du phosphoryle (10).

Le brut d'hydrolyse après concentration est passé sur résine Dowex 50WX8 (50–100 mesh) préalablement mise sous forme H^+; on élue à l'eau et recueille la fraction comprise entre pH 2 et pH 7. Cette fraction fournit les aminoacides phosphoniques cristallisés purs par analyse élémentaire et dont la structure est confirmée par rmn ^1H. Les composés isolés fondent avec décomposition aux environs de 230–260°C à l'exception de **3***j* pour lequel le point de décomposition se situe vers 134°C.

Conclusion

L'ensemble de nos résultats montre que les phosphonopyruvates sont des réactifs prometteurs qui représentent une source potentielle originale d'aminoacides phosphoniques malgré l'importance des effets stériques qui représentent les facteurs limitatifs les plus influents.

Partie expérimentale

Les spectres rmn ^1H sont enregistrés à 60 MHz sur Perkin-Elmer R 24 A ou Varian T 60; les solvants sont $CDCl_3$, CCl_4 ou D_2O; le Me_4Si sert de référence interne; les abréviations suivantes sont utilisées: s = singulet, d = doublet, t = triplet, m = multiplet, bl = bande large. Les spectres rmn ^{13}C sont enregistrés à 20 MHz sur Varian CFT 20 ($CDCl_3$, Me_4Si interne). Les spectres ir sont tracés sur Beckman Acculab TM 2 (liquide pur ou pastilles de KBr). Les spectres de masse sont enregistrés à 75 eV (300 μA) sur JEOL JMS D 100 (couplage CPG). Les points de fusion sont déterminés sur banc Kofler et ne sont pas corrigés. La purification des acides aminophosphonocarboxyliques est réalisée sur résine Dowex 50 WX 8 (50–100 mesh). Les analyses élémentaires (C, H, N Technicon) sont en accord avec les formules brutes à ±0.3% près.

Preparation des phosphonopyruvates (Tableau 1)

Exemple-type: essai **1***c*

Dans un ballon à quatre tubulures équipé d'un agitateur mécanique, d'un thermomètre plongeant, d'une ampoule isobare et d'un réfrigérant, on place sous argon 5×10^{-2} mol de *n*-butyllithium dans l'hexane, préalablement dosé (≃ 1.45 *M*); on refroidit à −20°C et introduit un volume égal de tétrahydrofuranne (≃ 35 cm³). Le méthanephosphonate de diéthyle (7.6 g, 5×10^{-2} mol) dans 20 cm³ de THF est introduit goutte à goutte à −65°C. La solution devient rapidement trouble; après 10 min à −65°C, on ajoute l'iodure de cuivre (I) (5×10^{-2} mol + 10%) et élève graduellement la température jusqu'à −30°C. Après 60 min à −30°C, le chlorure de méthoxalyle (6.7 g, 5.5×10^{-2} mol) dans 35 cm³ d'éther est ajouté goutte à goutte; la solution se décolore lentement. Après addition, on maintient la température 5 h à −30°C puis revient lentement à 20°C. On hydrolyse par 40 cm³ d'eau, favorise la précipitation des sels, puis filtre sur fritté garni de Célite, lave le fritté 3 fois par 60 cm³ de CH_2Cl_2, puis repasse la totalité du filtrat sur le même fritté. La solution limpide est décantée et la phase aqueuse extraite une fois à CH_2Cl_2. La phase organique séchée est évaporée et le résidu distillé, pé 115–120°C/1 Torr (rdt = 33%); rmn ^1H (CCl_4) δ(ppm): 1.28 (t, 6H), 3.36 (d, 2H, $^2J_{H-P}$ = 22 Hz), 3.8 (s, 3H), 4.0 (m, 6H), 5.23 (d, $^2J_{H-P}$ = 11 Hz); rmn ^{13}C ($CDCl_3$) δ (ppm): 16.30 (d, CH_3—CH_2—O, $^3J_{P-C}$ = 5.8 Hz), 38.25 (d, CH_2—P, $^1J_{P-C}$ = 127.9 Hz), 53.25 (s, CH_3—O), 62.82 (d, CH_3—CH_2—O, $^2J_{P-C}$ = 5.5 Hz), 89.41 (d, P—CH=C, $^1J_{P-C}$ = 179 Hz), 159.6 (d, C=O, $^2J_{P-C}$ = 49.8 Hz).

Essai **1***g*

Dans le même appareillage que précédemment, on place 5×10^{-2} mol de *n*-butyllithium (≃ 1.45 *M* dans l'hexane), refroidit à −20°C et ajoute un volume équivalent de THF. Le méthanephosphonate de diéthyle (7.6 g, 5×10^{-2} mol) dans 20 cm³ de THF est introduit à −65°C; la solution se trouble. Après 10 min à −65°C, on ajoute l'iodure d'éthyle (7.95 g, 5.1×10^{-2} mol) lentement et laisse la température remonter peu à peu à 20°C. Après 10 min à 20°C, on refroidit à nouveau à −55°C et ajoute 5×10^{-2} mol de *n*-butyllithium. Le mélange est agité 30 min à −55°C. Après addition de CuI à −55°C, la suite des opérations est identique à l'exemple précédent; on distille 7.8 g (rdt = 56%) de phosphonopyruvate, pé 113–117°C/0.3 Torr; rmn ^1H (CCl_4) δ (ppm): 0.93 (t, 3H), 1.33 (m, 9H), 1.86 (m, 2H), 4.13 (m, 7H).

Essai **1***h*

Même appareillage que précédemment et mêmes quantités de *n*-butyllithium et de THF. L'éthanephosphonate de diéthyle (8.3 g, 5×10^{-2} mol) est métallé à −55°C pendant 30 min. L'iodure de méthyle (7.24 g, 5.1×10^{-2} mol) est ajouté à −70°C, puis la température ramenée lentement à 20°C. Après 10 min à 20°C, on refroidit à nouveau à −50°C et ajoute 5×10^{-2} mol de *n*-butyllithium. Après 90 min à −50°C, l'iodure de cuivre (I) est introduit et les opérations poursuivies comme précédemment; pé 115–119°C/0.4 Torr (rdt = 52%); rmn ^1H (CCl_4) δ (ppm): 1.33 (m, 9H), 1.43 (d, 6H, $^3J_{H-P}$ = 16 Hz), 4.13 (m, 6H).

Amination réductrice des phosphonopyruvates (Tableau 2)

En présence d'acétate d'ammonium. Exemple-type: essai **2**d

Un mélange de *O,O*-diéthylphosphono-3 pyruvate d'éthyle (1 g, 3.79×10^{-3} mol), d'acétate d'ammonium sec (3.1 g, 3.97×10^{-2} mol), de cyanoborohydrure de sodium (0.175 g, 2.78×10^{-3} mol) et de tamis moléculaire 4 Å (≃ 0.5 g) dans 25 cm³ d'éthanol absolu est agité magnétiquement 48 h à 25°C dans un flacon hermétiquement clos. Après filtration du tamis, le mélange réactionnel est acidifié à pH 2 par HCl concentré. L'éthanol est évaporé et le résidu dilué par 20 cm³ d'eau. La phase aqueuse est lavée à l'éther (3 × 25 cm³), alcalinisée à pH 9 par KOH en pastilles, saturée avec NaCl et extraite à CH_2Cl_2 (4 × 25 cm³). L'extrait séché et évaporé

donne 0.54 g (54%) d'une huile identifiée à l'amino-2 *O,O*-diéthylphosphono-3 propionate d'éthyle; ir (liq. pur) ν: 3370 et 3290 (NH_2), 1735 (CO), 1240 et 1025 (O—P(O)) cm^{-1}; rmn ^1H ($CDCl_3$) δ (ppm): 1.3 (2t, 9H), 2.4 (s, 2H), 2.9 (m, 2H), 3.3 à 4.6 (m, 7H).

En présence de bromure d'ammonium: essai **2**d′

Une solution équimolaire de NH_4Br et de NH_3 est préparée comme suit. Dans 50 cm^3 d'éthanol absolu, on dissout 2.5×10^{-2} mol de Na, puis ajoute 5×10^{-2} mol de NH_4Br sec; NaBr précipite. Au mélange obtenu, on ajoute le *O,O*-diéthylphosphono-3 pyruvate d'éthyle (1.26 g, 5×10^{-3} mol) et le tamis moléculaire 4 Å (≃ 0.5 g). Après traitement analogue au précédent, on recueille 0.69 g (55% brut) d'un mélange d'amino-2 *O,O*-diéthylphosphono-3 propionate d'éthyle (en particulier ir ν: 1735 (CO) cm^{-1}) et de *O,O*-diéthylphosphono-3 propionamide (en particulier ir ν: 1675 (CO) cm^{-1} et rmn ^1H δ: 7.4 (bl, C(O)—NH_2) ppm).

En présence d'une amine primaire. Exemple-type: essai **2**j *($R_5 = CH_3$)*

Un mélange de *O,O*-diéthylphosphono-3 pyruvate d'éthyle (0.99 g, 3.93×10^{-3} mol), de méthylamine (2.2 g de la solution à 33% dans l'éthanol, 2.36×10^{-2} mol), de $NaBH_3CN$ (0.175 g, 2.78×10^{-3} mol) et de tamis moléculaire 4 Å (≃ 0.5 g), dans 12 cm^3 d'éthanol absolu est ajusté à pH 7 par addition d'acide acétique, puis agité pendant 72 h à 25°C dans un flacon fermé. Le mélange, traité comme précédemment donne 0.67 g (64% brut) d'un mélange de *N*-méthylamino-2 *O,O*-diéthylphosphono-3 propionate d'éthyle majoritaire (en particulier ir ν: 1730 (CO) cm^{-1} et rmn ^1H δ: 2.4 (s, CH_3—N) ppm et de *O,O*-diéthylphosphono-3 *N*-méthylpropionamide (en particulier ir ν: 1670 (CO) cm^{-1}).

Réduction du phosphonopyruvate **1**d

Un mélange de *O,O*-diéthylphosphono-3 pyruvate d'éthyle (3.12 g, 1.23×10^{-2} mol), de $NaBH_3CN$ (0.77 g, 1.23×10^{-2} mol) et de 1 cm^3 d'acide formique pur dans 30 cm^3 d'éthanol absolu est agité pendant 96 h à 25°C dans un flacon bouché. Le mélange est acidifié à pH 2 par HCl concentré. L'éthanol est évaporé; le résidu repris à l'eau est alcalinisé à pH 9 par KOH en pastilles. L'extraction par CH_2Cl_2 (4×25 cm^3) donne 1.87 g (59%) d'hydroxy-2 *O,O*-diéthylphosphono-3 propionate d'éthyle, ir (liq. pur) ν: 3150 (OH), 1740 (CO), 1240 et 1025 (O—P(O)) cm^{-1}; rmn ^1H ($CDCl_3$) δ (ppm): 1.3 (m, 9H), 2.3 (m, 2H), 3.8 à 4.9 (m, 8H); sm: 255 ($M + 1$), 209 (M − OEt), 181, pic de base (M − C(O)OEt), 153 (181 − C_2H_4), 125 (153 − C_2H_4).

Hydrolyse d'un aminoesterphosphonocarboxylique (Tableau 3)

Exemple-type: essai **3**d

L'amino-2 *O,O*-diéthylphosphono-3 propionate d'éthyle (0.43 g, 1.7×10^{-3} mol) est porté au reflux pendant 12 h dans 5 cm^3 d'HCl aqueux 6 *M*. La solution refroidie est extraite par CH_2Cl_2 (2×6 cm^3) et évaporée; le résidu repris à l'eau est évaporé à nouveau (2 fois), puis dissous dans 30 cm^3 d'eau bouillante et décoloré au noir animal. La solution refroidie, incolore (pH ≃ 1), est passée sur colonne chargée de résine Dowex 50 × W 8 (50–100 mesh) préalablement régénérée en cycle H^+. La colonne est éluée à l'eau. Après élution des ions Cl^-, la fraction de pH 2 à 7 est collectée (≃ 80 cm^3); évaporée, elle donne 0.20 g (70%) d'acide amino-2 phosphono-3 propionique (phosphonoalanine) cristallisé pur, pf 225–230°C (déc.) (lit. (2) pf 228°C); rmn ^1H (D_2O) δ (ppm): 2.2 (m, 2H), 4.2 (m, 1H). *Anal.* calc. pour $C_3H_8NO_5P$: C 21.31, H 4.77, N 8.28; trouvé: C 21.65, H 4.84, N 8.24.

Proton and carbon-13 nuclear magnetic resonance studies of the conformational properties of seven-membered heterocycles. 2,4-Benzodithiepin and its derivatives

F. SAURIOL-LORD AND M. ST-JACQUES

Département de Chimie, Université de Montréal, C.P. 6210, Montréal (Qué.), Canada H3C 3V1

Received June 28, 1979

F. SAURIOL-LORD and M. ST-JACQUES. Can. J. Chem. **57**, 3221 (1979).

The conformational properties of 1,3-dithia-5,6-benzocycloheptene (**7**) (2,4-benzodithiepin), three 2,2-dialkyl derivatives, and two monosubstituted derivatives (2-CH_3 and 2-OCH_3) have been investigated by ^1H and ^{13}C dnmr methods. It is reported that the most stable conformation of the seven-membered ring is a chair on which, in the case of the monosubstituted compounds, the 2-CH_3 group adopts an equatorial position while the 2-OCH_3 group takes the axial position. Only for the 2,2-pentamethylene derivative (**10**) was a minor amount (13%) of TB form detected. These results are markedly different from those found previously for the oxygen analogs and the conformational effect of the cyclic heteroatoms will be discussed in terms of the anomeric and steric effects.

F. SAURIOL-LORD et M. ST-JACQUES. Can. J. Chem. **57**, 3221 (1979).

On a étudié les propriétés conformationnelles du dithia-1,3 benzo-5,6 cycloheptène (benzo-2,4 dithiépine) (**7**), de trois dérivés dialkyl-2,2 et de deux dérivés monosubstitués (CH_3-2 et OCH_3-2) en utilisant les méthodes de la rmn dynamique du ^1H et du ^{13}C. Dans le cas des composés monosubstitués on note que la conformation la plus stable des cycles à 7 est la forme chaise dans laquelle le groupe CH_3 en position 2 occupe la position équatoriale tandis que le groupe OCH_3 est axial. On a détecté de faibles quantités (13%) de forme bateau tordu seulement dans le cas du dérivé pentaméthylène-2,2 (**10**). Ces résultats sont très différents de ceux obtenus antérieurement pour les analogues oxygénés et l'effet conformationnel des hétéroatomes dans ces molécules sera discuté en termes d'effets anomériques et stériques.

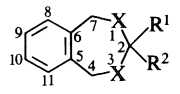
[Traduit par le journal]

Recently results from ^1H and ^{13}C nmr studies (1) of seven-membered heterocyclic compounds containing the —O—CR_2—O— and —O—CHR—O— moieties such as in 2,4-benzodioxepin, its monosubstituted, and its disubstituted derivatives (i.e. **1–6**), have revealed that the ring conformations were determined by the nature and pattern of substitution. Thus were observed: a mixture of chair (C) and twist-boat (TB) forms for **1**, a TB conformation for the dialkyl derivatives **2**, **3**, and **4**, a C form for the 2-methyl derivative **5**, and a TB form for the 2-methoxy derivative **6**; that is, two different ring conformations were observed for the monosubstituted compounds.

It is of obvious interest to extend such observations to ring systems containing other heteroatoms, such as S and N, in order to delineate all of the factors governing the conformational features of seven-membered heterocycles.

The current interest in the properties of 1,3-dithianes (2) suggests that a study of seven-membered heterocycles containing the —S—CR_2—S— and —S—CHR—S— fragments such as for compounds **7–12** ought to yield valuable complementary information useful in characterizing the fundamental differences between the conformational properties of similar families of six and seven-membered heterocycles.

Compounds **7–12** were consequently prepared and studied by ^1H and ^{13}C nmr under experimental conditions similar to those used for compounds **1–6** and the results reported herein show that the sulfur atoms lead to strikingly different conformational properties from those reported for the corresponding oxygen heterocycles **1–6**. Furthermore the observations made are helpful to understand some of the conformational consequences of the anomeric effect (3) in the seven-membered ring.



1, X = O	**7**, X = S	$R^1 = R^2 = H$
2, X = O	**8**, X = S	$R^1 = R^2 = CH_3$
3, X = O	**9**, X = S	R^1, R^2 = tetramethylene
4, X = O	**10**, X = S	R^1, R^2 = pentamethylene
5, X = O	**11**, X = S	$R^1 = H, R^2 = CH_3$
6, X = O	**12**, X = S	$R^1 = H, R^2 = OCH_3$

Results

Compounds **7**, **8**, **9**, and **10** gave ^1H nmr spectral changes at low temperatures whereas ^{13}C nmr spectral modifications were observed only for compounds

0008-4042/79/243221-09$01.00/0

9 and **10**. Spectral and dynamic results will be presented successively as observations from the spectra of each nucleus investigated.

In this work, instead of calling **7** by its systematic name (1,5-dihydro-3*H*-2,4-benzodithiepin), it will be referred to as a derivative of benzocycloheptene and therefore called 1,3-dithia-5,6-benzocycloheptene (1) in order to facilitate comparisons with benzocycloheptene and 1,3-dithianes. Consequently substituents in **8**–**12** are located on C-2.

^1H Nuclear Magnetic Resonance Spectra

Compounds **7**–**12** were not sufficiently soluble in CHF_2Cl, the solvent used for compounds **1**–**6**, and consequently most of the spectra were recorded for solutions in tetrahydrofuran; methylene chloride was also used for **10**. Because signals of the aromatic protons do not provide useful conformational information, only the signals of the aliphatic protons will be analysed in detail in this section.

The 100 MHz ^1H nmr room temperature spectrum of the unsubstituted parent compound **7** shows two singlets, one at δ 3.979 (H(2); methylene protons on C-2) and the other at δ 4.000 (H(4,7); methylene protons on C-4 and C-7). Each signal splits at lower temperature (coalescence temperature $T_c \approx -34°C$ for the most intense signal) to give two overlapping AB quartets at −90°C which are easily assignable from intensity arguments. It is pertinent to point out here that the H(2) signal was not reported to split in an earlier communication (4). At −90°C, the upfield lines of each AB pattern are observed to be broader than the downfield lines, most likely because of unresolved long range coupling (5). A free energy of activation ($\Delta G^{\neq}$) of 11.0 kcal/mol at T_c is calculated for the dynamic process using standard equations (6) with a transmission coefficient of one-half (*vide infra*). This value is comparable to the 10.9 kcal/mol reported earlier (4) from spectral observations at 60 MHz on a solution of **6** in $CHCl_3$/*m*-F-toluene. Table 1 contains a summary of the pertinent parameters.

The ^1H nmr spectrum of **8** (2,2-dimethyl) at room temperature shows two aliphatic singlets at δ 3.944 (H(4,7) and at δ 1.675 (CH_3)). At lower temperature the methyl signal gives a doublet while the H(4,7) line splits into an AB quartet. The pertinent spectral and dynamic parameters are given in Table 1.

The H(4,7) methylene protons at δ 3.960 of **9** (2,2-tetramethylene) also showed the typical singlet to quartet spectral change at low temperatures as summarized in Table 1.

The ^1H nmr spectra of compound **10** (2,2-pentamethylene) have been recorded in both THF-d_8 and CD_2Cl_2. Thus the room temperature spectrum in CD_2Cl_2 shows an H(4,7) singlet at δ 3.912 which splits to give two overlapping AB patterns of equal intensity at −90°C whose components were assigned from intensity patterns. The pertinent data is reported in Table 1 where $\Delta G^{\neq}$ is calculated at −32°C for the AB pattern with the larger chemical shift difference.

The ^1H nmr spectrum of **10** dissolved in THF-d_8 revealed, in addition to the two equally intense AB patterns for H(4,7), two other peaks located at 4.11 and 3.99 ppm and originating from a minor conformation. Because one of the THF-d_8 residual proton signals falls in this region, further ^1H nmr studies of this compound were not carried out since detailed information could be obtained more easily from ^{13}C nmr spectra as reported next.

Finally, compounds **11** (2-methyl) and **12** (2-methoxy) showed temperature independent ^1H nmr spectra as indicated in Table 1.

^{13}C Nuclear Magnetic Resonance Spectra

Only compounds **9** and **10** (the 2,2-tetramethylene and 2,2-pentamethylene derivatives respectively) gave rise to temperature dependent ^{13}C nmr spectra.

Table 2 contains the pertinent ^{13}C chemical shift data for compounds **7**, **8**, **11**, and **12** at high and low temperatures for purpose of comparison with the corresponding data determined for **9** and **10** above and below coalescence of the modified signals.

The assignment of the various carbon signals is relatively straightforward and was made from symmetry arguments which distinguished between the C-2 and the more intense C-4,7 signals. The C-5,6 signal is the least intense of the three aromatic lines owing to relaxation effects on these non-protonated carbon atoms. The remaining two aromatic signals belonging to the two different aromatic carbon pairs left were assigned by analogy with previous conclusions for benzocycloheptene (7).

The spectral modification observed for compound **9** is limited to the C-2′,5′ signals (δ 43.63) of the five-membered ring which splits into a doublet below −34°C (T_c) whose equally intense components are separated by 14.6 Hz at −90°C. A $\Delta G^{\neq}$ value of 11.9 kcal/mol was calculated at T_c. The pertinent shift data is summarized in Table 2.

The ^{13}C nmr spectral investigation of **10** (2,2-pentamethylene) was carried out at two frequencies (22.63 and 75.4 MHz) in three different solvents (tetrahydrofuran, methylene chloride-d_2, and diethyl ether).

Firstly, the simplest spectral behavior was observed in methylene chloride-d_2 at 22.63 MHz whereby at low temperatures only the C-2′,6′ and the C-3′,5′ signals each split into doublets with equally intense

TABLE 1. ^{1}H nuclear magnetic resonance spectral and dynamic parameters[a] for compounds **7** to **12**

Compound	Temperature (°C)	δ_A	δ_{av}	δ_B	$^2J_{AB}$(Hz)[b]	T_c(°C)	$\Delta G^{\ddagger}$(kcal/mol)[c]

12	25	~4.7		[h]	14.8		

[a]At 100 MHz for solutions in THF-d_8 unless mentioned otherwise and containing internal Me_4Si. Unless otherwise mentioned, the data refer to the signals of the benzylic methylene protons on C-4 and C-7.
[b]The estimated uncertainty in coupling constants is ±0.5 Hz. Absolute values of couplings are given.
[c]Calculated at T_c using a transmission coefficient of one-half. The errors in $\Delta G^{\ddagger}$ are estimated to be 0.5 kcal/mol for 7 and **10** and 0.3 for **8** and **9**.
[d]This signal arises from the methylene protons H(2).
[e]This signal belongs to the methyl protons.
[f]The solvent is CD_2Cl_2 instead of THF-d_8. Owing to overlap of THF lines with the upfield components of the AB patterns at −90°C complete analysis was not possible at 100 MHz.
[g]The chemical shifts for two overlapping AB quartets are reported here.
[h]The upfield part of the AB quartet overlapped with signals from the solvent and was not further analysed.

TABLE 2. ^{13}C nuclear magnetic resonance chemical shift data for compounds **7** to **12** at high and low temperatures[a]

[a]At 22.63 MHz for solutions in THF (unless mentioned otherwise) containing internal Me_4Si and CD_2Cl_2 (13%) for field locking purpose.
[b]The indicated signal has undergone a splitting into two lines of equal intensities at low temperatures due to the non equivalence of C-2′ and C-5′. Signals not assigned.
[c]Due to strong overlap with a solvent signal, the assignment could not be made unambiguously.
[d]Solution in CD_2Cl_2; spectra taken at 22.63 MHz.
[e]Two equally intense lines arising from the non equivalence of C-2′ and C-6′. Signals not assigned to the respective carbons.
[f]Two equally intense lines arising from C-3′ and C-5′. Signals not assigned to the respective carbons.
[g]Solution in diethyl ether; spectrum at −90°C taken at 75.4 MHz.
[h]The symbols Mj and Mn stand for: Mj = major conformer and Mn = minor conformer.

lines. The C-2′ and C-6′ lines coalesce at −34°C and the $\Delta G^{\ddagger}$ value calculated is 11.2 kcal/mol. Furthermore it was observed that several lines (C-2 and C-5,6) broaden somewhat at intermediate temperatures and then sharpen up at lower temperatures. Such an observation is compatible with the existence of a mixture of conformers, one of which is less abundant than 5% (8).

The 22.63 MHz ^{13}C nmr spectra of **10** in THF showed, in addition to the above splitting, the presence at −80°C of lesser intense lines belonging to a minor conformation (about 13%). In fact the C-2 and C-5,6 lines clearly show a splitting into two unequal lines. Thus the C-2 line (δ_c 58.73) splits into two lines located at 57.48 and 61.05 ppm (the latter being less intense), whereas the C-5,6 line (δ 140.59) splits into two lines located at 138.61 and 141.46 ppm (the former being less intense).

Because some overlap was observed between one of the THF signals and some signals belonging to **10**, the spectra was also recorded in diethyl ether at 22.63 MHz. It showed results similar to those reported for the THF solution with the advantage that all the signals of **10** were clearly visible at room temperature. On the other hand, the low temperature spectra showed obstruction from the solvent lines of diethyl ether as was the case in THF. More satisfactory spectra were obtained only at higher field (75.4 MHz) for both solvents but since the diethyl ether solution gave less overlapping, the data obtained for this solvent is summarized in Table 2.

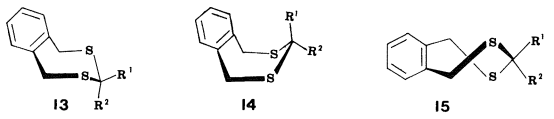
The assignment of the signals of **10** was made through comparison with the shifts of the other disubstituted derivatives **8** and **9**. For the spectrum of **10** in methylene chloride-d_2, the signals of the six-membered ring carbon atoms observed at room temperature were assigned from intensity arguments (C-4′ being least intense) and substituent effects predicted (1) to shift the C-2′ and C-5′ signals more downfield than C-3′ and C-5′.

The assignment of the signals of the two conformers of **10** in diethyl ether was also carried out through comparisons. The signals of the major conformer appeared at chemical shifts very similar to those observed in methylene chloride-d_2. The weaker signals (labeled Mn in Table 2) could also be assigned readily; in this case relative intensities permitted the assignment of the less intense line at 25.95 ppm to C-4′ and the more intense line at 24.22 ppm to C-3′,5′.

Discussion

Conformations of the Seven-membered Rings

Previously published (4) low temperature 60 MHz ^1H nmr spectra of **7** showed a spectral change for the H(4,7) signals but apparently not for H(2). Consequently the nature of its most stable conformation could not be deduced with absolute certainty. On the other hand, the 100 MHz data reported in Table 1 show that the methylene protons on C-2 are non-equivalent at −90°C thus ruling out the TB form (**15**; $R^1 = R^2 = H$) as the major conformation. The absence of a ^{13}C nmr spectral change indicates that only one conformation can be detected by nmr. Because TB is less energetic than B (**14**), then the most stable conformation of **7** must be the chair (**13**) as was the case (1) for the oxygen analog of **7**, namely **1** which, in contrast, was found to exist as a mixture of conformations involving a minor amount of TB in addition to C.



The 2,2-dimethyl derivative **8** is found to exist only in the C form in agreement with the nonequivalence of the methyl ^1H nmr signals at −90°C as reported in Table 1. Interestingly the ^{13}C methyl signals were found to be accidentally equivalent at low temperatures contrary to the proton signals. Our data therefore confirm earlier 60 MHz ^1H nmr observations (4).

In the case of **9** (2,2-tetramethylene), the ^{13}C signals of C-2′ and C-5′ (of the five-membered ring) show non-equivalence in agreement with axial and equatorial positions of the chair conformation. Thus, it is seen that the most stable conformations of the seven-membered ring of **8** and **9** are different from those of the oxygen analogs **2** and **3** for which only the TB form was detected by nmr (1).

For compound **10** (2,2-pentamethylene) it is the ^{13}C nmr data which are most revealing. They provide clearcut evidence for the existence of a mixture of conformations in both tetrahydrofuran and diethyl ether. Table 2 and Fig. 1 show that the ^{13}C chemical shift of the C-5,6 signals is most informative and, as was the case (1) for **2**, **3**, and **4**, suggest that C is the major conformer while TB is the minor conformer. Furthermore, in methylene chloride-d_2, the amount of TB form decreases beyond the minimum detectable limit of ^{13}C nmr. These observations are to be contrasted with earlier ones for **4** which showed that only the TB form was detected (1).

The absence of spectral changes for **11** (2-methyl) is compatible with a single conformation which is most clearly established to be the chair with an equatorial methyl group from argument based on the ^{13}C chemical shift of C-4,7 given in Table 2 and shown in Fig. 1. Thus the absence of a significant upfield γ-shift (*vide infra*) relative to the parent compound **7** argues most convincingly in favor of the chair form

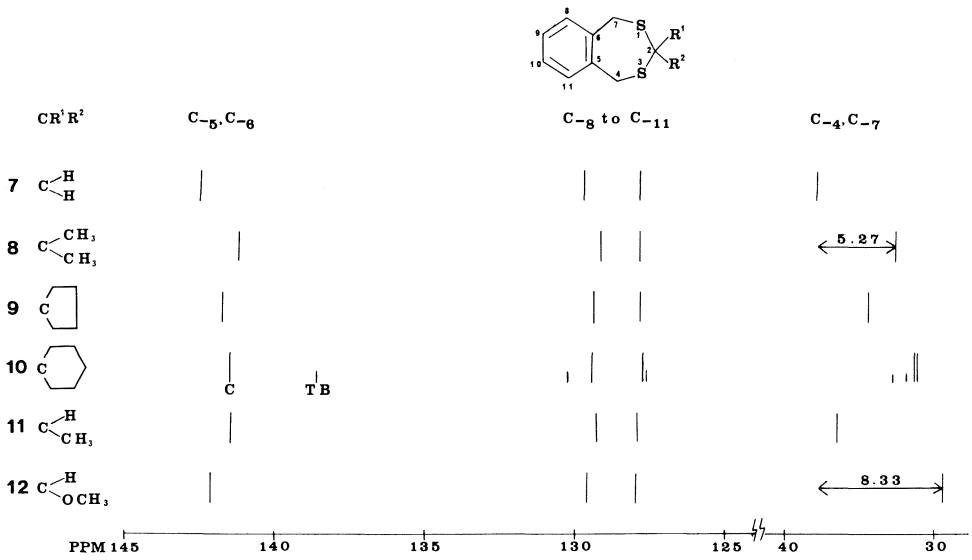


FIG. 1. Diagram comparing the carbon-13 chemical shifts at low temperature of compounds **7** to **12** summarized in Table 2.

which is also the conformation adopted by the oxygen analog **5**.

Compound **12** (2-methoxy) is also characterized by the absence of spectral changes unlike observations reported for its analog **6**. The ^{13}C chemical shift of the C-5,6 signal shown in Fig. 1 is in agreement (1) with C rather than TB. Furthermore the strong upfield γ-shift (8.33 ppm) of the C-4,7 signal suggests that the 2-methoxy group must be located at the C-2 axial position of the chair form.

Conformational Consequences of the Anomeric and Steric Effects

The conclusion that the chair form is the most stable for all sulfur heterocycles **7–12** differs radically from results reported previously (1) for the series of compounds **1–6** and summarized earlier in the text.

The differences brought about by the change of the ring heteroatoms can be explained quite well in terms of the so-called "anomeric effect" modulated by differences in steric interactions.

First introduced in the carbohydrate field to explain the axial preference of polar substituents in pyranose sugars (9), the anomeric effect has later been generalized to systems containing the R—X—C—Y moiety where X and Y have at least one unshared electron pair (10). As a consequence it was shown that a gauche arrangement about the X—C bond was most stable.

Although explained in several ways (3, 10), the anomeric effect is essentially the manifestation of electronic interactions which stabilize those conformations possessing the geometrical features favoring the interactions.

Two cases must be examined with respect to our work. The first one involves the two heteroatoms of the seven-membered ring, while the second case is concerned with the additional effect caused by the oxygen atom of the methoxy substituent in **6** and **12**.

The analysis of the acetal bond sequence —O(1)—C—O(3)— of **1** can best begin with results for dimethoxymethane for which it was established that the g^+g^+ (TB-like) conformation is more stable than the g^+g^- (C-like) arrangement (11). Furthermore, the solvent effect observed (1) for **1** whereby the proportion of the TB form increases with decreasing polarity of the solvent (21% in CHF_2Cl (1.48 *D*) to 33% in dimethyl ether (1.30 *D*)) is in line with the trend expected from consideration of predictions made from the generalized anomeric effect (10). Thus, the preferential stabilization of TB with respect to C for **1** reduces the free energy difference (ΔG^0) between these two conformations to 0.57 kcal/mol in CHF_2Cl at $-130°C$ or 0.40 kcal/mol in dimethyl ether at $-128°C$ and consequently signals for both C and TB forms of **1** are detected by nmr. In contrast only chair signals were detected for benzocycloheptene (12).

The origin of the anomeric effect has been attributed to the participation of an *anti* lone pair of electrons in a stabilizing n–σ^* interaction (13). In addition, it has been suggested that a distinction should be made between the two lone pairs of a given oxygen atom whereby one is 2*p*-like and a better donor than the other lone pair which is sp^2-like and a poorer donor (14).[1]

The analysis of the relative electronic stabilization in the C and TB forms is consequently dependent on the model selected. Firstly, when it is assumed that

[1]See also ref. 13, p. 167.

both lone pairs are equivalent, it is difficult to conclude that C should not be as stabilized as TB because each C—O bond of the C form as well as of TB contains an *anti* lone pair. If, on the other hand, the oxygen lone pairs are considered to be different, then the *anti* lone pairs in C are sp^2-like whereas in TB one *anti* lone pair is 2*p*-like while the other is sp^2-like. The second model therefore appears to predict a greater stabilization of TB.

It is also conceivable that a greater steric interaction may exist in the C form of **1**, between the axial protons on C-2, C-4, and C-7, than for the C form of benzocycloheptene. This factor could then contribute partially to the smaller energy difference between the C and TB forms of **1**. Considering that a solvent change is expected to alter electronic effects but not steric effects (15), the observed solvent effect on the C:TB ratio (3.8 in CHF_2Cl and 2.0 in dimethyl ether) may be useful to assess the relative importance of the various factors. This observation argues in favor of an electronic origin and it is in line with predictions made through consideration of the stereoelectronic effect, but most likely is not solely due to it because other electronic effects related to the dipole and quadrupole moments of the whole molecule may also be significant. It therefore appears unrealistic to select one of the orbital models for the stereoelectronic effect from the results for **1**.

Contrastingly, our results for **7** indicate that the energy difference between C and TB is too large to permit detection of both conformations by nmr. This observation is no doubt related to the longer C—S bond length (16) (C—S = 1.82 Å, C—O = 1.43 Å, and C—C = 1.54 Å) either through its effect on the degree of stabilization by the anomeric effect for the S—C—S fragment and/or its consequence on steric repulsion between the axial protons in C.

It is interesting to note that for the simplest model, 2,4-dithiapentane, vibrational analysis suggested that the g^+g^- arrangement (or GG′, C-like) is the least energetic (17) and that a mixture of three other conformations was thought to exist in the liquid phase. Another report (18), in contrast, concluded in favor of a single planar form on the basis of photoelectron spectroscopy data.

Systematized information from theoretical origin has suggested that the lone pairs of S are better intrinsic donors than those of O in a $n \rightarrow \sigma^*$ interaction and furthermore that the C—S bond is a better acceptor than C—O.[2] The extent of orbital overlap in the S—C—S fragment is expected to be weaker than for the O—C—O moiety (19) because of the longer S—C bond. The result of these opposing effects appears to have escaped sufficient quantification for application to compound **7**.

Our experimental results for **7** are therefore significant in that they show that the C form, with a g^+g^- arrangement about the —S—C—S— bonds, is most stable and that TB, with a g^+g^+ arrangement, is not detected by either ^1H or ^{13}C nmr. Furthermore, our observation that C is the most stable conformation for the 2,2-disubstituted compounds **8**, **9**, and **10** shows that the longer C—S bonds attenuate the effect of steric repulsion in these compounds. Such steric effects were strongly destabilizing for **2**, **3**, and **4** which were reported to exist only in the TB form (1).

Nevertheless, the observation of a minor amount of TB ($\sim$13% in THF at $-90°C$) for **10** indicates that the free energy difference between the C and TB forms of the seven-membered ring is not very large and that seemingly small differences as exist between **8**, **9**, and **10** are sufficient to lead to detectable amounts of the minor TB conformation. Furthermore, the solvent effect noted for **10** is rationalizable in terms of electronic effects of which the stereoelectronic $n \rightarrow \sigma^*$ effect could be dominant.

The presence of the 2-methoxy substituent in **6** and **12** further complicates the evaluation of the stereoelectronic stabilization for the various possible conformations of each of these compounds.

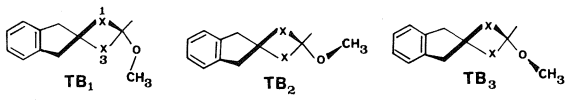
Let us begin with the examination of 2-methoxy-1,3-dioxane (**16**) which can serve as a model for **6**. It has recently been observed[3] that **16** exists as a mixture of conformers in CHF_2Cl whereby, at $-148°C$, 30% of chair with the substituent in the axial position (represented by C-a) and 70% of chair with an equatorial methoxy group (represented by C-e) were observed. Because steric interactions should be strong in the C-a conformation of **6** as a consequence of the somewhat greater puckering of the seven-membered ring (12), this form is not expected to be more dominant than for **16**. But instead of a mixture of C-a (minor) and C-e (major) forms, only the TB form was detected for **6** in CHF_2Cl.

The assessment of the relative importance of stereoelectronic interactions in the various conformations of orthoformates is more complex than in acetals. Results published for trimethoxymethane (20), the simplest model compound, revealed that it exists as a mixture of two conformers, called TGG and TGG′, in solution and in the vapor phase. It was also suggested that TGG′ is more stable by about 0.6 kcal/mol. The spatial arrangements about the three C—O bonds for these two conformations are very similar to those characterizing two of the three possible TB conformations of **6** which arise from

[2]Reference 13, p. 154.

[3]F. Sauriol. Unpublished results.

different rotational positions of the methoxy group. Thus the TB_2 (X = O) form is equivalent to TGG and TB_3 (X = O) is equivalent to TGG′.



Rotation of the methoxy group is expected (21) to be rapid at −150°C on the nmr time scale so that it is not possible to determine whether or not a mixture of rotational forms actually exists for **6**. Nevertheless, results for the simple model fit very well with our identification of TB as the most stable ring conformation for **6**. It therefore appears that a steric interaction destabilizes C-a and that TB becomes the most stable conformation of **6** because it is stabilized by the stereoelectronic interactions whereas C-e is not.

With regard to compound **12**, the longer C—S bonds should attenuate the importance of steric repulsion in the C-a form as was found to be the case for the disubstituted derivatives **8**, **9**, and **10**. Consequently the anomeric effect, which is expected to stabilize C-a at least as much as TB, best explains the observation of the single C-a form for **12**. It is interesting to point out that the analogous six-membered heterocycle 2-methoxy-1,3-dithiane has also been found[3] to exist solely in the C-a form in CHF_2Cl and in $CBrF_3$.

Conformational Dynamics

The conformational inversion of the chair form of benzocycloheptene and its derivatives is known to involve a rate-determining chair-to-boat step (1, 22, 23). Consequently the $\Delta G^{\ddagger}$ values reported in Table 1 characterize this interconversion process for compounds **7** to **9**. Thus it is seen that the substitution of a *gem*-dimethyl group on C-2 affects $\Delta G^{\ddagger}$ only slightly as was observed to be the case for analogous substitution on 1,3-dithiane (24).

The complete description of the averaging processes responsible for the spectral changes observed for **10** must focus on the inversion processes of both the six- and seven-membered rings. Considering that 1,1-dialkyl cyclohexanes are characterized by $\Delta G^{\ddagger}$ values in the range 10–11 kcal/mol,[4] it can be concluded that at −90°C the ring inversion of the chair form of both rings is slow on the nmr time scale. But because $\Delta G^{\ddagger}$ for chair inversion of the seven-membered ring is expected to be slightly higher than for the six-membered ring, then the spectral change of the benzylic protons of **10** yields a $\Delta G^{\ddagger}$ value characteristic of the larger ring. Furthermore, the ^{13}C nmr spectral change observed for **10** in tetrahydrofuran and diethyl ether, which provides direct information on the chair-to-boat step, is compatible with the above conclusion.

Finally, no dynamic information was obtained for **11** and **12** because of the absence of a spectral change as a consequence of the existence of only one conformation detectable by nmr. Nevertheless it is expected that $\Delta G^{\ddagger}$ for chair inversion ought to be comparable to the values determined for compounds **7**–**10**.

^1H and ^{13}C Chemical Shifts

Table 1 reveals that the chemical shifts of the individual methylene protons on C-4 (and C-7) determined at low temperatures are very similar for compounds **7**, **8**, and **9** for which the chemical shift differences are 0.78, 0.83, and 0.74 ppm respectively. In addition, the shift differences of 0.92 and 0.53 ppm determined for **10** are also comparatively large.

The upfield halves of the AB patterns of the H(2) and H(4) methylene protons of **7** were observed to be broader than the lower field halves in accord with long range coupling (5) expected for equatorial protons. Consequently the axial H(2) and H(4) protons are downfield from the equatorial protons as was reported for the methylene protons α to the sulfur atom in thiane and 1,3-dithiane (25, 26). This specific effect of sulfur has been explained in terms of the C—S bond anisotropy (25).

The particularly large chemical shift differences in **7**, **8**, **9**, and **10** arise because in the parent benzocycloheptene the benzylic methylene protons are separated by −0.106 ppm (12) compared to 0.48 ppm for cyclohexane (27), where the negative sign indicates that for benzocycloheptene the axial protons absorb at lower field contrary to the observation for cyclohexane. The contribution from the C—S bond anisotropy therefore adds on to these basic reference values.

The ^{13}C chemical shifts also show certain characteristics of importance. Firstly the C-2 signal of **7** appears about 7 ppm downfield from that for 1,3-dithiane (2*b*); this difference is too large to be caused by the different solvents and must arise as a consequence of ring size. Methyl and dimethyl substitution produce a downfield shift of the C-2 signal by 11.7 and 13.9 ppm respectively at room temperature; these values are very close to the 10.2 and 13.1 ppm determined for the six-membered analogs (2*b*). Table 2 further shows that lowering the temperature affects the C-2 chemical shift of **7** and **11** about equally but that **8** is perturbed only slightly. Consequently the substituent effects determined at low temperatures are slightly different (i.e. 11.4 and 11.1 ppm).

The trend of C-2 substitution effects for the di-

[4]Reference 6, p. 582.

substituted compounds **8**, **9**, and **10** (+13.9, +24.5, and +19.2 ppm at room temperature) is similar to that observed for analogously substituted cyclohexane derivatives (+3.2, +15.5, and +5.5 ppm) (28).

Probably the most important ^{13}C substituent parameter is the so-called γ-effect because of its utility in providing stereochemical information (29). Thus for the series **8–12** the chemical shift of the carbons 4 and 7 are governed by this effect. Table 2 reveals that for **8** the C-4,7 upfield shift is −3.37 ppm at room temperature; this value is somewhat comparable to the −2.89 ppm determined for 2,2-dimethyl-1,3-dithiane (2*b*). It is interesting to note that the γ-effect for **8** determined at −80°C becomes −5.27 ppm as shown in Fig. 1. Furthermore, the trend observed for the C-4,7 shifts in **8**, **9**, **10** (Mj) as depicted in Fig. 1 is similar to that observed for analogously substituted derivatives of cyclohexane (28) as well as for **2**, **3**, and **4** (1).

The very small γ-shift observed for **11** indicates the absence of an axial substituent (29) and is compatible with a chair conformation with an equatorial group. In contrast, the C-4,7 signal of **12** is shifted upfield by −6.39 ppm at room temperature (−8,33 ppm at low temperature as shown in Fig. 1). This large upfield shift is in accord with substitution at the axial position so that **12** exists as a chair with OCH_3 located solely in the axial position within the limits of detection by nmr. The corresponding upfield shift for 2-methoxy-1,3-dithiane is −5.66 at low temperature.[3]

It is interesting to note that the axial and equatorial methyl ^{13}C signals of **8** are accidentally equivalent at low temperature whereas two C-2′,5′ signals are observed for **9** and two C-2′,6′ signals for **10**. The particularity effect of sulfur on ^{13}C chemical shifts has been noted previously (26).

The aromatic signals of the chair conformations are somewhat similar for all compounds as seen in Fig. 1. Furthermore, in the case of **10**, the C-5,6 TB signal is most different from that of the C form; a separation of 3.7 ppm is observed. A similar upfield shift of the C-5,6 TB signal was also reported (1) for **1**.

Distinct TB signals are also observed for the other aromatic carbons as well as for C-4,7 and other carbons. However, the fact that only chair signals are observed for **7**, the reference compound, makes it difficult to attempt to rationalize the chemical shifts characteristic of the TB form. As was shown for **1**, proper reference parameters are required for a convincing explanation of substituent effects on the chemical shifts for a given conformation (1). Moreover, the different effects noted previously as a result of substitution of O by S suggest that extrapolations from one series to the other is dangerous (26).

Experimental

Melting points are uncorrected and were determined using a Büchi melting point apparatus. High-resolution mass spectra at 70 eV were recorded using an Associated Electrical Industries Model MS-902 spectrometer.

The variable temperature ^1H nmr spectra at 100 MHz were obtained using a JEOL JNM-4H-100 spectrometer equipped with a temperature control unit Model JES-VT-3 under conditions described earlier (1).

The variable temperature ^{13}C nmr spectra were recorded in the FT mode with a Bruker WH-90 spectrometer operating at 22.63 MHz and equipped with the Bruker variable temperature accessory as described elsewhere (1). The pulse repetition was normally set equal to the acquisition time, except for the integration of the signals of **10** at −90°C, when a pulse repetition time of 5 s was used.

The rate constants were determined at the coalescence temperature using the equation $k = \Pi\Delta\nu\sqrt{2}$ for singlet to doublet splitting in ^{13}C nmr spectra (i.e., for **9** and **10**; in the case of **10** where the lines are of unequal intensity the equation provides an acceptable estimate (30) and the equation $k = \Pi(\Delta\nu^2 + 6J^2)^{1/2}/\sqrt{2}$ for singlet to AB splitting (31) in ^1H nmr spectra (i.e., for **7** to **10**). The free-energy barriers (ΔG^+) were calculated from standard equations (6) using a transmission coefficient of one-half which is most appropriate to describe the chair-to-boat step of the chair inversion.

Syntheses

Compounds **7** to **12** were prepared from 1,2-benzenedimethanethiol (32) (**17**) used as starting material based on a procedure published by Shahak and Bergmann (33). The starting dithiol **17** was prepared from 1,2-benzenedimethanol (Aldrich) using standard reactions involving a transformation into the dichloro derivative with hydrochloric acid and zinc dichloride (34) followed by conversion into the dithiol using thiourea.[5]

*1,3-Dithia-5,6-benzocycloheptene (**7**)*

Compound **7** was prepared by a procedure already published (33). Its ^1H nmr spectrum was identical to that published (4) and its ^{13}C nmr chemical shifts reported in Table 2 confirmed the structure of **7**.

*2,2-Dimethyl-1,3-dithia-5,6-benzocycloheptene (**8**)*

A mixture of 2.2 g of the dithiol **17**, 1 mL of acetone, 60 mL of isopropanol, and 5 mL of a solution of 30% sulfuric acid in methanol was refluxed using a Dean–Stark apparatus to collect about 30 mL of distillate. The reddish solution remaining in the reaction flask was then cooled and a solid compound precipitated; it was filtered and recrystallized from isopropanol A white solid (mp 134–135°C) was thus obtained in about 40% yield. Its ^1H nmr spectrum was identical to that published (4) for **8** and the ^{13}C nmr data reported in Table 2 confirmed the structure.

*2,2-Tetramethylene-1,3-dithia-5,6-benzocycloheptene (**9**)*

This compound was prepared by a procedure identical to that used for **8** from 0.91 g of the dithiol **17**, 25 mL of isopropanol, 0.48 mL of cyclopentanone, and 2.1 mL of 30% sulfuric acid in methanol. After recrystallization from methanol about 47% of **9** was obtained (mp 125–126°C). This product was characterized by its ^1H and ^{13}C nmr spectra (Tables 1 and 2) and by its high-resolution mass spectrum. *Mol. Wt.* calcd. for $C_{13}H_{16}S_2$: 236.0692; found (ms 70 eV): 236.0773.

*2,2-Pentamethylene-1,3-dithia-5,6-benzocycloheptene (**10**)*

This compound was prepared by a procedure similar to that

[5]Reference 34, p. 497.

used for **8** and **9** from 1.5 g of **17**, 30 mL of isopropanol, 0.88 g of cyclohexanone, and 2.6 mL of 30% sulfuric acid in methanol. Recrystallization from methanol gave 42% of compound **10** (mp 97.5–98°C) which was characterized by its ^1H and ^{13}C nmr spectra (Tables 1 and 2) and by its mass spectrum. *Mol. Wt.* calcd. for $C_{14}H_{18}S_2$: 250.0849; found (ms 70 eV): 250.0847.

*2-Methyl-1,3-dithia-5,6-benzocycloheptene (**11**)*

This compound was prepared by the same procedure as **8** using 1.6 g of **17**, 0.54 mL of acetaldehyde, 30 mL of isopropanol, and 0.55 mL of concentrated hydrochloric acid. Recrystallization in isopropanol gave 40% of **11** (mp 118–119°C) which was characterized by its ^1H and ^{13}C nmr spectra (Tables 1 and 2) and by its mass spectrum. *Mol. Wt.* calcd. for $C_{10}H_{12}S_2$: 196.0380; found (ms 70 eV): 196.0382.

*2-Methoxy-1,3-dithia-5,6-benzocycloheptene (**12**)*

The preparation of this compound involved a procedure recently published for six-membered rings (35).

A solution of 15 mL of *n*-butyllithium in hexane (0.018 mol) and 25 mL of anhydrous THF were placed in a 50 mL flask which was maintained at 0°C under a nitrogen atmosphere. A solution of 1.7 g (10 mmol) of **17** in 10 mL of dry THF was then added dropwise. After the addition and 5 min of stirring, 1.15 g (10 mmol) of dichloromethylmethyl ether were added dropwise. The reaction mixture was then stirred at room temperature for 2 h. Evaporation of the solvent gave an orange oil. The addition of chloroform dissolved most of the product. The solution was then filtered and the chloroform evaporated, after which 15 mL of methanol were added to the residue. The methanol was decanted from the viscous product and the washing procedure was repeated. Chromatography on silica gel (elution with ether) gave pure **12** as a white crystalline compound which sublimed at about 95°C in a sealed capillary. The pure compound was characterized by its ^1H and ^{13}C nmr spectra (Tables 1 and 2) and by its mass spectrum. *Mol. Wt.* calcd. for $C_{10}H_{12}S_2O$: 212.0329; found (ms 70 eV): 212.0832.

Acknowledgments

We wish to acknowledge the contribution of Mr. A. Blanchette for the preparation of some of the compounds studied, the technical assistance of Mr. R. Mayer, and financial assistance from the National Research Council of Canada.

Received June 4, 1979

W. V. F. BROOKS, JACK PASSMORE, and E. KEITH RICHARDSON. Can. J. Chem. **57**, 3230 (1979).

$SeBr_3AsF_6$ and $TeBr_3AsF_6$ were prepared from the elements and an excess of bromine and arsenic pentafluoride, as well as from $Se_4(AsF_6)_2$ and $Te_4(AsF_6)_2$ with excess bromine. $SeBr_3SbF_6$ was prepared from $Se_4(SbF_6)_2$ and bromine, and $TeBr_3AsF_6$ from tellurium tetrabromide and arsenic pentafluoride. Br_3AsF_6 was found to oxidize arsenic trifluoride and sulphur dioxide to arsenic pentafluoride and SO_2BrF respectively. Reaction pathways to the tribromochalcogen cations are discussed. Raman spectra of the tribromochalcogen salts were obtained. Assignments were confirmed, and force constants derived from normal coordinate analyses and compared with those derived for SBr_3^+, PBr_3, $AsBr_3$, and $SbBr_3$.

W. V. F. BROOKS, JACK PASSMORE et E. KEITH RICHARDSON. Can. J. Chem. **57**, 3230 (1979).

On a préparé l'hexafluoroarsenate de tribromosélénium et l'hexafluoroarsenate de tribromotellure à partir de leurs éléments et d'un excès de brome, ainsi qu'à partir du $Se_4(AsF_6)_2$ et du $Te_4(AsF_6)_2$ et d'un excès de brome. Le $SeBr_3S_6F_6$ est préparé à partir du $Se_4(SbF_6)_2$ et du brome, et le $TeBr_3AsF_6$ est obtenu à partir du tétrabromure de tellure et du pentafluorure d'arsenic. On a trouvé que le Br_3AsF_6 oxyde le trifluorure d'arsenic et le bioxyde de soufre respectivement en pentafluorure d'arsenic et en SO_2BrF. On discute des schémas de réaction des cations tribromochalcogènes. On a obtenu les spectres Raman des sels de tribromochalcogènes. Les attributions sont confirmées et les constantes de forces dérivées des analyses normales de coordonnées sont comparées à celles obtenus pour SBr_3^+, PBr_3, $AsBr_3$ et $SbBr_3$.
[Traduit par le journal]

Salts of MF_3^+ and MCl_3^+ (M = S, Se, and Te) (1–6) have been prepared and characterized. These species are of interest as simple chalcogen halogen cations, and as species that may be given on autoionisation of the neutral chalcogen tetrahalides. Trihalochalcogen cations have been prepared as salts of very weakly basic anions, where the tetrahalochalcogen has not been reported, e.g. SBr_3AsF_6 and SeI_3AsF_6 are stable whereas SBr_4 and SeI_4 are as yet unknown (7, 8). The 1:1 adduct $TeBr_4 \cdot AlBr_3$ has been prepared (9, 10) and assigned an ionic formulation on the basis of nqr spectra (11). On completion of this work the preparation of $SeBr_3AlCl_4$ and $SeBr_3AlBr_4$ were reported, and ionic formulations assigned on the basis of Raman spectra (12).

The preparations and Raman spectra of $SeBr_3AsF_6$, $SeBr_3SbF_6$, and $TeBr_3AsF_6$, briefly referred to in an earlier publication (7), are reported below.

Experimental

Except where stated, apparatus, reagents, and techniques are the same as those described (7, 8, 13). Elemental analyses were by Alfred Bernhardt, West Germany.

Literature methods (14) were used to prepare $Te_4(AsF_6)_2$ and $Se_4(AsF_6)_2$. Tellurium tetrabromide was prepared from the elements, and Br_3AsF_6 and Br_3SbF_6 by the method of Glemser and Smalc (15) via the corresponding O_2^+ salt. The preparation of $Se_4(SbF_6)_2$ was a modification of that used to prepare $Se_4(Sb_2F_{11})_2$ (16). Selenium (Se_8 3.28 mmol) and SbF_5 (27.3 mmol) were refluxed at 110°C for 2 days in SO_2 (6.3 g). Removal of the volatiles left 8.007 g of a pale yellow solid consisting of what was presumed to be $Se_4(SbF_6)_2$ and a reduced antimony fluoride, however, it probably contained $Se_4^{2+}(Sb_2F_{11})_2^-$ as well. This mixture was used in subsequent reactions.

Preparation of $SeBr_3AsF_6$

Reactions involving selenium, or tellurium, bromine, and arsenic pentafluoride went to completion within a few minutes of reaching room temperature. The chalcogen and bromine were allowed to react in the solvent before the addition of arsenic pentafluoride. The soluble product was filtered through the sintered glass frit, followed by condensing the solvent (AsF_3 or SO_2) back onto the solid and refiltering in the closed system. This process was repeated until the soluble product was extracted, unless otherwise specified.

In a typical reaction Se (2.216 mmol) and Br_2 (4.06 mmol) were reacted with AsF_5 (4.00 mmol) in SO_2 (8.26 g) solution. A copious yellow precipitate formed that had some solubility in SO_2. Following filtration traces of insoluble unreacted selenium and a pale yellow soluble crystalline solid (1.1097 g or 2.16 mmol assuming $SeBr_3AsF_6$) were obtained on removal of the volatiles SO_2, AsF_3, unreacted AsF_5 and Br_2. *Anal.* calcd. for $SeBr_3AsF_6$: Se 15.55, Br 47.22, As 14.76, F 22.45; found: Se 15.28, Br 47.10, As 14.33, F 22.58.

$Se_4(AsF_6)_2$ (1.58 mmol) was reacted with Br_2 (12.33 mmol) in SO_2 (10 g), yielding 3.11 mmol of the soluble highly crystalline $SeBr_3AsF_6$ and 2.93 mmol of $SeBr_4$, the identity of which was inferred from its physical properties (17, 18). $Se_4(AsF_6)_2$ (1.96 mmol) and Br_2 (24.34 mmol) were reacted

0008-4042/79/243230-07$01.00/0

TABLE 1. Various preparations

Reactants	Quantity of SO_2	Products
1, $Se_4(AsF_6)_2$ (0.79 mmol) Cl_2 (3.81 mmol)	11.7 g	$SeCl_3AsF_6$ (1.49 mmol)[a] $SeCl_4$
2, $Te_4(AsF_6)_2$ (0.79 mmol) Br_2 (6.69 mmol)	5 g	$TeBr_3AsF_6$ (1.46 mmol) $TeBr_4$[b] (1.87 mmol)
3, $Te_4(AsF_6)_2$ (2.33 mmol) Br_2 (15.26 mmol) AsF_5[c] (9.58 mmol)	10 g	$TeBr_3AsF_6$ (7.48 mmol)
4, $TeBr_4$ (3.82 mmol) AsF_5 (7.65 mmol)	11.3 g	$TeBr_3AsF_6$[d] (3.62 mmol) Br_2, AsF_3

[a]Solution (SO_2) and solid Raman spectra identified the soluble solid as $SeCl_3AsF_6$ (5) and the insoluble solid as $SeCl_4$ (12, 19). Each component showed small impurity peaks due to the other since $SeCl_4$ is slightly soluble in SO_2.
[b]Contained some $TeBr_3AsF_6$.
[c]AsF_5 added last.
[d]SO_2BrF (20) was not observed in any of the infrared spectra taken of the volatiles reaction products.

in SO_2 (8 g) followed by addition of AsF_5 (6.58 mmol) to give $SeBr_3AsF_6$ (7.05 mmol).

Preparation of $SeBr_3SbF_6$

In a typical reaction $Se_4(SbF_6)_2$ (0.527 g mixture, calculated ca. 0.47 mmol $Se_4(SbF_6)_2$) was reacted with Br_2 (2.00 mmol) in SO_2 (5.5 g) solution. Filtration and slow evacuation of the volatiles gave 0.595 g (1.07 mmol assuming $SeBr_3SbF_6$) of soluble pale yellow crystals (single) and 0.252 g of insoluble yellow solid, containing a reduced antimony fluoride and some $SeBr_4$.

Preparation of Another Bromoselenium Cation

Se (14.16 mmol) and Br_2 (17.83 mmol) were reacted with AsF_5 (17.65 mmol) in SO_2 (5.75 g) and gave 5.70 g (7.64 mmol assuming $Se_2Br_5AsF_6$) deep purple crystals (soluble in SO_2). In another experiment Se (36.34 mmol), Br_2 (38.42 mmol), and AsF_5 (20.65 mmol) yielded 10.08 g (13.50 mmol assuming $Se_2Br_5AsF_6$) purple crystals and 1.262 g grey–purple insoluble solid (which probably contains elemental selenium and $SeBr_4$).

The same purple crystals were also prepared by pouring Br_2 (5.25 mmol) in SO_2 (8.34 g) onto $Se_4(AsF_6)_2$ (1.23 mmol). Filtration followed by evacuation of the volatiles (SO_2 and Br_2) left 1.68 g (2.25 mmol assuming $Se_2Br_5AsF_6$) solid.

X-ray powder photographs of this material, from a variety of different preparations, were the same and did not contain lines attributable to $SeBr_3AsF_6$. X-ray photographs of a single crystal obtained at -5°C and also showed the material was different from $SeBr_3AsF_6$. *Anal.* calcd. for $Se_2Br_5AsF_6$: Se 21.16, Br 53.53, As 10.03, F 15.27; found: Se 21.06, Br 53.42, As 9.87, F 15.00. An independent determination of selenium and arsenic by atomic absorption methods supported this formulation. Crystals decomposed slowly at room temperature, in the X-ray beam, and under irradiation in the laser beam.

Preparation of $TeBr_3AsF_6$

In a typical reaction, tellurium (9.01 mmol) and Br_2 (20.6 mmol) were reacted with AsF_5 (15.5 mmol) in SO_2 (7 g) solution. Filtration and two washings, followed by evacuation of the volatiles yielded 4.29 g (7.71 mmol assuming $TeBr_3AsF_6$) of a soluble, beige, highly crystalline solid containing single crystals, and 0.68 g of a less soluble beige solid containing $TeBr_3AsF_6$ and $TeBr_4$ (19). *Anal.* calcd. for $TeBr_3AsF_6$: Te 22.94, Br 43.09, As 13.47, F 20.49; found: Te 23.10, Br 42.81, As 13.07, F 20.68. Other reactions leading to $TeBr_3AsF_6$ are given in Table 1.

Stability of $SeBr_3AsF_6$, $SeBr_3AsF_6$, and $TeBr_3AsF_6$

Yellow crystalline $SeBr_3AsF_6$ (mp 144–152°C) and white crystalline $TeBr_3AsF_6$ (mp 175–185°C) were stored under dry nitrogen in sealed Pyrex glass vessels at 0°C for a year without detectable signs of decomposition. Yellow crystalline $SeBr_3SbF_6$ (decomposes at 100°C) showed purple discolouration after 4 months.

Reaction of Br_3AsF_6 with AsF_3

Solid Br_3AsF_6 (1.19 mmol) was reacted with AsF_3 (22.62 mmol), yielding two immiscible liquids. Volatiles (0.3164 g or 1.81 mmol assuming AsF_5) were distilled from the vessel held at -78°C, and identified by its infrared spectrum as AsF_5. The remainder (3.1832 g) contained AsF_3 and bromine. Involatile material was not observed.

Reaction of Br_3AsF_6 with SO_2

Sulphur dioxide (5.15 mmol) was condensed into Br_3AsF_6 (2.09 mmol), giving AsF_5, Br_2, SO_2, and SO_2BrF. The intensities of the SO_2 and SO_2BrF bands in the infrared were about the same indicating comparable quantities of both were present. Involatile material was not observed. SO_2BrF was also a product of the reaction of Br_3SbF_6 and SO_2.

Reactions of KBr with AsF_5 in SO_2

KBr (5.49 mmol) and AsF_5 (13.94 mmol) were reacted in SO_2 (4.6 g). The products consisted of SO_2, traces of SO_2BrF and AsF_5 (combined weight 5.35 g) volatile at -78°C; Br_2 and AsF_3 (combined weight 0.75 g) volatile at room temperature; as well as 1.524 g of solid, the Raman spectrum and powder diffraction photograph of which were identical to that of $KAsF_6$ (21). In addition to the bands attributable to AsF_3 and Br_2, the Raman spectrum of the material volatile at room temperature showed peaks at 436 cm^{-1}, 872 cm^{-1}, and 1309 cm^{-1} using the 5145 Å (green) exciting wavelength. The intensity decreased and the peak broadened in the order 436 > 872 > 1309 cm^{-1}.

Results and Discussion

Preparation of Tribromoselenium(IV) and Tribromotellurium(IV) Hexafluoroarsenate(V)

$SeBr_3AsF_6$ and $TeBr_3AsF_6$ were prepared es-

sentially quantitatively from the respective element, bromine, and a slight excess of arsenic pentafluoride in arsenic trifluoride or sulphur dioxide solution according to reaction [1].

[1] $2M + 3Br_2 + 3AsF_5 \rightarrow 2MBr_3AsF_6 + AsF_3$

(M = Se or Te)

The tellurium salt was also prepared quantitatively from tellurium tetrabromide and arsenic pentafluoride according to reaction [2].

[2] $2TeBr_4 + 3AsF_5 \rightarrow 2TeBr_3AsF_6 + AsF_3 + Br_2$

The polyatomic cations Se_4^{2+} and Te_4^{2+} have been well characterized; however, their chemistry has not been intensively studied (14*b*, 23, 24). These cations with excess bromine readily formed the corresponding tribromochalcogen(IV) salt and chalcogen tetrabromide according to reaction [3].

[3] $M_4^{2+}(AsF_6)_2^- + 7Br_2 \rightarrow 2MBr_3AsF_6 + 2MBr_4$

(M = Se or Te)

The addition of arsenic pentafluoride to the products led to complete conversion of selenium and tellurium to the corresponding tribromochalcogen(IV) salt. $SeBr_3SbF_6$ was prepared from $Se_4(SbF_6)_2$ and bromine. Excess chlorine reacts with $Se_4(AsF_6)_2$ to give $SeCl_3AsF_6$ and $SeCl_4$.

A different selenium bromine cation was prepared by the reaction of $Se_4(AsF_6)_2$ and Br_2 in a molar ratio of 1:5, and in the reaction of selenium, bromine, and arsenic pentafluoride in the ratio $Se:Br_2:AsF_5$ of 4:5:3. Preparative and analytical evidence points to $Se_2Br_5AsF_6$ as the formulation of the salt.

Reaction Pathways to MBr_3^+ (M = S, Se, and Te), Salts

A bromine polyatomic cation cannot be an intermediate in reactions leading to MBr_3^+ (M = S, Se, and Te) salts as Br_3AsF_6 reacts rapidly with both AsF_3 and SO_2 according to reactions [4] and [5], and SO_2BrF was not detected in reactions using sulphur dioxide solvent.

[4] $2Br_3AsF_6 + AsF_3 \rightarrow 3AsF_5 + 3Br_2$

[5] $Br_3AsF_6 + SO_2 \rightarrow AsF_5 + Br_2 + SO_2BrF$

Chalcogen polyatomic cations, however, may be intermediates, and both Se_4^{2+} and Te_4^{2+} react with bromine to yield chalcogen tribromide cations, probably via species related to $Se_2Br_5^+$ and/or $S_2Br_3^+$ (25, 26). A number of bromochalcogen cation species may be relatively stable and include species related to $(S_7I)^+$ (27, 28). Bromine and chalcogen lead to chalcogen bromide. Tellurium tetrabromide and arsenic pentafluoride may react according to reaction [6], however, $TeBr_3AsBrF_5$ itself is not detected as a product but $TeBr_3AsF_6$ and Br_2 (reaction [2]). Potassium chloride and SbF_5 give related products (29, 30).

[6] $TeBr_4 + AsF_5 \rightarrow TeBr_3AsBrF_5$

The resonance Raman spectrum observed in SO_2 and AsF_3 solutions of SBr_3AsF_6 (7) is also observed in a Raman spectra of the volatile products of KBr and AsF_5 in SO_2. The species responsible for this resonance Raman spectrum is therefore not a sulphur–bromine species, and not an intermediate, in the formation of SBr_3^+ salts.

Raman Spectra

Raman spectra of $SeBr_3AsF_6$ and $TeBr_3AsF_6$ in the solid state and in SO_2 or AsF_3 solution are given in Fig. 1. Table 2 lists the frequencies and assignments by comparison with the corresponding anions (21), $AsBr_3$ (22), and $SbBr_3$ (31, 32). The assignments

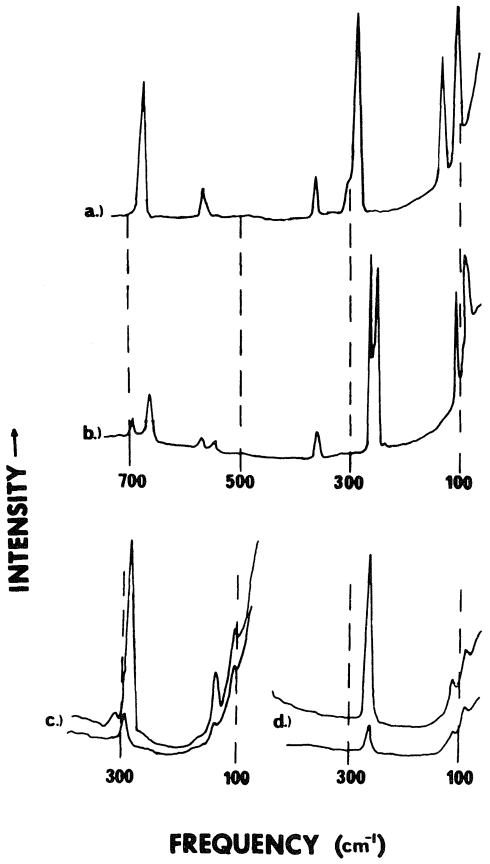

FIG. 1. Raman spectra of $SeBr_3^+$ and $TeBr_3^+$ cations. (*a*) Solid $SeBr_3AsF_6$; (*b*) solid $TeBr_3AsF_6$; (*c*) $SeBr_3AsF_6$ in SO_2 solution; (*d*) $TeBr_3AsF_6$ in SO_2 solution. For (*c*) and (*d*) the upper spectra are with parallel polarization and the lower with perpendicular polarization. Slit width = 4 cm^{-1} using 5145 Å line in all cases.

TABLE 4. Force constants (Newton m^{-1}) of group V tribromides and group VI tribromide cations

Force constant	Value						
	PBr_3	SBr_3^+	$AsBr_3$	$SeBr_3^+(C_{3v})$	$SeBr_3^+(C_{2v})$	$SbBr_3$	$TeBr_3^+$
F_r	170.8(2)	201.1(2)	164.2(2)	168.1(1)	166.4(1)	151.9(1)	186.2(2)
F_α	25.9(1)	27.7(1)	19.4(1)	25.6(2)	26.1(2)	15.3(2)	18.1(2)
$F_{\alpha\alpha'}$	5.4(1)	4.9(1)	2.7(1)	5.6(2)	5.3(2)	2.3(1)	2.1(1)
$F_{r\alpha}$	2.4(1)	6.2(2)	−0.6(2)	−6.0(2)	−6.3(1)	−7.7(2)	5.9(3)

and frequencies of $SeBr_3^+$ are essentially in agreement with those recently reported (12) for $SeBr_3 \cdot AlCl_4$ and $SeBr_3AlBr_4$.

The spectra support an essentially ionic formulation for the salts. The peaks attributed to $SeBr_3^+$ are similar in solution and in the solid state, with the exception of $\nu_3(SeBr_3)^+$ which is split in the solid state. The four Raman active bands (two polarized and two depolarized) expected for $(SeBr_3)^+$ are observed and, as expected (7, 33, 34), are at higher frequencies than the corresponding bands for the isoelectronic molecule $AsBr_3$.

The Raman spectra of solid $TeBr_3AsF_6$ and the solution are similar in the bending region but differ in the TeBr stretching region. Peaks in the stretching region are similar to those in the Raman spectrum of $SbBr_3$ (solid) (32), $TeCl_3AsF_6$, $SeCl_4$, $TeCl_4$, and $TeBr_4$ (19). The symmetry of $SeBr_3^+$ in $SeBr_3AsF_6$, and $SeBr_3SbF_6$ and $TeBr_3^+$ in $TeBr_3AsF_6$ is C_1 (35). Therefore, the origin of the complexity of the solid state spectra is most likely due to the low symmetry of the tribromochalcogen ion in the solid state, as has been proposed for $AsBr_3$ (22) and $SbBr_3$ (31). In solution the complex peaks collapse into one broad partially polarized band. The broad peak in the stretching region shifts slightly to higher wavenumbers under perpendicular polarization suggesting that $\nu_3(TeBr_3)^+$ is at slightly higher wavenumbers. The four Raman bands expected for $TeBr_3^+$ are at higher frequencies than their $SbBr_3$ counterparts.

$TeBr_4$ is isomorphous with $TeCl_4$ (36); the structure is a tetramer with $TeCl_3^+$ and Cl^- ions at the apexes of a distorted cube, and therefore can be regarded as $(TeCl_4)_4$ or $[(TeCl_3)^+Cl^-]_4$ with strong anion–cation interaction (37). The Raman spectrum of $TeBr_3^+$ in the solid state in the tellurium bromine stretching region is similar to that of $TeBr_4$ (250(s), 226(s), 220(s)) (19), but at somewhat higher wavenumbers. It is therefore reasonable to suppose that $TeBr_4$ is $[(TeBr_3)^+Br^-]_4$ with stronger anion–cation interaction than that in $TeBr_3AsF_6$. Similar conclusions were reached from an nqr study (11) and by earlier workers on the basis of vibrational spectra of $TeBr_4$ (9, 19). A comparison of Raman data for $SeBr_3^+$ in $SeBr_3AsF_6$ and $SeBr_3SbF_6$ with infrared data for $SeBr_4$ (9, 19) allows a weaker but similar conclusion to be made concerning $SeBr_4$.

Normal Coordinate Analysis

In order to compare force constants of isoelectronic group V tribromides with the tribromochalcogen cations and to check their assignments, we did a normal coordinate analysis and force constant determination on the six species: SBr_3^+, $SeBr_3^+$, $TeBr_3^+$, PBr_3, $AsBr_3$, and $SbBr_3$. Frequencies (Table 2 and ref. 7) were taken from liquid phase or solution (SO_2 for $SeBr_3AsF_6$ and $TeBr_3AsF_6$ and AsF_3 for SBr_3AsF_6) Raman spectra. The symmetry of all tribromo species was assumed to be C_{3v} and parameters are given in Table 3. The Wilson **F** and **G** matrix method (41) was used with a harmonic valency force field including off diagonal

terms. The frequencies were calculated for all the principal isotopic species so that means of isotopic frequencies were compared to observed frequencies. The calculated isotopic splittings are all too small to be observed in solution spectra. The force constants were determined by a least-squares fitting procedure (42).

A pyramidal XY_3 molecule with C_{3v} symmetry has six independent harmonic force constants; these are the diagonal stretching, the diagonal bending, and the four off diagonal interactions (stretch–stretch′, bend–bend′, adjacent stretch–bend, and opposite stretch–bend). Most vibrational analyses of pyramidal trihalides have followed Howard and Wilson (43) in setting the two stretch–bend interaction terms to zero. We found this choice unsatisfactory for the PBr_3 and SBr_3^+ cases; there are strong correlations and the maximum observed minus calculated frequency differences were more than 10 cm^{-1}. We found that setting the stretch–stretch and opposite stretch–bend interaction constants to zero and adjusting the remaining four constants gave good results in all cases (calculated and observed frequencies differing by less than 1 cm^{-1}). The derived force constants are listed in Table 4. As expected the force constants for the tribromochalcogen cations are higher than that of the corresponding group V tribromides. To study the effects of the lowered symmetry in the crystalline state, we repeated the calculations with a C_{2v} geometry of $SeBr_3^+$. Keeping the three stretching constants and the three bending constants equal, the geometric change from C_{3v} to lower symmetry introduced an effect comparable to the isotopic shifts; thus the C_{3v} model should be a reasonable approximation for the solid phase. However, the geometric change must be accompanied by a significant change in force constants, which most likely accounts for the complications in the solid state spectra.

Exact comparisons with the force fields reported elsewhere for these and similar molecules are not possible because of the different assumptions mentioned above. However, the diagonal constants show the trends observed in comparable treatments. Thus, the group V trichlorides (5, 44) and bromides show a decrease in both constants, from PX_3 to SbX_3; however, the stretching force constants for SeX_3^+ (5) are smaller than those for SX_3^+ and TeX_3^+ (X = Cl, Br) while the bending constants for SX_3^+, SeX_3^+, and TeX_3^+ show a steady decrease. The reason for the low stretching constant for SeX_3^+ is not altogether clear.

Istituto Chimico dell'Università, Camerino, 62032, Italy

Received June 4, 1979

ANNA LAURA BANDINI, GUIDO BANDITELLI, GIOVANNI MINGHETTI, and FLAVIO BONATI. Can. J. Chem. **57**, 3237 (1979).

The complexes (L—L)M(pz)$_2$ {(L—L) = $(Ph_2PCH_2)_2$, M = Pt, Pd; (L—L) = 2,2′-dipyridine, M = Pt} and (L—L)M(pz′)$_2$ {(L—L = $(Ph_2PCH_2)_2$, M = Pt; (L—L) = 2,2′-dipyridine, M = Pt, Pd} where pzH = pyrazole and pz′H = 3,5-dimethylpyrazole, behave as ligands towards suitable acceptors affording 1:1 or 1:2 adducts.

The 1:1 adducts are obtained by reaction with group IIB metal halides, cobalt(II) chloride, copper(II), or zinc(II) sulphate and are likely to be binuclear complexes, (ligand)MX_2, with two pyrazolato anions bridging the different metals.

The nature of the 1:2 adducts [(ligand)$_2$M′][BF_4]$_2$ (M′ = Zn, Ni, Co) as well as of the adduct (dipy)Pt(pz)$_2$·2Rh(CO)$_2$Cl, are discussed.

ANNA LAURA BANDINI, GUIDO BANDITELLI, GIOVANNI MINGHETTI et FLAVIO BONATI. Can. J. Chem. **57**, 3237 (1979).

Les composés (L—L)M(pz)$_2$ {(L—L) = $(Ph_2PCH_2)_2$, M = Pt, Pd; (L—L) = 2,2′-dipyridine, M = Pt} et (L—L)M(pz′)$_2$ {(L—L) = $(Ph_2PCH_2)_2$, M = Pt; (L—L) = 2,2′-dipyridine, M = Pt, Pd} où pzH = pyrazole et pz′H = 3,5-diméthylpyrazole, peuvent complexer sur des accepteurs convenables en conduisant à des composés d'addition 1:1 ou 1:2.

Les complexes 1:1 sont obtenus pour réaction avec des alogenures des metaux du deuxième groupe B, avec cobalt dichlorure et avec les sulfates de cuivre(II) ou de zinc(II). Ils peuvent être, raisonnablement, regardés comme des complexes binucléaires où les deux anions pyrazolate se conduisent comme des ligands pontés entre les differents metaux.

On discute de la nature des composés d'addition 1:2 [(ligand)$_2$M′][BF_4]$_2$ (M′ = Zn, Ni, Co) aussi que du complex (dipy)Pt(pz)$_2$·2Rh(CO)$_2$Cl.

Introduction

In a preceding paper of ours (1) a series of palladium(II) and platinum(II) azolates, (L—L)M(az)$_2$, were described, where L—L is a chelating ligand and azH is a 1-unsubstituted azole. In any of these square planar complexes, the azolato anions are coordinated to the metal through one of the nitrogen atoms; the uncoordinated nitrogens, which are basic and can be protonated, are still available as donor sites, so that the complexes can be thought of as potentially bidentate ligands.

	A	B	C	D	E	F	G	H
M	Pt	Pt	Pt	Pt	Pd	Pd	B	Ga
R	Me	H	Me	H	Me	H	H	H
L—L	dpe	dpe	bipy	bipy	bipy	dpe	2H	2Me
n	0	0	0	0	0	0	−1	−1

The behaviour of these molecules as ligands towards selected acceptors is described in this paper. The chelating ligand, L—L, is either 1,2-bis(diphenylphosphine)ethane or the less flexible 2,2′-dipyridyl; the azole is either pyrazole, (pzH), or the more sterically demanding 3,5-dimethylpyrazole (pz′H); the metal is palladium(II) or platinum(II), so that the resulting molecules do not bear any formal charge and, especially in the case of platinum, are kinetically inert. These last points had been already exploited by us (2) in another type of platinum(II) containing bidentate ligands, i.e. (L)(L′)Pt–C(OR)=NR′]$_2$, while the lack of charge constitutes one notable difference between the species A—F and the anionic dihydrobis(1-pyrazolyl)borate(III), G (3), dimethylbis(1-pyrazolyl)gallate(III), H (5), and its (2-*N*,*N*-dimethylamino)ethoxy analogue (6).

Discussion

By reaction of the ligands A—F with Lewis acids, stable 1:1 or 2:1 adducts were obtained (see Table 1). The 2:1 adducts formed when an aquo-cation was employed and the anion was a very weak nucleophile

as in the case of the complexes $[\{(dpe)Pt(pz')_2\}_2Zn](BF_4)_2$, **VIII**, $[\{(dpe)Pt(pz)_2\}_2Ni](BF_4)_2$, **XI**, $[\{(bipy)Pt(pz')_2\}_2Ni](BF_4)_2$·$H_2O$, **XVII**, and $[\{(dpe)Pd(pz')_2\}_2Co](BF_4)_2$·2$H_2O$, **XXIV**. Their formulae were established by elemental analyses, spectra, and by the value of the electrical conductivity in solution. The ionic nature of these compounds in the solid state was evidenced by the presence of only one strong and broad vibration due to the BF_4^- ion with tetrahedral symmetry at ca. 1050 cm^{-1}, thus ruling out more complicated structures. The ir spectra also gave evidence on the presence (or absence) of the water molecules. The proton nmr spectra of the compounds **XI** and **XVII** showed the required bands due to the chelating ligand and to the pyrazolato groups. The ^4J(Pt—H) = 7 Hz was quite evident in the spectrum of the compound **XVII** (Table 2), thus allowing the methyl signal having the ^{195}Pt satellites to be assigned to the 5-Me and the other methyl signal to the 3-Me group.

In the adducts, coordination around the platinum(II) or palladium(II) atom is reasonably assumed to be square planar; in the zinc adduct, **VIII**, coordination around the zinc atom is likely to be tetrahedral, while various possibilities arise for the nickel(II) and cobalt(II) derivatives, especially if the molecule(s) of water is inside the coordination sphere.

The observed diamagnetism and electronic spectrum of **XI**, both in acetonitrile solution and in the solid state, suggest square planar nickel(II) (7). Similar evidence, also in acetonitrile, suggests the same coordination for the compound **XVII**. Here, if the water molecule is not far away from the nickel atom, a strongly elongated square pyramidal coordination (8) cannot be excluded completely, but is unlikely since other pyrazolates, e.g. [Me_2Ga-

TABLE 2. Proton magnetic resonance data[a]

Compound	Solvent	Chelating ligand	Pyrazole ring protons: 3- and 5-substituents	Pyrazole ring protons: 4-substituent

[a]τ units; Varian NEVA, 60 MHz operating at room temperature; s = singlet, d = doublet, t = triplet, m = multiplet, br = broad.
[b]Not observed owing to insufficient solubility.
[c]The 5-CH is probably covered by absorptions due to the aromatic protons.
[d]These data are reported for comparison (ref. 1).

$(pz)_2]_2Ni$ (4*b*) or $[Me_2B(pz)_2]_2Ni$ (9) were found to contain square planar nickel(II).

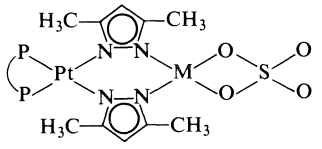
On the other hand, a tetrahedral coordination may be suggested for the violet paramagnetic cobalt(II) derivative, **XXIV**, on the evidence of the visible spectrum and on the assumption that the two water molecules are outside the cobalt coordination sphere. By comparison, the related mononuclear $[Co(pz'H)_4]^{2+}$ ion was shown (9*b*) to contain tetrahedrally coordinated cobalt(II). The reaction leading to the compound **XXIV** afforded also two other products in small yields. One of them is white and cobalt-free, the other is blue and paramagnetic; on the basis of elemental analyses, electrical conductivity, ir, and electronic spectra, formulae like $[(bipy)_2Pd_2(\mu\text{-}pz')_2]\ (BF_4)_2$, **XXV**, and $[(bipy)Co(pz'H)_2]\ (BF_4)_2$, **XXVI**, are suggested.

