We had prepared a crystalline form of a Co(III)–CyDTA complex, and it was of interest to investigate the nature and the stability of the complex in solution. Previous work by Jacobsen and Selmer-Olsen showed that a 1:1 complex formed between these reactants, but that in the presence of excess cobalt(II) ion some of the ligand was oxidized (1). We had not observed an oxidation reaction, and a further study of the system was undertaken. It is known that Co(III) is a highly reactive species, but is stabilized by complex formation. Both Jacobsen and Selmer-Olsen (1), and Martinez and Mendoza (2), have used CyDTA to determine micro quantities of cobalt(III) ion in solution. Jacobsen and Selmer-Olsen carried out their investigation in solutions buffered at pH 4.6. Except when excess cobalt ion resulted in the partial oxidation of CyDTA, as noted above, an otherwise stable 1:1 complex was observed, regardless of the oxidant (1). Martinez and Mendoza determined that a 1:1 complex was formed in basic media using H_2O_2 as the oxidizing agent (2). They did not report an oxidation process such as Jacobsen observed. Working with ligands similar to CyDTA, Arribas and co-workers (3) have reported that two cobalt(III) complexes can form in solution. The aquated species, $Co(H_2O)Y^-$, is relatively unstable and loses a molecule of water to form the 'normal', CoY^-, complex. Flaschka and Ganchoff reported that these two complex species are characterized by absorbance maxima at two different wavelengths (4). Schwarzenbach showed that with cobalt(III) and a polydentate ligand such as EDTA, one co-ordination site can be freed from the primary ligand, and that substitution by a different ligand, such as a halogen or an hydroxyl ion, can occur (5). In the light of these studies, we wish to report a significant additional characteristic of the reaction between cobalt(III) and the polydentate ligand CyDTA.

Experimental

Reagents

All reagents were of analytical reagent quality: $Co(NO_3)_2 \cdot 6H_2O$, Fisher Scientific; $KC_2H_3O_2$, Baker Chemical Co.; H_2O_2, 30%, Baker Chemical Co.; murexide indicator, Fisher Scientific; disodiumethylenedinitrilotetraacetic acid (Na_2EDTA), 99+%, Fisher Scientific; *trans*-1,2-cyclohexanedinitrilotetraacetic acid (CyDTA), 98%, Pflatz & Bauer (dec. > 210°C, homogeneous on tlc, nmr comparable to Aldrich spectrum No. 16A).

Apparatus

All spectrophotometric measurements were made with a Pye Unicam uv–visible spectrophotometer, model 2000, equipped with a thermostated cell and linear recorder. Perkin-Elmer 1.0 cm silica cells were used. A Corning pH meter, model 10, was used to determine the pH of all the reaction solutions.

Procedure

An aqueous stock solution of 0.025 *M* cobalt(II) nitrate hexahydrate was prepared by the direct weighing of the salt. The solution was standardized with 0.5 *M* EDTA using murexide indicator. An aqueous stock solution, 0.025 *M* in CyDTA and 0.1 *M* in potassium acetate, was prepared by the direct weighing of the salts. For all of the reaction solutions, the desired volume of each stock solution was measured accurately into 50 mL volumetric flasks. The ionic strength was held constant with potassium acetate, and the pH was adjusted to 4.6 with acetic acid, if necessary. Hydrogen peroxide (5 mL) was added to each solution and to a reference blank. The solutions were heated in a boiling water bath for at least 30 min. After cooling to room temperature, each solution was diluted to volume. The absorbance was recorded at 25°C, using the prepared blank as the reference. The slope-ratio method (*6a*), the mole ratio method (*6b*), and Job's method (*6c*) were carried out to investigate the molar composition and the stability of the cobalt(III)–CyDTA complex.

In each case, two series of solutions were prepared so that both the metal and the ligand concentration could be held constant with respect to the other. For the slope-ratio determination, millilitre increments of one reactant were added to reaction flasks containing 25 mL of the fixed component. For the mole ratio determination the concentration of one component was varied (1–12 mL; $2.50 \times 10^{-5} - 3.00 \times 10^{-4}$ mol). For Job's method, the volume of each component was varied in millilitre increments to maintain a concentration of 5.00×10^{-4} mol (20 mL).

Results and Discussion

Oxidized solutions of Co(II)–CyDTA have two absorbance maxima; the lower absorptivity is observed at 380 nm, the higher at 540 nm. The absorbance of aqueous solutions of CyDTA is negligible at these wavelengths. Solutions of Co(II) exhibit a very low absorbance at 540 nm. The absorbance of all the oxidized solutions was stable up to 8 days. No variation in the wavelength of maximum absorbance was observed when Co(II) or an unoxidized mixture of reactants was used as the reference.

The data in Fig. 1 constitute a slope-ratio determination (*6a*). Beer's law is obeyed at both wavelengths. In theory, the ratio of the slope of a pair of

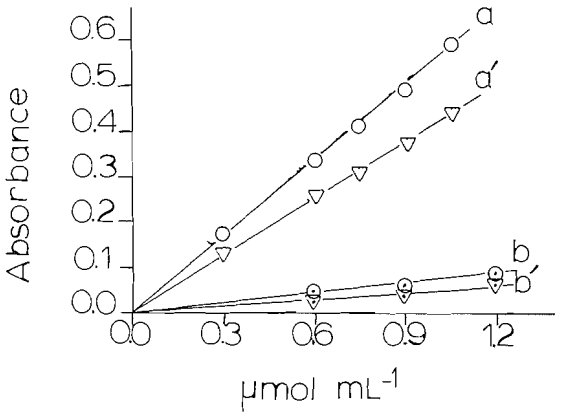

FIG. 1. The slope-ratio analysis of Co(III) with CyDTA at 540 nm (*a* and *b*), and at 380 nm (*a'* and *b'*). (*a*, *a*) per 7.5 mol mL^{-1} Co(II); (*b*, *b'*) per 7.5 mol mL^{-1} CyDTA; total volume, 50 mL; $\mu = 4.6$; 25°C; $\mu = 0.1$.

lines at a particular wavelength corresponds to the ratio of the components in a complex. Lines *a* and *a'* show the absorbance as a function of the CyDTA concentration. At 540 nm the molar absorptivity is 554 M^{-1} cm^{-1}, and at 380 nm the value is 404 M^{-1} cm^{-1} (lines *a* and *a'*, respectively). Jacobsen and Selmer-Olsen reported the molar absorptivity at 545 nm of only 305 M^{-1} cm^{-1}, but attributed low absorbance to the oxidation of ligand by excess Co(II) (1). We did not observe any oxidation of CyDTA. Lines *b* and *b'* show the change in the absorbance as a function of Co(II) ion concentration. The absorbance values for this series of solutions were expected to be identical to the first series (lines *a* and *a'*; assuming a 1:1 complex), because the limiting concentration was the same. The value calculated at 540 nm for line *b* is 73 M^{-1} cm^{-1}, and 47 M^{-1} cm^{-1} at 380 nm, a considerable difference from the complimentary series. There was no evidence that a more strongly absorbing species was formed initially, then decomposed. The ratio of the slope at each wavelength indicates a 1:8 Co(III):CyDTA complex. However, it is important to note that this method is valid only when one complex is formed.

Figures 2 and 3 show the absorbance values for the mole ratio determination (*6b*). When the concentration of CyDTA was fixed, the initial absorbance values were low, in accord with line *b* in Fig. 1. At the Co(II):CyDTA ratio 0.8, the absorbance of the solutions rose sharply, then became constant at a 1:1 mole ratio (Fig. 2). When the concentration of the Co(II) ion was fixed, the absorbance increased much more steeply, corresponding to line *a* in Fig. 1. The absorbance dropped suddenly, however, with the first increment of a molar excess of CyDTA. A second

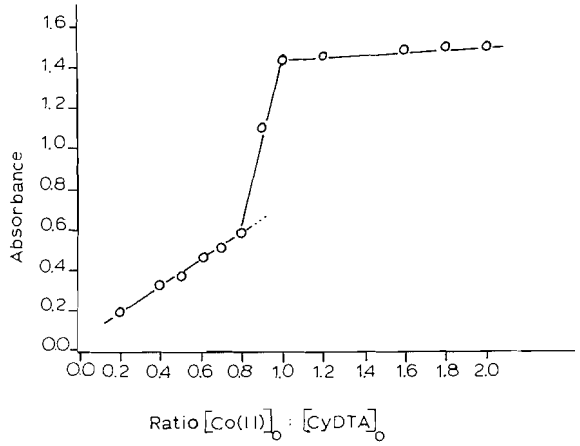

FIG. 2. The mole-ratio analysis of Co(III) with CyDTA at 540 nm. $[CyDTA]_0$ = 5 mL 0.025 *M* stock; total volume, 50 mL; pH = 4.6; 25°C, μ = 0.1.

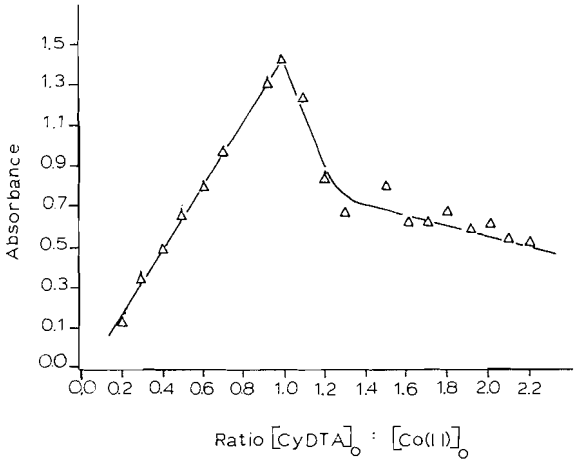

FIG. 3. The mole-ratio analysis of Co(III) with CyDTA at 540 nm. $[Co(II)]_0$ = 5 mL 0.025 *M* stock; total volume, 50 mL; pH = 4.6; 25°C, μ = 0.1.

inflection in the absorbance values was observed at the ratio 1.25 (Fig. 3). Repetition of these measurements at three wavelengths (380, 540, and 600 nm) and with different concentrations of reactants (using 4 mL and 6 mL of the fixed component in separate trials) gave the same results. There is some scatter in the data near the second inflection point in Fig. 3. This was also observed in the other trials. It is believed to be related to the instability of a second complex species.

When the mole fraction of CyDTA was increased according to Job's method (6*c*), the regularly increasing absorbance values dropped abruptly at a mole fraction 0.5, then decreased gradually. These data are shown in Fig. 4. When the mole fraction of Co(II) was increased, the trend in the absorbance rose sharply at mole fraction 0.5, then decreased steadily with excess Co(II).

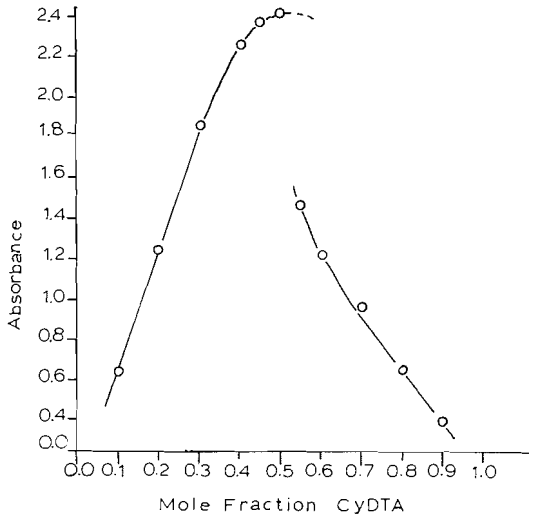

FIG. 4. The analysis of Co(III) with CyDTA by Job's method at 540 nm. Total volume, 50 mL; total concentration = 0.500 mmol (20 mL, 0.025 *M*); pH = 4.6; 25°C, μ = 0.1.

Several experimental variations were made to detect an artificial cause for these deviations from the expected behavior. In the light of Jacobsen and Selmer-Olsen's observations (1), separate solutions of Co(II) and CyDTA were allowed to react with hydrogen peroxide. When they were then mixed together and allowed to react, no loss of reactivity was detected. Complex formation between Co(II) and the acetate buffer ions was also investigated. When Co(II) was allowed to react with acetate ions under the same reaction conditions, no spectral evidence for a cobalt–acetate complex was observed. Because the analogous reaction between Co(II) and EDTA has been studied (7), that reaction was carried out under identical conditions of concentration and pH. The spectral data showed only that the known 1:1 complex was formed.[2]

These sets of data indicate, then, that more than one stable complex is being formed between Co(III) and CyDTA. Jakubiec and Boltz (8) observed similar data in a mole ratio determination of molybdate complexes with germanium, and Cheng and Goydish (9) reported absorbance minima in a Job's plot for palladium and mercury complexes with thio-Micheler's reagent. We believe that this is the first report of a higher order complex of a metal ion with a polyaminopolycarboxylic acid.

The work of Asmus and co-workers (10) which has been applied and extended by Langmyhr and co-workers (11) and others (12) treats data like those displayed in Fig. 4. Langmyhr and Stumpe (11*a*) found that when Job's curve exhibits an absorbance maxima at mole ratio 0.5, but shows inflection points

[2]Data were submitted to the referees.

in the absorbance curve near both limits, the molar co-efficients are equal but greater than one. In our case, such a parabolic inflection is observed only when the mole ratio favors the ligand, CyDTA. We believe that the Job's plot in Fig. 4 is reflecting the formation of two different complexes which form as the molar ratio of the reactants changes.

The method of Asmus and co-workers (10*a*) was used to resolve the stoichiometry and the equilibrium constant for the complex that forms between Co(III) and CyDTA when the ligand is in excess. The results are shown in Fig. 5. The data show clearly that 2 mol of CyDTA react with Co(II). From the intercept of the straight line, the value of the conditional formation constant was found to be $1.96 \times 10^5\ M^{-2}$ for the reaction in [2] below:

[1] $\text{Co(II)} + \text{CyDTA} \overset{K_1}{\rightleftharpoons} \text{Co(III)CyDTA}$

$\varepsilon = 554$ (540 nm)

[2] $\text{Co(II)} + 2\text{CyDTA} \overset{K_2}{\rightleftharpoons} \text{Co(III)(CyDTA)}_2$

$\varepsilon = 73$ (540 nm)

The spectral evidence for the 1:1 complex is clear from Figs. 2 and 3. This complex has a high molar absorptivity, and it is expected to have a large overall formation constant, characteristic of most CyDTA complexes (13). Jacobsen and Selmer-Olsen (1) calculated $\log K_f = 21.9$ for the 1:1 complex. Because of the abrupt inflection points which we recorded, the apparent formation constant cannot be determined accurately from these spectral data.

The description of this system is complicated by the effects which the absorbance and the formation constant of the higher order complex have on the 1:1 complex. Because the measured absorbance is an additive combination of both absorbing species, the calculated molar absorptivity values are undoubtedly high (1, 14). Secondly, the spectra indicate that excess

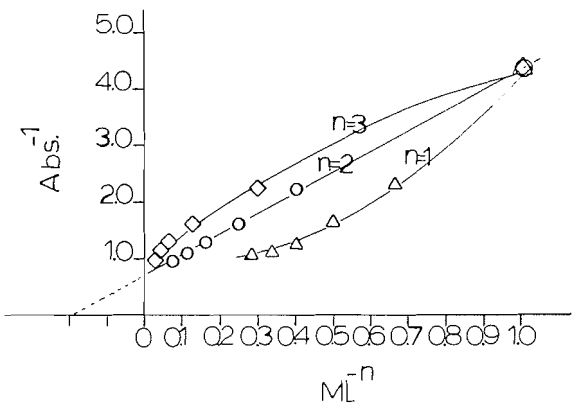

FIG. 5. The plot of absorbance^{-1} with mL^{-n} for 0.025 *M* CyDTA with 5.0 mL 0.025 *M* Co(II). Total volume, 50 mL; pH = 4.6; 25°C, $\mu = 0.1$.

ligand binds with a strongly absorbing species and diminishes its absorbance (presumably by forming a less strongly absorbing complex).

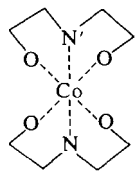
With reference to eqs. [1] and [2] above, in Fig. 1, lines *a* and *a'* show that when the concentration of Co(II) is sufficiently high, the formation of ML by eq. [1] is favored. Equilibrium [2] is suppressed by the concentration of Co(II) and K_1 expected $> K_2$.

Lines *b* and *b'* show that the high concentration of CyDTA enhances the effect of [2] to form the low absorbing ML_2 species at the expense of the 1:1 complex. Excess ligand, coupled with a relatively high stability constant, K_2, diminishes the concentration (absorbance) of the 1:1 complex (Fig. 2).

In Fig. 3, the strongly absorbing 1:1 species predominates initially. The presence of excess ligand shifts the equilibrium according to eq. [2] and decreases the concentration of the 1:1 complex.

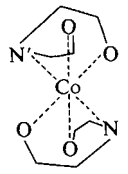
From these data, and for a polydentate chelating agent, it is now only possible to speculate on a structure for a higher order complex. Yalman (15) has made an extensive study of Co(III) complexes with EDTA. He reported that both a monomeric Co(III) complex and a peroxodicobalt[(III), (III)] species can form during the oxidation with H_2O_2. Although the dimer exhibits a low molar absorptivity, these two complexes are characterized by different absorbance maxima. Also, the dimeric species forms in the presence of excess Co(II) ions, rather than with an excess of ligand as we have observed. Similarly, El-Awady and Hugus (16) reported that Co(III) can form a doubly bridged (through —OH) species with ethylenediamine, $Co(en)_4(OH)_2^{4+}$, in basic media.

We propose that the 1:2 Co(III):CyDTA complex can be formed in a chain structure. Using molecular models, it can be shown that one iminodiacetate 'arm' of the *trans*-CyDTA molecule can be directed away from the other sufficiently to be able to enter into complex formation with two different Co(III) ions (e.g. axial–axial C—N bonds in the 'boat' conformation). Two simplified arrangements of metal and ligand that could form in this manner are shown in **I** and **II** below.



I

In **I** the four oxygen atoms occupy the equatorial positions, and are from two different CyDTA molecules (N and N'). The other iminodiacetate group of each molecule is directed toward other Co^{3+} ions. In the second arrangement, **II**, a nitrogen atom from



II

different CyDTA molecules occupies an equatorial position; oxygen atoms occupy the axial positions.

The paired inflection points at the M:L ratio 0.8 (Fig. 2) and L:M 1.25 (Fig. 3) suggest that the chain structure is composed of 4 metal atoms and 5 CyDTA molecules. The general M:L ratio, then, is M_nL_{n+1}.

Since both the 1:1 and the 1:2 complexes have absorbance maxima at the same wavelength, it might be that the structure shown in **II** is most like that of the 1:1 complex in which two equatorial positions are occupied by nitrogen atoms. Either structure is admittedly awkward. However, both of the reactants have a very strong propensity to enter into complex formation, and it is only when there is an excess of ligand and an extensive degree of protonation that the higher order complex is observed.

Our continuing study of this system will include an attempt to isolate both of the complexes in crystalline form. Molecular weight determination, X-ray analyses, and perhaps nmr studies will be very informative.

Specific binding of phenylalanine and tryptophan to β-nicotinamide adenine dinucleotide[1]

KLAUS J. NEUROHR AND HENRY H. MANTSCH

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada, K1A 0R6

Received March 7, 1979

KLAUS J. NEUROHR and HENRY H. MANTSCH. Can. J. Chem. 57, 2297 (1979).

This ^{1}H nmr study provides the first experimental evidence for specific complex formation between the coenzyme nicotinamide adenine dinucleotide (β-NAD^+) and the two aromatic amino acids phenylalanine and tryptophan. It is shown that the interaction is of the stacking type and occurs between the aromatic side chains of these amino acids and the adenine moiety of NAD^+. Binding parameters were obtained from dilution studies, taking into account the self-association of NAD^+. The apparent microscopic association constants for complex formation of phenylalanine and tryptophan with excess NAD^+ in aqueous solutions are 1.35 M^{-1} and 11.35 M^{-1}, respectively, indicating that the adenine moiety of NAD^+ can discriminate between phenylalanine and tryptophan by a stronger binding to the latter. The results are discussed with regard to the interaction of NAD^+ with dehydrogenases.

KLAUS J. NEUROHR et HENRY H. MANTSCH. Can. J. Chem. 57, 2297 (1979).

Dans ce travail, on rapporte les premières preuves expérimentales, basées sur une étude rmn ^{1}H, pour la formation de complexes spécifiques entre le dinucléotide de la nicotinamide et de l'adénine (β-DNA^+) et les deux acides aminés aromatiques phénylalanine et tryptophane. On montre que l'interaction en est une d'empilement et qu'elle se produit entre les chaînes latérales aromatiques de ces acides aminés et la portion adénine du DNA^+. On a obtenu les paramètres de liaison à partir d'études de dilution en tenant compte de l'auto-association du DNA^+. Les constantes d'association microscopiques apparentes pour la formation de complexes entre la phénylalanine et le tryptophane et un excès de DNA^+ en solutions aqueuses sont respectivement 1.35 M^{-1} et 11.35 M^{-1} ce qui indique que la portion DNA^+ peut distinguer la phénylalanine du tryptophane grâce au site de liaison plus fort avec ce dernier. On discute des résultats en rapport avec l'interaction de la DNA^+ avec les déshydrogénases.

[Traduit par le journal]

Introduction

Numerous nmr studies have been undertaken to investigate the dynamic conformation of β-nicotinamide adenine dinucleotide (NAD^+) in aqueous solution (1–19). A detailed discussion of the existing nmr literature on this subject was made recently by Ellis and co-workers (20). However, the results are often conflicting, the most argued question being the location of the two heterocyclic base moieties relative to each other and to the corresponding ribose moieties. While the nicotinamide moiety is known to be essential for the catalytic activity of all NAD^+-dependent dehydrogenases (21), the role of the somewhat remote adenine moiety is thought to be that of anchoring the NAD^+ molecule onto the corresponding enzyme (22, 23). This would require its recognition and (or) binding to a specific amino acid grouping on the enzyme.

In the present investigation we provide the first experimental evidence for specific complex formation between two aromatic amino acids, phenylalanine and tryptophan, and the adenine moiety of NAD^+.

Experimental Section

Materials and Sample Preparation

All chemicals were products of the highest available purity. Phenylalanine, tryptophan, and β-NAD^+ were from Sigma Chem. Co. The nmr samples were prepared in 99.8% D_2O containing 10 mM phosphate buffer, 1 mM NaCl, 1 mM *tert*-butanol, and 100 μM EDTA. The pH of the solutions was adjusted with NaOD or DCl to a "pH" (meter reading) of 7.3. The phenylalanine and tryptophan concentration was kept constant at 25 mM, while that of NAD^+ varied from 17 mM to 266 mM for complex formation and from 4 mM to 532 mM for the study of NAD^+ self-association. Individual NAD^+ concentrations were determined from the ultraviolet A_{260}, using ε_{max} = 17 900.

Nuclear Magnetic Resonance Measurements

All ^{1}H nmr spectra were taken with a Varian XL-100/12 spectrometer operating at 100 MHz under a 16 K Varian 620/L data system. The digital resolution was 0.25 Hz (0.0025 ppm); the 90° pulse-time was 20 μs. Between 20 and 12 000 transients were accumulated, depending on the dilution of the samples. Typically three, but at least two, independent measurements were made for each sample. The probe temperature was 32 ± 0.5°C. Chemical shifts were measured with respect to *tert*-butanol as internal reference.

Results and Discussion

The Self-association of NAD^+

In order to quantitate the interaction of phenylalanine and tryptophan with excess NAD^+, it is necessary to correct for the degree and influence of self-association of the latter under identical conditions. Therefore we have accurately measured the concentration dependence of the ^{1}H nmr chemi-

[a]Chemical shifts were measured relative to internal *tert*-butanol and converted to the TMS scale by adding 1.24 ppm.
[b]Negative values indicate shifts to lower and positive values shifts to higher field compared to infinite dilution.
[c]Ultraviolet spectroscopically determined concentrations using $\varepsilon_{260}^{mM} = 17.9$.
[d]Zero concentration chemical shifts were obtained through extrapolation of experimental shifts.
[e]Due to overlap with other signals no accurate values could be given.

cal shifts for all aromatic protons of NAD^+. These are displayed in Table 1. Chemical shift assignments are based on those originally reported by Jardetzky and Wade-Jardetzky (2) and confirmed later unequivocally (13). The letters A and N are used to distinguish between protons located in the adenine (A) and the nicotinamide (N) moiety using the standard numbering scheme for the two bases. Over the concentration range investigated, from 4 m*M* to 532 m*M*, the adenine protons A2 and A8 undergo considerable upfield shifts with increasing concentration, while at the same time the nicotinamide protons N2, N4, N5, and N6 all undergo downfield shifts. It is interesting to note that the chemical shifts of the A1′ and N1′ protons of the contiguous bases also change in opposite directions, reflecting different shielding environments for the two bases.

While it is possible to rationalize the upfield shifts of the adenine protons with increasing concentration only in a unique situation in which two aromatic rings come close to each other, the corresponding downfield shifts of the nicotinamide protons could be associated with other intermolecular interactions such as hydrogen bonding or electrostatic (dipolar) interactions. The concentration profiles reported here for the A2 and A8 protons in NAD^+ are typical for intermolecular base-stacking interactions and resemble those observed with the A2 and A8 protons in adenine nucleotides (24). The existence of such intermolecular base-stacking interactions with adenine nucleotides in aqueous solutions has been demonstrated not only by nmr, but also by vapor pressure osmometry, microcalorimetry, sedimentation equilibrium, and ultraviolet hypochromism (25). It is generally agreed that this association proceeds beyond the dimer stage.

Earlier studies (4, 8, 13) had pointed out that the ^{1}H nmr chemical shifts of NAD^+ can vary with concentration; however, so far no attempts have been made to obtain equilibrium constants from the data. We have analyzed the concentration-dependent chemical shifts of the adenine NAD^+ protons by the isodesmic model of Dimicoli and Hélène (26). This takes into account both dimer and *n*-mer formation and is illustrated in Fig. 1 for the A2 and A8 protons of NAD^+. A plot according to this model of $(\delta\sigma/c_0)^{1/2}$ versus δσ (δσ being the difference between the individual chemical shifts at concentration c_0 and the corresponding chemical shift at infinite dilution) gave straight lines for both protons. From the slope of each of these, a micro-

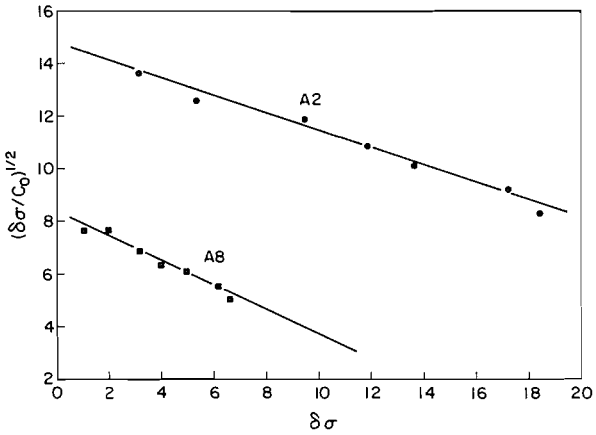

FIG. 1. Self-association of NAD^+ at 32°C and pH 7.3 as a plot of $(\delta\sigma/c_0)^{1/2}$ versus $\delta\sigma$ for the A2 and A8 protons of its adenine moiety.

scopic equilibrium constant (K_c) and the corresponding Gibbs energy change (ΔG^0) were obtained, while the x-axis intercept yielded the corresponding dimer shifts ($\delta\sigma_{A_2}$). The results shown in Table 2 also include the corresponding constants for the 5′-AMP self-association (28), evaluated on the basis of the same isodesmic model.

It is very interesting that the A2 and A8 proton-averaged apparent equilibrium constant for the self-association of NAD^+ ($\overline{K}_c = 4.62\ M^{-1}$) and the derived standard Gibbs energy change ($\overline{\Delta G}^0 = -3.85\ \text{kJ mol}^{-1}$) are more than twice those found for the self-association of 5′-AMP ($\overline{K}_c = 1.93\ M^{-1}$ and $\overline{\Delta G}^0 = -1.65\ \text{kJ mol}^{-1}$), which itself was thought to be strongly self-associated in concentrated aqueous solutions. Accordingly the tendency for self-association of NAD^+ is about 2.4 times greater than that of 5′-AMP.

While it is difficult to derive an accurate stacking geometry for the NAD^+ aggregates in aqueous solutions from only these data, it is possible to draw the following conclusions. (*i*) The adenine moiety of NAD^+ is involved in a base-stacking pattern. (*ii*) The nicotinamide moiety of NAD^+ does not participate in the stacking, but could be involved in the association through hydrogen bonding or dipole–dipole interactions. (*iii*) The association is intermolecular.

These conclusions are in very good agreement with the first X-ray study of NAD^+ recently reported by Saenger *et al.* (29) in which the authors showed that in the lithium complex, the crystal conformation of NAD^+ is "extended" due to an intermolecular base stacking, and not "folded" which would be the consequence of an intramolecular base stacking between the adenine and nicotinamide moieties.

TABLE 2. Microscopic equilibrium constants (K_c)[a], standard Gibbs energy changes (ΔG^0), and ^1H nmr dimer shifts[b] ($\delta\sigma_{A_2}$) for the self-association of NAD^+ and 5′-AMP at 32°C and pH 7.3

	K_c (M^{-1})	ΔG^0 (kJ mol^{-1})	$\delta\sigma_{A_2}$ (Hz)
NAD^+ (A2)	4.72	−3.9	22.7
NAD^+ (A8)	4.52	−3.8	8.2
5′-AMP (A2)	1.96	−1.67	44.6
5′-AMP (A8)	1.91	−1.63	18.0

[a]Both the equilibrium constants and the standard Gibbs energy changes reported here are based on concentrations as recommended by the ICSU Commission on Biothermodynamics (27).

[b]Dimer shifts were calculated according to the isodesmic model of Dimicoli and Hélène (26), which takes into account n-mer formation. This model considers the magnetic anisotropy of nearest neighbours only and assumes that the effects are additive. The change in chemical shift of a molecule located inside an n-mer, relative to the free molecule, is therefore twice that observed in the dimer.

Formation of Base-stacking Complexes between Phenylalanine or Tryptophan and NAD^+

We have monitored the ^1H nmr chemical shifts of individual protons located in the aromatic side groups of phenylalanine and tryptophan in the presence of varying amounts of NAD^+. Illustrated in Fig. 2 is the dependence on NAD^+ concentration of the H_c chemical shift of 25 mM tryptophan. The H_c singlet which is representative for the aromatic side group is easily distinguishable from the other aromatic protons of tryptophan and NAD^+. The resulting plot shows a steep decrease of the H_c chemical shift of tryptophan at low NAD^+ con-

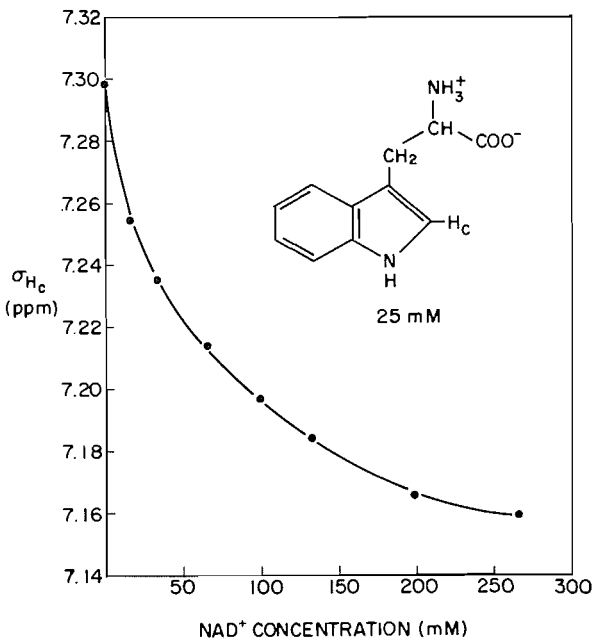

FIG. 2. Variation of the H_c chemical shift of 25 mM tryptophan as induced by complex formation with NAD^+ at 32°C and pH 7.3.

centrations, leveling off above 250 mM NAD^+. The H_c proton resonance of 25 mM tryptophan, in the absence of NAD^+, is at 7.30 ppm and the total chemical shift difference between "free" and "NAD^+-complexed" tryptophan is 14 Hz (0.14 ppm).

The five aromatic protons of phenylalanine are not resolved in the 100 MHz spectrum and appear as a singlet at 7.37 ppm in 25 mM phenylalanine. In the presence of an increasing NAD^+ concentration, this singlet undergoes an upfield shift similar to that displayed in Fig. 2 for the H_c resonance of tryptophan. For the NAD^+ concentration range investigated, the total chemical shift difference between "free" and "NAD^+-complexed" phenylalanine is also 14 Hz. However, the concentration profile of phenylalanine differs from that of tryptophan, which, as shown later, leads to different binding parameters. The similarity between the behavior of the two aromatic amino acids suggests that the observed upfield shifts of the aromatic protons are due to the same phenomenon, a base-stacking interaction with the NAD^+ molecule. Since the rate of exchange between the free and NAD^+-complexed amino acids is rapid on the ^1H nmr time-scale, only one resonance is observed for each proton monitored. Therefore, the measured chemical shifts in Fig. 2 represent the weighted average of chemical shifts for the free and NAD^+-complexed tryptophan molecules.

In order to extract the corresponding binding parameters, we have analysed these ^1H nmr chemical shift data by a modified Scatchard plot (28), using the mathematical model derived by Deranleau (30) and extended by Dimicoli and Hélène (26) to the case where the component in excess self-associates strongly.

$$[1]\quad \frac{\Delta\sigma}{\delta\sigma} = \left(\frac{K_c - k}{2K_c}\right)\frac{\Delta\sigma}{\delta\sigma_{A_2}} + \left(\frac{k}{2K_c}\right)\frac{\Delta\sigma_{BAB}}{\delta\sigma_{A_2}}$$

The variables in this equation have the following meaning. The parameters $\delta\sigma$, $\delta\sigma_{A_2}$, and K_c account for the self-association of NAD^+ and represent respectively the difference between the NAD^+ proton chemical shift at a given concentration and that at infinite dilution, the NAD^+ complex shift, and the microscopic association constant for NAD^+ self-association. $\Delta\sigma$ is the difference between the proton chemical shifts of the amino acids in the presence and absence of NAD^+. This is illustrated in Fig. 3 for the interaction of the two NAD^+ protons A2 and A8 with the H_c tryptophan proton. According to [1] a plot of $\Delta\sigma/\delta\sigma$ versus $\delta\sigma/\delta\sigma_{A_2}$ yielded straight lines, from the slope of which the microscopic association constant for complex formation, k, is calculated, while the complex shift $\Delta\sigma_{BAB}$ can be derived from the x-axis intercept. The k values obtained from the A2 and A8 NAD^+ protons are in good agreement (Table 3). A similar treatment of the experimental data obtained with 25 mM phenylalanine and excess NAD^+ yielded the corresponding constants given in Table 3.

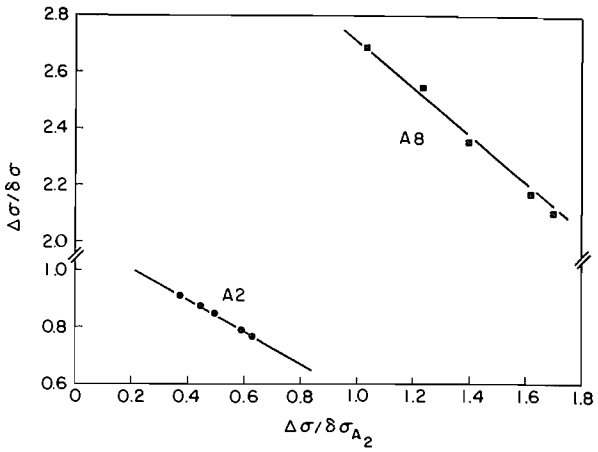

FIG. 3. Graphical evaluation of the constants for complex formation between 25 mM tryptophan and excess NAD^+, according to the formalism of Dimicoli and Hélène (26).

TABLE 3. Microscopic association constants (k) and standard Gibbs energy changes ($\overline{\Delta G}^0$) for the complex formation of phenylalanine and tryptophan with NAD^+ at 32°C and pH 7.3

	k		$\bar{k}$	$\overline{\Delta G}^0$
	A2	A8	(M^{-1})	(kJ mol^{-1})
Phenylalanine	1.4	1.3	1.35	−0.76
Tryptophan	10.1	12.6	11.35	−6.2

It is interesting that the proton-averaged association constant ($\bar{k}$) for complex formation of tryptophan with NAD^+ is an order of magnitude larger than that for the phenylalanine:NAD^+ complex. This is also revealed by the corresponding difference in binding strength as shown by the standard Gibbs energy changes in Table 3. These experimental data show that the adenine moiety of NAD^+ not only can recognize aromatic amino acids by a through-space base-stacking interaction, but can also discriminate between phenylalanine and tryptophan residues by a stronger binding to the latter.

Concluding Remarks

The largest group of biological redox reactions is catalysed by enzymes requiring NAD^+ as cofactor; so far over 150 different NAD^+-dependent dehydrogenases have been described (21–23). However, the forces involved in the recognition and binding

of NAD^+ to these dehydrogenases are far from understood. Recently Zens *et al.* (17) showed that the effective correlation time for the N4-NAD^+ proton was substantially shorter than that for the A8-NAD^+ proton when bound to chicken breast lactate dehydrogenase. Therefore they concluded that the adenine portion of NAD^+ is immobilized to a greater extent by the enzyme than the nicotinamide moiety, and that the latter does not interact with the enzyme to the extent as the adenine moiety in the absence of the substrate. These conclusions are strongly supported by the data from our present investigation which indicate that only the adenine moiety of NAD^+ is involved in the specific recognition through base-stacking interaction with individual aromatic amino acids.

In aqueous solutions NAD^+ is unlikely to possess a unique conformation such as the well-defined solid state stacking pattern in the Li–NAD^+ complex (29). Instead, due to an increased conformational flexibility about the pyrophosphate and (or) the glycosidic linkage, the adenine moiety of NAD^+ may be able to assume a geometry which optimizes both in-plane hydrogen bonding and out-of-plane base-stacking interactions with a given receptor macromolecule. The hydrophobic base-stacking interaction with suitable aromatic amino acyl groupings lining the NAD^+ binding site could be a major factor in fitting the adenine moiety into the hydrophobic pocket of NAD^+-dependent dehydrogenases.

Heats of vaporization and gaseous heats of formation of some five- and six-membered ring alkenes

RICHARD FUCHS AND L. ALAN PEACOCK

Department of Chemistry, University of Houston, Houston, TX 77004, U.S.A.

Received January 16, 1979

RICHARD FUCHS and L. ALAN PEACOCK. Can. J. Chem. 57, 2302 (1979).

The heats of vaporization of 1-methylcyclopentene, 3-methylcyclopentene, ethylidenecyclopentane, 1-ethylcyclopentene, methylenecyclohexane, allylcyclopentane, vinylcyclohexane, ethylidenecyclohexane, allylcyclohexane, 3,3-diethylpentane, 2,2,4,4-tetramethylpentane, and *trans*-2,2,5,5-tetramethyl-3-hexene have been measured by the gas chromatography – calorimetry method. These values have been combined with previously reported liquid heats of formation to give gaseous values of ΔH_f. The results indicate that the internal double bond is favored by about 0.5 kcal over the *exo* in both 5- and 6-membered rings, but the *endo–exo* differences are much smaller than previously believed. Several of the liquid heat capacities that were measured were not well predicted by group additivity schemes.

RICHARD FUCHS et L. ALAN PEACOCK. Can. J. Chem. 57, 2302 (1979).

Utilisant une méthode combinant la chromatographie en phase gazeuse et la calorimétrie, on a mesuré les chaleurs de vaporisation des hydrocarbures suivants: méthyl-1 cyclopentène, méthyl-3 cyclopentène, éthylidènecyclopentane, éthyl-1 cyclopentène, méthylènecyclohexane, allylcyclopentane, vinylcyclohexane, éthylidènecyclohexane, allylcyclohexane, diéthyl-3,3 pentane, tétraméthyl-2,2,4,4 pentane et tétraméthyl-2,2,5,5 hexène-3 *trans*. On a combiné ces valeurs avec les chaleurs de formation de ces liquides qui avaient été rapportées antérieurement afin d'en tirer les valeurs de ΔH_f en phase gazeuse. Les résultats indiquent que les doubles liaisons internes sont favorisées par environ 0.5 kcal/mol par rapport aux doubles liaisons *exo* dans les cycles à 5 et à 6 chaînons; toutefois la différence entre *endo* et *exo* est beaucoup plus faible que ce qu'on croyait antérieurement. En se basant sur les schémas d'additivité des groupes, il aurait été impossible de prédire adéquatement plusieurs des capacités calorifiques mesurées.

[Traduit par le journal]

A much discussed concept more than two decades ago was the idea that the internal (endocyclic) double bond is thermodynamically favored over the exocyclic double bond in six-membered ring systems, whereas the reverse was believed to be true in five-membered rings (1). However, Turner and Garner (2) measured the heat of hydrogenation (acetic acid solution, 25°C) of 1-methylcyclohexene, methylenecyclohexane, 1-methylcyclopentene, and methylenecyclopentane, and found that hydrogenation of the *exo* double bond is more exothermic in both the five-membered ring (by 3.7 kcal/mol) and six-membered ring (2.1 kcal/mol). Furthermore, treatment of methylenecyclopentane with acid converts it largely to 1-methylcyclopentene. It was concluded that 1-methylcyclopentene is the more stable of the two isomers, and this implies that the *endo* double bond is more stable than the *exo* in other cyclopentane derivatives as well.

This implication is open to possible criticism. First, methylenecyclohexane and methylenecyclopentane are dialkylethylenes, whereas 1-methylcyclohexene and 1-methylcyclopentene are trisubstituted. Open chain trialkylethylenes are known to be less exothermically hydrogenated than dialkyl isomers (3, 4), and this may be the source of the observed differences in the cyclic isomers. In a later paper (2), a comparison was also made of the heats of hydrogenation of ethylidenecyclopentane and 1-ethylcyclopentene, and of ethylidenecyclohexane and 1-ethylcyclohexene. The difference for each ring system was only 1.2–1.3 kcal/mol, but still suggested greater stability of the *endo* double bond. However, a second reservation arises from measurement of heats of hydrogenation in acetic acid solution, rather than in the gas phase.

The relationship between the gaseous and solution heats of hydrogenation as measured by Turner and Garner (2) is

$$\Delta H_{H_2}(g) = \Delta H_{H_2}(soln) + \Delta H_v(alkane) - \Delta H_v(alkene) + \Delta H_s(alkene) - \Delta H_s(alkane)$$

Without experimental measurement of the appropriate heats of solution in acetic acid and heats of vaporization and correction of the data to the gaseous state there is no assurance that valid conclusions will be drawn. It is usually assumed that the

0008-4042/79/172302-03$01.00/0

ΔH_v and ΔH_s effects are small, but in unpublished studies we have observed solution values in the range of 0.4 kcal/mol more exothermic to 2.5 kcal/mol less exothermic than gaseous values.

For this reason, the relative stabilities of *endo* and *exo* double bonds are still somewhat in doubt, particularly of the cyclopentane derivatives. It has occurred to us that comparisons of the gaseous heats of formation (ΔH_f(g)) of 1-ethylcyclohexene vs. ethylidenecyclohexane, and 1-ethylcyclopentene vs. ethylidenecyclopentane, all of which are trisubstituted ethylenes, might be a reasonable basis for comparison. Unfortunately, although heats of combustion and liquid heats of formation have been reported for these compounds (5), a value of ΔH_f(g) has been reported only for 1-ethylcyclohexene. Measurement of the values of ΔH_v required to convert ΔH_f(l) to ΔH_f(g) has therefore been undertaken by the gas chromatography – calorimetry technique (6–8) for ethylidenecyclohexane, 1-ethylcyclopentene, and ethylidenecyclopentane.

Values of ΔH_v have also been measured, and ΔH_f(g) calculated for the related alkene derivatives of cyclopentane and cyclohexane, 3-methylcyclopentene, methylenecyclohexane, allylcyclopentane, and vinylcyclohexane, and for the highly branched open chain hydrocarbons, *trans*-2,2,5,5-tetramethyl-3-hexene, 2,2,4,4-tetramethylpentane, and 3,3-diethylpentane. ΔH_v of allylcyclohexane has also been measured.

Experimental

Hydrocarbon samples were obtained from Chemical Samples Company, and were stated to be of 99% or greater purity. This purity was confirmed by gas chromatography. Heats of vaporization were measured using the technique, apparatus, and gc capillary column (II) previously described (7). The gc values of ΔH (v → DC-200) were corrected to 25°C using additivity rules to estimate liquid (9) and gaseous (10) heat capacities. Several liquid heat capacities were measured for compounds for which the calculated values of Shaw (9) and of Luria and Benson (11) show a large disparity. C_p(l) was measured in a 10 mL vacuum jacketed calorimeter, magnetically stirred, and immersed in a water bath at 25.00°C, regulated to ±0.002°C. C_p(l) values were calculated relative to water (17.98 cal/mol K) and *n*-heptane (53.77 cal/mol K). Each value (Table 1) was calculated from the mean of 4–10 heating curves which showed a standard deviation of 0.3% or less.

Results and Discussion

The experimental heats of vaporization of the 12 hydrocarbons, the measured liquid heat capacities, and the calculated liquid and gaseous heat capacities (9, 10) are listed in Table 1. The values of ΔH_v and previous values of ΔH_f(l) have been used (Table 2) to calculate ΔH_f(g).

[f]Estimated (5) 10.41 ± 0.10.
[g]Estimated (5) 9.12 ± 0.10.

From the data of Table 2 it may be seen that $\Delta H_f(g)$ for 1-ethylcyclopentene is 0.39 ± 0.33 kcal/mol more exothermic than $\Delta H_f(g)$ of ethylidenecyclopentane. Similarly, the value for 1-ethylcyclohexene (-15.16 ± 0.26 (5)) is 0.47 ± 0.32 kcal/mol more exothermic than that of ethylidenecyclohexane. Comparison of these two pairs of trialkylethylenes indicates that with comparably substituted double bonds the five- and six-membered ring systems show a similar preference for the *endo* double bond. This is a considerably smaller $\Delta H_f(g)$ difference than exists between 1-methylcyclohexene ($\Delta H_f(g) = -10.34 \pm 0.20$ kcal/mol (5)) and methylenecyclohexane (-6.07 ± 0.90 kcal/mol).

$\Delta H_f(g)$ for 1-methylcyclopentene is 2.62 ± 0.25 kcal/mol more exothermic than that of 3-methylcyclopentene. This is quite comparable to the 2.79 ± 0.22 kcal/mol difference in $\Delta H_f(g)$ (5), and the 2.7 kcal/mol difference in gaseous heats of hydrogenation (4), between 1-butene and *trans*-2-butene. This seems to be a matter of alkyl substitution differences rather than conformational stability differences.

Vinylcyclohexane is 3.47 ± 0.34 kcal/mol less exothermic in $\Delta H_f(g)$ than 1-ethylcyclohexene. This is very similar to the 3.51 ± 0.25 kcal/mol difference in $\Delta H_f(g)$, and 3.4 kcal/mol difference in $\Delta H_{H_2}(g)$ between 2-methyl-2-butene and 3-methyl-1-butene, again suggesting that the cyclic compounds differ in double bond substitution rather than conformational stability. The 5.60 ± 0.34 kcal/mol more exothermic $\Delta H_f(g)$ of vinylcyclohexane relative to allylcyclopentane is essentially identical to the ethylcyclohexane–propylcyclopentane difference (5), and is mainly a reflection of the 6.1 kcal/mol greater strain in the cyclopentane ring (12).

The observation that $\Delta H_f(g)$ for 3,3-diethylpentane is 0.99 ± 0.49 kcal/mol more exothermic than that of *n*-nonane is concordant with the observation that 3-ethylpentane and 3-ethylhexane have $\Delta H_f(g)$ values 0.4–0.5 kcal/mol more exothermic than the isomeric *n*-alkanes.

It is noteworthy that neither the Shaw (9) nor the Luria and Benson (11) liquid heat capacity group parameters very accurately predict values for the cyclic unsaturated compounds, and the calculated vs. experimental differences are as large as 4 cal/mol K.

Acknowledgments

This research was supported by the Robert A. Welch Foundation, Grant E-136. We wish to thank Professor N. L. Allinger for helpful discussion, and for furnishing a sample of 3-methylcyclopentene.

Synthesis of potential DNA bisintercalative agents of the phenanthridinium class

J. WILLIAM LOWN, BRIAN C. GUNN,[1] KRISHNA C. MAJUMDAR,[1] AND E. MCGORAN[1]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received January 17, 1979

J. WILLIAM LOWN, BRIAN C. GUNN, KRISHNA C. MAJUMDAR, and E. MCGORAN. Can. J. Chem. 57, 2305 (1979).

The syntheses are described of certain bis(5-alkyl-3,8-diamino-6-phenylphenanthridinium)dichlorides linked through the 8-amino group with diamide bridges, as well as bis(5-alkyl-3,8-diamino-6-alkylphenanthridinium)dichlorides linked through the 6-position by methylene bridges, as potential double intercalators into duplex nucleic acids. The work explores the syntheses of bisethidium compounds via permissible points of attachment of the chromophore consistent with optimal fluorescence enhancement upon intercalation.

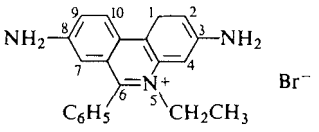
J. WILLIAM LOWN, BRIAN C. GUNN, KRISHNA C. MAJUMDAR et E. MCGORAN. Can. J. Chem. 57, 2305 (1979).

On décrit la synthèse de certains dichlorures de bis(alkyl-5 diamino-3,8 phényl-6 phénanthridinium) liés par le groupe amino en 8 à des ponts diamides ainsi que des dichlorures de bis(alkyl-5 diamino-3,8 alkyl-6 phénanthridinium) dont les positions 6 sont reliées par des ponts méthylènes; il s'agit de substances qui pourraient être doublement intercalées dans les acides nucléiques doubles. Le travail explore la synthèse des composés biséthidium par l'intermédiaire de points d'attaches permis pour un chromophore en accord avec une augmentation optimale de la fluorescence lorsque les produits sont intercalés.

[Traduit par le journal]

Introduction

There is accumulating evidence that many planar aromatic molecules including antibiotics, antimalarials, carcinogens, and mutagens intercalate, i.e., insert between the base pairs of double helical DNA (1–4). Among the most useful, in an analytical sense, has been the trypanocidal phenanthridinium derivative ethidium bromide **E** (3, 5). When the latter intercalates into duplex DNA its intrinsic fluorescence exhibits a quantum yield increase of about 25-fold (6). For this reason ethidium bromide has been widely used in spectrofluorimetric studies of nucleic acids (6–13). For example, ethidium bromide



E

has been used to probe circular DNA structure (14), tRNA (9, 15), 5S RNA (16, 17), chromatin (18), and ribosomal RNA (19) as well as tRNA–protein interactions (20). Recently the fluorescence characteristics of ethidium have provided the basis of a number of useful and sensitive assays for the determination of the different types of chemical interaction of antitumor agents with nucleic acid cell targets (21–32).

The recognition of the concept of bisintercalation in the case of the quinoxaline antibiotic echinomycin (34) and in the synthetic bisintercalators of the bisacridine (35–42), bisacridinium (43), bisphenanthridinium (44–48), bisellipticine (49), and bisanthracycline (50) classes has led to increased binding upon interaction with DNA. The efficiency of DNA binding of such drugs is sensitively dependent on the nature of the linker, its length, and on its points of attachment to the two chromophores (43–46). In this paper we examine the synthesis of bisphenanthridinium compounds at different permissible points of attachment consistent with the requirements for good fluorescence enhancement upon DNA binding.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Infrared spectra were recorded on a Perkin-Elmer grating infrared spectrophotometer model 421 and generally only the principal peaks are reported. Absorption spectra were measured in either distilled water or 'spectro-grade' solvents and were run on either a Beckman DB spectrophotometer, a Gilford 250 spectrophotometer, or a Unicam SP1700 UV spectrophotometer. Proton magnetic resonance spectra were recorded on Varian A-60 and HA-100 analytical instruments and were generally measured on 10–15% (w/v) solutions of the compound in the appropriate deuterated solvent. The reference compound was tetramethylsilane (TMS). Line positions are reported in ppm from the reference. Mass spectra were determined with Associated Electrical Industries MS2, MS9, MS12, or MS50 (DS50) mass spectrometers. In general the ionization energy was 70 eV. Peak measurements were made by comparison with perfluo-

rotributylamine at a resolving power of 1500. Kieselgel DF-5 (Camag, Switzerland) and Eastman Kodak precoated sheets were used for thin layer chromatography. Microanalyses were carried out by Mrs. D. Mahlow of this department.

Materials

The following α,ω-diacid chlorides required for this study were either available commercially or were synthesized from the appropriate dicarboxylic acids by established procedures. Each were purified by distillation under reduced pressure immediately before use: hexandioic, bp 116–118°C/12 Torr; heptandioic, bp 137°C/15 Torr; octandioic, bp 147–148°C/12 Torr; nonandioic, bp 158–159°C/12 Torr; decandioic, bp 192–193°C/11 Torr; undecandioic bp 198–199°C/11 Torr; dodecandioic acid chloride, bp 184–185°/10 Torr.

2-Acetamidobiphenyl

This acyl derivative was prepared in 97% yield by the method of Morgan and Walls (51).

4′-Nitro-2-acetamidobiphenyl ***1***

The foregoing acetamido derivative was nitrated with fuming nitric acid at 0°C to give the 4′-nitro-2-acetamidobiphenyl **1** in 55% yield by the procedure of Scarborough and Waters (52).

4′-Amino-2-acetamidobiphenyl

This amine, described by Finzi and Mangini (53), was prepared by treating 16.0 g (62 mmol) of the 4′-nitro-2-acetamidobiphenyl with 16.0 g (0.285 g-at.) of reduced iron powder in aqueous ethanol solution containing a trace of concentrated hydrochloric acid. After the work-up 10.5 g (75% yield) of the desired amine was obtained.

2,4′-Diaminobiphenyl ***2***

Hydrolysis of the above acetamido derivative by refluxing in ethanol containing 10% concentrated hydrochloric acid for 3 h yielded quantitatively the desired diaminobiphenyl **2**, mp 56°C (aqueous ethanol) (lit. (53) mp 56°C).

2,4-Diamino-4-nitrobiphenyl ***3***

A modification of the method of Finzi and Mangini (53) was used. A solution of 15 g (80 mmol) of 2,4-diaminobiphenyl in concentrated sulfuric acid (mixed at 0°C) was stirred in an ice–ethanol bath to a temperature of −2°C. Then 8.5 g (9 mL, 80 mmol) of *n*-propyl nitrate in 10 mL of glacial acetic acid was added dropwise such that the temperature did not rise above −2°C. Stirring was continued for 1 h and the mixture was poured into 250 g of ice and neutralized with saturated aqueous sodium carbonate solution. The resulting brown solid was collected and taken up in the minimum of concentrated hydrochloric acid and reprecipitated with concentrated ammonium hydroxide as a red solid. After collection and thorough washing with water the product **3** was recrystallized from aqueous ethanol as bright red rosettes, 10 g (55% yield), mp 177°C (aq. EtOH) (lit. (53) mp 177–178°C).

4′-Acetamido-2-benzamido-4-nitrobiphenyl ***4***

Benzoyl chloride (1.04 g, 7.4 mmol) was added dropwise with stirring to a solution of 2.0 g (7.4 mmol) of 4′-acetamido-2-amino-4-nitrobiphenyl in 25 mL of dry nitrobenzene. The mixture was heated at 140°C for 45 min and on cooling deposited crystals of the benzamido compound which were collected and washed with cold ether. The product was purified by recrystallization from aqueous pyridine as off-white needles, 2.3 g (83% yield), mp 185–187°C (lit. (54) mp 187°C).

8-Acetamido-3-nitro-6-phenylphenanthridine ***5***

4′-Acetamido-2-benzamido-4-nitrobiphenyl (1 g, 2.7 mmol) was cyclized to the corresponding phenanthridine by refluxing in 5 mL of phosphoryl chloride for 2 h. Upon cooling the mixture was cautiously poured onto ice and neutralized with ammonium hydroxide. The resulting yellow phenanthridine was collected, washed thoroughly with water, dried, and recrystallized from aqueous pyridine as yellow plates, 0.7 g (73% yield), mp 295–297°C (lit. (54) mp 297°C).

2-Amino-4′-carboethoxyamino-4-nitrobiphenyl 7

This urethane derivative was obtained in 76% yield together with a minor amount of the isomer **6** from the foregoing diaminonitrobiphenyl and ethyl chloroformate by a procedure similar to that described by Walls (55).

2-Benzamido-4′-carboethoxyamino-4-nitrobiphenyl

The foregoing amine was treated with benzoyl chloride in nitrobenzene to furnish the benzamide in 80% yield as described by Walls (55).

8-Carboethoxyamino-3-nitro-6-phenylphenanthridine ***8***

This phenanthridine was obtained in 42% yield by the treatment of the benzamido derivative with phosphoryl chloride at 120°C for 1 h (55).

8-Amino-3-nitro-6-phenylphenanthridine

Hydrolysis of the foregoing phenanthridine derivative with concentrated sulfuric acid at 140°C for 0.5 h afforded the free aminophenanthridine in almost quantitative yield, mp 228°C (EtOH) (lit. (55) mp 227–227.5°C).

N,N′-*[8,8′-Bis(3-nitro-6-phenyl)phenanthridinyl]sebacamide* ***9***

A dry benzene solution (10 mL) of 0.13 g (0.43 mmol) of 8-amino-3-nitro-6-phenylphenanthridine was treated with 52 mg (0.215 mmol) of decandioic acid chloride. An immediate precipitate formed and the mixture was heated under reflux for 2 h by which time evolution of hydrogen chloride ceased. The mixture was next treated with concentrated ammonium hydroxide until slightly basic and then concentrated *in vacuo*. The yellow gum which remained was triturated with 50% aqueous ethanol. Refluxing the solution for 15 min, cooling, and filtering afforded the amide **9** ($n = 8$). Recrystallization from aqueous pyridine gave pure **9** as orange-yellow crystals, mp 164–166°C, resolidifying at 170°C and remaining unmelted at 300°C. Infrared ($CHCl_3$) ν_{max}: 3320 (NH), 2840, 2920, 2980 (CH_2), 1660 (amide C=O), 1520, 1340 (NO_2), 1610 (aryl ring) cm^{-1}. *Anal.* calcd. for $C_{48}H_{20}N_6O_6$: N 9.48; found: N 9.63.

Similarly prepared by the above procedure was the corresponding dodecandiamide ($n = 10$) derivative **9** ($n = 10$) in 66% yield, mp 176°C, resolidifying at 180°C and unmelted at 300°C. Infrared ($CHCl_3$) ν_{max}: 3340 (NH), 2835, 2920, 2975 (CH_2), 1665 (amide CO), 1530, 1350 (NO_2), 1605 (aryl ring) cm^{-1}. *Anal.* calcd. for $C_{52}H_{48}N_6O_6$: N 9.85; found: N 9.75.

N,N′-*[8,8′-Bis(3-amino-6-phenyl)phenanthridinyl]sebacamide* ***10*** *(n = 8)*

This bisamine was prepared by treating the foregoing compound **9** ($n = 8$) with reduced iron powder in aqueous ethanol solution containing a trace of concentrated hydrochloric acid. After work-up as described in previous examples 80% yield of the bisamino compound **10** ($n = 8$) was obtained, mp 169°C. *Anal.* calcd. for $C_{48}H_{24}N_6O_2$: N 11.72; found: N 11.96.

8-Carboethoxyamino-5-methyl-3-nitro-6-phenylphenanthridinium Methyl Sulfate ***11***

8-Carboethoxyamino-3-nitro-6-phenylphenanthridine **8** was converted to the quaternary salt in 80% yield by the method of Walls, utilizing freshly distilled dimethyl sulfate in dry nitrobenzene at 180°C for 30 min. The crude salt was washed with ether to remove excess solvent and recrystallized from water as yellow plates (55).

8-Amino-5-methyl-3-nitro-6-phenylphenanthridinium Chloride

Removal of the carboethoxy group was accomplished as previously described by treating 0.6 g (1.16 mmol) of the above salt **11** with 2 mL of 70% sulfuric acid for 30 min at 135°C. After work-up the aminophenanthridinium salt was obtained in quantitative yield (0.5 g). Metathesis with saturated aqueous sodium chloride gave the corresponding chloride salt as brown-red plates (55).

N,N′-[*8,8′-Bis(5-methyl-3-nitro-6-phenyl-phenanthridinium)*]-*sebacamide Dichloride* ***12*** *(*n = *8)*

To a solution of 0.3 g (0.82 mmol) of 8-amino-5-methyl-3-nitro-6-phenylphenanthridinium chloride in 5 mL of dry nitrobenzene was added 0.098 g (0.41 mmol) of sebacyl chloride. When addition was completed the mixture was refluxed for 2 h until no more hydrogen chloride was evolved and then cooled to room temperature. Addition of ether precipitated the desired product as an orange-brown solid. Recrystallization from aqueous methanol afforded an orange amorphous solid, 0.21 g (48% yield), mp 110°C (resolidifies and remelts at 210°C). *Anal.* calcd. for $C_{50}H_{46}Cl_2N_6O_6$: C 66.88, H 5.12, Cl 7.91, N 9.36; found: C 66.53, H 5.18, Cl 8.02, N 9.57.

Similarly prepared by the above procedure was the corresponding dodecandiamide (*n* = 10) derivative **12** (*n* = 10) in 44% yield, mp 110°C (resolidifies and remelts at 215°C). *Anal.* calcd. for $C_{52}H_{50}Cl_2N_6O_6$: Cl 7.66, N 9.08; found: Cl 7.87, N 9.15.

N,N′-[*8,8′-Bis(3-amino-5-methyl-6-phenylphenanthridinium)*]-*sebacamide Dichloride* ***13***

A solution of 0.2 g (0.22 mmol) of *N,N′*-[8,8′-bis(5-methyl-3-nitro-6-phenylphenanthridinium)]sebacamide dichloride in 25 mL of 1:1 aqueous ethanol was mixed with 61.6 mg (1.1 mg-at.) of reduced iron powder and 1 drop of concentrated hydrochloric acid. The mixture was refluxed for 1.5 h, cooled, and filtered through Celite to give a purple filtrate. Concentration *in vacuo* and addition of sodium chloride resulted in precipitation of a red solid which was collected and recrystallized from aqueous ethanol as fine, deep-red crystals, 0.17 g (92% yield), mp > 300°C. Nmr (CD_3OD) δ: 1.24–1.8 (br, m, 12H, 6 CH_2), 2.18–2.4 (m, 4H, $2CH_2$), 4.45 (brs, 6H, $2CH_3$), 5.9 (brs, 4H, $2NH_2$), 7.25–8.73 (m, 22H, Ar), 9.45 (s, 2H, exch. NH). Infrared ($CHCl_3$) ν_{max}: 3450, 3420, 2930, 2865, 1670, 1450, 1245, 850 cm^{-1}. *Anal.* calcd. for $C_{50}H_{50}Cl_2N_6O_2$: C 71.68, H 5.97, Cl 8.48, N 10.03; found: C 71.24, H 6.02, Cl 8.57, N 10.25.

4,4′-Diamino-2-nitrobiphenyl ***15***

This nitrobenzidine was obtained in 84% yield by nitration of benzidine **14** with potassium nitrate in concentrated sulfuric acid according to the procedure of Leslie and Turner (55).

4,4′-Dicarboethoxyamino-2-nitrobiphenyl ***16***

The foregoing nitro compound was treated with ethyl chloroformate to furnish the diurethane in 87.5% yield as described by Leslie and Turner (56).

2-Amino-4,4′-dicarboethoxyaminobiphenyl ***17***

This compound was prepared from the corresponding nitro derivative in 75% yield by reduction by reduced iron metal in aqueous ethanol containing a trace of concentrated hydrochloric acid (56).

N,N′-*Di*[*2-(4,4′-dicarboethoxyamino)biphenyl*]*sebacamide* ***18*** *(*n = *8)*

To a solution of 1.7 g (5 mmol) of 2-amino-4,4′-dicarboethoxyaminobiphenyl in 20 mL of dry benzene was added dropwise with stirring 0.58 g (2.5 mmol) of decandioic acid chloride (sebacyl chloride). The resulting mixture was refluxed gently until the evolution of hydrogen chloride ceased, approx. 1 h. Then it was treated with ammonium hydroxide solution until just basic and heated under reflux again for a short period. The benzene was removed *in vacuo* to afford **18** (*n* = 8) as a cream colored solid which was purified by recrystallization from ethanol, 2.0 g (95% yield), mp 223°C. Mass spectrum *m/e* (% relative abundance): 369 (40.6) $\frac{1}{2}(P - C_8H_{18})$; 323 (64.6) $\frac{1}{2}(P - C_8H_{18}—C_2H_5OH)$; 277 (100) $\frac{1}{2}(P - C_8H_{18}—2C_2H_5OH)$. The ir spectrum ($CHCl_3$) ν_{max}: 3240–2410 (NH), 1695 (CO, carbamate), 1650 (CO, amide) cm^{-1}. The ^{1}Hmr spectrum ($(CD_3)_2SO$) δ: 9.6 (d, 4H, carbamate NH), 9.05 (s, 2H, amide NH), 7.14–7.65 (m, 14H, aryl protons), 4.16 (q, 8H, carbamate CH_2), 2.15 (br t, 4H, —amide CH_2), 1.26 (t, 12H, —carbamate CH_3), 1.05–1.68 (m, 12H, aliphatic $6CH_2$). *Anal.* calcd. for $C_{46}H_{56}N_6O_{10}$: C 64.79, H 6.59, N 9.85; found: C 64.62, H 6.9, N 10.27.

The additional bisamides in Tables 1 and 2 were prepared by the same general procedure.

1,4-Bis(3,8-dicarboethoxyaminophenanthridin-6-yl)butane ***19*** *(*n = *4)*

A solution of 2.0 g (2.5 mmol) of *N,N′*-bis(4,4′-dicarboethoxyamino-2-diphenylyl)adipamide in 7.0 mL of freshly redistilled phosphorus oxychloride was heated under reflux for 2.5 h. When cooled, the excess phosphorus oxychloride was removed under reduced pressure and the residue was poured into ice-water. Neutralization with concentrated ammonium hydroxide solution, followed by filtration and washing with water, gave the bisphenanthridine as an olive-green solid. Decolorization with charcoal and recrystallization from aqueous pyridine afforded the purified phenanthridine as a buff colored amorphous solid dec. > 300°C. The spectral and analytical data on this and related compounds are given in Tables 3 and 4.

1,4-Bis(3,8-diaminophenanthridin-5-yl)butane ***20*** *(*n = *4)*

This aminophenanthridine was prepared by treating 0.2 g (0.26 mmol) of 1,4-bis(3,8-dicarboethoxyaminophenanthridin-6-yl)butane with 2 mL of 70% sulfuric acid. After heating at 135°C for 1 h the mixture was diluted with water and neutralized with concentrated ammonium hydroxide solution. The resulting colloidal red precipitate was collected and dried. Recrystallization from aqueous dimethylformamide gave the product as fine red-brown needles, 0.1 g (85% yield), mp > 300°C with slow decomposition from 250°C. Nmr spectrum ($(CD_3)_2SO$) δ: 1.2–2.05 (br m, 4H, $2CH_2$), 3.1 (br m, 4H, $2CH_2$), 5–5.9 (br s, 8H, $4NH_2$), 6.87–8.35 (m, 2H, Ar). Infrared ($CHCl_3$) ν_{max}: 3455, 2924, 2860, 1480, 1245 cm^{-1}.

1,4-Bis(3,8-diamino-5-ethyl-6-phenanthridinium)butane dibromide ***21*** *(*n = *4)*

A solution of 0.28 g (0.36 mmol) of the 1,4-bis(3,8-dicarboethoxyaminophenanthridin-6-yl)butane in 8 mL of dry nitrobenzene was converted to the corresponding salt by treatment with 0.12 g (0.72 mmol) of diethyl sulfate at 180°C for 30 min. After cooling, the mixture was triturated with ice-cold ether. Continued washing with ether gave a dark-brown solid which was extracted with boiling water to remove it from a tarry material. The orange solution thus obtained was concentrated to 3 mL *in vacuo* and treated with 7 mL of concentrated sulfuric acid and the mixture heated at 110°C for 1 h. Upon cooling, the mixture was poured into water, and neutralized with concentrated ammonium hydroxide solution. Addition of potassium bromide precipitated a red-purple solid. Crystallization from water gave the phenanthridinium salt as small red-purple crystals, 45 mg (18% yield), mp > 300°C (slow decomposition from 230°C). Nmr spectrum ($(CD_3)_2SO$) δ: 1.3–1.9 (t, overlapping m, 10H, $2CH_3$, $2CH_2$), 2.4 (br m, 4H,

Results

Our initial synthetic efforts towards potential bisintercalative phenanthridinium compounds were directed towards linkage through position 8 of the ethidium chromophore **E**. To permit discrimination between the 3 and 8 amino substituents the transformations in Scheme 1 were carried out. Selective acetylation occurs in the aniline ring of **3** since the nitro substituted ring is deactivated. The ring closure of **4** to **5** proceeds in only low yield but when ethyl chloroformate was employed for NH_2 protection, as in **6**, much improved yields resulted although the acylation was not completely selective (Scheme 2, **3** to **6** and **7**). Benzoylation followed by treatment of the acyl derivative with phosphorus oxychloride afforded the cyclization product **8**. Coupling of the free 8-NH_2 group of the product of acid hydrolysis of **8** with two diacyl chlorides proceeded smoothly to produce the 3-nitro bisphenanthridine compounds **9** in which the nitro groups could be reduced to the corresponding 3-aminoanalogues **10**.

The pair of compounds **9** resisted all attempts at quaternization of the phenanthridine nitrogen-5. In view of this the phenanthridine moiety was quatern-

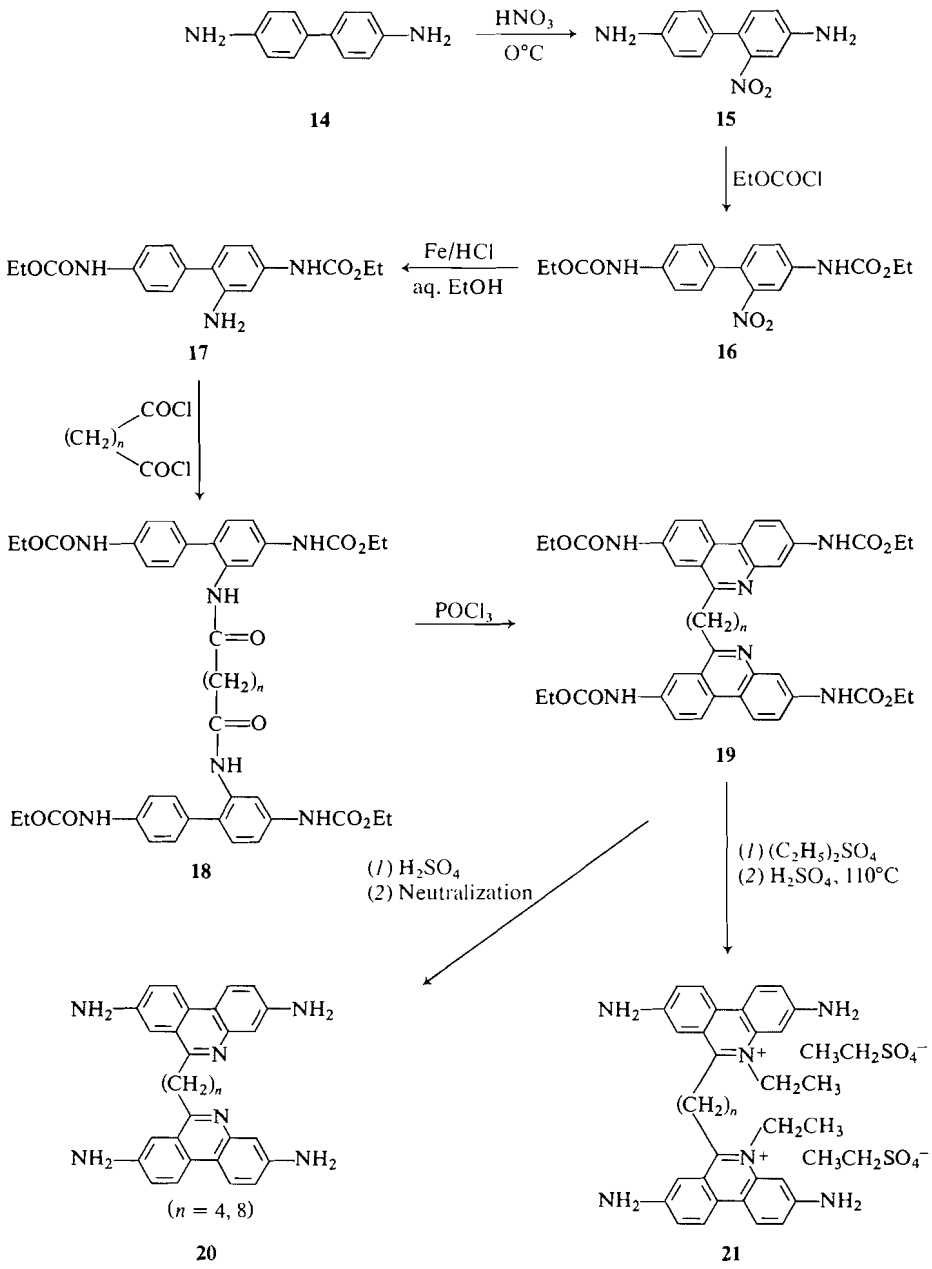

SCHEME 4

ized prior to coupling by alkylation of the relatively unhindered **8** with dimethyl sulfate to give **11** followed by acid generation of the free 8-amino group from **11** and condensation with two diacyl chlorides to give the compounds **12**. Reduction of the nitro group in **12** with iron and hydrochloric acid afforded the 8-linked bisphenanthridinium compounds **13** as outlined in Scheme 3.

Since our previous examination of the substituent requirements in the ethidium moiety for intercalation and fluorescence enhancement had also shown that the 6-aryl substituent may be replaced by an alkyl group without materially affecting the intercalative binding to DNA, a series of bisphenanthridinium compounds was prepared in which the chromophores were linked through the 6-position. Low temperature nitration of 4,4′-diaminobiphenyl **14** afforded compound **15** in 84% yield. Ethyl chloroformate gave the amino group product **16** in 87.5% yield. The nitro group in **16** was reduced in 75% yield by reduced iron metal in aqueous ethanol containing a trace of concentrated hydrochloric acid.

The selectively protected triamine **17** was condensed with diacyl chlorides to give the six 6-linked bisbiphenyl derivatives **18** where $n = 4, 5, 7, 10–12$, all in excellent yields. Ring closure was effected by heating each of the **18** compounds with phosphorus oxychloride to give the bisphenanthridines **19**. The best yields were obtained where $n = 4$, 8, and 10. In contrast to the previous example of **9**, quaternization of **19** with dimethyl sulfate proceeded normally. Deblocking of the 3 and 8 aminoacyl groups was effected smoothly with sulfuric acid at 110°C and afforded a new 6-linked bisphenanthridinium compound **21**. The synthetic plan is given in Scheme 4.

Discussion

The results of our previous studies indicated that among the permissible points of attachment of a linker in the projected synthesis of potential fluorescent bisintercalators on the ethidium chromophore **E** were the 8- and 6-positions (33). These allowed positions together with the requirement of N-5 alkylation are consistent with optimal fluorescence enhancement. The syntheses described here show it is feasible to prepare such bisphenanthridinium compounds linked through the 8- and 6-positions. One factor which influences the synthetic strategy is the resistance to N-5 quarternization noted in compounds **9**. It is possible that this is the result of steric hindrance as a result of stacking of the chromophores in solution for which there is spectroscopic evidence (46, 47). Consequently in the 8-position linked series it is recommended to quarternize the chromophore prior to condensation. By contrast, in the C-6 linked series it is evident that the topology of, for example **19**, is such that stacking of the phenanthridine moieties does not occur and consequently alkylation at N-5 can proceed normally. Le Pecq and co-workers have synthesized a bisphenanthridinium compound in which an alkylamino chain connects the ring nitrogen, and have concluded that it does not double-intercalate in DNA because of steric factors (45). By contrast, in the case of bisphenanthridinium compounds linked through either the *meta* (44) or *para* (48) positions of a 6-aryl substituent there is some evidence for double intercalation in DNA. It is evident then that steric constraints for effective double intercalation into DNA impose further restrictions on the chemical type, sites of attachment, and length of linkers in addition to those required for optimal fluorescence. These factors together with DNA binding characteristics of new bisphenanthridinium salts will be discussed in a subsequent paper.

Reçu le 3 janvier 1979

MAURICE VINCENS, CLAUDE DUMONT et MICHEL VIDAL. Can. J. Chem. **57**, 2314 (1979).

Dans le cadre d'une étude stéréochimique des alcools secondaires α-cycliques nous avons déterminé les configurations relatives des [éthyl-2 éthylidène-3 cyclopropyl(1*R**,2*R**)]-1 éthanol *E*, *R** et *S**. Le traitement en milieu basique de ces alcools secondaires diastéréoisomères conduit aux [éthyl-2 vinyl-3 cyclopropyl(1*R**,2*S**,3*S**)]-1 éthanol *R** et *S**; l'oxymercuration cyclisante de ces dérivés cyclopropaniques fournit les éthyl-6 diméthyl-2,4 oxa-3 bicyclo[3.1.0^{1,5}]hexanes *diendo*, *diexo*, et *exo–endo*. Les attributions de structure à ces éthers bicycliques, fondées sur des études en ir et rmn du ^{1}H et du ^{13}C, permettent d'attribuer les configurations relatives des alcools vinylcyclopropaniques et cyclopropylidéniques.

MAURICE VINCENS, CLAUDE DUMONT, and MICHEL VIDAL. Can. J. Chem. **57**, 2314 (1979).

During a stereochemical study of α-cyclic secondary alcohols, the relative configurations of the *E*, *R**, and *S** isomers of 1-(2-ethyl-3-ethylidene(1*R**,2*R**)cyclopropyl)ethanol was determined. Treatment in a basic medium of these secondary diastereomeric alcohols leads to the *R** and *S** isomers of 1-(2-ethyl-3-vinyl(1*R**,2*S**,3*S**)cyclopropyl)ethanol. Cyclic oxymercuration of these cyclopropanoic derivatives yields the di-*endo*, di-*exo*, and *exo–endo* derivatives of 6-ethyl-2,4-dimethyl-3-oxabicyclo[3.1.0.^{1,5}]hexane. The determination of the structure as bicyclic ethers, based on ir and ^{1}H and ^{13}C nmr studies, permits the assignment of the relative configurations of the vinylcyclopropanoic and cyclopropylidene alcohols.

[Journal translation]

Introduction

L'étude de l'induction asymétrique, au cours de la réduction des cétones α-cyclopropylidéniques et des transpositions en milieu acide des alcools secondaires qui résultent de cette réduction, nous a conduits à envisager l'identification par voie chimique des configurations relatives des [alkyl-2 éthylidène-3 cyclopropyl(1*R**,2*R**)]-1 éthanol *E*, *R** et *S**. Ce travail s'intègre, par ailleurs, dans l'élaboration d'une méthode générale d'identification chimique des configurations relatives d'alcools secondaires diastéréoisomères dans les séries vinylcyclopropanique, cyclopropanique et cyclopropénique. Ces attributions restent actuellement très délicates; la littérature ne mentionne, en effet, que quelques tentatives fondées généralement sur des données spectrophotométriques (1–3).

La méthode que nous avons utilisée comporte deux phases:

Une filiation chimique est établie entre les [éthyl-2 éthylidène-3 cyclopropyl(1*R**,2*R**)]-1 éthanol *E*, *S** et *R** (**1** et **2**) et les [éthyl-2 vinyl-3 cyclopropyl(1*R**, 2*S**,3*S**)]-1 éthanol *S** et *R** (**3** et **4**) ou les [éthyl-2 vinyl-3 cyclopropyl(1*R**,2*S**,3*R**)]-1 éthanol *S** et *R** (**5** et **6**). Cette filiation peut être facilement réalisée en provoquant la migration de la double liaison cyclopropylidénique de **1** et **2** en milieu basique (4)

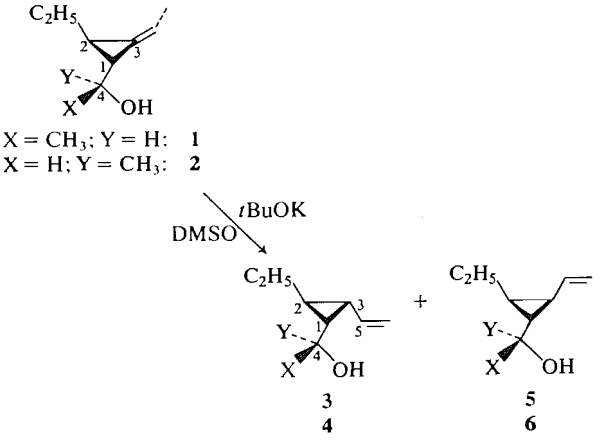

SCHÉMA 1

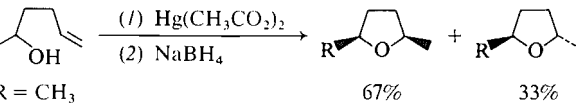
car, dans ces conditions expérimentales, les configurations relatives des carbones 1, 2 et 4 ne sont pas modifiées.

Les configurations relatives des alcools vinylcyclopropaniques **3** et **4** sont identifiées. La détermination des configurations relatives des carbones cyclopropaniques 1, 2 et 3 est fondée sur l'étude en résonance magnétique nucléaire du proton des glissements chimiques induits par un chélate des terres rares: Eu(dpm)$_3$ d'une part et les valeurs des constantes de couplage des protons cyclopropaniques d'autre part.

0008-4042/79/172314-07$01.00/0

Les configurations relatives des carbones 1 et 4 ont pu être établies en déterminant celles de ces deux centres de chiralité dans les éthyl-6 diméthyl-2,4 oxa-3 bicyclo[3.1.0^{1,5}]hexanes obtenus par oxymercuration cyclisante de ces alcools γ,δ-éthyléniques **3** et **4**.

L'oxymercuration des alcools γ,δ-éthyléniques, suivie d'une réduction par le borohydrure de sodium, fournit des oxolannes substitués (5–7). Cette cyclisation dépend du degré de substitution de l'atome de carbone terminal de la chaîne insaturée: une double substitution conduit à des hétérocycles à six chaînons, une monosubstitution à des hétérocycles à cinq et à six chaînons. Lorsque le carbone terminal n'est pas substitué et que l'on utilise l'acétate mercurique comme agent cyclisant, l'hétérocyclisation est spécifique; seule la structure tétrahydrofurannique est isolée (5). L'emploi de ce sel mercurique permet, en effet, d'éviter le réarrangement du cycle au cours de la réduction de l'organomercurique.



R = CH_3	67%	33%
R = *t*Bu	22%	78%

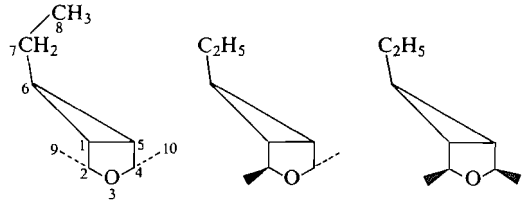
SCHÉMA 2

La proportion d'isomères *cis* et *trans* obtenus est très sensible à la taille des substituants portés par le carbone fonctionnel. Sans préjuger du mécanisme réactionnel, qui n'est pas totalement élucidé, tout se passe comme si une importante contrainte stérique était défavorable à la formation du dérivé *cis*. Il faut cependant noter que lorsque cette contrainte n'est pas trop importante (cas ou R = CH_3) le dérivé *cis* se forme majoritairement. Signalons enfin que la démercuration de l'organomercurique, réalisée en milieu basique par le borohydrure, conduit à des proportions de dérivés *cis* et *trans* souvent différentes de celles observées pour les organomercuriques (6). Compte tenu de l'ensemble de ces observations, l'oxymercuration des alcools vinylcyclopropaniques **3** et **4** suivie d'une réduction par $NaBH_4$ en milieu basique doit conduire respectivement aux éthers bicycliques **8**, **9** et **7**, **8**; la détermination des configurations relatives de **7** et **9** doit permettre de remonter à celles de **3** et **4** et par conséquent à celle des alcools secondaires cyclopropylidéniques **1** et **2**.

Partie expérimentale

Synthèse des (éthylidène-3 cyclopropyl) méthyl cétone E *et* Z *(**13** et **14**)*

Le diéthyl-2,3 cyclopropènecarboxylate d'éthyle **10** (0.5 mol) est traité par 1.8 mol de potasse dans le *n*-butanol (solution–suspension 6 *M*) pendant 20 h à 125°C. Après évaporation de l'alcool, le mélange réactionnel est amené à pH 2 par addition d'acide chlorhydrique 4 *N*. Après extraction à l'éther la distillation fournit le mélange des acides cyclopropylidéniques (**11** + **12**) avec un rendement de 80%.



7 **8** **9**

SCHÉMA 3. Ethyl-6 diméthyl-2,4 oxa-3 bicyclo[3.1.0.^{1,5}]hexanes **7**, **8** et **9**.

A 0.2 mol de ce mélange d'acides, en solution dans 200 mL d'éther anhydre, on ajoute 0.4 mol de méthyllithium (0.8 *M* dans l'éther) en 30 min. Le mélange réactionnel est porté au reflux pendant 2 h après la fin de l'addition. Après hydrolyse à 0°C, en milieu acide (pH > 3) et extraction à l'éther, le mélange des cétones **13** et **14** est isolé par distillation (rdt = 75%). Ces composés sont séparés par cpv sur colonne Carbowax (20%) de 6 m (Chromosorb WAW 60/80, gaz vecteur: H_2, θ = 140°C).

*Cétone **13***: n_D^{20} 1.4620; ir (film): ν(C=O) = 1695, ν(C=C) = 1740 cm^{-1}; rmn (C_6D_6/TMS): δH_1 = 2.01 (1H, m), δH_2 = 1.90 (1H, m), δ(=—H) = 5.61 (1H, m), δ(CH_3—=) = 1.65 (3H, m), δ(CH_3—CH_2) = 0.82 (3H, t), δ(CH_3—CH_2) = 1.22 (2H, 5 raies), δ(CH_3—CO) = 2.05 ppm (3H, s). Les valeurs des constantes de couplage sont déterminées à partir d'une solution de **13** dans CCl_4 à laquelle on ajoute des quantités variables de Eu(dpm)$_3$ selon le couplage étudié: ^3J(=—H, =—CH_3) = 6.4 Hz, ^5J(=—CH_3, H_1) = ^5J(=—CH_3, H_2) = 1.9 Hz, ^4J(=—H, H_1) = ^4J(=—H, H_2) = 2.0 Hz, ^3J(CH_2, H_2) = 5.6 Hz, ^3J(CH_2, CH_3) = 6.5 Hz, ^3J(H_1, H_2) = 4.9 Hz.

*Cétone **14***: n_D^{20} 1.4630; ir (film): ν(C=O) = 1702, ν(C=C) = 1735 cm^{-1}; rmn (C_6D_6/TMS): δH_1 = 1.98 (1H, m), δH_2 = 1.90 (1H, m), δ(H—=) = 5.83 (1H, m), δ(CH_3—=) 1.55 (1H, m), δ(CH_3—CH_2) = 0.79 (3H, t), δ(CH_3—CH_2) = 1.17 (2H, 5 raies), δ(CH_3—CO) = 2.02 ppm (3H, s). Couplages (CCl_4, Eu(dpm)$_3$): ^3J(=—H, =—CH_3) = 6.3 Hz, ^5J(=—CH_3, H_1) = ^5J(=—CH_3, —H_2) = 1.7 Hz, ^4J(=—H, H_1) = ^4J(=—H, H_2) = 2.1 Hz, ^3J(CH_2, H_2) = 5.3 Hz, ^3J(CH_3, CH_2) = 6.6 Hz, ^3J(H_1, H_2) = 5.2 Hz.

[*Ethyl-2 éthylidène-3 cyclopropyl(1*R*,2R*)*]-1 éthanol* E, S* *(**1**) et* R* *(**2**)*

A une solution de 4 × 10^{-3} mol de cétone **13** dans 5 mL d'éther anhydre, on ajoute 10^{-2} mol de $AlLiH_4$ en solution–suspension dans l'éther. Le reflux est maintenu pendant 1 h après la fin de l'addition. Après hydrolyse, la phase organique est extraite à l'éther et le mélange d'alcools est récupéré par une distillation rapide. Les alcools cyclopropylidéniques **1** et **2** sont séparés par cpv sur colonne Carbowax (10%) de 4 m (Chromosorb P NAW 60/80, gaz vecteur: H_2, θ = 130°C).

*Alcool **1***: ir (film): ν(O—H) = 3360 ν(C=C) = 1640 cm^{-1}; rmn (CCl_4/TMS): δ(CH_3—CH_2) entre 1 et 1.4 ppm (3H), δ(=—H) = 5.78 (1H, m), δ(=—CH_3) = 1.79 (3H, 6 raies), δ(CH_3—CHOH—) = 1.16 (3H, d), δH_4 = 3.30 ppm (1H, m); ^3J(=—H, =—CH_3) = 6.4 Hz, ^3J(H_1, H_4) = 6.2 Hz.

*Alcool **2***: ir (film): ν(O—H) = 3360 ν(C=C) = 1640 cm^{-1}; rmn (CCl_4/TMS): δ(CH_3—CH_2) entre 1 et 1.4 ppm, δ(=—H) = 5.70 (1H, m), δ(=—CH_3) = 1.76 (3H, 6 raies), δ(CH_3—CHOH) = 1.17 (3H, d), δH_4 = 3.25 ppm (1H, m); ^3J(=—H, =—CH_3) = 6.1 Hz, ^3J(H_1, H_4) = 6 Hz.

Acides [éthyl-2 vinyl-3 cyclopropyl(1R,2S*)] carboxyliques 3R* (15) et 3S* (16)*

L'ester cyclopropénique **10** (22 mmol) est traité par 16 mmol de potasse en solution–suspension dans le *n*-butanol (12 *M*). Le mélange réactionnel est maintenu à 170°C pendant 10 h. Après évaporation de l'alcool et hydrolyse, les acides organiques sont précipités par addition d'une solution chlorhydrique 4 *N* (pH 2–3). Après extraction, la distillation fournit le mélange d'acides pé 65–70°C/0.2 Torr) qui sera utilisé brut pour l'étape suivante. Ces acides ont cependant été caractérisés sous forme d'esters obtenus en traitant une partie du mélange précédent par le diazométhane en solution éthérée. Ces esters sont alors séparés sur colonne Ucon Oil (20%) de 3.3 m (Chromosorb WAW 60/80, gaz vecteur: H_2, θ = 140°C).

Ester 1R, 2R*, 2S*, 3R**: ir (film): ν(=C—H) = 3080, ν(C=O) = 1723, ν(C=C) = 1634, ν(=C—H) = 905 cm^{-1}; rmn (CCl_4/TMS): δ(CO_2Me) = 3.65 (3H, s), δ(CH_3—CH_2) = 1.00 (3H, t), δ(CH_3—CH_2) = 1.45 (2H, m), δ(CH=CH_2) = 5.1–5.6 (3H, non analysable), $\delta H_{1,2}$ = 1.30–1.70 (2H, non analysable), δH_3 = 2.05 ppm (1H, m). Couplages (CCl_4, Eu(dpm)$_3$): $^3J(H_1, H_2)$ = 5.5 Hz, $^3J(H_1, H_3)$ = 5.5 Hz, $J(H_2, H_3)$ = 9.2 Hz.

Ester 1R, 2S*, 3S**: ir (film): ν(=C—H) = 3075, ν(C=O) = 1721, ν(C=C) = 1629, ν(=C—H) = 901 cm^{-1}; rmn (CCl_4/TMS): δ(CO_2Me) = 3.65 (3H, s), δ(CH_3—CH_2) = *1.02* (3H, t) et *1.40* (2H, m), δ(CH=CH_2) = 5.75 (1H, m), 5.17 (1H, m), 4.98 (1H, m), $\delta H_{1,2,3}$ = entre 1.3 et 1.9 ppm (3H, m). Couplages (CCl_4, Eu(dpm)$_3$): $^3J(H_1, H_2) \simeq {}^3J(H_2, H_3) \simeq 5$ Hz, $^3J(H_1, H_3)$ = 9.0 Hz.

[Ethyl-2 vinyl-3 cyclopropyl]-1 éthanol 3 à 6

Le mélange des acides (**15**, **16**) est réduit en cétones vinylcyclopropaniques par le méthyllithium dans l'éther anhydre selon le mode opératoire décrit pour la préparation des cétones **13** et **14**. Le mélange de cétones (**17**, **18**) ainsi obtenu est traité par $AlLiH_4$ (mode opératoire identique à celui décrit précédemment pour la préparation des alcools cyclopropylidéniques **1** et **2**); après hydrolyse et extraction à l'éther de la phase organique, le mélange d'alcools est distillé rapidement et utilisé brut pour le traitement par l'acétate mercurique. Ces alcools on été, par ailleurs, isolés par cpv sur colonne Carbowax (20%) de 4 m (Chromosorb P NAW 60/80, gaz vecteur: H_2, θ = 150°C).

Alcool 1R, 2S*, 3S*, S* (3)*: t_R (cpv) = 15 min; ir: ν(=CH_2) = 3078, ν(=C—H) = 2995, ν(C=C) = 1638, ν(=C—H) = 900 et 812 cm^{-1}; rmn (CCl_4/TMS): δ(CH=CH_2) = 5.54 (1H, m), 5.15 (1H, m), 4.95 (1H, m), δ(CH_3—CH_2, $H_{1,2,3}$) 0.90 à 1.30 (8H, m), δ(CHOH) = 3.34 (1H, 8 raies), δ(COH—CH_3) = 1.23 ppm (3H, d); couplages (CCl_4, Eu(dpm)$_3$): $^3J(CHOHCH_3)$ = 6.3 Hz, $^3J(CH$—$CHOH)$ = 8.7 Hz, $^3J(H_1, H_2)$ = 4.7 Hz.

Alcool 1R, 2S*, 3S*, R* (4)*: t_R(cpv) = 18 min; ir: ν(=CH_2) = 3078, ν(=CH) ≃ 3000, ν(C=C) = 1635, ν(=C—H) = 900 et 815 cm^{-1}; rmn (CCl_4/TMS): δ(CH=CH_2) = 4.80 à 5.40 (3H, m), δ(CH_3—CH_2, $H_{1,2,3}$) = 0.90 à 1.30 (8H, m), δ(CHOH) = 3.38 (1H, 8 raies), δ(COH—CH_3) = 1.17 ppm (3H, d); couplages: $^3J(CHOH$—$CH_3)$ = 6.1 Hz, $^3J(CH$—$CHOH)$ = 8.5 Hz, $^3J(H_1, H_2)$ = 5.2 Hz.

Alcool 1R, 2S*, 3R*, S* (5)*: t_R(cpv) = 24 min; ir: ν(=CH_2) = 3068, ν(=CH) = 2995, ν(C=C) = 1638, ν(=CH_2) = 900 à 920 cm^{-1}; rmn (CCl_4/TMS): δ(CH=CH_2) = 5.45 (1H, m), 5.08 (1H, m), 4.88 (1H, m), δ(CH_3—CH_2, $H_{1,2,3}$) = 0.95 à 1.40 (8H, m), δ(CHOH) = 3.20 (1H, 8 raies), δ(COH—CH_3) = 1.18 ppm (3H, d); couplages: $^3J(CHOH$—$CH_3)$ = 6.1 Hz, $^3J(CH$—$CHOH)$ = 8.5 Hz.

Alcool 1R, 2S*, 3R*, R* (6)*: t_R(cpv) = 25.5 min; ir: ν(=CH_2) = 3065, ν(=CH) = 2995, ν(C=C) = 1637, ν(=CH_2) = 900 à 920 cm^{-1}; rmn (CCl_4/TMS): δ(CH=CH_2) = 5.44 (1H, m), 5.17 (1H, m), 4.86 (1H, m) δ(CH_3—CH_2, $H_{1,2,3}$) = 0.90 à 1.40 (8H, m), δ(CHOH) = 3.24 (1H, 8 raies), δ(COH—CH_3) = 1.18 ppm (3H, d); couplages: $^3J(CHOH$—$CH_3)$ = 6.1 Hz, $^3J(CH$—$CHOH)$ = 6.6 Hz.

Hétérocyclisation des alcools secondaires vinylcyclopropaniques 3 et 4 par l'acétate mercurique

Préparation de l'organomercurique

A une solution de 2 mmol d'acétate mercurique dans 3 mL de THF sont ajoutés lentement 2 mmol d'alcool **3** (ou **4**). L'agitation est maintenue pendant 20 min (test à la soude négatif: absence d'ions Hg^{2+}).

Réduction de l'organomercurique in situ *par le borohydrure de sodium*

Après avoir refroidi le mélange réactionnel précédent dans un bain eau–glace, on ajoute lentement en agitant une solution de soude (10%) jusqu'à un pH neutre ou légèrement basique. La réduction s'effectue ensuite en ajoutant lentement 1.5 mmol de borohydrure de sodium en solution dans le minimum de soude à 10%. L'agitation est poursuivie pendant 3–4 h (jusqu'à obtention de mercure métallique). La phase organique est extraite à l'éther, lavée à l'eau et le THF est distillé lentement sous vide.

Le mélange de dérivés bicycliques **8** et **9** (ou 7 et **8**) est analysé par cpv analytique sur colonne Carbowax de 6.6 m, $\theta_{injecteur}$ 160°C, $\theta_{colonne}$ 80°C.

En fait la synthèse des composés **7**, **8** et **9** a été réalisée à partir du mélange d'alcools vinylcyclopropaniques **3** à **6** selon le même mode opératoire. La séparation de **7**, **8** et **9** se fait par cpv sur colonne Ucon Oil de 3.3 m, $\theta_{colonne}$ 70°C. Les alcools **5** et **6** sont récupérés inchangés en cpv. Leur présence rend difficile l'évaluation du rendement en composés bicycliques (≃80%).

Migration de la double liaison cyclopropylidénique des alcools 1 et 2

A 80°C, sous atmosphère anhydre, on ajoute à 0.03 mol de tertiobutylate de potassium dans 10 mL de DMSO anhydre 0.006 mol d'alcool **1** ou **2**. Après 5 h de réaction à 80°C, on hydrolyse à froid avec 80 mL d'eau, extrait à l'éther et sèche sur sulfate de sodium. On obtient le mélange d'alcools (**3** + **5**) ou (**4** + **6**), avec un rendement de 60% environ que l'on isole par cpv sur colonne Ucon Oil (20%) de 3.3 m (Chromosorb WAW 60/80, gaz vecteur: H_2, θ = 140°C).

Résultats et discussion

Identification par voie chimique des éthyl-2 éthylidène-3 cyclopropyl(1R,2R*)-1 éthanol E, S* (1) et R* (2)*

Alcools éthylidènecyplopropaniques 1 et 2

Le traitement en milieu basique du diéthyl-2,3 cyclopropènecarboxylate d'éthyle **10** conduit à un mélange des acides éthyl-2 éthylidène-3 cyclopropanecarboxyliques *Z* et *E* (**11** et **12**). La réduction de ce mélange d'acides en solution dans l'éther par le méthyllithium fournit les composés carbonylés **13** et **14**.

Ces composés **13** et **14** présentent en infrarouge les bandes d'absorption normalement attendues ν(=O)

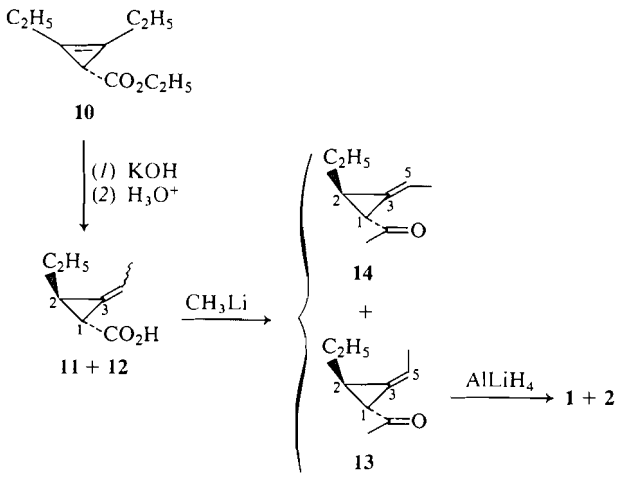


SCHÉMA 4

$\simeq$ 1700 cm^{-1} et $\nu(C{=}C) \simeq 1740\ cm^{-1}$. Dans ces dérivés la relation *trans* des protons cyclopropaniques **1** et **2** est démontrée sans ambiguité par la valeur de la constante de couplage $J_{H_1-H_2} \simeq 5$ Hz. Une relation *cis* se traduirait, en effet, par une valeur de cette constante de l'ordre de 8 Hz (9). Par ailleurs, les positions relatives du méthyle vinylique et du groupement fonctionnel qui différencient **13** et **14** sont déterminées par l'étude, en résonance magnétique nucléaire du proton, des glissements induits par un chélate de terre rare ($Eu(dpm)_3$). Compte tenu des positions relatives de ces deux groupes le glissement induit, observé pour le groupe méthyle dans **14**, doit être très nettement supérieur à celui observé dans le cas de **13**. Les valeurs expérimentales mesurées sont suffisamment différenciées pour permettre d'attribuer la configuration *E* à **13** et *Z* à **14**. En effet, les pentes (Δ) des courbes $\delta i = f(C\ Eu/(Co\ S)$, pour les méthyles et les hydrogènes vinyliques sont:

	13	**14**
$\Delta(=\!-Me)$	142	235
$\Delta(=\!-H)$	285	240

(δi est évalué en Hz, C Eu et Co S représentent respectivement la concentration en chélate et en dérivé carbonylé).

La réduction par l'aluminohydrure de lithium de la cétone cyclopropylidénique *E* (**13**) dans l'éther au reflux conduit au mélange des alcools stéréoisomères **1** et **2** (dans les proportions 43/57) qui sont isolés par cpv. Les carbones 1, 2, 3, 5 qui ne participent pas à la réaction de réduction présentent des configurations identiques à celle de **13**. Cette rétention de configuration est confirmée par la valeur des constantes de couplage $^3J_{H_1-H_2}$ voisine de 5 Hz dans les deux alcools d'une part et par l'étude des glissements induits par $Eu(dpm)_3$ qui, comme précédemment dans le cas de **13**, démontre que les dérivés **1** et **2** présentent bien une configuration *E*.