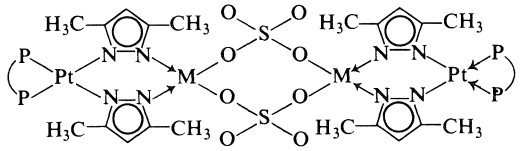
The 1:1 adducts (see Table 1) were obtained when the ligands A—F were reacted with a metal halide or a metal sulphate, generally in methanol solution or in ether suspension. In the case of $(dpe)Pd(pz)_2 \cdot CdI_2$, **XXVII**, ether had to be used, since in methanol scrambling of the ligands occurred and $(dpe)PdI_2$ was isolated.

The 1:1 adducts are thermally stable solids and are sparingly soluble in organic solvents, which have a remarkable tendency to be included in the crystals. In particular, the compounds, $(bipy)Pt(pz')_2CdI_2$, **XII**, and $(bipy)Pt(pz')_2CoCl_2$ could be isolated with (**XIII** and **XV**) or without (**XII** and **XIV**) 1 mol of clathrated dichloromethane; solvent molecules can probably fit into the holes of a crystal lattice in which the bulky and rather unflexible bipyridine or 3,5-dimethylpyrazolato ligands have to be accommodated.

When the solubility was sufficient, e.g. **III**, the determinations of the molecular weight and of the molar conductivities showed the complexes to be monomeric, ruling out dimeric, ionic formulae such as $[(dpe)Pt(\mu\text{-}pz')_2Zn(\mu\text{-}pz')_2Pt(dpe)]^{2+}[ZnCl_4]^{2-}$. The very limited, although not negligible solubility of the 1:1 adducts **I** and **II**, between zinc(II) or copper(II) sulphate and $(dpe)Pt(pz')_2$, did not allow a reliable molecular weight determination but argues against a polymeric structure. These two compounds, which

are not electrolytes in CH_2Cl_2, are likely to be either monomers, (dpe)Pt(μ-pz′)$_2$M(SO_4), or dimers, (dpe)Pt(μ-pz′)$_2$M(μ-SO_4)$_2$M(μ-pz′)$_2$Pt(dpe).





No distinction is possible on the basis of the infrared spectrum for the sulphate group, which has C_{2v} symmetry in both cases; moreover, strong vibrations due to the Pt-containing ligands are present in the regions typical for sulphate adsorptions. Related (pyrazole)$_2$M(SO_4) species have been reported and were assumed to be mononuclear (8*b*).

The complexes [(bipy)Pd(pz′)$_2$·$PdCl_2$·0.5H_2O]$_n$, **XXIII**, and [(bipy)Pt(pz′)$_2$·$PdCl_2$]$_n$, **XVI**, are insoluble, so that polymeric structures where the ligands bridge two $PdCl_2$ moieties are more likely.

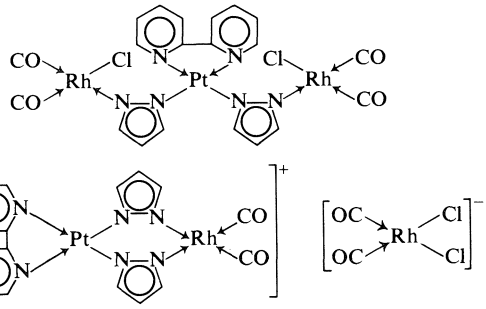
The infrared spectra (4000–250 cm^{-1}) of these 1:1 adducts show all the vibrations due to the metal-containing ligand, thus suggesting that the gross structure of the latter is unaltered after the reaction. In the low-frequency region, where metal–halogen stretching frequencies are expected, a rather complicated pattern is present owing to ligand vibrations. This precludes any safe assignment.

The proton nmr spectra (Table 2) were recorded for those compounds which were sufficiently soluble. The 3,5-dimethylpyrazolates showed always two sets of methyl groups; of these the one at higher field should be assigned to the set nearer to the transition element because, when this is platinum, coupling with ^{195}Pt can be observed. The actual value of the ^4J(Pt—H) is 4.5 Hz in (dpe)Pt(pz′)$_2$·CdI_2 and is quite similar to that recorded for the ligand itself or the protonated species [(dpe)Pt(pz′H)$_2$]$^{2+}$ (4 or 5 Hz respectively).

Although also the proton in the 4 position of the pyrazolato ring was coupled to the platinum in the parent molecule, (dpe)Pt(pz′)$_2$ (J = 4 Hz), only a broadening of the signal was recorded in the case of its CdI_2 derivative, as had already been observed for the related [(dpe)Pt(pz′H)$_2$]$^{2+}$ cation (1). No such coupling was observed in the adducts of the palladium containing ligands; however, two 4-CH signals instead of one, together with the required two methyl signals, were recorded for a CD_3CN solution of (bipy)Pd(pz′)$_2$·$ZnBr_2$. Two magnetically non-equivalent 4-CH groups can presently be explained only if the two pyrazolato ligands cannot occupy symmetrical positions, owing perhaps to steric crowding.

In the blue, paramagnetic (nmr criterion) and non-electrolyte cobalt(II) compounds, the transition metal atom is surrounded pseudo-tetrahedrally by the ligands. Such an arrangement of the ligands was proposed on magnetic and spectral evidence for the blue bimetallic species (dpe)Pt⊣C(OR)=N(Ar)→]$_2$$CoCl_2$ (2), for the blue bis(3,5-dimethylpyrazole)- or bis(1,3,5-trimethylpyrazole) dichlorocobalt(II) (10*a*) and is now supported by an X-ray structure carried out for bis(3,5-dimethyl-4-ethylpyrazole)dichlorocobalt(II) (10*b*).

The reaction of dimeric dicarbonylchlororhodium(I) was carried out with the complex (bipy)-Pt(pz)$_2$ and a 2:1 adduct was isolated, for which the following structures are possible



plus a more complicated one, analogous to that proposed for an adduct between a porphyrin and [(CO)$_2$RhCl]$_2$ (11), involving a pentacoordinated rhodium(I). The value of the electric conductance, both in acetone and in dichloromethane solution, supports the ionic structure, which may be present even in the solid state since the pattern of the infrared absorptions in the ν_{CO} region does not change from solid state (Nujol) to solution (CH_2Cl_2) spectra.

The behaviour of the ligand (bipy)Pt(pz)$_2$, therefore, is different from that of the (dpe)Pt⊣C(OMe)=N—Ar]$_2$ or (Ph$_3$P)(ArNC)Pt⊣C(OMe)=N—Ar]$_2$ ligands which give non-ionic adducts where they act as exo-bidentate ligands. In addition another difference lies in the stability of the solution, which is very limited in the case of (dpe)Pt⊣C(OMe)=N(Ar)→Rh(CO)$_2$Cl]$_2$. Both adducts are decomposed by reaction with a classical ligand, such as Ph_3P, according to the reactions:

$$\text{(bipy)Pt(pz)}_2\cdot[\text{Rh(CO)}_2\text{Cl}]_2 + 4\text{Ph}_3\text{P} \rightarrow \text{(bipy)Pt(pz)}_2 + 2\text{(CO)(Ph}_3\text{P)}_2\text{RhCl} + 2\text{CO}$$

$$\text{(dpe)Pt⊣C(OMe)=NAr]}_2[\text{Rh(CO)}_2\text{Cl}]_2 + 4\text{Ph}_3\text{P} \rightarrow \text{(dpe)Pt⊣C(OMe)=NAr]}_2 + 2\text{(CO)(Ph}_3\text{P)}_2\text{RhCl} + 2\text{CO}$$

Experimental

The starting materials, A—F, were prepared as described in our preceding paper (1). General techniques and spectroscopic methods have been described previously (2). Analytical and other data are given in Table 1, nmr data in Table 2, spectroscopic data in Table 3, and conductivity data in Table 4. All the analytical samples were pumped to constant weight (ca. 0.1 Torr, 25°C). Evaporation was always carried out under reduced pressure (water aspirator).

Preparation of the Adducts

A·$CdBr_2$, **IV**. To a stirred methanol suspension (40 mL) of the compound A (202 mg; 0.26 mmol), a solution of $CdBr_2$·$4H_2O$ (90 mg; 0.26 mmol) in warm methanol was added. After stirring for 15 min, the solution was evaporated to dryness and the residue was extracted with dichloromethane (40 mL). Diethyl ether (50 mL) was added to the extract and the crude compound crystallized out upon concentration. Recrystallization was achieved by concentrating a solution in CH_2Cl_2/Et_2O (70 + 70 mL). The colourless compound is sparingly soluble in CH_2Cl_2 and is insoluble in chloroform, acetone, benzene, or acetonitrile. The preparation of A·CdI_2, **V**, A·$ZnCl_2$, **III**, A·$ZnSO_4$, **I**, green A·$CuSO_4$, **II**, and of $[A_2Zn][BF_4]_2$, **VIII**, was carried out similarly from CdI_2, $ZnCl_2$, $ZnSO_4$·$7H_2O$, $CuSO_4$·$5H_2O$, and $Zn(BF_4)_2$·$6H_2O$; the crude products were crystallized from CH_2Cl_2/Et_2O (between 1/1 to 1/4 volume ratio).

A·$HgCl_2$, **VI**. A solution of mercury(II) chloride (86 mg; 0.316 mmol) in diethyl ether (25 mL) was added to a stirred suspension of the compound A (216 mg; 0.275 mmol) in the same solvent. After stirring for 1 h the colourless precipitate was filtered and washed with ether. The white compounds A·$HgBr_2$, **VII**, B·$HgCl_2$, X, B·$CdCl_2$, **IX**, and yellow E·$ZnBr_2$, **XXI**, were obtained similarly from the appropriate reagents, sometimes with longer reaction times (6 h for **X** and **XXI**, 24 h for **IX**), and were then crystallized twice from CH_2Cl_2/Et_2O or CH_3CN/dry Et_2O.

C·CdI_2, **XII**, and C·CdI_2·CH_2Cl_2, **XIII**. Cadmium(II) iodide (105 mg; 0.28 mmol) in methanol (2 mL) was added to a solution of the compound C (149 mg; 0.27 mmol) in the same solvent (30 mL) whereupon a yellow precipitate formed at once. In this case the reaction mixture was evaporated to dryness and the residue was extracted with dichloromethane (40 mL). Addition of petroleum ether gave a yellow precipitate, which did not dissolve again completely in dichloromethane (0.25 L), affording the yellow compound **XIII** (60 mg). From the clear extract the orange yellow compound **XII** (110 mg) precipitated upon concentration to a small volume.

The compounds C·$CoCl_2$, **XIV**, $[C_2Ni][BF_4]_2$·$2H_2O$, **XVII**, and C·$PdCl_2$, **XVI**, were obtained similarly from C and anhydrous $CoCl_2$, $Ni(BF_4)_2$·$6H_2O$ or $(PhCN)_2PdCl_2$ in methanol solution. The emerald-green (cobalt), pale pink (nickel), or pale yellow (palladium) precipitates were purified by crystallization from acetonitrile/diethyl ether or, in the last

case, by washing with methanol and ether. The emerald-green compound **XV** was obtained by washing **XIV** with dichloromethane.

D·$[Rh(CO)_2Cl]_2$, **XIX**. Compound D (197 mg; 0.407 mmol), $[Rh(CO)_2Cl]_2$ (158 mg; 0.407 mmol), and ether (50 mL) were stirred 4 h. The orange yellow precipitate was filtered and crystallized by concentration from CH_2Cl_2/Et_2O. Infrared carbonyl stretching frequencies at 2080, 2065, 2020, and 1990 (CH_2Cl_2 solution) and at 2070, 2050, 2010, 1990, 1970, and 1940 cm^{-1} (Nujol mull).

D·$CoCl_2$, **XVIII**. After 10 min a methanol solution (50 mL) of the compound D (199 mg; 0.41 mmol) and of anhydrous cobalt(II) chloride (70 mg; 0.54 mmol) in the same solvent (20 mL) gave a blue precipitate (152 mg); additional precipitate (66 mg) was obtained upon concentration of the blue mother liquor. The combined precipitates were extracted with acetonitrile and the blue product (200 mg) was obtained by concentrating the extract in the presence of ether. The compound is sparingly soluble in acetonitrile with a blue colour, which becomes yellow upon addition of methanol and gives back the blue colour upon addition of ether or of hexane; it dissolves in methanol with a yellow colour, while in ethanol, where it is sparingly soluble, only a blue colour was observed for the solution.

E·$CoCl_2$, **XXII**. The blue precipitate which formed upon addition of dry $CoCl_2$ (30 mg; 0.23 mmol) to a methanol solution (20 mL) of E (100 mg; 0.22 mmol) was crystallized from acetonitrile/ether. The pale pink $[B_2Ni][BF_4]_2$, **XI**, was obtained and purified similarly from B and $Ni(BF_4)_2·6H_2O$.

F·CdI_2, **XXVII**. Cadmium(II) iodide (80 mg; 0.22 mmol), compound F (139 mg; 0.22 mmol), and diethyl ether (40 mL) were stirred for 1 day under nitrogen. The pale yellow compound (200 mg) was filtered and washed with ether; it could not be crystallized from CH_2Cl_2/Et_2O. The same product could not be obtained by carrying out the reaction in methanol.

Received June 15, 1979

F. CAPITAN, A. GUIRAUM, J. L. VILCHEZ, and J. F. ARENAS. Can. J. Chem. **57**, 3243 (1979).

The reduction of the 1,2,7-trihydroxyanthraquinone-3-methylamino-*N*,*N*-diacetic acid at dropping mercury electrode has been investigated. The reduction involves two electrons as well as either one or two hydrogen ions depending on the pH. Two alternative reaction mechanisms are proposed. Five acid-dissociation constants have been determined by potentiometric and spectrophotometric methods. A sequence for the dissociation of the protons is proposed. Thermal gravimetric and differential analysis of the anhydrous and dihydrated reagent are reported.

F. CAPITAN, A. GUIRAUM, J. L. VILCHEZ et J. F. ARENAS. Can. J. Chem. **57**, 3243 (1979).

La réduction de l'acide 1,2,7-trihydroxyanthraquinone-3-méthyle-amino-*N*,*N*-diacétique a été etudiée à l'électrode à goutte de mercure à differents valeurs du pH avec un tampon acétique. La réduction se fait avec l'intervention de deux électrons ainsi que d'un ou deux ions H^+ selon que le pH soit au-dessous de 7.76 ou au-dessus de cette valeur là respectivement. Deux mécanismes de réaction ont été établis. On a fait la détermination potentiométrique et spectrophotométrique de cinq constantes de dissociation et on a proposé une séquence pour la dissociation des protons. On a étudié également l'analyse thermique du composé anhydre et hydraté.

Introduction

Prior to this work, several analytical applications of anthrapurpurin complexan (1,2,7-trihydroxyanthraquinone-3-methylamino-*N*,*N*-diacetic acid) were studied (1, 2).

There are only a few data in the literature concerning dissociation constants of anthraquinone complexans. To our knowledge, only those of alizarin complexan (3) and sulphonated alizarin complexan (4) have been reported. Likewise, few data have been reported concerning the polarographic behaviour of anthraquinonic derivatives (5–7) but no attention has yet been paid to their complexans. In this work, we have determined five dissociation constants of anthrapurpurin complexan by potentiometric and spectrophotometric methods and investigated the reduction of the reagent at the dropping mercury electrode at different values of pH in some acetic–acetate buffers. The reaction mechanism has been established and one of the pK values has been determined from the polarographic data and found to be in good agreement with that determined by potentiometric and spectrophotometric methods. Accordingly, the order of dissociation of the protons has been established.

The thermal behaviour of the reagent has also been investigated and the solubility in distilled water determined.

Experimental

Anthrapurpurin complexan was synthesized according to Belcher's method (8). The infrared spectrum of the solid in KBr pellets was recorded on a Beckman 4240 spectrophotometer. The nmr spectrum of the reagent dissolved in dimethyl sulfoxide was recorded on a Perkin Elmer R20 spectrometer. To increase the solubility of the sample we synthesized the acetic triester methyl diester derivative by consecutive esterification of the three phenolic groups and the two carboxylic groups. The elemental analysis of this derivative agrees with the empirical formula $C_{27}H_{25}NO_{10}$. Its nmr spectrum was recorded in deuterated chloroform. The mass spectrum of the reagent could not be recorded because of its low volatility, thus the spectrum of the pentamethylic derivative was recorded on a Hewlett-Packard 5930 A spectrometer. Thermal analyses were carried out with a Setaram GDTD thermoanalyzer fitted with a B70 thermobalance using Pt/Pt–Rh thermocouples. Analyses were always performed in a static air atmosphere using 20 mg samples in platinum melting pots of 5 mm inner diameter and heating at the rate of 10°C/min. Calcinated alumina with the same particle size as the sample was used to record TDA diagrams. A Beckman Research potentiometer was used to perform potentiometric titrations and a Beckman ACTA 3 spectrophotometer was used for the spectrophotometric determination of dissociation constants.

Polarograms were recorded on a Sargent XVI polarograph and an AMEL 471 multipurpose unit. Controlled-potential coulometric reactions were carried out on a Metrohm-Herisau

[1]To whom all correspondence should be addressed.

0008-4042/79/243243-04$01.00/0

E-524 potentiostat and pH was measured with a Radiometer pH-29 pH-meter. The sce was used as reference electrode in all cases, a water-jacketed cell through which water was circulated from a thermostat was used to control temperature at 25°C and oxygen was removed by bubbling nitrogen of 99.997% of purity through the solutions. Different acetic–acetate buffers were used as supporting electrolytes in the pH range of 3.75 to 8.70. Capillaries were calibrated at pH = 4.60. Drop time as well as flow of mercury was determined as a function of the height of the mercury column (a lineal dependence between m and h being observed). Samples for polarography were prepared in all cases starting with a bulk solution 10^{-3} M of anthrapurpurin complexan and diluting with the supporting electrolyte up to the required concentration.

Results

The ir spectrum of anthrapurpurin complexan has been recorded in the range 4000–250 cm^{-1}, the most significant features being the following: the broad band at 3460 cm^{-1} must be assigned to ν(OH), that at 1743 cm^{-1} must be assigned to ν(C=O), and that at 1295 cm^{-1} is probably due to a C—N stretching vibration. None of these bands are recorded in the ir spectrum of 1,2,7-trihydroxyanthraquinone (6).

Only signals from aliphatic protons have been recorded in the nmr spectrum of the reagent. That at 3.67 ppm corresponds to the methylenic —CH_2—COOH protons and that at 4.10 ppm corresponds to the methylamino —CH_2—N< protons. No additional signal could be observed. In the nmr spectrum of the esterified derivative the following signals have been recorded: 2.34 ppm corresponding to the methylic protons CH_3—COO— in positions 2- and 7-, 2.45 ppm corresponding to CH_3—COO— in position 1-, 3.53 ppm corresponding to the methylenic protons —CH_2—COO^-, 3.67 ppm corresponding to methylic protons —COO—CH_3, and 4.03 ppm corresponding to methylamino protons —CH_2—N<. A complex signal is recorded in the range 7.5–8.3 ppm originated by the aromatic protons in positions 4-, 5-, 6-, and 8-.

The mass spectrum of the pentamethylic derivative of the reagent shows the molecular peak at 471 m/e which agrees wth the expected molecular weight for this compound.

The solubility of the reagent in distilled water has been determined by the Rose method (9) and found to be 0.19 g/L.

Thermal gravimetric and differential analyses of the anhydrous and dihydrated compound have been performed. The anhydrous reagent, Fig. 1, shows an endothermic effect at 184°C which is followed by an exothermic effect at 190°C. The loss of mass amounts to nearly 10.9% and may correspond to a decarboxylation, the calculated loss being 11%. The elemental analysis of a sample of the reagent heated up to

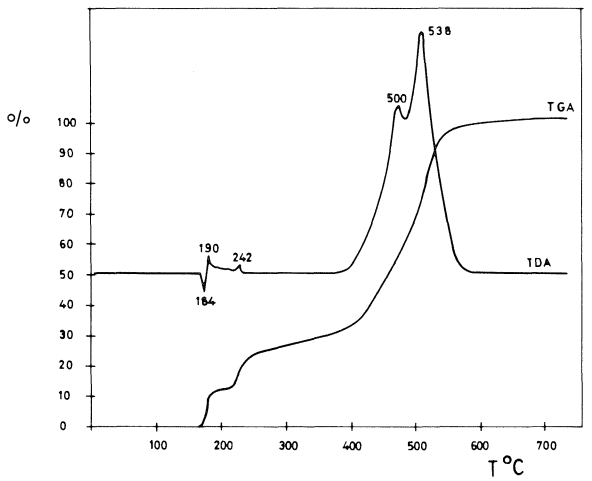

FIG. 1. Thermal analysis of anhydrous anthrapurpurin complexan.

184°C for half an hour is in accordance with this hypothesis. An additional exothermic effect is observed at 242°C with a loss of mass amounting again to nearly 10.9%. Such loss may be caused by a further decarboxylation. The ir spectrum of a sample of the reagent heated up to 245°C for 1 h does not show bands assignable neither to ν(C=O) nor to ν(OH) vibrations. This observation agrees with the proposed interpretation. Finally, two large exothermic effects are observed at 500°C and 530°C which should correspond to the combustion of the sample. The hydrated compound shows the same effects as the anhydrous one but two additional endothermic effects can be seen at 87°C and 140°C with a loss of mass amounting to nearly 4% for each one. The first effect may correspond to the loss of one molecule of lattice water and the second one to the loss of one molecule of strongly hydrogen-bonded water.

Only one polarographic wave has been observed in the polarograms recorded from aqueous solutions of anthrapurpurin complexan at different concentrations, temperatures, and pH. Figure 2 shows a representative polarogram at pH = 4.60. First of all, we investigated the dependence of i_d on the height of the mercury column as well as on pH. The results were obtained from a 10^{-4} M solution at pH = 4.60. The plot of i_d vs. $h^{1/2}$ shows a linear dependence which proves that the wave height is diffusion-controlled. The temperature coefficient of i_d has been investigated in the range between 20°C and 85°C with 2.5×10^{-4} M solutions at pH = 4.60. The temperature coefficient is found to be $d(\log i_d) \div dT = 0.0063$ (close to the theoretical value 0.007) confirming the diffusion-controlled nature of the

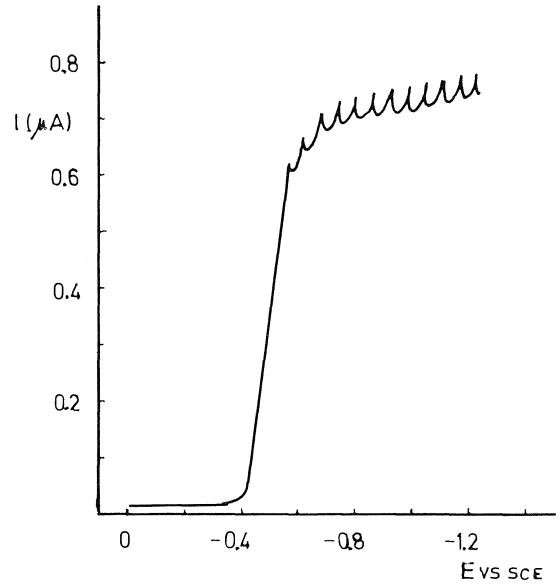

FIG. 2. Polarographic wave of anthrapurpurin complexan at pH = 4.60.

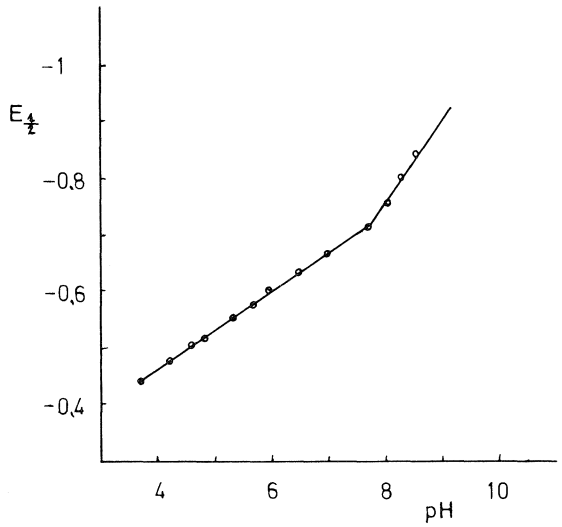

FIG. 3. Dependence of half-wave potential on pH.

polarographic wave. Then, we studied the dependence of the half-wave potential on pH to determine how many hydrogen ions are involved in the reduction. Polarograms were recorded from 2.5×10^{-4} M solutions in the range of pH between 3.75 and 8.70. Values of $E_{1/2}$ as well as those of $n\alpha$ were calculated in each case. Figure 3 shows the plot of $E_{1/2}$ vs. pH. One can observe two straight lines the slopes of which are 0.0697 and 0.12 depending on whether pH is lower or higher than 7.76. Accordingly, the number of hydrogen ions involved in the reduction must be either $p = 1$ or $p = 2$ respectively. The intersection point at pH = 7.76 defines the value of a pK which agrees with that of pK_3 determined by potentiometric and spectrophotometric methods.

On the other hand, we checked that the diffusion current is proportional to the solute concentration, i.e., that Ilkovic's equation holds in the concentration range between 6×10^{-6} M and 5×10^{-4} M at pH = 4.60. In all cases we also calculated $E_{1/2}$ which was independent of concentration. There is a linear dependence of i_d on concentration. The slope of i_d vs. concentration was found to be 2.708 μA cm^3/mol. Hence, the diffusion current constant is $I = i_d/m^{2/3} \cdot t^{1/6} c = 607 D^{1/2} n = 2.41$ and the diffusion coefficient $D = 3.9 \times 10^{-6}$ cm^2/s, where $n = 2$, $m = 0.68$ mg/s, and $t = 9.7$ s. Such values for I and D agree with those previously published for some anthraquinones (5). Finally, we carried out a controlled-potential coulometry to determine n, i.e., the number of electrons involved in the reduction. A mercury pool was used as the cathode and a platinum wire as the auxiliary electrode, the reference electrode was a sce. The concentration of the sample before and after the electrolysis was measured polarographically to ensure that reduction reached completion. The electrolyzed samples contained 0.1640 g of solute in 100 mL of solution, a continuous stream of nitrogen was passed during the electrolysis at the end of which the wave at $E_{1/2} = -0.5$ V had disappeared but a new one did appear at $E_{1/2} = -1.22$ V. Therefore, it appears that the reduction involves two electrons in the range of pH investigated.

Finally, the acid-dissociation constants of anthrapurpurin complexan have been determined by potentiometric (10–12) and spectrophotometric methods (13) at ionic strength $\mu = 0.1$. A maximum of five dissociation constants have been determined in the range of pH investigated and their pK values are collected in Table 1 together with that obtained fron the polarographic method.

Discussion

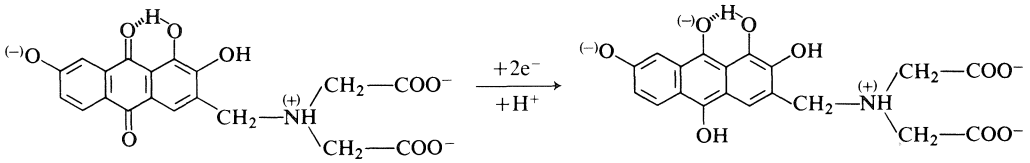
Taking into account the above results we have proposed a mechanism for the reduction of anthrapurpurin complexan at the dme.

The reduction of any anthraquinone may proceed along two different pathways depending on the substituents, pH and supporting electrolyte (5–7): (*a*) by

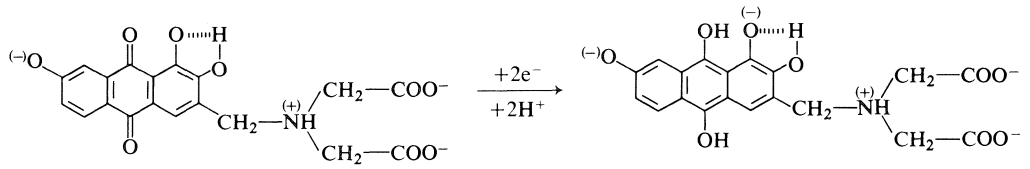
TABLE 1. Selected pK values of anthrapurpurin complexan

Method	pK_1	pK_2	pK_3	pK_4	pK_5
Potentiometric	3.0	5.3	7.6	10.0	11.0
Spectrophotometric	—	5.5	7.6	—	—
Polarographic	—	—	7.76	—	—

pH lower than 7.76



pH higher than 7.76



capturing one electron to form a semiquinone system, or (*b*) by capturing two electrons to form a hydroquinone. In this case the number of electrons involved in the reduction has been two in the whole range of pH we have investigated. Therefore, it seems reasonable to assume that the product of the reduction is the hydroquinone derivative. However, the number of hydrogen ions involved is either one or two depending on pH. It seems possible to explain these mechanisms by assuming that the —OH substituent in position 1 is not dissociated at pH lower than 7.76. Accordingly, the quinone oxygen in position 9 is reduced to $—O^-$ and hydrogen-bonded to —OH in position 1. At pH higher than 7.76 the —OH group in position 1 is dissociated and may be hydrogen-bonded to —OH in position 2; therefore, the second hydrogen ion is captured to form the hydroquinone derivative.

Consequently, the order of dissociation of the protons seems to be as follows: (*a*) the second carboxyl group proton (the first one is transferred to the nitrogen atom during the dissolution of the reagent, (*b*) the phenolic proton in position 7), (*c*) idem in position 1, (*d*) idem in position 2, and (*e*) the proton at the imino group. The phenolic proton in position 7 seems to dissociate before those in positions 1 and 2 provided that it is not linked by any intramolecular hydrogen bond.

Coefficients *B* de viscosité dans les systèmes ternaires aqueux. III. Halogénures alcalins – alcool *tert*-butylique – eau à 25°C

MARC PALMA ET JEAN-PIERRE MOREL

Laboratoire d'Etudes des Interactions Solutés-Solvants, Groupe de Chimie Physique, Université de Clermont, Bât. 6 Chimie, B.P. 45, 63170 Aubiere, France

Reçu le 12 juillet 1979

MARC PALMA et JEAN-PIERRE MOREL. Can. J. Chem. **57**, 3247 (1979).

Nous avons mesuré, à 25°C, le coefficient *B* de viscosité de HCl, LiCl, NaCl, KCl, RbCl, KI et KBr dans les mélanges hydroorganiques contenant de $X = 10$ à 40% en poids d'alcool *tert*-butylique, les concentrations en électrolyte variant entre 0.1 et 0.3 *M*.

Les courbes $B = f(X)$ présentent des points d'inflexion et des minimums dont la position peut s'expliquer par les propriétés structurales du solvant mixte.

On observe, dans l'eau, une relation linéaire entre l'entropie d'hydratation et le coefficient *B* des ions. De la même façon, on peut mettre en évidence, pour tous les mélanges étudiés, une corrélation linéaire entre l'entropie de solvatation et le coefficient *B* des électrolytes.

Ces corrélations permettent de caractériser deux zones distinctes ($X < 20\%$ et $X > 20\%$) dans la gamme des mélanges eau–*tert*-BuOH.

MARC PALMA and JEAN-PIERRE MOREL. Can. J. Chem. **57**, 3247 (1979).

We have measured the coefficient of viscosity *B* at 25°C of HCl, LiCl, NaCl, KCl, RbCl, KI, and KBr in the mixtures of aqueous organic solvents containing from 10 to 40% *tert*-butyl alcohol by weight (X), the concentration of electrolyte varying from 0.1 to 0.3 *M*.

Plots of $B = f(x)$ show points of inflexion and minima whose positions can be explained by the structural properties of the mixed solvent.

In water, a linear relationship between the entropy of hydration and coefficient *B* of the ions is observed. In the same way, it can be shown that a linear correlation exists between the entropy of solvation and coefficient *B* of the electrolytes for all the mixtures studied.

These correlations lead to the characterization of two distinct zones ($X < 20\%$ and $X > 20\%$) for the range of *tert*-butyl alcohol – water mixtures.

[Journal translation]

Introduction

Nous avons abordé l'étude de la viscosité des solutions ternaires aqueuses contenant un électrolyte et un nonélectrolyte par le système NaCl – alcool *tert*-butylique – eau (1). Ces premiers résultats nous ont conduit ensuite à examiner les systèmes MX–*t*-BuOH–eau (MX: halogénure alcalin, *t*-BuOH: alcool *tert*-butylique) pour des concentrations en électrolyte et en alcool dans l'eau inférieures à 2 *M* (2); dans cette approche, MX et *t*-BuOH étaient considérés comme des solutés dans l'eau. Les résultats que nous présentons ici concernent les mêmes systèmes où MX reste un soluté alors que la concentration en *t*-BuOH devient assez grande pour qu'on puisse considérer cet alcool comme un co-solvant de l'eau. Il s'agira donc, en fait, de déterminer de façon classique le coefficient *B* de la loi de Jones–Dole des halogénures alcalins dans les mélanges eau–*t*-BuOH.

Depuis quelques années, nous avons étudié nombre de propriétés thermodynamiques de divers solutés, en particulier celles des halogénures alcalins (3–5) dans les mélanges aqueux contenant jusqu'à 40% en poids d'alcool *tert*-butylique; ce co-solvant nous paraissait le plus typique de ce qu'il est convenu d'appeler les "promoteurs hydrophobes de la structure de l'eau". Les nombreux résultats obtenus ont mis en évidence des relations entre: propriétés à dilution infinie du soluté et propriétés structurales du solvant. La difficulté de rendre compte quantitativement de ces dernières fait qu'il est cependant difficile de proposer des modèles précis de solvatation.

Le coefficient *B* de la loi de Jones–Dole (6) est une grandeur caractéristique des interactions ion–solvant particulièrement parlante. Aussi, l'étude de la viscosité des solutions aqueuses d'électrolyte a-t-elle donné lieu à de nombreux travaux (6–9). Si l'on considère des petits ions comme ceux des halogénures alcalins dont la taille est de l'ordre de grandeur de la taille d'une molécule d'eau, l'effet de volume de type Einstein (10) sur la viscosité du solvant peut-être négligé; on peut alors considérer que l'effet observé rend essentiellement compte de l'interaction ion–solvant, c'est-à-dire de la modification du solvant dans la cosphère de l'ion. Aucune théorie ne permet la prévision du coefficient *B* de viscosité; cependant on peut dire que ce paramètre, qui chiffre l'augmentation ou la diminution de viscosité d'un solvant provoquées par la présence d'un électrolyte, rend compte

en fait de la modification des degrés de liberté des molécules d'eau dans la zone perturbée par l'ion. Deux relations empiriques importantes justifient ce point de vue: la relation linéaire entre B et l'entropie d'hydratation des ions, d'abord proposée par Frank et Evans (11), puis développée par Nightingale (12); la relation linéaire entre B et un coefficient analogue qui traduit les variations de l'inverse du temps de relaxation longitudinale, T_1, du proton des molécules d'eau en rmn, avec la concentration en électrolyte; cette corrélation a été mise en évidence par Engel et Hertz (13).

Les mesures de coefficient B d'électrolyte dans les mélanges hydroorganiques sont peu nombreuses. Les plus significatives sont celles de Feakins et coll. (14), pour les halogénures alcalins dans les mélanges eau–méthanol. Les variations de B sont cependant assez faibles lorsque varie le pourcentage en poids de méthanol ajouté dans l'eau. Notre projet est d'examiner ce qu'il en est dans les mélanges eau–t-BuOH; les résultats obtenus nous permettront de vérifier si les corrélations établies dans l'eau se conservent dans ces milieux.

Partie expérimentale

Appareillage

Sa description détaillée a déjà été faite précédemment (1, 15). Il s'agit d'un dispositif automatique réunissant un ensemble viscosimétrique Fica (avec viscosimètre à tube capillaire de diamètre = 0.5 mm de type Ubbelohde), un densimétre digital Anton Paar et une burette à dilution.

Produits

Les halogénures alcalins sont des produits purs pour analyses "Merck". Ils ont été maintenus pendant 48 h dans une étuve à 150°C avant utilisation. L'alcool *tert*-butylique a été purifié au laboratoire selon la méthode habituelle (16). L'eau est tridistillée dans un appareil en quartz, les solvants et les solutions sont filtrés sur verre fritté de porosité no 4.

Traitement des données et choix du domaine de concentration

Nous avons vu ailleurs (1) que la méthode de détermination du coefficient B de Jones–Dole consiste à représenter la droite $F = (\eta_r - 1 - A\sqrt{c})/c$ en fonction de c, A étant la valeur calculée de ce coefficient à l'aide de la formule de Falkenhagen et Vernon (17). Le coefficient B se détermine en extrapolant cette droite à concentration nulle. Le calcul théorique de l'incertitude relative $\Delta F/F$ montre que celle-ci peut s'écrire sous la forme suivante:

$$[1] \quad \frac{\Delta F}{F} = \frac{\Delta \eta_r}{|\eta_r - 1 - A\sqrt{c}|} + \left| 1 + \frac{A/2\sqrt{c}}{\eta_r - 1 - A\sqrt{c}} \right| \frac{\Delta c}{c}$$

Quand la concentration devient suffisamment faible, la précision sur F peut devenir très mauvaise. Par ailleurs, l'expérience montre que F peut s'écrire sous la forme:

$$[2] \quad F = B + Dc + Ec^2 + \ldots$$

Au-delà d'une certaine concentration, Ec^2 devient grand devant ΔF, et la méthode de détermination de B citée plus haut n'est plus valable. La mesure du coefficient B doit donc s'effectuer à l'interieur d'un domaine de concentration relativement étroit. L'importance du choix de ce domaine s'illustre bien lorsqu'on examine dans la littérature les déterminations connues des coefficients B(2).

Les mesures ont été effectuées ici pour des molarités comprises en général entre 0.1 et 0.3.

Résultats

Les valeurs des coefficients B des électrolytes dans les différents mélanges eau–t-BuOH sont rassemblées dans le tableau 1.[1]

Discussion

1. Variations des coefficients B *avec la composition du solvant*

Les variations du coefficient B des différents halogénures alcalins avec le pourcentage X de t-BuOH dans le mélange hydroorganique sont représentées par les courbes des figs 1 et 2. On a porté sur celles-ci la grandeur de transfert ΔB_t, différence entre la valeur de B dans un mélange donné et la valeur de B dans l'eau. Pour tous les électrolytes étudiés, sauf HCl, on peut faire les constations suivantes: B passe par un minimum pour un solvant contenant entre 20 et 25% en poids de t-BuOH; pour les chlorures

[1]On peut obtenir la série complète des données expérimentales, à un prix nominal, en s'adressant au Dépôt de données non publiées, ICIST, Conseil national de recherches du Canada, Ottawa (Ont.), Canada K1A 0S2.

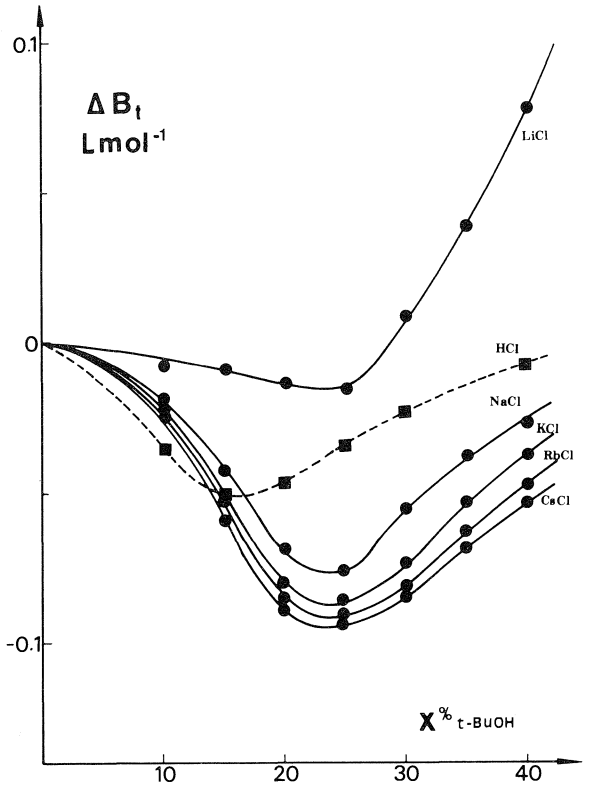

FIG. 1. Coefficients B de transfert des chlorures alcalins de l'eau aux mélanges eau – alcool *tert*-butylique.

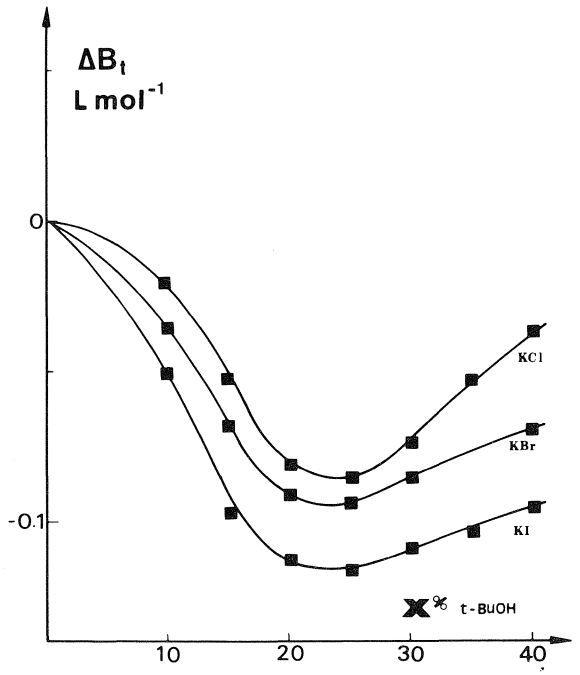

FIG. 2. Coefficients B de transfert des halogénures de potassium de l'eau aux mélanges eau – alcool *tert*-butylique.

alcalins, la profondeur du minimum augmente quand croît le rayon du cation, de même pour les halogénures de potassium, celle-ci augmente quand croît le rayon de l'anion; les courbes présentent un point d'inflexion marqué pour une composition de l'ordre de 15% en poids de *t*-BuOH.

La courbe représentative du coefficient B de HCl se différencie des autres courbes par la position de son minimum déplacée vers $X = 15\%$.

Si, sans chercher à distinguer le rôle respectif des zones A et B de Frank (18), on admet que l'électrolyte est globalement promoteur de la structure du solvant si $B > 0$ et briseur si $B < 0$, on peut énoncer la conclusion qualitative suivante: les électrolytes étudiés sont, soit moins promoteurs, soit plus briseurs, dans les mélanges étudiés que dans l'eau.

Ceci peut s'expliquer si l'on admet que ces mélanges sont plus structurés que l'eau pure: dans ces milieux, l'action des ions promoteurs qui induisent autour d'eux une structure de symétrie centrale (zone A) est moins marquée que dans l'eau ($B > 0$ mais plus petit que dans l'eau); au contraire, les ions briseurs dont l'influence est déterminée par celle de leur zone B, ont une action d'autant plus efficace que le milieu est plus structuré ($B < 0$ mais plus petit que dans l'eau). Ces conclusions doivent, à notre avis, être fortement nuancées. Le raisonnement ci-dessus

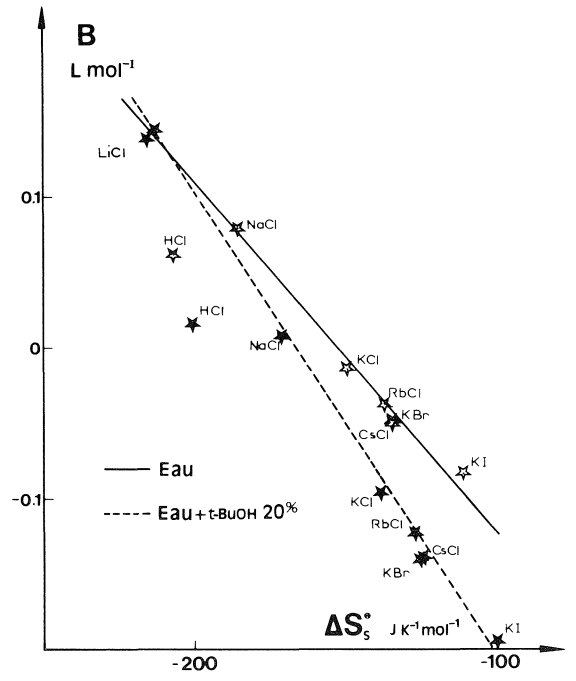

FIG. 3. Variation des coefficients B de viscosité des halogénures alcalins en fonction de leurs entropies de solvatation dans l'eau et dans un mélange eau – alcool *tert*-butylique à 20%.

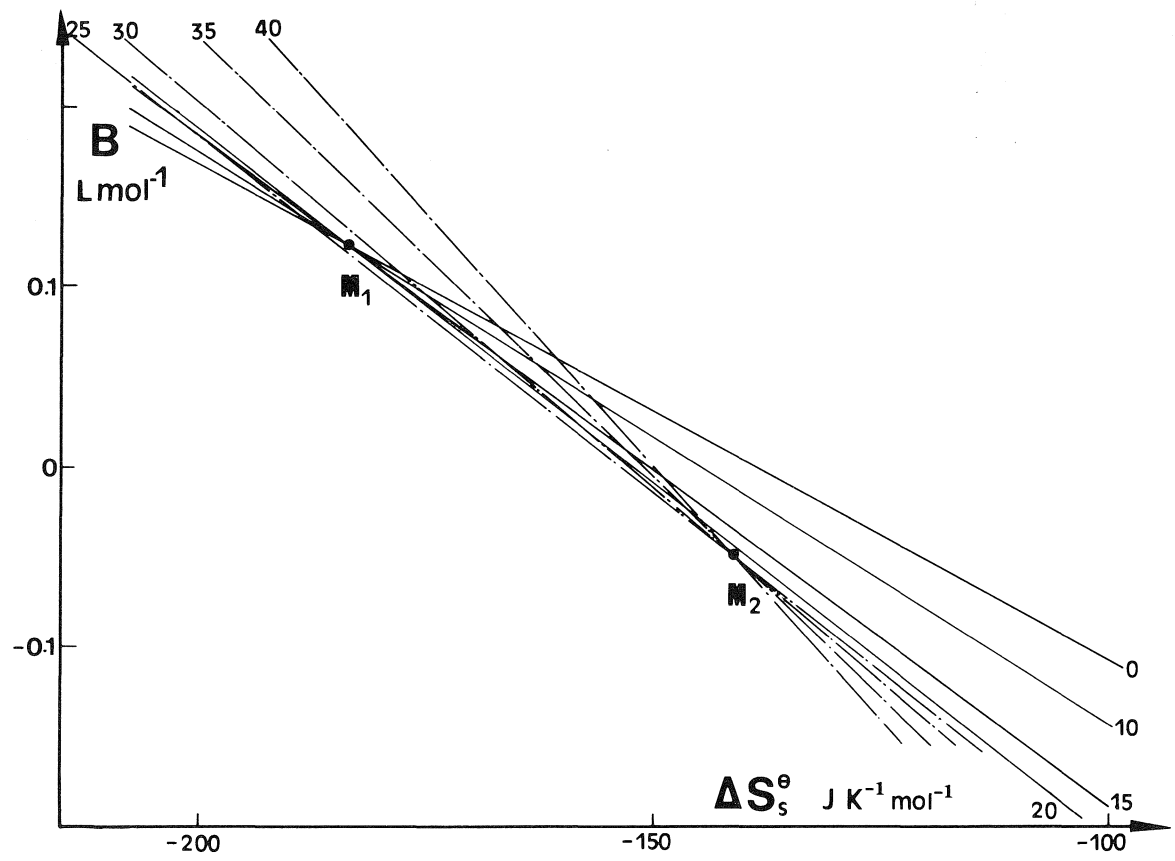

FIG. 4. Variation des coefficients B de viscosité des halogénures alcalins en fonction de leurs entropies de solvatation dans les mélanges eau – alcool *tert*-butylique.

est au mieux valable dans les mélanges très riches en eau où seule cette dernière intervient dans la cosphère des ions; quand on atteint des pourcentages assez élevés de *t*-BuOH dans le solvant, les molécules d'alcool sont elles aussi impliquées dans la solvatation des ions et sans doute même dans la zone A. Ce phénomène peut expliquer la croissance de B pour les fortes valeurs de X, et le fait que le minimum est d'autant moins prononcé que le cation ou l'anion est petit, c'est-à-dire comporte une zone A importante. Du fait de la superposition des deux effets: modification de la structure de l'eau et intervention des molécules d'alcool dans la solvatation, il est probable que le minimum des courbes $B = f(X)$ ne correspond pas au mélange de structure maximum; celui-ci se traduirait plutôt par la présence du point d'inflexion situé vers $X = 15\%$, point significatif d'un changement de tendance. Les derniers travaux relatifs à la structure des mélanges eau–*t*-BuOH montrent d'ailleurs que la composition en question correspond à la possibilité de formation d'un quasi-clathrate $(H_2O)_{21}$–*t*-BuOH, structure privilégiée dont la présence a pu être mise en évidence (19, 20).

2. Relations coefficient B — *entropie*

L'interprétation des courbes $\Delta B_t = f(X)$ reste assez délicate, tout comme celle des courbes relatives aux grandeurs thermodynamiques des électrolytes à dilution infinie dans les mélanges eau–*t*-BuOH. Il est cependant remarquable de constater la similitude des courbes des figs 1 et 2, avec celles représentant les variations de l'entropie de transfert ΔS_t^θ des mêmes électrolytes entre l'eau et les mêmes mélanges (3): au minimum de ΔB_t correspond un maximum de ΔS_t^θ et la présence du point d'inflexion pour la même valeur de X se trouve dans les deux familles de courbes. Il est donc probable qu'une relation précise existe entre les valeurs de B et l'entropie des ions dans les milieux étudiées.

Dans l'eau, Nightingale (12) a montré l'existence d'une corrélation linéaire entre B et l'entropie d'hydratation ΔS_h^θ des ions (grandeur thermo-

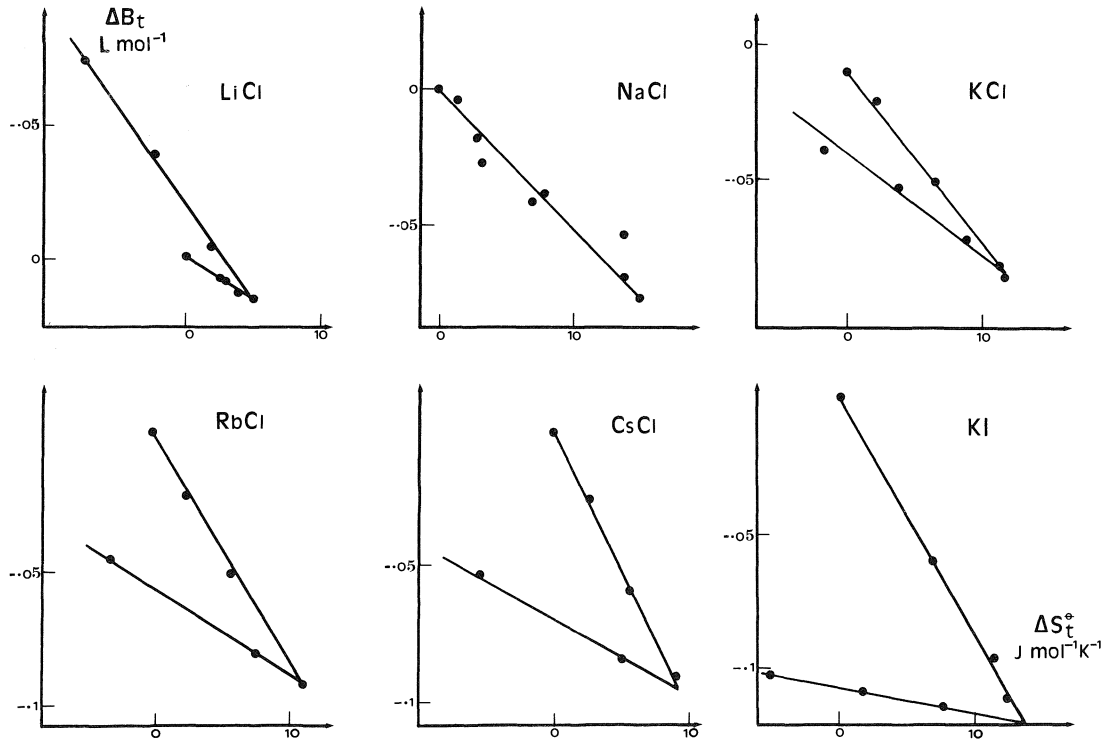

FIG. 5. Coefficients B de transfert des halogénures alcalins en fonction de leurs entropies de transfert de l'eau aux mélanges eau – alcool *tert*-butylique.

dynamique relative au passage de la phase gazeuse à l'état standard dans l'eau). Il nous est facile de calculer les entropies de solvatation ΔS_s^θ des différents électrolytes:

$$[3] \quad \Delta S_s^\theta = \Delta S_h^\theta + \Delta S_t^\theta$$

les valeurs de ΔS_h^θ étant celles données par Desnoyers et Jolicoeur (21).

Nous ne chercherons pas à attribuer leurs valeurs propres aux ions, ni pour B, ni pour ΔS_s^θ; le choix arbitraire que nous pourrions faire n'apporterait rien aux conclusions que nous allons tirer.

La fig. 3 montre que dans le cas où $X = 20\%$, la corrélation linéaire qui existe dans l'eau est conservée. (HCl ne se place pas sur la droite ni dans un cas, ni dans l'autre.) Il en est de même dans tous les mélanges c'est-à-dire pour toutes les valeurs de X étudiées. Sur la fig. 4, nous avons simplement tracé les droites moyennes traduisant toutes ces corrélations. Analytiquement, si l'on écrit:

$$[4] \quad B(MX) = a\Delta S_h^\theta(MX) + b \text{ dans l'eau}$$

on peut alors écrire, pour tous les mélanges de composition X:

$$[5] \quad B(MX) = (a' + \alpha X)\Delta S_s^\theta(MX) + (b' + \beta X)$$

relation qui traduit l'existence des deux faisceaux de droites de la fig. 4. Le traitement des valeurs numériques par la méthode des moindres carrés, avec B en mol^{-1} L et ΔS_s^θ en J K^{-1} mol^{-1} dans l'échelle des molarités, conduit aux valeurs suivantes:

Pour $X = 10, 15, 20$:

$$a' = a = -2.3 \times 10^{-3}$$
$$\alpha = 3.5 \times 10^{-5}$$
$$b' = b = 0.3$$
$$\beta = -0.8 \times 10^{-2}$$

Pour $X = 25, 30, 35, 40$:

$$a' = -1.8 \times 10^{-3} \neq a$$
$$\alpha = 5.0 \times 10^{-5}$$
$$b' = -0.3 = -b$$
$$\beta = -0.8 \times 10^{-2}$$

Ces deux groupes de valeurs traduisent nettement l'évolution différente de la même corrélation suivant

la zone de composition des mélanges que l'on considère, la frontière entre ces zones se situant vers la composition qui correspond au minimum des courbes $B = f(X)$, soit entre 20 et 25% en poids de *t*-BuOH. La signification précise des différents paramètres est naturellement difficile à donner; ceux-ci ont toutefois le mérite de faire apparaître clairement l'existence de deux types de milieux solvants dans le domaine que nous avons étudié: de l'eau pure jusqu'à un pourcentage un peu supérieur à 20% en poids de *t*-BuOH, le mélange se comporte essentiellement comme l'eau même si ses propriétés structurales évoluent, c'est donc une structure de type essentiellement aqueux qui détermine les grandeurs thermodynamiques et de transport qui traduisent la solvatation; pour des pourcentages en alcool allant de 25 à 40%, il s'agit d'un autre type de milieu où les caractéristiques de la structure aqueuse ont disparu.

Les courbes de la fig. 5 où est porté ΔB_t en fonction de ΔS_t^{θ}, c'est-à-dire les fonctions de transfert, traduisent de façon encore plus spectaculaire la discontinuité entre les deux types de milieu: il apparait ici deux corrélations linéaires distinctes suivant la zone de composition pour un électrolyte donné.

Conclusion

Des variations importantes ont été observées pour les valeurs des coefficients *B* des halogénures alcalins dans les mélanges eau–*t*-BuOH; celles-ci peuvent s'interpréter en admettant que l'alcool ajouté augmente la structure de la phase aqueuse, au moins dans les milieux les plus riches en eau. Nous considérons comme plus interessantes les observations suivantes.

Dans tous les solvants mixtes étudiés, il existe, comme dans l'eau, une relation de proportionnalité entre l'entropie de solvatation des ions et leur coefficient *B* de viscosité. Ces deux grandeurs macroscopiques traduisent donc, d'une façon semble-t-il assez générale, les mêmes phénomènes au niveau moléculaire: le bilan global de la modification des degrés de liberté du solvant due à la présence de l'ion.

De plus l'étude des corrélations entre ΔS^{θ} et *B* permet de mettre en évidence, dans les mélanges étudiés, deux zones bien définies: celle des mélanges riches en eau au comportement déterminé par leur structure de type aqueux, et, pour des pourcentages en alcool supérieurs à 20%, des mélanges hydro-organiques qui ne recélent sans doute plus rien de la structure tridimensionnelle de l'eau.

A ^1H and ^{13}C nuclear magnetic resonance study of silicon and germanium chalcogenide derivatives

JOHN E. DRAKE, BORIS M. GLAVINĆEVSKI, ROBYN HUMPHRIES, AND ABDUL MAJID

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received June 28, 1979

JOHN E. DRAKE, BORIS M. GLAVINĆEVSKI, ROBYN HUMPHRIES, and ABDUL MAJID. Can. J. Chem. **57**, 3253 (1979).

This paper reports the ^1H and ^{13}C nmr parameters of the disilyl- and digermyl-chalcogenide species $(Me_nH_{3-n}M)_2E$, where M = Si, Ge; E = O, S, Se, Te and n = 0 to 3. The general pattern of changing shifts is markedly influenced by methyl substitution.

JOHN E. DRAKE, BORIS M. GLAVINĆEVSKI, ROBYN HUMPHRIES et ABDUL MAJID. Can. J. Chem. **57**, 3253 (1979).

On rapporte les paramètres rmn du ^{13}C et du ^1H des espèces chalcogénides disylilés et digermylés $(Me_nH_{3-n}M)_2E$ ou M = Si, Ge; E = O, S, Se, Te et n = 0 à 3. Le schéma général des changements des déplacements chimiques est fortement influencé par la substitution du méthyle.

[Traduit par le journal]

Introduction

In a recent study of bis(methylgermyl) and bis(dimethylgermyl) chalcogenides, a comprehensive table was presented of their ^1H nmr parameters along with other spectroscopic data (1). We report herein similar data for the silicon analogues along with ^{13}C nmr shift data for both the silicon and germanium counterparts. Despite claims to the contrary, the theoretical principles and molecular parameters affecting ^{13}C nmr parameters, at least for organometallic compounds, are still not well understood (2) and it is difficult to advance beyond empirical correlations to rationalise trends in such parameters as chemical shifts or coupling constants (3–6).

Experimental

The species $(Me_nH_{3-n}Si)_2E$ were prepared by methods developed in our laboratory for the analogous germanium compounds (1).

The natural abundance carbon-13 spectra were obtained on a Bruker CPX 100 (FT model) spectrometer operating at a resonance frequency of 22.639 MHz, at a probe temperature of 35°C. All spectra were recorded under ^1H noise-decoupling conditions. The samples were sealed in capillaries as neat liquids and the capillaries were placed coaxially in 5 mm tubes containing $CDCl_3$ which served as a lock and TMS as standard.

The proton spectra were recorded on a JEOL C-60HL spectrometer operating at a resonance frequency of 60 MHz at room temperature. Chemical shifts are in ppm ($\delta \pm 0.02$ ppm) to low field of internal TMS in CCl_4 solution (5% v/v). Chemical shifts of the tellurides were measured relative to cyclohexane. Deviations for coupling constants of neat liquids are J(HH) ± 0.05 Hz, J(SiH) ± 1.0 Hz, and J(CH) ± 0.2 Hz.

Results and Discussion

The ^1H nmr parameters for the whole series of $(Me_nH_{3-n}Si)_2E$ compounds ($n = 0 \rightarrow 3$; E = O, S, Se, Te) are presented in Table 1, along with their ^{13}C chemical shifts, as well as those of their germanium analogues.

α-^1H and α-^{13}C Chemical Shifts

It is a general trend in methyl-hydrido-silane (3) and -germane (7) derivatives of the type $Me_nH_{3-n}MX$ (M = Si, Ge; X = F, Cl, Br, I; n = 0, 1, 2) that the α-proton shifts are principally controlled by the inductive effect. The same is also true for the series of chalcogermanes (1) of the type $(Me_nH_{3-n}Ge)E$ (E = O, S, Se, Te) and for the series $(H_3Si)_2E$, a distinctive trend in the α-proton chemical shifts (δ(SiH)) shows a steady up-field shift as the chalcogen changes from O → S → Se → Te (see Table 1 and Fig. 1(*a*)). Thus, the less electron-withdrawing chalcogens are expected to leave the α-protons more shielded. The trend is relatively large with the total shift (Δ^1H, O → Te) from oxygen to tellurium being 0.90, but considerably less than in the $(H_3Ge)_2E$ series where Δ^1H, O → Te, is 1.69 (1) (Fig. 1(*b*)). This difference mainly arises because of the much higher shifts of the oxides of germanium, suggesting that oxygen is not as effectively electronegative relative to silicon as it is to germanium. This is expected if $(p$–$d)\pi$ bonding is more important in the silanes. The trend persists but is less marked (Δ^1H, O → Te, = 0.41) for the series $(MeH_2Si)_2E$ (Fig. 1(*c*)) again reflecting what was found for $(MeH_2Ge)_2E$ (Fig. 1(*d*); Δ^1H, O → Te, = 1.06 (1)). An examination of the corresponding α-^{13}C chemical shifts for the monomethylated series (Fig. 1(*c*) and (*d*)) confirms similar progressive high field shifts ($\Delta^{13}C$, O → Te, = 3.45 (Si) and 3.48 (Ge)). However, as can be seen from

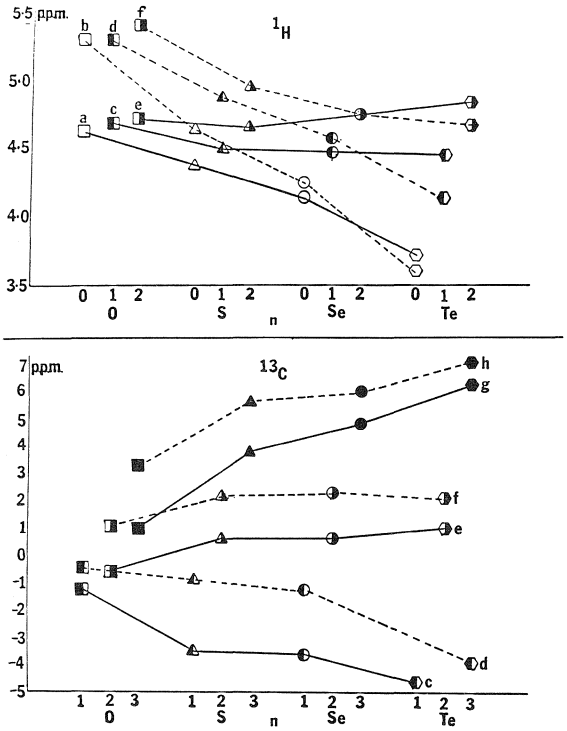

FIG. 1. Change in α-^1H and α-^{13}C chemical shifts with changing number of methyl groups and chalcogens in the series $(Me_nH_{3-n}M)_2E$ drawn to emphasize result of chalcogen changes. $(H_3Si)_2E$ = *a*; $(H_3Ge)_2E$ = *b*; $(MeH_2Si)_2E$ = *c*; $(MeH_2Ge)_2E$ = *d*; $(Me_2HSi)_2E$ = *e*; $(Me_2HGe)_2E$ = *f*; $(Me_3Si)_2E$ = *g*; and $(Me_3Ge)_2E$ = *h*. Oxides □; sulfides △; selenides ○; tellurides ⬡; silicon series —; germanium series

Fig. 1(*e*, *f*, *g*, *h*) there is a reversal in the direction of the trend for both the silicon and germanium $(Me_2HM)_2E$ compounds ($\Delta^{13}C$, O → Te, = −1.49 (Si) and −1.03 (Ge)) which is more marked for the $(Me_3M)_2E$ derivatives ($\Delta^{13}C$, O → Te, = −5.27 (Si) and −3.83 (Ge)). The α-proton shifts in the $(Me_2HSi)_2E$ series also show a slight overall downfield shift (Fig. 1(*e*)) although the $(Me_2HGe)_2E$ series still maintains the upfield shift. Nevertheless, the general trends imply that the factors resulting in an overshadowing of the inductive effect influence both the α-^1H and α-^{13}C chemical shifts and have a similar effect on both the silicon and germanium derivatives.

The effect of successive substitution of protons by methyl groups within the $(Me_nH_{3-n}M)_2E$ series where the chalcogen is unchanged is illustrated in Fig. 2 for the α-^1H and ^{13}C shifts respectively. In general, (*i*) increasing methylation results in a decreased shielding of the α-carbons (8) as well as the α-protons; (*ii*) the effects are much more marked in the $(Me_nH_{3-n}M)_2Te$ compounds ($\Delta^{13}C$, *n* = 1 to 3, = −10.92 (Si) and −11.04 (Ge); Δ^1H, *n* = 0 to 2, −1.11 (Si) and −1.06 (Ge) (1)), becoming progressively less marked through the selenium and sulfur series and being relatively small in the $(Me_nH_{3-n}M)_2O$ compounds ($\Delta^{13}C$, *n* = 1 to 3, = −2.20 (Si) and −3.25 (Ge); Δ^1H, *n* = 0 to 2, −0.08 (Si) and −0.12 (Ge) (1)); (*iii*) the general pattern of changing shifts is similar on silicon and germanium compounds.

β-^1H *Chemical Shifts*

The trends in the CH_3 resonance shifts are typical

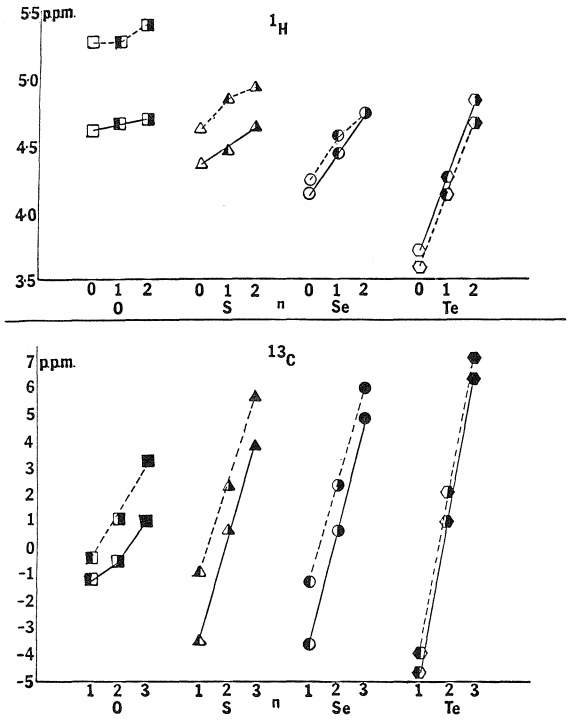

FIG. 2. Change in the α-^{1}H and α-^{13}C chemical shifts drawn to emphasize changes in number of methyl groups. Symbols as in Fig. 1.

of observation on the related halogeno-silanes (3) and halogeno- (7) and chalco- (1, 9) germanes. Thus, there is a shift to higher field with increasing methyl substitution and a shift to lower field as the chalcogen changes from the more electronegative but smaller oxygen atom through to the less electronegative but bulkier tellurium atom. β-Proton shifts are generally assumed to be related to anisotropic rather than inductive effects and this is also apparently the case with these $(Me_nH_{3-n}Si)_2E$ species.

Coupling Constants

The ^{13}C- and ^{29}Si-proton coupling constants were evaluated from the well-resolved satellites of the β- and α-proton resonances. Satellites were also observed that arose from long-range spin–spin coupling involving ^{77}Se and ^{125}Te suggesting that exchange, if any, of silyl groups must be slow.

The largest trend in changing values of coupling constants arises in the decrease in $J(^{29}SiH)$ as methyl groups substitute for protons. Assuming that the lower value indicates a decrease in *s*-character (6, 10) and that Bent's rule is operative (11), then the methyl group is behaving as a less-electronegative group than hydrogen. This further suggests that the "methyl-effect" is not one primarily associated with an inductive contribution. On the other hand, the increase, albeit very slight, in the value of $J(^{29}SiH)$ along the series O → S → Se → Te, implies an increasing electronegativity from oxygen to tellurium which violates chemical sense. However, as with the α-chemical shifts, the effect of methyl substitution is more pronounced than the change of chalcogen. A comparison of the values of $J(^{13}CH)$ in the silicon series with those of the corresponding germanium series (1) shows the consistent feature of decrease with methyl-substitution and increase along the series O → S → Se → Te. The trends are small but, in contrast to $J^{29}SiH$, of about the same magnitude. The absolute values are about 8 Hz higher for the germanes than for the silanes, implying that the silicon moieties are less electronegative than their germanium counterparts, which is consistent with the findings of others (12).

By contrast, the values of the vicinal coupling constants $J(_{HH}{}^{vic})$ are consistently higher in the silanes than in germanes (1), although trends related to changes in the number of methyl groups and the nature of the chalcogen are identical. This is not unexpected for compounds that are presumably structurally similar with a slightly longer H—C—M—H distance for the germanes (7, 13). The long range *J*(H—Si—Te—Si—H′) coupling is observed and its value of 0.59 Hz fits into the general series of similar compounds that have been studied (14–16) and in particular, finishes the sequence of $H_3SiESiH_3$ compounds where *J*(HH′) is 0.70, 0.63, and 0.59 Hz for S, Se, and Te, respectively.

The synthesis of cyclic peptides by the four component condensation (4 CC)

AMADEO FAILLI, HANS IMMER, AND MANFRED GÖTZ

Department of Chemistry, Ayerst Research Laboratories, P.O. Box 6115, Montreal, P.Q., Canada H3C 3J1

Received November 1, 1978

This paper is dedicated to Prof. Karel Wiesner on the occasion of his 60th birthday

AMADEO FAILLI, HANS IMMER, and MANFRED GÖTZ. Can. J. Chem. **57**, 3257 (1979).

Since cyclic peptides constitute a group of natural and synthetic products of considerable practical and theoretical significance, model experiments were carried out to explore the scope of the four component condensation for the synthesis of these structures.

AMADEO FAILLI, HANS IMMER et MANFRED GÖTZ. Can. J. Chem. **57**, 3257 (1979).

Depuis que les peptides cycliques ont été reconnus comme groupe de composés naturels et synthétiques d'une importance théorique et pratique considérable, des expériences pilotes ont été réalisées dans le but d'explorer la portée de la condensation à quatre constituants lors de la synthèse de ces peptides cycliques.

[Traduit par le journal]

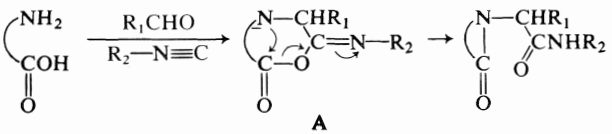
Introduction

In spite of the remarkable versatility of the four component condensation (4 CC) (1), the reaction has not been widely applied to the solution of problems in medicinal chemistry. Notable exceptions are the synthesis of a penam derivative (2), work towards the preparation of an oxacepham derivative (3), and reports from our laboratories dealing with the synthesis of *N*-amino-peptides (4, 5) and the potential anti-Parkinson drug pareptide (6).

Cyclic peptides constitute a group of natural and synthetic products of considerable practical and theoretical significance (7, 8); they act as hormones, antibiotics, toxins, and also affect membrane function. Hence our interest in synthetic approaches to cyclic peptides by the 4 CC.

Results

The preparation of cyclic tripeptides by traditional methods is only successful if *N*-substituted amino acids are employed, for instance proline or sarcosine, since the *cis* configuration of the amide bonds in the linear tripeptide is sufficiently stable to allow ring closure (9, 10). On the other hand, a few syntheses of cyclic tetrapeptides containing exclusively *N*-unsubstituted amino acids as building blocks have been reported (11*a*, *b*). The preparation of *N*-unsubstituted cyclic tripeptides by the 4 CC appears feasible since the primary addition product **A** constitutes a 12-membered ring, which then collapses to the strained cyclic tripeptide, similar to the formation of a strained β-lactam from a 7-membered ring (2, 3).



A

To test this hypothesis, triglycine was used as a model compound in the 4 CC. Disappointingly, the two products isolated turned out to be substituted cyclic hexaglycines, resulting from a doubling reaction (11*b*, 12) (Scheme 1). It follows that **A** was either never formed or the collapse of **A** to the desired 9-membered ring was disfavoured in comparison to the intermolecular reaction of two molecules of **A**. An intermolecular 4 CC and a subsequent intramolecular 4 CC could also account for the products isolated, and similarly the collapse of a 24-membered ring, initially created by a double 4 CC. Since two asymmetric centres are present in **1** or **2** both a racemate and the *meso* form are obtained in each case.

The facile formation of cyclic hexapeptides by a doubling reaction in the course of a 4 CC indicates that similar compounds should be generated by a single 4 CC, provided a suitable linear hexapeptide is employed as starting material. In a model experiment hexaglycine underwent the 4 CC in the presence of isobutyraldehyde and cyclohexyl isonitrile to yield the desired racemic cyclic hexapeptide **3** (Scheme 2).

This result encouraged us to attempt the ring closure of a slightly modified C-terminal eledoisin hexapeptide. In view of the blood pressure lowering effect of eledoisin and many of its shortened analogs (13), these molecules were modified in a variety of ways in an attempt to prolong their biological half-life (5, 14–17). A hitherto unreported ring closed eledoisin derivative would be less prone to attack by

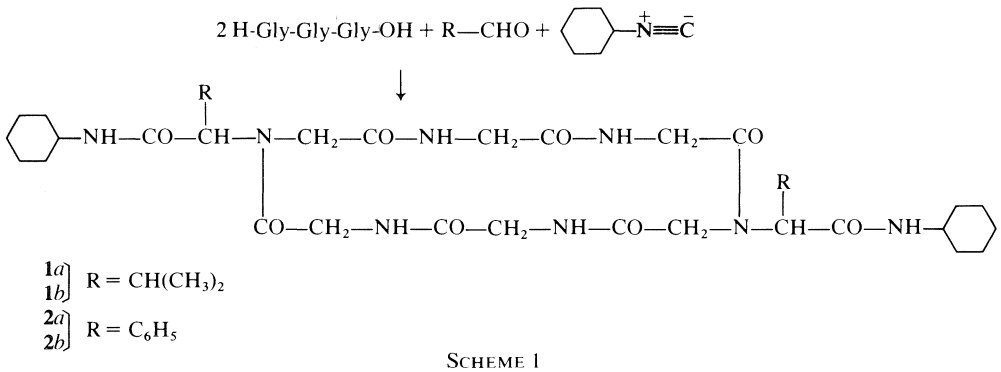
0008-4042/79/243257-05$01.00/0



SCHEME 1

exopeptidases. The starting material **4** (H-Ala-Phe-Val-Gly-Leu-Met-OH) has not been described previously and it was obtained by conventional methods as shown in Scheme 3.

On cyclization of **4** with isobutyraldehyde and cyclohexyl isocyanide the diastereomeric mixture **5***a*, *b* was isolated (Scheme 4). On chromatography **5***a*, *b* could readily be separated. The combined yield of cyclic material amounted to 33%, comparable to yields achieved by other cyclization reactions (18, 19). It should be noted that none of the yields reported in this communication was maximized.

Compounds **5***a* and **5***b* were without effect on the cardiovascular system.[1]

In the type of cyclization described in this paper a new substituent is introduced as side chain in the original amino acid sequence. It should be noted that appropriate choice of the aldehyde (20) will lead to substituents which can be removed after cyclization. Experiments towards this goal are in progress.

Experimental

The nmr spectra were obtained on a Varian A-60A spectrometer, mass spectra on an LKB 9000S spectrometer, and ir spectra on a Perkin Elmer 225 infrared spectrophotometer.

Synthesis of **1**a *and* **1**b

Isobutyraldehyde (2.16 g, 30 mmol) was added under stirring to a suspension of glycyl-glycyl-glycine (1.7 g, 9 mmol) in dry ethylene glycol (15 mL). The ice cold mixture was treated dropwise with cyclohexyl isonitrile (0.97 g, 9 mmol) and left at room temperature for 5 days. After dilution with water the precipitate was collected, washed with water, and chromatographed on silica gel. On elution with $CHCl_3$/CH_3OH (95:5) isomers **1***a* and **1***b* were isolated. Isomer **1***a*: recrystallized from $CHCl_3$/CH_3OH; mp 286–287°C (dec.); yield: 380 mg (12%); ir (Nujol) ν: 3350, 3290, 1692, 1640, 1550; nmr ($CDCl_3$/CD_3OD 4:1): 1.00 and 1.05 (2d, J = 7 Hz, 12H, $(CH_3)_2CH$) ppm; ms (*m*/*e*: 704(M^+), 686, 668. *Anal.* calcd. for $C_{34}H_{56}N_8O_8 \times 0.94\%$ H_2O (K. Fischer): C 57.30, H 8.04, N 15.75; found: C 57.05, H 8.04, N 15.45. Isomer **1***b*: recrystallized from acetone; mp 210°C (dec.); yield: 230 mg (8%); ir (Nujol) ν: 3530, 3350, 3060, 1680, 1640, 1540; nmr ($CDCl_3$/CD_3OD 4:1): 1.04 (2d, J = 7 Hz, 12H, $(CH_3)_2CH$) ppm; ms (*m*/*e*): 704(M^+), 686, 668. Isomers **1***a* and **1***b* were homogenous on tlc (system: $CHCl_3$/CH_3OH 92:8; charring with H_2SO_4). *Anal.* calcd. for $C_{34}H_{56}N_8O_8 \times 0.84\%$ H_2O (K. Fischer): C 57.44, H 8.03, N 15.76; found: C 56.83, H 7.85, N 15.34.

Synthesis of **2**a *and* **2**b

Benzaldehyde (10.6 g, 100 mmol) was added under stirring to a suspension of glycyl-glycyl-glycine (5.67 g, 30 mmol) in dry ethylene glycol (50 mL). The ice cold mixture was treated dropwise with cyclohexyl isonitrile (3.27 g, 30 mmol) and left at room temperature for 9 days. H_2O (100 mL) and $CHCl_3$ (150 mL) were added, followed by traces of CH_3OH to prevent formation of a gum. On standing a colorless solid separated (800 mg, **2***a*). The aqueous phase was exhaustively extracted with $CHCl_3$; the combined organic layers were dried and evaporated to dryness. The residue was triturated with acetone and the separated solid collected (842 mg, **2***b*). On silica gel chromatography of the mother liquor additional quantities of both isomers were isolated. Isomer **2***a*: recrystallized from $CHCl_3$/CH_3OH; mp 330–333°C (dec.); yield: 1.309 g (11.3%); ir (Nujol) ν: 3340, 3270, 3220, 3050, 1670, 1650, 1632, 1574, 1546; ms (*m*/*e*): 772(M^+), 754, 736. *Anal.* calcd. for $C_{40}H_{52}N_8O_8 \times 0.22\%$ H_2O (K. Fischer): C 62.02, H 6.78, N 14.45; found: C 61.52, H 6.86, N 14.30. Isomer **2***b*: recrystallized from $CHCl_3$/CH_3OH; mp 341–343°C (dec.); yield: 579 mg (5%); ir (Nujol) ν: 3340, 3250, 3090, 1665, 1650,

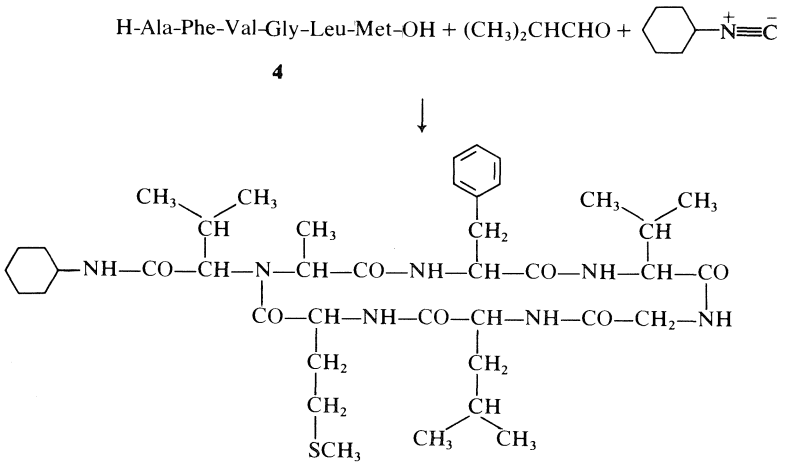
SCHEME 3

1562, 1520. The sample was not volatile enough to give a useful mass spectrum. Isomers **2***a* and **2***b* were homogenous on tlc (system: $CHCl_3/CH_3OH$ 92:8; charring with H_2SO_4). *Anal.* calcd. for $C_{40}H_{52}N_8O_8$: C 62.10, H 6.77, N 14.35; found: C 62.09, H 6.83, N 14.28.

Hexaglycine Trifluoroacetate

A mixture of *N*-benzyloxycarbonyl hexaglycine (21) (3.6 g, 7.28 mmol) and anhydrous CF_3COOH (12 mL) was refluxed for 90 min under stirring. The solvent was removed *in vacuo*, the residue treated with H_2O and neutralized with cold



5*a*, *b*

SCHEME 4

NH_4OH. The solid was collected, washed with H_2O and C_2H_5OH, dissolved in hot, dilute NH_4OH, charcoalized, and filtered. The solution was concentrated *in vacuo*, the precipitate collected and washed with H_2O, followed by C_2H_5OH; mp dec. >240°C; yield: 2.47 g (60%); nmr (TFA): 4.25 (s, CH_2) ppm. *Anal.* calcd. for $C_{12}H_{20}N_6O_7$: C 39.96, H 5.55, N 23.33; found: C 40.06, H 5.56, N 22.82. A suspension of hexaglycine (2.24 g, 6.24 mmol) was stirred with CF_3COOH (8 mL) until complete solution was achieved. The excess acid was removed *in vacuo*, the residue triturated with ether, the solid collected and washed with ether; mp 227°C (dec.). Homogenous on electrophoresis (pH 1.6; Ninhydrin).

Synthesis of **3**

In the course of 8 h, a warm solution of hexaglycine trifluoroacetate (2.94 g, 6.19 mmol) in dry DMSO (5 mL) was added dropwise to a vigorously stirred solution of isobutyraldehyde (1.52 g, 20.64 mmol), cyclohexyl isonitrile (0.68 g, 6.19 mmol), and triethylamine (0.620 g, 6.19 mmol) in dry DMSO (15 mL). The pH was adjusted to 7 with pyridine and the mixture was stirred at room temperature for 5 days. The solvent was removed *in vacuo* and the residue chromatographed on silica gel ($CHCl_3/CH_3OH$, 9:1). The desired fractions were combined, evaporated, and triturated with acetone/ether/hexane. Yield: 624 mg (19%); mp 317–320°C (dec.); ir (Nujol) ν: 3300, 1670, 1540; nmr (DMSO): 0.94 (d, J = 7 Hz, 6H, $(CH_3)_2CH$) ppm; ms (*m/e*): 523(M^+), 505. Homogenous on tlc (system: $CHCl_3/CH_3OH$ 85:15; I_2 and charring with H_2SO_4). *Anal.* calcd. for $C_{23}H_{37}N_7O_7$: C 52.76, H 7.12, N 18.72; found: C 52.93, H 7.24, N 18.55

Boc-Phe-Val-Gly-OEt

$(C_2H_5)_3N$ (3.03 g, 30 mmol) was added to a cold solution of H-Val-Gly-OEt × HCl (22) (7.14 g, 30 mmol) in dry DMF (65 mL). The mixture was filtered into a cold solution of Boc-Phe-ONp (22) (11.6 g, 30 mmol) in dry DMF (33 mL). After 3 days at 0°C the solution was poured into ice/H_2O, the product collected, washed with H_2O, and dried. The material was recrystallized from CH_3OH/IPE; mp 160–162°C; yield: 11.94 g (88%); $[\alpha]_D^{25} = -13.9°$ (*c* 1.0 in DMF); nmr ($CDCl_3$): 0.84, 0.97 (2d, J = 3 Hz, 6H, $(CH_3)_2CH$), 1.24 (t, J = 7 Hz, 3H, CH_3CH_2O), 1.36 (s, 9H, $(CH_3)_3C$), 7.21 (s, 5H, arom) ppm; ms (*m/e*): 449(M^+). Homogenous on tlc (system: C_6H_6/EtOAc 50:50; charring with ammonium molybdate). *Anal.* calcd. for $C_{23}H_{35}N_3O_6$: C 61.43, H 7.84, N 9.34; found: C 61.44, H 8.05, N 9.26.

Boc-Ala-Phe-Val-Gly-OEt

Boc-Phe-Val-Gly-OEt (11.2 g, 25 mmol) was deprotected with cold CF_3COOH in the usual way. The H-Phe-Val-Gly-OEt × CF_3COOH obtained was dissolved in dry DMF (45 mL) and $(C_2H_5)_3N$ (35 mL) was added at 0°C, followed by Boc-Ala-OTcp (23, 24) (9.2 g, 25 mmol) in dry DMF (59 mL). After 24 h at 0°C the solution was poured into ice/H_2O, the product was collected, washed with H_2O, dried, and recrystallized from CH_3OH/IPE; mp 207–209°C; yield: 11.96 g (90%); $[\alpha]_D^{25} = -24.3°$ (*c* 1.0 in DMF). Homogenous on tlc (system: MeOH/EtOAc 2:98; charring with ammonium molybdate). *Anal.* calcd. for $C_{26}H_{40}N_4O_7$: C 59.98, H 7.74, N 10.76; found: C 60.18, H 7.94, N 10.73.

Boc-Ala-Phe-Val-Gly-OH

NaOH (1 *N*, 24.4 mL) was added in the course of 15 min to Boc-Ala-Phe-Val-Gly-OEt (10.4 g, 19.8 mmol) suspended in CH_3OH (57 mL) and $CH_3OCH_2CH_2OH$ (57 mL) at 0°C under stirring. After 2 h at room temperature the solution was poured into ice/H_2O and acidified with 1 *N* HCl (24.4 mL) and 15 drops of AcOH. The product was collected, washed with H_2O, and dried. Yield: 8.95 g (88%); nmr (DMSO): 0.87 (d, J = 7 Hz, 6H, $(CH_3)_2CH$), 1.13 (d, J = 7 Hz, 3H, CH_3CH), 1.35 (s, 9H, $(CH_3)_3C$), 7.24 (s, 5H, arom) ppm; $[\alpha]_D^{25} = -22.6°$ (*c* 1.0 in DMF). *Anal.* calcd. for $C_{24}H_{36}N_4O_7$ × 0.3% H_2O (K. Fischer): C 58.33, H 7.36, N 11.33; found: C 58.07, H 7.30, N 11.32.

Boc-Ala-Phe-Val-Gly-Leu-Met-OCH_3

H-Leu-Met-OCH_3 × CF_3COOH (2.08 g, 5.32 mmol), obtained from Boc-Leu-Met-OCH_3 (25) by deprotection with CF_3COOH, was dissolved in dry DMF (10 mL) and mixed with $(C_2H_5)_3N$ (0.8 mL) at 0°C. The mixture was added under stirring at −15°C to Boc-Ala-Phe-Val-Gly-OH (2.62 g, 5.32 mmol) and CDI (0.862 g, 5.32 mmol) in dry DMF (10 mL). After stirring overnight at room temperature the solvent was removed *in vacuo*, the residue triturated with 5% $NaHCO_3$ solution, collected by filtration, washed with H_2O, and dried. Recrystallized from CH_3OH/H_2O; mp 254–255°C; yield: 3.13 g (78%); $[\alpha]_D^{25} = -31.3°$ (*c* 2.0 in DMF); nmr (DMSO): 0.90 (d, J = 6 Hz, 6H, $(CH_3)_2CH$), 1.30 (d, J = 7 Hz, 3H, CH_3CH), 1.48 (s, 9H, $(CH_3)_3C$), 2.05 (s, 3H, CH_3S), 3.65 (s, 3H, CH_3O), 7.25 (s, 5H, arom) ppm. Homogenous on tlc (system: $CHCl_3/CH_3OH$, 95:5; charring with ammonium molybdate). *Anal.* calcd. for $C_{36}H_{58}N_6O_9S$: C 57.58, H 7.78, N 11.19; found: C 57.92, H 7.89, N 10.89.

Boc-Ala-Phe-Val-Gly-Leu-Met-OH

A mixture of Boc-Ala-Phe-Val-Gly-Leu-Met-OCH_3 (3.65 g, 4.86 mmol) in hot $CH_3OCH_2CH_2OH$ (97 mL) and CH_3OH (97 mL) was added to cold H_2O (25 mL) with vigorous stirring. The suspension was cooled to 5°C, treated with 1 *N* NaOH (9.7 mL) and stirred for 24 h at room temperature. The solution was poured into ice/brine containing 1 *N* HCl (10.7 mL) and AcOH (5 drops). The collected solid was washed with water and recrystallized from CH_3OH/H_2O; mp 252–281°C (dec.); yield: 3.43 g (95%); $[\alpha]_D^{25} = -26.5°$ (*c* 2.0 in DMF); nmr (DMSO): 1.36 (s, 9H, $(CH_3)_3C$), 2.06 (s, 3H, CH_3S) ppm. *Anal.* calcd. for $C_{35}H_{56}N_6O_9S$: C 57.04, H 7.66, N 11.44; found: C 57.03, H 7.62, N 10.93.

*H-Ala-Phe-Val-Gly-Leu-Met-OH (***4***)*

Boc-Ala-Phe-Val-Leu-Met-OH (4.14 g, 5.63 mmol) was deprotected by treatment with CF_3COOH. The CF_3COOH was removed *in vacuo* and the residue triturated with ether. The solid was collected, washed with ether, and dried *in vacuo*; mp 260–263°C (dec.); yield: 4.23 g (100%). The free base was prepared by treatment of the salt with 2 *N* NH_4OH. The solid was collected, washed with H_2O and EtOH, and dried *in vacuo*. The material is insoluble in DMF; mp 262–264°C (dec.); yield 1.56 g (44%). *Anal.* calcd. for $C_{30}H_{48}N_6O_7S$ × 1.07% H_2O (K. Fischer): C 55.97, H 7.63, N 13.05; found: C 55.30, H 7.59, N 12.85.

Synthesis of **5**a, b

In the course of 5.5 h H-Ala-Phe-Val-Gly-Leu-Met-OH × CF_3COOH (2.14 g, 2.85 mmol) in dry DMF (37 mL) was dropped into a stirred solution of $(CH_3)_2$ CHCHO (0.684 g, 9.5 mmol), cyclohexylisonitrile (0.314 g, 2.85 mmol), and dry $(C_2H_5)_3N$ (0.288 g, 2.85 mmol) in dry DMF (7 mL). The pH was adjusted to 7 with pyridine and the clear solution remained at room temperature for 65 h. The solvent was removed *in vacuo* and the residue chromatographed on silica gel. The isomers were separated by elution with C_6H_6/IPA (95:5). Both isomers were separately rechromatographed and triturated with hexane.

Isomer ***5a***: mp 158–175°C (dec.); yield: 319 mg (14%); $[\alpha]_D^{25} = -182°$ (*c* 1.0 in DMF); ms (*m/e*) = 799 (M^+). *Anal.* calcd. for $C_{41}H_{65}N_7O_7S$: C 61.55, H 8.19, N 12.25, S 4.00;

found: C 61.27, H 8.26, N 11.81, S 4.12. Amino acid analysis: Gly 1, Val 1.02, Met 0.98, Leu 0.96, Phe 1.0. Isomer ***5b***: mp 155°C (dec.); yield: 424 mg (18.6%); $[\alpha]_D^{25} = -77°$ (*c*1.0 in DMF); ms (*m/e*) = 799 (M^+). *Anal.* calcd. for $C_{41}H_{65}N_7O_7S$: C 61.55, H 8.19, N 12.25, S 4.00; found: C 60.57, H 8.13, N 11.76, S 3.87. Amino acid analysis: Gly 1, Val 0.97, Met 0.95, Leu 0.94, Phe 0.97.

Hydrolysis of cyclic unsymmetrical *anti* imidate salts. New evidence for stereoelectronic control

PIERRE DESLONGCHAMPS, UKKEN OUSEPH CHERIYAN, AND ROLAND J. TAILLEFER

Laboratoire de Synthèse Organique, Département de Chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received February 27, 1979

This paper is dedicated to Prof. Karel Wiesner on the occasion of his 60th birthday

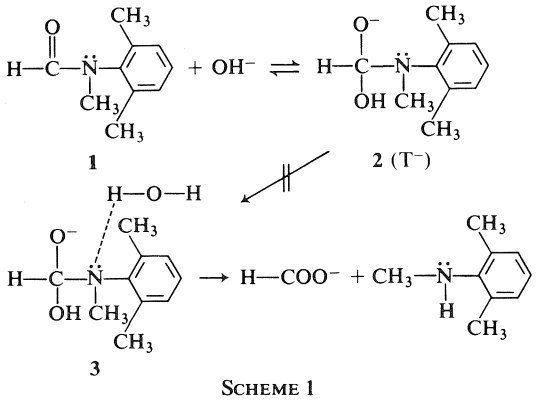
PIERRE DESLONGCHAMPS, UKKEN OUSEPH CHERIYAN, and ROLAND J. TAILLEFER. Can. J. Chem. **57**, 3262 (1979).

The synthesis and the hydrolytic behavior of the cyclic imidate salts **7**, **8**, and **9** is reported. Under acidic conditions, the salt **7** gives the ester ammonium salt **21** and the salt **9** gives a 1:1 mixture of the ester ammonium salt **22** and the amide alcohol **23** as the rotamer **23***B* only. Under basic conditions, the salt **7** (or **8**) gives a 2:8 (or 1:9) mixture of the amide alcohol rotamers **25***A* and **25***B* (or **27***A* and **27***B*) under kinetically controlled conditions. The salt **9** gives, as the kinetic product, the amide alcohol rotamer **23***B* only. These results can be rationalized on the basis of the stereoelectronic theory for the cleavage of tetrahedral intermediates and by taking into account that the nitrogen in tetrahedral intermediates must be either protonated under acidic conditions, or hydrogen bonded with the solvent under basic conditions, in order to observe the cleavage of a C—N bond.

PIERRE DESLONGCHAMPS, UKKEN OUSEPH CHERIYAN et ROLAND J. TAILLEFER. Can. J. Chem. **57**, 3262 (1979).

La synthèse et l'hydrolyse des imidates cycliques **7**, **8** et **9** sont rapportées. En milieu acide, l'imidate **7** se transforme en sel d'ammonium ester **21** et l'imidate **9** donne un mélange (1:1) du sel d'ammonium ester **22** et d'amide alcool **23** sous la forme du rotamère **23***B* seulement. En milieu basique, l'imidate **7** (ou **8**) donne un mélange dans le rapport 2:8 (ou 1:9) des rotamères **25***A* et **25***B* (ou **27***A* et **27***B*) de l'amide alcool **25** (ou **27**). L'imidate **9** conduit à l'amide alcool **23** sous forme du rotamère **23***B* seulement. Ces résultats peuvent etre expliqués en utilisant la théorie de controle stéréoélectronique pour le bris des intermédiaires tétraédriques, et en tenant compte du fait que l'azote de l'intermédiaire tétraédrique doit être protoné en milieu acide ou doit former un pont hydrogène avec le solvant lors du bris d'un lien C—N.

In the course of our studies (1, 2) on the ^{18}O carbonyl–oxygen exchange in the basic hydrolysis of tertiary amides, we have shown (2) that the nitrogen of tetrahedral intermediates in the T^- ionic form (cf. **2** in Scheme 1) must be hydrogen bonded with

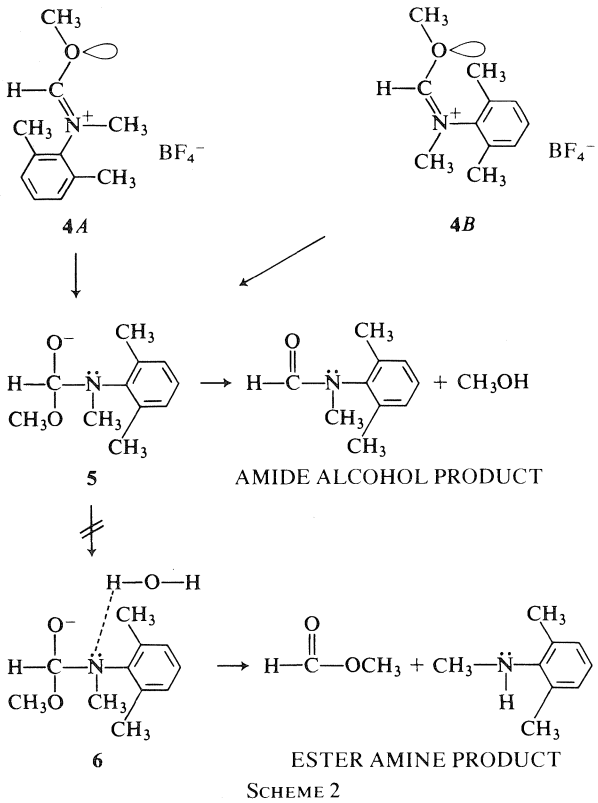


SCHEME 1

the solvent in order to observe a cleavage of the C—N bond. More specifically, we have shown that *N*-2,6-dimethylphenyl-*N*-methylformamide (**1**) is completely resistant to hydrolysis but undergoes extensive carbonyl–oxygen exchange under basic conditions (Scheme 1). This result was interpreted in the following way: compound **1** must form the tetrahedral intermediate **2** so that carbonyl–oxygen exchange can take place, but **2** cannot yield the hydrolysis products because the presence of the two methyl groups on the phenyl ring prevents the formation of a hydrogen bond between the tertiary nitrogen and water (**2** ⇸ **3**).

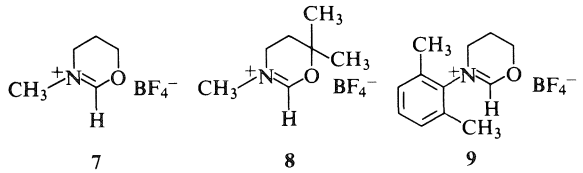
We have also observed a similar result in our recent studies (3) on the hydrolysis of *syn* imidate salts derived from unsymmetrical tertiary formamides. We have shown that the basic hydrolysis of the two unsymmetrical imidate salts **4***A* and **4***B* derived from *N*-2,6-dimethylphenyl-*N*-methylformamide (**1**) (Scheme 2) gave only the amide alcohol products under basic conditions. This result was again explained by taking into account that the nitrogen in the resulting tetrahedral intermediate **5** cannot become hydrogen bonded (**5** ⇸ **6**) with the solvent. Consequently, the C—N bond cleavage to yield the ester amine products cannot take place, while the carbon–oxygen bond cleavage to yield the amide alcohol products takes place readily. These findings were further confirmed by our study on the isomerization of salts **4***A* and **4***B* with methanol (3).

0008-4042/79/243262-10$01.00/0



SCHEME 2

We have also undertaken a study of the hydrolysis of unsymmetrical imidate salts which have an *anti* configuration. We wish now to report this work.



Synthesis

We have selected the cyclic imidate salts **7**, **8**, and **9** for this study. Due to their cyclic nature, these salts are *anti* imidate salts.[1] The synthesis of these three salts is described in Scheme 3 and the details of these procedures can be found in the experimental section.

Acid Hydrolysis

The hydrolytic behavior of imidate salts **7** and **9** was first studied under acidic conditions by the action of water in acetonitrile.[2] Under those conditions, the imidate salt **7** was slowly hydrolyzed to yield the ester ammonium salt **21** exclusively (Scheme 4). The imidate salt **9** behaved in a completely different manner giving a $\simeq$1:1 mixture of the ester ammonium salt **22** and the amide alcohol **23** and some fluoroboric acid (Scheme 5). Again, the hydrolysis is a slow process, and it could be observed that at the beginning of the reaction, the amide alcohol **23** was first formed as the least stable rotamer **23***B* only, which then slowly isomerized to give an equilibrium mixture of **23***A* (67%) and **23***B* (33%).[3]

The configuration of the two rotamers **23***A* and **23***B* was determined by nmr comparison with the two rotamers **24***A* and **24***B* whose configuration was rigorously established (3).[4]

Basic Hydrolysis

The hydrolytic behavior of the imidate salts **7**, **8**, and **9** was also studied under basic conditions. The hydrolysis of salt **7** with excess sodium hydroxide in water–acetonitrile (1:5) at room temperature is an instantaneous reaction which gave the amide alcohol **25** exclusively, as an equilibrium mixture of the two amide rotamers **25***A* (40%) and **25***B* (60%) (Scheme 4).[5]

When the same reaction was carried out at 0°C, the amide alcohol **25** was again the only product formed, but the ratio of the rotamers was found to be 23% (**25***A*) and 77% (**25***B*). The equilibrium ratio of 40:60 was then reached on standing. The slow rate of equilibration of the two rotamers at 0°C (Table 1) indicates that the rotamers **25***A* and **25***B*, in the ratio of 23:77, were the direct products of hydrolysis. This finding was further confirmed by repeating the experiment at −10°C and at 10°C. Again, it gave only the amide alcohol and the isomeric ratio was essentially the same (20:80 and 25:75 respectively).

We have also treated the ester ammonium salt **21**

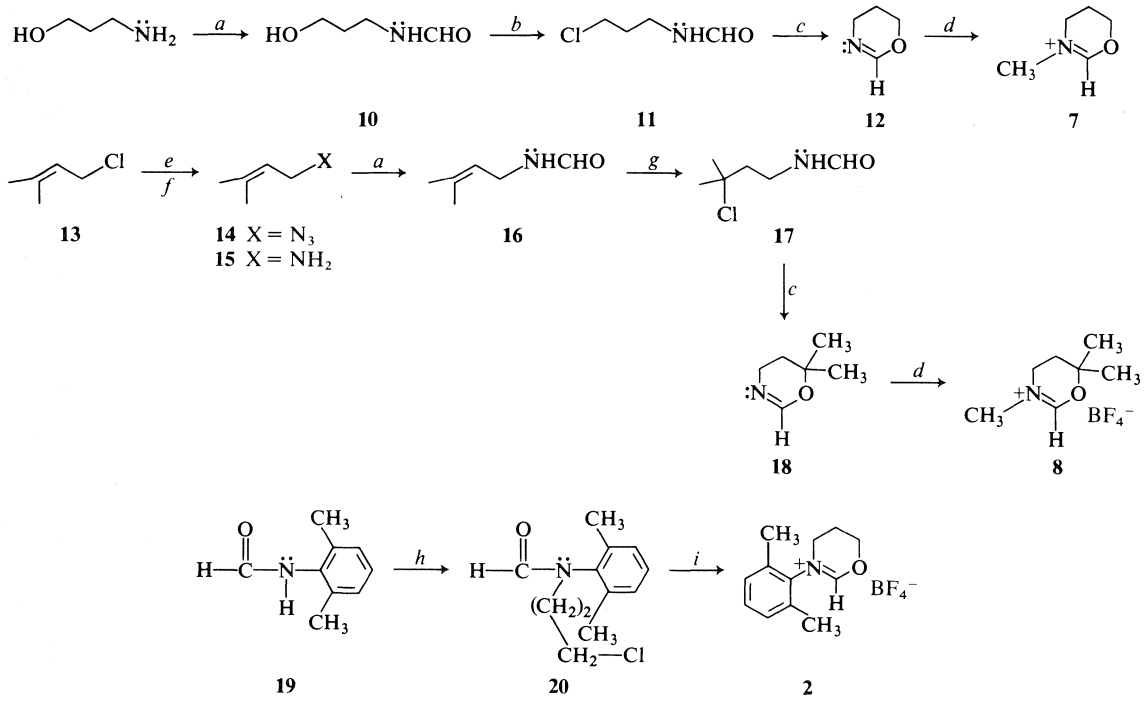
[1]In *anti* imidate salts, derived from formamide, the C—H bond is *anti* to the O—alkyl bond (cf. **7**, **8**, **9**). In *syn* imidate salts, the C—H bond is *syn* to the O—alkyl bond (cf. **4***A* and **4***B*) (4).

[2]The hydrolysis of imidate salt **8** was not studied under those conditions.

[3]We have also observed that the equilibrium ratio of the two amide alcohol rotamers **23***A* and **23***B* varies considerably with the solvent used. In pure water, the ratio is 25% (**23***A*) and 75% (**23***B*). In water–acetonitrile (2:5), it is 55% and 45%. In water–acetonitrile (1:5), it is 67% and 33% and in pure acetonitrile, the ratio is 74% to 26%.

[4]The formamide hydrogen in **24***A* and **24***B* appears at 8.11 and 8.47 ppm in acetonitrile. The formamide hydrogen in **23***A* and **23***B* appears at 8.13 and 8.49 ppm respectively in the same solvent.

[5]The configuration of the amide rotamers was established by nmr spectroscopy. The N—methyl resonance appears at a higher field in the rotamer *B* (5): amide alcohol **25**:**25***A* (2.93 ppm, N—CH_3) and **25***B* (2.77 ppm, N—CH_3); amide alcohol **27**:**27***A* (2.91 ppm, N—CH_3) and **27***B* (2.78 ppm, N—CH_3). Also, the coupling constant of the N—CH_3 group is larger in the rotamers **B** (rotamers **A** $\simeq$ 0.4 Hz and rotamers **B** $\simeq$ 0.8 Hz in acetonitrile).



SCHEME 3. (*a*) $HCOOC_2H_5$, heat; (*b*) $(C_6H_5)_3P$, CCl_4; (*c*) $AgBF_4$; NaOH; (*d*) $(CH_3)_3O^+BF_4^-$; (*e*) NaN_3; (*f*) $LiAlH_4$; (*g*) HCl, 0°C; (*h*) NaH–THF–$ClCH_2CH_2CH_2Br$; (*i*) $AgBF_4$.

under the same basic conditions at 0°C. There is again an instantaneous reaction which gave only the amide alcohol **25** with the same ratio of amide rotamers **25***A* (20%) and **25***B* (80%).

The hydrolysis of the imidate salt **8** gave similar results. Basic hydrolysis of **8** at 0°C gave only the amide alcohol product as a mixture of the two rotamers **27***A* and **27***B* in a 1:9 ratio. On standing, the equilibrium mixture of the two amide rotamers was then obtained (**27***A* (41%) and **27***B* (59%)). The slow rate of equilibration of the two rotamers (Table 2) shows that the rotamers **27***A* and **27***B* in the 1:9 ratio were the direct product of hydrolysis.

The basic hydrolysis of the imidate salt **9** gave a different result. Treatment of the salt **9** with sodium hydroxide in water–acetonitrile (1:5) led to an instantaneous reaction yielding exclusively the amide alcohol **23** in the form of the least stable rotamer **23***B* only (Scheme 5). On standing, isomerization of **23***B* took place to give the equilibrium mixture of **23***A* (67%) and **23***B* (33%).

When the 1:1 mixture of the ester ammonium salt

[a]Imidate salt **8** was hydrolyzed with NaOD in CD_3CN/D_2O. The hydrolysis was instantaneous giving amide alcohol **27** only. The interconversion of **27***A* and **27***B* was followed by nmr spectroscopy (cf. Experimental).

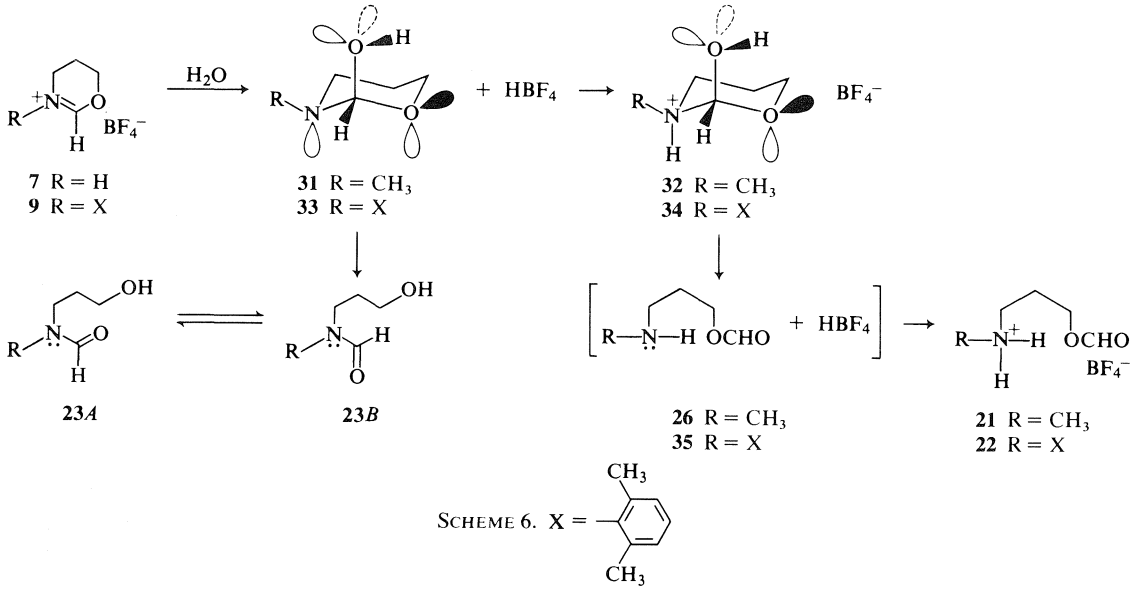
Hydrolysis of salt **9** was also carried out with sodium hydroxide in water only. The reaction is instantaneous and also gave the amide alcohol **23** in the form of the rotamer **23***B* only. Then, isomerization took place to give an equilibrium mixture of **23***A* (25%) and **23***B* (75%). The salt **9** was then hydrolyzed with water only giving 28% of the amide alcohol **23** and 72% of the ester ammonium salt **22**. The hydrolysis was slow and, again at the beginning, **23** appeared in the form of **23***B* only, slowly equilibrating to a mixture of **23***A* (25%) and **23***B* (75%).[3] When sodium hydroxide was added to the above aqueous solution, we obtained 28% of the amide alcohol **23** and 72% of the amine alcohol **29**.

Discussion

Acidic Hydrolysis

The result obtained with the imidate salt **7** under acidic conditions is the predicted result for *anti* imidate salts (4), i.e., 100% of the ester ammonium salt **21**, and it can be readily explained in the following way. Water reacts with the salt **7** (Scheme 6) with stereoelectronic control (6) to yield the tetrahedral intermediate **31** which is then rapidly protonated by the fluoroboric acid produced, to give the T^+ ionic form **32**. Then the intermediate **32**, which has an electron pair on each oxygen properly oriented to eject the amino group (6), can break down to yield the corresponding amine ester **26** which is then rapidly protonated to give the ester ammonium salt **21**.

The difference in behavior of the imidate salt **9** can be explained by the presence of the two methyl groups on the phenyl ring. The salt **9** (Scheme 6) must first react with water to form the tetrahedral intermediate **33** in the neutral form T^0. However, it is difficult to protonate the nitrogen in **33** to give **34** (T^+) because of the presence of the two methyl groups on the phenyl ring (2, 3). Consequently **33**, as well as giving



34 (T^+) which leads to the ester ammonium salt **22** via **35**, would also cleave to give the amide alcohol product as the rotamer **23***B* only. The precise manner by which **33** can yield the rotamer **23***B* will be discussed later.

Basic Hydrolysis

Imidate Salts 1 and 8

In resume, the basic hydrolysis of imidate salt **7** gives a mixture (2:8) of the amide alcohol rotamers **25***A* and **25***B* as the kinetic products of the reaction. Isomerization follows to yield the equilibrium ratio (4:6) of **25***A* and **25***B*. The basic hydrolysis of the ester ammonium salt **21** gives an identical result (Scheme 4).

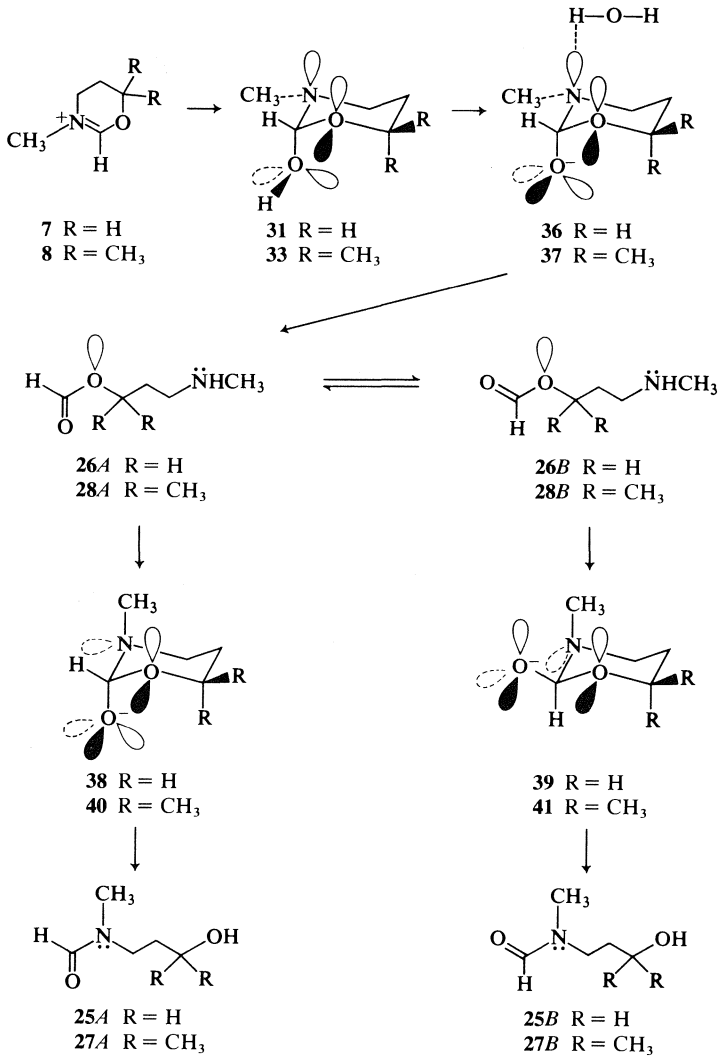
The above results suggest that the amine ester **26** is likely to be an intermediate in the hydrolysis of the imidate salt **7**. The exclusive formation of the amine ester product **26** first is not surprising (Scheme 7). We have previously shown that *anti* imidate salts always give, under basic conditions, the amine ester product under kinetically controlled conditions (4). Indeed, reaction of hydroxide ion on salt **7** with stereoelectronic control must give the intermediate **31**, which after removal of a proton on the hydroxyl group (T^-) and after hydrogen bonding with the solvent (→**36**), breaks down to yield the amine ester **26**. Then this amine ester **26**, being a reactive ester would recyclize rapidly to give new tetrahedral intermediates which then yield the amide rotamers **25***A* and **25***B* in the 2:8 ratio.

The amide rotamers **25***A* and **25***B* must be formed respectively from the stereoelectronically controlled cleavage of the tetrahedral intermediates **38** and **39** and the formation of these two intermediates is the result of the attack of the amino group on the *Z* (**26***A*) and the *E* (**26***B*) forms (7) of the ester function in the amine ester **26**. The results show that the route **26***B* → **39** → **25***B* is preferred over the route **26***A* → **38** → **25***A*. However, on the basis of the present knowledge, it is difficult to rationalize the observed preference for one pathway.

The basic hydrolysis of the imidate salt **8** gave a result similar to that observed with the imidate salt **7**. It can therefore be interpreted in the same manner. The salt **8** must have first produced the amine ester **28** via **33** and **37**. The amine ester **28** was then transformed into a 1:9 mixture of the amide rotamers **27***A* and **27***B* via the routes **28***A* → **40** → **27***A* and **28***B* → **41** → **27***B*.

Imidate Salt 9

The basic hydrolysis of imidate salt **9** takes a different course from salts **7** and **8**, yielding first the amide rotamer **23***B* only, which is then isomerized to the equilibrium mixture of **23***A* and **23***B* (Scheme 5). The basic hydrolysis of the corresponding ester ammonium salt **22** gives either a mixture of **23***A* and **23***B* plus the amine alcohol **29** (in acetonitrile–water) or only the amine alcohol **29** (in water). These results show that the amine ester **30** is not an intermediate in the hydrolysis of **9**. The formation of the amide rotamer **23***B* is therefore the result of the direct fragmentation of a tetrahedral intermediate which is formed from **9**. The hydrolysis of salt **9** is particularly interesting as it shows a complete transmission of stereochemistry from the reactant to the product of the reaction (**23***B*).



SCHEME 7

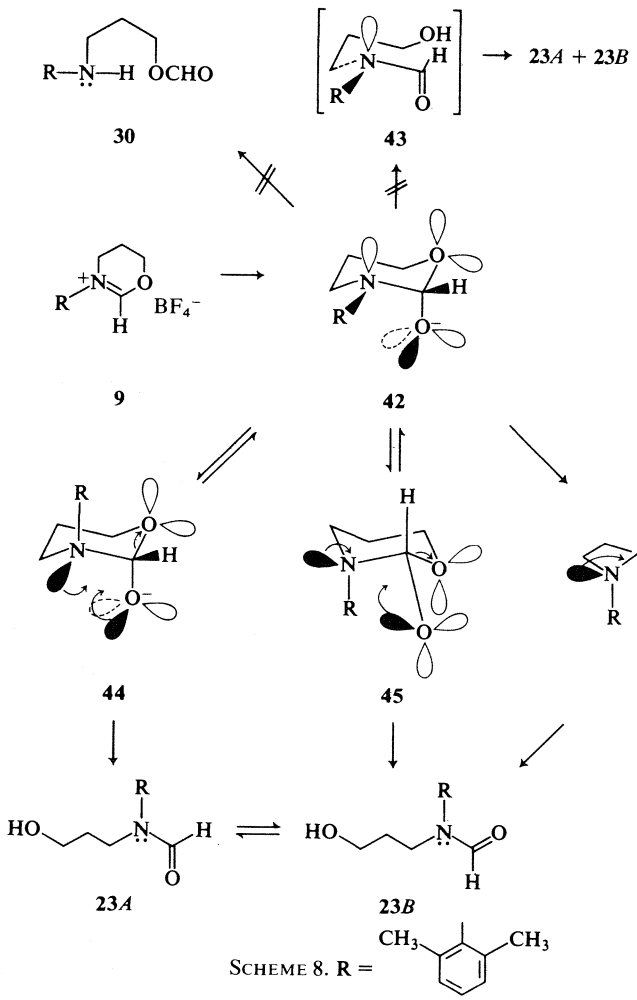
The reaction of hydroxide ion on **9** with stereoelectronic control should give **42** (Scheme 8). However, **42** cannot break down with stereoelectronic control to give either the amide alcohol rotamer **23***A* or **23***B*. Furthermore, the intermediate **42** cannot yield the amine ester **30** because the tertiary nitrogen cannot be hydrogen-bonded to the solvent (1–3).

If the intermediate **42** could break down without stereoelectronic control, it would yield first **43** which would then be transformed into both the rotamers **23***A* and **23***B*. Indeed, **43** is an intermediate during the thermal isomerization of **23***A* and **23***B*. This hypothesis must therefore be eliminated.

The intermediate **42** could, however, undergo conformational changes to give either the intermediate **44** (by nitrogen inversion) or the intermediate **45** by chair inversion. Since **44** and **45** can break down with stereoelectronic control to give **23***A* and **23***B*, respectively, this means that the conversion of **42** into **44** would not occur, while that of **42** into **45** would take place readily. In both intermediates **44** and **45** the bulky 2,6-dimethylphenyl group becomes axially oriented; it would therefore be quite surprising that one process would be favored energetically and this rationalization must be rejected.

The specific formation of rotamer **23***B* from **9** can, however, be explained in the following way. The reaction of hydroxide ion with **9** would occur with stereoelectronic control to yield the intermediate **42**. This intermediate would then be converted into the half-boat conformer **46** which has the proper orbital orientation to give the amide alcohol rotamer **23***B* only.

In **42**, the hydroxyl group and the 2,6-dimethyl-



SCHEME 8. R =

phenyl group undergo very severe steric interactions. This steric interaction can, however, be lessened on going from **42** to **46**, and it would therefore be the driving force for the specific conversion of **42** into the half-boat **46**. This can be seen by the examination of the conversion of **42** into **46** with space filling molecular models. Thus, **9** would first give **42** which would then generate **46**, which would break down to the amide rotamer **23***B*. The half-boat **46** would not be converted into **44** and **45** because these conversions would involve more energy than the breakdown of **46** with stereoelectronic control to give the amide rotamer **23***B*.

Experimental

Vapor-phase chromatographic (vpc) analyses and separations were carried out on a Varian aerograph instrument model 2800 with a thermal conductivity detector. The ir spectra were taken on a Perkin-Elmer 257 spectrophotometer. Proton nmr spectra were recorded on a Varian A-60 or a Bruker WP-60 instrument. Chemical shifts are reported in δ values relative to tetramethylsilane as internal standard. Mass spectral assays were obtained using a Hitachi-Perkin-Elmer RMU-6-A instrument at 70 eV.

Syntheses

N-*(3-Hydroxypropyl)formamide (**10**)*

A mixture of 3-amino-1-propanol (10 g, 0.13 mol) and ethyl formate (10 g, 0.135 mol) was refluxed overnight. Fractional distillation yielded pure amide **10** (10 g, 75%); bp 138–139°C/0.7 Torr; ir ν_{max} ($CHCl_3$): 3430 and 1680 cm^{-1}; nmr ($CDCl_3$) δ: 1.8 (2H, m), 3.7 (4H, m), 8.3 (1H, b s); ms *m/e*: 103 (M^+). An analytical sample was prepared by vpc (5 ft. $\frac{1}{4}$ in., 10% SE-30, 150°C). *Anal.* calcd. for $C_4H_9NO_2$: C 46.59, H 8.80; found: C 47.03, H 8.92.

N-*(3-Chloropropyl)formamide (**11**)*

A mixture of *N*-(3-hydroxypropyl) formamide **10** (5.15 g, 0.05 mol) and triphenylphosphine (13.2 g, 0.05 mol) was refluxed in a mixture of carbon tetrachloride (75 mL) and dichloromethane (50 mL) for 18 h. The solvents were then removed by distillation at atmospheric pressure. The residual liquid on distillation gave pure chloroamide **11** (2.4 g, 40%); bp 120–122°C/0.5 Torr; ir ν_{max} ($CHCl_3$): 3440, 3300, and 1690 cm^{-1}; nmr ($CDCl_3$) δ: 2.15 (2H, m), 3.7 (4H, m), 8.5 (1H); ms *m/e*: 121, 123 (M^+). An analytical sample was prepared by

vpc (5 ft, ¼ in., 10% SE-30, 100°C). *Anal.* calcd. for C_4H_8NOCl: C 39.52, H 6.63; found: C 39.83, H 7.01.

Iminoether ***12***

To a solution of the chloroamide **11** (1.62 g, 13.3 mmol) in nitromethane (25 mL) in a flask covered with aluminium foil, silver tetrafluoroborate (2.6 g, 13.3 mmol) was added and stirred overnight. The reaction mixture was then filtered and the filtrate concentrated to give a white solid that was only sparingly soluble in dichloromethane. Hydrogen chloride gas was bubbled into a suspension of the product in dichloromethane for 1 h. It was then filtered and the residue was dissolved in acetonitrile and again filtered. The latter filtrate on concentration yielded the fluoroborate salt of **12** (2 g); nmr (CD_3CN) δ: 2.3 (2H, m), 3.6 (2H, t), 4.8 (2H, t), 8.5 (1H, b s).

The crude salt (1.65 g, 9.5 mmol) was suspended in dichloromethane (50 mL) and cooled to 0°C in an ice bath. A cold solution of sodium hydroxide (15 mL, 1 *N*) saturated with sodium chloride was added with stirring. The organic layer was separated and the aqueous layer was extracted with dichloromethane. The extracts were combined, washed with brine, and dried over sodium sulfate. Fractional distillation yielded pure iminoether **12** (8) (400 mg); bp 120–121°C; ir ν_{max} (CH_2Cl_2): 1660 cm^{-1}; nmr ($CDCl_3$) δ: 2.0 (2H, m), 3.2 (2H, t), 4.3 (2H, t), and 7.2 (1H, b).

Imidate Salt ***7***

To a suspension of trimethyl oxonium fluoroborate (167 mg, 1.13 mmol) in dichloromethane (15 mL), a solution of the iminoether **15** (96 mg, 1.13 mmol) in dichloromethane (5 mL) was added dropwise and stirred overnight. The solvent was then distilled off to give a viscous liquid (220 mg) insoluble in dichloromethane. This product was used without further purification; ir ν_{max} (CH_3CN): 1695 and 1030 cm^{-1}; nmr (CD_3CN) δ: 2.3 (2H, m), 3.3 (3H, s), 3.5 (2H, t), 4.5 (2H, t), and 8.21 (1H, s).

1-Chloro-3-methyl-2-butene ***13***

Dry lithium chloride (2.47 g, 0.058 mol) was dissolved in a minimum amount of dimethylformamide (35 mL). This was mixed with collidine (7.62 g, 0.063 mol, distilled over calcium hydride) and 3-methyl-2-butene-1-ol (5.01 g, 0.058 mol). The reaction mixture was then cooled in an ice bath with stirring. Methane sulfonyl chloride (7.21 g, 0.063 mol) was added dropwise under an atmosphere of nitrogen (9). After the addition was complete, the stirring was continued for 1½ h at 0°C. It was then poured over 300 g of crushed ice and extracted with ice-cold 1:1 pentane/ethyl ether (3 × 200 mL). The extracts were then combined and washed four times with 50 mL each of saturated copper nitrate solution, followed by water. They were then dried over anhydrous sodium sulfate and the solvent was fractionally distilled off to give a liquid residue (4 g). The nmr spectrum of the liquid showed it to be the desired allylic chloride (95%) containing the mesylate of the saturated alcohol as an impurity. Attempted distillation resulted in decomposition. This crude product was used without further purification.

1-Azido-3-methyl-3-butene ***14***

The allyl chloride **20** (1.8 g, 18 mmol) was dissolved in pentane (100 mL) and stirred with a solution of sodium azide (3.2 g, 50 mmol) and tetrabutyl ammonium hydrosulfate (680 mg, 2 mmol) in water (20 mL) overnight at room temperature. The pentane layer was then separated, washed with brine, dried over sodium sulfate, and fractionally distilled to give the azide **14** (10) (1 g, 52%); ir ν_{max} ($CHCl_3$): 2350 cm^{-1}; nmr ($CDCl_3$) δ: 1.72 (3H), 1.9 (3H), 3.1 (2H, d), and 5.3 (1H, m); ms *m/e*: 111 (M^+). An analytical sample was prepared by vpc (5 ft, ¼ in., 10% SE-30, 80°C). *Anal.* calcd. for $C_5H_9N_3$: C 54.03, H 8.16; found: C 53.85, H 8.05.

1-Amino-3-methyl-2-butene ***15***

A solution of the azide **14** (600 mg, 5.4 mmol) in ether was added dropwise to lithium aluminium hydride (500 mg, excess) suspended in ether (25 mL) with stirring. The stirring was continued overnight after the addition was complete. The reaction mixture was cooled to 0°C and decomposed with saturated sodium sulfate solution (3 mL). It was then filtered, dried over Na_2SO_4, and fractionally distilled to give the amine **15** (360 mg, 78%); ir ν_{max} (CH_3CN): 3500 cm^{-1}; nmr (CD_3CN) δ: 1.7 (6H), 3.1 (3H, d), and 5.2 (1H, m); ms *m/e*: 85 (M^+). Hydrochloride salt: mp 197–200°C (lit. (11) mp 201°C).

1-Formamido-2-methyl-2-butene ***16***

1-Amino-3-methyl-2-butene **15** (210 mg, 2.47 mmol) was refluxed in ethyl formate (10 mL) overnight. Removal of solvent yielded the amide **16** (220 mg) which was purified by vpc (5 ft, ¼ in., 10% SE-30, 110°C); ir ν_{max} ($CHCl_2$): 3440, 1680 cm^{-1}; nmr ($CDCl_3$) δ: 1.6 (6H), 3.9 (2H, t), 5.2 (1H, m), and 8.2 (1H, s); ms *m/e*: 113 (M^+).

Chloroformamide ***17***

The amide **16** (110 mg, 1 mmol) was dissolved in dry dimethoxyethane (15 mL) and cooled at 0°C. Dry hydrogen chloride gas was bubbled through this solution for 30 min. The reaction mixture was then stirred overnight. Removal of the solvent at reduced pressure yielded the crude chloroformamide **17** (145 mg) which was used without purification; ir ν_{max} ($CHCl_3$): 3440 and 1685 cm^{-1}; nmr ($CDCl_3$) δ: 1.6 (6H), 2.0 (2H, m), 3.5 (2H, m), and 8.2 (1H); ms *m/e*: 149, 151 (M^+).

Iminoether ***18***

Silver tetrafluoroborate (162 mg, 0.83 mmol) was suspended in nitromethane (10 mL) and cooled to 0°C. The chloroformamide **17** (125 mg, 0.83 mmol) dissolved in nitromethane (10 mL) was then added dropwise with stirring. After the addition was complete, the stirring was continued overnight. The silver chloride formed was filtered off and the filtrate was evaporated to dryness to give the hydrofluoroborate salt of **18** (160 mg); nmr (CD_3CN) δ: 1.4 (6H, s), 2.15 (2H, m), 3.7 (2H, t), and 8.3 (1H).

This salt (160 mg) was dissolved in dichloromethane (20 mL) and cooled to 0°C. This solution was then shaken with sodium hydroxide (2 mL, 2 *N*) saturated with sodium chloride. The organic layer was separated and the aqueous layer was extracted with dichloromethane. The combined extracts were washed with brine and dried over sodium sulfate. The residual liquid obtained after fractional distillation of the solvent was purified by vpc (5 ft, ¼ in., 10% SE-30, 100°C) to give the iminoether **18** (12) (25 mg); nmr ($CDCl_3$) δ: 1.45 (6H, s), 1.9 (2H, t), 3.5 (2H, t), and 8.0 (1H).

Imidate Salt ***8***

The iminoether **18** (12.8 mg, 0.11 mmol) and trimethyloxonium tetrafluoroborate (15 mg, 0.1 mmol) were mixed in dichloromethane (10 mL) and the mixture was stirred overnight. Removal of the solvent yielded crude **8** (21 mg) as a solid which was recrystallized from ether–dichloromethane; mp 109–110°C; ir ν_{max} (CH_2Cl_2): 1680 and 1040 cm^{-1}; nmr (CD_3CN) δ: 1.5 (6H, s), 2.2 (2H, m), 3.4 (3H, s), 3.6 (2H, m), and 8.1 (1H). *Anal.* calcd. for $C_7H_{14}NOBF_4$: C 39.10, H 6.56; found: C 38.05, H 6.94.

N-(2,6-Dimethylphenyl)-N-(3-chloropropyl)formamide ***20***

Sodium hydride (16 g, 57%, 0.033 mol) washed with dry hexane was suspended in dry tetrahydrofuran and cooled in an ice bath. *N*-(2,6-Dimethylphenylformamide) **19** (4.2 g, 0.028 mol) was then added with stirring. A brisk effervescence took place and a white voluminous precipitate was formed immediately. The reaction mixture was then allowed to warm up to room temperature and stirred for 3 h. 1-Bromo-3-chloro-

propane (4.47 g, 0.028 mol) was then added dropwise followed by dimethylsulfoxide (50 mL). The stirring was continued overnight and it was poured into cold water (100 mL). The organic layer was separated and the aqueous layer was extracted with dichloromethane. The extracts were combined, washed with water, and dried over sodium sulfate. The removal of the solvent and fractional distillation of the residue under reduced pressure yielded the amide **20** (4.4 g, 65%); bp 132°C/0.2 Torr; ir ν_{max} ($CHCl_3$): 1675 cm^{-1}; nmr ($CDCl_3$) δ: 2.0 (2H, m), 2.25 (6H, s), 3.75 (4H, m), 7.35 (3H, m), and 8.25, 8.53 (1H); ms *m/e*: 225, 227 (M^+). *Anal.* calcd. for $C_{12}H_{16}NOCl$: C 63.85, H 7.14; found: C 63.78, H 7.41.

Imidate Salt ***9***

A solution of the amide **20** (702 mg, 3.12 mmol) dissolved in nitromethane (30 mL) was added to silver tetrafluoroborate (608 mg, 3.12 mmol) in a flask covered with aluminium foil and the mixture was stirred overnight. The reaction mixture was then filtered and the solvent was distilled off under reduced pressure. The residue was dissolved in dichloromethane and hydrogen chloride gas was bubbled until the precipitation of silver chloride was complete. It was then filtered and the residue obtained on concentrating the filtrate was crystallized from dichloromethane to give pure imidate salt **9** (600 mg, 75%); mp 181–182°C; ir ν_{max} (CH_2Cl_2): 1660 cm^{-1}; nmr (CD_3CN) δ: 2.4 (6H, s), 2.6 (2H, m), 4.0 (2H, t), 5.0 (2H, t), 7.5 (3H), and 8.6 (1H, s). *Anal.* calcd. for $C_{12}H_{16}NOBF_4$: C 52.02, H 5.82; found: C 51.88, H 5.71.

Acidic Hydrolysis

Imidate Salt ***7***

The imidate salt **7** (6 mg, 0.03 mmol) was dissolved in CD_3CN (500 μL) and D_2O (40 μL). After 4 h, only ester ammonium salt **21** could be detected; nmr (CD_3CN/D_2O) δ: 8.1 (1H, s, formyl proton), 4.15 (3H, t, OCH_2), 3.1 (3H, s, $\overset{+}{N}CH_3$). The solution was then cooled in ice-water, ice-cold deuterated sodium hydroxide (1 *N* NaOD, 100 μL) was added and an nmr spectrum was immediately recorded. Only amide **25** could be detected (20% **25***A*, 80% **25***B*).

Imidate Salt ***9***

The imidate salt **9** (4 mg, 0.015 mmol) was dissolved in CD_3CN (500 μL) and D_2O (50 μL) and the hydrolysis was followed by nmr. The hydrolysis was complete in about 18 h to give amide alcohol **23** and ester ammonium salt **22** in the ratio of 1:1. After 4 h of reaction, only conformer **23***B* of the amide product had begun to appear. The ratio of the two conformers after 29 h was **23***A*:**23***B* = 2:1.

Basic Hydrolysis

Imidate Salt ***7***

Imidate salt **7** (24 mg, 0.12 mmol) was dissolved in CD/CN (500 μL), deuterated sodium hydroxide (1 *N* NaOD)D_2O, 200 μL, 0.2 mmol) was added at room temperature, and an nmr spectrum was immediately recorded. Only amide **25***A* (40%) and **25***B* (60%) could be detected. In a separate experiment, imidate **7** (45 mg, 0.24 mmol) was dissolved in acetonitrile (1 mL) and shaken with sodium hydroxide (500 μL, 1 *N*, 0.5 mmol). The solution was then extracted with dichloromethane to give amide **25** (19 mg) which was purified by vpc (5 ft, ¼ in., 10% SE-30, 140°C); ir ν_{max} ($CHCl_3$): 3425, 1670 cm^{-1}; nmr ($CDCl_3$) δ: 1.8 (2H, m, CH_2—CH_2CH_2), 2.83, 2.91 (3H, two s, N—CH_3), 3.5 (4H, m, N—CH_2, OCH_3), 8.0 (1H, s, formyl proton); ms *m/e*: 117 (M^+).

In another experiment, imidate salt **7** (15 mg, 0.08 mmol) was dissolved in CD_3CN and cooled to 0°C, ice-cold deuterated sodium hydroxide (100 μL of 2 *N* NaOD/D_2O, 0.2 mmol) was added, and an nmr spectrum was immediately recorded at 0°C. The only product formed was amide alcohol **25***A* and **25***B* in the ratio 23:77. The conversion of **25***A* into **25***B* was then followed by nmr spectroscopy (Table 1) until equilibration.

In another experiment, imidate salt **7** (5 mg, 0.03 mmol) was dissolved in CD_3CN (500 μL) and cooled to −10°C in the nmr probe. Ice-cold deuterated sodium hydroxide (100 μL of 1 *N* NaOD/D_2O, 0.1 mmol) was added and the spectrum recorded immediately. The spectrum showed 20% of **25***A* and 80% of **25***B*. The same experiment was repeated at +10°C and the spectrum revealed 25% of **25***A* and 75% of **25***B*.

Imidate salt **7** (6 mg, 0.03 mmol) was dissolved in CD_3CN (500 μL) and D_2O (40 μL). The hydrolysis was followed by nmr spectroscopy and it was complete after 4 h giving only ester ammonium salt **21**. The solution was then cooled to 0°C and ice-cold deuterated sodium hydroxide (100 μL of 1 *N* NaOD/D_2O) was added. A spectrum was immediately recorded at 0°C showing 20% of **25***A* and 80% of **25***B*.

Imidate Salt ***8***

Imidate salt **8** (6 mg, 0.03 mmol) was dissolved in CD_3CN (500 μL) and cooled to 0°C. Ice-cold deuterated sodium hydroxide (100 μL, 1 *N* NaOD/D_2O, 0.1 mmol) was added and an nmr spectrum was immediately recorded. The only product formed was amide alcohol **27***A* and **27***B* in the ratio of 1:9. The conversion of **27***A* into **27***B* was followed by nmr spectroscopy (Table 2) until equilibration.

In a separate experiment, imidate salt **8** (8 mg, 0.04 mmol) was shaken with sodium hydroxide (1 *N*, 500 μL). The solution was then saturated with sodium chloride and extracted with dichloromethane. The organic extracts were combined, washed with brine, and dried over anhydrous sodium sulfate. Distillation of solvent gave a viscous liquid; ir ν_{max} ($CHCl_3$): 3600 (sharp), 3420 (broad), 1670, and 1020 cm^{-1}; nmr (CD_3Cl_3) δ: 1.20 (6H, s, *gem*-dimethyl group), 1.70 (2H, m, CH_2), 2.82, 2.93 (3H, two s, N—CH_3), 3.45 (2H, m, N—CH_2), 7.91, 8.00 (1H, two s, formyl proton); ms *m/e*: 145 (M^+).

Imidate Salt ***9***

Imidate salt **9** (40 mg, 0.14 mmol) was dissolved in CD_3CN (500 μL) and placed in an nmr tube. Deuterated sodium hydroxide (300 μL, 1 *N* NaOD/D_2O, 0.3 mmol) was added and the spectrum was immediately recorded. The hydrolysis was instantaneous and gave only the amide alcohol in the conformation **23***B*. It slowly isomerized to give an equilibrium mixture of **23***A* (67%) and **23***B* (33%) when kept for more than 73 h; nmr (CD_3CN/D_2O/NaOD) δ: **23***A*: 2.0 (m), 2.35 (s), 3.7 (m), 7.32 (s), 8.1 (s); **23***B*: 2.0 (m), 2.5 (s), 4.0 (m), 7.4 (s), 8.5 (s).

In a separate experiment, imidate **9** (155 mg, 0.56 mmol) was dissolved in acetonitrile (1 mL) and shaken with sodium hydroxide (800 μL, 1 *N*, 0.8 mmol). The solution was immediately treated with acetic anhydride and pyridine (20 mL, 1:1). The solution was kept overnight and then concentrated under vacuum. The residue was dissolved in dichloromethane and washed with water. Solvent evaporation gave a yellow oil, the spectra of which corresponded to the acetate of amide alcohol **23**. It was purified by chromatography on silica gel; ir ν_{max} ($CHCl_3$): 1740, 1675 cm^{-1}; nmr ($CDCl_3$) δ: 2.0 (2H, m), 2.1 (3H, s), 2.3 (6H), 3.7 (2H, m), 4.15 (2H, t), 7.3 (3H), 8.16, 8.5 (1H); ms *m/e*: 249 (M^+), 189 (M^+ − 60). Purification by preparative vpc gave an analytical sample. *Anal.* calcd. for $C_{14}H_{19}NO_3$: C 67.45, H 7.68; found: C 67.65, H 7.54.

The imidate salt **9** (4 mg, 0.015 mmol) was dissolved in CD_3CN (500 μL) and D_2O (50 μL) and the hydrolysis was followed by nmr spectroscopy. After 30 h, the hydrolysis was complete (50% amide alcohol **23** and 50% ester ammonium salt **22**) and the amide alcohol was at equilibrium (67% **23***A*, 33% **23***B*). Deuterated sodium hydroxide (50 μL, 1 *N*

NaOD/D_2O, 0.05 mmol) was then added and a spectrum recorded immediately. The reaction mixture contained 70% amide alcohol **23** at its equilibrium concentration (67% **23***A*, 33% **23***B*) and 30% of amine alcohol **30**. In a separate experiment, imidate salt **9** (10 mg, 0.94 mmol) was dissolved in water (500 μL) and kept overnight. The solution was then treated with sodium hydroxide (1 *N*, 100 μL), saturated with sodium chloride, and extracted with ether. The combined ether extracts were washed with brine, dried over anhydrous sodium sulfate, and filtered. Solvent evaporation gave a viscous oil (6 mg). Thin layer chromatographic analysis (ethyl acetate) indicated two products which were separated by thick layer chromatography to give amide alcohol **23**, identified by comparison with authentic material, and amine alcohol **29**; ir ν_{max} (CH_2Cl_2): 3360, 1470, and 1020 cm^{-1}; nmr (CD_3CN) δ: 1.76 (3H, m), 2.27 (6H, s), 3.05 (2H, t), 3.66 (2H, t), 7.13 (3H, m); ms *m/e*: 179 (M^+).

Imidate salt **9** (5 mg, 0.02 mmol) was dissolved in deuterium oxide (500 μL). After 4 h the hydrolysis was complete, giving ester ammonium salt **22** (72%) and amide alcohol **23** (28%).[6] Deuterated sodium hydroxide (100 μL, 1 *N* NaOD/D_2O, 0.1 mmol) was then added and an nmr spectrum was immediately recorded to reveal the presence of amide alcohol **23** (28%) and amine alcohol **29** (72%). No *trans* acylation reaction was detected.

Treatment of vinyl acetate with ozone yields the mixed anhydride of acetic and formic acids and formaldehyde oxide. The formaldehyde oxide can be trapped by reaction with ketones yielding the corresponding ozonides. Thermal decomposition of these ozonides gave the corresponding lactone and (or) the corresponding olefin carboxylic acid. The ozonides were also prepared by the ozonolysis of the corresponding olefins.

RICHARD LAPALME, H.-JÜRG BORSCHBERG, PIERRE SOUCY et PIERRE DESLONGCHAMPS. Can. J. Chem. **57**, 3272 (1979).

L'ozonolyse de l'acétate de vinyle donne l'anhydride mixte des acides acétique et formique ainsi que l'oxyde du formaldéhyde. Ce dernier peut être piégé par des cétones pour conduire aux ozonides correspondants. La décomposition thermique de ces ozonides donne les lactones ou les acides oléfines carboxyliques correspondants. Les ozonides ont aussi été préparés par l'ozonolyse des oléfines correspondants.

In connection with our investigation toward the total synthesis of ryanodine (1), it became important to find a complementary method to the Baeyer–Villiger oxidation of sterically hindered ketones. We wish to report a study which shows that the thermal decomposition of ozonides is a method which can replace the Baeyer–Villiger reaction in some cases.

Ozonolysis of vinyl acetate (CH_2Cl_2, $-78°C$) gave acetic–formic mixed anhydride and an insoluble white solid which is the result of the polymerization (2) of the carbonyl oxide of formaldehyde (formaldehyde oxide (**1**)) (3) (Scheme 1). Filtration gave a dichloromethane solution of practically pure acetic–formic mixed anhydride which was characterized further by a reaction with cyclohexylamine, yielding *N*-cyclohexylformamide (90%) and *N*-cyclohexylacetamide (10%) (4). The *dry* peroxide polymer of **1** is explosive (shock sensitive); it can be reduced with bisulfite or dimethylsulfide.[1]

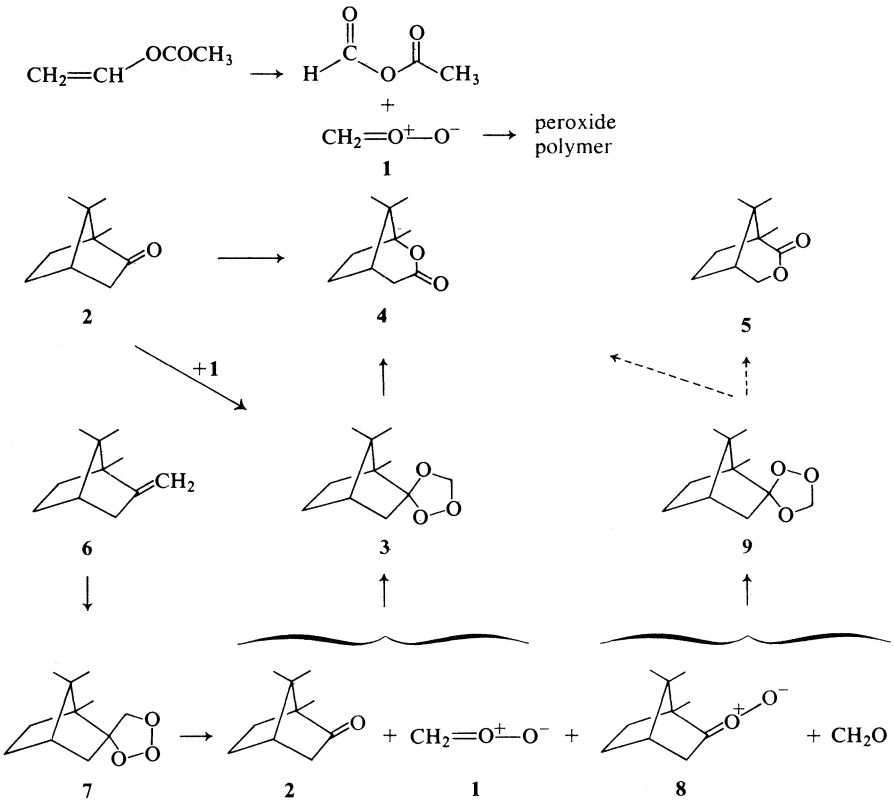
Ozonolysis of vinyl acetate (7 equiv., $-78°C$, CH_2Cl_2) in the presence of camphor (**2**) (1 equiv.) gave in high yield an ozonide, characterized by nmr at $-78°C$ (two broad singlets at 5.22 and 5.12 ppm). Decomposition of the ozonide started upon warming to room temperature. After reflux in benzene for 1 h, the lactone **4** (5) was isolated in 63% yield after purification. The isomeric lactone **5** (5) was not detected. Thus, formaldehyde oxide (**1**) produced from vinyl acetate has reacted with camphor to form an ozonide. The configuration of the ozonide must correspond to structure **3** which is the result of the attack of **1** on the least hindered face of the carbonyl group in camphor. Since, only one lactone (**4**) was obtained, the decomposition of the ozonide **3** is completely specific.

We have studied also the ozonolysis of 2-methylenebornane (**6**) at $-78°C$ followed by reflux in benzene. It gave a $\simeq 1:1$ mixture of the isomeric lactones **4** and **5** in a low yield of 14% and camphor (9%). This result can be rationalized in the following way. Ozonolysis of **6** gives first the molozonide **7** which can decompose into the two carbonyl oxides **1** and **8** plus camphor and formaldehyde. Recombination yields a mixture of the isomeric ozonides **3** and **9**. The thermal decomposition of the ozonide **3** would produce only the lactone **4** while that of the ozonide **9** could either produce only the lactone **5** or a mixture of **4** and **5**. The low yield can be explained by the difficulty of recombination of the two carbonyl oxides **1** and **8** with camphor and formaldehyde respectively to give the ozonides **3** and **9**. Therefore, most of the carbonyl oxides would have produced dimeric or polymeric peroxides, which would be stable at the boiling point of benzene (6). It is also possible that both ozonides **3** and **9** gave only the lactone **4** and the formation of the isomeric lactone **5** would come from the decomposition of another unidentified "peroxide" species.

The tricyclic ketone **10** (7) was also treated with vinyl acetate and ozone to give the ozonide **11** iso-

[1]At any time, this explosive polymeric peroxide should be handled with all precautions.

0008-4042/79/243272-06$01.00/0



SCHEME 1

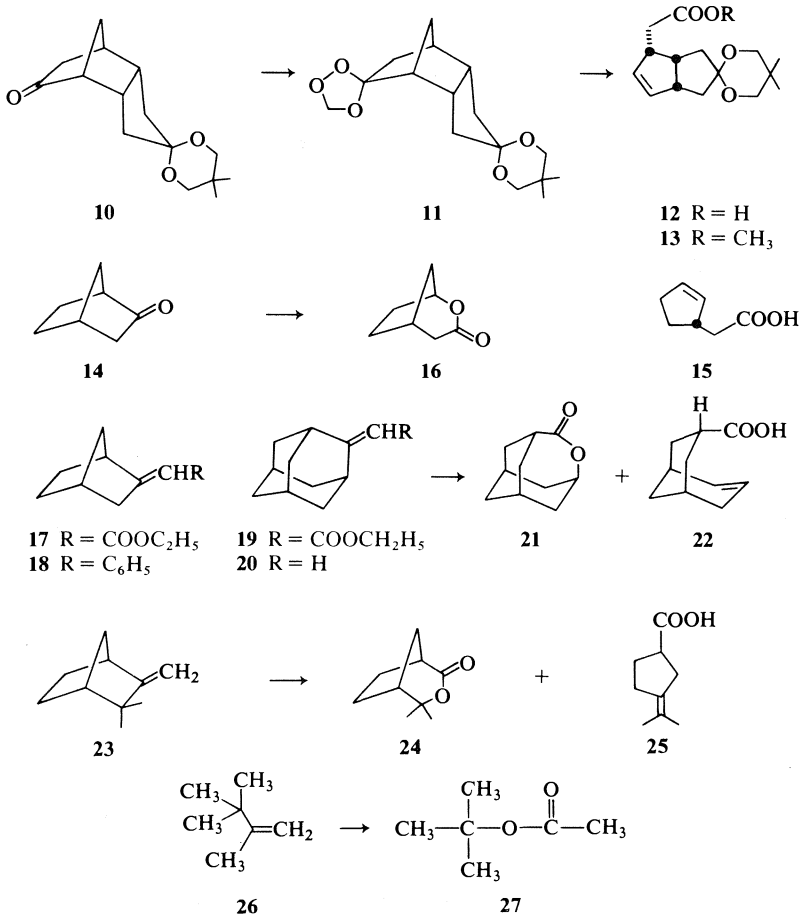
lated in 48% yield (Scheme 2). This stable ozonide is not reduced with dimethylsulfide at 20°C but it can be reduced with triphenylphosphine giving the ketone **10** in quantitative yield. The stereochemistry assigned to **11** is again based on the expectation that formaldehyde oxide **1** will prefer to react with the least hindered face of the carbonyl group in **10**. Thermal decomposition (benzene reflux, 4 h) gave the starting ketone **10** (40%) and the unsaturated olefin carboxylic acid **12** (15%, identified with an authentic sample of the corresponding methyl ester **13** (7)).

2-Norbornanone (**14**) was also treated with vinyl acetate – ozone followed by a reflux in benzene. It gave a complex mixture of unidentified olefin carboxylic acids and the lactone **16** (20%) (8). The olefin carboxylic acid **15** was not found in the mixture. The olefins **17**–**20** were also treated with ozone and the presumed ozonides were decomposed thermally by reflux in benzene. Compound **17** gave a mixture of **14** (8%), **15** (30%), and **16** (16%). Compound **18** gave **14** (16%) and **16** (10%) plus benzaldehyde (58%). The adamantane unsaturated ester **19** gave a small quantity of adamantanone (2%) and a mixture (62%) of lactone **21** (9) and olefin acid **22**. The relative percentage of **21** and **22** was not determined. On heating in the presence of *p*-toluenesulfonic acid, the olefin acid **22** was converted into the lactone **21**. 2-Methyleneadamantane (**20**) gave 15% of adamantanone and about 30% of a mixture of compounds **21** and **22**.

We have also found in the literature (10) that the ozonolysis of camphene (**23**) does not give a stable ozonide, and the compounds **24** and **25** are isolated in high yield. Similarly, 2,3,3-trimethyl-1-butene (**26**) gives an unstable ozonide which rearranges to *tert*-butyl acetate (**27**) (11).

The product formation from the thermal decomposition of the ozonides can be explained in the following manner. On heating, the weak peroxide bond of an ozonide such as **28** (Scheme 3) must cleave to give first a diradical such as **29** (12) which can either give the original ketone **30** and the diradical **31**, or formaldehyde and the diradical **32** which can fragment further to form the diradical **33**. The diradical **33** (R = H) can then either abstract a hydrogen to yield the corresponding olefin carboxylic acid **34** or form the lactone **35** (R = H). The diradical **33** (R = CH_3) would give the lactone **35** (R = CH_3).

We prefer the above mechanism to the one where



SCHEME 2

the rearragement would occur via the direct transformation of the carbonyl oxide (**28** → **36** → **37** → **38** → **35**) (see p. 747 in ref. 13).

This preliminary exploratory work shows that the thermal decomposition of ozonides gives products which are identical or equivalent to those obtained in the Baeyer–Villiger oxidation of ketones. It shows also that the vinyl acetate – ozone procedure is an interesting method to produce ozonides. However, this method has two important disadvantages: (*a*) the formaldehyde oxide (**1**) reacts with itself to yield an explosive insoluble peroxide polymer, and (*b*) the polymerization of formaldehyde oxide (**1**) competes with the reaction of **1** with ketones, a large excess of vinyl acetate being essential.

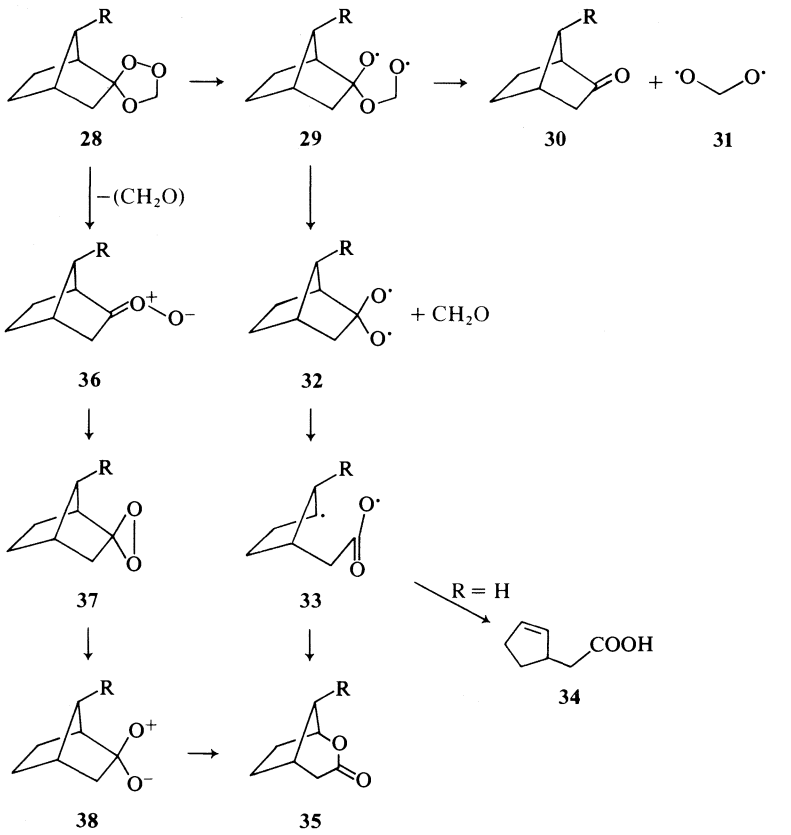
It would be interesting to find a carbonyl oxide which would be either slow to polymerize or at least would give a soluble polymer (less explosive). This carbonyl oxide reagent could be useful as a complementary method for the Baeyer–Villiger reaction in some specific cases.

We have tried the ozonolysis of ethyl vinyl ether in the presence of camphor. After heating in benzene, we have isolated camphor (70%) and the lactone **4** (30%). Formation of an insoluble polymer was not observed and we did not experience an explosion. The reaction of ozone with ethyl vinyl ether must have given first formaldehyde and the expected "stabilized" carbonyl oxide **39** (Scheme 4). Some of the carbonyl oxide **39** produced must have been trapped by camphor; however, most of **39** must have reacted with the formaldehyde produced.

We have treated the ryanodine synthetic intermediate **40** (1) with ozone in the presence of excess of either vinyl acetate or ethyl vinyl ether on a small scale. We have recovered compound **40** quantitatively; the anticipated conversion **40** → **41** did not take place. This result indicated that the dimerization or polymerization process of carbonyl oxide was faster than its reaction with the ketone functions of compound **40**.

Experimental

The ir spectra were taken on a Perkin-Elmer 257 spectrophotometer. Vapor phase chromatographic (vpc) analyses were carried out on a Varian aerograph instrument model 90-P. Proton nmr spectra were recorded on a Varian A-60 or a

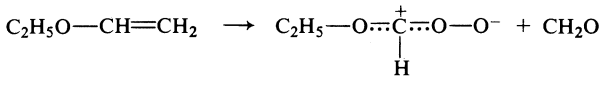


SCHEME 3

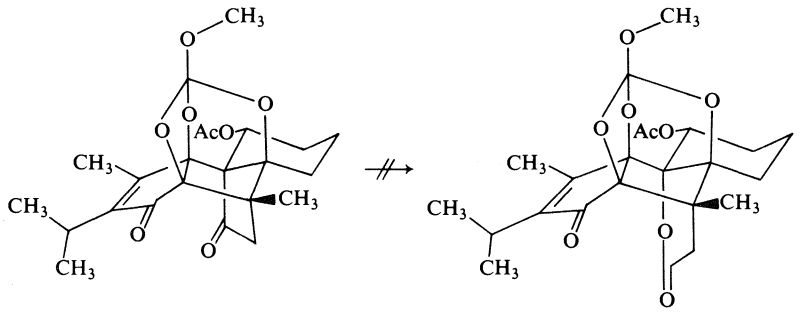
Brüker WP-60 instrument, Chemical shifts are reported in δ values relative to tetramethylsilane as internal standard (A-60) or relative to chloroform (WP-60). The carbon nmr spectrum was recorded on a Brüker HX-90 instrument. The ozonolysis reactions were carried out using a Welsbach Ozonator, model T-816. The mass spectra were taken on a Hitachi-Perkin-Elmer RMU-6 mass spectrometer. Anhydrous magnesium sulfate was used as the drying agent in working up reactions. Low boiling petroleum ether (bp 30–60°C) was used as solvent. Thin layer chromatography (tlc), both analytical and preparative, was carried out on silica gel. Adamantanone, 2-cyclopentaneacetic acid, and 2-norbornanone are commercial products (Aldrich Chemical Co.).

2-Methylenebornane **6**

2-Methylisoborneol (14) was prepared by the reaction of a large excess of methyl magnesium bromide on camphor in ether. Thionyl chloride (2.2 mL, 3 equiv.) was added dropwise to a cold solution (0°C) of 2-methylisoborneol (1.83 g, 10.9 mmol) in dry pyridine (75 mL). After 0.5 h, the reaction mixture was poured on ice and extracted with ether. The organic phase was washed with hydrochloric acid (2 *N*), water, and



39



SCHEME 4

sodium bicarbonate (5%). After drying, the volume of ether was reduced (to ≃10 mL) by distillation. The vpc analysis showed a mixture of 2-methylenebornane **6** (67%) and the corresponding isomeric *endo* olefin (33%). Pure 2-methylenebornane **6** (15) was obtained by vpc; ir ($CHCl_3$)$_3$): 1650 cm^{-1}; nmr ($CDCl_3$) δ: 4.7 (2H, m, olefinic hydrogens), 0.92 (3H, s, CH_3), 0.90 (3H, s, CH_3), and 0.77 (3H, s, CH_3).

*Ethyl 2-Norbornylidene Acetate **17***

The compound **17** was prepared by the reaction of the lithium salt of trimethylsilyl ethyl acetate on 2-norbornanone in anhydrous tetrahydrofuran (16). Ethyl 2-norbornylidene acetate **17** was isolated in 26% yield by vpc as a mixture of the two geometrical isomers; ir ($CHCl_3$): 1703 and 1658 cm^{-1}; nmr ($CDCl_3$) δ: 5.7 (0.2H, m, olefinic hydrogen), 5.5 (0.8H, m, olefinic hydrogen), 4.1 (2H, q, J = 7 Hz), and 1.28 (3H, t, J = 7 Hz).

*2-Benzylidene Norbornane **18***

2-Benzyl-2-*endo*-hydroxynorbornane (17) (mp 61–63°C; nmr ($CDCl_3$) δ: 7.48 (5H, s, aromatic hydrogens) and 2.87 (2H, s, benzylic hydrogens)) was prepared by the reaction of benzyl magnesium chloride on 2-norbornanone in ether.

2-Benzyl-2-*endo*-hydroxynorbornane (313 mg, 1.55 mmol) was dehydrated with pyridine (20 mL) and thionyl chloride (0.7 mL) by following a procedure similar to the one described for the preparation of 2-methylenebornane (**6**). A mixture was obtained (230 mg) which contained the desired *exo* olefin **18** (80%) and the corresponding isomeric *endo* olefin (20%).

The above mixture (230 mg) was heated for 2 h at 120°C in dimethylsulfoxide containing potassium *tert*-butoxide (250 mg). The cooled reaction mixture was poured on ice and extracted with a mixture of ether and petroleum ether (1:3). The organic phase was washed with water, dried, and evaporation of the solvent under reduced pressure gave a yellow oil which was filtered through a short column of silica gel (petroleum ether). The olefin **18** (215 mg, ≃95% yield) was obtained pure as a mixture of two geometrical isomers (4:1 ratio); i.r. ($CHCl_3$): 1660, 1600, 1490, and 1442 cm^{-1}; nmr ($CDCl_3$) δ: 7.43 (5H, b s, aromatic hydrogens), 6.43 (0.8H, t, J = 2.5 Hz, olefinic hydrogen), and 6.26 (0.2H, m, olefinic hydrogen).

*Ethyl 2-Adamantylidene Acetate **19***

The compound **19** was prepared in 45% yield by the reaction of the lithium salt of trimethylsilyl ethyl acetate on adamantanone in anhydrous tetrahydrofuran (16;) ir ($CHCl_3$): 1705, 1655, 1445, and 1230–1195 cm^{-1}; nmr ($CDCl_3$) δ: 5.58 (1H, s, olefinic hydrogen), 4.13 (2H, q, J = 7 Hz), and 1.27 (3H, t, J = 7 Hz).

*2-Methyleneadamantane **20***

2-Methyl 2-adamantanol (mp 212–213°C; nmr ($CDCl_3$) δ: 1.4 (3H, s)) was prepared by the reaction of methyl magnesium bromide on admantanone in ether (18). Thionyl chloride (0.3 mL) was added dropwise to a cold solution (0°C) of 2-methyl 2-adamantanol (502 mg, 3.0 mmol) in dry pyridine (0.7 mL). After 45 min, the reaction mixture was poured on ice and extracted with ether. The organic phase was washed with hydrochloric acid (2 *N*), water, and sodium bicarbonate (5%). Drying and evaporation of the solvent gave a waxy solid (430 mg). Preparative tlc (hexane) gave pure 2-methyleneadamantane **20** (19); nmr ($CDCl_3$) δ: 4.6 (2H, s, olefinic hydrogens), 2.55 (2H, m), and 2.1–1.8 (12 H, m).

Ozonolysis of Vinyl Acetate

A stream of ozone in oxygen was passed through a cold solution (−78°C) of freshly distilled vinyl acetate (989 mg, 11.6 mmol) in dry dichloromethane (15 mL) until a light blue color appeared. Excess ozone was removed by bubbling nitrogen while the solution was allowed to warm up to room temperature. The white explosive polymer was removed by filtration through cotton. Proton nmr of the solution showed two singlets at 8.9 (1H) and 2.2 (3H) δ indicating the presence of acetic formic mixed anhydride. The solution was cooled to 0°C and cyclohexyl amine (2.9 g, 30 mmol) was added. After 1 h at room temperature, dichloromethane was added. The organic phase was then washed with hydrochloric acid (*N*) and sodium bicarbonate (5%). Drying and evaporation gave a mixture (1.36 g) of *N*-cyclohexylformamide (90%) and *N*-cyclohexylacetamide (10%) which were identified by nmr and vpc comparison with an authentic sample (4).

*Oxidation of Camphor (**2**)*

(a) O_3/Vinyl Acetate

A stream of ozone in oxygen was passed through a cold solution (−78°C) of camphor (154 mg, 1 mmol) and freshly distilled vinyl acetate (550 mg, 6 mmol) in dry dichloromethane (10 mL) until a light blue color appeared. Excess ozone was then removed by bubbling nitrogen. Proton nmr at −78°C showed two singlets at 5.22 and 5.12 δ indicating the presence of the ozonide **3**. The solution was then allowed to warm up to room temperature. Thin layer chromatography with ether hexane (1:1) showed one non-polar compound. Removal of the white explosive polymer by filtration through cotton gave a colorless solution. Dichloromethane (50 mL) was added and the resulting solution was washed with sodium bicarbonate (0.1 *N*, 3 × 10 mL). Drying and evaporation of the solvent under reduced pressure was followed by the addition of benzene (10 mL), and the solution was refluxed for 1 h. The crude product was shown to contain lactone **4** only by tlc analysis. Preparative tlc with ether/hexane (1:1) gave pure lactone **4** as a waxy solid (107 mg, 63%). Compound **4** was shown to be identical (ir and nmr) with the major product obtained from the Baeyer–Villiger oxidation of camphor with peracetic acid (5).

(b) O_3/Ethyl Vinyl Ether

A stream of ozone in oxygen was passed through a cold solution (−78°C) of camphor (50 mg, 7 mmol) and freshly distilled ethyl vinyl ether (720 mg, 70 mmol) in dry dichloromethane. Excess ozone was removed as before. Benzene was added and the dichloromethane was removed by distillation. The benzene solution was refluxed for 1 h and cooled to room temperature. Analysis by ir, nmr, and tlc showed that a mixture of camphor and lactone **4** was obtained, vpc measurement indicating 70% camphor and 30% lactone **4**.

*Oxidation of 2-Methylenebornane (**6**)*

A stream of ozone in oxygen was passed through a cold solution (−78°C) of 1-methylenebornane (91 mg, 0.6 mmol) in dichloromethane (20 mL) until a light blue color developed. Thin layer chromatographic analysis in ether/hexane (1:1) indicated two non-polar compounds which did not correspond to either the isomeric lactones **4** and **5** or camphor. A work-up similar to the one carried out for the oxidation of camphor was done. The mixture was then refluxed for 1 h in benzene. Analysis by ir, nmr, vpc, and tlc showed the presence of the isomeric lactones **4** and **5** (14% yield, in a ≃1:1 ratio) and camphor (9%).