Alcools vinylcyclopropaniques 3 à 6

Les traitements de **1** et de **2** par le tertiobutylate de potassium dans le DMSO à 80°C conduisent respectivement aux mélanges d'isomères vinylcyclopropaniques **3** + **5** et **4** + **6**. Les dérivés **3** à **6** sont isolés par cpv. La migration de la double liaison cyclopropylidénique, le long de la chaîne éthylidénique, ne modifie pas les positions relatives des substituants portés par le cycle propanique. La relation *trans* des groupes éthyle et hydroxyméthyle est, en effet, facilement contrôlée par le valeur de la constante de couplage $^3J_{H_1-H_2}$ qui reste de l'ordre de 5 Hz. Cette méthode si elle permet d'assurer la filiation entre les alcools cyclopropylidéniques d'une part et les alcools vinylcyclopropaniques **3** ou **4** d'autre part est cependant difficile à mettre en oeuvre dans un but préparatif car elle nécessite la purification préalable en cpv de **1** et **2**. Pour cette raison, l'identification de **3** et **4**, fondée sur l'oxymercuration de ces alcools, a été réalisée à partir du mélange d'alcools **3** à **6** obtenu par la série de réactions suivantes.

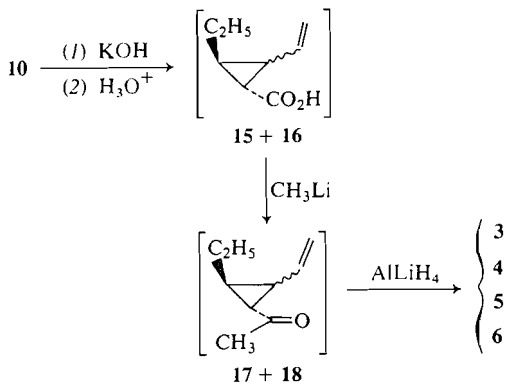

SCHÉMA 5

Traité par une solution suspension de potasse dans le *n*-butanol à 170°C, l'ester cyclopropénique **10** conduit au mélange d'acides vinylcyclopropaniques **15** + **16**; la réduction de ce mélange d'acides par le méthyllithium fournit les cétones **17** + **18** qui traitées par $AlLiH_4$ permettent d'accéder facilement aux mélanges d'alcools vinylcyclopropaniques **3** + **4** + **5** + **6**.

Identification des [*éthyl-2 vinyl-3 cyclopropyl(1*R*, *2*S*,*3*S*)]-*1 éthanol* S* *(3) et* R* *(4) et des* [*éthyl-2 éthylidène-3 cyclopropyl(1*R*,*2*R*)]-*1 éthanol* E,S* *(1) et* R* *(2)*

Le mélange des quatre diastéréoisomères **3** à **6**, sou-

TABLEAU 1. Déplacements chimiques dans $CDCl_3$/TMS en ppm

	H_2	H_1–H_5	H_4	H_6	$(CH_3)_2$	$(CH_3)_4$	CH_3—CH_2	CH_3—CH_2
7[a]	—	—	—	—	1.12	1.12	—	—

9[c]	4.20	Entre 1.20[c] et 1.30	4.20	0.60	1.24	1.24	0.94	Entre 1.20 et 1.30

[a]Enregistré à 60 MHz.
[b]Enregistré à 250 MHz.
[c]Superposés, non analysables.

mis à l'oxymercuration cyclisante, fournit les trois éthers bicycliques **7**, **8** et **9**. Dans les conditions expérimentales que nous avons utilisées ($Hg(AcO)_2$/THF à 20°C), les alcools **5** et **6** restent inchangés et sont récupérés à la fin de la réaction. L'examen des modèles de Dreiding démontre que dans ces dérivés la distance OH-double liaison est supérieure à 3 Å; valeur trop élevée pour permettre l'oxymercuration cyclisante.

Par ailleurs, l'hétérocyclisation de chaque alcool diastéréoisomère **3** et **4**, isolé en cpv et traité séparément, conduit respectivement aux couples **8** + **9** et **7** + **8**

$$\mathbf{4} \rightarrow \mathbf{7}\ (15\%) + \mathbf{8}\ (85\%)$$

$$\mathbf{3} \rightarrow \mathbf{8}\ (25\%) + \mathbf{9}\ (75\%)$$

L'absence de composé **7** dans l'un des mélanges réactionnels et de composé **9** dans l'autre, démontre clairement que la réaction ne provoque pas d'épimérisation du carbone fonctionnel. Le substituant porté par le carbone du cycle tétrahydrofurannique situé en α de l'oxygène et provenant du groupe vinyle devant, selon la littérature (6), présenter la configuration *exo* et *endo*.

La connaissance de la configuration *diendo* ou *diexo* des composés **7** et **9** permet d'attribuer sans ambiguité aux diastéréoisomères **3** et **4** les configurations relatives qui suivent:

alcool vinylcyclopropanique **3**: 1*R**,2*S**,3*S**,4*S**

alcool vinylcyclopropanique **4**: 1*R**,2*S**,3*S**,4*R**

Comme nous l'avons vu, la migration de la double liaison en milieu basique dans les alcools cyclopropylidéniques **1** et **2** ne modifie pas les configurations des centres chiraux C_1 et C_2 ni évidemment celle de C_4. Il est donc possible d'affecter les configurations:

alcool cyclopropylidénique **1**: 1*R**,2*R**,4*S**

alcool cyclopropylidénique **2**: 1*R**,2*R**,4*R**

Identification des éthyl-6 diméthyl-2,4 oxa-3 bicyclo [3.1.0^{1,5}]hexanes diendo *7*, exo–endo *8*, diexo *9*

L'identification de ces dérivés est fondée sur leur étude en infrarouge et en résonance magnétique nucléaire du ^1H et du ^{13}C. Cependant l'hétérocycle **7**, instable à température élevée, n'a pû être isolé qu'en très faible quantité en cpv. Pour cette raison l'étude de ce dérivé en rmn du ^{13}C n'a pas été abordée; par ailleurs le spectre de rmn de ^1H réalisé sur une solution très diluée n'est que partiellement analysable.

Identification des composés 7 à 9 par résonance magnétique nucléaire de ^1H (Tableaux 1 et 2)

L'ensemble des données rmn est en accord avec les structures proposées: **8** et **9**. Notons, en particulier, que les spectres de ces composés révèlent la présence d'un cycle propanique (δH_6 = 0.60 et 0.70 ppm) et du groupe éthyle; la valeur des constantes de couplage $^3J_{H_1-H_6} \simeq {}^3J_{H_5-H_6} \simeq 3.4$ Hz établit la relation *trans* de H_6 d'une part et de H_1 et H_5 d'autre part.

La non équivalence des groupes méthyles doublets (δ = 1.12 et 1.18 ppm) et des hydrogènes (δ = 4.05 et 4.18 ppm), situés en position 2 et 4, permet d'affirmer que l'oxa-3 bicyclo[3.1.0^{1,5}]hexane **8** présente deux méthyles, l'un *endo*, l'autre *exo*. L'examen des modèles de Dreiding démontre que le cycle tétrahydrofurannique très contraint est plan; la rigidité de l'ensemble bicyclique due à la jonction cyclopropanique *cis* (en C_1 et C_2) ne permet pas d'envisager de déformations. D'après les modèles, les angles dièdres α = (H_2, C_2—C_1, H_1) et β = (H_5, C_5—C_4, H_4) du composé **8** valent 95° et 25° environ. Les valeurs trouvées pour les constantes de couplage $^3J \simeq 0$ et $^3J \simeq 3.8$ Hz ne peuvent être affectées, selon les courbes de Karplus, qu'aux angles dièdres α et β respectivement.

L'équivalence des groupes $(CH_3)_{2\text{ et }4}$ dans les composés **7** et **9** et de H_2 et H_4 (δ = 4.20 ppm) dans **9** caractérise l'existence d'un plan de symétrie. Ces deux hétérocycles ne peuvent donc présenter que des configurations *diexo* ou *diendo*. Dans le cas du composé **9** les constantes $^3J_{H_1-H_2}$ et $^3J_{H_4-H_5}$ sont nulles (raies fines). Les interactions stériques entre $(CH_3)_2$ et $(CH_3)_4$ restant très faibles dans les structures *diendo* et *diexo*, on peut affirmer que les angles dièdres α et β sont voisins de 95° et que le composé **9** présente une configuration *diexo*.

TABLEAU 2. Valeurs des constantes de couplage en Hz

	$J_{H_2-H_1}$	$J_{H_5-H_4}$	$J_{H_6-H_7}$	$J_{H_7-H_8}$	$J_{H_1-H_6}$ ou $J_{H_5-H_6}$	$J_{H_2-(CH_3)_2}$	$J_{H_4-(CH_3)_4}$
7	—	—	—	—	—	6.30	
8	0	3.8	6.8	7	3.4 en moyenne	6.10	5.90
9	0	0	6.8	7	3.4	6.30	

TABLEAU 3. Déplacement chimique et multiplicité des différents carbones en rmn du ^{13}C des composés **8** et **9** δ en ppm

C_1	C_2	C_4	C_5	C_6	C_7	C_8	C_9	C_{10}
				Composé **8**				
28.81 ou 30.05	76.58	72.41	28.81 ou 30.05	20.14	24.39	13.66	20.66	17.80
				Composé **9**				
31.32	77.58	77.58	31.32	25.90	24.70	13.45	24.47	24.47

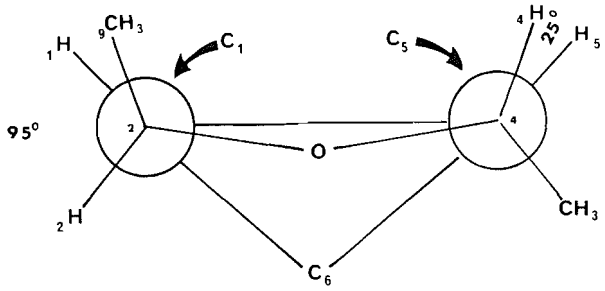

SCHÉMA 6. Angles dièdres du composé **8**. α = (H_2, C_2—C_1, H_1) et β = (H_5, C_5—C_4, H_4).

En conséquence la configuration de **7** qui possède un plan de symétrie est *diendo*.

Confirmation des attributions de structure à 8 et 9 par résonance magnétique nucléaire du ^{13}C (Tableau 3)

Lorsque l'on passe de la structure **9** à **8** puis à **7**, on remplace successivement les relations *trans* entre $(CH_3)_{2\text{ ou }4}$ et C_6 par des arrangements *cis* (gauches). On peut donc prévoir que l'on observera, chaque fois, un blindage de C_6 et du carbone de l'un des méthyles quelque soit, d'ailleurs, l'origine de cet effet γ-gauche (8). Il est alors particulièrement important d'attribuer avec certitude les sites de C_6 et des carbones des groupes $(CH_3)_{2\text{ et }4}$ C_9 et C_{10}.

L'examen des données expérimentales résumées dans le Tableau 3 implique les conclusions suivantes.

Composé 9: les multiplicités des pics dans le spectre hors-résonance, les intensités des signaux et l'effet α de l'oxygène permettent de réaliser une attribution très sûre pour tous les carbones. La présence de trois groupes de deux carbones équivalents (δ (ppm) = 24.47, 31.32 et 77.58) confirme l'existence d'un plan de symétrie.

Composé 8: les neuf atomes de carbones sont non équivalents; ce dérivé ne possède pas de plan de symétrie. Les pics de C_7, C_2 et C_4 sont identifiés respectivement à partir de la multiplicité des signaux et des glissements chimiques. Le carbone C_8, étant très éloigné du carbone qui subit une inversion de configuration (C_4), son signal peut être facilement identifié par comparaison des glissements chimiques des carbones de **8** et de **9**. Cet ensemble de données permet d'attribuer les pics de résonance des carbones C_9 et C_{10}.

La comparaison des glissements chimiques de C_9 et C_{10} démontre que l'un des signaux est, dans l'isomère asymétrique, considérablement blindé par rapport à sa position dans l'isomère symétrique; ce dernier doit donc présenter une configuration *diexo* (**9**). On doit alors observer, pour l'isomère asymétrique, un blindage important de l'un des carbones tertiaires cyclopropaniques par rapport aux valeurs déterminées pour l'isomère symétrique. C'est effectivement ce que l'on observe; ce résultat confirme l'attribution de la configuration *diexo* au composé **9**.

Conclusion

Les attributions de configuration aux éthyl-6 diméthyl-2,4 oxa-3 bicyclo[3.1.0^{1,5}] *exo–endo* et *diexo* réalisées en rmn ^1H sont confirmées par l'étude de ces dérivés en rmn ^{13}C.

Ces attributions sont en accord avec les prévisions que l'on pouvait formuler sur la stéréosélectivité de la réaction de cyclisation par oxymercuration. En effet, la contrainte stérique existant entre un méthyle *endo* et le carbone C_6 du cycle propanique défavorise le dérivé *exo–endo* par rapport au dérivé *diexo*; de

même, le dérivé *diendo* est fortement défavorisé devant l'isomère *exo–endo*.

Cette méthode permet de distinguer les [alkyl-2 vinyl-3 cyclopropyl(1*R**,2*S**,3*S**)]-1 éthanol *R** et *S** ou les[alkyl-2 éthylidène-3 cyclopropyl(1*R**,2*R**)]-1 ethanol *R** et *S**. Elle doit également permettre d'atteindre les configurations relatives des alcools secondaires α-cyclopropaniques (saturés), α-cyclopropéniques et α-spiropentaniques. Le travail en cours dans notre laboratoire permettra vraisemblablement d'établir une filiation chimique entre les alcools α-cycliques et les alcools cyclopropylidéniques de configuration connue à l'aide de réactions qui ne modifient pas les centres de chiralité (réduction par $AlLiH_4$, migration de la double liaison en milieu basique, pontages carbéniques).

Received February 12, 1979

JAN BRON and R. WALLACE. Can. J. Chem. **57**, 2321 (1979).

A relatively simple model, previously used to describe polyatomic vibrations of nonlinear triatomic molecules, has been employed to evaluate the fundamentals, first overtones and combination bands of CX_4 and CX_3Cl (X = H, D). Relatively good agreement is obtained between calculated and observed frequencies. Interesting splittings of certain overtone and combination bands result from these calculations.

JAN BRON et R. WALLACE. Can. J. Chem. **57**, 2321 (1979).

On a utilisé un modèle relativement simple, employé antérieurement pour décrire les vibrations polyatomiques de molécules triatomiques qui ne sont pas linéaires, pour évaluer les bandes fondamentales, premières harmoniques et combinées du CX_4 et du CX_3Cl (X = H, D). On a obtenu un assez bon accord entre les fréquences calculées et observées. Des dédoublements intéressants de certaines bandes harmoniques et combinées découlent de ces calculs.

[Traduit par le journal]

Introduction

Efforts have recently been made by various researchers (1–7) to develop a model capable of describing large amplitude vibrations in molecules. The traditional normal mode theory (8) has proved rather cumbersome in this respect whereas an alternate starting point, involving internal coordinates and a "Morse" approximation of the molecular potential has proved to be quite successful, especially in accounting for the higher overtones of X—H bonds. Currently, attempts are being made to extend the domain of applicability of this approach by application to larger molecules containing bonds other than X—H, and by inclusion of the bending modes.

The present work is in many ways a complementary development to some studies (4) recently completed for the molecules CH_2X_2 (X = F, Cl, Br, I). In that study, only C—H and C—X stretching motions were included, but a large basis set (210 members) made possible the prediction of C—H stretches up to the sixth overtone. While agreement with observed transition energies was in general good, the principal shortcoming of the study appeared to be the omission of the bending modes. The present study also concerns molecules containing five atoms, includes the bending modes in a restricted fashion, and, because of the increase in the basis set this generates, limits itself to lower overtones, combination bands, and the effect of isotopic substitution, which is easily included.

The results to be presented have been derived using the model proposed by Wallace (7), and developed by Bron and Wallace in a series of papers (1). The only modification of that model is the explicit introduction of symmetry coordinates. This is required because the coordinate redundancy problem is more easily dealt with in symmetry coordinates. In addition, the Hamiltonian matrix attains a simpler form.

The importance of a method to determine the energies of excited states should not be overlooked. There is currently substantial practical interest in isotope effects (9) and the possibility of laser isotope separation (10).

Calculations

The equations presented in our recent paper (1*c*) can also be used for symmetry coordinates (i.e. linear combinations of internal coordinates) if the symbol R_i is replaced by S_i, where S_i represents symmetry coordinate *i*. Computational details follow.

From the molecular geometry and the atomic masses the **G** matrix with respect to internal coordinates is calculated by means of the defining matrix equations (11, 12)

$$[1] \quad \mathbf{G} = \mathbf{B}\mathbf{M}^{-1}\mathbf{B}^t; \quad \mathbf{R} = \mathbf{B}\mathbf{X}$$

In [1], **B** defines the transformation from Cartesian

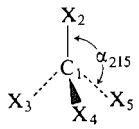
TABLE 1. Definitions and values of various parameters used in the calculations [a]

(*a*) CX_4 (X = H, D)

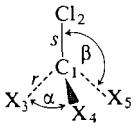


r(C—X) = 1.0936 Å
α(X—C—X) = 109.471222°

$R_1 = \Delta r_{12}$; $R_2 = \Delta r_{13}$; $R_3 = \Delta r_{14}$; $R_4 = \Delta r_{15}$;
$R_5 = \Delta\alpha_{314}$; $R_6 = \Delta\alpha_{415}$; $R_7 = \Delta\alpha_{315}$; $R_8 = \Delta\alpha_{213}$;
$R_9 = \Delta\alpha_{214}$; $R_{10} = \Delta\alpha_{215}$

$S_1^{(A)} = (R_1 + R_2 + R_3 + R_4)/2$; $S_2^{(F)} = (R_1 + R_4 - R_2 - R_3)/2$;
$S_3^{(F)} = (R_1 + R_2 - R_3 - R_4)/2$; $S_4^{(F)} = (R_1 + R_3 - R_2 - R_4)/2$;
$S_5^{(E)} = (2R_8 + 2R_6 - R_9 - R_7 - R_5 - R_{10})/\sqrt{12}$;
$S_6^{(E)} = (R_9 + R_7 - R_5 - R_{10})/2$; $S_7^{(F)} = (R_5 - R_{10})/\sqrt{2}$;
$S_8^{(F)} = (R_6 - R_8)/\sqrt{2}$; $S_9^{(F)} = (R_7 - R_9)/\sqrt{2}$
$F_{rr} = 5.234$ mdyn/Å; $F_{\alpha\alpha} = 0.62496$ mdyn Å
$F_{rr'} = 0.058$ mdyn/Å; $F_{\alpha\alpha'} = 0.1$ mdyn Å; $F_{\alpha\alpha}' = 0.127$ mdyn Å
$D_r = 8.09322 \times 10^{-12}$ erg; $D_\alpha = 48.7512 \times 10^{-12}$ erg

(*b*) CX_3Cl (X = H, D)



r(C—X) = 1.085 Å; r(C—Cl) = 1.780 Å
α(X—C—X) = 110.83°
β(X—C—Cl) = 108.07°

R_i's are defined the same as for CX_4

$S_1^{(A)} = (R_2 + R_3 + R_4)/\sqrt{3}$; $S_2^{(E)} = (2R_2 - R_3 - R_4)/\sqrt{6}$;
$S_3^{(E)} = (R_3 - R_4)/\sqrt{2}$; $S_4^{(A)} = R_1$;
$S_5^{(E)} = (2R_6 - R_7 - R_5)/\sqrt{6}$; $S_6^{(E)} = (R_7 - R_5)/\sqrt{2}$;
$S_7^{(E)} = (2R_8 - R_9 - R_{10})/\sqrt{6}$; $S_8^{(E)} = (R_9 - R_{10})/\sqrt{2}$;
$S_9^{(A)} = PS_{2a} - QS_{2b}$; $P = (1 + K)/(2 + 2K^2)^{1/2}$;
$Q = (1 - K)/(2 + 2K^2)^{1/2}$; $K = -3 \sin\beta \cos\beta/\sin\alpha$;
$S_{2a} = (A - B)/\sqrt{6}$; $S_{2b} = (A + B)/\sqrt{6}$;
$A = R_5 + R_6 + R_7$; $B = R_8 + R_9 + R_{10}$

$F_{ss} = 3.20$ mdyn/Å; $F_{rr} = 5.22$ mdyn/Å; $F_{rs} = 0.0$ mdyn/Å
$F_{rr'} = 0.061$ mdyn/Å; $F_{\alpha\alpha} = 0.533$ mdyn Å; $F_{\beta\beta} = 0.74$ mdyn Å
$F_{a\beta} = 0.1$ mdyn Å; $F_{\alpha\alpha'} = 0.047$ mdyn Å; $F_{\beta\beta'} = 0.1$ mdyn Å
$F_{a\beta}' = 0.1$ mdyn Å

$D_r = 8.09322 \times 10^{-12}$ erg; $D_s = 2.8953 \times 10^{-12}$ erg;
$D_\alpha = D_\beta = 48.7512 \times 10^{-12}$ erg

[a]See text for comments.

coordinates (**X**) to internal coordinates (**R**). The diagonal matrix, **M**, lists the masses of the atoms in the molecule; each atomic mass is repeated three times along the diagonal. From force constants in internal coordinates, which are defined by

$$[2] \quad 2V = \mathbf{R}^t\mathbf{F}\mathbf{R}$$

the force constants in symmetry coordinates can be calculated. The $\mathscr{G}$ and $\mathscr{F}$ matrices in symmetry coordinates can be obtained from the transformations

$$[3] \quad \mathscr{G} = \mathbf{U}\mathbf{G}\mathbf{U}^t; \quad \mathscr{F} = \mathbf{U}\mathbf{F}\mathbf{U}^t; \quad \mathbf{S} = \mathbf{U}\mathbf{R}$$

The **U** matrix defines the orthonormal transformation of internal coordinates to symmetry coordinates. It should be noted that, if in the equations presented previously, R_i is changed to S_i, the quantities F_{ij} and G_{ij} should be changed to $\mathscr{F}_{ij}$ and $\mathscr{G}_{ij}$.

It has been argued that the transformation of the "internal coordinate" model to a "symmetry coordinate" model is difficult to justify on the grounds that there is little reason to assume separability of the molecular potential in symmetry coordinates. Such arguments are countered by the following observations. (*1*) While the "internal coordinate" model has reflected the separability of the potential in internal

coordinates, its success does not depend upon that separability. It is assumed that the internal coordinate potential is approximately separable, but it must be remembered that the oscillators are coupled via kinetic energy terms in the Hamiltonian. Separability of the potential does not imply separability of the oscillators. (*2*) As its starting point, the normal coordinate model assumes separable harmonic oscillators in symmetry coordinates (i.e. both kinetic and potential energy terms are assumed separable). The "internal coordinate" model assumes symmetrized, coupled Morse oscillators in internal coordinates. The present model assumes coupled Morse oscillators in symmetry coordinates. The degree to which this assumption is useful is best judged a posteriori, by the results obtained.

In the present study only the first overtone and combination bands will be considered for the molecules CX_4 and CX_3Cl. The corresponding basis functions expressed in terms of symmetry coordinates can then be defined as

	Excitations	States	Permutations
	0	$\|000\ 000\ 000\rangle$	1
[4]	1	$\|100\ 000\ 000\rangle$	9
	2	$\|110\ 000\ 000\rangle$	36
	2	$\|200\ 000\ 000\rangle$	9

A total of 55 basis functions will therefore be included. Table 1 lists all the parameters that have been used to obtain the results to be presented. The quantities in Table 1 require further explanation. The geometries of methane (13) and methyl chloride (14) can be found in the literature. Definitions of symmetry coordinates have also been described (15, 16). For convenience, the parameters D_i have been given the same values in both internal and symmetry coordinates. This is not a good approximation, but does not seriously affect the lower states. From a "first estimate" of F_{ij}, the listed values for the force constants have been obtained by iterative fitting to the observed fundamentals of CH_4 and CH_3Cl. As before (2), the geometries, force constants, and D_i's have been taken equal for molecules differing only in isotopic substitution.

Results and Discussion

A comparison of the calculated and observed values for the fundamentals, overtone and combination levels for CH_4 and CD_4, as listed in Table 2, shows that agreement is generally good. In order to keep the number of parameters to a minimum, no interactions, via the potential energy, between the stretching and bending modes have been allowed. In other words, all force constants, F_{ij}, corresponding to stretch–bend interactions have been taken as zero. Bond stretch–bend interactions occur in the kinetic energy term of the Hamiltonian and, therefore, stretch–bend interactions have been included in a restricted sense. It is also notable that approximations such as setting the tetrahedral angle equal to 109.5°, rather than 109.47122°, lead to fictitious removal of degeneracies due to distortion of molecular symmetry.

	4441(2)	—	3278(2)	—

[a]Observed values are from ref. 15; unit of energy is cm^{-1}.
[b]The integer in brackets denotes the degeneracy of the energy level or sublevel.

The interesting splittings of overtone and combination bands, which are in accordance with the tables given by Herzberg (13), should be noted. These splittings have been obtained by numerical analysis and, therefore, without the explicit use of group theory. As the magnitudes of the splittings have not been reported in the literature, the accuracy of the calculated values cannot be assessed.

Table 3 lists the energy levels for CH_3Cl and CD_3Cl. Again, fair agreement between observed and calculated values is obtained. Not all of the bonds in these molecules are of the same type, there being three C—H(D) bonds and one C—Cl bond. In Table 1 it may be seen how complicated the definition of the symmetry coordinates is. As expected, splittings of certain overtone and combination bands result, but, once again, experimental data regarding these splittings are lacking.

As pointed out above, the force constants F_{ij} have been obtained from an iterative fitting. Better agree-

[a]Observed values are from refs. 13, 14; units of energy is cm^{-1}.

ment between calculated and observed values may be obtained by involving the force constants corresponding to bend–stretch interactions in the fitting process. Also, additional anharmonic higher order interaction terms in the potential energy expression may lead to improvement in agreement between observed and calculated frequencies. The main purpose of this paper is, in fact, to show that there is an alternative to the complex perturbation method traditionally used in this type of computation. Alternatives to the Morse potential will be the subject of future discussion. The calculations were not complicated by "resonances" as we used the variation method instead of second order perturbation theory. Nielsen points out (8) that resonances are artifacts of (second order) perturbation theory.

Clionamide, a major metabolite of the sponge *Cliona celata* Grant

RAYMOND J. ANDERSEN AND RICHARD J. STONARD

Departments of Oceanography and Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received April 3, 1979

RAYMOND J. ANDERSEN and RICHARD J. STONARD. Can. J. Chem. 57, 2325 (1979).

Clionamide, the major metabolite of the burrowing sponge *Cliona celata*, has been isolated. The structure of clionamide (**1**) was shown to be (2*S*)-*N*-((1*E*)-5,6,7-trihydroxystyr-1-yl)-2-amino-3-(6-bromoindol-3-yl)propionamide by spectral analysis and by interconversion to its tetracetyl derivative **2**. The structure of **2** was determined from spectral data and extensive chemical degradation and was confirmed by the synthesis of its ultimate hydrogenation product, *N*-(5,6,7-triacetoxypheneth-1-yl)-2-acetamido-3-(indol-3-yl)propionamide (**11**).

RAYMOND J. ANDERSEN et RICHARD J. STONARD. Can. J. Chem. 57, 2325 (1979).

On a isolé le clionamide, le métabolite principal de l'éponge *Cliona celata*. Faisant appel à une analyse spectrale et au fait qu'il peut être transformé en son dérivé tétraacétylé **2**, on a démontré que la structure du clionamide (**1**) correspond au (2*S*)-*N*-(1*E*)-trihydroxy-5,6,7 styryl-1) amino-2 (bromo-6 indolyl-3)-3 propionamide. On a déterminé la structure de **2** à partir de données spectrales et d'une dégradation chimique élaborée et on l'a confirmée grâce à la synthèse de son produit ultime d'hydrogénation, le *N*-(triacétoxy-5,6,7 phénéthyl-1) acétamido-2 (indolyl-3)-3 propionamide. (**11**).

[Traduit par le journal]

Cliona celata, a cosmopolitan member of the Clionidae family of burrowing sponges, is found in British Columbia marine waters either free living or embedded in the calcium carbonate shells of the giant barnacle *Balanus nubilus* and the rock scallop *Hinnites multirugosus*. There has been considerable interest in the ability of the Clionidae to burrow into biogenic calcium carbonate (1). Frequently this burrowing is cited as a major source of coral reef erosion. Our interest in the antibiotic activity displayed by crude methanol extracts of *C. celata* (2) has prompted us to investigate the secondary metabolites associated with this sponge. We now wish to report the structure of clionamide (**1**), the major metabolite.

Initial attempts to purify crude *Cliona* metabolites involved silica gel, LH20, and reversed phase high pressure liquid chromatography. All such efforts failed due to the high polarity and instability of the compounds. Acetylation of the crude extracts facilitated the chromatographic purification of the derivatives on silica gel. The structure of the major acetylated metabolite, tetracetyl clionamide (**2**), has been described in a preliminary communication (3). A small-scale isolation using acetic anhydride-d_6 for derivatization produced tetracetyl clionamide-d_{12} (**3**), revealing that the phenol acetates and the acetamide were not natural features of clionamide. We have now been able to isolate pure clionamide (**1**) as a rather unstable yellow powder by a rapid acid extraction procedure followed by silica gel preparative thin layer chromatography (ptlc) (see

Experimental). Dim lighting and an inert nitrogen atmosphere were absolutely essential to obtaining good yields of **1**.

Clionamide (**1**) gives positive ninhydrin and ferric chloride tests. It fails to show a parent ion in the electron impact mass spectrum and its infrared spectrum displays little of diagnostic value beyond a

0008-4042/79/172325-04$01.00/0

large OH/NH absorption at $\approx 3300\ cm^{-1}$ and a broad amide carbonyl absorption at $1635\ cm^{-1}$. Attempts to obtain a ^1H nmr spectrum of clionamide in acetone-d_6 resulted in the rapid and quantitative formation of the deuterated acetonide **4**. The acetonide methyl resonances appear at δ 1.42 and 1.47 in the nondeuterated acetonide **5**. A ^1H nmr spectrum of clionamide obtained in methanol-d_4 shows none of the exchangeable protons. The non-exchangeable protons are trivially assigned by analogy with the assigned signals for tetracetyl clionamide (**2**) (3). Clionamide (**1**) can be quantitatively tetracetylated to give **2**.

Tetracetyl clionamide (**2**), obtained as colourless needles, mp 209–211°C, has the molecular formula $C_{27}H_{26}Br\ N_3O_8$. The presence of a bromo indole residue was indicated by a strong fragment ion at *m/e* 208/210 (1:1) in the mass spectrum. The infrared spectrum (1760, 1627 cm^{-1}) and the ^{13}C nmr spectrum (δ 168.6 (1C), 169.3 (2C), 170.7 (1C), 171.2 (1C)) showed that **2** contained five carbonyls, two of them equivalent. The ^1H nmr spectrum indicated that one of the carbonyls belonged to an acetamide functionality (δ 1.84 (3H)) and that three others were associated with phenol acetates (δ 2.23 (9H)). The ^1H nmr spectrum also contained resonances at δ 6.09 (d, 1H, J = 15 Hz), 7.32 (q, 1H, J = 10, 15 Hz), and 8.64 (d, 1H, J = 10 Hz, D_2O exchange) appropriate for a *trans*-disubstituted olefin which has a heteroatom containing one exchangeable proton attached to one of the olefinic carbons.

Chemical degradation revealed the nature of the olefinic substituents. Ozonolysis of **2** followed by reductive work-up gave 3,4,5-triacetoxybenzaldehyde (**9**) which was identical to an authentic sample. Hydrolysis of **2** with hydrochloric acid in acetonitrile gave in low yield the bromo amide **6**. Hydrogenolysis of **6** converted it cleanly into the debromo amide **7**. Comparison of the debromo amide **7** to an authentic sample of 2-acetamido-3-(indol-3-yl)propionamide showed them to be identical. The absolute stereochemistry of **7** was determined to be *S* by comparison of its optical rotation with the literature value (4). Hence, the *trans*-disubstituted olefin must bear 3,4,5-triacetoxyphenyl and (2*S*)-2-acetamido-3-(bromoindol-3-yl)propionamidyl substituents.

The aromatic region in the ^1H nmr of the bromo methyl ester **8** (δ 7.16 (q, 1H, J = 8, 1.5 Hz), 7.50 (d, 1H, J = 8 Hz), and 7.58 (d, 1H, J = 1.5 Hz)), obtained by hydrolysis of **2** with concentrated sulfuric acid in methanol, indicated that the bromine atom must be attached to either carbon-5 or -6 of the indole ring. Comparison of the ^1H nmr of **8** to that of authentic *N*-acetyl-5-bromotryptophan methyl ester proved them different. Thus the bromine resides on carbon-6 and tetracetyl clionamide (**2**) must be (2*S*)-*N*-((1E)-5,6,7-triacetoxystyr-1-yl)-2-acetamido-3-(6-bromoindol-3-yl)propionamide.

Confirmation of the suggested structure for **2** was obtained by stepwise hydrogenation to give the diamides **10** and **11**. A synthetic sample of *N*-(5,6,7-triacetoxypheneth-1-yl)-2-acetamido-3-(indol-3-yl)-propionamide was shown to be identical to the diamide **11**.

Clionamide exhibits only very mild antibiotic activity which cannot account for the potency of the crude *Cliona* extracts. Structural studies on the more active *Cliona* metabolites are under way. The triphenolic portion of clionamide should possess good calcium chelating properties and we are currently investigating the possibility that it may play a role in the burrowing activities of the sponge.

Experimental

Melting points were determined on a Fisher-Johns apparatus and are uncorrected. ^1H nmr spectra were recorded on Varian XL-100, HA-100, and Nicolet-270 spectrometers. ^{13}C nmr spectra were recorded on a Varian CFT-20 spectrometer. TMS was used as an internal standard in all ^1H and ^{13}C nmr spectra. Low resolution mass spectra were obtained on an A.E.I. MS-902 spectrometer and high resolution mass spectra were recorded on an A.E.I. MS-50 spectrometer. Ultraviolet spectra were recorded on a Cary-14 spectrophotometer, ir spectra were recorded on a Perkin-Elmer Model 700B spectrophotometer, and optical rotations were measured on a Perkin-Elmer Model-141 polarimeter using a 1 cm cell unless otherwise indicated.

High pressure liquid chromatography (hplc) was performed on a Perkin-Elmer Series 2 instrument equipped with a Perkin-Elmer LC55 UV detector system. Merck silica gel 60 PF-254 was used for ptlc. The hplc solvents used were Fisher hplc grade, water was glass distilled; all other reagents and solvents were reagent grade.

Isolation of Clionamide (1)

Cliona celata was collected at 20 metres' depth in Barkley Sound and Howe Sound, British Columbia. The fresh sponge (~1 kg) was homogenized with methanol in a Waring Blendor and the solids were removed by filtration. The methanol extract was concentrated, partitioned between ethyl acetate and water, and the organic layer rapidly extracted with 1 *M* H_2SO_4. The acid layer was covered with fresh ethyl acetate; the two phases were mixed and deoxygenated by a rapid flow of nitrogen, and sodium bicarbonate was added until carbon dioxide evolution ceased. After drying over Na_2SO_4 and concentration, the ethyl acetate extract was purified by ptlc ($CHCl_3$–CH_3OH, 5:2) to give **1** (250 mg) as an unstable yellow powder; R_f (silica, $CHCl_3$–CH_3OH, 3:1) 0.24 ($FeCl_3$ and ninhydrin positive); $[\alpha]_D$ +32.1° (*c* 2.12, CH_3OH); uv(CH_3OH) λ_{max} (nm): 227 (ε 3.1 × 10^4), 291 (ε 1.1 × 10^4), 296 (ε 1.2 × 10^4), 311 (sh) (ε ≈ 9.4 × 10^3); ir (KBr), ν_{max}: 3350–3200 (b), 1635, 1605, 1500 cm^{-1}; ^{13}C nmr (CD_3OD): 30.4 (1C), 56.2 (1C), 106.1 (2C), 115.3 (1C), 116.1 (1C), 116.5 (1C), 116.7 (1C), 120.9 (2C), 123.2 (1C), 126.1 (1C), 127.6 (1C), 128.9 (1C), 129.2 (1C), 139.0 (1C), 147.2 (2C), 172.2 ppm (1C); ^1H nmr (100 MHz, $CD_3C{\equiv}N$–CD_3OD, 10:1) δ: 3.00 (dd, 1H, J = 7, 14 Hz, —CH_2CH<), 3.23 (dd, 1H, J = 5.5, 14 Hz, —CH_2CH<), 3.85 (t, 1H, J = 7 Hz, —CH_2CH<), 6.03 (d,

1H, J = 14.5 Hz, —*CH*=CHNH—), 6.39 (s, 2H, ϕ-*H*), 7.15 (s, 1H, indole, H-2), 7.17 (dd, 1H, J = 1.6, 7.5 Hz, indole, H-5), 7.20 (d, 1H, J = 14.5 Hz, —CH=*CH*NH—), 7.53 (d, 1H, J = 7.5 Hz, indole H-4), 7.57 (d, 1H, J = 1.6 Hz, indole H-7); spin decoupling (100 MHz, $CD_3C{\equiv}N$–CD_3OD, 10:1), $^1H_{obs}$ − {$^1H_{irr}$}, δ: 6.03(bs, 1H) − {7.20}, 7.17(s, 1H) − {7.53}, 7.53(s, 1H) − {7.17}, 7.57(s, 1H) − {7.17}. A 5 mg sample of **1** applied to a 0.65 cm disc of Schleicher and Schuell adsorbent paper gave a 1 mm zone of inhibition of the growth of *Staphylococcus aureus*.

Acetylation of Clionamide (1). A. With Acetic Anhydride

Excess acetic anhydride (10 mL) was added to a solution of **1** (100 mg) in pyridine (2 mL) and the reaction mixture was stirred overnight, at room temperature, under an atmosphere of nitrogen. Evaporation *in vacuo* and purification by ptlc ($CHCl_3$–CH_3OH, 10:1) gave tetracetyl clionamide (**2**, 82 mg), mp 209–211°C (THF – isopropyl ether); $[\alpha]_D$ +45° (*c* 0.7, acetone, 10 cm microcell); uv (CH_3OH) λ_{max} (nm): 227 (ε 5.9 × 10^4), 290 (ε 3.7 × 10^4); ir (KBr) ν_{max}: 3418, 3280, 1760, 1627 cm^{-1}; ^{13}C nmr ($CD_3C{\equiv}N$): 20.4 (1C), 20.9 (2C), 23.1 (1C), 28.3 (1C), 55.2 (1C), 111.3 (1C), 112.1 (1C), 115.1 (1C), 115.5 (1C), 118.3 (2C), 121.0 (1C), 122.7 (2C), 125.5 (2C), 127.7 (1C), 136.3 (1C), 138.4 (1C), 145.0 (2C), 168.1 (1C), 168.9 (2C), 171.0 (1C), 171.9 ppm (1C); ^1H nmr (100 MHz, $CD_3C{\equiv}N$) δ: 1.85 (s, 3H, —NH*Ac*), 2.23 (s, 9H, —O*Ac*), 3.06 (dd, 1H, J = 8, 14 Hz, —*CH*$_2$CH<), 3.24 (dd, 1H, J = 6, 14 Hz, —*CH*$_2$CH<), 4.59 (q, 1H, J = 7 Hz, D_2O − t, J = 7 Hz, —CH$_2$*CH*<), 6.09 (d, 1H, J = 15 Hz, —*CH*=CH—NH—), 6.70 (d, 1H, J = 7.5 Hz, D_2O exchange, —*NH*Ac), 7.06 (s, 2H, ϕ-*H*), 7.10 (s, 1H, indole, H-2), 7.15 (q, 1H, J = 2, 9 Hz, indole H-5), 7.32 (q, 1H, J = 10, 15 Hz, D_2O − d, J = 15 Hz, —CH=*CH*—NH—), 7.51 (d, 1H, J = 9 Hz, indole H-4), 7.67 (d, 1H, J = 2 Hz, indole H-8), 8.65 (d, 1H, J = 9 Hz, D_2O exchange, —CH=CH—*NH*—), 9.23 (b, 1H, D_2O exchange, indole H-1); spin decoupling (100 MHz, $CD_3C{\equiv}N$), $^1H_{obs}$ − {$^1H_{irr}$}, δ: 3.06 (d, 1H, J = 14 Hz) − {4.59}, 3.24 (d, 1H, J = 14 Hz) − {4.59}, 4.59 (d, 1H, J = 7.5 Hz) − {3.15}, 4.59 (t, 1H, J = 7 Hz) − {6.70}, 6.70 (bs, 1H) − {4.59}, 7.32 (d, 1H, J = 9 Hz) − {6.09}, 7.32 (d, 1H, J = 15 Hz) − {8.65}, 8.65 (bs, 1H) − {7.32}; ms *m/e*: 601/599 (9.3, M^+, 1:1), 542/540 (15.5, $M^+ - C_2H_5NO$, 1:1), 500/498 (9.5, $M^+ - C_2H_5NO - C_2H_2O$, 1:1), 210/208 (100, 1:1). *Exact Mass* calcd. for $C_{27}H_{26}{}^{81}Br\ N_3O_8$: 601.0874; found: 601.0889. *Anal.* calcd. for $C_{27}H_{26}BrN_3O_8$: C 54.01, H 4.36, N 7.00; found: C 53.89, H 4.40, N 7.09.

Higher yields of **2** could be obtained by acetylation of the initial crude ethyl acetate extract and purification by column chromatography (silica (Merck), CH_2Cl_2–EtOAc gradient).

Acetylation of Clionamide (1). B. With Acetic Anhydride-d_6

A small sample of the crude ethyl acetate extract (250 mg) was acetylated with acetic anhydride-d_6. Work-up as described for acetylation of clionamide (**1**) with acetic anhydride gave tetracetyl clionamide-d_{12} (**3**, 20 mg) which had a ^1H nmr spectrum identical to that of tetracetyl clionamide (**2**) except for the absence of signals at δ 1.85 (s, 3H) for acetamide and δ 2.23 (s, 9H) for three phenol acetates.

Clionamide Acetonide (5) and Clionamide Acetonide-d_6 *(4)*

Clionamide (**1**, 30 mg) was dissolved in acetone or acetone-d_6 for 1 h at room temperature. Concentration and purification by ptlc ($CHCl_3$–MeOH, 5:2) gave the acetonide **5** (19 mg) or the deuteroacetonide **4** respectively as stable oils; **5**: R_f ($CHCl_3$–CH_3OH, 3:1) 0.54 ($FeCl_3$ and ninhydrin positive); uv (CH_3OH) λ_{max} (nm): 229 (ε 2.5 × 10^4), 297 (ε 1.7 × 10^4), 315 (sh) (ε ≃ 1.4 × 10^4); ir (KBr) ν_{max}: 3300 (b), 2950, 1635 (b), 1605, 1508 cm^{-1}; ^1H nmr[1] (270 MHz, $(CD_3)_2CO$) δ: 1.42 (3H, s, acetonide-*CH*$_3$), 1.47 (s, 3H, acetonide-*CH*$_3$), 3.11 (dd, 1H, J = 7.5, 14.5 Hz), 3.31 (dd, 1H, J = 5, 14.5 Hz), 3.86 (dd, 1H, J = 5, 7.5 Hz), 6.50 (2H, s), 6.75 (d, 1H, J = 14.2 Hz), 6.83 (d, 1H, J = 14.2 Hz), 7.14 (dd, 1H, J = 2, 8.5 Hz), 7.28 (s, 1H), 7.57 (d, 1H, J = 2 Hz), 7.58 (d, 1H, J = 8.5 Hz), 10.09 (bs, 1H, D_2O exchange); ^{13}C nmr ($(CD_3)_2CO$): 27.6 (1C), 28.3 (1C), 30.3 (1C), 59.1 (1C), 105.7 (2C), 106.0 (1C), 110.1 (1C), 111.9 (1C), 114.9 (1C), 115.3 (1C), 116.6 (1C), 120.7 (1C), 121.3 (2C), 122.6 (2C), 125.6 (1C), 125.7 (1C), 129.5 (1C), 146.8 (1C), 174.2 ppm (1C); ms *m/e*: 475/473 (0.02, M^+, 1:1), 210/208 (100, 1:1). High resolution mass measurement was performed on the diacyl derivative of **5**; *Exact Mass* calcd. for $C_{26}H_{26}{}^{81}BrN_2O_6$: 557.0965; found: 557.0990.

The deuteroacetonide **4** was identical (tlc, uv, ^1H nmr, ms) to **5** with the exception of the absence of ^1H nmr signals at δ 1.42 (s, 3H) and δ 1.47 (s, 3H) for two acetonide methyl groups and the complex nature of the signals in the mass spectrum.

Ozonolysis of Tetracetyl Clionamide (2)

Ozone was passed through a solution of **2** (150 mg) in methanol (40 mL), at −78°C, for 5 min. The solution was flushed with oxygen, excess dimethyl sulfide was added, and the mixture allowed to warm to room temperature. Evaporation of the reaction mixture followed by purification by ptlc (EtOAc) gave the aldehyde **9** (60 mg) as a colourless oil.

The aldehyde **9** was identical in all respects (tlc, ir, ^1H nmr, ms) with 3,4,5-triacetoxybenzaldehyde prepared from gallic acid by acetylation, reaction with thionyl chloride, and Rosenmund reduction (6).

Hydrolysis of Tetracetyl Clionamide (2). A. With Hydrochloric Acid (7)

Tetracetyl clionamide (**2**, 145 mg) was dissolved in acetonitrile (15 mL, 0.1% H_2O) and concentrated HCl (0.25 mL in 2 mL $CH_3C{\equiv}N$) was added. After 48 h at room temperature the solvent was evaporated and the residue purified by ptlc ($CHCl_3$–CH_3OH, 5:1) to give the bromo amide **6** (21 mg); $[\alpha]_D$ +4.6° (*c* 3.2, CH_3OH); ^1H nmr (100 MHz, $(CD_3)_2CO$) δ: 1.87 (s, 3H), 3.13 (dd, 1H, J = 8.2, 14.2 Hz), 3.29 (dd, 1H, J = 6, 14.2 Hz), 4.71 (dd, 1H, J = 8.2, 6 Hz), 6.40 (b, 1H, D_2O exchange, —CON*H*$_2$), 6.93 (b, 1H, D_2O exchange, —CON*H*$_2$), 7.17 (dd, 1H, J = 8.8, 1.7, indole H-5), 7.20 (b, 1H, D_2O exchange, —*NH*Ac), 7.30 (s, 1H, indole H-2), 7.61 (d, 1H, J = 1.7 Hz, indole H-7), 7.64 (d, 1H, J = 8.8 Hz, indole H-4), 10.21 (b, 1H, D_2O exchange, indole H-1); ms *m/e*: 325/323 (2.9, M^+, 1:1), 266/264 (43.3, $M^+ - C_2H_5NO$, 1:1), 210/208 (100, $M^+ - C_4H_7N_2O_2$, 1:1), 129 (35.4), 128 (12.2). *Exact Mass* calcd. for $C_{13}H_{14}{}^{79}BrN_3O_2$: 323.0269; found: 323.0251.

Hydrogenolysis of the Bromo Amide 6

The procedure outlined for the hydrogenolysis of the bromo indole **10** was followed (5% Pd/C, 6 mg). Purification was performed by hplc (silica A, hexane – isopropyl alcohol gradient) to give the debromo amide **7** (8.4 mg from 31.3 mg of **6**); $[\alpha]_D$ +11° (*c* 1.0, CH_3OH) (lit. $[\alpha]_D{}^{23}$ +20 ± 1° (*c* 2%, CH_3OH) (4)). The debromo amide **7** was identical, except for optical rotation, with authentic 2-acetamido-3-(indol-3-yl)-propionamide prepared by ammonolysis of racemic *N*-acetyl tryptophan in the presence of DCC.

Hydrolysis of Tetracetyl Clionamide (2). B. With Sulphuric Acid – Methanol

Tetracetyl clionamide (**2**, 150 mg) was dissolved in CH_3OH –

[1]Amide N—H signals were not observed in acetone solution (see ref. 5).

H_2SO_4 (3:1) (10 mL) and stirred at room temperature until tlc indicated that **2** had been consumed. The reaction mixture was neutralized ($NaHCO_3$), concentrated, and the aqueous solution extracted with ethyl acetate. Concentration of the ethyl acetate layer followed by purification by ptlc (EtOAc) gave the bromo methyl ester **8** (25 mg); ^1H nmr (270 MHz, $(CD_3)_2CO$) δ: 1.88 (s, 3H), 3.14 (dd, 1H, J = 7, 15 Hz), 3.25 (dd, 1H, J = 6, 15 Hz), 3.63 (s, 3H), 4.80 (m, 1H), 7.16 (dd, 1H, J = 1.5, 8 Hz, indole H-5), 7.21 (s, 1H, indole H-2), 7.35 (b, 1H, D_2O exchange), 7.50 (d, 1H, J = 8 Hz, indole H-4), 7.58 (d, 1H, J = 1.5 Hz, indole H-7), 10.32 (b, 1H, D_2O exchange); ms *m/e*: 340/338 (16.6, M^+, 1:1), 281/279 (46.7, 1:1), 210/208 (100, 1:1).

The bromo methyl ester **8** differed (^1H nmr) from authentic 2-acetamido-3-(5-bromoindol-3-yl)propionic acid methyl ester prepared from racemic 5-bromo tryptophan; ^1H nmr (270 MHz, $(CD_3)_2CO$) δ: 1.89 (s, 3H), 3.14 (dd, 1H, J = 7, 15 Hz), 3.24 (dd, 1H, J = 6, 15 Hz), 3.63 (s, 3H), 4.76 (q, 1H, J = 7 Hz), 7.19 (dd, 1H, J = 1.5, 9 Hz, indole H-6), 7.24 (s, 1H, indole H-2), 7.34 (d, 1H, J = 9 Hz, indole H-7), 7.36 (b, 1H, D_2O exchange), 7.70 (d, 1H, J = 1.5 Hz, indole H-4), 10.33 (b, 1H, D_2O exchange).

Catalytic Hydrogenation of Tetracetyl Clionamide (**2**)

Palladium on charcoal catalyst (5%, 15 mg) was added to a solution of **2** (60 mg) in methanol (20 mL). The solution was stirred under an atmosphere of hydrogen overnight, filtered through Celite, concentrated, and purified by ptlc (EtOAc) to give **10** (26 mg) as a colourless oil; $[\alpha]_D$ +6.2° (*c* 4.37, acetone); uv (CH_3OH) λ_{max} (nm): 224 (ε 3.38 × 10^4), 283 (ε 6.02 × 10^3); ^1H nmr (100 MHz, $(CD_3)_2CO$) δ: 1.88 (s, 3H), 2.24 (s, 9H), 2.67 (t, 2H, J = 7 Hz, —CH_2CH_2NH—), 3.12 (m, 2H), 3.38 (m, 2H, D_2O − t, J = 7 Hz, —CH_2CH_2NH—), 4.63 (m, 1H), 6.94 (s, 2H), 7.11 (m, 1H), 7.24 (s, 1H), 7.60 (d, 1H, J = 2 Hz), 7.62 (d, 1H, J = 9 Hz), 10.40 (b, 1H, D_2O exchange); ms *m/e*: 603/601 (0.3, M^+, 1:1), 544/542 (2.7, M^+ − C_2H_5NO, 1:1), 210/208 (100, 1:1). *Exact Mass* calcd. for $C_{27}H_{28}{}^{81}BrN_3O_8$: 603.1040; found: 603.1020.

Hydrogenolysis of the Bromo Indole ***10***

Palladium on charcoal catalyst (5%, 10 mg) was added to a solution of **6** (26 mg) in CH_3OH (15 mL) containing 0.2% CH_3CO_2H. The reaction mixture was stirred at room temperature, under an atmosphere of hydrogen, for 72 h, filtered through Celite, concentrated, and purified by ptlc (EtOAc) to give **11** (8 mg) as a colourless oil; ir (KBr) ν_{max}: 3400, 1760, 1635 cm^{-1}; ^1H nmr (270 MHz, $(CD_3)_2CO$) δ: 1.81 (s, 3H), 2.25 (s, 9H), 2.64 (t, 2H, J = 7 Hz), 3.10 (m, 2H), 3.32 (m, 2H, D_2O − t, J = 7 Hz), 4.48 (m, 1H), 6.85 (s, 2H), 7.00 (t, 1H, J = 9 Hz, indole H-5), ~7.0 (1H, D_2O exchange), 7.06 (t, 1H, J = 9 Hz, indole H-6), 7.10 (s, 1H, indole H-2), 7.25 (d, 1H, J = 8 Hz, D_2O exchange), 7.35 (d, 1H, J = 8 Hz, indole H-7), 7.64 (d, 1H, J = 9 Hz, indole H-4), 10.14 (b, 1H, D_2O exchange, indole H-1); spin decoupling (100 MHz, $(CD_3)_2CO$–D_2O), $^1H_{obs}$ − {$^1H_{irr}$}, δ: 2.65 (s, 2H) − {3.36}, 3.12 (b, 2H) − {4.52}, 3.36 (s, 2H) − {2.65}, 4.52 (s, 1H) − {3.12}; ms *m/e*: 523 (0.3, M^+), 481 (0.5, M^+ − C_2H_2O), 464 (14.6, M^+ − C_2H_5NO), 422 (14.7), 380 (14.3), 130 (100). *Exact Mass* calcd. for $C_{27}H_{29}N_3O_8$: 523.1954; found: 523.1970.

Synthesis of the Secondary Amide ***11***

5-Hydroxydopamine hydrochloride (86.0 mg) was added, as a solid, to a solution of DCC (90.7 mg), (*S*)-*N*-acetyltryptophan (105.3 mg), and triethylamine (0.25 mL) in THF–$CH_3C{\equiv}N$ (10:1) (50 mL). The reaction mixture was stirred at room temperature overnight, filtered through Celite, and evaporated. The crude residue was acetylated ($(CH_3CO)_2O$–pyridine, 20:1), evaporated *in vacuo*, and purified twice by ptlc ($CHCl_3$–CH_3OH, 20:1) to give a colourless oil (66.5 mg) identical (tlc, uv, ^1H nmr, ir, ms) to the ultimate hydrogenation product **11** of tetracetyl clionamide (**2**).

Received February 26, 1979

CATHERINE ELISABETH MARIE FOUQUES and LAWRENCE G. WERBELOW. Can. J. Chem. **57**, 2329 (1979).

Practical consequences attributable to nonvanishing imaginary spectral components of the second rank spherical harmonic angular correlation function are described in detail. This analysis presumes the absence of macroscopic spatial anisotropies. Modulation frequency, anisotropy, and cross correlation of interaction between a nuclear spin and the extranuclear environment are considered. These findings permit a critical assessment of the second-order ultrafine dynamic frequency shift in the nuclear magnetic resonance experiment.

CATHERINE ELISABETH MARIE FOUQUES et LAWRENCE G. WERBELOW. Can. J. Chem. **57**, 2329 (1979).

Les conséquences pratiques attribuables à la valeur non-nulle des composantes spectrales imaginaires de la fonction de corrélation angulaire harmonique tensorielle de rang deux sont décrites en détails. Cette analyse suppose l'absence d'anisotropies spatiales macroscopiques. La fréquence de modulation, l'anisotropie et la corrélation croisée de l'interaction entre un spin nucléaire et l'environnement extranucléaire sont considérés. Ces résultats permettent un accès critique du déplacement de fréquence dynamique du deuxieme ordre dans l'expérience de résonance magnétique nucléaire.

Introduction

The interaction between a nuclear spin and the extranuclear environment (heat bath or lattice) can be written in the concise form

$$[1]\quad \mathscr{H}(t) = \mathscr{H}_0 + \sum_{\eta} \xi_{\eta} \sum_{k} (-1)^k T_{\eta}^{\,k} V_{\eta}^{\,-k}(t)$$

The indicated summation extends over all interactions (η) and projections of interaction (k). Equation [1] presumes that all nonspin degrees of freedom can be treated classically without loss of generality. The eigenstructure of $\mathscr{H}_0$ is manifest in chemical shift and multiplet structure parameters.

In marked contrast, the time dependent interactions are defined such that these perturbative terms vanish when ensemble averaged and hence do not contribute in first order to the spectral features of the nuclear magnetic resonance experiment. However, an iterative expansion of the Liouville equation retaining terms to second order in this perturbation demonstrates that whenever motional narrowing obtains, the perturbation-response characteristics of nuclear paramagnetism can be quantitatively described by rate constants of the functional form (1)

$$[2]\quad \text{Rate} \sim 2 \sum_{\eta} \sum_{\eta'} \underbrace{\xi_{\eta}\xi_{\eta'}} \sum_{k} \langle |T_{\eta}^{\,k}| \rangle \langle |T_{\eta'}^{\,-k}| \rangle \int_0^{\infty} \underbrace{\langle V_{\eta'}^{\,k}(t) V_{\eta}^{\,-k}(0) \rangle} (\cos \omega_k t - i \sin \omega_k t)\, dt$$

interaction strengths

lattice correlation of fluctuation

spin matrix elements "selection rules"

spectral density of fluctuation

For certain coherence rates, a summation over eigenbasis is also implied.

This illustrative expansion indicates that these rates are parameterized by an interaction strength, ξ, and a weighted sum of terms related to the fluctuation of interaction. Evaluation of the weighting

0008-4042/79/172329-04$01.00/0

factors, $\langle|T_\eta^k|\rangle$, is a straightforward exercise in the application of the quantum theory of angular momenta. Evaluation of the lattice correlation is much more difficult and is highly model dependent (2). As a prelude to ensuing discussion, it is sufficient to state that the lattice functions, V^k, for the chemical shift anisotropy, intramolecular dipole–dipole and quadrupolar interactions are the kth projections of the second rank spherical harmonic which define the relative orientation of the principal axis of interaction in the laboratory frame of reference. Hence, these interactions provide information on molecular reorientation and angular correlation. The random field, spin rotation, and scalar coupling mechanisms are sensitive to other lattice correlations which will not be discussed further in this work.

Inspection of [2] clearly reveals that the spectral representation of this lattice correlation function is complex valued. This of course does not necessarily imply that the correlation function itself is complex valued (3). Although various time inversion and time reversal arguments suggest that the correlation function is an even function of time, this function is introduced into magnetic relaxation theory in a causal manner and hence the odd (purely imaginary) component survives the one-sided Fourier transformation. Whereas the real component of this spectral representation is responsible for the randomization of phase coherence and the establishment of Boltzmann distributions, the imaginary component must be identified with an ultrafine second-order shift in the various single and multiple quantum coherences.

If extreme narrowing arguments obtain, it can be rationalized that this ultrafine shift is negligible. Likewise, if nonextreme narrowing arguments obtain, the adiabatic contribution to the linewidth renders the ultrafine shift negligible in a relative sense. However, for certain spin systems characterized by coincident Lorentzians, it is conceivable that because of cancellatory effects, the width of at least one spectral composite will be insensitive to the adiabatic term. The necessity to consider ultrafine dynamic frequency shifts has recently been illustrated for multiply degenerate spin one-half systems relaxed by dipolar interactions (4) and for multipolar spin systems relaxed by quadrupolar interactions (5).

It is the purpose of this work to expose the functional form of the dynamic frequency shift and subsequently discuss more fully the possible significance of this term in context of the nuclear magnetic resonance experiment.

Theory

The influence of dipolar, quadrupolar, shift anisotropy, and mutually interfering interactions can be described in terms of two complementary spectral density functions

$$[3]\quad \begin{Bmatrix} J_{\eta\eta'}(\omega) \\ Q_{\eta\eta'}(\omega) \end{Bmatrix} = \xi_\eta\xi_{\eta'} \begin{Bmatrix} \mathrm{Re} \\ \mathrm{Im} \end{Bmatrix} \int_0^\infty \langle Y_2^0(\Omega_\eta(t)) \times Y_2^0(\Omega_{\eta'}(0))\rangle \exp(-i\omega t)\,dt$$

It is assumed that the perturbation limit obtains necessitating consideration of only second-order terms. Absence of applied time dependent rf fields and macroscopic orienting potentials is implicit.

Although numerous dynamical models exist which enable microscopic parameterizations of the spherical harmonic correlation function (2), the present discussion assumes that molecular reorientation is described adequately by a diffusional-type process. Utilizing standard methods, it has been shown that the real component of the one-sided Fourier transform of the spherical harmonic correlation function introduced in [3] can be cast into the general form (6)

$$[4]\quad J_{\eta\eta'}(\omega)/\xi_\eta\xi_{\eta'} = \mathrm{Re}\int_0^\infty \langle Y_2^0(\Omega(t))\,Y_2^0(\Omega'(0))\rangle \times \exp(-i\omega t)\,dt = \left(\frac{1}{16\pi}\right)\sum_{k=-2}^{2} a_k b_k/(b_k^2+\omega^2)$$

where

$$a_0 = 3\sin^2\theta\sin^2\theta'\sin 2\phi\sin 2\phi'$$

$$a_{\pm1} = 12\cos\theta\cos\theta'\sin\theta\sin\theta' \begin{Bmatrix} \sin\phi\sin\phi' \\ \cos\phi\cos\phi' \end{Bmatrix}$$

$$a_{\pm2} = 3\sin^2\theta\sin^2\theta'\cos 2\phi\cos 2\phi' \begin{Bmatrix} \cos^2(\beta/2) \\ \sin^2(\beta/2) \end{Bmatrix} + (3\cos^2\theta - 1)(3\cos^2\theta' - 1) \begin{Bmatrix} \sin^2(\beta/2) \\ \cos^2(\beta/2) \end{Bmatrix} \pm \sqrt{3}\cos(\beta/2)\sin(\beta/2)[(3\cos^2\theta - 1) \times \sin^2\theta'\cos 2\phi' + (3\cos^2\theta' - 1) \times \sin^2\theta\cos 2\phi]$$

$$b_0 = 4D_1 + D_2 + D_3$$

$$b_{\pm1} = D_1 + \begin{Bmatrix} 4D_2 + D_3 \\ D_2 + 4D_3 \end{Bmatrix}$$

$$b_{\pm2} = 2(D_1 + D_2 + D_3) \pm 2(D_1^2 + D_2^2 + D_3^2 - D_1D_2 - D_1D_3 - D_2D_3)^{1/2}$$

$$\beta = \tan^{-1}\left(\frac{\sqrt{3}(D_2 - D_3)}{D_1 - D_2 - D_3}\right)$$

The ith component of the diagonalized diffusion tensor is denoted by D_i. The polar angles, $(\theta,\phi) \equiv \Omega$, position the vector interaction in this same frame.

Simplification of [4] results whenever symmetric top or spherical top approximations obtain.

The imaginary component of the one-sided Fourier transform of the spherical harmonic correlation function can be deduced from the absorption–dispersion relations, the Kramers–Kronig relations or, equivalently, from the realization that the Fourier transform of a causal function yields real and imaginary components related by a Hilbert transform (7),

$$[5]\quad Q_{\eta\eta'}(\omega) = (-\xi_\eta\xi_{\eta'}/\pi\omega) \star \mathrm{Re}\int_0^\infty \langle Y_2^{\,0}(\Omega(t)) \times Y_2^{\,0}(\Omega'(0))\rangle \exp(-i\omega t)\,dt = \left(\frac{-1}{\pi\omega}\right) \star J_{\eta\eta'}(\omega)$$

where $\star$ is the convolution operation.

Since convolution is a linear operation,

$$[6]\quad Q_{\eta\eta'}(\omega)/\xi_\eta\xi_{\eta'} = (16\pi)^{-1} \sum_{k=-2}^{2} a_k\omega b_k^{\,2}/(b_k^{\,2} + \omega^2)$$

The coefficients, a_k and b_k, are defined in [4]. This expression is valid for the general asymmetric top rotator in the absence of orienting potentials.

Discussion

The existing nmr literature provides very little discussion of the second-order dynamic frequency shift term. Explicit considerations of this term exist in a few scattered studies for some simple dipolar relaxed spin systems (8–10). In each of these instances, it was rationalized that the ultrafine corrections were insignificant and hence did not justify closer scrutiny. For example, the single quantum coherence rate for two identical spin one-half nuclei relaxed by dipolar interactions is given by the expression (10)

$$[7]\quad \langle I_+(t)\rangle/\langle I_+(0)\rangle = \mathrm{Re}\,[\exp(-t/T_2 + i\omega_0\tau_2 t/2T_1)]$$

Isotropic modulation of interaction (correlation time: τ_2) was assumed.

These studies in conjunction with other similar comments (11) have promulgated minimal interest in the second-order shift term. However, as noted in the introductory comments, certain instances have recently been exposed where these terms are indeed significant. Hence, a closer inspection of [6] is justifiable.

Well known features are readily apparent from expression [6]. Since $Q(\omega) = -Q(-\omega)$, whereas $J(\omega) = J(-\omega)$, all diagonal Redfield terms (spin–lattice relaxation),

$$[8]\quad R_{\alpha\alpha\beta\beta} \equiv \langle\alpha|T_\eta^{\,k}|\beta\rangle\langle\beta|T_{\eta'}^{\,-k}|\alpha\rangle\{J_{\eta\eta'}(\omega_{\alpha\beta}) + J_{\eta\eta'}(-\omega_{\alpha\beta}) + Q_{\eta\eta'}(\omega_{\alpha\beta}) + Q_{\eta\eta'}(-\omega_{\alpha\beta})\}$$

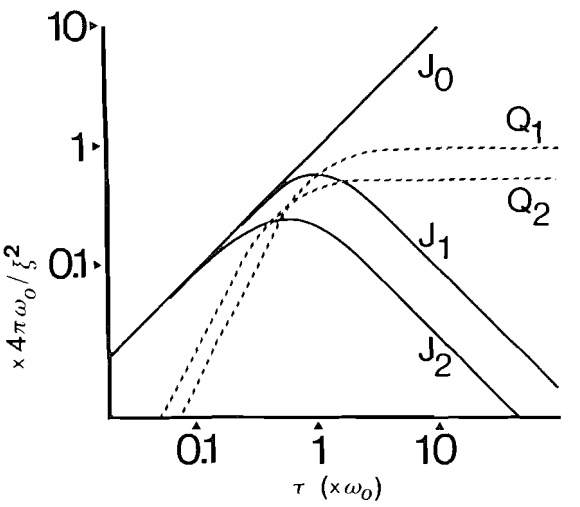

FIG. 1. Plot of $J_0(0)$, $J_1(\omega_0)$, $J_2(2\omega_0)$, $Q_1(\omega_0)$, and $Q_2(2\omega_0)$, measured in units of $\xi_\eta^{\,2}/4\pi\omega_0$ versus the reorientational correlation time τ, measured in units of $1/\omega_0$. It is assumed that the spherical harmonic angular correlation function is of the form

$$\langle Y_2^{\,k}(\Omega(t))\,Y_2^{\,-k}(\Omega(0))\rangle = (-1)^k\left(\frac{1}{4\pi}\right)\exp(-t/\tau).$$

This figure may also be utilized to deduce more general diffusional correlations where

$$\langle Y_2^{\,k}(\Omega(t))\,Y_2^{\,-k}(\Omega(0))\rangle = (-1)^k\left(\frac{1}{4\pi}\right) \times \sum_{i=1}^{5} \alpha_i\exp(-t/\tau_i);\quad \sum_i \alpha_i = 1.$$

For the cross correlation terms,

$$\sum_i \alpha_i = P_2(\cos(\Omega - \Omega')).$$

are unaffected by odd spectral components (12). Since Q is odd and continuous, the zero frequency shift, $Q(0)$, vanishes.

All other relevant features of the dynamic shift term can be easily deduced with the graphical aid of Fig. 1. This figure plots $J_k(k\omega_0)$ and $Q_k(k\omega_0)$, measured in the natural units of interaction, $\xi^2/4\pi$ inversely weighted by the Larmor frequency, $\omega_0 = \gamma B_0$, versus the reorientational correlation time, τ, measured in units of $1/\omega_0$. Assumed isotropic reorientation for this rudimentary plot is reflected by the occurrence of a single point of inflection in the J_1 and J_2 curves. For cross-correlation functions, the ordinate must be further scaled by the factor, $P_2(\hat{\eta}\cdot\hat{\eta}')$.

The left-hand portion of this figure corresponds to the extreme narrowing regime, $J_0 \simeq J_1 \simeq J_2$. In this same limit, it is important to note that the analogous ratio, Q_1/Q_2 does not equal unity. This feature suggests that conventional formulations of the extreme narrowing approximation when considering second-order shifts must be strengthened (4). In the viscous liquid regime of nmr (right-hand

portion of this figure), $Q_k = J_0 J_k$ ($\xi^2/4\pi\omega_0 \equiv 1$). Since Q_k is larger than J_k by the same factor by which it is smaller than J_0, evolution expressions for any quantum coherence which is independent of the adiabatic contribution will be dominated by the dynamic frequency shift term.

Since it is well known that anisotropic and internal motions radically influence the effectiveness of both T_1 and T_2 relaxation processes (for example, ref. 13), perhaps the singly most important question to be resolved is the importance of such motions on the dynamic shift term. In doing so, it must be remarked that [6] is equally valid for single internal rotations if this motion is coincident with any of the principal diffusion axes. Equations [4] and [6] are also amenable to other general interpretations with suitable identifications and assumptions (for example, see comments on papers in ref. 14).

Since T_2 is on the order of J_0 ($= \sum_k (1/b_k)$), whereas $\int_0^\infty J(\omega)\, d\omega$ is constant valued ($\xi^2/8$), the presence of high frequency reorientational anisotropies contribute very little to the density at zero frequency resulting in narrowed single quantum coherences. Likewise, for heteronuclear spin systems, it is well known that the longitudinal magnetization damping constants are on the order of J_1. Hence, in striking contrast, motional anisotropies may increase or decrease the effectiveness of the longitudinal damping rates depending on relative ratios of the various b_k's and ω_0; i.e., depending on whether the motions add to or subtract from the density at ω_0.

In previous studies (4, 5, 8–10), it has been demonstrated that the second-order shift behaves much like the imaginary counterpart of a heteronuclear T_1: there is no adiabatic contribution. However, it also behaves like a T_2 which is insensitive to modulation frequencies less than some critical frequency. For the dynamic shift, this critical frequency is the Larmor frequency. Thus, in nonextreme narrowing, internal motions and other high frequency anisotropies result in unaltered or diminished shifts. Enhancement is never realized.

These expressions may also prove helpful for the analysis of esr spectra where effects attributable to dynamic frequency shifts are well known.

Conclusions

Ramifications of a general expression for the second-order dynamic frequency shift are discussed in detail. It is clearly illustrated that the absence of the adiabatic linewidth contribution is the central criterion necessitating considerations of these shifts. It is noted that the dynamic shift demonstrates both conventional "T_1-stereotyped" and "T_2-stereotyped" reorientational response behavior. It is argued that the influence of motional anisotropies only diminishes the relative importance of the dynamic shift term. Within the framework provided by Fig. 1 and [6], the interested reader can assess the importance of the dynamic shift term for more specialized purposes.

Comment: Ultrasonic velocities for deuterium oxide – water mixtures at 298.15 K

STEFAN ERNST AND JACEK GLINSKI
Institute of Chemistry, Wrocław University, ul. F. Joliot-Curie 14, 50-383 Wrocław, Poland

Received February 23, 1979

STEFAN ERNST and JACEK GLINSKI. Can. J. Chem. 57, 2333 (1979).

The results of highly precise measurements of ultrasonic velocity in mixtures of deuterium oxide with water by Kiyohara *et al.* were used to calculate and discuss the excess velocity of sound in this system.

STEFAN ERNST et JACEK GLINSKI. Can. J. Chem. 57, 2333 (1979).

Les résultats de mesures de haute precision de la vitesse ultrasonique en mélange d'oxide de deuterium et d'eau par Kiyohara *et al.* ont été utilisé pour calculer et discuter la vitesse excessible du son dans ce système.

Mixtures of H_2O with deuterium oxide are very interesting from the point of view of physicochemistry of solutions. Both the components (H_2O and D_2O) are very similar in almost all their physical properties. Their molecular radii and masses are close in value and the molecules have a similar symmetry and distribution of charges. Therefore, all the deviations of those mixtures from ideality are small and difficult to measure. Thus the results of sound velocity measurements in water–D_2O mixtures published recently (1) seem to be of particular interest. The high precision of those measurements makes it possible to calculate reliable values of two parameters characterizing deviations of the system from ideality: the 'excess' compressibility and 'excess' velocity of sound. The former was calculated by the authors on the basis of a thermodynamically justified and exact expression for the adiabatic compressibility of an ideal mixture (2). Moreover, deviations of the sound velocity from additivity were calculated:

$$[1] \quad \Delta u = u - \sum_i x_i u_i^0$$

where x_i is the mole fraction of the ith component; u_i^0, velocity of sound in the pure ith component; u, sound velocity in the mixture. In our opinion those deviations do not properly characterize the deviations of the acoustic properties of the mixture from ideality since according to the thermodynamic criterion of ideality of a mixture:

$$[2] \quad \bar{G} = \sum_i x_i \mu_i + RT \sum_i x_i \ln x_i$$

(where $\bar{G}$ is the mean molar free enthalpy and μ_i^0 is the chemical potential of the ith component) the sound velocity in an ideal mixture should differ from the molar fraction average of the velocities in the pure components. Since neither energy nor volume effects accompany the mixing of the components of an ideal mixture the time of propagation of a plane acoustic wave through an ideal mixture layer of thickness l should equal the sum of times the wave needs to pass through the separate layers of the pure components of thickness $lx_{v,i}$ (where $x_{v,i}$ is the volume fraction of the component i):

$$[3] \quad \frac{l}{u_{id}} = \sum_i \frac{lx_{v,i}}{u_i}$$

Thus

$$[4] \quad u_{id} = \left(\sum_i \frac{x_{v,i}}{u_i} \right)^{-1}$$

where u_{id} is the velocity of sound in the ideal mixture.

For a binary mixture eq. [4] can be written as

$$[5] \quad u_{id} = \frac{u_1 u_2}{x_{v,1} u_2 + x_{v,2} u_1}$$

Using the above relation, Natta and Baccaredda (3) interpolated sound velocity values for real mixtures which obviously cannot lead to exact results because of the nonideal behaviour of those mixtures.

0008-4042/79/182333-02$01.00/0

The 'ideal' sound velocity can also be calculated on the basis of the Laplace equation:

$$[6] \quad u_{id} = (1/\rho_{id}\beta_{id})^{1/2}$$

where ρ_{id} is the density and β_{id} the compressibility coefficient of the ideal mixture. The u_{id} values calculated from eq. [6] should be equal to those obtained by eq. [4].

The u_{id} values were calculated according to eqs. [4] and [6] using the data of Kiyohara, Halpin, and Benson (1) (the β_{id} values were calculated from β and β^E). The corresponding excess velocities $u^E = u - u_{id}$ are illustrated in Figs. 1 and 2, where the solid curves were calculated from

$$[7] \quad u^E = x(1-x)[A + B(2x-1) + C(2x-1)^2 + D(2x-1)^3]$$

with A, B, C, and D coefficients found numerically using the least-squares approximation: $A = -1.1126$, $B = -0.04925$, $C = 0.1932$, $D = -0.1378$ for u_{id} calculated from eq. [4] and $A = 0.1120$, $B = -0.2283$, $C = 0.2144$, $D = 0.01032$ for u_{id} calculated from eq. [6].

In spite of our expectations, the excess velocities calculated from eq. [4] in the whole concentration range differ from those calculated from eq. [6]. We suppose these differences result from errors in the parameter values used for calculating β_{id}. Even if the errors are small, they can seriously affect the excess velocity calculated from the relation:

$$[8] \quad u^E = u - u_{id} = \left(\frac{1}{\rho_{exp}\beta_{exp}}\right)^{1/2} - \left(\frac{1}{\rho_{id}\beta_{id}}\right)^{1/2}$$

because of the slight deviations of the H_2O–D_2O system from ideality. Therefore, the excess velocities calculated from

$$[9] \quad u^E = u - u_{id} = \frac{x_{v,1}u(u_2 - u_1) + u_1(u - u_2)}{x_{v,1}(u_2 - u_1) + u_1}$$

seem to be more reliable because their accuracy is affected only by the errors in the sound velocity measurements, which are extremely small in ref. 1 (standard deviation of 0.014 m s^{-1}).

The excess velocities calculated from the latter relation are negative in the whole concentration range and about ten times smaller than deviations from additivity on a mole fraction basis calculated by Kiyohara, Halpin, and Benson. Thus, like the adiabatic compressibilities, the velocities show only small negative deviations from the ideal values and a slight asymmetric variation with the mole fraction. This is probably due to the similarities of the structures and intermolecular interactions of both the components.

Les calculs de la vitesse excessive du son dans les mélanges D_2O–H_2O par Ernst et Glinski sont discuté et on présente quelques résultats récents.

[Traduit par le journal]

In their paper, Ernst and Glinski (1) have used results from an ultrasonic study in our laboratory (2) to calculate the excess velocities of sound in D_2O–H_2O mixtures. The twofold purpose of the present paper is to comment on the definition of excess sound velocity and to draw attention to a recent note (3) in which the derivation of excess isentropic compressibilities from our earlier results (2) is corrected.

The excess velocity u^E is the difference between the observed velocity u and the value u^{id} in the corresponding ideal mixture.

$$[1] \quad u^E = u - u^{id}$$

As pointed out by Ernst and Glinski, the concept of an ideal reference system is clearly defined for thermodynamic properties by

$$[2] \quad \mu_i^{id}(T,p,x_i) = \mu_i^0(T,p) + RT \ln x_i$$

where $\mu_i^{id}(T,p,x_i)$ is the chemical potential of component i in the mixture at temperature T, pressure p, and mole fraction x_i, and $\mu_i^0(T,p)$ is the chemical potential of the pure component at the same temperature and pressure. Unfortunately the velocity of sound in a mixture is not in general one of its thermodynamic properties.

Ernst and Glinski suggest two formulae for u^{id}. The first of these is

$$[3] \quad u^{id} = \left[\sum_i (\phi_i^0/u_i^0)\right]^{-1}$$

where u_i^0 is the velocity in pure component i, and

$$[4] \quad \phi_i^0 = x_i V_i^0/V^{id}$$

is the volume fraction of i in the mixture stated in terms of the unmixed components. In eq. [4], V_i^0 is the molar volume of pure component i and

$$[5] \quad V^{id} = \sum_i x_i V_i^0$$

is the molar volume of the ideal mixture. The second formula is

$$[6] \quad u^{id} = \left(V^{id}/\kappa_s^{id} \sum_i x_i M_i\right)^{1/2}$$

where κ_s^{id} is the isentropic compressibility of the ideal mixture, and M_i is the molar mass of component i. The authors express surprise that values of u^E calculated from eq. [3] and eq. [6] differ, and suggest that eq. [3] provides a better basis for the evaluation of u^{id}.

It appears to us that eq. [3], which depends on an intuitive model for the passage of a wave through layers of the unmixed components, is unsuitable for defining an ideal thermodynamic value of u. Equation [6], which follows from the Laplace equation under conditions where dispersion is negligible (waves of low frequency and small amplitude), is the correct way of relating u to thermodynamic properties and ideal thermodynamic behavior. In our paper on D_2O–H_2O (2), we fitted the deviation of u from linearity on a mole fraction basis, i.e.

$$[7] \quad \Delta u = u - x_1 u_1^0 - x_2 u_2^0$$

with a polynomial form to provide an algebraic representation of our results. We agree with Ernst and Glinski that Δu "does not properly characterize the deviations of the acoustic properties of the mixture from ideality", and we carefully avoided using the term excess velocity in discussing Δu. We believe that Δu provides a simple empirical way for summarizing the acoustic behavior of a mixture.

In applying eq. [6] to D_2O–H_2O mixtures, Ernst and Glinski used values of κ_s^{id} derived from data in

[1]NRCC No. 17512.
[2]National Research Council of Canada Research Associate.

0008-4042/79/182335-02$01.00/0

our paper (2). A recent note (3), which was not available to Ernst and Glinski, discusses the formulae which have been used in our laboratory to evaluate κ_s^{id}. In some of our earlier work we used the approximation

$$[8] \quad \kappa_s^{id} = \sum_i \phi_i^0 \kappa^0_{s,i}$$

where $\kappa^0_{s,i}$ is the isentropic compressibility of pure component i. In more recent work, including our paper on D_2O–H_2O (2), we used the expression

$$[9] \quad \kappa_s^{id} = \kappa_T^{id} C_v^{id}/C_p^{id}$$

with κ_T^{id}, the isothermal compressibility of the ideal mixture, equal to the volume fraction average of the values for the pure components

$$[10] \quad \kappa_T^{id} = \sum_i \phi_i^0 \kappa_{T,i}^0$$

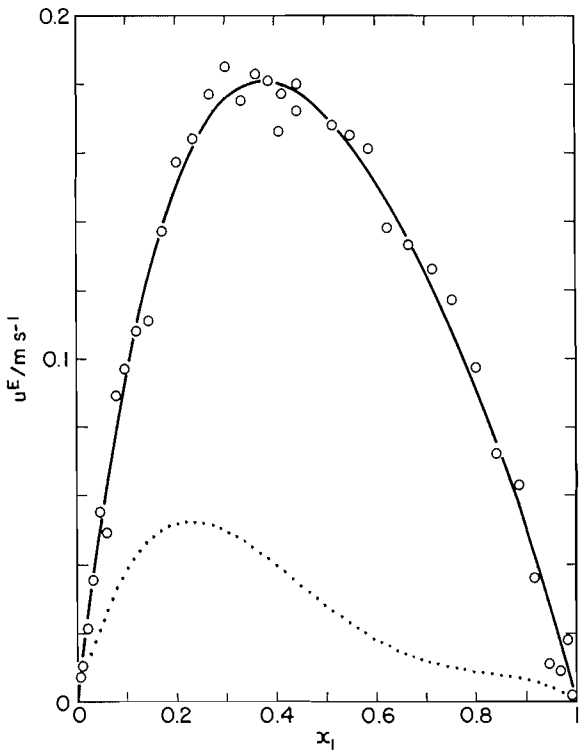

FIG. 1. Excess velocities of sound in $D_2O(1)$–$H_2O(2)$ mixtures at 298.15 K. Points, ○, derived from experimental results (2) using eq. [13] for κ_s^{id}. Curves: — least-squares representation by eq. [15]; ··· calculated by Ernst and Glinski (1) from our original κ_s^E values based on the approximation of C_v^{id} by eq. [12].

and C_p^{id}, the molar heat capacity of the ideal mixture at constant pressure, equal to the mole fraction average

$$[11] \quad C_p^{id} = \sum_i x_i C_{p,i}^0$$

Following Van Dael (4) we also adopted a mole fraction average for C_v^{id}, the molar heat capacity of the ideal mixture at constant volume,

$$[12] \quad C_v^{id} = \sum_i x_i C^0_{v,i}$$

and erroneously stated that this procedure was exact. We have since realized that eq. [12] is only approximate and that in some cases its use can alter the values of κ_s^{id} considerably. As indicated in our paper, the expression for κ_s^{id} which follows from eq. [2] is

$$[13] \quad \kappa_s^{id} = \kappa_T^{id} - TV^{id}(\alpha^{id})^2/C_p^{id}$$

where α^{id}, the coefficient of thermal expansion of the ideal mixture, is the volume fraction average of the values for the pure components

$$[14] \quad \alpha^{id} = \sum_i \phi_i^0 \alpha_i^0$$

and κ_T^{id}, V^{id}, and C_p^{id} are as given above.

Excess velocities of sound in D_2O–H_2O mixtures at 298.15 K, calculated from our experimental results (2) using eq. [13] to evaluate κ_s^{id}, are plotted against x_1, the mole fraction of D_2O, in Fig. 1. Also shown is their representation by the equation

$$[15] \quad u^E/\text{m s}^{-1} = x_1(1 - x_1)[0.684 + 0.300 \times (1 - 2x_1) + 0.196(1 - 2x_1)^2]$$

which has a standard deviation of 0.007 m s^{-1}. For comparison, the dotted curve in the same figure is that derived from our original κ_s^E values by Ernst and Glinski. The recalculated values of u^E are larger than those which depend on the approximate expression for C_v^{id} (eq. [12]), and the variation of u^E with mole fraction is less skewed.

The electron-donating properties of some phenylfurans. Charge transfer studies

RAFIE ABU-EITTAH AND MAHER M. HAMED

Department of Chemistry, Faculty of Science, University of Cairo, Giza, Egypt

Received November 20, 1978

RAFIE ABU-EITTAH and MAHER M. HAMED. Can. J. Chem. 57, 2337 (1979).

The formation of the molecular complexes of some phenylfurans with TCNE has been investigated by spectroscopic methods. The formation constants were determined by graphical and iterative procedures and some thermodynamic parameters were calculated. The formed molecular complexes were π ones. Diphenylfuran proved to be a much stronger electron donor than phenylfuran and the latter stronger than furan. Results at hand suggest that the donors investigated assume an all-planar conformation.

RAFIR ABU-EITTAH et MAHER M. HAMED. Can. J. Chem. 57, 2337 (1979).

Faisant appel à des méthodes spectroscopiques, on a étudié la formation de complexes moléculaires de quelques phénylfurannes avec le TCNE. On a déterminé les constantes de formation par des méthodes graphiques et itératives et on a calculé quelques paramètres thermodynamiques. Les complexes moléculaires qui se forment sont du type π. Le diphénylfuranne est un donneur d'électron beaucoup plus fort que le phénylfuranne et ce dernier est plus fort que le furanne. Les résultats obtenus suggèrent que les donneurs étudiés adoptent une conformation complètement plane.

[Traduit par le journal]

Introduction

The charge transfer interaction of some five-membered heterocycles with TCNE has been investigated and it has been found that these heterocycles act as π-electron donors (1–3). Ginns and Strong (4) studied the furan–iodine charge transfer complex in the gas phase. The band maximum of the charge transfer complex (~284 nm) was independent of furan pressure or temperature and was blue shifted (31 nm) from its position in the liquid phase complex. The 1:1 complex was exclusively formed.

The charge transfer interaction of furan, thiophene, and pyrrole with maleic anhydride was investigated (5). Sometimes two charge transfer transitions, from the highest MO's of the donors to the lowest vacant MO of the acceptors, were observed.

Dobrescu-Ciureanu and Sahini (6) applied a perturbation treatment to describe the electronic structure of molecular complexes formed by iodine with several five-membered heterocycles (including furan). Lang (7) has studied the iodine complexes of a number of heterocyclic donors.

The study of molecular complexes in which furan acts as an electron donor is rarely found in the literature. In this work the charge transfer complexes of some phenylfurans with TCNE were investigated. Measurements at different temperatures lead to the computation of some thermodynamic parameters of the molecular complex. The ionization potentials of the donors were calculated from the energies of the charge transfer bands.

Experimental

Materials

Tetracyanoethylene (TCNE, Fluka AG purum grade) was purified by crystallization from chlorobenzene. Chloroform (B.D.H. Analytical reagent) was used without further purification (scanning the spectra of a purified version of chloroform in which the stabilizer was removed gave the same values of band maxima and band intensity as those obtained when A.R. grade solvent was used without purification). Phenylfurans were prepared by the methods reported in literature (8–10).

Measurements

The absorption spectra were measured with a Beckman DK-1 spectrophotometer using 1.0 cm^3 fused silica cells.

Results and Discussion

(I) Equilibrium Studies

(i) 2-Phenylfuran + TCNE System

On mixing a solution of 2-phenylfuran (D) with that of TCNE (B), the following equilibrium is established for the 1:1 complex

$$D + B \rightleftharpoons D{\cdot}B$$

$$[1] \quad K = [DB]/[D][B] = [C]/([D]_0 - [C])([B]_0 - [C])$$

where [DB] = [C] = concentration of charge transfer complex, $[D]_0$ and $[B]_0$ = initial concentrations of the donor and acceptor respectively. If A is the absorbance of the mixture, if Beer's law is obeyed, and if a 1.0 cm optical path is used, eq. [1] can be transformed (11) to eq. [2]:

$$[2] \quad \frac{[D]_0[B]_0}{\Delta A} = \frac{1}{K\Delta\varepsilon} + \frac{[D]_0 + [B]_0}{\Delta\varepsilon} - \frac{[C]}{\Delta\varepsilon}$$

0008-4042/79/182337-05$01.00/0

where, ΔA = absorbance due to charge transfer complex only and $\Delta\varepsilon = \varepsilon_C - \varepsilon_D - \varepsilon_B$. Equation [2] is the Scott's (12) form of the Benesi–Hildebrand (13) relation. If one chooses a wavelength where absorbance is due only to the charge transfer complex then ΔA is replaced by A and $\Delta\varepsilon$ is replaced by ε_C in the above equation. Equation [2] is used to determine K and ε_C graphically (the relation between $[D]_0[B]_0/A$ is plotted against $[D]_0 + [B]_0$, from the slope and intercept one calculates ε_C, K). The results thus obtained are approximate (the last term of eq. [2] is neglected) and show some discrepancies. Iterative procedures eliminate the approximations. The Rosenbrock (14) optimization method is used to get accurate values of K and ε_C. This method depends on minimizing the sum of the squares of the differences between observed and calculated absorbances as outlined. Equation [2] is rearranged to

$$[3]\quad \frac{A}{\varepsilon_C} - \left([D]_0 + [B]_0 + \frac{1}{K}\right) + \frac{\varepsilon_C[D]_0[B]_0}{A} = 0$$

Equation [3] is a second order one and can be solved if K and ε_C are known. One defines the function $Y(K,\varepsilon_C)$ as

$$[4]\quad Y(K, \varepsilon_C) = \sum_{i=1}^{n} [A_{obs} - A_{calcd}]^2$$

where n is the number of experimental data.

The values of K and ε_C which give the minimum value of the function Y are the nearest to the correct values. Equation [3] is solved iteratively to get values of K and ε_C which minimize the value of the Y function. The entry values of K and ε_C are the ones obtained from the graphical method.

Figure 1 shows the absorption spectra (500–700 nm) of mixtures of 2-phenylfuran and TCNE at 18°C when chloroform was used as a solvent and a blank. A broad band with a maximum around 610 nm is observed and represents the maximum of a charge transfer transition since neither the donor nor the acceptor absorb light in that region. The formation of the molecular complex 2-phenylfuran–TCNE has been investigated at different temperatures. The observed increase of absorbance on cooling indicates the exothermic nature of the process of complex formation. The relation between $[D]_0[B]_0/A$ versus $[D]_0 + [B]_0$ is given in Fig. 2, the straight line relationship is apparent and approximate values of K and ε_C are calculated from the slope and intercept. The iteratively computed formation constants are given in Table 1, the decrease of the product $K\varepsilon_C$ with the increase of temperature is a further evidence that the process of complex formation is an exothermic one.

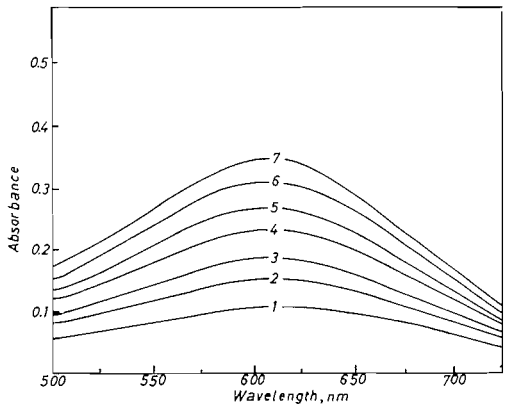

FIG. 1. Absorption spectra of pure TCNE(B) = 0.0027 M, 2-phenylfuran(D) = 0.0856 M, and their mixed solutions at 18.0°C. The concentrations of 2-phenylfuran are: (*1*) 0.0214 M, (*2*) 0.0321 M, (*3*) 0.0428 M, (*4*) 0.0535 M, (*5*) 0.0642 M, (*6*) 0.0749 M, (*7*) 0.0856 M; pure B and D show no absorbance. [TCNE] = 0.0027 M in all solutions.

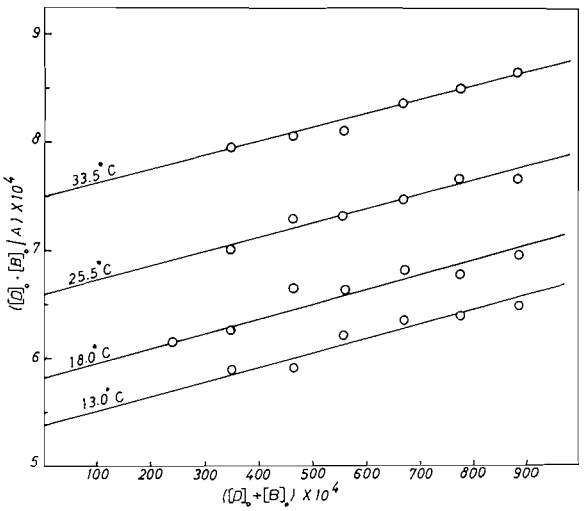

FIG. 2. Relation between $[D]_0[B]_0/A$ and $[D]_0 + [B]_0$ for 2-phenylfuran–TCNE system.

It may be interesting to compare the properties of the two molecular complexes: Furan–TCNE and 2-phenylfuran–TCNE. Yoshida and Kobayashi (5) have indicated that the molecular complex Furan–TCNE possesses two charge transfer transitions at 445 and 295 nm respectively. The determined value (graphically) of K was 0.35 ± 0.01. The broad band characteristic of the 2-phenylfuran + TCNE system makes it difficult to characterize two charge transfer bands analogous to those found when furan is the donor. In the latter case the two charge transfer transitions were assigned to transitions from the two highest occupied MO's of the donor to the lowest vacant MO of the acceptor.

*Gr = graphical, I = iterative.

The numerical value of K for the system 2-phenylfuran + TCNE is about five to six times larger than that for the system furan + TCNE. Therefore, the electron donating properties of 2-phenylfuran is much stronger than that of furan alone. Two important conclusions could be drawn from this result. First, the charge transfer complex in both systems is a π complex. If the n contribution has a significant role the basic (electron donor) properties of 2-phenylfuran should not differ from that of furan. Second, the π conjugation in 2-phenylfuran is pronounced (the molecule assumes an all-planar configuration). If the coplanarity of 2-phenylfuran is significantly distorted the charge transfer complex with TCNE should be of similar properties as that of furan + TCNE or benzene + TCNE; this similarity was not found in this work.

*(ii) 2-*p*-Tolylfuran + TCNE System*

To confirm the above results, complex formation between 2-*p*-tolylfuran, as a donor, and TCNE as an acceptor has been investigated by means of spectroscopic methods. The same procedures followed in studying 2-phenylfuran + TCNE were adopted. Results are given in Table 1.

(iii) 2,5-Diphenylfuran + TCNE System

Following the same procedures as above, the complex formation between 2,5-diphenylfuran and TCNE was studied. The charge transfer complex possesses a broad band with a maximum around 720 nm. The values of K and ε_C were calculated as before and results are given in Table 1. It can be seen that the electron donating property of the diphenyl isomer is very pronounced compared with that of the phenylfuran or the tolylfuran. Such a result gives evidence that the donors investigated in this work act as pure π donors and that their planarity is not apparently distorted. The large increase in the value of K for the complex 2,5-diphenylfuran–TCNE compared to those of both phenylfuran or tolylfuran with TCNE is evidence for the quazi rigid conformation of the donor. It also indicates that the size of the donor and acceptor plays a role in strengthening the overlap of the constituents of the molecular complex which in turn increases the stability of the complex.

The correlation between the planarity of the donor and the stability of the charge transfer complex is urged in the following way. Experimentally it is found that the charge transfer complex of either phenylfuran or tolylfuran is more pronounced than that of either furan or benzene with the same acceptor. Consequently, one concludes that phenylfuran and tolylfuran are stronger electron donors

than either furan or benzene. Since in all cases the molecular complex is a π one, then phenylfuran or tolylfuran would be stronger π donors (than benzene or furan) only if the conjugation on the molecule is not disturbed, that is, if the molecule is in an all-planar configuration. In these cases the donors (phenyl or tolylfurans) are described as being quazi rigid conformers and not free rotators. Molecular orbital calculations (15) on 2-phenylfuran supported such a conclusion and have shown that the height of the rotation barrier is of the order of 0.3 eV and that the all-planar conformer of 2-phenylfuran is the most stable one. Using the same way of reasoning one predicts the coplanarity of 2,5-diphenylfuran from the characteristics of its charge transfer complex with TCNE as compared to those of phenylfuran or tolylfuran with the same donor.

(II) Thermodynamic Properties of the Studied Complexes

The iteratively computed values of K at different temperatures were used to calculate ΔG^0 for the complex formation. The relation between $R \ln K$ and $1/T$ was plotted, the computed values of ΔH^0 and ΔS^0 are given in Table 2.

The interaction between the electron donor (D) and the electron acceptor (A) to form the molecular complex (D·A) has been described by Mulliken (16). The ground and excited states of the complex can be described by the wave functions.

$$\Psi_N = \lambda\psi_0(D, A) + \nu\psi_1 (D^+—A^-)$$

$$\Psi_E = \lambda^*\psi_1(D^+—A^-) - \nu^*\psi_0(D, A)$$

where ψ_0 refers to the nonbond wave function and ψ_1 corresponds to the dative-bond wave function. The ratio between the coefficient of the dative bond to the nonbond wave functions is given by (17–19)

$$\nu^2/\lambda^2 = -\Delta H^0/E_{ct}$$

This ratio varied between 0.07–0.19 (Table 2) for the aryl substituted furan + TCNE systems. The value of this ratio is high compared to that of many strong molecular complexes.

(III) Ionization Potentials of the Donors

A general expression deduced by Matsen (20) that relates the energy of the charge transfer transition for the complexes formed by a series of donors with the same acceptor to the donors ionization potential is

$$E_{ct} = mI_D + n$$

where m and n are constants. A number of equations of this form have been suggested to calculate the ionization potential of the donors (20–24). Aloisi *et al.* (25) determined the parameters m and n for a number of acceptors and substituted benzene and polynuclear hydrocarbons as donors. When TCNE is the acceptor, the relation is

$$I_D \text{ (eV)} = 5.21 + 1.65 \times 10^{-4}\nu \text{ (cm}^{-1}\text{)}$$

Ionization potentials calculated from this equation are given in Table 3, values calculated or measured by other methods are not available. However, the values obtained in this work (from charge transfer studies) seem to be reasonable (values do not differ significantly from theoretically calculated ones and the trend of the variation of the determined ionization potentials is in the right direction). A theoretical value for the lowest ionization potential of 2-phenylfuran was calculated from

$$[5] \quad I_D = \sum_{\mu,\nu} C_\mu F_{\mu\nu} C_\nu$$

where the C's are the SCF coefficients of the atomic orbitals and $F_{\mu\nu}$ are the off-diagonal elements of the F matrix (15). The off-diagonal elements, $F_{\mu\nu}$, were calculated using the relation

$$F_{\mu\nu} = \langle X_\mu|f|X_\nu\rangle - \tfrac{1}{2}P_{\mu\nu}\left\langle X_\mu X_\nu \left| \frac{1}{r_{12}} \right| X_\mu X_\nu \right\rangle$$

the symbols have their conventional meanings.

$$\beta_{\mu\nu}^{\text{core}} = \langle X_\mu|f|X_\nu\rangle$$

The resonance integral, $\beta_{\mu\nu}$, is calculated using the formula (26)

$$\beta_{\mu\nu} = [S_{\mu\nu}/(1 + S_{\mu\nu})]\,[(I_\mu + I_\nu)/2]$$

where I's are the appropriate ionization potentials for the atomic orbitals μ and ν. The zero differential overlap approximation was adopted and the electron-repulsion integrals were calculated using the Nishimoto–Mataga relation (27). The following

TABLE 2. Thermodynamic parameters calculated for the studied molecular complexes

Donor	$-\Delta H^0$	$-\Delta S^0$	ν^2/λ^2
2-Phenylfuran	3.13±0.14	9.30±0.49	0.07
3-*p*-Tolylfuran	4.56±0.16	13.72±0.79	0.10
2,5-Diphenylfuran	7.50±1.2	20.45±0.38	0.19

TABLE 3. Ionization potential of the studied phenylfuran calculated from ct results

Donor	$(\lambda_{max})_{ct}$ (nm)	E_{ct}	$h\nu$*	I_D (eV)
2-Phenylfuran	610	2.03	4.48	7.9
2-*p*-Tolylfuran	640	1.94	4.40	7.8
2,5-Diphenylfuran	720	1.72	3.83	7.5

*Energy of the lowest electronic transition of the donor.

parameters were used (28) (eV)

$$\alpha_C = -11.16, \alpha_O = -31.42$$

$$\gamma_{CC} = 11.13, \gamma_{OO} = -16.12$$

A value of 8.6 eV was obtained for the ionization potential of 2-phenylfuran which is slightly higher, but of the same order of magnitude, than the experimental one. The calculations, by means of eq. [5], were done on the basis that the highest occupied MO of 2-phenylfuran is a π one. The correspondance between the two values suggests that the charge transfer complex is a pure π charge transfer complex, that is the highest occupied MO of donors is a π molecular orbital.

A satisfactory empirical relationship exists between the free energy of formation of the complexes, ΔG^0, and the ionization potential of the donor, I_D. For the studied arylfurans + TCNE systems, the relation between ΔG^0 and I_D can be expressed by

$$[6] \qquad \Delta G^0 = 0.013 I_D - 3879 \text{ cal}$$

A linear relationship also exists between the energy of the charge transfer complex (E_{ct}) and ionization potential of the donor for the studied complexes, that may be expressed by the relationship

$$E_{ct} = 0.80 I_D - 4.3 \text{ eV}$$

which can be rearranged to read

$$I_D = 5.4 + 1.55 \times 10^{-4} \nu_{ct} (\text{cm}^{-1})$$

This equation does not differ significantly from that given by Aloisi *et al.* (25) for the molecular complexes of substituted benzene polynuclear hydrocarbons and TCNE.

T. A. ONDRUS, E. E. KNAUS, and C. S. GIAM. Can. J. Chem. **57**, 2342 (1979).

The regiospecific 1,3-dipolarcycloaddition reaction of 1,2-dihydropyridines **1** with organic azides **2** afford 2,7-diazabicyclo[4.1.0]hept-4-enes **4**, whereas solutions of **1** also containing lithium hydroxide give predominately **4** along with the diazo product **6**. In contrast, the dimeric product **7** was obtained from the reaction of **1***a* with hydrazoic acid. Catalytic hydrogenation of **4** gives rise to a tautomeric mixture of **9** and **10**; when R^2 is methanesulfonyl or *p*-aminobenzenesulfonyl only **9** was obtained. Treatment of **4** with neutral alumina gives rise to the 1,2,5,6-tetrahydropyridylidenes **8** which are likewise reduced to a mixture of **9** and **10** or **9**.