*Oxidation of the Tricyclic Ketal Ketone **10***

A stream of ozone in oxygen was passed through a cold solution (−70°C) of tricyclic ketone **10** (60 mg, 0.24 mmol) and freshly distilled vinyl acetate (80 μL) in dry dichloromethane (5 mL) until a light blue color developed. The solution was allowed to warm up slowly to 0°C while nitrogen was passed through it until it was reduced to ≃0.5 mL. Preparative tlc with ether/hexane (1:1) gave the ozonide **11** (30 mg,

48%); ir ($CHCl_3$): 1112, 1089, 1075, and 992 cm^{-1}; nmr ($CDCl_3$) δ: 5.15 (1H, s), 5.03 (1H, s), 3.49 (4H, s), and 0.96 (6H, s); ms *m/e*: 296 (M^+); ^{13}C nmr ($CDCl_3$) δ: 115 (s), 111.5 (s), 94.2 (t), 73.1 (t), 71.1 (t), 46.9 (d), 41.1 (t), 40.3 (d), 39.7 (d), 33.9 (t), 33.2 (t), 32.6 (t), 29.7 (s), and 25.6 (q, one signal for both methyl groups). Analysis by ^{13}C nmr showed only one product. Analysis by ^1H nmr showed two equal singlets for the methylene group of the ozonide ring. There is at least one example in the literature of a methylene dioxy group (OCH_2O) where the two hydrogens have different chemical shifts but no coupling ($J = 0$ Hz) between the two of them (20)

A solution of the ozonide **11** (27 mg, 0.09 mmol) in dry benzene was refluxed during 4 h. After concentrating the solution to about 3 mL, an excess of ethereal diazomethane was added. The solvent was then evaporated. Separation by preparative tlc gave tricyclic ketal ketone **10** (10 mg, 40%) and the olefin ester **13** (13 mg, 51%) which was found identical (ir, nmr) with an authentic sample (7).

*Oxidation of 2-Norbornanone (**14**)*

2-Norbornanone (125 mg, 1.14 mmol) was oxidized with ozone and vinyl acetate (592 mg, 6.82 mmol) in dichloromethane (10 mL) by following the procedure described for camphor. After reflux with benzene for 18 h, the solution was evaporated and ether was added. The solution was treated with an excess of diazomethane and evaporated to dryness. Column chromatography with silica gel using ether gave the bicyclic lactone **16** (28 mg, ≃20%) (identified by ir and nmr) and a complex mixture of methyl ester products (120 mg). The vpc and tlc analyses showed the absence of the methyl ester of the olefin carboxylic acid **15** by comparison with an authentic sample.

*Oxidation of Ethyl 2-Norbornylidene Acetate **17***

A stream of ozone in oxygen was passed through a cold solution (−78°C) of ethyl 2-norbornylidene acetate (**17**) (154 mg, 0.86 mmol) in a mixture of dichloromethane and pentane (1:1, 15 mL) until a light blue color developed. Excess ozone was removed by bubbling nitrogen. Benzene (20 mL) was added, most of the dichloromethane and pentane were removed by distillation, and the mixture was refluxed for 3 h. The solution was concentrated to about 3 mL and treated with excess ethereal diazomethane. Comparison with standard solutions by vpc analysis showed a mixture of 2-norbornanone **14** (8%), the methyl ester of cyclopentaneacetic acid **15** (30%), and the lactone **16** (16%). These compounds were further identified by ir and nmr comparison with authentic samples.

*Oxidation of 2-Benzylidenenorbornane (**18**)*

2-Benzylidenenorbornane (**18**) (115 mg, 0.62 mmol) was oxidized by ozone following the procedure described for compound **17**. A mixture of 2-norbornanone (**14**) (16%), lactone **16** (10%), and benzaldehyde (58%) was obtained (vpc and nmr).

*Oxidation of Ethyl 2-Adamantylidene Acetate **19***

Ethyl 2-adamantylidene acetate (**19**) (208 mg, 0.94 mmol) was oxidized by ozone following the procedure described for compound **17**. After reflux in benzene, tlc analysis showed the presence of adamantane lactone **21** and the olefin carboxylic acid **22**. A few crystals of *p*-toluenesulfonic acid were added and the mixture was refluxed for 4 h. Comparison with standard solutions by vpc analysis showed a mixture of adamantanone (2%) and adamantanelactone (**21**) (62%). The reaction product **21** was shown to be identical by nmr with authentic adamantanelactone (9).

*Oxidation of 2-Methyleneadamantane (**20**)*

2-Methyleneadamantane (**20**) (69 mg, 0.46 mmol) was oxidized by ozone following the procedure described for compound **17**. After reflux in benzene for 3 h, *p*-toluenesulfonic acid (3 mg) was added and refluxing was continued for 1 h. Vapor phase chromatographic and nmr analyses showed a mixture of adamantanelactone **21** (30%) and adamantanone (15%).

Organic sulfur mechanisms. 21. The reaction of arylsulfenes with sulfur dioxide[1]

JAMES FREDERICK KING AND MOHAMMAD ASLAM

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received April 6, 1979

This paper is dedicated to Prof. Karel Wiesner on the occasion of his 60th birthday

JAMES FREDERICK KING and MOHAMMAD ASLAM. Can. J. Chem. **57**, 3278 (1979).

Phenylsulfene and diphenylsulfene (**2**), obtained by reaction of 2,6-lutidine with appropriate precursors, react with sulfur dioxide to give, respectively, benzaldehyde and benzophenone, in confirmation of the suggestion of Staudinger and Pfenninger that the benzophenone formed in the reaction of diphenyldiazomethane (**1**) with sulfur dioxide arises from reaction of the latter with the sulfene (**2**). The reaction of sulfenes with sulfur dioxide would appear to have only limited scope, all known examples occurring with a sulfene having at least one aryl group attached to the sulfene carbon atom; even with these sulfenes the reaction is apparently readily precluded in the presence of most other sulfene traps. ^{18}O-Labelling experiments in the reaction of diphenylsulfene (**2**) with sulfur dioxide indicate that the oxygen atoms in about two-thirds of the benzophenone molecules come from the sulfur dioxide, whereas **2** itself supplies the oxygen atoms for the remaining third. Previously suggested mechanisms predict that the benzophenone oxygens come only from the sulfur dioxide. General processes that could lead to the observed labelling pattern are discussed and specific examples presented. The available evidence, including reported labelling studies on the related reaction of sulfur dioxide with sulfur trioxide, provides a basis for excluding certain possible mechanisms and for preferring some over others, but is not sufficient to establish a single mechanism for the reaction of arylsulfenes with sulfur dioxide.

JAMES FREDERICK KING et MOHAMMAD ASLAM. Can. J. Chem. **57**, 3278 (1979).

Le phénylsulfène et le diphénylsulfène (**2**) obtenus par la réaction de la lutidine-2,6 avec des précurseurs appropriés, réagissent avec le bioxyde de soufre pour conduire respectivement à la benzaldéhyde et à la benzophénone. Ceci est en accord avec la suggestion de Staudinger et Pfenninger qui stipule que la benzophénone obtenue lors de la réaction du diphényldiazométhane (**1**) avec le bioxyde de soufre provient de la réaction de ce dernier avec le sulfène (**2**). La réaction des sulfènes avec le bioxyde de soufre semblerait avoir une étendue limitée puisque tous les exemples connus se rapportent à des sulfènes ayant au moins un groupement aryle attaché à l'atome de carbone du sulfène: même avec ces sulfènes, la réaction apparemment est empêchée facilement en présence de la plupart des pièges à sulfènes. Les expériences de marquage isotopique à l'^{18}O dans la réaction du diphénylsulfène (**2**) avec le bioxyde de soufre indiquent que les atomes d'oxygène des molécules de benzophénone dans la proportion de 2/3 environ proviennent du bioxyde de soufre alors que le composé **2** lui-même fournit le 1/3 des oxygènes restants. Les mécanismes suggérés antérieurement prédisent que les atomes d'oxygène de la benzophénone proviennent seulement du bioxyde de soufre. Tout en présentant des exemples spécifiques, on discute des techniques générales qui conduiraient au type de marquage isotopique observé. Les preuves disponibles, incluant les études de marquage isotopique publiées sur la réaction apparentée du bioxyde de soufre avec le trioxyde de soufre, fournissent un point de départ pour exclure certains mécanismes possibles et pour préférer quelques uns à d'autres, mais ce n'est pas suffisant pour établir un mécanisme approprié pour la réaction des sulfènes aromatiques avec le bioxyde de soufre.

Introduction

The reaction of a diazoalkane with sulfur dioxide was first reported in 1916 by Staudinger and Pfenninger (1), whose observations and proposed mechanisms may be summarized by Scheme 1. Since episulfones such as **3** very readily lose sulfur dioxide to form the olefin, the sequence **1** → **2** → **3** followed by the desulfonylation provides a useful synthesis of symmetrical alkenes,[2] though the general applicability of this route is considerably reduced by the incursion of two other reactions. One of these leads to Δ^3-1,3,4-thiadiazoline 1,1-dioxides (**7**), and thence, sometimes apparently spontaneously, to the azine

[1]Part 20: Can. J. Chem. **55**, 2323 (1977).

[2]For a review of sulfene to episulfone (or olefin) reactions see ref. 2. The intermediacy of the sulfene in this sequence follows from the observation by Opitz and Fischer (3, 4) of the characteristic adduct in the reaction of diazomethane and sulfur dioxide in the presence of 1-pyrrolidinoisobutene. Further examples of this experiment have recently been cited by Tanabe *et al.* (5, 6) as evidence for sulfene formation in the reaction of diazoalkanes and sulfur dioxide; these authors neglect, however, to acknowledge the prior work of Opitz and Fischer.

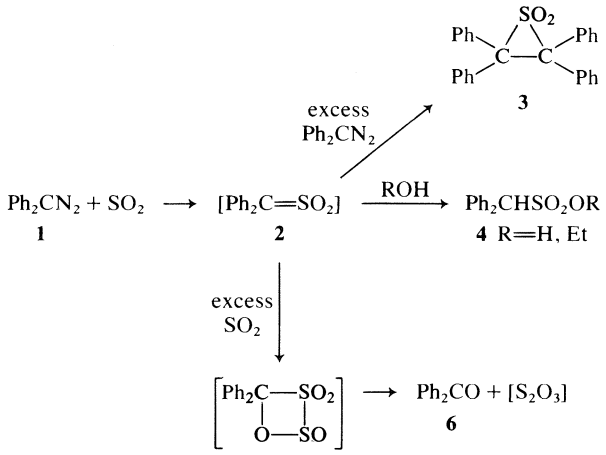
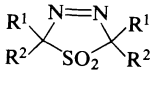


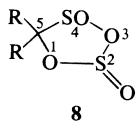
SCHEME 1

$R^1R^2C{=}N{-}N{=}CR^1R^2$ (7–9). The other competitive process is the reaction which forms the subject of the present paper, namely the formation of the simple carbonyl compound, e.g., benzophenone (**6**), originally suggested by Staudinger and Pfenninger (1) as arising from reaction of the sulfene (**2**) with sulfur dioxide. In studying this reaction our primary aim was to obtain further knowledge of sulfenes, as part of our continuing investigation of the chemistry of these species (10); we also hoped perhaps to learn something that would be helpful in improving the Staudinger–Pfenninger alkene synthesis.

What little information that was available at the start of this work showed that the formation of benzophenone was not unique. Tokura and coworkers had reported formation of (*a*) up to 22%



7



8

yields of benzaldehyde in the reaction of sulfur dioxide with phenyldiazomethane (11), (*b*) increasing amounts of 1,4-dibenzoylbenzene with increase in solvent polarity from the reaction with 1,4-bis[α-diazobenzyl]-benzene (12), and (*c*) a small amount of benzil from the reaction with azibenzil (13). Recently Brophy *et al.* (9) have described the formation of some substituted pivalophenones and related compounds from the corresponding diazoalkanes and sulfur dioxide; these authors suggested that the ketones might arise from the five-membered ring intermediate **8**, rather than the analogue of Staudinger and Pfenninger's four-membered ring intermediate (**5**) (in the mechanistic discussion which follows we shall refer to these routes, which are shown in Scheme 2, as the "BCHS" and "SP" mechanisms, respectively). Even more recently Tanabe and Nagai have reported the formation from bis(*p*-methoxyphenyl)diazomethane of up to 67% yields of 4,4′-dimethoxybenzophenone as well as smaller amounts of the corresponding tetraphenylethylene and bis(*p*-methoxyphenyl) sulfide, and also of the observation of a small amount of *p*-tolualdehyde from *p*-tolyldiazomethane (14).

Our initial aims were to define the scope of the reaction and to find if, in fact, the reaction really does involve a sulfene, and, if so, by what mechanism. In this paper we describe our findings (*a*) that sulfur dioxide indeed reacts with some sulfenes to form the ketone (or aldehyde), (*b*) that the reaction is apparently favoured when at least one of the substituents of the sulfene ($RR^1C{=}SO_2$) is an aryl group, and (*c*) that the reaction of **2** cannot be proceeding exclusively via the simplest SP or BCHS mechanisms and may well be occurring by a quite different route.

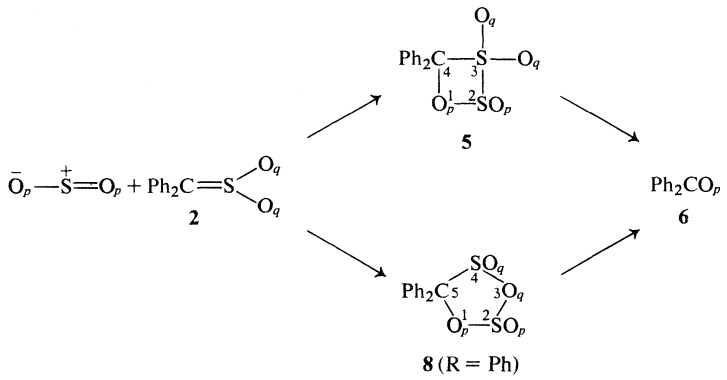
Results and Discussion

Sulfene Intermediacy and the Scope of the Reaction

The obvious experiment to ascertain if sulfenes and sulfur dioxide react as proposed, is simply to generate a sulfene by a known route in the presence of sulfur dioxide, and to determine if any of the ketone (or aldehyde) is formed. Though the action of tertiary amines on alkanesulfonyl halides and related compounds provides the most generally useful route to sulfenes, the requirement that sulfur dioxide be present creates a problem arising from the tendency of sulfur dioxide and amines to form complexes (15):

$$R_3N + SO_2 \rightleftharpoons R_3N{\cdot}SO_2$$

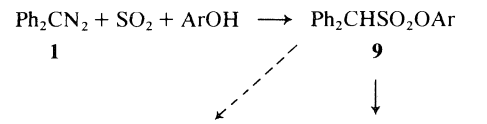
The result is that with pyridine or triethylamine, for example, the above equilibrium is evidently sufficiently far to the right that it is difficult to maintain simultaneously a sufficiently high concentration of the base to form the sulfene at a reasonable rate while having a high enough concentration of sulfur dioxide to test if it actually reacts with the sulfene. 2,6-Lutidine, however, presumably because the two methyl groups decrease the tendency for complex formation, was found to react with phenylmethanesulfonyl chloride in the presence of excess sulfur dioxide to give a small amount (~10%) of benzaldehyde. The fate of the major part of the phenylmethanesulfonyl chloride was not determined, but in view of the known tendency for phenylsulfene to react with chloride ion leading (in the absence of sulfur dioxide) ultimately to the thiobenzoyl chloride



Staudinger–Pfenninger (SP) mechanism: **2** → **5** → **6**
Brophy–Collins–Hobbs–Sternhell (BCHS) mechanism: **2** → **8** → **6**
p = ^{18}O content of the starting SO_2
q = ^{18}O content of the sulfonyl group in the ester (**9***c*)

SCHEME 2

S-oxides (16, 17), we tried the reaction of phenylmethanesulfonic anhydride instead of the chloride and obtained a much improved yield of benzaldehyde (50%, isolated as the 2,4-dinitrophenylhydrazone). In the absence of sulfur dioxide no benzaldehyde was formed; use of pyridine instead of 2,6-lutidine led to a lower (10%) yield of benzaldehyde. In our hands further variation of reaction conditions or reagents did not increase the yield of benzaldehyde. This result should perhaps be viewed in the light of the observation of Tokura *et al.* (11) that even in liquid sulfur dioxide the reaction with phenyldiazomethane gives mainly the products of the episulfone route and at most only a minor amount (22%) of benzaldehyde.



a Ar = *p*-nitrophenyl
b Ar = 2,4-dinitrophenyl
c Ar = 2-chloro-4-nitrophenyl

SCHEME 3

We then turned to the reaction of sulfur dioxide with **2** (generated, of course, by a route other than reaction of **1** with SO_2). Such a system was expected also to be useful for our planned ^{18}O-labelling experiments (see the next section), owing to the greater ease with which small quantities of benzophenone may be handled as compared with benzaldehyde. The obvious starting materials, i.e., diphenylmethanesulfonyl chloride or the anhydride, were unfortunately unavailable; neither the chloride nor the anhydride have to our knowledge been described, and all attempts in our laboratory to make the chloride have failed. This difficulty is general to the synthesis of any sulfonyl derivative RSO_2Z in which the corresponding cation, R^+, is relatively stable and Z is a good leaving group; instead of RSO_2Z one simply obtains R—Z.[3]

We have achieved partial success by adjusting the leaving group tendency of Z by varying the substituents in the esters **9**, prepared as shown in Scheme 3. The *p*-nitrophenyl ester (**9***a*) was found to be unreactive to 2,6-lutidine, whereas **9***b* underwent ready desulfonylation to **10**, perhaps as indicated by the broken arrows in Scheme 3. Ester **9***c*, however, was found to react with 2,6-lutidine and sulfur dioxide in methylene chloride to give benzophenone in 15–25% yields; the only other identified product (other than 2-chloro-4-nitrophenol) was the ether (**10***c*). As evidence that diphenylsulfene (**2**) is formed under these conditions, we found that the ester (**9***c*) with 2,6-lutidine reacts with sulfene trapping reagents to form the appropriate products: i.e., with *p*-toluidine we obtained the *p*-toluidide[4] (Ph_2CHSO_2NH—*p*-Tol), and with 1-morpholino-2-methylpropene the characteristic sulfene–enamine cycloadduct (5, 6).

The extent of conversion of diphenylsulfene (**2**) to

[3]For example, diphenylmethanesulfonic acid with thionyl chloride gives benzhydryl chloride, presumably by a mechanism analogous to that shown by the broken arrows in Scheme 3.

[4]Notwithstanding a contrary report (18) it was found originally by Dr. D. R. K. Harding in these laboratories (see ref. 10) that Ph_2CHSO_2NH—*p*-Tol is also readily prepared from **1** and SO_2 in the presence of *p*-toluidine. Another error in the same paper has also been corrected by Harding (private communication). He found that hydrolysis of diphenylmethanesulfonpiperide with aqueous HCl gives no sign of diphenylmethane as originally reported (18), but rather a good yield of benzhydryl chloride, formed presumably via the benzhydryl cation in a manner related to the conversion of **9** to **10** in Scheme 3.

benzophenone (**6**) can be seen to be roughly comparable to that of phenylsulfene to benzaldehyde, the mediocre yield in the overall conversion of **9***c* to **6** being partly due to the formation of **10***c*, a separate, "non-sulfene" reaction. In practice the best yields of benzophenone were obtained using a limited amount of sulfur dioxide. With a larger amount of sulfur dioxide such that it became the major solvent component, the ratio of **6** to **10***c* was distinctly reduced. In view of the greater ionizing power of sulfur dioxide as compared with methylene chloride,[5] this observation is consistent with the ionization mechanism, **9** → Ph_2CH^+ → **10** shown in Scheme 3. As a further test of this mechanism we treated benzhydryl chloride, which would be expected (21) to give the benzhydryl cation under these conditions, with the same mixture of 2,6-lutidine, 2-chloro-4-nitrophenol, sulfur dioxide, and methylene chloride as used in most of the above experiments. The only product (in 70% yield) was the ether (**10***c*), without any sign of either benzophenone (**6**) or the ester (**9***c*). This result (*a*) serves to confirm our earlier conclusion that benzophenone (**6**) and the ether (**10***c*) are formed by quite different routes, and (*b*) indicates that the fragmentation of **9***c* to the benzhydryl cation, sulfur dioxide, and the aryloxide anion is essentially irreversible under these conditions.

The above results confirm the original suggestion of Staudinger and Pfenninger that sulfenes react with sulfur dioxide to form the carbonyl analogue. It is clear, however, that sulfur dioxide is an inefficient sulfene trap, failing to compete with diphenyldiazomethane, *p*-nitrophenol, 2,4-dinitrophenol, 2-chloro-4-nitrophenol, 1-morpholino-2-methylpropene, *p*-toluidine, and probably chloride ion, often apparently when these other sulfene traps are present in relatively small amounts. This conclusion is borne out by our experience in trying to observe reaction of other sulfenes with sulfur dioxide. 1-Phenyldiazoethane gave a 5% yield of acetophenone, and reaction of methanesulfonic anhydride with 2,6-lutidine and sulfur dioxide gave no sign of formaldehyde. Apart from the original report (1) of benzophenone formation (in 80% yield) the only high yield conversions of sulfenes to ketones are those reported by Brophy *et al.* (9) in reactions of diazoalkanes of the general formula $ArRCN_2$ in which R is a bulky group such as *t*-butyl or 1-adamantyl; successively lower yields of the ketone were obtained on changing R to an isopropyl or methyl group, the major products in the latter case being derived presumably from the episulfone and Δ^3-1,3,4-thiadiazoline (**7**) routes.

^{18}O-Labelling and the Mechanisms of the Sulfene – Sulfur Dioxide Reaction and the Sulfur Dioxide – Sulfur Trioxide Exchange

In the simplest form of the SP or BCHS mechanisms,[6] the oxygen of benzophenone comes entirely from the sulfur dioxide with none whatever from the sulfene (**2**) (see Scheme 2). Obviously this suggestion may be tested by an ^{18}O-labelling experiment if one has a method of providing labelled sulfur dioxide in the presence of unlabelled sulfene (and preferably vice versa as well). Whereas the original Staudinger–Pfenninger procedure would not do for such an experiment because it does not allow different levels of labelling for the sulfene and the sulfur dioxide, the reaction of ester **9***c* with 2,6-lutidine and sulfur dioxide is well-suited. Although the ready desulfonylation (**9***c* → **10***c*) is inconvenient because it lowers the yield of benzophenone, there is a compensating advantage in that it is particularly easy to determine the ^{18}O content of the sulfonyl function simply by heating a sample of the ester (**9***c*) in a flask attached directly to the mass spectrometer and determining the composition of the sulfur dioxide produced. In addition, the ^{18}O-labelled ester is readily obtained using ^{18}O-labelled sulfur dioxide in the synthesis shown in Scheme 3.

Preliminary ^{18}O-labelling experiments indicated that our determinations of the ^{18}O contents of the starting sulfur dioxide and of the benzophenone product were subject to considerable uncertainty, deriving perhaps from the ability of these compounds (particularly the sulfur dioxide) to exchange oxygen atoms with water. It is evident from the data in Table 1 that even when the ^{18}O contents of the sulfur dioxide were determined just before and just after the reaction they must be regarded as only approximate values; note particularly the differences between the "initial" and "final" values in runs 1 and 2. Control experiments with labelled ester (**9***c*) and labelled benzophenone (**6**) show that they undergo little or no ^{18}O exchange during the reaction. In addition, with the workup and analysis used there is no extensive loss of label from the benzophenone, although it seems likely that the accumulation of a sequence of small effects leads to low values for the determined ^{18}O contents of **6**; a rough estimate of the accumulated loss of about 1% (or rather less for the smaller

[5]Since data directly comparing the polarity of liquid sulfur dioxide and methylene chloride seem scarce, we adduce the following. Empirical methods (19) indicate that the polarity of methylene chloride is comparable to (or slightly less than) that of nitrobenzene, which in turn may be inferred to be much less polar than sulfur dioxide from Lichtin's estimate (20) that the ionization constants for triarylmethyl chlorides are about 10^{10} times greater in liquid sulfur dioxide than in nitrobenzene.

[6]We assume in this discussion that O-1, S-2, and its sulfinyl oxygen in **5** and **8** (as formed initially, at least) derive from the sulfur dioxide, and the sulfur bonded to carbon and the attached oxygens come from the sulfene (**2**).

TABLE 1. ^{18}O-labelling in the reaction of ester **9***c* with 2,6-lutidine and sulfur dioxide in methylene chloride[a]

	^{18}O percentage			
	Sulfur dioxide			
Run No.	Initial[b]	Final[b]	Ester **9***c*[c]	Benzophenone
1	13.2	10.1	(0.2)[d,e]	5.5 (6±0.5)[f]
2	13.6	15.8	(0.2)[d,e]	5.6 (6±0.5)
3	0.3[d]	[e]	19.3	5.7 (6±0.5)
4	0.3[d]	0.7	15.0	3.1 (3.5±0.5)

[a]The molar ratio of **9***c*: base: SO_2 was 1:26:34.
[b]"Initial" refers to a sample taken just prior to sealing the ampoule and "final" to one taken immediately upon opening (see Experimental).
[c]Refers to the ^{18}O content of the oxygens of the sulfonyl group only, as determined on the thermally extruded sulfur dioxide. Control experiments showed only natural abundance levels of ^{18}O in the other oxygens.
[d]Natural abundance.
[e]Not determined.
[f]Values without parentheses are obtained directly from ms; those in parentheses are estimated from these taken with control experiment data (see text).

^{18}O content in run 4) leads to the values given in parentheses in Table 1. Taking both the variability in determining the ^{18}O content of the labelled sulfur dioxide used as the starting material and the above correction for the ^{18}O content of the product (**6**), we estimate that starting with sulfur dioxide containing about 13 ± 3% ^{18}O we obtain benzophenone with ~6 ± 1% ^{18}O, i.e., that perhaps 50 ± 20% of the original label from the sulfur dioxide appears in the benzophenone (**6**). Similarly it would appear from runs 3 and 4 that about 30 ± 10% of the label originally in the sulfonyl groups of the ester (**9***c*) shows up in the benzophenone.

Rough though these results are, they show clearly that the oxygen of the benzophenone cannot come *exclusively* from either the sulfur dioxide or from the ester (**9***c*). This in turn requires that the reaction cannot proceed exclusively via a simple formation and decomposition of either **5** or **8** (R = Ph) (or both), since such a mechanism must give the same ^{18}O content in the benzophenone as in the sulfur dioxide used, i.e., ~13% in runs 1 and 2 and natural abundance in runs 3 and 4 (or slightly higher owing to the very small ^{18}O enrichment of the excess sulfur dioxide by introduction of labelled SO_2 from the process **9***c* → **10***c* + SO_2).

It would appear from the above results that this system, in which a portion of the label comes from one starting material and the remainder from the other, illustrates an interesting and potentially general problem which would appear, rather surprisingly, not to have been previously observed in labelling experiments with the heavier elements (i.e., those which show small isotope effects). The more usual circumstance is that all of the label of the product comes from one starting material only, in which case it is readily seen that in the absence of labelling losses and of any isotope effects, the extent of labelling in the product must be the same as that in the starting material. In fact, this was observed in the present study in the preparation of a sample of [^{18}O]benzophenone by hydrolysis of diphenyldichloromethane with ^{18}O-enriched water; the ^{18}O contents were the same within experimental error (~20%). When the potentially labelled atoms derive from *two* starting materials, only one of which is labelled, it is obvious that the extent of the labelling in the product cannot be as great as that of the labelled starting material since a portion of the potentially labelled atoms must come from an unlabelled source. If (taking for illustrative purposes the present case which uses ^{18}O-labelling) we define

$$f_1 = \frac{^{18}O \text{ content of product}}{^{18}O \text{ content of the first starting material}}$$

then (in the absence of labelling losses and isotope effects) the fraction f_1 is simply the fraction of the potentially labelled (i.e., oxygen) atoms in the product that derive from the starting material with the label. If there are only two starting material sources for the potentially labelled atoms, then f_2, the fraction of these atoms that derive from the second starting material, is simply $1 - f_1$. In other words, if one carries out two labelling experiments, the first with (only) one starting material labelled and the second with (only) the other labelled, then $f_1 + f_2 = 1$ (or, if expressed as percentages must add up to 100). By extension, if a product has three (or four, etc.) sources of the potentially labelled atom, the three (or four, etc.) labelling experiments would give three (or four, etc.) f values summing to unity.

In the example at hand we note that the sum of 50 ± 20% and 30 ± 10% is 80 ± 30%, i.e., the labelling experiments comply with the requirement of

complementarity for *two* label sources only if we take the values in the upper range of the error limits, say ~65% and ~35%, respectively. An alternative possibility is that there is a third oxygen source in these reactions, but this is not in accord with our observation that diphenyldiazomethane reacted with labelled sulfur dioxide (17.0% ^{18}O) to give benzophenone with essentially the same (16.9%) ^{18}O content. If there are only two sources of the potentially labelled atom, it would appear that about two of every three benzophenone oxygens derive from sulfur dioxide and one of every three from the sulfene (**2**) formed from the ester (**9***c*).

Having concluded earlier that neither the simple SP or BCHS routes accounts for this result we should now provide one which does. It rapidly becomes apparent, however, that there is no shortage of possible mechanisms but rather of information for distinguishing the correct one. Our present discussion will therefore merely illustrate, with examples, the general ways of accounting for our results, and mention some experiments in this and the related sulfur trioxide – sulfur dioxide system which may be helpful in limiting the problem. We follow Staudinger and Pfenninger's lead in pointing to sulfene – sulfur dioxide cycloadducts as possible key intermediates[7] and list the other possible simple cycloadducts (**11**, **12**, and **13**), which, in addition to **5** and **8** (R = Ph) have (*a*) the sulfur atoms at either the sulfonyl or sulfinyl oxidation levels, and (*b*) the sulfene carbon tetracoordinated. In addition we note the cyclic esters **14** and **15**, which by desulfinylation and desulfonylation, respectively, could give benzophenone (**6**). *A propos* of these species we point out that desulfinylation of an intermediate α-sultine (like **14**) has been suggested to account for the thermal conversion of sulfenes to their carbonyl analogues (24), and in the oxidation of sulfines to their carbonyl analogues (25, 26); semi-empirical calculations on the sulfene – α-sultine interconversion have led to the prediction that it is an "allowed" pathway (27). The corresponding desulfonylation of an α-sultone (**15**) would be expected from the known behaviour of episulfones (1, 2) to occur readily. Mixed sulfinic–sulfonic anhydrides (whether cyclic, like **11**, or acyclic) have not, to our knowledge, been isolated, though such a species has been suggested as an intermediate in the formation of the thiobenzoyl chloride *S*-oxides (17, 28).

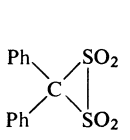
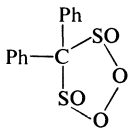
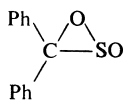
11



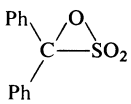
12



13



14



15

We perceive two general categories of mechanisms by which the benzophenone oxygen may come from either of the two sources

I. *Competition* between two reactions, with the oxygen of the benzophenone (**6**) coming in one reaction from the sulfur dioxide and in the other from the sulfonyl group of the ester (**9***c*).

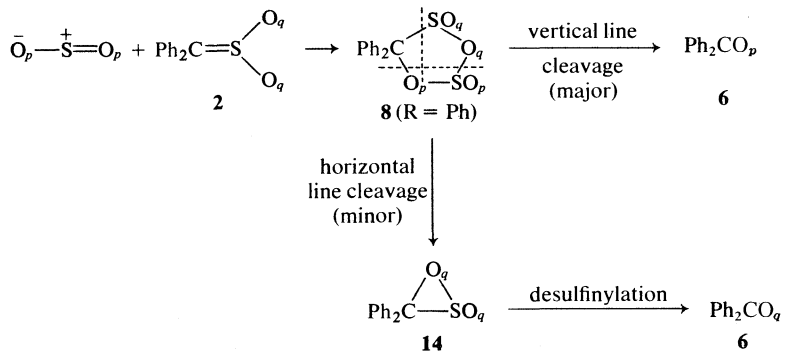
II. *Equilibration* of oxygens.

In the simplest case of competition, or Category I, process, the fractions f_1 and f_2 (defined above) merely indicate the relative rates of the two competing reactions. With equilibrium (Category II) reactions there are two possibilities, (A) a *partial* exchange involving *all* of the sulfur dioxide and sulfene oxygens, and (B) *complete* exchange of *some* of these oxygens. Note that *complete* exchange of *all* of these oxygens would, because of the large excess of the sulfur dioxide employed, simply give a product (**6**) with essentially the same ^{18}O content as the original sulfur dioxide, contrary to experiment. The fractions f_1 and f_2 with Category IIA reflect the relative rates of exchange vs. product formation, and with Category IIB, the number of oxygen atoms from each source undergoing equilibration.

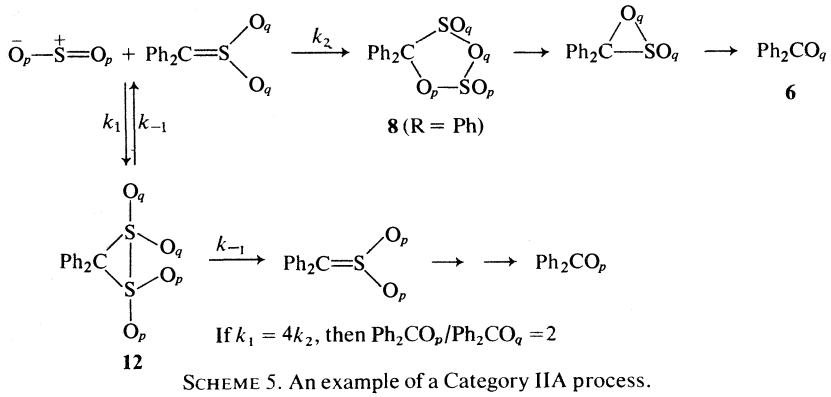
Scheme 4 illustrates a possible Category I mechanism. In addition to the BCHS process, **2** → **8** → **6**, there is a second (minor) mode of decomposition of **8** to give **14** (as indicated by the horizontal broken line), which then would desulfinylate to give **6** in which the oxygen derives from the sulfene (**2**) rather than from the sulfur dioxide. If we designate the ^{18}O content of each oxygen atom of the original sulfur dioxide by *p*, and that of each oxygen of the sulfonyl group of the ester (**9***c*), and hence of the sulfene (**2**), by *q*, then ^{18}O contents at various positions as the reaction proceeds are as shown in Scheme 4. To account for the observed ^{18}O content of the final product (**6**), one merely has to postulate that the "major" cleavage of **8** is twice as fast as the "minor".

An example of a Category IIA process is shown in Scheme 5, the (partial) equilibration occurring by way of the symmetrical α-disulfone (**12**) (note that **13** would also serve). The requisite labelling in the product (**6**), would arise if k_1 (leading to **12**) were *four* times k_2 (leading to **8**), since half of the disulfone (**12**)

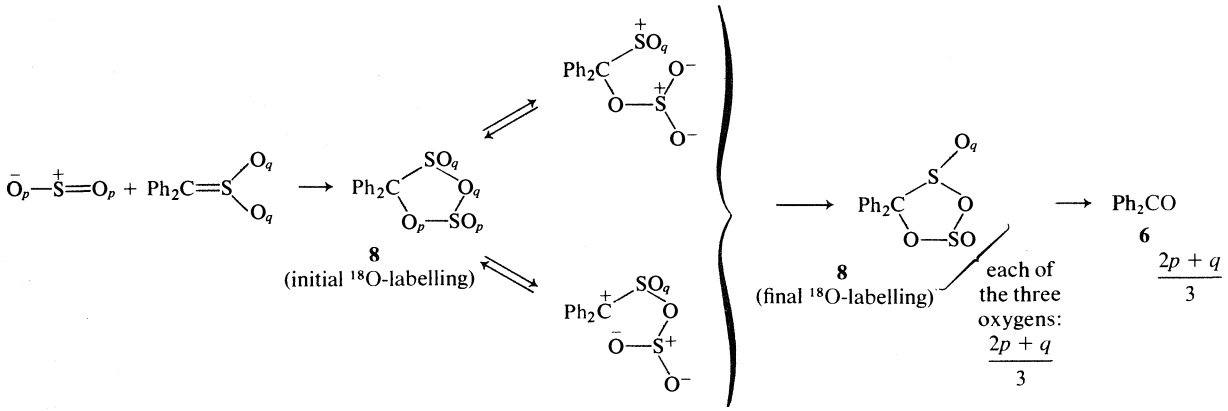
[7]See also the discussions of the thermal (22) and photochemical (23) reactions of sulfur dioxide with ketene, the carbonyl analogue of sulfene.



SCHEME 4. An example of a Category I process.



SCHEME 5. An example of a Category IIA process.

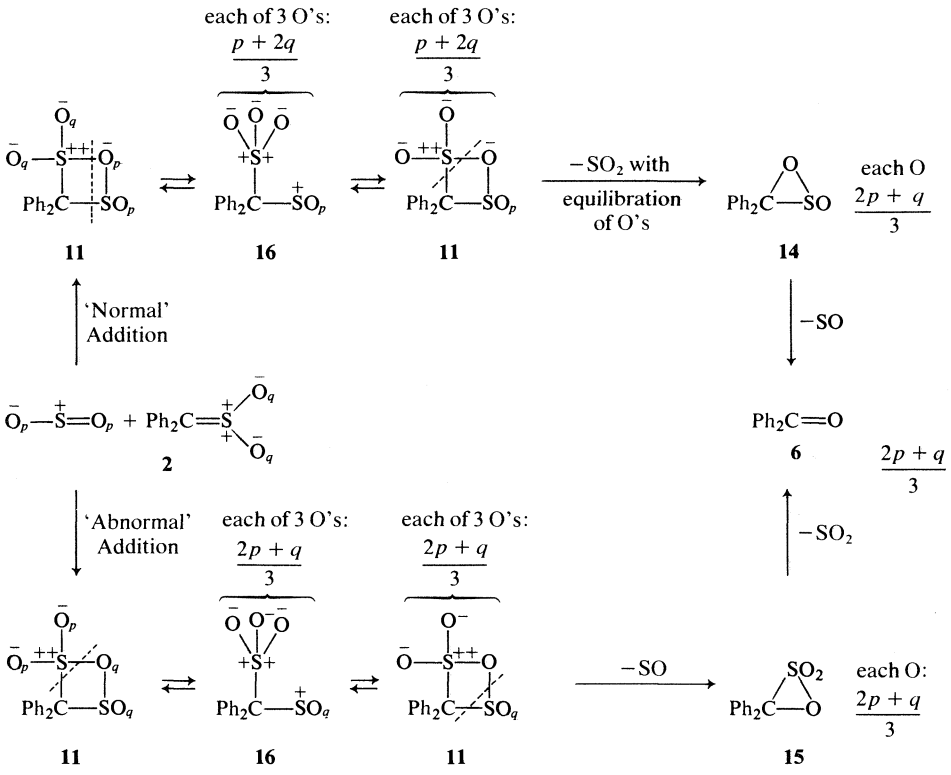


SCHEME 6. One example of a Category IIB process.

would have to return to the original sulfene (**2**) and sulfur dioxide.

Perhaps the most interesting of these categories is that labelled IIB, which, in the present system, would require *two* sulfur dioxide oxygens to equilibrate with *one* sulfene oxygen and then have one of these oxygens incorporated into the benzophenone (**6**). Scheme 6 shows one way by which this might occur. A rapid equilibration as shown would give the labelling pattern indicated by "**8** (final ^{18}O-labelling)", which by either of the decomposition modes shown in Scheme 4 would give **6** with ^{18}O content $(2p + q)/3$, i.e., in which the benzophenone had 2/3 of the ^{18}O content of the sulfur dioxide and 1/3 of that of the sulfonyl group of the original ester (**9***c*), as required by experiment.

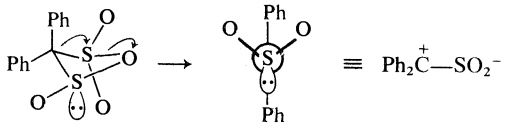
Scheme 7 summarizes two other possible routes. These involve **11**, which could conceivably be formed from the sulfene (**2**) and sulfur dioxide in either of two ways, the "normal" route (i.e., without change



SCHEME 7

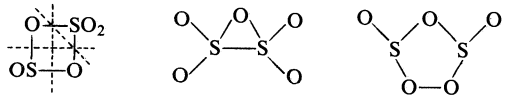
of formal oxidation levels of the sulfur atoms) or the "abnormal" route (i.e., with reduction of the sulfene sulfur and oxidation of the sulfur of the sulfur dioxide).[8] After equilibration of some of the oxygens as shown, the ^{18}O content of the benzophenone is $(2p + q)/3$, in agreement with experiment.

One feature of the "normal" addition route (**2** + SO_2 → **11** → **14** → **6**) which perhaps requires further explanation is the formation of **14** from **11** with equilibration of the oxygen atoms (as noted in Scheme 7). One possible way for this to arise could be by way of **17**, itself formed from **11**, perhaps in the conformation having a quasi-equatorial sulfinyl oxygen. Zwitterion **17** must be distinguished from the sulfene (**2**), which in principle may be obtained from **17** by rotating about the C—S bond and rehybridizing the sulfur; obviously postulation of **17** in this scheme implies the hypothesis that the cyclization **17** → **14** is faster than conversion to the sulfene (**17** → **2**).



11 **17**

In this context we point out that **18**, a species obviously analogous to **11**, may be proposed to account for the remarkable observation (29) that *ready ^{18}O exchange but no ^{35}S exchange is observed between sulfur dioxide and sulfur trioxide*. Simple cycloaddition–cycloreversion via the "normal" route through **18** accounts for these observations in a



18 **19** **20**

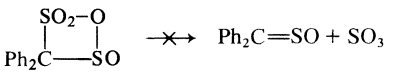
simple fashion and at the same time affords a parallel for **11**, the species derived by cycloaddition to a carbon analogue of sulfur trioxide, i.e., the sulfene (**2**). Again we refer to the reaction in which the sulfur atoms retain their original oxidation levels as "normal" (the two modes of this are shown by the horizontal and vertical broken lines in **18**) and that (shown by the oblique broken line in **18**) involving oxidation–reduction as "abnormal". Note that simple "abnormal" cycloaddition–cycloreversion leads to no exchange, whereas either "normal" addition followed by "abnormal" reversion (or the

[8] "Normal" and "abnormal" reactions of sulfenes are defined and discussed elsewhere (17).

complementary "abnormal" followed by "normal" sequence) would lead to exchange of *both* oxygen and sulfur, contrary to the reports (29).

Another process which is excluded by the absence of sulfur exchange is the formation of the symmetrical cyclic anhydrides **19** and **20**. In view of the analogy between sulfenes and sulfur trioxide one might question the likelihood of the formation of the sulfene analogues **12** and **13**; the available data, however, do not allow a definite exclusion of the exchange via **12** or **13**. In an attempt to ascertain if the sulfene (**2**) and sulfur dioxide were, in fact, exchanging oxygen atoms, we carried out the reaction of labelled **9***c* with 2,6-lutidine and sulfur dioxide in the presence of *p*-toluidine as a sulfene trap. We found that the ^{18}O content of the *p*-toluidide so obtained (11.3%) was nearly that of the starting ester (12.5%); a control experiment in which the *p*-toluidide was formed from **9***c* (^{18}O content 5.4%) without sulfur dioxide gave essentially the same ^{18}O content (5.3%) in the product. The above experiment, though it indicates the absence of a *rapid* ^{18}O exchange between sulfur dioxide and the sulfene (**2**), does not exclude a slow reaction; the failure to observe extensive loss of ^{18}O may simply reflect the ease of trapping of the sulfene by *p*-toluidine before exchange can occur.

A final possibility which can apparently be excluded experimentally is a cycloreversion from **11** to give thiobenzophenone *S*-oxide (**21**) and sulfur trioxide, with **21** going to benzophenone (**6**) under the



11 **21**

reaction conditions.[9] We found that treatment of **21** with either sulfur dioxide or sulfur trioxide gave no benzophenone, and also that the presence of added **21** in a reaction of **1** with sulfur dioxide gave merely unreacted **21** and no additional **6**. It seems likely that **21** is not converted to **6** under these conditions and therefore cannot be a precursor of **6** in the reaction of diphenylsulfene (**2**) with sulfur dioxide.

Concluding Summary

In view of the experimental and mechanistic complexity of the foregoing, it would seem useful to summarize the points which emerge from this study.

(1) The formation of a ketone or aldehyde in the reaction of a diazoalkane with excess sulfur dioxide very probably proceeds via the sulfene, since, in addition to previous work (3, 4) consistent with the formation of sulfenes from those starting materials, we find that the same sulfene generated by another route in the presence of sulfur dioxide gives the same ketone or aldehyde.

(2) To date the reaction of sulfur dioxide with sulfenes has been observed only with sulfenes bearing at least one aryl group on the sulfene carbon; it appears as the major reaction only with diaryl sulfenes or with certain arylalkyl sulfenes with a bulky alkyl group.

(3) An array of experiments, including ^{18}O-labelling studies, have been carried out to shed some light on the mechanism of the reaction, and though the ^{18}O-labelling results are only approximate, our experiments allow certain conclusions to be drawn.

(*a*) Neither the simple Staudinger–Pfenninger mechanism (via **5**) nor a variant process by way of **8** can be the *only* process operating.

(*b*) A *complete* exchange of oxygen atoms between sulfur dioxide and the sulfene (**2**) is similarly excluded.

(*c*) Mechanistic categories capable of accounting for the ^{18}O results are classed according to whether they involve (I) competition between two routes giving different labelling, or (II) equilibration of oxygen atoms, with the latter category subdivided into processes in which there is (A) competition between an oxygen exchange and a route to **6**, or (B) a complete exchange of a limited number of oxygens. Examples of each of the categories are given in Schemes 4–7.

(*d*) Cycloadduct **18** is pointed to as a species which may be formed from reaction of sulfur dioxide with sulfur trioxide and which accounts particularly easily for the reported ready exchange of oxygen atoms and lack of exchange of sulfur atoms between the two compounds. If we may argue from the analogy of sulfur trioxide with sulfenes we would favour the route involving "normal" formation of **11** (see Scheme 7) over reactions proceeding via **12**, **13**, or the "abnormal" route to **11**.

(*e*) An attempt to detect sulfene – sulfur dioxide oxygen exchange showed little or no exchange.

(*f*) From experiments with thiobenzophenone *S*-oxide (**21**) we conclude that **21** is probably not a precursor of benzophenone (**6**) in the diphenylsulfene – sulfur dioxide reaction.

Experimental

Spectra were determined using the following instruments: nmr, Varian T-60, HA-100 or XL-100; ir, Beckman Acculab 4 using 0.1 mm NaCl cells; ms, Varian MAT 311A mass spectrometer. The nmr and ir spectra refer to solutions in $CDCl_3$ and $CHCl_3$, respectively. Melting points were obtained with a Kofler Hot Stage and are uncorrected. Methylene

[9]Photodecomposition of the analogous ketene – sulfur dioxide cycloadduct is postulated to give sulfine (CH_2=SO) as well as carbon dioxide, which is directly observed (23). Thermolysis (at 130°C) or photolysis of thiobenzophenone *S*-oxide (**21**) forms benzophenone in good yield (30).

chloride and 2,6-lutidine were dried by distillation from calcium hydride and stored over molecular sieves (Fisher 4Å). Methylene chloride extracts were dried over anhydrous magnesium sulfate. Solvents were evaporated using a rotary evaporator under reduced pressure. Anhydrous ether was that supplied by Fisher Scientific Co. Ltd., phenylmethanesulfonyl chloride was Eastman White Label material (sold as α-toluenesulfonyl chloride). Diphenyldiazomethane was obtained by yellow mercuric oxide oxidation of benzophenone hydrazone (Aldrich) (31). Thick layer chromatography was carried out with MN-Kieselgel G/UV_{254}.

Reaction of Phenylmethanesulfonyl Chloride with Sulfur Dioxide and 2,6-Lutidine

Liquid sulfur dioxide (10 mL) was collected in a flask. After addition of phenylmethanesulfonyl chloride (0.38 g, 2 mmol) in methylene chloride (10 mL) and 2,6-lutidine (2.32 mL, 20 mmol) the flask was sealed with a glass stopper held firmly in place with masking tape. The reaction mixture was stirred for 3 h and then diluted with methylene chloride (40 mL) and washed with dilute HCl (2 × 50 mL) and water (50 mL). Drying of the solution followed by evaporation of the methylene chloride gave the product (30 mg). The ir and nmr spectra showed the presence of benzaldehyde and some extraneous peaks apparently due to the lutidine. In a separate experiment an acidified solution of 2,4-dinitrophenylhydrazine in absolute alcohol was added directly to methylene chloride layer. On cooling, benzaldehyde 2,4-dinitrophenylhydrazone separated out as an orange-red crystalline solid (58 mg, 10%); this was recrystallized from absolute alcohol, mp 237–238°C; mixed mp with an authentic sample 236–238°C.

Phenylmethanesulfonic Anhydride

Phenylmethanesulfonyl chloride (20 g, 0.1 mol) was dissolved in a mixture of dioxane (80 mL) and water (20 mL) and the solution cooled in an ice bath. Triethylamine (20 g, 0.20 mol) was added dropwise during 10 min and the solvent evaporated under reduced pressure. The residue was dissolved in the minimum amount of water, and the solution poured through a column of Rexyn 101 resin (H^+ form) suspended in water. The water was removed first by evaporation under reduced pressure and then by azeotropic distillation with benzene using a Dean–Stark apparatus. Evaporation of the benzene gave phenylmethanesulfonic acid (13 g) as a dark brown, oily liquid.

The acid was converted to the anhydride by dissolving in dry benzene (60 mL) and treating with *N,N'*-di-*p*-tolylcarbodiimide (8.9 g, 0.04 mol) in benzene (35 mL) for 1 h as described by Khorana (32). Removal of the *N,N'*-di-*p*-tolylurea by filtration followed by evaporation of the benzene gave the crude anhydride (12.0 g, 98%). Recrystallization from $CHCl_3$–ether (with decolorizing charcoal) gave phenylmethanesulfonic anhydride (10.2 g, 83% yield) as a white solid, mp 110–112°C; nmr δ: 7.38 (5H, s) and 4.7 (2H, s) ppm; ir ν_{max}: 1405 and 1190 (vs) cm^{-1}. *Anal.* calcd. for $C_{14}H_{14}O_5S_2$: C 51.53, H 4.32, S 19.61; found: C 51.51, H 4.39, S 19.44.

Reaction of Phenylmethanesulfonic Anhydride with Sulfur Dioxide and Tertiary Amines

Phenylmethanesulfonic anhydride (320 mg, 1 mmol) and 2,6-lutidine (1.16 mL, 10 mmol) in methylene chloride (10 mL) was added to sulfur dioxide (30 mL) as above and the reaction mixture allowed to stand at room temperature for 3 h. Addition of 2,4-dinitrophenylhydrazine solution as above gave benzaldehyde 2,4-dinitrophenylhydrazone (71 mg, 50%) mp 237–241°C, identified by ir and nmr spectra, as above.

When a mixture of phenylmethanesulfonic anhydride (326 mg, 1.0 mmol) and 2,6-lutidine (1.16 mL, 10 mmol) in methylene chloride (50 mL) without sulfur dioxide was allowed to stand for 3 h at room temperature and then worked up by washing with dilute hydrochloric acid and water, the ir and nmr spectra showed no sign of benzaldehyde, the recovered material (105 mg) consisting largely of unchanged phenylmethanesulfonic anhydride.

When pyridine (1.61 mL, 20 mmol) was mixed with the anhydride (652 mg, 2.0 mmol) in methylene chloride (20 mL), and sulfur dioxide bubbled into the mixture and the product treated with 2,4-dinitrophenylhydrazine as described above, benzaldehyde 2,4-dinitrophenylhydrazone was obtained in 10% yield (30 mg). In the absence of sulfur dioxide the reaction of the anhydride with pyridine gave after workup a mixture of *cis*- and *trans*-stilbenes with no sign of any benzaldehyde visible in either the ir or the nmr spectrum.

*Preparation of the Aryl Diphenylmethanesulfonates (**9**)*

*(a) 2-Chloro-4-nitrophenyl Diphenylmethanesulfonate (**9**c)*

Diphenyldiazomethane (1 g, 5.2 mmol) in anhydrous ether (15 mL) was mixed with 2-chloro-4-nitrophenol (1 g, 6 mmol) also in anhydrous ether (25 mL) and the mixture cooled in an ice bath. Triethylamine (0.5 mL) was added from a dropping funnel and sulfur dioxide simultaneously bubbled in until the purple colour of the diphenyldiazomethane had disappeared. Dilute HCl (20 mL) was added immediately and the yellowish-white solid collected by filtration, dissolved in methylene chloride (30 mL), and washed first with dilute HCl and then with water. Evaporation of the solvent gave the crude ester (1.45 g, 69%). Recrystallization from methylene chloride–hexanes gave yellowish-white crystals of **9***c*, mp 123–125°C (with evolution of gas); nmr δ: 5.89 (1H, s), a pair of multiplets centered at 7.4 and 7.6 (total 10H) characteristic of the geminal diphenyl groups, and the characteristic pattern of the 2-chloro-4-nitrophenyl group from 7.0 to 8.3 (3H) ppm; ir ν_{max}: 1350 (s) and 1175 (s) cm^{-1}. *Anal.* calcd. for $C_{19}H_{14}ClNO_5S$: C 56.51, H 3.49, N 3.46, S 7.94, Cl 8.78; found: C 56.62, H 3.46, N 3.34, S 7.88, Cl 8.59.

*(b) p-Nitrophenyl Diphenylmethanesulfonate (**9**a)*

Treatment of diphenyldiazomethane (1.0 g, 5.2 mmol) and *p*-nitrophenol (1.45 g, 10.4 mmol) in ether and triethylamine (0.5 mL) and sulfur dioxide as above, gave, after recrystallization from chloroform–ether, **9***a* as a yellowish crystalline solid (0.8 g, 42%), mp 128–130°C; nmr δ: 5.79 (1H, s), a pair of multiplets centered at 7.4 and 7.6 (10H) characteristic of the two phenyl groups, a pair of doublets centered at 7.0 (2H) and 8.2 (2H) ppm due to the *p*-nitrophenyl group; ir ν_{max}: 1525 (s), 1350 (s), 1150 (s) cm^{-1}. *Anal.* calcd. for $C_{19}H_{15}NO_5S$: C 61.78, H 4.09, N 3.79, S 8.68; found: C 61.68, H 4.00, N 3.69, S 8.64.

*(c) 2,4-Dinitrophenyl Diphenylmethanesulfonate (**9**b)*

Diphenyldiazomethane (0.5 g, 2.6 mmol) and 2,4-dinitrophenol (2.37 g, 13 mmol) in ether (115 mL) were treated with triethylamine (0.25 mL) and sulfur dioxide and, subsequently, dilute HCl (50 mL), as above. The reaction mixture was transferred to a separatory funnel. The ether layer was separated and washed with saturated sodium bicarbonate solution (4 × 50 mL) and finally with water (50 mL). Evaporation of the ether under reduced pressure at room temperature gave the crude ester (**9***b*) (0.76 g, ~70% yield), contaminated with about 20% 2,4-dinitrophenyl diphenylmethyl ether (**10***b*) as judged from the peak at 6.51 ppm (presumed to be due to **10***b*). Recrystallization from chloroform–ether gave the ester (**9***b*) as yellowish crystals (still containing about 20% of **10***b*), mp 87–88°C (with bubbling), nmr δ: 6.03, (s, 1H), a pair of multiplets centered at 7.39, 7.64 ppm characteristic of the 2,4-dinitrophenyl system; ir ν_{max}: 1540 (m), 1345 (s) 1170 (s) cm^{-1}. Because of the apparent ease with which **9***b* loses SO_2 to give **10***b*, no serious attempt was made to obtain the pure ester (**9***b*).

Preparation of Diphenylmethanesulfonyl p-*Toluidide*

Diphenyldiazomethane (1.0 g, 5.2 mmol) was dissolved in anhydrous ether (15 mL) and a solution of *p*-toluidine (1.0 g, 10.4 mmol) in anhydrous ether (25 mL) added and the mixture cooled in an ice bath. Sulfur dioxide was bubbled in until the purple colour of diphenyldiazomethane disappeared. The reaction mixture was washed with dilute HCl (50 mL); drying and evaporation of the ether gave a gummy solid which was recrystallized from ether–pentane to yield a white crystalline solid (0.75 g, 43% yield), mp 132°C; nmr δ: 2.18 (3H, s), 5.28 (1H, s), 6.35 (1H, s, NH-band which disappeared on shaking with D_2O), 6.84 (4H, m), two multiplets centered at 7.23, 7.43 (10 H) ppm characteristic of the diphenyl system; ir ν_{max}: 3380 (w), 1385 (s), 1340 (s), 1150 (s) cm^{-1}; ms *m/e*: calcd. M^+ 337.1136; found M^+ 337.1135.

*Reaction of 2-Chloro-4-nitrophenyl Diphenylmethanesulfonate (***9c***) with 2,6-Lutidine in the Presence of* p-*Toluidine*

2-Chloro-4-nitrophenyl diphenylmethanesulfonate (**9***c*) (200 mg, 0.5 mmol) was dissolved in methylene chloride (1.0 mL), *p*-toluidine (106 mg, 1 mmol) and 2,6-lutidine (1.5 mL) were added, and the reaction mixture stirred for 48 h. The reaction was worked up by diluting it with methylene chloride (50 mL) and washing this layer first with dilute HCl (2 × 25 mL), saturated sodium bicarbonate solution (3 × 25 mL), and finally with water (25 mL). Drying of the solution and evaporation of the methylene chloride gave the product (156 mg). The nmr and ir spectra showed it to be diphenylmethanesulfonyl *p*-toluidide (90% yield). The spectra showed no sign of any diphenylmethyl 2-chloro-4-nitrophenyl ether in the reaction product.

*Reaction of 2-Chloro-4-nitrophenyl Diphenylmethanesulfonate (***9c***) with 2,6-Lutidine in the Presence of 2-Methyl-1-morpholinopropene*

2-Chloro-4-nitrophenyl diphenylmethanesulfonate (**9***c*) (200 mg, 0.5 mmol) was dissolved in methylene chloride (1.0 mL). 2,6-Lutidine (1.5 mL) and 2-methyl-1-morpholinopropene (33) (77 mg, 0.55 mmol) were added and the reaction mixture stirred for 48 h. The reaction was worked up by diluting the mixture with methylene chloride (50 mL) followed by washing this solution with dilute HCl (2 × 25 mL), saturated sodium bicarbonate solution (4 × 25 mL), and finally with water (25 mL). Drying of the solution and evaporation of the methylene chloride gave the crude product (179 mg, 96%) which contained about 15% of starting material. Separation of the crude product with thick-layer chromatography using ether–pentane (4:1) gave 2,2-diphenyl-3-morpholino-4,4-dimethylthietane 1,1-dioxide (130 mg, 70%). Recrystallization from methylene chloride – hexanes gave a product melting at 150–153°C; mixed mp with an authentic sample (6), 151–153°C; ms: M^+ calcd. 371.1555; found 371.1547. The nmr and ir spectra were identical to those of the authentic sample (ms: M^+ found 371.1547). Though the reported mp (136–137°C) differs from that given here, the above evidence clearly shows (*a*) that the products obtained by the two routes are identical, and (*b*) that our materials and that made by Tanabe *et al.* (6) are identical and have the assigned structure; it is unclear whether the lower mp reported by these authors derives from polymorphism or impurity, or is merely a misprint.

*Reaction of 2-Chloro-4-nitrophenyl Diphenylmethanesulfonate (***9c***) with Sulfur Dioxide and 2,6-Lutidine*

Liquid sulfur dioxide (0.75 mL) was collected in a seal-off ampoule (13 mm OD with a 7 mm neck, 14 cm long after sealing) cooled in a dry ice – acetone bath. The ester (**9***c*) (200 mg, 0.5 mmol) in methylene chloride (1 mL) and 2,6-lutidine (1.5 mL, 13 mmol) were added and the ampoule sealed, allowed to come to room temperature, and shaken for 48 h. The ampoule was then cooled and opened, the sulfur dioxide allowed to evaporate, and the reaction mixture diluted with methylene chloride (50 mL). The methylene chloride layer was washed with dilute HCl (2 × 20 mL), several times with saturated sodium bicarbonate solution and finally with water, and dried. Evaporation of the solvent gave the product (80 mg) estimated to consist of ~16 mg of benzophenone and ~64 mg of the ether (**10***c*) (38% yield) by comparison of the ir spectrum with spectra of authentic mixtures. Acidification and extraction of the combined $NaHCO_3$ washes gave a material shown by ir to be 2-chloro-4-nitrophenol mixed with a little benzophenone; tlc gave the phenol (34 mg, 43%) and benzophenone (5 mg), total benzophenone yield 21 mg (23%). In another experiment the crude product (65 mg) on thick-layer chromatography using pentane–ether (4:1) gave benzophenone (15 mg, 17%) and diphenylmethyl 2-chloro-4-nitrophenyl ether (**10***c*) (30 mg, 18%). The ir and nmr spectra of both materials were identical to those of authentic samples.

When the reaction was carried out identically except that methylene chloride was omitted from the reaction mixture, the crude product was estimated by ir spectra comparisons to contain about 5 mg of benzophenone (6% yield).

*Thermal Desulfonylation of 2-Chloro-4-nitrophenyl Diphenylmethanesulfonate (***9c***)*

The ester (**9***c*) (0.25 g, 0.62 mmol) was dissolved in chloroform (25 mL) and the solution refluxed on a steam bath for 3 h. Evaporation of the solvent followed by recrystallization from chloroform–hexanes gave 2-chloro-4-nitrophenyl diphenyl ether (**10***c*) (0.15 g, 71%), mp 125–126°C; nmr δ: 6.35 (s, 1H), and multiplets in the ranges 7.15–7.55 and 6.88–8.25 ppm characteristic of the diphenyl and 2-chloro-4-nitrophenyl systems respectively; ir ν_{max}: 1520 (m), 1480 (m), 1340 (s), 1265 (s) cm^{-1}; ms: M^+ calcd. 339.0662; found 339.0663.

Reaction of 1-Phenyl-1-diazoethane with Sulfur Dioxide

A solution of 1-phenyl-1-diazoethane (~2.0 g, 15 mmol) in ether (50 mL) was prepared by HgO oxidation of acetophenone hydrazone in the presence of KOH and CaO following the procedure of Day *et al.* (34) for the preparation of 4-diazooctane; the solution showed a strong band at 2060 cm^{-1}. This solution was added dropwise with stirring to liquid sulfur dioxide (50 mL). When the addition was complete the sulfur dioxide was evaporated. A white solid which separated out was removed by filtration; nmr and mass spectra indicated the solid to be 1,2-dimethyl-1,2-diphenylethene. To the filtrate an acidified solution of 2,4-dinitrophenylhydrazine was added and an orange-red crystalline precipitate of acetophenone 2,4-dinitrophenylhydrazone separated out (225 mg, 5%). Recrystallization from absolute ethanol gave a material melting at 239°C; mixed mp with an authentic specimen, 239–240°C.

Reaction of Methanesulfonic Anhydride with Sulfur Dioxide and 2,6-Lutidine

A solution of 2,6-lutidine (1.16 mL, 10 mmol) in methylene chloride (10 mL) was cooled in dry ice and saturated with sulfur dioxide. Methanesulfonic anhydride (35) (174 mg, 1 mmol) was added, the flask was sealed with a stopper (held firmly with masking tape), allowed to come to room temperature, and held there for 3 h. The reaction mixture was extracted with water (2 × 10 mL) and to this extract a saturated solution of dimedone (20 mL) in 10% alcohol added. No sign of any of the dimedone derivative of formaldehyde was observed.

^{18}O-Labelling Analyses

Water–^{18}O purchased from Merck, Sharp and Dohme Canada Limited was the ^{18}O source for these experiments; the ^{18}O contents given herein for the ^{18}O-labelled water used in these experiments are taken directly from the labels. Our ^{18}O analyses were carried out on a Varian MAT 311A mass spectrometer using 25 ev and inlet temperature 100°C for the SO_2 analyses and 20 ev and probe temperature 18°C for benzophenone samples. With each set of analyses a natural abundance sample of the compound was run and the values of the $M + 1$ and $M + 2$ peaks found to agree satisfactorily with expected values, i.e., Δ (found % − calcd. %) $\leq \pm 0.3\%$. Relative abundances of the peaks were obtained by averaging values from three or more concurring traces. In calculating the abundance of ^{18}O-containing species, correction was made for the ^{34}S content of SO_2 (4.4368% relative to $^{32}S = 100$) and the ^{13}C satellite contribution to the $M + 2$ peak of benzophenone (0.98%) (36). The value quoted in the tables for percentage ^{18}O for the sulfur dioxide is the average of the values calculated from the percentages of $S^{16}O_2$ and $S^{16}O^{18}O$, i.e., from the expressions

$$100 - 10\sqrt{\%\, S^{16}O_2} \quad \text{and} \quad 50 - 5\sqrt{100 - 2 \times (\%S^{18}O^{16}O)}$$

respectively. Whereas these values were invariably in good agreement, that from the percentage of $S^{18}O_2$, i.e., $10\sqrt{\%\, S^{18}O_2}$, was sometimes rather different and was discarded, since the error in measuring the comparatively small $S^{18}O_2$ peak rendered this value much the least reliable.

^{18}O-Labelled Sulfur Dioxide

^{18}O-Labelled water (0.5 g, 96.5 at.% ^{18}O) was introduced into a 20 cm long, 16 mm OD thick-walled tube closed at one end and with an Ace Glass 0-4 Teflon vacuum stopcock with O-rings, at the other end. The tube was cooled in a dry ice – acetone bath and sulfur dioxide (~2 mL, Matheson anhydrous) condensed from a lecture bottle. The stopcock was closed, the mixture was allowed to come to room temperature, and the tube shaken for 48 h. The tube was then connected to a short drying train consisting of a small gas wash bottle containing concentrated H_2SO_4 followed by a tube lightly packed with glass wool; the (Tygon) tubing leading from this was connected to an ampoule (13 mm OD with 7 mm neck, total length 14 cm when subsequently sealed) cooled in a dry ice – acetone bath, and the ^{18}O-labelled sulfur dioxide allowed to condense in the ampoule. The tubing was then clamped, disconnected from the drying train, and immediately connected to the inlet of the mass spectrometer. A typical mass spectrum showed the following relative intensities for the *m/e* 64, 66, and 68 peaks: 100, 34.92, and 3.54, corresponding to $S^{16}O_2$, $S^{16}O^{18}O$, and $S^{18}O_2$ percentages of respectively 75.37, 22.98, and 1.65; these in turn (from the equations given above) yield values of 13.2, 13.2, and 12.8% ^{18}O, respectively.

2-Chloro-4-nitrophenyl Diphenylmethanesulfonate ^{18}O-Labelled at the Sulfonyl Group

A mixture of diphenyldiazomethane (0.75 g, 3.9 mmol) and 2-chloro-4-nitrophenol (1.5 g) in ether containing triethylamine was treated with ^{18}O-labelled sulfur dioxide (20.5% ^{18}O) as described above for the unlabelled ester. The recrystallized product melted at 120–123°C; the nmr and ir spectra were identical to those of unlabelled **9***c* except that the band at 1175 cm^{-1} had diminished and two additional bands at 1155 (m) and 1135 (m) cm^{-1} had appeared.

To determine the ^{18}O content of the sulfonyl group, the ester (200 mg) was placed in a round-bottomed flask attached directly to the heated inlet of the mass spectrometer. The flask was evacuated and heated gently with a stream of hot air. The mass spectrum of the evolved SO_2 showed 19.3% ^{18}O.

*Reaction of 2-Chloro-4-nitrophenyl Diphenylmethanesulfonate (**9***c*) with ^{18}O-Labelled Sulfur Dioxide and of the Labelled Ester with Unlabelled Sulfur Dioxide*

The labelled liquid sulfur dioxide (0.75 mL) was collected in an ampoule and its mass spectrum obtained as described above. The ^{18}O content thus obtained is given as the "initial" value in Table 1. The ester (**9***c*) (200 mg, 0.5 mmol) in methylene chloride (1 mL) and 2,6-lutidine (1.5 mL, 13 mmol) were added and the ampoule sealed and shaken at room temperature for 48 h. The ampoule was then cooled in a dry ice – acetone bath, the neck scratched with a file near the sealed tip, and the neck attached to the inlet system of the mass spectrometer with rubber tubing pushed onto the neck of the ampoule well below the scratch. The neck of the ampoule was then broken at the scratch and the mass spectrum obtained from the sulfur dioxide thus admitted to the instrument; the ^{18}O content so obtained is the "final" value in Table 1.

The crude benzophenone was isolated as described above for the unlabelled ester. Control experiments, however, indicated that the chromatographic purification led to loss of most of the ^{18}O and the following procedure for partial removal of the ether (**10***c*) was used. The crude product was extracted with mixed hexanes (5 mL, Fisher Spectranalyzed) and the solvent evaporated. The residue after evaporation was further extracted with hexanes and the extract evaporated, and this residue subjected to the extraction–evaporation procedure a further time to give a mixture estimated by comparison of the ir spectrum with those of authentic mixtures to contain in a typical run about 18 mg (20% yield) of benzophenone and about 10 mg of **10***c*. The ^{18}O contents of the benzophenone samples are given in Table 1.

In another experiment, which gave benzophenone with 5.5% ^{18}O, the $NaHCO_3$ layers were combined, acidified with HCl, and extracted with CH_2Cl_2. The ratios of the *m/e* 173, 174, 175, and 176 peaks of the 2-chloro-4-nitrophenol so obtained were identical to those of authentic natural abundance material. The ether (**10***c*) obtained from the hexane extractions was similarly found to show peaks at *m/e* 339, 340, 341, and 342 identical to those found with the natural abundance ether.

The same quantities and procedure were used for the reaction of natural abundance SO_2 with the ester **9***c* labelled at the sulfonyl group, to give a mixture containing, typically, 14 mg of benzophenone and 8 mg of **10***c*; Table 1 gives the ^{18}O contents of the benzophenone samples.

To determine if the presence of the ether (**10***c*) affected the ms determination of ^{18}O content, samples of labelled benzophenone (15 mg) were mixed with the ether (**10***c*) (10 mg) and dissolved in methylene chloride. The solvent was then evaporated and the ^{18}O contents of the "unmixed" and "mixed" samples determined. The respective values were as follows: 24.6 and 23.6%, 8.7 and 8.6%, 7.7 and 7.2%, 6.0 and 5.9%, i.e., the "mixed" samples showed slightly lower ^{18}O contents (in somewhat varying measure).

The following experiments were carried out to determine the extent (if any) to which benzophenone underwent ^{18}O exchange under the conditions of the reaction and workup. (*1*) ^{18}O-Enriched sulfur dioxide (0.5 mL, 5.5% ^{18}O) was collected in an ampoule and benzophenone (80 mg) and **10***c* (25 mg) in methylene chloride (1 mL), and 2,6-lutidine (1.5 mL) added, and the tube sealed and shaken overnight. The ms of the benzophenone obtained following the usual workup showed no sign of any incorporation of ^{18}O. (*2*) Liquid sulfur dioxide (0.75 mL) was collected in an ampoule and ^{18}O-labelled benzophenone (50 mg, 21.5% ^{18}O), 2-chloro-4-nitrophenone (60 mg)

and **10***c* (50 mg) in methylene chloride (1 mL), and 2,6-lutidine (1.5 mL) added and the tube sealed and shaken at 25°C for 48 h. The benzophenone obtained after the usual workup showed 20.9% ^{18}O. (*3*) Reaction of labelled ester (**9***c*) (200 mg, 18.9% ^{18}O) precisely as before except that the reaction was stopped after 6 h gave unreacted ester (**9***c*) (along with benzophenone and **10***c*). Analysis of the ester (as above) showed 18.6% ^{18}O. (*4*) Reaction of **9***c* (200 mg) as before except for the addition of labelled benzophenol (25 mg, 21.5% ^{18}O) to the initial reaction mixture gave after workup a product (45 mg) containing benzophenone with 15.3% ^{18}O. With the usual 14–20% yield of benzophenone (10–15 mg) and no exchange (but merely dilution of the label) the calculated range for the ^{18}O content of the benzophenone would be 13.5–15.4%.

^{18}O-Enriched Benzophenone

(a) *From Diazomethane and Labelled Sulfur Dioxide*

Liquid sulfur dioxide (0.5 mL, 17.0% ^{18}O) was collected in a cooled flask and a solution of diphenyldiazomethane (**1**) (65 mg, 0.34 mmol) in methylene chloride (1.5 mL) added dropwise with stirring. After addition was complete and the purple colour of **1** had disappeared the sulfur dioxide was evaporated and the product dissolved in methylene chloride and washed with water. Drying of the methylene chloride layer and evaporation of the solvent gave an oil which was extracted with hexanes to give a product (50 mg, 82%) the ir spectrum of which was identical to that of benzophenone except for an additional peak at 1642 ($>C=^{18}O$) cm^{-1}. Mass spectrometric analysis showed 16.9% ^{18}O.

(b) *From Diphenyldichloromethane and ^{18}O-Labelled Water*

Diphenyldichloromethane (37) (1.5 g, 6.3 mmol) was mixed with ^{18}O-labelled water (0.5 g, ~20% ^{18}O) in 1,2-dimethoxyethane (5 mL) and the reaction mixture heated at reflux overnight. The dimethoxyethane was evaporated and the aqueous residue extracted with methylene chloride (5 mL). The methylene chloride layer was washed with water (5 mL), dried, and evaporated giving an oil which on addition of hexanes and cooling gave [^{18}O]benzophenone as a white, crystalline solid (0.7 g, 61%). The ir spectrum except for the peak at 1642 ($>C=^{18}O$) cm^{-1} was identical to that of ordinary benzophenone. Mass spectral analysis showed 21.5% ^{18}O.

Reaction of Benzhydryl Chloride with 2,6-Lutidine and 2-Chloro-4-nitrophenol in Sulfur Dioxide and Methylene Chloride

A solution of benzhydryl chloride (200 mg, 1 mmol), prepared by refluxing benzhydrol in excess thionyl chloride (the method of Gilman and Kirby (38) but without the toluene), and 2-chloro-4-nitrophenol (175 mg, 1 mmol) in methylene chloride (1 mL) was added to an ampoule containing liquid sulfur dioxide (0.75 mL), and the tube sealed and shaken at room temperature for 24 h. Upon workup diphenylmethyl 2-chloro-4-nitrophenyl ether (**10***c*) (236 mg, 70%) was obtained. The nmr and ir spectra were identical to those of authentic **10***c*; spectra of the crude product showed no sign of any benzophenone or 2-chloro-4-nitrophenyl diphenylmethanesulfonate (**9***c*).

Attempted Reactions of Thiobenzophenone S-*Oxide (**21**)*

(a) *With Sulfur Trioxide*

Thiobenzophenone *S*-oxide (**21**) (39) (90 mg, 0.42 mmol) was dissolved in methylene chloride (10 mL) and liquid sulfur trioxide (Sulfan, Allied Chemical) (5 drops) was added. The reaction mixture was stirred for 15 min and then worked up by pouring onto ice (50 g), separating the methylene chloride layer, and washing it with water. Evaporation of the solvent gave back thiobenzophenone *S*-oxide (60 mg), identified by ir spectrum, with no sign of benzophenone.

(b) *With Sulfur Dioxide*

Thiobenzophenone *S*-oxide (**21**) (100 mg) in ether was mixed with liquid sulfur dioxide (5 mL). After 15 min the mixture was worked up giving unreacted **21** (90%).

Reaction of Diphenyldiazomethane with Sulfur Dioxide in the Presence of Thiobenzophenone S-*Oxide*

A solution of diphenyldiazomethane (**1**) (100 mg, 0.55 mmol) in anhydrous ether (15 mL) was added dropwise with stirring to a mixture of liquid sulfur dioxide (10 mL), thiobenzophenone *S*-oxide (110 mg, 0.52 mmol), and anhydrous ether (5 mL). Stirring was continued a further 5 min and the sulfur dioxide and ether evaporated to give an oil (215 mg), which was extracted with anhydrous ether (25 mL). Evaporation of the ether gave a product (164 mg), the ir spectrum of which, by comparison with authentic mixtures, showed it to be a roughly equimolar mixture of benzophenone and thiobenzophenone *S*-oxide.

*Reaction of ^{18}O-Labelled 2-Chloro-4-nitrophenyl Diphenylmethanesulfonate (**9c**) with 2,6-Lutidine and* p-*Toluidine*

(a) *In the Absence of Sulfur Dioxide*

Reaction of ^{18}O-labelled **9***c* (64 mg, 0.16 mmol, 5.4% ^{18}O) with *p*-toluidine (35 mg, 0.32 mmol) and 2,6-lutidine (0.5 mL) in methylene chloride as described above for the unlabelled ester (**9***c*) gave labelled diphenylmethanesulfonyl *p*-toluidide (47 mg, 88%) which on recrystallization from ether–pentane melted at 132–134°C. The nmr and ir spectra (except for an additional band at 1130 cm^{-1} in the latter) were identical to those of the unlabelled amide. The ^{18}O content of the sulfur dioxide evolved on heating (to ~120°C) essentially as already described for the ester (**9***c*) was found to be 5.3%.

(b) *In the Presence of Sulfur Dioxide*

^{18}O-Labelled ester (**9***c*) (200 mg, 0.5 mmol, 12.5% ^{18}O) in methylene chloride (1 mL), *p*-toluidine (~524 mg, 4.9 mmol), and 2,6-lutidine (1.5 mL, 13 mmol) were added to liquid sulfur dioxide (0.75 mL) in an ampoule which was then sealed and shaken at room temperature for 48 h. Workup as described for the experiment without *p*-toluidine gave a crude product (90 mg) which on thick-layer chromatography using pentane–ether (4:1) gave benzophenone (7.5 mg, 8%), diphenylmethyl-2-chloro-4-nitrophenyl ether (**10***c*) (7 mg, 4%), and diphenylmethanesulfonyl *p*-toluidide (50 mg, 29%). The *p*-toluidide was recrystallized from ether–pentane, mp 132–133°C; the nmr and ir spectra (except for the added peak at 1130 cm^{-1}) were identical to those of the natural abundance amide; ^{18}O content (obtained as described above) 11.3%.

*Partial Reaction of ^{18}O-Labelled 2-Chloro-4-nitrophenyl Diphenylmethanesulfonate (**9c**) with Sulfur Dioxide*

Liquid sulfur dioxide (0.75 mL) was collected in an ampoule. The ester (**9***c*) (18.9% ^{18}O, 200 mg, 0.5 mmol) in methylene chloride (1 mL) and 2,6-lutidine (1.5 mL) were added and the ampoule sealed and shaken for 6 h. The product (140 mg) obtained after the usual workup was shown by its ir and nmr spectra to consist of unreacted ester (>75%) plus some benzophenone (**6**) and the ether (**10***c*). Determination of the ^{18}O content as above showed 18.6% ^{18}O in the recovered ester (**9***c*).

Acknowledgements

We are particularly indebted to Mr. Doug Hairsine for the mass spectrometric determinations of ^{18}O content and to Dr. S. K. Wong for valuable sugges-

tions regarding their interpretation. We are grateful to the National Research Council of Canada for financial support of this work.

Derivatives of fused 3-hydroxymethyl-pyran-4-ones as a mobile keto–allyl system

ADOLF PHILIPP AND IVO JIRKOVSKY[1]

Ayerst Laboratories, P.O. Box 6115, Montreal, P.Q., Canada H3C 3J1

Received May 9, 1979

This paper is dedicated to Prof. Karel Wiesner on the occasion of his 60th birthday

ADOLF PHILIPP and IVO JIRKOVSKY. Can. J. Chem. **57**, 3292 (1979).

Syntheses of 3-hydroxymethyl-4*H*,5*H*-pyrano(3,4-c)(1)benzopyran-4-one, **7**, and 3-hydroxymethyl-4*H*,5*H*-(1)benzothiopyrano(4,3-b)pyran-4-one, **8**, from 2,2-difluoro-4-methyl-5*H*-(1)benzopyrano- and (1)benzothiopyrano(3,4-e)-1,3,2-dioxaborins, **3** and **4**, are reported. Upon treatment with a solution of sodium cyanide, the corresponding mesylates **9** and **10** as well as the chloromethyl derivatives **11** and **12** yielded 3-methyl-4-oxo-4*H*,5*H*-pyrano(3,2-c) (1)benzopyran-2-carbonitrile, **13**, and 3-methyl-4-oxo-4*H*,5*H*-(1)benzothiopyrano(4,3-b)pyran-2-carbonitrile, **14**, respectively; these nitriles were converted to carboxylic acids **21** and **22** via methyl esters **19** and **20**. Reaction of the mesylate **10** with dimethylamine afforded a normal displacement product **23**. A similar reaction of **12** required longer time and led to the vinylogous amide **24**.

ADOLF PHILIPP et IVO JIRKOVSKY. Can. J. Chem. **57**, 3292 (1979).

On décrit la synthèse de la hydroxyméthyl-3-4*H*,5*H*-pyrano (3,4-c) benzo(1) pyranone-4, **7**, et la hydroxyméthyl-3-4*H*,5*H*-benzo(1) thiopyrano(4,3-b) pyranone-4, **8**, à partir des difluoro-2,2-méthyl-4-5*H*-benzo(1) pyrano et benzo(1) thiopyrano (3,4-e)-dioxaborines-1,3,2, **3** et **4**. Les mésylates correspondants **9** et **10** aussi bien que les dérivés chlorométhylés **11** et **12** traités par une solution de cyanure de sodium conduisent respectivement aux méthyl-3-oxo-4-4*H*,5*H*-pyrano(3,2-c) benzo(1)-pyrannecarbonitrile-2, **13**, et méthyl-3-oxo-4-4*H*,5*H*-benzo(1) thiopyrano(4,3-b)pyrannecarbonitrile-2, **14**; ces nitriles sont transformés via les esters méthyliques **19** et **20** en acides carboxyliques **21** et **22**. Le mésylate **10** réagit avec la diméthylamine pour conduire par un déplacement normal au produit **23**. Une réaction semblable du composé **12** requiert un temps plus long et conduit à l'amide vinylogue **24**.

[Traduit par le journal]

Current interest in the chemistry of fused pyran-4-ones is due largely to their potential antiallergic activity (1). Two synthetic approaches are being used for the construction of condensed systems with a pyran-4-one ring: the classical Kostanecki reaction (2) involving acylation of aromatic *o*-hydroxyketones or their condensation with diethyl oxalate, and the dual formylation of fused 2,2-difluoro-4-methyl-1,3,2-dioxaborins with the Vilsmeier reagent (3). The former method provides annelated pyran-4-ones with a 2-substituent, whereas the latter affords analogous 3-formyl-pyran-4-ones. A reaction sequence connecting these two routes would be clearly of synthetic value.

Using 4*H*,5*H*-pyran(3,2-c) (1)benzopyran-4-one[2] and 4*H*,5*H*-(1)benzothiopyrano(4,3-b)pyran-4-one as model systems, we now wish to describe the conversion of 3-hydroxymethyl derivatives to their 3-methyl analogs functionalized in position 2.

The treatments of chroman-4-one **1** and thiochroman-4-one **2** with boron trifluoride – acetic anhydride – acetic acid (4, 5) afforded dioxaborins **3** and **4** respectively (Scheme 1). The action of phosphorus oxychloride and dimethylformamide (3) on these complexes produced aldehydes **5** and **6** in high yields and the subsequent reductions with sodium borohydride in methanol at 0°C gave the desired alcohols **7** and **8**. The mesylations were carried out by adding mesyl chloride to a solution of **7** or **8** in methylene chloride and triethylamine at −5°C. The same reaction yielded the chloromethyl derivatives **11** and **12** when carried out at room temperature for a longer period of time. The latter conversions were monitored by tlc to demonstrate an intermediacy of the mesylates. Treatment of **11** and **12** with sodium cyanide in aqueous tetrahydrofuran afforded nitriles **13** and **14** in a 50% yield. A similar reaction of **9** and **10** with sodium cyanide resulted in decreased yields of **13** and **14**. Alkaline hydrolysis of the nitriles furnished the enol-lactones **17** and **18**; the proposed intermediacy of **15** and **16** plausibly accounts for the loss of the cyano group. The nitriles **13** and **14** were converted to the methyl esters **19** and **20** via the corresponding imino esters (6); hydrolysis of **19** and **20** with methanolic sodium hydroxide produced carboxylic acids **21** and **22** respectively.

On treatment with an excess of cold 40% aqueous

[1]Author to whom correspondence should be addressed.

[2]The incentive for the first synthesis of this heterocyclic system stemmed from a desire to obtain direct evidence for the structure of a fungal metabolite citromycetin and its degradation product di-*O*-methylcitromycin (4).

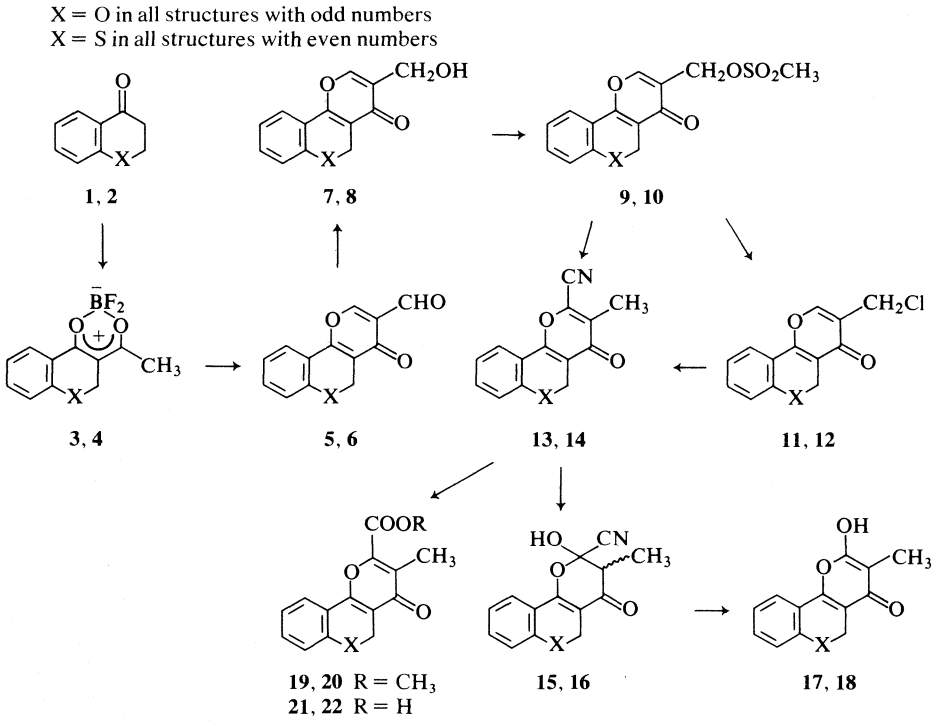
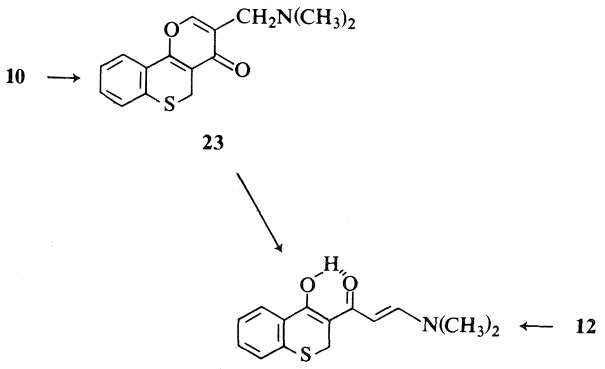


SCHEME 1

dimethylamine, the mesylate **10** was readily transformed into the amine **23** (Scheme 2). Attempts to prepare this amine from the chloro-derivative **12** yielded the vinylogous amide **24**. A prolonged reaction of **23** with aqueous dimethylamine in tetrahydrofuran resulted also in the formation of **24**. The *trans* configuration of this compound is apparent from its ^{1}Hmr spectrum (the coupling constant of the olefinic protons J = 12 Hz, cf. ref. 7). The generation of **24** from **23** can be explained in terms of a Michael addition of dimethylamine in position 2 followed by a retro-Mannich reaction and opening of the pyranone ring (8).



SCHEME 2

In view of the above reactions, it appears that the present systems function as typical Michael acceptors. The mode of formation of the nitriles **13** and **14** presumably involves an attack of CN^- at position 2 which may initiate an addition–elimination sequence or an S_N2' reaction. In any event, the subsequent isomerization of the C=C bond leads to a resonance-stabilized product which is not the case in the comparable reaction with dimethylamine, where only a normal displacement product can be isolated.

Experimental

Melting points are uncorrected. The infrared spectra were obtained with a Perkin-Elmer 225 spectrometer. Proton magnetic resonance (^{1}Hmr) spectra were determined with a Varian CFT-20 instrument using deuteriochloroform as solvent, unless otherwise stated. Chemical shift values are expressed on the δ scale (ppm), relative to tetramethylsilane internal standard. Mass spectra were recorded on an LKB 9000 S spectrometer.

*Preparation of Dioxaborins **3** and **4***

A stream of boron trifluoride gas was passed through a cooled solution of chroman-4-one **1** (9) (35.6 g) in glacial acetic acid (106 mL) and acetic anhydride (71 mL) until the mixture turned deep red and precipitation occurred. After standing overnight at room temperature, the product was collected on a filter, washed with a small amount of cold acetic acid, and air dried to yield 43 g (75%) of crude 2,2-difluoro-4-methyl-5*H*-(1)benzopyrano(3,4-e)-1,3,2-dioxaborin **3**. Analytically pure material was obtained by recrystallization from chloroform–ether; lemon yellow crystals, mp

196–197°C (lit. (*4b*) mp 196–197°C, yield 26%); ^{1}Hmr (DMSO-d_6) δ: 2.42 (s, 3H, CH_3), 5.23 (s, 2H, CH_2). *Anal.* calcd. for $C_{11}H_9BF_2O_3$: C 55.51, H 3.81; found: C 55.75, H 3.87.

Similarly, thiochroman-4-one **2** (10) was converted to **4** in 60% yield; orange-yellow crystals, mp 183–185°C; ^{1}Hmr δ: 2.50 (s, 3H, CH_3), 3.81 (s, 2H, CH_2). *Anal.* calcd. for $C_{11}H_9BF_2O_2S$: C 52.00, H 3.57; found: C 51.82, H 3.56.

*Preparation of Aldehydes **5** and **6***

Phosphorus oxychloride (23 g) was slowly added to dry dimethylformamide (79 g) at 5°C. The mixture was stirred for 15 min, the dioxaborin **4** (18.9 g) was added, and the resultant solution was heated at 100°C for 90 min. After cooling, the mixture was poured onto crushed ice, stirred for 2 h, and a brownish precipitate was collected by filtration. The crude product was washed with water, dried, and recrystallized from benzene to give 15.5 g (85%) of 4-oxo-4*H*,5*H*-(1)benzothiopyrano(4,3-b)pyran-3-carboxaldehyde **6**: mp 141–143°C; ir($CHCl_3$): 1700 and 1640 cm^{-1}; ^{1}Hmr δ: 3.99 (s, 2H, CH_2), 8.38 (s, 1H, O—CH═), 10.26 (s, 1H, CH═O); *m/e*: 244. *Anal.* calcd. for $C_{13}H_8O_3S$: C 63.91, H 3.30; found: C 64.00, H 3.42.

Using the same procedure, 4-oxo-4*H*,5*H*-pyrano(3,2-c)(1)-benzopyran-3-carboxaldehyde **5** was prepared from **3** in 70% yield: mp 192–194°C (benzene); ir(Nujol): 1705 and 1660 cm^{-1}; ^{1}Hmr (DMSO-d_6) δ: 5.15 (s, 2H, CH_2), 8.77 (s, 1H, O—CH═), 10.03 (s, 1H, CH═O); *m/e*: 228. *Anal.* calcd. for $C_{13}H_8O_4$: C 68.42, H 3.53; found: C 68.51, H 3.53.

*Preparation of Alcohols **7** and **8***

To a stirred solution of **6** (47.9 g) in methanol (4400 mL) was added over 15 min sodium borohydride (9.9 g) at 0°C. The mixture was stirred at room temperature for 2 h, then evaporated under reduced pressure, and the residue was partitioned between water and chloroform. The organic layer was washed with saturated brine, dried over anhydrous magnesium sulfate, filtered, and the solvent was removed on a Rotavapor leaving a brownish residue. Trituration of this solid with ether afforded 35.4 g (73%) of **8**, mp 143–145°C. Recrystallization from methanol provided an analytical specimen, mp 147–149°C; ir(Nujol): 3300 and 1655 cm^{-1}; ^{1}Hmr (DMSO-d_6) δ: 3.92 (s, 2H, CH_2S), 4.41 (dd, J_1 = 5.5 Hz, J_2 = 1 Hz, 2H, CH_2O, upon deuteration collapses into narrow doublet), 5.18(t, J_1 = 5.5 Hz, 1H, OH), 8.19(m, 1H, O—CH═). *Anal.* calcd. for $C_{13}H_{10}O_3S$: C 63.35, H 4.09; found: C 63.26, H 4.07.

In an identical manner, **5** was reduced to **7** in 55% yield: mp 188–189°C (methanol); ir(Nujol): 3380 and 1670 cm^{-1}; ^{1}Hmr (DMSO-d_6) δ: 4.32(dd, J_1 = 5 Hz, J_2 = 1 Hz, 2H, CH_2OH, upon deuteration collapses into narrow doublet), 5.15 and 5.17(s + t, J_1 = 5 Hz, 2H + 1H, CH_2O and OH), 8.15(m, 1H, O—CH═); *Anal.* calcd. for $C_{13}H_{10}O_4$: C 67.82, H 4.38; found: C 67.66, H 4.51.

*Preparation of Mesylates **9** and **10***

To a stirred suspension of the alcohol **8** (2.64 g) in methylene chloride (150 mL) was added triethylamine (2.1 mL) followed by methanesulfonyl chloride (0.9 mL) at −5°C. The mixture was stirred in an ice bath for 20 min, and then washed successively with cold water, 3 *N* HCl, 10% $NaHCO_3$, and again with water. Customary work-up of the organic phase afforded 3.4 g (98%) of **10**: mp 138–139°C (chloroform–ether); ir($CHCl_3$): 1655, 1365, and 1175 cm^{-1}; ^{1}Hmr δ: 3.15 (s, 3H, CH_3), 3.98 (s, 2H, CH_2S), 5.13(s, 2H, CH_2O), 8.12(s, 1H, O—CH═). *Anal.* calcd. for $C_{14}H_{12}O_5S_2$: C 51.83, H 3.73; found: C 51.75, H 3.59.

Under similar conditions, the alcohol **7** was converted to the mesylate **9** (yield 75%): mp 167–168°C (chloroform–ether); ir(Nujol): 1657, 1350, and 1175 cm^{-1}; ^{1}Hmr(DMSO-d_6) δ: 3.24(s, 3H, CH_3), 5.01 and 5.16 (s + s, 4H, CH_2O), 8.52 (s,1H, O—CH═). *Anal.* calcd. for $C_{14}H_{12}O_6S$: C 54.54, H 3.92; found: C 54.60, H 3.81.

*Preparation of Chloromethyl Compounds **11** and **12***

To a stirred suspension of the alcohol **8** (35.3 g) in methylene chloride (1000 mL) was added triethylamine (34 mL) followed by methanesulfonyl chloride (12.2 mL) at 5°C. The mixture was stirred overnight at ambient temperature, evaporated on a Rotavapor, and the residue was chromatographed on a silica gel column. Elution with chloroform afforded 26.3 g (69%) of **12**; yellow crystals, mp 151–153°C (benzene); ^{1}Hmr δ: 3.95(s, 2H, CH_2S), 4.47(s, 2H, CH_2Cl), 8.05(s, 1H, O—CH═); *m/e*: 266 and 264. *Anal.* calcd. for $C_{13}H_9ClO_2S$: C 58.98, H 3.42; found: C 59.00, H 3.65.

From a similar reaction of **7**, compound **11** was obtained in 75% yield; mp 163–165°C (benzene–ether); ^{1}Hmr(DMSO-d_6) δ: 4.48(s, 2H, CH_2Cl), 5.15(s, 2H, CH_2O), 8.52(s, 1H, O—CH═); *m/e*: 250 and 248. *Anal.* calcd. for $C_{13}H_9ClO_3$: C 62.79, H 3.65; found: C 62.80, H 3.67.

*Preparation of Nitriles **13** and **14***

A mixture of **12** (28 g), tetrahydrofuran (800 mL), sodium cyanide (10.4 g), and water (800 mL) was stirred overnight at room temperature, concentrated under reduced pressure, and extracted with chloroform. Evaporation of the extracts gave a paste which was chromatographed on silica gel. Elution with chloroform yielded 13.6 g (50%) of **14**; yellow crystals, mp 144–145°C (chloroform–ether); ir($CHCl_3$): 2240 and 1635 cm^{-1}; ^{1}Hmr δ: 2.25(s, 3H, CH_3), 3.95(s, 2H, CH_2S); *m/e*: 255. *Anal.* calcd. for $C_{14}H_9NO_2S$: C 65.86, H 3.55, N 5.53; found: C 65.85, H 3.65, N 5.79.

Essentially the same procedure was used for the transformation of **11** to **13** (column chromatography of the crude product over silica gel was carried out using 5% ethyl acetate – benzene eluent), yield 50%; mp 179–181°C (chloroform–ether); ir($CHCl_3$): 2230 and 1640 cm^{-1}; ^{1}Hmr δ: 2.25(s, 3H, CH_3), 5.20(s, 2H, CH_2O); *m/e*: 239. *Anal.* calcd. for $C_{14}H_9NO_3$: C 70.29, H 3.79, N 5.86; found: C 70.52, H 3.71, N 5.86.

*Alkaline Hydrolyses of Nitriles **13** and **14***

A mixture of **13** (100 mg), methanol (5 mL), and 10% sodium hydroxide (4 mL) was refluxed for 2 h, diluted with water, washed with ether, and acidified with hydrochloric acid. The precipitate was collected and recrystallized from ethyl acetate to afford 35 mg (36%) of **17**; mp 279–281°C; ir(Nujol): 3100 and 1653 cm^{-1}; ^{1}Hmr(DMSO-d_6) δ: 1.93(s, 3H, CH_3), 5.15(s, 2H, CH_2O); *m/e*: 230. *Anal.* calcd. for $C_{13}H_{10}O_4$: C 67.82, H 4.38; found: C 67.54, H 4.19.

Similar treatment of **14** (100 mg) produced 28 mg (29%) of **18**: mp 275–277°C (methanol); ir(Nujol): 3100–2900 and 1650 cm^{-1}; ^{1}Hmr(DMSO-d_6) δ: 1.95(s, 3H, CH_3), 3.89(s, 2H, CH_2S); *m/e*: 246. *Anal.* calcd. for $C_{13}H_{10}O_3S$: C 63.40, H 4.09; found: C 63.68, H 4.22.

*Preparation of Methyl Esters **19** and **20***

A suspension of the above nitrile **14** (1.41 g) in dry methanol (200 mL) was saturated with hydrogen chloride and left at ambient temperature overnight. The resultant solution was refluxed for 4 h, evaporated, and the residue was partitioned between 10% sodium bicarbonate and chloroform. Usual work-up of the organic phase yielded 1.28 g (80%) of **20**; mp 148–150°C (methanol); ir($CHCl_3$): 1735 and 1640 cm^{-1}; ^{1}Hmr δ: 2.35(s, 3H, CH_3), 3.94, and 3.96(s + s, 5H, CH_2S and CH_3O). *Anal.* calcd. for $C_{15}H_{12}O_4S$: C 62.48, H 4.20; found: C 62.58, H 4.11.

In a similar manner, **13** was converted to **19** in 60% yield; mp 119–120°C (methanol); ir($CHCl_3$): 1735 and 1650 cm^{-1};

^{1}Hmr(DMSO-d_6) δ: 2.21(s, 3H, CH_3), 3.92 (s, 3H, CH_3O), 5.10(s, 2H, CH_2O). *Anal.* calcd. for $C_{15}H_{12}O_5$: C 66.17, H 4.44; found: C 66.14, H 4.50.

*Preparation of Carboxylic Acids **21** and **22***

To a solution of sodium hydroxide (0.5 g) in methanol (50 mL) was added **20** (1.6 g), and the mixture was refluxed for 2 h. The solvent was removed on a Rotavapor, the residue was dissolved in water and washed with ether. The aqueous solution was then added to 3 *N* hydrochloric acid (25 mL) upon stirring. The precipitate was collected by filtration, washed with water, and dried to give 1.5 g (98% of 3-methyl-4-oxo-4*H*,5*H*-(1)benzothiopyrano(4,3-b)pyran-2-carboxylic acid **22**, mp 300–301°C. An analytical sample was crystallized from aqueous dimethyl sulfoxide; mp 302–303°C; ir(Nujol): 2800 and 1728 cm^{-1}; ^{1}Hmr(DMSO-d_6) δ: 2.21(s, 3H, CH_3), 3.91(s, 2H, CH_2S); *m/e*: 274. *Anal.* calcd. for $C_{14}H_{10}O_4S$: C 61.30, H 3.68; found: C 61.60, H 3.64.

In a similar experiment starting with **19**, 3-methyl-4-oxo-4*H*,5*H*-pyrano(3,2-c) (1)benzopyran-2-carboxylic acid **21** was obtained in 85% yield; mp 270–272°C (aqueous dimethyl sulfoxide); ir(Nujol): 2900–2800 and 1725 cm^{-1}; ^{1}Hmr (DMSO-d_6) δ: 2.25(s, 3H, CH_3), 5.18(s, 2H, CH_2O); *m/e*: 258. *Anal.* calcd. for $C_{14}H_{10}O_5$: C 65.12, H 3.90; found: C 65.30, H 3.95.

*3-(*N,N-*Dimethylaminomethyl)-4*H,5H-*(1)benzothiopyrano-(4,3-b)pyran-4-one **23***

A solution of **10** (2.09 g) in tetrahydrofuran (40 mL) and 40% aqueous dimethylamine (2.5 mL) was stirred at room temperature for 15 min, diluted with brine, and extracted with chloroform. The combined extracts were concentrated and chromatographed on basic alumina. Elution with 5% ethyl acetate – benzene afforded 1.31 g (77%) of **23**: mp 82.5–84.5°C (benzene–ether): ^{1}Hmr δ: 2.32 (s, 6H, CH_3N), 3.49(s, 2H, CH_2N), 3.99(s, 2H, CH_2S), 7.95(s, 1H, O—CH═); *m/e*: 273. *Anal.* calcd. for $C_{15}H_{15}NO_2S$: C 65.91, H 5.53, N 5.12; found: C 65.89, H 5.59, N 5.05.

*3-[3-(Dimethylamino)-1-oxo-2-propen-1-yl-]thiochroman-4-one **24***

A solution of **12** (265 mg) in tetrahydrofuran (9 mL) and 40% aqueous dimethylamine (0.9 mL) was kept at room temperature and monitored by tlc. After 15 and 60 min, the chromatograms showed that the major component of the mixture was unchanged **12**. The mixture was allowed to stand 24 h, evaporated, and chromatographed over silica. Elution with chloroform afforded 132 mg (50%) of **24**; mp 153–155°C (benzene); ir(Nujol): 1627 cm^{-1}: ^{1}Hmr δ: 3.01(s, 6H, CH_3N), 3.75(s, 2H, CH_2S), 5.09, and 7.80(doublets, J = 12Hz, 1H + 1H, CH═CH). *Anal.* calcd. for $C_{14}H_{15}NO_2S$: C 64.34, H 5.79, N 5.36; found: C 64.17, H 5.95, N 5.30.

In another experiment, to a solution of amine **23** in tetrahydrofuran was added an excess of 40% aqueous dimethylamine, and the mixture was kept at room temperature for several days. Customary work-up and chromatography afforded **24**, identical with the material obtained by the foregoing procedure in every respect; yield 55%.

The synthesis of 5,6-dihydro-3,3-dimethyl-4,1-benzoxazonine-2,7(1*H*,3*H*)dione and its conversion into 1,3-dihydro-3,3-dimethylfuro[3,4-*b*] quinolines

CHRISTOPHER A. DEMERSON AND LESLIE G. HUMBER

Ayerst Research Laboratories, Montreal, P.Q., Canada H3C 3J1

Received June 11, 1979

This paper is dedicated to Prof. Karel Wiesner on the occasion of his 60th birthday

CHRISTOPHER A. DEMERSON and LESLIE G. HUMBER. Can. J. Chem. **57**, 3296 (1979).

Periodate oxidation of 1,1-dimethyl-1,3,4,9-tetrahydropyrano[3,4-*b*]indole **1** gave 5,6-dihydro-3,3-dimethyl-4,1-benzoxazonine-2,7(1*H*,3*H*)dione **2**, a member of the novel 4,1-benzoxazonine ring system. Its conversion into 1,3-dihydro-3,3-dimethylfuro[3,4-*b*]quinolines is described.

CHRISTOPHER A. DEMERSON et LESLIE G. HUMBER. Can. J. Chem. **57**, 3296 (1979).

L'oxydation du diméthyl-1,1 tétrahydro-1,3,4,9 pyrano[3,4-*b*] indole **1** par le periodate donne la dihydro-5,6 diméthyl-3,3 benzoxazonine-4,1(1*H*,3*H*) dione 2,7 (**2**) un membre du nouveau système cyclique benzoxazonine-4,1. On décrit sa transformation en dihydro-1,3 diméthyl-3,3 furo[3,4-*b*] quinolines.

[Traduit par le journal]

During the past few years a number of reports from these laboratories have centred on the 1,3,4,9-tetrahydropyrano[3,4-*b*]indole ring system. Our investigations have led to the preparation of derivatives that are pharmacologically active as antiinflammatory (1, 2) and antidepressant (3) agents. As part of our continuing studies we now wish to report on the conversion of 1,3,4,9-tetrahydropyrano[3,4-*b*]indoles to novel 4,1-benzoxazonines, and subsequently into furo[3,4-*b*]quinolines.

The oxidative cleavage of indolic double bonds has been well documented. Witkop and co-workers have studied a variety of methods such as ozonolysis (4, 5), oxidation by peracids (6), and autoxidation (7). In 1966 Dolby and Booth reported the sodium periodate cleavage of a number of indoles (8). Since this latter method was reported to be facile and afford good yields we applied it to the oxidation of pyrano-[3,4-*b*]indoles. Periodate treatment of compound **1** in methanol–water afforded 5,6-dihydro-3,3-dimethyl-4,1-benzoxazonine-2,7(1*H*,3*H*)dione **2**, the first example of a 4,1-benzoxazonine, in an 85% yield. This compound was converted to a number of other 4,1-benzoxazonine derivatives, shown in Scheme 1, which is self-explanatory.

When the 4,1-benzoxazonine **2** was stirred with sodium hydride in tetrahydrofuran for a short interval and then made neutral, 3,4-dihydro-3,3-dimethylfuro[3,4-*b*]quinoline-9(1*H*)-one **12** (Scheme 2) precipitated out in an 86% yield. The structure was established by ^{1}Hmr spectroscopy. That the compound did not exist in its tautomeric quinolinol form was clear from the infrared spectrum. Also, the uv spectrum had maxima at 239, 314, and 326 nm, typical for quinolones (9).

Reaction of the furo[3,4-*b*]quinoline-9-one **12** with phosphorus oxychloride gave the chloro compound **13**. Replacement of the chlorine atom occurred readily on treatment with a variety of primary alkylamines to produce the compounds **14**–**20** listed in Table 1. The reactions were done in hot phenol, and as a consequence the 9-phenoxy derivative **21** (Scheme 2) was a by-product.

The 9-aminoalkyloxy derivatives (**21**–**24**, Table 1) were formed in one step by the action of the appropriate amino-alkanol on the intermediary sodium furo[3,4-*b*]quinolate, which was prepared either from the 4,1-benzoxazonine **2** or from the quinolone **12**. Compound **25** was obtained from the epoxide **24** by reaction with isopropylamine.

The furo[3,4-*b*]quinoline ring system is not novel (10). However a general method for the preparation of substituted derivatives has not previously been available. The approach described in this report utilizes, as starting material, pyrano[3,4-*b*]indoles, of which a large number of substituted derivatives are readily attainable (1–3). Thus, a wide variety of 4,1-benzoxazonines and furo[3,4-*b*]quinolines are now accessible.

The furo[3,4-*b*]quinolines were evaluated in the Ayerst Pharmacology Department for their ability to decrease the blood pressure of spontaneously hypertensive rats, using the protocol described by Vavra *et al.* (11). While some representatives of this class possessed weak antihypertensive properties, none was of sufficient interest to be considered a candidate for further development.

Experimental

Melting points were taken on a Thomas-Hoover apparatus

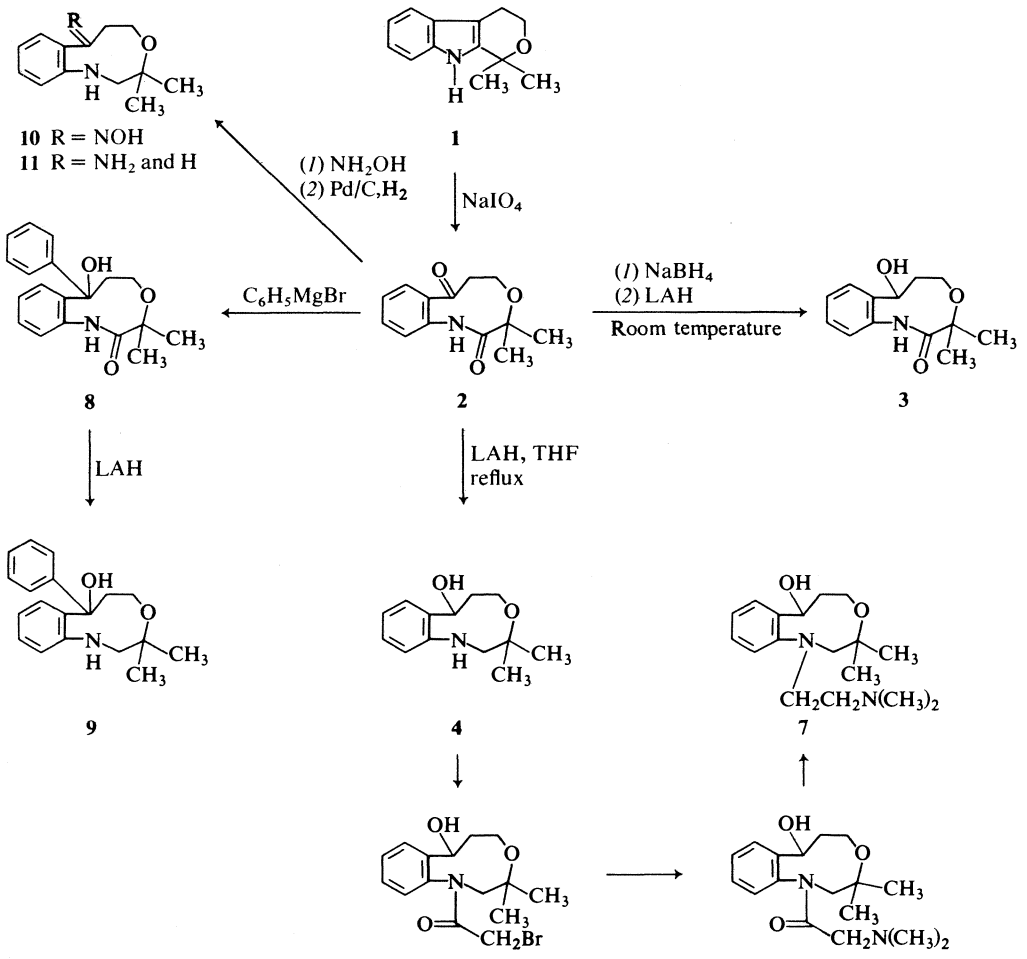

SCHEME 1

and need no correction. The ^{1}Hmr spectra were determined using a Varian A-60A spectrometer and the chemical shifts (δ) are reported in parts per million downfield from TMS. Analyses were performed by Dr. G. Schilling and staff of our laboratories.

*5,6-Dihydro-3,3-dimethyl-4,1-benzoxazonine-2,7(1*H*,3*H*)dione* **2**

A solution of the pyrano[3,4-*b*]indole **1** (3) (25.7 g, 0.127 mol) in methanol (600 mL) was added dropwise to sodium metaperiodate (60.6 g, 0.28 mol) in water (300 mL). After stirring at 22°C for 24 h, the resulting precipitate was filtered off and washed with methanol. The filtrate was concentrated *in vacuo*, water added, and the product filtered off. Extraction of the aqueous filtrate with dichloromethane, drying (Na_2SO_4), and concentrating *in vacuo* afforded more solid. The combined materials were recrystallized from acetone to give the 4,1-benzoxazonine **2** (25 g, 85%), mp 146–148°C; ir ($CHCl_3$): 3360, 1675 (b) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.45 (6H, s, *gem* dimethyl), 2.80 (2H, bm, CH_2CO), 4.06 (2H, bm, CH_2O), 7.42 (4H, m, aromatic), 8.17 (1H, bs, NH). *Anal.* calcd. for $C_{13}H_{15}NO_3$: C 66.93, H 6.48, N 6.01; found: C 66.60, H 6.52, N 6.01.

*3,3-Dimethyl-7-hydroxy-1,5,6,7-tetrahydro-4,1-benzoxazonin-2(3*H*)-one* **3**

The 4,1-benzoxazonine **2** (20 g, 0.086 mol) was added portionwise to a cooled mixture of sodium borohydride (20 g, 0.53 mol) in methanol (500 mL). After stirring at 22°C for 2 h, the reaction was concentrated *in vacuo*, and the residue partitioned between chloroform and water. The chloroform phase was washed with water, dried (Na_2SO_4), and evaporated *in vacuo* to give a solid. Recrystallization from acetonitrile afforded the alcohol **3** (10 g, 49%), mp 141–142°C; ir ($CHCl_3$): 3310, 3200, 3080, 1655 cm^{-1}. *Anal.* calcd. for $C_{13}H_{17}NO_3$: C 66.36, H 7.28; found: C 66.00, H 7.29.

Alternatively the alcohol **3** can be prepared in a comparable yield by stirring the 4,1-benzoxazonine **2** with a 5-fold excess of lithium aluminium hydride in ether at 22°C for 2 h.

3,3-Dimethyl-1,2,3,5,6,7-hexahydro-4,1-benzoxazonin-7-ol **4**

A solution of the 4,1-benzoxazonine **2** (15 g, 0.064 mol) in tetrahydrofuran (300 mL) was added dropwise to a cooled stirring mixture of lithium aluminium hydride (12.16 g, 0.32 mol) in tetrahydrofuran (250 mL). After 20 h of refluxing the

excess hydride was destroyed with tetrahydrofuran–water (2:1). The addition of 20% sodium hydroxide solution (12 mL), filtration, and concentration *in vacuo* gave an oil. This was partitioned between water and chloroform, the chloroform phase washed with water, dried (Na_2SO_4), and concentrated *in vacuo* to afford the alcohol **4** (12.8 g, 90%) as a solid, mp 148–151°C (acetone); ^{1}Hmr ($CDCl_3$) δ: 1.13 (6H, s, *gem* dimethyl), 1.85 (2H, m, CH_2), 3.09 (2H, d, J = 2.5 Hz), 3.15 (2H, m, CH_2O), 3.75 (2H, bs, NH, OH), 5.13 (1H, 2d, J_1 = 7.5 Hz, J_2 = 5 Hz), 7.08 (4H, m, aromatic). *Anal.* calcd.

for $C_{13}H_{19}NO_2$: C 70.55, H 8.65, N 6.33; found: C 70.79, H 8.73, N 6.30.

1-Bromoacetyl-1,2,3,5,6,7-hexahydro-3,3-dimethyl-4,1-benzoxazonin-7-ol ***5***

Bromoacetyl bromide (14 g, 0.069 mol) was added to a stirring mixture of the alcohol **4** (14 g, 0.064 mol), benzene (400 mL), and 2 *N* sodium hydroxide (45 mL) at 0°C. After 1 h, more 2 *N* sodium hydroxide (20 mL) was added and stirring continued for a further 40 min. The phases were separated and the benzene layer washed with 2 *N* hydrochloric acid, water, dried (Na_2SO_4), and evaporated to give the product **5** (12.6 g, 56%); ^{1}Hmr ($CDCl_3$) δ: 1.09 (3H, s, CH_3), 1.35 (3H, s, CH_3), 1.5 (2H, m, CH_2), 2.5 (2H, m, OCH_2), 3.09 (1H, d, J = 15 Hz, CH_2Br), 4.38 (1H, d, J = 15 Hz, CH_2Br), 5.64 (1H, d, J = 4 Hz, CHO), 7.2 (4H, m, aromatic).

*1-(*N,N*-Dimethylglycyl)-1,2,3,5,6,7-hexahydro-3,3-dimethyl-4,1-benzoxazonin-7-ol* ***6***

A mixture of the bromo compound **5** (12.65 g, 0.037 mol), 40% aqueous dimethylamine (175 mL), and tetrahydrofuran (250 mL) was stirred at 22°C for 2 h. Most of the solvent was evaporated off *in vacuo*, the residue diluted with water, and extracted (× 3) with chloroform. Concentration of the extracts gave a solid that was crystallized from ethyl acetate – petroleum ether (bp 30–60°C) to afford the amine **6** (9.6 g, 83%), mp 113–115°C; ir ($CHCl_3$): 3600, 3420, 1655 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.1 (3H, s, CH_3), 1.38 (3H, s, CH_3), 2.18 (6H, s, $N(CH_3)_2$), 2.66 (1H, s, OH), 3.65 (2H, q, J = 7 Hz, $COCH_2N(CH_3)_2$), 5.53 (1H, m, CHO), 7.2 (4H, m, aromatic). *Anal.* calcd. for $C_{17}H_{23}N_2O_3$: C 66.64, H 8.55, N 9.15; found: C 66.55, H 8.53, N 9.00.

1-[2-(Dimethylamino)ethyl]-1,2,3,5,6,7-hexahydro-3,3-dimethyl-4,1-benzoxazonin-7-ol hydrochloride ***7***

A mixture consisting of the dimethylamino compound **6** (5.2 g, 0.018 mol), lithium aluminium hydride (5.0 g, 0.13 mol), and tetrahydrofuran (150 mL) was refluxed for 18 h. The excess hydride was decomposed with tetrahydrofuran–water (2:1), the reaction filtered, and the filtrate evaporated *in vacuo*. The residue was partitioned between water and chloroform, and the chloroform phase concentrated *in vacuo* to yield the amino alcohol **7** (5.13 g) as an oil. It was converted into the hydrochloride (3.14 g, 50%), mp 253–254°C; ^{1}Hmr (DMSO-d_6) δ: 0.88 (3H, s, CH_3), 1.23 (3H, s, CH_3), 2.42 (6H, s, $N(CH_3)_2$), 5.6 (1H, m, CHO), 7.3 (4H, m, aromatic). *Anal.* calcd. for $C_{17}H_{28}N_2O_2 \cdot HCl$: C 62.08, H 8.89, N 8.52, Cl 10.78; found: C 61.98, H 8.89, N 8.43, Cl 10.59.

*3,3-Dimethyl-7-hydroxy-7-phenyl-1,5,6,7-tetrahydro-4,1-benzoxazonin-2(3*H*)-one* ***8***

Bromobenzene (31.4 g, 0.2 mol) in dry diethyl ether (30 mL) was added dropwise to magnesium turnings (4.8 g, 0.2 g-at.) in diethyl ether (50 mL). After 10 min of refluxing, the 4,1-benzoxazonine **2** (11.7 g, 0.05 mol) in tetrahydrofuran (100 mL) was added and refluxing continued for 2 h. Saturated aqueous ammonium chloride solution was added and the solution extracted with chloroform. The extract was dried (Na_2SO_4), evaporated *in vacuo*, and the residue crystallized from benzene–acetonitrile to afford the alcohol **8** (4.5 g, 30%), mp 131–132°C; ^{1}Hmr (DMSO-d_6) δ: 1.17 (3H, s, CH_3), 1.33 (3H, s, CH_3), 2.2 (2H, m, CH_2), 3.8 (1H, bs, OH), 8.0 (9H, m, aromatic). *Anal.* calcd. for $C_{19}H_{21}NO_3$: C 73.96, H 6.79, N 4.49; found: C 74.03, H 6.87, N 4.34.

3,3-Dimethyl-1,2,3,5,6,7-hexahydro-7-phenyl-4,1-benzoxazonin-7-ol ***9***

The alcohol **8** (8 g, 0.026 mol) and lithium aluminium hydride (8 g, 0.2 mol) in tetrahydrofuran (200 mL) was refluxed for 24 h. The excess hydride was destroyed with tetrahydrofuran–water (2:1), and the resulting slurry filtered. The filtrate was concentrated *in vacuo* and the product crystallized from ethanol to afford the amine **9**, (5.0 g, 65%), mp 147–148°C; ir ($CHCl_3$): 3580, 3350 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.0 (3H, s, CH_3), 1.2 (3H, s, CH_3), 2.0 (2H, m, CH_2), 3.1 (2H, s, NCH_2), 3.3 (2H, t, J = 5 Hz, OCH_2), 4.15 (2H, bs, OH, NH), 7.1 (9H, m, aromatic). *Anal.* calcd. for $C_{19}H_{23}NO_2$: C 76.73, H 7.80, N 4.71; found: C 76.95, H 7.81, N 4.71.

*3,3-Dimethyl-5,6-dihydro-4,1-benzoxazonine-2,7(1*H*,3*H*)-dione oxime* ***10***

A solution consisting of sodium acetate (37.5 g, 0.46 mol), hydroxylamine hydrochloride (31.5 g, 0.45 mol), and the 4,1-benzoxazonine **2** (50 g, 0.214 mol) in 1.2 L of ethanol was stirred at 22°C for 2 days. Filtration gave the oxime **10** (30 g, 57%), mp 205–206°C (ethanol); ^{1}Hmr (DMSO-d_6) δ: 1.32 (6H, bs, *gem* dimethyl), 2.7 (2H, m, CH_2), 3.96 (2H, m, CH_2O), 7.35 (4H, m, aromatic), 9.4 (1H, bs, NH), 11.2 (1H, bs, NOH). *Anal.* calcd. for $C_{13}H_{16}N_2O_3$: C 62.88, H 6.50, N 11.28; found: C 62.35, H 6.63, N 11.27.

*7-Amino-3,3-dimethyl-1,5,6,7-tetrahydro-4,1-benzoxazonin-2(3*H*)-one* ***11***

The oxime **10** (1 g, 0.004 mol) in ethanol (100 mL) containing concentrated hydrochloric acid (0.4 mL) and 5% palladium on carbon (0.2 g) was hydrogenated at atmospheric pressure for 18 h. Filtration, concentration *in vacuo*, and crystallization from ethanol afforded the amine **11** as its hydrochloride (0.67 g, 60%), mp 165–167°C; ir (Nujol): 3400, 1665 cm^{-1}; ^{1}Hmr (D_2O) δ: 1.15 (3H, s, CH_3), 1.38 (3H, s, CH_3), 2.15 (2H, m, CH_2), 3.9 (2H, m, CH_2O), 4.9 (1H, m, CHO), 7.5 (4H, m, aromatic).

*3,4-Dihydro-3,3-dimethylfuro[3,4-*b*]quinolin-9(1*H*)-one* ***12***

The 4,1-benzoxazonine **2** (11.66 g, 0.05 mol) in tetrahydrofuran (250 mL) was added dropwise to a stirring mixture of sodium hydride (4.8 g of a 55% dispersion, 0.1 mol) in tetrahydrofuran (220 mL). After 0.5 h at 22°C the reaction was neutralized with glacial acetic acid. The resulting precipitate was filtered, triturated with water, and dried to afford furo[3,4-*b*]quinolinone **12** (9.3 g, 86%), mp 335–340°C (dec.) (methanol); ir (Nujol): 3220, 3180, 3100, 1610, 1580, 1504 cm^{-1}; uv λ_{max}: 326 (14 000), 314 (12 800), 239 (33 000); ^{1}Hmr (DMSO-d_6) δ: 1.54 (6H, s, *gem* dimethyl), 4.92 (2H, s, CH_2O), 7.4 (3H, m, aromatic), 8.19 (1H, m, aromatic), 11.9 (1H, bs, NH). *Anal.* calcd. for $C_{13}H_{13}NO_2$: C 72.54, H 6.09, N 6.51; found: C 72.30, H 6.15, N 6.45.

*9-Chloro-1,3-dihydro-3,3-dimethylfuro[3,4-*b*]quinoline* ***13***

Powdered furo[3,4-*b*]quinoline **12** (6.5 g, 0.03 mol) was added portionwise to vigorously stirring phosphorus oxychloride (26 mL) at 22°C. After 1 h the reaction was poured into crushed ice (340 mL). A small amount of residue was filtered off after the ice melted and the filtrate made alkaline with 50% sodium hydroxide solution (75 mL). Filtration gave the chloro compound **13** (5.96 g, 85%), mp 108–110°C (petroleum ether, bp 60–80°C); uv: λ_{max}: 320 (6280), 306 (5060), 294 (4740), 225 (31 800); ^{1}Hmr ($CDCl_3$) δ: 1.62 (6H, s, *gem* dimethyl), 5.22 (2H, s, CH_2), 7.67 (2H, m, aromatic), 8.15 (2H, m, aromatic). *Anal.* calcd. for $C_{13}H_{12}ClNO$: C 66.81, H 5.18, N 5.99; found: C 67.01, H 5.43, N 5.71.

*9-Substituted-1,3-dihydro-3,3-dimethylfuro[3,4-*b*]quinolines* ***14–20*** *(Table 1)*

A mixture of the chloro compound **13** (0.05 mol), the appropriate alkylamine (0.12 mol), and phenol (20 g) was heated at 150°C for 20 h. The reaction was taken into chloroform, washed with 10% sodium hydroxide solution, and extracted with 5% aqueous hydrochloric acid. The acid extract was washed with diethyl ether and then made alkaline with 10% aqueous sodium hydroxide. Extraction with diethyl

ether, followed by drying (Na_2SO_4) and concentration afforded the title compounds.

1,3-Dihydro-3,3-dimethyl-9-phenoxyfuro[3,4-b]quinoline ***21***

Silica gel chromatography of the products **14**–**20** described above using benzene–acetone–triethylamine (7:2:1) afforded compound **21** as a solid in yields of 5–40% (calculated from the chloro compound **13**).

9-Substituted-1,3-dihydro-3,3-dimethylfuro[3,4-b]quinolines ***22*** *and* ***23***

A solution of 4,1-benzoxazonine **2** (10 g, 0.043 mol) in tetrahydrofuran (100 mL) was added dropwise over a 1 h period to a stirring suspension of sodium hydride (5 g of a 55% dispersion in mineral oil, 0.11 mol). After stirring for a further 1 h at 22°C the appropriate aminoalkyl chloride (0.15 mol) was added and the reaction refluxed for 18 h. Filtration and concentration *in vacuo* afforded the title compounds.

9[(2,3-Epoxy)propyloxy]-3,4-dihydro-3,3-dimethylfuro[3,4-b]quinoline ***24***

This compound was prepared as described above except that the intermediate sodium furo[3,4-*b*]quinolate (see Scheme 2) was obtained by the treatment of the furo[3,4-*b*]quinolone **12** with excess sodium hydride.

1-(1,3-Dihydro-3,3-dimethylfuro[3,4-b]quinolin-9-yloxy)-3-(isopropylamino)-2-propanol ***25***

A mixture consisting of the epoxide **24** (0.5 g, 0.0018 mol), isopropylamine (10 mL), and benzene (10 mL) in a pressure bottle was heated at 100°C for 18 h. Concentration *in vacuo* afforded the amine **25**, mp 132–135°C (cyclohexane).

Solvent effects on the photocycloaddition and photoenolisation reactions of isophorone

JANICE DEBORAH SHILOFF AND NORMAN ROBERT HUNTER[1]

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received June 18, 1979

This paper is dedicated to Prof. Karel Wiesner on the occasion of his 60th birthday

JANICE DEBORAH SHILOFF and NORMAN ROBERT HUNTER. Can. J. Chem. **57**, 3301 (1979).

The influence of solvent on two photochemical reactions of isophorone has been investigated. The photocycloaddition of isopropenyl acetate to isophorone (3,5,5-trimethylcyclohex-2-en-1-one) (**1**) is best achieved using methanol as solvent. Photodeconjugation of isophorone (**1**) to the exocyclic methylene isomer **2** proceeds most efficiently in ethyl acetate.

JANICE DEBORAH SHILOFF et NORMAN ROBERT HUNTER. Can. J. Chem. **57**, 3301 (1979).

On a étudié l'influence du solvant sur deux réactions photochimiques de l'isophorone. La photocycloaddition de l'acétate d'isopropényle sur l'isophorone (triméthyl-3,5,5 cyclohexèn-2-one-1) (**1**) se produit plus facilement si on utilise le méthanol comme solvant. La photodéconjugaison de l'isophorone en l'isomère **2** possédant un méthylène exocyclique se produit avec un meilleur rendement lorsqu'on utilise l'acétate d'éthyle comme solvant.

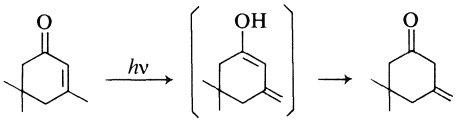
Introduction

In a recent review on the photocatalyzed enolisation process Sammes (1) indicated that the general utility of the photoisomerisation of α,β-unsaturated ketones to their β,γ-isomers is restricted by the many competing photoreactions which α,β-enones undergo. Earlier Dauben *et al.* (2) had reported the effects of alkyl substitution on the photochemistry of 2-cyclohexenones and summarized the known photodeconjugation reactions of β-alkyl α,β-cyclohexenones. More recently Chapman and Weiss (3) and Nakanishi and Sato (4) have provided short reviews on photodeconjugation of enones and Tada and Miura (5) reported on the photoenolisation of four β-methyl α,β-enones.

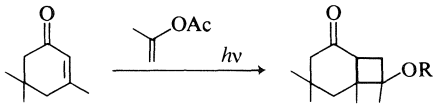
The only systematic investigation of the effect of solvent on the photodeconjugation reaction is Jennings' study of isophorone photochemistry (6). In that report Jennings indicated that solvent polarity played a very important role in the competition between isophorone photodimerisation and photodeconjugation. In very polar solvents the yield of dimer was highest and decreased to zero in very non-polar solvents. Jennings also reported that irradiation of isophorone (**1**) in heptane at −13°C gave a single, unstable, product which was proven by chemical and spectroscopic methods to be the deconjugated enone 3-methylidene-5,5-dimethylcyclohexanone (**2**) (Scheme 1) which probably arises via the transient enol.

Our interest in the photodeconjugation reaction was aroused when we repeated the photocycloaddition of isopropenyl acetate to isophorone according to the procedure of Valenta and Liu (7) (Scheme 2). In the literature procedure, a 0.5 *M* solution of isophorone in benzene was irradiated for four days in the presence of a 20-fold molar excess of isopropenyl acetate to give the photoadduct **3** which could not be distilled because of the presence of polymeric by-products.



1 **2**

SCHEME 1



1

3 R = Ac
4 R = H

SCHEME 2

When we monitored this reaction by gas chromatography, we observed that one important competing reaction was the photodeconjugation of isophorone to the exomethylene compound **2**. Compound **2** slowly isomerized back to **1** on standing in the photolysis solution. It was our feeling that by a judicious choice of solvent, the yield of both the photodeconjugation and the photocycloaddition reactions could be substantially improved. The results of our investigation are described below.

Results and Discussion

At the outset of our investigation, we laid down

[1]To whom enquiries should be addressed.

0008-4042/79/243301-03$01.00/0

several criteria to be met for the two reaction types. Firstly, both reactions must proceed with complete selectivity on the basis of solvent change only. Secondly, both reactions should be amenable to scale-up and thirdly, the products must be readily isolable in high yield and purity. The small-scale reactions which were carried out to determine appropriate solvent choices are described in the Experimental.

The deconjugated enone **2** was prepared by irradiation of a 0.1 *M* solution of isophorone (**1**) in ethyl acetate. After 14 h of irradiation gc analysis indicated a greater than 95% conversion of **1** to **2**. Careful evaporation of the solvent yielded a colourless liquid which gave spectral data in agreement with that recorded by Jennings (6) for compound **2**. The ethyl acetate solution of **2** obtained after photolysis could be stored at 0°C for several weeks without appreciable reversion to **1**.[2]

We next turned our attention to the photocycloaddition of isopropenyl acetate to isophorone. Many of the earlier studies of photocycloaddition reactions (7–9) are characterized by the use of non-polar solvents and a large excess of alkene. In this study we have used methanol as solvent and only a four-fold excess of the alkene relative to isophorone. These modifications allow the preparation of photoadduct **3** in 71% yield after distillation. In order to effect comparison of this photoproduct with that reported (7), the ketoacetate **3** was hydrolyzed to the known ketoalcohol **4** (7) in 88% yield after distillation. Our procedure provides improvement over the literature procedure in terms of reaction time, ease of purification, and increased yield.

The dramatic effect of solvent in the course of isophorone photoreactions reported in this paper can be understood in terms of the reported dualistic nature of the triplets arising from enone photolysis (10) and the effect of solvent upon these triplet states (4). Our results indicate that many enone photoreactions may be profoundly affected by the appropriate choice of solvent.

Experimental

Infrared spectra were recorded with a Pye Unicam SP1000 infrared spectrometer using a neat film or in CCl_4 as solvent. Proton magnetic resonance spectra were recorded with a Varian EM-360 spectrometer using CCl_4 as solvent and tetramethylsilane as internal standard. Mass spectra were measured with a Finnigan-1015 quadrupole mass spectrometer. Gas chromatographic analyses were done on a 10% SE-30 column using an Hewlett-Packard 700 chromatograph with flame ionization detection.

All photoreactions were carried out using a Photochemical Research Associate PRA-R400 photoreactor after purging the solvent with dry N_2 gas. Solvents were used as obtained from commercial sources. Isopropenyl acetate was used as obtained from J. T. Baker Chemical Co. and isophorone (Aldrich Chemical Co. Inc.) was distilled prior to use.

Small-scale Reactions

The small-scale reactions were set up in Pyrex test-tubes in a "merry-go-round" assembly using a 0.25 *M* solution of isophorone (0.35 g per 10 mL of solvent) and a 1.0 *M* solution of isopropenyl acetate (1.0 g per 10 mL of solvent) for each of the solvents studied. The reactions were monitored at two hour intervals by gas chromatography. All the photoadducts have longer reaction times than isophorone while the deconjugated isomer **2** had a shorter retention time. In methanol as solvent, exclusive photoadduct formation was observed. In ethyl acetate, exclusive deconjugation was observed. Benzene and hexane gave mixtures of deconjugation and cycloaddition products as well as extensive polymerization of isopropenyl acetate.

3-Methylidene-5,5-dimethylcyclohexane (2)

Isophorone (4.50 mL, 4.15 g, 0.03 mol) in ethyl acetate (300 mL) was irradiated through a Pyrex filter in a PRA-R400 photoreactor for 14 h at which time gc indicated greater than 95% conversion of isophorone into the deconjugated isomer **2**. Careful evaporation of a 10 mL aliquot of the ethyl acetate solution, at less than 30°C, gave a clear colourless liquid (0.135 g, 98% of theoretical) which had the following spectral data: mass spectrum, $C_9H_{14}O$ requires *m/e* 138; *m/e* found: 138 (fragmentation pattern identical to isophorone); infrared (neat): 1720 ($\rangle C{=}O$) and 1640 ($\rangle C{=}CH_2$) cm^{-1}; ^{1}Hmr indicated that the sample contained less than 10% isophorone. The ^{1}Hmr peaks due to **2** are δ: 4.75 (2H, bs, $\rangle C{=}CH_2$), 2.93 (2H, bs, H's on C-2), 2.15 (2H, bs), and 2.27 (2H, bs) due to H's on C-4 and C-6, and 0.98 (6H, sharp singlet, CH_3's on C-5). The ^{1}Hmr spectrum was in agreement with the spectrum published in the literature (6).

7-Acetoxy-4,4,6,7-tetramethylbicyclo[4.2.0]octan-2-one (3)

The PRA-R400 photoreactor, equipped with a Pyrex filter system, was charged with isophorone (10.0 g, 0.072 mol, 0.24 *M*), 300 mL of methanol, and isopropenyl acetate (30.0 g, 0.30 mol) and cooled in an ice-water bath. After 6.5 h of irradiation gc analysis indicated essentially total consumption of the isophorone, no deconjugation, and no polymerization of the isopropenyl acetate. The reaction was worked up by evaporation of the solvent and unconsumed isopropenyl acetate followed by addition of 100 mL of toluene and evaporation of the toluene to give the crude product (16.27 g, 0.068 mol, 94%). The crude product was distilled at 1.5 Torr in a Kugelrohr (130°C air bath temperature) to yield, as the major fraction collected, 12.21 g (0.051 mol, 70.8%) of pure **3** as a mixture of diastereomers. Mass spectrum for $C_{14}H_{22}O_3$ requires *m/e* 238; *m/e* found: 238 (M^+), 196 (loss of $CH_2{=}C{=}O$), base peak 43 ($CH_3{-}C{\equiv}O^+$). Infrared (CCl_4): 1705 ($\rangle C{=}O$) and 1730 ($CH_3{-}\underset{\underset{O}{\|}}{C}{-}O{-}$) cm^{-1}; ^{1}Hmr: complex absorption pattern showing acetate methyl peaks at 1.93 and 1.97 δ and saturated methyl singlets (eight peaks) in the region 0.87 to 1.30 δ.

7-Hydroxy-4,4,6,7-tetramethylbicyclo[4.2.0]octane-2-one (4)

7-Acetoxy-4,4,6,7-tetramethylbicyclo[4.2.0]octan-2-one (11.90 g, 0.05 mol) was dissolved in methanol (125 mL) with

[2]This process affords, for the first time, a ready source of **2** for further chemical studies. The results of these studies, as well as kinetic studies of the photodeconjugation reaction, will be reported in a future communication.

slight warming on the steambath. After the solution had cooled to ambient temperature, anhydrous potassium carbonate (20.7 g, 0.15 mol) was added. The resulting mixture was stirred for 6 h and then worked up by pouring into 300 mL of H_2O and extracting the organic product with methylene chloride (3 × 75 mL). The organic extracts were washed with water (2 × 50 mL), dried, and evaporated. The resulting oil was distilled at 1.2 Torr in a Kugelrohr (120–140°C air bath temperature) to give the keto alcohol **4** (8.62 g, 0.044 mol, 88%). Mass spectrum for $C_{12}H_{20}O_2$ requires *m/e* 196; *m/e* found: 196. Infrared (neat): 3450 (OH) and 1700 ($\diagdown\!\!\diagup$C=O) cm^{-1}; ^{1}Hmr (CCl_4): complex pattern showing OH absorption at 3.98 δ and at least five methyl singlets in the region 0.9 to 1.23 δ.

Allyloxyanthraquinones showed unusual behaviour during the Claisen rearrangement. Thus, 1-allyloxyanthraquinone **9** rearranged very readily in the presence of benzylamine while 2-allyloxyanthraquinone **13** refused to do rearrangement even under very drastic conditions. On the other hand, 1,2-diallyloxyanthraquinone rearranged with the loss of the 2-allyloxy group as the result of a retro-ene reaction which has not been previously observed[1] while 1,4-di(2′-chloro-2′-propenyloxy)anthraquinone **18** rearranged to give, as a major product, the unsymmetrically substituted anthraquinone **19** which is useful in the synthesis of anthracycline aglycones.

C. M. WONG, R. SINGH, K. SINGH et H. Y. P. LAM. Can. J. Chem. **57**, 3304 (1979).

Les allyloxyanthraquinones ont un comportement inhabituel pendant la transposition de Claisen. Alors que l'allyloxy-1 anthraquinone **9** se transforme très facilement en présence de la benzylamine, l'allyloxy-2 anthraquinone **13** au contraire est réfractaire, même dans des conditions très drastiques. D'un autre côté, la diallyloxy-1,2 anthraquinone se transpose en perdant le groupement allyle en position 2; c'est le résultat d'une réaction ène-rétro qui n'a pas été observée antérieurement,[1] tandis que la di(chloro-2′ propényloxy-2′)-1,4 anthraquinone **18** se transpose pour donner comme produit principal l'anthraquinone **19** substituée d'une façon non symétrique et qui est utile à la synthèse des aglycones anthracyclines.

[Traduit par le journal]

Introduction

The Claisen rearrangement of aryl allyl ethers, generally known as a form of [3,3]-sigmatropic rearrangement, can be used synthetically as a substitute for the Fries rearrangement or Friedel–Crafts reaction for functionalizing an aromatic ring, including deactivated ring systems. Information concerning the mechanistic studies, yields of ortho- and para-rearrangement products, effects of the solvent polarity, and the use of bases as catalysts have been compiled and discussed by Rhoads and Paulins (1). Its exploitation in natural product synthesis was also reviewed in a recent article by Ziegler (2). Furthermore, the use of transition metal salts and acidic solvents as catalysts, and acid anhydrides as trapping agents, has been reported to show favorable results in some isolated cases of Claisen rearrangement (2–6). However, not much work has been reported on anthraquinone systems, except some short publications such as those by Kende *et al.* (7*a*), Roberts and Rutledge (7*b*), and Sheinmann and co-workers (7*c*), which prompted us to report our results in this area of studies.

In connection with our synthetic and structure–activity relationship studies of antitumor anthracyclines (8) such as 4-demethoxydaunomycin (**1**), adriamycin (**2**), daunomycin (**3**), and carminomycin (**4**), an unsymmetrically functionalized anthraquinone such as **22** would be of great interest as an intermediate for the construction of the tetracyclic aglycones of **1**, **2**, **3**, **4**, and other rhodomycinones (9). Conversion of **22** to **5** followed by Michael addition and Claisen condensation between **5** and methyl vinyl ketones **6** could furnish the tetracyclic compound **7** in a one step process.

Another aspect in our design of this group of antibiotics is to select an inexpensive starting material and convert it in a simple way to a potentially useful intermediate such as **5**. The ready availability of the very inexpensive quinizarin (**8**) makes it attractive although many attempts to functionalize its phenolic ring properly by Friedel–Crafts or Reimer–Tiemann type reactions were un-

[1]This result was reported as part of the author's presentation to the symposium of anthracycline antitumor antibiotics at the 61st conference of the Chemical Institute of Canada, Winnipeg, Man., June, 1978. A similar result was also reported by Scheinmann and co-workers (7*c*).

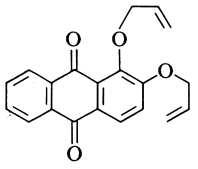
Results and Discussion

When 1-allyloxyanthraquinone (**9**) was heated in a sealed tube immersed in an 180°C oil bath for 12 h, 1-hydroxy-2-allylanthraquinone (**10**) was isolated in about 70% yield. However, when the rearrangement was carried out in *o*-xylene solution containing 5% of benzylamine in a 150°C oil bath for 4 h, **10** was isolated in 88% yield together with a trace of 1-(*N*-benzylamino)anthraquinone (**11**) which became the only product (4% yield) when the *o*-xylene solution was heated at 105°C for 72 h. In the absence of benzylamine, less than 10% of **10** was isolated after 120 h of heating at 150°C. Other reagents such as *N*,*N*-dimethylaniline, acid anhydrides, and titanium chloride (3–6) gave inferior yields or isomerization of the allyl double bond or decomposition of both products and starting material. It is evident that benzylamine is a superior basic catalyst in the Claisen rearrangement of simple allyloxyanthraquinones. However, when 2,6-diallyloxyanthraquinone (**12**) or 2-allyloxyanthraquinone (**13**) was heated in 1,2,4-trimethylbenzene in a sealed tube for as long as 96 h, in the presence of a variety of catalysts and with temperatures up to 240°C, no rearrangement was observed.

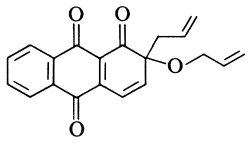
Kinetics and the stereochemistry requirement of Claisen rearrangement have been quite thoroughly studied and a negative entropy has been proposed as a reflection of the high degree of order in the transition state which favors the chairlike transition over the boatlike transition (2). Furthermore, selective migration of the allyl group has been reported. Thus, 2-allyloxynaphthalene gave only 1-allyl-2-hydroxynaphthol, while 2-allyloxyphenanthrene gave only 1-allyl-2-hydroxyphenanthrene and 3-allyloxyphenanthrene gave only 4-allyl-3-hydroxyphenanthrene (10). The rationale for such specificity is the localization of the double bonds in the aromatic nucleus during the transition state, in the form having, in the case of 2-allyloxynaphthalene, the double bond at C1—C2 positions and in the case of 2-allyloxyphenanthrene and 3-allyloxyphenanthrene, the double bonds at C1—C2, C3—C4 positions, respectively.

However, no Claisen rearrangement of 2-allyloxyanthraquinone or similar compounds has been reported and our finding indicated that such a system is extremely resistant to rearrangement. Explanation in terms of the stereochemistry requirement and localization of double bonds as in the cases of 2-allyloxynaphthalene and 2-allyloxyphenanthrene is unsatisfactory because there is no obvious interference with the formation of the chairlike transition nor is there any severe steric interaction that completely retards the rearrangement. Furthermore, localization of double bonds of anthraquinones should allow 2-allyloxyanthraquinone to form 1-allyl-2-hydroxyanthraquinone. Thus, it is very likely that the great reluctance is due to the electronic effect of the quinone structure. Although this kind of electronic effect has not been indicated as a decisive factor in sigmatropic rearrangement, its influence can be seen easily in the case of an *endo* versus *exo*- $\pi^4s + \pi^2s$ cycloaddition process involving quinone or other dienophiles.

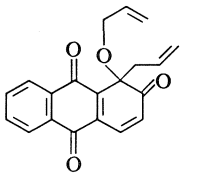
Considering the C2 and C3 positions of anthraquinone as equally electron-deficient, it is discernible that the C2 of **9**, being electron deficient, can easily overlap with the C3, π orbital. On the other hand, the C1 position of **12** or **13**, having higher electronic density than the C2 of **9**, will be less ready to overlap with the C3, π orbital. Furthermore, the contribution of the C2=$\overset{+}{O}$—$^{-2}$ resonance form of **12** or **13** will definitely shorten the C1′—O bonds as compared to the corresponding C1′—O bond of **9** making the



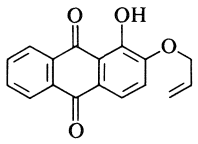
14



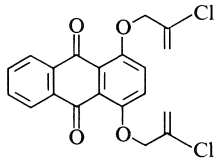
15



16



17



18

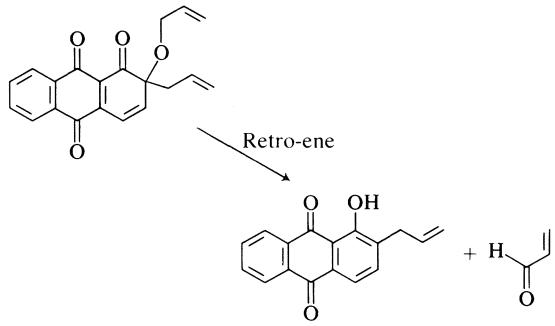
former bonds stronger and more resistant to the rearrangement.

It is possible that there could be other factors influencing the rearrangement process. The explanation advanced above can account for, at least in part, the great reluctance of 2-allyloxyanthraquinone and its analogues toward the concerted [3,3]-sigmatropic rearrangement.

To look further into the inert nature of the 2-allyloxyanthraquinone, 1,2-diallyloxyanthraquinone (**14**) was heated in *o*-xylene solution containing 5% benzylamine with the hope that the dienone **15** or **16** could be isolated. Instead, the only major identifiable product in about 40% yield was 1-hydroxy-2-allylanthraquinone (**10**) plus a trace of 1-hydroxy-2-allyloxyanthraquinone (**17**). A similar result was obtained when the reaction was carried out in the absence of benzylamine.

The formation of **10** could only be explained if **15** instead of **16** was formed as a product of [3,3]-sigmatropic rearrangement followed by a retro-ene process (Eq. [1]).

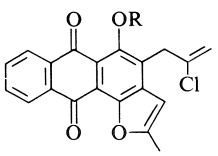
[1]



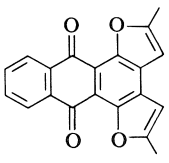
Further investigation of sigmatropic rearrangement on anthraquinones revealed some practical applications toward the preparation of **5** which would be an important intermediate to anthracyclines starting from the inexpensive quinizarin **8**.

When 1,4-di(2′-chloro-2′-propenyloxy) anthraquinone (**18**) was refluxed for 60 h in *o*-xylene solution containing 10% *N*,*N*-dimethylbenzylamine, the major product, isolated in 40% yield, was the unsymmetrically functionalized anthraquinone **19**. The other major products were the pentacyclic compound **20** in about 15% yield and the uncyclized anthraquinone **21** in about 5% yield. Isomerization of the chloropropenyl groups under this condition was negligible.

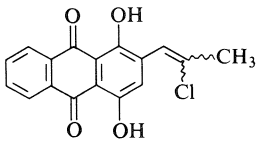
The formation of **19** enables the differentiation of two identical groups which can be easily introduced



19 R = H
22 R = CH_3



20



21

unsymmetrically into a deactivated aromatic system. The successful conversion of the methyl ether **22** to **5** via ozonolysis and the development of **5** into tetracyclic aglycones of anthracycline antitumor antibiotics are in progress and will be reported later.

Experimental

All infrared spectra (cm^{-1}) were recorded on a Perkin-Elmer infrared 710A spectrophotometer using methylene chloride as solvent. Nuclear magnetic resonance spectra (δ) were recorded on a Varian A56/60A MHz spectrometer using deuterated chloroform as solvent and tetramethylsilane as internal standard. Mass spectra were recorded on a Finnigan Model 1015 mass spectrometer. High resolution mass spectra

2. 
were recorded on an A.E.I. MS9 spectrometer. Melting points were measured on a Fisher-Johns apparatus and were uncorrected. Microanalyses were performed by Dr. Daessle of Montreal.

*Preparation of 1-Allyloxyanthraquinone (**9**)*

An acetone solution (300 mL) containing 1-hydroxyanthraquinone (5 g), pulverized potassium carbonate (15 g), and allyl bromide (8 mL) was refluxed for 24 h with vigorous stirring under anhydrous conditions. The acetone solution was cooled, filtered, and evaporated to dryness under reduced pressure and the residue was redissolved in chloroform (150 mL). The insoluble potassium carbonate residue was removed by filtration and the chloroform solution was evaporated to dryness under reduced pressure to give a solid yellow residue which was purified by recrystallization from chloroform–ether, mp 138–140°C; ir: 1675, 1592; nmr: 4.75 (t of d, 2H, J = 4 Hz and 15 Hz, —O—CH_2—CH=CH_2), 5.39 (m, 1H, CH=CH_2), 5.65 (m, 1H, —CH=CH_2), 6.22 (m, 1H, —O—CH_2—CH=CH_2). Mass spectrum m/e^+: 264.

*Preparation of 2-Allyl-1-hydroxyanthraquinone (**10**)*

An *o*-xylene solution (50 mL) containing 5% benzylamine and 1-allyloxyanthraquinone (3.7 g) (**9**) was heated under a nitrogen atmosphere in an oil bath at 145–150°C for 4 h with stirring. The *o*-xylene solution was evaporated under reduced pressure and the semi-solid residue was crystallized from ether to give, after filtration, a yellow crystalline product (3.3 g), mp 114–116°C; ir: 1670 (ketone), 1635 (hydrogen bonded ketone), 1595 (aromatic); nmr: 12.90 (s, 1H, —OH), 8.40–7.20 (m, 6H's, aromatic), 6.70–5.50 (m, 3H's, —CH=CH_2), 3.50 (d, 2H's, allylic H's). *Anal.* calcd. for $C_{17}H_{12}O_3$: C 77.27, H 4.55; found: C 77.12, H 4.32.

*The Preparation and Sigmatropic Rearrangement of 1,2-Diallyloxyanthraquinone (**14**)*

1,2-Diallyloxyanthraquinone (**14**) was prepared from the corresponding 1,2-dihydroxyanthraquinone under similar conditions to those described for the preparation of **9** and was purified by recrystallization from chloroform–ether, mp 114–116°C; ir: 1670, 1590; nmr: 4.64 (d, 4H, —O—CH_2—CH=CH_2), 5.20–6.70 (m, 6H, —CH=CH_2), 7.10–8.40 (m, 6H's, aromatic); mass spectrum m/e^+: 320.

An *o*-xylene solution (50 mL) containing the 1,2-diallyloxyanthraquinone (**14**) was refluxed under a nitrogen atmosphere for 96 h. The dark brown solution was evaporated to dryness under reduced pressure and the residue was separated by preparative tlc on silica. The major product in about 38% yield was isolated and characterized as 1-hydroxy-2-allylanthraquinone (**10**).

*Preparation of 1,4-Di-(2′-chloro-2′-propenyloxy)anthraquinone (**18**)*

An acetone solution (1 L) containing quinizzarin (24 g), pulverized potassium carbonate (50 g) and potassium iodide (5 g), and 2,3-dichloro-1-propene (44 g) was refluxed for 56 h or until the colour of the solution changed from blue to orange. The cooled solution was filtered and then evaporated to dryness under reduced pressure and the residue was dissolved in chloroform (1 L) which was filtered once more to remove the small amount of potassium carbonate residue. Evaporation of the chloroform solution to dryness under reduced pressure gave the 1,4-di(2′-chloro-2′-propenyloxy)anthraquinone (**18**) (20.4 g) which could be purified by recrystallization from chloroform–ether, mp 145–147°C; ir: 1670 (ketone), 1630 (allyl), 1595 and 1585 (aromatic); nmr: 4.65 (broad s, 4H, allylic H), 5.50 (m, 2H, CCl=CH(E)), 5.92 (m, 2H, CCl=CH(Z)), 7.20–8.40 (m, 6H, aromatic); mass spectrum m/e^+: 388.

*Preparation of 2-Methyl-5-(2′-chloro-2′-propenyl)-6-hydroxyfura(a)anthraquinone (**19**), 2,7-Dimethyldifura(a,c)anthraquinone (**20**), and 1,4-Dihydroxy-2,3-di(2′-chloro-2′-propenyl)anthraquinone (**21**)*

An *o*-xylene solution (200 mL) containing 10% of *N*,*N*-dimethylbenzylamine and 1,4-di-(2′-chloro-2′-propenyloxy)-anthraquinone (15 g) was refluxed for 60 h in an oil bath kept at 170°C under a nitrogen atmosphere which was maintained by fitting a nitrogen balloon over the condenser. The xylene solution was evaporated to dryness under reduced pressure and the residue was redissolved in chloroform (300 mL). The chloroform solution was filtered to remove the *N*,*N*-dimethylbenzylamine hydrochloride. The filtrate was washed with 0.1 *N* hydrochloric acid (2 × 100 mL), dried over anhydrous magnesium sulfate, and was evaporated to dryness under reduced pressure. The products were separated by pressurized (15 lb/in^2) column chromatography over DSF-5 Kieselgel (Camag, Switzerland) with chloroform as eluting solvent.

Fractions that contained 1,4-dihydroxy-2,3-di(2′-chloro-1′-propenyl)anthraquinone (**21**) were combined and evaporated to dryness. Recrystallization of the residue from chloroform gave **21** as red crystals (800 mg), mp 176–178°C; ir: 3600–2800 (broad), 1630, 1595; nmr: 2.42 (d, 3H, J = 1Hz, C=CHClCH_3), 6.89 (q, 1H, J = 1 Hz, HC=CClCH$_3$), 7.74–8.5 (m, 5H, aromatic), 12.9 (s, 1H, —OH), 13.60 (s, 1H, —OH). Mass spectrum m/e^+: 314.

2-Methyl-5-(2′-chloro-2′-propenyl)-6-hydroxy fura(*a*)-anthraquinone (**19**) was isolated as above and was crystallized from chloroform–ether to give yellow crystals (5.8 g), mp 194.5–196°C; ir: 3600–2800 (broad), 1680, 1640, 1605; nmr: 2.58 (s, 3H, C=C—CH_3), 3.90 (s, 2H, benzylic), 5.08–5.24 (m, 2H, Cl—C=CH_2), 6.46 (broad s, 1H, Ph—CH=C), 7.55–8.40 (m, 4H, aromatic); high resolution mass spectrum, m/e^+ calcd. for $C_{20}H_{13}O_4Cl$: 352.0499; found: 352.0501. *Anal.* calcd. for $C_{21}H_{15}O_4Cl$ (methyl ether): C 68.85, H 4.13, Cl 9.56; found: C 68.86, H 4.27, Cl 9.36.

Similarly, 2,7-dimethyl difura(*a.c*)anthraquinone (**20**) was isolated from the eluent as yellow crystals (2.0 g) after recrystallization from chloroform–ether, mp 295°C (dec); ir: 1670, 1570; nmr: 2.65 (d, 6H, J = 1.5 Hz, C=C—CH_3), 5.80 (m, 2H, C=CH), 7.60–8.40 (m, 4H, aromatic); mass spectrum m/e^+: 316.

A total synthesis of ring A aromatic *D*-homosteroids and the conversion of one of them to estrone and its derivatives are described. The key reaction is a catalysed addition of 6-methoxy-1-vinyl-3,4-dihydronaphthalene to 2,6-dimethyl-1,4-quinone which proceeds with orientation inversion compared to the thermal addition. Reactions with several other quinones are described. The synthetic sequence includes a hydride reduction in which an apparently more hindered carbonyl group of an enedione system is reduced preferentially. Cyclization of a 1,6-keto aldehyde under acidic conditions gives the desired acetyl cyclopentene derivative, while a predominant formation of cycloheptenones is observed when the same cyclization is performed with base.

On décrit une synthèse totale de stérodides *D*-homo dont le cycle A est aromatique ainsi que la transformation de l'un d'entre eux en estrone et en ses dérivés. La réaction fondamentale consiste en une addition catalysée du méthoxy-6 vinyl-1 dihydro-3,4 naphtalène sur la diméthyl-2,6 quinone-1,4 et dont l'orientation est l'inverse de celle d'une addition thermique. On décrit également des réactions impliquant plusieurs autres quinones. La série de réactions comprend entre autres une réduction par un hydrure où apparemment le groupe carbonyle le plus encombré d'un système ènedione est réduit préférentiellement. La cyclisation du cétoaldéhyde-1,6 en milieu acide conduit au dérivé acétylcyclopentène désiré; mais en milieu basique la même réaction permet d'obtenir des cyclohepténones comme produit principal.

Introduction

Since the first reported total synthesis of a steroid, that of equilenin in 1939 (1), the development and refinement of synthetic strategies involved in the efficient preparation of more complex steroids[1] has contributed significantly to the increasing sophistication of organic synthesis. In the 1940's and 1950's, the total synthesis of any steroid with three or more chiral centers presented a major challenge and this was taken up by some of the leading laboratories in the world. As a consequence of their pioneering and successful development of new synthetic tools and of new methods required to achieve regio- and stereocontrol, even relatively complex steroids are reasonably accessible by total synthesis in the 1970's.

There are, however, at least two important reasons why studies of steroid total synthesis should continue. Because of the varied and important biological activities of steroids, it is of interest to prepare new compounds in order to find new biological agents. For this purpose, total synthesis is often more versatile than a partial synthesis. The second reason concerns synthetic strategy. In spite of the dramatic developments during the past forty years, the efficiency of the synthetic pathways can still be greatly improved. This can lead, at the same time, to the discovery of new general strategies or to the refinement of known methods.[2]

In this and subsequent articles, we wish to report on our study of several years belonging to the second category. The general scheme for a synthesis of steroids shown in Fig. 1 not only has, as its crucial step, a reaction already observed (as a dimerization) eighty-two years ago by Ipatief (4) and elaborated into a synthetically useful form by Diels and Alder in 1928 (5), but involves a general strategy, the elaboration of steroid ring C by a Diels–Alder reaction, proposed soon after this reaction was discovered and attempted many times since (6). However, the scheme did not work efficiently because the regio- and stereochemistry of the addition was not controlled.

Apart from this problem, this approach has the

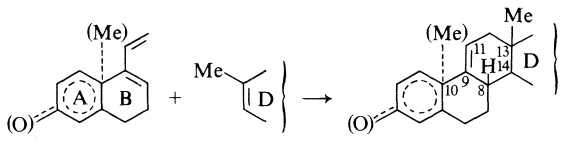

FIG. 1. General scheme for steroid synthesis.

following synthetic advantages. (*1*) Many required AB dienes should be readily available by synthesis. (*2*) A large number of relatively simple dienophiles, with or without preformed ring D, should be suitable. (*3*) The method should work for ring A aromatic as well as for C(10)-methylated steroids. (*4*) The C(9)—C(11) double-bond, useful for the introduction of important C(11)-functionality, is formed automatically. (*5*) The required *cis* relationship of C(8)—H and C(13)—CH_3 is established in an addition in which the potential ring D atoms lie *endo* (7) (i.e., the C(13)-methyl group is *exo*). With a suitable functionality in ring D, it should subsequently be possible to establish either stereochemistry at C(14). (*6*) For C(10)-methylated steroids, the desired *cis* relationship of the methyl groups at C(10) and C(13) would be a consequence of a preferred addition of the dienophile from the direction *anti* to the C(10)-methyl group of the diene.

This paper deals with the preparation of ring A aromatic *D*-homosteroids in which 1,4-quinones are used as dienophiles. One of the adducts is then converted into estrone and its derivatives. Subsequent papers describe the solution of stereochemistry in the synthesis of C(10)-methylated steroids, the synthesis of progesterone derivatives, and the use of simpler (non-quinonoid) dienophiles. In this progression, an increasing understanding of the addition has permitted an approach to more complex steroids by a series of synthetic pathways of improving efficiency.

Diels–Alder Additions

Readily available (8) diene **1** is the starting material suitable for the synthesis of ring A aromatic steroids by the method shown in Fig. 1. Previous studies indicated that mixtures of regioisomers, often in relatively poor yield, are obtained in additions of **1** to such a priori suitable dienophiles as citraconic anhydride (**15**) (9) and various cyclopentenones (6). In the absence, at the initiation of our work, of any simple dienophiles whose addition could be reliably controlled, we decided to use suitably substituted quinones (10, 11).

Table 1 summarizes the results of thermal and catalysed additions. Reaction of 2,6-dimethyl-1,4-benzoquinone (**2**) with diene **1** in boiling benzene gives a good yield of adduct **3**. No trace of the regioisomer **4** could be found in crystallization mother-liquors. In contrast, the same addition in ether with 1.3 mol equivalents of boron trifluoride etherate at −15°C gives adduct **3** in 10–15% yield and the desired adduct **4** in 69% yield (11). Since diene **1** alone is very unstable under acidic conditions, the good yield of the addition testifies to the high rate of the catalysed reaction (12). Structures of **3** and **4** were proven in the following simple way. The two compounds gave the corresponding (and different) C(8)—C(9) double-bond isomers **16** on treatment with acid. Compound **16** obtained from **4** instantaneously gave a dark purple color in alcoholic solution after addition of sodium hydroxide, indicating the extended chromophore **17**. A similar treatment of **16** obtained from **3** led to no chromophore change. Treatment of adduct **4** with sodium bicarbonate in boiling methanol gave a 94% yield of the desired isomer **18**.[3] In contrast, compound **3** proved stable to these (and stronger) basic conditions. As expected, the *syn-cis* isomer is thus converted into the more stable *anti–trans* isomer **18** in the case of adduct **4**, while the *syn–cis* isomer is more stable than the *syn–trans* isomer in the case of adduct **3**.

The complete stereochemistry of adduct **4** and its isomer **18** also follows rigorously from their conversion into estrone described below. It should be noted that only *endo* adducts (quinone ring *endo* to the diene) are obtained. This is reasonable since a greater effect by secondary attractive interactions (13) can be expected with quinones. During our extensive study of thermal and catalysed additions of quinones, described in this and subsequent publications, we have not encountered a single case in which the *exo*-product is formed even in minor quantities. This clearly constitutes an additional synthetic advantage in the use of quinones as dienophiles.

While the preparation of **18** was sufficient for the completion of the planned steroid synthesis, it was decided to explore the observed and unusual orientation reversal further. The addition of 2,5-dimethyl-1,4-benzoquinone (**5**) to **1** under thermal conditions also leads to the exclusive formation of the *endo*-"ortho"-adduct **6**, while the catalyst again reverses orientation, giving the "meta"-adduct **7** as the major product.[4] As shown in Table 1, three addi-

[3]Its structure is supported by the 220 MHz nmr spectrum in which the C(14)—H atom appears as a clean doublet (J = 18 Hz) at δ 2.63. The assignment of this signal was confirmed by a base catalysed deuterium exchange.

[4]Throughout, the term "ortho" is used for compounds in which the angular substituent (methyl, acetyl, or methoxycarbonyl) is at C(14) (steroid numbering) and thus next to the ring B methylene group. This substituent is at C(13) in the "meta"-adducts.

TABLE 1. Thermal and catalysed additions of diene **1** to quinones

Dienophile	Catalyst	Solvent	Temperature	Time	Total yield (%)	"Ortho"-adduct[4] (% of total yield)	"Meta"-adduct[4] (% of total yield)
2	—	C_6H_6	Boiling	24 h	82	100 (**3**)	0 (**4**)[a]

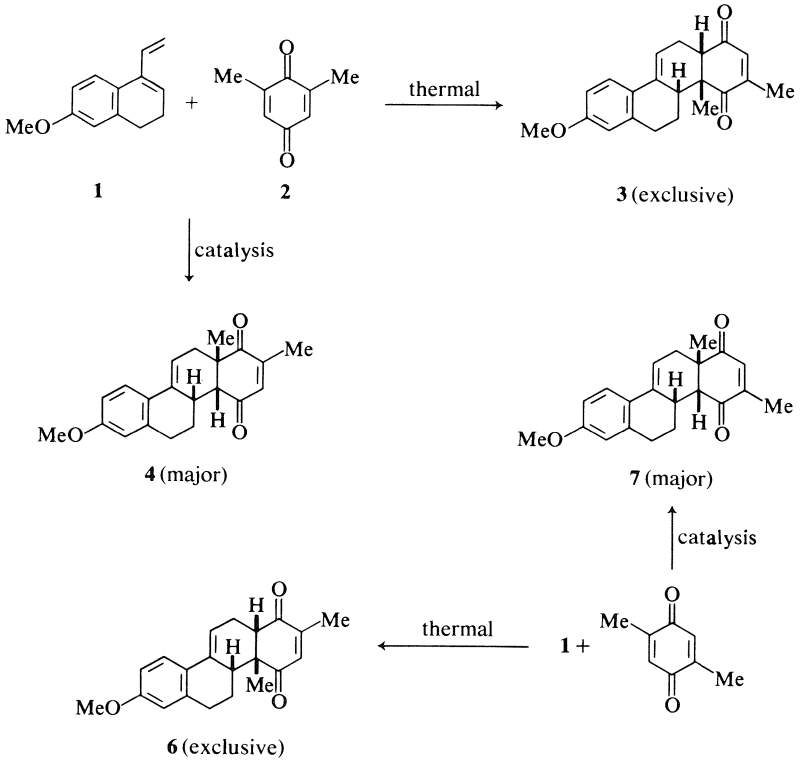
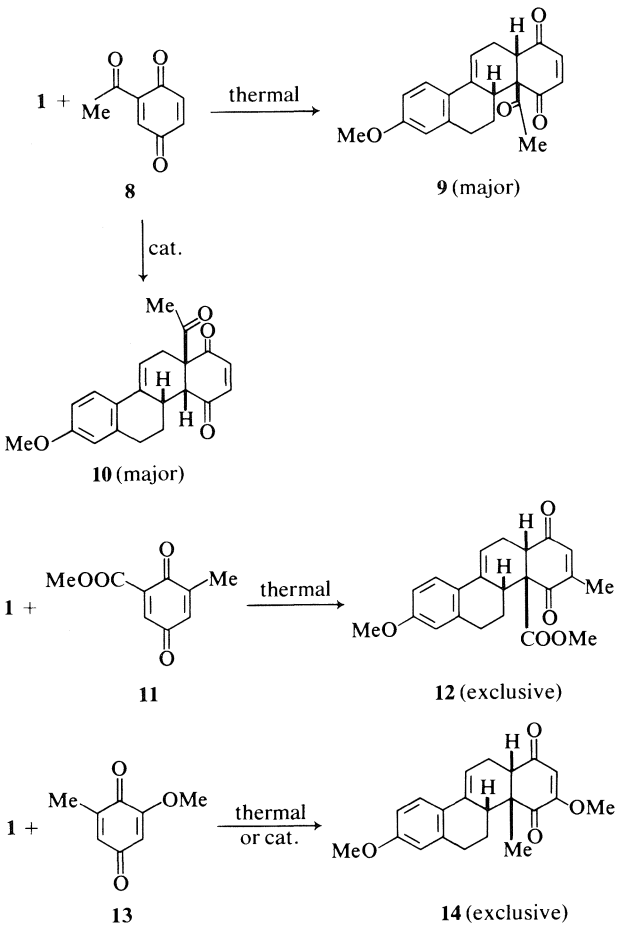
[a]Yields and ratios determined by product isolation.
[b]Yields and ratios determined by comparison of nmr spectra of crude and analytically pure products.



tional quinones, 2-acetyl-1,4-benzoquinone (**8**), 2-carbomethoxy-6-methyl-1,4-benzoquinone (**11**), and 6-methoxy-1,4-toluquinone (**13**), were examined. It should be noted that, in thermal additions, only quinone **8** gives any "meta"-adduct and that in a minor quantity. In catalysed additions, quinone **13** forms a clear exception to the general "meta"-adduct dominance. Structure, including stereochemistry, of all adducts was determined by methods similar to those used for compounds **3** and **4** (see Experimental).