T. A. ONDRUS, E. E. KNAUS et C. S. GIAM. Can. J. Chem. **57**, 2342 (1979).

La réaction de cycloaddition dipolaire-1,3 régiospécifique des dihydro-1,2 pyridines (**1**) avec les azotures organiques (**2**) conduit aux diaza-2,7 bicyclo[4.1.0]heptènes-4 (**4**) alors que des solutions de **1** contenant de l'hydroxyde de lithium conduisent à la formation prédominante de **4** aux côtés du diazo **6**. Par opposition, on obtient le produit dimère **7** lors de la réaction de **1***a* avec l'acide hydrazoïque. L'hydrogénation catalytique de **4** donne lieu à la formation du mélange tautomère de **9** et **10**; si R^2 est le méthanesulfonyle ou le *p*-aminobenzènesulfonyle, on n'obtient que le composé **9**. Si l'on traite **4** avec de l'alumine neutre, on obtient les tétrahydro-1,2,5,6 pyridylidènes (**8**) qui sont aussi réduits en un mélange de **9** et **10** ou **9**.

The 1,3-dipolarcycloaddition reaction of dienamines with organic azides is an attractive method for the synthesis of pharmacologically interesting bicyclic compounds. Mitomycin C is one of the few examples where a fused aziridine ring is an active alkylating agent. Most aziridinyl quinones active as antitumor agents possess multiple aziridinyl groups (1) and are known to cross-link DNA (2). It was therefore of interest to prepare bicyclic ring structures in which 1,2,3-triazoline or aziridine is fused to a tetrahydropyridine ring.

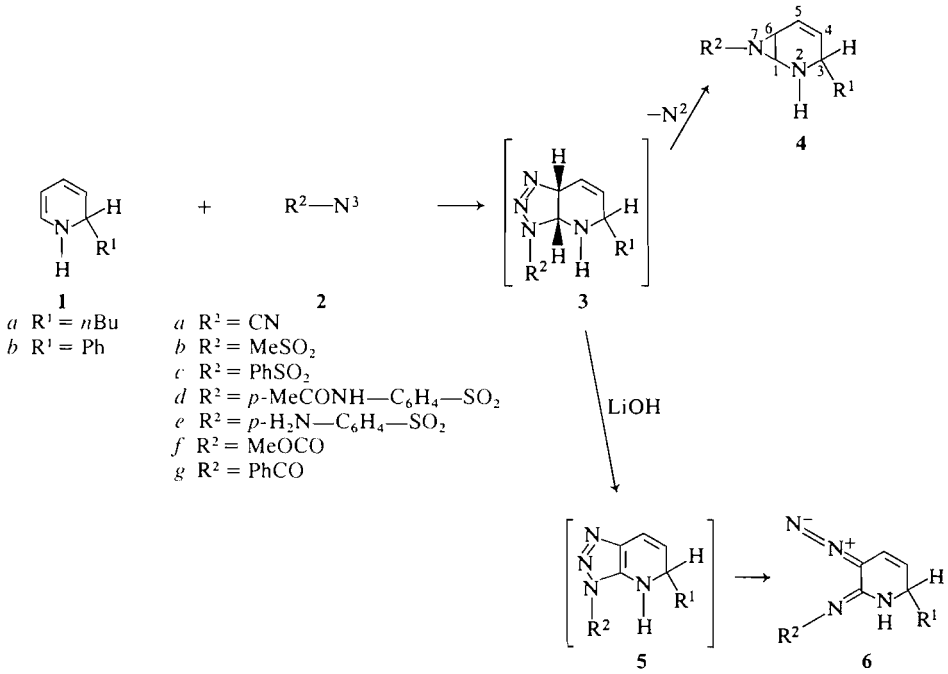
In earlier studies we showed that reaction of *N*-methoxycarbonyl (methanesulfonyl, acetyl)-1,2-dihydropyridines with cyanogen azide gave a 1:1 mixture of stereoisomers *E*- and *Z*-1,2,3,4-tetrahydropyridylidene-4-cyanamides (3). The regiospecific 1,3-dipolarcycloaddition reaction of dienamines **1** with organic azides **2** now provides a quantitative route to 2,7-diazabicyclo[4.1.0]hept-4-enes **4**. A preliminary account of this work has been published (4).

Reaction of 2-butyl-1,2-dihydropyridine **1***a* (lithium hydroxide free) with cyanogen azide **2***a* at 0°C under an atmosphere of nitrogen proceeds rapidly with evolution of nitrogen to yield 3-*n*-butyl-7-cyano-2,7-diazabicyclo[4.1.0]hept-4-ene **4***a* in quantitative yield (see Scheme 1).[2] Under similar conditions **1***b* gave **4***b* (100%). Although the cycloaddition reaction may occur at either the C3—C4 and (or) C5—C6 olefinic bonds no addition product other than **4** was detected (4). If the triazoline intermediate **3** is the product of electronic control the nitrogen atom bearing the R^2-substituent should be directed to the carbon of the enamine double bond bearing the enamine ring nitrogen (5). The reacting species in all of these reactions is the molecular organic azide since loss of nitrogen to give nitrenes occurs above 40°C (6). Similar reactions of 2-butyl-1,2-

[1]To whom inquiries should be addressed.

[2]The preparation of 1,2-dihydropyridines **1** by hydrolysis of the corresponding *N*-lithio-1,2-dihydropyridine with 1 equiv. of water produces 1 equiv. of lithium hydroxide. Although most of the lithium hydroxide rapidly precipitates out of anhydrous ether or tetrahydrofuran, about 5% remains suspended in the solvent. The suspended lithium hydroxide is completely removed if an excess of water is added followed by drying with anhydrous sodium sulfate.

0008-4042/79/182342-08$01.00/0



SCHEME 1. Substituents R^1 and R^2 for **4** and **6** are as illustrated in Table 1.

dihydropyridine **1***a* (lithium hydroxide free) with methanesulfonyl **2***b*, benzenesulfonyl **2***c*, *p*-acetamidobenzenesulfonyl **2***d*, *p*-aminobenzenesulfonyl **2***e*, and methoxycarbonyl **2***f* azides also afforded **4** in quantitative yields (see Table 1). On the other hand, reaction of **1***a* containing 0.05 equiv. lithium hydroxide[2] with sulfonyl azides **2***b–e* gave **4** as well as the unexpected 3-diazo-1,2,3,6-tetrahydropyridylidene-2-sulfonamides **6**. The most plausible mechanism for the formation of **6** involves base catalyzed proton abstraction of one of the bridgehead protons of the triazoline adduct **3**. Elimination of hydride would then afford the more aromatic 1,2-dihydropyridine triazole intermediate **5** which could ring open to give **6**. A similar mechanism has been proposed for opening of the adducts obtained from reactions of organic azides and ethoxyacetylene (7, 8).

The reaction of **1***a* with benzoyl azide **2***g* (5 equiv.) was also investigated. Although the ^1H nmr spectrum of the unpurified reaction product exhibited signals expected for 3-*n*-butyl-7-benzoyl-2,7-diazabi-

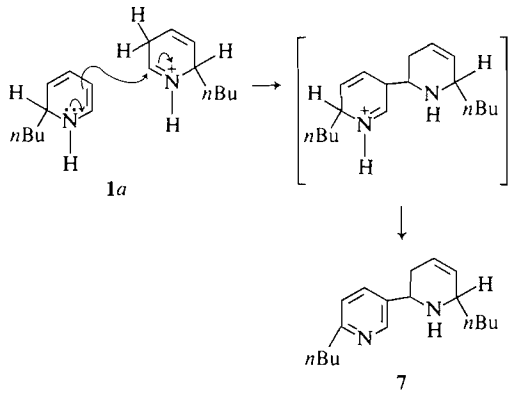
TABLE 1. Reaction of 1,2-dihydropyridines with organic azides

Compound	1,2-Dihydropyridine (R^1)	Organic azide (R^2)	Yield (%) 4	Yield (%) 6
a	*n*Bu	CN	100	
	*n*Bu[a]	CN	79	
b	Ph	CN	100	
c	*n*Bu	$MeSO_2$	100	
	*n*Bu[a]	$MeSO_2$	42.9	17.5
d	*n*Bu	$PhSO_2$	100	
	*n*Bu[a]	$PhSO_2$	40.7	34.1
e	*n*Bu	*p*-MeCONH—C_6H_4—SO_2	100	
	*n*Bu[a]	*p*-MeCONH—C_6H_4—SO_2	79	12.5
f	*n*Bu	*p*-H_2N—C_6H_4—SO_2	100	
	*n*Bu[a]	*p*-H_2N—C_6H_4—SO_2	78.5	1.3
g	*n*Bu	MeOCO	100	

[a]Solution of **1***a* contains 5% of the lithium hydroxide formed upon treatment of *N*-lithio-2-butyl-1,2-dihydropyridine with 1 equiv. water.

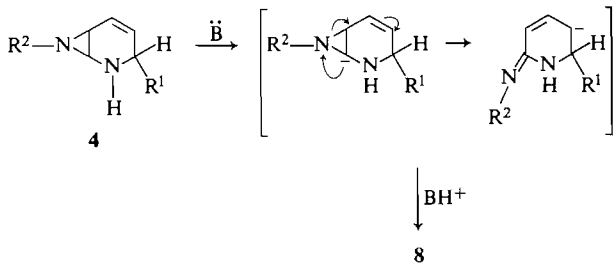
cyclo[4.1.0]hept-4-ene **4**, the only product recovered after preparative silica gel G tlc was the ring opened product **8** (R^1 = *n*Bu, R^2 = PhCO) (39.7%).

Treatment of **1***a* with hydrazoic acid yielded the unexpected 6,6′-di-*n*-butyl-1,2,3,6-tetrahydro-2,3′-dipyridyl **7** (64.7%) and 2-*n*-butylpyridine (12.2%). The most likely mechanism for the formation of **7** involves protonation of **1***a* at the C5 position by hydrazoic acid to give a 2,5-dihydropyridyl imminium species which could undergo nucleophilic attack at its highly electrophilic C6 position by **1***a*. Subsequent aromatization of the 2,5-dihydropyridine dimeric intermediate would afford **7**.



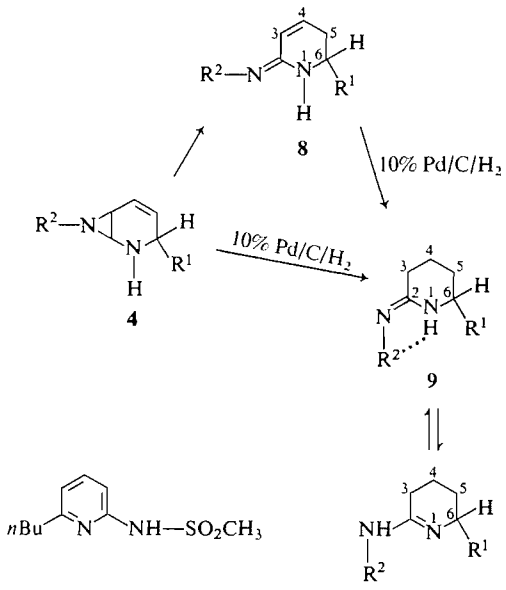
1*a* **7**

Neutral aluminum oxide chromatography (Brockman Activity 1) of the 2,7-diazabicyclo[4.1.0]hept-4-enes **4** gives rise to 1,2,5,6-tetrahydropyridylidene-2-cyan (sulfon) amides **8** in good yield (see Table 2). One possible mechanism for the formation of the alkylidene-2-cyan (sulfon) amides **8** may involve initial abstraction of the active C(1)H of **4** followed by opening of the aziridine ring and migration of the olefinic bond. Triethylamine also catalyzes the conversion of **4** to **8**. On the other hand, chromatography of **4***a* (R^1 = *n*Bu, R^2 = CN) on an acidic alumina (Brockman Activity 1) column gave **8***a* (7.7%) and unchanged **4***a* (92.3%). In contrast silica gel G tlc of **4***g* (R^1 = *n*Bu, R^2 = MeOCO) gives a quantitative yield of **8***e*.



4 **8**

Hydrogenation of 7-cyano (methoxycarbonyl)-2,7-diazabicyclo[4.1.0]hept-4-enes **4** with 10% palladium on charcoal and hydrogen gas at 35 psi gives a tautomeric mixture of piperidylidene-2-cyan (methoxycarbonyl) amide **9** and 3,4,5,6-tetrahydropyridyl-2-cyan (methoxycarbonyl) amide **10** (see Scheme 2 and Table 2). The ultraviolet spectrum of the tautomeric mixture **9***f* ⇌ **10***f* (R^1 = *n*Bu, R^2 = CN) exhibited one band at 244 nm attributed to the Ṅ—C=N group. The infrared spectrum shows the presence of two NH bands. The piperidine NH of **9***f* exhibits an absorption at 3240 cm^{-1} while the cyanamide **10***f* displays a NH absorption at 3120 cm^{-1}. The spectrum also displays a cyano band at 2180 cm^{-1} and imine bands at 1605 cm^{-1} due to **9***f* and at 1645 cm^{-1} due to **10***f*. The existence of a similar tautomeric equilibrium between piperidylidene-2-ethoxycarbonylamide and 3,4,5,6-tetrahydropyridyl-2-ethoxycarbonylamide has been reported (9). On the other hand, catalytic hydrogenation of **4***c* (R^1 = *n*Bu, R^2 = $MeSO_2$) afforded 6-*n*-butylpiperidylidene-2-methanesulfonamide **9***h* (91.8%) and 6-*n*-butylpyridyl-2-methanesulfonamide **11** (7.5%). The infrared spectrum of **9***h* lacked those absorptions expected for tautomer **10***h*. 6-*n*-Butylpyridyl-2-methanesulfonamide **11** likely arises as a result of dehydrogenation of an intermediate **8***c* (9). In a similar reaction, hydrogenation of **4***f*, possessing an R^2 *p*-aminobenzenesulfonyl group, afforded **9***i* in quantitative yield.



SCHEME 2. Substituents R^1 and R^2 for **8**, **9**, and **10** are as illustrated in Table 2.

Hydrogenation of 6-*n*-butyl-1,2,5,6-tetrahydropyridylidene-2-cyan (methanesulfon) amides **8** gave products identical to those obtained from reduction of **4**. For example, hydrogenation of **8***a* (R^1 = *n*Bu, R^2 = CN) gave a tautomeric mixture of **9***f* and **10***f*

TABLE 2. Chemical transformation of 3-substituted-2,7-diazabicyclo[4.1.0]hept-4-enes **4**

Compound	Procedure	R^1	R^2	Yield (%) 8	9 ⇋ 10	11
a	Neutral Al_2O_3 chrom. of **4**	*n*Bu	CN	79		
b	Al_2O_3 catalyzed opening of **4**	Ph	CN	100		
c	Neutral Al_2O_3 chrom. of **4**	*n*Bu	$MeSO_2$	100		
d	Neutral Al_2O_3 chrom. of **4**	*n*Bu	*p*-H_2N—C_6H_4—SO_2	92		
e	Silica gel G tlc of **4**	*n*Bu	MeOCO	100		
f	Pd/C/H_2 reduction of **4**	*n*Bu	CN		100	
g	Pd/C/H_2 reduction of **4**	Ph	CN		100

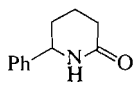
i	Pd/C/H_2 reduction of **4**	*n*Bu	*p*-H_2N—C_6H_4—SO_2		100[a]	
j	Pd/C/H_2 reduction of **4**	*n*Bu	MeOCO		63.4	
f	Pd/C/H_2 reduction of **8**	*n*Bu	CN		100	
h	Pd/C/H_2 reduction of **8**	*n*Bu	$MeSO_2$		91.5[a]	7.8

[a]The ir and ^{1}H nmr spectra exhibited absorptions only for tautomer **9**.

while hydrogenation of **8***c* (R^1 = *n*Bu, R^2 = $MeSO_2$) afforded **9***h* (91.5%) and the aromatic sulfonamide **11** (7.8%) (see Table 2).

Acid hydrolysis of a tautomeric mixture of **9***g* and **10***g* (R^1 = Ph, R^2 = CN) using a 10% H_2SO_4/MeOH solution (1:10 v/v) gave 6-phenyl-2-piperidone **12** (39%), thereby providing further evidence in support of structures **9** and **10**. The appearance



12

of the carbonyl band of **12** at 1640 cm^{-1} is in good agreement with that of 2-piperidone which appears at 1653 cm^{-1}. The carbonyl group of *N*-ethyl-3-piperidone hydrochloride appears at 1724 cm^{-1} (Aldrich Library of IR spectra).

The reactions of organic azides with 1,4-dihydropyridines are now in progress to broaden the scope of this reaction.

Experimental

Melting points were determined with a Büchi capillary apparatus and are uncorrected. Ultraviolet spectra were recorded on a Unicam SP 1800 spectrometer using absolute ethanol as solvent. Infrared spectra (potassium bromide unless otherwise noted) were taken on a Perkin-Elmer 267 or Unicam SP 1000 spectrometer. Nuclear magnetic resonance spectra were determined for solutions in deuterochloroform with TMS as internal standard with a Varian EM-360 spectrometer. Mass spectra were measured with an AEI-MS-50 mass spectrometer and these exact mass measurements are used in lieu of elemental analysis. All of the products described gave rise to a single spot on tlc using a solvent system less polar and more polar than the spectific solvent system described for purification of the reaction mixture. No residue remained after combustion of the products purified by the chromatographic procedures used. *Warning*: Cyanogen azide is a hazardous material. It should be handled only in solution. Concentration to pure material will result in violent detonation by heat or shock (10).

*2-*n*-Butyl-1,2-dihydropyridine (**1**a)*

To a solution of *n*-butyllithium (1.28 g, 20 mmol) in 50 mL anhydrous ether, under a nitrogen atmosphere at 0°C, pyridine (1.58 g, 20 mmol) was added dropwise with stirring. The resulting dark brown solution was stirred at 0°C for 35 min to afford *N*-lithio-2-*n*-butyl-1,2-dihydropyridine (20 mmol).

The dropwise addition of water (0.36 g, 20 mmol) with stirring at 0°C to the above solution afforded 2-*n*-butyl-1,2-dihydropyridine **1***a*. Removal of the supernatant via a syringe provided a solution of **1***a* containing about 0.05 equiv. suspended lithium hydroxide.

*2-*n*-Butyl-1,2-dihydropyridine (**1**a, Lithium Hydroxide Free)*

To a solution of *N*-lithio-2-*n*-butyl-1,2-dihydropyridine (4.29 g, 30 mmol), prepared from *n*-butyllithium (30 mmol) and pyridine (30 mmol) as described above, in 100 mL anhydrous ether under a nitrogen atmosphere, water (2.0 g, 110 mmol) was added dropwise with stirring at 0°C. The resulting pale yellow solution of **1***a* was stirred for 10 min, anhydrous sodium sulfate (25 g) was added, and the mixture was stirred for an additional 15 min at 0°C. The solution was allowed to stand without agitation for 5 min after which an aliquot of the supernatant containing the required amount of **1***a* was removed using a syringe under a nitrogen atmosphere.

*3-*n*-Butyl-7-cyano-2,7-diazabicyclo[4.1.0]hept-4-ene (**4**a)*

A solution of lithium hydroxide free **1***a* (2.74 g, 20 mmol) in 67 mL dry ether was added slowly with stirring to a solution of cyanogen azide (25 mmol), prepared from cyanogen bromide (2.65 g, 25 mmol) and sodium azide (8.125 g, 125 mmol) as reported previously (3), in 100 mL acetonitrile under a nitrogen atmosphere at 0°C. The reaction was allowed to proceed at 0°C for 1 h prior to warming to 25°C. Removal of the solvent *in vacuo* gave a light orange solid which on recrystallization from 100 mL ether–hexane (1:4 v/v) afforded **4***a* (3.54 g, 100%); mp 75°C; ir: 3225 (m, NH), 2180 (s, C≡N), and 1605 (s, C=C) cm^{-1}; ^{1}H nmr δ: 0.9 (t, J = 7 Hz, 3H, $CH_2CH_2CH_2CH_3$), 1.1–1.9 (m, 6H, $CH_2CH_2CH_2CH_3$), 3.21 (m, 1H, H-6), 3.3 (m, 1H, H-1), 4.17 (m, 1H, H-3), 5.8 (m, 2H, H-4, H-5), 8.63 (b s, 1, NH, exchanges with deuterium oxide). *Exact Mass* calcd. for $C_{10}H_{15}N_3$: 177.1266; found (high resolution ms): 177.1265. Reaction of **1***a* (20 mmol), containing lithium hydroxide (1 mmol), with cyanogen azide (40 mmol) as described above afforded **4***a* (79%).

*3-Phenyl-7-cyano-2,7-diazabicyclo[4.1.0]hept-4-ene (**4**b)*

A solution of lithium hydroxide free **1***b* (3.1 g, 20 mmol) in

100 mL dry tetrahydrofuran[3] was added slowly with stirring to a solution of cyanogen azide (20 mmol) in 100 mL acetonitrile under a nitrogen atmosphere at 0°C. The reaction was maintained at 0°C for 1 h and after warming to 25°C removal of the solvent *in vacuo* gave an orange solid. Recrystallization from 100 mL ether–hexane (1:4 v/v) yielded **4***b* (3.94 g, 100%); mp 147°C; ir: 3235 (m, NH), 2180 (s, C≡N), and 1610 (s, C=C) cm^{-1}; ^1H nmr δ: 3.2 (m, 1H, H-6), 3.3 (m, 1H, H-1), 5.08 (m, 1H, H-3), 5.77 (m, 2H, H-4, H-5), 7.26 (m, 5H, C_6H_5), 7.82 (b s, 1, NH, exchanges with deuterium oxide). *Exact Mass* calcd. for $C_{12}H_{11}N_3$: 197.0953; found (high resolution ms): 197.0954.

*3-*n*-Butyl-7-methanesulfonyl-2,7-diazabicyclo[4.1.0]hept-4-ene (**4**c) and 6-*n*-Butyl-3 diazo-1,2,3,6-tetrahydropyridylidene-2-methanesulfonamide (**6**c)*

A solution of **1***a* (2.74 g, 20 mmol) containing lithium hydroxide (0.024 g, 1 mmol) in 50 mL dry ether was added slowly with stirring to a solution of methanesulfonyl azide (2.42 g, 20 mmol) in 50 mL dry ether under a nitrogen atmosphere at 0°C. The reaction was allowed to proceed 1 h at 0°C before warming to 25°C. Addition of water (50 mL), extraction with chloroform (2 × 50 mL), drying (sodium sulfate), and removal of the solvent *in vacuo* afforded a reddish black semi-solid which was subjected to preparative tlc on six 8 in × 8 in. silica gel G plates, 0.75 mm in thickness, using benzene – ethyl acetate (2:1 v/v) as development solvent. Extraction with warm methanol (50 mL) of the band having R_f 0.59 gave **6***c* (0.894 g, 17.5%); ir: 3290 (m, NH), 2090 (s, N_2), and 1580 (s, C=N) cm^{-1}; ^1H nmr δ: 0.96 (t, J = 7 Hz, 3H, $CH_2CH_2CH_2CH_3$), 1.15–1.85 (m, 6H, $CH_2CH_2CH_2CH_3$), 3.02 (s, 3H, SO_2CH_3), 4.33 (m, 1H, H-6), 5.3 (d, $J_{4,5}$ = 10 Hz of d, $J_{5,6}$ = 4 Hz of d, $J_{1,5}$ = 1.5 Hz, 1H, H-5), 6.11 (d, $J_{4,5}$ = 10 Hz of d, $J_{4,6}$ = 1.5 Hz, 1H, H-4), 8.1 (b s, 1H, NH, exchanges with deuterium oxide). *Exact Mass* calcd. for $C_{10}H_{16}N_4O^{32}S$: 256.0994; found (high resolution ms): 256.0984. Extraction of the band with R_f 0.51 afforded 2-*n*-butyl pyridine (0.21 g, 7.7%). Extraction of the band with R_f 0.36 yielded **4***c* (1.974 g, 42.9%); ir: 3280 (m, NH) and 1600 (s, C=C) cm^{-1}; ^1H nmr δ: 0.9 (t, J = 7 Hz, 3H, $CH_2CH_2CH_2CH_3$), 1.1–1.8 (m, 6H, $CH_2CH_2CH_2CH_3$), 2.93 (s, 3H, SO_2CH_3), 3.06 (m, 2H, H-1, H-6), 4.05 (m, 1H, H-3), 5.76 (m, 2H, H-4, H-5), 8.40 (b s, 1, NH, exchanges with deuterium oxide). *Exact Mass* Calcd. for $C_{10}H_{18}N_2O_2{}^{32}S$: 230.1089; found (high resolution ms): 230.1085.

Reaction of lithium hydroxide free **1***a* (2.7 g, 20 mmol) in 67 mL dry ether with methanesulfonyl azide (2.42 g, 20 mmol) in 50 mL dry ether under a nitrogen atmosphere at 0°C was allowed to proceed for 1 h prior to warming to 25°C. Removal of the solvent *in vacuo* gave **4***c* (4.6 g, 100%); identical (ir, ^1H nmr) with the same product described above.

*3-*n*-Butyl-7-benzenesulfonyl-2,7-diazabicyclo[4.1.0]hept-4-ene (**4**d) and 6-*n*-Butyl-3-diazo-1,2,3,6-tetrahydropyridylidene-2-benzenesulfonamide (**6**d)*

A solution of **1***a* (2.74 g, 20 mmol) containing lithium hydroxide (0.024 g, 1 mmol) in 50 mL of dry ether was added slowly with stirring to a solution of benzenesulfonyl azide (3.67 g, 20 mmol) in 50 mL dry ether under a nitrogen atmosphere at 0°C. The reaction was allowed to proceed 1 h at 0°C before warming to 25°C. Addition of water (50 mL), extraction with chloroform (2 × 50 mL), drying (Na_2SO_4), and removal of the solvent *in vacuo* afforded a reddish black semi-solid which was subjected to preparative tlc using six 8 in. × 8 in. silica gel G plates, 0.75 mm in thickness, with benzene – ethyl acetate (4:1 v/v) as development solvent. Extraction of the band having R_f 0.68 using warm methanol (50 mL) gave **6***d* (2.17 g, 34.1%); mp: 103–104°C (dec. with evolution of gas); ir: 3280 (m, NH), 2090 (s, N_2), and 1570 (s, C=N) cm^{-1}; ^1H nmr δ: 0.85 (t, J = 7 Hz, 3H, $CH_2CH_2CH_2CH_3$), 1.05–1.8 (m, 6H, $CH_2CH_2CH_2CH_3$), 4.3 (m, 1H, H-6), 5.2 (d, $J_{4,5}$ = 10.5 Hz of d, $J_{5,6}$ = 4 Hz of d, $J_{1,5}$ = 1.5 Hz, 1H, H-5), 6.04 (d, $J_{4,5}$ = 10.5 Hz of d, $J_{4,6}$ = 1.25 Hz, 1H, H-4), 7.5 (m, 3, *meta* and *para* phenyl hydrogens), 7.98 (m, 2, *ortho* phenyl hydrogens), 8.26 (b s, 1, NH, exchanges with deuterium oxide). *Exact Mass* calcd. for $C_{15}H_{18}N_4O_2{}^{32}S$: 318.1150; found (high resolution ms): 318.1137. *Anal.* calcd. for $C_{15}H_{18}N_4O_2{}^{32}S$: C 56.58, H 5.70, N 17.6, O 10.05, S 10.07; found: C 56.48, H 5.72, N 17.6, O 9.87, S 10.04. Extraction of the band with R_f 0.53 afforded **4***d* (2.38 g, 40.7%); mp: 106°C; ir: 3205 (m, NH) and 1600 (s, C=C) cm^{-1}; ^1H nmr δ: 0.88 (t, J = 7 Hz, 3H, $CH_2CH_2CH_2CH_3$), 1.1–1.8 (m, 6H, $CH_2CH_2CH_2CH_3$), 3.06 (m, 2H, H-1, H-6), 4.07 (m, 1H, H-3), 5.72 (m, 2H, H-4, H-5), 7.5 (m, 3, *meta* and *para* phenyl hydrogens), 7.98 (m, 2, *ortho* phenyl hydrogens), 8.78 (b s, 1, NH, exchanges with deuterium oxide). *Exact Mass* calcd. for $C_{15}H_{20}N_2O_2{}^{32}S$: 292.1245; found (high resolution ms): 292.1232.

Reaction of lithium hydroxide free **1***a* (2.7 g, 20 mmol) in 67 mL dry ether with benzenesulfonyl azide (3.67 g, 20 mmol) in 50 mL dry ether under a nitrogen atmosphere at 0°C was allowed to proceed for 1 h prior to warming to 25°C. Removal of the solvent *in vacuo* gave **4***d* (5.84 g, 100%) identical (ir, ^1H nmr) with the same compound described above.

*3-*n*-Butyl-7-(N-acetyl)sulfanilyl-2,7-diazabicyclo[4.1.0]hept-4-ene (**4**e) and 6-*n*-Butyl-3-diazo-1,2,3,6-tetrahydropyridylidene-2-(N-acetyl)sulfanilamide (**6**e)*

A solution of **1***a* (1.37 g, 10 mmol) containing lithium hydroxide (0.012 g, 0.5 mmol) in 50 mL dry ether was added slowly with stirring to a solution of *N*-acetylsulfanilyl azide (2.42 g, 10 mmol) in 75 mL ether–acetonitrile (2:1 v/v) under a nitrogen atmosphere at 0°C. The reaction was allowed to proceed 1 h at 0°C before warming to 25°C. Addition of water (50 mL), extraction with chloroform (2 × 50 mL), drying (Na_2SO_4), and removal of the solvent *in vacuo* afforded a red semi-solid which was subjected to preparative tlc on six 8 in. × 8 in. silica gel G plates, 0.75 mm in thickness, using benzene – ethyl acetate (1:2 v/v) as development solvent. Extraction of the band having R_f 0.45 with warm methanol (50 mL) gave **6***e* (0.471 g, 12.5%); mp: 77°C (dec. with evolution of a gas); ir: 3300 (m, NH), 3180 (m, NH), 2090 (s, =N_2), and 1585 (s, C=N) cm^{-1}; ^1H nmr δ: 0.8 (m, 3H, $CH_2CH_2CH_2CH_3$), 1.05–1.8 (m, 6H, $CH_2CH_2CH_2CH_3$), 2.17 (s, 3H, $COCH_3$), 4.26 (m, 1H, H-6), 5.2 (d, $J_{4,5}$ = 10 Hz of d, $J_{5,6}$ = 4 Hz of d, $J_{1,5}$ = 1.25 Hz, 1H, H-5), 5.98 (d, $J_{4,5}$ = 10 Hz of d, $J_{4,6}$ = 1.25 Hz, 1H, H-4), 7.73 (m, 4H, C_6H_4), 8.1 (b s, 1, NH, exchanges with deuterium oxide), 8.68 (b s, 1, CONH, exchanges with deuterium oxide). *Exact Mass* calcd. for $C_{17}H_{21}N_3O_3{}^{32}S$: 347.1304 ($M^+$ − 28 due to loss of N_2); found (high resolution ms): 347.1304. Extraction of the band at R_f 0.26 yielded **4***e* (2.76 g, 79%), mp 126°C; ir: 3300 (m, NH), 3180 (m, NH), 1675 (s, C=O), and 1590 (s, C=C) cm^{-1}; ^1H nmr δ: 0.9 (t, J = 7 Hz), 3H, $CH_2CH_2CH_2CH_3$), 1.05–1.8 (m, 6H, $CH_2CH_2CH_2CH_3$), 2.18 (s, 3H, $COCH_3$), 3.06 (m, 2H, H-1, H-6), 4.1 (m, 1H, H-3), 5.75 (m, 2H, H-4, H-5), 7.8 (m, 4H, C_6H_4), 8.7 (b s, 1, NH, exchanges with deuterium oxide), 9.0 (s, 1H, CONH, exchanges with deuterium oxide). *Exact Mass* calcd. for $C_{17}H_{23}N_3O_3{}^{32}S$: 349.1460; found (high resolution ms): 349.1463.

Reaction of lithium hydroxide free **1***a* (0.685 g, 5 mmol) in 17 mL dry ether with *N*-acetylsulfanilyl azide **2***d* (1.2 g, 5 mmol) in 50 mL ether–acetonitrile (2:1 v/v) under a nitrogen

[3]Lithium hydroxide free 2-phenyl-1,2-dihydropyridine **1***b* is prepared by the same procedure as **1***a* except phenyllithium is used in place of *n*-butyllithium.

atmosphere at 0°C was allowed to proceed for 1 h prior to warming to 25°C. Removal of the solvent *in vacuo* gave **4***e* (1.75 g, 100%), identical (ir, ^{1}H nmr) with the same compound described above.

*3-*n*-Butyl-7-sulfanilyl-2,7-diazabicyclo[4.1.0]hept-4-ene (**4**f) and 6-*n*-Butyl-3-diazo-1,2,3,6-tetrahydropyridylidene-2-sulfanilamide (**6**f)*

A solution of **1***a* (1.37 g, 10 mmol) containing lithium hydroxide (0.012 g, 0.5 mmol) in 50 mL dry ether was added slowly with stirring to a solution of sulfanilyl azide **2***e* (1.98 g, 10 mmol) in 50 mL ether under a nitrogen atmosphere at 0°C. The reaction was allowed to proceed for 1 h at 0°C before warming to 25°C. Addition of water (50 mL), extraction with chloroform (2 × 50 mL), drying (Na_2SO_4), and removal of the solvent *in vacuo* afforded an orange solid which was subjected to preparative tlc on six 8 in. × 8 in. silica gel G plates, 0.75 mm in thickness, using benzene – ethyl acetate (1:2 v/v) as development solvent. Extraction of the fraction having R_f 0.88 using 50 mL warm methanol gave **6***f* (0.042 g, 1.3%), mp 134°C (dec. with evolution of a gas); ir: 3460 (m, NH_2), 3360 (m, NH_2), 3310 (m, NH), 2090 (s, N_2), and 1590 (s, C=N) cm^{-1}; ^{1}H nmr δ: 0.88 (t, J = 7 Hz, 3H, $CH_2CH_2CH_2CH_3$), 1.05–1.8 (m, 6H, $CH_2CH_2CH_2CH_3$), 4.27 (m, 3H, H-6, NH_2, exchanges with deuterium oxide), 5.2 (d, $J_{4,5}$ = 10 Hz of d, $J_{5,6}$ = 4 Hz of d, $J_{1,5}$ = 1.5 Hz, 1H, H-5), 6.0 (d, $J_{4,5}$ = 10 Hz of d, $J_{4,6}$ = 1.25 Hz, 1H, H-4), 6.68 (m, 2H, *ortho* amino phenyl hydrogens), 7.72 (m, 2H, *ortho* sulfonyl phenyl hydrogens), 8.16 (b s, 1, NH, exchanges with deuterium oxide). *Exact Mass* calcd. for $C_{15}H_{19}N_3O_2{}^{32}S$: 305.1194 ($M^+$ − 28 due to loss of N_2); found (high resolution ms): 305.1195. Extraction of the band having R_f 0.54 afforded **4***f* (2.41 g, 78.5%), mp 132°C; ir: 3460 (m, NH_2), 3360 (m, NH_2), 3290 (m, NH), and 1590 (s, C=C) cm^{-1}; ^{1}H nmr (DMSO-d_6) δ: 0.87 (t, J = 7 Hz, 3H, $CH_2CH_2CH_2CH_3$), 1.1–1.8 (m, 6H, $CH_2CH_2CH_2CH_3$), 3.0 (m, 2H, H-1, H-6), 4.1 (m, 1H, H-3), 4.8 (b s, 2H, NH_2, exchanges with deuterium oxide), 5.71 (m, 2H, H-4, H-5), 6.7 (m, 2H, *ortho* amino-phenyl hydrogens), 7.65 (m, 2H, *ortho* sulfonyl phenyl hydrogens), 8.6 (b s, 1H, NH, exchanges with deuterium oxide). *Exact Mass* calcd. for $C_{15}H_{21}N_3O_2{}^{32}S$: 307.1355; found (high resolution ms): 307.1353.

Reaction of lithium hydroxide free **1***a* (0.274 g, 2 mmol) in 7 mL dry ether with sulfanilyl azide **3***e* (0.396 g, 2 mmol) in 50 mL dry ether under a nitrogen atmosphere at 0°C was allowed to proceed for 1 h prior to warming to 25°C. Removal of the solvent *in vacuo* gave **4***f* (0.614 g, 100%), identical (ir, ^{1}H nmr) with the same compound described above.

*3-*n*-Butyl-7-methoxycarbonyl-2,7-diazabicyclo[4.1.0]hept-4-ene (**4**g)*

A solution of lithium hydroxide free **1***a* (1.37 g, 10 mmol) in 33 mL dry ether was added slowly with stirring to a solution of methoxycarbonyl azide **2***f* (1.01 g, 10 mmol) in 50 mL dry ether under a nitrogen atmosphere at 25°C. The reaction was allowed to proceed for 1 h and then completed as described previously to afford **4***g* (2.1 g, 100%); ir (neat): 3210 (m, NH), 1730 (s, C=O), and 1590 (s, C=C) cm^{-1}; ^{1}H nmr δ: 0.9 (t, J = 7 Hz, 3H, $CH_2CH_2CH_2CH_3$), 1.1–1.9 (m, 6H, $CH_2CH_2CH_2CH_3$), 3.1 (m, 2H, H-1, H-6), 3.75 (s, 3H, OCH_3), 4.1 (m, 1H, H-3), 5.82 (m, 2H, H-4, H-5), 9.8 (b s, 1, NH, exchanges with deuterium oxide). *Exact Mass* calcd. for $C_{11}H_{18}N_2O_2$: 210.1368; found (high resolution ms): 210.1365.

*6-*n*-Butyl-1,2,5,6-tetrahydropyridylidene-2-phenylcarbonyl-amide (**8**, R^1 = n*Bu*, R^2 = *PhCO*)*

A solution of lithium hydroxide free **1***a* (1.37 g, 10 mmol) in 67 mL dry ether was added slowly with stirring to a solution of benzoyl azide (7.35 g, 50 mmol) in 50 mL dry ether under a nitrogen atmosphere at 25°C. The reaction was allowed to proceed for 24 h before warming to 25°C. Addition of water (50 mL), extraction with chloroform (2 × 50 mL), drying (Na_2SO_4), and removal of the solvent *in vacuo* afforded a red oil which was subjected to preparative tlc on six 8 in. × 8 in. silica gel G plates, 0.75 mm in thickness, using benzene–ether (3:1 v/v) as development solvent. Extraction of the band having R_f 0.93 with 50 mL methanol afforded unreacted benzoyl azide (3.5 g, 47.7%). Extraction of the fraction having R_f 0.61 gave rise to **8** (1.02 g, 39.7%); ir: 3180 (m, NH), 1640 (s, C=O), 1595 (s, C=C), and 1560 (s, C=N) cm^{-1}; ^{1}H nmr δ: 0.9 (t, J = 7 Hz, 3H, $CH_2CH_2CH_2CH_3$), 1.1–1.9 (m, 6H, $CH_2CH_2CH_2CH_3$), 2.38 (m, 2H, H-5), 3.6 (m, 1H, H-6), 6.14 (d, $J_{3,4}$ = 10 Hz of d, $J_{3,5}$ = 2.0 Hz of d, $J_{3,5'}$ = 1.5 Hz, 1H, H-3), 6.6 (d, $J_{3,4}$ = 10 Hz of d, $J_{4,5}$ = 5.0 Hz of d, $J_{4,5'}$ = 3.5 Hz, 1H, H-4), 7.4 (m, 3H, *meta* and *para* phenyl hydrogens), 8.3 (m, 2H, *ortho* phenyl hydrogens), 10.6 (b s, 1H, NH, exchanges with deuterium oxide). *Exact Mass* calcd. for $C_{16}H_{20}N_2O$: 256.1576; found (high resolution ms): 256.1573. Extraction of the band having R_f 0.36 afforded 2-*n*-butylpyridine (0.208 g, 39.7%).

*6,6′-Di-*n*-butyl-1,2,3,6-tetrahydro-2,3′-dipyridyl (**7**)*

A solution of lithium hydroxide free **1***a* (2.74 g, 20 mmol) in 67 mL dry ether was added slowly with stirring to a solution of hydrazoic acid (34.4 mL of 5.8 *M*, 20 mmol) in 50 mL dry benzene under a nitrogen atmosphere at 25°C. The reaction was allowed to proceed for 24 h before warming to 25°C. Addition of water (50 mL), drying (Na_2SO_4), and removal of the solvent *in vacuo* gave a reddish brown oil. Preparative tlc was effected on six 8 in. × 8 in. silica gel G plates, 0.75 mm in thickness, using benzene–methanol (7:1 v/v) as development solvent. Extraction of the band having R_f 0.75 with 50 mL warm methanol afforded 2-*n*-butylpyridine (0.329 g, 12.2%). Extraction of the band having R_f 0.62 yielded **7** (0.873 g, 64.7%) which showed ir and ^{1}H nmr spectra identical to those of an authentic sample of **7** previously reported (11).

*6-*n*-Butyl-1,2,5,6-tetrahydropyridylidene-2-cyanamide (**8**a)*

Elution of **4***a* (0.406 g, 2.3 mmol) from a 2.5 cm × 33 cm neutral alumina column (Brockman Activity 1) using ethyl acetate (300 mL) gave a white solid which was subjected to preparative tlc on six 8 in. × 8 in. silica gel G plates, 0.75 mm in thickness, using ether – ethyl acetate (9:1 v/v) as development solvent. Extraction of the fraction having R_f 0.8 with 50 mL warm methanol gave 6-*n*-butyl-1,2,5,6-tetrahydropyridylidene-2-cyanamide **8***a* (0.321 g, 79%), mp 61°C; ir: 3240 (m, NH), 2180 (s, C≡N), 1645 (s, C=C), and 1575 (s, C=N) cm^{-1}; ^{1}H nmr δ: 0.9 (t, J = 7 Hz, 3H, $CH_2CH_2CH_2CH_3$), 1.1–2.0 (m, 6H, $CH_2CH_2CH_2CH_3$), 2.4 (m, 2H, H-5), 3.6 (m, 1H, H-6), 6.3 (m, 1H, H-3), 6.65 (m, 1H, H-4), 7.45 (m, 1H, NH, exchanges with D_2O). *Exact Mass* calcd. for $C_{10}H_{15}N_3$: 177.1266; found (high resolution ms): 177.1265.

*6-Phenyl-1,2,5,6-tetrahydropyridylidene-2-cyanamide (**8**b)*

A suspension of 5 g neutral alumina (Brockman Activity 1) in 25 mL chloroform containing **4***b* (0.216 g, 1.1 mmol) was stirred at 25°C for 72 h. Extraction with ethyl acetate (100 mL) and removal of the solvent *in vacuo* afforded **8***b* (0.218 g, 100%), mp 129°C; ir: 3190 (m, NH), 2180 (s, C≡N), 1650 (s, C=C), and 1580 (s, C=N) cm^{-1}; ^{1}H nmr δ: 2.6 (m, 2H, H-5), 4.65 (m, 1H, H-6), 6.35 (m, 1H, H-3), 6.56 (m, 1H, H-4), 7.25 (m, 5H, C_6H_5), 8.52 (b s, 1, NH, exchanges with D_2O). *Exact Mass* calcd. for $C_{12}H_{11}N_3$: 197.0953; found (high resolution ms): 197.0943.

*6-*n*-Butyl-1,2,5,6-tetrahydropyridylidene-2-methanesulfonamide (**8**c)*

Elution of **4***c* (0.364 g, 1.6 mmol) from a neutral alumina column (Brockman Activity 1) 2.5 cm × 20 cm using benzene –

ethyl acetate (4:1 v/v) (400 ml) gave **8***c* in quantitative yield; ir (neat): 3310 (m, NH), 1640 (s, C=C), and 1580 (s, C=N) cm^{-1}; ^1H nmr δ: 0.91 (t, J = 7 Hz, 3H, $CH_2CH_2CH_2CH_3$), 1.1–1.8 (m, 6H, $CH_2CH_2CH_2CH_3$), 2.42 (m, 2H, H-5), 2.97 (s, 3H, SO_2CH_3), 3.6 (m, 1H, H-6), 5.92 (m, 1H, H-3), 6.7 (d, $J_{3,4}$ = 10 Hz of d, $J_{4,5}$ = 5 Hz of d, $J_{4,5'}$ = 3.5 Hz, 1H, H-4). *Exact Mass* calcd. for $C_{10}H_{18}N_2O_2{}^{32}S$: 230.1089; found (high resolution ms): 230.1085.

6-n-*Butyl-1,2,5,6-tetrahydropyridylidene-2-sulfanilamide (***8***d)*

Elution of **4***f* (1.73 g, 5.6 mmol) from a neutral alumina column (Brockman Activity 1) 2.5 cm × 20 cm after standing for 1 week using chloroform – ethyl acetate (19:1 v/v) gave **8***d* (1.6 g, 92%), mp 162°C; ir: 3450 (m, NH_2), 3350 (m, NH_2), 3320 (m, NH), 1630 (s, C=C), and 1580 (s, C=N) cm^{-1}; ^1H nmr δ: 0.95 (t, J = 7 Hz, 3H, $CH_2CH_2CH_2CH_3$), 1.1–1.8 (m, 6H, $CH_2CH_2CH_2CH_3$), 2.34 (m, 2H, H-5), 3.55 (m, 1H, H-6), 4.2 (m, 2H, NH_2, exchanges with deuterium oxide), 5.95 (d, $J_{3,4}$ = 10 Hz of d, $J_{3,5}$ = 2 Hz, 1H, H-3), 6.6 (m, 1H, H-4), 6.65 (m, 2H, *ortho* amino phenyl hydrogens), 7.75 (m, 2H, *ortho* sulfonyl phenyl hydrogens), 8.1 (b s, 1H, NH, exchanges with deuterium oxide). *Exact Mass* calcd. for $C_{15}H_{21}N_3O_2{}^{32}S$: 307.1354; found (high resolution ms): 307.1364.

6-n-*Butyl-1,2,5,6-tetrahydropyridylidene-2-methoxycarbonylamide (***8***e)*

Preparative tlc of **4***g* (0.432 g, 2.06 mmol) was effected on six 8 in. × 8 in. silica gel G plates, 0.75 mm in thickness, using benzene – ethyl acetate (1:9 v/v) as development solvent. Extraction of the fraction having R_f 0.28 using methanol (50 mL) afforded **8***e* (0.432 g, 100%); ir (neat): 3260 (m, NH), 1650 (s, C=O), 1630 (s, C=C), and 1570 (s, C=N) cm^{-1}; ^1H nmr δ: 0.9 (t, J = 7 Hz, 3H, $CH_2CH_2CH_2CH_3$), 1.1–1.8 (m, 6H, $CH_2CH_2CH_2CH_3$), 2.4 (m, 2H, H-5), 3.6 (m, 1H, H-6), 3.73 (s, 3H, OCH_3), 6.0 (d, $J_{3,4}$ = 10 Hz of d, $J_{3,5}$ = 2.0 Hz of d, $J_{3,5'}$ = 1.5 Hz, 1H, H-3), 6.6 (d, $J_{3,4}$ = 10 Hz of d, $J_{4,5}$ = 5.0 Hz of d, $J_{4,5'}$ = 3.5 Hz, 1H, H-4), 9.6 (b s, 1H, NH, exchanges with deuterium oxide). *Exact Mass* calcd. for $C_{11}H_{18}N_2O_2$: 210.1368; found (high resolution ms): 210.1365.

6-n-*Butylpiperidylidene-2-cyanamide (***9***f) and 6*-n-*Butyl-3,4,5,6-tetrahydropyridyl-2-cyanamide (***10***f)*

Hydrogenation of **4***a* (0.12 g, 0.68 mmol) or **8***a* (0.123 g, 0.695 mmol) in 75 mL methanol using 45 mg 10% palladium on charcoal and hydrogen gas at 35 psi for 4 h at 25°C followed by filtration and removal of the solvent *in vacuo* afforded the tautomeric mixture 6-*n*-butylpiperidylidene-2-cyanamide (**9***f*) and 6-*n*-butyl-3,4,5,6-tetrahydropyridylidene-2-cyanamide (**10***f*) in quantitative yield (0.121 g and 0.124 g respectively); ir: 3240 (**9***f*) (m, NH), 3120 (**10***f*) (m, NH), 2180 (s, C≡N), 1645 (**10***f*) (s, C=N), and 1605 (**9***f*) (s, C=N) cm^{-1}; ^1H nmr δ: 0.9 (t, J = 7 Hz, 3H, $CH_2CH_2CH_2CH_3$), 1.1–2.3 (m, 10H, $CH_2CH_2CH_2CH_3$, H-4, H-5), 2.7 (m, 2H, H-3), 3.4 (m, 1H, H-6), 8.0 (b s, 1H, NH, exchanges with D_2O). *Exact Mass* calcd. for $C_{10}H_{17}N_3$: 179.1422; found (high resolution ms): 179.1418.

*6-Phenylpiperidylidene-2-cyanamide (***9***g) and 6-Phenyl-3,4,5,6-tetrahydropyridyl-2-cyanamide (***10***g)*

Hydrogenation of **4***b* (0.132 g, 0.67 mmol) or **8***b* (0.137 g, 0.695 mmol) in 75 mL methanol using 45 mg 10% palladium on charcoal and hydrogen gas at 35 psi for 4 h at 25°C followed by filtration and removal of the solvent *in vacuo* afforded the tautomeric mixture of **9***g* and **10***g* in quantitative yield; ir: 3230 (m, NH) (**9***g*), 3140 (m, NH) (**10***g*), 2170 (s, C≡N), 1600 (s, C=N) (**10***g*), and 1575 (s, C=N) (**9***g*) cm^{-1}; ^1H nmr δ: 1.5–2.3 (m, 4H, H-4, H-5), 2.7 (m, 2H, H-3), 4.6 (m, 1H, H-6), 7.3 (m, 5H, C_6H_5), 7.45 (b s, 1H, NH, exchanges with D_2O). *Exact Mass* calcd. for $C_{12}H_{13}N_3$: 199.1110; found (high resolution ms): 199.1100.

6-n-*Butylpiperidylidene-2-methanesulfonamide (***9***h) and 6*-n-*Butylpyridyl-2-methanesulfonamide (***11***)*

Hydrogenation of **4***c* (0.121 g, 0.526 mmol) or **8***c* (0.181 g, 0.787 mmol) in 75 mL methanol using 75 mg 10% palladium on charcoal and hydrogen gas at 35 psi for 4 h at 25°C, followed by filtration and removal of the solvent *in vacuo*, gave a colorless oil. Preparative tlc was effected on two 8 in. × 8 in. silica gel G plates, 0.75 mm in thickness, using benzene – ethyl acetate (1:2 v/v) as the development solvent. Extraction of the band having R_f 0.91 with 50 mL methanol afforded **11** (0.009 g, 7.5% and 0.014 g, 7.8% respectively); ir: 3240 (m, NH) cm^{-1}; ^1H nmr δ: 0.93 (t, J = 7 Hz, 3H, $CH_2CH_2CH_2CH_3$), 1.1–1.9 (m, 4H, $CH_2CH_2CH_2CH_3$), 2.7 (t, J = 7 Hz, 2H, $CH_2CH_2CH_2CH_3$), 3.17 (s, 3H, SO_2CH_3), 6.67 (d, $J_{3,4}$ = 7.5 Hz of d, $J_{3,5}$ = 1.0 Hz, 1H, H-3), 6.98 (d, $J_{4,5}$ = 9.0 Hz of d, $J_{3,5}$ = 1.0 Hz, 1H, H-5), 7.6 (d, $J_{4,5}$ = 9.0 Hz of d, $J_{3,4}$ = 7.5 Hz, 1H, H-4), 8.4 (b s, 1H, NH, exchanges with deuterium oxide). *Exact Mass* calcd. for $C_{10}H_{16}N_2O_2{}^{32}S$: 228.0932; found (high resolution ms): 228.0930. Extraction of the band having R_f 0.46 afforded **9***h* (0.112 g, 91.8% and 0.167 g, 91.5% respectively); ir: 3280 (m, NH), 1600 (s, C=N) cm^{-1}; ^1H nmr δ: 0.9 (t, J = 7 Hz, 3H, $CH_2CH_2CH_2CH_3$), 1.1–2.15 (m, 10H, $CH_2CH_2CH_2CH_3$, H-4, H-5), 2.46 (m, 2H, H-3), 2.95 (s, 3H, SO_2CH_3), 3.37 (m, 1H, H-6), 8.3 (b s, 1H, NH, exchanges with deuterium oxide). *Exact Mass* calcd. for $C_{10}H_{20}N_2O_2{}^{32}S$: 232.1245; found (high resolution ms): 232.1244.

6-n-*Butylpiperidylidene-2-sulfanilamide (***9***i)*

Hydrogenation of **4***f* (1.74 g, 5.6 mmol) or **8***d* (0.116 g, 0.38 mmol) in 100 mL methanol using 0.93 g 10% palladium on charcoal and hydrogen gas at 35 psi for 4 h at 25°C followed by filtration and removal of the solvent *in vacuo* gave **9***i* in quantitative yield, mp 136°C; ir: 3455 (m, NH_2), 3355 (m, NH_2), 3300 (m, NH), and 1590 (s, C=N) cm^{-1}; ^1H nmr δ: 0.86 (t, J = 7 Hz, 3H, $CH_2CH_2CH_2CH_3$), 1.1–2.1 (m, 10H, $CH_2CH_2CH_2CH_3$, H-4, H-5), 2.4 (m, 2H, H-3), 3.3 (m, 1H, H-6), 4.5 (b s, 2H, NH_2, exchanges with deuterium oxide), 6.6 (m, 2H, *ortho* amino phenyl hydrogens), 7.65 (m, 2H, *ortho* sulfonyl phenyl hydrogens), 8.37 (b s, 1H, NH, exchanges with deuterium oxide). *Exact Mass* calcd. for $C_{15}H_{23}N_3O_2{}^{32}S$: 309.1511; found (high resolution ms): 309.1516.

6-n-*Butylpiperidylidene-2-methoxycarbonylamide (***9***j) and 6*-n-*Butyl-3,4,5,6-tetrahydropyridyl-2-methoxycarbonylamide (***10***j)*

Hydrogenation of **4***g* (0.434 g, 2.07 mmol) in 75 mL methanol using 300 mg 10% palladium on charcoal and hydrogen gas at 35 psi for 4 h at 25°C followed by filtration and removal of the solvent *in vacuo* afforded a light brown oil. Preparative tlc was effected on six 8 in. × 8 in. silica gel G plates, 0.75 mm in thickness, using ethyl acetate – isopropanol (9:1 v/v) as development solvent. Extraction of the fraction having R_f 0.51 with 50 mL methanol afforded the tautomeric mixture of **9***j* and **10***j* (0.278 g, 63.4%); ir: (neat): 3210 (m, NH) (**9***j*) and 3150 (m, NH) (**10***j*), 1635 (s, C=O), and 1590 (s, C=N) cm^{-1}; ^1H nmr δ: 0.9 (t, J = 7 Hz, 3H, $CH_2CH_2CH_2CH_3$), 1.1–2.2 (m, 10H, $CH_2CH_2CH_2CH_3$, H-4, H-5), 2.48 (m, 2H, H-3), 3.45 (m, 1H, H-6), 3.71 (s, 3H, OCH_3), 10.2 (b s, 1H, NH, exchanges with deuterium oxide). *Exact Mass* calcd. for $C_{11}H_{20}N_2O_2$: 212.1525; found (high resolution ms): 212.1522.

*6-Phenyl-2-piperidone (***12***)*

A solution of the tautomeric mixture of **9***g* and **10***g* (0.2 g,

1.0 mmol) and 10 mL 10% sulfuric acid in 100 mL methanol was heated under reflux at 64°C for 20 h. The solution was neutralized to pH 7 using 10% aqueous sodium hydroxide, filtered, and the solution was heated *in vacuo* to remove the methanol. Extraction of the remaining aqueous mother liquor with chloroform (3 × 50 mL), drying (sodium sulfate), and removal of the solvent *in vacuo* afforded a tan colored solid. Recrystallization from petroleum ether (bp 30–60°C) gave 6-phenyl-2-piperidone (**12**) (0.068 g, 38.7%), mp 137°C; ir: 3180 (m, NH) and 1640 (s, C=O) cm^{-1}; ^1H nmr δ: 1.5–2.1 (m, 4H, H-4, H-5), 2.27 (m, 2H, H-3), 4.4 (m, 1H, H-6), 6.8 (m, 1H, NH, exchanges with D_2O), 7.21 (m, 5H, C_6H_5). *Exact Mass* calcd. for $C_{11}H_{13}NO$: 175.0997; found (high resolution ms): 175.1001.

SCOTT D. TANNER, GERVASE I. MACKAY, and DIETHARD K. BOHME. Can. J. Chem. **57**, 2350 (1979).

Rate constants measured with the flowing afterglow technique at 297 ± 2 K are reported for the protonation of CH_2O by H_3^+, N_2H^+, CH_5^+, HCO^+, $C_2H_5^+$, H_3O^+, H_3S^+, and $HCNH^+$ and for the subsequent deprotonation by NH_3. The rate constants are compared with predictions of various theories for ion–molecule collisions. The protonation was observed to proceed in the absence of competing channels and further decomposition and is discussed in terms of the energetics of the two sites of protonation and the energetics and mechanism of H_2 elimination. The rate measurements provide evidence for the room-temperature conversion of the adduct $C_2H_3^+ \cdot H_2$ to the more stable isomer derived from the direct protonation of C_2H_4.

SCOTT D. TANNER, GERVASE I. MACKAY et DIETHARD K. BOHME. Can. J. Chem. **57**, 2350 (1979).

Opérant à 297 ± 2 K et faisant appel à la technique de lueur d'écoulement résiduelle, on a mesuré les constantes de vitesse pour la protonation de CH_2O par H_3^+, N_2H^+, CH_5^+, HCO^+, $C_2H_5^+$, H_3O^+, H_3S^+ et $HCNH^+$ et la déprotonation subséquente par NH_3. On compare les constantes de vitesse avec celles que l'on peut prédire à l'aide de diverses théories relatives aux collisions ion–molécule. On a observé que la protonation se produit même s'il n'existe pas d'autres chemins en compétition et d'autres décompositions et on en discute en termes des énergies des deux sites de protonation et de l'énergie et du mécanisme d'élimination de H_2. Les mesures de vitesse fournissent des preuves à l'effet de la transformation, à température ambiante, de l'adduit $C_2H_3^+$ en son isomère plus stable dérivé de la protonation directe de C_2H_4.

Introduction

Ion-molecule reactions of gaseous formaldehyde have been receiving an increasing amount of attention in the past few years. This is especially evident from the recent incorporation of formaldehyde into models of the ion chemistry proceeding in such diverse chemical environments as dense interstellar clouds (1), hydrocarbon flames (2), and planetary atmospheres, particularly the earth's stratosphere (3, 4). However, quantitative information on the rates of such reactions is still rather sparse. Here we present the results of a flowing afterglow study of the room-temperature kinetics of ion–molecule reactions which lead to the protonation of formaldehyde. Such reactions play an integral part in these chemical models. Their study also provides further fundamental insight into the kinetics of proton-transfer reactions in general.

Experimental

The measurements were carried out in a conventional flowing plasma mass-spectrometer (flowing afterglow) system in a manner which has been described previously (5).

Monomeric formaldehyde was prepared from paraformaldehyde (Fisher Scientific, Purified Grade) by an adaption of the method developed by Spence and Wild (6). Paraformaldehyde was distilled at low pressures at ~370 K. The formaldehyde was then dried by passing it through a cold trap at 195 K and frozen out at liquid nitrogen temperatures. A gaseous mixture of ~5% formaldehyde was used in these studies and the partial pressure of formaldehyde was maintained below 7 Torr to avoid polymerization. The monomer could be stored at these partial pressures for several days with negligible polymerization. It was introduced into the flowing afterglow sufficiently downstream of the ion production region to ensure that the reactant ions were thermalized by collisions with H_2 carrier gas molecules to the ambient temperature of 297 ± 2 K prior to reaction. The total pressure in the reaction region ranged from 0.29 to 0.68 Torr and the effective reaction length had values of 59 and 85 cm.

The gases used were hydrogen (Linde, Very Dry Grade, 99.95% H_2), methane (Matheson, Ultra High Purity, 99.97% CH_4), ethylene (Matheson, C.P. Grade, 99.5% C_2H_4), acetylene (Matheson, Purified Grade, 99.6% C_2H_2), carbon monoxide (Matheson, Coleman Grade, 99.99% CO), and nitrogen (Matheson, Prepurified Grade, 99.998% N_2).

Results and Discussion

The measurements were performed in H_2 carrier gas in which a variety of protonating agents with proton affinities intermediate between H_2 and CH_2O could be conveniently prepared upstream of the reaction region. This was accomplished for X = N_2, CO, CH_4, C_2H_4, H_2O, H_2S, and HCN through rapid proton transfer reactions of the type

0008-4042/79/182350-05$01.00/0

[1] $H_3^+ + X \rightarrow XH^+ + H_2$

the H_3^+ itself resulting from the reaction

[2] $H_2^+ + H_2 \rightarrow H_3^+ + H$

After their formation, the H_3^+ and XH^+ ions were allowed to undergo many thousands of collisions in the H_2 buffer gas upstream of the reaction region in order to establish Maxwell–Boltzmann energy distributions prior to reaction. Some ambiguity exists about the structure of the protonated heteroatomic species CO and HCN for which there are two possible sites of protonation. *Ab initio* molecular orbital calculations reported to date indicate that the proton affinity of the carbon site in the CO molecule is only ca. 18 kcal mol^{-1} higher than that of the oxygen site and that both the HCO^+ and COH^+ systems prefer a linear arrangement of nuclei in their ground states at equilibrium (7, 8). In the case of protonated HCN, calculations predict that the linear acetylene-like isomer, H—C≡N^+—H, lies ca. 70 kcal mol^{-1} lower in energy than the formaldehyde-like isomer, $\begin{matrix} H \\ \diagdown \\ C{=}N^+ \\ \diagup \\ H \end{matrix}$ (9). Consequently, it appears that two isomers are energetically accessible in the protonation of CO and HCN by H_3^+ according to reactions [3] and [4], where the exothermicity is given in kcal mol^{-1}. The experiments

[3] $H_3^+ + CO \rightarrow HCO^+ + H_2 + 42$
$\rightarrow COH^+ + H_2 + 28$

[4] $H_3^+ + HCN \rightarrow HCNH^+ + H_2 + 70$
$\rightarrow H_2CN^+ + H_2 + 0$

reported here do not provide any information about the extent of initial formation of the high energy isomer in either case. However, should such formation be occurring to any significant extent, we can expect isomerization to proceed to the low energy form, if not unimolecularly or by collision with H_2 carrier molecules, then by the proton transfer reactions

[5] $COH^+ + CO \rightarrow HCO^+ + CO + 18$

[6] $H_2CN^+ + HCN \rightarrow HCNH^+ + HCN + 70$

which would be encouraged to proceed by the presence of CO and HCN, respectively, upstream of the reaction region. Evidence for the ultimate preferential formation of the HCO^+ isomer under our experimental operating condition is given elsewhere (10). The $C_2H_5^+$ ions were prepared in two ways, either directly by proton transfer to C_2H_4 or indirectly through H_2 association

[7] $C_2H_3^+ + H_2 + M \rightarrow C_2H_5^+ + M$

preceded by proton transfer from H_3^+ to C_2H_2 (11).

Rate constants were measured in separate experiments in each of which the desired protonating agent was established as the major positive ion present in the flowing plasma. Figure 1 shows the decays of H_3^+, HCO^+, and H_3O^+ observed upon the addition of CH_2O into the reaction region under conditions of only partial conversion of H_3^+ to HCO^+ (relatively small additions of CO upstream). H_3O^+ results from proton transfer to H_2O impurity. The concomitant rise in the $m/e = 31$ signal is a manifestation of the production of protonated formaldehyde to which we have assigned the structure CH_2OH^+ (*vide infra*). The initial signal at $m/e = 31$ is accounted for by the ^{18}O isotope of HCO^+. No other primary product ions were observed. CH_2OH^+ appears to react further with CH_2O to form the cluster ion $CH_2OH^+ \cdot CH_2O$ presumably by three-body association. There was no evidence for the association of

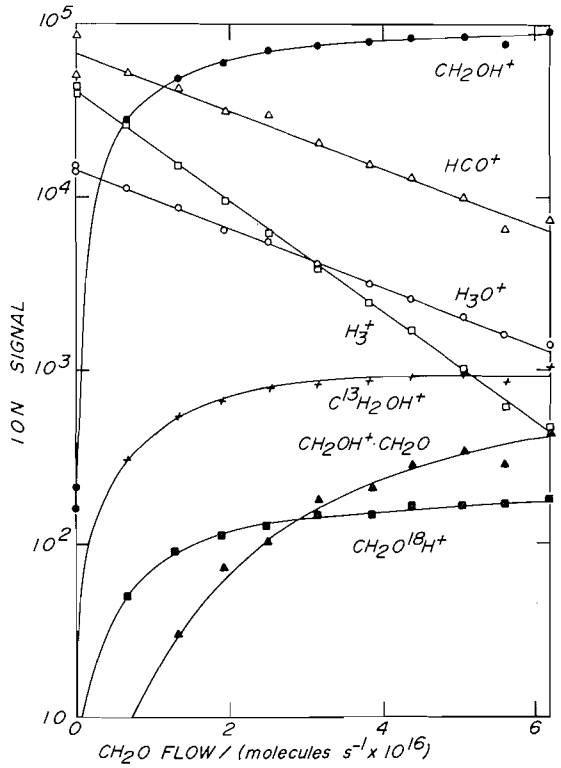

FIG. 1. The variation in the dominant ion signals recorded upon the addition of formaldehyde into a H_2–CO plasma in which HCO^+, H_3^+, and H_3O^+ are initial major ions: $T = 297$ K, $P = 0.421$ Torr, $v = 7.8 \times 10^3$ cm s^{-1}, $L = 60$ cm, and the flow of CO = 3.12×10^{16} molecules s^{-1}.

TABLE 1. Rate constants at 297 ± 2 K (in units of 10^{-9} cm^3 molecule^{-1} s^{-1}) for reactions of the type $XH^+ + CH_2O \rightarrow CH_2OH^+ + X$

XH^+	k_{expt}[a]	k_{AADO}[b]	k_{expt}/k_{AADO}	$-\Delta H_{298}$[c]
H_3^+	6.3±1.6(4)	6.68	0.94	70 ±2
N_2H^+	3.3±0.8(3)	2.87	1.1	54 ±2

$HCNH^+$	≥1.6	2.90	≥0.6	−0.1±0.4[e]

[a]The mean value together with the estimated accuracy of the measurements. The number of measurements is given in parentheses.
[b]The collision rate constant calculated using the angular momentum conserved-average dipole orientation theory with $C = 0.257$ (16), $\alpha = 2.81$ Å^3 (17), $\mu_D = 2.33$ D (18), and $I = 2.16 \times 10^{-39}$ g cm^2 (19).
[c]Standard enthalpy change based on PA(CH_2O) = 170.9 ± 1.2 kcal mol^{-1} (15, 20) and PA(H_2, N_2, CH_4, CO, C_2H_4) = 101 ± 1 (21), 117 ± 1 (unpublished results from this laboratory), 131 ± 2 (unpublished results from this laboratory), 143 ± 1 (23), and 159 ± 3 (24) kcal mol^{-1}, respectively.
[d]Derived from $H_3^+ + C_2H_4$ or $C_2H_3^+ + H_2 + M$.
[e]Standard enthalpy change based on equilibrium constant measurements performed in this laboratory (15).

CH_2OH^+ with the H_2 carrier gas molecules to form either the adduct $H_2COH^+ \cdot H_2$ or protonated methanol, $CH_3OH_2^+$. The observed rise in the $m/e = 33$ signal is completely accounted for by the ^{18}O isotope of CH_2OH^+. Our failure to observe $CH_2OH^+ \cdot H_2$ is consistent with the equilibrium constant measurements reported by Hiraoka and Kebarle (12) which suggest that this ion is stable only at low temperatures. Also, according to a recent study of the metastable decomposition of $CH_3OH_2^+$ (13), the formation of $CH_3OH_2^+$ from $CH_2OH^+ + H_2$ has an activation energy of 31 kcal mol^{-1}. The ^{18}O isotope also rules out significant formation (<0.2%) of $CH_3OH_2^+$ by the two-body reaction [8]

[8] $$CH_2OH^+ + CH_2O \rightarrow CH_3OH_2^+ + CO$$

which is 33 ± 4 kcal mol^{-1} exothermic and which appears to have been observed previously in the ion-cyclotron double resonance (ICR) experiments of Karpas and Klein (14). The CH_3O^+ in the ICR experiments was generated at relatively low pressures in CH_2O from CH_2O^+ and CHO^+ and was observed to produce not only CH_5O^+ but also a variety of $C_2H_xO_y^+$ ions. In fact, a number of these channels are endothermic so that it is necessary to surmise, as Karpas and Klein have done, that excited CH_3O^+ ions were present under their experimental conditions.

Table 1 summarizes the rate constants determined in this laboratory for the reactions of seven XH^+ ions with CH_2O. Measurements associated with the reactions of H_3S^+ and $HCNH^+$ with CH_2O have been reported previously in the context of a determination of their equilibrium constants (15). Very few other measurements appear to be available for comparison. Fehsenfeld and co-workers (4) have recently reported a flowing afterglow value of (2.2 ± 0.9) × 10^{-9} cm^3 molecule^{-1} s^{-1} for the reaction of H_3O^+ with CH_2O at room temperature which is somewhat lower than the value determined here, but there is agreement within the overall uncertainties of the two sets of measurements. Recent SIFT measurements in which HCO^+ was produced from CH_2O at low pressures indicated a rate constant of (3.2 ± 1.0) × 10^{-9} cm^3 molecule^{-1} s^{-1} which is in good agreement with the present result (25). Karpas and Klein (14) have reported a value of 6.1 × 10^{-10} cm^3 molecule^{-1} s^{-1} for the same reaction proceeding under the less well defined conditions of their ICR cell.

Figure 2 compares the measured rate constants with capture rate constants predicted by various ion–molecule collision theories: the Langevin theory which ignores the influence of the permanent dipole moment of CH_2O (26), the angular momentum-conserved average dipole orientation (AADO) theory (16), and the locked-dipole limit (27, 28). It is encouraging that the AADO theory predicts rate constants for the reactions studied here which are essentially within the uncertainty of the experimental measurements.

All of the reactions in Table 1 appeared to proceed predominantly by proton transfer unaccompanied by other competing channels and further decomposition of the protonated product. The isotopic labelling studies of Karpas and Klein (14) have shown that proton transfer and not H_2 transfer is responsible for the conversion of HCO^+ to CH_2OH^+. Some ambiguity exists regarding the actual site of protonation. Molecular orbital calculations have predicted an energy difference of at least 40 kcal mol^{-1} between the two tautomers corresponding to C and O protonation, viz. CH_3O^+ and CH_2OH^+ (9). Consequently it appears that two isomers may be energetically accessible in the protonation of CH_2O by H_3^+, N_2H^+, and possibly CH_5^+. For each of these ions the proton transfer reaction exothermicity

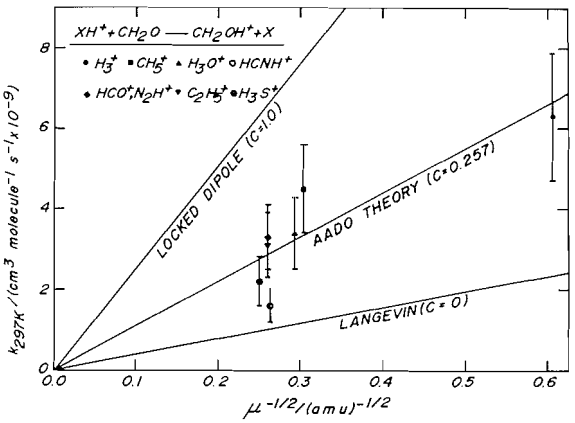

FIG. 2. A comparison of the measured rate constants with capture rate constants predicted by classical theories of collision for proton-transfer reactions with formaldehyde at 297 ± 2 K. The solid bars represent the estimated accuracy of the measurements.

>40 kcal mol^{-1} (see Table 1). The least endothermic route of decomposition of the CH_2OH^+ isomer corresponds to a symmetry-forbidden vicinal H_2 elimination which is ca. 28 kcal mol^{-1} endothermic and requires an excess energy of at least ca. 61 kcal mol^{-1} according to measurements of the kinetic energy release in the metastable decomposition of CH_2OH^+ (29). Such an excess energy is not available from any of the XH^+ ions used in this study except perhaps H_3^+:

[9a] $H_3^+ + CH_2O \rightarrow CH_2OH^+ + H_2 + 70$

[9b] $\hookrightarrow HCO^+ + H_2 - 28$

Also, Bowen and Williams have reported measurements which appear to indicate that the high energy CH_3O^+ tautomer loses H_2 in an exothermic symmetry-allowed reaction with a small activation energy (30). A second route of dissociative proton transfer can therefore be envisaged for the stronger acids H_3^+, N_2H^+, CH_5^+, e.g.,

[10a] $H_3^+ + CH_2O \rightarrow CH_3O^+ + H_2 + 30$

[10b] $\hookrightarrow HCO^+ + H_2 + 12$

Careful measurements of the $m/e = 29$ signal in the H_3^+ experiments, although complicated by the presence of N_2 and (or) CO impurities, provided an upper limit of ca. 1% to the occurrence of dissociation either via reaction [9b] or reaction [10b] under our experimental operating conditions.

The rate constant determined for the reaction of $C_2H_5^+$ with CH_2O was observed to be independent of the chemical history of this ion and there was no evidence for the formation of either CH_5O^+ or $C_3H_5O^+$ which may be conceived to proceed via "solvated" proton transfer according to

[11] $C_2H_3^+ \cdot H_2 + CH_2O \rightarrow CH_2OH^+ \cdot H_2 + C_2H_2$

or a switching reaction of the type

[12] $C_2H_3^+ \cdot H_2 + CH_2O \rightarrow C_2H_3^+ \cdot CH_2O + H_2$

Apparently the hydrogen adduct, $C_2H_3^+ \cdot H_2$, formed by the association of $C_2H_3^+$ with H_2 rearranges its structure at room temperature into that corresponding to the more stabler isomer derived from the direct protonation of C_2H_4 with H_3^+. This is in complete analogy with the behaviour proposed by Hiraoka and Kebarle for the corresponding isomers of $C_2H_7^+$ (31). These authors were able to characterise a loose hydrogen adduct, $C_2H_5^+ \cdot H_2$, approximately 8 kcal mol^{-1} less stable than the protonated ethane structure, $C_2H_7^+$. It was observed only at temperatures sufficiently low (−130 to −160°C) to prevent the interconversion which has a small activation energy. The facile formation at room temperature of the ethyl ion from $C_2H_3^+ + H_2$ is also in accord with observations of a small or negligible release of kinetic energy in what is conceived to be a concerted 1,1-elimination of H_2 from the ethyl cation to the vinylium ion (32). Theoretical treatments of the structures and relative energies of the ethyl and vinylium ions and possible transition states associated with their interconversion have recently been discussed and summarized by Dewar and Rzepa (33).

The reactions of protonated formaldehyde itself were not investigated in great detail. The recent SIFT measurements of Adams *et al.* (25) have shown that this ion is unreactive towards H_2, O_2, CO_2, COS, and CH_4 and reacts by proton transfer with NH_3 and CH_3OH which have proton affinities greater than that of CH_2O. We have studied the proton transfer reaction with NH_3 in these investigations and have determined a rate constant of $(1.7 \pm 0.4) \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} which compares favorably with the SIFT value (2.0 ± 0.4), a previous flowing afterglow value (≃2), and an ICR value $(2.3 \pm 0.1) \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} (22, 34).

The dual role of the coinitiator in the cationic polymerization of isobutene

KENNETH E. RUSSELL AND LINDA G. M. C. VAIL
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received March 16, 1979

KENNETH E. RUSSELL and LINDA G. M. C. VAIL. Can. J. Chem. 57, 2355 (1979).

The influence of 2,4- and 2,6-dimethylphenol, 2,3,6- and 2,4,6-trimethylphenol, 2,3,4,6- and 2,3,5,6-tetramethylphenol, 2,6-diisopropylphenol, 2-*tert*-butyl-4-methylphenol and 2,4-di-*tert*-butylphenol on the stannic chloride initiated polymerization of isobutene has been investigated. At −78.5°C and with 0.185 *M* stannic chloride, these phenols act as coinitiators. Rates of polymerizaiton reach maximum values at phenol concentrations which depend greatly on the number and positions of alkyl substituents; molecular weights decrease continuously with phenol concentration. Phenols without 4-substituents are incorporated in polyisobutenes as end groups and those with 4-substituents give rise largely to olefinic end groups. Termination of polymerization occurs mainly by attack at a free 4-position or at the OH group. The initial *tert*-butyl carbenium ion is more readily terminated by 2,6-di-*tert*-butylphenol than the polymer carbenium ion.

The rate and molecular weight results are interpreted in terms of a simplified reaction scheme in which termination occurs spontaneously or by reaction with uncomplexed phenol. Rate constants for termination by methyl-substituted phenols are of the order of one tenth of the propagation rate constant while those for 2-*tert*-butyl-4-alkylphenols are about one hundredth of the propagation rate constant.

KENNETH E. RUSSELL et LINDA G. M. C. VAIL. Can. J. Chem. 57, 2355 (1979).

On a étudié l'influence des diméthyl-2,4 (et -2,6), des triméthyl-2,3,6 (et -2,4,6), des tétraméthyl-2,3,4,6 (et -2,3,5,6), du diisopropyl-2,6, du *tert*-butyl-2 méthyl-4 et du di-*tert*-butyl-2,4 phénols sur la polymérisation de l'isobutène catalysée par le chlorure stannique. A −78.05°C et avec 0.18 *M* de chlorure stannique, ces phénols agissent comme coinitiateurs. Les taux de polymérisation atteignent des valeurs maximales à des concentrations de phénols qui dépendent grandement du nombre et de la position des substituants alkyles; les poids moléculaires diminuent progressivement avec la concentration de phénol. Les phénols qui ne portent pas de substituants en position 4 sont incorporés dans les polyisobutylènes sous forme de groupes terminaux; ceux qui portent un substituant en position 4 donnent principalement lieu à des groupes terminaux portant des liaisons doubles. La terminaison de la polymérisation se produit principalement par une attaque au niveau de la position 4 vacante ou du groupe OH. Le carbocation *tert*-butyle initial est plus facilement piégé par le di-*tert*-butyl-2,6 phénol que le carbocation du polymère.

On interprète la cinétique et les poids moléculaires en termes d'un schéma réactionnel simplifié dans lequel la terminaison se produit spontanément ou par réaction avec un phénol qui n'est pas complexé. Les constantes de vitesse pour la terminaison par des phénols porteurs de groupes méthyles sont environ un dixième de la constante de vitesse de propagation alors que celles des *tert*-butyl-2 alkyl-4 phénols sont égales à un centième de la constante de vitesse de propagation.

Introduction

Isobutene undergoes cationic polymerization in the presence of Lewis acids such as aluminum chloride (1), titanium tetrachloride (2), and stannic chloride (3). With most metal halides, a coinitiator such as water (3) or trichloracetic acid (2) is also required. Polymerizations proceed at measurable rates at −78.5°C with stannic chloride as the Lewis acid and alkylphenols as coinitiators (4); the polymerization mixtures are homogeneous over a wide range of reactant concentrations. Phenolic coinitiators have the advantage that the number, type, and position of alkyl substituents can be varied, and the influence of particular variables on the rate and degree of polymerization readily studied.

In earlier work it was shown that certain unhindered phenols increase the rate of polymerization of isobutene in ethyl chloride when stannic chloride is used as initiator (4). Over the concentration ranges studied, the rate continuously increased with phenol concentration for the coinitiators 2,6-dimethylphenol and 2,3,4,6-tetramethylphenol. On the other hand, 2-*sec*-butylphenol and 2,6-diisopropylphenol gave lower rates of polymerization as their concentrations were raised. Phenol itself caused a sharp rise in rate of polymerization at concentrations

0008-4042/79/182355-09$01.00/0

up to 0.02 *M* but addition of larger amounts caused the rate to go through a maximum and to decrease in the concentration range 0.025–0.07 *M*. It was predicted that the coinitiators 2,6-dimethylphenol and 2,3,4,6-tetramethylphenol would follow the same general behavior as phenol provided that the polymerization was studied over a sufficiently wide range of coinitiator concentrations. One objective of the present study was to determine whether this prediction was correct.

The proposed mechanism (4) includes a termination step in which the growing polymer carbenium ion reacts with free uncomplexed phenol, the phenol thereby becoming incorporated as a polymer end group. It was found that 2-*sec*-butylphenol and 2,6-diisopropylphenol were incorporated in the polyisobutene (5) but the fraction of polymer molecules with end groups derived from phenol was thought to be predominant. The position of attack of the polymer carbenium ion on the phenol was not firmly established. Recently it has been found that the polyisobutene chain is attached at the 4-position of 2,6-di-*tert*-butylphenol (6), a substance which acts as a strong retarder for the polymerization. Unhindered phenols which lack a substituent at the 4-position should also be susceptible to attack by polyisobutene carbenium ions. If the 4-position is blocked by a methyl or *tert*-butyl group, attack might occur at a 2- or 6-position, if free, or at the oxygen of the OH. The relative importance of these various termination steps can be investigated by means of rate and molecular weight studies and by end group analysis. The major objective of this work was then to obtain a more detailed understanding of the ways in which phenols act as terminating agents.

Experimental

Materials

Isobutene, ethyl chloride, and stannic chloride were purified by distillation on the vacuum line as described earlier (4). The solid phenols were recrystallized from methanol–water or ethanol–water mixtures and then sublimed at low pressure. The low melting solid, 2,6-di-*tert*-butylphenol, was purified by chromatography on a neutral alumina column with petroleum ether and benzene as eluents, followed by sublimation. The liquid phenols, 2,4-dimethylphenol and 2,6-diisopropylphenol were also subjected to chromatography.

2,4,6-Trimethylphenol-*d* and 2,3,5,6-tetramethylphenol-*d* were prepared by exchange with D_2O. A few drops of D_2O were added to a weighed amount of the phenol in the reaction tube which was then immersed in liquid nitrogen and evacuated. Ethyl chloride (0.3 mL) was condensed in the tube, the mixture was allowed to reach equilibrium, and the solvent and D_2O then removed by allowing them to vaporize repeatedly into a 100 mL volume and the vapor then pumped off. This treatment leads to effectively complete removal of water and no loss of phenol, the rate and degree of polymerization being unaffected when H_2O was used instead of D_2O.

Procedure

Polymerization mixtures for kinetic studies were prepared as described in an earlier study (4). The initial monomer concentration was 3.2 *M*, and the total stannic chloride concentration 0.185 *M*; the temperature was normally −78.5°C but some measurements were made at −63°C. Initial rates of polymerization obtained from dilatometric measurements were in good agreement with those determined by polymer precipitation. When required, the whole course of the polymerization could be followed by dilatometry. For molecular weight studies the polymer was precipitated after 10–20% reaction by addition of ethanol at −78.5°C, washing with cold ethanol, and drying in a vacuum oven at 40°C. High molecular weight samples for membrane osmometry were not reprecipitated but in polymerizations where the phenol concentration was high it was necessary to remove traces of free phenol by reprecipitation as its presence affected both molecular weight analysis by vapor pressure osmometry and spectroscopic analysis of phenol end groups.

Number average molecular weights, $\overline{M}_n$, of polyisobutenes of molecular weight greater than 8000 were determined by means of a Hewlett Packard HP-501 membrane osmometer with Sartorius SM 11536 or SM 11539 membranes; the latter allowed determination of $\overline{M}_n$ in the 8000 to 15 000 range with only a small correction because of polymer diffusion through the membrane. The solvent for these studies was toluene. Molecular weights less than 8000 were determined either by means of a Hewlett Packard 302B vapor pressure osmometer with carbon tetrachloride as solvent or by gel permeation chromatography. The gel chromatograph was a Water Associates GPC 200 instrument with toluene as eluent and the operating temperature was 60°C. Some recent studies were made by means of a Waters Associates ALC/GPC 244 chromatograph with refractive index and uv absorbance detection. The instruments were calibrated using standard polystyrene samples and molecular weights were calculated by the hydrodynamic volume method (7). The advantage of gel permeation chromatography is that it gives satisfactory estimates of molecular weight for samples containing small amounts of residual phenol; reprecipitation removes a little of the very low molecular weight polyisobutene in addition to free phenol.

Nuclear magnetic resonance spectra were obtained by means of a Bruker HFX-60 spectrometer. For studies of complexing between the phenols and stannic chloride the solvent was ethyl chloride or deuterated chloroform; with ethyl chloride, spectra were determined at temperatures down to 180 K and occasionally 143 K. The solutions containing the alkyl phenol (0.02–0.27 *M*) and stannic chloride (0.06–0.27 *M*) were made up on the vacuum line and stored at low temperatures.

End group analyses were made using three techniques. ^1H nmr spectra were obtained of polyisobutenes in deuterated chloroform or carbon tetrachloride solution. The presence of phenol end groups and the position of attack of the polymer carbenium ion on the phenol were investigated by means of absorptions in the δ = 6.4–7.2 ppm region. The presence of terminal olefinic groups was investigated using absorptions in the δ = 4.6–4.9 ppm region. The esr spectra of benzene solutions of polymers whose phenolic end groups had been oxidized by lead dioxide were determined by means of a Varian V4502 spectrometer. For concentration studies of radicals of long life, low microwave power was used and the standard was a solution of 2,2-diphenyl-1-picrylhydrazyl. Concentrations of phenolic end groups were normally estimated from uv spectra. Absorbances were measured at the higher wavelength maximum of the polymer substituted

phenol ($\lambda_{max} \sim 284$ nm) and the extinction coefficient was assumed to be that of the phenol under study with an alkyl substituent in the 4-position.

Results

Complex Formation between Alkylphenols and Stannic Chloride

Addition of stannic chloride to an ethyl chloride solution of a phenol causes the OH proton resonance to move to a lower field. The magnitude of the change increases with stannic chloride concentration and with decrease in temperature. After due allowance for phenol dimerization, the results are interpreted (4) in terms of complex formation between stannic chloride and the phenol.

[1] $SnCl_4 + ArOH \rightleftharpoons SnCl_4 \cdot ArOH$

The 1:1 complexes are favored at low concentrations of weak donors but if the phenol concentration is high and the temperature low, some 1:2 complex formation may also occur. The nmr data yield the following estimates of the equilibrium constant, K_X, for reaction [1] at -78.5°C: 2,6-dimethylphenol, 2.5 M^{-1}; 2,6-diisopropylphenol, 2 M^{-1}; 2,6-di-*tert*-butylphenol, 0.0 M^{-1}; 2,4-dimethylphenol, 15 M^{-1}; 2-*tert*-butyl-4-methylphenol, 2M^{-1}; 2,4-di-*tert*-butylphenol, 2 M^{-1}; 2,3,6-trimethylphenol, 3 M^{-1}; 2,4,6-trimethylphenol, 15 M^{-1}; 2,3,5,6-tetramethylphenol, 3 M^{-1}; 2,3,4,6-tetramethylphenol, 15 M^{-1}. It was not possible to observe directly, even at 143 K, the value of the chemical shift, δ, for the OH proton in the 1:1 complex, and the assumption was made that $\delta = 10.0$ ppm for all complexes (4). The uncertainty in the concentration of complex may be as high as 20% and the corresponding uncertainty in K_X approximately 40%. ΔH values for reaction [1] range from -1.3 kcal mol^{-1} for complex formation between stannic chloride and 2,6-diisopropylphenol to -3.2 kcal mol^{-1} for complex formation with 2,4,6-trimethylphenol. These values of K_X and ΔH are preferred to those determined earlier (4) because they apply to the same solvent as that used in kinetic experiments and to the same temperature range.

Rates of Polymerization

A typical plot of extent of reaction vs. time for a reaction mixture containing 3.2 *M* isobutene, 0.185 *M* stannic chloride in ethyl chloride, and 0.008 *M* 2,3,4,6-tetramethylphenol is shown in Fig. 1*a*. There is no observable induction period, the rate decreases continuously with time, and the apparent internal order with respect to monomer is close to one. This type of reaction curve was observed at all concentrations of 2,4,6-trimethylphenol and 2,3,4,6-tetramethylphenol and at all but the lowest concentrations of 2,4- and 2,6-dimethylphenol, 2,3,6-trimethylphenol, and 2,3,5,6-tetramethylphenol. At concentrations of these latter phenols less than 0.005 *M* there is some sigmoid character in the conversion–time curves. With 2-*tert*-butyl-4-methylphenol and 2,6-diisopropylphenol, deviations from first order behavior are apparent at all concentrations up to 0.2 *M* (Fig. 1*b*). The rates recorded are those observed for the initial stages of the polymerization and the detailed behavior at high conversion was not investigated.

The broad effect of phenol concentration on initial rate of polymerization is shown in Table 1. These alkylphenols increase the rate of polymerization of isobutene in the presence of stannic chloride at -78.5°C and are therefore all regarded as active coinitiators. 2,6-Diisopropyl phenol gives lower rates than those observed in an earlier study (4) but the recorded rates are believed to be due to the phenol and not to some very active remaining impurity. With the di-, tri-, and tetramethylphenols there is a common pattern of behavior. The initial rate of polymerization rises sharply at low phenol concentrations and then reaches a maximum value; at high phenol concentrations, the rate decreases as more phenol is added. The results for 2,3,5,6-tetramethylphenol are shown in Fig. 2*a*. At concentrations less than 0.005 *M*, this is a very active coinitiator whether judged on the basis of concentration of total phenol in the system or of 1:1 complex with stannic chloride. The rate reaches a maximum, however, at 0.007 *M* 2,3,5,6-tetramethlyphenol and drops to low values at concentrations in the 0.02–

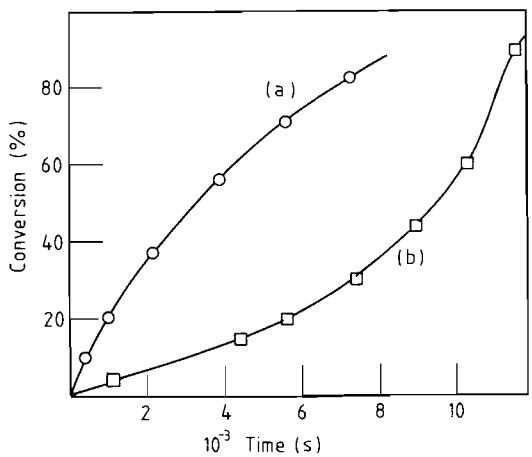

FIG. 1. Plots of conversion vs. time for (*a*) 0.008 *M* 2,3,4,6-tetramethylphenol; (*b*) 0.05 *M* 2-*tert*-butyl-4-methylphenol. Isobutene concentration 3.2 *M*; stannic chloride concentration 0.185 *M*; temperature -78.5°C.

TABLE 1. Effect of coinitiator on rate of polymerization and molecular weight

Phenol	Phenol concentration (M)	Polymerization rate $\times 10^4$ ($M\,s^{-1}$)	Molecular weight
2,4,6-Trimethyl-	0.006	6.6	210 000
	0.020	16.4	145 000

	0.245	12.5	84 000

0.06 M range. 2,4,6-Trimethylphenol shows a similar behavior (Fig. 2*b*), but the highest rates of polymerization are observed at a phenol concentration of 0.063 M. The optimum coinitiator concentrations are $<0.012\,M$ for 2,6-diisopropylphenol, 2,6-dimethylphenol, 2,3,6-trimethylphenol, and 2,3,5,6-tetramethylphenol, in the range 0.018–0.063 M for phenol (4), 2,4-dimethylphenol, 2,4,6-trimethylphenol, and 2,3,4,6-tetramethylphenol, and $>0.1\,M$ for 2,4-di-*tert*-butylphenol and 2-*tert*-butyl-4-methylphenol.

The hindered phenols, 2,6-di-*tert*-butyl-4-methylphenol and 2,4,6-tri-*tert*-butylphenol, do not increase the rate of polymerizaion of isobutene in the presence of stannic chloride. If they are added to polymerization mixtures containing coinitiators such as 2,6-dimethylphenol (0.009 M) or 2,4-di-*tert*-butylphenol (0.033 M), they have little or no effect on the rate of polymerization at concentrations of 2,6-di-*tert*-butyl-4-alkylphenol up to 0.06 M. The small decreases in rate observed at higher concentrations can probably be ascribed to these phenols acting as inert diluents.

At low concentrations, 2,4,6-trimethylphenol-*d* and 2,3,5,6-tetramethylphenol-*d* give rise to rates of polymerization which are close to 50% of the rates

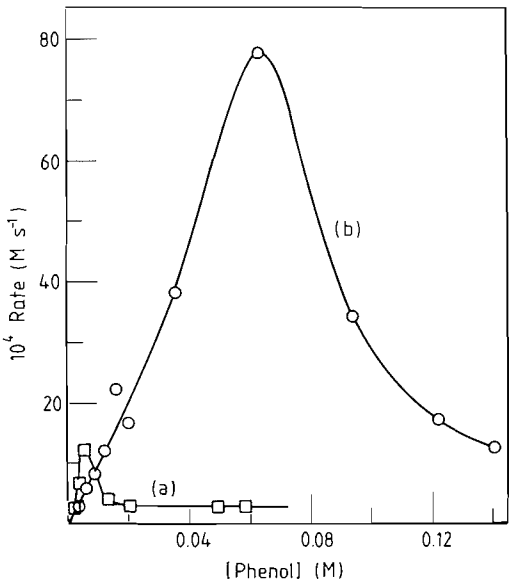

FIG. 2. The effect of total phenol concentration on the rate of polymerization: (*a*) 2,3,5,6-tetramethylphenol, (*b*) 2,4,6-trimethylphenol.

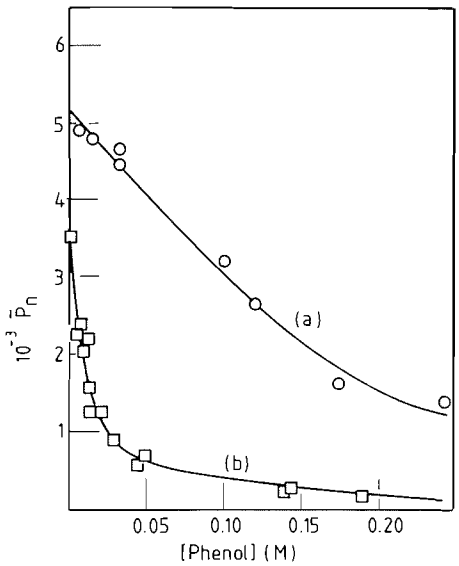

FIG. 3. The effect of phenol concentration on the degree of polymerization: (*a*) 2,4-di-*tert*-butylphenol, (*b*) 2,6-dimethylphenol.

observed with the normal phenols under similar conditions. At higher concentrations of 2,3,5,6-tetramethylphenol-*d* (0.01–0.1 *M*) the isotope effect on rate decreases, but with 2,4,6-trimethylphenol-*d* it is maintained at concentrations up to 0.1 *M*.

A brief study was made of the influence of temperature on the rate of polymerization with 2,4,6-trimethylphenol as coinitiator. At −63°C and at concentrations of added phenol in the range 0.09–0.3 *M*, the rates of polymerization were half the values observed at −78.5°C. Part of this decrease can be ascribed to the lower concentration of initiating complex at the higher temperature, but the overall reaction does appear to have a small negative activation energy.

Molecular Weight Studies

Addition of almost any phenol to a reaction mixture causes a decrease in the degree of polymerization, the magnitude of the effect increasing with concentration of added phenol. Two extreme types of behavior are exemplified by the coinitiators 2,4-di-*tert*-butylphenol and 2,6-dimethylphenol (Fig. 3). With 2,4-di-*tert*-butylphenol there is a slow but steady decrease in molecular weight as its concentration is increased from 0.006–0.25 *M*. In order to reduce the molecular weight to half its value at very low phenol concentration, it is necessary to add 2,4-di-*tert*-butylphenol at a concentration greater than 0.1 *M*. With 2,6-dimethylphenol on the other hand there is a much sharper drop in molecular weight as phenol is added. A reduction to one half the molecular weight is effected by addition of only 0.01 *M* 2,6-dimethylphenol and at 0.1 *M* the molecular weight is about one tenth of that at very low phenol concentration. Some typical values of the polymer molecular weights are given in Table 1. 2,6-Diisopropylphenol and 2,4-dimethylphenol are most active in reducing the molecular weight, followed closely by 2,6-dimethylphenol, 2,3,6-trimethylphenol, and 2,3,5,6-tetramethylphenol. 2,4,6-Trimethylphenol and 2,3,4,6-tetramethylphenol are slightly less active than the corresponding phenols which lack a 4-methyl substituent, and the least active phenols in the table are 2-*tert*-butyl-4-methylphenol and 2,4-di-*tert*-butylphenol.

2,6-Di-*tert*-butylphenol reduces the molecular weight of polyisobutene produced in the presence of an active coinitiator such as 2,6-dimethylphenol; for example, addition of 0.024 *M* 2,6-di-*tert*-butylphenol to a reaction mixture already containing 0.019 *M* 2,6-dimethylphenol reduces the molecular weight from 70 000 to 13 000. If however, the 2,6-di-*tert*-butylphenol possesses a methyl or a *tert*-butyl group at the 4-position, the molecular weight remains essentially unaffected at concentrations of hindered phenol up to 0.06 *M*. Deuteration of an active phenol does not significantly affect the extent to which it reduces the molecular weight of the polymer; 0.14 *M* 2,4,6-trimethylphenol-*d* gives a molecular weight of 150 000 and 0.058 *M* 2,3,5,6-tetramethylphenol-*d* a molecular weight of 40 000, values which are comparable to those obtained with the undeuterated phenols under similar conditions.

End Groups

Polyisobutenes obtained in the presence of 0.05 *M* 2,6-di-*tert*-butylphenol, 2,6-diisopropylphenol, 2,6-dimethylphenol, 2,3,6-trimethylphenol, and 2,3,5,6-tetramethylphenol possess a high proportion of phenolic end groups. Spectroscopic data provide strong evidence that the polyisobutene chain is attached at the 4-positions of these phenols. ^{1}H nmr spectra of polyisobutenes produced in the presence of 2,6-di-*tert*-butylphenol and 2,6-dimethylphenol show single resonances in the aromatic region, as would be anticipated if the end groups contained equivalent *meta* protons. Oxidation of the polymers produced in the presence of 2,6-di-*tert*-butyl-, 2,6-diisopropyl-, and 2,6-dimethylphenol by means of lead dioxide yields radicals whose stabilities and esr spectra are similar to those of the corresponding phenoxy radicals with a *tert*-butyl group in the 4-position. With 2,6-diisopropylphenol for example, a persistent radical is obtained whose hyperfine splittings can be assigned to the α-protons of the isopropyl groups (3.2 G) and the *meta*-protons of the ring (1.7 G); the relatively large splitting due to the *para*-proton in 2,6-diisopropylphenoxyl is absent from the spectrum of the oxidized polymer. The uv spectra of the polymers show maxima at 284 nm, consistent with alkyl substitution at the 4-position. The absorbance at 284 nm for the polymer produced in the presence of 0.012 *M* 2,6-diisopropylphenol indicates the presence of 30% phenolic end groups and for 0.05 *M* phenol in the reaction mixture this rises to 85%. For 0.05 *M* 2,6-dimethylphenol, the percentage of phenolic end groups is estimated to be 70% and for 0.05 *M* 2,3,5,6-tetramethylphenol only 42%, but in all cases the percentage increases with the concentration of phenol in the reaction mixture.

The 2,4-dialkylphenols give largely olefinic end groups even at a phenol concentration of 0.1 *M*. The presence of olefinic groups is indicated by resonances close to $\delta = 4.6$ and 4.8 ppm in the ^{1}H nmr spectrum (5); at the same time the resonances in the aromatic regions are weakened. The uv and nmr studies show that polyisobutene prepared in the presence of 0.15 *M* 2,4-dimethylphenol contains about 40% phenolic and 60% olefinic end groups. The phenolic groups arise mainly from attack of the polymer carbenium ion at the 6-position but some ether formation via simultaneous attack at the OH is not excluded. With the *ortho-tert*-butyl phenols studied, the end groups appear to be almost entirely olefinic even at high phenol concentration; the molecular weights of the isolated polymers are, however, relatively high and the error limits correspondingly large. The uv and nmr data for polymers produced in the presence of 2,4,6-trimethylphenol and 2,3,4,6-tetramethylphenol indicate that the end groups are olefinic. There is no significant absorbance at 284 nm but a weak absorbance in the 265–275 nm region suggests the presence of some phenol ether in the polymer.

Polyisobutenes with phenol end groups may have such end groups concentrated in a particular fraction or distributed evenly over the whole molecular weight range of the polymer. Gel permeation chromatography, with simultaneous uv and refractive index detection, of polyisobutenes with various phenolic contents shows that the percentage of phenolic end groups does not vary significantly with molecular weight. Gel permeation chromatography was also used to investigate the presence of very low molecular weight alkyl phenols in the products. In the standard technique for isolation and purification of the polymer such alkylphenols are removed along with the excess coinitiator. If, however, the reaction is stopped by the addition of a small amount of alcohol and the solvent and monomer removed, a product is obtained which contains the excess phenol and any other low molecular weight materials. In larger scale experiments with 0.2 *M* 2,6-di-*tert*-butylphenol in the reaction mixture, the number of moles of 2,4,6-tri-*tert*-butylphenol was over 5 times the number of moles of phenol-terminated polymer. The 2,4,6-tri-*tert*-butylphenol was initially identified by gel permeation chromatography, the μ-styragel columns resolving the 2,4,6-tri-*tert*-butylphenol from the reactant, 2,6-di-*tert*-butylphenol. In experiments where the 2,6-di-*tert*-butylphenol had almost completely reacted, low molecular weight phenol was sublimed from the product mixture and was shown by mp and mixture mp to be almost pure 2,4,6-tri-*tert*-butylphenol.