Orientation

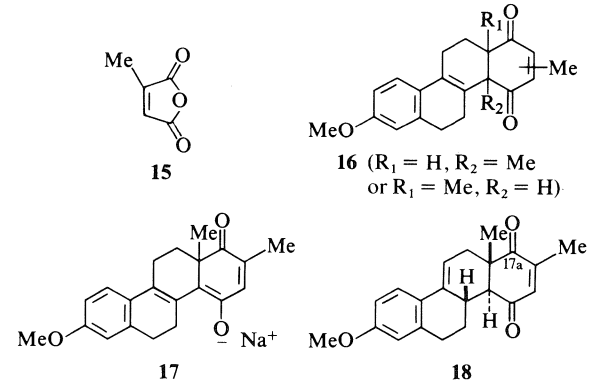
From a purely synthetic standpoint, these results clearly create a very favourable situation. Catalysed additions leading to compounds **4**, **7**, and **10** provide *D*-homosteroids with suitable C(13)-substituents in a simple manner. At the same time, all the thermal



additions give fair to good yields of C(14)-substituted compounds available for other purposes. In contrast to this simple picture of synthetic strategy based on products obtained, the mechanistic questions concerning these orientation reversals are very complex.

The results of the thermal additions alone are unusual. In order to assess the general orientation tendencies of diene **1**, we have repeated its addition to citraconic anhydride (**15**) (9) and have extensively studied its thermal addition to such simple dienophiles as methyl acrylate, acrylonitrile, and methyl *trans*-crotonate.[5] In all these cases, the "ortho"- and "meta"-adducts are formed in approximately equal quantities, with a slight preference (if any) for "meta"-addition up to a maximum product ratio of 2:1! Diene **1** is thus an interesting "orientation probe" for which the sum of all factors favouring "ortho"- addition is almost exactly equal to the sum of effects favouring "meta"-adducts in additions to non-quinonoid dienophiles including **15**. Considering the strong "ortho"-preference shown by quinones (Table 1), what is then, for example, the nature of the difference between citraconic anhydride (**15**) and the two dimethyl quinones **2** and **5**? Superficially, they clearly have structural similarities. The situation is all the more remarkable since the observed "ortho"-preference is largely independent of the nature of the quinone substituent. The activating methoxycarbonyl group in **11** and acetyl group in **8** show an orientation effect comparable to that of the deactivating methyl group in **2** and **5** in thermal additions.

It would be inappropriate to include an exhaustive discussion of this problem[6] in this presentation of a steroid synthesis. One aspect of the present study must, however, be mentioned since it is relevant to results and conclusions recently reached elsewhere. In an important experimental study of methyl quinone additions, Bohlmann *et al.* (16*b*) suggested that a steric effect is necessary to explain the *ortho*-predominance in thermal additions in which the frontier molecular orbital (FMO) theory in its presently applied form (14) fails to make the correct predictions. Houk *et al.* (17), using a perturbation



[5]Dr. Jagabandhu Das. Unpublished experiments in this Department (Ph.D. Dissertation, University of New Brunswick, 1978).

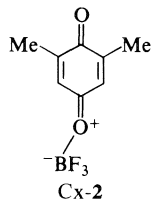
[6]This requires the consideration of *all* thermal and catalysed additions of diene **1** to various dienophiles and of the used quinones to many dienes and a consideration of the complicating fact that thermal additions of **1** to non-quinonoid dienophiles do not lead exclusively to *endo* adducts. At the present time, we are studying two aspects of the problem. Dr. Masatoshi Kakushima of our Department is calculating the molecular properties of appropriate model dienes and dienophiles in order to establish whether a qualitative explanation of the results can be provided by molecular orbital theory (13, 14). In addition, we have experiments in progress which are designed to probe the question whether the transition state geometries of thermal quinone additions and of all catalysed additions (15) are similar to or significantly different from those of thermal additions of non-quinonoid dienophiles. Any such possible geometric differences involving unsymmetrical transition states (16) would clearly have to be taken into account in a complete rationalization of the orientation results.

approach, explained these and similar results by postulating that a methyl group situated on the reacting double-bond of a dienophile can assume acceptor properties via the π^* CH_3 orbital (in addition to its deactivating donor properties), and thus direct a nucleophilic attack to the remote alkene terminus.

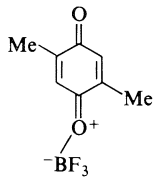
Our results indicate that the quinones are indeed "anomalous" compared to other (simpler) dienophiles, and that a more exact definition of the role of a methyl group situated on the dienophile double-bond (17) will not be sufficient to explain the pronounced "ortho"-effect observed in thermal additions of quinones. (*1*) Citraconic anhydride (**15**) and dimethyl quinones **2** and **5** all possess a reacting methyl alkene moiety, yet **15** reacts with diene **1** to give an *ortho*:*meta* ratio of adducts of ~1:1,[5] comparable to that observed in additions of methyl acrylate, acrylonitrile, and methyl *trans*-crotonate to **1**. In contrast, **2** and **5** give exclusively the "ortho"-adduct. (*2*) Quinones **8** and **11**, containing the activating acetyl and methoxycarbonyl groups, respectively, (instead of a methyl group) on their reacting double-bonds, also show a pronounced "ortho" preference in their thermal additions.

The comparable results of thermal additions of diene **1** to the two dimethyl quinones, **2** and **5**, furthermore show that the strong *ortho*-preference is independent of the position of a methyl group on the non-reacting double-bond of the quinone. This clearly constitutes a serious limitation to any postulates of an electronic non-identity of the two quinone carbonyl groups, at least in the ground state. An analysis of this problem is in progress.[6]

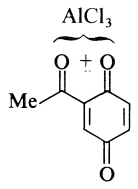
The complete rationalization of the results of the catalysed reactions is also difficult and should clearly not be undertaken before the thermal reactions are understood.[6] The ease of the catalysed reactions is no doubt due to the complexing of the Lewis acid with the dienophiles (12) and the consequent lowering of their LUMO energy (15*c*). Concerning the question of the reacting complex (or complexes)[7] in the catalysed reactions described here, our previous



Cx-**2**



Cx-**5**



Cx-**8**

work with simpler dienes (10) indicates that quinone **2** probably adds exclusively in the form shown in formula Cx-**2** (= complexed **2**). The postulate of Cx-**2** as the reacting species is, for example, sufficient to explain the exclusive formation of the "meta"-adduct in a reaction with *trans*-1,3-pentadiene (10). Because of the symmetry of **5**, its two carbonyl groups are identical and its reacting form must thus be Cx-**5**, the only uncertainty being the attachment of the catalyst *syn* or *anti* to the neighbouring methyl group. Finally, there is little doubt that, for electronic reasons, acetyl quinone **8** will complex at one (or both) carbonyl groups indicated in formula Cx-**8**. Since only one addition of the methoxy quinone **13** has been studied and since it is, furthermore, not a priori obvious which of the carbonyl groups in **13** could be expected to possess greater Lewis basicity, it would be unwise to speculate on the nature of the reacting complex of **13** at the present time.

Ring D Contraction

Dione **18**, prepared from diene **1** in two steps in a 65% yield, contains the number of carbon atoms and an arrangement of groups in ring D suitable for the creation of a 5-membered ring D with an acetyl group at C(17). Two methods were available in principle: a 1,2-rearrangement of a suitably reduced derivative leading directly to a 5-membered ring or a ring opening of a derivative by double-bond cleavage followed by ring closure. The latter proved more efficient.

Reduction of **18** with lithium aluminum tri-*tert*-butoxyhydride in tetrahydrofuran at room temperature gave alcohol **19**[8] in a 94% yield of isolated

[7]We have so far not succeeded in the determination of any of the quinone ⇌ complex equilibria by spectroscopic methods, mainly because of the apparent predominance of uncomplexed species. It should, furthermore, be noted that the "reacting complex" will be determined not only by these equilibria, but also by the relative rates of subsequent additions. A serious uncertainty concerns the form of diene **1** in these catalysed reactions. Since diene **1** polymerizes readily under acidic conditions (in the absence of dienophile), it proved impossible to examine **1** + Lewis acid spectroscopically. We assume that a large number of molecules of **1** are complexed (presumably on —OCH_3) under the reaction conditions, but that the more reactive uncomplexed molecules of **1** react with complexed quinone.

[8]The site of the reduction (but not the stereochemistry) follows rigorously from spectroscopic data. The stereochemical assignment is supported by a hydrogenation study (see Experimental).

crystalline product. Since ring D of **18** contains four trigonal carbon atoms, it is unlikely that this remarkable specificity arises simply from a preferred axial attack by hydride ion from the less hindered α-side. The situation is reminiscent of preferential hydride reductions of unsymmetrically substituted anhydrides at the apparently "more hindered" carbonyl group (18) and the observed result may be explicable by an electronic difference between the two carbonyl groups (19) and/or by the postulate that the angle of attack (20) by the reducing agent is such that the path to the C(17a)-carbonyl group is, in fact, less hindered.

Since alcohol **19** and the corresponding acetate prepared from it could not be reduced cleanly, **19** was converted to the unstable mesylate **20** which was, without purification, treated with zinc dust in boiling benzene–methanol (1:1) (21). The resulting mixture of α,β- and β,γ-unsaturated ketones was then equilibrated by treatment with sodium carbonate in boiling aqueous methanol to give pure ketone **21**. An 81% overall yield of crystalline **21** was obtained in the five steps from adduct **4** in a run in which intermediates were not purified.

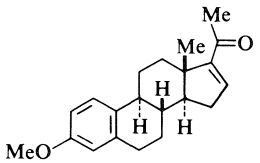
27

Catalytic hydrogenation of **21** with palladium on calcium carbonate in glacial acetic acid gave an 84% yield of crystalline **22**. An ir spectrum of the mother liquors showed no appreciable signal corresponding to a saturated carbonyl group, but the nmr spectrum indicated a second product, presumably isomeric at C(9). This reduction to **22** stabilized rings B and C and simplified subsequent transformations. It should be noted that, should C(11)-oxygenated derivatives be required in an application of this sequence, the appropriate electrophilic attack at C(11) could be performed using **21**.

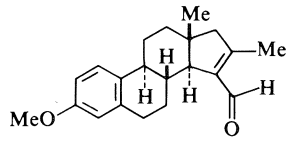
The following three-step sequence proved most efficient for the conversion of the C(15)-carbonyl group in **22** into a methylene group. Reduction of **22** with sodium bis(2-methoxyethoxy)aluminum hydride (22) in dry ether gave the mixture of epimeric alcohols **23** efficiently. In contrast, reductions with sodium borohydride and lithium aluminum hydride gave complex mixtures of products. Acetylation then led to acetate mixture **24**. Compounds **23** and **24** were not purified due to instability. Since the reported method using lithium in ethyl amine (23) not only reductively removed the acetoxyl function, but also reduced the anisol ring, the following milder modification was developed. Treatment of acetate mixture **24** with excess lithium in refluxing liquid ammonia and tetrahydrofuran led to crystalline olefin **25**, obtained in a 78% overall yield for the three steps from enone **22**.

The synthetic strategy used required that the ring D double-bond remain at C(16)—C(17) during the conversion **18** → **25**. While the method described above achieves this in high yield, it does involve six synthetic steps. All attempts, both at the enedione stage **18** and with enone **22**, to shorten the sequence by double reductions and by more vigorous reductions led to complex mixtures and to double-bond migrations. For example, treatment of **22** with zinc amalgam in boiling benzene–ethanol and concentrated hydrochloric acid gave a good yield of an olefin with two olefinic hydrogen atoms.

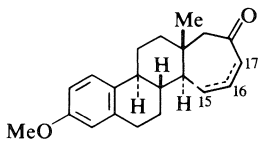
Olefin **25** has the functionality suitable for its conversion into a C(17)-acetyl derivative of estrone by a sequence involving double-bond cleavage and aldol condensation. Treatment of **25** with osmium tetroxide in dry pyridine (24) gave a mixture of two isomeric vicinal diols **26** which was converted by lead tetraacetate in tetrahydrofuran into oily keto aldehyde **27**, homogeneous in thin-layer chromatography. Finally, treatment of **27** with equal volumes



28



29



30 C_{15}—C_{16} olefin
31 C_{16}—C_{17} olefin

of tetrahydrofuran and 5% hydrochloric acid at 75°C for 40 h gave the desired crystalline enone **28** in a 60% yield based on olefin **25**. The nmr spectrum of mother liquors clearly indicated the formation of

a small amount of the alternative 5-membered ring D product, **29**.

The overall conversion **1** + **2** → **28** involves thirteen steps and is achieved in a 22% yield. This is a minimum yield since recrystallized intermediates were used at several stages.

The cyclization of keto aldehyde **27** deserves further comment. In contrast to previously reported results with similar systems (25), treatment of **27** with aqueous potassium hydroxide and tetrahydrofuran at reflux temperature for 16 h gave a mixture of three products, **28**, **30**, and **31**, in an approximate ratio of 1:3:1 and a total yield of 71%. No trace of cycloheptenones **30** and **31** could be detected in crystallization mother liquors from acidic cyclization of **27** described above. Basic treatment of pure **30** gave an equilibrium mixture of **30** and **31**. Basic treatment of **28** did not give any cycloheptenone products, while acidic treatment of **30** did not lead to any detectable amounts of cyclopentenes **28** and **29**. While these data do not reveal all details of the two cyclizations, they do indicate that the base catalysed condensation is probably governed by the preferential formation of the primary enolate ion (formed from **27**), while the reaction with acid proceeds via the more substituted enol. Depending on conditions used, a reasonable yield of five-membered or seven-membered ring D derivatives of keto aldehyde **27** can thus be obtained.

Enone **28** was converted to *d,l*-estrone methyl ether by the reported Beckmann rearrangement of the corresponding oxime and the subsequent hydrolysis of the resulting *N*-acetyl enamine (26). *d,l*-Estrone was then obtained by demethylation with pyridine hydrochloride (27). A detailed comparison of the synthetic compounds with natural estrone and with literature data is described in the Experimental.

For the synthesis of estrone itself and that of its simple derivatives, the strategy described above clearly does not match the elegant simplicity of the approach (28) based on an original discovery by Ananchenko and Torgov (29). It is longer and the direct preparation of optically active compounds would require a chiral induction in the catalysed Diels–Alder step **1** + **2** itself. However, it has certain advantages. (*1*) The C(9)—C(11) double-bond in intermediates **18**–**21** offers possibilities for the functionalization of ring C. (*2*) It automatically provides a C(17)-acetyl sidechain and a possibility of a nucleophilic attack at C(16) in enone **28**. (*3*) Formation of adduct **10** indicates that it should be possible to introduce a wide variety of C(13)-substituents. (*4*) Finally, as will be described in subsequent publications of this series,[9] the method works well with dienes possessing the C(10)-methyl group and with both quinonoid and non-quinonoid dienophiles. This provides opportunity for the direct total synthesis of C(10)-alkylated steroids for which, in our opinion, additional synthetic strategies are needed.

[9]See also refs. 11 and 30.

Experimental

Melting points were determined on a Kofler hot stage and are uncorrected. Ultraviolet (uv) spectra were recorded on a Perkin–Elmer 402 spectrophotometer in ethanol solution. The wavelengths are reported in nanometers (nm) with ε values in parentheses. Infrared (ir) spectra were determined on a Perkin–Elmer 457 instrument in chloroform solution. Values are given in wave-numbers (cm^{-1}) calibrated to the polystyrene band at 1601 cm^{-1}. Proton magnetic resonance (^{1}Hmr) spectra were obtained on a Varian T-60 spectrometer using deuterochloroform as solvent; chemical shift values are given in δ (ppm) scale relative to tetramethylsilane (TMS) used as internal reference. High resolution ^{1}Hmr spectra were recorded by the Canadian 220 MHz NMR Centre, Department of Medical Genetics, University of Toronto. Low resolution mass spectra (ms) were measured on a Hitachi Perkin–Elmer RMU-6D mass spectrometer. High resolution mass spectra were measured by Dr. A. M. Hogg, University of Alberta, Edmonton. Microanalyses were performed by Dr. F. Pascher, Mikroanalytisches Laboratorium, Bonn, West Germany. The following abbreviations have been used: s, singlet; d, doublet; dd, double doublet; t, triplet; m, multiplet; sh, shoulder; dec., decomposition; Et_2O, ethyl ether; Ac_2O, acetic anhydride.

Thermal Addition of 2,6-Dimethyl-1,4-benzoquinone. Adduct 3

Diene **1** (8) (680 mg, 5.0 mmol) and 2,6-dimethyl-1,4-benzoquinone (31) (950 mg, 5.1 mmol) were reacted in dry benzene (25 mL) under reflux for 24 h. The solvent was removed *in vacuo* and the residue crystallized from ethyl acetate to give **3** (1.323 g, 82.3%), mp 164–167°C; ir ν_{max}: 1680, 1610; ^{1}Hmr δ: 1.5 (3H, s, C(14)—CH_3), 2.1 (3H, d, J = 2 Hz, C(16)—CH_3), 3.8 (3H, s, CH_3O), 6.0 (1H, m, C(11)—H); ms *m/e*: 322 (M^+). *Mol. Wt.* calcd. for $C_{21}H_{22}O_3$: 322.1569; found (high resolution ms): 322.1575.

No isomer of **3** could be detected in the ^{1}Hmr spectrum of mother liquors. Compound **3** was unchanged after 1 h treatment with $NaHCO_3$ in boiling methanol.

Catalysed Addition of 2,6-Dimethyl-1,4-benzoquinone

A solution of diene **1** (2.380 g, 12.7 mmol) in Et_2O (5 mL) was added to a solution of quinone **2** (1.680 g, 12.4 mmol) and BF_3 etherate (2.320 g, 16.5 mmol) in 20 mL of Et_2O at −15°C. Light tan crystals of **4** began to form almost immediately. After 30 min, the crystals were collected by filtration and washed with Et_2O. Recrystallization from ethyl acetate gave adduct **4** (2.720 g, 69%), mp 194–196°C; ir ν_{max}: 1680 (broad), 1635, 1610; ^{1}Hmr δ: 1.4 (3H, s, C(13)—CH_3), 2.0 (3H, d, J = 2 Hz, C(17)—CH_3), 3.1 (1H, d, J = 5 Hz, C(14)—H), 3.8 (3H, s, CH_3O), 6.1 (1H, m, C(11)—H); ms *m/e*: 322 (M^+). *Mol. Wt.* calcd. for $C_{21}H_{22}O_3$: 322.1569; found (high resolution ms): 322.1570.

Adduct **3** (0.459 g, 11.4%) was obtained from concentrated ethyl acetate mother liquors.

Approximately the same yield and the same ratio of the two isomers was obtained in reactions at −20°C, 0°C, and at ambient temperature using 1.3, 2.0, and 2.3 mol equiv. of BF_3 etherate. The reaction was much slower with less than 1.0 mol equiv. of BF_3 etherate.

*Isomerization of Adduct **4** to **18***

Adduct **4** (1.610 g, 5.0 mmol) and $NaHCO_3$ (322 mg, 3.8

mmol) were suspended in dry methanol (100 mL). The mixture was stirred and heated under reflux until all of **4** had dissolved (30 min). About one half of the methanol was evaporated *in vacuo* and water (50 mL) was added. The light yellow precipitate was filtered and crystallized from methanol to give **18** (1.521 g, 94%), mp 148–149°C; ir ν_{max}: 1680, 1625, 1605; ^{1}Hmr δ: 1.2 (3H, s, C(13)—CH_3), 2.0 (3H, d, J = 2 Hz, C(17)—CH_3), 3.8 (3H, s, CH_3O), 6.1 (1H, m, C(11)—H); ms *m/e*: 322 (M^+). *Anal.* calcd. for $C_{21}H_{22}O_3$: C 78.23, H 6.88, O 14.89; found: C 78.39, H 6.92, O 14.86.

*Acidic Isomerization of Adducts **3** and **4***

Compound **4** (100 mg) was treated with Dowex 50-X in boiling ethanol (10 mL) for 15 h. The resin was removed by filtration and the solvent was evaporated *in vacuo* to give **16** (C(13)—CH_3, C(14)—H) (88 mg, 88%), mp 103–105°C (methanol). The yellow alcoholic solution of **16** (C(13)—CH_3, C(14)—H) instantaneously turns dark purple (enolate **17**) on addition of aqueous NaOH: ir ν_{max}: 1675, 1610; ^{1}Hmr δ: 1.3 (3H, s, C(13)—CH_3), 2.0 (3H, d, J = 2 Hz, C(17)—CH_3), 3.4 (1H, broad s, C(14)—H), 3.8 (3H, s, CH_3O), no signal in the 5.0–6.3 region; ms *m/e*: 322 (M^+).

Compound **3** (100 mg) was heated under reflux in glacial acetic acid (5 mL) for 30 min. Water (40 mL) was added and the product was extracted with Et_2O to give **16** (C(13)—H, C(14)—CH_3) (99 mg) obtained as a hard resin. Attempts to crystallize the compound were unsuccessful; similar results were obtained when **3** was treated with Dowex 50-X in methanol or with *p*-toluenesulfonic acid in benzene. Alcoholic solution of **16** (C(13)—H, C(14)—CH_3), did not change color on treatment with aqueous NaOH; ir ν_{max}: 1680, 1610; ^{1}Hmr δ: 1.5 (3H, s, C(14)—CH_3), 2.0 (3H, d, J = 2 Hz, C(16)—CH_3), 3.8 (3H, s, CH_3O), no signal in the 5.0–6.3 region; ms *m/e*: 322 (M^+).

*Thermal Addition of 2,5-Dimethyl-1,4-benzoquinone. Adduct **6***

Diene **1** (372 mg, 2.0 mmol) and 2,5-dimethyl-1,4-benzoquinone (32) (272 mg, 2.0 mmol) were reacted in dry benzene (10 mL) under reflux for 15 h. The solvent was evaporated *in vacuo* and the residue crystallized from Et_2O to give **6** (410 mg, 64%), mp 166–169°C (ethyl acetate). The mother liquor did not contain any amount of **7** or another isomer of **6** detectable by ^{1}Hmr spectroscopy; ir ν_{max}: 1680 (very broad), 1630, 1615; ^{1}Hmr δ: 1.5 (3H, s, C(14)—CH_3), 2.0 (3H, d, J = 2 Hz, C(17)—CH_3), 3.8 (3H, s, CH_3O), 6.0 (1H, m, C(11)—H); ms *m/e*: 322 (M^+). *Anal.* calcd. for $C_{21}H_{22}O_3$: C 78.23, H 6.88, O 14.89; found: C 78.00, H 6.85, O 14.82.

Catalysed Addition of 2,5-Dimethyl-1,4-benzoquinone

Diene **1** (372 mg, 2.0 mmol) and 2,5-dimethyl-1,4-benzoquinone (272 mg, 2.0 mmol) were dissolved in dry Et_2O (10 mL). A solution of BF_3 etherate (300 mg, 2.10 mmol) in dry Et_2O (5 mL) was added and the mixture was maintained at 0°C for 25 min. Addition of triethyl amine (1 mL) was followed by addition of water (25 mL), the organic layer was separated, dried, and evaporated *in vacuo*. The methyl region of the ^{1}Hmr spectrum of the crystalline residue indicated the presence of only two adducts in an ~3:1 ratio. Crystallization from ethanol gave **7** (257 mg, 40%), mp 151–152°C; ir ν_{max}: 1680 (broad), 1635, 1615; ^{1}Hmr δ: 1.4 (3H, s, C(13)—CH_3), 2.0 (3H, d, J = 2 Hz, C(16)—CH_3), 3.1 (1H, d, J = 5 Hz, C(14)—H), 3.8 (3H, s, CH_3O), 6.1 (1H, m, C(11)—H); ms *m/e*: 322 (M^+). *Anal.* calcd. for $C_{21}H_{22}O_3$: C 78.23, H 6.88, O 14.89; found: C 77.76, H 6.86, O 15.15.

A second crystallization crop (78 mg, 12.1%) was mainly **6** containing a small amount of **7** (^{1}Hmr spectrum). The actual yields in this catalysed addition are much higher than those given. The combined mother liquors contain only **6** and **7** as ^{1}Hmr detectable compounds.

*Reactions of Adducts **6** and **7***

Compound **6** was found to be stable to $NaHCO_3$ in boiling methanol. Treatment of **6** (100 mg) in boiling acetic acid (5 mL) for 30 min, followed by addition of H_2O (30 mL), extraction with $CHCl_3$, drying of the organic layer, and evaporation *in vacuo* gave a residue which was crystallized from methanol to give the $\Delta^{8,9}$-isomer of **6** (75 mg, 75%), mp 108–111°C. An alcoholic solution of this compound did not change color on treatment with aqueous NaOH; ir ν_{max} (CCl_4): 1685, 1640, 1615; ^{1}Hmr δ: 1.5 (3H, s, C(14)—CH_3), 2.0 (3H, d, J = 2 Hz, C(17)—CH_3), 3.8 (3H, s, CH_3O), no signal in the 5.0–6.3 region; ms *m/e*: 322 (M^+).

Adduct **7** (30 mg) was treated with $NaHCO_3$ (5 mg) in boiling methanol (5 mL) for 3 min. Water (15 mL) was added, the mixture was neutralized with dilute HCl, the solid was collected by suction and recrystallized from methanol to give 14-iso **7** (28 mg, 93%) mp 170–172°C; ir ν_{max}: 1680, 1630, 1610; ^{1}Hmr δ: 1.2 (3H, s, C(13)—CH_3), 2.1 (3H, d, J = 2 Hz, C(16)—CH_3), 3.8 (3H, s, CH_3O), 6.1 (1H, m, C(11)—H); ms *m/e*: 322.

Treatment of **7** (50 mg) in boiling acetic acid (3 mL) for 30 min, followed by addition of H_2O (15 mL), extraction with $CHCl_3$, drying of the organic layer, and evaporation *in vacuo* gave a yellow crystalline residue which was recrystallized from Et_2O to give the $\Delta^{8,9}$-isomer of **7** (45 mg, 90%), mp 141–144°C. Its alcoholic solution gave a dark purple color after addition of a drop of aqueous NaOH; ir ν_{max} (CCl_4): 1690, 1640, 1615; ^{1}Hmr δ: 1.3 (3H, s, C(13)—CH_3), 2.0 (3H, d, J = 2 Hz, C(16)—CH_3), 3.4 (1H, broad s, C(14)—H), 3.8 (3H, s, CH_3O), no signal in the 5.0–6.3 region; ms *m/e*: 322 (M^+).

Thermal Addition of 2-Acetyl-1,4-benzoquinone

Diene **1** (353 mg, 1.92 mmol) was dissolved in dry benzene (20 mL) at ambient temperature and 2-acetyl-1,4-benzoquinone (33) (240 mg, 1.60 mmol) was added in one portion. The reaction mixture at once became dark (π-complex), but after several min the colour disappeared and the reaction was completed. After 30 min, the solvent was evaporated *in vacuo* and yellow crystals (520 mg, 97%) were collected by filtration. The methyl region of the ^{1}Hmr spectrum (at 220 MHz) revealed the presence of only two adducts (singlets at δ 2.17 and 2.28) in a ratio of 1:7 (**10**:**9**). Recrystallization from Et_2O gave pure **9**, mp 139–140°C; ir ν_{max}: 1690 (broad), 1610; ^{1}Hmr δ: 2.3 (3H, s, C(14)—acetyl), 3.7 (1H, t, J = 7 Hz, C(13)—H), 3.8 (3H, s, CH_3O), 6.1 (1H, m, C(11)—H); ms *m/e*: 336 (M^+). *Mol. Wt.* calcd. for $C_{21}H_{20}O_4$: 336.1362; found (high resolution ms): 336.1359.

Reactions in dry Et_2O or in acetone at ambient temperature gave a comparable yield and ratio of products (1:7) as determined by ^{1}Hmr spectra. A reaction in which **1** (353 mg, 1.92 mmol) in boiling benzene (10 mL) was added rapidly to a boiling solution of quinone **8** (240 mg, 1.60 mmol) in benzene (10 mL) and in which the solution was evaporated *in vacuo* after 3 min gave a crystalline product (535 mg, ~100%) which according to the 220 MHz ^{1}Hmr spectrum contained adducts **10** and **9** in a ratio of 1:5.

Adduct **9** (84 mg, 0.25 mmol) was treated with concentrated HCl (2 drops) in $CHCl_3$ (10 mL) at ambient temperature for 30 min. Dilution with $CHCl_3$ (20 mL), washing with saturated $NaHCO_3$ solution and then H_2O, drying and evaporation *in vacuo* gave the crude $\Delta^{8,9}$-isomer of **9** (84 mg) as yellow foam; ir ν_{max}: 1710, 1680, 1610; ^{1}Hmr δ: 2.3 (3H, s, C(14)—acetyl), 3.5 (1H, dd, J = 6 and 4 Hz, C(13)—H), 3.8 (3H, s, CH_3O), no signal in the 5.0–6.3 region; ms *m/e*: 336 (M^+).

Pure adduct **10** was obtained in the following experiment.

Catalysed Addition of 2-Acetyl-1,4-benzoquinone

$AlCl_3$ (230 mg, 1.7 mmol), freshly sublimed in a stream of dry HCl gas, was added to a solution of quinone **8** (240 mg,

1.6 mmol) in dry CH_2Cl_2 (20 mL) cooled in a Dry Ice – acetone bath to −78°C. A cooled solution of diene **1** (350 mg, 1.9 mmol) in CH_2Cl_2 (5 mL) was added rapidly, the mixture stirred at −78°C for 20 min and poured into ice-water. Separation of the CH_2Cl_2 layer, Et_2O extraction of the aqueous layer, washing and drying of combined organic layers, and evaporation to a small volume *in vacuo* gave a yellow crystalline product (535 mg, ~100%). Its ^{1}Hmr spectrum established the **9**:**10** ratio to be approximately 1:3. The mixture was dissolved in boiling Et_2O (15 mL); on cooling, yellow crystals of pure **9** (130 mg), mp 139–140°C, separated. Concentration of the mother liquor to about 5 mL and cooling to −15°C gave crystals which on recrystallization under the same conditions gave pure adduct **10** (363 mg), mp 188–205°C dec.; ir ν_{max}: 1685 (broad); ^{1}Hmr δ: 2.2 (3H, s, C(13)—acetyl), 3.8 (3H, s, CH_3O), 3.9 (1H, d, one branch covered by CH_3O, C(14)—H), 6.0 (1H, m, C(11)—H); ms *m/e*: 336 (M^+). *Mol. Wt.* calcd. for $C_{21}H_{20}O_4$: 336.1362; found (high resolution ms): 336.1366.

Isomerization of **10** (84 mg, 0.25 mmol) with HCl was done in the same way as with adduct **9** (see above). The resulting yellow foam (84 mg) crystallized from Et_2O to give pure $\Delta^{8,9}$-isomer of **10**, mp 131–132°C; ir ν_{max}: 1710 (sh), 1675, 1600; ^{1}Hmr δ: 2.3 (3H, s, C(13)—acetyl), 3.8 (3H, s, CH_3O), 4.0 (1H, broad s, C(14)—H), no signal in the 5.0–6.3 region; ms *m/e*: 336 (M^+).

*Thermal Addition of 2-Carbomethoxy-6-methyl-1,4-benzoquinone (**11**)*

A solution of quinone **11** (34) (1.800 g, 10.0 mmol) in dry Et_2O (50 mL) was added to diene **1** (1.953 g, 10.5 mmol) in dry Et_2O (50 mL) cooled in an ice–salt bath to −20°C. Crystalline product started to separate immediately. The mixture was stirred at −20°C for 1 h and at ambient temperature for 2 h. Filtration gave adduct **12** (3.220 g, 88%) as yellow crystals, mp 192–195°C (ethyl acetate); ir ν_{max}: 1750, 1730, 1715, 1685, 1615; ^{1}Hmr δ: 2.1 (3H, d, J = 2 Hz, C(16)—CH_3), 3.6 (1H, t, left branch covered by CH_3O, J = 8 Hz, C(13)—H), 3.8 (6H, s, $2CH_3O$), 6.1 (1H, m, C(11)—H); ^{1}Hmr (220 MHz) δ: clear t at 3.6 (1H, J = 8 Hz, C(13)—H); ms *m/e*: 366 (M^+). *Anal.* calcd. for $C_{22}H_{22}O_5$: C 72.11, H 6.05, O 21.83; found: C 71.99, H 5.96, O 21.84.

The same result and yield of crystalline **12** (88%) was also obtained in reactions in Et_2O at −20°C for 60 min, and in Et_2O or benzene at 22°C for 60 min.

*Reactions of Adduct **12***

Adduct **12** remained unchanged on treatment with $NaHCO_3$ in boiling methanol.

Adduct **12** (366 mg, 1.0 mmol) was treated with sodium acetate (100 mg) in boiling Ac_2O (10 mL) for 75 min. The solvent was removed *in vacuo*, the residue treated with dry Et_2O (50 mL), sodium acetate removed by filtration, and Et_2O evaporated to give the $\Delta^{13,17a}$-enol acetate of **12** (316 mg, 77%) as dark yellow crystals, mp 218–220°C; ir ν_{max}: 1760 (broad), 1650, 1610; ^{1}Hmr δ: 2.0 (3H, d, J = 2 Hz, C(16)—CH_3), 2.3 (3H, s, O-acetyl), 3.7 (3H, s, CH_3O), 3.8 (3H, s, CH_3O), 5.7 (1H, m, C(11)—H); ms *m/e*: 408 (M^+).

The **12**-enol acetate (100 mg, 0.25 mmol) was treated with dry Na_2CO_3 (100 mg) in boiling methanol (5 mL) for 30 min. After stirring at ambient temperature for an additional 2 h, H_2O (5 mL) was added and the precipitate recrystallized from ethyl acetate to give pure **12** (72 mg, 79%).

The above hydrolysis of **12**-enol acetate was repeated using CH_3OD and D_2O to give **12** deuterated at C(13), mp 190–192°C; ^{1}Hmr δ: no signal at 3.6, m at 2.4–2.7 narrower; ms *m/e*: 367 (M^+).

Adduct **12** (100 mg) was treated with Dowex-50X resin (50 mg) in boiling 95% ethanol (10 mL) for 6 h. Removal of the resin by filtration and evaporation of the solvent *in vacuo* gave a yellow solid which could not be crystallized. Precipitated from hot methanol, it melted at 101–115°C dec.; ir ν_{max} (CCl_4): 1750, 1690, 1615; ^{1}Hmr δ: 2.0 (3H, d, J = 2 Hz, C(16)—CH_3), 3.7 (1H, m, C(13)—H), 3.8 (6H, s, $2CH_3O$), no signal in the 5–6.3 region; ms *m/e*: 366 (M^+). This $\Delta^{8,9}$-isomer of **12** did not give an extended chromophore on treatment of its ethanolic solution with NaOH.

Thermal Addition of 6-Methoxy-1,4-toluquinone

Diene **1** (93 mg, 0.50 mmol) was treated with quinone **13** (35) (76 mg, 0.50 mmol) in boiling benzene for 15 h. Evaporation of solvent *in vacuo* and crystallization from ethyl acetate gave **14** (81 mg, 48%), mp 165–167°C; ir ν_{max}: 1710, 1670, 1610; ^{1}Hmr δ: 1.5 (3H, s, C(14)—CH_3), 3.8 (6H, s, $2CH_3O$), 5.9 (1H, s, C(17)—H), 6.0 (1H, m, C(11)—H), the 1.7–3.0 region similar to that of **3** and different from that of **4**; ms *m/e*: 338 (M^+). *Mol. Wt.* calcd. for $C_{21}H_{22}O_4$: 338.1518; found (high resolution ms): 338.1516. *Anal.* calcd. for $C_{21}H_{22}O_4$: C 74.50, H 6.55, O 18.95; found: C 74.15, H 6.57, O 19.21.

No isomeric adduct was detectable in crystallization mother liquors.

Catalysed Addition of 6-Methoxy-1,4-toluquinone

A solution of diene **1** (186 mg, 1.0 mmol) in dry Et_2O (5 mL) was added to a solution of **13** (152 mg, 1.0 mmol) and BF_3 etherate (300 mg, 2.1 mmol) in dry Et_2O (5 mL) at 0°C. After 20 min, triethylamine (1 mL) and then H_2O (20 mL) was added, Et_2O layer separated, washed, dried, and evaporated. Crystallization from ethyl acetate gave **14** (105 mg, 31%), mp 163–166°C. No isomeric adduct was detectable in the total reaction product and in crystallization mother liquors.

*Reduction of Enedione **18***

A solution of **18** (1.530 g, 4.72 mmol) and lithium aluminum tri-*tert*-butoxyhydride (2.000 g, 7.88 mmol) in dry tetrahydrofuran (50 mL) was stirred at ambient temperature for 15 min. Dilution with H_2O, extraction with $CHCl_3$, drying of the organic extract with $MgSO_4$, and evaporation *in vacuo* gave a white solid which was filtered and washed with Et_2O to give **19** (1.433 g, 94%), mp 211–213°C (ethanol–Et_2O); ir (KBr) ν_{max}: 1650 (broad), 1610, 1575; ^{1}Hmr δ: 0.9 (3H, s, C(13)—CH_3), 2.0 (3H, narrow m, C(17)—CH_3), 3.8 (3H, s, CH_3O), 4.3 (1H, m, C(17a)—H), 5.9 (2H, m, C(11)—H and C(16)—H); ms *m/e*: 324 (M^+). *Mol. Wt.* calcd. for $C_{21}H_{24}O_3$: 324.1726; found (high resolution ms): 324.1731.

*Reactions of Alcohol **19**. Catalytic Hydrogenation of **18** and **19** (R = O-acetyl)*

A mixture of **19** (R = OH) (180 mg), sodium acetate (50 mg), and Ac_2O (10 mL) was refluxed for 2 h. Ac_2O was removed *in vacuo*, the residue was dissolved in benzene, sodium acetate filtered off, solvent evaporated, and the residue crystallized from ether to give **19** (R = O-acetyl) (178 mg, 84%), mp 182–184°C; ir (KBr) ν_{max}: 1750, 1680, 1655, 1640, 1615; ^{1}Hmr δ: 1.0 (3H, s, C(13)—CH_3), 1.9 (3H, narrow m, C(16)—CH_3), 2.2 (3H, s, acetyl), 3.8 (3H, s, CH_3O), 5.9 (3H, dm, C(11)—H, C(16)—H and C(17a)—H); ms *m/e*: 366 (M^+).

Acetate **19** (R = O-acetyl) (70 mg) was dissolved in hot ethanol (15 mL), solution cooled to ambient temperature, PtO_2 (5 mg) added, and the mixture stirred in H_2 atmosphere at normal pressure for 60 min. The catalyst was filtered, washed with hot $CHCl_3$, the solvent was removed *in vacuo* and the residue was crystallized from $CHCl_3$–Et_2O to give tetrahydro-**19** (R = O-acetyl) (64 mg, 90%), mp 172–175°C; ir (KBr) ν_{max}: 1740, 1720, 1615; ^{1}Hmr δ: 0.9 (3H, s, C(13)—CH_3), 1.0 (3H, d, J = 7 Hz, C(17)—CH_3), 2.2 (3H, s, acetyl), 3.8 (3H, s, CH_3O), 5.1 (1H, d, J = 5 Hz, C(17a)—H); ms *m/e*: 370 (M^+).

Since a single isomer was obtained in high yield in this hydrogenation, it is assumed that the newly introduced H-atoms at C(9) and C(17) are both α.

A mixture of enedione **18** (100 mg) and PtO_2 (10 mg) in methanol (10 mL) was stirred in H_2 atmosphere at normal pressure. Three mol equivalents of H_2 were absorbed in 10 min, The usual workup gave a residue which on crystallization from Et_2O–hexane afforded hexahydro-**18** (99 mg, ~98%), mp 173–176°C; ir ν_{max}: 3610, 3480 (broad), 1720, 1615, 1580; ^{1}Hmr δ: 0.8 (3H, s, C(13)—CH_3), 1.0 (3H, d, J = 7 Hz, C(17)—CH_3), 3.8 (3H, s, CH_3O), 3.9 (1H, d, J = 5 Hz, C(17a)—H); ms *m/e*: 328 (M^+).

Acetylation of this hexahydro-**18** compound (100 mg) in boiling Ac_2O (5 mL), followed by crystallization of the residue from $CHCl_3$–Et_2O gave a compound (98 mg, 86%), mp 172–175°C, identical in all respects with tetrahydro-**19** (R = O-acetyl) described above. The fact that the same C(17a)-epimer is obtained as the only product by catalytic hydrogenation and by hydride reduction of the C(17a)-carbonyl group in **18** provides strong support for the stereochemistry assigned to **19**.

*Conversion of **19** to **21***

Alcohol **19** (1.433 g, 4.42 mmol) was reacted with mesyl chloride (1.140 g, 10 mmol) in dry pyridine (20 mL) at 0°C for 16 h. The solution was diluted with H_2O (80 mL) and extracted with $CHCl_3$. Combined $CHCl_3$ extracts were washed with 5% HCl and brine and dried over $MgSO_4$. Removal of the solvent *in vacuo* and crystallization of the residue from Et_2O–hexane gave crude **20** (1.420 g, 78%); ir ν_{max}: 1680, 1660 (sh), 1640 (sh), 1610; ^{1}Hmr δ: 0.9 (3H, s, C(13)—CH_3), 2.0 (3H, narrow m, C(17)—CH_3), 3.2 (3H, s, mesyl), 3.8 (3H, s, CH_3O), 5.5 (1H, m, C(17a)—H), 6.0 (2H, m, C(11)—H and C(16)—H).

Crude mesylate **20** (1.420 g, 3.53 mmol) was refluxed in benzene–methanol (1:1, 100 mL) for 12 h with freshly activated Zn dust. Fresh portions of Zn were added every few hours; the total of Zn used was 6 g. The mixture was filtered, the solid washed with benzene, the combined filtrate extracted with H_2O, and the organic layer dried over $MgSO_4$ and evaporated *in vacuo* to give a crystalline residue (1.176 g, ~100%) showing two spots on tlc and consisting of **21** and its β,γ-unsaturated isomer (nmr, ir).

The mixture was treated with Na_2CO_3 (0.5 g) in boiling methanol (100 mL) and H_2O (5 mL) for 30 min. Dilution with H_2O (200 mL), extraction with benzene, drying over $MgSO_4$, evaporation *in vacuo*, and crystallization of the residue from benzene–hexane gave **21** (900 mg, 83%), mp 174–176°C; ir (KBr) ν_{max}: 1670, 1650 (sh), 1640 (sh), 1610; ^{1}Hmr δ: 0.9 (3H, s, C(13)—CH_3), 1.9 (3H, broad s, C(17)—CH_3), 3.8 (3H, s, CH_3O), 5.9 (2H, m, C(11)—H and C(16)—H). *Mol. Wt.* calcd. for $C_{21}H_{24}O_2$: 308.1776; found (high resolution ms): 308.1777.

*Conversion of Adduct **4** to **21** without Purification of Intermediates*

Adduct **4** (1.610 g, 5.0 mmol) was isomerized with $NaHCO_3$ (322 mg) in methanol (100 mL). Partition of the product between H_2O and $CHCl_3$ and evaporation of solvent *in vacuo* gave crude **18** which was reduced with lithium aluminum tri-*tert*-butoxyhydride (2.000 g, 7.88 mmol) in dry tetrahydrofuran (50 mL). Partition of the product between H_2O and $CHCl_3$ and evaporation of $CHCl_3$ *in vacuo* gave crude **19** from which mesylate **20** was prepared as described above. The crude mesylate was reduced with Zn dust (6 g) in boiling benzene–methanol (1:1, 100 mL). After solid material was removed by filtration, K_2CO_3 (2.0 g) in H_2O (5 mL) was added, the mixture refluxed for 30 min, and the product obtained by partition between H_2O and benzene. Drying over $MgSO_4$, evaporation *in vacuo*, and crystallization from benzene–hexane gave light tan needles of **21** (1.254 g, 81% for the 5 steps), mp 174–176°C.

*Catalytic Reduction of **21***

Enone **21** (930 mg, 3.0 mmol) was hydrogenated in glacial acetic acid (20 mL) containing 10% Pd on $CaCO_3$ (100 mg) at normal pressure until 1 mol of H_2 was taken up. After filtration and washing of the catalyst with benzene, the filtrate was neutralized with aqueous $NaHCO_3$ and the product extracted with benzene. Drying over $MgSO_4$, evaporation *in vacuo* and crystallization from benzene–hexane gave **22** (785 mg, 84%), mp 142–144°C; ir (KBr) ν_{max}: 1675, 1640, 1600, 1580; ^{1}Hmr δ: 0.9 (3H, s, C(13)—CH_3), 1.9 (3H, broad s, C(17)—CH_3), 3.8 (3H, s, CH_3O), 3.8 (1H, narrow m, C(16)—H). *Mol. Wt.* calcd. for $C_{21}H_{26}O_2$: 310.1933; found (high resolution ms): 310.1930.

*Conversion of Enone **22** to Olefin **25***

Sodium bis(2-methoxyethoxy)aluminum hydride (0.84 mL of 70% benzene solution, 6.0 mmol) was added dropwise to a solution of **22** (752 mg, 2.42 mmol) in dry Et_2O (20 mL) at ambient temperature. The mildly exothermic reaction was completed in ~10 min. The complex was destroyed with a small quantity of 2.5% aqueous KOH, product extracted with Et_2O, solution washed with brine, dried over $MgSO_4$, and evaporated *in vacuo* (20°C) to give crude **23** (755 mg): two spots in tlc; ir (CCl_4) ν_{max}: 3620, 1610; ^{1}Hmr δ: 0.9 and 1.0 (total 3H, two s in 1:4 ratio, C(13)—CH_3), 1.7 (3H, narrow m, C(17)—CH_3), 3.8 (3H, s, CH_3O), 4.3 (1H, broad m, C(15)—H), 5.7 (1H, m, C(16)—H). Compound **23** slowly decomposed on chromatography and on heating its solutions above 20°C.

Crude **23** (755 mg, 2.42 mmol) was treated with freshly distilled Ac_2O (15 mL) in dry pyridine (15 mL) at ambient temperature for 72 h. Dilution with Et_2O, neutralization with aqueous $NaHCO_3$, repeated extraction with Et_2O, washing of combined extracts with 5% aqueous HCl and brine, drying over $MgSO_4$, and evaporation *in vacuo* (all operations at or below 20°C) gave crude **24** (~800 mg); ir (CCl_4) ν_{max}: 1730, 1610; ^{1}Hmr δ: 0.9 and 1.0 (total 3H, two s, C(13)—CH_3), 1.7 (3H, broad s, C(17)—CH_3), 2.0 (3H, s, acetyl), 3.8 (3H, s, CH_3O), 5.3–5.7 (2H, two m, C(16)—H and C(15)—H).

Crude **24** from above was dissolved in dry tetrahydrofuran (50 mL) and added to liquid NH_3 (200 mL). The solution was allowed to reflux (−33°C) and Li metal (100 mg, 14.5 mmol) was added; deep blue color persisted during the reaction. After 30 min, small portions of solid NH_4Cl were added until color had discharged, NH_3 allowed to evaporate, residue in Et_2O washed with 5% aqueous HCl and brine, dried over $MgSO_4$, solvent evaporated *in vacuo*, and residue crystallized from Et_2O–methanol to give platelets of **25** (557 mg, 78% from **22**), mp 96–97°C (lit. (36) mp 96°C); ir (KBr) ν_{max}: 1610, 1580; ^{1}Hmr δ: 0.8 (3H, s, C(13)—CH_3), 1.7 (3H, broad s, C(17)—CH_3), 3.8 (3H, s, CH_3O), 5.4 (1H, m, C(16)—H). *Mol. Wt.* calcd. for $C_{21}H_{28}O$: 296.2141; found (high resolution ms): 296.2141.

*Formation of Keto Aldehyde **27***

A solution of olefin **25** (500 mg, 1.69 mmol) in dry pyridine (17 mL) containing OsO_4 (476 mg, 1.87 mmol) was stirred at ambient temperature for 2 h. $NaHSO_3$ (1.02 g, 9.8 mmol) in H_2O (10 mL) was added and the solution was stirred at 20°C for 30 min. The light red solution was poured into brine, extracted with $CHCl_3$, combined $CHCl_3$ extracts were washed with 5% aqueous HCl, dried over $MgSO_4$, and evaporated *in vacuo* to give crude diol **26** (~560 mg) showing two spots in tlc.

Crude **26** (560 mg, 1.69 mmol) in dry tetrahydrofuran (15 mL) was treated with lead tetraacetate (914 mg, 2.06 mmol)

at 0°C for 5 min. Partition between $CHCl_3$ and a saturated $NaHCO_3$ solution, washing of organic layer with 5% aqueous HCl, drying over $MgSO_4$, and evaporation *in vacuo* gave oily **27** (550 mg, ~99%), homogeneous in tlc; ir (CCl_4) ν_{max}: 2710, 1720 (broad), 1610; ^{1}Hmr δ: 0.9 (3H, s, C(13)—CH_3) 2.0 (2H, s, —CH_2—C=O), 2.3 (3H, s, CH_3—C=O), 3.7 (3H, s, CH_3O), 9.7 (1H, narrow t, —CH=O); ms *m/e*: 328 (M^+). Due to instability, **27** was not purified further.

Cyclization to ***28***

Crude **27** (550 mg, 1.68 mmol) was heated in tetrahydrofuran (20 mL) and 5% aqueous HCl (20 mL) at 75°C for 40 h. The solution was poured into brine, extracted with $CHCl_3$, organic extracts dried over $MgSO_4$, and evaporated *in vacuo* to give crude product (520 mg) which was crystallized from methanol yielding yellowish needles of **28** (317 mg, 60.5%), mp 160–161.5°C (acetone–methanol) (lit. (36) mp 161–163°C); ir (KBr) ν_{max}: 1660, 1610, 1585; uv λ_{max}: 229 (14 000), 277 (2 700), 287 (2 380); ^{1}Hmr δ: 0.9 (3H, s, C(13)—CH_3), 2.3 (3H, s, CH_3—C=O), 3.8 (3H, s, CH_3O), 6.8 (1H, m overlapping with aromatic protons, C(16)—H). *Mol. Wt.* calcd. for $C_{21}H_{26}O_2$: 310.1933; found (high resolution ms): 310.1927.

The ^{1}Hmr spectrum of the residue (~200 mg) from crystallization of **28** indicated the presence of aldehyde **29** (signal at δ 10.0, s) and of additional **28**.

Base Catalysed Condensation of ***27***

A solution of **27** (80 mg, 0.24 mmol) in tetrahydrofuran (1 mL) and 2.5% aqueous KOH (5 mL) was heated to reflux under N_2 for 16 h. Extraction with $CHCl_3$, washing of combined extracts with 5% aqueous HCl and brine, drying over $MgSO_4$, and evaporation *in vacuo* gave a residue which was purified by preparative tlc (silica gel, Et_2O – petroleum ether, 3:7) to give:

28 (10 mg, 13%), mp 159–161°C;

30 (32 mg, 40%), mp 151–153°C (methanol); ir (CCl_4) ν_{max}: 1710, 1670 (small), 1610; ^{1}Hmr δ: 1.0 (3H, s, C(13)—CH_3), 3.8 (3H, s, CH_3O), 5.8 (2H, m, C(15)—H and C(16)—H); ms *m/e*: 310 (M^+);

31 (14 mg, 18%), oily; ir (CCl_4) ν_{max}: 1665 (broad), 1610; uv λ_{max}: 220 (10 800); ^{1}Hmr δ: 1.0 (3H, s, C(13)—CH_3), 2.5 (2H, s, —CH_2—C=O), 3.8 (3H, s, CH_3O), 6.0 (1H, dm, $J \simeq 12$ Hz, C(17)—H), 6.5 (1H, m, overlapping with aromatic protons, C(16)—H); ms *m/e*: 310 (M^+).

d,l-*Estrone Methyl Ether*

A solution of **28** (242 mg, 0.78 mmol) in pyridine (4 mL) and ethanol (20 mL) containing $NH_2OH \cdot HCl$ (139 mg, 2.20 mmol) was heated under reflux for 45 min. Solution in $CHCl_3$, washing with 5% aqueous HCl and brine, drying over $MgSO_4$, and evaporation *in vacuo* gave crude oxime (270 mg), mp 178–184°C.

The oxime was reacted with methanesulfonyl chloride (0.4 mL, 5.2 mmol) in dry pyridine (12 mL) at 0°C for 30 min and at 20°C for 3 h. Water was added and the product was extracted with $CHCl_3$. The solvent was removed *in vacuo* and the residue dissolved in methanol (20 mL) containing 5% aqueous NaOH (5 mL). This solution was refluxed for 3 h, partitioned between H_2O and $CHCl_3$, and the combined extracts dried over $MgSO_4$ and evaporated *in vacuo*. Crystallization of the residue gave *d,l*-estrone methyl ether (90 mg) and additional product (28 mg) was obtained by preparative tlc on silica gel for a total yield of 53%, mp 140–143°C (acetone–methanol) (lit. (27) mp 143–144°C); ir ν_{max}: 1730, 1610, 1570; (KBr) 1740, 1710, 1680; ^{1}Hmr δ: 0.9 (3H, s, C(13)—CH_3), 3.8 (3H, s, CH_3O).

The synthetic material was found identical in ir spectra ($CHCl_3$ and KBr), ^{1}Hmr spectra, and ms with the methyl ether prepared (27) from natural *d*-estrone. The synthetic and natural materials were also found identical on tlc with several solvent systems.

d,l-*Estrone*

The methyl ether (35 mg, 0.12 mmol) was mixed with freshly prepared pyridine hydrochloride (1.0 g) and heated at 210°C under N_2 for 40 min. The cooled mixture was dissolved in $CHCl_3$, the solution washed with 5% aqueous HCl and brine, dried over $MgSO_4$, and the solvent evaporated *in vacuo*. The residue was dissolved in Et_2O and the product extracted with 17% aqueous KOH. Acidification of the aqueous layer, extraction with ether, drying over $MgSO_4$, removal of solvent *in vacuo*, and crystallization of the residue from methanol gave *d,l*-estrone (13 mg, 59%), mp 249–253°C (acetone) (lit. (27) mp 251–254°C); ir ν_{max}: 3610 (sharp), 3340 (broad), 1735, 1610; ms *m/e*: 242 (M^+).

Synthetic *d,l*-estrone was found to be identical with natural estrone in ir ($CHCl_3$), ms, and tlc.

Acknowledgements

Support of this work by the National Research Council of Canada in the form of operating grants and of fellowships to R.K. and G.A.M. is gratefully acknowledged. A generous quantity of quinone **2** was kindly donated by the Hoffmann-La Roche Co., Nutley, N.J. We thank Professor Pierre Deslongchamps, Université de Sherbrooke, for many discussions in which, several years ago, the orientation problem in general and the possibility of steroid syntheses by a guided Diels–Alder reaction in particular received thorough attention.

1*H*-Pyridazino[3,4,5-de]phthalazine (**4**) and 3-hydrazino-1(or 9)*H*-pyridazino[3,4,5-de]-phthalazine (**6**) represent intramolecular hydrazones of the drugs hydralazine and dihydralazine, respectively. These novel heterocycles were synthesized by several different routes starting from 2,6-dimethylbenzoic acid, 3-methylphthalic anhydride, or hemimellitic acid. Tetrabromination of 2,6-dimethylbenzoic acid with bromine and carbon tetrachloride under free radical conditions followed by treatment with dilute aqueous hydrazine hydrate produced pure **4** in yields up to 58%. Treatment of 3-methylphthalic anhydride with 2 mol of *N*-bromosuccinimide under radical conditions followed by reaction of the dibromo compound with hydrazine hydrate in methyl Cellosolve produced 3-oxo-3*H*-2,9(or 1,2)-dihydropyridazino[3,4,5-de]phthalazine in 60% yield. This intermediate was converted to the 3-thiono compound or 3-chloro-1(or 9)*H*-pyridazino[3,4,5-de]phthalazine from which the hydrazine **6** was generated by hydrazine hydrate treatment. This hydrazine was further characterized by conversion with acid chlorides to novel tetracyclic condensed triazoles or by nitrous acid to a tetracyclic condensed tetrazole. The unsubstituted heterocycle **4** was uninteresting in pharmacological screens but the hydrazine **6** resembled hydralazine by lowering blood pressure in several animal test models and in limited clinical trials.

JOHN E. FRANCIS, KARL J. DOEBEL, PAULA M. SCHUTTE, EDGAR C. SAVARESE, STEPHEN E. HOPKINS et ERNST F. BACHMANN. Can. J. Chem. **57**, 3320 (1979).

Les composés suivants: 1*H*-pyridazino[3,4,5-de] phtalazine (**4**) et hydrazino-3 1*H* ou 9*H*-pyridazino[3,4,5-de] phtalazine (**6**) représentent des hydrazones intramoléculaires dans les drogues hydralazine et dihydralazine respectivement. Ces nouveaux hétérocycles sont synthétisés selon différentes méthodes en partant de l'acide diméthyl-2,6 benzoïque, de l'anhydride méthyl-3 phtalique ou de l'acide hémimellitique. La tétrabromation de l'acide diméthyl-2,6 benzoïque par le brome dans le tétrachlorure de carbone sous forme de radical libre suivi du traitement par l'hydrate d'hydrazine diluée produit le composé **4** à l'état pur avec des rendements pouvant atteindre 58%. Le traitement de l'anhydride méthyl-3 phtalique avec 2 mol de *N*-bromosuccinimide dans des conditions radicalaires suivi de la réaction du composé dibromé avec l'hydrate d'hydrazine dans le méthyl Cellosolve conduit au dérivé: oxo-3 3*H*-dihydro-2,9 (ou 1,2) pyridazino[3,4,5-de] phtalazine avec un rendement de 60%. Cet intermédiaire est transformé en composé thiono-3 ou chloro-3 1 (ou 9) *H* pyridazino[3,4,5-de] phtalazine qui traité par l'hydrate d'hydrazine conduit à l'hydrazine **6**. Cet hydrazine est de plus caractérisé par sa transformation en triazoles tétracycliques condensés à l'aide de chlorures d'acides ou en tétrazoles tétracycliques condensés. L'hétérocycle **4** non substitué n'est pas intéressant du point de vue pharmacologique mais l'hydrazine **6** ressemble à l'hydralazine en ce sens qu'elle fait baisser la pression sanguine lors de plusieurs tests chez les animaux et dans des essais cliniques limités.

[Traduit par le journal]

The antihypertensive drug hydralazine (**1**) synthesized by Druey more than thirty years ago (1) has staged a comeback recently (2) because the disturbing side effects produced by the body's reaction to the arteriolar dilating mechanism of action are counteracted by co-administration of a diuretic agent and a β-adrenergic blocking drug (3). Although the combination of a diuretic and a β-blocker is effective in the treatment of many patients with high blood pressure, the addition of an arteriolar dilating agent is effective for the treatment of a further population of resistant cases (4).

Druey prepared many modifications of the hydralazine structure, including dihydralazine (**2**), marketed in Europe. He also defined the most important structure–activity relationships in this class of compounds and suggested that the hydrazones of hydralazine could be useful prodrugs of the active principle (5). This concept is supported by a report on the investigational drug budralazine (**3**) (6) that

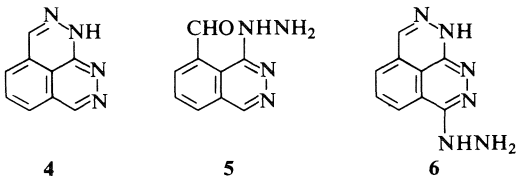
1 2 3

describes the metabolic pattern of this drug as similar to that of hydralazine (7, 8). Hydrazones of hydralazine derived from acetone, pyruvic acid, and α-ketoglutaric acid were identified in the serum and urine of patients taking hydralazine and these compounds may contribute significantly to the action of the parent drug (8).

On the basis of Druey's hypothesis, we investigated a novel heterocyclic system that is formally an internal hydrazone of hydralazine, namely, 1*H*-pyridazino[3,4,5-de]phthalazine (**4**),[2] the intramolecular cyclization product of the hitherto unknown 1-hydrazinophthalazine-8-carboxaldehyde (**5**). In the course of this work, we prepared a similar structure related to dihydralazine, namely, the hydrazino compound **6**, a second important target.

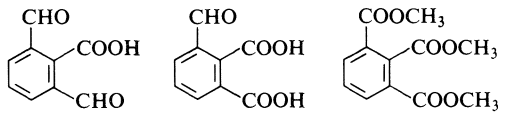


4 5 6

Since portions of this work have appeared only in the patent literature (9, 10) and in reviews (11, 12), we wish to describe the synthesis of the target compounds, some of the properties of this novel heterocyclic system, and the biological results related to the rationale for this project.

In designing the synthesis of these compounds, we saw that all nine carbon atoms could be derived from an oxidized 1,2,3-trimethylbenzene, in which the 2-methyl group is at the highest oxidation stage (carboxylic acid or equivalent) and the 1- and 3-substituents are at the aldehyde stage or the carboxylic acid stage. The nitrogen atoms could then be introduced by the use of hydrazine. Therefore, the heterocycle **4** would be prepared from 2,6-diformylbenzoic acid (**7**) or an equivalent synthon, whereas the hydrazine **6** would be generated from 3-formylphthalic acid (**8**) or equivalent. A hemimellitic acid derivative, such as the triester **9**, seemed another likely starting material as it could be reacted with hydrazine and then reduced to the desired product. In fact, we carried out all of these proposed schemes successfully.

The unsubstituted heterocycle was prepared first by a straightforward approach. 2,6-Dimethylbenzoic acid (**10**) (13) was converted to 2,6-bis(dibromomethyl)benzoic acid (**11**) smoothly with 4 mol of

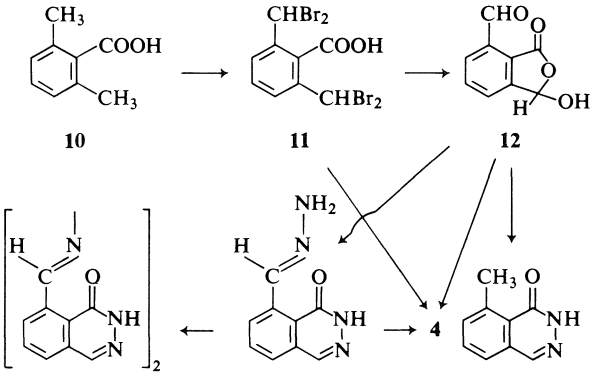


7 8 9

bromine in carbon tetrachloride at reflux under tungsten lamp illumination. The tetrabromo compound crystallized directly from the reaction, usually in high yield and good purity. The reaction was unsuccessful when *N*-bromosuccinimide was tried. Treatment of **11** with aqueous base followed by aqueous acid gave the desired intermediate, assigned structure **12** rather than **7** based on infrared spectral data indicating a hydroxyphthalide structure (14, 15). Either **11** or **12** on prolonged reflux in a 10–15% solution of hydrazine hydrate (99–100%) in water yielded the desired heterocycle **4**. When the reaction was worked up after an hour or hydrazine hydrate in ethanol was used as the reaction medium, the hydrazone of 1(2*H*)-phthalazinone-8-carboxaldehyde (**13**) was the only product isolated. Attempted purification of **13** by recrystallization from water, methyl Cellosolve, acetic acid, or attempted derivatization with benzaldehyde or acetic anhydride yielded only the highly insoluble azine **14** on workup. Attempted intramolecular cyclization of **13** in hot dimethylformamide or dimethylacetamide produced some of the desired tricyclic product but contaminated by starting material and unidentified impurities. The dry hydrazone could be sublimed unchanged but attempted aqueous acidic hydrolysis or treatment with aqueous sodium hydroxide produced the azine. Attempted cyclization in 10% aqueous organic bases such as piperidine or pyridine produced largely the azine and only traces of the desired heterocycle. However, when the hydrazone was heated at reflux in 10% aqueous hydrazine hydrate for a day, the tricyclic structure was obtained in good yield. The aldehyde **12** was reacted with more concentrated aqueous hydrazine hydrate in attempts to improve the yield and reduce the amount of solvent. Up to a strength of 40% hydrazine hydrate, the yield of **4** was still acceptable although contamination increased, but with 60 or 85% aqueous hydrazine hydrate, the hydrazone **13** was the only isolable product after

[2]In previous publications and patents, compounds with this ring system were called 1,2,8,9-tetraazaphenalenes. The text name is preferred by Chemical Abstracts.

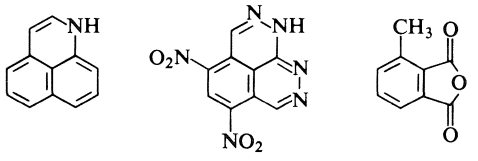
three days at reflux. After one week at reflux, the only isolable product, surprisingly, was the Wolff–Kishner product 8-methyl-1(2*H*)-phthalazinone (**15**). A small amount of this same material was isolated as the only identifiable product from the reaction of **11** with hydrazine hydrate in refluxing methyl Cellosolve.



10 **11** **12**

14 **13** **15**

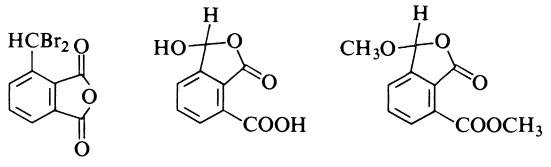
The tricyclic product **4** was obtained in bright yellow crystals from ethanol or water and was very stable up to its decomposition point just below 300°C. It was stable to aqueous acid and base and formed salts with methanesulphonic, hydrochloric, and maleic acids. This stability contrasts sharply with that of 1*H*-benzo[de]quinoline **16** (16) even though both heterocycles have the required number of π electrons to satisfy the Huckel rule for aromaticity (17). The ^{1}Hmr spectrum of **4** at room temperature showed a seven peak multiplet in the aromatic region (A_2B pattern) corresponding to three protons. The protons at positions 3 and 7 appeared as a singlet and the exchangeable proton on nitrogen was visible downfield as a broad singlet in deuterated dimethylsulphoxide. Thus, although the structure **4** is written for convenience as if hydrogen were localized at N-1, the molecule behaves as a tautomeric hybrid symmetrical about the line joining carbons at positions 9a, 9b, and 5. The ^{13}Cmr spectrum also agrees with this structure, although the carbon at position 9b could not be located in the spectrum. Treatment of **4** with fuming nitric acid in sulphuric acid gave the 4,6-dinitro derivative **17** in 49% yield. Attempted reduction of **17** to a mono- or diamino compound gave only intractable material.



16 **17** **18**

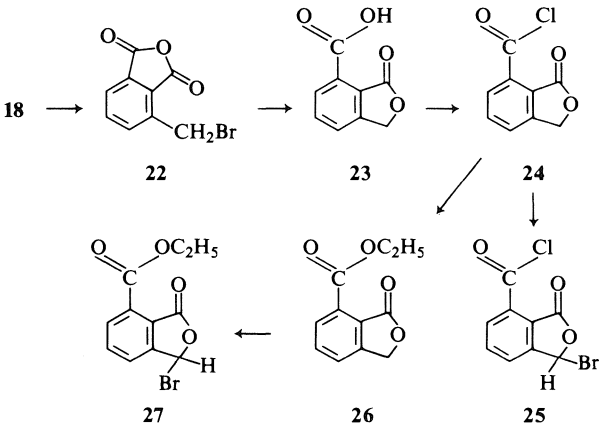
A more versatile intermediate for preparing all of the pyridazino[3,4,5-de]phthalazines unsubstituted at positions 4, 5, and 6 was derived from 3-methylphthalic anhydride (**18**) (17). Bromination of this anhydride with 2 mol of *N*-bromosuccinimide in carbon tetrachloride, heated and illuminated by an immersion-type Mercury vapour lamp, gave the dibromomethyl compound **19**. This was converted by aqueous base followed by acid to the cyclized form of **8**, the hydroxyphthalide structure **20**. This valuable intermediate combined excellent shelf life with sufficient reactivity for our purposes although we explored other reactive intermediates with a similar oxidation state. For example, treatment of **20** with methanol and sulphuric acid gave mainly the reactive *pseudo*-ester **21**.

Another route to reactive intermediates involved a two-stage oxidation. Monobromination of **18** yielded the bromomethyl compound **22** (19) which was converted by aqueous base followed by acid to phthalide-7-carboxylic acid (**23**) (20). Conversion to the acid chloride **24** (20) followed by bromination



19 **20** **21**

under radical conditions gave the highly reactive intermediate **25**. Alternatively, **24** was converted to the ethyl ester **26** and then brominated to intermediate **27**.

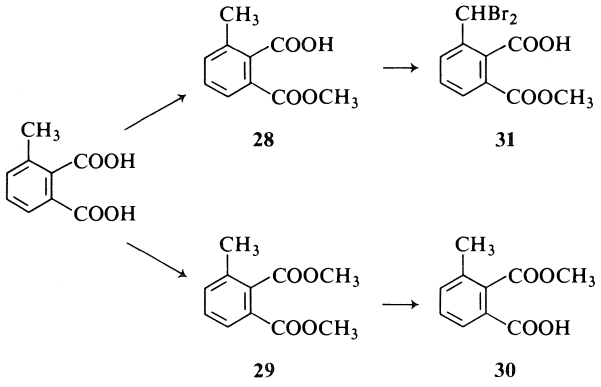


22 **23** **24**

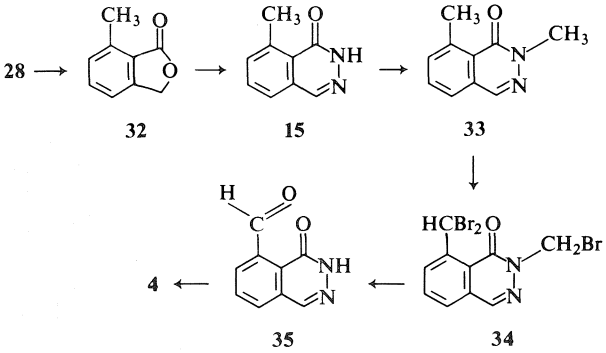
27 **26** **25**

The work of Bird and Turner on the selective esterification of 3-chlorophthalic acid (21) encouraged our similar approach with 3-methylphthalic acid. Treatment of the diacid with methanol and sulphuric acid gave the desired half ester **28** in 65% yield along with 26% of the diester **29** (22). Careful saponifica-

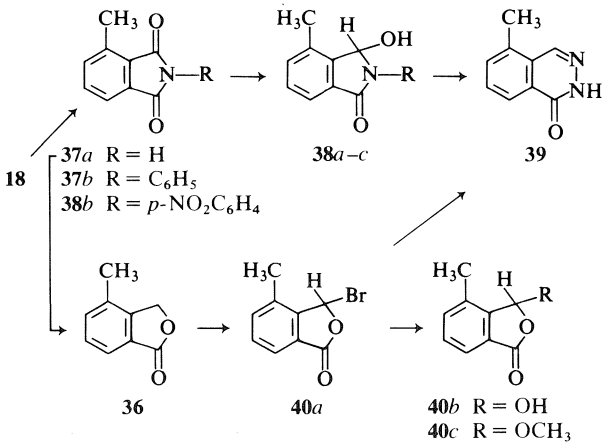
tion of **29** produced the alternate half ester, 2-carbomethoxy-3-methylbenzoic acid (**30**). Free radical bromination of **28** produced the dibromomethyl derivative **31**, which was now at the desired oxidation



stage. The structure of the half ester **28** was elucidated unambiguously by a classical approach. Reduction of the sodium salt of **28** with sodium borohydride and aluminum chloride in diglyme followed by an acid workup yielded 7-methylphthalide (**32**) (23). Treatment of **32** with *N*-bromosuccinimide followed by ethanolic hydrazine hydrate yielded 8-methyl-1-(2*H*)-phthalazinone (**15**). Methylation of **15** gave the 2-methyl derivative **33** which was smoothly brominated to the tribromo compound **34**. Aqueous alkaline treatment of **34** followed by neutralization produced 1(2*H*)-phthalazinone-8-carboxaldehyde (**35**), not obtained previously. This aldehyde was converted smoothly by 10% hydrazine hydrate to the tricyclic compound **4**. This sequence proved the structure of the intermediates, as well as that of the half ester **30**, over which there is some uncertainty in the literature (24, 25). This also completed another synthesis of the main target structure.



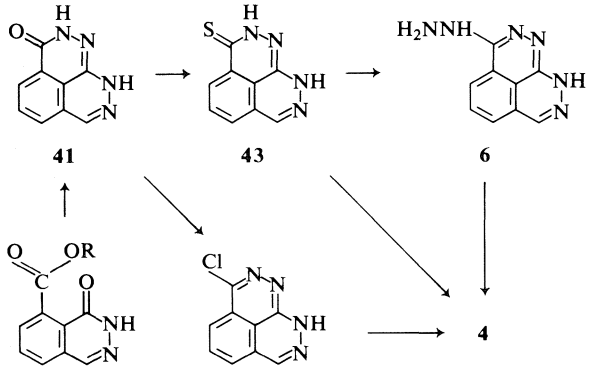
Regrettably, other attempts to use the bulk of the methyl group in preparing key intermediates were unsuccessful. Reduction of 3-methylphthalic anhydride with zinc – cupric sulphate in acid gave a 53:47 mixture of 4-methylphthalide (**36**) and 7-methylphthalide (**32**) as determined by a combination of vapour phase chromatographic separation and infrared spectral analysis. Reduction of the anhydride with 0.5 mol of lithium aluminum hydride in tetrahydrofuran gave a methylphthalide mixture only slightly richer in the desired 7-methylphthalide (59:41). Unknown to us at the time, Newman and Leegwater carried out a variation of this reduction leading to 7-methylphthalide in 69% yield (23). Conversion of **18** to 3-methylphthalimide **37***a* (26) followed by treatment with zinc – cupric sulphate in alkali gave a phthalide mixture so enriched in the undesired isomer (91:9) that it served as a method for preparing 4-methylphthalide. Another promising route was suggested by the work of Horii *et al.* (27) on the reduction of phthalimides to hydroxyphthalimidines. Accordingly, 3-methylphthalimide (**37***a*), the *N*-phenyl compound **37***b*, and the *p*-nitrophenyl derivative **37***c* were each reduced with methanolic sodium borohydride to the corresponding hydroxyphthalimidine (**38***a–c*). Each of these compounds, on treatment with ethanolic hydrazine hydrate, gave the undesired 5-methyl-1(2*H*)-phthalazinone **39**.



This same phthalazinone was prepared by bromination of 4-methylphthalide with *N*-bromosuccinimide followed by ethanolic hydrazine hydrate. The bromo compound **40***a* was further characterized by conversion to 3-hydroxy-4-methylphthalide **40***b* and its methyl ether **40***c*. No attempt was made to determine how much of the desired intermediates could be gleaned from the mother liquors of **38***a–c* once it became obvious that this approach was unsuitable for large scale preparations, especially since more viable routes were discovered.

The intermediates **19**, **20**, **21**, **25**, and **31** were all converted in one or two stages to 3-oxo-3*H*-2,9(or 1,2)-dihydropyridazino[3,4,5-de]phthalazine **41**, a versatile intermediate for many derivatives with this ring

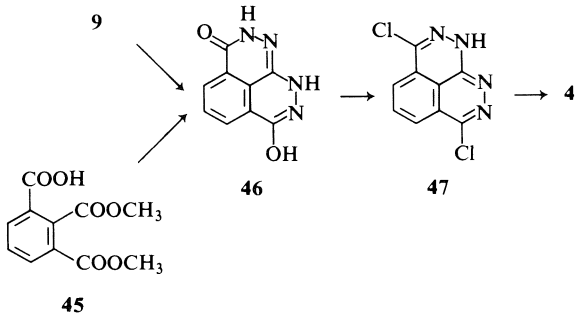
system (9, 10). The shortest route, treatment of **19** with hydrazine hydrate in methyl Cellosolve at reflux for 24 h or more, produced **41** in 75–80% yields. Milder treatment of intermediates **19** or **20** with hydrazine hydrate gave 3,4-dihydro-4-oxo-5-phthalazinecarboxylic acid (**42***a*) which was further reacted with 85% hydrazine hydrate over 3½ days to produce **41** in 65% yield. The intermediate **27** was converted in ethanolic hydrazine hydrate to the ester **42***b* which was used for other purposes, but the methyl ester **42***c* was prepared from the acid **42***a* either by treatment with diazomethane or by reaction with thionyl chloride followed by methanol, and this ester was converted to **41** in refluxing ethanolic hydrazine hydrate.



42*a* R = H
42*b* R = C_2H_5
42*c* R = CH_3

The cyclic hydrazide **41** was converted to the thiohydrazide **43** with phosphorous pentasulphide in pyridine which was then reacted with hydrazine hydrate, preferably in boiling methyl Cellosolve, to produce the second major synthetic target **6**. This was characterized as a dihydrochloride or a dimesylate but was most conveniently purified by conversion to its benzylidene hydrazone which was recrystallized and then boiled with hydrochloric acid until the benzaldehyde steam distilled out of the mixture and the dihydrochloride of **6** remained. Alternatively, **41** was converted to the chloro compound **44** with phosphoryl chloride from which **6** was prepared with hydrazine hydrate. Compounds **43** and **44** were converted to the parent heterocycle **4**, although in poor yield, by the use of Raney nickel in ethanol – methyl Cellosolve and red phosphorous in hydriodic acid, respectively. The hydrazine **6** was converted to **4** rather well with cupric sulphate at neutral pH in the presence of oxygen or, even better, by warming in phosphate buffer at pH 7.2. When the reaction was carried out in deuterium oxide, 3-deuterio-1(or 9)*H*-pyridazino[3,4,5-de]phthalazine was obtained.

Finally, the tricyclic system was synthesized from trimethyl hemimellitate **9** (28) or dimethyl-3-carboxyphthalate **45** (20). Each of these esters was reacted with hydrazine hydrate in methyl Cellosolve at prolonged reflux to form a bright orange high melting solid believed to be 7-hydroxy-3-oxo-3*H*-2,9-dihydropyridazino[3,4,5-de]phthalazine **46**, or a tautomer, which was converted with phosphorous pentachloride – phosphoryl chloride to the 3,7-dichloro compound **47**, as its hydrochloride from which **4** was obtained after treatment with red phosphorous and hydriodic acid.



The hydrazine **6** was further derivatized in different ways. Reaction with aromatic aldehydes generally yielded coloured high melting solids (see Experimental). With benzoyl or acetyl chloride or trifluoroacetic acid, three examples of a new heterocyclic system **48***a–c*, were obtained. Nitrous acid treatment of **6** produced yet another new heterocycle, the condensed tetrazole **49**.

Biological Results

The target compounds **4** and **6** were investigated for antihypertensive activity. Compound **4** was tested intravenously in the anaesthetized cat and the Nembutal anaesthetized dog. Impressive falls in blood pressure were observed with increased intensity and duration of action as the dose was increased. The compound also caused a fall in blood pressure with tachycardia in the normotensive rat. In the Goldblatt dog (29), it caused hypotension of short duration i.v. but only marginal oral activity. In the neurogenic hypertensive dog (30), the compound was inactive. Acute LD_{50} studies indicated an insufficient therapeutic index to warrant further study.

The dihydrochloride of **6**, under the code number *GPA 1595*, caused pronounced and prolonged blood pressure depression i.v. in the anaesthetized cat with increased coronary and femoral artery flow and increased cardiac contractile force. In DOCA rats it caused a substantial blood pressure fall when given orally. In the Goldblatt dog, *GPA 1595* given i.v. produced a pronounced drop in blood pressure within thirty minutes and a gradual drop in blood pressure by the oral route. The peak effect at $4\frac{1}{2}$ h was accompanied by pronounced tachycardia. Good activity in this model was demonstrated even at low oral doses. Based on acute and chronic toxicity studies, this drug was much less toxic than **4** and was recommended for clinical trial. In limited trials, *GPA 1595* caused hypotension in man accompanied by tachycardia and a high incidence of headache as one might expect of a peripheral vasodilator. Since no advantage over hydralazine could be demonstrated, the compound was not further pursued clinically. The benzylidene hydrazone of **6** was inactive in the anaesthetized cat i.v. but showed significant blood pressure activity orally in the Goldblatt dog after $3\frac{1}{2}$ h, possibly as it was acting as a pro-drug of *GPA 1595*. None of the other derivatives of **6** were of pharmacological interest.

Key intermediates in the synthesis of **4** and **6** proved to be valuable sources of many other tricyclic compounds and these will be reported in later publications.

Experimental

Melting points (uncorrected) were determined on a Thomas-Hoover capillary apparatus or, if above 220°C, on a Reichart hot stage apparatus. Infrared spectra (ir) reported in wave numbers (cm^{-1}) for the principal peaks in Nujol (N), potassium bromide (KBr), or chloroform ($CHCl_3$), were measured on a Perkin-Elmer model 137 calibrated with respect to the 1602 cm^{-1} band of polystyrene or on a model 457 grating instrument. Proton magnetic resonance spectra (^{1}Hmr) were measured on a Varian A-60D or a Varian EM-390 spectrometer in DMSO-d_6 unless otherwise stated, with peaks reported in ppm relative to tetramethylsilane as internal standard. Ultraviolet spectra (uv) were recorded on a Cary 14B spectrophotometer in nanometers with ε values in parentheses.

*2,6-Bis(dibromomethyl)benzoic Acid (**11**)*

In a 3 L, 3-necked Pyrex flask equipped with magnetic stirrer, dropping funnel, and upright condenser, a solution of 2,6-dimethylbenzoic acid **10** (17 g) (13) in carbon tetrachloride (1200 mL) was heated to incipient reflux under close range illumination with a 250 W tungsten lamp. Bromine (75 g) in CCl_4 (350 mL) was added dropwise rather rapidly to maintain vigorous reflux. During this period of about 30 min, HBr was evolved vigorously and a white precipitate formed. When evolution ceased, the mixture was cooled, filtered, and the precipitate washed with fresh solvent and oven dried at reduced pressure. The yield of **11** was 90% of theory and required no further purification, mp 203–206°C; ir (N): 1675; ^{1}Hmr ($CDCl_3$): 7.6–8.6 (m, 3*H*, aryl + C*H*Br_2). *Anal.* calcd. for $C_9H_6Br_4O_2$: C 23.21, H 1.30, Br 68.64; found: C 23.49, H 1.07, Br 68.69.