Discussion

The rate of polymerization of isobutene (3.2 *M*) in ethyl chloride initiated by stannic chloride (0.185 *M*) at −78.5°C is increased by the addition of any of the phenols studied except the 2,6-di-*tert*-butylphenols. The various 2,6-dimethylphenols increase the rate from less than $5 \times 10^{-6}\ M\ s^{-1}$ in the absence of phenol to $4\text{–}12 \times 10^{-4}\ M\ s^{-1}$ in the presence of 0.005 *M* phenol. Under these conditions the polymer molecular weights remained above 100 000 so that these alkyl phenols can be used at low concentrations to obtain greatly increased rates of polymerization without seriously reducing molecular weights. For reasons given earlier (4), the initiation reaction with phenol as coinitiator is con-

sidered to be reaction [2]:[1]

[2] $SnCl_4 \cdot ArOH \cdot CH_2{=}C(CH_3)_2 \rightarrow (CH_3)_3C^+ \cdot OAr^- \cdot SnCl_4$

The deuterium isotope effect on rate of polymerization indicates that the initiation step, involving proton transfer from phenol to monomer, is slow. At higher concentrations the rates for the various methyl-substituted phenols all reach maximum values, and further addition of these coinitiators causes a decrease in rate of polymerization. In the concentration range studied (0.012–0.12 *M*), increase of 2,6-diisopropylphenol concentration always decreases the rate of polymerization but since the rates are greater than that observed in the absence of added phenol, it is likely that 2,6-diisopropylphenol behaves like the methyl-substituted phenols with an optimum concentration less than 0.012 *M*.

The molecular weight of the polyisobutene is lowered by the addition of a phenol, the reduction becoming larger as the phenol concentration is raised. Phenols thus act as terminating or transfer agents in the polymerization of isobutene. 2,6-Di-*tert*-butylphenol reduces the rate and molecular weight to about the same extent and is therefore a terminating agent. With the other phenols the situation is more complicated because they act as coinitiators, but the simultaneous decrease in rate and molecular weight at higher concentrations of most phenols suggests that termination is again the more important chain breaking reaction.

Two types of end group are formed. Phenols with a vacant 4-position are incorporated in the polymer, the extent increasing with the concentration of added phenol; the preferred position of attack is the vacant 4-position. The 2,4,6-trimethylphenols give olefinic end groups and although some *O*-alkylation may occur, their main function is to increase the rate of proton transfer from the carbenium ion to the negative ion. The two termination steps are shown in [3] and [4].

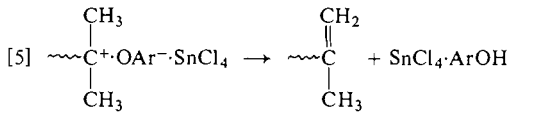
[3] 
[4] 
The extent to which phenols terminate by one or both of these mechanisms should be influenced by the basicities of the various sites and by steric factors. Information on the basicities comes from studies of the protonation of methyl-substituted phenols in FSO_3H (8, 9). When the *para*-position of the phenol is unsubstituted, as in 2,6-dimethyl-, 2,3,6-trimethyl-, and 2,3,5,6-tetramethylphenol, protonation occurs almost exclusively at this site. Relative to other centers on the phenol, the 4-position is thus strongly basic, and the polymer carbenium ion attacks at this position, provided that there are no major steric effects. Proton loss occurs from C-4 to give a polyisobutene chain terminated by phenol. Substitution of a methyl group on C-4 reduces the basicity of this carbon and protonation on C-2, C-6, or oxygen can now compete with *para*-protonation. 2,4,6-Trimethylphenol is protonated at oxygen and C-4, but the end groups in the polymerization are almost entirely olefinic and there is no evidence for displacement of the 4-methyl by the polyisobutene carbenium ion. 2,4-Dimethylphenol is largely protonated at oxygen and C-6; the polymerization product possesses both olefinic end groups and some resulting from attack of the carbenium ion at C-6. Reaction [4] appears to proceed most readily with a phenol which possesses a relatively basic oxygen atom.

Further information on the termination reactions is provided by the molecular weight studies. Addition of 2,6-di-*tert*-butyl-4-methylphenol does not affect the polymer molecular weight, thus providing confirmatory evidence that a methyl group at the 4-position prevents attack of the growing carbenium ion on this center in the phenol. It also shows that neither the oxygen in a highly hindered phenol nor a basic carbon (C-4) to which a methyl group is attached readily facilitates the termination reaction [4]. 2,4-Dimethylphenol at a total concentration of 0.1 *M* reduces the polymer molecular weight to below 10 000, while 2-*tert*-butyl-4-methyl- and 2,4-di-*tert*-butylphenol reduce it to about 100 000 at the same total concentration. This result strongly sug-

[1]A referee points out that analytical evidence for the initiating complex is desirable, since monomer complexing is unlikely to proceed to completion.

gests that it is the phenolic oxygen in 2,4-dimethylphenol which is largely responsible for the proton transfer reaction [4] because it is the main basic center to which access is restricted in the 2-*tert*-butylphenols.

The simple mechanism proposed in an earlier paper (4) includes initiation by reaction [2] with rate constant k_i, and termination by reaction [3] with rate constant k_{t2}. Spontaneous termination [5]



[5]

is also considered with rate constant k_{t1}. Chain propagation is assumed to have a rate constant, k_p, which does not vary with the substituents in the phenol. If these are the only important steps in the polymerization, the overall rate, R_p, is given by [6]

$$[6] \quad R_p = \frac{k_p k_i [X][M]}{k_{t1} + k_{t2}[ArOH]_f}$$

where X is the initiating complex and $[ArOH]_f$ is the concentration of free phenol in the polymerization mixture. The number average degree of polymerization, $\bar{P}_n$, is given by [7].

$$[7] \quad \bar{P}_n = \frac{k_p[M]}{k_{t1} + k_{t2}[ArOH]_f}$$

For 2,6-dimethyl-, 2,3,6-trimethyl-, 2,3,5,6-tetramethyl-, and 2,6-diisopropylphenol, plots of $[X]/R_p$ vs. $[ArOH]_f$ and of $1/\bar{P}_n$ vs. $[ArOH]_f$ are linear. The values of k_{t2}/k_p so obtained are respectively 0.13, 0.08, 0.09, and 0.28 at the reaction temperature of $-78.5°C$. In all cases k_{t1}/k_p was found to be close to 6×10^{-4} *M*. The rate constants for the initiation reaction, k_i, were estimated to be 3.2×10^{-5}, 1.7×10^{-5}, 1.9×10^{-5}, and 1.1×10^{-5} s^{-1} for 2,6-dimethyl-, 2,3,6-trimethyl-, 2,3,5,6-tetramethyl-, and 2,6-diisopropylphenol. The simple reaction scheme thus provides a satisfactory interpretation of the rate and molecular weight data and this is supported by the end group results. Termination by reaction [4] may also occur but because of the relatively high basicity of C-4, it is much less important than termination by reaction [3].

The maximum rates of polymerization for 0.063 *M* 2,4,6-trimethylphenol and 0.030 *M* 2,3,4,6-tetramethylphenol are higher than the maximum rates observed with the other phenols. These 2,4,6-trimethylphenols complex more strongly with stannic chloride and the higher rates can be partly ascribed to higher concentrations of initiating complex and lower concentrations of free phenol. Termination involving attack of the polyisobutene carbenium ion at C-4 does not occur to a significant extent. A major mode of termination has been removed and this too can contribute to relatively high rates of polymerization and polymer molecular weights. It is found, however, that the rates and molecular weights are significantly reduced at higher concentrations of these two phenols. The 4-methyl group increases the basicity of the oxygen which can then participate more readily in proton transfer from the carbenium ion and increase the rate of termination by reaction [4]. Quantitative analysis of the molecular weight results, assuming that reaction [4], rate constant k_{t3}, and reaction [5] are only important termination reactions, provides estimates of k_{t3}/k_p. The values for 2,4,6-trimethyl- and 2,3,4,6-tetramethylphenol are 0.04 and 0.10 respectively; k_{t1}/k_p is again close to 6×10^{-4} *M*. Plots of $[X]/R_p$ vs. $[ArOH]_f$ are not linear, however, and this casts doubt on the method of analysis. Similar difficulties are met with when 2,4-dialkylphenols are used as coinitiators. The molecular weight results lead to k_{t3}/k_p values of 0.25, 0.016, and 0.008 for 2,4-dimethyl-, 2-*tert*-butyl-4-methyl-, and 2,4-di-*tert*-butylphenol; the estimated error is $\pm 30\%$ and no allowance has been made for the simultaneous attack on C-6. The rate plots deviate from linearity and it is clear that 4-alkylphenols affect the reaction rate in more ways than are described in the simple reaction scheme. One factor which has been neglected is the possible formation of 1:2 stannic chloride – phenol complexes at higher concentrations of the more strongly basic phenols. A second is possible increased solvation of the growing carbenium ion by free phenol with a consequent change in its reactivity in propagation and termination reactions. Bywater and Worsfold (10), working with the boron trifluoride – water – diphenylethylene system, have shown that the concentration of carbenium ions passes through a maximum at room temperature when $[BF_3] = 2[H_2O]$, and drops fairly rapidly at higher concentrations of added water. If the stannic chloride – phenol – isobutene system were to behave in comparable fashion, the higher phenol concentrations would lead to a reduction in carbenium ion concentration rather than in its reactivity.

Polymerizations performed in the presence of high concentrations of 2,6-di-*tert*-butylphenol indicate that the initial carbenium ion may have an unusually high reactivity towards bases. With 0.2 *M* 2,6-di-*tert*-butylphenol, a high yield of 2,4,6-tri-*tert*-butylphenol is formed in addition to polymer with di-*tert*-butylphenol end groups. The *tert*-butyl carbenium ion appears to be more reactive towards 2,6-di-*tert*-butylphenol than monomer, whereas the reverse is true for the growing polymer carbenium ion. The coinitiators used in this study are somewhat

less basic than 2,6-di-*tert*-butylphenol but it is possible that they also reduce the concentration of carbenium ions by deactivating the initiating center before it adds a second monomer unit. In these circumstances the free phenol reduces the overall rate of polymerization by removing both the initial active centers and the growing carbenium ions and this may in part explain the surprisingly sharp drop in rate observed with some phenols as their concentrations are increased beyond the optimum values.

The dual role of the coinitiator has been recognized for some time. Water acts as a coinitiator in the polymerization of isobutene and its consumption during the reaction was thought to be, or to be associated with, a kinetic termination (11). Anisole cannot, like phenol, initiate polymerization but it has been shown to be a chain-breaking agent in the cationic polymerization of isobutene (12) and styrene (13). A significant conclusion from the present study is that the coinitiator terminates polymerization by aiding proton transfer from the polymer carbenium ion to the negative ion, in addition to becoming incorporated in the polymer. Knowledge of the concentrations of initiator–coinitiator complex and of free coinitiator leads to a rationalization of the observed rate, molecular weight, and end group data, but a fuller understanding must await better knowledge of the various species present and of the subtle effects exerted by the bases in solution.

Carbon-13 nuclear magnetic resonance studies of the cholesteryl ester – phosphatidylcholine system

ROBERT J. CUSHLEY AND BRUCE J. FORREST

Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received March 26, 1979

ROBERT J. CUSHLEY and BRUCE J. FORREST. Can. J. Chem. **57**, 2364 (1979).

Using difference spectroscopy, ^{13}C spin–lattice relaxation measurements on 40% egg phosphatidylcholine multilamellar liposomes (containing 25 mol% cholesteryl palmitate) – 60% D_2O indicate the ester contributes negligibly to the microviscosity of the acyl chains in the bilayers.

At 37°C, spin–spin and spin–lattice relaxation measurements have been obtained for 25 mol% cholesteryl linoleate in both egg phosphatidylcholine and dipalmitoyl phosphatidylcholine multilayers and indicate: (*a*) T_1 values of the linoleate ester chain are 0.5 times those of the lecithin chain carbons, and (*b*) $T_2^* = 16 \pm 6$ ms for *all* discernable linoleate carbons. At 52°C, cholesteryl ring carbons C5 and C6 yield T_2^* values of 23 and 20 ms, respectively. These studies suggest the esters reside in an environment whose "fluidity" approaches that found in very low density lipoprotein (VLDL).

ROBERT J. CUSHLEY et BRUCE J. FORREST. Can. J. Chem. **57**, 2364 (1979).

En se basant sur de la spectroscopie de différence, des mesures de relaxation spin–réseau ^{13}C sur des solutions à 40% de liposomes multicouches de phosphatidylcholine d'oeuf (contenant 25 mol% de palmitate de cholestéryle) dans 60% de D_2O indiquent que la contribution de l'ester à la microviscosité des chaînes acyles des doubles couches est négligeable.

A 37°C, on a obtenu des mesures de relaxation spin–spin et spin–réseau pour des solutions à 25% de linoléate de cholestéryle dans des multicouches de phosphatidylcholine d'oeuf ainsi que dephosphatidylcholine de dipalmitoyle et ces résultats indiquent: (*a*) que les valeurs T_1 de l'ester linoléate correspondent à 0.5 fois celles des carbones de la chaîne de lécithine et (*b*) que $T_2^* = 16 \pm 6$ ms pour *tous* les carbones de linoléate discernables. A 52°C, les valeurs T_2^* des carbones 5 et 6 du cholestérol sont respectivement 23 et 20 ms. Ces études suggèrent que l'ester se trouve dans un environnement dont "la fluidité" est semblable à celle que l'on trouve dans des lipoprotéines de très basse densité (LTBD).

[Traduit par le journal]

Introduction

Plasma lipoproteins provide the vehicle for the transport, and hence metabolism, of cholesterol and its fatty acid esters. Because of the key role played by lipoproteins, much effort has gone into determining composition, structure, and interactions of the various components. In particular, recent ^{13}C nmr studies on human high density lipoprotein (HDL), low density lipoprotein (LDL), and very low density lipoprotein (VLDL) (1–4) have established that high resolution spectra are obtained for the lipid components of lipoproteins. Use of model systems, including cholesteryl oleate (CO) and cholesteryl linoleate (CLa), neat and in $CHCl_3$ solution (1, 3), in mixture with the triglyceride triolein (4, 5), and in a lamellar liquid crystalline mixture with egg phosphatidylcholine (egg PC) (3), have established that the acyl chains of the lipid experience a microviscosity lower than found for phosphatidylcholine at the same temperature. That is, the lipid chains in lipoprotein could be said to be more "fluid" than the lipid chains in lecithin. The cholesterol, on the other hand, experienced a much higher microviscosity and, based on comparison of spin–spin and spin–lattice relaxation rates for cholesterol carbons, the cholesteryl moiety appears most likely to be undergoing rapid, anisotropic motions. However, the cholesteryl ring was said to demonstrate "a liquid rather than a liquid-crystalline mobility" in cholesteryl esters (1, 4). Unfortunately, because ^{13}C resonance signals of the acyl chains of cholesteryl esters, triglycerides, and phospholipids overlap, unique parameters attributed only to esters are difficult to attain.

A further significant feature of cholesteryl esters is their connection to the initiation process of atherosclerosis. The most significant changes in lipid content in aortic tissue is the increment in cholesteryl ester concentration (6). That cholesteryl ester accumulates more rapidly than free cholesterol has been shown by St. Clair *et al.* (7) to occur in pigeon aorta after 14 days of feeding cholesterol and in only 3 days in rabbit aorta (8). It has been reported that permeability to lactate, iodide, and

0008-4042/79/182364-07$01.00/0

glucose is much higher in sclerotic human aorta than in normal tissue (9, 10). The suggestion has been made that, even before morphological changes appear, certain areas of the artery are predisposed to lesions and these areas show increased cholesteryl ester content (11).

In this report, we present data on the interactions between cholesteryl esters and phospholipids. We have measured ^{13}C relaxation times for systems containing (*1*) the saturated ester cholesteryl palmitate (CP) in egg PC multibilayers, and (*2*) the unsaturated ester cholesteryl linoleate (CLa) in mixtures of either egg PC or dipalmitoyl phosphatidylcholine (DPPC) multibilayers. These studies were performed at temperatures of 37 and 52°C. The ratio of cholesteryl ester to phosphatidylcholine was set at 1:3 which is consistent with that found in aortic intima of young humans (12). This ratio is somewhat higher in HDL (1:1) and LDL (2:1); however, the general results apply equally to the lipoprotein case.

Data are obtained only for ester resonances by using difference spectra and mixtures of cholesteryl esters and phospholipids in combinations such that the gel → liquid crystalline phase transition temperature for phospholipids or the liquid crystalline → isotropic phase transition temperature for the ester are separated by the temperature of the nmr run.

Experimental

Egg yolk phosphatidylcholine (egg PC) was extracted from fresh egg yolks by the method of Singleton *et al.* (13). Thin layer chromatographic analysis ($CHCl_3$:MeOH:H_2O = 65:25:4) showed a single spot when sprayed with 50% H_2SO_4 and heated, or when exposed to I_2 vapour. The fatty acid composition was determined by glpc analysis of the corresponding methyl esters using the methylating agent, Methelute (methanolic trimethylanilinium hydroxide) 0.2 *M* (Aldrich). Peaks were identified by comparison with known standards. D,L-Dipalmitoylphosphatidylcholine (DPPC), 99%, cholesteryl palmitate (CP), 99%, and cholesteryl linoleate (CLa), 99%, were obtained from Sigma Chemical Co., and used without further purification.

Lecithin multilamellar liposomes, 40% w/v in either D_2O or 0.3 *M* sucrose in D_2O, were prepared by mechanical shaking of the dry lipid with a suitable volume of the aqueous phase. These dispersions were stabilized by approximately 6 heat–freeze–thaw cycles. Homogeneous, mixed dispersions of phosphatidylcholine:cholesteryl ester = 3:1 mole ratio were prepared in a similar manner by first co-dissolving both components in chloroform, solvent evaporation, and exhaustive pumping to obtain the dry lipid mixture.

Carbon-13 nmr spectra were determined at either 37 or 52°C at 25.2 MHz on a temperature controlled Varian XL-100-15 nmr spectrometer operating in the pulse Fourier transform mode using an internal ^2H field-frequency lock and an 8K dataset. T_1 relaxation times were measured using a $(\pi/2|_{0^\circ} - \tau - \pi/2|_{0^\circ} - AT)_n$ scheme. The data acquisition, AT, occurs at the conclusion of every two pulse sequence separated by a delay time, τ. A field spoiling pulse, duration = 50 μs, is applied during the delay time (14). The error in the T_1 and T_2^* relaxation times is ±10%. Chemical shifts (δ) are ppm downfield from external tetramethylsilane (TMS).

Results and Discussion

We have found that 25 mol% cholesteryl palmitate or linoleate could be suspended in 40% w/v egg PC or DPPC multilamellar liposomes prepared in D_2O (this is a 53 mol% solution of egg PC) for up to 12 h and in 0.3 *M* sucrose for several days. These samples appeared macroscopically homogeneous; however, in light of previous work (15–17), it is probable that ester in excess of approximately 5 mol% is present as a *separate phase*, either trapped between the "onion skin" layers of the egg PC liposomes, or as patches within the hydrophobic region of the bilayers.

The ^{13}C nmr spectrum of 40% w/v egg PC multilamellar liposomes in D_2O at 37°C is shown in Fig. 1*A*. Well resolved signals for carbonyl (δ 173–174), unsaturated carbons (δ 128–129), choline (δ 60–72), and acyl chain (δ 23–32) are found while the choline $N^+(CH_3)_3$ and fatty acid CH_3 groups are extremely sharp lines at δ 54.3 and δ 14.4, respectively. The spectrum is determined some 40°C above the gel to liquid crystalline phase transition for egg PC, and the resonances, although broad, are still resolved. This is so since the carbons undergo a rapid, coupled reorientation along the molecular long axis and thus reflect only the orientational order of the carbon nucleus in the bilayer and not the long correlation time for liposome rotation, ~0.1 s (18–21). Such an explanation is necessary and sufficient to explain the gradient in T_1 (see Table 1) along the acyl chain.

The intensities of the resonance signals in Fig. 1*A* are consistent with a 60:40 ratio of saturated to unsaturated fatty acids in egg PC. The glpc analysis gave 42.7% palmitic acid, 16.9% stearic acid, 27.7% oleic acid, 11% linoleic acid, and 1.6% palmitoleic acid.

The effect of adding 25 mol% CP to egg PC multilamellar liposomes (40% w/v in D_2O at 37°C) is shown in Fig. 1*B*. The spectra in Figs. 1*A* and 1*B* are very similar. The spin lattice relaxation times for the resonance signals in Fig. 1*A* (column 2) and for the signals in Fig. 1*B* (column 3) appear in Table 1. Within experimental error, the relaxation behaviour of the system is identical, whether the 25 mol% of cholesteryl palmitate is present or absent. The difference spectrum (Fig. 1*C*) yields a "baseline" indicating that the cholesteryl palmitate contributes negligibly to the observed intensity; i.e., the spectrum

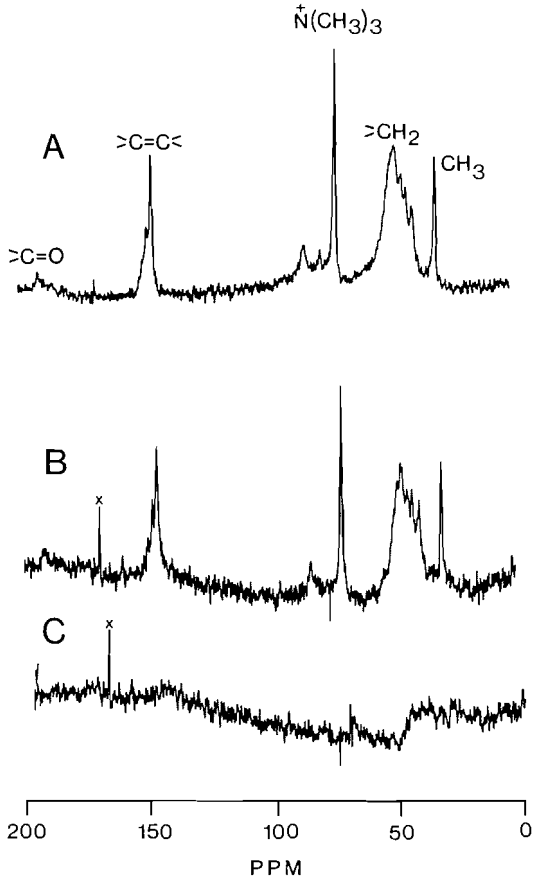

FIG. 1. (*A*) Proton noise decoupled ^{13}C nmr spectrum of a 40% w/v egg phosphatidylcholine multilamellar dispersion in D_2O at 37°C. Sweep width = 5000 Hz; rf pulse = 15 μs (60° flip angle); dataset = 8192; line broadening = 2 Hz. Field increases to the right. (*B*) Proton noise decoupled ^{13}C nmr spectrum of a 40% w/v egg phosphatidylcholine dispersion in D_2O containing 25 mol% cholesteryl palmitate at 37°C. Spectral parameters identical to (*A*). X is a spectrometer artifact. (*C*) Difference spectrum, (*B*) − (*A*).

is wholly due to the egg PC resonances. This is expected since, at 37°C, CP exists as a solid within the liposomes and the slow overall rotation of liposomes does not average out the ^{13}C–^{1}H dipolar interaction, hence, the ^{13}C resonance signals are significantly broadened and lost in the baseline noise. We conclude that there is no effect upon the microviscosity of the PC acyl chain by incorporation of large amounts of cholesteryl ester.

The ^{13}C nmr spectrum of a 40% w/v solution of egg PC liposomes containing 25 mol% cholesteryl linoleate in a 0.3 *M* sucrose solution in D_2O, and at 37°C, is featured in Fig. 2. The resonances of fatty acids esterified to cholesterol, and those esterified to lecithin overlap. Hence, the only peak which may be assigned to lecithin alone is that of $-N^+(CH_3)_3$ (δ 54.3).

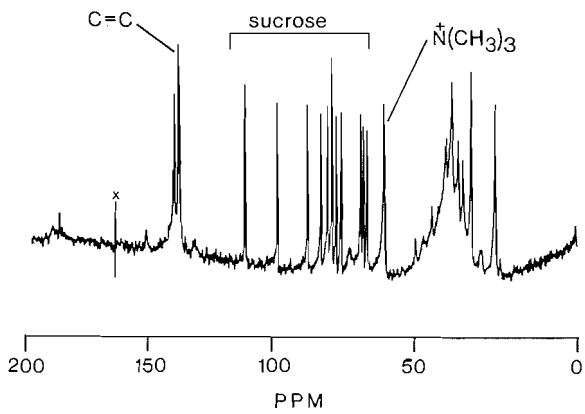

FIG. 2. Proton noise decoupled ^{13}C nmr spectrum of a 40% w/v dispersion of egg phosphatidylcholine plus 0.3 *M* sucrose in D_2O containing 25 mol% cholesteryl linoleate at 37°C. Spectral parameters as in Fig. 1.

In order to elucidate the origin of the sharp components of the spectrum of the egg PC-cholesteryl linoleate mixed liposomes, further experiments were undertaken using the fully saturated phospholipid, dipalmitoyl phosphatidylcholine (DPPC). The spectrum of a DPPC multilamellar dispersion in 0.3 *M* sucrose at 37°C is shown in Fig. 3*A*. Note that the only resonance resolved due to DPPC is that of the $N^+(CH_3)_3$ carbons. Even this resonance is severely broadened (width at half-height = 70 Hz) since the phospholipid is below the gel → liquid crystalline phase transition temperature (T_m = 41°C). (All of the sharp resonances downfield from the trimethylammonium resonance are due to sucrose.)

The spectrum in Fig. 3*A* may be compared with that obtained for DPPC multilamellar liposomes containing 25 mol% cholesteryl linoleate under identical conditions (Fig. 3*B*). At 37°C, the cholesteryl linoleate is in the isotropic liquid state (T_m = 35.5°C) while DPPC is in the gel state. While the lecithin trimethylammonium resonance is still extremely broad, the intensity and sharpness of the resonances in the olefinic region are clear. The δ 129.0 and δ 130.7 olefinic resonances may be unequivocally assigned to the 10,12 and 9,13 carbons, respectively, of the linoleate moiety of the cholesteryl ester since DPPC possesses two fully saturated fatty acid chains. In addition, a family of sharp lines is present upfield in the region of the alkyl carbons and must also be due to the cholesteryl ester. Figure 4*A* shows the ^{13}C nmr spectrum of pure DPPC multilamellar liposomes in 0.3 *M* sucrose at 52°C, 11 deg. above the gel → liquid crystalline transition temperature. In addition to the trimethylammonium resonance, three other very broad resonances are resolved. They are, moving to higher field, carbons 4–13 of the palmitate chains, the penultimate carbons

TABLE 1. Carbon-13 spin–lattice relaxation times (s) of 40% w/v egg phosphatidylcholine multilamellar dispersions in 0.3 *M* sucrose/D_2O (37°C)

Carbon	Egg PC	Egg PC + 25 mol% cholesteryl palmitate (CP)	Egg PC + 25 mol% cholesteryl linoleate (CLa)
$N^+(Me)_3$	0.52	0.44	0.50
$(CH_2)_n$	0.48	0.46	0.24

($\omega - 1$) of the palmitate chains which appear as a high field shoulder, and the terminal methyls (ω) – the resonance at highest field. The spectrum of a 3:1 mixture of DPPC – cholesteryl linoleate liposomes at 52°C is shown in Fig. 4*B*. In addition to sharp resonances due to the linoleate moiety, resonances are also resolved for carbons of the steroid nucleus, notably those of the unsaturated carbons C5 and C6 which flank the linoleate olefinic carbons. Assignments are given in Table 2. The difference spectrum, DPPC with cholesteryl linoleate minus DPPC, is shown in Fig. 4*C*. Even above the T_m of DPPC, therefore, the intensity of the sharp spectral lines is due only to the ester, although certain of

TABLE 2. Carbon-13 assignments of cholesteryl linoleate carbons in 40% w/v dispersions of dipalmitoyl phosphatidylcholine in 0.3 *M* sucrose/D_2O at 50°C (Fig. 4*B*). Primed numbers refer to carbons of the linoleate chain. Italicized numbers refer to carbons of the cholesteryl moiety

these peaks are superimposed on very broad phospholipid resonances.

The spin–lattice relaxation times for 40% w/v egg PC + 25 mol% cholesteryl linoleate were measured and appear in Table 1 (column 4). The relaxation times are much shorter than those obtained for the lecithin carbons alone or in the presence of 25 mol% cholesteryl palmitate with the exception of the lone resonance assigned to the phospholipid $N^+(CH_3)_3$ which yields a relatively unchanged relaxation time (0.52 vs. 0.50 s). The ^{13}C T_1 relaxation times for lecithin dispersions with incorporated cholesteryl linoleate reflect the motional freedom of the ester since it is only the ester carbons which contribute to the spectral intensity. The constancy of the spin–lattice relaxation time of the $N^+(CH_3)_3$ peak in free egg PC or egg PC with either cholesteryl palmitate or cholesteryl linoleate added indicates the ester is apparently not associated with the headgroup region.

It is interesting that the linoleate moiety of the cholesterol ester exhibits such low spin–lattice relaxation times. The T_1's are approximately half those observed for phospholipid fatty acid chains, although these values do increase as the chain terminus is approached. Relaxation times of 0.24, 0.51, 0.61, and 1.98 s were determined for the $(CH_2)_n$, $\omega - 2$, $\omega - 1$, and ω carbons, respectively. Thus, a fluidity gradient exists along the cholesteryl ester chain. However, the lower values indicate more limited mobility than experienced by phospholipid fatty acid chains at the same temperature. This phenomenon has been previously noted for a single linoleate carbon, C14, of enriched cholesteryl linoleate present in a turbid dispersion of lecithin, sphingomyelin, cholesterol, and cholesterol linoleate (22, 23). The value of 0.25 s determined for the relaxation time of C14 in the previous investigations is in excellent agreement with the value of 0.26 s determined for the lecithin – cholesteryl linoleate dispersion in this work. A comparison between the T_1's for CLa in egg PC multibilayers at 37°C and the "ester" T_1's for LDL and HDL at 36°C (1) indicates the relaxation times of CLa in egg PC are approximately 40% longer whereas they are only ~6% longer than the T_1's measured for VLDL (1). Comparison of spin–lattice relaxation of CLa in egg PC vs. relaxation of the related ester, cholesteryl oleate (CO), 0.56 *M* in $CHCl_3$ at 48°C (1), indicates that the CO spin–lattice relaxation times are >300% longer than those of CLa. A neat solution of CO, at 48°C, has T_1 = 240 ms for the unsaturated chain carbons C9 and C10 (5) which is from 25–37% shorter than the CLa unsaturated carbons (Table 1). In sum, the microviscosity of the acyl chain of CLa in model membranes composed of CLa:egg PC is essentially the same as the microviscosity one calculates for VLDL and lower than the microviscosity calculated for LDL and HDL. On the other hand, it is several times higher than the calculated microviscosity for CO in chloroform solution.

From the work of Janiak *et al.* (15) it may be reasonably assumed that less than 5% of the CLa is present in a homogeneous phospholipid–ester lamellar phase; i.e., where the ester molecules would be intercalated between PC molecules. The excess ester would be present as a separate phase.

At 37°C, this separate phase of CLa may be either present as small isotropic lipid droplets captured in the aqueous phase between the lamellae of the liposomes, or as patches of ester in the hydrocarbon interior of the bilayers. It has been reported (24) that extremely small quantities (0.1–0.5%) of cholesteryl esters may be suspended in aqueous solution above the melting point of the ester. Considering the large amounts of ester used in the present study, it is highly unlikely that the excess ester is suspended as droplets in the aqueous phase. Rather, it is more probable that small ester droplets are associated with the hydrophobic region of the phospholipid bilayer.

At 37°C, CLa is just above the cholesteric → isotropic phase transition (34–35°C). The average spin–spin relaxation time, T_2*, where $T_2^* = \pi\Delta\nu_{1/2}$ and $\Delta\nu_{1/2}$ is the linewidth at half-height, for *all* acyl chain carbons of CLa in DPPC multilayers at 37°C is 16 ms ± 6 ms (Table 3). The T_2* of phospholipid —$N(CH_3)_3$ = 5 ms, and of the high field sucrose resonance = 25 ms, in the same system. When the temperature is raised to 52°C, the acyl chain carbon T_2*'s increase only marginally to an average value of 18.5 ms, and this is seen to be due essentially to the olefinic carbons C9 to C13 (Table 3). At 52°C, T_2* for choline $\overset{*}{N}(CH_3)_3$ is increased to essentially equal that of the ester (14 ms). The linewidths of carbons of the rigid cholesteryl moiety of the ester are so large, e.g., for C5 and C6, that they are not observed at 37°C. Upon increasing the temperature to 52°C, however, C5 and C6 are visible with T_2* values of 23 and 20 ms, respectively. A comparison with the cholesteryl ester C5 and C6 positions in lipoproteins indicates that the microviscosity of the rigid steroid nucleus of CLa in egg DPPC at 37°C is approximately equal to that experienced in VLDL, while at 52°C the spectrum resembles that found for LDL and HDL. The lipoprotein spectra were determined at 40°C (2). For the only T_2* value reported for a cholesteryl ring carbon, T_2* of C6 was found to be ~30 ms and ~20 ms in LDL and HDL, respectively, at 36°C (1). The greater linewidths of the cholesteryl ring carbons at 37°C in the present study, i.e., broadened to the point of disappearance, are consistent with the fact that line narrowing anisotropic motion of the type encountered by the acyl chain carbons is not possible in the rigid steroid moiety (18–21).

TABLE 3. Carbon-13 spin–spin relaxation times (T_2*) of 25 mol% cholesteryl linoleate in 40% w/v DPPC dispersions at two temperatures

Conclusion

Saturated and unsaturated cholesteryl esters form stable multilamellar systems with phosphatidylcholines up to ratios of PC:CE = 3:1. Even at the highest ester concentration, 25 mol%, there is no discernible effect of the ester on the PC acyl chain or head group motions as reflected by ^{13}C T_1 measurements. The microviscosity of the ester chain carbons, as estimated from the spin–lattice relaxation rates, indicates a medium just like that of VLDL.

The form of the ^{13}C spectrum for cholesteryl esters in PC bilayers depends critically on the cholesteric → isotropic phase transition temperature, T_m. The fact that the first visible signs of atherosclerotic lesions, the so-called stage I type (25), are fatty streaks and lipid crystals, suggests that there is an inhomogeneous distribution of esters in the lesions. The fatty streaks would be rich in unsaturated esters like cholesteryl linoleate, $T_m < 37°C$, while lipid crystals would be rich in saturated esters like cholesteryl palmitate, $T_m > 37°C$. That is, the abundance of various esters in the aorta may be less important than their distribution. The properties of the two forms, as shown by ^{13}C nmr, are quite different. Indeed, thermotropic birefringence studies have indicated significant heterogeneity between clusters of ester droplets in human aorta (26).

Some reactions of 10-substituted-10*H*-pyrido[3,2-*b*][1,4]benzothiazine-*n*-butyllithium adducts with acyl and sulfonyl chlorides

FRANK M. PASUTTO AND EDWARD E. KNAUS[1]

Faculty of Pharmacy and Pharmaceutical Sciences, University of Alberta, Edmonton, Alta., Canada T6G 2N8

Received March 12, 1979

FRANK M. PASUTTO and EDWARD E. KNAUS. Can. J. Chem. **57**, 2371 (1979).

Reaction of 10*H*-pyrido[3,2-*b*][1,4]benzothiazines **1** possessing a 10-methyl **1***f*, 10-(3-dimethylaminopropyl) **1***b*, or 10-(2-dimethylaminopropyl) **1***c* substituent, with *n*-butyllithium and methyl chloroformate or diethyl chlorophosphate affords predominantly 1,2-dihydropyridines **11** and the 4-substituted derivatives **12**. The 1,7-disubstituted product **15***b* was obtained from reaction of the 10-methyl compound **1***f* with *p*-fluorobenzoyl chloride. On the other hand, treatment of the 10-methyl analog **1***f* with trifluoromethanesulfonyl chloride gave the unexpected 4-chloro derivative **12***c* and **13***c* which probably arises from the 1-trifluoromethanesulfonyl-1,2-dihydropyridine **11***c* via elimination of trifluoromethanesulfonic (sulfinic) acid. The N-10 dealkylated product **1***a* was obtained from reaction of the 10-(1-methyl-2-dimethylaminoethyl) analog **1***g* with *n*-butyllithium and methyl chloroformate, whereas a similar reaction employing the 10-(2-dimethylaminoethyl) derivative **1***h* gave rise to the *N*-methoxycarbonyl derivative **18**. On the other hand, reaction of **1***h* with *n*-butyllithium alone gave the N-10 *n*-hexyl product **19**. Mechanisms for the formation of **1***a*, **11**, **12**, **13**, **15**, **16**, and **19** are described.

FRANK M. PASUTTO et EDWARD E. KNAUS. Can. J. Chem. **57**, 2371 (1979).

La réaction des 10*H*-pyrido[3,2-*b*][1,4]benzothiazines **1** portant, en position 10, des groupes méthyle (**1***f*), diméthylamino-3 propyle (**1***b*), ou diméthylamino-2 propyle (**1***c*), avec du *n*-butyllithium et du chloroformate de méthyle ou du chlorophosphate de diéthyle conduit principalement aux dihydro-1,2 pyridines **11** et aux dérivés **12** substitués en position 4. On a obtenu le produit **15***b* disubstitué en 1,7 par réaction du composé **1***f* avec le chlorure de *p*-fluorobenzoyle. Par ailleurs, la réaction de **1***f* avec le chlorure di trifluorométhanesulfonyle conduit au dérivé chloro-4 inattendu (**12***c*) et à **13***c* qui provient probablement de la trifluorométhanesulfonyl-1 dihydro-1,2 pyridine **11***c* par élimination d'acide trifluorométhanesulfonique (sulfinique). On obtient le produit **1***a* qui ne porte pas de groupe alkyle sur l'azote N-10 par réaction de l'analogue (méthyl-1 diméthyl-amino-2 éthyl)-10 (**1***g*) avec le butyllithium et le chloroformate de méthyle alors qu'une réaction semblable avec le dérivé (diméthylamino-2 éthyl)-10 (**1***h*) conduit au dérivé **18** portant un *N*-méthoxycarbonyle. Par ailleurs, la réaction de **1***h* avec le *n*-butyllithium seul fournit le produit **19** portant un groupe *n*-hexyle sur l'azote en 10. On décrit des mécanismes pour la formation de **1***a*, **11**, **12**, **13**, **15**, **16** et **19**.

[Traduit par le journal]

10*H*-Pyrido[3,2-*b*][1,4]benzothiazine (**1***a*) is an analog of phenothiazine in which an annular nitrogen atom is incorporated into the ring system. Several N-10 derivatives of **1***a* in clinical use are more potent than their phenothiazine analogs. Prothipendyl (**1***b*) is a more useful antihistaminic agent than Promethazine while Isothipendyl (**1***c*), Pipazethate (**1***d*), and Pervetral (**1***e*) are employed as antihistaminic, antitussive, and antiemetic agents respectively (1).

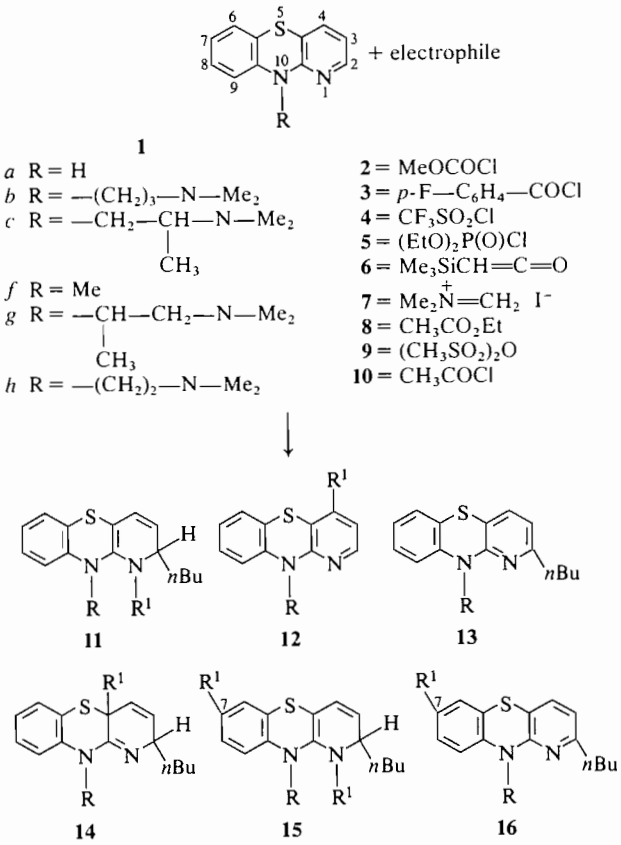
In an earlier study we showed that reaction of 10-methyl-10*H*-pyrido[3,2-*b*][1,4]benzothiazine **1***f* with *n*-butyllithium affords a mixture of the C-4 proton abstraction product **12** (R = Me, R^1 = Li) and 2-*n*-butyl-4a-lithio-10-methyl-2,4a-dihydropyridyl[3,2-*b*]-[1,4]benzothiazine (**14**, R = Me, R^1 = Li) which results from nucleophilic addition at the C-2 position. Treatment of **12** and **14** with deuterium oxide gave the deuterated products **12** and **14** (R = Me, R^1 = D) in a ratio of 1:4.4 (2). We now describe the preparation of other N-10 substituted-10*H*-pyrido[3,2-*b*]-[1,4]benzothiazine-*n*-butyllithium adducts and their

[1]To whom inquiries should be addressed.

0008-4042/79/182371-08$01.00/0



SCHEME 1. The R and R^1 substituents for products **11**–**16** are as illustrated in Table 1.

reactions with acyl and sulfonyl chlorides (see Scheme 1).

Reaction of **12** and **14** (R = Me, R^1 = Li), obtained from treatment of **1***f* with *n*-butyllithium (2), with methyl chloroformate (**2**) afforded the 1,2-dihydropyridyl derivative **11***a* (79.7%) and the 4-methoxycarbonyl product **12***a* (19.8%). Metalation at the C-4 position of **1***f* appears to be regiospecific since proton abstraction at C-6 was not observed (2). Abstraction of the C-4 rather than the C-2 proton of **1***f* is attributed to the known *ortho*-directing influence of the sulfur atom (3, 4).

Treatment of the 10-methyl derivative **1***f* with *n*-butyllithium and then *p*-fluorobenzoyl chloride (**3**) gave the 1,7-di-*p*-fluorobenzoyl-1,2-dihydropyridyl product **15***b* (35%) and the 2-*n*-butyl-7-*p*-fluorobenzoyl derivative **16***b* (2.5%) (see Table 1). The ^{1}H nmr spectrum (δ) of **15***b* exhibited a 12H multiplet at 6.64–7.82 attributed to the phenyl hydrogens and the C-4H. The C-2H and C-3H appeared as a 2H multiplet from 5.6–6.11 while the *N*-methyl signal was present as a 3H singlet at 3.08. The *n*-butyl absorption appeared as a 9H multiplet at 0.77–2.08. These assignments are consistent with the structure 1,7-di-*p*-fluorobenzoyl-2-*n*-butyl-10-methyl-1,2-dihydropyridyl[3,2-*b*][1,4]benzothiazine. The most plausible mechanism for the formation of **15***b* would involve initial formation of **11***b* which could undergo electrophilic substitution at C-7 to give 1,7-di-*p*-fluorobenzoyl-2-*n*-butyl-10-methyl-1,2-dihydropyridyl[3,2-*b*][1,4]benzothiazine **15***b*. The ^{1}H nmr spectrum (δ) of **16***b* exhibited a 2H doublet ($J_{2',3'}$ = 10) of doublets ($J_{2',F}$ = 6) at 7.8 due to the $C_{2'}$-H (*ortho*-benzoyl hydrogens), a 7H multiplet at 6.73–7.39 attributed to the remaining phenyl and pyridyl hydrogens, a 3H singlet at 3.5 due to the *N*-methyl group, a 2H triplet (J = 7) at 2.72 assigned to the α-methylene of the *n*-butyl group, and a 7H multiplet at 0.72–2.01 due to the remaining *n*-butyl hydrogens. These assignments are consistent with 2-*n*-butyl-7-*p*-fluoro-benzoyl-10-methyl-10*H*-pyrido[3,2-*b*][1,4]benzothiazine (**16***b*). Compound **16***b* could arise via the loss of the 1-*p*-fluorobenzoyl substituent from **15***b* as *p*-fluorobenzaldehyde.

Reaction of the 10-methyl analog **1***f* with *n*-butyllithium and trifluoromethanesulfonyl chloride (**4**) afforded the 4-chloro derivative **12***c* (14.5%) and **13***c* (44.4%). The high yield of **13***c* was unexpected since the reaction of 1-azaphenothiazines **1***b*, **1***c*, and **1***f* with other electrophiles as diethyl chlorophosphate, methyl chloroformate, and *p*-fluorobenzoyl chloride gave very low yields of **13**. In some reactions **13** was not detected (see Table 1). On the other hand, reactions of 1-azaphenothiazines **1***b* and **1***f* with trifluoromethanesulfonyl chloride gave **13***c* and **13***f* in 44.4% and 27.7% yield respectively. These high yields suggest that **13***c* arises from the 1,2-dihydropyridyl product **11***c* via fission of the N^1—S bond with loss of trifluoromethanesulfonic(sulfinic) acid, since this bond is expected to be quite labile due to the strong negative inductive effect of the trifluoromethyl group. Elimination of trifluoromethanesulfinic acid could occur spontaneously or trifluoromethanesulfonic acid as a result of reaction with water which is added in the workup procedure.

The ^{1}H nmr spectrum of **12***c* appeared initially to be consistent with the structure 4-trifluoromethanesulfonyl-10-methyl-10*H*-pyrido[3,2-*b*][1,4]benzothiazine (**12**, R^1 = SO_2CF_3). However, the mass spectral data did not agree. Elemental analysis subsequently indicated that the R^1-substituent was a chloro rather than a trifluoromethanesulfonyl substituent, which was also consistent with the mass spectral data. The most likely mechanism for the formation of **12***c* involves nucleophilic attack by **12** (R = Me, R^1 = Li) at chlorine, the driving force being elimination of sulfur dioxide and a trifluoromethyl carbanion which is stabilized by the strong negative inductive

TABLE 1. Reactions of 10-substituted-10*H*-pyrido[3,2-*b*][1,4]benzothiazine-*n*-butyllithium adducts with electrophiles

Electrophile	R	R^1	Yield (%) 11	12	13	14	15	16	Recovered 1

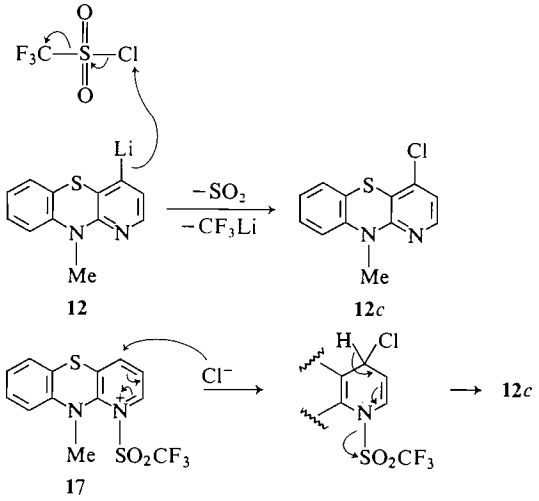
[a]Purification by column chromatography on silica gel gave a 54.5% yield of 11*d*.
[b]The R^1-substituent of 14*e* is Et.
[c]Product 14*g* was also detected in the ^1H nmr spectrum of the thin-layer fraction (R_f 0.69) but it could not be isolated in sufficient amount to allow unequivocal characterization.

effect of the fluorine atoms. Alternatively **12***c* could arise via the *N*-methanesulfonylpyridinium chloride **17**.

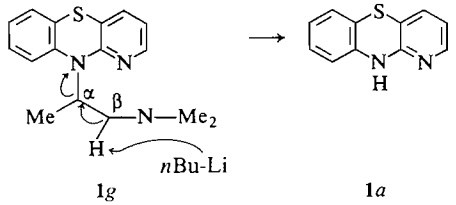


The ^1H nmr spectrum of the reaction mixture, obtained from treatment of the 10-(3-dimethylaminopropyl) analog **1***b* with *n*-butyllithium and then deuterium oxide was virtually identical in the 3.5–7 δ region to that reported for the 10-methyl derivative **1***f* (2). Reaction of **1***b* with *n*-butyllithium therefore gives rise to a mixture of **12** and **14** (R = $-(CH_2)_3-NMe_2$, R^1 = Li) which on treatment with methyl chloroformate afforded the 1,2-dihydropyridyl product **11***d* (31.4%) and 4-substituted product **12***d* (7.5%). A similar reaction employing diethyl chlorophosphate (**5**) yielded the 1,2-dihydropyridyl derivative **11***e* (16.7%), the 4-diethylphosphoryl derivative **12***e* (9.3%), and 2-*n*-butyl-4a-ethyl-10-(3-dimethylaminopropyl)-2,4a-dihydropyridyl[3,2-*b*][1,4]-benzothiazine (**14***e*, 2.5%). The most plausible mechanism for the formation of **14***e* involves nucleophilic attack by the C-4a carbanion of **14** (R = $-(CH_2)_3-NMe_2$, R^1 = Li) at the ethyl group of diethyl chlorophosphate as reported previously for **14** (R = Me, R^1 = Li) (2).

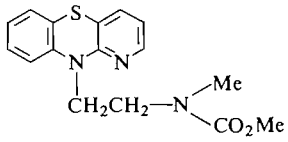
The reaction of the 10-(3-dimethylaminopropyl) analog **1***b* with trifluoromethanesulfonyl chloride gave rise to the 4-chloro product **12***f* (8.3%) and the 2-butyl derivative **13***f* (27.7%). It is expected that **12***f* and **13***f* arise via the same mechanisms proposed for the formation of **12***c* and **13***c*.

The reaction of the 10-(2-dimethylaminopropyl) analog **1***c* with *n*-butyllithium and diethyl chlorophosphate proceeded as expected to give low yields of **11***g* (14.1%), **12***g* (7.9%), and **13***g* (2.4%). Similarly, treatment with methyl chloroformate afforded **11***h* (38.5%) and **12***h* (8.5%). On the other hand, reaction of the isomeric 1-methyl-2-dimethylaminoethyl derivative **1***g* with *n*-butyllithium and methyl chloroformate afforded 10*H*-pyrido[3,2-*b*][1,4]benzothiazine (1*a*) (15.2%) as the only isolable product. Product 1*a* could arise following abstraction of the β-hydrogen and elimination as illustrated below or as a result of attack by *n*-butyllithium at the α-carbon of 1*g*.

The ^1H nmr spectrum of the reaction mixture, obtained from treatment of 10-(2-dimethylamino-

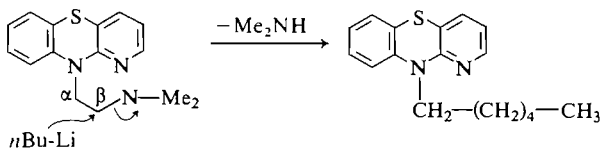


ethyl)-10*H*-pyrido[3,2-*b*][1,4]benzothiazine (**1***h*) with *n*-butyllithium and then deuterium oxide, was void of absorptions in the 3.5–7 δ region which would suggest that **14** (R = —$(CH_2)_2$—NMe_2, R^1 = Li) was not generated. Repetition of this reaction employing methyl chloroformate in place of deuterium oxide afforded the unexpected **18** (24.4%) and **1***h* (32.1%). Replacement of an *N*-methyl group by an alkoxycarbonyl group has been reported. Thus treatment of codeine (5), tropines (6, 7), and erythromycin (8) with ethyl chloroformate gave the corresponding *N*-ethoxycarbonyl products resulting from loss of the *N*-methyl substituent.



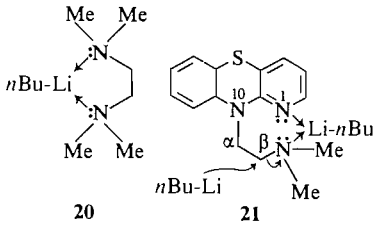
18

When the 10-(2-dimethylaminoethyl) derivative **1***h* was allowed to react with *n*-butyllithium, followed by quenching with water, the unexpected **19** (25.9%) was obtained probably as a result of nucleophilic attack by *n*-butyllithium at the β-carbon of **1***h* resulting in elimination of dimethylamine. The structure of **19** was confirmed by an unambiguous synthesis from reaction of **1***a* with sodium hydride and *n*-hexyl chloride.



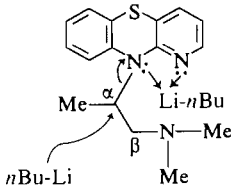
1*h* **19**

It is well documented that a Lewis base such as *N*,*N*,*N*^{1},*N*^{1}-tetramethylethylenediamine converts *n*-butyllithium into a coordinated monomeric reagent **20** (9). The 10-(2-dimethylaminoethyl)azaphenothiazine **1***h* has three nitrogens available for complexation with *n*-butyllithium, viz. N-1, N-10, and the side chain dimethylamino nitrogen. One could speculate that coordination of *n*-butyllithium could occur with the N-1 and side chain nitrogen as illustrated by structure **21**, the N-1 and N-10 nitrogens, or the N-10 and side chain nitrogen. The existence of a complex such as **21** may help to explain why the reaction of **1***h* with *n*-butyllithium gave rise to product **19**. The side chain nitrogen of **21** would attain some positive character thereby facilitating attack at the β-carbon and elimination of dimethylamine.



20 **21**

The observation that reaction of the 10-(2-dimethylaminopropyl) analog **1***c* with *n*-butyllithium and methyl chloroformate gave **11***g*, **12***g*, and **13***g*, while a similar 10-(1-methyl-2-dimethylaminoethyl) derivative **1***g* afforded only **1***a*, warrants comment. One would expect that steric repulsion between the α-methyl in **1***g* and the *peri* C-9H and the N-1 free electron pair would be greater than that of the β-methyl in **1***c*. If this is so, coordination of *n*-butyllithium with the N-1 and N-10 nitrogens of **1***g* as illustrated by **22** may be more favourable than coordination between N-1 and the side chain nitrogen. The coordination complex **22** would confer slight

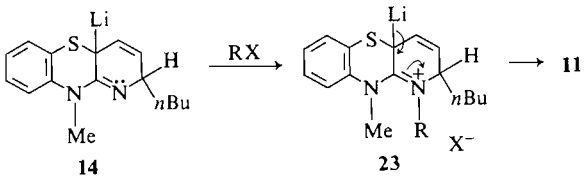


22

positive character to the N-10 nitrogen, facilitating attack at the α-position by *n*-butyllithium and elimination of 10*H*-pyrido[3,2-*b*][1,4]benzothiazine (**1***a*) as observed, thereby relieving steric repulsion between the α-methyl substituent and the *peri*-positions. Alternatively **1***a* could also arise as a result of nucleophilic attack at the β-hydrogen as described previously. These postulates are at best tenuous and are presented solely to rationalize the dependence of the reaction products obtained on the R-substituent of **1**. The possibility of intermolecular complexation also exists. No allowance has been made for the effect of conformational differences of **1** on chemical reactivity.

The reaction of adducts **14** (R = Me, —$(CH_2)_3$—N—Me_2, R^1 = Li) with methyl chloroformate and diethyl chlorophosphate affords 1,2-dihydropyridyl **11** and 4-substituted pyridyl derivatives **12** in good yield (See Table 1). On the other hand, treatment of a mixture of **12** and **14** (R = Me, R^1 = Li) with trimethylsilyketene **6** (10), dimethyl(methylene)ammonium iodide **7** (11), ethyl acetate **8**, methanesulfonic anhydride **9**, or acetyl chloride **10**, followed by quenching with deuterium oxide, gave a reaction product which exhibited a ^{1}H nmr spectrum identical to that of **12** and **14** (R = Me, R^1 = D). This indicated that the electrophilic reagents **6–10** were not

involved in the reaction. It could be proposed that any electrophile which is not able to form an iminium intermediate **23** would not react further to form a 1,2-dihydropyridyl derivative **11**. Although the intermediate **23** provides a plausible pathway to **11**, certain observations suggest that other, as yet unexplained, factors are also involved. Reaction of **14**



(R = Me, R^1 = Li) with acetyl chloride and methanesulfonyl chloride did not afford any isolable product other than the starting material **1***f*. Both reagents should be capable of forming intermediates **23**. It is also surprising that the 4-substituted product **12** expected from acylation of **12** (R = Me, R^1 = Li) was not produced. The absence of 1,2-dihydropyridines **11** in reactions employing electrophiles as dimethyl(methylene)ammonium iodide **7** and trimethylsilylketene **6** was previously rationalized in terms of their inability to form the iminium species **23**. However, there is no apparent explanation why the 4-substituted compounds **12** are not obtained with these electrophilic reagents.

Reactions of 2-, 3-, and 4-azaphenothiazines having varied functionality at the N-10 position with other organolithium reagents and electrophiles are now in progress to determine the generality and mechanisms of these reactions.

Experimental

Melting points were determined with a Büchi capillary apparatus and are uncorrected. Nuclear magnetic resonance spectra were determined for solutions in deuterochloroform with TMS as internal standard with a Varian EM-360A spectrometer. Infrared spectra (potassium bromide unless otherwise noted) were taken on a Unicam SP-1000 or Perkin Elmer 267 spectrometer. Mass spectra were measured with an AEI-MS-50 mass spectrometer and these exact mass measurements are used in lieu of elemental analyses. All of the products described gave rise to a single spot on tlc using a solvent system less polar and more polar than the specific solvent system described for purification of the reaction mixture. No residue remained after combustion of the products purified by tlc. Kieselgel silica gel DF-5 (Camag) was used for preparative thin-layer chromatography using 20 cm × 20 cm plates of 0.75 mm thickness.

*4-Lithio-10-substituted-10*H*-pyrido*[3,2-b][*1,4*]*benzothiazine* (***12***) *and 2-*n*-Butyl-4a-lithio-10-substituted-2,4a-dihydropyridyl*[3,2-b][*1,4*]*benzothiazine* (***14***) (*R^1 = Me, $-(CH_2)_3-N-Me_2$, $-CH_2-CH(CH_3)-N-Me_2$; R^1 = Li*)*

General Procedure

To a solution of ***1*** (5 mmol) in 125 mL anhydrous tetrahydrofuran, under a nitrogen atmosphere at 0°C, *n*-butyllithium (0.32 g, 5 mmol) was added dropwise with stirring. The reaction was stirred at 0°C for 1 h to afford a golden brown solution of ***12*** and ***14*** which was then cooled to −77°C and the appropriate electrophile (5–6 mmol) in 2 mL anhydrous tetrahydrofuran was added dropwise. The resulting solution was stirred at −77°C for 45–90 min before warming to room temperature over a 1–3 h period. The reaction products were isolated as described in individual cases.

*1-Methoxycarbonyl-2-*n*-butyl-10-methyl-1,2-dihydropyridyl-*[3,2-b][*1,4*]*benzothiazine* (***11***a) *and 4-Methoxycarbonyl-10-methyl-10*H*-pyrido*[3,2-b][*1,4*] *benzothiazine* (***12***a)

n-Butyllithium (0.32 g, 5 mmol), 10-methyl-10*H*-pyrido-[3,2-*b*][1,4]benzothiazine (**1***f*) (1.07 g, 5 mmol), and methyl chloroformate (0.567 g, 6 mmol) were stirred at −77°C for 1 h and allowed to warm to room temperature over a 3 h period as described in the general procedure. The resulting reddish-orange solution was treated with water (100 mL), extracted with dichloromethane (100 mL), and dried (Na_2SO_4). Evaporation of the solvent *in vacuo* gave a dark red oil (1.75 g) of which 1.1 g was subjected to preparative thin-layer chromatography on 12 silica gel plates using benzene – ethyl acetate (20:1 v/v) as the development solvent. Extraction of the silica gel fraction R_f 0.85 gave **11***a* as a dark yellow oil (0.827 g, 79.7%); ir(film): 1725 (s, C=O), 1632, and 1568 (s, C=C) cm^{-1}; ^{1}H nmr δ: 6.66–7.26 (m, 4H, Ph), 5.48–5.92 (m, 2H, H-3, H-4), 4.8 (m, 1H, H-2), 3.7 (s, 3H, OMe), 3.18 (s, 3H, NMe), 0.68–1.98 (m, 9H, *n*Bu). *Exact Mass* calcd. for $C_{18}H_{22}N_2O_2{}^{32}S$: 330.1397; found (high resolution ms): 330.1400. Extraction of the silica gel fraction R_f 0.53 gave a red solid (0.169 g, 19.8%). Recrystallization from hexanes (bp 68.4–68.9°C) gave **12***a* as a red solid; mp 118–120°C (dec.); ir: 1711 (s, C=O) cm^{-1}; ^{1}H nmr δ: 8.03 (d, $J_{2,3}$ = 5 Hz, 1H, H-2), 7.19 (d, $J_{2,3}$ = 5 Hz, 1H, H-3), 6.6–7.36 (m, 4H, Ph), 3.94 (s, 3H, OMe), 3.39 (s, 3H, NMe). *Exact Mass* calcd. for $C_{14}H_{12}N_2O_2{}^{32}S$: 272.0617; found (high resolution ms): 272.0615.

*1,7-Di-*p*-fluorobenzoyl-2-*n*-butyl-10-methyl-1,2-dihydropyridyl-*[3,2-b][*1,4*]*benzothiazine* (***15***b) *and 2-*n*-Butyl-7-*p*-fluorobenzoyl-10-methyl-10*H*-pyrido*[3,2-b][*1,4*]*benzothiazine* (***16***b)

n-Butyllithium (0.32 g, 5 mmol), 10-methyl-10*H*-pyrido-[3,2-*b*][1,4]-benzothiazine (**1***f*) (1.07 g, 5 mmol), and *p*-fluorobenzoyl chloride (0.875 g, 5.5 mmol) were stirred at −77°C for 1 h and allowed to warm to room temperature over a 2.5 h period as described in the general procedure. The resulting dark red solution was treated with water (60 mL), extracted with dichloromethane (3 × 50 mL), and dried (Na_2SO_4). Evaporation of the solvent *in vacuo* gave a dark red oil (2.037 g) of which 0.85 g was subjected to preparative thin-layer chromatography on 10 silica gel plates using benzene – ethyl acetate (25:1 v/v) as the development solvent. Extraction of the silica gel fraction R_f 0.94 gave **16***b* as a yellow waxy solid (0.02 g, 2.5%), mp 93–96°C; ir: 1660 (s, C=O) cm^{-1}; ^{1}H nmr δ: 7.8 (d, $J_{2',3'}$ = 10 Hz of d, $J_{2',F}$ = 6 Hz, 2H, H-2'), 6.73–7.39 (m, 7H, Ph, pyridyl hydrogens), 3.5 (s, 3H, NMe), 2.72 (t, $J_{CH_2CH_2}$ = 7 Hz, 2H, $-CH_2-C_3H_7$), 0.72–2.01 (m, 7H, $CH_2-C_3H_7$). *Exact Mass* calcd. for $C_{23}H_{21}N_2O^{32}SF$: 392.1354; found (high resolution ms): 392.1359. Extraction of the silica gel fraction R_f 0.58 gave a red oil (0.302 g) of which 0.2 g was rechromatographed on four silica gel plates using benzene as development solvent. This gave two fractions R_f 0.43 and R_f 0.31. Extraction of the silica gel fraction R_f 0.43 gave **1***f* as a yellow solid (0.03 g, 10.2%) identical (^{1}H nmr) with an authentic sample. Extrac-

tion of the silica gel fraction R_f 0.31 gave a red solid which was dissolved in chloroform and precipitated from solution by the addition of methanol. This gave **15***b* as a red solid (0.137 g, 35%); mp 84–86°C (dec.); ir: 1681 (s, C=O) and 1635 (s, C=C) cm^{-1}; ^1H nmr δ: 6.64–7.82 (m, 12H, Ph, H-4), 5.6–6.11 (m, 2H, H-2, H-3), 3.08 (s, 3H, NMe), 0.77–2.08 (m, 9H, *n*Bu). *Exact Mass* calcd. for $C_{30}H_{26}N_2O_2{}^{32}SF_2$: 516.1677; found (high resolution ms): 516.1680.

*4-Chloro-10-methyl-10*H*-pyrido[3,2-*b*][1,4]benzothiazine (**12**c) and 2-*n*-Butyl-10-methyl-10*H*-pyrido[3,2-*b*][1,4]benzothiazine (**13**c)*

n-Butyllithium (0.16 g, 2.5 mmol), 10-methyl-10*H*-pyrido-[3,2-*b*][1,4]benzothiazine (**1***f*) (0.535 g, 2.5 mmol), and trifluoromethanesulfonyl chloride (0.463 g, 2.75 mmol) were stirred at −77°C for 1 h and allowed to warm to room temperature over a 1.5 h period as described in the general procedure. The resulting dark yellow solution was treated with water (50 mL), extracted with dichloromethane (3 × 50 mL), and dried (Na_2SO_4). Evaporation of the solvent *in vacuo* gave a brownish red oil (0.819 g) of which 0.8 g was subjected to preparative thin-layer chromatography on 12 silica gel plates using benzene – ethyl acetate (10:1 v/v) as the development solvent. Extraction of the silica gel fraction R_f 0.97 gave **13***c* as a yellow oil (0.293 g, 44.4%) identical (^1H nmr) with an authentic sample (2). Extraction of the silica gel fraction R_f 0.64 gave a yellow semi-solid (0.143 g) which was rechromatographed on two silica gel plates using benzene as the development solvent. This gave two fractions R_f 0.41 and R_f 0.28. Extraction of the silica gel fraction R_f 0.28 gave **1***f* as a light yellow solid (0.027 g, 5.2%) identical (^1H nmr) with an authentic sample. Extraction of the silica gel fraction R_f 0.41 gave **12***c* as a light yellow solid (0.09 g, 14.5%), mp 74–75°C; ^1H nmr δ: 7.89 (d, $J_{2,3}$ = 5.5 Hz, 1H, H-2), 6.8–7.33 (m, 4H, Ph), 6.76 (d, $J_{2,3}$ = 5.5 Hz, 1H, H-3), 3.39 (s, 3H, NMe). *Exact Mass* calcd. for $C_{12}H_9N_2{}^{32}S^{37}Cl$: 250.0144; found (high resolution ms): 250.0141. *Exact Mass* calcd. for $C_{12}H_9N_2{}^{32}S^{35}Cl$: 248.0174; found (high resolution ms): 248.0168. *Anal.* calcd. for $C_{12}H_9N_2SCl$: C 57.95, H 3.65, N 11.26, S 12.88; found: C 57.95, H 3.73, N 11.24, S 12.83.

*1-Methoxycarbonyl-2-*n*-butyl-10-(3-dimethylaminopropyl)-1,2-dihydropyridyl[3,2-*b*][1,4]benzothiazine (**11**d) and 4-Methoxycarbonyl-10-(3-dimethylaminopropyl)-10*H*-pyrido[3,2-*b*][1,4]benzothiazine (**12**d)*

In a dry nitrogen atmosphere *n*-butyllithium (0.18 g. 2.81 mmol) was added dropwise with stirring to a solution of **1***b* (0.8 g, 2.81 mmol) in anhydrous tetrahydrofuran (125 mL) at 0°C. The resulting greenish brown solution was stirred at 0°C for 1 h, cooled to −77°C, and methyl chloroformate (0.318 g, 3.37 mmol) in anhydrous tetrahydrofuran (2 mL) was added dropwise. The reaction was stirred at −77°C for 1 h and allowed to warm to room temperature over a 2 h period. The resulting light brown solution was treated with water (75 mL), extracted with dichloromethane (4 × 50 mL), and dried (Na_2SO_4). Evaporation of the solvent *in vacuo* gave a brown oil (1.067 g) of which 0.65 g was subjected to preparative thin-layer chromatography on 12 silica gel plates using benzene – ethyl acetate (2:1 v/v) as the development solvent. Extraction of the silica gel fraction R_f 0.15 gave a yellow oil which was rechromatographed on four silica gel plates using ether–methanol (3:1 v/v) as the development solvent. This gave a single fraction R_f 0.87 which was extracted to give **11***d* as a yellow oil (0.215 g, 31.4%). Alternatively, chromatography of the reaction product on a 2.5 cm × 28 cm silica gel column and elution with ether (800 mL) gave **11***d* as a yellow oil (54.5%); ir (film): 1724 (s, C=O), 1635 (s, C=C) cm^{-1}; ^1H nmr δ: 6.7–7.34 (m, 4H, Ph), 5.42–5.93 (m, 2H, H-3, H-4), 4.79 (m, 1H, H-2), 3.52–3.88 (m, 2H, $CH_2CH_2CH_2NMe_2$), 3.69 (s, 3H, OMe), 2.14–2.45 (m, 2H, $CH_2CH_2CH_2NMe_2$), 2.14 (s, 6H, NMe_2), 0.69–2 (m, 11H, *n*Bu, $CH_2CH_2CH_2NMe_2$). *Exact Mass* calcd. for $C_{22}H_{31}N_3O_2{}^{32}S$: 401.2130; found (high resolution ms): 401.2135. Extraction of the silica gel fraction R_f 0.07 gave a yellowish brown oil (0.293 g) which was rechromatographed on four silica gel plates using chloroform–methanol (5:1 v/v) as the development solvent. This gave two fractions R_f 0.53 and R_f 0.45. Extraction of the silica gel fraction R_f 0.53 gave **12***d* as a bright yellow oil (0.044 g, 7.5%); ir (film): 1731 (s, C=O) cm^{-1}; ^1H nmr δ: 7.98 (d, $J_{2,3}$ = 5 Hz, 1H, H-2), 6.64–7.32 (m, 5H, Ph, H-3), 4.01 (m, 2H, $CH_2CH_2CH_2NMe_2$), 3.9 (s, 3H, OMe), 1.7–2.6 (m, 4H, $CH_2CH_2CH_2NMe_2$), 2.2 (s, 6H, NMe_2). *Exact Mass* calcd. for $C_{18}H_{21}N_3O_2{}^{32}S$: 343.1350; found (high resolution ms): 343.1348. Extraction of the silica gel fraction R_f 0.45 gave 10-(3-dimethylaminopropyl)-10*H*-pyrido[3,2-*b*][1,4]benzothiazine (**1***b*) as a light yellow oil (0.06 g, 12.3%) identical (^1H nmr) with an authentic sample.

*1-Diethylphosphoryl-2-*n*-butyl-10-(3-dimethylaminopropyl)-1,2-dihydropyridyl[3,2-*b*][1,4]benzothiazine (**11**e), 4-Diethylphosphoryl-10-(3-dimethylaminopropyl)-10*H*-pyrido[3,2-*b*][1,4]benzothiazine (**12**e), and 2-*n*-Butyl-4a-ethyl-10-(3-dimethylaminopropyl)-2,4a-dihydropyridyl-[3,2-*b*][1,4]benzothiazine (**14**e)*

In a dry nitrogen atmosphere *n*-butyllithium (0.213 g, 3.33 mmol) was added dropwise with stirring to a solution of **1***b* (0.79 g, 2.77 mmol) in anhydrous tetrahydrofuran (125 mL) at 0°C. The resulting greenish brown solution was stirred at 0°C for 45 min, allowed to warm to room temperature over a 0.5 h period, cooled to −77°C, and diethyl chlorophosphate (0.575 g, 3.33 mmol) in anhydrous tetrahydrofuran (2 mL) was added dropwise. The reaction was stirred at −77°C for 1.5 h and allowed to warm to room temperature over a 2 h period. The resulting dark yellow solution was treated with water (100 mL), extracted with chloroform (7 × 50 mL), and dried (Na_2SO_4). Evaporation of the solvent *in vacuo* gave a light brown oil (1.309 g) of which 0.72 g was subjected to preparative thin-layer chromatography on 10 silica gel plates using chloroform–methanol (5:1 v/v) as the development solvent. Extraction of the silica gel fraction R_f 0.87 gave **11***e* as a dark yellow oil (0.122 g, 16.7%); ir (film): 1271 (s, P=O), 1629, and 1568 (s, C=C) cm^{-1}; ^1H nmr δ: 6.67–7.38 (m, 4H, Ph), 5.4–5.95 (m, 2H, H-3, H-4), 4.43 (m, 1H, H-2), 3.53–4.32 (m, 6H, $(OCH_2CH_3)_2$, $—CH_2(CH_2)_2NMe_2$), 2.12–2.55 (m, 2H, $CH_2CH_2CH_2NMe_2$), 2.12 (s, 6H, NMe_2), 0.78–2.03 (m, 17H, *n*Bu, $CH_2CH_2CH_2NMe_2$), $(OCH_2CH_3)_2$). *Exact Mass* calcd. for $C_{24}H_{38}N_3O_3P^{32}S$: 479.2363; found (high resolution ms): 479.2354. Extraction of the silica gel fraction R_f 0.55 gave **14***e* as a yellow oil (0.014 g, 2.5%); ir (film): 1629 (s, C=N, C=C) cm^{-1}; ^1H nmr δ: 6.9–7.35 (m, 4H, Ph), 6.1 (d, $J_{3,4}$ = 10 Hz of d, $J_{2,3(4)}$ = 1.75 Hz, 1H, H-3 or H-4), 5.55 (d, $J_{3,4}$ = 10 Hz of d, $J_{2,3(4)}$ = 2 Hz, 1H, H-3 or H-4), 3.6–4.5 (m, 3H, H-2, $CH_2CH_2CH_2NMe_2$), 2.2 (s, 6H, NMe_2), 0.72–2.6 (m, 18H, *n*Bu, Et, $CH_2CH_2CH_2NMe_2$). *Exact Mass* calcd. for $C_{22}H_{33}N_3{}^{32}S$: 371.2388; found (high resolution ms): 371.2389. Extraction of the silica gel fraction R_f 0.05 gave **12***e* as a yellow oil (0.06 g, 9.3%); ir (film): 1266 (s, P=O) cm^{-1}; ^1H nmr δ: 8.09 (t, $J_{2,3}$ = $J_{2,31P}$ = 5 Hz, 1H, H-2), 6.72–7.3 (m, 5H, H-3, Ph), 3.74–4.5 (m, 6H, OCH_2CH_3, $CH_2CH_2CH_2NMe_2$), 1.62–2.65 (m, 4H, $CH_2CH_2CH_2NMe_2$), 2.22 (s, 6H, NMe_2), 1.32 (t, $J_{CH_2CH_3}$ = 7 Hz, 6H, OCH_2CH_3). *Exact Mass* calcd. for $C_{20}H_{28}N_3O_3P^{32}S$: 421.1582; found (high resolution ms): 421.1595. Extraction of silica gel fraction R_f 0.41 gave a brown oil (0.11 g) which was rechromatographed on two silica gel

plates using chloroform–methanol (2:1) as the development solvent. This gave a single fraction R_f 0.64 which was extracted to give **1***b* as a yellow oil (0.056 g, 12.9%) identical (^{1}H nmr) with an authentic sample.

*4-Chloro-10-(3-dimethylaminopropyl)-10*H*-pyrido[3,2-*b*][1,4]-benzothiazine (**12**f) and 2-*n*-Butyl-10-(3-dimethylaminopropyl)-10*H*-pyrido[3,2-*b*][1,4]benzothiazine (**13**f)*

In a dry nitrogen atmosphere *n*-butyllithium (0.122 g, 1.91 mmol) was added dropwise with stirring to a solution of **1***b* (0.534 g, 1.91 mmol) in anhydrous tetrahydrofuran (125 mL) at 0°C. The resulting greenish brown solution was stirred at 0°C for 1 h, cooled to −77°C, and trifluoromethanesulfonyl chloride (0.385 g, 2.29 mmol) in anhydrous tetrahydrofuran (2 mL) was added dropwise. The reaction was stirred at −77°C for 0.5 h and allowed to warm to room temperature over a 2 h period. The resulting lime green solution was treated with water (75 mL), extracted with dichloromethane (6 × 50 mL), and dried (Na_2SO_4). Evaporation of the solvent *in vacuo* gave a brown oil (0.683 g) of which 0.6 g was subjected to preparative thin-layer chromatography on nine silica gel plates using chloroform–methanol (5:1 v/v) as the development solvent. Extraction of the silica gel fraction R_f 0.79 gave **13***f* as a yellow oil (0.158 g, 27.7%); ^{1}H nmr δ: 6.74–7.4 (m, 4H, Ph), 7.1 (d, $J_{3,4}$ = 8 Hz, 1H, H-4), 6.57 (d, $J_{3,4}$ = 8 Hz, 1H, H-3), 4.1 (t, $J_{CH_2CH_3}$ = 7 Hz, 2H, CH_2CH_2-CH_2NMe_2), 0.69–2.81 (m, 13H, $CH_2CH_2CH_2NMe_2$, *n*Bu), 2.35 (s, 6H, NMe_2). *Exact Mass* calcd. for $C_{20}H_{27}N_3{}^{32}S$: 341.1920; found (high resolution ms): 341.1924. Extraction of the silica gel fraction R_f 0.46 gave a yellow oil (0.087 g) which was rechromatographed on two silica gel plates using chloroform–methanol (5:1 v/v) as the development solvent. This gave two fractions R_f 0.58 and R_f 0.5. Extraction of the silica gel fraction R_f 0.5 gave **1***b* as a yellow oil (0.015 g, 3.1%) identical (^{1}H nmr) with an authentic sample. Extraction of the silica gel fraction R_f 0.58 gave **12***f* as a yellow oil (0.051 g, 8.3%); ^{1}H nmr δ: 7.82 (d, $J_{2,3}$ = 5.5 Hz, 1H, H-2), 6.8–7.29 (m, 4H, Ph), 6.74 (d, $J_{2,3}$ = 5.5 Hz, 1H, H-3), 4.02 (t, $J_{CH_2CH_3}$ = 7 Hz, 2H, $CH_2CH_2CH_2NMe_2$) 1.76–2.57 (m, 4H, $CH_2CH_2CH_2NMe_2$), 2.2 (s, 6H, NMe_2). *Exact Mass* calcd. for $C_{16}H_{18}N_3{}^{32}S^{37}Cl$: 321.0877; found (high resolution ms): 321.0867. *Exact Mass* calcd. for $C_{16}H_{18}N_3{}^{32}S^{35}Cl$: 319.0907; found (high resolution ms): 319.0898.

*1-Diethylphosphoryl-2-*n*-butyl-10-(2-dimethylaminopropyl)-1,2-dihydropyridyl[3,2-*b*][1,4]benzothiazine (**11**g), 4-Diethylphosphoryl-10-(2-dimethylaminopropyl)-10*H*-pyrido[3,2-*b*][1,4]benzothiazine (**12**g), and 2-*n*-Butyl-10-(2-dimethylaminopropyl)-10*H*-pyrido[3,2-*b*][1,4]benzothiazine (**13**g)*

In a dry nitrogen atmosphere *n*-butyllithium (0.162 g, 2.53 mmol) was added dropwise with stirring to a solution of **1***c* (0.72 g, 2.53 mmol) in anhydrous tetrahydrofuran (125 mL) at 0°C. The resulting dark brown solution was stirred at 0°C for 1 h, cooled to −77°C, and diethyl chlorophosphate (0.524 g, 3.03 mmol) in anhydrous tetrahydrofuran (2 mL) was added dropwise. The reaction was stirred at −77°C for 1 h and allowed to warm to room temperature over a 2 h period. The resulting light orange solution was treated with water (100 mL), extracted with chloroform (6 × 50 mL), and dried (Na_2SO_4). Evaporation of the solvent *in vacuo* gave a dark reddish brown oil (0.984 g) of which 0.9 g was subjected to preparative thin-layer chromatography on 10 silica gel plates using chloroform–methanol (5:1 v/v) as the development solvent. Extraction of the silica gel fraction R_f 0.93 gave a yellow oil (0.256 g) which was rechromatographed on four silica gel plates using chloroform–methanol (5:1 v/v) as the development solvent. This gave two fractions R_f 0.88 and R_f 0.72. Extraction of the silica gel fraction R_f 0.88 gave **11***g* as a yellow oil (0.156 g, 14.1%); ir (film): 1270 (s, P=O), 1630, and 1565 (s, C=C) cm^{-1}; ^{1}H nmr δ: 6.8–7.23 (m, 4H, Ph), 5.4–5.92 (m, 2H, H-3, H-4), 3.3–4.67 (m, 7H, $(OCH_2CH_3)_2$, H-2, CH_2), 2.7 (m, 1H, CH), 2.23 (s, 6H, NMe_2), 0.71–1.86 (m, 15H, *n*Bu, $(OCH_2CH_3)_2$), 0.98 (d, J_{CH_3CH} = 6.5 Hz, 3H, Me). *Exact Mass* calcd. for $C_{24}H_{38}N_3O_3P^{32}S$: 479.2363; found (high resolution ms): 479.2369. Extraction of the silica gel fraction R_f 0.72 gave **13***g* as a yellow oil (0.019 g, 2.4%); ^{1}H nmr δ: 6.5–7.38 (m, 6H, Ph, H-2, H-3), 4.28 (d, J_{CH_2CH} = 6.5 Hz, 2H, CH_2), 3.1 (m, 1H, CH), 2.64 (d, $J_{CH_2CH_2C_2H_5}$ = 7 Hz, 2H, $CH_2C_3H_7$), 2.38 (s, 6H, NMe_2), 0.7–1.86 (m, 7H, $CH_2C_3H_7$), 1.06 (d, J_{CH_3CH} = 6.5 Hz, 3H, Me). *Exact Mass* calcd. for $C_{20}H_{27}N_3{}^{32}S$: 341.1920; found (high resolution ms): 341.1917. Extraction of the silica gel fraction R_f 0.61 gave a yellow oil (0.094 g) which was rechromatographed on one silica gel plate using chloroform–methanol (5:1 v/v) as the development solvent. This gave a single fraction R_f 0.67 which gave **12***g* as a yellow oil (0.077 g, 7.9%); ir (film): 1268 (s, P=O) cm^{-1}; ^{1}H nmr δ: 8.16 (t, $J_{2,3} = J_{2,31P}$ = 5 Hz, 1H, H-2). 6.89–7.5 (m, 5H, H-3, Ph), 3.96–4.51 (m, 6H, CH_2, $(OCH_2CH_3)_2$), 3.11 (m, 1H, CH), 2.33 (s, 6H, NMe_2), 1.36 (t, $J_{CH_2CH_3}$ = 7 Hz, 6H, $(OCH_2CH_3)_2$), 1.07 (d, J_{CH_3CH} = 6.5 Hz, 3H, CH_3). *Exact Mass* calcd. for $C_{20}H_{28}N_3O_3P^{32}S$: 421.1583; found (high resolution ms): 421.1580.

*1-Methoxycarbonyl-2-*n*-butyl-10-(2-dimethylaminopropyl)-1,2-dihydropyridyl[3,2-*b*][1,4]benzothiazine (**11**h) and 4-Methoxycarbonyl-10-(2-dimethylaminopropyl)-10*H*-pyrido[3,2-*b*][1,4]benzothiazine (**12**h)*

In a dry nitrogen atmosphere *n*-butyllithium (0.162 g, 2.53 mmol) was added dropwise with stirring to a solution of **1***c* (0.072 g, 2.53 mmol) in anhydrous tetrahydrofuran (125 mL) at 0°C. The resulting dark brown solution was stirred at 0°C for 1 h, cooled to −77°C, and methyl chloroformate (0.286 g, 3.03 mmol) in anhydrous tetrahydrofuran (2 mL) was added dropwise. The reaction was stirred at −77°C for 1 h and allowed to warm to room temperature over a 2 h period. The resulting light brown solution was treated with water (100 mL), extracted with chloroform (5 × 50 mL), and dried (Na_2SO_4). Evaporation of the solvent *in vacuo* gave a dark reddish brown oil (1.038 g) of which 0.9 g was subjected to preparative thin-layer chromatography on 12 silica gel plates using ethyl acetate – ether (5:1 v/v) as the development solvent. Extraction of the silica gel fraction R_f 0.34 gave **11***h* as a yellow oil (0.338 g, 38.5%); ir (film): 1726 (s, C=O), 1630 (s, C=C) cm^{-1}; ^{1}H nmr δ: 6.74–7.32 (m, 4H, Ph), 5.49–5.96 (m, 2H, H-3, H-4), 4.9 (m, 1H, H-2), 3.4–3.8 (m, 2H, CH_2), 3.72 (s, 3H, OMe), 3.0 (m, 1H, CH), 2.3 (s, 6H, NMe_2), 0.69–1.88 (m, 9H, *n*Bu), 1.07 (d, J_{CH_3CH} = 6.5 Hz, 3H, Me). *Exact Mass* calcd. for $C_{22}H_{31}N_3O_2{}^{32}S$: 401.2130; found (high resolution ms): 401.2146. Extraction of the silica gel fraction R_f 0.14 gave a dark yellow oil (0.25 g) which was rechromatographed on six silica plates using chloroform–methanol (5:1 v/v) as the development solvent. This gave two fractions R_f 0.8 and R_f 0.73. Extraction of the fraction R_f 0.8 gave **12***h* as a yellow oil (0.064 g, 8.5%); ir (film): 1729 (s, C=O) cm^{-1}; ^{1}H nmr δ: 8.0 (d, $J_{2,3}$ = 5 Hz, 1H, H-2), 6.7–7.32 (m, 4H, Ph), 7.16 (d, $J_{2,3}$ = 5 Hz, 1H, H-3), 4.08–4.3 (m, 2H, CH_2), 3.9 (s, 3H, OMe), 3.08 (m, 1H, CH), 2.29 (s, 6H, NMe_2), 1.0 (d, J_{CH_3CH} = 6.5 Hz, 3H, CH_3). *Exact Mass* calcd. for $C_{18}H_{21}N_3O_2{}^{32}S$: 343.1350; found (high resolution ms): 343.1347. Extraction of the silica gel fraction R_f 0.73 gave **1***c* as a yellow oil (0.075 g, 12%) identical (^{1}H nmr) with an authentic sample.

10H-Pyrido[3,2-b][1,4]benzothiazine (1a)

In a dry nitrogen atmosphere *n*-butyllithium (0.202 g, 3.16 mmol) was added dropwise with stirring to a solution of **1***g* (0.9 g, 3.16 mmol) in anhydrous tetrahydrofuran (125 mL) at 0°C. The resulting dark brown solution was stirred at 0°C for 1.5 h, cooled to −77°C, and methyl chloroformate (0.358 g, 3.79 mmol) in anhydrous tetrahydrofuran (2 mL) was added dropwise. The reaction was stirred at −77°C for 1 h and allowed to warm to room temperature over a 2 h period. The resulting orange-red suspension was treated with water (100 mL), extracted with chloroform (8 × 50 mL), and dried (Na_2SO_4). Evaporation of the solvent *in vacuo* gave a brown oil (0.856 g) of which 0.8 g was subjected to preparative thin-layer chromatography on 12 silica gel plates using benzene–ether (1:1 v/v) as the development solvent. Extraction of the silica gel fraction R_f 0.54 gave 10*H*-pyrido[3,2-*b*]-[1,4]benzothiazine (**1***a*) as a yellow solid (0.09 g. 15.2%) identical (^{1}H nmr, mp) with an authentic sample.

*10-(2-*N*-Methoxycarbonyl-2-*N*-methylaminoethyl)-10H-pyrido[3,2-b][1,4]benzothiazine (18)*

In a dry nitrogen atmosphere *n*-butyllithium (0.165 g, 2.58 mmol) was added dropwise with stirring to a solution of **1***h* (0.7 g, 2.58 mmol) in anhydrous tetrahydrofuran (30 mL) at 0°C. The resulting dark brown solution was stirred at 0°C for 40 min, cooled to −77°C, and methyl chloroformate (0.488 g, 5.17 mmol) in tetrahydrofuran (2 mL) was added dropwise. The resulting solution was stirred at −77°C for 0.5 h and allowed to warm to room temperature over a 3.5 h period. The resulting dark brown solution was treated with water (50 mL), extracted with ether (3 × 100 mL), and dried (Na_2SO_4). Evaporation of the solvent *in vacuo* gave a dark brown oil (0.711 g) of which 0.6 g was subjected to preparative thin-layer chromatography on seven silica gel plates using benzene–ether (5:1 v/v) as the development solvent. Extraction of the silica gel fraction R_f 0.40 gave **18** as a dark yellow oil (0.167 g, 24.4%); ir (film): 1710 (s, C=O) cm^{-1}; ^{1}H nmr δ: 8.0 (d, $J_{2,3}$ = 5 Hz of d, $J_{2,4}$ = 1.75 Hz, 1H, H-2), 6.59–7.34 (m, 6H, Ph, H-3, H-4), 4.29 (m, 2H, $CH_2CH_2NCH_3(CO_2Me)$, 3.51–3.95 (m, 2H, $CH_2CH_2NCH_3(CO_2Me)$, 3.74 (s, 3H, OMe), 3.04 (s. 3H, NMe). *Exact Mass* calcd. for $C_{16}H_{17}N_3O_2{}^{32}S$: 315.1038; found (high resolution ms): 315.1042. Extraction of the silica gel fraction R_f 0.15 gave **1***h* as a light brown oil (0.19 g, 32.1%) identical (^{1}H nmr) with an authentic sample.

*10-*n*-Hexyl-10H-pyrido[3,2-b][1,4]benzothiazine (19)*

In a dry nitrogen atmosphere **1***h* (0.8 g, 2.95 mmol) in anhydrous tetrahydrofuran (5 mL) was added dropwise with stirring to a solution of *n*-butyllithium (0.567 g, 8.86 mmol) in anhydrous tetrahydrofuran (50 mL) at 0°C. This solution was stirred at 0°C for 1 h and allowed to warm to room temperature over a 1 h period. The resulting dark brown solution was treated with water (50 mL), extracted with ether (2 × 100 mL), and dried (Na_2SO_4). Evaporation of the solvent *in vacuo* gave a reddish brown oil (1.084 g) of which 0.33 g was subjected to preparative thin-layer chromatography on seven silica gel plates using benzene–ether (5:1 v/v) as the development solvent. Extraction of the silica gel fraction R_f 1 gave a dark yellow oil which was rechromatographed on one silica gel plate using petroleum ether (bp 35–60°C) as the development solvent. This gave a single fraction R_f 0.05 which was extracted to give **19** as a yellow oil (0.066 g, 25.9%); ^{1}H nmr δ: 8.01 (d, $J_{2,3}$ = 5 Hz of d, $J_{2,4}$ = 1.75 Hz, 1H, H-2), 6.59–7.38 (m, 6H, Ph, H-3, H-4), 4.1 (t, $J_{NCH_2CH_2C_4H_9}$ = 7 Hz, 2H, $NCH_2C_5H_{11}$), 0.65–2.11 (m, 11H, $NCH_2C_5H_{11}$). *Exact Mass* calcd. for $C_{17}H_{20}N_2{}^{32}S$: 284.1343; found (high resolution ms): 284.1347. This material was identical (ir, ^{1}H nmr) with an authentic sample of **19** prepared from the reaction of **1***a* with sodium hydride and *n*-hexyl chloride described below.

10*H*-Pyrido[3,2-*b*][1,4]benzothiazine **1***a* (0.5 g, 2.5 mmol) was added to a suspension of sodium hydride (0.120 g, 5 mmol) in toluene (40 mL) and the mixture was heated under reflux for 1 h. A solution of *n*-hexylchloride (0.333 g, 2.75 mmol) in toluene (3 mL) was added dropwise and the mixture was allowed to reflux for a further 66 h. After cooling to 25°C, 15 mL methanol and then 50 mL water was added slowly. Extraction with methylene chloride (4 × 50 mL) and evaporation of the solvent gave a brown oil which was purified on a 2.5 cm × 23 cm silica gel column. Elution with petroleum ether (bp 37–57°C) (200 mL) gave a hydrocarbon oil which was discarded. Elution with petroleum ether – ether (1:1 v/v) (300 mL) gave **19** (0.278 g, 39.2%) identical (^{1}H nmr, ir) with the same product described previously. Further elution with the same eluant (300 mL) gave **1***a* (0.21 g, 42% recovery).

Received November 30, 1978

F. G. HERRING, J. M. PARK, S. J. RETTIG, and J. TROTTER. Can. J. Chem. **57**, 2379 (1979).

Crystals of Ni(II) bis(morpholine-*N*-carbodithioate) are monoclinic, $a = 4.291(1)$, $b = 20.584(2)$, $c = 8.365(1)$ Å, $\beta = 97.39(2)°$, $Z = 2$, space group $P2_1/n$. The structure was solved by Patterson and Fourier syntheses and was refined by full-matrix least-squares procedures to $R = 0.036$ and $R_w = 0.044$ for 1800 reflections with $I \geq 3\sigma(I)$. The crystal structure consists of discrete molecules having approximate C_{2h} and exact (crystallographic) C_i symmetry. The nickel atom is coordinated to four sulphur atoms in a planar arrangement with Ni—S = 2.2122(7) and 2.2134(6) Å and S—Ni—S = 79.16(2) and 100.84(2)°.

The electron paramagnetic resonance spectra of ^{63}Cu(II) bis(morpholine-*N*-carbodithioate) and ^{63}Cu(II) bis(pyrrolidine-*N*-carbodithioate) doped in the respective Ni(II) analogues have been recorded at room temperature. The spin Hamiltonian parameters obtained from an analysis of the spectra of the polycrystalline samples have been used to investigate the bonding in these complexes. The results are compared to previous studies in carbodithioates.

F. G. HERRING, J. M. PARK, S. J. RETTIG et J. TROTTER. Can. J. Chem. **57**, 2379 (1979).

Les cristaux du bis(morpholine *N*-carbodithioate) Ni(II) sont monocliniques, $a = 4.291(1)$, $b = 20.584(2)$, $c = 8.365(1)$ Å, $\beta = 97.39(2)°$, $Z = 2$, groupe d'espace $P2_1/n$. On a résolu la structure par des synthèses de Patterson et de Fourier et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur de $R = 0.036$ et de $R_w = 0.044$ pour 1800 réflexions avec $I \geq 3\sigma(I)$. La structure cristalline comprend des molécules individuelles de symétrie approximative C_{2h} et de symétrie exacte (cristallographique) C_i. L'atome de nickel est coordonné à quatre atomes de soufre avec un arrangement planaire où Ni—S = 2.2122(7) et 2.2134(6) Å et S—Ni—S = 79.16(2) et 100.84(2)°.

Opérant à la température ambiante, on a enregistré le spectre de résonance paramagnétique électronique du ^{63}Cu bis(morpholine *N*-carbodithioate) et ^{63}Cu bis(pyrrolidine-*N*-carbodithioate) dopé avec son analogue au Ni(II). On a utilisé les paramètres Hamiltonien des spins provenant d'une analyse des spectres d'échantillons polycristallins pour étudier les liaisons dans ces complexes. On compare les résultats avec ceux obtenus dans des études antérieures de carbodithioates.

[Traduit par le journal]

The complexes formed by dithiocarbamates with transition metal ions have been the subject of many studies (1–4). These complexes have intriguing spectroscopic and structural properties arising from contributions of resonance structures which lead to an effective dianion electronic structure (1). The overall bonding to the transition metal is therefore very covalent leading to, for example, epr hyperfine parameters which are quite different from those in complexes where the donor atom is a harder base.

The binary complexes of dialkyldithiocarbamates with Cu(II) are very stable and their epr spectra have been widely investigated both in the solid state and frozen solution (5–8). Copper(II) bisdiethyldithiocarbamate has also been used to study fast Lewis acid–base reactions (9) as a probe of molecular motion in liquids (10). In order that a complex of Cu(II) can be used as a probe of molecular motion in liquids it is necessary that the anisotropies of the epr spin Hamiltonian be accurately determined. The g-tensor and hyperfine tensor can be obtained with sufficient accuracy from polycrystalline samples of the Cu(II) complex in the Ni(II) analogue; however, in doing so it is necessary to be sure that the environment in the host lattice does not include any dimeric interactions nor non-square planar coordination as, for example, in the case of the diethyldithiocarbamates of Zn(III) and Cu(II). In addition 'to accurately determine hyperfine parameters' it is desirable that the shape of the spin probe be as well defined as possible. To this end a dithiocarbamate ligand with the N-atom in a ring structure is suitable, and consequently we have investigated the utility of pyrrolidine-*N*-carbodithioate and morpholinecarbodithioate as ligands.

The present paper describes the epr of ^{63}Cu(II)-bis(pyrrolidine-*N*-carbodithioate) and ^{63}Cu(II) bis-(morpholine-*N*-carbodithioate) doped in their Ni(II) analogues together with the X-ray crystal structure analysis of the Ni(II) bis(morpholine-*N*-carbodi-

0008-4042/79/182379-07$01.00/0

thioate), that of the pyrrolidine-*N*-carbodithioate already having been determined (12). The results are used to compare the bonding in these compounds with that of the pyrrole analogue (13).

Experimental

Preparation of Compounds

Potassium morpholinecarbodithioate was prepared by mixing stoichiometric quantities of morpholine, carbon disulphide, and potassium hydroxide in water. The resultant salt was used to prepare the Ni(II) and ^{63}Cu(II) complexes by mixing the respective chloride and salt in water. The resultant precipitate was repeatedly washed and then recrystallized from chloroform. Crystals of Ni(II) bis(morpholinecarbodithioate) for the X-ray diffraction studies were obtained by slow evaporation at ambient temperature of a saturated chloroform solution.

The ^{63}Cu(II) bis(pyrrolidinecarbodithioate) was prepared as above using the ammonium salt which was obtained from Aldrich Chemicals. The $^{63}CuCl_2$ was prepared as described previously (10). All compounds studied in this work gave the correct microanalytical results for C, H, and N.

Electron Paramagnetic Resonance

Electron paramagnetic resonance (epr) spectra of polycrystalline samples of the ^{63}Cu(II) complex doped (1 : 1000) in the Ni(II) analogues were recorded at room temperature (22°C) in an X-band (9.05 GHz) spectrometer. The $NiCl_2$ used to prepare the Ni analogue of the carbodithioate under consideration often contained a high level of Cu(II) (mixed isotopes) which obscured the epr spectrum of the ^{63}Cu(II) carbodithioate doped in the Ni carbodithioate. This situation was remedied by coprecipitating the Cu(II) impurity with the Ni carbodithioate by pretreating a $NiCl_2$ solution with half an equivalent of the potassium carbodithioate. The resulting solution was filtered and the supernatant liquid, containing purified $NiCl_2$, used to prepare the Ni(II)bis(carbodithioate). The Ni complex prepared in this way proved to be free of Cu(II) at the operating levels of the epr spectrometer, and was subsequently used as a host for the Cu(II) complex.

The magnetic field of the epr spectrum was calibrated using a proton magnetometer and the microwave frequency was accurately measured using an HP 5425L counter equipped with an X-band plug-in.

The epr spectrum of ^{63}Cu(II) bis(morpholinecarbodithioate) is shown in Fig. 1. The g-tensor and hyperfine tensor were obtained by simulating the observed spectrum using a computer program described previously (14). The results of the simulations for the morpholine complex are shown in Fig. 2 and the spin Hamiltonian parameters used are presented in Table 1. The results for the pyrrolidine-*N*-carbodithioate are also included in Table 1.

X-ray Crystallographic Analysis of Ni(II) Bis(morpholine-N-carbodithioate)

The crystal chosen for study, grown by slow evaporation of a chloroform solution, was mounted with $(\bar{1}\bar{1}0)$ normal to the goniostat axis and had dimensions of ca. 0.6 × 0.2 × 0.35 mm. Unit-cell and space group data were obtained from film and diffractometer measurements. The unit-cell parameters were refined by least squares on 2 sin θ/λ values for 16 reflections measured on a diffractometer with MoK_α radiation (λ = 0.71073 Å). Crystal data (at 22°C) are:

$C_{10}H_{16}N_2NiO_2S_4$ fw = 383.22

Monoclinic, $a = 4.291(1)$, $b = 20.584(2)$, $c = 8.365(1)$ Å, $\beta = 97.39(2)°$, $V = 732.6(2)$ Å^3, $Z = 2$, $\rho_c = 1.737$ g cm^{-3}, $F(000) = 396$, $\mu(MoK_\alpha) = 18.6$ cm^{-1}. Absent reflections: $0k0$, $k = 2n$, $h0l$, $h + l \neq 2n$ define uniquely the space group $P2_1/n$ (alternate setting of $P2_1/c$, C_{2h}^5, No. 14).

Intensities were measured with zirconium-filtered MoK_α radiation on a Datex-automated General Electric XRD-6 diffractometer. A θ–2θ scan at 4° min^{-1} over a range of (1.80 + 0.86 tan θ)° in 2θ was employed. Background counts of 10 s were measured at each end of the scan. Data were measured to 2θ = 65°. The intensities of the check reflections, measured every 50 reflections throughout the data collection,

†cm^{-1} × 10^4.

decreased uniformly to final values which were 0.93 times the initial values and appropriate corrections were made. After data reduction, an absorption correction was applied using the Gaussian integration method (15, 16). Transmission factors ranged from 0.582 to 0.728. Of the 2656 independent reflections measured, 1800 (68%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + B + (0.025S)^2$ with S = scan count and B = time-averaged background count.

The positions of the sulphur atoms were determined from the Patterson function assuming the nickel atom to be situated at the origin, and those of the O, N, and C atoms from a subsequent difference map. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to $R = 0.100$, a difference map gave the coordinates of all 8 independent hydrogen atoms, which were included in all subsequent cycles of refinement with isotropic thermal parameters. The scattering factors of ref. 17 were used for the non-hydrogen atoms and those of ref. 18 for hydrogen atoms. Anomalous scattering factors from ref. 19 were used for the Ni and S atoms. The weighing scheme, $w = (|F_o|/5.5)^2$ if $|F_o| < 5.5$, $w = 1$ if $5.5 \leq |F_o| \leq 25.0$, $w = (25.0/|F_o|)^2$ if $|F_o| > 25.0$, and $w = 0.144$ for the unobserved reflections, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. A type I anisotropic extinction correction (Thornley–Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (20–22). Extinction parameters are given in Table 2. Convergence was reached at $R = 0.036$ and $R_w = 0.044$ for 1800 reflections with $I \geq 3\sigma(I)$. For all 2656 planes $R = 0.061$ and $R_w = 0.051$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.15 and 0.68σ respectively. The mean error in an observation of unit weight was 0.4784. The final positional and thermal parameters appear in Tables 3 and 4 respectively.[1] Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 3. Rigid-body thermal motion analysis (23) has been carried out using the computer program MGTLS. The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0010 Å^2. Analysis of the 7-atom group consisting of C(1) plus the six morpholine ring atoms gave physically reasonable results (rms $\Delta U_{ij} = 0.0008$ Å^2). The appropriate bond lengths have been corrected for libration (24), using shape parameters q^2 of 0.08 for all atoms involved. Corrections to bonds involving atoms not included in the rigid-body were estimated using independent motion corrections based on the ΔU_{ij}. Corrected and uncorrected bond lengths are given in Table 5 and corrected bond angles in Table 6. Intra-annular torsion angles for the chelate and morpholine rings are given in Table 7.

Individual molecules of $Ni(S_2CNC_4H_8O)_2$ have exact (crystallographic) C_i symmetry with the nickel atoms located at the inversion centres (0,0,0) and $(\frac{1}{2},\frac{1}{2},\frac{1}{2})$. The molecule (Fig. 3) effectively has C_{2h} symmetry, the mirror plane being normal to the NiS_4 plane and containing Ni, C(1), N, and O. Bond lengths and angles are consistent with C_{2h} symmetry within experimental error but the C_{2h} symmetry is broken by a small twist of the morpholine ring with respect to the $C(1)S_2$ plane (the angle between normals to the C(1) and N coordination groups being 3.2°). This is assumed to be a result of packing forces.

The NiS_4 group is exactly planar as a result of the molecular inversion centre. Important mean[2] structural parameters are in excellent agreement with those found for related molecules (see Table 8). The relatively long mean Ni—S distance of 2.2128(6) Å is as expected for a dithiocarbamate ligand which generates a weak crystal field (32). Although the $Ni(S_2CNC_2)_2$ group is planar to within ±0.116 Å, deviations of this magnitude represent highly significant deviations from planarity. The four-membered chelate ring, NiS_2C, is slightly but significantly ($x^2 = 29.0$) non-planar as are the coordination groups of C(1) and N (displaced −0.011(2) and 0.073(2) Å respectively from the planes defined by their substituents). The morpholine ring adopts a nearly regular chair conformation, slightly distorted by the nearly planar coordination at nitrogen. Bond lengths

*a and e refer to axial and equatorial respectively.

[1]Structure factors and thermal parameters (Table 4) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[2]Here and elsewhere in this report mean values refer to weighted means with rms deviations from the mean in parentheses.

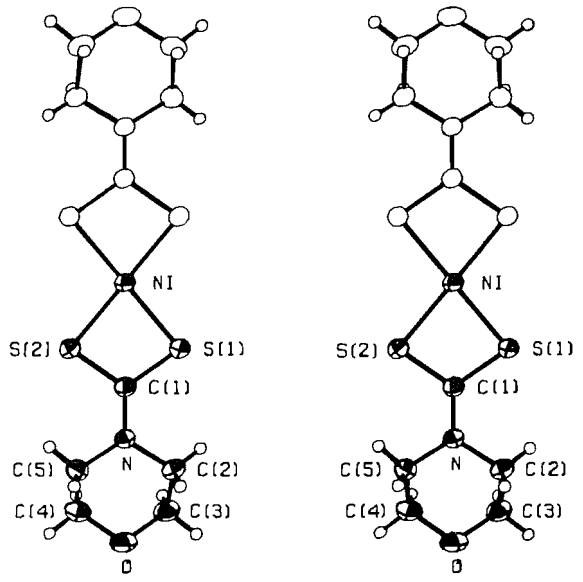

FIG. 3. Stereoview of the $Ni(S_2CNC_4H_8O)_2$ molecule. 50% thermal ellipsoids are shown for the non-hydrogen atoms; hydrogen atoms have been given artificially small temperature factors for the sake of clarity.

and angles in the morpholine ring are as expected. A possibly significant difference between the mean axial and equatorial C—H bond distance (1.02(2) vs. 0.93(4) Å) has been noted.

The crystal structure viewed along a^* is shown in Fig. 4. It has been noted that packing in compounds of this type is generally dominated by S···H and/or M···H contacts (11, 12, 29, 30, 32–34). The present structure is no exception, being made up of discrete molecules of $Ni(S_2CNC_4H_8O)_2$ linked by weak C—H···S interactions (S(2)···H(3e)(x, y, $1 + z$) = 2.95(3) and (S2)···H(4e)($x - \frac{1}{2}$, $\frac{1}{2} - y$, $\frac{1}{2} + z$) = 2.98(4) Å). All other intermolecular distances are greater than the sum of van der Waals radii. The shortest Ni···S contact is 3.847(1) Å (Ni···S(1) ($x - 1$, y, z and $2 - x$, $1 - y$, $1 - z$)), and does not represent any significant interaction.

Analysis of the epr Data for the Cu(II) Morpholine and Pyrrolidine N-carbodithioates

The spin Hamiltonian parameters obtained for the copper(II) complexes of the morpholinecarbodithioate and pyrrolidine-*N*-carbodithioate liquids are given in Table 1. The hyperfine and g-tensor show an orthorhombic character which can be attributed to a S(1)—Cu—S(2) angle of less than 90° and variations in Cu—S(1) and Cu—S(2) bond lengths; both of these distortions lead to symmetries less than D_{4h} and cause a splitting of the d_{xz} and d_{yz} orbitals producing the observed non-axial character. The magnitudes of the spin Hamiltonian parameters are typical for most dithiocarbamates with the possible exception of the pyrrolle-*N*-carbodithioate; this can be seen from Table 9 where the results for other complexes are collected. The parameters in Table 9 are all for the copper-63 complex doped in the nickel analogue with the exception of the pyrrole derivative (13). The crystal structures of the diethyl, morpholine, and pyrrolidine carbodithioates of Ni(II) are known (11, 12) and a summary of pertinent results is shown in Table 8. A consideration of the data in this table shows that only very weak axial interactions at the nickel atom occur in these lattices so that the spin Hamiltonian parameters obtained reflect a square planar environment free of additional interactions. This is not the case in Zn diethyldithiocarbamate, for example, where the environment is close to square pyramidal (11). The parameters for the Cu(II)-bis(pyrrole-carbodithioate) were obtained in the Cd(II) analogue and by use of mixed Cu isotopes; the latter fact leads to relatively inaccurate spin Hamiltonian parameters due to overlap of the ^{63}Cu and ^{65}Cu lines in the perpendicular region of the spectrum. The results for dimethyldithiocarbamate were obtained using Cu(II)-63 in the Ni(II) complex (25). Unfortunately the crystal structure for Ni(II) bis(dimethyldithiocarbamate) has not been determined so that the exact environment around the Ni(II) is not known and consequently absolutely reliable comparisons cannot be made, but the results are included for completeness.

The ligand environment around the Cu or Ni in dithiocarbamates corresponds to D_{2h} symmetry. A crystal field calculation by Choi *et al.* (26) for D_{2h} symmetry and four sulphur ligands shows as expected a $^2B_{1g}$ ground state. The application of group theory shows that the antibonding molecular orbitals are (27):

$$\psi_{B_{1g}} = \alpha d_{xy} - \tfrac{1}{2}\alpha'[-\sigma_{xy}^{(1)} + \sigma_{xy}^{(2)} + \sigma_{xy}^{(3)} - \sigma_{xy}^{(4)}]$$

$$\psi_{A_g} = \beta d_{x^2-y^2} - \tfrac{1}{2}\beta'[-p_{xy}^{(1)} - p_{xy}^{(2)} + p_{xy}^{(3)} + p_{xy}^{(4)}]$$

$$\psi_{A_g} = \gamma d_{z^2} - \tfrac{1}{2}\gamma'[\sigma_{xy}^{(1)} + \sigma_{xy}^{(2)} - \sigma_{xy}^{(3)} - \sigma_{xy}^{(4)}]$$

$$\psi_{B_{3g}} = \delta d_{yz} - \tfrac{1}{2}\delta'[p_z^{(1)} + p_z^{(2)} - p_z^{(3)} - p_z^{(4)}]$$

$$\psi_{B_{2g}} = \varepsilon d_{xz} - \tfrac{1}{2}\varepsilon'[p_z^{(1)} - p_z^{(2)} + p_z^{(4)} - p_z^{(3)}]$$

using the notation of Gersmann and Swalen (27). The magnetic parameters are:

[1] $g_{zz} = g_e - (\delta\lambda/\Delta E_{x^2-y^2})(\alpha^2\beta^2)$

[2] $g_{xx} = g_e - (2\lambda/\Delta E_{xz})(\alpha^2\varepsilon^2)$

[3] $g_{yy} = g_e - (2\lambda/\Delta E_{yz})(\alpha^2\delta^2)$

[4] $A_{zz} = -K - \frac{4}{7}\alpha^2 P - 2\lambda\alpha^2 P\left(\frac{4\beta^2}{\Delta E_{x^2-y^2}} + \frac{3}{14}\frac{\delta^2}{\Delta E_{yz}} + \frac{3}{14}\frac{\varepsilon^2}{\Delta E_{xz}}\right)$

[5] $A_{xx} = -K + \frac{2}{7}\alpha^2 P - \frac{22}{14}\frac{\lambda\alpha^2\varepsilon^2}{\Delta E_{xz}}$

[6] $A_{yy} = -K + \frac{2}{7}\alpha^2 P - \frac{22}{14}\frac{\lambda\alpha^2\delta^2}{\Delta E_{yz}}$

These equations have been modified so that the Fermi contact term is represented by $-K$ and not $-\alpha^2 k$. The latter form is based upon the misconception that the Fermi contact term for d^9 systems is proportional to the square of the M.O. coefficient of the *d*-orbital in the single electron M.O.; this has been shown to be incorrect by McGarvey (28). The other symbols have their usual meaning and we adopt the values $\lambda = -828\ cm^{-1}$ and $P = 360 \times 10^{-4}\ cm^{-1}$.

The evaluation of the bonding parameters, α, β, δ, ε, and K requires a knowledge of the electronic spectrum of the dithiocarbamates of Cu(II). Recently Choi *et al.* (26) have performed an analysis of the electronic spectra of these complexes and the results can be summarized as the $d_{xy} \rightarrow d_{xz}$ and $d_{xy} \rightarrow d_{yz}$ occurring at ca. 2.30 μm^{-1}, $d_{xy} \rightarrow d_{x^2-y^2}$ at ca. 1.90 μm^{-1} and $d_{xy} \rightarrow d_{z^2}$ at ca. 1.60 μm^{-1}. The only disconcerting aspect of this interpretation is the very large extinction coefficient (or molar absorbtivity) of the band at 2.30 μm^{-1} which is unexpected for a *d–d* band. Choi *et al.* (26) provide a reasonable explanation of this large extinction coefficient and the orbital order is supported by crystal field calculations.

It is easy to show that the Fermi contact term can be obtained from:

$$-K = [(A_{xx} + A_{yy} + A_{zz}) - P(\Delta g_{xx} + \Delta g_{yy} + \Delta g_{xx})]/3$$

and α^2 from:

$$\alpha^2 = 7[-A_{zz} - K + P(\Delta g_{zz} + (3/14)\Delta g_{xx} + (3/14)\Delta g_{yy})]/(4P)$$

where $\Delta g_{xx} = g_{xx} - 2.0023$, etc., and the signs of A_{xx}, A_{yy}, and A_{zz} are taken to be negative. Once α^2 has been obtained β^2 can be obtained from eq. [1] with a knowledge of $\Delta E(xy \rightarrow x^2 - y^2)$ together with Δg_{xx} and Δg_{yy}. Finally we determined an average value of δ^2 by neglecting the slight orthorhombic character (i.e. setting $\delta^2 = \varepsilon^2$ and $\Delta E_{xz} \approx \Delta E_{yz}$) and using $g = \frac{1}{2}(g_{xx} + g_{yy})$ with the appropriate average of eq. [2] and eq. [3]. This was done since the electronic spectra do not permit a resolution of the $\Delta E(xy \rightarrow yz)$ transitions and this procedure is in accord with previous work where only $g_\perp$ is measured. We note that the above method of calculation of bonding parameters makes no assumptions as to the dependence of the Fermi contact term on α^2, nor does it assume that the Fermi contact term is a constant for all dithiocarbamates as is done in the method adopted by Bereman and Nalewajek (13). The results of the calculations are given in Table 9.

Discussion

It is appropriate to discuss our epr results in relation to previous studies. The most extensive epr studies have been carried out on $Cu(DEDTC)_2$ (5–8) and there is some variation in the spin Hamiltonian parameters. The variations in spin Hamiltonian parameters are well understood in terms of axial interactions or lowering of symmetry which cause $g_\parallel$ to increase and $A_\parallel$ to decrease (40). Thus if a study of the spectrum of $Cu(DEDTC)_2$ is made in even a mildly coordinating solvent quite large increases in $g_\parallel$ and decreases in $A_\parallel$ can be observed (40). This presumably accounts for the difference in hyperfine parameters observed for $Cu(DEDTC)_2$ in chloroform: toluene glass (10, 40), and $Cu(DEDTC)_2$ in the Ni analogue where axial interactions are minimal. We therefore feel that the hyperfine parameters obtained in the Ni(II) analogue reflect more closely those that would be obtained for the Cu(II) complex free of any non-specific interactions.

Weeks and Fackler (5) determined the spin Hamiltonian parameters of $Cu(DEDTC)_2$ in the Ni analogue and deduced from them the bonding parameters using various degrees of approximation. The results obtained by them using $\Delta E(xy \rightarrow x^2 - y^2) = 1.60\ \mu m^{-1}$ and $\Delta E(xy \rightarrow xz) = 2.0\ \mu m^{-1}$ are $\alpha = 0.74$, $\beta = 0.72$, and $\delta = 0.82$ which are in fair agreement with our results which were obtained using the electronic excitation energies of Choi *et al.* (14). Gersmann and Swalen (27) also determined the bonding parameters in $Cu(DEDTC)_2$ using the spin Hamiltonian parameters deduced from spectra recorded from samples in a frozen chloroform–toluene mixture. As mentioned above the g- and A-values obtained from this glass are subject to error and consequently they obtained bonding parameters that are substantially different in the π-bonding (δ) coefficient; they calculated $\alpha = 0.77$, $\beta = 0.74$, and $\delta = 0.94$. In like manner Bereman and Nalewajek (13) also computed erroneously high values of δ for $Cu(DEDTC)_2$, using the Gersmann and Swalen spin Hamiltonian parameters and the incorrect assump-

TABLE 9. Bonding parameters deduced from spin Hamiltonian and spectral parameters for some dithiocarbamates

Ligand amine	$g_{\parallel}$	$g_{\perp}$	$\lvert A_{\parallel}\rvert^a$	$\lvert A_{\perp}\rvert^a$	α	β	δ	K^a
Dimethylamine[b]	2.079	2.016	153.5	35.1	0.683	0.701	0.657	87.2

[c]Reference 5.
[d]Reference 3. The assignment of the electronic spectrum by Bereman and co-workers was used. $\Delta E(x^2 - y^2) = 1.89\ \mu m^{-1}$ and $\Delta E(xz) = 2.75\ \mu m^{-1}$.

tion that the Fermi contact term, K, is given by $(3/7)\alpha^2$ (28). In summary the results on $Cu(DEDTC)_2$ show that $\alpha = 0.69$ to 0.74, $\beta = 0.70$ to 0.74, and $\delta = 0.76$ to 0.82, i.e. a value of $\delta = 0.9$ is too high.

The spin Hamiltonian parameters for Cu bis-(pyrrole-*N*-carbodithioate) determined both in chloroform–toluene glass and the Cd analogue are somewhat different from the other compounds. This could reflect either that the environment of the complex contained axial interactions or that the π-bonding in this complex is truly different from the other dithiocarbamates as suggested by Bereman and Nalewajek. If we discard the former caution then the results of the calculations indicate that the bonding in these compounds is modified in both the σ-framework as exemplified by the variation in β- and the π-framework as exemplified by δ. However, in order to fully substantiate the claim of Bereman and Nalewajek (13) another investigation of the Cu bis(pyrrole-*N*-carbodithioate) should be carried out using a single isotope and a proven interaction free matrix.

Received January 11, 1979

PREM P. SINGH, BUTA R. SHARMA, and PARKASH C. CHOPRA. Can. J. Chem. 57, 2386 (1979).

Excess volumes, V^E, of binary mixtures of β-picoline and γ-picoline with ethanol, *n*-propanol, and *n*-butanol have been measured as a function of composition at 308.15 K by a dilatometric method. The V^E data are negative for all the mixtures studied here and suggest that the strong N---H—O interactions outweigh those due to the breaking of the O—H---O bonds.

PREM P. SINGH, BUTA R. SHARMA, and PARKASH C. CHOPRA. Can. J. Chem. 57, 2386 (1979).

Faisant appel à une méthode dilatométrique et opérant à 308.15 K, on a mesuré les volumes en excès, V^E, de mélanges binaires de β-picoline et de γ-picoline avec l'éthanol, le *n*-propanol et le *n*-butanol. Les données de V^E sont négatives pour tous les mélanges étudiés ici et suggèrent que les interactions N---H—O sont plus fortes que celles dues au bris des liaisons O—H---O.
[Traduit par le journal]

Introduction

Alcohols are strongly self-associated (1) but there is considerable disagreement as to the identification of the predominant associated species (2–5). Furthermore, for binary solution rich in alcohol, a three dimensional network of hydrogen-bonded alcohol molecules is believed to be present (6, 7). The purpose of the present investigation is to study the effect of β-picoline or γ-picoline on the excess volumes of their mixtures with some normal alcohols.

Experimental

Materials

Analytical grade β-picoline, γ-picoline, ethanol, *n*-propanol, and *n*-butanol were purified by standard procedures (8). Purities of the final samples were checked by measuring their densities at 298.15 ± 0.01 K, the results (except for *n*-butanol) agreed to within 0.00005 g cm^{-3} (0.00012 g cm^{-3} in the case of *n*-butanol) with those in the literature (9–12). Excess volumes as a function of composition[2] were determined dilatometrically (13) in a water bath controlled to ±0.01 K. The uncertainties in the V^E values is about 0.3%.

Results

The results at 308.15 ± 0.01 K are given in Table 1 and were fitted to the expression:

$$[1]\quad V^E/x_1x_2\ \text{cm}^3\ \text{mol}^{-1} = A + B(x_1 - x_2) + C(x_1 - x_2)^2$$

where A, B, and C are adjustable parameters and x_1 and x_2 are the mole fractions of components 1 and 2 in the mixture. These parameters were evaluated by fitting experimental values of V^E/x_1x_2 to eq. [1] by the method of least squares and are recorded together with the standard deviation, $\sigma(V^E)$, in Table 1.

Discussion

We are unaware of any data at 308.15 K with which to compare our results for these mixtures. Kowalski *et al.* (9) have determined the molar excess volumes of α-, β-, and γ-picolines (1) with some aliphatic alcohols (2) at 298.15 and 313.15 K. Assuming that V^E varies linearly in the temperature range 298.15–313.15 K for all the mixtures studied by these workers (9), we evaluated V^E values at 308.15 K for the mixtures studied in the present investigation. Our V^E values for β-picoline (1) + *n*-propanol (2) at 308.15 K are in excellent agreement (0.004 cm^3 mol^{-1}) with their V^E values for $x_{\beta\text{-picoline}} \geq 0.7$. In the rest of the β-picoline concentration range their values are consistently more negative than ours; the maximum difference being 0.02 cm^3 mol^{-1} at $x_{\beta\text{-picoline}} = 0.3$. For β-picoline (1) + *n*-butanol (2) our V^E values at 308.15 K are in excellent agreement with their V^E values (9) for $x_{\beta\text{-picoline}} \leq 0.15$ and $x_{\beta\text{-picoline}} \geq 0.6$. In the intermediate β-picoline concentration range their V^E values (9) are more negative than ours and differ by as much as 0.01 cm^3 mol^{-1} at $x_{\beta\text{-picoline}} = 0.3$. Furthermore our V^E data at 308.15 K for γ-picoline (1) + *n*-propanol (2) are in excellent agreement

TABLE 1. Values of the parameters of eq. [1] for the various mixtures at 308.15 K; also given is the standard deviation $\sigma(V^E)$

Mixture	A	B	C	$\sigma(V^E)$ $cm^3\ mol^{-1}$
β-Picoline (1) + ethanol (2)	−1.5920	0.4089	0.0166	0.0007
β-Picoline (1) + *n*-propanol (2)	−1.3200	0.3452	−0.0496	0.0006
β-Picoline (1) + *n*-butanol (2)	−1.0720	0.2263	0.1175	0.0006
γ-Picoline (1) + ethanol (2)	−1.6400	0.6178	−0.0427	0.0006
γ-Picoline (1) + *n*-propanol (2)	−1.3320	0.4364	0.0782	0.0004
γ-Picoline (1) + *n*-butanol (2)	−1.0200	0.2367	0.2482	0.0006

($< 0.002\ cm^3\ mol^{-1}$) with their V^E values for $x_{\gamma\text{-picoline}} \leq 0.5$. However, for $x_{\gamma\text{-picoline}} \geq 0.5$, their V^E values are consistently more negative than ours; the maximum difference being $0.015\ cm^3\ mol^{-1}$ at $x_{\gamma\text{-picoline}} = 0.6$. For γ-picoline (1) + *n*-butanol (2) mixture, our V^E values at 308.15 K agree within $0.002\ cm^3\ mol^{-1}$ with the V^E values derived from the reported V^E data for this mixture at 298.15 and 313.15 K for $x_{\gamma\text{-picoline}} \geq 0.6$. In the rest of the γ-picoline concentration range, their V^E values are more negative than ours and differ by as much as 0.03 at $x = 0.2$. Again the excess volumes, V^E, for all the mixtures studied here are negative and the curves of V^E against x_1 are not symmetrical about $x_1 = 0.5$; they are slightly skewed towards the alkanol-rich end of the mole fraction scale. Furthermore V^E for an equimolar mixture increases in the order *n*-butanol > *n*-propanol > ethanol when the other component is β-picoline or γ-picoline at 308.15 K.

Various studies (14–16) indicate that alcohols are self-associated. The addition of the picoline would then cause rupture of some of the hydrogen bonds (since the picoline would try to adjust itself in the three dimensional hydrogen-bonded network and as such gives rise to increased steric repulsion between the alkyl chain of the alcohol and the picoline ring) so that the resulting alcohol chain fragments then interact with picolines. Since the observed V^E would be the cumulative sum of the contributions due to these factors, the observed V^E data for all these mixtures suggest that the contribution to V^E due to the O—H---N interactions always outweigh those due to the breaking of the O—H---O bonds. Furthermore, since self-association in alcohol varies in the order ethanol > *n*-propanol > *n*-butanol, the addition of a picoline would cause appreciable O—H---O bond rupture in *n*-propanol and *n*-butanol as compared to that in ethanol so that V^E for β- or γ-picoline (1) + *n*-butanol (2) would be more positive than that of β- or γ-picoline (1) + *n*-propanol (2). This has, in fact, been observed. Such a scheme of molecular interactions is also consistent with similar interpretation on the excess thermodynamic function data (17–20) on alcohol + amine mixtures.

Stereochemical aspects of the Pummerer reaction. Regioselectivity as a criterion for the differentiation of ylide and E2 pathways in the product-determining step of the reactions of benzyl methyl halo- and oxysulfonium cations

SAUL WOLFE AND PETER MICHAEL KAZMAIER

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received December 11, 1978

SAUL WOLFE and PETER MICHAEL KAZMAIER. Can. J. Chem. 57, 2388 (1979).

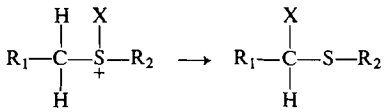
The conversion of *p*-Y-$C_6H_4CH_2\overset{+}{S}(X)CH_3$ (X = Cl, OCH_3, $OCOCH_3$, $OCOCHCl_2$, $OCOCF_3$) to a regioisomeric mixture of *p*-Y-$C_6H_4CHXSCH_3$ and *p*-Y-$C_6H_4CH_2SCH_2X$ has been studied as a function of X, Y, and deuteration in the benzyl and methyl positions. The conclusion is reached that, when X is acyloxy, the transformation of the sulfonium cation to an α-thiocarbonium ion and thence to the products proceeds via an E2 pathway. Trifluoroacetic anhydride is a much more reactive reagent than acetic anhydride for Pummerer reactions of benzyl methyl sulfoxides. However, with other sulfoxides, this reagent is not as effective as acetic anhydride. Acetyl trifluoroacetate is not effective as a Pummerer reagent.

SAUL WOLFE et PETER MICHAEL KAZMAIER. Can. J. Chem. 57, 2388 (1979).

On a étudié l'influence de X et Y ainsi que de la deutération des positions benzyle et méthyle sur la conversion de *p*-Y-$C_6H_4CH_2\overset{+}{S}(X)CH_3$ (X = Cl, OCH_3, $OCOCH_3$, $OCOCHCl_2$, $OCOCF_3$) des mélanges régio-isomères de *p*-Y-$C_6H_4CHXSCH_3$ et *p*-Y-$C_6H_4CH_2SCH_2X$. On arrive à la conclusion que si X est un acyloxy, la transformation du cation sulfonium en un ion α-thiocarbonium, et donc en produit, s'effectue par une réaction E2. L'anhydride trifluoroacétique est beaucoup plus réactif que l'anhydride acétique pour les réactions de Pummerer des sulfoxydes de méthyle benzyle. Toutefois avec d'autres sulfoxydes ce réactif n'est pas aussi efficace que l'anhydride acétique. Le trifluoroacétate d'acétyle n'est pas efficace comme réactif de Pummerer.

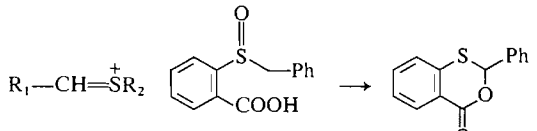
[Traduit par le journal]

The Pummerer reaction, e.g., **1** → **2** (1), is an internal redox process, in which tetravalent sulfur (**1**, X = halogen, alkoxy, acyloxy) is reduced, and the adjacent carbon atom is oxidized. A vinylogous Pummerer reaction is also known (2). The sulfonium cation substrates **1** are prepared by halogenation of sulfides, or by alkylation or acylation of sulfoxides. In the Pummerer reactions of alkoxysulfonium salts (3), alkylation and redox can be performed in separate steps; however, when X is halogen (4) or acyloxy (5), the intermediate sulfonium cation is not isolable, and its intervention has to be inferred by indirect means.



1 **2**

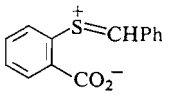
There is extensive evidence (1) that the conversion of **1** to **2** proceeds via the α-thiocarbonium ion **3**, and that intermolecular capture of this carbonium ion by X^- occurs, except in a few special cases (6, 7). One of these (6) is the transformation of benzyl-2-carboxyphenyl sulfoxide (**4**) to 2-benzyl-1,3-benzoxathian-6-one (**5**), which occurs (6*a*) with partial asymmetric induction in the formation of the C—O bond of the product. This interesting result has a number of practical and mechanistic implications, which have prompted the investigations reported in this and the following three papers.



3 **4** **5**

Ab initio SCF-MO calculations (8) suggest that there is significant π-overlap between carbon and sulfur in an α-thiocarbonium ion, leading to a rather high barrier to rotation about the C—S bond. Therefore, if it is assumed that the α-thiocarbonium ion **6** is an intermediate in the conversion of **4** to **5**, the observed transfer of chirality from sulfur to carbon can be understood in terms of a preferential removal of one of the diastereotopic methylene protons of **4** (or a sulfonium cation derived from **4**), followed by C—O bond formation prior to rotation about the C—S bond of **6**. However, the direction and magnitude of such selectivity will depend upon the manner in which the elements of HX are eliminated

0008-4042/79/182388-09$01.00/0

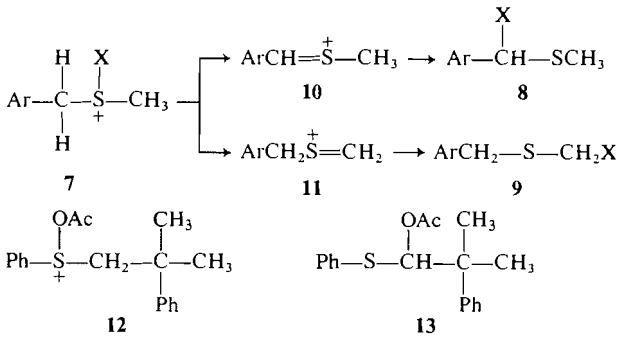


6

from the sulfonium cation to form the α-thiocarbonium ion.

If C—H bond-breaking precedes S—X bond-breaking, the reaction will proceed via a sulfonium ylide (1). On the other hand, when S—X bond-breaking precedes C—H bond-breaking, the reaction will proceed via a dication (9). Between these two extremes, an E2 process is operative. Each of these pathways has different stereochemical consequences.

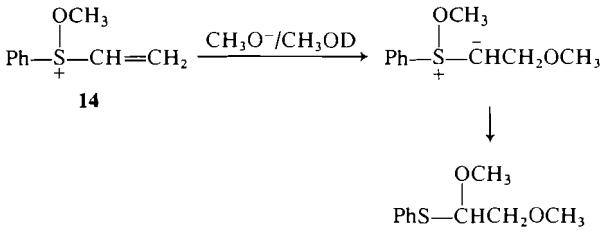
In the case of a sulfonium cation such as **7**, the Pummerer reaction can lead to two regioisomers, viz., **8** and **9**, the regiochemistry being determined during the conversion of **7** to the mixture of α-thiocarbonium ions **10** and **11**. Interconversion of **10** and **11** prior to capture by X^- seems unlikely, since rearrangement of the α-thiocarbonium ion has not been observed even in the case of the substrate **12**, which affords **13** as the sole Pummerer product (10).



7 10 8 11 9

12 13

The proportions of **10** and **11** and, therefore, of **8** and **9**, that will be formed from an *ylide* precursor will depend upon the acidities of the benzyl and methyl protons. On the basis of the work of Johnson (3) and Wilson (4) and their collaborators, the relevant acidity here is the kinetic acidity. For example, no significant deuterium incorporation is observed when an alkoxysulfonium cation is rearranged to an α-alkoxysulfide in deuteriomethanol. In addition, conversion of the methoxyvinylsulfonium cation **14** to the sulfide **15** proceeds with only 8.3% incorporation of deuterium. Since it is well established (11) that the kinetic acidities of benzyl protons adjacent to sulfur are much higher than those of methyl protons adjacent to sulfur, it can be expected that, when the Pummerer reaction of **7** proceeds via an ylide intermediate, the benzyl-substituted regioisomer **8** will predominate.



14 15

The same result is anticipated in the case of a dication mechanism. In this case, the regiochemistry of the deprotonation step is governed by the relative stabilities of α-thiobenzyl and α-thiomethyl *carbonium* ions.

The specific objectives of the present paper are to examine the regiochemistry of Pummerer reactions of **7** as a function of the electrophile X, the presence of deuterium in the methyl and benzyl positions, and the presence of *para*-substituents in the benzene ring. As one result of this work, the relationship between the ratio **8**/**9** and the mechanism of HX loss from **7** would appear to have the form shown in Fig. 1. It has also become clear that acyloxysulfonium cations having the general structure **7** undergo the Pummerer reaction via an E2 pathway.

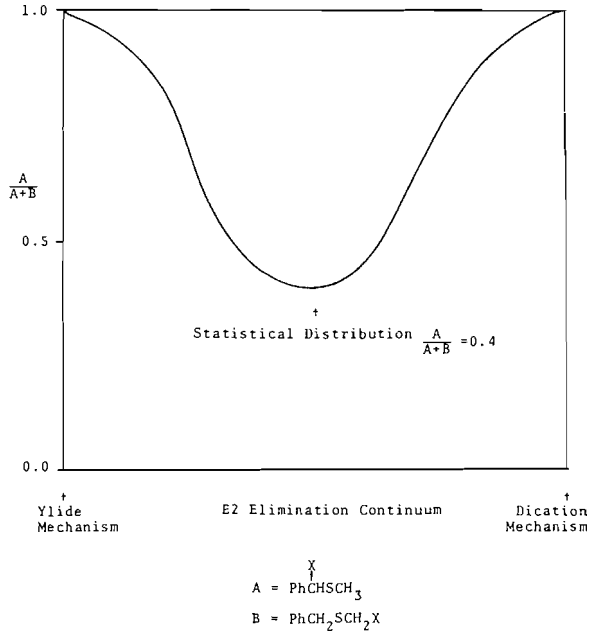


FIG. 1. Schematic representation of the ratio of regioisomers produced in the reaction **7** → **8** + **9**, as a function of C—H and S—X bond-breaking in the product-determining transition state. The 'statistical distribution' of 0.4 is the ratio of the number of benzylic hydrogens to the total number of hydrogens adjacent to sulfur.

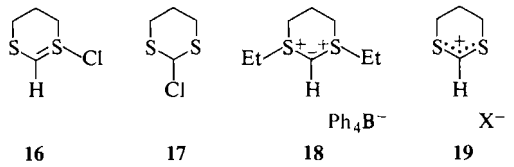
Results and Discussion

Table 1 summarizes the regioselectivity observed in the reactions of benzyl methyl sulfide, benzyl methyl sulfoxide, and benzyl methyl methoxysulfonium fluoroborate under various Pummerer conditions. With the exception of entries 1 and 8, no regioselectivity is evident in these reactions. We believe that the benzyl regioselectivity observed in entry 1 constitutes evidence for an ylide pathway, especially in view of the alkaline reaction conditions employed in this case. However, in the case of the benzyl regioselectivity observed in entry 8, either an ylide or a dication pathway is possible. For example, Tuleen and Stephens (14) have found that the chlorination of unsymmetrical sulfides with sulfuryl chloride or *N*-chlorosuccinimide (NCS) leads to substitution at the *more substituted* carbon atom (cf. eq. [1]). This result is incompatible with an ylide pathway, in which the relative proportions of the regioisomers are controlled by the relative acidities of methyl and isopropyl hydrogens (15).

[1] $CH_3-S-CH(CH_3)_2 \xrightarrow{NCS} ClCH_2S-CH(CH_3)_2 + CH_3S-C(Cl)(CH_3)_2$

~1 ~10

On the other hand, Kruse *et al.* (16) have reported that an ylide, assigned structure **16**, can be characterized spectroscopically as an intermediate in the chlorination of 1,3-dithiane with sulfuryl chloride in chloroform solvent, and that this ylide rearranges to 2-chloro-1,3-dithiane (**17**) at room temperature.



16 **17** **18** **19**

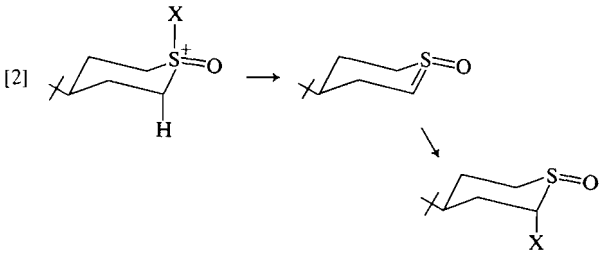
The assignment of structure **16** to this intermediate was based upon the appearance of a sharp singlet at δ 6.90 in the ^{1}Hmr spectrum, assigned to the C2 proton. However, if this assignment is correct, then the C2 proton of **16** is *almost 5 ppm further downfield* than the C2 proton of the 1,3-bissulfonium ylide **18**, which appears at 2.02 ppm (17). Chemical shifts near 2 ppm have also been observed for the C2 protons of a number of acyclic 1,3-bissulfonium fluoroborates (18) and tetraphenylborates (19).

The dithienium cation **19** (X = BF_4^-) has been described by Corey and Walinsky (20). Its ^{1}Hmr spectrum (in CD_3NO_2) shows the C2 proton at 11.10 ppm. This chemical shift is close to that (10.65) of the C2 proton of **17** in sulfur dioxide solvent at −50°C (21). According to Arai and Oki (21, 22), the nmr spectra of **17** and other α-chlorosulfides are very dependent upon the temperature and the solvent, because of the occurrence of the ionization process **17** ⇄ **19** (X = Cl^-). Since the C2 proton of **17** is found at 6.2 and 6.21 ppm in deuteriochloroform and carbon disulfide, respectively, a permissive reinterpretation of the observations of Kruse *et al.* is that the chlorosulfonium cation **20** is converted, by loss of HCl, to **19** (X = Cl^-), and that the 6.90 chemical shift of the C2 proton reflects the position of the **17** ⇄ **19** equilibrium in the presence of the small amounts of sulfur dioxide produced from the sulfuryl chloride reagent. A dication pathway would not be ruled out by this interpretation. Likewise, a dication pathway is not ruled out by the observation (4) that the product isotope effects (k_H/k_D) for the chlorination and bromination of 2,2-d_2-thiophane (**21**) are 5.1 and 3.6, respectively. Indeed, although their discussion differs somewhat from that given here, Wilson and Albert (4) consider that their bromination results are consistent with 'the El extreme transition state.'

Regardless of the precise interpretation to be given to the benzyl regioselectivity observed in entry 8 of Table 1, the lack of regioselectivity seen in entries

20 **21**

2–7 must be interpreted in terms of a mechanism in which neither an ylide nor a dication is an intermediate. It seems reasonable to suppose that an E2 process is operative in these cases, especially since the stereochemical course of the alpha-halogenation of sulfoxides has already been found to be best interpreted in terms of E2 elimination of HX from a haloxosulfonium cation (23) (eq. [2]).



[2]

Table 2 shows the regioselectivities obtained in the Pummerer reactions of a series of deuterated benzyl methyl sulfoxides with trifluoroacetic anhydride (TFAA) in chloroform at 25°C. These results demonstrate that there is a significant hydrogen isotope effect in the product-determining step of the reaction. The magnitude of this effect (k_H/k_D) is calculated to be 4.0; this value is obtained by division of the **8**/**9** ratio of entry 5 by the **8**/**9** ratio of entry 1.

This result is consistent with the suggestion that the mechanistic change signalled by the lack of regioselectivity in the Pummerer reactions of the acyloxysulfonium and chloro- and bromosulfoxonium cations is a change to an E2 pathway. Such a conclusion is also supported by the observation that carbon–hydrogen bond-breaking occurs in the product-determining step of the reaction, and by the results of an examination of the effects of *para*-substituents upon the regioselectivity of the reaction. These results are presented in Table 3, and were obtained under the same conditions as those of Table 2. The Hammett σ–ρ plot for the effects of the *para*-substituents upon the regioselectivity of the reaction is shown in Fig. 2. This gives a ρ-value of 1.0.

[3]

For E2 reactions of the type shown in eq. [3], ρ values range from +2.07 to +3.77 as the leaving group Y is varied from iodide to trimethylammonium (25). The increase in ρ for the poorer leaving group

[a]Reactions were performed at 25°C in deuteriochloroform with 1 equiv. of trifluoroacetic anhydride, and a concentration of 0.32 *M*.
[b]The σ values were obtained from ref. 24.
[c]Determined by integration of the ^{1}Hmr spectra.

can be interpreted in terms of increased carbanionic character in the transition state. The application of these and other analogies to the elimination of trifluoroacetic acid from **7** (X = OTFA) leads to the expectation of a large positive ρ for an ylide mechanism, a small positive or negative ρ for an E2 mechanism (depending upon the degree of C—H and S—X bond-breaking in the transition state), a zero ρ for a cyclic *cis*-elimination mechanism (26), and a large negative ρ for a dication mechanism (27). The value 1.0 obtained in the present work appears to be consistent only with an E2 mechanism, with some carbanionic character in the transition state, and a very good leaving group.

Thus the interpretation of the results of Table 1 in terms of Fig. 1, the isotope effect studies of Table 2, and the *para*-substituent studies of Table 3, lead in each case to the conclusion that the Pummerer reactions of acyloxysulfonium cations proceed via an E2 pathway. The assumption that this E2 elimination process takes an *anti* stereochemical course has interesting consequences, as will be seen in the following two papers.

The use of trifluoroacetic anhydride (TFAA) as a reagent for Pummerer reactions is a relatively recent development (28). As seen in Table 1, this permits the reaction to be performed at much lower temperatures than is the case with acetic anhydride and, in the case of benzyl methyl sulfoxide as the substrate, the product is obtained in significantly higher yield. In a comparative study based upon the dis-

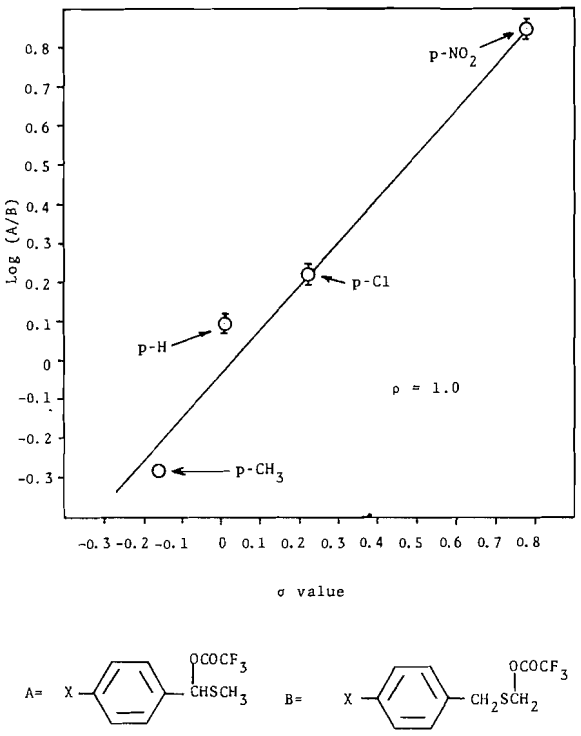

FIG. 2. Hammett plot showing the substituent effect upon the regioselectivity of the reaction of benzyl methyl sulfoxide with trifluoroacetic anhydride in chloroform at 25°C.

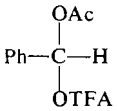
appearance of the sulfoxide, the reaction in acetic anhydride *solvent* was complete in 2 h at 130°C, while the reactions with dichloroacetic anhydride (1.4 equiv.) and TFAA (1.0 equiv.) were complete in 70 min and 5 min at 25°C, respectively. It was, therefore, of interest to examine the reactions of TFAA with other sulfoxides. These results and others taken from the literature are collected in Table 4.

Although the data are not extensive, the failures in the cases of thiophane sulfoxide and the phthalimidopenicillin sulfoxide are noteworthy. Since it is known that thiophane sulfoxides do react successfully with acetic anhydride (30), we suggest that TFAA may succeed as a Pummerer reagent when relatively acidic α-hydrogens are present, and when the α-thiocarbonium ion is sufficiently reactive for capture by the poorly nucleophilic trifluoroacetate anion. The rearrangement of the thiazolidine sulfoxide is reminiscent of the Morin rearrangement (31) of a penicillin sulfoxide to a Δ^3-cephem; however, the Morin rearrangement itself fails when TFAA is substituted for acetic anhydride because of rapid cleavage of the β-lactam by the trifluoroacetic acid product.

The mixed anhydride acetyl trifluoroacetate (ATFA) was also examined as a reagent for the



22

Pummerer reaction. However, the reaction of this compound with benzyl methyl sulfoxide led only to the mixed acylal **22**, identified by comparison with an authentic specimen prepared by the reaction of ATFA with benzaldehyde (32).

Experimental

General

Melting points were determined on Kofler hot-stage or Meltemp equipment, and are uncorrected. Refractive indices were measured on a Bausch and Lomb refractometer. The ^{1}Hmr spectra were obtained on Varian T60, Varian EM360, Varian HA100, or Bruker HX16 spectrometers; 10% solutions were employed. The ^{13}Cmr spectra were obtained on a Bruker HX16 spectrometer, equipped with a BSV 3PM pulse unit and a BNC-12 computer. Tetramethylsilane (TMS) or sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) were employed as internal standards, as required. Mass spectra were obtained on JEOL JMS-01SC, Hitachi Perkin Elmer RMU-6E or Dupont 21-491B mass spectrometers under electron impact conditions at 70 eV. Infrared spectra were recorded on either Perkin Elmer 180 or Acculab 6 instruments. Ultraviolet spectra were obtained on a Unicam SP800 spectrometer. Analyses are by Galbraith Laboratories, Knoxville, TN.

The ^{13}Cmr spectra were assigned by correlations within series of compounds. In some instances, ^{1}H–^{13}C coupling was used to confirm these assignments. Column chromatography was performed with 60 mesh silica gel (Merck). Thin layer chromatography was performed on silica gel plates containing a fluorescent indicator. Spots were observed under ultraviolet light, or were visualized with ninhydrin, 10% phosphomolybdic acid in ethanol, ceric sulfate in ethanol, or iodine vapour. Solvents were routinely distilled before use and dried as required by standard procedures. Materials were of reagent grade purity obtained from commercial sources.

The substrates benzyl methyl sulfoxide, *RS*/*SR*-benzyl-α-*d* methyl sulfoxide, *RR*/*SS*-benzyl-α-*d* methyl sulfoxide, benzyl-α,α-d_2 methyl sulfoxide, *p*-nitrobenzyl methyl sulfoxide, *p*-methoxybenzyl methyl sulfoxide, *p*-methylbenzyl methyl sulfoxide benzyl phenyl sulfoxide, and thiophane-*S*-oxide were synthesized by standard procedures (33–36). Only the synthesis of *p*-methylbenzyl methyl sulfoxide, a new compound, is reported here. The penicillin sulfoxide was obtained from Mr. R. J. Bowers, whom we thank.

p-*Methylbenzyl Methyl Sulfoxide*

Sodium *meta*-periodate (6.52 g, 33.7 mmol) was suspended in water/methanol (40 mL/10 mL). The solution was cooled to 0°C in a salt–ice bath and *p*-methylbenzyl methyl sulfide (5.12 g, 33.7 mmol) was added in one portion. After stirring at 0°C overnight, the reaction mixture was extracted with chloroform (5 × 20 mL) and the organic phase was dried (magnesium sulfate). After removal of the solvent, the syrupy product was chromatographed on silica gel (ether/methylene chloride, then methanol) to yield a crystalline product (5.21 g, 92%), mp 66°C; ^{1}Hmr ($CDCl_3$) δ: 7.13 (4H, s), 4.10, 3.87 (2H, AB, 12), 2.40 (3H, s), 2.33 (3H, s); ^{13}Cmr ($CDCl_3$) δ: 138.0, 136.7, 129.9, 129.6 (phenyl), 59.9 (PhCH_2SO), 37.2 ($SOCH_3$), 21.1 (CH_3); ir (KBr): 1025 (s, sulfoxide) cm^{-1}; uv (water, 25°C) λ_{max} (log ε): 231 (3.49).

[a]Yields were determined by ^{1}Hmr integration of crude reaction mixtures because the products were moisture-sensitive.
[b]These compounds were characterized on the basis of their spectral characteristics and by hydrolysis to benzaldehyde.
[c]Present work.
[d]Isolated as a by-product in an aminosulfurane synthesis.
[e]Isolated yields.
[f]A complex mixture of products resulted in this case.
[g]The reaction led to loss of the β-lactam ring.

Anal. calcd. for $C_9H_{12}OS$: C 64.24, H 7.19; found: C 64.69, H 7.51.

Reaction of Benzyl Methyl Methoxysulfonium Fluoroborate with Sodium Methoxide

In a dry box, carefully dried benzyl methyl sulfoxide (1.76 g, 11.4 mmol) in methylene chloride (5 mL) was added over a 5 min period to trimethyloxonium fluoroborate (2.35 g, 11.4 mmol). The reaction mixture was stirred for 1 h. Addition of ether afforded an oil, which crystallized upon standing in the refrigerator. After trituration of the crystals with ether, sodium methoxide in methanol (15.0 mL of 0.834 *N*) was added over a period of 5 min at 25°C. The reaction mixture was immediately evaporated to dryness, giving a milky oil. This was poured into brine (pH 7), to which a small portion of sodium carbonate had been added to raise the pH to 8.0. The mixture was extracted with ether (4 × 10 mL) and the combined extracts were dried over anhydrous sodium sulfate containing a small amount of sodium carbonate. Evaporation yielded a syrup (557 mg, 31%) consisting of a 2:1 mixture of α-methoxybenzyl methyl sulfide and benzyl methyl sulfide. Attempts to separate the two components by chromatography on Florisil were abandoned after some isomerization to α,α-dimethyl thiotoluene and α,α-dimethoxytoluene was detected.

Reaction of Benzyl Methyl Sulfoxide with Acetic Anhydride

Benzyl methyl sulfoxide (0.0969 g, 0.629 mmol) was dissolved in acetic anhydride (10 mL) and the solution was heated to 130°C for 2 h. After cooling, the reaction mixture was poured into saturated potassium bicarbonate. The aqueous solution was extracted with chloroform (4 × 20 mL). After drying (magnesium sulfate), and evaporation of the solvent, the product was isolated as a colourless syrup (48 mg, 39%). ^{1}Hmr indicated formation of the two isomers (α-acetoxybenzyl methyl sulfide/α-acetoxymethyl benzyl sulfide) in the ratio 45/55. α-Acetoxybenzyl methyl sulfide: ^{1}Hmr ($CDCl_3$) δ: 7.35 (5H, s), 6.95 (1H, s), 2.10 (3H, s), 2.15 (3H, s). α-Acetoxymethyl benzyl sulfide: ^{1}Hmr ($CDCl_3$) δ: 7.30 (5H, s), 5.05 (2H, s), 3.85 (2H, s), 2.03 (3H, s).

Reaction of Benzyl Methyl Sulfide with Sulfuryl Chloride

Sulfuryl chloride (8.1 mL, 13.5 g, 0.1 mol) was added drop-

wise (36 min) to a solution of benzyl methyl sulfide in methylene chloride (20 mL). After the addition was complete, the solution was refluxed (1 h). Evaporation of the solvent and distillation (bp 102–106°C/12 Torr (lit. (13) bp 118–121°C/14 Torr) yielded a colourless oil which rapidly turned orange (12.8 g, 86%); ^{1}Hmr ($CDCl_3$) δ: 7.40 (5H, m), 6.07 (1H, s), 2.32 (3H, s).

Reaction of Benzyl Methyl Sulfoxide with Dichloroacetic Anhydride

To benzyl methyl sulfoxide (90 mg, 0.6 mmol) in chloroform (0.5 mL) was added dichloroacetic anhydride (278 mg, 0.86 mmol). The reaction was followed by ^{1}Hmr at room temperature, and was complete in 70 min. There were two products, viz., α-dichloroacetoxybenzyl methyl sulfide and benzyl α-dichloroacetoxymethyl sulfide in the ratio 53/47. α-Dichloroacetoxybenzyl methyl sulfide: ^{1}Hmr ($CDCl_3$) δ: 7.45 (5H, s), 7.05 (1H, s), 6.05 (1H, s), 2.18 (3H,s). Benzyl α-dichloroacetoxymethyl sulfide: ^{1}Hmr ($CDCl_3$) δ: 7.38 (5H, s), 5.95 (1H, s), 5.23 (2H, s), 3.92 (2H, s).

Reaction of Benzyl Methyl Sulfoxide with Trifluoroacetic Anhydride

Benzyl methyl sulfoxide (25 mg, 0.16 mmol) was dissolved in carbon tetrachloride (0.5 mL) containing trifluoroacetic anhydride (0.16 mmol). After 5 min, a ^{1}Hmr spectrum of the reaction mixture indicated that the starting material had disappeared and that a mixture of the two regioisomeric trifluoroacetoxybenzyl methyl sulfides had been produced. The ratio of the two regioisomers (methyl α-trifluoroacetoxybenzyl sulfide/benzyl α-trifluoroacetoxymethyl sulfide) was 53/47. Methyl α-trifluoroacetoxybenzyl sulfide: ^{1}Hmr ($CDCl_3$) δ: 7.40 (5H, s), 7.03 (1H, s), 2.13 (3H, s). Benzyl α-trifluoroacetoxymethyl sulfide: ^{1}Hmr ($CDCl_3$) δ: 7.30 (5H, s), 5.23 (2H, s), 3.87 (2H, s).

General Procedure for the Reaction of Deuterated Benzyl Methyl Sulfoxides with Trifluoroacetic Anhydride

Trifluoroacetic anhydride (0.16 mmol) was added to benzyl methyl sulfoxide (0.16 mmol) in deuteriochloroform (0.5 mL) at ambient temperature. The ^{1}Hmr spectrum was run immediately and the proportions of the regioisomers were estimated from the peak integrals of undeuterated portions of the substrate. For benzyl methyl sulfoxide-d_5, the relative proportions of the two regioisomers were estimated from the integrals of the two phenyl peaks.

General Procedure for the Reaction of p-*Substituted Benzyl Methyl Sulfoxides with Trifluoroacetic Andydride*

Trifluoroacetic anhydride (0.16 mmol) was added to a solution of the sulfoxide (0.16 mmol) in deuteriochloroform (0.5 mL) and the ^{1}Hmr spectrum was run. The proportions of the two regioisomers were estimated from the integrals of the methine proton (δ ca. 7.0) of the benzyl substituted regioisomer and the SCH_2O methylene hydrogens (δ ca. 5.0) of the methyl substituted regioisomer.

Reaction of Benzyl Phenyl Sulfoxide with Trifluoroacetic Anhydride

Trifluoroacetic anhydride (0.3 mL, 2 mmol) was added to benzyl phenyl sulfoxide (40 mg, 0.19 mmol) in deuteriochloroform (0.5 mL) and the ^{1}Hmr spectrum was recorded immediately. This indicated a quantitative yield of α-trifluoroacetoxybenzyl phenyl sulfide; ^{1}Hmr ($CDCl_3$) δ: 7.0–7.5 (11H, m). This product proved very hygroscopic and, on exposure to moist air, the odour of benzaldehyde was apparent. Addition of 2,4-dinitrophenylhydrazine produced benzaldehyde-2,4-dinitrophenylhydrazone. Recrystallization from ethyl acetate yielded red crystals (202 mg, 31%), mp 234–239°C (lit. (37) mp 237°C).

*Reaction of Thiolane-*S*-Oxide with Trifluoroacetic Anhydride*

Thiolane-*S*-oxide (1.0 g, 9.6 mmol) was dissolved in carbon tetrachloride (9.6 mL). The mixture was cooled to 4°C and trifluoroacetic anhydride (1.4 mL, 9.6 mmol) was added in one portion. Within seconds, the reaction mixture had separated into two layers, the upper layer consisting of a deep red oil. The product was not investigated further.

Reaction of N-*Benzoyl-2,2-dimethyl-4*R-*methoxycarbonyl-1,3-thiazolidine-*S*-oxide with Trifluoroacetic Anhydride at 25°C and −30°C*

Trifluoroacetic anhydride (0.3 mL, 2 mmol) was added to *N*-benzoyl-2,2-dimethyl-4*R*-methoxycarbonyl-1,3-thiazolidine-*S*-oxide (38) (24 mg, 0.081 mmol) in deuteriochloroform (0.5 mL). There was an immediate change in the ^{1}Hmr spectrum and the sole product detectable by nmr was identified as *N*-benzoyl-2,3-dehydro-5-methoxycarbonyl-3-methyl-1,3-thiazine by comparison with an authentic sample (39); ^{1}Hmr ($CDCl_3$) δ: 7.52–7.57 (5H, s), 5.97 (1H, t, 3), 5.62 (1H, s), 3.82 (3H, s), 3.50 (2H, d, 3), 1.67 (3H, s). Repetition of the reaction at −30°C gave identical results.

Reaction of Methyl N-*Phthalimidopenicillinate-*R*-oxide with Trifluoroacetic Anhydride*

Trifluoroacetic anhydride (0.10 mL, 0.71 mmol) was added in one portion to a solution of methyl *N*-phthalimidopenicillinate-*R*-oxide (15.1 mg, 0.04 mmol) in deuteriochloroform (0.5 mL). After 1 min, the ^{1}Hmr spectrum showed the absence of the β-lactam protons (δ 4.0–6.0) and the reaction was not investigated further.

Acetyl Trifluoroacetate (40, 41)

Acetic anhydride (3.35 mL, 0.0355 mol) and trifluoroacetic anhydride (5.00 mL, 0.0355 mol) were dissolved in carbon tetrachloride (10 mL). The reaction was stirred at ambient temperature for 48 h, and the infrared spectrum was monitored periodically. During this period, the 1760 cm^{-1}/1820 cm^{-1} peaks of acetic anhydride and the 1800 cm^{-1}/1860 cm^{-1} peaks of trifluoroacetic anhydride were replaced by the 1780 cm^{-1}/1850 cm^{-1} peaks of acetyl trifluoroacetate. The yield was quantitative.

Reaction of Benzyl Methyl Sulfoxide with Acetyl Trifluoroacetate

Benzyl methyl sulfoxide (300 mg, 1.95 mmol) was dissolved in deuteriochloroform (2 mL). To this was added, dropwise, acetyl trifluoroacetate (0.25 mL, 2 mmol), and the progress of the reaction was monitored by ^{1}Hmr. The product of the reaction was α-acetoxy-α-trifluoroacetoxytoluene; ^{1}Hmr ($CDCl_3$) δ: 7.73 (1H, s), 7.42 (5H, s), 2.15 (3H, s); ir: 1785 cm^{-1}. Evaporation of the solvent below 20°C yielded a syrup (280 mg). 2,4-Dinitrophenylhydrazine (Brady's reagent) gave a positive aldehyde and ketone test, and the addition of semicarbazide hydrochloride and methanol (1 mL) followed by 10 drops of pyridine yielded the semicarbazone of benzaldehyde (45 mg, 15%), mp 211–213°C (lit. (37) mp 217°C).

α,α-Diacetoxytoluene

Benzaldehyde (14.3 g, 0.135 mol) and acetic anhydride (28.6 g. 0.277 mol) were mixed under nitrogen and cooled in an ice bath. Concentrated sulfuric acid (0.2 mL) was then added dropwise. A deep purple colour developed after the addition of the first drop. After 25 min, ^{1}Hmr indicated that all of the benzaldehyde had been consumed. The reaction mixture was poured into ice-cold saturated sodium bicarbonate solution, and stirred until gas evolution ceased (15 min). Extraction with methylene chloride (3 × 70 mL), drying over anhydrous sodium sulfate, and evaporation yielded a syrup, which crystallized upon cooling at −10°C (28.0 g, 99%). Recrystallization from ethanol yielded white needles (23.7 g,

84%); mp 39–44°C (lit. (32) mp 44–45°C); ir (Nujol): 1750 (s, acetate) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 7.67 (1H, s), 7.43 (5H, s), 2.13 (6H, s); ^{13}Cmr ($CDCl_3$) δ: 168.6 (carbonyl), 135.6, 129.7, 128.6, 126.6 (phenyl), 89.7 (CH), 20.7 (CH_3).

α-Acetoxy-α-trifluoroacetoxytoluene

Benzaldehyde (14.3 g, 0.135 mol) and acetyl trifluoroacetate (32 mL, 0.280 mol) were mixed at 4°C, and concentrated sulfuric acid (0.2 mL) was added. The solution turned purple immediately. ^{1}Hmr showed that the reaction was complete within 5 min. The product was flash distilled to yield a colourless, water-white liquid (14.1 g, 40%), n_D^{24} 1.4376; ^{1}Hmr ($CDCl_3$) δ: 7.77 (1H, s), 7.48 (5H, s), 2.17 (3H, s); ir (film): 1785 (s, carbonyl) cm^{-1}.

α,α-Trifluoroacetoxytoluene

Benzaldehyde (14.3 g, 0.135 mol) and trifluoroacetic anhydride (40 mL, 0.280 mol) were mixed at 4° C. Concentrated sulfuric acid (ca 0.2 mL) was added and the solution turned dark purple. The progress of the reaction was followed by ^{1}Hmr. The reaction was complete after ca. 8 h. The product was flash distilled to yield a water-white liquid (33.7 g, 79%), n_D^{24} 1.3988; ^{1}Hmr ($CDCl_3$) δ: 7.82 (1H, s), 7.55 (5H, s); ^{13}Cmr ($CDCl_3$) δ: 156 (q, 44, carbonyl), 132.2, 129.8, 127.6 (phenyl), 115.1 (q, 285, CF_3), 94.6 (CH); ir (film): 1795 (s, $OCOCF_3$) cm^{-1}.

Stereochemical aspects of the Pummerer reaction. Diastereotopic selectivity in the deprotonation of oxysulfonium cations

SAUL WOLFE AND PETER MICHAEL KAZMAIER

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received December 11, 1978

SAUL WOLFE and PETER MICHAEL KAZMAIER. Can. J. Chem. 57, 2397 (1979).

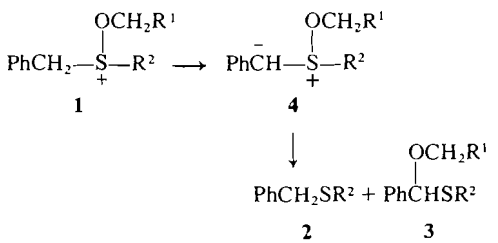
The diastereomeric *RS*/*SR*- and *RR*/*SS*-benzyl-α-*d* methyl sulfoxides have been subjected to the Pummerer reaction with acetic anhydride and with trifluoroacetic anhydride. The ethoxysulfonium fluoroborate derivatives of these sulfoxides have been subjected to the Pfitzner–Moffatt reaction with sodium hydride in tetrahydrofuran. The deuterium contents of the starting materials and of the Pfitzner–Moffatt product have been determined by mass spectrometry. The deuterium contents of the α-acyloxybenzyl methyl sulfoxides formed in the Pummerer reaction have been determined by ^{1}Hmr spectroscopy. The resulting data permit the calculation of the diastereotopic selectivities and isotope effects associated with the deprotonation of oxysulfonium cations. The selectivities are found to be lower by a factor of about 10 than those observed in the formation of the benzyl-α-*d* methyl sulfoxides by hydrogen–deuterium exchange of benzyl methyl sulfoxide. Nevertheless, the existence of selectivity in the Pummerer reactions rules out a sulfurane and a dication as sole product-determining intermediates. The factors contributing to this low selectivity are discussed.

SAUL WOLFE et PETER MICHAEL KAZMAIER. Can. J. Chem. 57, 2397 (1979).

On a soumis les benzyl α-*d*-méthylsulfoxydes diastéréomères *RS*/*SR* et *RR*/*SS* à la réaction de Pummerer sous l'influence des anhydrides acétique et trifluoroacétique. On a soumis les fluoroborates d'éthoxysulfonium dérivés de ces sulfoxydes à la réaction de Pfitzner–Moffatt avec l'hydrure de sodium dans le tétrahydrofuranne. Utilisant la spectroscopie de masse, on a déterminé les quantités de deuterium présentes dans les composés initiaux et dans les produits Pfitzner–Moffatt. Utilisant la spectroscopie rmn ^{1}H, on a déterminé les quantités de deutérium présentes dans les α-acyloxybenzyl méthylsulfoxydes qui se forment au cours de la réaction de Pummerer. Les données qui en découlent permettent de calculer les sélectivités diastéréotopes et les effets isotopiques associés à la déprotonation des cations oxysulfonium. On a trouvé que les sélectivités sont d'environ 10 fois plus faibles que celles observées lors de la formation de benzyl α-*d*-méthylsulfoxydes par échange hydrogène–deutérium du benzyl méthylsulfoxyde. Toutefois l'existence d'une sélectivité dans les réactions de Pummerer élimine la possibilité de l'existence d'un sulfuranne ainsi que d'un dication comme seuls intermédiaires conduisant à des produits. On discute des facteurs contribuant à cette faible sélectivité.

[Traduit par le journal]

When the alkoxysulfonium cation **1** is treated with base it is converted to a mixture of the benzyl sulfide **2**, by a Pfitzner–Moffatt reaction (1), and the benzaldehyde thioacetal **3**, by a Pummerer reaction (2). The proportions of the Pfitzner–Moffatt and Pummerer products depend upon the specific experimental conditions (3), but the alkoxysulfonium ylide **4** is an intermediate in both cases. Since sulfonium cations have a pyramidal configuration at sulfur (4), the methylene protons of **1** are diastereotopic, and some selectivity should, therefore, be expected in the deprotonation which forms the ylide (5), regardless of the subsequent chemical and (or) stereochemical fate of this species.



As discussed in the preceding paper (6), proton loss from the *acyloxysulfonium* cation **5** proceeds via an E2 process, which leads to a mixture of the α-thiocarbonium ions **6** and **7** and, thence, to the mixture of Pummerer products **8** and **9**. If it is assumed that the E2 elimination of acetic acid from **5** occurs with *anti*-periplanar stereochemistry, the Pummerer reaction of conformation **5***a* will involve loss of the pro-*S* hydrogen, and the reaction of conformation **5***b* will involve the loss of the pro-*R* hydrogen from the benzylic position.

If the transition states associated with the elimination of acetic acid from **5***a* and **5***b* differ in energy, then, according to the Curtin–Hammett principle (7), diastereotopic selectivity should again be ob-

0008-4042/79/182397-07$01.00/0

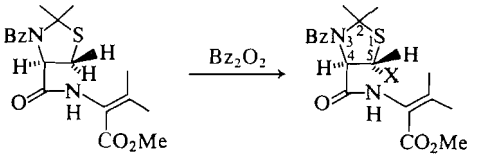
served in the removal of the methylene protons. Consequently, selectivity is expected, regardless of whether the deprotonation of an oxysulfonium cation follows an ylide or an E2 pathway. However, it is difficult to demonstrate this point experimentally in the Pfitzner–Moffatt and Pummerer reactions,[1] for a number of experimental and theoretical reasons.

For example, if selectivity exists in the deprotonation of an oxysulfonium cation, a transfer of chirality from sulfur to carbon in the Pummerer reaction is, in principle, possible. But, if a 'free' carbonium ion is formed subsequently, any stereochemical information gained in the deprotonation step would appear to be lost in the planar carbonium ion intermediate.

A transfer of chirality from sulfur to carbon might be demonstrable if selective deprotonation to form an ylide were followed by an intramolecular transfer of the oxy substituent. However, the barrier to rotation about the C—S bond of an acyclic sulfonium ylide is calculated (9) to be less than 10 kcal/mol, and pyramidal inversion at sulfur is much more rapid in a sulfonium ylide (10) than in a sulfonium cation. Thus it seems unlikely that the required intramolecular transfer from sulfur to carbon could compete successfully with stereomutation of the oxysulfonium ylide. In addition, when the sulfur substituent is alkoxy, the intramolecular transfer corresponds to a [1,2] sigmatropic rearrangement, and is predicted (11) to occur thermally in a concerted manner only with inversion of configuration at carbon. Such antarafacial processes have not been observed (12).

On the other hand, a suprafacial [2,3] sigmatropic rearrangement (11) is well established in the literature (13), and such a reaction is possible in the case of an acyloxysulfonium ylide (14). However, as already noted (6), acyloxysulfonium ylides do not appear to be intermediates in the Pummerer reactions of acyloxysulfonium cations such as **5**. Moreover, the conditions normally employed to generate an acyloxysulfonium cation from a sulfoxide also promote rapid epimerization at sulfur (15), which masks any potential asymmetric induction. For example, optically active benzyl methyl sulfoxide is racemized by 1 equiv. of trifluoroacetic anhydride at −65°C, but the Pummerer reaction with the same reagent is not observed below −30°C (16).

Despite these various problems, asymmetric induction in the Pummerer reaction has been achieved in a few systems. In the conversion of **10** to **11** (X = OBz) (14), only the epimer shown is produced. However, since **11** (X = OMs) is converted to **11** (X = Cl) with *retention* of configuration, it is apparent that asymmetric induction at C5 of the thiazolidine ring of this compound is controlled by the asymmetry at C4, and is not inherent in the Pummerer reaction itself.



10 11

The conversion of (+)-**12** to (+)-**13** with dicyclohexylcarbodiimide (17) and to (−)-**13** with acetic anhydride (17, 18) and the conversion of optically active **14** to optically active **15** (19) with acetic anhydride are true examples of asymmetric induction in the Pummerer reaction. According to Stridsberg and Allenmark (17) the asymmetric induction observed in the formation of **13** is caused by the stereoselective removal of one of the methylene protons of **12**. However, Oae has argued (2*c*, 19) that the formation of optically active **15***a* cannot be explained in this manner if an ylide intervenes.

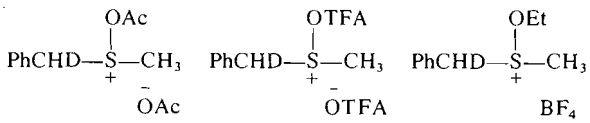
a X = CN
b X = C≡CH

The purpose of the present paper is to report that diastereotopic selectivity can be observed in the Pfitzner–Moffatt and Pummerer reactions of benzyl methyl ethoxy-, acetoxy-, and trifluoroacetoxysulfonium salts, by the use of the diastereomeric benzyl-α-*d* compounds (5*a*) as substrates. In the following paper, a similar procedure is employed to demon-

[1]Diastereotopic selectivity in the conversion of sulfoxides to α-halosulfoxides is well established (8).

strate that diastereotopic selectivity also exists in the conversion of **12** to **13**, and is responsible for the asymmetric induction.

For the present experiments, benzyl methyl sulfoxide, benzyl-α-d_2 methyl sulfoxide, and the *RS*/*SR*- and *RR*/*SS*-benzyl-α-*d* methyl sulfoxides were prepared by the procedures described previously (*5a*, *b*). Conversion to the acetoxy- and trifluoroacetoxysulfonium salts **16** and **17** was achieved *in situ* by reaction with acetic anhydride and trifluoroacetic anhydride, respectively. Conversion to the ethoxysulfonium salt **18** was accomplished with triethyloxonium fluoroborate (20).



16 **17** **18**

Method

We employ the descriptors *A* and *B* to refer, respectively, to the more rapid and less rapid methylene sites of hydrogen–deuterium exchange of benzyl methyl sulfoxide in NaOD–D_2O (*5a*). Therefore, D_AH_B is the *RS*/*SR*-benzyl-α-*d* diastereomer (21), H_AD_B is the *RR*/*SS*-benzyl-α-*d* diastereomer, H_AH_B is the parent compound, and D_AD_B is the benzyl-α-d_2 compound. If k_A and k_B are the appropriate rate constants for the removal of H_A and H_B from H_AH_B, then the selectivity *S* is defined by $S = k_A/k_B$. To obtain this quantity for a Pfitzner–Moffatt or Pummerer reaction, it is necessary to work with the deuterated compounds D_AH_B and H_AD_B. This introduces a primary isotope effect, *I*, which must be taken into account. The assumption that the isotope effects at the two sites are equal (22) permits the calculation of *S* and *I* from eqs. [1] and [2] (23), where k_1/k_2 refers to the ratio k_A/k_B for D_AH_B, and k_1'/k_2' refers to the ratio k_A/k_B for H_AD_B.

$$[1] \quad S = (k_1/k_2)^{1/2}(k_1'/k_2')^{1/2}$$

$$[2] \quad I = (k_1'/k_2')^{1/2}(k_2/k_1)^{1/2}$$

For reactions of the type $PhCH_2\overset{+}{S}XCH_3 \rightarrow PhCHXSCH_3 + PhCH_2SCH_2X$, in which two regioisomers are formed, the ratios k_1/k_2 and k_1'/k_2' were determined by ^{1}Hmr. Within the accuracy of this method (10%), the substrate consisted entirely of either D_AH_B or H_AD_B. In such cases, the quantities k_1/k_2 and k_1'/k_2' could be calculated using eqs. [3] and [4],

$$[3] \quad k_1/k_2 = (d_1^{DAHB} - d_1^{S})/(d_1^{DAHB} - d_0^{S})$$

$$[4] \quad k_1'/k_2' = (d_1'^{HADB} - d_0'^{S})/d_1'^{HADB} - d_1'^{S})$$

where d_1^{DAHB} is the mole fraction of D_AH_B present in the starting sulfoxide sample (i.e., 1.0 in experiments analysed by ^{1}Hmr), d_1^{S} is the mole fraction of monodeuterated benzyl-substituted sulfide formed in the Pummerer reaction of D_AH_B, d_0^{S} is the mole fraction of undeuterated benzyl-substituted sulfide formed by the Pummerer reaction of D_AH_B, $d_1'^{HADB}$ is the mole fraction of H_AD_B present in the starting sulfoxide sample (i.e., 1.0 in experiments analysed by ^{1}Hmr), $d_1'^{S}$ is the mole fraction of monodeuterated benzyl-substituted sulfide formed in the Pummerer reaction of H_AD_B, and $d_0'^{S}$ is the mole fraction of undeuterated benzyl-substituted sulfide formed by the Pummerer reaction of H_AD_B.

The quantities d_1^{S}, d_0^{S}, $d_1'^{S}$, and $d_0'^{S}$ were determined by integration of the methine signal of the product (ca. δ 6.8) relative to an internal reference peak, usually the S-methyl peak at ca. δ 2.13.

For reactions of the type $PhCH_2\overset{+}{S}XCH_3 \rightarrow PhCHXSCH_3$, leading to a single regioisomer, analysis of the data was performed by mass spectrometry. If Z_m, Z_{m+1}, and Z_{m+2} are the heights of the *M*, *M* + 1, and *M* + 2 peaks of H_AH_B (normalized so that $Z_m + Z_{m+1} + Z_{m+2} = 1.00$), and Q_m, Q_{m+1}, and Q_{m+2} are the peak heights of a deuterated substrate, i.e., D_AH_B or H_AD_B, then

$$[5] \quad Q_m = Z_mD_0'$$

$$[6] \quad Q_{m+1} = Z_mD_1' + Z_{m+1}D_0'$$

$$[7] \quad Q_{m+2} = Z_mD_2' + Z_{m+1}D_1' + Z_{m+2}D_0'$$

where D_0', D_1', and D_2' are the mole fractions of the undeuterated, monodeuterated, and dideuterated species in the deuterated substrate. Equations [5]–[7] can be rearranged to give

$$[8] \quad D_0' = Q_m/Z_m$$

$$[9] \quad D_1' = (Q_{m+1} - Z_{m+1}D_0)/Z_m$$

$$[10] \quad D_2' = (Q_{m+2} - Z_{m+1}D_1 - Z_{m+2}D_0)/Z_m$$

The quantities Q_m, Q_{m+1}, and Q_{m+2} were obtained by measurement of the peak heights of the molecular ion cluster of the deuterated sample, and were normalized so that $Q_m + Q_{m+1} + Q_{m+2} = 1.0$. The quantities Z_m, Z_{m+1}, and Z_{m+2} could be determined by measurement of the peak heights of the molecular ion cluster of H_AH_B, but more accurate values were available by calculation using Beynon's equations (24). Table 1 lists the values of Z_m, Z_{m+1}, and Z_{m+2} calculated for benzyl methyl sulfoxide and benzyl methyl sulfide. The experimentally determined Z_m, Z_{m+1}, and Z_{m+2} values of benzyl methyl sulfoxide are included for comparison.

Equations [11] and [12] allow k_1/k_2 and k_1'/k_2' to be calculated,

$$[11]\quad k_1/k_2 = [d_1^{DAHB} - (d_1^{S} - d_2^{DADB})]/[d_1^{DAHB} - (d_0^{S} - d_0^{HAHB})]$$

$$[12]\quad k_1'/k_2' = [d_1'^{HADB} - (d_0'^{S} - d_0'^{HAHB})]/[d_1'^{HADB} - (d_1'^{S} - d_2'^{DADB})]$$

where d_2^{DADB}, d_1^{DAHB}, and d_0^{HAHB} are the relative amounts of dideuterated, monodeuterated, and undeuterated species in D_AH_B; $d_2'^{DADB}$, $d_1'^{HADB}$, and $d_0'^{HAHB}$ are the relative amounts of dideuterated, monodeuterated, and undeuterated species in H_AD_B, and d_0^{S}, d_1^{S}, and $d_0'^{S}$ and $d_1'^{S}$ are the corresponding quantities for the sulfide products from D_AH_B and H_AD_B.

Results and Discussion

Table 2 shows the results obtained in the Pummerer reactions of the benzyl-α-*d* methyl sulfoxides with acetic anhydride and with trifluoroacetic anhydride. Table 3 contains the deuterium analyses of the D_AH_B and H_AD_B benzyl methyl sulfoxides, and of the benzyl methyl sulfides formed from their derived ethoxysulfonium fluoroborates by reaction with sodium hydride in tetrahydrofuran. The selectivities and deuterium isotope effects calculated from these data are collected in Table 4.

TABLE 1. Relative abundances of Z_m, Z_{m+1}, and Z_{m+2} calculated from Beynon's equations

Compound	Molecular formula	Z_m	Z_{m+1}	Z_{m+2}
$PhCH_2\overset{O}{\overset{\|}{S}}CH_3$	$C_8H_{10}OS$	0.8695	0.08376	0.04674
$PhCH_2\overset{O}{\overset{\|}{S}}CH_3$[a]	$C_8H_{10}OS$	0.8680	0.0838	0.0440
$PhCH_2SCH_3$	$C_8H_{10}S$	0.8714	0.0836	0.04505

TABLE 2. Deuterium content of the α-acyloxybenzyl methyl sulfoxides formed in the Pummerer reactions of the D_AH_B and H_AD_B benzyl methyl sulfoxides[a]

Sulfoxide	Reagent	Temp. (°C)	d_0[b,c]	d_1[b,c]
D_AH_B	Ac_2O[d]	130	0.13	0.87
H_AD_B	Ac_2O[d]	130	0.19	0.81
D_AH_B	TFAA[e]	25	0.17	0.83
H_AD_B	TFAA[e]	25	0.14	0.86

[a]See text for the definitions of these isomers.
[b]Determined by ^{1}Hmr in CCl_4.
[c]The error in these measurements is 10% of the reported value.
[d]The solvent used was acetic anhydride with a sulfoxide concentration of 0.06 *M*.
[e]The solvent was CCl_4 with a sulfoxide concentration of 0.5 *M* and a TFAA concentration of 0.4 *M*.

In each case, the selectivity observed in the deprotonation of the oxysulfonium cation is opposite to that seen in the hydrogen–deuterium exchange which forms D_AH_B and H_AD_B, and is smaller by a factor of at least 10. However, the selectivities observed in the present work should be regarded as lower limits, for several reasons associated with the experimental conditions that were needed to obtain the results.

For example, as already mentioned (15), it is well established that the Pummerer reactions of acyloxysulfonium salts are complicated by a competing epimerization at sulfur. The relative rates of the two processes have been studied in several systems. Aryl benzyl sulfoxides are racemized in acetic anhydride at 100°C, a temperature at which the Pummerer reaction is not observed. For aryl methyl sulfoxides, the Pummerer reaction is faster than epimerization by a factor of 4.3 at 110°C. If epimerization is faster than the Pummerer reaction in the present work, D_AH_B (or H_AD_B) will be transformed to a 1:1 mixture of D_AH_B + H_AD_B, and all stereochemical information will be lost. Treatment of benzyl methyl sulfoxide with 1 equiv. of trifluoroacetic anhydride in methylene chloride at −65°C (25) followed, after 5 min, by addition of aqueous tetrahydrofuran, led to quantitative recovery of the compound. Repetition of this experiment with D_AH_B led to the recovery of a 1:1 mixture of the two diastereomers. Thus it is not surprising that little selectivity is evident in the Pummerer reaction when trifluoroacetic anhydride is employed as the reagent.

It is known (3) that the Pfitzner–Moffatt mode of decomposition of the oxysulfonium ylide derived from **18** is favoured in non-polar solvents. Therefore, this ylide was generated in tetrahydrofuran using sodium hydride as a non-nucleophilic base; these conditions avoid epimerization at sulfur and lead exclusively to the Pfitzner–Moffatt product. The high reactivity of sodium hydride, as can be seen from the negligible isotope effect which is observed in this case, would be expected to lead to reduced selectivity (26). In fact, the Pfitzner–Moffatt reaction exhibits the highest selectivity of the reactions studied in the present work.

In an attempt to find conditions that would lead to an increase in the selectivity of the Pfitzner–Moffatt reaction, the salt **19** was reacted with 2,6-lutidine in acetone, a solvent and base combination that is known (3) to minimize epimerization at sulfur. However, this reaction led, unexpectedly, to a 1:1 mixture of the acetal **20** and the dithioacetal **21**. It is suggested that this reaction proceeds via the sulfonium cation **22**, which is formed by the addition of the α-thiocarbonium ion **6** (an intermediate in the Pummerer reaction) to the thioacetal **23**. The mech-

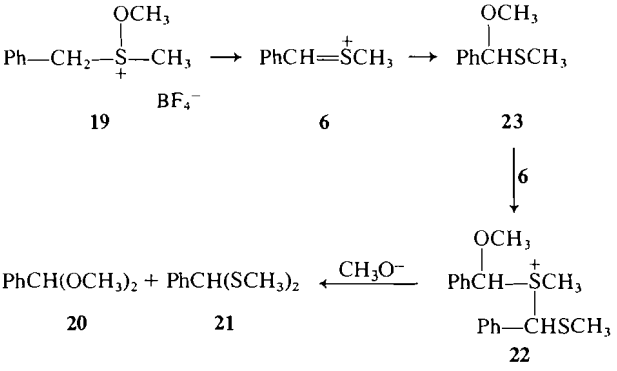
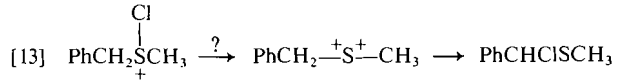
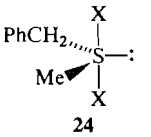
anism is written in this manner to account for the formation of a *mixture* of acetal and thioacetal (cf. ref. 27), and for the finding that **23** is stable to the action of 2,6-lutidine in acetone.



In the preceding paper (6), it was argued that a dication mechanism could not be ruled out for the reaction shown in eq. [13], which leads to the α-chlorobenzyl regioisomer exclusively. On the other hand, the Pummerer reactions of benzyl methyl acyloxysulfonium cations were considered to proceed via an E2 pathway. The observation of diastereotopic selectivity in the present work, while not proving the E2 pathway, is sufficient to rule out a dication mechanism for the acyloxysulfonium cations. The methylene protons of a dication are enantiotopic (28).



The same argument applies to the sulfurane **24**, which could be considered as an intermediate in the Pummerer reactions of the present work. The intervention of such species in Pummerer reactions has often been considered (2), but no definite evidence on this point has appeared. The sulfurane **24** is expected to exist in the trigonal bipyramidal geometry shown (29); the methylene protons of this molecule are *enantiotopic*. No selectivity between these protons could exist if the Pummerer reaction proceeds solely via **24**.



24

X = OAc, OTFA

Finally, it should be recognized that the selectivities reported here refer to acyclic molecules. Much higher selectivities are expected for cyclic, conformationally constrained systems (30). Extensions of the present work to appropriate molecules of this type are under active investigation.

Experimental

General experimental methods and syntheses of the *RS*/*SR*- and *RR*/*SS*-benzyl-α-*d* methyl sulfoxides have been described previously (5*a*, *b*, 6).

*Reaction of Benzyl-α-*d *Methyl Sulfoxide with Acetic Anhydride*

Benzyl-α-*d* methyl sulfoxide (D_AH_B or H_AD_B) (96 mg, 0.62 mmol) was dissolved in acetic anhydride (10 mL) and heated at 130°C for 2 h. The reaction mixture was poured into ice-cold saturated potassium bicarbonate. Extraction with chloroform (4 × 75 mL) and evaporation of the solvent after drying (magnesium sulfate) yielded a mixture of acetoxysulfides. The amount of hydrogen/deuterium on the methine carbon of α-acetoxybenzyl methyl sulfoxide was determined by integration using the acetoxy and SCH_3 protons as an internal reference.

*Reaction of Benzyl-α-*d *Methyl Sulfoxide with Trifluoroacetic Anhydride*

Benzyl-α-*d* methyl sulfoxide (D_AH_B or H_AD_B) (42 mg, 0.27 mmol) was suspended in carbon tetrachloride (0.5 mL), and trifluoroacetic anhydride (0.3 mL, 2 mmol) was added at 25°C. A ^{1}Hmr spectrum of the product was taken immediately, and the proton/deuterium content of the methine hydrogen of the α-trifluoroacetoxybenzyl methyl sulfide was measured by integration using the integral of the SCH_3 group as an internal reference.

*Reaction of Benzyl-α-*d *Methyl Ethoxysulfonium Fluoroborate with Sodium Hydride*

Benzyl-α-*d* methyl sulfoxide (0.500 g, 3.25 mmol) was weighed into a dry flask, and triethyloxonium fluoroborate (1.9 mL of 2.4 *M*, 4.56 mmol) in methylene chloride was added dropwise. After the solution was homogeneous, the sulfonium salt was precipitated with ether, and triturated further with ether. The ether was removed and dry tetrahydrofuran (10 mL) was added. To this was added sodium hydride (0.155 g, 50% dispersion, 3.23 mmol) in one portion, and the mixture was stirred at room temperature overnight. Then methanol (ca. 20 mL) was added, and the precipitated sodium fluoroborate was removed by filtration. The benzyl methyl sulfide was isolated by chromatography (silica gel, methylene chloride/petroleum ether (50–100) 5:1) and analysed by mass spectrometry.

*Epimerization of Benzyl-α-*d *Methyl Sulfoxide with Trifluoroacetic Anhydride at −65°C*

Benzyl-α-*d* methyl sulfoxide (D_AH_B) (100 mg, 0.65 mmol) was dissolved in methylene chloride (10 mL), and the solution was cooled to −65°C. Trifluoroacetic anhydride (0.4 mL of 1.63 *M*, 0.65 mmol) was added dropwise (2 min). The mixture became cloudy for a moment and then became clear. After 5 min, water (10 mL) and tetrahydrofuran (1 mL) were added and the mixture was allowed to warm to room temperature. Evaporation of the solvent led to a quantitative recovery of the sulfoxide. The ^{1}Hmr spectrum of this material showed two singlets (δ 4.20 and δ 3.88) in the benzyl region in the ratio 1:1, corresponding to a 1:1 mixture of D_AH_B and H_AD_B.

Received December 19, 1978

SAUL WOLFE, PETER MICHAEL KAZMAIER, and HILLAR AUKSI. Can. J. Chem. 57, 2404 (1979).

The cyclization of benzyl 2-carboxyphenyl sulfoxide (**1**) to 2-benzylbenzoxathiane-6-one (**2**) has been examined by a combination of ^{18}O-labelling of the sulfoxide oxygen, stereoselective deuterium labelling in the benzylic position, and the use of optically active compounds. With dicyclohexylcarbodiimide (DCC) as the cyclizing agent, the reaction proceeds with 55.8% retention of the sulfoxide oxygen, 57.8% preference for abstraction of one of the diastereotopic methylene protons, and it produces a 61.4/38.6 mixture of enantiomers. It is proposed that all three experimental observables are controlled by the competition between initial attack of the DCC upon the sulfoxide oxygen and upon the carboxyl group, and a mechanism is proposed for the reaction which clarifies the relationship between these observables. In agreement with earlier work by Stridsberg and Allenmark, DCC affords **2** having the opposite sign of rotation from **1**, and acetic anhydride affords **2** having the same sign of rotation as **1**. Asymmetric induction in the latter reaction is significantly less than with DCC because of competing epimerization at sulfur, but the origin of the differences in the sign of rotation of **2** under the different conditions has been clarified by the finding that there is less than 40% retention of the sulfoxide oxygen with acetic anhydride as the reagent.

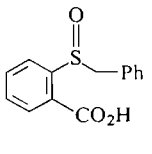
SAUL WOLFE, PETER MICHAEL KAZMAIER et HILLAR AUKSI. Can. J. Chem. 57, 2404 (1979).

On a étudié la cyclisation du benzyl carboxy-2 phényl sulfoxyde (**1**) en benzyl-2 benzoxathianone-6 (**2**) en combinant des méthodes de marquage de l'oxygène du sulfoxyde avec du ^{18}O et de marquage stéréosélectif au deutérium de la position benzylique ainsi que par l'utilisation de composés optiquement actifs. Lorsqu'on utilise la dicyclohexylcarbodiimide (DCC) comme agent de cyclisation, la réaction se produit avec 55.8% de retention de l'oxygène du sulfoxyde, avec une préférence de 57.8% pour l'enlèvement de l'un des protons diastéréomères du méthylène et il se forme un mélange 61.4/38.6 d'énantiomères. On suggère que les trois résultats expérimentaux observés sont contrôlés par une compétition entre une attaque initiale du DCC sur l'oxygène du sulfoxyde et sur le groupement carboxyle et on propose un mécanisme pour la réaction qui clarifie la relation entre ces observations. En accord avec les travaux antérieurs de Stridsberg et de Allenmark, le DCC fournit un composé **2** dont le signe de la rotation est inverse de celui de **1** alors que l'anhydride acétique conduit à un produit **2** dont la rotation est la même que celle de **1**. L'induction asymétrique dans cette dernière réaction est beaucoup moins importante qu'avec le DCC à cause de l'épimérisation au niveau du soufre qui est en compétition; toutefois on a pu clarifier l'origine des différences dans le signe de la rotation des produits **2** obtenus selon diverses conditions en trouvant que le taux de retention de l'oxygène du sulfoxyde est moins de 40% lorsque le réactif est l'anhydride acétique.
[Traduit par le journal]

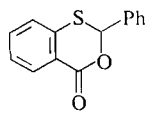
The reaction of benzyl 2-carboxyphenyl sulfoxide (**1**) with acetic anhydride (1) or with dicyclohexylcarbodiimide (DCC) (2) leads to 2-benzyl-1,3-benzoxathian-6-one (**2**), via an intramolecular Pummerer reaction (3). On the basis of the mechanistic studies of Oae and Numata (1), the rate-determining step in this reaction is the formation of the cyclic acyloxysulfonium cation **3**. Stridsberg and Allenmark (2, 4) also consider **3** to be an intermediate in the reaction and, in their investigations of the stereochemical course of the reaction, these workers have demonstrated that the conversion of **3** to **2** proceeds with asymmetric induction. For example, the reaction of optically pure (+)−**1** with DCC in ethylene chloride solvent at 25°C gave (−)−**2** having 29.9% optical purity; in acetic anhydride solvent at 100°C, (+)−**1** afforded (+)−**2** having 11.2% optical purity. Both groups of workers propose that the product-determining step in the overall reaction is the deprotonation of **3** to the cyclic acyloxysulfonium ylide **4**. To account for the asymmetric induction, Stridsberg and Allenmark have suggested (4) that diastereotopic selectivity exists in this deprotonation step, and that the diastereomeric ylides thus formed are converted to different enantiomers of the product.

The two groups of workers propose different mechanisms for the formation of **3** from **1**. According to Oae and Numata, the reaction is initiated by activation of the carboxyl group (**1** → **5**), followed

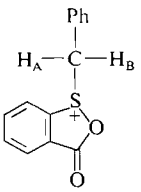
0008-4042/79/182404-08$01.00/0



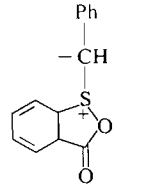
1



2

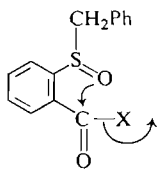


3

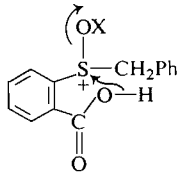


4

by rate-determining ring closure by the sulfoxide oxygen (**5** → **3**). On the other hand, Stridsberg and Allenmark, by analogy with the mechanism of the Pfitzner–Moffatt reaction (5), prefer an initial activation of the sulfoxide oxygen (**1** → **6**), followed by ring closure by the carboxyl group. These two pathways can be distinguished by ^{18}O-labelling experiments, since the sequence **1** → **5** → **3** predicts retention of the sulfoxide oxygen, and the sequence **1** → **6** → **3** predicts loss of the sulfoxide oxygen. One of the objectives of the present work is to provide the results of such experiments and to relate these results to the *direction* of the asymmetric induction observed under the different reaction conditions.



5



6

A second objective of the present work is to determine whether diastereotopic selectivity does exist in the deprotonation step of the reaction, and whether such selectivity can be related to the *magnitude* of the observed asymmetric induction. A third objective is to propose a new mechanism for the transformation of the cation **3** to the product **2**. This mechanism is consistent with experimental observations on the Pummerer reactions of acyloxysulfonium cations (6, 7), and it takes into account some theoretical calculations on the stereochemical properties of sulfonium ylides (8), which suggest that stereomutation of **4** would be sufficiently rapid to result in loss of the stereochemical integrity of diastereomers.

In the present mechanism, the deprotonation step is considered to proceed via an E2 pathway (6), with an *anti*-periplanar relationship between the C—H and S—O bonds. Thus conformation **3***a*[1] will lead to the α-thiocarbonium ion **7***a*, with loss of the pro-*S* benzylic proton, and conformation **3***b*[1] will lead to the α-thiocarbonium ion **7***b*, with loss of the pro-*R* benzylic proton. Because rotation about the C—S bond of an α-thiocarbonium ion is slow (9), in contrast to rotation about the C—S bond of a sulfonium ylide (8), collapse of the ion pair **7***a* is expected to lead to *S*-**2**, and collapse of the ion pair **7***b* is expected to lead to *R*-**2**, with net inversion of configuration at carbon. Since reactions **3***a* → **7***a* and **3***b* → **7***b* proceed via diastereomeric transition states, *S*-**2** and *R*-**2** will be produced in different amounts (10). Inspection of **7***a* and **7***b* suggests that the transition state leading to the latter α-thiocarbonium ion should be favoured significantly.

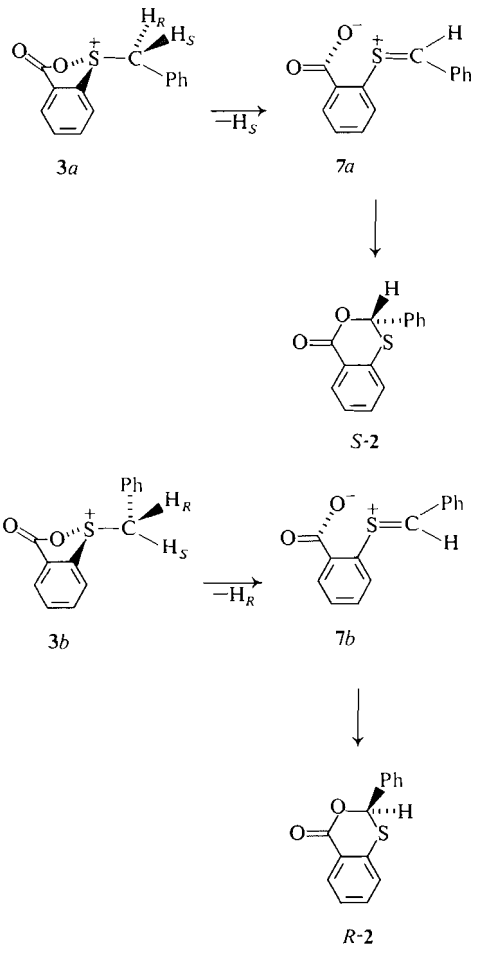
Consequently, *R*-**2** is expected to be the predominant enantiomer produced from the *R*-enantiomer of **3**, and it will be formed with loss of the pro-*R* benzylic proton. However, whether *R*-**3** or *S*-**3** is the intermediate in a reaction initiated from the *R*-enantiomer of **1** will depend upon which of the sequences **1** → **5** → **3** and **1** → **6** → **3** is operative under the specific reaction conditions. The above analysis will apply to a reaction initiated with *R*-**1** in which **3** is formed by the sequence **1** → **5** → **3**, with retention of configuration at sulfur (and retention of the sulfoxide oxygen). The analysis will also apply to a reaction initiated with *S*-**1**, in which **3** is formed by the sequence **1** → **6** → **3**, with *inversion* of configuration at sulfur (and *loss* of the sulfoxide oxygen).

Several aspects of this mechanistic proposal are, in principle, susceptible to experimental test. The first is the prediction that C—O bond formation occurs with net inversion of configuration at the benzylic carbon. To establish this point would require knowledge of the absolute configurations of **2**, **3**, and prochirally labelled **3**. None of this information is, as yet, available. A second is the prediction that the proportions of *R*-**2** and *S*-**2** are related to the relative rates of abstraction of the pro-*R* and pro-*S* methylene protons, respectively, and that these, in turn, are related to the fate of the sulfoxide oxygen of **1**.

Method

The procedure for the determination of diastereotopic selectivity in the deprotonation step was the same as that described in the preceding paper (7), using mass spectrometry, and was predicated upon

[1]The argument is presented for the *R*-enantiomer of **3**.



the assumption that the diastereomeric benzyl-α-*d* derivatives of **1** would be accessible by hydrogen–deuterium exchange. This assumption proved to be correct. In D_2O solvent at 30°C, the diastereotopic methylene protons of a 0.4 *M* solution of **1** were observed to be anisochronous (δ_A 4.32; δ_B 3.88). In *N* NaOD–D_2O, the downfield proton of the AB quartet (H_A) exchanged more rapidly than H_B, corresponding to the sequence of events $H_AH_B \rightarrow D_AH_B \rightarrow D_AD_B$. Such observations are now well established in the literature (11).

Figure 1 shows the results obtained in a typical experiment, in which the relative amounts of H_AH_B and D_AH_B were determined by integration of ^{1}Hmr spectra of the reaction mixture as a function of time. Scheme 1 is a simplified description of the processes which occur in this system. The rate of disappearance of H_AH_B provides $k_A + k_B$, where k_A and k_B are pseudo-first-order rate constants for the exchange of H_A and H_B, respectively. The rate of disappearance of D_AH_B provides k_B/J, where J is the secondary deuterium isotope effect. For $J = 1.34$,

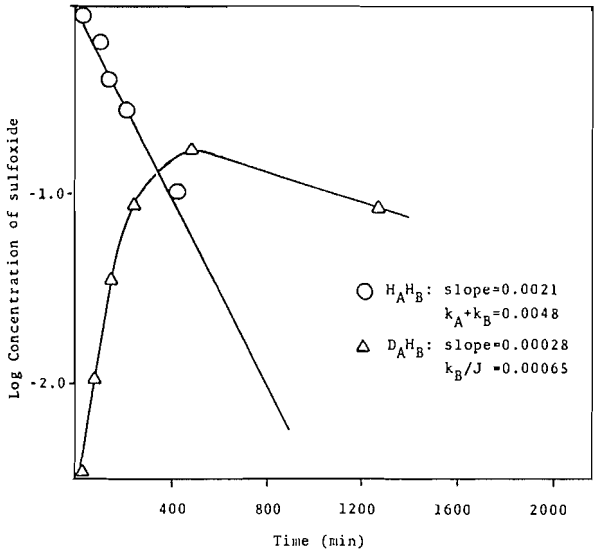


FIG. 1. Hydrogen–deuterium exchange of benzyl 2-carboxyphenyl sulfoxide (0.4 *M*) at 30°C in 1.0 *N* NaOD–D_2O.

the value observed in the hydrogen exchange of benzyl methyl sulfoxide (12), k_A and k_B were calculated to be 0.0040 min^{-1} and 0.00087 min^{-1}, respectively, leading to a ratio $k_A/k_B = 4.6$ at 30°C.

Although this result means that the D_AH_B diastereomer of **1** will be contaminated by H_AD_B, the proportions of the two are known, because the rate constants are known, and this permits appropriate corrections to be made to the selectivity results, as described below.

The H_AD_B diastereomer of **1** was synthesized by permitting the exchange of **1** to proceed to D_AD_B, and then carrying out a back exchange in NaOH–H_2O.

For the synthesis of ^{18}O-labelled **1**, benzyl 2-carboxyphenyl sulfide was oxidized with pyridinium perbromide in pyridine containing 12.678 at.% ^{18}O-enriched H_2O. Mass spectral analysis of the resulting sulfoxide indicated 13.08% ^{18}O-enrichment of the sulfoxide oxygen, based on analysis of M^+, and 12.56% enrichment, based on analysis of the *M*-91 peak. The average of these two values, 12.82 ± 0.55%, was used in the computation of the results.

Optically active **1** was prepared via the brucine salt, as described by Stridsberg and Allenmark (4).

However, in our hands, this led more readily to the *levo*-enantiomer.

The optically active sulfoxide and each of the isotopically labelled sulfoxides were converted to **2** in parallel experiments conducted using the same reagents and solvents.

Results and Discussion

Table 1 shows the deuterium analyses of the D_AH_B and H_AD_B diastereomers of **1** and of the cyclized product **2** obtained from these diastereomers under three sets of experimental conditions: (*i*) DCC in 1,2-dichloroethane, initially at 0°C for 1 h, and then at room temperature; (*ii*) acetyl trifluoroacetate (ATFA) in methylene chloride at 0°C for 1.5 h; (*iii*) acetic anhydride solvent at 114°C for 2 h. The selectivities and deuterium isotope effects calculated (7) from these data are collected in Table 2.

In the work of Oae and Numata (1), a kinetic isotope effect (k_H/k_D) of 1.07 was observed in the cyclization of **8**, a result consistent with the formulation **8** → **9** as the *rate*-determining step of the reaction. The isotope effects listed in Table 2 refer to the *product*-determining step, and are compatible with an E2 process.

Conversion of the selectivities shown in the second column of Table 2 to the true selectivities shown in the third column was achieved in the following manner. Solution of the differential equations for the exchange sequence $H_AH_B \rightarrow (D_AH_B + H_AD_B) \rightarrow D_AD_B$, and substitution of the

values of k_A, k_B, and J provided an estimate of the ratio $[D_AH_B]/[H_AD_B]$ as a function of time. Evaluation of this expression for t = 402 min, the time at which D_AH_B was isolated, gave $[D_AH_B]/$

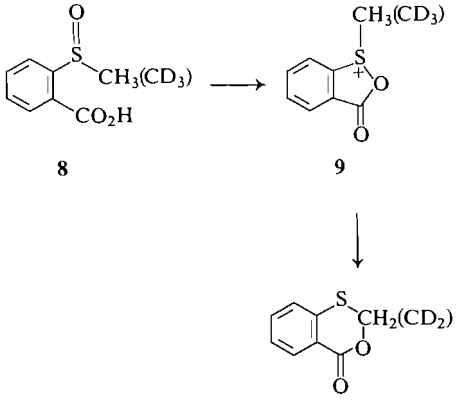

TABLE 3. Calculation of apparent selectivity as a function of true selectivity for a monodeuterated sample mixture containing 89% D_AH_B and 11% H_AD_B[a,b]

True selectivity (S')	Loss of deuterium[c]	Loss of hydrogen[c]	Apparent selectivity[d]
1.0	0.5000	0.5000	1.0000
0.9	0.4795	0.5205	0.9212
0.8	0.4567	0.5433	0.8405
0.7	0.4312	0.5688	0.7580
0.6	0.4025	0.5975	0.6736
0.5	0.3700	0.6300	0.5873
$10^{-\infty}$	0.1100	0.8900	0.1236

[a]Deuterium in this calculation is only a convenient label and the isotope effect is therefore taken to be 1.0.
[b]The relative proportions 0.89 and 0.11 were estimated from the solution of the differential equations (see text).
[c]The loss of deuterium and hydrogen were calculated by loss of deuterium $= S'/(1 + S')(0.89) + 1/(1 + S')(0.11)$ and loss of hydrogen $= 1/(1 + S')(0.89) + S'/(1 + S')(0.11)$.
[d]The apparent selectivity is the ratio of (loss of deuterium)/(loss o hydrogen).

$[H_AD_B] = 8.1$. Table 3 shows the apparent selectivity as a function of the true selectivity for a mixture of diastereomers having this composition. Interpolation in this table was used to obtain the true selectivities of Table 2.

The absence of selectivity in the case of ATFA as the Pummerer reagent is not surprising, since this reagent promotes rapid epimerization of sulfoxides (7). The same factor is responsible for the low selectivity observed with acetic anhydride (4, 7). For example, Stridsberg and Allenmark observed 31% racemization of optically active **1** after 3 min in acetic anhydride solvent at 100°C. In contrast, with DCC, we observed no racemization of optically active **1** after 1 h under the cyclization conditions.