*3-Hydroxyphthalide-7-carboxaldehyde (**12**)*

The acid **11** (37.2 g) was added gradually to a stirring solution of 5% aqueous Na_2CO_3 (600 mL), heated on a steam bath until a clear solution was obtained, and then cooled and acidified with concentrated HCl. The white precipitate was collected (9.12 g) and combined with a second crop (2.57 g) obtained from the mother liquor by continuous chloroform extraction over 24 h. Recrystallization from benzene–hexane yielded a colourless solid, mp 127–133°C, unchanged by further recrystallizations; ir (N): 3250, 1740, 1690, 1590. *Anal.* calcd. for $C_9H_6O_3$: C 60.67, H 3.40; found: C 60.62, H 3.25.

*1(2H)-Phthalazinone-8-carboxaldehyde Hydrazone (**13**)*

(*a*) The aldehyde **12** (6.0 g) was added to a stirring solution of hydrazine hydrate (99–100%, 100 mL) in water (65 mL) and heated at reflux for 30 min. The hot solution was filtered free of a little solid and refrigerated overnight. The off-white solid was collected, washed with water, and dried *in vacuo* at 40°C for 66 h, mp 235–237°C. A portion was sublimed at 120°C/0.05 Torr for microanalysis, mp 235–237°C; ir (KBr): 3380, 3275, 3175, 1635, 1560; ^{1}Hmr: 7.3 (br s, NH_2), 7.8–8.4 (m, 3*H*, aryl + —C*H*=N—), 9.6 (s, vinyl ring *H*), 12.5 (br s, N*H*). *Anal.* calcd. for $C_9H_8N_4O$: C 57.43, H 4.29, N 29.77; found: C 57.28, H 4.23, N 30.04.

(*b*) A mixture of 50% hydrazine hydrate (4 mL), ethanol (10 mL), and the acid **11** (466 mg) was stirred at reflux for 18 h. The clear solution was evaporated at reduced pressure, triturated with water, and filtered. The precipitate (240 mg) was identical to the product obtained in method (*a*).

*Azine **14***

A mixture of the hydrazone **13** (4.7 g) and 0.1 *N* NaOH (550 mL) was heated under reflux for 24 h, cooled, and the white precipitate collected, washed with water, and oven dried *in vacuo*. Yield: 17.4 g (37%), mp > 350°C; ir (N): 3250, 1670. *Anal.* calcd. for $C_{18}H_{12}N_6O_2$: C 62.78, H 3.52, N 24.41; found: C 62.71, H 3.57, N 24.47.

*3-(Dibromomethyl)phthalic Anhydride (**19**)*

A mixture of 3-methylphthalic anhydride (81 g) (**18**), *N*-bromosuccinimide (182 g), benzoyl peroxide (140 mg), and carbon tetrachloride (1.5 L) was irradiated and heated at reflux in a Pyrex vessel with a 100 W Hanovia insertion-type ultraviolet lamp under magnetic stirring and moisture exclusion. The mixture turned brick red and an additional 140 mg of peroxide were added. The reaction was continued for 16.5 h, cooled, filtered free of succinimide and evaporated to dryness at reduced pressure. The residual solid was dissolved in hot ether, decolourized with charcoal, and the filtrate reduced in volume on a steam bath as *n*-hexane was gradually added to incipient crystallization. After refrigeration over 18 h the white solid was collected, washed with *n*-hexane, and dried *in vacuo*. The product (120 g, 75%), mp 93–94.5°C, was used without further purification. Another sample, recrystallized from ether–hexane, gave colourless needles, mp 93–95°C; ir (N): 1850, 1790, 1755; ^{1}Hmr: 7.6–8.6 (m, 3*H*, aryl + C*H*Br_2). *Anal.* calcd. for $C_9H_4Br_2O_3$: C 33.78, H 1.26, Br 49.92; found: C 33.66, H 1.20, Br 49.41.

*3-Hydroxyphthalide-7-carboxylic Acid (**20**)*

The anhydride **19** (40 g) was added in portions to a hot solution of 2 *N* NaOH (500 mL) under stirring. The clear solution was acidified with concentrated HCl, heated at 80°C for 0.5 h, and evaporated to dryness at reduced pressure. The residue was dissolved in hot water (600 mL), treated with

charcoal, and filtered. After 3 days at 5°C, the filtrate yielded colourless blocks (21.3 g, 88%), mp 163.5–166°C. Two recrystallizations from water raised the mp to 165.5–168.5°C; ir (N): 3320, 2800–2200 (broad), 1720, 1590; ^{1}Hmr: ~7.0 (br s, OH), 7.7–8.1 (m, 3*H*, aryl + benzylic *H*). *Anal.* calcd. for $C_9H_6O_5$: C 55.68, H 3.12; found: C 55.98, H 2.99.

*Methyl-3-methoxyphthalide-7-carboxylate (**21**)*

A mixture of hydroxyphthalide **20** (19 g), absolute methanol (167 mL), and concentrated H_2SO_4 (10 mL) was heated at reflux under moisture exclusion for 5 h. The mixture was distilled to remove ca. 100 mL of liquid, poured into ice-water (350 mL), and extracted with $CHCl_3$ (3 × 100 mL). The extract was washed with 5% Na_2CO_3, dried (Na_2SO_4), and concentrated to dryness at reduced pressure. The residue was triturated with ether to obtain the first crop (6.6 g), mp 94–97°C. Concentration of the mother liquor and gradual treatment with *n*-hexane gave two additional crops of solid (4.7 g). The first crop was twice recrystallized from ether to afford colourless needles, mp 94–97°C; ir (CCl_4): 1790, 1735; ^{1}Hmr ($CDCl_3$): 3.7 (s, CH_3O), 4.1 (s, CH_3O), 6.4 (s, —CH—), 7.7–8.0 (m, 3*H*, aryl). *Anal.* calcd. for $C_{11}H_{10}O_5$: C 59.48, H 4.54; found: C 59.66, H 4.35.

*Phthalide-7-carboxylic Acid (**23**)*

Crude 3-bromomethylphthalic anhydride (**22**, prepared according to ref. 19) (47.6 g, mp 74–87°C) was suspended in ethanol (100 mL) and aqueous 2 *N* NaOH (500 mL) and stirred at 80°C for 15 min. The pale yellow solution was cooled, acidified with concentrated HCl, heated 1 h at 80°C, and then refrigerated overnight. The crystalline product (35 g, 100%), mp 166–169°C, was twice recrystallized from methanol to give the pure sample as colourless blocks, mp 168.5–171°C (lit. (20) mp 170–172°C); ir ($CHCl_3$): 2750–2600 (broad), 1740, 1715, 1290. *Anal.* calcd. for $C_9H_6O_4$: C 60.66, H 3.40; found: C 60.41, H 3.35.

*Phthalide-7-carbonyl chloride (**24**)*

The acid **23** was converted to the acid chloride **24** in refluxing benzene–$SOCl_2$ after 3 h. One recrystallization from benzene – *n*-hexane gave the pure product (73%), mp 92–96.5°C; ir ($CHCl_3$): 1770, 1720, 1290.

*Ethyl Phthalide-7-carboxylate (**26**)*

Acid chloride **24** (30.8 g) was heated at reflux in absolute ethanol (184.5 mL) for 30 min, cooled, and the first crop of ester collected. Evaporation of the mother liquor and trituration with cold ethanol gave the second crop. Recrystallization of the combined material from benzene yielded white crystals (23.1 g, 65%), mp 89.5–92.5°C. Recrystallization from ethanol gave the pure ester, mp 90.5–92°C; ir ($CHCl_3$): 1770, 1720; ^{1}Hmr ($CDCl_3$): 3.1 (t, CH_3), 4.45 (q, CH_2—CH_3), 5.3 (s, benzylic CH_2), ~7.7 (m, 3*H*, aryl). *Anal.* calcd. for $C_{11}H_{10}O_4$: C 64.07, H 4.89; found: C 64.10, H 4.88.

*2-Carbomethoxy-6-methylbenzoic Acid (**28**)*

3-Methylphthalic acid was obtained by dissolution of the anhydride **18** in dilute aqueous NaOH at 80°C within 0.5 h, acidification with HCl, and recrystallization of the resulting precipitate from ethyl acetate – *n*-hexane, mp 156.5°C (lit. (26) mp 154°C). A mixture of 3-methylphthalic acid (18 g), methanol (180 mL), and concentrated H_2SO_4 (10 mL) was heated at reflux for 6 h under moisture exclusion. It was concentrated at reduced pressure to one-third volume, poured into ice-water, and extracted with chloroform. The chloroform solution was extracted with 10% aqueous Na_2CO_3 and the carbonate layer acidified with concentrated HCl, whereupon the crude ester crystallized (12.7 g, mp 85–98°C). Three recrystallizations from benzene–hexane yielded the pure product (8.0 g, 41%), mp 110.5–111.5°C; ir ($CHCl_3$): 2700–2300 (broad), 1720. *Anal.* calcd. for $C_{10}H_{10}O_4$: C 61.85, H 5.19; found: C 61.97, H 5.08.

The chloroform layer containing the diester **29** was dried (Na_2SO_4) and concentrated at reduced pressure to a pale yellow oil (5.5 g) which gradually crystallized. It was recrystallized from benzene–hexane, mp 40–44°C (lit. (22) mp 42.5–44°C); ir ($CHCl_3$): 1720.

*2-Carbomethoxy-3-methylbenzoic Acid (**30**)*

Dimethyl 3-methylphthalate (**29**, 20.79 g) in ethanol (25 mL) was added to a solution of KOH (5.61 g) in water (75 mL) and the mixture heated 2 h at reflux on the steam bath. The pH was adjusted to 8 with a few drops more of alkali and the solution extracted with ether. The ether extract was washed with brine, dried over Na_2SO_4, and concentrated to dryness to recover 3.8 g of diester. The alkaline solution was cooled and acidified with concentrated HCl to produce the crude monoester (15.05 g), mp 66–84°C. It was twice recrystallized from benzene–hexane with charcoal, twice from methanol–water, and again from benzene–hexane to yield the pure half ester (7.05 g), mp 114–115°C; ir (N): 2700–2300 (broad), 1720, 1690 (shoulder). *Anal.* calcd. for $C_{10}H_{10}O_4$: C 61.85, H 5.19; found: C 62.05, H 4.95. Mixed mp with **28**: 67–84°C.

*7-Methylphthalide (**32**)*

(*a*) Sodium methoxide (16.7 g) in methanol (500 mL) was reacted with 2-carbomethoxy-6-methylbenzoic acid (**28**, 58.6 g) in methanol (500 mL) and the clear solution evaporated to dryness *in vacuo*. The dry powder was kept in a desiccator over P_2O_5 until ready to be used. This sodium salt (54 g) was treated with 1 *M* $NaBH_4$ in dry diglyme (distilled over CaH_2 and then $LiAlH_4$) (500 mL). Under vigorous stirring and moisture exclusion, 2 *M* $AlCl_3$ in dry diglyme (200 mL) was added dropwise. The exotherm was controlled with an ice bath during addition, stirred at 75°C for 1 h, cooled, and then quenched in ice (500 mL) containing concentrated HCl (200 mL). The mixture was heated 1 h at 60–80°C, allowed to stand overnight, and extracted with chloroform. The dried (Na_2SO_4) chloroform solution was distilled at the water pump to remove chloroform and diglyme and the residual oil distilled at high vacuum. The fraction bp 106–120°C/0.8 Torr (21.4 g, 58%) solidified in the receiver and was recrystallized from benzene–hexane, methanol–water, and again from benzene–hexane to afford pure 7-methylphthalide, mp 86–87.5°C (lit. (23) mp 83–85°C); ir ($CHCl_3$): 1750; ^{1}Hmr ($CDCl_3$): 2.6 (s, CH_3), 5.2 (s, CH_2), ~7.3 (m, 3*H*, aryl). *Anal.* calcd. for $C_9H_8O_2$: C 72.96, H 5.44; found: C 72.92, H 5.28.

(*b*) 7-Methylphthalide was also prepared from 2,6-dimethylbenzoic acid essentially as described by Newman and Leegwater (23) except that the acid was brominated rather than the methyl ester.

*8-Methyl-1(2H)phthalazinone (**15**)*

A mixture of 7-methylphthalide (14.8 g), *N*-bromosuccinimide (18 g), benzoyl peroxide (50 mg), and carbon tetrachloride (200 mL) was heated to incipient reflux under moisture exclusion and then illuminated externally by a 1000 W tungsten lamp. A vigorous reaction occurred, the mixture turned dark orange, and gradually it became colourless. The mixture was cooled, filtered free of succinimide, and concentrated to dryness at reduced pressure. The pale yellow oil (22.85 g), ir ($CHCl_3$): 1780, thought to be 3-bromo-7-methylphthalide, was used directly without further purification. The bromophthalide (18 g), absolute ethanol (200 mL), and hydrazine hydrate (20 mL) were stirred at reflux 18 h. The solution was evaporated to one-half its volume and the crystalline material collected. Addition of water to the filtrate gave a

second crop. The combined product (11.3 g, 87%), mp 184–187.5°C, was recrystallized from ethanol with charcoal and twice from 1:1 ethanol – 0.05 *N* HCl to afford white crystals, mp 191–192.5°C; ir (N): 3120, 1650, 1565; ^{1}Hmr: 2.9 (s, C*H*$_3$), 7.5–7.9 (m, 3*H*, aryl), 8.3 (s, vinyl *H*), 12.6 (s, N*H*). *Anal.* calcd. for $C_9H_8N_2O$: C 67.49, H 5.04, N 17.48; found: C 67.34, H 4.95, N 17.25.

*2,8-Dimethyl-1(2*H*)-phthalazinone (**33**)*

A mixture of 8-methyl-1(2*H*)-phthalazinone (1.6 g), 4 *N* NaOH (2.5 mL), methyl iodide (1 mL), and methanol (25 mL) was heated at reflux for 1 h, quenched in ice-water and the precipitate washed with water and air dried. This material (1.0 g), mp 98–101°C, was combined with 1.5 g from a second run and recrystallized from cyclohexane to afford the pure material (1.6 g), mp 98–101°C; ir (N): 1640, 1575; ^{1}Hmr: 2.86 (s, C*H*$_3$), 3.68 (s, N—C*H*$_3$), ~7.4 (m, 3*H*, aryl), 7.83 (s, vinyl *H*). *Anal.* calcd. for $C_{10}H_{10}N_2O$: C 68.94, H 5.79, N 16.09; found: C 68.72, H 5.66, N 16.20.

*2-Bromomethyl-8-dibromomethyl-1(2*H*)-phthalazinone (**34**)*

A mixture of 2,8-dimethyl-1(2*H*)-phthalazinone (400 mg), benzoyl peroxide (20 mg), and carbon tetrachloride (50 mL) was raised to reflux and bromine (0.5 mL) in CCl_4 (50 mL) added dropwise. The mixture was heated and illuminated externally 3 h longer with a 250 W infrared lamp. The solution was evaporated to dryness and the residual solid (600 mg), mp 124–140°C, recrystallized from benzene–hexane to give the pure compound (400 mg), mp 156–159°C; ir (N): 1650; ^{1}Hmr: 5.97 (s, N—C*H*$_2$—Br), 7.4–8.5 (m, 3*H*, aryl), 8.2 (s, vinyl *H*), 8.86 (s, C*H*Br$_2$). *Anal.* calcd. for $C_{10}H_7Br_3N_2O$: C 29.23, H 1.72, N 6.82, Br 58.34; found: C 29.16, H 1.80, N 6.87, Br 58.27.

*1(2*H*)-Phthalazinone-8-carboxaldehyde (**35**)*

A mixture of **34** (6.3 g) and 5% aqueous Na_2CO_3 (200 mL) was heated 1 h on a steam bath, filtered hot, cooled, and the pH adjusted to 7 with HCl. The resulting white precipitate (1.0 g), mp 251–253°C, was recrystallized from water to give the pure aldehyde, mp 252–254°C. *Anal.* calcd. for $C_9H_6N_2O_2$: C 62.06, H 3.48, N 16.09; found: C 61.84, H 3.38, N 16.23.

*Reduction of 3-Methylphthalimide(**37**a): 4-Methylphthalide (**36**)*

Zinc dust (72 g) and cupric sulphate solution (400 mg of the salt in 14 mL of water) were stirred into a paste and treated with 20% NaOH solution (160 g). The mixture was cooled to 4°C and 3-methylphthalimide (**37***a*, 58.8 g) (26) added gradually over 0.5 h under stirring and external cooling and then 0.5 h longer at 5–8°C. It was diluted with water (100 mL) and stirred vigorously on a steam bath for 3 h. The mixture was filtered free of inorganic insolubles, acidified with concentrated HCl, heated 1 h on a steam bath, cooled, and extracted with chloroform. The extracts were dried (Na_2SO_4), concentrated, and the residual oil (48 g) distilled *in vacuo*. The fraction bp 124–131°C/1–0.9 Torr (27 g, 50%) was crystallized from benzene–*n*-hexane. The product (19.2 g), mp 66.5–68.5°C, was pure by vpc analysis and identical to a sample from another run purified by alumina chromatography (Woelm, neutral, activity I) and recrystallized from benzene–*n*-hexane, mp 69–70.5°C; ir ($CHCl_3$): 1750; ^{1}Hmr ($CDCl_3$): 2.4 (s, C*H*$_3$), 5.2 (s, C*H*$_2$), ~7.4 (m, 3*H*, aryl). *Anal.* calcd. for $C_9H_8O_2$: C 72.95, H 5.44; found: C 72.96, H 5.36.

In another run, the concentrated $CHCl_3$ extract was distilled and the fraction bp 118–132°C/0.3 Torr (45%) subjected to vpc analysis directly. The ratio of 4-methylphthalide to 7-methylphthalide was 91:9.

*3-Bromo-4-methylphthalide (**40**a)*

4-Methylphthalide (14.8 g) was brominated as described for 7-methylphthalide (**32**) but without external illumination. The product was obtained as a solid (14.7 g), mp 86–90°C, analytically pure, from the reaction after 50 min, ir ($CHCl_3$): 1790. *Anal.* calcd. for $C_9H_7BrO_2$: C 47.61, H 3.11, Br 35.20; found: C 47.59, H 2.85, Br 35.07.

*3-Hydroxy-4-methylphthalide (**40**b)*

A mixture of 3-bromo-4-methylphthalide (5.0 g) and water (8.2 mL) was heated 35 min at reflux, the solid broken up with a spatula, water (20 mL) added, and reflux continued 25 min longer. The mixture was filtered hot and a white solid (1.2 g), mp 276.5–280°C, collected. This was thought to be *bis*(4-methyl-3-phthalidyl) ether. The filtrate was cooled and white needles (2.15 g), mp 115–116.5°C, twice recrystallized from benzene–hexane to give the pure compound, mp 117.5–119°C; ir (N): 3550, 1765. *Anal.* calcd. for $C_9H_8O_3$: C 65.85, H 4.92; found: C 65.68, H 4.84.

*3-Methoxy-4-methylphthalide (**40**c)*

A mixture of **40***a* (4.0 g), methanol (25 mL), and concentrated HCl (5 drops) was heated 1.5 h at reflux, cooled, filtered free of white solid (0.9 g, 281–291°C, ir identical to high melting solid in previous reaction), and evaporated at reduced pressure to a yellow syrup (2.5 g). Three crystallizations from methanol–water gave the pure sample, mp 61–63.5°C; ir ($CHCl_3$): 1765; ^{1}Hmr: 2.4 (s, C*H*$_3$), 3.5 (s, C*H*$_3$O), 6.6 (s, C*H*, benzylic), 7.5–7.8 (m, 3*H*, aryl). *Anal.* calcd. for $C_{10}H_{10}O_3$: C 67.40, H 5.66; found: C 67.21, H 5.57.

Reduction of 3-Methylphthalic Anhydride

(*a*) Lithium aluminum hydride (1.82 g) in dry tetrahydrofuran (THF) (150 mL) was added gradually to a stirring solution of 3-methylphthalic anhydride (13 g) in dry THF (300 mL) at 0°C under moisture exclusion. The milky white suspension was stirred 1.5 h longer, excess hydride destroyed with ethyl acetate, and the mixture poured into ice and HCl. It was extracted with ether, the ether dried (Na_2SO_4), concentrated to a pale yellow oil (11.9 g), and distilled *in vacuo*. The product bp 114–123°C/0.9 Torr (8.86 g, 75%) was a mixture of 4-methylphthalide and 7-methylphthalide in the ratio 41:59, as shown by vpc/ir analysis.

(*b*) A slurry of 3-methylphthalic anhydride (13 g), glacial acetic acid (40 g), and concentrated HCl (29 g) was treated gradually with a paste of zinc dust (17.8 g) in cupric sulphate (95 mg) in water (3.5 mL) at 25–30°C. It was heated 5 h on a steam bath under vigorous stirring, allowed to stand 16 h, filtered free of solid, diluted with water (75 mL), adjusted to pH 5 with K_2CO_3, heated 1 h and then cooled. The white solid which formed was dried over P_2O_5 (9.9 g) and vacuum distilled. The fraction bp 134–145°C/1 Torr (8.22 g, 70%) was a 53:47 mixture of 4-methyl- and 7-methylphthalide (vpc/ir analysis).

*3-Methyl-*N*-phenylphthalimide (**37**b)*

A mixture of 3-methylphthalic anhydride (24.3 g), aniline (13.7 mL), and glacial acetic acid (100 mL) was heated 16 h at reflux, quenched in ice (200 mL), and the resulting precipitate washed with water and recrystallized from ethanol to give the pure product (26.7 g, 75%), mp 143.5–146°C; ir ($CHCl_3$): 1760, 1710. *Anal.* calcd. for $C_{15}H_{11}NO_2$: C 75.95, H 4.68, N 5.91; found: C 75.84, H 4.69, N 6.01.

Similarly, 3-methyl-*N*-(*p*-nitrophenyl)phthalimide (**37***c*) was prepared in 81% yield, mp 273–276°C. Recrystallized from dimethylformamide, white crystals, mp 274–276°C, were obtained. Infrared (KBr): 1775, 1730. *Anal.* calcd. for $C_{18}H_{10}N_2O_4$: C 63.83, H 3.58, N 9.92; found: C 64.19, H 3.71, N 10.02.

*3-Hydroxy-4-methylphthalimidine (**38**a)*

Sodium borohydride (3.8 g, 0.1 mol) in methanol (90 mL) was added dropwise under vigorous stirring at 25–30°C to a suspension of 3-methylphthalimide (8.05 g, 0.05 mol) in 9:1 methanol–water (60 mL). It was stirred 16 h, treated with glacial acetic acid until a clear solution was obtained, and evaporated to dryness at reduced pressure. The residue was triturated with water and the solid, mp 155–179°C, recrystallized from methanol (30 mL) to give a white solid (1.35 g, 17%), mp 187–189.5°C, which showed a major spot in tlc and only a trace impurity; ir (N): 3250, 1675. *Anal.* calcd. for $C_9H_9NO_2$: C 66.23, H 5.56, N 8.58; found: C 65.89, H 5.56, N 8.48.

By a similar route 3-methyl-*N*-(*p*-nitrophenyl)phthalimidine (**37***c*) was converted to 4-hydroxy-3-methyl-*N*-(*p*-nitrophenyl)-phthalimidine (**38***c*) after 66 h reaction in 70% yield, mp 233–236°C. Recrystallization from glacial acetic acid gave one spot material in tlc, mp 232–235°C; ir (N): 3350, 1675. *Anal.* calcd. for $C_{15}H_{12}N_2O_4$: C 63.37, H 4.25, N 9.85; found: C 63.24, H 4.38, N 10.01.

Similarly, except that a 4:1 ratio of borohydride to substrate was used, 4-hydroxy-3-methyl-*N*-phenylphthalimidine (**38***b*) was prepared from **37***b* in 26% pure yield, mp 152.5–154°C; ir ($CHCl_3$): 3520, 1700; ^{1}Hmr: 2.45 (s, CH_3), 6.59 (s), 6.63 (s, O*H*, benzylic *H*), 7.2–7.9 (m, 8*H*, aryl). *Anal.* calcd. for $C_{15}H_{13}NO_2$: C 75.29, H 5.47, N 5.86; found: C 75.16, H 5.49, N 6.04.

*5-Methyl-1(2*H*)phthalazinone (**39**)*

(*a*) A mixture of **38***a* (8.15 g), water (50 mL), and hydrazine hydrate (50 mL) was heated 16 h at reflux, cooled, and filtered. The white solid (7.75 g, 97%), mp 213.5–215°C was recrystallized from methanol to give the pure product (6.2 g), mp 214–216°C; ir (N): 3120, 1645, 1595, 1550; ^{1}Hmr: 2.7 (s, CH_3), ~7.6 (m, 2*H*, aryl), ~8.2 (m, *H* at C-8), 8.6 (s, vinyl *H*), 12.8 (s, N*H*). *Anal.* calcd. for $C_9H_8N_2O$: C 67.48, H 5.04, N 17.49; found: C 67.40, H 5.02, N 17.49.

(*b*) A suspension of **40***a* (23.9 g) in ethanol (250 mL) was reacted with hydrazine hydrate (25.2 mL) at reflux for 16 h. Water (100 mL) was added, the solution evaporated to one-half volume, cooled, and the yellow precipitate (11.3 g, 71%), mp 151.5–167°C, recrystallized from ethanol – 0.05 *N* HCl to afford the pure product, mp 209–213°C, with an identical ir spectrum to that from method (*a*).

(*c*) Reaction of **38***b* (1.5 g), ethanol (50 mL), and hydrazine hydrate (5 mL) after 18 h at reflux was incomplete. The whole was concentrated to dryness and reacted with 50% hydrazine hydrate (40 mL) at reflux over 18 h, cooled, and the white precipitate (770 mg) mp 208–211°C, recrystallized from methanol to give the pure product, mp 213.5–215.5°C, identical (ir) to that of method (*a*).

(*d*) By the same route, **38***c* was converted to the phthalazinone derivative, mp 212.5–213.5°C, identical (ir) to that from method (*a*).

*1*H*-Pyridazino[3,4,5-de]phthalazine (**4**)*

(*a*) To a suspension of 2,6-bis(dibromomethyl)benzoic acid (46.5 g) in water (1150 mL) was added hydrazine hydrate (173 mL) and the mixture rapidly raised to reflux and stirred 64 h. The hot mixture was filtered and the filtrate allowed to cool to about 10°C. The yellow precipitate (13.3 g, 78%) was recrystallized from ethanol in sparkling yellow crystals (10.4 g). In several other runs, the product was recrystallized from boiling water. On the hot stage apparatus, the product changed crystal form in the range 190–240°C and melted with decomposition in the range 294–298°C; ir (KBr): (region 3500–800, principal peaks): 3200, 3120, 3030, 2800–2200 (broad), 1620, 1610, 1590, 1550, 1490, 1450, 1425, 1375, 1340, 1170, 980, 900, 860, 850. ^{1}Hmr: 7.45–7.9 (m, 3*H*, aryl), 8.3 (s, 2*H*, vinyl), 12.5 (s, N*H*); uv (neutral 3A ethanol): 250 (7900); 330 (11250); (acidic 3A ethanol): 243 (9600), 251 (8300), 311 (9250), 335 (5400), 350 (5600), 367 (2850); (alkaline 3A ethanol): 349 (12150), 367 (15100), 378 (16450); ^{13}Cmr (Varian CFT-20): 121.55 (C-4, C-6), 134.04 (C-5), 126.68 (C-3a, C-6a), 140.73 (C-3, C-7), 180.92 (C-9a). (C-9b could not be detected.) Mass spectra (A.E.I. MS-9) *m/e*: 170 (mol. ion), 142 (—N_2), 115 (—N_2, —HCN), 114 (—$2N_2$).

(*b*) Hydrazine hydrate (122 mL) was added to a suspension of 3-hydroxyphthalide-7-carboxaldehyde (**12**) (30.2 g) in water (1040 mL) and the mixture stirred 66 h at reflux. The solution was filtered hot and then allowed to cool overnight to room temperature. The yellow solid (22.14 g, 77%) was recrystallized from ethanol to give a sample (16.9 g), mp 293–298°C dec., identical (ir) to that of method (*a*).

(*c*) A mixture of 1(2*H*)-phthalazinone-8-carboxaldehyde hydrazone (**13**) (940 mg), hydrazine hydrate (10 mL), and water (100 mL) yielded after 24 h reflux crude **4**, mp 279–288°C dec., in 82% yield. Recrystallization from ethanol gave the product identical (ir) to that of method (*a*).

(*d*) Under similar conditions, 1(2*H*)-phthalazinone-8-carboxaldehyde (**35**) was converted to **4**, mp 291–296°C dec., in 58% yield.

*4,6-Dinitro-1*H*-pyridazino[3,4,5-de]phthalazine (**17**)*

Fuming nitric acid (100 mL) was added dropwise at 10°C to a stirring solution of concentrated H_2SO_4 (100 mL) and **4** (17.0 g) was added gradually at a rate to maintain a temperature of 15–23°C. It was stirred 15 min longer and then quenched in ice-water. A small amount of solid was filtered off and the filtrate adjusted to pH 8 with 20% NaOH. The dark red precipitate was dissolved in boiling water (3 L), filtered, and the filtrate acidified with acetic acid and cooled overnight. The red precipitate which formed (12.8 g) was twice recrystallized from dimethylformamide–water (6:1) to give the pure product, mp > 350°C; ir (N): 3100, 1640, 1615, 1565, 1535, 1340; ^{1}Hmr: 9.24 (s, *H* at C-5), 9.5 (s, 2*H*, vinyl), 10.1 (broad s, N*H*). *Anal.* calcd. for $C_9H_4N_6O_4$: C 41.53, H 1.55, N 32.30; found: C 41.53, H 1.76, N 32.28.

*Reaction of **12** with 60% Hydrazine Hydrate: 8-Methyl-1(2*H*)-phthalazinone (**15**)*

Hydrazine hydrate (45 mL) was added to a suspension of 3-hydroxyphthalide-7-carboxaldehyde (1.78 g) in water (30 mL) to afford a clear solution. After 30 min at reflux, an aliquot (3 mL) was cooled, filtered, and the precipitate identified (ir) as the hydrazone **13**. After 6 h at reflux, the aliquot was mainly **13** with some **4** present (ir, tlc). This mixture appeared to remain unchanged after 23 h and 48 h, but after 166 h at reflux, the remainder was cooled and the product (840 mg), mp 197–199°C, identified (ir) as largely 8-methyl-1(2*H*)-phthalazinone (**15**). Recrystallization from ethanol – 0.05 *N* HCl gave the pure product, mp 188–191°C. The same result was observed with 85% hydrazine hydrate as the reaction medium.

*3,4-Dihydro-4-oxo-5-phthalazine Carboxylic Acid (**42**a)*

A mixture of 3-hydroxyphthalide-7-carboxylic acid (**20**) (30.2 g), hydrazine hydrate (50 mL), and water (100 mL) was stirred at reflux for 16 h, cooled, acidified with dilute HCl, and the off-white product (32.2 g), mp 300–306°C, recrystallized from glacial acetic acid, mp 303.5–306°C; ir (N): 2700–2200 (broad), 1700, 1655, 1585. *Anal.* calcd. for $C_9H_6N_2O_3$: C 56.84, H 3.18, N 14.73; found: C 57.02, H 3.15, N 14.65.

The same product was obtained from 3-(dibromomethyl)-phthalic anhydride in 50% hydrazine hydrate and ethanol at reflux or hydrazine hydrate – chloroform at reflux.

*Ethyl-3,4-dihydro-4-oxo-5-phthalazinecarboxylate (**42**b)*

Ethyl phthalide-7-carboxylate **26** was converted to the 3-bromo compound **27** as described for 7-methylphthalide and obtained in quantitative yield as a pale yellow oil, ir (CH_2Cl_2): 1800 and 1720. The oil (25.2 g) was dissolved in absolute ethanol (172 mL), whereupon some white solid formed. Hydrazine hydrate (17.25 mL) in ethanol (172 mL) was added cautiously and the mixture stirred 16 h at reflux. It was filtered hot and the filtrate evaporated to dryness at reduced pressure, suspended in 1 *N* HCl, and extracted with chloroform. The dried (Na_2SO_4) extract was filtered through Woelm neutral alumina, grade II (100 g), concentrated to dryness and recrystallized from ethanol to give the pure ester (8.3 g, 43%), mp 169.5–171.5°C; ir ($CHCl_3$): 1730, 1670, 1600. *Anal.* calcd. for $C_{11}H_{10}N_2O_3$: C 60.54, H 4.62, N 12.84; found: C 60.54, H 4.62, N 12.62.

*Methyl-3,4-dihydro-4-oxo-5-phthalazinecarboxylate (**42**c)*

A mixture of the acid **42***a* (100 g) and thionyl chloride (250 mL) was stirred at reflux under moisture exclusion for 2.5 h. It was concentrated at reduced pressure, taken up in benzene (50 mL), filtered, and the precipitate (96.9 g, 88%, calculated as the acid chloride) kept in a desiccator until ready for use. The acid chloride (232.5 g) in absolute methanol (2 L) was stirred 18 h at reflux and then refrigerated. The ester crystallized in colourless needles (220.1 g, 97%), mp 210–212°C.

The original sample of this ester was obtained by reaction of **42***a* with ethereal diazomethane in methanol in 82% yield. Recrystallized from methanol, it melted at 207–209°C; ir (N): 1730, 1670; ^{1}Hmr: 4.0 (s, C*H*$_3$O), 7.8–8.3 (m, 3*H*, aryl), 8.6 (s, vinyl *H*), 13.0 (s, N*H*). *Anal.* calcd. for $C_{10}H_8N_2O_3$: C 58.82, H 3.95, N 13.72; found: C 58.77, H 3.99, N 13.86.

*3-Oxo-3*H*-2,9(or 1,2)-dihydropyridazino[3,4,5-de]phthalazine (**41**)*

(*a*) A mixture of 3-(dibromomethyl)phthalic anhydride (**19**) (95.26 g), hydrazine hydrate (120 mL), and methyl Cellosolve (490 mL) was stirred 24 h at reflux, cooled, and the yellow solid washed with water, methanol, and oven dried *in vacuo*. The crude product (45.0 g, 80%), mp > 350°C, was recrystallized from dimethylformamide to give a microcrystalline powder, mp > 350°C; ir (N) (range 3500–800, principal peaks): 3260 (sh), 3180, 2850, 1655, 1630, 1610, 1590, 1200, 870, 840; ^{1}Hmr (CD_3COOD): ~7.9 (m, 3*H*, aryl), 8.4 (s, vinyl *H*). *Anal.* calcd. for $C_9H_6N_4O$: C 58.06, H 3.25, N 30.09; found: C 57.92, H 3.58, N 30.28.

(*b*) A mixture of **21** (1.11 g), hydrazine hydrate (4 mL), and absolute ethanol (10 mL) was stirred 94 h at reflux. It was filtered hot and the precipitate washed with water, methanol, and recrystallized from dimethylformamide to give the pure product (0.82 g, 88%), mp > 350°C, identical (ir) to that from method (*a*).

(*c*) Phthalide-7-carbonyl chloride **24** was converted to the 3-bromo compound **25** as described in the bromination of 7-methylphthalide. It was obtained as a solid which fumed in air, ir ($CHCl_3$): 1800 and 1720 in 67% yield. The crude **25** (28.7 g), ethanol (279 mL), and hydrazine hydrate (50 mL) after 18 h reflux with the usual workup and purification gave 2.2 g (11%) identical to that from method (*a*).

(*d*) The half ester **28** (9.7 g) was converted to the dibromo compound **31** as described for the synthesis of **11**. The crude **31** was obtained as an oil (ir (N): 2700–2300 (broad) and 1720), dissolved in cold ethanol (100 mL), treated cautiously with 50% aqueous hydrazine hydrate (40 mL), and stirred 72 h at reflux. Hot filtration yielded a first crop (1.54 g) of yellow solid and the filtrate was concentrated to dryness and heated in glacial acetic acid for 66 h, evaporated to dryness, and triturated with methanol to produce a second crop (1.8 g). Recrystallization from dimethylformamide gave pure **41** (1.29 g, 14%) identical (ir) to that of method (*a*).

(*e*) A mixture of **42***a* (3.16 g), hydrazine hydrate (170 mL), and water (30 mL) was stirred 84 h at reflux, cooled, poured into excess 5% aqueous Na_2CO_3, and the yellow product collected, washed, and dried. The yield was 2.4 g (65%), mp > 350°C, identical (ir) to that from method (*a*).

*3-Thiono-3*H*-2,3(or 9)-dihydropyridazino[3,4,5-de]phthalazine (**43**)*

A mixture of **41** (44.14 g), phosphorous pentasulphide (58.29 g), and pyridine (356 mL) was stirred 2.5 h at reflux, cooled, and poured into a stirring solution of ice-cold saturated brine (1 L). After 1.5 h stirring, the orange-red product was collected, suspended in water, refiltered, and dried at 100°C *in vacuo*. The crude product (35.0 g, 73%), mp 298–320°C, was suitable for further experiments. A portion was recrystallized from methyl Cellosolve – water (insoluble material removed), and then dimethylformamide–water to give the analytical sample, mp 318–322°C (stage preheated to 250°C); ir (N) (3500–800 principal peaks): 3230 (sh), 3130, 1615, 1580, 1550, 1370, 1330, 1230, 1210, 1182, 840; ^{1}Hmr: 7.8–8.8 (m, 4*H*, aryl + vinyl), 5.3 (br s, 2N*H*). *Anal.* calcd. for $C_9H_6N_4S$: C 53.45, H 2.99, N 27.71; found: C 53.37, H 3.00, N 27.85.

*3-Chloro-1(or 9)*H*-pyridazino[3,4,5-de]phthalazine (**44**)*

A mixture of phosphoryl chloride (60 mL), water (10 drops), and **41** (9.3 g) was stirred 20 h at reflux, evaporated at reduced pressure to a brown foam, triturated with cold ethanol, and a yellow solid (8.6 g), mp ~270°C dec., collected. On standing, a second and third crop of solid precipitated from the ethanol solution. The combined material (11.1 g) was dissolved as well as possible in excess hot 1 *N* HCl, filtered, and the filtrate cooled and made basic with 20% aqueous Na_2CO_3. The resulting tan precipitate was washed with water and dried *in vacuo*. This material **44** was pure enough for further work.

A second sample of **44** (12.0 g) was suspended in dry methanol (200 mL), methanesulphonic acid (4.6 mL) added, and the solution refrigerated at −8°C. The precipitate (11.0 g, 37%), mp 244–246°C dec., was twice recrystallized from methanol, the first with charcoal, to give the pure sample, mp 246–249°C dec.; ir (N): 2800–2200 (broad), 1630, 1595, 1555; ^{1}Hmr: 2.6 (s, C*H*$_3$—S), 8.1–8.6 (m, 3*H*, aryl), 9.2 (s, vinyl *H*), 13.0 (s, 2N*H*). *Anal.* calcd. for $C_9H_5ClN_4 \cdot CH_4O_3S$: C 39.94, H 3.02, N 18.63, Cl 11.79, S 10.66; found: C 39.98, H 3.09, N 18.73, Cl 11.62, S 10.56.

*3-Hydrazino-1(or 9)*H*-pyridazino[3,4,5-de]phthalazine Dihydrochloride (**6**)*

A mixture of 85% hydrazine hydrate (500 mL) and **43** (30 g) was stirred vigorously at reflux for 20 h. It was cooled, filtered, and the yellow precipitate washed with water and dried *in vacuo*. The free base (21.0 g) was suspended in excess 3 *N* HCl, filtered free of insoluble material, and the filtrate concentrated to dryness at reduced pressure. The residue was taken up in a minimal quantity of water and crystallized by addition of cold concentrated HCl. A second crystallization by this method gave the analytical sample, mp 245–248°C dec.; ir (N): (3500–800, principal peaks): 2700–1900 (broad), 1620, 1600, 1575, 1550, 1525, 1320, 1160, 955, 850, 813; ^{1}Hmr (D_2O, sodium 3-(trimethylsilyl)-1-propane sulphonate as internal standard): 8.0–8.45 (m, 3*H*, aryl), 8.6 (s, vinyl *H*); uv (H_2O): 228 (19100), 269 (9550), 311 (7050), 367 (4770). *Anal.* calcd. for $C_9H_6N_2 \cdot 2HCl$: C 39.57, H 3.69, N 30.77, Cl 25.97; found: C 39.68, H 4.34, N 30.78, Cl 25.65.

The dimethane sulphonate was prepared in ethanol and recrystallized from methanol–ether, mp 235–237°C dec. *Anal.* calcd. for $C_9H_8N_6 \cdot 2CH_4O_3S$: C 33.67, H 4.11, N 21.42; found: C 33.94, H 4.40, N 21.46.

Benzylidene Hydrazone of ***6***

To a stirring solution of the dihydrochloride of **4** (14.4 g) in water (150 mL) and ethanol (100 mL) was added at 50°C a solution of benzaldehyde (5.5 mL) in ethanol (50 mL). A thick mass quickly formed and water (100 mL) was added to aid stirring. After 5 min, 1 *N* $NaHCO_3$ (130 mL) was added, whereupon the precipitate turned from yellow to orange. The mixture was stirred another 10 min at 50–55°C, cooled, filtered, and the product washed with water, then ethanol, and dried *in vacuo*. The crude product (14.9 g, 98%), mp 260–265°C, resolidified and remelted at 325–335°C, was recrystallized three times from methyl Cellosolve to give bright orange needles, mp 268–270°C/336–340°C dec.; ir (N): (3500–1500 region): 3250, 3050, 1625, 1595, 1560, 1545, 1525. *Anal.* calcd. for $C_{16}H_{12}N_6$: C 66.65, H 4.20, N 29.15; found: C 66.49, H 4.25, N 29.06.

The following hydrazones, prepared similarly, had C, H, and N analyses within 0.3. The aldehyde, colour of hydrazone, recrystallization solvent, and mp are indicated: 3-nitrobenzaldehyde, red, DMF, 305–308/ > 350°C; 3,4-dichlorobenzaldehyde, orange, DMF, 313–320/ > 350°C; *p*-acetamidobenzaldehyde, orange, methyl Cellosolve – water, mp 213–217/ ~330°C dec.; veratraldehyde, orange, DMF–H_2O, mp 235–237°C; 4-cyanobenzaldehyde, reddish-orange, DMF, mp 305–310/ > 350°C; 3,4,5-trimethoxybenzaldehyde, orange, methyl Cellosolve – water, mp 265–267°C; *trans*-cinnamaldehyde, red, DMF, mp 243–247/ > 350°C; 2-pyridinecarboxaldehyde, orange, DMF, mp 257–258°C; indole-3-carboxaldehyde, orange, DMF–H_2O, mp 305–310/ > 350°C.

*3-Deuterio-1(or 9)*H*-pyridazino[3,4,5-de]phthalazine*

A mixture of **6** (1 g), deuterium oxide (99.5%, 100 mL), and $CuSO_4$ crystals (20 mg) was adjusted to pH 8 with a little anhydrous Na_2CO_3. It was stirred at room temperature while air was bubbled in over 18 h. The mixture was filtered free of dark solid, concentrated to dryness at reduced pressure, and extracted with chloroform (4 × 50 mL). Evaporation of the chloroform left a yellow solid (0.2 g), mp 257–262°C dec., which was recrystallized from ethanol to give 0.14 g, mp 268–270°C dec.; ir (KBr) (3000–800, principal peaks): 2850 (broad), 1657, 1620, 1610, 1585, 1450, 1368, 1170, 850; ^{1}Hmr: 7.2–7.6 (m, 3*H*, aryl), 8.2 (s, 1*H*, vinyl), 11.8 (broad s, N*H*).

*9-Phenyl-6*H*-pyridazino[3,4,5-de][1,2,4]triazolo[3,4-a]-phthalazine (****48****a)*

The dihydrochloride of **6** (14.0 g) was added gradually to a stirring solution of benzoyl chloride (6.5 mL) in pyridine (100 mL). After the initial exotherm, it was stirred 2 h at reflux, poured into ice-water, and stirred 16 h. The precipitate was washed with water and ethanol thoroughly and the crude **48***a* (13.0 g, 89%) mp 298–338°C dec., was recrystallized twice from methyl Cellosolve, once with charcoal, to give pale yellow crystals, mp 332–342°C dec.; ir (N): 3020, 1625, 1600, 1530; uv (CH_3OH): 279.5 (28500), 348 (6200). *Anal.* calcd. for $C_{16}H_{10}N_6$: C 67.11, H 3.53, N 29.36; found: C 66.99, H 3.68, N 29.52.

By the use of acetyl chloride in pyridine, the 9-methyl derivative **48***b*, mp > 355°C, was obtained. Infrared (N): 3020, 1625, 1600, 1520. *Anal.* calcd. for $C_{11}H_8N_6$: C 58.92, H 3.60, N 37.48; found: C 58.65, H 3.74, N 37.60.

*9-Trifluoromethyl-6*H*-pyridazino[3,4,5-de][1,2,4]triazolo-[3,4-a]phthalazine (****48****c)*

The dihydrochloride of **6** (65.7 g) in trifluoroacetic acid (200 mL) was stirred 20 h at reflux, poured into ice-water (600 mL), and the precipitate (64.3 g) recrystallized twice from dimethylformamide to afford the pure **48***c*, mp 314–315°C; ir (N): 3110, 1630, 1608, 1595, 1530, 1278, 1188, 1178, 1135. *Anal.* calcd. for $C_{11}H_5F_3N_6$: C 47.49, H 1.81, N 30.21, F 20.49; found: C 47.38, H 1.96, N 30.13, F 20.17.

*6*H*-Pyridazino[3,4,5-de]tetrazolo[5,4-a]phthalazine (****49****)*

A solution of **6**·2HCl (44 g) in water (900 mL) cooled to 0°C was treated dropwise with $NaNO_2$ (10.65 g) in water (150 mL) to maintain a temperature of 0–5°C. A tan solid gradually precipitated during addition. It was stirred 30 min longer and the precipitate washed with water and air dried. The crude tetrazole **49** (34 g, 100%) was recrystallized three times from DMSO (once with charcoal), washed thoroughly with ethanol, and dried *in vacuo*, mp > 350°C; ir (N): 3050, 1620, 1600, 1580, 1530. *Anal.* calcd. for $C_9H_5N_7$: C 51.18, H 2.39, N 46.43; found: C 51.02, H 2.35, N 46.13.

Preparation of ***4*** *from Hemimellitic Esters*

A mixture of trimethyl hemimellitate (**9**) (28) (2.52 g), hydrazine hydrate (20 mL), and methyl Cellosolve (80 mL) was stirred 46 h at reflux, cooled, and the yellow-orange precipitate washed well with water and methanol and dried *in vacuo*. Crude **46** (1.6 g), mp > 350°C, ir (N): 3500, ~3200, 2700–2200 (broad), 1630, 1585, 1565, 1530 was also obtained in 37% yield from dimethyl-3-carboxyphthalate (**45**) in refluxing 50% aqueous hydrazine hydrate after 47 h.

Crude **46** (10 g), phosphorous pentachloride (25 g), and phosphoryl chloride (125 mL) were heated at reflux under moisture exclusion for 22 h. The dark mixture was cooled, quenched in ice-water and filtered. The product (2.75 g), mp > 330°C was combined with a second crop (2.85 g) obtained by evaporation of the mother liquor to 100 mL, (ir (N): 2800–2200 (broad), 1615, 1565, 1540) and used without purification. A portion (500 mg), red phosphorous (8 g), and 47% hydriodic acid (120 mL) was stirred at reflux 18 h, cooled, filtered, and the filtrate concentrated to one-half volume, neutralized with 5% aqueous Na_2CO_3 and concentrated to dryness. The residue was taken up in hot ethanol (200 mL), filtered free of residual solid, and again concentrated to dryness. The residue was taken up in water, treated with $NaHSO_3$ (1 g) and acetic acid (5 drops), and extracted with hot chloroform. The dried chloroform extract was concentrated to dryness and identified as **4** by ir and tlc in four different solvent systems compared to authentic **4**.

Preparation of ***4*** *from* ***43***

A mixture of **43** (4.04 g), ethanol (200 mL), and methyl Cellosolve (200 mL) was treated with Raney nickel (about 20 g), heated 4 h on a steam bath, filtered hot, cooled, and again filtered. The filtrate was concentrated to dryness, taken up in boiling ethanol (500 mL), filtered free of solid, and again concentrated to dryness. The residue was taken up in boiling water (800 mL), filtered, and cooled. The product formed from the filtrate (0.4 g) was identical to authentic **4**, as shown by ir and tlc.

Preparation of ***4*** *from* ***44***

Crude **44** (4.82 g), 47% hydriodic acid (60 mL), and red phosphorous (4 g) were stirred 18 h at reflux, poured into ice-water, filtered, and the filtrate concentrated to dryness at reduced pressure. The residual yellow solid was suspended in water, made alkaline with Na_2CO_3, washed with water, and dried. The product (1.3 g, 38%) was identical (ir) to authentic **4**.

Preparation of ***4*** *from* ***6***

The dihydrochloride of **6** (60 mg) was suspended in 1 *M* sodium phosphate buffer, pH 7.2 (30 mL), and heated at 80°C

for 20 h. It was evaporated to dryness, washed with ether, and the residual solid suspended in warm ethanol and filtered. The ethanol extract was concentrated to dryness and the yellow crystalline residue (32 mg, 94%) was pure by tlc and identical (ir) to **4**.

Metabolites of bird's nest fungi. Part 11.[1] Diterpenoid metabolites of *Cyathus earlei* Lloyd

WILLIAM A. AYER AND SING PING LEE

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received May 23, 1979

This paper is dedicated to Prof. Karel Wiesner on the occasion of his 60th birthday

WILLIAM A. AYER and SING PING LEE. Can. J. Chem. **57**, 3332 (1979).

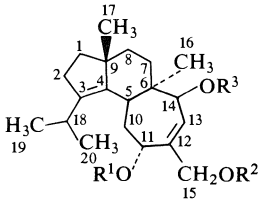
The bird's nest fungus *Cyathus earlei* Lloyd produces new diterpenoid metabolites of the cyathin type. Cyathatriol is shown to have structure **1** and has been correlated with cyathin A_3. 11,15-*O*,*O*-Diacetylcyathatriol (**2**), 15-*O*-acetylcyathatriol (**3**), and 11-*O*-acetylcyathatriol (**4**) have also been isolated. The first cyathins containing only two oxygens, cyathin B_2 (**19**) and allocyathin B_2 (**12**), are also described.

WILLIAM A. AYER et SING PING LEE. Can. J. Chem. **57**, 3332 (1979).

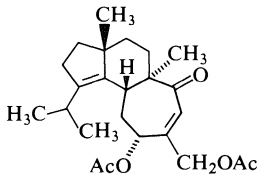
Les champignons des nids d'oiseau *Cyathus earlei* Lloyd produisent deux nouveaux métabolites diterpéniques du type cyatine. On a montré que le cyathatriol a la structure **1** et on l'a relié à la cyathyne A_3. On a également isolé les composés suivants: *O*,*O*-diacétyl 11,15 cyathatriol (**2**), *O*-acétyl-15-cyathatriol (**3**) et le *O*-acétyl-11-cyathatriol (**4**). On a également décrit les premières cyathines contenant seulement deux oxygènes, soient la cyathine B_2 (**19**) et l'allocyathine B_2 (**12**).

[Traduit par le journal]

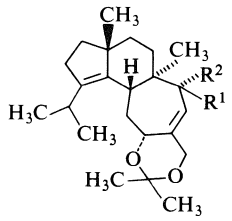
Cyathus earlei Lloyd is a tropical or subtropical species of bird's nest fungus (family Nidulariaceae) which is known to occur in Cuba, Puerto Rico, Mexico, and Hawaii (2). As part of our investigation of the nature of the metabolites of various bird's nest fungi[2] we have examined the metabolites formed when *C. earlei* is grown in liquid culture. Extraction with ethyl acetate of the mycelium obtained after sixty-five days growth on Brodie medium (ref. 2, p. 36) gave six new compounds belonging to the "cyathin" group (4) of diterpenoids. The compounds were separated by chromatography over silica gel. First eluted was a compound $C_{20}H_{28}O_2$ (cyathin B_2)[3] followed by an isomeric substance (allocyathin B_2). The next three substances eluted are acetyl derivatives of the most polar compound, $C_{20}H_{32}O_3$, for which we propose the name cyathatriol. Cyathatriol is shown below to possess structure **1**, and the intermediate compounds are 11,15-*O*,*O*-diacetylcyathatriol (**2**), 15-*O*-acetylcyathatriol (**3**), and 11-*O*-acetylcyathatriol (**4**).



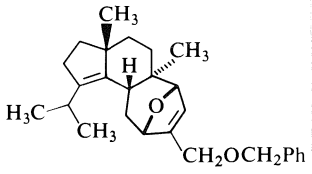
1 $R^1 = R^2 = R^3 = H$
2 $R^1 = R^2 = Ac, R^3 = H$
3 $R^1 = H, R^2 = Ac, R^3 = H$
4 $R^1 = Ac, R^2 = R^3 = H$
5 $R^1 = R^2 = R^3 = Ac$
10 $R^1 = R^3 = H, R^2 = —CH_2Ph$



6



7 $R^1 = OH, R^2 = H$
8 $R^1, R^2 =$ Carbonyl
9 $R^1 = H, R^2 = OH$



11

Acetylation (Ac_2O, pyridine) of cyathatriol (**1**) provided *O*,*O*,*O*-triacetylcyathatriol (**5**). Acetylation of 15-*O*-acetylcyathatriol (**3**) and 11-*O*-acetylcyathatriol (**4**) under similar conditions produce the same triacetyl derivative **5**, and hydrolysis of **3** and **4** gave cyathatriol (**1**). Acetylation of 11-*O*-acetylcyathatriol **4** under mild conditions gave 11,15-*O*,*O*-diacetylcyathatriol (**2**). Oxidation of **2** with manganese dioxide gave *O*,*O*-diacetylcyathin A_3 (**6**), identical in all respects with an authentic sample (4). Cyathatriol was also correlated with cyathin A_3 via its acetonide **7** which on oxidation with Collins' reagent furnished cyathin A_3 acetonide (**8**). These experiments define the structure of cyathatriol except for the configuration of the hydroxyl group at C-14.

The positions of the acetyl groups in **2**, **3**, and **4** were apparent from the ^{1}Hmr spectra of these com-

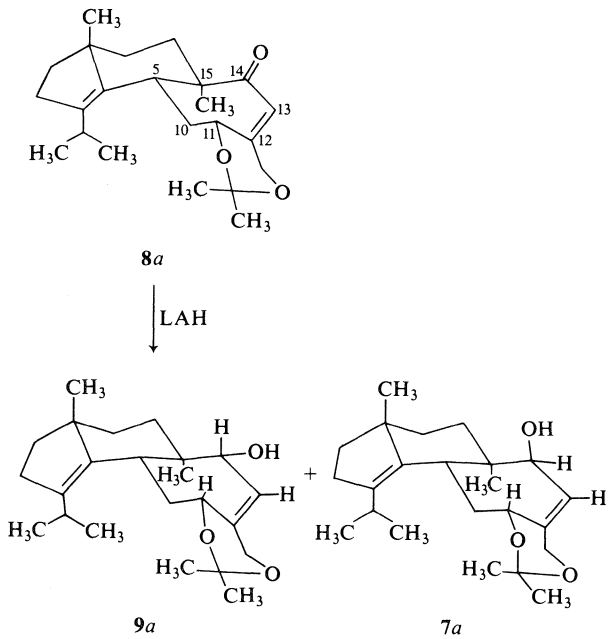
[1]For part 10, see ref. 1.
[2]For a review of earlier work, see ref. 3.
[3]For the system of trivial nomenclature, see ref. 4.

0008-4042/79/243332-06$01.00/0

pounds. Thus **2** shows a multiplet at δ 5.85 for the hydrogen at C-11 (the reason for the very low chemical shift is discussed below) and a two proton AB quartet at δ 4.44 for the C-15 methylene group. The signal for the hydrogen on C-14 appeared at δ 3.70 as a doublet spin coupled (J = 6 Hz) to the olefinic proton at C-13. The assignment also follows from the oxidation of **2** to *O*,*O*-diacetylcyathin A_3 (**6**). In compound **3** the signal for the C-15 methylene group appears at δ 4.60, and in **4** the C-11 hydrogen is shifted downfield to δ 5.95.

The low field position of the C-11 hydrogen in cyathatriol (δ 4.85) and the acetyl derivatives, some of which are mentioned above, provided the first indication that the hydroxyl group at C-14 is β-oriented since a hydroxyl group proximate in space to a hydrogen is strongly deshielding (5).

Further evidence for the stereochemistry at C-14 was obtained by a study of the lithium aluminum hydride (LAH) reduction of cyathin A_3 acetonide (**8** = **8***a*) illustrated in Scheme 1. Study of Dreiding models clearly indicated that LAH reduction of the carbonyl group should occur predominantly from the less hindered β-face of the molecule and indeed the unnatural epimer **9** (= **9***a* in Scheme 1) was the major product of the reduction (ratio **9**:**7** = 7:1). Both ^{1}Hmr and ^{13}Cmr support the assigned structures and stereochemistry (it is assumed that ring C exists in the chair form indicated). Thus the C-11 hydrogen which appears at δ 4.80 in **7***a* (deshielded by C-14 β-OH) appears at δ 4.15 in **9***a*. The coupling between the olefinic hydrogen at C-13 and the hydrogen at C-14 is ca. 6 Hz in **7***a*, consistent with a dihedral angle approaching 0°, and less than 1 Hz in **9***a*, as expected for a dihedral angle approaching 90° (6). In the ^{13}Cmr spectrum[4] of **7***a* the methyl group at C-6 resonates at δ 17.6, whereas in **9***a* it resonates at δ 12.1, demonstrating the γ-gauche relationship (7) of the hydroxyl and methyl groups in the latter compound. Conversely, C-5 is upfield in **7***a* (δ 39.1) relative to **9***a* (δ 45.0).



SCHEME 1

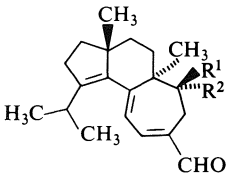
In order to demonstrate chemically the *trans*-relationship between the hydroxyls at C-11 and C-14 we decided to attempt the formation of an internal ether. It was first necessary to block the C-15 oxygen function. The use of 15-*O*-acetylcyathatriol (**3**) was not possible since it is rapidly isomerized to 11-*O*-acetylcyathatriol (**2**) in the presence of bases such as pyridine or triethylamine. However, treatment of cyathatriol with a limited amount of sodium hydride and benzyl bromide gave the C-15 benzyl ether **10**. When **10** was treated briefly with an ethereal solution of methanesulfonyl chloride and triethylamine the ether **11** was obtained in low yield. The orientation of the ethereal oxygen is not clearly defined by the ^{1}Hmr spectrum, however we favor the β-orientation since the hydrogen at C-5 has an unusually low chemical shift (δ 3.20), attributed to the deshielding effect of the ethereal oxygen. This assignment is also consistent with mesylation of the less hindered C-11 hydroxyl followed by backside displacement by the hydroxyl group at C-14.

Allocyathin B_2, assigned structure **12**, was obtained as a pale yellow oil and showed a very informative uv spectrum. The spectrum (λ_{max}: 266 nm (ε 5150) and 325 nm (ε 12 100)) is very similar to that of anhydrocyathin B_3 (**13**), previously obtained from cyathin B_3 (8). The ^{1}Hmr was also similar to that of **13** except that the hydrogen *vicinal* to the hydroxyl group in **12** gives rise to absorption at δ 3.63 (dd, J's 6 and 1 Hz). The ir spectrum of **12** shows hydroxyl absorption and only one carbonyl absorption (1675 cm^{-1}). Oxidation of allocyathin B_2 with Collins' reagent gave anhydrocyathin B_3 (**13**), confirming structure **12** except for the configuration at C-14. Reduction of anhydrocyathin B_3 (**13**) with LAH provided a mixture of diols **14** and **15** in a ratio of ca. 2:1. Oxidation of **14** with MnO_2 gave allocyathin B_2 (**12**). Similar oxidation of **15** provided 14-epiallocyathin B_2 (**16**). The assignment of con-

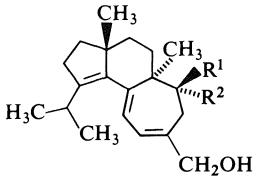
[4]For a discussion of the ^{13}Cmr spectra of the cyathins, see ref. 1. Complete assignments for cyathatriol and its derivatives are detailed in the accompanying paper discussing the biosynthesis of these compounds.

figuration in **12** and **16** is based on application of Brewster's benzoate rule (9). Thus $[M]_D$**17** − $[M]_D$**12** = +78.1° indicating the *S* configuration at C-14 in **12**, and $[M]_D$**18** − $[M]_D$**16** = −26.5° indicating the *R* configuration in **16**. It thus appears that allocyathin B_2 has the same configuration at C-14 as cyathatriol.

Cyathin B_2 is assigned structure **19** on the basis of the following evidence. The infrared spectrum shows the presence of a unconjugated ketone (1710 cm^{-1}) and an α,β-unsaturated aldehyde (2710, 1698, 1645 cm^{-1}). The unsaturated aldehyde gives rise to absorption in the uv at 228 nm (ε 6100). The ^{1}Hmr spectrum also shows the unsaturated aldehyde system (δ 9.38 (s) and 6.60 (m)) and, in addition shows an AB quartet (J = 14 Hz) at δ 3.32 and 3.64 for the protons of the C-13 methylene group. A similar set of signals (δ 3.09, 3.69, J = 11 Hz) appears for the C-13 methylene protons in anhydrocyathin B_3 (**13**). In an attempt to correlate cyathin B_2 with cyathin B_3 (**20**) cyathin B_2 was treated with alkaline hydrogen peroxide in methanol. A mixture of products was obtained, none of which corresponded to cyathin B_3. The least polar component of the mixture, however, was anhydrocyathin B_3 (**13**). A possible mechanism for the transformation of **19** into **13** is illustrated in Scheme 2, where an initially formed epoxide **A** undergoes β-elimination to give **B**, which in turn undergoes nucleophilic addition and subsequent β-elimination (for brevity, written as one step in **B**) to give **C** which undergoes vinylogous β-elimination (to **D**) followed by tautomerization to the fully conjugated triene system in **13**. This transformation establishes most of the features of structure **19** and together with the spectroscopic data provides strong evidence for the structure of cyathin B_2 (**19**).



12 R^1 = OH, R^2 = H
13 R^1 = R^2 = Carbonyl
16 R^1 = H, R^2 = OH
17 R^1 = OBz, R^2 = H
18 R^1 = H, R^2 = OBz



14 R^1 = OH, R^2 = H
15 R^1 = H, R^2 = OH

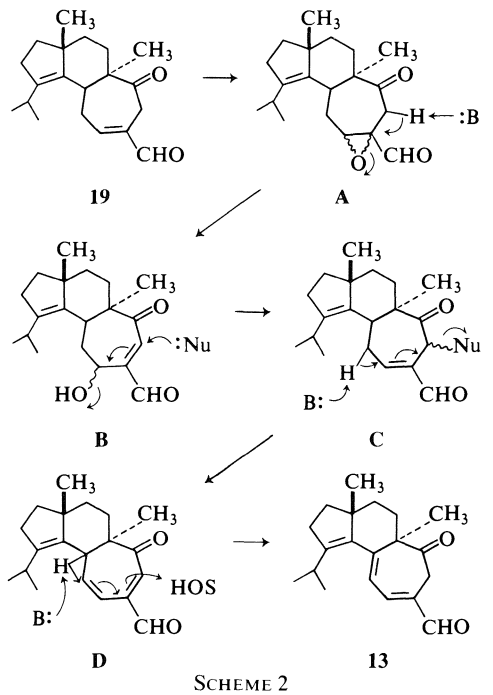

SCHEME 2

All six compounds described herein show moderate antibiotic activity against *Staphyloccocus aureus*.

Experimental

High resolution mass spectra were recorded on an AEI MS-50 mass spectrometer, coupled to a DS 50 computer. Infrared spectra were recorded on a Unicam SP 1000 or a Nicolet 7199 FT spectrometer and uv spectra on a Cary model 14 M spectrometer. ^{1}Hmr spectra were determined on a Varian HA-100 spectrometer with TMS as internal standard. Melting points were recorded on a Fisher-Johns melting point apparatus and are uncorrected. Specific rotations at the D line were determined using a Perkin-Elmer 141 automatic polarimeter.

Silica gel tlc plates were 0.5 mm silica gel G (E. Merck, Darmstadt) containing 1% electronic phosphor (General Electric, Cleveland). Compounds were detected by viewing under uv light or by spraying with 30% sulfuric acid and charring. All solvents were reagent grade and were distilled prior to use. Unless otherwise specified, anhydrous magnesium sulfate was used as a drying agent for organic solutions and silica gel 60 (BDH Chemicals) as absorbant for column chromatography. Skellysolve B refers to Skelly Oil Company light petroleum, bp 62–70°C.

Growth of Cyathus earlei *Lloyd and Isolation of Metabolites*

Slant tubes of *Cyathus earlei* Lloyd ATCC 38343 were obtained from H. J. Brodie (strain 1286). The fungus was grown in liquid still culture at room temperature on Brodie medium (2) in 2.8 L Fernbach flasks (1 L medium/flask, total 18 L). After 30 days growth the broth was decanted and the mycelium reflooded with fresh sterile Brodie medium. Five weeks later the mycelium was removed by filtration and placed in Soxhlet thimbles and extracted with ethyl acetate for 4 days. The ethyl acetate extract was washed with water, dried over sodium sulfate, and concentrated to a viscous brown oil (7.7 g). A portion (4 g) of the crude extract was subjected to column chromatography over silica gel (200 g). Progress of the separation was

monitored by thin layer chromatography (tlc). Elution with Skellysolve B – benzene (1:9) gave *cyathin* B_2 (51 mg). Elution with benzene afforded *allocyathin* B_2 (210 mg). Elution with ether–benzene (1:9) gave *15-O-acetylcyathatriol* (310 mg) followed by *11,15*-O,O-*diacetylcyathatriol* (46 mg). Elution with ether–benzene (1:4) gave *11*-O-*acetylcyathatriol* (132 mg). Finally, elution with ether–benzene (2:3) gave cyathatriol (22 mg).

Cyathin B_2 (**19**)

Cyathin B_2 was obtained as a viscous syrup; ir (CCl_4): 2710, 1710, 1698, 1645 cm^{-1}; uv (CH_3OH) λ_{max}: 228 nm (ε 6100); ^{1}Hmr (CCl_4) δ: 0.99 (s, 3H), 1.02 (d, J = 6 Hz, 6H), 1.10 (s, 3H), 3.32 (d, J = 14 Hz, 1H on C-13), 3.64 (dd, J's 14 and 1 Hz, 1H on C-13), 6.60 (m, C-11, H), 9.38 (s, 1H). *Exact mass* calcd. for $C_{20}H_{28}O_2$: 300.2090; found (ms): 300.2092.[5]

Allocyathin B_2 (**12**)

Allocyathin was obtained as a yellow syrup which showed a single spot on tlc, $[\alpha]_D^{25}$ +87.1° (*c* 0.95, CH_3OH); ir (CCl_4): 3600, 2720, 1675, 1570 cm^{-1}; uv (hexane) λ_{max}: 266 (ε 5150), 325 nm (ε 12 100); ^{1}Hmr (CCl_4) δ: 0.96 and 1.05 (each 3H, d, J = 6 Hz), 0.97 (s, 3H), 1.01 (s, 3H), 2.80 (heptet, J = 6 Hz, H on C-18), 3.09 (dd, J's 18 and 6 Hz, 1H on C-13), 3.63 (dd, J's 6 and 1 Hz, H on C-14), 5.84 (d, J = 8 Hz, H on C-10), 6.68 (dd, J's 8 and 1 Hz, H on C-11), 9.37 (s, 1H). *Exact mass* calcd. for $C_{20}H_{28}O_2$: 300.2090; found (ms): 300.2092. *Anal.* calcd. for $C_{20}H_{28}O_2$: C 80.02, H 9.40; found: C 80.04, H 9.70.

11,15-O,O-*Diacetylcyathatriol* (**2**)

11,15-*O,O*-Diacetylcyathatriol crystallized from Skellysolve B – ether, mp 123–124°C; ir (CCl_4): 3600, 3500, 1745 cm^{-1}; ^{1}Hmr (CCl_4) δ: 0.70 (s, 3H), 0.95 (d, J = 6 Hz, 6H), 1.10 (s, 3H), 1.98 (s, 3H), 2.00 (s, 3H), 2.90 (heptet, J = 6 Hz, H on C-18), 3.00 (dd, J's 10 and 1 Hz, 1H at C-5), 3.70 (d, J = 6 Hz, 1H), 4.34 (dd, J's 14 and 1 Hz, 1H on C-15), 4.54 (dd, J's 14 and 1 Hz, 1H on C-15), 5.82 (dd, J's 6 and 1 Hz, 1H on C-13), 5.85 (m, 1H on C-11). *Anal.* calcd. for $C_{24}H_{36}O_5$: C 71.25, H 8.96; found: C 70.96, H 9.07. The highest peak in the mass spectrum corresponded to the molecular ion – H_2O. *Exact mass* calcd. for $C_{24}H_{34}O_4$ ($M^+ - H_2O$): 386.2457; found: 386.2454.

15-O-*Acetylcyathatriol* (**3**)

15-*O*-Acetylcyathatriol was obtained as a viscous oil showing a single spot on tlc; ir (CCl_4): 3600, 3500, 1745 cm^{-1}; ^{1}Hmr (CCl_4) δ: 0.75 (s, 3H), 0.98 (d, J = 6 Hz, 6H), 1.07 (s, 3H), 2.05 (s, 3H), 3.00 (m, 2H, H's on C-5 and C-18), 3.82 (d, J = 6 Hz, H on C-14), 4.60 (s, 2H on C-15), 4.70 (m, H on C-11), 5.65 (d, J = 6 Hz, H on C-13). *Exact mass* calcd. for $C_{22}H_{34}O_4$: 362.2457; found: 362.2479. *Anal.* calcd. for $C_{22}H_{34}O_4$: C 72.87, H 9.45; found: C 72.58, H 9.48.

11-O-*Acetylcyathatriol* (**4**)

11-*O*-Acetylcyathatriol crystallized from ether, mp 165–166°C; ir (CCl_4): 3500, 1710 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.80 (s, 3H), 0.97 (d, J = 6 Hz, 6H), 1.10 (s, 3H), 2.10 (s, 3H), 3.02 (br d, J = 10 Hz, H on C-5), 3.90 (d, J = 6 Hz, H on C-14), 4.06 (s, 2H on C-15), 5.86 (dd, J's 6 and 1 Hz, H on C-13), 5.95 (m, H on C-11). *Exact mass* calcd. for $C_{22}H_{34}O_4$: 362.2457; found: 362.2496. *Anal.* calcd. for $C_{22}H_{34}O_4$: C 72.87, H 9.45; found: C 72.51, H 9.54.

[5]Where combustion analysis is not reported, molecular formulas were determined by high resolution mass spectrometry. Eventual correlation with compounds of established molecular formula validates the deductions made in this manner.

Cyathatriol (**1**)

Cyathatriol was obtained as a white powder which crystallized from acetone, mp 172–173°C; ir (film): 3300 cm^{-1}; ^{1}Hmr (acetone-d_6) δ: 0.80 (s, 3H), 0.94 (d, J = 6 Hz, 3H), 0.95 (d, J = 6 Hz, 3H), 1.07 (s, 3H), 3.00 (m, H's on C-5 and C-18), 3.76 (d, J = 6 Hz, H on C-14), 4.12 (s, 2H on C-15), 4.85 (ddd, J's 8, 4, and 1 Hz, H on C-11), 5.87 (dd, J's 6 and 1 Hz, H on C-13). *Exact mass* calcd. for $C_{20}H_{32}O_3$: 320.2351; found: 320.2336. *Anal.* calcd. for $C_{20}H_{32}O_3$: C 74.94, H 10.07; found: C 74.67, H 10.14.

Cyathatriol (**1**) *from* **3** *and* **4**

15-*O*-Acetylcyathatriol (20 mg) in methanol (2 mL) containing potassium carbonate (20 mg) was stirred at room temperature for 16 h. The reaction mixture was diluted with water (10 mL) and extracted with ether (3 × 50 mL). The ether extract was dried and evaporated to give crystalline cyathatriol (16 mg).

11-*O*-Acetylcyathatriol was hydrolyzed under the same conditions to give cyathatriol.

Preparation of 11,14,15-O,O,O-*Triacetylcyathatriol from* **3**, **4**, *and* **1**

To a solution of 15-*O*-acetylcyathatriol (**3**, 20 mg) in pyridine (1 mL) there was added acetic anhydride (30 μL). The solution was left at room temperature for 24 h, then diluted with ether (50 mL) and washed successively with 1*M* HCl, saturated $NaHCO_3$, and brine. The organic solution was worked up in the usual manner to give an oil (32 mg). Purification by column chromatography yielded 11,14,15-*O,O,O*-triacetylcyathatriol (**5**, 24 mg) as a colorless oil; ir (CCl_4): 1735 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.85 (s, 3H), 0.98 (d, J = 6 Hz, 3H), 0.99 (d, J = 6 Hz, 3H), 1.09 (s, 3H), 2.10 (s, 6H), 2.14 (s, 3H), 2.90 (heptet, H on C-18), 4.41 (d, J = 14 Hz, H on C-15), 4.68 (d, J = 14 Hz, H on C-15), 4.87 (d, J = 6 Hz, H on C-14), 4.90 (m, H on C-11), 5.84 (dd, J's 6 and 1 Hz, H on C-13). The highest peak in the mass spectrum corresponded to loss of acetic acid from the molecular ion. *Exact mass* calcd. for $C_{24}H_{36}O_4$ ($M^+ - CH_3COOH$): 386.2463; found: 386.2465.

In a similar fashion both 11-*O*-acetylcyathatriol (**4**) and cyathatriol (**1**) were transformed to the same triacetyl derivative.

11,15-O,O-*Diacetylcyathatriol* (**2**) *from 11*-O-*Acetylcyathatriol* (**4**)

A solution of 11-*O*-acetylcyathatriol (**4**, 10 mg) in methylene chloride (1 mL) was cooled to 0°C and pyridine (50 μL) and acetic anhydride (30 μL) added. After 18 h at 0°C the reaction mixture was worked up in the usual manner to give a product which was purified by chromatography over silica gel using benzene as eluant to give 11,15-*O,O*-diacetylcyathatriol (7 mg), identical (mp, ir, ^{1}Hmr, ms) with an authentic sample.

O,O-*Diacetylcyathin* A_3 (**6**) *from 11,15*-O,O-*Diacetylcyathatriol* (**2**)

A mixture of **2** (13 mg) and activated (10) manganese dioxide (100 mg) in CH_2Cl_2 was stirred at room temperature for 1.5 h. The reaction mixture was filtered and the filter cake washed thoroughly with ether. Concentration of the filtrate gave an oil (13 mg) which was chromatographed using benzene–ether (4:1) to give *O,O*-diacetylcyathin A_3 (**6**), identical (ir, ^{1}Hmr ms) with an authentic sample.

Cyathatriol Acetonide (**7**)

Cyathatriol (**1**, 30 mg) was dissolved in 2,2-dimethoxypropane (2 mL) at 35°C and *p*-toluenesulfonic acid (3 mg) added. After 5 min water (10 mL) was added and the solution was extracted with ether. Evaporation of the ether gave **7** as a white solid (31 mg), mp 189–190°C from ether, $[\alpha]_D^{25}$ −21.4°

(MeOH); ir ($CHCl_3$): 3600, 3500 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.76 (s, 3H), 0.97 (d, J = 6 Hz, 6H), 1.09 (s, 3H), 1.38 (s, 6H), 3.05 (heptet, H on C-18), 3.22 (dd, J's 10 and 1 Hz, H on C-5), 3.65 (d, J = 6 Hz, H on C-14), 3.80 (d, J = 12 Hz, H on C-15), 4.48 (ddd, J's 12, 1, and 1 Hz, H on C-15), 4.70 (m, H on C-11), 5.60 (dd, J's 6 and 1 Hz). *Exact mass* calcd. for $C_{23}H_{36}O_3$: 360.2665; found: 360.2676. *Anal.* calcd. for $C_{23}H_{36}O_3$: C 76.60, H 10.07; found: C 76.70, H 10.35.

Compound **7** was further characterized as its 14-*O*-benzoyl derivative, mp 151–153°C (from Skellysolve B – ether), $[\alpha]_D^{25}$ −1.7° (*c* 0.35, MeOH).

*Cyathin A_3 Acetonide (**8**) from Cyathatriol Acetonide (**7**)*

Chromium trioxide (21 mg) was added to a stirred solution of pyridine (32 μL) in CH_2Cl_2 (2 mL). After 10 min a solution of **7** (14 mg) in CH_2Cl_2 (0.5 mL) was introduced and the reaction mixture was stirred at room temperature for a further 5 min. After work-up in the usual manner and purification of the product by chromatography over silica gel (eluant benzene–ether 9:1), cyathin A_3 acetonide (**8**, 11 mg) was obtained, identical (ir, ^{1}Hmr, ms) with an authentic sample.

*Reduction of Cyathin A_3 Acetonide (**8**)*

To a solution of **8** (50 mg) in ether (6 mL) at 0°C was added $LiAlH_4$ (10 mg). The reaction mixture was stirred for 20 min, then a solution of 10% aqueous $NaHCO_3$ was added and the mixture was extracted with ether. The extract was dried and concentrated and the residue chromatographed over silica gel to give cyathatriol acetonide (**7**, 4.2 mg) and *14-epicyathatriol acetonide* (**9**, 28.1 mg), mp 186–187°C, $[\alpha]_D^{25}$ −17.0° (*c* 0.27, MeOH); ir (CCl_4): 3600 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.79 (s, 3H), 0.99 (d, J = 6 Hz, 6H), 1.10 (s, 3H), 1.40 (s, 6H), 2.65 (dd, J's 10 and 1, H on C-5), 3.00 (heptet, H on C-18), 3.82 (d, J = 13 Hz, 1H on C-15), 4.10 (broad s, H on C-14), 4.21 (m, H on C-11), 4.40 (ddd, J's 13, 1, 1 Hz, 1H on C-15), 5.27 (broad s, H on C-13). *Exact mass* calcd. for $C_{23}H_{36}O_3$: 360.2665; found: 360.2676.

14-Epicyathatriol acetonide (**9**) was further characterized as its 14-*O*-benzoyl derivative, mp 157–158°C (from Skellysolve B – ether), $[\alpha]_D^{25}$ +12.2° (*c* 0.35, MeOH).

*15-O-Benzylcyathatriol (**10**)*

A solution of cyathatriol (**1**, 6.8 mg) in ether (2 mL) was treated with sodium hydride (6 mg) and benzyl bromide (10 μL) and then heated under reflux for 24 h. The reaction mixture was poured into ice water (10 mL) and extracted with ether (3 × 50 mL). The extract was dried and concentrated to give an oil (5.4 mg) which was purified by chromatography over silica gel (eluant benzene) to give the ether **10** (4.5 mg) as a colorless oil; ir ($CHCl_3$): 3500; ^{1}Hmr ($CDCl_3$) δ: 0.80 (s, 3H), 0.98 (d, J = 6 Hz, 6H), 1.10 (s, 3H), 3.00 (heptet, H on C-5), 3.85 (d, J = 6 Hz, H on C-14), 4.12 and 4.25 (AB quartet, J = 12 Hz, H's on C-15), 4.59 (s, 2H benzyl methylene), 4.85 (m, H on C-11), 5.80 (dd, J's 6 and 1 Hz, H on C-13), 7.35 (s, 5H). The highest peak in the mass spectrum was for $M^+ - H_2O$. *Exact mass* calcd. for $C_{27}H_{36}O_2$ ($M^+ - H_2O$): 392.2712; found: 392.2713.

*Formation of Cyclic Ether **11***

The benzyl ether **10** (6 mg) in ether (2 mL) at 0°C was treated with triethylamine (15 μL) and methanesulfonyl chloride (7 μL). After 5 min the reaction mixture was diluted with ether (20 mL) and washed with dilute HCl. Evaporation of the ether gave a crude oil (6 mg) which was chromatographed on silica gel to give the ether **11** as a colorless oil (2 mg); ir, no OH absorption; ^{1}Hmr ($CDCl_3$) δ: 0.97 (d, J = 6 Hz, 3H), 0.98 (d, J = 6 Hz, 3H), 1.00 (s, 3H), 1.12 (s, 3H), 2.85 (heptet, H on C-18), 3.20 (dd, J's 7 and 4 Hz, H on C-5), 3.72 (br s, H on C-14), 3.80 (s, 2H), 4.27 (d, J = 12 Hz, 1H on C-15), 4.30 (m, 1H, H on C-11?), 4.39 (d, J = 12 Hz, 1H on C-15), 5.50 (br s, H on C-13), 7.20 (s, 5H). *Exact mass* calcd. for $C_{27}H_{36}O_2$: 392.2715; found: 392.2731.

*Oxidation of Allocyathin B_2 (**12**)*

Chromium trioxide (36 mg) was added to a stirred solution of pyridine (57 μL) in CH_2Cl_2 (3 mL). After 15 min a solution of **12** (18 mg) in CH_2Cl_2 (0.5 mL) was added and the mixture was stirred for 5 min. The precipitated material was filtered off and washed with ether. The organic solutions were combined and evaporated. The residue was purified by ptlc to give anhydrocyathin B_3 (**13**, 16 mg), identical (tlc, ir, ^{1}Hmr, uv, ms) with an authentic sample (9).

*Attempted Epoxidation of Cyathin B_2 (**19**)*

Cyathin B_2 (12.5 mg) was dissolved in ice cold methanol (1 mL) and 1 *M* NaOH (80 μL) and 30% H_2O_2 (5 μL) were added. The solution was kept at 0°C for 24 h, then diluted with water (10 mL) and extracted with ether, to yield an oil (12 mg) which was subjected to ptlc to give anhydrocyathin B_3 (**13**, 2 mg), which could be followed by its yellow color, identical with an authentic sample.

*Reduction of Anhydrocyathin B_3 (**13**)*

A mixture of **13** (42 mg), LAH (20 mg), and ether (6 mL) was stirred at room temperature for 15 min, then excess hydride was destroyed by addition of saturated $NaHCO_3$. Extraction with ether and the usual work-up provided an oil which was separated into two components by ptlc (triple elution with ether) to give diols **14** (25 mg) and **15** (13 mg). *Diol **14*** showed the following properties: ir ($CHCl_3$): 3500; ^{1}Hmr ($CDCl_3$) δ: 0.98 (s, 3H), 0.99 (d, J = 6 Hz, 6H), 1.05 (s, 3H), 2.84 (heptet, H on C-18), 3.60 (dd, J's 5 and 2 Hz, H on C-14), 4.10 (s, 2H on C-15), 5.59 (d, J = 8 Hz, H on C-10), 6.05 (dd, J's 8 and 1 Hz, H on C-11). *Exact mass* calcd. for $C_{20}H_{30}O_2$: 302.2246; found: 302.2242. *Diol **15*** had the following properties: ir ($CHCl_3$): 3500 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.96 (d, J = 6 Hz, 3H), 0.96 (s, 3H), 1.00 (d, J = 6 Hz, 3H), 1.10 (s, 3H), 3.75 (dd, J's 10 and 2 Hz, H on C-14), 4.12 (s, 2H on C-15), 5.45 (d, J = 8 Hz, H on C-10), 5.86 (dd, J's 8 and 2 Hz, H on C-11). *Exact mass* calcd. for $C_{20}H_{30}O_2$: 302.2246; found: 302.2242.