The enantiomeric excesses predicted for **2** on the basis of the selectivity data of Table 2 are 15.7 ± 2% with DCC as the reagent and 4.0 ± 5% with Ac_2O as the reagent. When the standard deviation is taken into account, it can be seen that the direction of the lower selectivity observed under the latter conditions (and, therefore, whether the optically active **2** obtained from optically active **1** will have the same sign of rotation under the two sets of reaction conditions) cannot be determined by the present procedure.

The results of a number of experiments starting with the optically active sulfoxide are summarized in Table 4. In agreement with Stridsberg and Allenmark (4), DCC affords **2** having the opposite sign of rotation and Ac_2O affords **2** having the same sign of rotation as the sulfoxide; in addition, the selectivity is higher with DCC than with Ac_2O, in agreement with the earlier work and with the diastereotopic selectivity data. In the present work, the observed enantiomeric excesses are 23% with DCC and 5.7% with Ac_2O, under the conditions of the selectivity experiments. These various observations seem to be consistent with the view that the optical purity of the cyclized product is related to the diastereotopic selectivity exhibited in the deprotonation step.

The experiments with ^{18}O-labelled sulfoxide provide information concerning the question of whether the diastereotopic selectivity is itself determined by the mode of formation of **3**. The results of these experiments are summarized in Table 5. It is clear that both of the previously suggested sequences **1** → **5** → **3** and **1** → **6** → **3** are operative under both sets of reaction conditions. With Ac_2O as the reagent, the cyclized product retains less than 50% of the label and, with DCC as the reagent, more than 50% of the label. This indicates that the pathway via **5** is slightly preferred when the DCC conditions are employed, and the pathway via **6** is slightly preferred when the Ac_2O conditions are employed; **6** is also the intermediate in the competing racemization of **1** under the latter conditions (13). It is noteworthy that, with DCC, the preference for H_B (57.2%) and the retention of the sulfoxide oxygen (55.8%) are the same, within experimental error. Table 6 shows these data together with the optical activity data, expressed in the same manner.

In terms of the mechanistic proposals presented in the Introduction, the results of the ^2H, ^{18}O, and optical activity experiments permit the stereo-

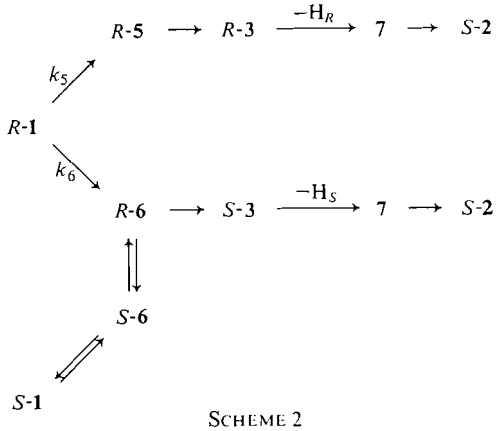
chemical course of the cyclization of **1** to **2** to be summarized as shown in Scheme 2. For a reaction initiated with *R*-**1**, the DCC conditions are predicted to lead to a preference for *R*-**2**, and the Ac_2O conditions are predicted to lead to a preference for *S*-**2**. We hope to report later concerning the absolute configurations of **1** and **2**.



SCHEME 2

Experimental

General experimental methods and procedures have been described previously (6, 7). Optical rotations were measured on a Perkin Elmer 141 polarimeter. 1,2-Dichloroethane was dried by stirring over calcium hydride for 48 h at room temperature, followed by distillation under dry nitrogen; it was stored, under dry nitrogen, in a flask equipped with a serum cap.

Benzyl 2-Carboxyphenyl Sulfide

Thiosalicylic acid (10 g, 0.065 mol) was dissolved in 50% aqueous ethanol (40 mL) in a three-necked flask equipped with a mechanical stirrer, and sodium hydroxide pellets (5.2 g, 0.136 mol) were added. Benzyl chloride (8.2 mL, 0.071 mol) was then added dropwise to the light yellow solution over a period of 15 min. After one half of the benzyl chloride had been added, a white solid began to precipitate out of solution. This redissolved upon the addition of 50% ethanol (120 mL). The progress of the reaction was monitored by treating aliquots with potassium triiodide solution until the persistence of the purple colour indicated that all of the mercaptide had been consumed (3.5 h). After acidification with 3 *N* hydrochloric acid, extraction with methylene chloride and drying (sodium sulfate) yielded, after evaporation, a crystalline product. Recrystallization from hot ethanol afforded white needles (13.9 g, 88%), mp 187–188°C (lit. (1) mp 186–187°C); ^{1}Hmr ($CDCl_3$/DMSO-d_6 1:1) δ: 8.0–7.0 (9H, m), 4.13 (2H, s); ^{13}Cmr ($CDCl_3$/DMSO-d_6 1:1) δ: 167.6 (C=O), 141.7, 136.4, 132.1, 129.1, 128.4, 127.8, 127.1, 125.4, 123.7 (phenyls), 36.4 (PhCH_2); ir (KBr): 1660 (carboxyl) cm^{-1}.

Benzyl 2-Carboxyphenyl Sulfoxide

Benzyl 2-carboxyphenyl sulfide (10 g, 0.041 mol) was suspended in 50% aqueous pyridine (50 mL). Pyridinium perbromide (9.8 g, 0.041 mol) was added in one portion. The sulfide dissolved rapidly and the orange colour faded to a pale yellow (5 min). After cooling of the reaction mixture in ice, concentrated hydrochloric acid was added to bring the pH to 1. The pasty solution was extracted with methylene chloride (4 × 50 mL), and each organic extract was washed with copper(II) sulfate solution and with brine. To liberate the sulfoxide from the green copper complex, the combined methylene chloride extracts were treated with hydrogen sulfide and the black precipitate was removed by filtration through Celite. After evaporation of the solvent, the crude product was recrystallized from ethyl acetate to yield cubic crystals (4.12 g, 39%), mp 160–173°C (dec.) (lit. (1) mp 170°C (dec.)); ^{1}Hmr ($CDCl_3$/DMSO-d_6 1:1) δ: 7.4–8.5 (4H, m), 7.23 (5H, s), 4.38 (1H, d, 12), 3.75 (1H, d, 12); ^{13}Cmr ($CDCl_3$/DMSO-d_6 1:1) δ: 167.0 (C=O), 147.7, 132.9, 131.8, 130.9, 130.3, 128.0, 127.8, 124.6 (phenyls), 62.5 (PhCH_2); ir (KBr): 1680 (carboxyl), 1000 (sulfoxide) cm^{-1}.

Kinetics of Hydrogen–Deuterium Exchange in Benzyl 2-Carboxyphenyl Sulfoxide

Benzyl 2-carboxyphenyl sulfoxide (520 mg, 2 mmol) was dissolved in 1 *N* NaOD (5.0 mL). Sodium 2,2-dimethyl-2-silapentanesulfonate (50 mg) was added as an internal standard and the reaction mixture was kept at 30 ± 5°C. An aliquot was transferred to an nmr tube and kept at the same temperature. Periodically, the ^{1}Hmr sample was scanned. The results were evaluated by cutting and weighing.

Preparation of D_AH_B by Hydrogen–Deuterium Exchange of Benzyl 2-Carboxyphenyl Sulfoxide

Benzyl 2-carboxyphenyl sulfoxide (520 mg, 2 mmol) was dissolved in 1 *N* NaOD (5.0 mL) and DSS (50 mg) was added as an internal standard. The reaction mixture was warmed in a water bath at 31°C and an aliquot was examined by ^{1}Hmr. After 402 min, the product was isolated by addition of cold 2.5 *N* hydrochloric acid (5.0 mL) and immediate collection of the white crystalline product. This sample was recrystallized

TABLE 6. Diastereotopic selectivity, asymmetric induction, and ^{18}O-transfer in the conversion of **1** to **2**

Reagent	% optical purity	Diastereotopic selectivity	% ^{18}O-retention
DCC	22.9 (61.4±0.4)[a]	0.73±0.03 (57.8±1.0)	55.8±4.5
Ac_2O	5.7 (52.8±0.4)[b]	0.92±0.10 (52.0±3.0)	36.4±5.5

[a]Numbers in parentheses refer to the percent of the major enantiomer of 2 which corresponds to these data.
[b]The major enantiomers under the Ac_2O and DCC conditions have opposite absolute configurations.

from hot ethyl acetate (30 mL) to yield 453 mg (87%) of the D_AH_B diastereomer.

Preparation of D_AD_B by Hydrogen–Deuterium Exchange of Benzyl 2-Carboxyphenyl Sulfoxide

Benzyl 2-carboxyphenyl sulfoxide (520 mg, 2 mmol) was dissolved in 1 *N* sodium deuteroxide (5.0 mL) and DSS (50 mg) was added as an internal standard. The reaction mixture was warmed in a water bath at 30°C, and an aliquot was observed by ^{1}Hmr. After 4 days, the peaks corresponding to the benzyl AB quartet had completely disappeared. Addition of 2 *N* sulfuric acid (20 mL) allowed the isolation of a quantitative yield of D_AD_B.

Preparation of H_AD_B by Hydrogen–Deuterium Exchange of Benzyl 2-Carboxyphenyl Sulfoxide

Benzyl 2-carboxyphenyl sulfoxide (D_AD_B) (520 mg, 2 mmol) was dissolved in 1 *N* sodium hydroxide (5.0 mL). After warming to 30°C for 12 h, the sulfoxide was recovered by the addition of 2 *N* sulfuric acid (ca. 20 mL) and analyzed by ^{1}Hmr. The sample was subjected to another 4 h of exchange and then isolated in the same way. Recrystallization from ethyl acetate yielded 290 mg of H_AD_B (56%).

General Procedure for the Reaction of α-Deuteriobenzyl 2-Carboxyphenyl Sulfoxide (D_AH_B or H_AD_B) with Dicyclohexylcarbodiimide

Dicyclohexylcarbodiimide (103 mg, 0.5 mmol) was dissolved in 1,2-dichloroethane, and α-deuteriobenzyl 2-carboxyphenyl sulfoxide was added in one portion to the ice-cold solution. After stirring for 1 h, the crystalline sulfoxide had dissolved and amorphous dicyclohexyl urea had precipitated. After a further 17 h of stirring, 2 drops of acetic acid were added and the urea was collected (98.5 mg). The 2-phenyl-1,3-benzoxathian-6-one was purified by chromatography on silica gel ($CHCl_3$/pyridine 100:1). The deuterium content of the 2-phenyl-1,3-benzoxathian-6-one was analyzed by mass spectrometry.

General Procedure for the Reaction of α-Deuteriobenzyl 2-Carboxyphenyl Sulfoxide (D_AH_B or H_AD_B) with Acetyl Trifluoroacetate

α-Deuteriobenzyl 2-carboxyphenyl sulfoxide (110 mg, 0.42 mmol) was dissolved in dry methylene chloride, and acetyl trifluoroacetate (0.3 mL (1.5 *M*), 0.45 mmol) was added in one portion to the ice-cold methylene chloride solution. The sulfoxide dissolved in ca. 50 min. After 90 min, tlc ($CHCl_3$/pyridine 100:1) showed only 1 spot (R_f 0.50) corresponding to 2-phenyl-benzoxathian-6-one. The volatile components were evaporated and the resulting syrup was chromatographed on silica gel ($CHCl_3$/pyridine 100:1). The deuterium content of the product was analyzed by mass spectrometry.

General Procedure for the Reaction of α-Deuteriobenzyl 2-Carboxyphenyl Sulfoxide with Acetic Anhydride at 114°C

α-Deuteriobenzyl 2-carboxyphenyl sulfoxide (38 mg, 0.15 mmol) was suspended in acetic anhydride (0.5 mL) and heated to 114°C for 2 h. The acetic anhydride was removed in a desiccator over potassium hydroxide (50 Torr), and the product was purified by chromatography on silica gel ($CHCl_3$). The deuterium content of the 2-phenyl-1,3-benzoxathian-6-one was determined by mass spectrometry.

Synthesis of ^{18}O-labelled Benzyl 2-Carboxyphenyl Sulfoxide

Pyridinium perbromide (0.6362 g, 2.66 mmol) was added in one portion to a stirred suspension of benzyl 2-carboxyphenyl sulfide (0.6511 g, 2.66 mmol) in a mixture of $H_2{}^{18}O$ (0.5 mL, 12.678 at.% enriched) and pyridine (4.5 mL). The reaction mixture rapidly became homogeneous (2 min), and stirring was continued for an additional 6 min. Methylene chloride (15 mL) was then added and the resulting mixture was acidified to pH 1 with dilute hydrochloric acid. A reddish oil separated initially and redissolved with continued stirring. The organic layer was separated, washed with water (6 × 10 mL), and filtered to obtain a fine white precipitate. This was air dried and then dissolved in hot ethyl acetate (30 mL). The ethyl acetate solution was dried over anhydrous magnesium sulfate and then reduced in volume to 5 mL. Cooling to −15°C gave 272 mg of the sulfoxide as a white crystalline solid. Recrystallization from ethyl acetate at −15°C gave 204 mg of material; ir (KBr): 1000 (^{16}O-sulfoxide), 997, 963 cm^{-1}.

Reaction of ^{18}O-labelled Sulfoxide with Dicyclohexylcarbodiimide

The sulfoxide (0.0534 g, 0.205 mmol) was added in one portion to an ice-cold solution of DCC (0.0423 g, 0.205 mmol) in 1,2-dichloroethane (7 mL). The resulting heterogeneous solution was stirred at 0°C (ice-bath) for 1 h and then at room temperature for 53 h. The reaction was quenched with acetic acid (3 drops). Filtration, followed by removal of the solvent gave 0.0878 g of a white solid. This was dissolved in chloroform and purified by plc, using a 2 mm silica gel plate and three elutions with chloroform. The product was extracted from the plate with methylene chloride to give 39.7 mg (80%) of **2** as a white crystalline solid.

Reaction of ^{18}O-labelled Sulfoxide with Acetic Anhydride

A 0.1441 *M* solution of the sulfoxide (37.5 mg, 0.1441 mmol) in acetic anhydride (1.0 mL) was heated, under nitrogen, at 130°C for 15 min. The solvent was then removed in a desiccator under high vacuum to give a pale yellow solid. The residue was dissolved in ethyl acetate, and purified by plc on a 2 mm silica gel plate which was eluted with benzene. The product was extracted from the plate with ethyl acetate to give 31.0 mg (89%) of **2** as a white crystalline solid.

Resolution of Benzyl 2-Carboxyphenyl Sulfoxide

Racemic sulfoxide (2.86 g, 0.011 mol) and brucine (dihydrate; 4.74 g, 0.011 mol) were dissolved together in boiling ethyl acetate – acetone (6:1) (118 mL). The solution was left at room temperature for 24 h and the crystalline salt (3.75 g) was isolated. The salt was treated with 100 mL of boiling ethyl acetate and, after cooling to room temperature, was filtered and dried (2.87 g). A small quantity of this salt was converted to the acid, which showed $[\alpha]_D^{26}$ −414.1 (*c* 0.5, EtOH). This ethyl acetate extraction was repeated, using 33 mL of boiling ethyl acetate, to yield 2.70 g of salt. The brucine salt was dissolved in methylene chloride (200 mL), and water (100 mL) and dilute hydrochloric acid were added to give the aqueous layer a pH of 2. The organic layer was separated, extracted with water (2 × 100 mL), filtered, and evaporated to give 1.37 g of sulfoxide. Recrystallization from boiling ethyl acetate gave 1.31 g of sulfoxide, $[\alpha]_D^{25}$ −358 (EtOH), which contained a trace of brucine (^{1}Hmr). The sulfoxide was, therefore, redissolved in methylene chloride (250 mL) and extracted with 1 *N* HCl (2 × 100 mL) and water (2 × 100 mL). The organic layer was separated, filtered and evaporated to give 0.79 g of material. Recrystallization from hot ethanol gave 0.60 g of sulfoxide having $[\alpha]_D^{25}$ −421.7 (EtOH), which still contained some brucine (^{1}Hmr). The material was suspended in water (50 mL), and sufficient sodium bicarbonate was added to bring the sulfoxide into solution. The solution was extracted with ether (2 × 50 mL) and acidified to pH 1 with 3 *N* HCl. The white precipitate was collected and extracted with methylene chloride (300 mL). This extract was dried over anhydrous magnesium sulfate and evaporated to give 0.58 g of sulfoxide. Recrystallization from hot ethanol

gave 0.45 g of material, mp 159.0–160.0°C; $[\alpha]_D^{21}$ −444 (EtOH).

Cyclization of cysteinylglycine sulfoxides under Pummerer reaction conditions

SAUL WOLFE, PETER MICHAEL KAZMAIER, AND HILLAR AUKSI
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received December 28, 1978

SAUL WOLFE, PETER MICHAEL KAZMAIER, and HILLAR AUKSI. Can. J. Chem. **57**, 2412 (1979).

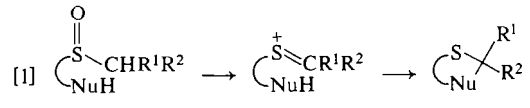
A number of sulfoxides derived from 3-benzylthiopropionic acid, *S*-benzylcysteine, and *S*-phenylcystelne have been synthesized and exposed to typical Pummerer reaction conditions. Cyclization of the *S*-benzyl sulfoxides to six-membered or seven-membered heterocyclic rings (1,3-thiazin-4-ones and 1,3,6-oxathiazepines) is observed only in acetic anhydride solvent and only after conversion of the carboxyl group to an amide or peptide. Cyclization of *S*-phenylcysteinyl amides to β-lactams could not be achieved. The thiazolidine isomers of the six- and seven-membered rIngs have been synthesized and found not to be intermediates in the acetic anhydride reactions. The thiazolidines do rearrange to the six- and (or) seven-membered rings in anhydrous trifluoroacetic acid solvent. *S*-Benzylphthalimidocysteinylglycine sulfoxide, a 3:2 mixture of epimers at sulfur, affords a 3:2 mixture of isomeric thiazinones. A mechanism for these cyclizations is proposed, and it is suggested that the configuration at sulfur controls the configuration at the new asymmetric centre in the product.

SAUL WOLFE, PETER MICHAEL KAZMAIER et HILLAR AUKSI. Can. J. Chem. **57**, 2412 (1979).

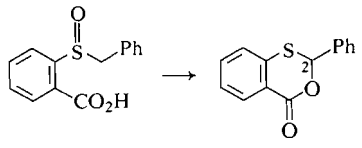
On a synthétisé un certain nombre de sulfoxydes provenant de l'acide benzylthio-3 propionique, de la *S*-benzylcystéine et de la *S*-phénylcystéine et on les a soumis à des conditions typiques de la réaction de Pummerer. On a observé la cyclisation des *S*-benzylsulfoxydes en hétérocycles à six- ou sept-chaînons (thiazine-1,3 ones-4 et oxathiazépines-1,3,6) que lorsque l'on utilise l'anhydride acétique comme solvant et seulement après avoir transformé le groupe carboxyle en amide ou en peptide. On n'a pas pu effectuer la cyclisation des *S*-phénylcystéinylamides en β-lactames. On a synthétisé les isomères thiazolidines des hétérocycles à six et sept chaînons et on a trouvé qu'ils n'étaient pas des intermédiaires lors des réactions dans l'anhydride acétique. Les thiazolidines se transposent en hétérocycles à six et sept chaînons par traitement dans de l'acide trifluoroacétique anhydre comme solvant. Le sulfoxyde de la *S*-benzylphtalimidocystéinylglycine sous forme d'un mélange 3:2 d'épimères au niveau du soufre fournit un mélange 3:2 de thiazinones isomères. On propose un mécanisme pour ces cyclisations et on suggère que la configuration au niveau du soufre contrôle la configuration du nouveau centre asymétrique dans le produit.

[Traduit par le journal]

There are a number of reports in the literature concerning the synthesis of heterocyclic compounds by intramolecular capture of the α-thiocarbonium ion intermediate of the Pummerer reaction (eq. [1])



[1]



1 2

(1). A particularly interesting example is the conversion of benzyl 2-carboxyphenyl sulfoxide (**1**) to 2-phenyl-1,3-benzoxathian-6-one (**2**) (2, 3), which proceeds (2) with asymmetric induction. In connection with some other investigations in progress in this laboratory (4), we wished to know whether the latter reaction could be extended to more complex sulfoxides carrying a neighbouring carboxyl or carboxyl-derived functional group. This paper describes some preliminary results of a detailed investigation of the effects of structure and reaction conditions upon the dehydrative cyclization of a number of sulfoxides derived from cysteine and 3-mercaptopropionic acid.

The series of 19 sulfides **3***a*–**3***s* listed in Table 1 was synthesized via the appropriate Schemes 1–3, and 15 of these sulfides were converted to the sulfoxides **4***a*–**4***o*, shown in Table 2. The conversion **3** → **4** was achieved using one of the following procedures, as appropriate: (*A*) hydrogen peroxide in methanol; (*B*) hydrogen peroxide in acetone; (*C*) sodium *meta*-periodate; (*D*) *m*-chloroperbenzoic acid in chloroform or methylene chloride; (*E*) hydrogen peroxide in acetic acid.

The initial experiments were performed using *S*-benzyl-L-cysteine sulfoxide (**4***h*) as the substrate, and were uniformly unsuccessful. As can be seen from

0008-4042/79/182412-14$01.00/0

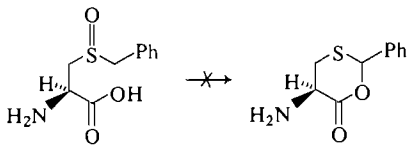
the observations collected in Table 3, none of the reaction conditions and reagents known to be effective for inter- and intramolecular Pummerer reactions (2–4) leads to the cyclic compound **6**.

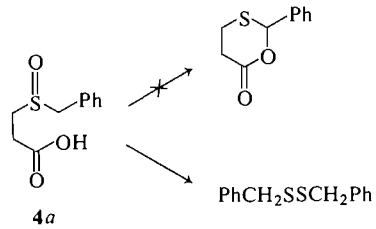


4*h* **6**

However, **4***h* differs from **1** as the substrate for an intramolecular Pummerer reaction in three important respects: (*i*) the presence of an amino group; (*ii*) the presence of a C—H bond beta to the sulfoxide; (*iii*) the absence of the conformational constraint imposed by the benzene ring. Clearly, the role of these structural variables required detailed examination under standard reaction conditions.

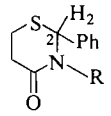
For the determination of the most appropriate reaction conditions, the cyclization **1** → **2** was re-examined, using acetic anhydride (Ac_2O), trifluoroacetic anhydride (TFAA), and acetyl trifluoroacetate (ATFA) as the dehydrating agents. The results of these experiments are shown in Table 4. The reactivities of the three anhydrides in the Pummerer reaction are TFAA > ATFA > Ac_2O (4*a*), but only in the latter case does the formation of **2** proceed cleanly. Therefore, acetic anhydride was selected as the reagent for all subsequent work.

The sulfoxide **4***a*, like **4***h*, afforded no cyclic product. Attention was next focused upon the effect of derivatization of the carboxyl group, and it was



4*a*

found (cf. ref. 8) that cyclization to a perhydro-2-phenyl-1,3-*thiazin*-4-one (**8**) occurs when the carboxyl group of **4***a* is converted to a carboxamido derivative and the product (**4***c*, **4***d*, **4***e*, **4***f*) exposed to acetic anhydride. The results obtained in the cyclizations of **4***c*–**4***f* to **8** (R = H, CH_3, *n*-C_4H_9, CH_2CO_2Et) are collected in Table 5.



8

Following these observations, the reactions of cysteine derivatives with acetic anhydride were re-examined, this time after conversion to the glycyl peptides **4***k*–**4***m*. As can be seen in Table 6, the establishment of experimental conditions for the dehydrative cyclization of **4***k* required considerable effort. The product of this reaction, assigned the oxathiazepine structure **9***a*, was formed only in acetic anhydride solvent, and only in the temperature range 75–80°C. The same conditions were then used to prepare the benzamido analog **9***b* from **4***l*. However, the phthalimido compound **4***m* afforded a different skeleton, which is assigned the *thiazinone*

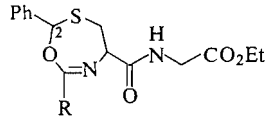
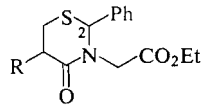
structure **10***a*. This product was formed as a 3:2 mixture of stereoisomers. Close examination of the reaction conditions for the cyclizations of **4***l* and **4***m* revealed that, in the conversion **4***l* → **9***b*, the sulfoxide is consumed after 3 h *at 78–79°C*, but the conversion of **4***m* to **10***a* required more than 6 h at this temperature; longer reaction times could not be investigated because of decomposition of **10***a*.





9*a* R = CH_3 (59% yield) **10***a* R = phthalimido (31% yield)
9*b* R = C_6H_5 (42% yield) **10***b* R = PhCONH

These observations are consistent with the general mechanism presented in Scheme 4, adapted from that proposed for the cyclization of **1** to **2** (2–4), in which the initial intermediate is the acetoxysulfonium cation **11**. With acetamido or benzamido substituents, this intermediate can be converted either to the six-membered cyclic oxysulfonium cation **12** or the five-membered cyclic oxysulfonium cation **13**. Only **13** is possible in the case of the phthalimido compound. Proton loss from **12** leads to the zwitterion **14**, which can cyclize by C—O bond formation to form an oxathiazepine (**9**), or by C—N bond formation to form a thiazolidine (**15**). Proton loss from **13** leads to the zwitterion **16**, which can cyclize to a thiazinone (**10**) or an imidate (**17**). The nature of the products and also the reaction times indicate that the six-membered ring **12** is formed more readily than the five-membered ring **13**.

The assignment of structure **10***a* to the dehydration product of **4***m* is based upon two features of its ^{1}Hmr spectrum and on detailed analysis of its high resolution mass spectrum. The ^{1}Hmr spectrum showed the H2 protons of the two stereoisomers at δ 6.03 and 5.63 ppm. These values can be compared to the H2 chemical shifts of the series of compounds **8**, which fall in the range 5.43–5.68δ. In compound **2**, which has a C—O bond, H2 appears at 6.53δ, and in compound **18** (4*a*), the tertiary proton appears at 6.95δ. The ^{1}Hmr spectrum of **10***a* also showed a large chemical shift difference between the diastereotopic methylene protons of the glycyl moiety (Δν = 1.94 and 0.94 ppm for the two isomers; J = 17 Hz in both cases). A similar non-equivalence was ob-

[a]A concentration of 1.32 *M* was used, unless stated otherwise.
[b]One equivalent of reagent was added, unless stated otherwise.
[c]Five equivalents of trifluoroacetic anhydride were used.
[d]Benzaldehyde was also produced, but was not isolated.
[e]Acetyl trifluoroacetate was used in excess.
[f]No 2,4-dinitrophenylhydrazine-active products were present.
[g]Recovered starting material.
[h]Inverse addition, i.e., DCC added to sulfoxide and TFA.
[i]Benzaldehyde was isolated as its 2,4-dinitrophenylhydrazone.

served in the ^{1}Hmr spectrum of **8** (R = CH_2CO_2Et) ($\Delta\nu$ = 1.37 ppm; J = 18 Hz).

The mass spectrum of **10***a* (see **19**) showed, in addition to M^+ (9.17%) (calcd. for $C_{22}H_{20}N_2O_5S$: 424.1093; found: 424.1097), peaks corresponding to fragmentation A (100%) (calcd. for $M - CH_2CO_2Et$: 337.0647; found: 337.0655), fragmentation B (26.87%) (calcd. for $C_6H_4(CO)_2NCH{=}CH_2$: 173.0477; found: 173.0482), and fragmentation C (20.73%) (calcd. for $C_6H_5C{=}S$: 121.0112; found: 121.0109).

That the cyclizations of **4***k* and **4***l* had proceeded in a different manner was immediately evident from the ^{1}Hmr spectra of **9***a* and **9***b*, and was confirmed by the high resolution mass spectra. In these compounds, H2 appeared at 6.10 and 6.18δ, but the glycyl methylene protons were found to be isochronous, and coupled to an adjacent NH proton. The mass spectrum of **9***a* (see **20**) showed, in addition to the molecular ion (2.90%) (calcd. for $C_{16}H_{20}N_2O_4S$: 336.1144; found: 336.1144), peaks corresponding to

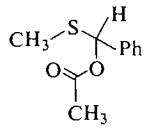
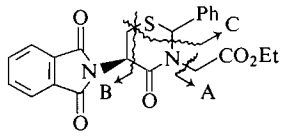
[a]The reaction was followed by tlc until the starting material had disappeared.
[b]Six equivalents of acetic anhydride were added.
[c]The temperature was increased gradually from 25–80°C.

$H_{22}N_2O_4S$: 398.1293; found: 398.1297) and the same two fragmentations as **9***a* (fragmentation A (100%): calcd. for $C_{14}H_{11}NOS$: 241.0567; found: 241.0564; fragmentation B (40.19%): found: 121.0122). Additional peaks identified in the mass



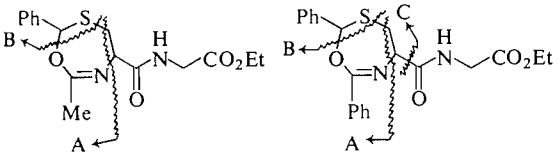
18

spectrum of **9***b* correspond to fragmentation C (18.90%) (calcd. for $C_{16}H_{14}NOS$: 268.0776; found: 268.0786) and fragmentation B + C (40.19%) (calcd. for C_9H_8NO: 146.0620; found: 146.0613).



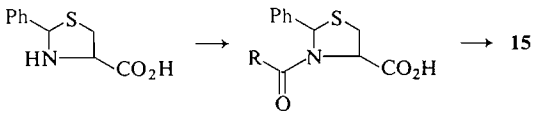
19

The ^{1}Hmr and mass spectral data just presented do not distinguish unequivocally between the thiazolidine structures **15** and the oxathiazepine structures **9**, and it was necessary, therefore, to



20 21

synthesize **15** (R = Me, Ph) by an alternative route for comparison with the products of the Pummerer reactions. The required thiazolidines were obtained by *N*-acylation of 2-phenylthiazolidine-4*R*-carboxylic acid (**22**) (16), followed by coupling with the ethyl ester of glycine. The non-identity of **9***a* and **15** (R = Me), and of **9***b* and **15** (R = Ph), was clearly evident from the different nmr, ir, and mass spectra, the different tlc behaviour, and from melting point and mixture melting point determinations of the pairs of isomers.

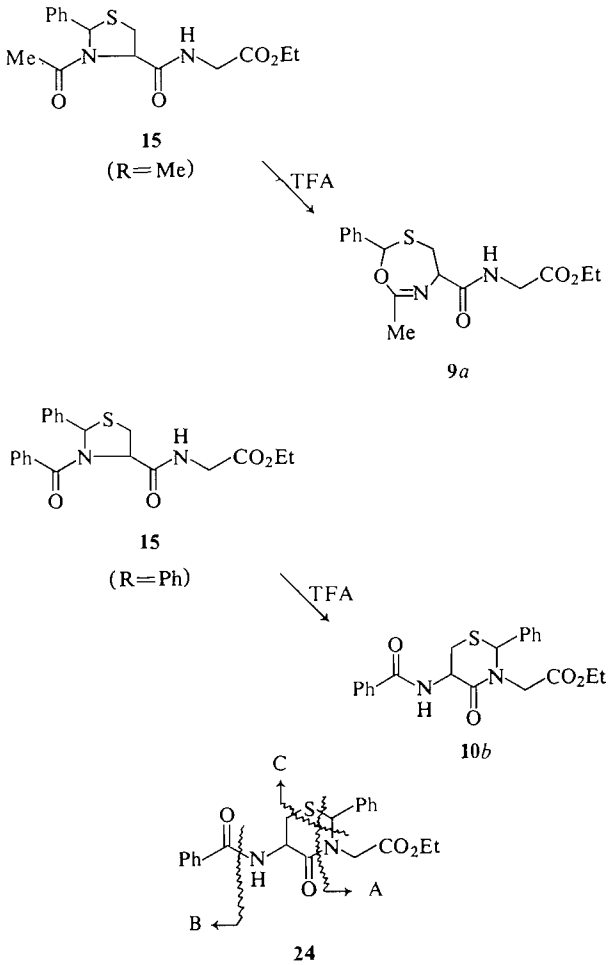


22 23

The thiazolidines **15** were stable to the Pummerer reaction conditions (Ac_2O, 79–80°C, 3 h). Consequently, these compounds cannot be intermediates in the Pummerer reactions. However, in anhydrous trifluoroacetic acid, the thiazolidines underwent rapid isomerization. The acetyl compound (**15**; R = Me) rearranged to **9***a*, identical in all respects to the material already described. The benzoyl compound (**15**; R = Ph) was converted to the *thiazinone* **10***b*. The ^{1}Hmr spectrum of **10***b* showed the characteristic large non-equivalence of the glycyl methylene protons ($\Delta\nu$ = 1.08 ppm; J = 17 Hz), and the mass spectrum (see **24**) showed the fragmentations indicated in A, B, and C.

Each of the five-membered, six-membered, and seven-membered heterocyclic rings of the present work has two asymmetric centres, so that two stereoisomers can exist in each case (cf. refs. 17, 18). A consideration of the configurations of **9**, **10**, and **15** is reserved for a subsequent publication (19). However, some comment concerning the formation of **10***a* as a 3:2 mixture of isomers seems pertinent at this point, since **4***m*, the sulfoxide precursor of **10***a*, was also found to have been formed as a 3:2 mixture of epimers at sulfur (based on integration of the phenyl region of the ^{1}Hmr spectrum). In terms of the mechanism presented in Scheme 4 and the stereochemical investigations of ref. 4, it is presently considered that **13** is formed from **11** with inversion of configuration at sulfur, that the transformation of **13** to **16** is an E2 elimination, which proceeds with stereospecific removal of one of the diastereotopic benzylic protons, and that the cyclization of **16** to **10***a* then leads to a single C2 epimer. It is noteworthy that only one epimer of **4***k* and **4***l* was apparently produced in the oxidations of each of the sulfides **3***i* and **3***k*, respectively, and only one epimer of **9***a* and **9***b* was detected in the Pummerer reactions of these sulfoxides. Attempts to secure a single epimer of **4***m* have not yet succeeded.

Finally, with the successful establishment of conditions for the cyclization of cysteinylglycine peptides to six- and seven-membered rings, a number of attempts were made to extend the reaction to the synthesis of β-lactams. For this purpose, the *S*-phenylcysteinylglycine sulfoxides **4***n* and **4***o* were prepared and subjected to the various reaction conditions summarized in Table 7. No evidence was obtained for the formation of **25** under these conditions. It seems probable, in any event, that the conditions required to form a β-lactam from **4***n* and **4***o* would also lead to rapid destruction of the product (20). To check this point, the methyl ester of phenylpenicillin was heated in acetic anhydride at



15 (R=Me) TFA 9*a*

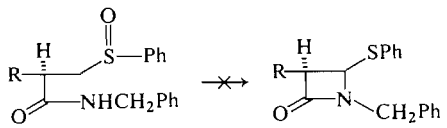
[a]Acetic anhydride was used as cosolvent.
[b]Time for complete disappearance of the starting material.
[c]As judged by the absence of peaks in the 4.0–6.5δ region and C=O stretch at ca. 1780–1800 cm^{-1}.
[d]Temperature was varied from 25–65°C.



4*n* R = AcNH
4*o* R = phthalimido

25

80°C for 1.5 h. The β-lactam ring did not survive these conditions.

Experimental

General methods employed in this work have been described in refs. 4*a–c*. High resolution mass spectra were obtained on an AEI-MS 3074/DS 50 instrument.

Ethyl 3-Benzylthiopropionate (3a)

A solution of sodium metal (3.92 g, 0.170 g-atom) in absolute ethanol (50 mL) was treated dropwise at room temperature with benzyl mercaptan (20.0 mL, 0.170 mol) and then with ethyl 3-bromopropionate (21.2 mL, 0.170 mol). When thin-layer chromatography indicated that the reaction was complete (2 h), water (50 mL) was added and the product extracted with methylene chloride (4 × 50 mL). After flash evaporation, the product was distilled under high vacuum (bp 134–136°C/0.23 Torr, lit. (5) bp 101–103°C/0.22 Torr) to yield ethyl 3-benzylthiopropionate (32.5 g, 87%); ^{1}Hmr ($CDCl_3$)δ: 7.28 (5H, s), 4.12 (2H, q, 7), 3.72 (2H, s), 2.62 (4H, m), 1.25 (3H, t, 7); ir(NaCl film): 1730 (ester) cm^{-1}.

3-Benzylthiopropionic Acid (3b)

Ethyl 3-benzylthiopropionate (2.37 g, 10.5 mmol) was cooled to 4°C and potassium hydroxide in 95% ethanol (22 mL of 0.494 *M*, 10.8 mmol) was added. The reaction mixture was stirred at 4°C (4 h) and then at 25°C (12 h). The reaction mixture was acidified to pH 1.5 with 2.5 *N* hydrochloric acid and extracted with methylene chloride (5 × 20 mL). After drying over sodium sulfate, evaporation of the methylene chloride extract yielded a crystalline solid which, on recrystallization from ethyl acetate – petroleum ether, produced colourless needles (1.44 g, 70%), mp 80–81°C (lit. (6) mp 80–82°C); ^{1}Hmr ($CDCl_3$)δ: 7.30 (5H, s), 3.73 (2H, s), 2.63 (4H, s); ir(KBr): 1695 (s, carboxylic acid) cm^{-1}.

3-Benzylthiopropionamide (3c)

Ethyl 3-benzylthiopropionate (5.00 g, 22.2 mmol) and concentrated ammonium hydroxide (25 mL) were shaken together in a sealed flask (24 h). The milky white solution was extracted with methylene chloride (5 × 20 mL) and this extract was dried over sodium sulfate. Evaporation yielded a partially crystalline residue (4.94 g). Trituration to remove unreacted ester yielded a white crystalline product (882 mg, 21%), mp 114–115°C (lit. (7) mp 110–111°C); ^{1}Hmr ($CDCl_3$)δ: 7.33 (5H, s), 5.5 (2H, s), 3.73 (2H, s), 2.60 (4H, m); ir(KBr): 3320, 3180 (s, NH), 1648 (s, amide I), 1622 (amide II) cm^{-1}.

*3-Benzylthio-*N*-methylpropionamide (3d)*

Ethyl 3-benzylthiopropionate (5.00 g, 22.2 mmol) and methylamine (25 mL of 40% aqueous solution) were shaken together for 17 h. The milky emulsion was extracted with methylene chloride (4 × 20 mL) and the combined organic fractions dried over sodium sulfate. Evaporation yielded a light yellow syrup (3.79 g, 82%), ^{1}Hmr ($CDCl_3$)δ: 7.30 (5H, s), 6.13 (1H, s), 3.73 (2H, s), 2.75 (3H, d, 4), 2.5 (4H, m); ir(NaCl film): 3280 (NH), 1640 (amide I), 1550 (amide II) cm^{-1}.

n-*Butyl 3-Benzylthiopropionamide (3e)*

Neat ethyl 3-benzylthiopropionate (5.00 g, 0.0222 mol) and *n*-butylamine (11.1 mL, 0.111 mol) were mixed at 25°C. The progress of the reaction was monitored by infrared spectroscopy during a period of 7 days. Then excess *n*-butylamine was evaporated and the product was purified by trituration with petroleum ether to yield white crystals (4.71 g, 84%), mp 41–56°C; ^{1}Hmr ($CDCl_3$)δ: 7.32 (5H, s), 6.6 (1H, s), 3.73 (2H, s), 3.20 (2H, q, 6), 2.9–2.2 (4H, m), 2.7–0.9 (7H, m); ir(KBr): 3380 (s, NH), 1630 (s, amide I), 1345 (s, amide II) cm^{-1}.

Ethyl 3-Benzylthiopropionylglycinate (3f)

3-Benzylthiopropionic acid (1.57 g, 8 mmol) and glycine ethyl ester hydrochloride (1.12 g, 8 mmol) were suspended in ethyl acetate (10 mL). The mixture was cooled to −5°C in a brine ice bath, and triethylamine (1.12 mL, 8 mmol) was added. After 5 min of stirring at −5°C, dicyclohexylcarbodiimide (1.65 g, 8 mmol) in ethyl acetate (10 mL) was added in one portion. During the addition, the temperature rose to −3°C. After 1 h the ice bath was removed. When thin-layer chromatography indicated that the reaction was complete (1 h at room temperature), the precipitate was collected and washed thoroughly with ethyl acetate. The ethyl acetate solution was washed with 5% citric acid solution (1 × 20 mL), saturated potassium bicarbonate (1 × 20 mL), and water (1 × 20 mL). After drying (sodium sulfate), the ethyl acetate was removed by flash evaporation to yield a syrup (2.23 g, 90%). The ^{1}Hmr analysis revealed that the product contained ca. 10% of dicyclohexylurea. This product was used in the next step without further purification; ^{1}Hmr ($CDCl_3$)δ: 7.27 (5H, s), 6.7 (1H, t, 4), 4.17 (2H, q, 6), 3.95 (2H, d, 4), 2.4–2.8 (4H, m), 1.93 (3H, t, 6).

Diphenylmethyl Glycinate p-*Toluenesulfonic Acid Salt*

The *p*-toluenesulfonic acid salt of glycine (4.94 g, 20 mmol) was dissolved in dimethylformamide (5 mL). Diphenyldiazomethane in dimethylformamide was added dropwise (15 min) until the red colour of the diphenyldiazomethane persisted

(7.5 mL of 2.8 *M*, 21 mmol). After the addition of anhydrous ether (100 mL), a yellow syrup separated. On cooling to −20°C for 3 days, the syrup crystallized (5.94 g). Recrystallization from acetone – diethyl ether yielded a white crystalline product (2.71 g, 33%), mp 138°C (lit. (21) mp 140–142°C); ^{1}Hmr ($CDCl_3$)δ: 7.68, 7.12 (4H, AA′BB′, 8), 7.35 (10H, s), 6.88 (1H, s), 3.90 (2H, s), 2.33 (3H, s); ir(KBr): 1737 (s, ester) cm^{-1}.

Diphenylmethyl 3-Benzylthiopropionylglycinate (3g)

Diphenylmethyl 3-benzylthiopropionylglycinate was synthesized by the procedure used for ethyl 3-benzylthiopropionate. The compound was isolated as a syrup (100%); ^{1}Hmr ($CDCl_3$)δ: 7.30 (10H, s), 7.25 (5H, s), 6.92 (1H, s), 4.12 (2H, d, 6), 3.70 (2H, s), 2.55 (4H, m); ir(film): 3330 (s, NH), 1735 (s, ester), 1670 (s, amide I), 1530 (s, amide II) cm^{-1}.

N-*Acetyl*-S-*benzyl*-L-*cysteine (3h)*

S-Benzyl-L-cysteine (2.1 g, 9.9 mmol), water (12 mL), and sodium hydroxide (2.06 mL of 6.79 *N*, 14 mmol) were cooled to 7°C. The pH was monitored with a pH meter. Acetic anhydride (4 mL, 42.1 mmol) was added in eight portions and sodium hydroxide (6.79 *N*) was added dropwise so as to keep the pH in the range 8–10. After the addition was complete (20 min), the ice bath was removed and the solution was stirred at 25°C for 40 min. The pH was then lowered to 1.0 by the addition of sulfuric acid (6.04 *N*), and the mixture was cooled to 7°C. The precipitated crystals were collected by filtration and recrystallized from isopropanol/hexane (1:1) to yield colourless needles (1.94 g, 77%), mp 143.5–147°C; $[\alpha]_D^{24}$ −41.3 (*c* 1.0, 95% EtOH) (lit. (9) $[\alpha]_D^{26}$ −41.5 (*c* 1.0, 95% EtOH); ^{1}Hmr (DMSO-d_6)δ: 8.23 (1H, d, 8), 7.30 (5H, s), 4.42 (1H, m), 3.77 (2H, s), 3.6–3.8 (2H, m), 1.90 (3H, s); ^{13}Cmr (DMSO-d_6)δ: 172.1, 169.4 (carbonyl), 138.1, 128.8, 128.3, 126.8 (phenyl), 51.8 (CH), 35.5 (SCH_2Ph), 32.5 (SCH_2-CH), 22.3 (CH_3).

N-*Acetyl*-S-*benzyl*-L-*cysteinylglycine (Ethyl Ester) (3i)*

N-Acetyl-*S*-benzyl-L-cysteine (5.147 g, 0.0203 mol), EEDQ (5.18 g, 0.0203 mol), and glycine ethyl ester hydrochloride (2.83 g, 0.0203 mol) were suspended in methylene chloride (100 mL). Triethylamine (3.11 mL, 0.0406 mol) was added in one portion and the mixture was stirred overnight at room temperature. The solution was then washed successively with 1 *N* hydrochloric acid (3 × 20 mL), saturated sodium bicarbonate (2 × 20 mL), and water (2 × 20 mL). Drying over sodium sulfate and evaporation afforded a yellow syrup which crystallized from ethyl acetate/petroleum ether, with scratching, to yield a white crystalline product (5.72 g, 83%), mp 108–109°C, (lit. (11) mp 116.5–117.5°C); $[\alpha]_D^{18.2}$ −8.6 (*c* 1.0, ethyl acetate); ^{1}Hmr ($CDCl_3$)δ: 7.30 (6H, m), 6.83 (1H, d, 7), 4.67 (1H, q, 7), 4.17 (2H, q, 7), 3.98 (2H, d, 6), 3.75 (2H, s), 2.80 (2H, d, 7), 1.98 (3H, s), 1.27 (3H, t, 7); ^{13}Cmr ($CDCl_3$)δ: 171.0, 170.5, 169.4 (carbonyl), 138.1, 129.0, 128.6, 127.2 (phenyl), 61.4 (OCH_2), 52.3 (CH), 41.5 (N—CH_2-CO), 23.0 (acetyl), 14.1 (CH_3CH_2); ir(film): 3260 (NH), 1742 (ester), 1640 (amide I), 1550 (amide II) cm^{-1}.

N-*Benzoyl*-S-*benzyl*-L-*cysteine (3j)*

Sodium carbonate (5.16 g, 60 mmol) and *S*-benzyl-L-cysteine (4.22 g, 20 mmol) were suspended in water (60 mL). The mixture was cooled to −4°C and benzoyl chloride (2.32 mL, 20 mmol) was added dropwise. After the addition was complete (10 min), the ice bath was removed and the reaction mixture was stirred at 25°C for 40 min. It was then extracted with ether (2 × 20 mL). Dropwise addition of concentrated hydrochloric acid (7 mL) precipitated a white solid, which was removed by filtration. Recrystallization from ethyl acetate afforded 4.78 g (76%), mp 100–106°C (lit. (12) mp 118–119°C); $[\alpha]_D^{24.5}$ −35.4 (*c* 1.0, absolute EtOH); ^{1}Hmr ($CDCl_3$/DMSO-d_6 1:1)δ: 8.13 (1H, d, 8), 7.3–8.0 (5H, m), 7.25 (5H, s), 4.8 (1H, m), 3.75 (2H, s), 3.8–4.2 (2H, m); ^{13}Cmr ($CDCl_3$/DMSO-d_6 1:1)δ: 173.3, 166.4 (carbonyl), 138.4, 134.5, 131.0, 128.8, 128.1, 127.4, 126.6 (phenyl), 53.2 (CH), 35.9 ($PhCH_2$), 33.4 ($CHCH_2S$); ir(KBr): 3500 (m, COOH), 3320 (s, NH), 1720 (s, COOH), 1620 (s, amide I), 1520 (s, amide II) cm^{-1}.

N-*Benzoyl*-S-*benzyl*-L-*cysteinylglycine (Ethyl Ester) (3k)*

N-Benzoyl-*S*-benzyl-L-cysteine (3.813 g, 0.0121 mol) and glycine ethyl ester hydrochloride (1.70 g, 0.0121 mol) were suspended in methylene chloride (50 mL). Triethylamine (1.85 mL, 0.0242 mol) and EEDQ (2.99 g, 0.0121 mol) were added and the reaction mixture was stirred overnight. The organic layer was washed successively with 1 *N* hydrochloric acid (2 × 20 mL), saturated sodium bicarbonate (1 × 20 mL), and water (2 × 20 mL), dried over sodium sulfate and evaporated under reduced pressure. Recrystallization of the product from ethyl acetate/petroleum ether afforded a white crystalline solid (2.359 g, 51%), mp 112–113°C; $[\alpha]_D^{27.2}$ −52.6 (*c* 1.0, ethyl acetate); ^{1}Hmr ($CDCl_3$)δ: 7–8 (12H, m), 4.83 (1H, q, 6), 4.18 (2H, q, 7), 4.02 (2H, d, 5), 3.83 (2H, s), 3.1–2.8 (2H, m), 1.27 (3H, t, 7); ^{13}Cmr ($CDCl_3$)δ: 171.0, 169.4, 167.5 (carbonyl), 138.0, 133.6, 131.8, 129.0, 128.5, 127.3, 127.1 (phenyls), 61.4 (OCH_2), 52.7 (N—*CH*—C), 41.5 (N—CH_2CO), 36.5 ($PhCH_2$), 33.5 ($CHCH_2S$), 14.0 (CH_3); ir(KBr): 3280 (NH), 1732 (ester), 1650 (amide I), 1620 (amide I), 1515 (amide II) cm^{-1}.

S-*Phenyl*-L-*cysteine (3o)*

L-Cysteine hydrochloride (2.25 g, 15.7 mmol) was stirred under nitrogen with 1.5 *N* sulfuric acid (50 mL) and cuprous chloride (2.55 g, 25.4 mmol). As the cuprous chloride dissolved, the solution turned black and then green. A second portion of L-cysteine hydrochloride (2.25 g, 15.7 mmol) was added and the solution was cooled to 0°C. The diazonium salt prepared from aniline (5.0 mL, 28 mmol) was added rapidly enough to keep the reaction temperature at 3°C and nitrogen evolution at a moderate rate. After the addition was complete (1 h), the reaction mixture was allowed to warm to room temperature and stirring was continued overnight.

The following day, the reaction mixture was heated to 90°C, and hydrogen sulfide was introduced until a filtered aliquot no longer yielded a precipitate with hydrogen sulfide. The mixture was filtered through Celite and the filtrate was extracted with ether (2 × 20 mL) to remove phenol. The pH was then adjusted to 6 with ammonium hydroxide, whereupon yellow crystals precipitated from the solution. These were purified by recrystallization from water to yield pale yellow crystals (1.478 g, 27%), mp 162–165°C, (lit.(14) mp 170–172°C (dec.)); $[\alpha]_D^{24.2}$ 57.5 (*c* 1.0, 1 *N* HCl); ^{1}Hmr (CF_3COOD)δ: 7.47 (5H, m), 4.57 (1H, t, 6), 3.72 (2H, d, 6); ^{13}Cmr (CF_3COOD)δ: 173.6 (carbonyl), 134.0, 131.9, 131.4, 130.9 (phenyl), 54.8 (CH), 36.1 (SCH_2); ir(KBr): 3420 (NH_3^+), 1610 (amino acid I), 1575 (carboxylate), 1505 (amino acid II) cm^{-1}.

Ethyl-S-*benzyl*-N-*phthaloyl*-L-*cysteinylglycinate (3m)*

S-Benzyl-L-cysteine (4.22 g, 20 mmol) was suspended in 30 mL of aqueous 0.66 *M* sodium carbonate. To this suspension was added *N*-carboethoxyphthalimide (Nefkens' reagent) (4.5 g, 20.5 mmol) in one portion, and the mixture was stirred and monitored for the disappearance of the reagent. After 1.5 h at 25°C, the product was isolated by extraction with methylene chloride (6 × 20 mL), followed by drying (sodium sulfate) and evaporation of the solvent. Attempts to crystallize

the product failed and it was, therefore, carried on to the next step, as follows. The acid was dissolved in methylene chloride (100 mL), and glycine ethyl ester hydrochloride (2.70 g, 20 mmol), EEDQ (5.15 g, 20.2 mmol of 97%), and triethylamine (2.3 mL, 20 mmol) were added. The reaction mixture was stirred overnight at 25°C and then washed successively with 2.5 *N* hydrochloric acid (1 × 30 mL), water (1 × 30 mL), 10% sodium bicarbonate (1 × 30 mL), water (1 × 30 mL), and brine (1 × 30 mL). It was then dried (sodium sulfate) and evaporated to yield a white crystalline solid (7.56 g). This was recrystallized from ethyl acetate/hexane to yield 6.604 g (77%), mp 109–112°C; ^{1}Hmr ($CDCl_3$)δ: 7.82 (4H, m), 7.32 (5H, s), 6.9 (1H, b), 4.98 (1H, t, 7), 4.23 (2H, q, 7), 4.00 (2H, d, 6), 3.75 (2H, s), 3.26 (2H, d, 6), 1.25 (3H, t, 7); ^{13}Cmr ($CDCl_3$)δ: 169.4 (amide), 167.9 (imide carbonyls), 137.1, 134.4, 131.7, 129.0, 128.7, 127.3, 123.7 (phenyls), 61.5 (OCH_2), 52.7 (CH), 41.6 ($N—CH_2CO_2$), 38.7 (SCH_2Ph), 30.4 (SCH_2CH), 14.0 (CH_3); ir(KBr): 3360 (s, NH), 1768 (m, phthaloyl), 1737 (s, ester), 1695 (s, phthaloyl), 1680 (s, amide I), 1525 (s, amide II) cm^{-1}.

S-*Benzyl*-N-*carbobenzoxycysteine* (*3*n)

Sodium bicarbonate (4.20 g, 50 mmol) and *S*-benzyl-L-cysteine (4.22 g, 20 mmol) were suspended in water (40 mL) and stirred vigorously. Benzyl chloroformate (3.62 mL (95%), 24 mmol) was added in seven portions. After the addition was complete (30 min) the reaction mixture was stirred overnight. After filtration of the aqueous solution and extraction of the filtrate with ether (3 × 20 mL), the aqueous layer was acidified to pH 1.0 with concentrated hydrochloric acid and extracted with ethyl acetate (5 × 20 mL). Drying (sodium sulfate) and evaporation of the ethyl acetate extract gave a white solid. Recrystallization from ethyl acetate yielded 1.17 g (17%), mp 92–93°C (lit. (13) mp 93–94°C); ^{1}Hmr ($CDCl_3$)δ: 7.33 (5H, s), 7.27 (5H, s), 5.6 (1H, d, 8), 5.10 (2H, s), 4.6 (1H, m), 3.77 (2H, s), 2.93 (2H, d, 4); ^{13}Cmr ($CDCl_3$)δ: 175.3 (carbonyl), 156.1 (urethane), 137.5, 128.5, 128.3, 128.1, 127.2 (phenyls), 67.4 ($PhCH_2O$), 53.4 (CH), 36.7 ($PhCH_2S$), 33.3 (SCH_2CH); ir(KBr); 3250 (m, NH), 1710 (s, COOH), 1650 (s, urethane), 1535 (amide II) cm^{-1}.

N-*Acetyl*-S-*phenyl*-L-*cysteine* (*3*p)

S-Phenyl-L-cysteine (3.650 g, 18.5 mmol) was cooled in an ice bath, and sodium hydroxide (6.79 *N*) was added in small portions to dissolve the substrate and provide a pH of 10–11. After dissolution was complete, acetic anhydride (7.0 mL, 74 mmol) was added in eight portions (one portion every 4 min). The solution was agitated thoroughly and during this addition sodium hydroxide (6.79 *N*) was added to maintain the pH at 10–11. After the addition was complete, the reaction mixture was stirred at ambient temperature for 3.5 h and then cooled to 3°C, and sulfuric acid (6.04 *N*) added until the pH was 1.5. The oil was extracted with methylene chloride (6 × 30 mL) and this extract was dried (sodium sulfate) and evaporated. The resulting light yellow oil crystallized upon addition of ethyl acetate/hexane (1:1) and reevaporation. The crude yield was 2.471 g. The product was recrystallized by dissolving it in warm isopropanol (15 mL), followed by addition of hexane at room temperature (2.43 g, 51%), mp 127–129°C (lit. (14) mp 142–143°C);[1] $[\alpha]_D^{29.0}$ −3 (*c* 1, ethanol); ^{1}Hmr ($CDCl_3$)δ: 7.2–7.5 (5H, m), 6.3 (1H, bs), 3.93 (2H, s), 3.5 (2H, s), 1.95 (3H, s); ^{13}Cmr ($CDCl_3$/DMSO-d_6)δ: 171.8, 169.4 (carbonyl), 135.5, 129.0, 126.0 (phenyl), 51.8 (methine), 34.9 (CH_2S), 22.4 (acetyl); ir(KBr): 3330 (s, NH), 1728 (s, COOH), 1628 (s, amide I), 1568 (s, amide II) cm^{-1}.

[1]The reported values refer to the anhydrous compound.

S-*Phenyl*-N-*phthaloyl*-L-*cysteine* (*3*r)

Anhydrous sodium carbonate (473 mg, 5.5 mmol) and *S*-phenyl-L-cysteine (986 mg, 5 mmol) were suspended in water (20 mL) and Nefkens' reagent (1.424 g, 6.5 mmol) was added in one portion. After stirring of this mixture for 2 h at ambient temperature, some greyish brown solid remained in the flask. The mixture was filtered, the filtrate extracted with methylene chloride (3 × 20 mL) and this extract was discarded. The aqueous phase was acidified with 3 *N* hydrochloric acid to pH 1.0 and again extracted with methylene chloride (5 × 20 mL). Drying (sodium sulfate) and evaporation of this extract gave a yellow syrup (1.209 g) which was purified by column chromatography (silica gel, ethyl acetate) to yield *S*-phenyl-*N*-phthaloyl-L-cysteine as a syrup (633 mg, 39%); ^{1}Hmr ($CDCl_3$)δ: 10.48 (1H, s), 7.75 (4H, s), 7.2 (5H, m), 5.0 (1H, m), 3.4–3.9 (2H, m); ir ($CHCl_3$, 5%): 1775, 1720 (s, Ft) cm^{-1}.

N-*Acetyl*-N′-*benzyl*-S-*phenyl*-L-*cysteinamide* (*3*q)

N-Acetyl-*S*-phenyl-L-cysteine (1.14 g, 5.76 mmol) and EEDQ (1.47 g (97%), 5.76 mmol) were suspended in methylene chloride (25 mL). Benzylamine (0.63 mL, 5.76 mmol) was added in one portion followed by triethylamine (0.08 mL, 5.76 mmol). After stirring for 12 h, the reaction mixture was washed successively with 2.5 *N* hydrochloric acid (2 × 20 mL), water (20 mL), saturated sodium carbonate (20 mL), and water (2 × 30 mL), and the organic phase was dried over anhydrous sodium sulfate and evaporated. The residual solid (1.25 g) was recrystallized from ethyl acetate (711 mg, 71%), mp 170–172°C; $[\alpha]_D^{24.8}$ +2.4 (*c* 0.5, $CHCl_3$); ^{1}Hmr ($CDCl_3$/DMSO-d_6 1:1)δ: 8.3–8.6 (2H, m), 7.23 (10H, m), 4.87 (1H, q, 7), 4.28 (2H, d, 6), 3.0–3.4 (2H, m), 1.88 (3H, s); ^{13}Cmr ($CDCl_3$/DMSO-d_6)δ: 170.0, 169.7 (carbonyl), 138.9, 136.0, 128.8, 128.7, 128.2, 127.2, 126.8, 126.5 (phenyl), 52.6 (CH), 42.6 (NCH_2Ph), 22.7 (CH_3); ir (KBr): 3280 (s, NH), 1625 (s, amide I), 1530 (s, amide II) cm^{-1}. *Anal.* calcd. for $C_{18}H_{20}N_2O_2S$: C 65.82, H 6.14; found: C 65.87, H 6.37.

N′-*Benzyl*-S-*phenyl*-N-*phthaloyl*-L-*cysteinamide* (*3*s)

S-Phenyl-*N*-phthaloyl-L-cysteine (628 mg, 1.92 mmol) was dissolved in methylene chloride (100 mL). Then EEDQ (495 mg, 2.0 mmol) was added in one portion, followed by benzylamine (0.209 mL, 1.92 mmol). The solution was stirred overnight. The next day, the light yellow solution was washed successively with 2.5 *N* hydrochloric acid (1 × 20 mL), water (1 × 20 mL), saturated sodium bicarbonate (1 × 20 mL), water (1 × 20 mL), and brine (1 × 20 mL), and it was then dried (sodium sulfate) and evaporated. The residue was dried under high vacuum to yield an off-white semicrystalline solid (622 mg, 78%). The product was recrystallized from ethyl acetate/hexane at room temperature to yield a white crystalline solid (317 mg, 40%), mp 131°C; ^{1}Hmr ($CDCl_3$)δ: 7.73 (4H, s), 7.27 (10H, m), 6.6 (1H, s), 4.93 (1H, t, 7), 4.40 (2H, d, 6), 3.83 (2H, d, 7). Exchange with D_2O confirmed the NH assignment (δ 6.6); ^{13}Cmr ($CDCl_3$)δ: 167.7, 167.5 (carbonyls), 137.7, 134.2, 131.6, 131.1, 129.0, 128.7, 127.6, 127.1, 123.5 (phenyls), 54.0 (CH), 43.7 (NCH_2Ph), 33.7 (SCH_2CH); ir(KBr): 3380 (m, NH), 1772 (m, *antisym* phthalimido), 1710 (s, *sym* phthalimido), 1640 (s, amide I), 1530 (m, amide II) cm^{-1} $[\alpha]_D^{25.0}$ −70.0 (*c* 1.0, $CHCl_3$).

Ethyl Benzylsulfinylpropionate (*4*b) (*Method* E)

Ethyl 3-benzylthiopropionate (30.00 g, 0.134 mol) was dissolved in glacial acetic acid (50 mL). Hydrogen peroxide (11.5 mL of 30%, 0.134 mol) was added dropwise to the reaction mixture at 10°C. After the addition was complete (10 min), the reaction mixture was stirred at 25°C for 1 h. The solvent was evaporated and the viscous residue was poured into saturated sodium bicarbonate (50 mL) and extracted with methylene chloride (4 × 50 mL). The organic

phase was washed with brine, dried (sodium sulfate), and concentrated to a viscous syrup. The compound was crystallized by solution in ether, cooling to 4°C, and addition of hexane with vigorous stirring (27.72 g, 86%), mp 62–63°C; ^{1}Hmr ($CDCl_3$)δ: 7.23 (5H, s), 4.12 (2H, q, 7), 3.98 (2H, s), 2.82 (4H, s), 1.25 (3H, t, 7); ^{13}Cmr ($CDCl_3$)δ: 171.1 (carbonyl), 130.1, 128.8, 128.2 (phenyl), 60.8 (OCH_2), 58.2 (CH_2Ph), 45.4 ($SOCH_2CH_2$), 26.29 (CH_2CO), 14.1 (CH_3); ir(KBr): 1718 (s, ester), 1018 (s, sulfoxide) cm^{-1}. *Anal.* calcd. for $C_{12}H_{16}O_3S$: C 60.00, H 6.71; found: C 60.37, H 7.03.

*Benzylsulfinylpropionic Acid (**4**a)*

Ethyl 3-benzylsulfinylpropionate (4.00 g, 16.7 mmol) was dissolved in absolute ethanol, and the solution was cooled to 4°C. Then potassium hydroxide (1.50 g, 27 mmol) was added in three portions. The reaction was complete within 10 min (tlc, $CHCl_3$/MeOH 5:1). After a further 15 min, the pH was lowered to 1.0 by the addition of 3 *N* hydrochloric acid, and the solid product was collected by filtration (1.81 g). Recrystallization from ethanol produced white needles (961 mg, 27%), mp 147°C; ^{1}Hmr ($CDCl_3$/DMSO-d_6 1:1)δ: 7.02 (5H, s), 3.68 (2H, s), 3.0–2.4 (4H, m); ir(KBr): 1710 (s, COOH), 982 (s, sulfoxide) cm^{-1}. *Anal.* calcd. for $C_{10}H_{12}O_3S$: C 56.59, H 5.70; found: C 55.79, H 6.23.

*3-Benzylsulfinylpropionamide (**4**c) (Method* A*)*

3-Benzylthiopropionamide (855 mg, 4.38 mmol) was dissolved in methanol/water (2.5 mL/2.5 mL) and the solution was stirred at 4°C. Then hydrogen peroxide (0.25 mL of 50%, 4.4 mmol) was added in one portion. The reaction was monitored by tlc (ethyl acetate) and was complete after 3 days. Solid sodium bisulfite was added at this time until a negative starch–iodide test was obtained. Evaporation of the solvent and recrystallization of the residue from ethyl acetate yielded colourless needles (408 mg, 52%), mp 127–131°C; ^{1}Hmr ($CDCl_3$)δ: 7.33 (5H, s), 4.00 (2H, ABq), 6.7 (2H, s), 2.4–3.3 (4H, m); ir(KBr): 3378, 3178, (s, NH), 1645 (s, amide I), 1620 (s, amide II), 1025 (s, sulfoxide) cm^{-1}.

*3-Benzylsulfinyl-*N*-methylpropionamide (**4**d) (Method* B*)*

3-Benzylthio-*N*-methylpropionamide (3.79 g, 18.1 mmol) was dissolved in acetone (25 mL), hydrogen peroxide (2.0 mL of 30%, 22 mmol) was added in one portion, and the mixture was shaken until it became homogeneous. After 5 days, thin-layer chromatography indicated that the reaction was not yet complete. Acetic acid (1.0 mL) was added and, in about 10 min, a white precipitate appeared. Solid sodium bicarbonate (ca. 500 mg) was added, and the product was recovered by evaporation of the solvent. Proton magnetic resonance indicated that the reaction was still incomplete. The product was purified by column chromatography (chloroform/methanol 6:1). Crystallization from ethyl acetate afforded a white crystalline solid (2.00 g, 43%), mp 134–135°C, (lit. (8) mp 138–140°C); ^{1}Hmr ($CDCl_3$)δ: 7.37 (6H, s), 4.00 (2H, s), 2.2–3.2 (7H, m); ^{13}Cmr ($CDCl_3$)δ: 170.7, (carbonyl), 130.0, 129.6, 129.0, 128.4 (phenyl), 58.4 (PhCH_2SO), 46.3 (CH_2-CH_2SO), 28.7 (CH_2CON), 26.2 (NCH_3); ir(KBr): 3295 (NH), 1630 (amide I), 1540 (amide II), 1020–1010 (sulfoxide) cm^{-1}.

*3-Benzylsulfinyl-*N*-butylpropionamide (**4**e)*

3-Benzylthio-*N*-butylpropionamide (4.34 g, 17.3 mmol) was oxidized by method *A* to give, after recrystallization from ethyl acetate, white flakes (2.74 g, 63%), mp 130°C; ^{1}Hmr ($CDCl_3$)δ: 7.33 (5H, s), 4.00 (2H, s), 2.5–3.4 (6H, m), 1.7–0.9 (7H, m); ^{13}Cmr ($CDCl_3$)δ: 170.0 (carbonyl), 130.1, 129.8, 128.8, 128.4 (phenyl), 58.2 (PhCH_2), 46.5 (CH_2CH_2SO), 39.3 (NCH_2), 31.4 (NCH_2CH_2), 28.7 (CH_2CO), 20.1 (CH_2CH_3), 13.7 (CH_3); ir(KBr): 3275 (s, NH), 1638 (s, amide I), 1550 (m, amide II), 1025 (s, sulfoxide) cm^{-1}.

*3-Benzylthiopropionylglycine-*S*-oxide (Ethyl Ester) (**4**f)*

3-Benzylthiopropionylglycine (2.23 g, 90% pure, 7.2 mmol) was oxidized by method *A* to give, after recrystallization from ethyl acetate, a white crystalline solid (1.287 g, 60%), mp 91–97°C; ^{1}Hmr ($CDCl_3$)δ: 7.35 (5H, s), 7.2 (1H, s), 4.17 (2H, q, 7), 4.03 (2H, s), 3.95 (2H, d, 5), 2.6–3.1 (4H, m), 1.27 (3H, t, 7); ^{13}Cmr ($CDCl_3$)δ: 170.8, 169.7 (carbonyl), 130.1, 129.8, 128.8, 128.3 (phenyl), 61.2 (OCH_2), 57.9 (PhCH_2), 45.8 (CH_2SO), 41.3 (NCH_2CO), 28.2 (CH_2CO), 14.1 (CH_3); ir(KBr): 3300 (NH), 1730 (ester), 1635 (amide I), 1545 (amide II), 1020 (sulfoxide) cm^{-1}.

*Diphenylmethyl 3-Benzylsulfinylpropionylglycinate (**4**g)*

Diphenylmethyl 3-benzylthiopropionylglycinate (1.20 g, 2.86 mmol) was oxidized by method *A* to give 1.05 g (84%), mp 152–153°C (dec.). *Anal.* calcd. for $C_{25}H_{25}NO_4S$: C 68.94, H 5.79; found: C 68.78, H 5.97.

S-*Benzyl-*L*-cysteine-*S*-oxide (**4**h)*

S-Benzyl-L-cysteine (5.00 g, 23.7 mmol) was oxidized by method *E* to give, after recrystallization from 30% ethanol, 4.36 g (81%) of product, mp 171–174°C (lit. (15) mp 163–165°C); $[\alpha]_D^{24}$ +5.8 (*c* 1.0, 0.1 *N* NaOH); ^{1}Hmr (D_2O)δ: 7.4 (5H, m), 4.50 (2H, m), 3.43 (2H, m); ir(Nujol): 1010 (s, sulfoxide) cm^{-1}.

Ethyl N*-Acetyl-*S*-benzyl-*L*-cysteinylglycinate-*S*-oxide (**4**k)*

Ethyl *N*-acetyl-*S*-benzyl-L-cysteinylglycinate (5.72 g, 0.017 mol) was oxidized by method *A* to give, after recrystallization from ethyl acetate, 4.438 g (77%), mp 148°C (dec.); ^{1}Hmr ($CDCl_3$/DMSO-d_6 1:1)δ: 8.34 (1H, m), 7.30 (5H, s), 5.2 (1H, s), 4.70 (1H, m), 4.23 (2H, q, 7), 4.12 (2H, s), 4.02 (2H, d, 6), 3.00 (2H, d, 7), 1.89 (3H, s), 1.22 (3H, t, 7); ir(KBr): 3275 (NH), 1725 (ester), 1640 (amide I), 1540 (amide II), 1025 (sulfoxide) cm^{-1}; ^{13}Cmr ($CDCl_3$/DMSO-d_6 1:1)δ: 170.5, 170.1, 169.8, (C=O), 131.0, 130.9, 130.3, 128.5, 127.8 (Ph), 60.6 (OCH_2), 57.9, (PhCH_2SO), 53.7 (CH), 47.8 (CH_2SO), 41.1 (NCH_2CO), 22.7 (CH_3CO), 14.0 (CH_3CH_2).

N-*Benzoyl-*S*-benzyl-*L*-cysteinylglycine-*S*-oxide (Ethyl Ester) (**4**l)*

N-Benzoyl-*S*-benzyl-L-cysteinylglycine (ethyl ester) (1.736 g, 4.49 mmol) was oxidized by method *A* to give, after recrystallization from ethyl acetate 1.533 g (82%), mp 156–157°C (dec.); ^{1}Hmr ($CDCl_3$/DMSO-d_6 1:1)δ: 7.2–8.1 (7H, m), 7.33 (5H, s), 5.1 (1H, m), 4.17 (2H, q, 7), 4.02 (2H, s), 3.90 (2H, d, 5), 3.3 (1H, m), 1.23 (3H, t, 7); ^{13}Cmr ($CDCl_3$/DMSO-d_6 1:1)δ: 170.1, 169.3, 166.7 (carbonyl), 133.8, 130.9, 131.4, 130.3, 128.5, 128.1, 127.6 (phenyl), 60.6 (OCH_2), 53.1 ($NCHCO$), 41.2 (NCH_2CO), 14.0 (CH_3); ir(KBr): 3270 (NH), 1735 (ester), 1655 (amide I), 1625 (amide I), 1520 (amide II), 1030 (sulfoxide) cm^{-1}.

S-*Benzyl-*N*-phthaloyl-*L*-cysteinylglycine-*S*-oxide (**4**m)*

Ethyl-*S*-benzyl-*N*-phthaloyl-L-cysteinylglycinate (4.26 g, 10 mmol) was oxidized by method *A* to give a colourless foam (3.362 g, 76%); ^{1}Hmr ($CDCl_3$)δ: 7.80 (4H, m), 7.35 (3H, s), 7.32 (2H, s), 5.43 (1H, t, 6), 4.08 (2H, q, 7), 4.08 (2H, s), 3.93 (2H, d, 6), 3.0–3.8 (2H, m), 1.23 (3H, t, 7); ir($CHCl_3$, 5%): 3380 (b, NH), 1780 (m, *antisym* phthalimido), 1730 (s, ester), 1700 (s, *sym* phthalimido), 1020 (m, sulfoxide) cm^{-1}.

N-*Acetyl-*N′*-benzyl-*S*-phenyl-*L*-cysteinamide-*S*-oxide (**4**n) (Method* D*)*

N-Acetyl-*N*′-benzyl-*S*-phenyl-L-cysteinamide (152 mg, 0.5 mmol) was dissolved in methylene chloride (25 mL) and *m*-chloroperbenzoic acid (101 mg of 85%, 0.5 mmol) was added. The reaction mixture was shaken until the peracid dissolved. After 22 h at 25°C the solution was washed with saturated sodium bicarbonate (4 × 7 mL) and brine (1 × 7 mL). It was

then dried (sodium sulfate) and evaporated to yield the sulfoxide (176 mg, 100%), mp 130–134°C; ^{1}Hmr ($CDCl_3$)δ: 7.58 (5H, s), 7.30 (5H, s), 7.9–7.3 (2H, m), 5.0 (1H, m), 4.45, 4.42 (2H, d + d), 3.2 (2H, s), 2.07, 1.93 (3H, s); ir(KBr): 3280 (s, NH), 1635 (s, amide I), 1530 (s, amide II), 1032 (s, sulfoxide) cm^{-1}.

N-*Phthaloyl*-N′-*benzyl*-S-*phenyl*-L-*cysteinamide*-S-*oxide* (**4o**)

N-Phthaloyl-*N*′-benzyl-*S*-phenyl-L-cysteinamide (165 mg, 0.399 mmol) was oxidized by method *D* to yield a syrup (175 mg, 100%); ^{1}Hmr ($CDCl_3$)δ: 7.73 (4H, s), 7.60 (1H, b), 7.46 (5H, s), 7.20 (5H, s), 5.2 (1H, m), 4.30 (2H, d, 6), 3.7 (2H, m); ^{13}Cmr ($CDCl_3$)δ: 167.9, 167.3, 166.6 (carbonyls), 137.4, 134.5, 134.2, 131.8, 131.4, 129.6, 129.4, 128.7, 128.1, 127.6, 127.4, 124.2, 123.8, 123.5 (aromatic), 55.8, 52.7 (CH), 49.2, 46.3 (SCH_2); ir($CHCl_3$, 5%): 3280 (m, NH), 1770, 1715 (s, Ft), 1680 (s, amide I), 1510 (s, amide II), 1030 (m, sulfoxide) cm^{-1}.

Cyclization of Benzyl 2-Carboxyphenyl Sulfoxide with Acetic Anhydride

Benzyl 2-carboxyphenyl sulfoxide (500 mg, 2.05 mmol) was suspended in acetic anhydride (5 mL) under nitrogen and heated to 125–150°C in an oil bath. When thin-layer chromatography indicated that the reaction was complete (75 min), the volatile components were removed under high vacuum. Column chromatography on silica gel (petroleum ether/ethyl acetate 5:1) yielded a pale yellow crystalline product (427 mg, 92%), mp 89.5–90°C (lit. (2, 3) mp 90–91°C); ^{1}Hmr ($CDCl_3$)δ: 8.3–6.5 (9H, m), 6.53 (1H, s); ^{13}Cmr ($CDCl_3$)δ: 163.7 (C=O), 138.7, 134.8, 133.7, 132.7, 129.8, 128.7, 127.4, 126.7, 124.3 (phenyl), 83.5 (CH); ir(KBr): 1720 (ester) cm^{-1}.

Cyclization of Benzyl 2-Carboxyphenyl Sulfoxide with Acetyl Trifluoroacetate

Benzyl 2-carboxyphenyl sulfoxide (500 mg, 2.05 mmol) was suspended in dry methylene chloride (1.46 mL) and cooled to 4°C under dry nitrogen. Acetyl trifluoroacetate (0.22 mL, 1.9 mmol) was added in one portion. The reaction mixture was stirred at 4°C for 30 min. After evaporation of the solvent, the pale yellow residue was chromatographed on silica gel (chloroform → chloroform/methanol 9:1). The first component eluted from the column corresponded to 2-phenyl-1,3-benzoxathian-6-one (314 mg, 73%) while the second component was identified as benzyl 2-carboxyphenyl sulfoxide (123 mg, 25%). Both compounds were identified by comparison with authentic samples.

Cyclization of Benzyl 2-Carboxyphenyl Sulfoxide with Trifluoroacetic Anhydride

Benzyl 2-carboxyphenyl sulfoxide (500 mg, 1.92 mmol) was suspended in dry methylene chloride (1.46 mL) under dry nitrogen. Trifluoroacetic anhydride (0.27 mL, 1.9 mmol) was added dropwise to this ice-cold solution over a period of 1 min. The ice bath was then removed and the first thin-layer chromatogram indicated that all of the starting sulfoxide had reacted (3–4 min). After evaporation of the solvent, the white crystalline residue was purified by column chromatography (silica gel). The first component (chloroform) was identified as 2-phenyl-1,3-benzoxathian-6-one (191 mg, 41%) by comparison with an authentic sample. The second component (chloroform/methanol 9:1) was identified as 2,2′-dithiosalicylic acid (170 mg, 58%) by comparison of its ir spectrum with that of an authentic sample; mp >260°C (lit. (22) mp 287–290°C); ^{1}Hmr ($CDCl_3$)δ: 7.1–8.2 (8H, m); ir(Nujol): 1670 (carboxyl) cm^{-1}.

Cyclization of 3-Benzylsulfinylpropionamide (**8**; *R* = *Ac*)

3-Benzylsulfinylpropionamide (3.7 mg, 1.5 mmol), and acetic anhydride (1.14 mL) were heated at 110°C for 30 min. The reaction mixture was then placed in a desiccator over potassium hydroxide under high vacuum to remove the solvent. The product was isolated by column chromatography on silica gel (benzene/ethyl acetate 3:1) followed subsequently by preparative thick-layer chromatography (chloroform) to yield a syrup (86 mg, 24%); ^{1}Hmr ($CDCl_3$)δ: 7.33 (5H, s), 6.88 (1H, s), 2.80 (4H, m), 2.60 (3H, s); ^{13}Cmr ($CDCl_3$)δ: 128.7, 127.7, 126.1 (phenyl), 57.2 (methine), 36.1 (SCH_2), 27.3 (CH_2CO), 21.9 (acetyl); ir(5% CCl_4 solution): 1695 cm^{-1}.

Cyclization of 3-Benzylsulfinyl-N-*methyl propionamide* (**8**; *R* = CH_3)

3-Benzylsulfinyl-*N*-methylpropionamide (500 mg, 2.36 mmol) was suspended in acetic anhydride (1.8 mL) and heated under nitrogen to 114–120°C. When thin-layer chromatography indicated that the reaction was complete (30 min), the reaction mixture was transferred to a vacuum desiccator and the solvent was removed over potassium hydroxide pellets. Purification by column chromatography on silica gel (benzene/ethyl acetate 3:1 to ethyl acetate by gradient elution) yielded a crystalline product (302 mg, 62%), mp 96°C (lit. (8) mp 95–97°C) after recrystallization from ether/hexane; ^{1}Hmr ($CDCl_3$)δ: 7.33 (5H, m), 5.43 (1H, s), 2.97 (3H, s), 2.80 (4H, m); ^{13}Cmr ($CDCl_3$)δ: 169.4 (C=O), 139.0, 128.7, 128.2, 126.4 (Ph), 64.1 (Ph*CH*), 35.5 (CH_2CH_2CO and NCH_3), 34.6, 22.2; ir(KBr): 1620 (amide I) cm^{-1}.

Cyclization of S-*Benzylsulfinyl*-N-*butylpropionamide* (**8**; *R* = n-C_4H_9)

S-Benzylsulfinyl-*N*-butylpropionamide (500 mg, 2 mmol) was suspended in acetic anhydride (1.5 mL) and heated at 114°C for 30 min. The acetic anhydride was then removed in a vacuum desiccator over potassium hydroxide pellets. The product was purified by column chromatography on silica gel (benzene to benzene/ethyl acetate 3:1 by gradient elution) to yield a syrup (139 mg, 28%); ^{1}Hmr ($CDCl_3$)δ: 7.33 (5H, s), 5.52 (1H, s), 3.0–0.8 (13H, m); ^{13}Cmr ($CDCl_3$)δ: 169.2 (carbonyl), 139.7, 128.6, 128.1, 126.6 (phenyl), 61.9 (methine), 47.8 (NCH_2), 34.4 (SCH_2), 29.6 (NCH_2CH_2), 21.9, 20.3 (CH_2CO + CH_2CH_3), 13.8 (CH_3); ir(KBr): 1630 (amide I) cm^{-1}.

Cyclization of Ethyl 3-Benzylsulfinylpropionylglycinate (**8**; *R* = CH_2CO_2Et)

Ethyl 3-benzylsulfinylpropionylglycinate (595 mg, 2 mmol) was suspended in acetic anhydride (2.6 mL) and the suspension was heated to 110°C. When tlc (ethyl acetate) indicated that the reaction was complete (30 min), the excess acetic anhydride was removed in a vacuum desiccator over potassium hydroxide pellets. Chromatography on silica gel (benzene → ethyl acetate) afforded *N*-(ethoxycarbonylmethyl)-perhydro-*S*-phenyl-1,3-thiazin-6-one as a syrup (295 mg, 53%); ^{1}Hmr ($CDCl_3$)δ: 7.33 (5H, s), 5.68 (1H, s), 4.70, 3.33 (2H, AB, 18), 4.25 (2H, q, 6), 2.87, (4H, s), 1.23 (3H, t, 6); ^{13}Cmr ($CDCl_3$)δ: 170.3, 168.8 (carbonyl), 138.9, 128.9, 127.1 (phenyl), 63.7, 61.2 (CH and OCH_2), 47.8 (NCH_2CO), 35.0 (SCH_2), 23.2 (CH_2-CO), 14.1 (CH_3); ir(KBr): 1735 (ester), 1640 (s, amide I) cm^{-1}.

Cyclization of **4**k *to* **9**a

A 0.323 *M* suspension of **4***k* (0.80 g, 2.26 mmol) in acetic anhydride (7.0 mL) was heated under nitrogen at 75–80°C for 3.75 h. The acetic anhydride was removed in a vacuum desiccator over potassium hydroxide pellets to give a yellow solid. Purification by column chromatography on silica gel using gradient elution (benzene → benzene/methanol 5:1) afforded two major fractions. The slower moving band (0.37 g) was unreacted sulfoxide. The faster moving band (0.43 g) was mainly **9***a* (^{1}Hmr), although it was a yellow oil.

The oil was dissolved in benzene (4 mL), and white crystals of **9***a* formed when the solution was allowed to stand at room temperature. The crystals (83 mg) were collected by suction filtration. Recrystallization from acetone (2.5 mL) at −11°C gave 25 mg of **9***a* as a white crystalline solid, mp 184.0–184.2°C. In a second experiment, 416 mg (59%) of **9***a* were obtained from 708 mg of **4***k*; ^{1}Hmr ($CDCl_3$)δ: 8.0–7.6 (1H, bs, N*H*), 7.53–6.87 (5H, m, Ph), 6.10 (1H, s, PhC*H*), 5.35–5.10 (1H, m, =N—C*H*), 4.22 (2H, q, J = 7 Hz, CH_2-CH_3), 4.06 (2H, d, J = 5.5 Hz, N—CH_2—CO; D_2O, 2H, s), 3.60–3.20 (2H, m, CH_2S), 1.97 (3H, s, CH_3), 1.30 (3H, t, J = 7 Hz, CH_2CH_3); ^{13}Cmr ($CDCl_3$)δ: 170.6, 169.8 (carbonyl), 134.5, 129.2, 128.3, 124.6 (phenyl), 66.4, 65.0, 61.6, 41.5 (NCH_2CO), 30.9 (SCH_2), 23.9 (CH_3) 14.2 (CH_3); ir (KBr): 3328, 1735, 1655, 1635, 1530 cm^{-1}; ms (50°C, 70 eV) *m/e* (relative intensity): 336.1144 (3), 179.0405 (66), 165.0326 (10.7), 164.0230 (100), 158.0318 (11.8), 137.0306 (13.7), 121.0109 (17.6), 118.0608 (13.6), 106.0116 (16.5), 104.0080 (15.5). *Anal.* calcd. for $C_{16}H_{20}N_2O_4S$: C 57.13, H 5.99, N 8.32, S 9.53; found: C 57.05, H 6.11, N 8.08, S 8.75.

Cyclization of **4***l* *to* **9**b

A suspension of **4***l* (200 mg, 0.5 mmol) in acetic anhydride (1.2 mL) was heated under nitrogen for 3 h at 78–79°C. The excess acetic anhydride was removed in a vacuum desiccator over potassium hydroxide pellets and the resulting syrup was chromatographed on silica gel (benzene → benzene/methanol 5:1) to yield 138 mg of a light yellow syrup which, on standing, solidified to an amorphous solid. Recrystallization from acetone at −78°C for 3 h and overnight at −15°C gave a pale yellow crystalline solid (61.7 mg). Recrystallization from acetone afforded 50.4 mg of **9***b* as a white solid, mp 118–121°C; ^{1}Hmr ($CDCl_3$)δ: 8.07–7.67 (1H, bs), 7.7–6.8 (5H, m), 7.26 (5H, s), 6.18 (1H, s), 5.38 (1H, t, J = 4.5 Hz), 4.22 (2H, q, J = 7 Hz), 4.07 (2H, d, J = 5.5 Hz; D_2O, 2H, s), 3.43 (2H, d, J = 4.5 Hz), 1.29 (3H, t, J = 7 Hz); ^{13}Cmr ($CDCl_3$)δ: 129.8, 129.1, 128.7, 127.4 (phenyl), 61.5, 59.2, 53.9 (*C*HCO), 41.8 (NCH_2CO), 31.8 (SCH_2), 14.2 (CH_3); ir($CHCl_3$, 5%): 1735 1670, 1650, 1500 cm^{-1}; ms (50°C, 70 eV) *m/e* (relative intensity): 398.1297 (0.8), 294.0009 (10), 268.0786 (18.9), 242.0596 (17.2), 241.0564 (100), 158.0300 (12.1), 146.0613 (40.2), 121.0122 (8.9).

Cyclization of **4**m *to* ***10***a

A suspension of **4***m* (0.735 g, 1.73 mmol) in acetic anhydride (5.2 mL) was heated under nitrogen at 75–80°C for 6 h, by which time tlc analysis indicated that, although **4***m* had not been consumed, some decomposition of the product was occurring. Evaporation of the solvent followed by drying under high vacuum gave 0.68 g of a deep yellow oil. This was chromatographed on silica gel using benzene/methanol to give 0.58 g of a pale yellow semi-solid which was rechromatographed on silica gel (benzene → 5% methanol/benzene) to give 0.42 g of a bright yellow oil. This was chromatographed again on silica gel and eluted with 1% methanol/benzene to give 0.13 g of a pale yellow oil. Preparative layer chromatography (benzene/ethyl acetate 5:1, four elutions) afforded 9.9 mg of material with mp 179.5–185°C. In a second experiment, 852 mg (2 mmol) of **4***m* was heated under nitrogen in acetic anhydride (6.06 mL) at 73–75°C for 20 min. Removal of the solvent in the usual manner yielded a syrup which was chromatographed on silica gel (benzene → benzene/methanol 5:1) to yield two components. The slower component proved to be unreacted sulfoxide (493 mg, 56%). The faster component was recrystallized from acetone to give 120 mg (31%) of **10***a*; ^{1}Hmr ($CDCl_3$)δ: 7.78 (4H, d), 7.42 (5H, s), 6.03 (0.6 H, s), 5.63 (0.4H, s), 5.43 (0.4H, t, J = 6 Hz), 5.22 (1H, t, J = 6 Hz), 4.83 (d, J = 17 Hz), 4.38 (d, J = 17 Hz), 4.18 (q, J = 7 Hz), 4.12 (q, J = 7 Hz), 3.58 (1H, q, J = 13, 12 Hz), 3.44 (d, J = 17 Hz), 3.29 (d, J = 17 Hz), 2.88 (1H, q, J = 13, 5Hz), 1.24 (t, J = 7 Hz), 1.22 (t, J = 7 Hz); ^{13}Cmr ($CDCl_3$)δ: 168.2, 167.5, 155.0 (carbonyl), 134.2, 132.1, 129.8, 129.2, 129.0, 127.6, 123.7 (aromatic), 65.4 (S*C*H(H)Ph), 62.5, 61.4 (OCH_2), 51.6, 51.1 (Ft*CH*), 49.2, 47.4 (NCH_2CO), 28.9 (SCH_2), 14.1 (CH_3); ir(KBr): 1770 (Ft), 1730 (ester), 1715 (Ft), 1667 (amide I) cm^{-1}; ms (50°C, 70 eV) *m/e* (relative intensity): 424.1097 (9), 338.0694 (20.7), 337.0655 (100), 200.0099 (41.7), 173.0482 (26.9), 172.0401 (24.5), 121.0109 (20.7), 118.0658 (78), 104.0293 (28.8).

Synthesis of ***15*** *(R = CH_3)*

L-Cysteine hydrochloride monohydrate (10.0 g, 57.1 mmol) was dissolved in 50% ethanol (175 mL) under nitrogen, benzaldehyde (7.0 mL, 63 mmol) was added in one portion, and the flask was sealed under nitrogen. The thiazolidine **22** began to crystallize out after 3.5 h and the flask was then stored for 16 h at −10°C. The product was collected by filtration (8.32 g, 70%), mp 163–164.5°C (lit. (16) mp 159–160°C). In a second preparation, L-cysteine hydrochloride (10.0 g) and potassium acetate (6.0 g, 61.5 mmol) were added to 50% aqueous ethanol (175 mL). Benzaldehyde (7.0 mL, 7.29 g, 68.7 mmol) was added to the suspension, and the resulting mixture was stirred for 5 min at room temperature to give a clear, homogeneous solution. Stirring was continued at room temperature for an additional 25 min during which time a white crystalline material began to precipitate. The reaction mixture was transferred to an ice-water bath and allowed to stand at 0°C for 24 h. The compound was then collected by filtration and air dried. The crystals were dissolved in hot ethanol (800 mL), the solution was filtered, and the filtrate allowed to cool to room temperature and then overnight in an ice-water bath. Filtration afforded 8.93 g (75%), mp 163–165°C (dec). The material was identical in all respects with that prepared above.

The thiazolidine **22** (2.68 g, 12.87 mmol) was added to water (20 mL), and the suspension was cooled to 0°C. Aqueous sodium hydroxide (10.9 *N*) was added dropwise until the mixture became homogeneous and the pH reached 8.0–9.0. Acetic anhydride (5.26 g, 51.48 mmol) was then added to the solution over a 20 min period, in five portions. During the addition the pH was maintained in the range 8–10 by addition of sodium hydroxide. After the addition of acetic anhydride was complete, the reaction mixture was removed from the ice-water bath and stirred at room temperature for 40 min, the pH being maintained at 8–10 by addition of sodium hydroxide. Acidification to pH 2 with dilute hydrochloric acid precipitated a white solid, which was collected and air dried. The material was dissolved in 20 mL of hot ethanol, filtered to remove some insoluble material and evaporated. The residue was dissolved in 70 mL of water/ethanol (10:1), hot water (55 mL) was added, and the solution was allowed to cool to room temperature. Further cooling in an ice-water bath precipitated 1.26 g (39%) of **23** (R = CH_3) as a white crystalline solid, mp 151–152°C; ^{1}Hmr ($CDCl_3$/DMSO-d_6)δ: 7.8–7.2 (5H, m), 6.20 (1H, s), 4.8 (1H, m), 3.3 (2H, m), 1.87 (3H, s); ^{13}Cmr (0.1 *N* NaOD)δ: 176.3, 175.5, 173.0 (carbonyl), 67.8, 67.1 (methines), 34.3, 32.3 (SCH_2), 22.6, 22.2 (acetyl); ir(KBr): 1715 (carboxyl), 1610 (amide) cm^{-1}.

The thiazolidine **23** (R = CH_3) (1.08 g, 4.30 mmol) was dissolved in methylene chloride (50 mL). *N*-Ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ) (1.06 g, 4.30 mmol) and then glycine ethyl ester hydrochloride (0.60 g, 4.30 mmol) were added to the methylene chloride solution (this particular order of mixing appears to be essential). Triethylamine (0.44 g, 4.30 mmol) was then added and the suspension was

stirred at room temperature for 16 h. The methylene chloride solution was extracted with aqueous 5% sodium bicarbonate (2 × 30 mL) and aqueous 5% hydrochloric acid (2 × 30 mL). The organic layer was dried over anhydrous magnesium sulfate, filtered, evaporated, and dried under high vacuum to give 1.40 g of crude **15** (R = CH_3) as a yellow-white foam. Crystallization from hot ethyl acetate (10 mL) followed by recrystallization from hot ethyl acetate gave 0.98 g (68%) of **15** (R = CH_3) as a white crystalline solid, mp 147.5–148.5°C; ^{1}Hmr ($CDCl_3$, 340 K)δ: 7.7–7.1 (6H, m), 6.12 (1H, bs), 5.10 (1H, dd, J = 6, 5 Hz), 4.24 (2H, q, J = 7 Hz), 4.07 (2H, d, J = 5 Hz), 3.65 (q, J = 5, 12 Hz), 3.18 (q, J = 6, 12 Hz), 2.00 (3H, s), 1.28 (3H, t, J = 7 Hz); ^{1}Hmr ($CDCl_3$, 300 K)δ: 7.8–7.2 (6H, m), 6.05 (1H, bs), 5.14 (1H, dd, J = 5, 6 Hz), 4.24 (2H, q, J = 2, 7 Hz), 4.12 (2H, d, J = 6 Hz), 3.66 (1H, q, J = 5, 12 Hz), 3.18 (1H, q, J = 6, 12 Hz), 2.00 (3H, s), 1.28 (3H, t, J = 7 Hz); ^{13}Cmr ($CDCl_3$)δ: 171.5, 169.9, 169.5 (carbonyl), 139.9, 128.9, 128.4, 126.7 (phenyl), 67.2, 65.0 (methine carbons), 61.4 (OCH_2), 31.3 (SCH_2), 23.0 (acetyl), 14.2 (CH_2CH_3); ir(KBr): 3395 (NH), 1738 (ester) cm^{-1}; ms (50°C, 70 eV) *m/e* (relative intensity >20%): 336 (M^+, 6), 293 ($M - CH_2CO$, 10), 206 ($C_{10}H_{10}N_2OS^+$, 3), 179 (30), 164 (44), 43 (100). *Anal.* calcd. for $C_{16}H_{20}N_2O_4S$: C 57.12, H 5.99; found: C 56.87, H 6.05.

*Synthesis of **15** (R = Ph)*

The thiazolidine **22** (5.77 g, 25.57 mmol) was added to water (30 mL), and the resulting suspension was cooled to 0°C and aqueous sodium hydroxide (13.4 *N*) was added until the mixture became homogeneous and the solution had a pH of 8.0–9.0. Benzoyl chloride (15.58 g, 110.8 mmol) was then added with stirring at a rate of 0.25 mL/min. During this addition the pH of the mixture was maintained in the range 8–10 by addition of sodium hydroxide solution. After the addition was complete, the reaction mixture was removed from the ice-water bath and stirred at room temperature for 40 min, the pH being maintained at 8–10. Filtration, followed by acidification to pH 2 with dilute hydrochloric acid, precipitated a light yellow product which was collected and air dried. The crude product was dissolved in hot ethanol (150 mL), the solution was filtered, and the filtrate reduced in volume to 50 mL. Cooling to 0°C gave 5.31 g of **23** (R = Ph) as a white crystalline solid. Recrystallization from hot ethanol (45 mL) gave 4.62 g (53%) as a white crystalline solid, mp 156.5–158°C; ^{1}Hmr ($CDCl_3$)δ: 11.13 (1H, s), 7.28 (10H, b), 6.13 (1H, bs), 5.13 (1H, t, J = 7 Hz), 3.34 (2H, d, J = 7 Hz); ir (KBr): 3300–2100, 1710, 1590, 1602 cm^{-1}.

The thiazolidine **23** (R = Ph) (2.24 g, 7.15 mmol) was dissolved in methylene chloride (100 mL). EEDQ (1.77 g, 7.15 mmol) and then glycine ethyl ester hydrochloride (1.00 g, 7.15 mmol) were added to the methylene chloride solution. The thiazolidine and EEDQ dissolved instantly, but the glycine ethyl ester hydrochloride remained in suspension. Triethylamine (0.73 g, 7.15 mmol) was added to the suspension, and the reaction mixture was stirred at room temperature for 17.5 h. The methylene chloride solution was extracted with aqueous 5% sodium bicarbonate (2 × 50 mL) and aqueous 5% hydrochloric acid (2 × 50 mL). The organic layer was dried over anhydrous magnesium sulfate, filtered, evaporated, and the residue dried under high vacuum to give 2.26 g of material as a white foam. Crystallization from ethyl acetate/petroleum ether at −15°C gave 1.09 g (38%) of **15** (R = Ph) as a white crystalline solid, mp 156.5–157.5°C; ^{1}Hmr ($CDCl_3$)δ: 7.70 (1H, bs), 7.30 (10H, s), 6.16 (1H, bs), 5.17 (1H, t, J = 7.5 Hz), 4.19 (2H, q, J = 7 Hz), 4.06 (2H, d, J = 7.5 Hz), 3.67 (1H, q, J = 8, 12 Hz), 3.20 (q, J = 7, 12 Hz), 1.27 (3H, t, J = 7 Hz); ir (KBr): 3270(s), 3066(m), 2967(w), 2917(w), 1751 and 1747(s), 1724(s), 1687(s), 1614(s), 1568(s) cm^{-1}.

*Stability of **15** (R = CH_3) in Acetic Anhydride*

The thiazolidine (0.1081 g) was dissolved in 1.0 mL of Ac_2O and the solution was heated for 3 h at 79–80°C. The solvent was then removed under high vacuum. The ^{1}Hmr spectrum of the residue was identical to that of **15** (R = CH_3).

*Rearrangement of **15** (R = CH_3) to **9**a in TFA*

The thiazolidine (0.0668 g) was dissolved in anhydrous trifluoroacetic acid (1 mL), and the solution was allowed to stand at room temperature for 1 h. The solvent was then removed and the residue dried under high vacuum and purified by plc (silica gel, four developments with benzene/methanol 5:1) to give three bands. The leading band (7.5 mg), R_f 0.54–0.62, was **15** (R = CH_3). The middle band (32.6 mg), R_f 0.33–0.50, was ***9a***. The trailing band, R_f 0.23–0.30, contained insufficient material for characterization.

*Rearrangement of **15** (R = Ph) to **10**b in TFA*

The thiazolidine (0.2002 g) was dissolved in anhydrous trifluoroacetic acid (2.0 mL), and the solution was allowed to stand at room temperature for 1 h. The solvent was then removed and the residue dried under high vacuum and subjected to plc (silica gel, three developments with benzene/methanol 5:1) to give three bands. The trailing band, R_f 0.59–0.66, was unreacted thiazolidine. The leading band (55.9 mg), R_f 0.79–0.88, was identified as ***10b***; ^{1}Hmr ($CDCl_3$)δ: 7.93–6.60 (6H, m, 1H exchanges with D_2O), 7.36 (5H, s), 5.78 (1H, s), 4.97 (1H, sextet, J = 5, 6, 13 Hz), 4.47 (1H, d, J = 17 Hz), 4.15 (2H, q, J = 7 Hz), 3.39 (1H, d, J = 17 Hz), 3.33 (2H, *AB*X, J = 13, 13, 6 Hz), 1.23 (3H, t, J = 7 Hz); ir (KBr): 3340 (m), 1737 (s), 1663 (s), 1627 (s) cm^{-1}; ms *m/e* (relative intensity >10%): 398 (M^+, 4.5), 277 (12), 192 (48), 190 (50), 118 (25), 105 (100), 91 (41), 77 (43), 51 (10).

Received January 12, 1979

FELIPE ALCUDIA, JOSÉ L. GARCÍA RUANO, JESÚS RODRÍGUEZ, and FÉLIX SÁNCHEZ. Can. J. Chem. **57**, 2426 (1979).

A conformational study of 1-X-2-propanol (X = SH, SMe, SOMe, SO_2Me, $^+SMe_2$) and their *O*-acetyl derivatives (X = SMe, SOMe, SO_2Me, and $^+SMe_2$) is reported. From the relative values of the vicinal coupling constants in ^1H nmr spectra it has been possible to establish the conformational preference. When a density of opposite charge is supported by heteratoms, polar factors determined a great predominance of that conformation in which the sulphur function has an *anti*-relationship with respect to the methyl group. In thiol and thioethers the conformational preference is not so marked.

FELIPE ALCUDIA, JOSÉ L. GARCÍA RUANO, JESÚS RODRÍGUEZ et FÉLIX SÁNCHEZ. Can. J. Chem. **57**, 2426 (1979).

On rapporte une étude conformationnelle des X-1 propanols-2 (X = SH, SMe, SOMe, SO_2Me, $^+SMe_2$) et de leurs dérivés *O*-acétylés. A partir des valeurs relatives de leurs constantes de couplage vicinal dans les spectres rmn ^1H, on a pu établir la préférence conformationnelle. Lorsque les hétéroatomes supportent des densités opposées de charges, des facteurs polaires favorisent une grande prédominance de la conformation dans laquelle la fonction sulfurée se trouve dans une relation *anti* par rapport au groupe méthyle. Dans le cas du thiol et du thioéther, la préférence conformationnelle n'est pas aussi marquée.

[Traduit par le journal]

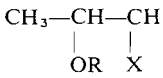
Introduction

The conformational analysis of some 2-thioderivatives of 1-phenylethanol and 1,2-diphenylethanol has been previously reported by us (1–4). Conformational preferences could be explained by taking into account polar and steric factors. However, we have made a theoretical study by CNDO/2 of 2-methylsulphonyl-1-phenylethanol (5) in which the results obtained suggest that stabilizing interactions between the phenyl group and the sulphur atom must also be considered. On the other hand, contrary to the experimental evidence, the intramolecular hydrogen bonding makes an important contribution to the conformational stability of rotamers around the C-S bond.

In the present paper, the conformational analysis of compounds **1–9** are reported in order to clarify these points.

The solubility of these compounds is greater than that in previous series and, as well, the phenyl group has been substituted by a methyl one. This suggests that their conformational study would throw some light on the above questions.

[1]For Parts I–V, see refs. 1–5.



1 R = H, X = SH
2 R = H, X = SCH_3
3 R = H, X = $SOCH_3$
4 R = H, X = SO_2CH_3
5 R = H, X = $^+S(CH_3)_2$
6 R = Ac, X = SCH_3
7 R = Ac, X = $SOCH_3$
8 R = Ac, X = SO_2CH_3
9 R = Ac, X = $^+S(CH_3)_2$

Results and Discussion

The synthesis of compounds **1–9** was carried out as indicated in Scheme 1 by means of procedures described in the Experimental.

The reaction of compound **2** with metaperiodate yields a mixture of two diastereomers. In this paper only one of them has been isolated and studied, but its configuration has not yet been determined. Compound **7** has been obtained from this isomer.

The method used for evaluating the conformational populations was the study of coupling constants[2] of the protons on C-1 and C-2. The possible

[2]The δ values are of little use in this analysis due to the difficulty in predicting substituent effects and the lack of comparable model systems.

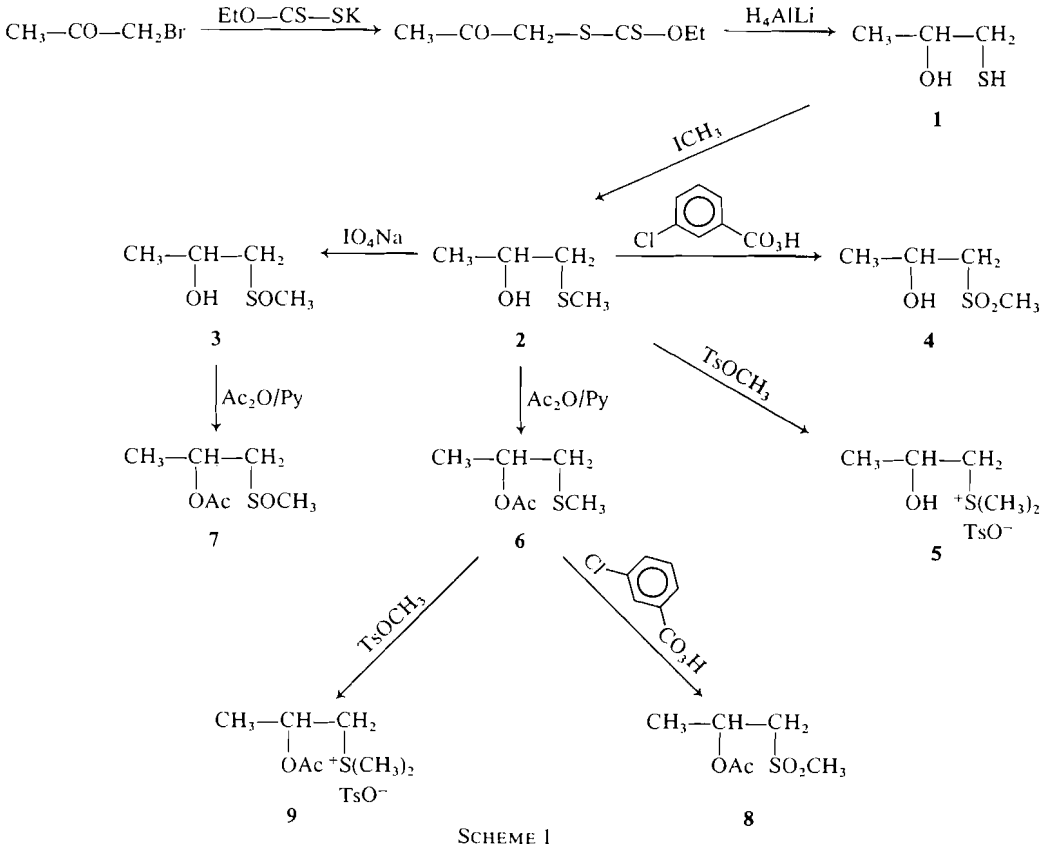

SCHEME 1

conformations of compounds **1–9** are given in Fig. 1. From the equilibrium shown in this figure and taking into account that $J_{trans} \gg J_{gauche}$, it may be deduced that very different values of the vicinal coupling constants are only compatible with a marked preference for conformations *A* or *B*.

The observed spectral parameters suggest a different conformational behaviour of compounds **1**, **2**, and **6** with respect to the others and so an independent study of both types of compounds was undertaken.

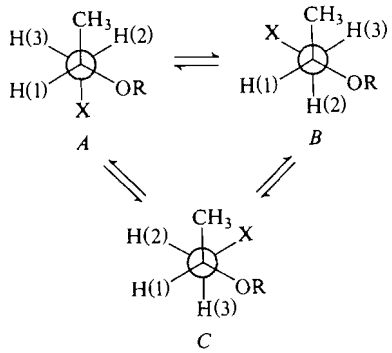

FIG. 1. Conformational equilibria of compounds **1–9** around the C(1)—C(2) bond.

The δ and *J* values obtained from computer analysis of the ^{1}H nmr spectra for compounds **3–5**, recorded in $CDCl_3$ and DMSO-d_6 at several concentrations, are given in Table 1.

The $J_{1,2}$ value is larger than $J_{1,3}$ in all cases, which is compatible with a marked predominance of either *A* or *B* conformations. In all other cases similar values for the two vicinal coupling constants were observed.

The spectra for sulphone **4** in DMSO-d_6 have shown that the proton on C-2, which appears at lower field (considered to be *gauche* with respect to H-1 from the J_{vic} values), is further coupled to the hydroxy proton ($^4J_{H-C-C-O-H} \simeq 0.5$ Hz). This atom sequence is typical in carbohydrate compounds in which the long range coupling constants are only observed when a *W* planar arrangement between involved protons becomes possible (6, 7). In compound **4**, this arrangement is only possible in the *A* conformer (Fig. 2). In addition, only one of the two methylene protons appears split as a consequence of this coupling and so we can exclude the possibility

*Methyl of the methylsulphonyl group.

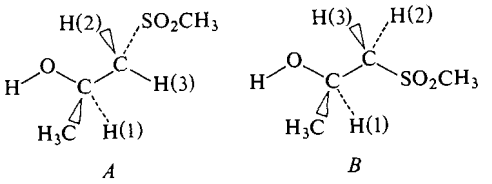

FIG. 2. Spatial arrangement of the H(3) and hydroxylic protons in conformations *A* and *B*.

of *B* being the preferred rotamer. On the other hand, this long range coupling permits us to carry out the unequivocal assignment of H-2 and H-3.

In previous studies (1–4), sulphoxides, sulphones, and the sulphonium salts showed a similar conformational preference. Therefore, it seems reasonable to assume that in sulphoxide **3** and in sulphonium salt **5**, the *A* conformation should be the most stable, as was observed in sulphone **4**.

The predominance of the *A* conformation can be explained assuming a strong electrostatic attraction between the heteroatoms, since the sulphur atom supports some positive charge. The intramolecular hydrogen bonding contribution is not negligible, at least in sulphone **4**, where conformational preference, deduced from the relative values of coupling constants, increases with dilution and decreases when the spectra were recorded in DMSO-d_6, as can be expected. On the other hand, the influence of the polarity change can be explained by taking into account the different association of solvents with conformers *A* and *B*. Nevertheless, the preference shown by salt **5** suggests that the relative contribution of the intramolecular hydrogen bonds, with respect to the electrostatic interaction, may be unimportant.

Another interesting feature is based on the long range coupling constants $^4J_{H-C-S-CH_2}$, observed in sulphone **4**. The staggered conformations around the C—S bond are indicated in Fig. 3. The $^4J_{Me,H(2)}$ and $^4J_{Me,H(3)}$ values are indicative of conformational populations of A_2 and A_1 respectively, as the most favourable spatial arrangement (*W*) between involved protons is present in these conformations. These values indicate that there is a preference for conformation A_1 in concentrated solutions of $CDCl_3$. This situation has been previously reported (1, 8) and has been attributed to an Me–OH attraction as a result of the delocalization of positive charge from the sulphur on the methyl group. The decrease in preference for A_1 with dilution, however, suggests that the shift of conformational equilibrium is the result of an inter/intramolecular interaction balance since rotamer A_1 presents the most favourable arrangement for an Me–OH attraction and intermolecular association by hydrogen bonds, whereas in A_2 and A_3 intramolecular hydrogen bonding is possible. This could explain the disagreement between the theoretical calculations (5) and the experimental finding (1) on 2-methylsulphonyl-1-phenylethanol. The theoretical study showed that rotamers A_2 and A_3 in the vapour state were more stable than A_1, due to the possibility of forming intramolecular hydrogen bonds.

The ^{1}H nmr parameters of compounds **7**–**9** are given in Table 2. From the relative values of vicinal coupling constants it can be deduced that the preference for conformation *A* in the *O*-acetyl derivatives **7** and **8** is less marked than in **3** and **4**. This can be explained by differences in steric and hydrogen bond effects between both types of compounds. However, the small influence of hydrogen bonds (deduced from the results obtained in sulphone **4** in DMSO-d_6) and the steric effect (as indicated by the results in salt **9** with respect to salt **5**), suggest additional factors, such as the electrostatic interactions between oxygen of the acetyl group and the heteroatoms in the sulphur function. These interactions ought to be stabilizing in salt **9** and more destabilizing in sulphone **8** than in sulphoxide **7**. Clearly, the relative contribution of the electrostatic interactions will be less in DMSO-d_6 as solvent. Taking into account the three mentioned effects the results obtained can be satisfactorily explained.

From the $^4J_{Me,H(2)}$ and $^4J_{Me,H(3)}$ values, the major contribution of the A_1 rotamer in the equilibrium $A_1 \rightleftharpoons A_2 \rightleftharpoons A_3$ can be deduced. Accordingly, the dilution effect is very small, since the intermolecular associations are less important in the acetoxy sulphone **8**, whereas the intramolecular ones will destabilize conformations A_2 and A_3 by electrostatic repulsion.

The ^{1}H nmr parameters of compounds **1**, **2**, and **6** are given in Table 3. The results can be rationalized according to the following points.

(*i*) There are no important differences in the $J_{1,2}$ and $J_{1,3}$ values in compounds **1** and **2**, and so only a slight preference for *A* or *B* conformations can be established.

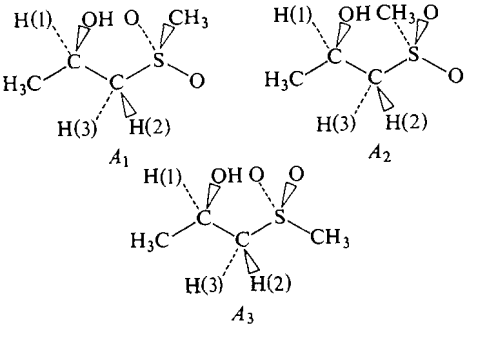

FIG. 3. Rotamers of compounds **6** around the C—S bond.

Compound	Free O—H (cm^{-1})	Intramolecular bonded O—H (cm^{-1})	$\Delta\nu$ (cm^{-1})
1	3616	3550	66
2	3614	3522	92

Infrared spectra recorded in CCl_4 at low concentration ($<10^{-2}$ *M*) have shown the presence of intramolecular hydrogen bonds in these compounds. The relative intensity of the associated OH band is larger than the free OH one (see Table 4) in both compounds and gives rise to the idea that the *A* rotamer is the most populated (9), as the intramolecular associations are not possible in *B*.

The variation of the J_{vic} values with changes in concentration and in solvent polarity supports the above assumption. Thus, the conformational preference increased with dilution (greater differences between vicinal coupling constants are observed) due to the predominance of intra- over intermolecular interactions. On the other hand, this preference disappears in compounds **2**[3] when DMSO-d_6 is used as a solvent.

(*ii*) In thioether **6** values of the vicinal coupling constants are in agreement with the impossibility of forming intramolecular hydrogen bonds and the small influence of dilution suggests that steric interactions may now be responsible for the conformational equilibrium shift. On the other hand, the values $J_{1,2} + J_{1,3}$ in compounds **1**, **2**, and **6** remain constant with dilution in all studied solvents. This is only possible if the contribution of the conformation *C* to the equilibrium is small or zero, due probably to steric effects.

(*iii*) Comparison of the $J_{1,2}$ and $J_{1,3}$ values for compound **6** with those for 2-thiomethyl-1-phenylethanol **10**, previously studied (2), is of great interest. In the latter compound the preference for conformation *B* could be proved although the population of *A* was also important ($J_{1,3} = 7.9$ and $J_{1,2} = 5.5$), whereas in compound **6** there is no preference ($J_{1,2}$ and $J_{1,3} = 6.2$–6.3). From the analysis of the interactions in compounds **6** and **10** it can be deduced that conformation *A* is equally stabilized in both compounds, but the rotamer *B* has an Me–SMe interaction in **6** and a Ph–SMe one in **10**; this latter interaction must be more stabilizing than Me–SMe. Taking into account that the steric hindrance of the phenyl group is larger than that of methyl (10), other factors have to be invoked to explain stability differences which must also be independent of solvent polarity.

The theoretical calculations by CNDO/2 of the different conformations of 2-methylsulphonyl-1-phenylethanol (5) showed a stabilizing interaction Ph–SO_2Me (ca. 4 kcal) due to d-π overlap of the sulphur atom with the phenyl group. Similar interactions may be responsible for the lower destabilization of the *gauche* Ph–SMe interaction with respect to the Me–SMe one.

[3]Compound **1** shows a deceptively simple spectrum in DMSO-d_6 at any concentration and so it is only possible to know the $J_{1,2} + J_{1,3}$ value.

Experimental

^{1}H nmr spectra were recorded on a Varian XL-100-15 spectrometer operating at 100 MHz by Fourier transform technique, using 16K of core in a Nicolet 1180 stored programme computer. The signal of the deuterated solvent was employed for deuterium field-frequency lock and TMS as an internal reference. The analyses of the spectra were carried out using a LAOCOON III programme (11, 12) on a Nicolet 1180 computer. We estimate the reliability of all values as 0.1 Hz, and the root mean square deviations for the calculated and the experimental lines were usually better than 0.05 Hz. Infrared spectra were recorded on a Pye-Unicam SP-1100 spectrometer. The studies on the intramolecular hydrogen bondings were carried out on a Beckman IR-4240 spectrophotometer. Mass spectra were obtained using a Hitachi Perkin Elmer RMU-6M spectrometer at 70 eV. Melting points were determined on a Kofler hot-stage and are, like the boiling points, uncorrected.

1-Mercapto-2-propanol ***1***

This compound was prepared by reaction of potassium ethylxanthate with bromoacetone following the procedure reported by Djerassi (13) for similar compounds; bp 50–52°C/10 Torr (lit. (14) bp 51°C/8 Torr).

1-Methylthio-2-propanol ***2***

A solution of **1** (7.99 g, 0.087 mol) in absolute ethanol (90 mL) was slowly added to a solution of sodium (2 g) in anhydrous ethanol (200 mL) and cooled at 0°C. It was then treated with a solution of methyl iodide (12 g, 0.087 mol) in ethanol and the reaction mixture was allowed to stand overnight at room temperature with constant stirring. Water (160 mL) was added and it was extracted with chloroform (3 × 75 mL). The chloroform extracts were dried ($MgSO_4$) and concentrated (rotary evaporator) to yield 7.1 g (77%) of **2**; bp 60–62°C/15 Torr (lit. (15) bp 55–58°C/10 Torr).

The Acetyl Derivative ***6***

This compound was prepared with acetic anhydride and pyridine, distilled at 68–70°C/15 Torr (lit. (16) 64–65°C/10 Torr).

1-Methylsulphonyl-2-propanol ***3***

To an ice-cooled solution of 3.2 g (0.015 mol) of sodium metaperiodate in 20 mL of water was added 1.62 g (0.015 mol) of **2**. The reaction mixture was stirred at 0°C for 4 h and was then allowed to stand overnight at room temperature. Ethanol (30 mL) was added and the sodium iodate formed was filtered. The solution was evaporated and treated with 50 mL of chloroform. The chloroform extracts were dried (Na_2SO_4) and concentrated to afford 1.8 g (97%) of **3** as a mixture of two diastereomers (two signals of similar intensity for the methyl group bonded to the sulphur atom in the ^{1}H nmr spectrum). The isolation of one of the diastereomers was carried out by repeated recrystallization from benzene, mp 89–91°C (lit. (17)

mp 89–90°C); ν_{max} (Nujol): 3277 and 1010 cm^{-1}; δ($CDCl_3$, 10%): 1.31 (3H, d, J = 6.2 Hz, CH_3—C), 2.63 (3H, s, CH_3—S), 2.83 (2H, m, —CH_2—), 4.35 (1H, m, —CH—), and 4.67 (1H, s, broad, OH). *Anal.* calcd. for $C_4H_{10}O_2S$: C 39.33, H 8.25, S 26.20; found: C 39.49, H 8.41, S 26.43.

The Acetyl Derivative **7**

This compound was prepared by reaction of isolated diastereomer **3** with acetic anhydride and pyridine; ν_{max} (Nujol): 1745, 1250, and 1010 cm^{-1}; δ($CDCl_3$, 10%): 1.39 (3H, d, J = 6.2 Hz, CH_3—CH), 2.03 (3H, s, CH_3—CO), 2.60 (3H, s, CH_3—S), 2.85 (2H, m, —CH_2—), 5.31 (1H, m, —CH—); significant peaks in ms *m/e*: 164 (M^+), 149, 121, 101 (base peak), 63, and 61.

1-Methylsulphonyl-2-propanol **4**

A solution of *m*-chloroperoxibenzoic acid (2.24 g, 0.013 mol) and 1-methylthio-2-propanol, **2** (0.53 g, 0.005 mol), in chloroform (50 mL) was stirred at room temperature for ca. 10 h. The solution was then washed with saturated aqueous sodium bicarbonate (200 mL), dried ($MgSO_4$), and concentrated to give 0.54 g (79%) of **4**. The solid was recrystallized from benzene, mp 67–69°C (lit. (18) mp 47–51°C); ν_{max} (Nujol): 3330, 1290, and 1125 cm^{-1}; δ($CDCl_3$, 10%): 1.32 (3H, d, J = 6.2 Hz, CH_3—C), 3.02 (3H, s, CH_3—S), 3.14 (2H, m, —CH_2—), 3.19 (1H, s, OH), and 4.41 (1H, m, —CH—). *Anal.* calcd. for $C_4H_{10}O_3S$: C 34.78, H 7.29, S 23.19; found: C 34.01, H 7.49, S 23.09.

The Acetyl Derivative **8**

This derivative was similarly obtained by reaction of **6** with *m*-chloroperoxibenzoic acid and recrystallized from CCl_4, mp 54–55°C; ν_{max} (Nujol): 1745, 1130, and 1050 cm^{-1}; δ($CDCl_3$, 10%): 1.41 (3H, d, J = 6.0 Hz, CH_3—CH), 2.06 (3H, s, CH_3—CO), 2.96 (3H, s, CH_3—S), 3.27 (2H, m, —CH_2—), and 5.37 (1H, m, —CH—).

Dimethyl(2-hydroxypropyl)sulphonium p-*Toluenesulphonate* **5**

A mixture of **2** (0.56 g, 0.0047 mol) and methyl *p*-toluenesulphonate (2 mL) was stirred at 30°C for 18 h. The reaction mixture was washed with ether (5 × 20 mL) and filtered to give 1.31 g (85%) of **5**. It was recrystallized from methanol, mp 120–122°C; ν_{max} (Nujol): 3330 cm^{-1}; δ(DMSO-d_6, 10%): 1.19 (3H, d, J = 6.0 Hz, CH_3—C), 2.27 (3H, s, CH_3—Ar), 2.87 (3H, s, CH_3—S), 2.89 (3H, s, CH_3—S), 3.35 (2H, m, CH_2), 4.09 (1H, m, OH), 5.57 (1H, d, CH), 7.07, and 7.45 (4H, AB system, J_{AB} = 8 Hz, aromatic H's). *Anal.* calcd. for $C_{12}H_{20}O_4S_2$: C 49.31, H 6.89, S 21.91; found: C 49.40, H 7.04, S 22.06.

The Acetyl Derivative **9**

This compound was similarly prepared from compound **6** by reaction with methyl *p*-toluenesulphonate. The purification of this compound by crystallization has not been possible due to its hydroscopic character. However, the spectroscopic data and the synthesis process are in accordance with its structure; ν_{max} (Nujol): 1750 cm^{-1}; δ($CDCl_3$, 10%): 1.27 (3H, d, J = 6.0 Hz, CH_3—CH), 1.99 (3H, s, CH_3—Ar), 3.07 (6H, s, $(CH_3)_2$—S), 3.75 (2H, m, CH_2), 5.13 (1H, m, CH), and 7.10–7.65 (4H, m, aromatic H's).

The nature of the NADP complex with manganese(II) ions as studied by proton and phosphorus magnetic resonance[1]

M. KIRK GREEN AND GEORGE KOTOWYCZ

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 1, 1979

M. KIRK GREEN and GEORGE KOTOWYCZ. Can. J. Chem. **57**, 2434 (1979).

Proton and phosphorus magnetic resonance techniques have been applied to study the conformation of the complex formed between Mn(II) ions and nicotinamide adenine dinucleotide phosphate (NADP) in aqueous solutions at a pH of 7.5 and 20°C. The dipolar correlation time (τ_c) for the Mn(II)–NADP complex at 20°C was calculated to be 1.7×10^{-10} s, based on the measurement of proton longitudinal relaxation time ratios and a literature value of τ_c for nicotinamide adenine dinucleotide (NAD). The τ_c, as well as the ^1H and ^{31}P relaxation data together with the measured stability constant for this complex, were used to calculate the distances from the ^1H and ^{31}P nuclei to the Mn(II) ion. These distances are 3.8 Å to A8, 5.0 Å to A2, 4.5 Å to A1′, 5.3 Å to N2, 5.4 Å to N6, 5.5 Å to N5, 5.8 Å to N1′, and 6.3 Å to N4. The distances to the linkage ^{31}P nuclei are 3.7 Å, and 3.3 Å to the adenosine ribose 2′-phosphate. Based on these distances, a model is proposed for the Mn(II)–NADP complex. In this complex, the Mn(II) ion is bonded to the oxygens of all three phosphates, and the adenine and nicotinamide bases are 7–8 Å apart and parallel. Hence the Mn(II) ion is located between and to one side of the two bases but is distinctly closer to the adenine base. The adenine base is in the *anti* conformation, whereas the nicotinamide moiety can be either *syn* or *anti*. Hence there is little or no close stacking of the two bases in the complex. The addition of Mg(II) ions to a solution of free NADP caused no observable shift of the aromatic proton peaks, indicating no differences in shielding effects. Hence the rings are probably similarly oriented in both free NADP and the metal–NADP complex. Effects on the transverse relaxation rates due to the paramagnetic metal ion (T_{2p}^{-1}) were also measured from the ^{31}P linewidths as a function of temperature. The lifetime of the metal ion in the complex is $4.0 \pm 0.5 \times 10^{-6}$ s and $\Delta H^{\neq}$ for the exchange process is 13.7 ± 0.5 kcal/mol.

M. KIRK GREEN et GEORGE KOTOWYCZ. Can. J. Chem. **57**, 2434 (1979).

On a appliqué les techniques de la résonance magnétique du proton et du phosphore pour étudier la conformation de complexes formés entre des ions Mn(II) et le phosphate de dinucléotide de la nicotinamide et de l'adénine (PDNA) en solutions aqueuses, à un pH de 7.5 et à 20°C. On a calculé que le temps de corrélation dipolaire (τ_c) du complexe Mn(II)–PDNA est de 1.7×10^{-10} s en se basant sur la mesure de rapports de temps de relaxation longitudinale protonique et sur une valeur de τ_c pour le dinucléotide de nicotinamide et d'adénine (DNA) trouvée dans la littérature. On a utilisé cette valeur de τ_c de même que des données de relaxation ^1H et ^{31}P ainsi que la constante de stabilité mesurée pour ce complexe pour calculer les distances entre les noyaux ^1H et ^{31}P de l'ion Mn(II). Ces distances sont 3.8 Å de A8, 5.0 Å de A2, 4.5 Å de A1′, 5.3 Å de N2, 5.4 Å de N6, 5.5 Å de N5, 5.8 Å de N1′ et 6.3 Å de N4. Les distances du noyau ^{31}P de liaison sont de 3.7 Å et 3.3 Å du phosphate-2′ de l'adénosine de ribose. En se basant sur ces distances, on propose un modèle pour le complexe Mn(II)–PDNA. Dans ce complexe, l'ion Mn(II) est lié aux oxygènes des trois phosphates et les bases adénine et nicotinamide sont parallèles et à 7–8 Å de distance. Donc le Mn(II) est situé entre les deux bases et beaucoup plus près de l'adénine. L'adénine est dans une conformation *anti* alors que la nicotinamide peut être soit *syn* ou *anti*. Donc il n'y a que peu ou pas de superposition entre ces deux bases dans le complexe. L'addition d'ions Mg(II) à une solution de PDNA ne provoque pas de déplacements appréciables des raies des protons aromatiques ce qui indique qu'il n'y a pas de différences dans les effets de blindage. Donc les cycles sont probablement orientés d'une façon similaire tant dans le PDNA que dans le complexe métal–PDNA. On a aussi mesuré les effets, sur les taux de relaxation transversale, des ions métalliques paramagnétiques (T_{2p}^{-1}) en se basant sur les largeurs de raies ^{31}P en fonction de la température. Le temps de vie de l'ion métallique dans le complexe est de $4.0 \pm 0.5 \times 10^{-6}$ s et le $\Delta H^{\neq}$ du processus d'échange est de 13.7 ± 0.5 kcal/mol.

[1]This is paper No. XIII in a series of studies of metal ion interactions with nucleotides and coenzymes. Paper No. XII is ref. 13. This study was presented at the Annual Conference and Exhibition of the Chemical Institute of Canada, Vancouver, B.C., June 3–6, 1979.

0008-4042/79/182434-10$01.00/0

Introduction

Several nuclear magnetic resonance (nmr) studies of the solution conformation of nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP)[2] (Fig. 1) have been performed (refs. 1–6 and references therein). Chemical shift measurements suggest that these coenzymes exist in an equilibrium involving folded and extended forms at room temperature and neutral pH (1, 3). Bose and Sarma (5) have evaluated the solution conformations of free NAD and NADP. It has been established that molecular association occurs between the nicotinamide and the adenine rings of NAD in a folded conformation in aqueous solution (7); however, Zens *et al.* (6) conclude from proton longitudinal relaxation time measurements that, for a time comparable to the reorientation correlation time for NAD, the aromatic rings do not get closer than 4.5 Å. X-ray studies of the lithium–NAD complex (8) indicate that this complex exists as a "dimer" of two NAD molecules arranged head-to-tail. Li^+ is coordinated tetrahedrally to adenine N7 and to three of the four pyrophosphate oxygens. The adenine is stacked intermolecularly on nicotinamide, and the conformation of NAD is "extended" as found in holoenzyme complexes. The planes of the adenine and nicotinamide rings are almost perpendicular to each other and separated by about 11.5 Å. Saenger and co-workers (9) have compared, in a very elegant manner, the conformation of NAD in solution, in the Li^+ complex, and in holoenzymes.

Enzymes involved in oxidative decarboxylations require Mg(II) or Mn(II) ion. Maloney and Dennis (10) have shown, for example, that the reverse reaction of the NADP-specific isocitrate dehydrogenase from pea stems is activated by Mn(II) ions and not Mg(II) ions. Westheimer (11) describes experiments involving mechanisms of enzymic decarboxylations, and finds that enzymic decarboxylations follow two mechanisms: (*a*) the compound is converted to a Schiff base salt; (*b*) a metal ion is bonded to a carbonyl oxygen atom in order to activate it.

The stability constant K_s for the Mn(II)–NADP complex has been determined previously (10, 12, 13). The stability constant is strongly pH dependent in the pH region of 6.1 where the 2′-phosphate ionizes. A value of K_s equal to $370 \pm 50\ M^{-1}$ that was previously obtained (13) is used to interpret the present results, since it was measured under the same experimental conditions that are used in the present study. Previous nmr studies of Co(II) binding to NAD and NADP (14, 15) indicate direct binding of the Co(II) ion to the pyrophosphate oxygens.

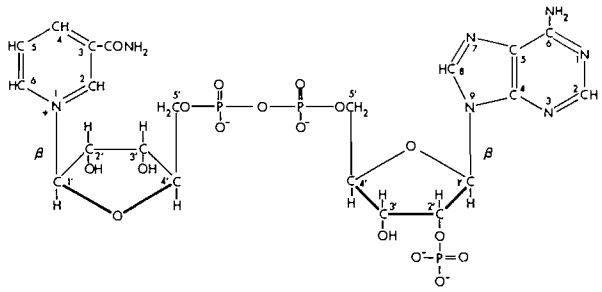

FIG. 1. Structure of NADP at a pH of 7.5. The related coenzyme NAD has a hydrogen instead of the PO_3^{2-} group at the adenine ribose 2′-position.

We have studied the solution conformation of NADP using the paramagnetic Mn(II) ion probe and ^1H and ^{31}P magnetic resonance relaxation techniques. These data for the Mn(II)–NADP complex are used to calculate the distances from the bound Mn(II) ion to eight protons and to three phosphorus nuclei of NADP in the complex. The value of the correlation time measured for NAD by Ellis and co-workers (6) was used for the calculation of τ_c for the complex. These distances give a picture of the conformation of the Mn(II)–NADP complex in solution. In addition, the temperature dependence of the ^{31}P transverse relaxation rates due to the paramagnetic metal ion (T_{2p}^{-1}) gives a value for the lifetime of the Mn(II) ion in the complex (τ_M) as well as the enthalpy of activation ($\Delta H^{\ddagger}$) for this process.

Experimental

Materials

The coenzymes NADP (monosodium salt) and NAD (free acid) were purchased from Sigma Chemical Co. They were purified to eliminate trace metal contaminants by passing a solution through a column of Chelex 100 (from Bio-Rad Laboratories) of mesh 100 to 200 and then lyophilizing the effluent solution. The purified coenzymes were then dissolved in 99.7% D_2O and lyophilized two to three times from D_2O. The resin was treated following standard procedures as recommended by the manufacturer. It was rinsed with 1 *N* HCl, methanol, and then 1 *N* NaOH, followed by equilibration with $NaKHPO_4$ buffer at a pH of 7 and extensive rinsing with doubly distilled deionized water until the effluent was of pH > 9. The D_2O that was used was vacuum distilled to eliminate paramagnetic impurities.

N-ethyl morpholine from Eastman Organic Chemicals was vacuum distilled for the nmr experiments. $MnCl_2 \cdot 4H_2O$ from Fisher Scientific Co. Ltd. and KCl from J. T. Baker Chemical Co. were used without further purification. For all experiments, 40 m*M* *N*-ethyl morpholine was used as the buffer.

[2]NAD, nicotinamide adenine dinucleotide; NADP, nicotinamide adenine dinucleotide phosphate; NMN, nicotinamide mononucleotide; T_{1p}^{-1}, effect on the longitudinal relaxation rate due to the paramagnetic metal ion; T_{2p}^{-1}, effect on the transverse relaxation rate due to the paramagnetic metal ion.

Methods

The NAD and NADP concentrations were measured by monitoring the solution absorbance at 260 nm using a Unicam SP2600 spectrophotometer. The samples for the proton and phosphorus magnetic resonance experiments were prepared in D_2O at a pH of 7.9 (uncorrected for D_2O solvents) to ensure that all of the phosphate moieties of NADP are deprotonated (net charge on the NADP anion is -3 (Fig. 1)). The measurements were carried out at 293 K. The KCl concentration was 0.153 *M* and the NADP concentration was 4.5–4.6 $\times$ 10^{-3} *M*, whereas the Mn(II) ion concentration ranged from 0–6 $\times$ 10^{-6} *M*. The Mn(II) stock solutions for both the nmr and the epr experiments used in the previous study (13) were prepared by weighing out the Mn(II) salt, and the solutions for the nmr experiments were prepared using H. E. Pedersen micropipets for maximum accuracy. The effects on the longitudinal relaxation rates of the observed nuclei due to the paramagnetic metal ions T_{1p}^{-1} were calculated according to [1]

$$[1] \quad 1/T_{1p} = (1/T_{1,Mn}) - (1/T_{1,0})$$

where $1/T_{1,Mn}$ denotes the relaxation rate of the NADP nuclei in solution in the presence of the paramagnetic species and $1/T_{1,0}$ denotes the relaxation rate of the same nuclei but in the absence of the Mn(II) ions. All proton magnetic resonance longitudinal relaxation times (T_1) were measured using the Varian HA-100-15 nmr spectrometer (100.0 MHz) interfaced with the Digilab FTS/NMR-3 Fourier transform system including the pulse unit (FTS/NMR 400-2) and the Nova 1200 computer. The temperature was maintained at 293 K using the Bruker B-ST 100/700 temperature controller. The T_1 measurements were carried out using the (180° $-$ τ $-$ 90°) two-pulse sequence and 50–200 pulse sequences were collected. The deuterium signal from D_2O was used for the lock signal. All T_1 calculations are based on measurements of peak heights. However, for the nicotinamide protons N4 and N6, average peak heights of the multiplets were used, whereas for the nicotinamide N5 proton and the adenine and nicotinamide A1′ and and N1′ protons, the peak height of one peak of each multiplet could only be measured.

The nuclear Overhauser effect experiments were run under conditions that were identical to the other nmr samples except that the NADP concentration was 0.05 *M* and the temperature was 304 K. The measurements were also carried out on the Digilab system at 100 MHz.

The ^{31}P nmr T_1 experiments were carried out at 110 MHz and 146 MHz using the Bruker 270 and 360 MHz nmr spectrometers. These measurements were carried out by Dr. B. D. Sykes and Dr. W. E. Hull, respectively. The measurements of the T_1 values at 110 MHz were carried out using the two-pulse sequence at 28°, whereas the T_1 experiments at 146 MHz were carried out using saturation recovery techniques at 25°. The effects on the transverse relaxation rates due to the paramagnetic metal ion T_{2p}^{-1} were measured from the linewidths at half height of the ^{31}P nmr spectra obtained at 36.43 MHz using the Bruker HFX-90 nmr spectrometer. $1/T_{2p}$ was calculated from the data using the relationship

$$[2] \quad 1/T_{2p} = \pi(\Delta\nu_{Mn} - \Delta\nu_0)$$

where $\Delta\nu_{Mn}$ is the linewidth at half-height of the given resonance in the presence of the Mn(II) ions and $\Delta\nu_0$ is the linewidth at half-height of the same resonance in the absence of the metal ion. The samples were prepared in the same way as for the ^1H nmr measurements.

Distance Calculations from the ^1H Nuclear Magnetic Resonance Data

Swift and Connick (16) obtained the relationship between the observed transverse relaxation time due to the paramagnetic ion T_{2p} and the inner sphere relaxation rate $1/T_{2M}$. This relationship is given by [3],

$$[3] \quad 1/T_{2p} = f_M/(T_{2M} + \tau_M)$$

Similarly, Luz and Meiboom (17) obtained the relationship between the observed longitudinal relaxation time due to the paramagnetic ion T_{1p} and the inner sphere relaxation rate $1/T_{1M}$. This is given by

$$[4] \quad 1/T_{1p} = f_M/(T_{1M} + \tau_M)$$

where f_M = [bound metal ion]/[observed ligand] and τ_M is the exchange lifetime. The theoretical expressions for T_{1M} and T_{2M} are given by Solomon and Bloembergen (18–20). For high magnetic field strengths, the contact term in the Solomon–Bloembergen equation for T_{1M} is negligible. In the fast exchange region ($\tau_M \ll T_{1M}$), a general equation for the calculation of r (distance between the paramagnetic centre and the proton under study) can be obtained from the dipolar term in T_{1M}. This equation may be written as (21)

$$[5] \quad r(\text{in Å}) = C[T_{1M}F(\tau_c)]^{1/6} = C\left[T_{1M}\left(\frac{3\tau_c}{1 + \omega_I^2\tau_c^2} + \frac{7\tau_c}{1 + \omega_s^2\tau_c^2}\right)\right]^{1/6}$$

where C is a physical constant equal to 812 for protons and 601 for phosphorus, ω_I is the nuclear magnetic resonance frequency (rad/s), and ω_s is the electron magnetic resonance frequency at the same field strength. The dipolar correlation time, τ_c, is given by $1/\tau_c = (1/\tau_r) + (1/\tau_s) + (1/\tau_M)$ where τ_r is the rotational correlation time and τ_s is the electron relaxation time.

Both [3] and [4] have an additional term arising from outer sphere relaxation. A contribution from this term, $1/T_{1,os}$, to T_{1p}^{-1} must be known before distances can be calculated using [5]. Comparison of the T_1 values for the *N*-ethyl morpholine proton resonances in a pure NADP solution with those measured for *N*-ethyl morpholine in a solution containing 1.0 μM Mn(II) ions gave a value of $1/T_{1p}$ for these resonances of about 0.05 s^{-1}. As *N*-ethyl morpholine complexes very weakly with Mn(II) ions (22), this value may be regarded as an upper limit on $1/T_{1,os}$ for the NADP protons. A comparison of this number with $1/T_{1p}$ for the NADP protons under the same conditions shows that outer sphere relaxation will not significantly affect any of the distances calculated from $1/T_{1p}$.

In a recent article, Koenig (23) has presented a novel derivation of the Solomon–Bloembergen equations and points out the difficulties involved in deriving reliable values for the number of water molecules bound to the Mn(II) ion in Mn(II)–protein complexes. However, in the present study, we are not concerned with the number of water molecules in the Mn(II)–NADP complex, as we have an independent method for obtaining a value of τ_c.

Results

A typical proton magnetic resonance spectrum for the aromatic and anomeric protons of NADP is shown in the top half of Fig. 2. The proton assignments are based on the work of Jardetzky and Wade-Jardetzky (1). However, there are different assignments, depending on the experimental conditions, in the literature concerning the adenine A1′ and the nicotinamide N1′ anomeric protons (1, 5, 24). We

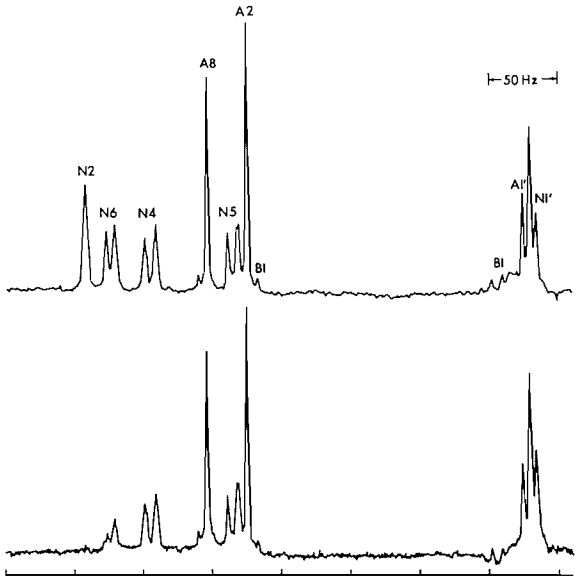

FIG. 2. The results of the nuclear Overhauser effect experiments on NADP. The aromatic nicotinamide (labelled N) and adenosine (labelled A) proton resonances as well as the anomeric proton resonances are shown. The top spectrum was obtained before irradiation, while for the bottom spectrum the irradiation frequency is centred on the N2 resonance. Peaks labelled B1 are images of the buffer peaks occurring at 1.1 and 2.4 ppm to low field of TMS. The temperature was 304 K.

have assigned these two anomeric protons on the basis of nuclear Overhauser effect (nOe) experiments (Fig. 2, bottom spectrum).

Egan *et al.* (25) observed an nOe of 0.14 for proton N1′ when proton N2 was irradiated, and 0.17 when proton N6 was irradiated in nicotinamide mononucleotide (NMN) at neutral pH and at 35°C. In the present experiments, the saturating irradiation frequency was centred on the N2 proton resonance, but also partially saturated the N6 proton. As was observed for NMN, an increase in intensity of about 30% was observed for the high field singlet of the triplet corresponding to the anomeric protons (an nOe due to both protons N2 and N6). This confirms that the N1′ proton resonance is to high field of the A1′ proton resonance. This assignment has been found to be valid over a very large concentration range of NADP (24). For NAD, the anomeric proton assignments are reversed (1, 5, 24). This suggests that the addition of the 2′-phosphate group, in comparing NAD to NADP, has a deshielding effect on the A1′ proton.

A typical set of proton T_1 inversion recovery spectra are shown in Fig. 3. The results of the T_1 measurements for the metal-free solutions, for NADP solutions containing Mn(II) ions, and for the calculated T_{1M} values obtained using [4], are given in Table 1.

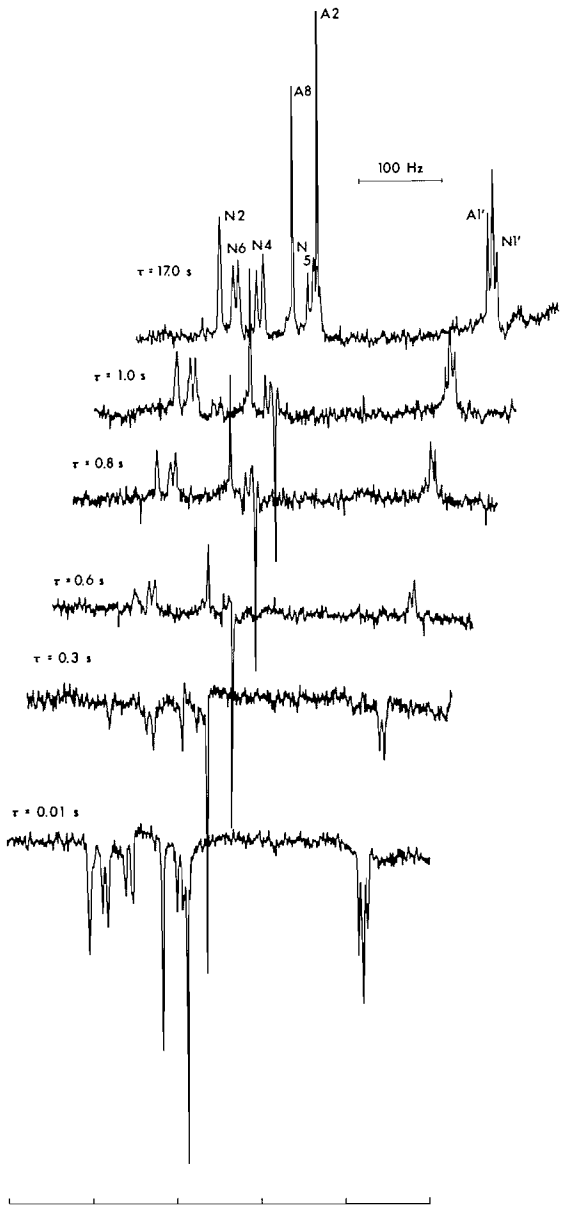

FIG. 3. Proton longitudinal relaxation time inversion recovery spectra for pure NADP (aromatic and anomeric proton region) at 20°C. Each spectrum consists of 50 pulse sequences.

The experimental ^{31}P, $T_{1,Mn}$ and $T_{1,0}$ data, together with the calculated T_{1M} values, are listed in Table 2. A plot of ln $1/fT_{2p}$ vs. $1/T$, based on ^{31}P linewidth measurements, is shown in Fig. 4. The fT_{2p} results for the ^{31}P nuclei are in the slow exchange limit ($\tau_M > T_{1M}$) and the lifetime τ_M for the metal ion in the complex is equal to $4.0 \pm 0.5 \times 10^{-6}$ s for all three phosphate groups. In addition, the enthalpy of activation $\Delta H^{\ddagger} = 13.7$ kcal/mol.

In order to use [5] to calculate the distances between the Mn(II) ion and the individual proton and

[a]The T_{1M} values are multiplied by 10^4. The temperature is 20°C. A total of eight separate samples were prepared and many of them were run twice.
[b]The standard deviation in T_{1M} is designated by σ.

^{31}P nuclei for which the relaxation times due to the paramagnetic metal ion were measured (Tables 1 and 2), the fast exchange limit for fT_{1p} must be applicable, i.e., $T_{1M} > \tau_M$, at 20°C. For the ^1H data, this was shown to be valid from a study of the temperature dependence of proton fT_{1p} values (26). In fact, at 20°C the adenine A8 proton has the greatest contribution from τ_M to T_{1M}. A comparison of the magnitudes of fT_{1p} ($=T_{1M} + \tau_M$) for this proton at 20°C ($T_{1M} = 2.25 \times 10^{-5}$ s) (Table 1) with the value for τ_M of 4×10^{-6} s obtained from the ^{31}P data, shows that τ_M is less than 20% of the value of fT_{1p} at 20°C.

[a]T_{1M} values are multiplied by 10^5.
[b]Samples 1, 3, and 5 were measured at 146 MHz at 25°C; samples 2 and 4 were obtained at 110 MHz at 28°C.
[c]T_{1M} values are calculated using the blank value of $T_{1,0}$ obtained at the same frequency as $T_{1,Mn}$.

For the ^{31}P fT_{1p} data, a comparison of the results in Table 2 with the $1/fT_{2p}$ data in Fig. 4 indicates that, for all three ^{31}P nuclei, the ratio of $1/fT_{2p}$ to $1/fT_{1p}$ is greater than 13, i.e., $(T_{1M} + \tau_M)/\tau_M > 13$ and therefore τ_M is less than 10% of $1/fT_{1p}$. Although the ^{31}P fT_{2p} values are in the slow exchange region, the fT_{1p} values are in the fast exchange region. Hence [5] can readily be applied to the ^1H and ^{31}P fT_{1p} data to calculate r.

In using [5], a value for the dipolar correlation time τ_c must be known. Assuming that $\tau_c = \tau_r$, this was accomplished by comparing our T_1 data for NADP under the present experimental conditions (0.005 M NADP, pD 7.9, 20°C) with the T_1 data obtained by Zens *et al.* (6, 27) (Table 3) for NAD (0.005 M NAD in phosphate buffer, pD 7.0, 5°C). Zens *et al.* (6) measured the τ_c equal to 2.8×10^{-10} s for NAD. Assuming that the predominant intramolecular relaxation mechanism is dipolar, then $T_1 \propto 1/\tau_c$, and the ratio of the T_1 data allows us to calculate a value for τ_c for NADP since the structures

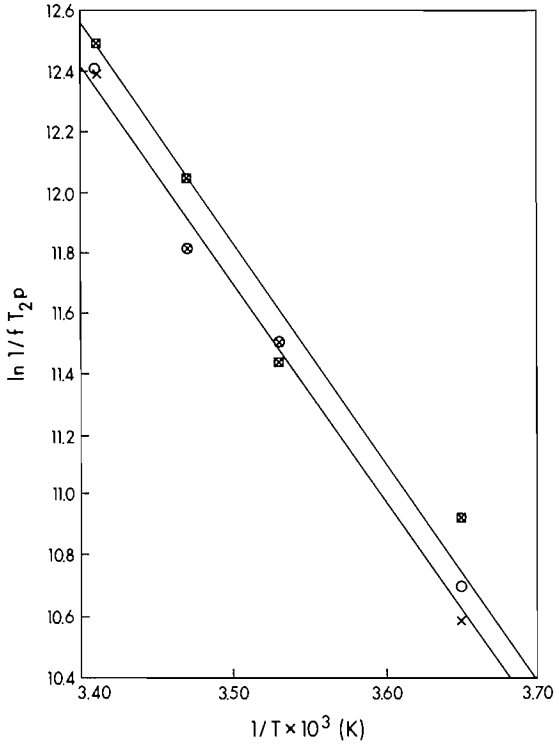

FIG. 4. A plot of the transverse relaxation rate ln $1/fT_{2p}$ vs. $1/T$ for the ^{31}P nuclei of NADP in the Mn(II)–NADP complex. The linewidth measurements were carried out on samples 2 and 4 (Table 4). The symbols represent the ^{31}P nuclei as follows: (⊠) ribose 2′-phosphorus; (○) low field diphosphate ^{31}P; (×) high field diphosphate ^{31}P.

of NADP and NAD are very similar. The results of these calculations are given in Table 3. For six of the eight protons which may be compared, $T_{1,NADP}/T_{1,NAD} \simeq 1.7$; hence $\tau_{c,NADP}/\tau_{c,NAD} = 0.60$ and τ_c for 0.005 M NADP at 20°C is then $0.60 \times 2.8 \times 10^{-10}$ s $= 1.7 \times 10^{-10}$ s. The ratio of 1.7 arises mainly from the fact that the experiments were carried out at two temperatures. Since τ_M is 4×10^{-6} s and τ_s is about 10^{-9} s (21), the short value of τ_c is dominated by τ_r as the other two correlation times are much longer, i.e., $\tau_c = \tau_r$.

The smaller $T_{1,NADP}/T_{1,NAD}$ ratios for the A8 and A1′ protons are likely due to the fact that NADP contains the PO_3^{2-} group at the adenosine ribose 2′-position, whereas in NAD this group is not present. The ^{31}P nucleus is expected to decrease the relaxation times of these two protons.

The temperature dependence of the dipolar correlation time τ_c is given by

$$[6] \quad \tau_c = \tau_0 \exp(-E_a/RT)$$

where E_a is the activation energy corresponding to the rotational correlation time (τ_r). For $T_1 \propto 1/\tau_c$, the above equation can be rearranged into the form

$$T_{1,a} = T_{1,b} \exp(E_a/R[1/T_b - 1/T_a])$$

where $T_{1,a}$ is the longitudinal relaxation time at temperature T_a, and $T_{1,b}$ is the relaxation time at temperature T_b. T_1 data for NADP were obtained at 20 and 30°C (Table 3) and these have been used to estimate a value for E_a equal to 4.9 ± 0.4 kcal/mol. This is in very good agreement with the value of 4.6 ± 0.3 kcal/mol obtained by Zens *et al.* (27) for NAD, and lends further support to our approach for calculating the correlation time. The value for τ_r is not expected to vary significantly between free NADP and the metal complex.

Alternative methods of calculating the correlation time for the complex such as using the T_{1M}/T_{2M} ratio or the frequency dependence of the ^{31}P T_{1M} data proved unsatisfactory. The former method proved unreliable for protons because accurate measurements of the proton linewidths could not be obtained due to signal overlap and a poor signal to noise ratio, especially in the presence of Mn(II) ions. T_{1M}/T_{2M} ratios for the ^{31}P data were not used because fT_{2p} values are in the slow exchange limit. The latter method proved unsatisfactory because of the inconsistency of the calculated τ_c values since the experiments were performed in two different laboratories. The calculated r values are not as sensitive to the variation of the T_{1M} data since they depend on the sixth root of T_{1M} and τ_c.

Using a value of 1.7×10^{-10} s for the correlation time and $F(\tau_c)$ at 100 MHz of 5.0×10^{-10} s^{-1} (20°C), the Mn(II) ion distances to the adenosine (A) and the nicotinamide (N) protons were calculated using [5] and are given in Table 4. From the table it is seen that all the distances to the adenosine moiety are shorter than those to the nicotinamide moiety. The error limits in the distance based on the standard deviation in T_{1M} are smaller than the 10% error limits that are quoted. The 10% error limits in r are based on a theoretical and experimental error analysis carried out by Mildvan (28). If τ_M contributes to fT_{1p}, then r (calculated) is greater than r (actual) by 0.1 Å. This is much smaller than the quoted error limits. The fact that the values of T_{1M} vary between each experiment for a given proton is due to the fact that the experiments were carried out on 0.005 M NADP solutions, and it was not always easy, working at such low concentrations, to obtain the optimum signal to noise ratio. In addition, when Mn(II) ions are added and the lines broaden, the overlap of resonances is more serious. This is the main reason for the range of T_{1M} values in Table 1. However, many experiments with a wide range of metal ion concentrations were carried out to reduce our standard deviation for T_{1M} for each proton.

The distance calculations based on the ^{31}P data

in Table 2 are given in Table 5. For the data at 110 MHz, τ_c equals 1.4×10^{-10} s at 28°C and $F(\tau_c) = 4.0 \times 10^{-10}\ s^{-1}$. For the 146 MHz data, obtained at 25°C, $\tau_c = 1.5 \times 10^{-10}$ s and $F(\tau_c) = 4.4 \times 10^{-10}\ s^{-1}$. These correlation times were obtained at the two temperatures using [6] and are slightly shorter due to the higher temperatures used for these experiments. The binding constant as a function of temperature was determined in our previous study (13) for the Mn(II)–NADP complex, so that the ratio f_M was determined also at both temperatures for use in [4]. The Mn(II) ion to ^{31}P distances were then calculated using [5].

In order to assess the effect of metal ion binding on the NADP conformation, and to compare this conformation with that of free NADP, proton chemical shifts of 0.003 *M* NADP in the absence and presence of Mg(II) ions at a concentration of 0.006 *M* were obtained. Maloney and Dennis (10) observed that the ratio of stability constants for the Mg(II)–NADP complex to that for the Mn(II)–NADP complex is $430\ M^{-1}/760\ M^{-1} = 0.56$. By applying this ratio of stability constants to our experimental conditions, about 1/2 of the NADP should be complexed in the presence of Mg(II). However, shifts greater than 0.5 Hz were not observed.

TABLE 4. T_{1M} values and calculated Mn(II)—proton distances for Mn(II)–NADP

[b]The correlation time τ_c equals 1.4×10^{-10} s at 28°C.
[c]The correlation time τ_c equals 1.5×10^{-10} s at 25°C.

Discussion

The previously measured value of $K_s = 370 \pm 50\ M^{-1}$ (13) for the first stability constant is used for the interpretation of the nmr relaxation time data since the nmr samples were prepared with essentially the same Cl^- ion concentration as was used in the previous epr study.

From the structure of NADP, the two *primary* metal ion binding sites per NADP can readily be located. These are the oxygen atoms of the diphosphate linkage and the oxygen atoms of the 2′-phosphate group. Distinct primary binding sites at either the nicotinamide C=O oxygen or with the adenine N7 nitrogen are unlikely, as these would normally act as secondary binding sites compared with the phosphate oxygens. Under the experimental conditions required for the nmr relaxation time measurements, [Mn(II)] ≪ [NADP], we postulate that for these low Mn(II) ion concentrations, one Mn(II) ion binds simultaneously to the oxygens of both the 2′-phosphate group and the diphosphate linkage. From an examination of molecular models, this is possible if the adenine ribose is in the 2′-*endo* conformation in the complex. This conclusion is also further supported by the ^{31}P nmr relaxation time data. The measurements carried out at 110 and

146 MHz indicate that the Mn(II) ion is between 3.3 and 3.8 Å from all three phosphorus nuclei, and is slightly closer to the ribose phosphorus than to the linkage phosphates. Finally, the data in Fig. 4 show equal exchange lifetimes, τ_M, for the three phosphorus nuclei. These results all indicate the presence of one metal ion in the Mn(II)–NADP complex which binds with the oxygens of the three phosphate groups.

In view of these results, the ^1H distances in Table 4 together with the Mn(II) to ^{31}P distances in Table 5 may now be analyzed. The Mn(II) to the N4 (6.2 Å) and to the N1′ (5.7 Å) distances are independent of the *syn–anti* ratio of the nicotinamide ring and these two distances can be used to place the Mn(II) ion about 4.5 Å from the ring centre. The Mn(II)—N2 and the Mn(II)—N(6) distances are equal (5.3–5.4 Å) and, together with the distance to N5, place the vector from the centre of the ring to the Mn(II) ion within $\pm 30°$ of the normal to the ring plane; i.e., the Mn(II) ion is located more or less directly above the plane of the ring. According to these data, the *syn* or *anti* conformation for the nicotinamide ring is possible.

All of the adenosine protons are closer to the Mn(II) ion (Mn(II)—A8 = 3.8 Å, Mn(II)—A2 = 5.0 Å, and Mn(II)—A1′ = 4.5 Å) than are the nicotinamide mononucleotide protons. This result is not surprising, considering the presence of the positive charge on the nicotinamide ring and the presence of the 2′-phosphate on the adenine ribose to which the Mn(II) ion also binds.

The adenine A8 and A1′ proton distances can be used to locate the metal ion. However, the distance of 5.0 Å to A2 is too short. This can be explained in terms of the 90% *anti*,10% *syn* ratio for NADP as has been observed for NAD in considering the adenine-ribose glycosidic linkage (6, 27). The distance that is measured is an average value $\langle 1/r^6 \rangle$. Hence, if for the *syn* conformation the A2 proton is 3.5–4 Å away from the metal, and in the *anti* conformation it is greater than 5 Å away, a value of 5 Å will still be observed, since the average value will be heavily weighted by the shorter distance. A similar calculation for A8 will change the distance by less than 0.1 Å.

The calculated Mn(II) to ^{31}P distances (Table 5) are 3.3 ± 0.3 Å to the 2′-ribose ^{31}P nucleus and 3.6 to 3.8 ± 0.4 Å to the linkage ^{31}P nuclei. As X-ray and other data indicate that these distances should be near 3.0 Å for inner sphere complexes (29, 30), the present Mn(II) to ^{31}P distances are interpreted in terms of a distorted inner sphere complex (29). This could arise from the simultaneous coordination of the Mn(II) ion by the diphosphate as well as by the ribose phosphate oxygens. Secondly, as discussed by Sloan *et al.* (31), if a rapid equilibrium between inner sphere and second sphere complexes were present, a time-averaged distance would be observed. At present, these two possibilities cannot be distinguished, but the distorted inner sphere complex is favored.

Blumenstein and Raftery (32) tentatively assigned the high field of the AB quartet to the linkage phosphorus resonance corresponding to the ^{31}P nucleus nearest the adenine base. These ^{31}P to Mn(II) ion distances, together with the Mn(II)–proton distances, allow us to consider the conformation of the Mn(II)–NADP complex. First of all, the Mn(II) ion sits in a pocket between the three phosphate groups and is bound to one oxygen from each of the linkage phosphates and to one, or two, of the ribose phosphate oxygens. The adenine ring is above the plane formed by the three phosphorus atoms and is tilted over this plane. The centre of the nicotinamide ring is about 4.5 Å from the Mn(II) ion. Since the nicotinamide ring can move in an arc with respect to the phosphate-bound Mn(II) ion, a family of conformations where both rings are parallel to each other and about 7–8 Å apart, to a conformation where the nicotinamide ring is roughly perpendicular to the adenine ring, and close to it, is possible. The former conformation is shown in Fig. 5. Hence, for the Mn(II)–NADP complex, we conclude that there is essentially no close stacking of the two rings in NADP. This is in agreement with the conclusions of Zens *et al.* (6) who concluded, based on the effects of deuteration on the proton T_1 values, that the two rings in free NAD are at least 4.5 Å apart. Even though distances are being measured for a molecule which is thought to exist in an equilibrium of folded and extended forms (1, 3), our results are not consistent with the presence of an equilibrium involving a folded form with closely stacked rings unless the folded form exists for only a short fraction of the time. Consequently, there appears to be no significant stacking of the two rings in the complex.

Finally, a comparison is drawn between the NADP conformation in the complex with that of free NADP in solution. In uncomplexed NADP, both aromatic rings may be in either the *syn* or *anti* conformation with respect to their contiguous ribose groups. Zens *et al.* (6) summarize the results of the experiments carried out on NAD (at 5°C) and find that the components within NAD behave in a manner analogous to 5′-AMP and NMN. Both the nicotinamide and adenine rings have a significant amount of flexibility about the glycosidic bond. Their results indicate that the adenine ring is about 92% in the *anti* conformation in the two-state microdynamic model. With regard to the pyridyl-ribose glycosidic linkage, nearly equal populations have been measured by Zens *et al.*

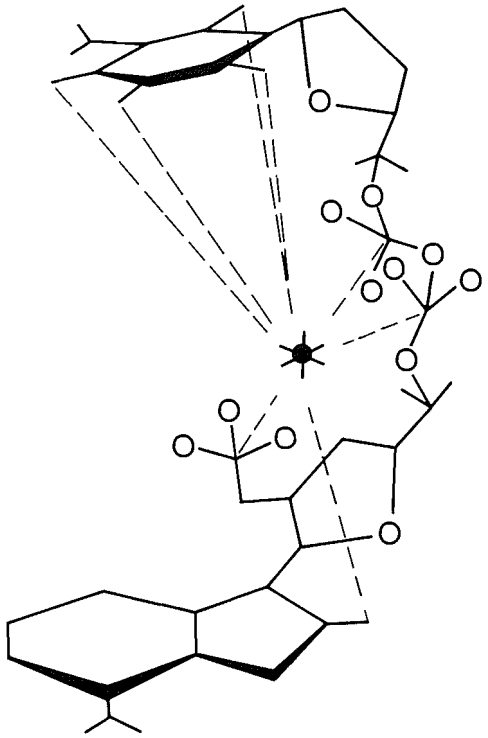

FIG. 5. The solution conformation of the Mn(II)–NADP complex. The nicotinamide ring may move in an arc perpendicular to the plane of the paper.

(27), whereas Sarma and Mynott (24) estimate that the nicotinamide ring is predominantly *syn* in NAD. In NMN, Egan *et al.* (25) observed nearly equal populations of the *syn* and *anti* conformers with a slight preference for the *anti*. Finally, Thornton and Bayley (33) have carried out conformational energy calculations on NAD. Two of their main conclusions are as follows. (*a*) *In vacuo*, the most stable structures exhibit *either* stacking interactions between the two rings *or* electrostatic interactions between the positive charge on the nicotinamide and the negatively charged pyrophosphate backbone. This latter interaction has been observed previously (32). (*b*) A variety of different conformations are observed for the electrostatically stabilized structures which are relatively extended compared to the stacked states.

As mentioned in the Results, binding of Mg(II) ions to NADP did not change the proton chemical shifts by more than 0.5 Hz. However, proton chemical shifts for the adenine and nicotinamide protons of 0.1–0.3 ppm to high field relative to those observed for NMN, 5′-AMP, and adenosine diphosphoribose have been observed (1, 24) and indicate the presence of intramolecular ring current diamagnetic shielding in the coenzyme with respect to its constituents. The absence of a change in the chemical shifts of the protons in the present experiment for the Mg(II)–NADP complex indicates no differences in shielding effects. Hence the rings probably have the same time-averaged spatial relationship both in the metal ion complex and in free NADP in solution. As the complete ribose spectrum could not be examined at 100 MHz, conclusions cannot be drawn with respect to changes in the conformation of the remainder of the molecule on Mg(II) ion binding.

JOHN W. BOVENKAMP, EDWARD J. LANGSTAFF, ROBERT Y. MOIR, and ROBERT A. B. BANNARD. Can. J. Chem. **57**, 2444 (1979).

Two methods, one more accurate, the other more convenient, were developed by which the dilatometer could be used with concurrent reactions of the second and third order. The more accurate method, employing a dilatometer of high specific surface area and equipped with a stable and responsive thermometer, was used in studying as many as six simultaneous oxirane scissions in acid solution. Interlocking double comparisons were made between cyclohexane and cyclopentane ring systems, between systems possessing or lacking a methoxyl substituent and between others having the substituent in varying orientations, between charged and uncharged nucleophiles, and between transition states of different degrees of protonation. Searching experimental checks were therefore possible in four main areas: (*i*) a quantitative dissection of the inductive effect from steric and conformational effects, and from dipole–ion or dipole–dipole interactions with the nucleophile, (*ii*) a quantitative demonstration of three main differences between transition states based on 5- and 6-membered rings, (*iii*) a proof that *syn*-1,3-effects in the transition states are very charge dependent, being large and positive with unfavourably arranged dipoles, and small or perhaps negative with favourable arrangements, and (*iv*) a rejection of certain proposed ion-pair alternatives to the A2 mechanism.

JOHN W. BOVENKAMP, EDWARD J. LANGSTAFF, ROBERT Y. MOIR et ROBERT A. B. BANNARD. Can. J. Chem. **57**, 2444 (1979).

On a développé deux méthodes, l'une précise et l'autre plus commode, faisant appel à un dilatomètre pour étudier des réactions concurrentes du deuxième et du troisième ordre; la méthode la plus précise, qui fait appel à un dilatomètre à grande surface spécifique équipé d'un thermomètre stable et sensible a été utilisée pour étudier jusqu'à 6 réactions de scissions simultanées d'oxiranne en solution acide. On a fait des comparaisons de recouvrement double entre les systèmes cyclopentanique et cyclohexanique, entre des systèmes avec ou sans substituants méthoxyles, entre d'autres systèmes portant le substituant dans diverses orientations entre des nucléophiles chargés ou non et entre des états de transition à divers degrés de protonation. Il a été possible de faire des vérifications expérimentales dans quatre domaines principaux; (*i*) une dissection quantitative entre l'effet inductif et les effets stériques et conformationnels ou les interactions dipole–ion ou dipole–dipole avec le nucléophile, (*ii*) une démonstration quantitative de trois différences principales entre les états de transition portés par des cycles à 5 et à 6 chaînons, (*iii*) une preuve que les effets *syn*-1,3, dans les états de transition dépendent beaucoup sur la charge; les effets étant importants et positifs lorsque les dipoles sont dans un arrangement non favorable et petits ou peut être négatifs lorsque les arrangements sont favorables et (*iv*) un rejet de certaines paires d'ions proposées comme alternative au mécanisme A2.

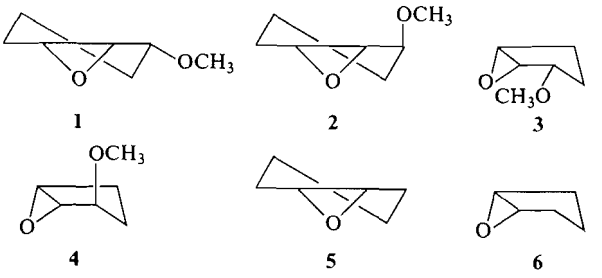
Introduction

Theories of oxirane scission (1, 2) attempt explanations in terms of polar, steric, and conformational effects. In the previous paper (3), a method was proposed which led to the recognition and measurement of certain polar effects in a particularly simple way. The simultaneous attack of two nucleophiles, under rigidly standardized conditions, was observed for each of the oxiranes **1** to **6**, and the relative yields of the products accurately measured. A simple double comparison technique (4) was then used to show that the rate of scission was very dependent both on the relative charge of nucleophile

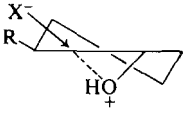
[1]Present address: Defence Research Establishment Ottawa, Ottawa, Ont., Canada K1A 0Z4.

0008-4042/79/182444-14$01.00/0



and substituent and on their orientation to each other in the transition state.[2] Surprisingly far reaching implications arose from these experiments. They suggested a dissection of the inductive effect and a method of attack upon the conformational parameters, both of which are continued in the present paper. Presumably they will bring about a reversal in current opinion as to the importance of charge effects in the formation of bridged intermediates during the reactions of olefins (6).

In our view, the concept of inductive effect should be separated from substituent–nucleophile interactions such as those discussed above. However, it has not been easy to separate polar effects from steric and conformational effects. Many years ago (7) it was suggested that **2** was preferentially attacked by nucleophiles at the position more remote from methoxyl because of the more unfavourable inductive effect at the nearer position. This view is now generally accepted (1, 2, 5, 8) but alternative explanations are still being offered (9). For example, it has been supposed that nucleophile, oxirane carbon, and leaving oxirane oxygen are nearly colinear in an oxirane-like transition state (see diagram below; contrary to the standard *trans*-diaxial picture), and that therefore steric interference occurs with the substituent in attack upon the nearer position of **2**, but not for that at the position more remote from methoxyl.[3] However, the idea fails completely to explain the similar results for the corresponding *cis*-oxirane **1**, as indeed had already been pointed out (7).



[2]The effect has been observed qualitatively, for a particular orientation of positive pyridinium and negative bromine, in a somewhat similar reaction (5).

[3]Three-dimensional models show that in **2**, anything resembling colinear attack at the oxirane position nearer the substituent is physically impossible. Colinear attack at the more remote position is not consistent with the very large charge effects observed (3). The transition states are in fact product-like rather than reactant-like (3, 10).

A similar lack of consistency applies to the suggestion (11) that the inhibition at the nearer position could be explained by conformational factors.[4] However, it was obviously imperative to provide a convincing and quantitative dissection of the inductive effect. In the present work, this was done in several ways, perhaps most directly in the comparison of pairs of compounds in which each member of a pair possessed exactly the same steric configuration, but a different positional structure, with respect to its partner. In the interval, Berti and his co-workers (9, 12) have described a most elegant solution to the problem. In the 3,4-epoxytetrahydropyrans, the ring oxygen has the same relation to the oxirane function as does the methoxyl oxygen in **1** to **4** but the steric effects are much smaller. Although the resulting dissection of the inductive effect differs from ours in important respects, there is no doubt that this is a most promising approach.[5]

In the previous work (3), an A2 mechanism was assumed for acid-catalyzed oxirane scission (13). In only a few instances (for example refs. 14 and 15 and the present work) has the third-order kinetics, required for the mechanism, been demonstrated. Indeed, the A1 mechanism has been frequently proposed in its place, and as frequently rejected (16). Recently (17), a more formidable challenge has appeared in the proposal of certain ion-pair mechanisms. Doubts have been expressed in regard to these (9, 18) and in the present work it is demonstrated that the A2 mechanism is still clearly preferable.

Second- and third-order differences form the basis of the present and the previous work (3). The importance of experimental accuracy cannot therefore be too strongly emphasized. In the gas–liquid chromatographic analysis, for example, "constant" errors due to nonlinearity in the detector and to baseline effects are much larger than the random errors which alone are reported in contemporary papers on mechanism. In our work (3), standard

[4]The suggestions arose from valid explanations offered for the 3-*tert*-butylcyclohexene oxides. However, substituent methoxyl lacks the size necessary either to impose the twist-boat conformation or to provide the steric blockage required in the explanations. Unpublished work (R. C. Cathcart and R. Y. Moir) shows how the chair and twist-boat conformations in the transition states may be distinguished.

[5]The value deduced for the inductive effect is less than half that calculated in the present work. In the tetrahydropyran work, effects caused by (*i*) the nucleophile-oxygen interactions and by (*ii*) the (field) effect due to the fact that the more remote oxirane position is much closer to the ring oxygen of the tetrahydropyrans than it is to the functionally similar methoxyl group in **1** to **4** are neglected. The relation of the nearer oxirane position to the electron withdrawing oxygen is the same in both series.

TABLE 1. Rate constants for the attack of charged and uncharged nucleophiles upon related oxiranes in acid solution[a,b]

Oxirane (and point of attack)[c]	Acid added	Initial molarity of acid	Apparent rate constant for attack at a single centre by: Chloride ($L^2 mol^{-2} min^{-1}$)	Methanol ($L mol^{-1} min^{-1}$)	Water ($L mol^{-1} min^{-1}$)
		Cyclohexane series

	HCl	0.15[h,i]	0.0224	0.00184	0.00184
Position 2[d]	$HClO_4$	0.15	—	9.78×10^{-5}	6.78×10^{-5}
	HCl	0.15	0.00180	9.78×10^{-5}	6.78×10^{-5}
Unsubstituted **6**[j]	$HClO_4$	0.015	—	0.0583	0.0521
(at a single centre)[k]	HCl	0.015	0.405	0.0576	0.0515

[a]The initial concentration of oxirane was 0.06 *M* and the initial ionic strength was adjusted to 0.215 *M* with sodium perchlorate. All reactions were carried out at 2.43°C in 50 wt.% aqueous methanol.
[b]Corrected results from the multi-tube dilatometers gave the composite rate constants k_N (for attack by chloride) and k_s (for attack by methanol and water). The individual rate constants were then calculated from the analysis of the reaction mixtures (3).
[c]Position 1 is the oxirane carbon more remote from methoxyl.
[d]Observed simultaneously with the corresponding attack at position 1.
[e]These solutions were 0.035 *M* in added sodium chloride.
[f]The temperature–time graph had the same form as that of the next entry.
[g]The temperature–time graph was assumed to be the same as the average graph for the corresponding perchloric acid system.
[h]k_s was assumed to be equal to that for the corresponding perchloric acid systems. The mixture was kept at reaction temperature for 9 days.
[i]k_s was assumed to be equal to that for the corresponding perchloric acid systems. The mixture was kept at reaction temperature for 7 days.
[j]One of 14 rate experiments employing $HClO_4$ was rejected, the rest showing, in six groups, an average standard deviation of the mean of 0.72% in k_s. Two of 19 experiments in which HCl was used were rejected, the rest showing, in 7 groups, a corresponding error figure of 0.46% in k_N and of 0.76% in k_s. At least 56% of the reaction (as judged by the acidity) was used for the direct measurement of k_N, 70–80% being usual.
[k]Experimental rate constants for oxiranes 5 and 6 were twice those reported in the table.

samples were therefore adjusted to have as nearly as possible the *same* composition as each unknown, and the success of the corrections was demonstrated by two independent methods of analysis. Similarly, although in the present work, good reproducibility in rate measurements (Table 1) has been obtained, more attention has been paid to those errors which, constant for any one reaction, increase rapidly with the rate of reaction, and which are almost totally neglected in current work. Our purpose was to ensure and to demonstrate the reliability of the values of the second- and third-order differences derived from the rate constants (Tables 2 and 3). In so doing a method for employing the dilatometer in reactions of higher order has been developed that hopefully will be of general interest and utility.

Comparison of the rates of scission of an oxirane by different nucleophiles under exactly the same conditions was, in brief, our whole method. It was therefore necessary to solve the general kinetic problem of simultaneous reactions which separately were of the second and third order (3) (by numerical integrations). Experimentally it was necessary to demonstrate that the method of solution was unaffected by extraneous sources of curvature in the rate plot. For example, ionic strengths varied slightly

TABLE 2. Effects of neighbouring methoxyl upon the rates of scission and formation of cyclohexane oxiranes[a]

Example	Oxirane	Related chlorohydrin[b]	Related transition state[c]	$\Delta^2F_s^{\ddagger d}$ (for scission)	$\Delta_s^{3\ddagger}$	$\Delta^2F_f^{\ddagger d,e}$ (for formation)	$\Delta_f^{3\ddagger}$	$(\Delta^2F_s^{\ddagger} - \Delta^2F_f^{\ddagger})$
1	*Cis*[f]			1.05	3.21	−0.76	2.68	1.81
	1	7						
2	*Trans*[g]			4.26	1.37	1.92		2.34
	2	8

	2	9						
4	*Cis*[g]			(>4)[h]		3.96		
	1	10						

[a]All numerical values are given in kcal/mol.
[b]The chlorohydrin was either formed from the epoxide in "acid-catalyzed" scission by chloride ion, or was converted to the same oxirane by base. For clarity in exposition different enantiomers of the oxiranes have been used in illustrating different reactions.
[c]Shown for the "acid-catalyzed" scissions, symbols for electric charge being omitted. For the corresponding formation reactions, —OH in these transition states is replaced by $—O^-$.
[d]$\Delta F^{\ddagger}$ for the reaction related to the indicated oxirane *minus* $\Delta F^{\ddagger}$ for that related to cyclohexene oxide. See [1] and [2].
[e]Values given were obtained by extrapolation of the experimental values from 20–2.43°C by the Arrhenius equation, and from 44–50 wt.% methanol by assuming that all free energies of activation suffered the same net change. By experiment, $\Delta F_f^{\ddagger}$ for compound 7 decreased by 7.5% when the solvent was changed from 87–44 wt.% methanol, whereas $\Delta F_f^{\ddagger}$ for cyclohexene chlorohydrin decreased by 7.6% on the same change of solvent.
[f]This example corresponds to attack at position 1 of the oxirane (that more remote from methoxyl), as in Table 1.
[g]Attack at position 2 of the oxirane.
[h]Reaction too slow to be observed.

during each reaction, and the constraints of the problem (3) did not allow us to swamp out the resulting effects completely. A large amount of experimental work was required to measure the effects of this variation upon the rate constants, and was justified less by its estimate of this very small quantity[6] than by the demonstration that the rate constants could be extracted without difficulty in the presence of this extraneous source of curvature. The same work was used in the comparison of two methods for compensation of temperature errors.

Oxirane scissions are exothermic, and the resulting rise in temperature may produce three main errors. With care, the first error, the direct effect upon the rate constant itself, is negligible (19). The second, larger error, here called the Tong–Olson effect (20), is discussed below. The third error applies especially to the dilatometry of concurrent reactions of different order. For these reactions (unlike first-order reactions) one must know the chemical sensitivity for each of the reaction orders involved and, in our method, one of these sensitivities must be obtained from a related first-order reaction. In such reactions, even when the Tong–Olson effect upon the rate constant is only 2–3%, the sensitivity, uncorrected for temperature rise, is commonly in error by more than 100%. Even though the resulting error in the rate constants is less by an order of magnitude, it is clear that corrections must be applied and verified. The agreement of two different methods of temperature compensation, one based on direct measurement and the other on the form of the observed capillary height – time curve, therefore completed our demonstration of the utility of the dilatometer in reactions of higher order.

Our work also applies to the use of the dilatometer in first-order reactions. Most workers appear to believe that the temperature effect is transient, its

[6]Fixed errors due to the neglect of activity coefficients in Table 1 cancelled essentially exactly for solvent, catalyst, and nucleophile, and perhaps largely for substrate, in the comparisons of Tables 2 and 3.

TABLE 3. Effect of neighbouring methoxyl on the rates of scission and formation of cyclopentane oxiranes[a]

Example	Oxirane	Related chlorohydrin[b]	Related transition state[c]	$\Delta^2F_s^{\ddagger d}$ $\Delta_s^{3\ddagger}$ (for scission)	$\Delta^2F_f^{\ddagger d,e}$ $\Delta_f^{3\ddagger}$ (for formation)	$(\Delta^2F_s^{\ddagger} - \Delta^2F_f^{\ddagger})$
1	*Cis*[f]			1.59	−0.08	1.67
	3	**11**			3.13	
2	*Trans*[g]			(>5.5)[h]	3.05	—
	4	**12**				
3	*Trans*[f]			2.47	0.95	1.52
	4	**13**		0.50	0.85	
4	*Cis*[g,h]			2.97	1.80	1.17
	3	**14**				

[a,b,c]As in Table 2.

[d]$\Delta F^{\ddagger}$ for the reaction related to the indicated oxirane *minus* $\Delta F^{\ddagger}$ for that related to cyclopentene oxide.

[e]Values given were obtained by extrapolation of the experimental values from 14.91–2.43°C, assuming the same change in $\Delta F^{\ddagger}$ as the average change in the cyclohexane series over the same range (acceptable because of the small variation in $\Delta S_f^{\ddagger}$ in the latter) and from 87–50 wt.% methanol by assuming a 5% reduction in $\Delta F_f^{\ddagger}$ for all examples. By experiment, $\Delta F_f^{\ddagger}$ declined by 6.035% for compound **12** and by 6.04% for compound **14**, when the solvent was changed from 87–44 wt.% methanol.

[f,g]As in Table 2.

[h]Interpretation of the drawings of the transition states may be aided by noting: (*i*) A 1,3-*syn*-diaxial-like relation does not exist between methoxyl and hydroxyl in example 4, though one does exist between methoxyl and chlorine in 3. (*ii*) Chlorine is nearly eclipsed by the pseudo-axial methoxyl in example 2. In all other examples, the corresponding relationship of chlorine is with H_y, and since this relation also exists in the reference reaction related to cyclopentene oxide, its primary effects cancel. See text. (*iii*) The degree of eclipsing between hydroxyl and methoxyl in example 1 is less severe than the effect between chlorine and methoxyl in example 2. (*iv*) Although drawn in the twist conformations the transition states are actually distorted to allow a surprisingly great degree of staggering of vicinal groups throughout the structures.

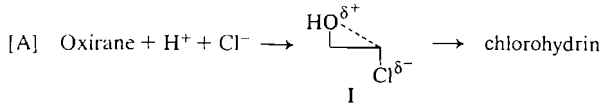
end signified by the onset of a pure first-order law of capillary rise (or fall). Tong and Olson (20) showed instead that temperature and reaction decay together (the source of the third error above), and moreover that the later part of the curve may very closely obey the first-order law and still yield a grossly erroneous rate constant. Simulated rate curves confirm the deceptive nature of this effect. The error is highly reproducible, not appearing in the experimental statistics. Moreover, its onset is sudden.[7,8] All these factors have led to a neglect of the Tong–Olson effect. Indeed, one may say that the resulting large and widespread errors have had a damaging effect on mechanism studies. The necessary temperature corrections may be made either by direct measurement or by Tong–Olson theory. In the latter method, a correction must be applied to their work (see Experimental).

[7]The first-order, corrected Tong–Olson theory agreed well with the observed overall temperature–time curves, though it missed details. Simulations were based on the corrected theory, random numbers being used to imitate the dispersion of the capillary readings. One simulation agreed well with a particular experiment performed in the cylindrical dilatometer (see Experimental); the simulated rate constant obtained from a straight part of the first-order rate plot was in error (with respect to the theoretical input) by only 0.49%, the correlation coefficient being −0.9999. A fourfold increase in the rate constant changed these values to 10.1% and −0.9990 respectively. Such a change could easily have been exceeded, for example, in an attempt to enforce first-order kinetics with excess hydrochloric acid. In a simulation of the faster of these reactions in the multi-tube dilatometer, the error was only 0.14% (in place of 10.1%), and the correlation coefficient −0.9999, showing the immense advantage of a mere doubling of the cooling constant (see Experimental).

[8]The cylindrical dilatometer had a cooling constant about four times better than that thought to be typical of traditional designs (20) which are not reviewed here. Furthermore our reactions were not especially fast. Nevertheless, the maximum temperature rise in the slower of the simulated reactions above was 0.24°C. Clearly, temperature rises of over 1 deg have often occurred in literature studies of the entropies of reaction. The largest maximum temperature rise observed in the multi-tube dilatometer was 0.110°C.

Discussion

Very great simplifications are made possible by the familiar method of double comparison. For the oxirane scission reaction [A],



I

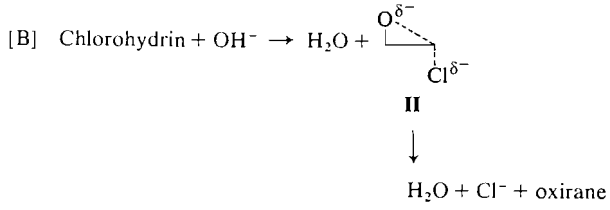
$$\Delta F_s^{\ddagger} = F_s^{\ddagger} - F_{ox}{}^0 - F_{H^+}{}^0 - F_{Cl^-}{}^0$$

(with $F_s^{\ddagger}$ as the standard free energy[9] of **I**), several ground state terms survive in the experimental quantity $\Delta F_s^{\ddagger}$. Some of these are removed by comparing the expression with that for a standard oxirane, so that, from the difference of the two values of $\Delta F_s^{\ddagger}$,

$$[1] \quad \Delta^2 F_s^{\ddagger} = \Delta F_s^{\ddagger} - \Delta F_{s^0}{}^{\ddagger} = (F_s^{\ddagger} - F_{s^0}{}^{\ddagger}) - (F_{ox}{}^0 - F_{ox^0}{}^0)$$

(s^0 and ox^0 refer to *the standard oxirane*). More important is the fact that the oxirane under investigation (e.g., example 1, Table 3, epoxide **3**) shares many characteristics in common with the corresponding standard (**6**). The influence of these characteristics cancels in $\Delta^2 F_s^{\ddagger}$ (see footnote *h* to Table 3).

The usefulness of the quantities $\Delta^2 F_s^{\ddagger}$ is much increased by comparing them with similar quantities derived from the related oxirane formation reactions [B], whose rates we have also measured,



$$[2] \quad \Delta^2 F_f^{\ddagger} = (F_f^{\ddagger} - F_{f^0}{}^{\ddagger}) - (F_{Ch}{}^0 - F_{Ch^0}{}^0)$$

where $F_f^{\ddagger}$ is the standard free energy of the transition state **II** belonging to the particular reaction under investigation, and $F_{Ch^0}{}^0$ is the standard free energy of the reference chlorohydrin (cyclohexene chlorohydrin for the examples in Table 2). The quantity $\Delta^2 F_f^{\ddagger}$ is the direct physical measure of the effect upon the rate of oxirane formation brought about by placing a substituent at a given position and orientation in the parent chlorohydrin. The analogous measure of the effect of a substituent on the rate of "acid-catalyzed" oxirane scission by a given nucleophile is given by $\Delta^2 F_s^{\ddagger}$. Values are listed in Tables 2 and 3.

The cancellation of effects possible in the use of these quantities is often startling. For reaction [B] of example 1 (Table 2), the chlorohydrin **7**, in moving to its transition state, has to be converted from one chair form to another, a process aided by the methoxyl group's change from the axial to the equatorial position. Since the *A* value for methoxyl is known to be 0.77 kcal/mol (21), it is evident from the experimental value for $\Delta^2 F_f^{\ddagger}$ that this conformational effect is the *only* surviving effect of methoxyl in the particular configuration of **7**. Obviously, the increased ease of deprotonation of the hydroxyl group caused by the methoxyl group must have been offset by the decreased nucleophilicity of the oxyanion in **II** due to the same cause. In contrast, both corresponding polar effects would be expected to work together to decrease the rate of the corresponding reaction [A] by which **7** is formed. In agreement with the postulated importance of these factors, it can be seen from $\Delta^2 F_s^{\ddagger}$ (1.05 kcal/mol) (example 1, Table 2) that methoxyl strongly decreases the rate of scission, whereas (from $\Delta^2 F_f^{\ddagger} = -0.76$ kcal/mol) it notably increases the rate of the corresponding formation of oxirane.

An interesting dissection for isolation of the inductive effect is possible. In the comparison of values of $\Delta^2 F^{\ddagger}$ for examples 1 and 2, or for examples 3 and 4 (Table 2), compounds similar in geometry both in the ground state and in the transition state are paired together, so that steric and conformational effects might be expected to cancel. The differences in $\Delta^2 F_f^{\ddagger}$ values might therefore be regarded as a measure of the polar effects of methoxyl upon the developing positive charge at the carbon being attacked by the oxyanion.[10] Confirmation of this analysis is seen in the fact that the two values of $\Delta_f{}^{3\ddagger}$ (2.60 and 2.68 kcal/mol) for the two very different transition state geometries, are in close agreement. Indeed, one may go further. In the previous paper (3), the geometrical orientation of the ring carbon – methoxyl dipole with respect to the C ··· Cl partial bond was shown to have a profound

[9]The Gibbs free energy is represented by *F* in these papers, to avoid confusion with the symbol *G* used for the *gauche* effect.

[10]Both this definition and the method of dissection of the inductive effect exclude a number of dipole–dipole interactions, included later in the conformational parameters. Close examination supports the simplicity of the dissection. For example, ground state hydrogen bonding terms (22) in hydroxylic solvents are thought to be small (3). Similarly, the inductive effect quoted is actually the difference between the effect in a 1,2-chloromethoxy compound and that in a 1,3-compound, but it has been argued (1) that the latter effect is nearly zero.

effect upon the rates of scission. Consideration of this fact together with the transition state geometries of Table 2 shows that the similar values quoted for $\Delta_f^{3\ddagger}$ in the two comparisons cannot be understood unless *the oxyanion and the leaving chloride bear almost equal charges in the transition states leading to the formation of the oxiranes* (reaction [B]). An important point in the analysis is that this is emphatically *not* the case in the corresponding transition states for reactions [A].[11,12]

The existence of a large inductive effect deduced from the base-catalyzed reactions [B] is confirmed in two independent ways. The true reverse reactions of [A] are the solvolysis of the chlorohydrins. In a previous paper (18), a study of the solvolysis of analogues of **8** and **9**, in which chlorine had been replaced by the tosyloxy group, was carried out. In spite of its large conformational advantage, the tosylate corresponding to **8** solvolyzed about 10 times slower than did the isomer corresponding to **9**, evidence for a very large inductive effect involving transition states exactly analogous to **I**. Reactions [A] allowed a more quantitative comparison. Comparison of $\Delta^2F_s^{\ddagger}$ values for examples 1 and 2 (Table 2) gave a value for the inductive effect of 3.21 plus "other effects" (e.g., different starting epoxides). A long and difficult analysis suggested that the sum of the "other effects" was small. This was confirmed by the more accurate comparison of $\Delta^2F_s^{\ddagger}$ values for examples 2 and 3 (Table 2), for which experimental errors are at a minimum[12] and ground state contributions vanish exactly. In this way, the inductive effect was found to be 1.37 plus an amount due to a large conformational effect in the transition state. In this case, the conformational effect could be estimated accurately by a method to be explained in a later paper,[13] giving a value for the inductive effect in the "acid-catalyzed" scissions [A] of 3.0 to 3.2 kcal/mol.

Intuitively one would expect (12) that the inductive effect would be larger in reactions [A] than in [B] because of the greater positive charge expected on oxirane carbon in the transition state of the former. However, the difference cannot be large, on account of the similarity of the ratios of yields of normal and abnormal products in acid- and base-catalyzed scissions in the present system (ref. 24 and this paper). Thus the quantitative separation of the inductive effect from steric and conformational effects is supported both by theory and by experiments made with different ground states and under very different conditions of scission, formation, and solvolysis.

One may use the well defined cyclohexane conformations as references to which the less regular cyclopentanes may be compared. Inspection of Table 1 shows that scission of the cyclohexane oxiranes is usually much faster than that of the corresponding cyclopentane derivatives. This fact has been noticed before (23, 25), and ascribed to the relatively greater increase in eclipsing interactions in going from oxirane to transition state in the cyclopentanes. By referring each oxide to its unsubstituted parent, most of these effects are removed, allowing those that remain to become clearly evident. When this is done, the reasons for the present confusion in the literature on cyclopentane conformations become immediately apparent. At times, the behaviour of the two ring systems can be similar indeed. As shown in the previous paper (3), the response of each ring system to dipole orientations is nearly the same. In the rate experiments, the closest similarity lies in examples 3 (Tables 2 and 3); for these both $\Delta^2F_s^{\ddagger}$ and $\Delta^2F_f^{\ddagger}$ are only slightly lower in value for the cyclopentanes than for the cyclohexanes. In particular, both ring systems show large 1,3-*syn*-like interactions in the transition states for either scission or formation of the oxiranes.

In contrast, there is a large difference in examples 4 of the two series. The quantity $\Delta_f^{3\ddagger}$ for examples 3 and 4 (i.e., from comparing $\Delta^2F_f^{\ddagger}$ for examples 4 and 3) is 2.60 kcal/mol for the cyclohexanes, but only 0.85 kcal/mol for the cyclopentanes. This difference amounts to a numerical verification of the previous conclusion (10) that cyclopentanes of the configuration shown in example 4 (Table 3) are able to avoid *syn*-1,3-like interactions in the transition states, whereas cyclohexane transition states of the same configuration (example 4, Table 2) are not able to avoid them. The reasons for the different behaviour in examples 3 and 4 have been given (10). Still another important source of confusion as to

[11]The dissection does not ignore the difference in ground state free energies between examples 1 and 2 due to the different chemical neighbour of methoxyl in each. Every ground state is compared with the transition state of the same positional structure. In view of footnote 10, the differences which survive the comparison essentially constitute the inductive effect.

[12]The extended comparisons are often aided by a cancellation of experimental errors. Each value quoted for $\Delta_f^{3\ddagger}$ and $\Delta_s^{3\ddagger}$ in the tables involves no more error contributions than those of a single $\Delta^2F_f^{\ddagger}$ or $\Delta^2F_s^{\ddagger}$ value, respectively. In two comparisons of $\Delta^2F_s^{\ddagger}$, namely of examples 2 and 3 in Table 2, and of 1 and 4 of Table 3, the cancellation is more extensive, each comparison involving an error equivalent to that of a single chemical analysis alone. In the least favourable comparison of the paper, the standard deviation is considerably less than that in tables of conformational parameters (23).

[13]Unpublished work with E. J. Langstaff.

the ability of the cyclopentane system to support *syn*-1,3-interactions is described below.

The second major difference between the cyclopentanes and cyclohexanes is illustrated by comparing examples 2 (Tables 2 and 3). Here $\Delta^2F_f^{\ddagger}$ is greater for the cyclopentane compound by 1.13 kcal/mol, and $\Delta^2F_s^{\ddagger}$ by at least 1.2 kcal/mol[14] than for the corresponding quantities in the cyclohexanes. Clearly these effects belong to the transition states, and a source is readily found in the near-eclipsing of chlorine and pseudo-axial methoxyl forced by the geometry of the cyclopentane transition state (10) but not by that of the cyclohexane series. In all the other examples, the corresponding effect is the interaction between chloride and pseudo-axial H_y (cf. example 1, Table 3), and the primary effect of this interaction cancels because of the method of comparison (see footnote *h*, Table 3) in examples 1, 3, and 4 (Table 3). A relatively large secondary effect appears in one of these. For example 1, oxirane formation is less favoured in the cyclopentanes than in the cyclohexanes (Table 2) by 0.68 kcal/mol, as measured by $\Delta^2F_f^{\ddagger}$. Model studies show that attempts to relieve the Cl/H_y interactions in the transition states result in a series of adjustments leading to the appearance of a smaller than normal dihedral angle between the ring carbon – methoxyl bond and the adjacent carbon–oxygen bond. This *extended gauche effect*, the third of the major differences brought to light in the present studies, serves further to emphasize that the relative behaviour of the two ring systems is strongly dependent upon the arrangement of the substituents.

The importance of polar effects in altering the main conformational parameters is made clearest by an approach which also underlines the fact that the dissections of the paper are based upon large and significant differences. Attack of chloride ion upon the *cis*-oxide **1** is (from Table 1) 29.5 times faster than the corresponding attack upon the *trans*-oxide **2**. With methanol as the nucleophile, reaction of the *cis*-oxide is only 3.9 times as fast as that of the *trans*. In other words, chloride ion is 7.6 times more selective than methanol, though it is much the more nucleophilic reagent. Polar effects have clearly upset the literal applicability of Hammond's hypothesis (26), and the influence of unfavourably oriented dipoles (3) is further shown by the fact that in the cyclopentane series, the reaction with methanol is actually slower with the *cis*-oxide **3** than it is with **4**.

[14]Tables 2 and 3 each contain one $\Delta^2F_s^{\ddagger}$ value given as a lower limit, estimated from the sensitivity of the glc method of analysis (3).

In the dissection already made, it has been repeatedly seen that transition state effects evident in reactions [A] appear also in those for reactions [B], experimental support for the intuitive idea that these states (**I** and **II**) differ mainly in the presence of an acidic proton in the former. This idea is easily made quantitative, and leads to a useful dissection of the polar effects (27).

If $\Delta F_p^{\ddagger}$ is the standard free energy for the (composite) reaction transferring a proton from solvent to transition state **II** (yielding **I**), and if $\Delta^2F_p^{\ddagger} = \Delta F_p^{\ddagger} - \Delta F_{p^0}^{\ddagger}$ is the corresponding comparison made with the transition states from the unsubstituted compounds, then

$$[3] \quad (\Delta^2F_s^{\ddagger} - \Delta^2F_f^{\ddagger}) = \Delta^2F_p^{\ddagger} + (F_{Ch}^{0} - F_{Ch^0}^{0}) - (F_{ox}^{0} - F_{ox^0}^{0})$$

where the other symbols are as in [1] and [2]. The values given in the final columns of Tables 2 and 3 do not correlate with any transition state effects, and it is now shown that they do correlate very well with certain ground state terms expected in [3]. Ignoring other effects, one would expect on conformational principles that chlorohydrins possessing a predominantly axial methoxyl in the ground state (such as **7** and **8**) would show higher values of F_{Ch}^{0} than, e.g., **9** and **10**. Similarly, one would expect the *trans*-oxides **2** and **4** to possess lower F_{ox}^{0} values than the corresponding *cis*-oxides **1** and **3**. All six tabulated values of $(\Delta^2F_s^{\ddagger} - \Delta^2F_p^{\ddagger})$ agree qualitatively with the hypothesis that these are the dominant surviving effects. This number of agreements is too large to be due to chance, and moreover the separate numerical values are all reasonable. The most convincing comparison is that of examples 2 and 3, Table 2, for which the experimental errors are at a minimum,[12] and for which the ground state contributions of the oxiranes to [3] vanish exactly. If the whole of the difference $(\Delta_p^{3\ddagger})$ between the two values of $(\Delta^2F_s^{\ddagger} - \Delta^2F_f^{\ddagger})$ is then attributed to ground state effects in the chlorohydrins **8** and **9**, and if every difference between **8** and **9** is ignored except the work required to convert methoxyl from the axial to the equatorial position, then $\Delta_p^{3\ddagger}$ would be calculated to have the *A* value for methoxyl, viz. −0.77 kcal/mol. This is exactly the experimental difference between the two values of $(\Delta^2F_s^{\ddagger} - \Delta^2F_f^{\ddagger})$ given in Table 2 for the comparison of 2 and 3.

The assumption that this wholesale cancellation of effects also applies to the comparisons of examples 1 and 2 (Table 2) and of 1 and 3 (Table 3) leads to a self-consistent quantitative conformational analysis

of the entire set of reactions given in Table 1.[15] Within the set, the analysis retains its quantitative value even if the assumption is in error, but for comparisons outside the system, errors in the assumption do affect the results. A careful inspection of the observed cancellations of the previous paragraph with respect to those assumed in this shows that ground state errors are small, but that a significant error[16] due to dipole orientations in the transition states is present. Although the error could be estimated, it seems better to say that with favourable orientations of the dipoles (as in the acid-catalyzed methanolysis of the *trans*-oxide **2**) the value of the conventional Z effect in the transition state is at most a small positive number, and may well be negative.

Among the rather far-reaching implications of this generalization may be mentioned an explanation for the observations of Berti and co-workers (28) on the preferential formation of certain "*cis*-onium" ions in, for example, addition reactions of 3-methoxycyclohexene. It also serves to remove a reservation previously expressed (2) regarding our conclusion that large positive values are possible for *syn*-1,3-like interactions in transition states of the cyclopentane series. Examination of the experimental basis for the objection (29) shows that it involves reactions of cyclopentane compounds having favourably arranged dipoles, i.e., a situation in which the corresponding cyclohexane compounds would also have failed to show a large positive Z effect.[17]

Lamaty and co-workers (17) felt they had obtained evidence supporting an ion-pair mechanism for oxirane scission, in place of the familiar A2 (1, 13, 31). Reactions with hydrogen chloride which showed the expected third-order kinetics in ionizing solvents were second order in less polar solvents. They proposed a kinetic scheme in which the rate-determining steps involved the formation of different ion-pairs in the two cases. Many other interpretations are possible including several which support the A2 mechanism.[18] In addition, double comparison allows us to remove from consideration one interesting class of ion-pair reactions. No one doubts that drawings like those of this paper represent very well the product determining states, whatever the mechanism. But the postulation of additional transition states and intermediates is possible, and as Wylde and co-workers have pointed out (17), one type would serve to separate the rate- and product-determining steps, thus making easier the union of theory and experiment, while at the same time remaining "invisible" kinetically and (from Curtin–Hammett theory) having no direct effect upon product distribution. Such intermediates may be thought of as doubly bridged, with both the oxirane oxygen and the incoming nucleophile bonded approximately symmetrically to the two oxirane carbons (in order to avoid immediate product determination at a rate-determining step). Species like these arise naturally from the ion-pair theory, and are prominent in several currently accepted mechanisms (18).

If the incoming nucleophile is water, and if proton transfers with the solvent remain rapid with respect to reactions of the intermediates, then it is easily seen (in contrast to the transition states shown in Fig. 1) that the incoming oxygen and the oxirane oxygen will be very similarly situated in such an intermediate. It is possible (and in our view likely) that in such an intermediate the distinction between the two oxygens would be lost. Dramatic support for the existence of these intermediates would therefore arise if two different oxiranes could be shown to proceed to the same product through a common intermediate.

Experiment shows that this is emphatically not the case. Each of the two diols (**15** and **16**) was formed in two different ways. Ground state effects cannot be important contributors to the $\Delta^2F^{\ddagger}$ values of Fig. 1 since in one case the *cis*-oxide leads to a very positive value and in the other to a

[15]For example, the experimentally accurate comparison of examples 1 and 4, Table 3, then leads to the estimate of 0.50 kcal/mol for the ground state A value of methoxyl in the cyclopentanes. From the rates of oxirane scission by methanol given in Table 1, one can estimate a value for the *syn*-1,3-interaction (Z effect) of substituent methoxyl and incoming methanol in the transition state of -0.57 kcal/mol. This value forms an interesting contrast with the uniformly high positive values of Z in the few examples known (23) for the ground state.

[16]The errors are such as to cause the quoted value for $Z(CH_3OH/OCH_3)$ to be too negative, and the quoted A value for methoxyl in the cyclopentanes to be too small, the error being much smaller in the second of these values.

[17]Surviving criticisms of our work point to the anomalies experienced when the methoxyl group is replaced by alkyl radicals (ref. 30, but see ref. 12). Unpublished work with R. C. Cathcart suggests that these are to be explained on the basis of polarization of the alkyl group by the incoming nucleophile.

[18]The difficulty is to avoid postulating a switch to acid-catalyzed A1 in the *less* polar solvents, the obvious way to do this being the suggestion of initial attack on the oxirane by un-ionized HCl, or the equivalent. Several versions of the A2 mechanism then show second-order kinetics and insensitivity to added chloride in the less polar solvents. J. Wylde, in a private communication, strongly doubts this explanation for the less polar solvents, but expresses complete agreement that A2 is the mechanism in aqueous methanol.