*Oxidation of Diols **14** and **15***

Activated MnO_2 (50 mg) was added to a solution of diol **15** (9 mg) in CH_2Cl_2 (2 mL) and the mixture stirred for 15 min, then filtered and the filter cake washed thoroughly with ether. Concentration of the filtrate gave the hydroxyaldehyde **16** (8.2 mg) as a colorless oil $[\alpha]_D^{25}$ +97.5° (*c* 0.6, MeOH); ir ($CHCl_3$): 3600, 2720, 1675, 1570 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.96 (s, 3H), 0.96 (d, J = 6 Hz, 3H), 1.00 (d, J = 6 Hz, 3H), 1.10 (s, 3H), 3.67 (dd, J's 10 and 2 Hz, H on C-14), 5.58 (d, J = 8 Hz, H on C-10), 6.64 (dd J's 8 and 2 Hz, H on C-11), 9.48 (s). *Exact mass* calcd. for $C_{20}H_{28}O_2$: 300.2090; found: 300.2092.

Oxidation of diol **14** in the same manner provided allocyathin B_2 (**12**).

*Benzoates **17** and **18***

Allocyathin B_2 (**12**, 10 mg) in $CHCl_2$ (1 mL) was treated with pyridine (0.1 mL) and benzoyl chloride (0.05 mL) and the solution kept at room temperature for 6 h, then diluted with ether and washed with dilute HCl. Work-up gave an oil which was purified by chromatography over silica gel (eluent, benzene) to give benzoate **17** as a colorless syrup (10 mg), $[\alpha]_D^{25}$ +84.5° (*c* 0.7, MeOH); ir ($CHCl_3$): 1710, 1665 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.96 (s, 3H), 1.01 (d, J = 6 Hz, 6H), 1.12 (s, 3H), 2.90 (heptet, H on C-18), 3.34 (dd, J's 18 and 6 Hz, 1H on C-13), 5.23 (dd, J's 6 and 1 Hz, H on C-14), 6.00 (d, J = 8 Hz, H on C-10), 6.80 (dd, J's 8 and 2 Hz, H on C-11), 7.40 (m, 3H

aromatic), 7.90 (m, 2H aromatic), 9.40 (s, 1H). *Exact mass* calcd. for $C_{27}H_{32}O_3$: 404.2351; found: 404.2352.

Under the same conditions 14-epiallocyathin B_2 (**16**) was benzoylated to give **18** as a colorless oil, $[\alpha]_D^{25}$ +71.0° (*c* 0.50, MeOH); ir ($CHCl_3$): 1710, 1665 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.96 (s, 3H), 0.99 (d, *J* = 6 Hz, 3H), 1.01 (d, *J* = 6 Hz, 3H), 1.26 (s, 3H), 2.80 (heptet, 1H), 3.06 (dd, *J*'s 18 and 2 Hz, 1H on C-13), 5.18 (dd, *J*'s 11 and 2 Hz, H on C-14), 5.84 (d, *J* = 8 Hz, C-10H), 6.70 (dd, *J*'s 8 and 2 Hz, H on C-11), 7.50 (m, 3H, aromatic), 8.02 (m, 2H, aromatic), 9.42 (s, 1H). *Exact mass* calcd. for $C_{27}H_{32}O_3$: 404.2351; found: 404.2352.

Metabolites of bird's nest fungi. Part 12.[1] Studies on the biosynthesis of the cyathins

WILLIAM A. AYER, SING PING LEE, AND THOMAS T. NAKASHIMA
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 8, 1979

This paper is dedicated to Prof. Karel Wiesner on the occasion of his 60th birthday

WILLIAM A. AYER, SING PING LEE, and THOMAS T. NAKASHIMA. Can. J. Chem. **57**, 3338 (1979).

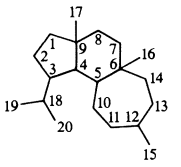
The cyathins are a group of diterpenoids of unique structure which are produced by bird's nest fungi of the family *Cyathus*. Biosynthetic studies utilizing [1-^{13}C], [2-^{13}C], and [1,2-$^{13}C_2$]acetate indicate that 11-*O*-acetylcyathatriol, produced by the fungus *C. earlei*, is formed from acetate via the isoprenoid pathway. The labelling experiments are consistent with a route involving cyclization–rearrangement of geranylgeranyl pyrophosphate as shown in Schemes 1 and 3.

WILLIAM A. AYER, SING PING LEE et THOMAS T. NAKASHIMA. Can. J. Chem. **57**, 3338 (1979).

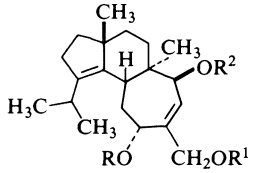
Les cyathines forment un groupe de diterpénoides à structure spéciale qui sont produits par les champignons de la famille *Cyathus* que l'on trouve dans les nids d'oiseaux. Les études biosynthétiques utilisant un acétate marqué au ^{13}C en positions [^{13}C-1], [^{13}C-2] et [$^{13}C_2$-1,2] indiquent que le *O*-acétyl-11 cyathatriol produit par le champignon *C. earlei* est formé à partir de l'acétate par l'intermédiaire d'un mécanisme isoprénoide. Les expériences de marquage sont en accord avec un cheminement impliquant une transposition accompagnée d'une cyclisation du phosphate de géranylgéranyle tel qu'indiqué dans les schémas 1 et 3.

[Traduit par le journal]

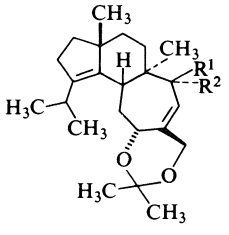
The cyathins are a unique type of diterpenoid produced by several species of bird's nest fungi of the genus *Cyathus* (family *Nidulariaceae*). They all possess the carbon skeleton **1** which we have named cyathane (2) although the parent hydrocarbon **1** is unknown.[2] In the preceding paper (1) we have described the metabolites isolated from the mycelium of liquid cultures of *Cyathus earlei* Lloyd. Since cyathatriol (**2**) and its derivatives 11-*O*-acetylcyathatriol (**3**), 15-*O*-acetylcyathatriol (**4**), and 11,15-*O*,*O*-diacetylcyathatriol (**5**) are produced in good yield and are easily isolated, it seemed an appropriate species for the study of some of the details of the biosynthesis of the cyathins. Since the cyathins appear to be diterpenoid in nature (2) and may thus be derived from acetate via mevalonic acid, "active isoprene," and geranylgeranyl pyrophosphate,[3] we have undertaken a study of the incorporation of ^{13}C-labelled acetate by *C. earlei* into cyathatriol and its derivatives, utilizing carbon-13 nuclear magnetic resonance (^{13}Cmr) to trace the biosynthetic pathway.[4]



1



2 R = R^1 = R^2 = H
3 R = Ac, R^1 = R^2 = H
4 R = R^2 = H, R^1 = Ac
5 R = R^1 = Ac, R^2 = H
6 R = R^1 = R^2 = Ac



8 R^1 = OH, R^2 = H
9 R^1 = H, R^2 = OH

In order to follow the labelling pattern it was first necessary to assign the chemical shifts of the carbons in cyathatriol and its derivatives. The ^{13}C chemical shifts of compounds **2** to **5** as well as those of *O*,*O*,*O*-triacetylcyathatriol (**6**) are summarized in Table 1. The assignments of the individual carbon resonances to specific carbon atoms are based largely on selective (**3**) and off-resonance (**3** and **4**) proton decoupling

experiments, and by comparison with our previously assigned ^{13}C spectra of related cyathins (6). Figure 1 shows a comparison of the ^{13}Cmr shifts observed for the previously assigned (6) *O,O*-diacetylcyathin A_3 (**7**) and for 11,15-*O,O*-diacetylcyathatriol (**5**) reported herein. The only difference in structure between the compounds in Fig. 1 is the replacement of the C-14 carbonyl group in **7** with a β-hydroxyl group in **5**. The changes in shielding should occur only in the proximity of the structural change. Using an additivity approach for this change (OH vs. carbonyl (7, 8)) reproduces the shielding changes observed.

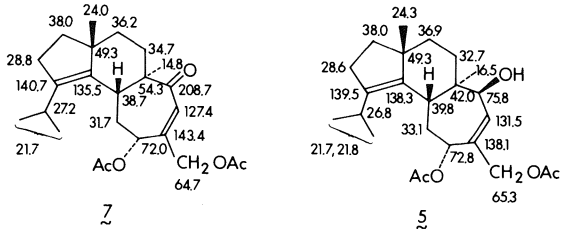

FIG. 1. Comparison of ^{13}Cmr data for *O,O*-diacetylcyathin A_3 (**7**) and 11,15-*O,O*-diacetylcyathatriol (**5**).

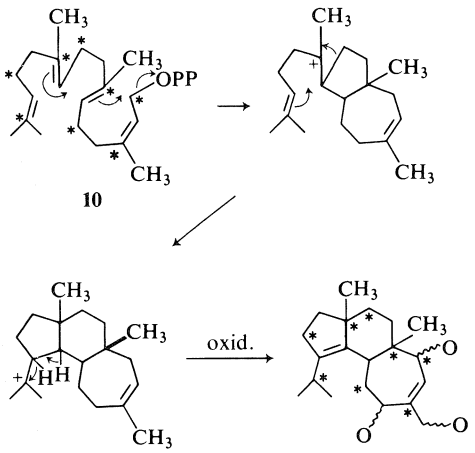
For all of the compounds the chemical shift of C-10 is very similar to that of C-7 and C-8. In order to distinguish between these carbons a Eu(fod)$_3$ shift study was undertaken with **3** and **4**. It was expected that complexation would be favored at C-11, C-15 rather than at C-14 and indeed in both cases C-11 shows a larger shift than C-14. Consequently, the signal in the δ 32–37 region which shows the largest Eu(fod)$_3$ shift is assigned to C-10.

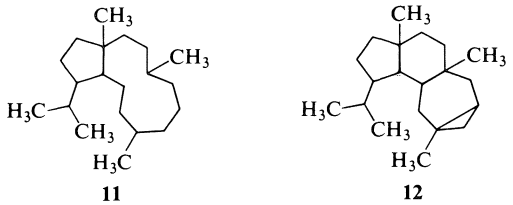
Table 1 also includes the shift values for cyathatriol acetonide (**8**) and 14-epicyathatriol acetonide **9** (1). The shift values for **8** agree well with those of **2**–**6** whereas the C-16 methyl signal in **9** appears at δ 12.1, reflecting the γ-*gauche* effect of the C-14 hydroxyl. The C-5 signal moves downfield to δ 45.0 in **9** (δ 39.1 in **8**), reflecting the fact that the C-14 hydroxyl is no longer γ-*gauche* to C-5.

The cyathane skeleton **1** is unique among the diterpenoids. We have earlier noted that the carbon



SCHEME 1

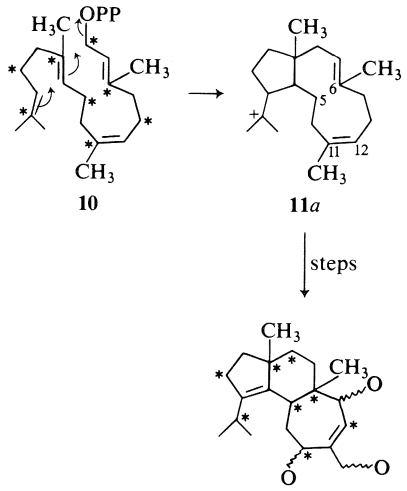
skeleton of the cyathins may be formed by cyclization–rearrangement of geranylgeranyl pyrophosphate (**10**) as shown in Scheme 1 (2). Recently, Faulkner and co-workers (9) have isolated from sea hares compounds with the carbon skeleton **11**



(dolabellane), which differ only in that they are bicyclic and the C-12 methyl group of cyathane appears at C-11 (cyathane numbering) in dolabellane. This same skeleton appears, in tetracyclic form, in compounds of the newly discovered verrucosane (**12**) class (10). This latter type of skeleton may be derived from geranylgeranyl pyrophosphate (**10**) as illustrated in Scheme 2 for the dolabelladiene cation **11***a*. Subsequent C-5 to C-6 bond formation and migration of the C-11 methyl to C-12 leads to the cyathane skeleton.

Incorporation of [^{13}C-1]-labelled acetate into the cyathins via mevalonic acid and geranylgeranyl pyrophosphate as shown in Scheme 1 would result in labelling at the asterisked carbons (C-2, C-6, C-8, C-9, C-10, C-12, C-14, C-18) whereas incorporation via Scheme 2 would result in a partly different distribution (C-2, C-5, C-6, C-8, C-9, C-11, C-13, C-18) as indicated in the scheme. In the first case C-10, C-12, and C-14 of ring C are labelled, in the second case it is C-5, C-11, and C-13.

Cyathus earlei was grown in liquid culture in the presence of sodium [1-^{13}C]acetate as described in the Experimental and 11-*O*-acetylcyathatriol (**3**) was isolated by chromatography. Figure 2 shows the ^{13}Cmr spectrum of the resulting enriched 11-*O*-acetylcyathatriol (spectrum A), the natural abundance spectrum and assignments (spectrum B), and the computer derived subtraction of B from A (curve C). The latter curve clearly shows that carbons 2, 6, 8, 9, 10, 12, 14, and 18 as well as the acetyl carbonyl carbon are derived from the carboxyl carbon of [1-^{13}C]acetate, in agreement with the biosynthetic pathway shown in Scheme 1. When sodium [2-^{13}C]acetate was added to growing *C. earlei*, 11-*O*-acetylcyathatriol enriched at the remaining carbons (2, 5, 6, 8, 9, 11, 13, and 18, and the acetyl methyl) was obtained. Figure 3 shows the



SCHEME 2

spectrum of the enriched as well as the natural abundance sample and the computer subtraction (curve C) identifies the enriched carbons. These experiments serve to eliminate from consideration the dolabellane route (Scheme 2) to the cyathins and are consistent with the pathway shown in Scheme 1.

The pathway shown in Scheme 1 involves a molecular rearrangement which may be detected using doubly-labelled sodium acetate (ref. 5, p. 164). The intact acetate units in geranylgeranyl pyrophosphate (**10***a*) derived via mevalonate are shown as heavy lines in **10***a* (Scheme 3). As illustrated in Scheme 3, the postulated rearrangement involves a scission of one of the acetate units (C-4, C-8) which will eliminate the ^{13}C—^{13}C coupling between C-4 and C-8, and these two carbons, along with C-1, C-7, C-11, and C-19, should appear as singlets in the proton-decoupled spectrum of 11-*O*-acetylcyathatriol (**3**) derived from [1,2-^{13}C]acetate if the C-4 to C-9 bond migration does occur. Figure 4 shows a comparison of the natural abundance spectrum (curve A) and the 100 MHz spectrum of **3** obtained by feeding experiments utilizing [1,2-^{13}C]acetate.

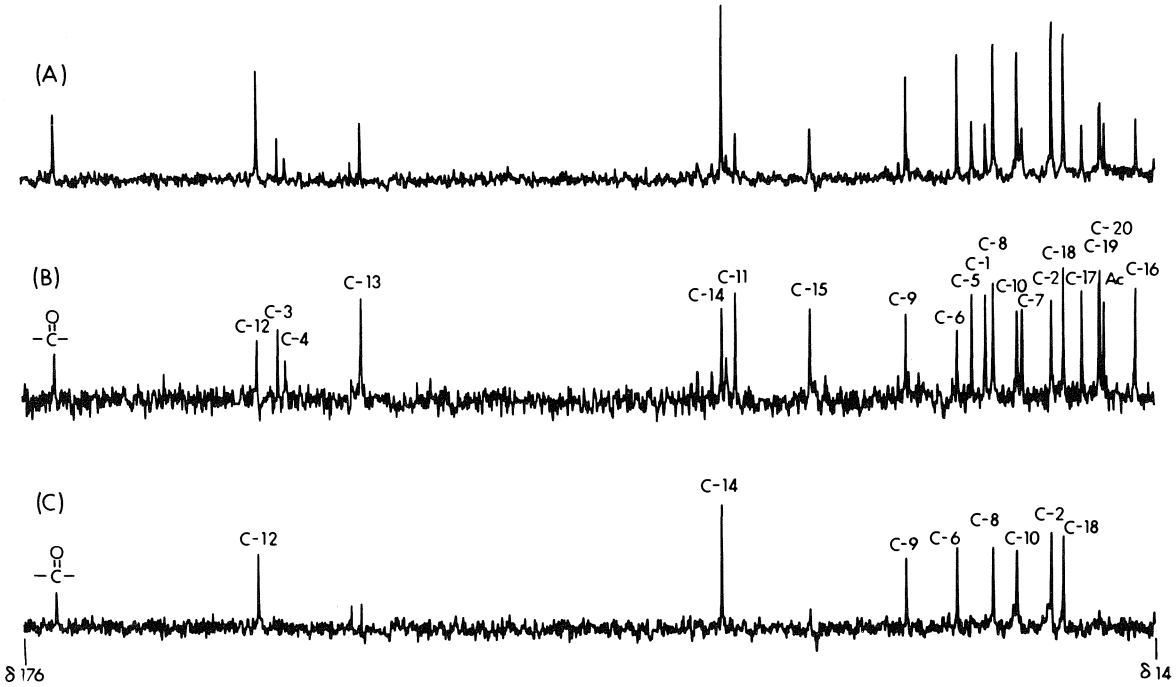


FIG. 2. Proton decoupled ^{13}Cmr spectra (22.6 MHz) of: (A) 11-*O*-acetylcyathatriol (**3**) from [1-^{13}C]acetate enrichment; (B) natural abundance spectrum of **3**; (C) computer derived subtraction of curve B from curve A.

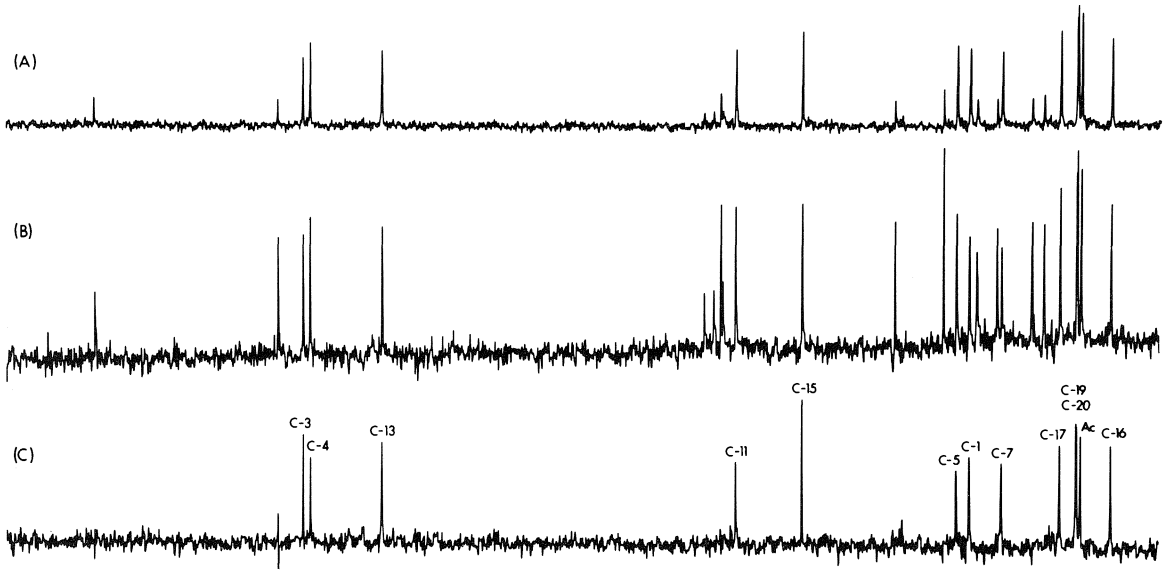

FIG. 3. Proton decoupled ^{13}Cmr spectra (22.6 MHz) of: (A) 11-*O*-acetylcyathatriol (**3**) from [2-^{13}C]acetate enrichment; (B) natural abundance spectrum of **3**; (C) computer derived subtraction of curve B from curve A.

Clearly C-4 and C-8 do not show ^{13}C—^{13}C coupling, consistent with the molecular rearrangement shown in Schemes 1 and 3.

In summary, the results reported herein indicate that the cyathins are biosynthesized from acetate, presumably via mevalonic acid, "active isoprene", and geranylgeranyl pyrophosphate, and the results are consistent with a cationic cyclization–rearrangement sequence of the type shown in Schemes 1 and 3.

Experimental

Instrumentation

The ^{13}Cmr spectra were determined in chloroform-d_1 (5% tetramethylsilane as standard) at a concentration of approximately 5–20% (w/v) in 5 or 10 mm sample tubes using a

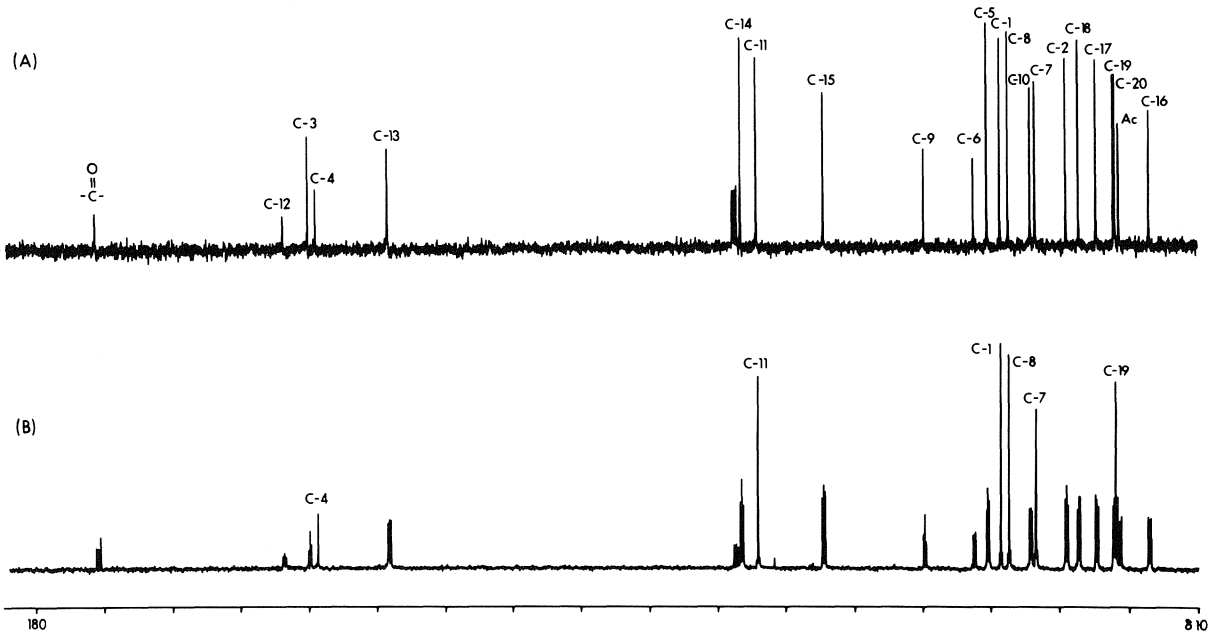

FIG. 4. Proton decoupled ^{13}Cmr spectra (100.6 MHz) of: (A) 11-*O*-acetylcyathatriol (**3**), natural abundance; (B) 11-*O*-acetylcyathatriol from [1,2-$^{13}C_2$]acetate enrichment.

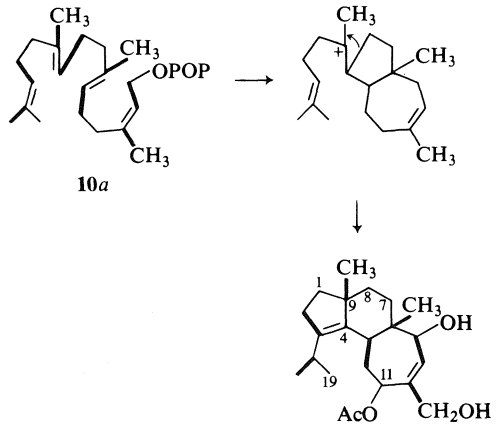

SCHEME 3

Bruker WP-60, HFX-90, or WH-400 spectrometer operating in the Fourier transform mode. A few drops of methanol-d_4 were added to the solutions of **2** and **5** to increase solubility. Because of the limited amount of material, **8** was dissolved in ca. 10 μL of methanol-d_4 and the spectrum determined in a 1.7 mm microprobe. For the shift study, a solution of Eu(fod)$_3$ in chloroform-d_1 was added dropwise to a solution of the substrate in chloroform-d_1 until approximately a 1:1 weight ratio was obtained. ^{1}Hmr spectra were recorded on a Varian HA-100-12 in. system or on a Varian HA-100-15 in. system interfaced to a Digilab FTS/NMR-3 data system.

Materials

Sodium [1-^{13}C]acetate and sodium [2-^{13}C]acetate (90% enriched) were purchased from Merck Sharp and Dohme Canada Ltd. Sodium [1,2-$^{13}C_2$]acetate was obtained from Prochem US Services Ltd. Brodie medium was prepared in the usual manner (11) and sterilized before use. Silica gel refers to E. Merck Silica Gel 60. Compounds **2–6, 8,** and **9** were obtained as previously described (1).

Incorporation of ^{13}C-labelled Acetate into 11-O-Acetylcyathatriol (3)

Cyathus earlei Lloyd ATCC 38343 (1) was grown in liquid still culture at room temperature in Brodie medium in 2 2.8-L Fernback flasks (1 L medium/flask). After fourteen days growth sodium [1-^{13}C]acetate (1.00 mmol/L) in water (5 mL, sterilized) was added to each flask. One week later a further 1.00 mmol was added to each flask. Two weeks later the culture broth was decanted and the mycelium was reflooded with fresh sterilized Brodie medium. Seven days after the reflood, sterilized sodium [1-^{13}C]acetate solution (2 mmol per flask) was again added. Three weeks later the mycelium was harvested by filtration, dried, and extracted with ethyl acetate in a Soxhlet apparatus. The crude extract (ca. 0.5 g) was subjected to chromatography over silica gel (25 g) as previously described (1). Elution with ether–benzene (3:7) afforded 11-*O*-acetylcyathatriol (40 mg) which was crystallized from ether, mp 165–166°C (1). The experiments with sodium [2-^{13}C]acetate and sodium [1,2-$^{13}C_2$]acetate were conducted in exactly the same way as described for sodium [1-^{13}C]acetate.

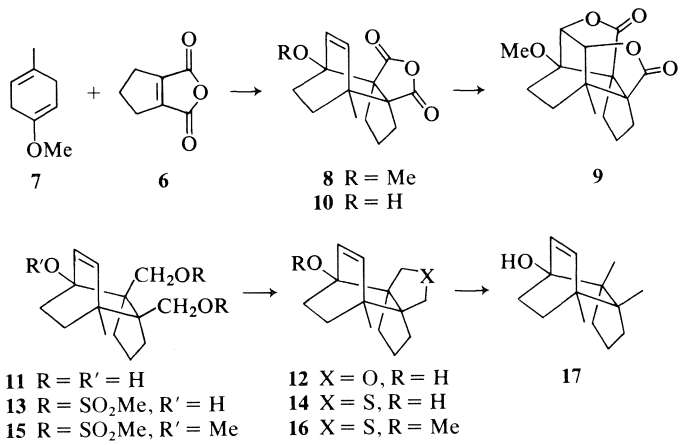


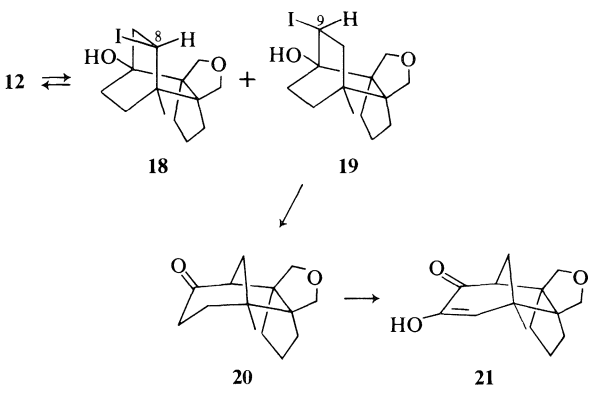
SCHEME 2

was confirmed by the formation of the bis-lactone **9**, mp 198–198.5°C, on alkaline bromination. After some preliminary experiments, **8** was first demethylated by boron tribromide in dichloromethane to the alcohol **10**, mp 264–265°C, in 96% yield. For the conversion of the anhydride group to two methyl groups, **10** was first reduced with lithium aluminum hydride in refluxing THF to give triol **11**, mp 230°C (dec.), in 84% yield. Although the attempted tosylation of **11** afforded mainly ether **12**, mp 206–208°C, mesylation (MsCl/Py) yielded dimesylate **13** as a colorless oil in 93% yield, and the latter was converted to sulfide **14**, mp 203–205°C, in 45% yield with anhydrous Na_2S in HMPA at 120°C (10).[2] Desulfurization of **14** with lithium in ethylamine at −20°C in the presence of 2-propanol yielded the desired olefin **17**, mp 188–190°C; *m/e* 206 (M^+), 110 (base peak); δ 0.81 (3H, s), 0.91 (3H, s), 1.01 (3H, s), 5.76 (1H, d, J = 8.5), 6.07 (1H, d, J = 8.5), in 87% yield.

Skeletal Rearrangement

The possibility of the rearrangement from tricyclo[5.2.2.$0^{2,6}$]undecane system to tricyclo[5.3.1.$0^{2,6}$]undecane was investigated utilizing the ether **12** as a model compound; **12** was treated with dry HI in dichloromethane to afford two iodides **18**, mp 121–123°C (58%), and **19**, mp 113.5–114.5°C (37%). The configuration of iodine was verified by the presence of W-type coupling (J = 2.5 Hz) in the signals due to H(8) (δ 4.72 ppm) in **18** and due to H(9) (δ 4.97 ppm) in **19**.

While **18** reverted to ether **12** when treated with diazabicycloundecane in refluxing benzene, **19** underwent smooth rearrangement to give ketone **20**, mp 132–135°C, ν 1702 cm^{-1}, quantitatively on treatment with potassium *tert*-butoxide in THF at room temperature. The structure of **20** was further confirmed by its conversion to the diosphenol **21**, mp 180–183°C, λ_{max} 273 nm (ε 5500) on alkaline oxidation (O_2, *t*-BuOK). Thus, the rearrangement to the barbatane carbon skeleton was achieved.

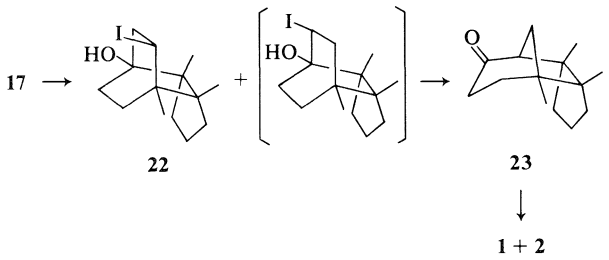


SCHEME 3

Synthesis of α- and β-Barbatenes (1 and 2)

Similar reaction of the hydrocarbon **17** with HI yielded two iodides, one of which was unstable and underwent the rearrangement upon contact with silica gel. Thus, chromatographic separation (SiO_2) of the products afforded the ketone **23**, mp 208–211°C, ν 1703 cm^{-1}, in 45% yield along with the iodide **22**. While Grignard reaction (MeMgI) and subsequent dehydration with $SOCl_2$ in pyridine yielded α-barbatene exclusively, dehydration using $POCl_3$ in pyridine afforded a ca. 1:1 mixture of α- and β-barbatenes. Separation of the products follows the known procedure (2) and the products are identified by comparison of their ir and nmr spectra with those of authentic specimens.

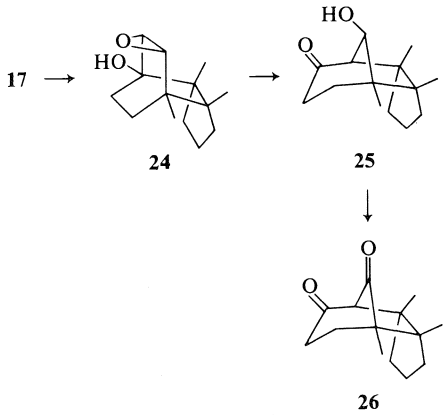
[2]In the same reaction using the corresponding methyl ether **15**, the sulfide **16** was obtained in over 65% yield.



SCHEME 4

Formal Synthesis of Gymnomitrol 3 and Isogymnomitrol 4

The unsaturated alcohol **17** was oxidized with *m*-chloroperbenzoic acid (0°C, 6 h) to give the epoxy alcohol **24**, mp 93–95°C, quantitatively, which on alumina chromatography underwent skeletal rearrangement to the ketoalcohol **25**, mp 228°C, in 61% yield. Jones' oxidation of **25** yielded the diketone **26**, amorphous solid, ν 1745, 1710 cm^{-1}. The nmr and ir spectra match the reported data for the same compound derived from natural gymnomitrol (6) and also match the complete spectra of a sample of **26** supplied by Coates (11*a*). Since **26** has been synthesized by Coates[3] and converted in three steps to gymnomitrol **3** and isogymnomitrol **4**, the acid-catalyzed rearrangement product of **3**, the present study completes the formal total synthesis of these alcohols in a completely different strategy.



SCHEME 5

A synthetic approach to quassin. Synthesis of a ring A *seco* derivative

NADA STOJANAC, ŽARKO STOJANAC, PETER S. WHITE, AND ZDENEK VALENTA

Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 5A3

Received August 9, 1979

This paper is dedicated to Prof. Karel Wiesner on the occasion of his 60th birthday

NADA STOJANAC, ŽARKO STOJANAC, PETER S. WHITE, and ZDENEK VALENTA. Can. J. Chem. **57**, 3346 (1979).

Synthesis of compound **16**, a ring A *seco* derivative of quassin (**1**), is described. The overall strategy consists of manipulations within a rigid system established by a Diels–Alder reaction, followed by unfolding of the molecule. The sequence includes a cyclization of a 1,5-bromoketone with Zn and a selective oxidation of one carbonyl group in a tricyclic diketo diester with peracetic acid.

NADA STOJANAC, ŽARKO STOJANAC, PETER S. WHITE et ZDENEK VALENTA. Can. J. Chem. **57**, 3346 (1979).

On décrit la synthèse du composé **16**, un dérivé cyclique A *seco* de la quassine (**1**). La stratégie globale consiste en des manipulations à l'intérieur d'un système rigide produit par une réaction de Diels–Alder suivie du déplissement de la molécule. La suite de réaction comprend une cyclisation de la bromocétone-1,5 à l'aide de zinc et une oxydation sélective du groupe carbonyle du dicéto ester tricyclique par l'acide peracétique.

[Traduit par le journal]

Some time ago, we reported a synthetic approach to quassin (**1**), the bitter principle of *Quassia amara* (1, 2), in which all but two skeletal carbon atoms (C(2) and C(3)) were introduced by reaction **2** + **3** → **4** proceeding in a regio- and stereospecific[1] manner (3). It was based on the expectation that the relatively complex stereochemistry of **1** could more readily be established in a rigid system. We now wish to report one sequence which exploits this strategy, and includes an unconventional formation of the C(14)—C(15) bond and an unfolding of the caged molecule to the *seco*-quassin derivative **16**.

Triketone **5**, mp 68–70°C, prepared from **4** in ~80% yield by reduction with Zn in acetic acid (3) followed by hydrolysis with concentrated HCl in CH_3OH at 20°C and an oxidation of the resulting mixture of two epimeric alcohols, mp's 120–121°C and 107–108°C, with Collins' reagent (4), was equilibrated with anhydrous K_2CO_3 in dry CH_3OH to give a 3 : 2 mixture of **5** and **6**.[2,3] Isomer **6**, mp 138–140°C, purified by chromatography (hexane–EtOAc 5 : 1),[3] gave **7**, mp 150–152°C, on treatment with ethoxyethynyl magnesium bromide. Aqueous oxalic acid in EtOH converted **7** into oily **8** which yielded the saturated ester **9**,[4] mp 140–142°C, on hydrogenation with PtO_2 in ethanol. Compound **9** contains all the skeletal C-atoms of quassin and all nonepimerizable chiral centres in quassin (C*'s in structure **1** and **5**–**9**) are established.

To form the C(14)—C(15) bond (see structure **1** and **11**), **9** was treated with *N*-bromosuccinimide in CCl_4 at 80–85°C in the presence of $(CH_3)_3COOH$ or benzoyl peroxide to give **10**, mp 110–112°C,[5] which on reaction with OsO_4 in benzene and a catalytic amount of pyridine for 10 days, followed by treatment of the osmate ester with Zn in acetic acid at 20°C for 2 days and by decomposition with H_2S in $CHCl_3$ at 0°C, gave the desired foamy triol **11** (acetonide, mp 156–158°C). The yield of **11** purified by chromatography (hexane–EtOAc 2 : 3)[3] was 40% based on **10**. OsO_4 added stereospecifically and the addition led to a geometry of the CH_2Br and C=O groups particularly suitable for the coupling.[6]

[1]Diene **2** and adduct **4** are mixtures of diastereomers at C—OAc. All synthetic compounds reported in this Communication are racemic.

[2]A longer sequence in which the equilibration at this centre goes quantitatively in the desired sense is reported in ref. 3.

[3]All reactions were performed under N_2. All reported chromatographic purifications involved short column chromatography on Silica Gel G.

[4]Chromatographic purification of **9** (hexane–EtOAc 4:1)[3] removed minor quantities of its side-chain C—CH_3 diastereomer. Yield of **9** was 50% for the three steps from **6**.

[5]Yields of this reaction varied considerably and unpredictably, the best yields being almost quantitative.

[6]The sequence could also be performed, less efficiently, by initial osmate decomposition and by subsequent treatment of the resulting diol or its cyclic carbonate with Zn. We have not been able to achieve this Zn—HOAc coupling in model open-chain systems. Similar bond formations in halo ketones with Na (5) and R_2CuLi (6) and in a halo epoxide with Li (7) are reported; it should be noted, however, that the additional functionality and the danger of 1,2-eliminations in our system demand an exceptionally mild treatment.

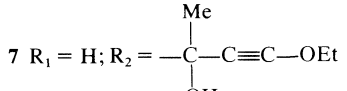
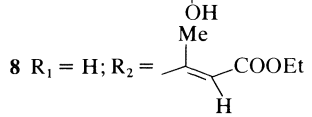
5 R_1 = acetyl; R_2 = H
6 R_1 = H; R_2 = acetyl





Cleavage of the *vic*-diol in **11** with H_5IO_6 in ether led to an unstable enol hemiacetal[7] which was immediately oxidized to lactone **12**, ν_{max} ($CHCl_3$) 3600, 3450, 1800 cm^{-1}, with Collins' reagent (4). Treatment of **12** with Ac_2O in pyridine at 100°C gave enone **13**, mp 166–167°C, λ_{max} (EtOH) 226 nm (ε 6880), ν_{max} 1800 cm^{-1}, ^{1}Hmr δ 6.00 (1H, s); its structure was established by X-ray diffraction. Hydrogenation of **13** with PtO_2 in EtOH gave ketone **14**, mp 141–142°C, ν_{max} 1800 cm^{-1}, no vinylic H in ^{1}Hmr spectrum, as the only product. Reaction of **14** with $NaOCH_3$ (10% in CH_3OH) under reflux for 20 h followed by treatment with ethereal diazomethane gave diketo diester **15**, mp 181–182°C. Finally, oxidation of **15** with 40% peracetic acid in HOAc–NaOAc at 65°C for 8 h gave the desired lactone **16**,[8] mp 144–145°C, ν_{max} 1735, 1720 (sh) cm^{-1}. The carbonyl

[7] ^{1}Hmr spectrum indicated a keto aldehyde ⇌ enol hemiacetal equilibrium.

[8] Relative configuration at C(4), C(5), C(8), C(10), and C(13) in **16** follows rigorously from the X-ray study of **13** and from previously reported transformations (3). The configuration at C(7) is clearly established by the position and shape of the ^{1}Hmr signal of the C(7)—H atom (δ 4.23, unresolved t, $W_{1/2}$ = 6 Hz), comparable to that in quassin (**1**). The configuration at C(14) must be as indicated because (*a*) the quantitative conversion **13** → **14** must involve a hydrogenation from the (less hindered) convex side and (*b*) for thermodynamic reasons, the two H-atoms at C(7) and C(14) can confidently be expected to be *cis* after the equilibrating conversion **14** → **15**. Several arguments (including thermodynamic stability) establish the configuration at C(9) (^{1}Hmr signal for C(9)—H at δ 3.15, s), the simplest being the fact that *an isomer* of **15** (β C(7)—H, β C(9)—H) was obtained in a sequence in which the secondary OH group in a derivative of **11** was first oxidized to a ketone which was subsequently cleaved without the use of equilibrating conditions.

16

group at C(11) proved inert to these oxidation conditions.

The overall yield of the sequence **11** → **16** was 60–70%, the lowest single step yield (~80%) being for the conversion **14** → **15**.

Six of the seven chiral centres of quassin are established in **16**. The seventh, C(4), has the incorrect configuration. Since quassin derivatives equilibrate at C(4) to give, quantitatively, compounds with the equatorial CH_3-group (1), it should prove possible to correct this after ring A formation, provided that the cyclization will be successful in spite of the juxtaposition of the two CH_3 groups at C(4) and C(10) in **16** and its derivatives.

This communication describes the stereocontrolled synthesis of the complex diterpene, (+)-ryanodol (**1**) (3, 4) (Scheme 1).

This compound exists in nature in the form of the α-pyrrole carboxylate ester derivative **2** known as ryanodine (3).

The two starting materials used in this construction are the readily available 5,6-dimethoxyindane (**3**) (5) and (+)-carvone (**4**) which were converted respectively into the two key building blocks, the *o*-spirolactone dienone **10** and the optically active (+)-isopropyl vinylketone acetal **15** (Scheme 2).

5,6-Dimethoxyindane (**3**) was first converted (CH_3OCHCl_2, $TiCl_4$, CH_2Cl_2) (6) into the corresponding aromatic aldehyde **5**[10,11] (mp 52°C) which was then cleaved (BBr_3, CH_2Cl_2) (7) to 4-formyl-5,6-dihydroxyindane (**6**, mp 130–131°C, 80% yield from **3**). Selective esterification of **6** ($BrCH_2COBr$, C_5H_5N, benzene) gave the monobromoacetate **7** (mp 110°C) which was cyclised (Na_2CO_3, THF, reflux) into lactone aldehyde **8** (mp 131–132°C, 80% yield from **6**). On Wolff–Kishner reduction of

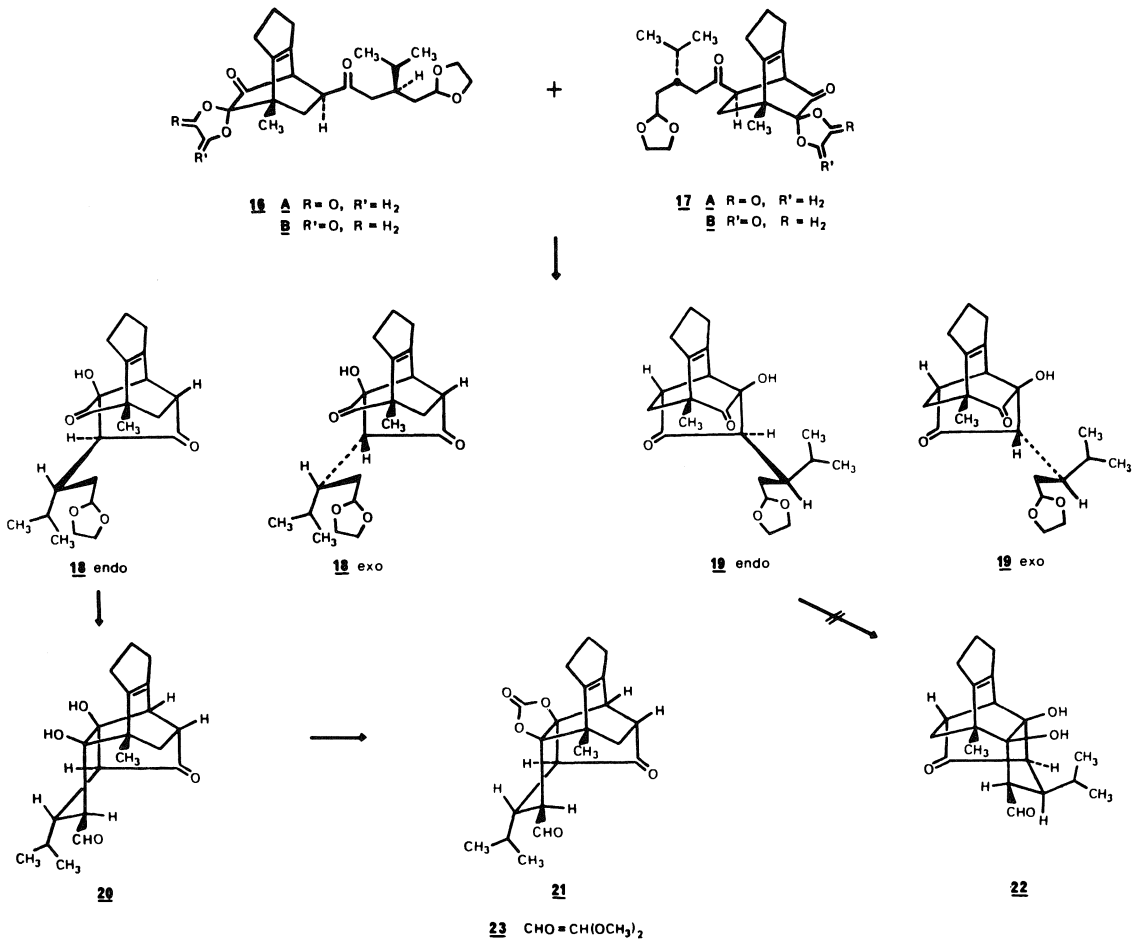
[10]For all substances, the spectra (ir, ^1H nmr, ms, and in selected cases ^{13}C nmr) were in agreement with the assigned structures. Satisfactory microanalyses were obtained for crystalline substances. All rotations are for chloroform solution unless stated otherwise.

[11]In some cases, where the yield of a reaction is not quantitative (>95%), minor products have been isolated and the structure determined. This information will appear in the detailed account.

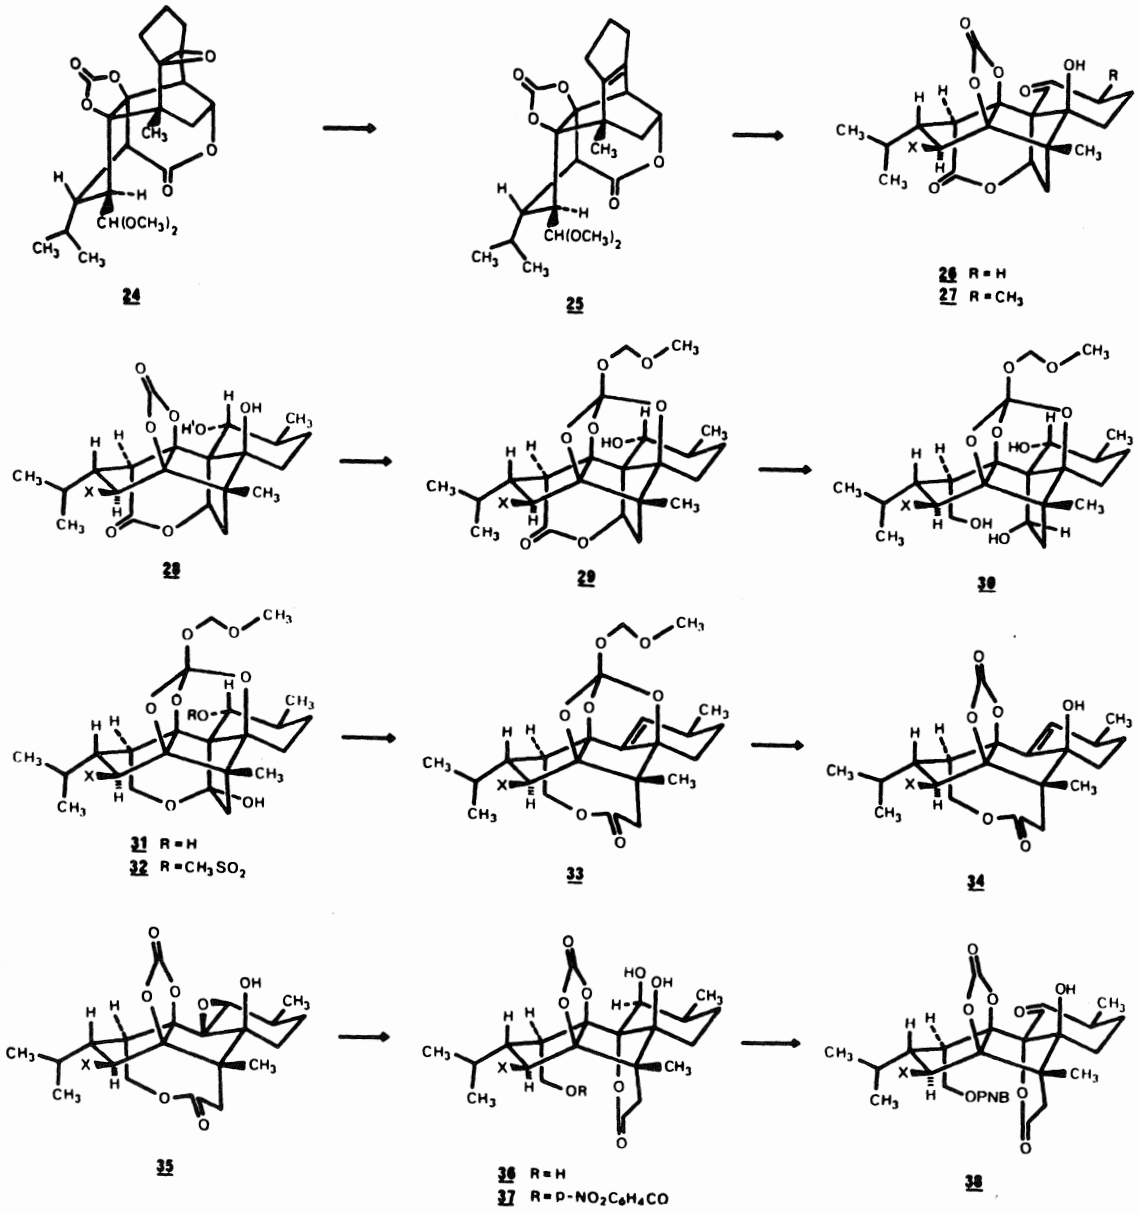


SCHEME 3

lactone aldehyde **8**, the aromatic lactone **9** (mp 75–76°C, 80% yield) was formed and then transformed (NaOH (1 equiv.), H_2O, CH_3CN; NBS) (8) to the *o*-spirolactone dienone **10** (mp 97–98°C, ≥95% yield).

d-Carvone (**4**) was reduced (Pt/H_2, ether) (9) to the dihydro derivative **11** which was then oxidized (O_3, $CH_3COOC_2H_5$; $Pd/C–H_2$) to yield the aldehyde carboxylic acid **12**. Acetalization ($(CH_2OH)_2$, *p*-TsOH, benzene; NaOH in CH_3OH) of **12** gave **13** which was then esterified (CH_3I, K_2CO_3, acetone) (10) and the resulting methyl ester **14** was purified by distillation (70% yield from carvone). The purified methyl ester **14** was hydrolysed (NaOH, CH_3OH) to the acetal carboxylic acid **13** which was finally converted (LiH, THF; CH_2=CHLi) into optically active isopropyl vinylketone acetal **15** ($[\alpha]_{578}$ +0.6°; 75% yield from **13**). Compound **15** was more conveniently prepared on a large scale by the following procedure: reduction ($LiAlH_4$, ether) of the methyl ester function in **14** (≃100% yield) to the corresponding primary alcohol followed by oxidation ($C_5H_5\overset{+}{N}HCrO_3Cl^-$, $NaHCO_3$, CH_2Cl_2, room temperature, 2.5 h), (11) to the expected aldehyde (93% yield). A Grignard reaction (CH_2=CHBr, Mg, ether) on this aldehyde followed by Jones oxidation (0°C) (12) gave isopropyl vinylketone acetal **15**.

Diene **10** was reacted (benzene, reflux, 1 h) with a slight excess of the dienophile **15** to give a 1:1 mixture of adducts **16** *A*, *B* and **17** *A*, *B* in quantitative yield (Scheme 3). This crude product was then converted (1 *N* NaOH, THF, room temperature) into a mixture of four diastereoisomers **18** and **19** (*exo* and *endo*) in which the *endo* epimers are the major isomers (*endo*/*exo* ≃ 3:1). This crude mixture was then treated under acidic (CH_3CO_2H—H_2O (7:3), 75°C, 2 h), followed by basic conditions (1 *N* NaOH, THF, room temperature) to yield the crude dihydroxyketoaldehyde **20**, which on further treatment ($COCl_2$, C_5H_5N, benzene) afforded the five-membered cyclic carbonate **21** (mp 186–188°C; $[\alpha]_D$ +121.3°), isolated by chromatography in 27% yield



SCHEME 4. X = $CH(OCH_3)_2$

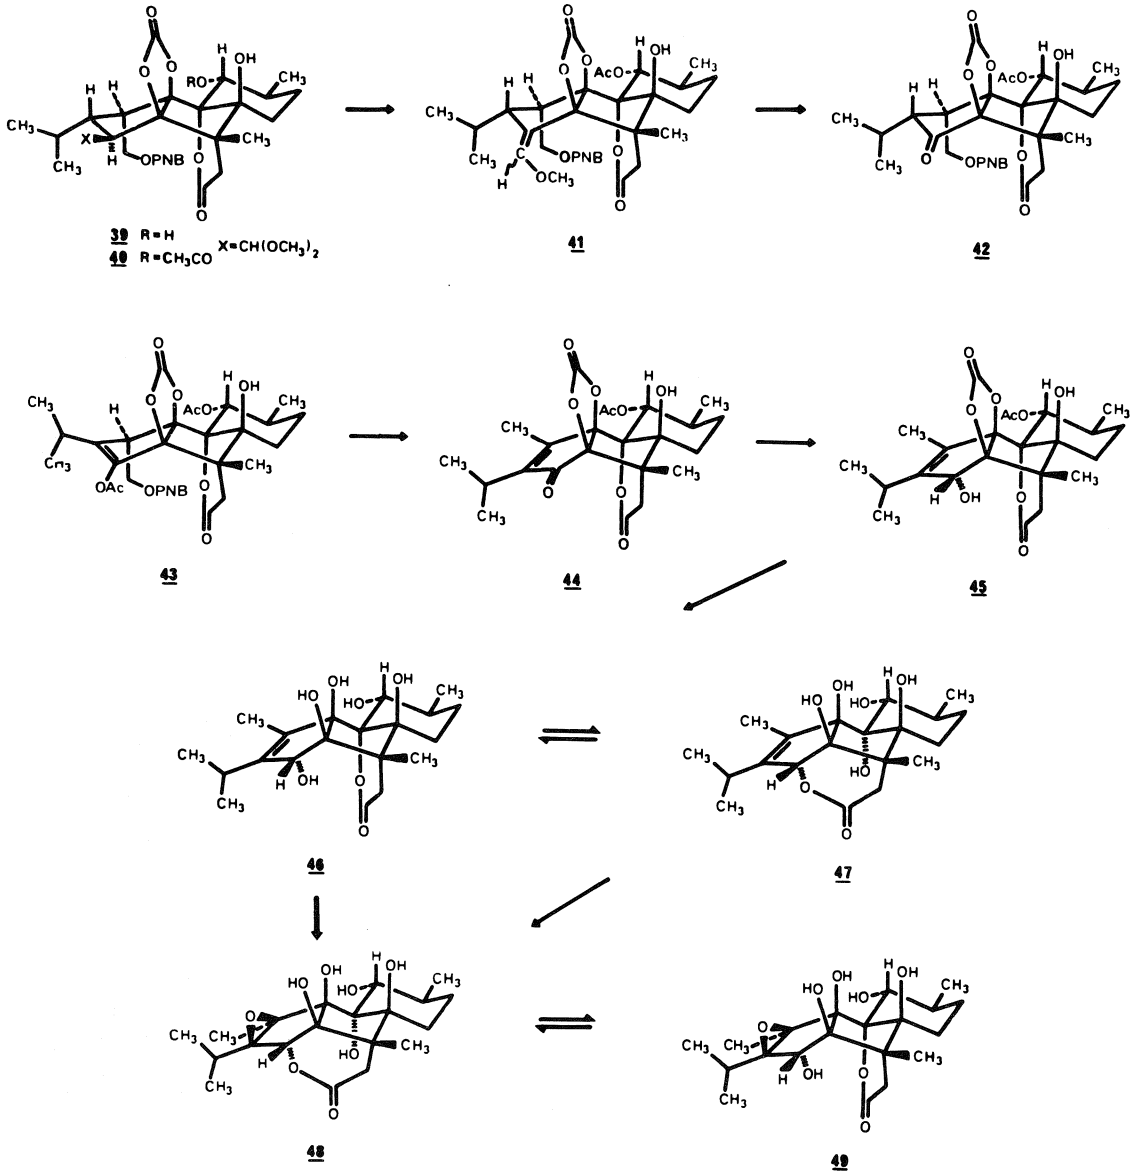
from **10**.[12,13,14] Compound **21** was further transformed (CH_3OH, $(CH_3O)_3CH$, *p*-TsOH) into the dimethoxyacetal derivative **23** (mp 114.7–115.2°C, $[\alpha]_D$ +121.3°).

Baeyer–Villiger oxidation (40% CH_3CO_3H, CH_3CO_2Na, room temperature, 15 h; 80°C, 1 h) of **23** gave the desired epoxylactone **24** (85%) accompanied by a small quantity (15%) of an isomeric lactone (Scheme 4). Retroepoxidation (WCl_6, *n*-BuLi (2 equiv.), THF, −78°C) (13) was carried out on this mixture and the olefin lactone **25** (mp 179–181°C, $[\alpha]_D$ −10.9°) was obtained pure by chromatography (80% yield from **23**). Ozonolysis of olefin lactone **25**

[12]The theoretical yield (**10** → **21**) is 50%, therefore this 27% represents 54% of the theoretical yield.

[13]The diastereoisomers **18** *endo* and **19** *endo* have been isolated by chromatography. Pure **18** *endo* was converted into **20** in quantitative yield, whereas **19** *endo* gave a complex mixture from which the expected isomeric pentacyclic compound **22** could not be isolated.

[14]The relative configuration of the isopropyl group in compounds **20** and **21** was determined by nmr on a derivative of **21** (see ref. 2, p. 1342).



SCHEME 5

(O_3, $CH_3COOC_2H_5$, *p*-TsOH; $(CH_3)_2S$) (14) resulted in the desired aldol condensation product **26** (mp 238–238.5°C, $[\alpha]_D$ −48.0° (THF), ≥90% yield) which was then converted (lithium diisopropylamide in THF, −78°C; $(C_2H_5)_3B$, −25°C, 3 h; CH_3I) (15) into the equatorial monomethylated derivative **27** (mp 245.5–254°C (dec.), $[\alpha]_D$ −56.6° (THF), 70% yield).

The ketone function in **27** was selectively reduced ($NaBH_4$, CH_3OH, THF, 0°C) to the equatorial alcohol product **28** (mp 257–267°C; >95% yield) which was further characterized ($(CH_3CO)_2O$, C_5H_5N) as the acetate derivative **28** (H′ = CH_3CO) (mp 244–246°C, $[\alpha]_D$ −34.7°). Compound **28** was then transformed (NaH, THF, $ClCH_2OCH_3$, room temperature) into the methoxymethylorthocarbonate hydroxylactone dimethoxyacetal **29** (mp 169.5–170°C, $[\alpha]_D$ −12.1°, 80% yield plus 13% recovery of **28**). The product **29** was further reduced ($LiAlH_4$, THF) to the triol **30** (foam, $[\alpha]_D$ −40.1°, 95% yield) which underwent a highly selective oxidation ($CrO_3 \cdot (C_5H_5N)_2$, CH_2Cl_2, −45 to −22°C, 1 h) (16) to give the hemiketaldiol **31** (mp 121–123°C, $[\alpha]_D$ −39.2°, 76% yield). The secondary alcohol of **31** was mesylated (CH_3SO_2Cl, C_5H_5N, 0°C, 1 h) to yield hemiketal mesylate **32** (89% yield).

Compound **32** underwent a high yield fragmentation under basic conditions (CH_3SOCH_3, CH_3SOCH_2Li, room temperature, 30 min) to furnish the large ring lactone olefin methoxymethylorthocarbonate dimethoxyacetal **33** which was immediately converted by mild acid hydrolysis ($\simeq$0.3 *N* HBF_4, THF, 0°C, 3 h) into the lactone olefin hydroxycarbonate dimethoxyacetal **34** (mp 220–223°C, $[\alpha]_D$ −126°, 97.5% yield from **32**).

Epoxidation of compound **34** (CF_3CO_3H, Na_2HPO_4, $ClCH_2CH_2Cl$, 4°C, 15 h) afforded the β-epoxide **35** (mp 173–175°C, $\simeq$98% yield). Treatment of the β-epoxide **35** under basic conditions (0.1 *N* NaOH (0.4 mol equiv.), $CH_3OCH_2CH_2OCH_3$, 5.5 h, room temperature) gave after chromatography the desired lactone triol carbonate dimethoxyacetal **36** (mp 246–248°C, $[\alpha]_D$ −32.9°, 77% yield from **34**). Compound **36** was converted (p-$O_2NC_6H_4COCl$, C_5H_5N, 0°C, 25 min) into the primary p-nitrobenzoate derivative **37** (mp 130–131°C, $[\alpha]_D$ −33.0°, uv (CH_3OH) λ_{max}: 259 nm (ε: 12 184), 95% yield) which was then oxidized ($CrO_3 \cdot 2C_5H_5N$, CH_2Cl_2, 25°C) (16) to yield the hydroxyketone lactone carbonate p-nitrobenzoate dimethoxyacetal **38** (foam, $[\alpha]_D$ −30.3°, 78% yield). Reduction of **38** ($LiBH_4$, THF, −30 to −20°C, 1.5 h) resulted in a mixture of the desired equatorial alcohol **39** (foam, $[\alpha]_D$ −15.3°, 73% yield) and the previously described axial alcohol product **37** which were separated by chromatography (Scheme 5). Compound **39** was then acetylated ($(CH_3CO)_2O$, C_5H_5N) to yield the equatorial acetate derivative **40** (mp 318–319°C (dec.), $[\alpha]_D$ −20.6°).

Degradation of ring *A* of compound **40** led to the carbonate acetate derivative **44** of oxoanhydroryanodol. Compound **40** was first converted (p-TsOH, benzene, reflux) to a mixture of enol ethers **41** which was then oxidized (O_3, CH_2Cl_2, −78 to −55°C; $(CH_3)_2S$) to the cyclopentanone product **42**. Compound **42** was transformed ($(CH_3CO)_2O$, CH_3CO_2Na, 100°C, 15 h) into the enolacetate **43** (mp 316–318°C (dec.)). The enol acetate **43** under basic conditions (DBN, benzene, 75°C, 2.5 h) gave the carbonate–acetate derivative **44** of oxoanhydroryanodol (mp 301–302°C, $[\alpha]_D$ +150.6°, uv (CH_3OH) λ_{max}: 238 nm (8775), 50% yield from **40**).[15]

Compound **44** was reduced ($NaBH_4$, THF, CH_3OH, 0°C, 2 h) to the *endo* allylic alcohol **45** (mp 300–301°C (dec.), $[\alpha]_D$ +89.6° (CH_3OH), $\geq$90% yield). Basic hydrolysis of **45** (1 *N* NaOH, THF, room temperature, 24 h) gave a mixture (ratio 3:1) of anhydroryanodol **46** (mp 148–150°C, $[\alpha]_D$ +54.3° (CH_3OH)) and epianhydroryanodol **47** (mp 227–228°C, $[\alpha]_D$ −97.8° (CH_3OH)) which were separated and identified with authentic samples.[16]

Epoxidation (CF_3CO_3H, Na_2HPO_4, $ClCH_2CH_2Cl$, room temperature) of either synthetic anhydroryanodol (**46**) or synthetic epianhydroryanodol (**47**) gave the β-epoxide **48** of epianhydroryanodol[17] (foam, $[\alpha]_D$ −41.7°). Finally, reductive cyclization of **48** yielded totally synthetic ryanodol (**1**) (mp 267–268°C, $[\alpha]_D$ +38.5°, $\geq$60% yield) which was found identical (^1H nmr, tlc, and mixed mp 266.5–267.5°C) with an authentic sample (mp 266–267°C, $[\alpha]_D$ +40.0°) of ryanodol (**1**) obtained from the basic hydrolysis of ryanodine (**2**) (3). The chemical reactivity of totally synthetic ryanodol (**1**) was also verified: treatment of totally synthetic **1** with p-toluenesulfonic acid in dioxane at room temperature during 24 h yielded the expected mixture of anhydroryanodol (**46**) and epianhydroryanodol (**47**).

This communication will be followed by a detailed account which will include the necessary investigative studies which led to the final solution described above.

[15]The experimental conditions for the conversion **40** → **44** have not been optimized.

[16]Basic hydrolysis of ryanodine (**2**) gives ryanodol (**1**) which can be transformed under acidic conditions into anhydroryanodol (**46**) (mp 150–151°C, $[\alpha]_D$ +53.3° (CH_3OH)) (3). Basic equilibration (1 *N* NaOH, THF, room temperature) of anhydroryanodol (**46**) resulted in a mixture (ratio 3:1) of **46** and epianhydroryanodol (**47**) (mp 225–226.5°C, $[\alpha]_D$ −103.2° (CH_3OH)).

[17]Utilizing **46** and **47** derived from the natural product, the following experiments were carried out: (*a*) epoxidation (Na_2HPO_4, CF_3CO_3H) of either **46** or **47** yielded the β-epoxide **48** (foam, $[\alpha]_D$ −43.2°, 85% yield) of epianhydroryanodol, (*b*) basic equilibration (1 *N* NaOH, THF) of **48** produced a mixture (ratio 3:2) of **48** and the β-epoxide **49** (mp 232–234°C (dec.), $[\alpha]_D$ +29.9° (CH_3OH)) of anhydroryanodol, and (*c*) reductive cyclization (Li, NH_3, THF) of either **48** or **49** furnished ryanodol ($\simeq$60% yield).

MASATOSHI KAKUSHIMA, LEONARD ALLAIN, ROBERT A. DICKINSON, PETER S. WHITE, and ZDENEK VALENTA. Can. J. Chem. **57**, 3354 (1979).

A total synthesis of (±)-5β,8α-androst-9(11)-ene-3,17-dione is described. The key step is a ring C forming $SnCl_4$-catalyzed Diels–Alder reaction in which the geometry of the diene controls *syn–anti* stereochemistry while the catalyst guides the addition to the desired *endo* orientation. A preparation of ethyl *E*-2-methyl-4-oxo-2-butenoate and the dehydration of a tertiary allylic alcohol by the pyrolysis of the corresponding tosyl carbamate are also described.

MASATOSHI KAKUSHIMA, LEONARD ALLAIN, ROBERT A. DICKINSON, PETER S. WHITE et ZDENEK VALENTA. Can. J. Chem. **57**, 3354 (1979).

On décrit une synthèse totale de la (±)5β,8α androstène-9(11)dione-3,17. L'étape clé de cette synthèse est la formation du cycle C par une réaction de Diels–Alder catalysée par le $SnCl_4$. Dans cette réaction, la géométrie du diène contrôle la stéréochimie *syn–anti* tandis que le catalyseur oriente l'addition vers la position *endo* désirée. On décrit également la préparation du méthyl-*E*-2 oxo-4 buten-2 oate d'éthyle et la déshydratation d'un alcool tertiaire allylique par pyrolyse du carbamate de tosyle correspondant.

In a continuation of our study of regio- and stereocontrol of the Diels–Alder reaction by Lewis acid catalysis (1–3),[1] we have investigated the potential of simple bifunctional dienophiles (2) for the construction of the steroid C-ring. We now wish to report a synthesis of the 8-epiandrostane derivative **13** in which the key step is a stannic chloride catalyzed addition of **4** to **8**. The accompanying communication describes the application of the method to the synthesis of steroids with normal C8-configuration.

Allyl alcohol **2** was prepared by the reported (5) treatment of **1**[2] with lithium acetylide followed by hydrogenation in pyridine (8). Reaction of **2** with *p*-toluenesulfonyl isocyanate (9*a*) in benzene at 20°C gave **3**, mp 138–145°C, which on bulb to bulb vacuum distillation (9*b*) at 170°C (1 Torr) yielded **4**, bp 140°C (1 Torr), in 58% yield from **2**.

Dienophile **8** was prepared from ethyl crotonate in a four step sequence in 65% overall yield. Deconjugative methylation (10) of ethyl crotonate gave **5**, bp 80°C (15 Torr), which was converted to **6** by a reaction with *m*-chloroperbenzoic acid. Epoxide **6** was briefly heated in absolute EtOH with anhydrous K_2CO_3 to give **7** which yielded oily dienophile **8**[3] on treatment with active MnO_2 or with pyridinium chlorochromate (11) followed by

[1]For earliest studies and recent reviews, see ref. 4.

[2]Racemic **1** was used for the synthesis reported here. Chiral **1** is accessible from methyl vinyl ketone and 2-methylcyclohexane-1,3-dione in an asymmetric synthesis using (*S*)-proline (6, 7).

[3]Treatment of **8** with $SnCl_4$ in CH_2Cl_2 for 4 days at 0°C gave a mixture of **8** (^{1}Hmr signal for olefinic H at δ 6.80) and its *Z*-isomer (^{1}Hmr signal for olefinic H at δ 6.15) in a ratio of 3.5:1.

chromatography on Kieselgel (100 mesh, Herrmann).

Reaction of **4** with **8** and anhydrous $SnCl_4$ (2) (1.6:1:0.8) in CH_2Cl_2 at 0°C for 4 days gave a mixture of at least four aldehydic adducts[4] in which one adduct strongly predominated (55–65%) as revealed by the inspection and integration of aldehydic proton signals in the 220 MHz ^{1}Hmr spectrum of the crude product. The use of excess **8** in this addition results in the formation of undesired dihydropyran derivatives (2, 12). A rigorous proof of structure and stereochemistry of the major adduct **9** is given below.

Reaction of the above mixture[5] with the sodium salt of triethyl phosphonoacetate in monoglyme followed by column chromatography[6] on Silica gel H (type 60) gave crude **10**[5,7] which was hydrogenated on 5% Pd–$BaSO_4$ in EtOH to give oily **11** in 48% overall yield from **4**. Hydrogenation of **10** (in quantities smaller than 100 mg) with $[(C_6H_5)_3P]_3RhCl$ (13) selectively reduces the 15,16-double bond. Blocking of the keto group in **11** with ethylene glycol and *p*-toluenesulfonic acid in boiling benzene, followed by Dieckmann condensation with excess potassium *tert*-butoxide (14) in boiling benzene gave crude[5] oily **12**. Finally, alkaline hydrolysis of **12** (0.25 *N* NaOH, 100°C, 3 h) followed by treatment with oxalic acid in H_2O–acetone[8] and column chromatography on Silica gel H (type 60) gave **13**, mp 198–199°C, ir (KBr) ν_{max}: 1730 and 1705 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.97 (3H, s), 1.50 (3H, s), and 5.70 (1H, m). Structure of **13** was established by X-ray diffraction. The overall yield of the conversion **4** → **13** was 24%.[5]

[4]Both the dienophile **8**[3] and any aldehydic adduct are susceptible to equilibration at the position α to the formyl group during the long reaction time required. (See also footnote 9.) $AlCl_3$ and $BF_3 \cdot Et_2O$ proved less suitable as catalysts for this and any other addition involving aliphatic bifunctional dienophiles (2).

[5]Due to instability of the aldehydes to oxidation and isomerization, a separation proved impractical. For efficiency, the entire sequence **4** + **8** ↠ **13** was performed with crude materials. Diester **10**[7] and the final product **13** were obtained in analytical purity for characterization and for the determination of the overall yield of the synthesis.

[6]Excess diene **4** and one of the minor adducts (16% of aldehydic adducts) were recovered unchanged.

[7]Crystallization from pentane – diisopropyl ether gave pure **10**, mp 89–90°C.

[8]Decarboethoxylation of **12** in wet dimethyl sulfoxide (15) gave **13** directly, but in a lower yield.

The formation of **9** as the major adduct is in agreement with our finding that catalyzed additions to diene **4** invariably proceed preferentially from the direction *syn* to the C10-methyl group.[9] Preferred complexation of the formyl group in dienophile **8** then controls orientation and *endo* stereochemistry (2) to give **9** as indicated in structure **14**. Details on *syn–anti* stereoselectivity in catalyzed additions to **4** and related dienes[9] will be reported shortly. The accompanying communication describes an efficient addition *anti* to the C10-methyl group of an appropriate diene.

[9]This *syn* preference is, however, not quantitative. *Syn–anti* ratios in the range of 2:1 to 4:1 are observed in catalyzed additions of diene **4** to quinones and to aliphatic bifunctional dienophiles. There is, therefore, no doubt that an *anti* adduct (isomeric with **9** at C8, C13, and C14) is present in a minor quantity in the mixture of aldehydes resulting from the addition **4** + **8** + $SnCl_4$ described here.

Total synthesis of androstanes

MASATOSHI KAKUSHIMA, JAGABANDHU DAS, GARY R. REID, PETER S. WHITE, AND ZDENEK VALENTA

Department of Chemistry, University of New Brunswick, P.O. Box 4400, Fredericton, N.B., Canada E3B 5A3

Received September 10, 1979

MASATOSHI KAKUSHIMA, JAGABANDHU DAS, GARY R. REID, PETER S. WHITE, and ZDENEK VALENTA. Can. J. Chem. **57**, 3356 (1979).

A total synthesis of androstane derivatives is described. The desired configuration at C8 and at C13 is achieved in a ring C forming $SnCl_4$-catalyzed Diels–Alder reaction. The preparation of methyl *Z*-2-methyl-4-oxo-2-pentenoate and the cyclization of a keto ester to a steroid 15,17-dione are also reported.

[9]This *syn* preference is, however, not quantitative. *Syn–anti* ratios in the range of 2:1 to 4:1 are observed in catalyzed additions of diene **4** to quinones and to aliphatic bifunctional dienophiles. There is, therefore, no doubt that an *anti* adduct (isomeric with **9** at C8, C13, and C14) is present in a minor quantity in the mixture of aldehydes resulting from the addition **4** + **8** + $SnCl_4$ described here.

Total synthesis of androstanes

A total synthesis of androstane derivatives is described. The desired configuration at C8 and at C13 is achieved in a ring C forming $SnCl_4$-catalyzed Diels–Alder reaction. The preparation of methyl *Z*-2-methyl-4-oxo-2-pentenoate and the cyclization of a keto ester to a steroid 15,17-dione are also reported.

On décrit une synthèse totale de dérivés de l'androstane. On a obtenu la configuration désirée au niveau des carbones en position 8 et 13 en réalisant la synthèse du cycle C selon une réaction de Diels–Alder catalysée par $SnCl_4$. On rapporte également la préparation du méthyl-2 oxo-4 pentène-2 oate de méthyle (*Z*) ainsi que la préparation d'un stéroide dione-15,17 obtenu par cyclisation d'un ester cétonique.

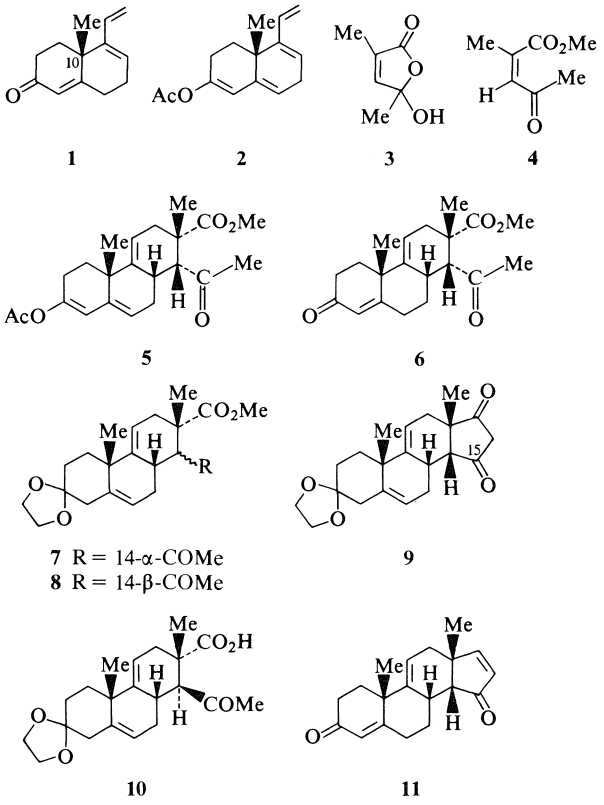
[Traduit par le journal]

In the preceding communication (1), we have described the $SnCl_4$-catalyzed addition of diene **1** to ethyl *E*-2-methyl-4-oxo-2-butenoate in which the geometry of **1** favors an addition *syn* to the C10-methyl group while a preferential complexing of the formyl group in the dienophile (2) determines orientation and *endo* stereochemistry. The resulting adduct then leads to 8-epi-androstanes by further transformations (1). We now wish to report the controlled addition of enol acetate **2** to the *Z*-dienophile **4** in which the side *anti* to the C10-methyl group of **2** is strongly favored and which therefore, via adduct **6**, leads to a facile synthesis of steroids with the desired configuration at C8 and at C13.

Oily enol acetate **2**, ir ($ChCl_3$) ν_{max}: 1750 and 1665 cm^{-1}, was prepared efficiently on treatment of **1** (1) with HBr in acetic anhydride at 20°C for 10 h. In a less convenient preparation, the reflux of **1** in isopropenyl acetate with *p*-toluenesulfonic acid first led mainly to the isomeric 3-acetoxy-2,4-diene (~24 h) which was converted to **2** under the same conditions in 130 h. The dienophile **4**, bp 62°C (20 Torr), ir (CCl_4) ν_{max}: 1740 and 1705 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 2.00 (3H, d, J = 2 Hz), 2.23 (3H, s), 3.80 (3H, s), 6.17 (1H, q, J = 2 Hz), was obtained in 88% yield by the treatment of **3** with CH_3I and K_2CO_3 in dry acetone at 20°C for 28 h; **3** is available in one step from a reaction of pyruvic acid, acetone, and 85% H_3PO_4 (3).

Reaction of **2** with **4** and anhydrous $SnCl_4$ (1:2:1.5) in CH_2Cl_2 at 0°C for 1 h gave **6**, mp 155–156°C, ir (CCl_4) ν_{max}: 1735, 1715, and 1680 cm^{-1}, in 70% yield based on consumed **2**.[1] The structure of **6** was established by X-ray diffraction.

To complete the steroid synthesis, **6** was simply converted into **7**, mp 150–158°C, in 85% yield by a reaction with ethylene glycol and *p*-toluenesulfonic acid in boiling benzene and **7** was then treated with dimsyl sodium (4)[2] to give dione **9**, mp approx. 191°C (dec.), uv λ_{max} (MeOH): 262 nm (ε 17 700), (MeOH–KOH): 264 nm (ε 22 100), (MeOH–HCl): 247 nm (ε 13 300); ir (KBr) ν_{max}: 3650–2250, 1645, and 1560 cm^{-1}, along with acid **10** which could be separated from **9** by fractional crystallization. The yield of the conversion **7** → **9** is at least 41% as determined by subsequent methylation described below.



Thus, steroid **9** was prepared from 2-methyl-

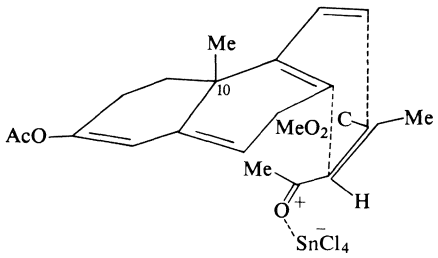
[1]The uncorrected yield of crystalline **6** after purification on a column of Silica gel H (type 60) was 55%. No other adduct was detected. Unused diene was recovered in the form **1**; the starting material **2** and the adduct **5** decompose to **1** and **6**, respectively, during the reaction. The primary adduct **5**, mp 129–131°C, could be isolated in a low yield (15–20%) under scrupulously anhydrous conditions and was found to give **6** on mild acid hydrolysis. The reaction of **1** with **4** and $SnCl_4$ is very slow under the conditions used.

[2]Dry dimethyl sulfoxide (10 equiv., 1 volume) was first reacted with NaH (2 equiv.) at 80°C for 30 min. Toluene (2 volumes) was then added at 110°C and, when distillation started, **7** (1 equiv.) in toluene (20 volumes) was slowly added while distillation continued. Additional toluene (20 volumes) was added during the distillation. We thank Professor R. H. Schlessinger, University of Rochester, N.Y., for valuable advice on this capricious cyclization.

cyclohexane-1,3-dione, methyl vinyl ketone, acetylene, acetone, and pyruvic acid in eleven synthetic steps; six to prepare **2**,[3] two to prepare **4**, and three to convert them into **9**. It should be noted that the conversion **2** → **6** → **9** is formally equivalent to a controlled addition of 2-methyl-2- cyclopentene-1,4-dione to diene **2**.

To determine the ring D cyclization yield and to characterize dione **9** further, crude cyclization product (**9** + **10**) was treated with CH_2N_2 in ether. Column chromatography on Silica gel H (type 60) then gave ester **8**, mp 207–208°C (21% yield from **7**), and the two ring D enol ethers of **9** (2:1 ratio, 41% yield from **7**). The major one (MeO at C15) was converted in 58% yield to enone **11**, mp 125–127°C, ir (CCl_4) ν_{max}: 1710, 1675, 1620, and 1595 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 5.70 (1H, m, C11—H), 5.78 (1H, broad s, C4—H), 6.00 (1H, d, J = 6 Hz, C16—H), and 7.23 (1H, d, J = 6 Hz, C17—H), by reduction with sodium bis(2-methoxyethoxy) aluminum hydride (Ventron Co.) followed by spontaneous dehydration of the alcohol in CCl_4 at 20°C and by hydrolysis of the resulting 15-methoxy-14,16-diene, ^{1}Hmr ($CDCl_3$) δ 6.34 (2H, sharp s, C16 and C17—H's), with 1 *N* HCl in acetic acid at 20°C for 20 h. The ring D structure of **11** and its precursors follows most clearly from the ^{1}Hmr signal corresponding to both ring D H-atoms of the above diene; the spectrum of the alternative 17-methoxy-14,16-diene would show two widely separated signals for the C16—(enol ether H) and C15—H atoms. The δ and J values for the two ring D H-atoms in **11** are in good agreement with data reported for a similar system (5).

Clearly, an addition *anti* to the C10-methyl group is favored by the geometry of diene **2** in this case; a preferred complexation on the oxygen atom



12

of the keto group in **4** (1, 2) then achieves the desired orientation and *endo* stereochemistry as shown in structure **12**.[4] The regioselectivities and the *syn–anti* and *endo–exo* stereoselectivities achieved by the use of bifunctional dienophiles in catalyzed additions as described in this and the preceding communications (1, 2) should prove of general use for the controlled construction of carbon frameworks.

[3]For preparation of diene **1**, see ref. 1 and references cited therein.

[4]The conformation of the complexed carbonyl group during addition is unknown; the one given in **12** is arbitrarily chosen. It is also not known whether $SnCl_4$ forms more than one bond during the reaction. (It is, for example, tempting to speculate that Sn also interacts with the 5,6-double bond of **2**.)