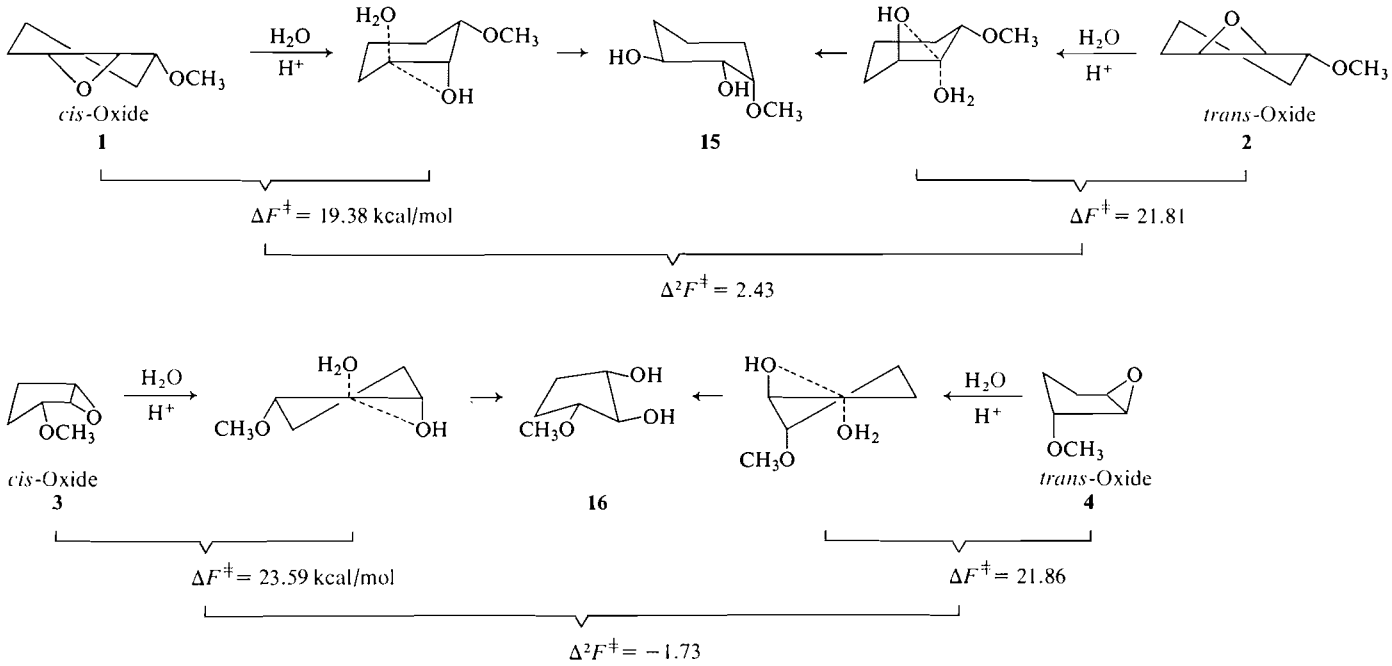


FIG. 1. Formation of the same product by two different routes.

very negative value of $\Delta^2F^{\ddagger}$, and in view of the dissections made above. Obviously the transition states must all be very unsymmetrical, maintaining throughout the reactions a strong distinction between the incoming hydroxyl group and the oxirane oxygen. Of course, the ion-pair theory could be adjusted to fit this evidence, but the fact remains that the A2 fits the evidence automatically, as it has all the other tests of these papers.

Experimental

Preparation and purification of the compounds mentioned in this paper, and the identification of reaction products in the scission and formation of the oxiranes, have been described previously (3, 7, 10, 24, 32). The methods of analysis of the reaction products in scission are described in the previous paper (3). Rates of oxirane formation were observed by a method resembling that of McCabe and Warner (33). Reactions of scission and of formation were conducted in an insulated Sargent bath equipped with a proportional heating control; temperatures varied less than 0.006 deg throughout the bath. The working differential thermometer was referred to a standard thermocouple calibrated with freezing mercury and with decomposing sodium sulfate decahydrate. It was checked at the freezing point of benzene, yielding 5.486°C during the "formation" work, and 5.481°C, during the "scission" work; the literature value (34) is 5.483°C. The initial operations of preparing and mixing the reaction sample and of filling the dilatometer have been described (3).

Dilatometry

The Multi-tube Dilatometers (See Fig. 2)

Good heat transfer, active convection, mechanical strength, and ease of filling were all obtained by forming the reservoir from six connecting tubes, five outlining the surface of a spheroid, the sixth being axial. The reaction dilatometer had a volume of 81.7 mL and, when filled with 50 wt.% aqueous methanol at 2.43°C, a thermal sensitivity of 6.63 cm deg^{-1} and a passive cooling constant of about 1.01 min^{-1}. These characteristics very closely matched those of the reference dilatometer. A thermistor (Yellowstone Instruments precision, 10 kΩ at 25°C) was placed, together with a little silicone oil, in a thermometer well present in each dilatometer, the thermistors being connected by shielded cable to opposite arms of a Wheatstone bridge. In view of the difficulties previously reported in the use of high impedance thermistors (19), care was taken to avoid ground loops and common ground pathways, and to isolate the bridge from the recorder (Varian model A-25) with an operational amplifier. Circuit analysis showed, however, that the principal difficulty lay in differential heating effects in the bridge resistors, temperature measurements stable to 0.001°C requiring the resistors to be matched in temperature within a few thousandths of a degree. Ordinary control circuits being ineffective, temperature oscillations in the bridge were prevented by (*i*) cementing the elements to a heat sink of high thermal capacity, (*ii*) using as heating elements of very low thermal capacity the actual resistors and transistors of the heating circuit, (*iii*) careful placement of the heating and sensing elements, and (*iv*) providing a dual "fast" and "slow" proportional control for the heater. No oscillations (to a sensitivity of 0.2% in voltage) could be detected in the heater drive, and no short or long term variations in the recorder output, due to the bridge, could be detected up to several hours at a sensitivity of 0.001°C. Calibration of the system agreed well with the theoretical analysis in showing a sensitivity at the recorder input of 0.40 V deg^{-1} and in verifying the expected very satisfactory linearity up to a temperature difference of at least 0.24°C. Roux and Viallard (35) have reported an interesting variation for a different purpose.

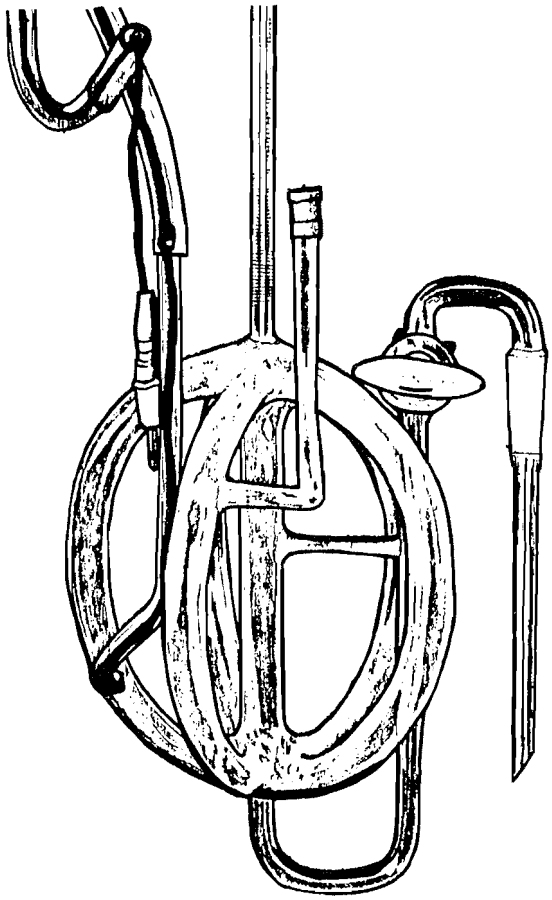

FIG. 2. The multi-tube dilatometer.

During a reaction, 95–197 points were observed beginning at 3.0 min after the mixing of the reactants for those observed at 0.5 and 1.0 min intervals and at 5 min for those observed at 5 min intervals. The kinetic bath was protected against air currents and strong light. Readings from the reaction dilatometer were corrected (*i*) by comparison with those of the reference dilatometer, (*ii*) for emergent stem temperature effects, if necessary, and (*iii*) for differential temperature effects detected by the thermistor, if the maximum temperature rise within the run was greater than 0.003°C. None of the experiments with cyclopentane derivatives but nearly all of those with cyclohexane compounds required the last correction (Table 1).

Cylindrical Dilatometers

The *cylindrical dilatometers* were of Eastham's pattern (36), modified to allow transfer from the mixing vessel to occur under the surface of the bath liquid. The reaction dilatometer, closely matched by its reference dilatometer, had a volume of

35.5 mL, a thermal sensitivity of 6.76 cm deg^{-1}, and an active cooling constant of about 0.64 min^{-1}. Temperature corrections were made by a modified Tong–Olson theory (see below) (20).

Determination of Pseudo-first-order Constants for Solvolysis. Perchloric Acid

The results in Table 1 were obtained by applying Guggenheim's method (37) to the corrected observations from the multi-tube dilatometers. From 31–97 pairs of points were used. With the faster reactions, all of the readings were taken in 1 day and there was at most one point between the two intervals. With the slower reactions, the readings of the first interval were taken one day while those of the second interval were taken on the next. In general, points prior to 5 min (or to 6.5 min in faster reactions) were not used in the fittings. Another method, reported below, was employed for the cylindrical dilatometers.

Determination of the Chemical Sensitivities of the Dilatometer for Use in Reactions of Mixed Order. Modification of the Tong–Olson Theory

For a reaction *at constant temperature* of an oxirane with aqueous methanolic hydrochloric acid, the capillary readings y_i at times t_i obey

$$[4] \quad y_i = y_0 + u_N[\mathrm{Ch}] + u_s D$$

where y_0 is the hypothetical reading at zero time, [Ch] the amount of oxirane (in mol L^{-1}) which has been converted to chlorohydrin at time t_i, and D the corresponding conversion by solvolysis. The final capillary reading (obtained as in the Guggenheim method) is y_f. For mixed reactions not of the same order, one must know the chemical sensitivities, u_N and u_s, in order to determine the rate constants k_N and k_s of the corresponding reactions. One of these sensitivities (u_s) was obtained by applying [4] to the solvolysis in perchloric acid, where [Ch] = 0. The procedure was straightforward for very slow reactions, or for reactions in which temperature corrections could be determined from thermistor readings. Values of u_s for the multi-tube dilatometer were found to be in the cyclohexane series, for solvolysis of the *trans-*, *cis-*, and unsubstituted oxiranes of Table 1, −151.8, −134.9, −138.5, and in the cyclopentane series, −130.7, −129.6, and −119.8 cm mol^{-1} L respectively.[19]

Temperature corrections for the cylindrical dilatometers were made by a curve fitting technique. For two sets of solvolyses of cyclohexene oxide at different acidities, differential least-squares curve fitting to the first-order Tong–Olson (20) eq. [5] in the four variables C_a, C_b, k, and g, gave

$$[5] \quad y_i - y_f = C_a e^{-kt} + C_b e^{-gt}$$

rapid convergences, stable to large perturbations in the initial estimates, and reproducible from run to run. As a by-product, the fittings gave values for the active cooling constant g, and for the first-order rate constant k, corrected for the Tong–Olson effect. In the neglect of thermal effects, the desired chemical sensitivity (u_s) can be obtained from $u_s = -C_a/[\mathrm{Ox}]_0$, where $[\mathrm{Ox}]_0$ is the initial concentration of oxirane. Tong and Olson suggested $u_s = -(C_a + C_b)/[\mathrm{Ox}]_0$, but this value is also grossly in error, since [5] neglects the initial events of mixing and transfer. A step-function calculation gave the remarkable result that in [6] the value of u_s is independent

$$[6] \quad -u_s[\mathrm{Ox}]_0 = C_a + \frac{(C_a' - C_a)(g - k')}{g(1 - k'/k)}$$

(under suitable circumstances) of these early events. From values of C_a and k obtained by fitting [5] to results from a solvolysis in 0.03 M aqueous methanolic perchloric acid, and values of C_a' and k' obtained from a similar solvolysis in 0.015 M acid, u_s for cyclohexene oxide was found to be −135.8 cm mol^{-1} L. Since a value of −136.0 was found from a very slow run in 0.0015 M acid, the method was confirmed.

Determination of the Rate Constants for Oxirane Scissions in Aqueous Methanolic Hydrochloric Acid

Curve fittings were performed with iterative differential least-squares routines (38), the required numerical integrations being carried out with a simple predictor-corrector (39). No more than three adjustable parameters were used, in order to avoid parameter sliding (40). The input data included the capillary readings, the chemical sensitivity (u_s), the initial oxirane concentration ($[\mathrm{Ox}]_0$), the initial acidity (A_0) and the final acidity (A_f), determined experimentally by titrations in triplicate of the spent reaction mixture at a definite temperature (usually 27.0°C) and corrected to obtain A_f at 2.43°C (the temperature at which all of the kinetic runs were carried out). Points prior to 5 min (6.5 min in the fastest reactions) were ignored in the curve fittings. The rate constants of Table 1 were obtained by application of the "main program" (see below) to corrected results from the multi-tube dilatometers. In this program, mechanism A2 was assumed, and the effect of changes in ionic strength during a reaction was ignored. Later, subsidiary programs were applied to reject A1 and similar mechanisms, and to show that the effect of changes in the ionic strength were negligible. Finally, it was shown that the experimentally more convenient method, in which temperature effects are not measured, may be used even for mixed nonlinear reactions, with varying ionic strength, and with temperature effects which cannot be neglected.

(a) The "Main Program"[20,21]: A2 Mechanism, Neglecting the Variations in Ionic Strength within Each Run

The equations of the mechanism are $\mathrm{d}D/\mathrm{d}t = -k_s[\mathrm{Ox}]A$ and $d[\mathrm{Ch}]/\mathrm{d}t = -k_N[\mathrm{Ox}]A(A + S)$, where [Ox] is the concentration of oxirane, A the titrable acidity, and S the concentration of added sodium chloride. Both rate constants are composite. In solving the system, it was not assumed that k_s had the same value as in perchloric acid. Instead, the parameter was eliminated by the use of [7] (3), which also served (together with elementary stoichiometry) to give [Ox], [Ch], and D (eq. [4]) and consequently the capillary readings y_i, as functions of the single chemical variable A. In this way [8]

[19]Rate constants obtained from the dilatometer are of very little value unless accompanied by values of the chemical sensitivity, thermal sensitivity, and cooling constant (see Introduction).

[20]Details are available from the authors.

[21]Extensive sets of further numerical integrations served to verify the adequacy of the mathematical procedure, and provided estimates for the closeness of fitting and of the errors in k_s and k_N caused by experimental errors in the fixed input parameters u_s, A_0, A_f, and $[\mathrm{Ox}]_0$; these errors turned out to be adequately represented by the external standard deviations (Table 1). A striking feature of the integration (illustrated later) was the absorption of errors into the dummy parameters u_N. A useful test was the fact that the value of k_N obtained from the end reaction independently of the main program, and of u_s and u_N, always agreed approximately with the final value of the program.

was obtained as an expression for the A2 mechanism. This differs from that derived for the A1 mechanism (eq. [9]):

$$[7] \quad k_N/k_s = \ln[(A_0 + S)/(A_f + S)]/[[Ox]_0 + A_f - A_0]$$

$$[8] \quad dA/dt = -f(A)$$

$$[9] \quad dA/dt = -kf(A)/[k_s + k_N(A + S_O)]$$

In [8] and [9],[22] $f(A)$ was a particular function of the time-variable acidity A, the adjustable constant k_N, and experimental constants. The corresponding equation for the capillary readings involved only k_N, u_N, and y_f as adjustable parameters. Convergence was consequently rapid. Initial estimates of the parameters (except y_f) were made by the program itself under the assumption, subsequently refined, that the end-reaction was pseudo first order.

(b) Rejection of the A1 Mechanism for the Attack of Chloride upon Oxirane

Although several other possibilities were considered, space can be given only to the limiting mechanism (13, 17). Its equation for the product ratios had exactly the same form as that of [7] applying to the A2 mechanism. Transformation of the rate equations led to [9] and since the denominator did not vary much within a single run, [9] was also almost indistinguishable from [8] for a single reaction. Indeed when [9] was applied to the same three sets of reactions (seven experiments in all) for *cis*-3-methoxycyclohexene oxide (**1**) which had given the results for the A2 mechanism reported in Table 1, the curve fittings gave average standard deviations per point in the capillary readings of only 0.011, 0.010, and 0.015 cm, close to the values for the A2 fitting of 0.010, 0.010, and 0.014 cm respectively. Careful inspection showed that there was little to choose between the two excellent fittings. Further, the average standard deviation of the mean value of the first-order rate constant k for the A1 fitting was only 0.44% within each set. The unsuitability of the A1 mechanism was shown by the change in rate constants between sets. The variation in k between the sets was 70%, increasing roughly with initial concentration of chloride ion. The same data gave for the A2 fittings a variation in k_N of only 5.2% and in k_s of only 2.7% with the same variation in the initial conditions (Table 1). Similar results were obtained with cyclohexene oxide.

(c) Inclusion of the Variation in Ionic Strength during a Reaction within the Rate Laws for A2

The approximations of [10] could easily be incorporated into the existing programs without an increase in the number of adjustable parameters. Because of the small variations within any one reaction, they were also sufficiently accurate,

$$[10] \quad \begin{aligned} k_s &= k_1 + k_2(A + S + W)^{1/2} \\ k_N &= k_s[k_3 + k_4(A + S + W)^{1/2}] \end{aligned}$$

where W is the concentration of added sodium perchlorate. Rate constants determined for solvolysis of cyclohexene oxide in aqueous methanolic perchloric acid, using both the cylindrical and the multi-tube dilatometers, gave a good fit to the experimental values of k_s for $k_1 = 3.359$ and $k_2 = 4.04$. For reactions in aqueous methanolic hydrochloric acid, the latter value was held fixed, but the value for k_1 was used only as an initial estimate. Variations in the product ratio with ionic strength, reported in the previous paper (3) for cyclohexene oxide, were fitted by a network procedure[20] to find values of k_3 and k_4. Suitable values of k_4 ranged from -15.0 at low ionic strength to -10.0 at the higher. The appropriate value (-11.0 for cyclohexene oxide under the conditions of Table 1) was supplied to the program as a fixed constant. The corresponding value of k_3 had to be calculated for each separate reaction with hydrochloric acid in an initial iterative routine, since [7] did not apply. The suitably altered "main program" then performed iterations with y_f, u_N, and k_1 as adjustable parameters. For the two sets of data for cyclohexene oxide used in Table 1, the new values for k_N and k_s at "half-reaction" (as judged by the acidity) differed from those reported in Table 1 by less than 0.6%. The difference in ionic strength to which each constant of Table 1 applies is therefore significant only for the *cis*-oxide **1**, and for it, the difference is negligible in the comparisons of Tables 2 and 3, as shown by similar curve fittings.

(d) Ionic Strength Effects in Parallel Reactions of Different Order. Comparison of Two Different Methods of Temperature Compensation

Conditions were purposely chosen so that temperature effects on the rate constant would be small, the more severe comparisons in u_N being used. Solvent, temperature, and initial oxirane concentration were as in Table 1, the added acid being hydrochloric. The reactions were conducted in the "cylindrical" dilatometers. Temperature corrections were made by a linearized Tong–Olson approximation. Points prior to 7 min were ignored in fitting the results to the "variable ionic strength" program described above, with $k_4 = -15.0$. Set 1 (4 trials, 0.03 M HCl, no added salts) gave $k_N = 31.0$ L^2 mol^{-2} min^{-1}, $k_s = 3.97$ L mol^{-1} min^{-1}, and $u_N = -55.4$ cm mol^{-1} L. Set 2 (3 trials, 0.015 M HCl, no added salts) gave values of 33.5, 3.85, and -68.0, respectively, and set 3 (4 trials, 0.015 M HCl, 0.03 M $NaClO_4$) gave 27.7, 4.11, and -55.2, respectively. The average external standard deviations of the mean for k_N and k_s were 0.69% and 0.68%. For comparison, temperature corrected results from the "multi-tube" dilatometer, obtained as in the previous section, were (*i*) (0.015 M HCl, 0.2 M $NaClO_4$), $k_N = 22.0$, $k_s = 5.31$, and $u_N = -57.5$ and (*ii*) (0.015 M HCl, 0.035 M NaCl, 0.165 M $NaClO_4$), 23.4, 5.48, and -54.9, respectively. These results lead one to expect a value of u_N for the *cylindrical* dilatometer of -55.0, close to that reported just above.

Fitted *without* temperature correction, the same three sets of data for the cylindrical dilatometer gave standard deviations in y_i very slightly higher than before. Values for k_N were 2–3% higher, and for k_s, lower by the same percentage, with respect to the corrected results. However, values for u_N (-447, -357, and -424) were about eight times the corrected values, illustrating the efficiency of this parameter in absorbing temperature errors.

Formation of Minor Isomers in Acid- and Base-catalyzed Scissions

Analysis of scission products formed from the *trans*-oxide **2** and the *cis*-oxide **3**, under the conditions of Table 1, have been reported (3). With hot aqueous perchloric acid, **2** gave 6.6% of minor isomer (by calibrated gas–liquid chromatography) in a heterogeneous reaction and **3** gave 6.7%. No minor isomer could be detected for the *cis*-oxide **1** under acid catalysis at 2.43°C, but hot aqueous base gave about 0.3% of minor isomer, easily detected by glc, in a heterogeneous

[22]Equation [9] is written to emphasize the resemblance in form to [8]. The symbols k_N and k_s do not have the same physical meaning in eqs. [8] and [9] since two different mechanisms are involved.

reaction. ("Minor isomer" corresponds to attack at position 2. See Table 2.)

Blank Experiments

No temperature rise occurred when cyclohexene oxide and solvent were mixed in the mixing vessel of the dilatometer. The capillary level did not fall over several hours (i.e., many half-lives for the acid-catalyzed reaction) after the mixture was forced into the dilatometer. Thus both the heat of mixing and the uncatalyzed solvolysis were negligible. A comparison run using sodium hydroxide as the catalyst was too slow for accurate measurement, but the slight capillary fall observed in 5 days corresponded to a rate constant no greater than 0.00012 L mol^{-1} min^{-1}. Reactions with methoxide in boiling methanol are also extremely slow (*7a*). By analogy, therefore, the uncatalyzed reaction with chloride ion was also negligible even in the least favourable of our examples. Solutions of aqueous methanol and hydrochloric (or perchloric) acid maintained titration values unchanged at least for several days, as did spent reaction mixtures; analytical (glc) values of the latter were also stable with time. Reactions concurrent with, or subsequent to, the acid-catalyzed scissions were therefore also negligibly slow.

Acknowledgements

The aid of the National Research Council of Canada, in financial support of this work and in the grant of studentships to J.W.B. and E.J.L., is gratefully acknowledged. We wish to thank Mr. C. Levay for his excellent glassblowing work on the dilatometers.

On the reliability of the inversion of the Arrhenius rate law

ANDREW W. YAU[1] AND HUW O. PRITCHARD

Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3

Received December 14, 1978

ANDREW W. YAU and HUW O. PRITCHARD. Can. J. Chem. 57, 2458 (1979).

A numerical test of the reliability of the Slater–Forst procedure for the inversion of the Arrhenius rate law is presented using the theoretical data for the reactions $N_2O \rightarrow N_2 + O$ and $CO_2 \rightarrow CO + O$ reported previously: the test results are positive. The sensitivity of the procedure to variations in the Arrhenius parameters is also examined.

ANDREW W. YAU et HUW O. PRITCHARD. Can. J. Chem. 57, 2458 (1979).

Faisant appel à des données théoriques relatives aux réactions $N_2O \rightarrow N_2 + O$ et $CO_2 \rightarrow CO + O$ rapportées antérieurement, on présente une méthode numérique permettant de mettre à l'épreuve l'exactitude de la méthode de Slater–Forst pour l'inversion de la loi de vitesse d'Arrhénius: les résultats de nos essais sont positifs. On examine aussi la sensibilité de la méthode aux variations des paramètres d'Arrhénius.

[Traduit par le journal]

I. Introduction

In an earlier publication (1), the microscopic reaction probability functions $k(E)$ for the spin-forbidden reactions

[1] $N_2O(\tilde{X}^1\Sigma^+) \rightarrow N_2(X^1\Sigma_g^+) + O(^3P)$

and

[2] $CO_2(\tilde{X}^1\Sigma_g^+) \rightarrow CO(X^1\Sigma^+) + O(^3P)$

were calculated in the framework of the theory of radiationless transitions. The calculation was two-dimensional, incorporating the two stretching degrees of freedom in a modified form of Rosen's relative co-ordinate system (2); also, all of the microscopic parameters required for the calculation were derived from spectroscopic data, and there were no adjustable parameters in the formulation. The computed $k(E)$ functions were of "kinetic accuracy": for both reactions, the high-pressure reaction rates calculated from the $k(E)$ functions were in reasonable agreement with experiment (3–5). The pre-exponential factor and activation energy were also computed: they vary only moderately with temperature, except at very low temperature for N_2O. Indeed, over a long range of temperature, the reaction rates may be very well approximated by a strict Arrhenius expression, viz.

[3] $k_\infty(T) \doteq A_\infty \exp(-E_\infty/RT)$

with $A_\infty = 1.41 \times 10^{12}\ s^{-1}$ and $E_\infty = 65.10$ kcal mol^{-1} for reaction [1] and $A_\infty = 1.80 \times 10^{12}\ s^{-1}$ and $E_\infty = 127.3$ kcal mol^{-1} for reaction [2] (1).

The inversion procedure of (experimental) high-pressure rate laws such as eq. [3] to obtain the microscopic reaction probability function $k(E)$ was first discussed by Slater (6) and was later re-derived and developed for unimolecular fall-off calculations by Forst (7). Despite the success to date (8) of the Slater–Forst procedure in unimolecular rate calculations, concerns have been voiced in the past regarding its validity: (*i*) that the experimental rate law is necessarily approximate; (*ii*) that the inversion procedure may be very sensitive to the fine structure of $k_\infty(T)$, and the loss of the latter through experimental scatter precludes obtaining even the overall shape of the $k(E)$ function; (*iii*) that (in the case of the strict Arrhenius rate law, eq. [3]), E_∞ is *not* equal to E_0, the critical energy of reaction; and that (*iv*) the $k(E)$ function is expected to be very sensitive to the assumed Arrhenius parameters, particularly near the threshold. Regarding (*i*), the $k(E)$ function obtained by the inversion of an approximate rate law is necessarily approximate; the question is how approximate is the function? As to (*ii*), we have argued previously (8) using the linearity property of Laplace Transform, that the loss of the fine-structure in $k_\infty(T)$ would mean a corresponding loss in the fine-structure, but not the overall shape, of $k(E)$ in the inversion procedure. Case (*iii*) actually arises out of an over-interpretation of eq. [3]: insofar as the inversion procedure is concerned, both A_∞ and E_∞ are *empirical* quantities and no assumption is made that E_∞ is equal to E_0. At this juncture, we note that

[1]Present address: Herzberg Institute of Astrophysics, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6.

0008-4042/79/182458-06$01.00/0

no *realistic* kinetic data (either theoretical or experimental) of $k(E)$ and $k_\infty(T)$ yet exist which may be used to examine (*iv*) in particular and to investigate the validity of the Slater–Forst procedure in general: hence, the present work using the $k(E)$ and $k_\infty(T)$ data in ref. 1.

II. Theory

We begin with an outline of the relevant theoretical results.

We define, for a discrete reactive state i, g_i as its degeneracy, ε_i as its energy, and k_i as its microscopic decay rate constant to product. The infinite-pressure rate constant $k_\infty(\beta)$ at inverse temperature β $(= 1/kT)$ is then (8)

$$[4] \qquad k_\infty(\beta) = \sum_j F(E_j) \exp(-\beta E_j)/Q(\beta)$$

where $Q(\beta)$ is the molecular partition function, the j-summation is over all energy levels, and

$$[5] \qquad F(E_j) = \sum_i k_i g_i$$

the i-summation being over states at energy E_j. $F(E_j)$ may thus be obtained as the inverse Laplace Transform of $k_\infty(\beta)Q(\beta)$, whence

$$[6] \qquad F(E_j) = \mathscr{L}^{-1}\{k_\infty(\beta)Q(\beta)\}$$

and, if the rate law is strict Arrhenius in form, i.e., eq. [3],

$$[7] \qquad F(E_j) = A_\infty P(E_j - E_\infty)$$

where $P(E_j)$ is the state-degeneracy at energy E_j.

Equations [4] and [7] may be compared with their corresponding solutions for a continuous system, where

$$[8] \qquad k_\infty(\beta) = \int_0^\infty f(E) \exp(-\beta E)\, dE/Q(\beta)$$

$$[9] \qquad f(E) = \rho(E)k(E)$$

and, in the case of the strict Arrhenius rate law,

$$[10] \qquad f(E) = A_\infty \rho(E - E_\infty)$$

$\rho(E)$ being the state-density at energy E and $k(E)$ the reaction probability function.

From a computational standpoint, eqs. [4]–[7] and eqs. [8]–[10] are equivalent.[2] This is because in unimolecular rate calculations, the reactant level spectrum is grouped into energy grids and the relevant integrations are carried out by stepwise summations over the energy grids. Thus, the quantity of computational interest is

$$[11a] \qquad \phi_k = \int_{E_k}^{E_{k+1}} f(E)dE/\Delta E$$

where ΔE is the grid size and E_k is the energy of the kth grid. Equivalently,

$$[11b] \qquad \phi_k = \sum F(E_j)/\Delta E$$

where the summation is over energy levels between E_k and E_{k+1}. It is obvious that at high energy $(E_k \gg E_\infty)$, eqs. [11*a*] and [11*b*] are very similar and ϕ_k varies only slightly with the assumed grid size ΔE. At low energy $(E_k \gtrsim E_\infty)$ on the other hand, the behaviour of ϕ_k may be expected to depend more strongly on ΔE. In particular, when ΔE becomes comparable with (or smaller than) the mean energy spacing near the zero point energy, the non-uniform distribution of energy levels there would imply, according to [7], a highly oscillatory distribution of ϕ_k which varies drastically with ΔE. However, this constitutes no serious problem in practical applications, cf. Section IV.

III. Reaction Probability Function ϕ_k

In the theoretical calculation (1) of the microscopic reaction probability, the reactant state is characterised, in the notation of ref. 1, by (v_{b1}, v_{b2}, v_{bend}, J, M_J) where v_{b1} and v_{b2} refer to the two stretching co-ordinates; v_{bend} denotes the doubly-degenerate bending quantum number, and J and M_J the rotational quantum numbers. The reaction probability $k_{v_{b1}\, v_{b2}\, v_{bend}\, J\, M_J}$ from the reactant state is assumed to be independent of v_{bend}, J, and M_J, whence

$$[12] \qquad k_{v_{b1}\, v_{b2}\, v_{bend}\, J\, M_J} = k_{v_{b1}\, v_{b2}\, 0\, 0\, 0}$$

with

$$[13] \qquad k_{v_{b1}\, v_{b2}\, 0\, 0\, 0} \equiv k_{v_{b1}\, v_{b2}} = \sum k^{u,\varepsilon_{u1},v_{u2}}_{b,v_{b1},v_{b2}}$$

where $k^{u,\varepsilon_{u1},v_{u2}}_{b,v_{b1},v_{b2}}$ is the microscopic reaction probability from the bound (b) reactant state (v_{b1}, v_{b2}) to the unbound (u) product state (ε_{u1}, v_{u2}) and the summation is over all accessible product states (ε_{u1}, v_{u2}). As discussed in ref. 1, the reaction probability $k_{v_{b1}\, v_{b2}}$ is a randomly fluctuating function of the reactant state energy. Nevertheless, the convolution of the bending and rotational motions has the effect of smoothing out these apparent fluctuations: of course, the reaction probability $k_{v_{b1}\, v_{b2}\, v_{bend}\, J\, M_J}$ still varies erratically as a function of the reactant state

[2]We have discussed previously (8) the conceptual difficulty associated with the state-density near the zero point energy in eq. [10], which does not arise in eq. [7].

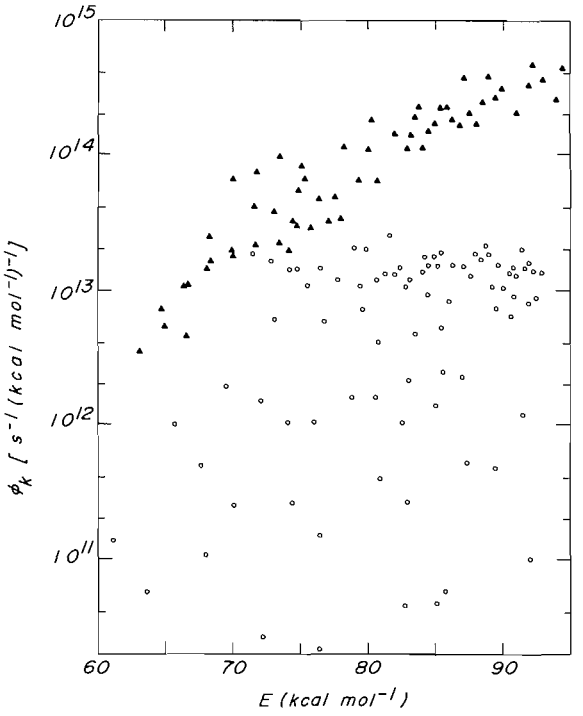

FIG. 1. Grained reaction probability function ϕ_k for the dissociation of N_2O calculated using eq. [11*b*] with $\Delta E = 0.05$ kcal mol^{-1}. E is the energy of the reactant state relative to the zero point energy. Open circles: bending and rotational motions excluded, eq. [14*a*]; solid triangles: bending motion included, eq. [14*b*].

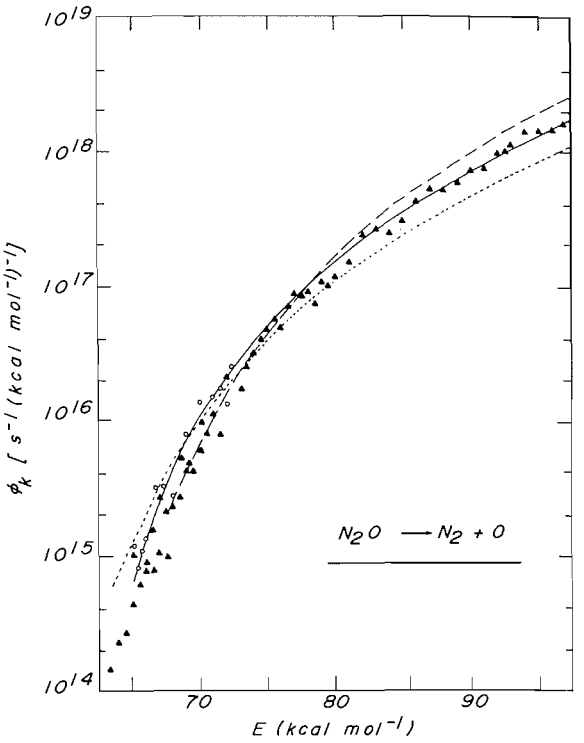

FIG. 2. Grained reaction probability function ϕ_k for the dissociation of N_2O, with $\Delta E = 0.05$ kcal mol^{-1}. E is the energy of the reactant state relative to the zero point energy. Solid triangles: exact probabilities from eq. [14*c*]; solid curve: approximation from inversion of Arrhenius rate law with $A_\infty = 1.41 \times 10^{12}$ s^{-1} and $E_\infty = 65.10$ kcal mol^{-1}, eq. [15]; dotted curve: eq. [15*a*] with $A_\infty' = 7.05 \times 10^{11}$ s^{-1} and $E_\infty' = 63.25$ kcal mol^{-1}; dashed curve: eq. [15*b*] with $A_\infty'' = 2.82 \times 10^{12}$ s^{-1} and $E_\infty'' = 67.87$ kcal mol^{-1}. The open circles indicate fluctuations of $\phi_{k,app}$ near the threshold.

energy, but now the enormous increase in the reactant state density means that over a typical energy range of ΔE ($\sim$0.1 kcal mol^{-1}), the *apparent* reaction probability distribution is smoothed out considerably. This is illustrated in Fig. 1 for the N_2O reaction, where we sum up the reaction probabilities from states in energy grids of 0.05 kcal mol^{-1}. When neither the bending nor the rotational motions are included, i.e.

$$[14a] \quad \phi_k = \{\sum g_{v_{b1}\, v_{b2}\, 0\, 0\, 0} k_{v_{b1}\, v_{b2}\, 0\, 0\, 0}\}/\Delta E$$

where the summation is over the (v_{b1}, v_{b2}, 0, 0, 0) states within E_k and E_{k+1}, the grained reaction function ϕ_k exhibits random fluctuations (open circles). On the other hand, as soon as the bending motions are included, i.e.

$$[14b] \quad \phi_k = \{\sum g_{v_{b1}\, v_{b2}\, v_{bend}\, 0\, 0} k_{v_{b1}\, v_{b2}\, v_{bend}\, 0\, 0}\}/\Delta E$$

the summation being over the (v_{b1}, v_{b2}, v_{bend}, 0, 0) states within E_k and E_{k+1}, the smoothing of ϕ_k immediately becomes apparent (filled triangles: note that in this case, only a representative fraction of data points is shown in the figure for the sake of clarity). The further smoothing of ϕ_k with the convolution of the rotational states, i.e.

$$[14c] \quad \phi_k = \{\sum g_{v_{b1}\, v_{b2}\, v_{bend}\, J\, M_J} k_{v_{b1}\, v_{b2}\, v_{bend}\, J\, M_J}\}/\Delta E$$

the summation being over the (v_{b1}, v_{b2}, v_{bend}, J, M_J) states within E_k and E_{k+1}, is shown by the quasi-smooth array of solid triangles in Fig. 2. Similar results are obtained for the CO_2 reaction; they will not be presented here.

IV. The "Arrhenius" Reaction Probability Function

Given the relevant spectroscopic parameters (Table 1 of ref. 1), it is a simple matter to calculate the reactant state-sum $G(E)$ and, combining eqs. [7] and [11*b*], the grained reaction probability function $\phi_{k,app}$,

$$[15] \quad \phi_{k,app} = A_\infty[G(E_{k+1} - E_\infty) - G(E_k - E_\infty)]/\Delta E$$

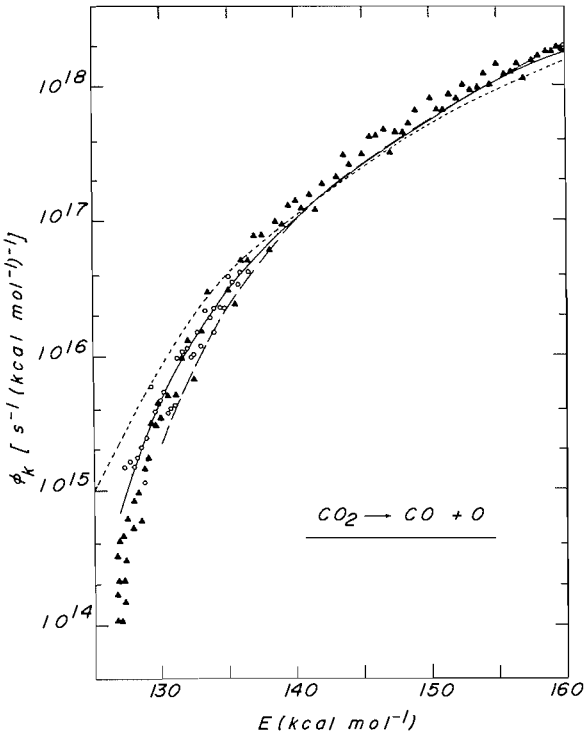

FIG. 3. Grained reaction probability function ϕ_k for the dissociation of CO_2 with $\Delta E = 0.05$ kcal mol^{-1}. See captions in Fig. 2: $A_\infty = 1.80 \times 10^{12}$ s^{-1}, $E_\infty = 127.3$ kcal mol^{-1}; $A_\infty' = 1.20 \times 10^{12}$ s^{-1}, $E_\infty' = 124.8$ kcal mol^{-1}; $A_\infty'' = 2.70 \times 10^{12}$ s^{-1} and $E_\infty'' = 129.8$ kcal mol^{-1}.

Equation [15] has been calculated using the Arrhenius parameters obtained in ref. 1 and compared with ϕ_k in Fig. 2 for N_2O and in Fig. 3 for CO_2. In both figures, the values of ϕ_k are represented by solid triangles, while $\phi_{k,app}$ is shown as a smooth curve: near the threshold, the $\phi_{k,app}$ values actually exhibit some fluctuations, as indicated by the open circles. The remarkable agreement between the solid curve and the triangles in the intermediate energy range (between 10 and 30 kcal mol^{-1} above the Arrhenius activation energy) should not be surprising: the strict Arrhenius law approximates the exact rates best at the medium temperatures (1000–3000 K in N_2O and 2000–5000 K in CO_2) where the reactive state population distribution (i.e., $F(E_j)$ exp $(-\beta E_j)$ in eq. [4]) peaks within this energy range. It is interesting to note that the high energy region of ϕ_k is important only at very high temperature, where the concept of an infinite pressure rate constant (in the Tolman sense (9)) becomes less well-defined (8). Conversely, the low energy region (near the threshold) of ϕ_k is important only at very low temperature (for recombination studies); hence we may expect the largest departure between ϕ_k and $\phi_{k,app}$ in this energy region. A flow chart illustrating the principal computational steps in this comparison is given in Fig. 4.

Figures 2 and 3 show that, at least for the two reaction systems studied here, the inversion of the strict Arrhenius rate law (eqs. [3] and [7]) does lead to a reasonable approximation to the exact reaction

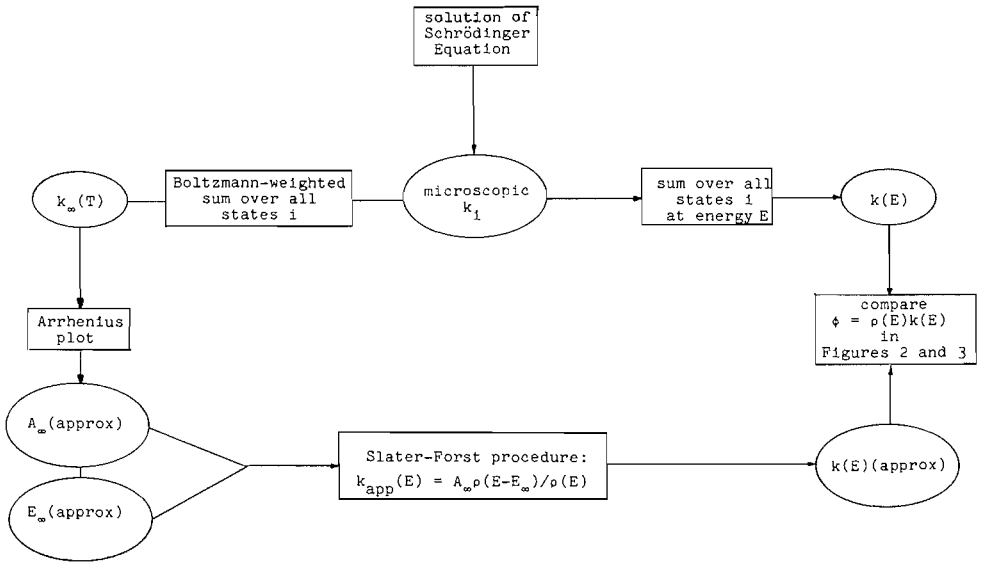

FIG. 4. Schematic flow chart of the test procedure.

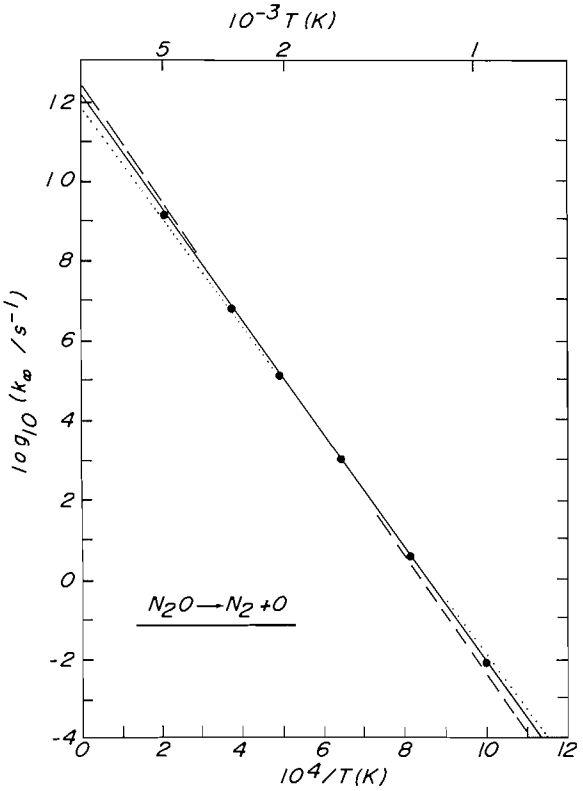

FIG. 5. Arrhenius plot of the infinite pressure rate constant for the dissociation of N_2O. Solid circles: computed (exact) rates from ref. 1; solid line: Arrhenius rate law with A_∞ = 1.41 × 10^{12} s^{-1} and E_∞ = 65.10 kcal mol^{-1}; dotted line: Arrhenius rate law with A_∞' = 7.05 × 10^{11} s^{-1} and E_∞' = 63.25 kcal mol^{-1}; dashed line: Arrhenius rate law with A_∞'' = 2.82 × 10^{12} s^{-1} and E_∞'' = 67.87 kcal mol^{-1}.

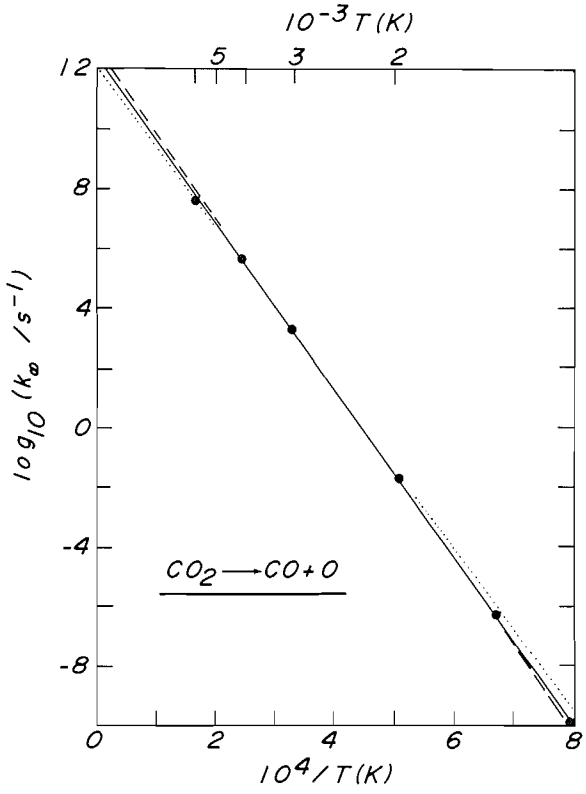

FIG. 6. Arrhenius plot of the infinite pressure rate constant for the dissociation of CO_2. Solid circles: computed (exact) rates from ref. 1; solid line: Arrhenius rate law with A_∞ = 1.80 × 10^{12} s^{-1} and E_∞ = 127.3 kcal mol^{-1}; dotted line: Arrhenius rate law with A_∞' = 1.20 × 10^{12} s^{-1} and E_∞' = 124.8 kcal mol^{-1}; dashed line: Arrhenius rate law with A_∞'' = 2.70 × 10^{12} s^{-1} and E_∞'' = 129.8 kcal mol^{-1}.

probability function. It is important to assess the sensitivity of the inversion procedure to variations of the Arrhenius parameters. For each reaction, two additional pairs of parameters have been chosen to test this sensitivity. For N_2O, A_∞' = 7.05 × 10^{11} s^{-1}, E_∞' = 63.25 kcal mol^{-1} and A_∞'' = 2.82 × 10^{12} s^{-1}, E_∞'' = 67.87 kcal mol^{-1}; for CO_2, A_∞' = 1.20 × 10^{12} s^{-1}, E_∞' = 124.8 kcal mol^{-1} and A_∞'' = 2.70 × 10^{12} s^{-1}, E_∞'' = 129.8 kcal mol^{-1}. They are compared with the "best" parameters (A_∞ = 1.41 × 10^{12} s^{-1} and E_∞ = 65.1 kcal mol^{-1} for N_2O and A_∞ = 1.80 × 10^{12} s^{-1} and E_∞ = 127.3 kcal mol^{-1} for CO_2) and the exact reaction rates in Figs. 5 (for N_2O) and 6 (for CO_2).

Going back to Figs. 2 and 3, the dotted curves denote the grained reaction probability functions $\phi_{k,app}'$ obtained using A_∞' and E_∞':

$$[15a] \quad \phi_{k,app}' = A_\infty'[G(E_{k+1} - E_\infty') - G(E_k - E_\infty')]/\Delta E$$

the dashed curves denote $\phi_{k,app}''$ obtained from A_∞'' and E_∞'':

$$[15b] \quad \phi_{k,app}'' = A_\infty''[G(E_{k+1} - E_\infty'') - G(E_k - E_\infty'')]/\Delta E$$

In both figures, these two curves intersect with the solid curve ($\phi_{k,app}$, eq. [15]) and with each other in the intermediate energy region. In other words, both $\phi_{k,app}'$ and $\phi_{k,app}''$ approximate the exact function best in this energy region. This is to be expected since both sets of Arrhenius parameters approximate the exact rates k_∞ best in the medium temperature range. As we have discussed previously (8), this is simply a consequence of the linearity property of the Laplace Transform.

Likewise, the divergent departure between $\phi_{k,app}'$ and $\phi_{k,app}''$ at very high energy is related to the corresponding departure between the respective Arrhenius expressions at very high temperature.

Here, it is pleasing to note that in the case of N_2O (Fig. 2), a factor of 4 variation in the pre-exponential factor results in only a factor of 2 variation of $\phi_{k,app}$ at 30 kcal mol^{-1} above E_∞. In experiments where a factor of 2 uncertainty in the A-factor is not atypical, the variation of $\phi_{k,app}$ in the corresponding energy region may be expected to be even smaller, as is illustrated in the case of CO_2 (Fig. 3).

Discrepancies between the respective $\phi_{k,app}$'s are most drastic near E_∞, but even here, the difference in absolute magnitude between $\phi_{k,app}'$ and $\phi_{k,app}''$ at and above E_∞'' is not phenomenal (a factor of 2 at E_∞'' for a variation of 4.6 kcal mol^{-1} in the Arrhenius activation energy in N_2O; a factor of 3 at E_∞'' for a variation of 5 kcal mol^{-1} in the Arrhenius activation energy in CO_2). Notice that even in this energy region, $\phi_{k,app}$ gives the best approximation to ϕ_k. The most serious difficulty is that $\phi_{k,app}$ is zero between the critical energy of reaction E_0 and the activation energy E_∞ ($E_\infty > E_0$) whereas ϕ_k is not. Note, however, that $\phi_{k,app}$ is *not* zero at E_∞; also, ϕ_k is small between E_0 and E_∞. Hence, the discrepancy between ϕ_k and $\phi_{k,app}$ in this region is unlikely to magnify in rate calculations of typical physical systems (unless the latter sample predominantly this energy region). From a computational standpoint, we may catagorise reaction systems into two classes: those in which ($E_\infty - E_0$) is large (such as N_2O), where ϕ_k is extremely small between E_∞ and E_0 (see ref. 1) and may therefore be well approximated by zero, and those in which E_0 and E_∞ are close to one another (such as CO_2), where simple procedures may be employed to interpolate between the zero value of $\phi_{k,app}$ at E_0 and the non-zero values of $\phi_{k,app}$ at and above E_∞. Alternatively, the overall fit to ϕ_k may be improved by a linear combination of more than one Arrhenius expression as suggested previously (8).

Conclusions

The present work represents a first attempt to test the sensitivity and reliability of the Slater–Forst procedure for inverting the strict Arrhenius rate law using purely theoretical (and realistic) rate data (1); at a later date, similar tests should be made for some adiabatic reactions, but we see no reason to expect that the results will be any less encouraging since the non-adiabatic reactions can be expected, in general, to be more non-Arrhenius. For the two reactions studied, the test results are indeed positive in the sense that (*i*) given the "best" Arrhenius parameters, the inversion procedure yields faithfully a very good approximation to the exact probability function. It is important to recognise the nature of the test we are making: if we simply take the exact computed $k_\infty(T)$ function and perform an inverse Laplace Transform, then we should (barring rounding errors) recover the original $k(E)$; however, the function upon which we apply the inverse Laplace Transform is not $k_\infty(T)$, but an approximate parametrisation of it, viz. $k_\infty(T) = A_\infty \exp(-E_\infty/RT)$. Moreover, by assuming that E_∞ can only be determined to within ± 2 or 3 kcal mol^{-1}, we have shown that (*ii*) reasonably approximate (experimental) rate laws would lead to reasonable approximations to the exact reaction probability function $k(E)$. It should also be noted that we are guaranteed approximate coincidence between the original theoretical and the doubly transformed values of $k(E)$ around the mean reaction energy, but what is remarkable about Figs. 2 and 3 is the fact that (*iii*) for these two reactions the inverse Laplace Transform approximation is uniformly satisfactory at all energies above the activation energy E_∞, including the very high energies which make little contribution to the reaction rate in the temperature ranges considered (1). Finally, it would appear that if it proves necessary (*iv*) simple interpolation procedures should prove adequate for synthesising approximate values of $k(E)$ between E_∞ and E_0 (the critical energy of the reaction), both when E_∞ and E_0 are far apart (e.g. N_2O) and when they are close to one another (e.g. CO_2).

Active surface centres in vanadium pentoxide/alkali metal sulphate heterogeneous catalysts for 2-propanol decomposition

DAVID VICTOR FIKIS, WILLIAM JOHN MURPHY,[1] AND ROBERT ANDERSON ROSS[2]

Department of Chemistry, Lakehead University, Thunder Bay, Ont., Canada P7B 5E1

Received December 11, 1978

DAVID VICTOR FIKIS, WILLIAM JOHN MURPHY, and ROBERT ANDERSON ROSS. Can. J. Chem. 57, 2464 (1979).

Infrared spectra of the surfaces of vanadium pentoxide and vanadium pentoxide containing 9.09 mol% caesium and potassium, as sulphates, have been determined after exposure to 2-propanol for various times. Interpretation of the spectra leads to the proposal that the principal source of catalyst activity may be associated with surface hydrogen and hydroxyl groups on V^{5+} and V^{4+} sites. The "stability" of the catalysts towards reduction by the alcohol was consistent with the activity series derived from kinetic measurements: V_2O_5 (pure) < V_2O_5 (Cs) < V_2O_5 (K). The degree of sample reduction has also been assessed qualitatively by measurements of the ratio of surface area before to that after reaction and the same catalyst sequence was established. The trend in surface area ratios was similar to that shown by the surface "Tammann" temperatures of vanadium pentoxide and alkali metal sulphates which has been taken to imply that the ease and (or) extent with which the sulphates enter into inter-solid reactions with the oxide in the preparation stage may exert influence on the subsequent reducibility of the individual members of the catalyst series.

DAVID VICTOR FIKIS, WILLIAM JOHN MURPHY et ROBERT ANDERSON ROSS. Can. J. Chem. 57, 2464 (1979).

On a déterminé les spectres infrarouges de surfaces de pentoxyde de vanadium et de pentoxyde de vanadium contenant 9.09 mol% de césium et de potassium, sous formes de sulfates, après les avoir exposées à du propanol-2 pour des temps variés. L'interprétation des spectres permet de suggérer que la source principale de l'activité catalytique est associée avec les hydrogènes et les groupes hydroxyles à la surface des sites V^{5+} et V^{4+}. La stabilité des catalyseurs vis-à-vis la réduction par l'alcool est en accord avec la suite d'activité dérivée de mesures cinétiques: V_2O_5 (pur) < V_2O_5 (Cs) < V_2O_5 (K). On a aussi déterminé qualitativement le degré de réduction d'échantillon à l'aide de mesures de rapports de surface avant et après la réaction et on a déterminé que l'ordre des catalyseurs est le même. La tendance dans les rapports des surfaces est semblable à celle obtenue grâce aux températures de surface "Tammann" du pentoxyde de vanadium et des sulfates de métaux alcalins; on en déduit que la facilité ou le degré de réactions inter-solides entre les sulfates et l'oxyde lors de la préparation peut influencer la facilité subséquente de la réduction de membres individuels de la série des catalyseurs.

[Traduit par le journal]

Introduction

We have recently reported the results of a kinetic study of 2-propanol decomposition on vanadium pentoxide and alkali metal promoted vanadium pentoxide catalysts (1). Mechanisms based on elimination-type reactions were proposed and some evidence of a relationship between catalyst activities and the presence of "acidic" species on the solid surface was presented. Similar preparations have been examined in a number of surface reactions including oxidation and oxygen-exchange systems (2–5) where catalyst activity trends can be explained in terms of variations in the surface mobility of the catalyst oxygen with the additive activity series: V_2O_5 (none) < Li_2SO_4 < Na_2SO_4 < K_2SO_4 < Rb_2SO_4 < Cs_2SO_4 (2–6).

Variations of the additive positions in this series were observed in studies of oxygen exchange from $O_2/C^{18}O_2$ systems (7) and, in particular, the sequence was not obtained for the heterogeneous decomposition of 2-propanol (1). The latter investigation has now been extended to include an infrared spectroscopic study of the catalyst surfaces in an attempt to identify active sites and to monitor the catalyst reduction process.

Experimental

Samples of vanadium pentoxide (>99.9% pure; Ventron, MA) and catalysts containing 9.09 mol% alkali metal sulphate (>99.9% pure; Ventron, MA) were prepared as previously described (1).

0008-4042/79/182464-06$01.00/0

Certified grade helium (> 99.9% pure; Canadian Liquid Air, Toronto) was passed through a series of saturators containing 2-propanol (Fisher "Spectranalyzed" grade) to obtain the required partial pressure of reactant and then directed through a Pyrex-lined tube furnace where samples were contained in Pyrex boats. Temperature was maintained at 300 ± 0.5°C by means of a "Thermo Electric 400" indicating controller. Samples were removed by quenching to room temperature after various exposure times prior to measurement of infrared spectra. Experiments in which hydrogen (> 99.9% pure; Canadian Liquid Air, Toronto) was substituted for 2-propanol were carried out in a similar manner.

Transmission infrared spectra of both used and fresh samples were determined using the KBr disc method. Specimens were prepared by grinding a mixture of the appropriate solid with KBr in an agate mortar and then pelletizing in the usual manner. The time during which water adsorption from the atmosphere could have occurred was kept to a minimum and the absence of water confirmed by scanning at ~3400 cm^{-1}. Pellets containing caesium and potassium sulphates had 0.95 mg of catalyst/200 mg KBr while pure V_2O_5 pellets contained 0.60 mg V_2O_5/200 mg KBr. Infrared spectra were measured using a Beckman IR-12 spectrometer. This method gave better defined spectra than those obtained with infrared ATR spectroscopy in parallel experiments.

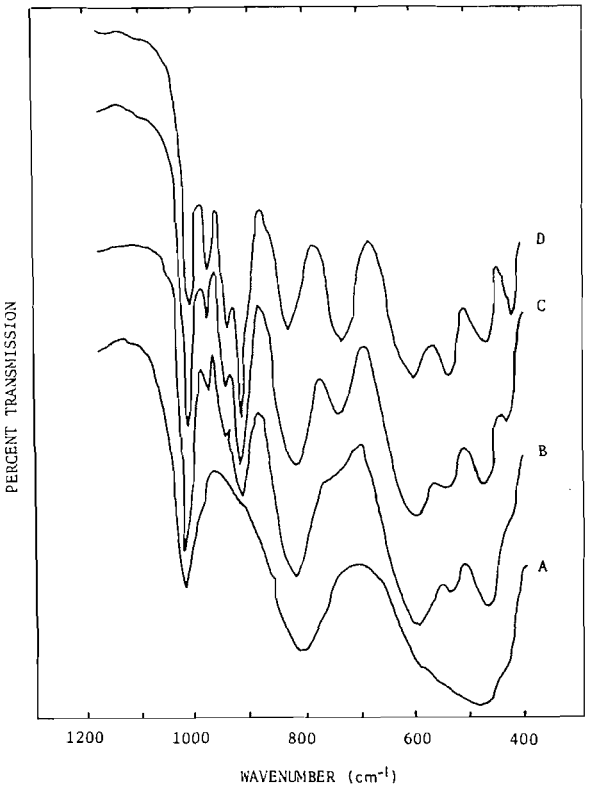

FIG. 1. Infrared spectra of vanadium pentoxide samples before and after exposure to 2 Torr (0.267 kPa) of 2-propanol at 300°C: (A) unexposed; (B) exposed for 7.5 min; (C) exposed for 15 min; and (D) exposed for 60 min.

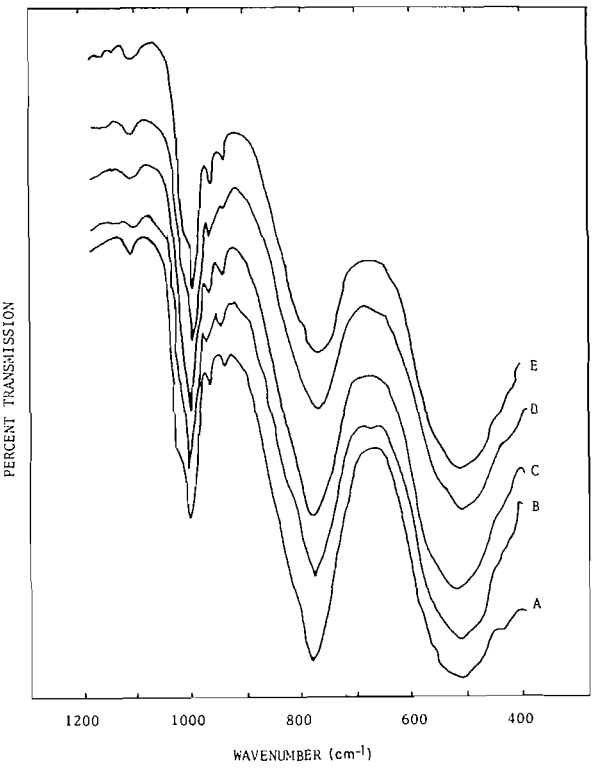

FIG. 2. Infrared spectra of potassium-promoted vanadium pentoxide samples before and after exposure to 2 Torr (0.267 kPa) of 2-propanol at 300°C: (A) unexposed; (B) exposed for 7.5 min; (C) exposed for 15 min; (D) exposed for 45 min; and (E) exposed for 90 min.

Results

Figures 1–3 show infrared spectra of V_2O_5 and V_2O_5 promoted with 9.09 mol% K_2SO_4 and Cs_2SO_4 before and after exposure to 2-propanol at 300°C. Figure 4 shows the infrared spectra of V_2O_5 after exposure to hydrogen at 300°C.

V_2O_5 exhibits a very characteristic spectrum before reaction (Fig. 1A), with three major peaks at 1020, 825, and 450–600 cm^{-1}, identified, respectively, as a V=O stretching vibration, a V—O—V stretching vibration, and possibly a V—O—V rocking vibration (7–10). After exposure to 2-propanol all three bands split into multiplets, Fig. 1B–D.

Prior to the action of 2-propanol, the potassium and caesium catalysts show splitting of the characteristic vanadium–oxygen peaks (Figs. 2A and 3A). The splitting is more clearly defined for the caesium sample and, unlike the potassium-promoted catalyst, includes the V—O—V bands.

The caesium sample shows an increase in splitting in step with increased exposure to 2-propanol (Fig. 2)

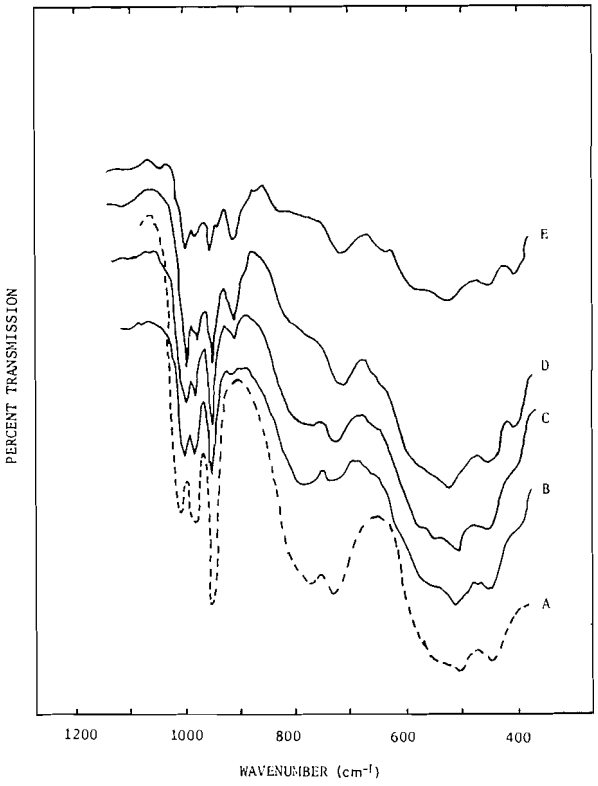

FIG. 3. Infrared spectra of caesium-promoted vanadium pentoxide samples before and after exposure to 2 Torr (0.267 kPa) of 2-propanol at 300°C: (A) unexposed; (B) exposed for 7.5 min; (C) exposed for 15 min; (D) exposed for 45 min; and (E) exposed for 90 min.

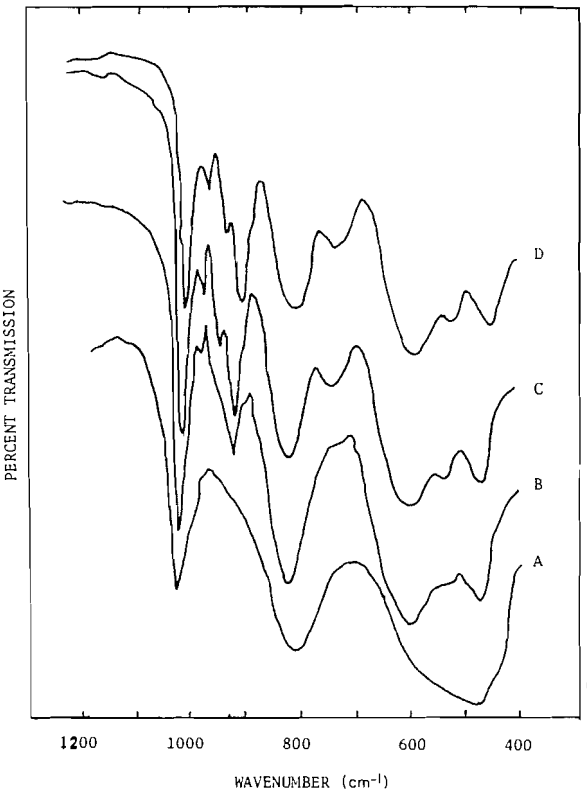

FIG. 4. Infrared spectra of vanadium pentoxide samples before and after exposure to hydrogen at 300°C: (A) unexposed; (B) exposed for 15 min; (C) exposed for 30 min; and (D) exposed for 45 min.

similar to V_2O_5 (Fig. 1), while the catalyst containing potassium appears unaffected (Fig. 3).

V_2O_5 exposed to hydrogen at 300°C (Fig. 4) does not show the rapid, extensive splitting characteristic of V_2O_5 exposed to 2-propanol under similar conditions (Fig. 1). Although both hydrogen and 2-propanol produce new bands at 925 and 750 cm^{-1}, the latter exhibits a longer induction period with hydrogen treatment.

Surface areas of the catalysts obtained during kinetic studies under similar conditions (1) are compared in Fig. 5 as a ratio of the values obtained before and after reaction. The figure includes data on the surface "Tammann" temperature, $0.3T_m$ (11) of V_2O_5 and all of the alkali metal sulphate additives studied here and previously (1).

Discussion

Characterisation of the Vanadium/Oxygen Species

The infrared spectra of freshly prepared samples of V_2O_5 and V_2O_5 containing alkali metal promoters have been reported (7) and the major bands, i.e., 1020, 825, and 600 cm^{-1}, correlated with the stretching frequencies of the V=O and V—O—V groups and with the frequency of the V—O—V group in a rocking vibration, in agreement with the literature (8, 12). In the present studies, the appearance of bands ranging from 1000–920 cm^{-1} on reaction of promoted and pure vanadium pentoxide samples with both hydrogen and 2-propanol may indicate that entities with structural similarities to V=O and V—O—V network species in V_2O_5 have been created. However, the V=O and V—O—V bonding states in V_2O_5 are not readily trackable (7) since the observed frequencies are influenced significantly by the lattice environments of the species.

The stretching frequency of "monomeric" V=O has been reported (13) at 987 cm^{-1} in pure $VOSO_4$, whereas that for $VOCl_3$ was 1035 cm^{-1} (9, 10). Recently, the V=O stretching frequencies for a series

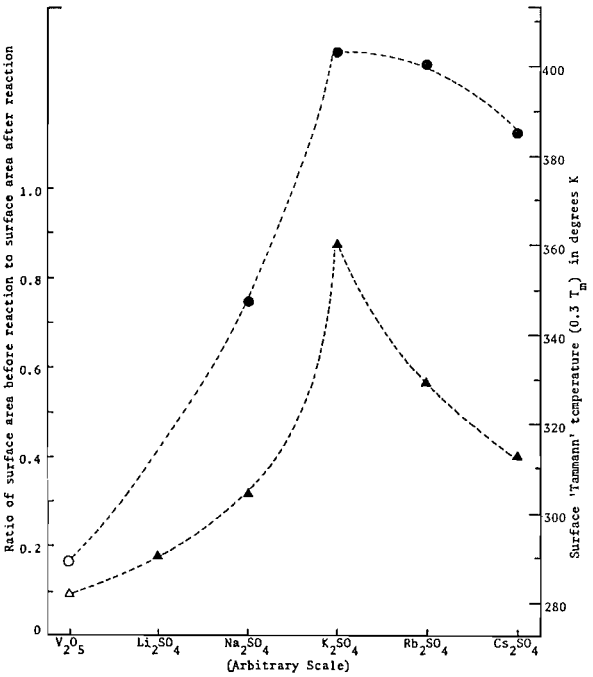

FIG. 5. Correlation diagram showing the ratio of surface area before and after reaction ((△) V_2O_5; (▲) melts containing 9.09 mol% alkali metal sulphate) and the surface "Tammann" temperature ($0.3T_m$) for V_2O_5 (○) and the added alkali metal sulphates (●).

of vanadyl complexes have been observed in which the ν(V—O) varied from 979 to 955 cm^{-1} (14) while the infrared frequencies of VO^{2+} in alkali halides have been shown to vary from 765 to 825 cm^{-1} (15). The displacement in V=O frequency may be a consequence of d_π–p_π metal–oxygen interactions which act to produce a stronger bond and hence a higher ν(V—O) (14, 15). Thus any lattice modification which enhances the d_π–p_π interactions would be expected to increase bond strength with the corollary that a diminution in d_π–p_π interactions would result in a weaker bond and lower ν(V—O).

Comparison of spectra A in Figs. 1–3 and, in particular, the stretching frequencies of the "V=O species" in these solids (Table 1) suggests that inclusion of an alkali metal in the pentoxide lattice affects the electron delocalisation of the surface. This phenomenon has been shown to have a marked effect on the catalytic activity (7) associated with V=O, probably through enhancement of d_π–p_π metal–oxygen interactions. However, such inclusions modify the crystal structure to an extent dependent, *inter alia*, on the size of the included atom and

TABLE 1. Stretching frequencies of the "V=O species"

Sample	ν(V—O) (cm^{-1})
V_2O_5	1020
V_2O_5 (K promoted)	1020, 1015, 1005
V_2O_5 (Cs promoted)	1020, 995, 965

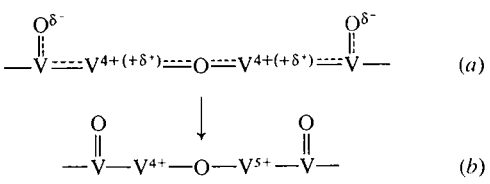
results in the "V=O species" ν(V—O) being split into a triplet, the splitting increasing with the size of the added metal atom (Table 1). This effect is parallelled by a corresponding splitting in the V—O—V stretching and rocking vibration frequencies as might be expected (Fig. 3A).

An examination of the structure of V_2O_5 indicates that V=O and V—OH are surface groups not found in the bulk material. On the other hand, the V—O—V species is present both on the surface and in the bulk. Comparison of transmission and reflectance (ATR) infrared spectra showed a minimal difference in the relative intensities associated with the V=O and V=OH entities thus confirming the allocation of the present data to surface species. (The ATR results were not so intense overall owing to light loss in the attachment.)

Decomposition of 2-Propanol

Figure 1 shows that with increase in exposure time of 2-propanol on V_2O_5 from 0 to 15 min, an increase in the intensity of the V=O band is observed, accompanied by a slight increase in the band frequency from 1020 to 1025 cm^{-1}. An increase of band intensity would suggest that the population of the species has increased which would generally have been expected to occur along with a decrease in the band width, as was observed initially (Fig. 1A, B). The frequency increase may be indicative of a decrease in the extent of delocalisation due to adsorption of 2-propanol on V^{4+} and V^{5+} sites as recently proposed (1, 12). Adsorption on the V^{4+}

[1]

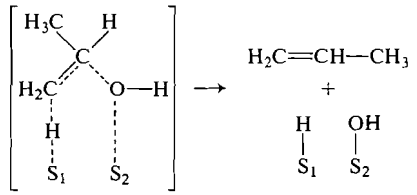


SCHEME I

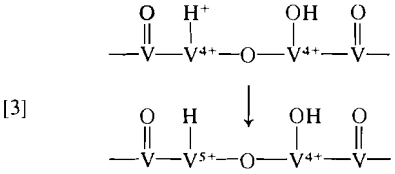
and V^{5+} sites would tend to reduce the extent of delocalisation and promote d_π–p_π metal–oxygen overlap through increased donation of electrons into *d* orbitals of vanadium.

We have proposed previously (1) that 2-propanol initially decomposes on vanadium pentoxide by a

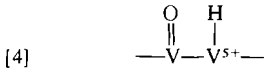
dehydration mechanism which may proceed from the intermediate



where S_1 and S_1 are V^{4+} and V^{5+}, respectively, thus yielding

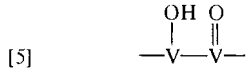


surface arrangements (2). The formation of



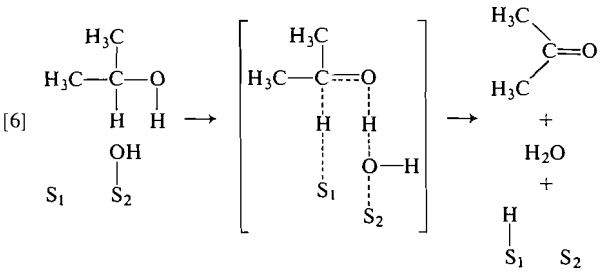
would be expected to decrease d_π–p_π metal–oxygen overlap in the V=O system due to the electron-accepting propensity of the vacant d orbital in V^{5+} which is adjacent to the V=O species. Such a mechanism could lead to a decrease in the metal–oxygen bond strength and a corresponding decrease in the ν(V—O). The appearance of the new band at 925 cm^{-1} may then be explained by the formation of a destabilised V=O species. The appearance of this band is also observed on reduction of V_2O_5 with H_2 (Fig. 4), indicating that it is unlikely to be ascribed to the presence of chemisorbed organic entities on the catalyst surface.

The appearance of the bands at 750 cm^{-1} may be related to the formation of surface hydroxide (16),

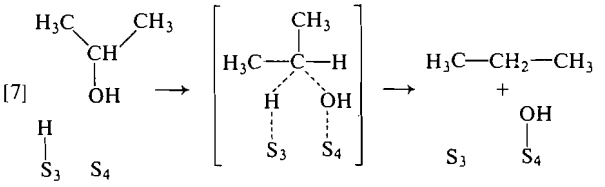


which would increase in degree of surface coverage with the progress of the reaction.

It was observed earlier that propane and acetone became significant decomposition products as the exposure time of V_2O_5 to the alcohol was increased and mechanisms of the type shown in [6] were proposed (1) to account for the formation of both products:



Now, if S_1 is V=O and S_2 is V^{4+} then this scheme could account for the gradual decrease in intensity of the 1020 cm^{-1} band and hence the number of V=O groups in the catalyst. Similarly, the active sites for propane formation may contribute to catalysis, thus



and if S_3 is V^{5+} adjacent to a V=O and S_4 is V^{5+} then the end result would be an increase in the surface population of V^{4+}—OH as indicated by the growth of the 750 cm^{-1} band with time (Figs. 1, 3).

Although the direct reaction of hydrogen on V_2O_5 produces both the 925 and 750 cm^{-1} band (Fig. 4), the former continues to grow with increase in exposure time, whereas the 750 cm^{-1} band appears to reach a steady level. The V—OH species, which gives rise to the 750 cm^{-1} band, can only be produced by hydrogen reaction with V=O and not, as in the case of the band at 925 cm^{-1}, by straight adsorption on V^{4+} sites.

Trends in the extent of reduction by hydrogen of a similar series of catalysts have been related to changes in the mobility of catalyst oxygen (6). Reduction of the present catalysts by exposure to 2-propanol did not exhibit such a relationship.

The infrared spectra of the promoted catalysts, before reaction, show splitting of the V=O and V—O—V bands which have been attributed to bond destabilization (7). The degree of bond destabilization and hence catalyst reduction, on exposure to 2-propanol, should be reflected by the extent of splitting in the infrared bands. Figures 1–3 show that the caesium- and potassium-promoted catalysts are less susceptible to reduction than pure vanadium pentoxide. Thus, the "stability" of the catalysts with respect to reduction by 2-propanol appears to be

[8] V_2O_5 (no additive) < V_2O_5 (Cs) < V_2O_5 (K)

The above trend parallels the catalyst activity series previously reported for 2-propanol decomposition (1). Minor variations in the levels of activity shown by other members of the series of alkali metal promoted catalysts may be related to the presence of different phases in the solid solutions and (or) changes in the extent of delocalization and destabilization of surface V=O and V—O—V bonds (7).

Recently, "atomic" hydrogen has been shown to be a more effective reducing agent for vanadium pentoxide than "molecular" hydrogen (17) which suggests that differences in reported reduction patterns for similar catalyst series based on V_2O_5 (1, 6) may be related to variations in the bonding level of adsorbed hydrogen, itself influenced by the redox potential of surface sites and by the form of dissociation on adsorption from the gaseous reactant.

The degree of catalyst reduction as related to solid sintering has also been demonstrated by measurements of surface area changes. If the ratio of surface area before reaction to that after reaction is taken as a broad qualitative measure of catalyst "stability", then the same series as that given by the infrared spectra is apparent (Fig. 5).

The similar trends shown by the surface "Tammann" temperatures (11) and the surface area ratios (Fig. 5) are taken simply to indicate the relative ease or extent with which the alkali metal sulphates and vanadium pentoxide enter into inter-solid reactions in the preparative melts which may later influence the reducibility and perhaps activity of the catalyst in a given reaction.

Figure 3 shows that similar general trends to those shown by V_2O_5 are observed with the reaction of 2-propanol on caesium-promoted samples. Initially, the population of the stronger V=O band, 1020 cm^{-1}, increases while that at 995 cm^{-1} decreases. No frequency shift was observed in the position of the V=O bands on reaction with 2-propanol probably through the modification of electronic features related to the incorporation of caesium in the pentoxide lattice. This feature would also explain the observation that the intensity of the 925 cm^{-1} band is not as large as that in pure V_2O_5 nor does it increase much with exposure time. Ultimately, however, the 750 cm^{-1} band intensity does increase significantly until it becomes the predominant V—O stretching band through the continual buildup of V—OH.

Figure 2 shows that the reaction of 2-propanol on potassium-promoted samples does not create new bands to any significant extent and so no new surface species of any permanency can be anticipated. The 1020 cm^{-1} band and the lower frequency bands all decrease in intensity at the same rates.

We conclude that the decomposition of 2-propanol on V_2O_5 and caesium-promoted V_2O_5 produces V—H and V—OH species in close proximity on the surface and that these remain there in a chemisorbed state after reaction. It has been proposed (12) elsewhere, however, that such species may react to give water,

$$[9]\quad \begin{matrix} H^+ & & OH \\ | & & | \\ V^{4+}—O—V^{4+}—O \end{matrix} \longrightarrow V^{5+}—O—V^{4+} + H_2O$$

which would mean that (*a*) the V=O species would not be destabilised since there would be a continual removal of adjacent V^{4+} and (*b*) the 750 cm^{-1} band would not be observed since the concentration of V—OH on the surface at any given time would be very small. Thus, it may be that variations observed in the surface structures of vanadium pentoxide and promoted catalysts with time of exposure to 2-propanol are related to kinetic differences in surface mechanisms such as the rate at which the latter reaction takes place with respect to the other steps involved in the overall decomposition.

Ionization of ethylene glycol in isodielectric acetonitrile + ethylene glycol mixtures at 25°C

KUMARDEV BOSE AND KIRON K. KUNDU[1]

Physical Chemistry Laboratories, Jadavpur University, Calcutta-700032, India

Received August 15, 1978[2]

KUMARDEV BOSE and KIRON K. KUNDU. Can. J. Chem. 57, 2470 (1979).

The autoprotolysis constants (K_s^m) of ethylene glycol in isodielectric acetonitrile + ethylene glycol mixtures have been determined at 25°C from emf measurements on the cell

Pt, H_2(g, 1 atm)|Na–glycoxide(m_1), NaCl(m_2), solvent|AgCl–Ag.

From these values, those of $\delta\Delta G^0$, the free energy of ionization of ethylene glycol in these mixed solvents relative to that in pure glycol, have been computed. The nature of variation of $\delta\Delta G^0$ with solvent composition has been compared with that in two other mixed systems: water + ethylene glycol and methanol + 1,2-propanediol and the intrinsic differences between the solvation characteristics of the various solvents have been pointed out. The standard free energies of transfer of the glycoxide ion, $\Delta G_t^0(OEg^-)$, from pure glycol to acetonitrile + glycol mixtures have also been estimated using $\Delta G_t^0(H^+)$ values obtained earlier. The glycoxide ion is increasingly desolvated as the acetonitrile content of the solvent increases, as indicated by increasingly positive values of $\Delta G_t^0(OEg^-)$. This behaviour has been compared with those of $\Delta G_t^0(H^+)$ and $\Delta G_t^0(Cl^-)$ determined previously.

KUMARDEV BOSE et KIRON K. KUNDU. Can. J. Chem. 57, 2470 (1979).

Opérant à 25°C, on a déterminé les constantes d'autoprotolyse (K_s^m) de l'éthylèneglycol dans des mélanges isodiélectriques acétonitrile–éthylèneglycol en se basant sur des mesures de fem de la cellule

Pt, H_2(g, 1 atm)/glycolate de Na(m_1), NaCl(m_2), solvant/AgCl–Ag

A partir de ces valeurs, on a calculé l'énergie libre d'ionisation, $\delta\Delta G^0$, de l'éthylèneglycol dans ces solvants mixtes par rapport au glycol pur. On a comparé la nature de la variation du $\delta\Delta G^0$ en fonction de la composition du solvant avec celle observée dans deux autres systèmes mixtes; eau–éthylèneglycol et méthanol–propanediol-1,2 et on identifie les différences intrinsèques entre les caractéristiques de solvatation de divers solvants. On a aussi évalué les énergies libres standard de transfert de l'ion glycolate, $\Delta G_t^0(EgO^-)$, du glycol pur à des mélanges acétonitrile–glycol en se basant sur les valeurs de $\Delta G_t^0(H^+)$ obtenues antérieurement. Quand la proportion d'acétonitrile dans le solvant mixte augmente, l'ion glycolate se désolvate progressivement et cet effet se reflète par des valeurs de $\Delta G_t^0(EgO^-)$ qui sont de plus en plus positives. On compare ce comportement avec ceux de $\Delta G_t^0(H^+)$ et $\Delta G_t^0(Cl^-)$ déterminés antérieurement.

[Traduit par le journal]

Introduction

The free energy of transfer, ΔG_t^0, of a solute from a standard state (usually the infinitely dilute solution) in a reference solvent to a standard state (also one of infinite dilution) in a second solvent is recognized as one of the most important quantities reflecting the intensity of solute–solvent interactions taking place in the chemical milleau under consideration. However, when a charged species, like an ion, is transferred from solvent A to solvent B, a sizeable contribution to the observed ΔG_t^0 arises from the difference in the dielectric constants of A and B. This so-called Born contribution (1) to ΔG_t^0 is due to the long-range coulombic interaction between the ion and the solvent regarded as a continuum. Solution chemists are much more interested in the remaining "non-Born" part of ΔG_t^0, often called the "chemical" part, which measures the specific and short-range interactions between the ion and its neighbouring solvent molecules.

To estimate and allow for the Born part and hence to determine the chemical part is a task involving too many unknowns and uncertainties, as has been pointed out (1, 2), and it would be unwise to interpret results obtained so tentatively. One, although admittedly not a general, way of solving this problem is to choose the solvents A and B in such a manner that their dielectric constants are more or less equal. The transfer of an ion between such isodielectric solvents entails no significant changes in the long-range ion–solvent interactions and the

[2]Revision received May 18, 1979.

0008-4042/79/182470-06$01.00/0

magnitude of the Born contribution is therefore negligibly small. Thus, ΔG_t^0 of an ion in an isodielectric solvent system is all 'chemical'' and so faithfully reflects the short-range and specific interactions which are of paramount interest in solution chemistry.

Lately, our attention has been focussed on several such isodielectric solvent systems, one being the acetonitrile (ACN) + ethylene glycol (EgOH) system. In previous papers (3) we have determined the ΔG_t^0's of various electrolytes and estimated those of some individual ions in these mixed solvents, the reference solvent being EgOH. It has been pointed out that in this isodielectric system consisting of a protic (EG) and a dipolar aprotic (ACN) solvent, the nature of short-range ion–solvent interactions as well as the essential difference between the solvation characteristics of the two solvent types should be clearly revealed.

Extensive studies (4–11*a*) of proton transfer equilibria and reaction kinetics have shown that the basicity in a protic solvent is greatly enhanced by the addition of a dipolar aprotic solvent. In the ACN + EgOH system, specifically, Kundu and Aiyar (8) have demonstrated that the H_- function increases as the ACN content of the solvent mixture increases. The most important reason for this type of behaviour is that dipolar aprotic solvents are extremely poor solvators of anions (2, 12, 13), especially those anions which can interact with solvents only through hydrogen bonding (besides coulombic forces). Such an anion is the glycoxide ion (OEg^-), and the present paper aims to present thermodynamic evidence for its varying solvation behaviour with regard to EgOH, a protic solvent, and ACN, a dipolar aprotic one, from the determination of autoprotolysis constants in ACN + EgOH mixtures.

Since both the acidic and the basic character of ACN are very weak (2, 6, 13), we are concerned with the single equilibrium

[A] $EgOH(s) \rightleftharpoons H^+(s) + OEg^-(s)$

i.e. the ionization of EgOH. Here s indicates that the reacting species are in the standard state in the given solvent (14) and $H^+(s)$ counts all H^+(solvated) that are seen by the electrode. Cell [B],

[B] Pt, H_2(g, 1 atm)|Na–glycoxide(m_1), NaCl(m_2), solvent|AgCl–Ag

was used for emf measurements at 25°C and the solvent contained 0, 20, 40, or 60 wt.% ACN; m_1, m_2 represent molalities.

Experimental

Purification of the solvents has been described earlier (3*a*). G. R. Merck grade sodium chloride was used after drying at 300°C. Clean bits of sodium metal were dissolved in pure EgOH and the solvent composition was adjusted to requirement by adding ACN (stock 1). Direct addition of sodium to a mixed solvent was avoided as this caused a vigorous reaction leading to undesirable products. Stock 1 was mixed with a NaCl solution in the solvent (stock 2) in such suitable proportion as to keep the ratio $m_{OG^-}:m_{Cl^-} \approx 1$ in the resulting mixture (stock 3). The OEg^- ion concentration in stock 3 was determined by titration with a standard HCl solution. Solutions for emf measurement were prepared by dilution (by weight) of stock 3 with the solvent. Two sets of solution were prepared for each solvent, each set having a different value of the $m_1:m_2$ ratio. Assuming that the salts are completely dissociated in the dilute solutions the ionic strength $\mu \approx (m_1 + m_2)d_s$, where d_s is the solvent density, was generally maintained between 0.01 and 0.05. Adequate care was taken to avoid absorption of moisture and CO_2 during preparation and handling of the solutions, using a dry-box whenever possible.

Cell design, electrode preparation, experimental procedure etc. have been described earlier (3*a*, 15). No poisoning of the platinum electrodes was observed. Equilibrium was reached in 5 h in pure EgOH and in 8–10 h in the mixed solvents. The equilibrium emf was only slightly affected by the hydrogen bubbling rate and could be reproduced to within ±0.5 mV by introducing a freshly platinized electrode.

Results and Discussion

The emf values were corrected to a hydrogen pressure of 1 atm as earlier (3*a*). The corrected emf values (E) recorded in Table 1 are accurate to within ±0.5 mV. The extrapolation function pK_s' given by [1] was then constructed;

$$[1] \quad pK_s' = \frac{F(E - E^0)}{(\ln 10)RT} - \log\frac{m_1}{m_2}$$

$$= pK_s^m - \log\frac{\gamma_{Cl^-} \cdot a_{EgOH}}{\gamma_{OEg^-}} = pK_s^m + f(\mu)$$

where the symbols carry their usual meaning (11*a*). The standard state is so chosen that at infinite dilution in a given solvent, $\gamma_{Cl^-} = \gamma_{OEg^-} = a_{EgOH} = 1$. The linear plots of pK_s' vs. μ (Fig. 1) were extrapolated to $\mu = 0$ to obtain values of pK_s^m (molal scale). Values of E^0 and d_s were taken from a previous paper (3*a*). The uncertainties in the pK_s^m values (Table 2) are ±0.01 for pure EgOH and ±0.02 for the mixed solvents. The values of pK_s' in each of the solvents when fitted to linear form by the method of least squares, furnish identical values of pK_s as well as their standard deviations as noted above.

In a mixed solvent system having at least one protic component ROH it is possible to define the ionization constant of ROH, i.e. the equilibrium constant for the general reaction [A], in a variety of ways depending on the standard state of ROH chosen. Hepler and co-workers (17) have derived

useful conclusions regarding the ionization of water in a number of mixed aqueous solvents by considering the quantity

$$[2] \quad K_{a/c} = C_H C_{OR} (y_\pm)^2 / C_{ROH}$$

where C_H, C_{OR}, and C_{ROH} represent the molar concentrations of H^+, OR^-, and ROH in the mixed solvent and $y_\pm$ is the mean molar activity coefficient. (For mixed aqueous solvents, ROH = H_2O.)

$K_{a/c}$ is related to our operational constant K_s^m by (14)

$$[3] \quad K_{a/c} = K_s^m d_s^2 / C_{ROH}$$

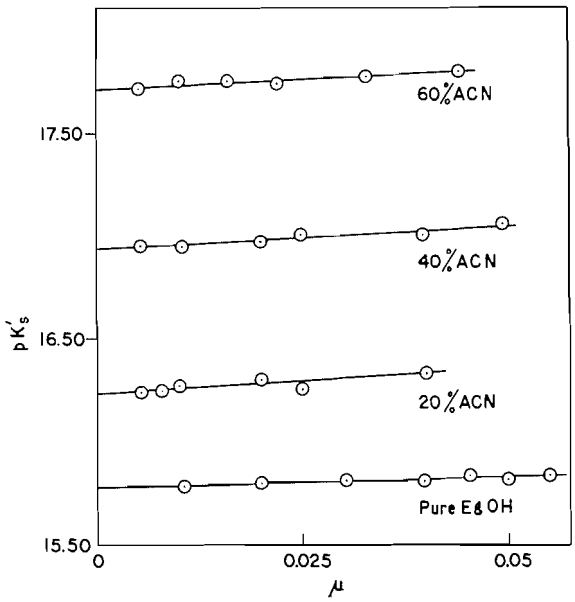

FIG. 1. Variation of pK_s' with μ in ACN + EgOH mixtures at 25°C.

where d_s is the density of the solvent. In terms of free energies, the ionization process may then be described by the quantity (14, 17)

$$[4] \quad \delta\Delta G^0 = {}_s\Delta G_{a/c} - {}_r\Delta G_{a/c}$$
$$= (\ln 10)RT\,[p({}_sK_{a/c}) - p({}_rK_{a/c})]$$

where $\Delta G_{a/c}$ is the free energy of ionization of ROH, and the subscripts s and r refer to quantities relating to the process occurring in a mixed solvent (s) and a "reference" solvent (r). It is usual to choose the pure solvent ROH as the reference solvent.

For the ACN + EgOH system (where ROH = EgOH), we have calculated the values of $\delta\Delta G^0$ using eqs. [3] and [4]; Fig. 2 shows the variation of $\delta\Delta G^0$ with mol% ACN. Moreover, as it was felt that a comparison of the behaviour of this system with that of others is likely to prove interesting, $\delta\Delta G^0$ values were also calculated for the H_2O + EgOH (ROH = EgOH) and the MeOH (methanol) + PgOH (1,2-propanediol) (ROH = PgOH) system, for which K_s^m data are available (15*a*, 16, 18). In Fig. 2, $\delta\Delta G^0$ is shown plotted against mol% H_2O and MeOH for the H_2O + EgOH and MeOH + PgOH systems respectively.

$\delta\Delta G^0$ plots for H_2O + EgOH and ACN + EgOH systems relate to the variation of the extent of ionization of EgOH in the presence of two different types of co-solvent. The decrease in $\delta\Delta G^0$ values for the former system may in part be accounted for by the increase in dielectric constant with increasing water content and the consequently greater ease of ionization; the remaining contribution is likely to arise from the greater net stability attained by the H^+ and OEg^- ions through increased solvation by water molecules. On the other hand, in the isodi-

electric ACN + EgOH system, the dielectric constant effect on $\delta\Delta G^0$ is negligibly small, but ACN being a dipolar aprotic solvent has little tendency to solvate either ion and ionization becomes more difficult with the progressive addition of ACN to EgOH, as shown by the rapidly increasing values of $\delta\Delta G^0$. The MeOH + PgOH system besides being isodielectric is also a protic–protic combination and as such there is little change in $\delta\Delta G^0$; whereas by comparison, the large change in dielectric constant accounts for a large part of the rapidly changing $\delta\Delta G^0$ in the H_2O + EgOH system, as indicated above. Again, ACN + EgOH and MeOH + PgOH are each an isodielectric system, and their average dielectric constants differ by only about 10 units; moreover EgOH and PgOH are much alike in chemical nature. Yet one observes a totally different nature of $\delta\Delta G^0$ plots for the two systems. This is because of the strongly contrasting solvation characteristics of MeOH and ACN: the protic MeOH is a good solvator for the hydrogen bonding ions while the dipolar aprotic ACN is not.

Informative as the above discussion might be,

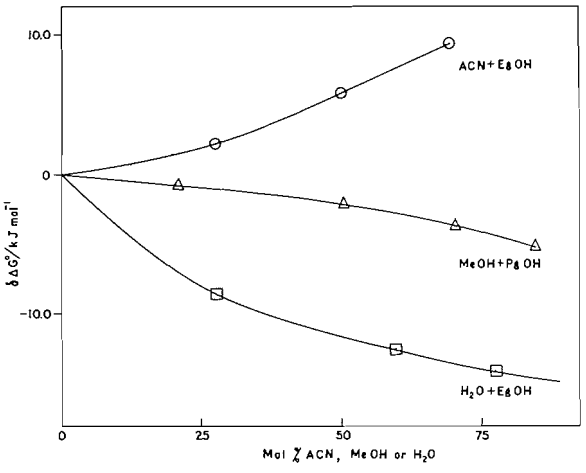

FIG. 2. Variation of $\delta\Delta G^0$ with mol% cosolvent at 25°C.

$\delta\Delta G^0$ plots can reflect no more than the overall solvation of the H^+ and OR^- ions. As shown earlier (14, 18), a knowledge of the ionic components of free energies should provide a clearer picture of specific ion–solvent interactions involved in the process. The evaluation and interpretation of the free energies of transfer of the OEg^- ion, $\Delta G_t^0(OEg^-)$, in ACN + EgOH mixtures are therefore in order.

The standard free energy on the mole fraction scale, corresponding to the process [A] in a mixed solvent ($_s\Delta G^0$) relative to that in pure EgOH ($_g\Delta G^0$) was computed by [5].

$$[5]\quad {}_s\Delta G^0 - {}_g\Delta G^0 = (\ln 10)RT[p({}_sK_s^m) - p({}_gK_s^m)] - 2RT \ln M_s/M_g$$

In this isodielectric system, the quantity ($_s\Delta G^0 - {}_g\Delta G^0$) is expected to reflect only the effects of the acidity and the basicity of the solvent (11*a*). This quantity is identical with ΔG_t^0(EgOH–EgOH)$_{sys}$, the free energy of transfer of EgOH molecules acting as an acid–base system from pure EgOH to a mixed solvent, i.e. the free energy change accompanying the process [C] (11*a*),

$$[C]\quad EgOH(S) + H^+(G) + OEg^-(G) \rightarrow EgOH(G) + H^+(S) + OEg^-(S)$$

which may be written as the sum of the processes [D] and [E],

$$[D]\quad H^+(G) \rightarrow H^+(S)$$

$$[E]\quad OEg^-(G) + EgOH(S) \rightarrow OEg^-(S) + EgOH(G)$$

In [C], [D], and [E], (G) and (S) denote that the species concerned are in the standard state in pure EgOH and the mixed solvent respectively. $\Delta G_t^0(H^+)$ and $\Delta G_{t,app}^0(OEg^-)$ are defined as the free energy changes for the processes [D] and [E] respectively, so that

$$[6]\quad {}_s\Delta G^0 - {}_g\Delta G^0 = \Delta G_t^0(EgOH-EgOH)_{sys} = \Delta G_t^0(H^+) + \Delta G_{t,app}^0(OEg^-)$$

When the standard state of EgOH molecules is referred to the particular solvent concerned, $\Delta G_{t,app}^{0}$-(OEg^-) is identical to $\Delta G_t^0(OEg^-)$, the standard free energy of transfer of the OEg^- ion from EgOH to that solvent, i.e. the free energy change for the process [F].

[F] $OEg^-(G) \rightarrow OEg^-(S)$

However, with pure EgOH as the standard state, these two quantities are related by [7] (11*a*),

[7] $\Delta G_t^0(OEg^-) = \Delta G_{t,app}^0(OEg^-) - RT\ln(a_{EgOH})_g^s$

where $(a_{EgOH})_g^s$ is the activity of EgOH in the mixed solvent referred to pure EgOH as the standard state. Assuming as earlier (3*a*) that Raoult's law is obeyed by this solvent system, we have $a_{EgOH} \approx x_{EgOH}$, the mole fraction of EgOH in the solvent, and combining [6] and [7], we get

[8] $\Delta G_t^0(OEg^-) = \Delta G_t^0(EgOH-EgOH)_{sys} - \Delta G_t^0(H^+) - RT\ln x_{EgOH}$

Substituting the value of $\Delta G_t^0(H^+)$ for each solvent mixture from an earlier paper (3*d*) and knowing the values of the other two terms on the right side of [8], those of $\Delta G_t^0(OEg^-)$ on the mole fraction scale were calculated; $\Delta G_t^0(EgOH\text{–}EgOH)_{sys}$ and $\Delta G_t^0(OEg^-)$ values are reported in Table 2.

$\Delta G_t^0(OEg^-)$ is shown plotted against mol% ACN in Fig. 3. Plots of $\Delta G_t^0(Cl^-)$ and $\Delta G_t^0(H^+)$, taken from a previous paper (3*d*), are also shown in Fig. 3, and are seen to be qualitatively similar to the $\Delta G_t^0(OEg^-)$ plot. The fact that all three increase with increasing proportions of ACN indicates a progressive desolvation of these ions as the solvent becomes richer in ACN. It is to be noted further that the relative desolvation of the anions OEg^- and Cl^- is greater than that of the H^+ ion. Such behaviour arises from a very typical characteristic of dipolar aprotics like ACN, namely, the marked inability to solvate small anions which interact wholly through hydrogen bonds and ion–dipole forces (2, 12, 13). In the case of ACN, in spite of the considerable polarization of the C≡N bond (19), the positive end of the dipole is located at an unfavourable position for interaction with anions (19, 20) and the hydrogen-bond donating capacity of the molecule is only very feeble (2, 13, 20). The relative desolvation of the OEg^- ion is the most marked, probably because in pure EgOH it undergoes the strongest stabilization through hydrogen-bonding and fits most easily into the solvent structure.

Similar, incidentally, is the case of the dimethylsulphoxide (DMSO) + water system (11) — another protic–dipolar aprotic combination, where solvation effects are more important than dielectric constant effects at least up to 60 wt.% DMSO. Thus, as the positive charge centre of DMSO molecule is surrounded by bulky groups and therefore not easily approachable, increasing addition of DMSO to water causes increasing desolvation of anions (11, 21). Again, the greater propensity of the protophilic OH^- (compared to Cl^-, say) to take part in the solvent structure through hydrogen-bonding stabilizes OH^- more than the Cl^- ion in water, and consequently $\Delta G_t^0(OH^-)$ is observed to be more positive than $\Delta G_t^0(Cl^-)$ for a given solvent mixture.

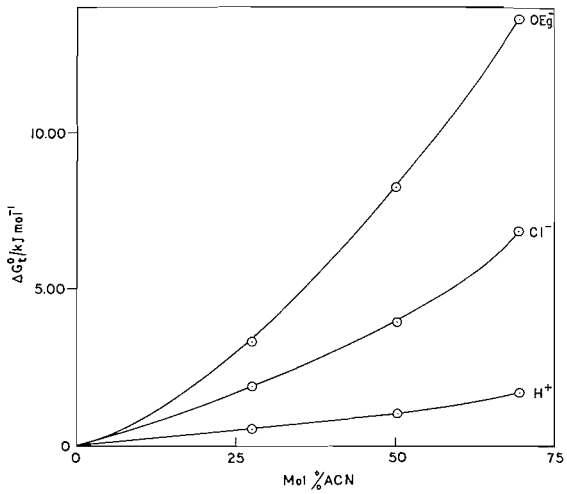

FIG. 3. Variation of ΔG_t^0 of various ions in ACN + EgOH mixtures at 25°C.

Free energies of transfer of some single ions from ethylene glycol to its isodielectric mixtures with acetonitrile at 25°C

KUMARDEV BOSE AND KIRON K. KUNDU[1]

Physical Chemistry Laboratories, Jadavpur University, Calcutta 700032, India

Received August 15, 1978[2]

KUMARDEV BOSE and KIRON K. KUNDU. Can. J. Chem. 57, 2476 (1979).

Free energies of transfer (ΔG_t^0) of the reference electrolyte Ph_4AsBPh_4 (Ph = phenyl) from ethylene glycol to its approximately isodielectric mixtures with acetonitrile have been determined at 25°C from the measurement of the solubilities of KPi, Ph_4AsPi, and KBPh (Pi = picrate) in these solvents. Using the assumption $\Delta G_t^0(Ph_4As^+) = \Delta G_t^0(Ph_4B^-) = \frac{1}{2}\Delta G_t^0(Ph_4AsBPh_4)$, ΔG_t^0 values for the individual ions K^+, Pi^-, Ph_4As^+, and Ph_4B^- have been estimated. These, in conjunction with previously determined values of ΔG_t^0 for MCl (M = Li, Na, K, Rb, Cs, and H), KBr and KI have provided ΔG_t^0 values for Cl^-, Br^-, I^-, and M^+ ions. Ionic ΔG_t^0's have been interpreted in terms of specific ion–solvent interactions. The contrasting behaviour of ethylene glycol and acetonitrile in ion-solvation is shown to be characteristic of the protic and dipolar aprotic solvent types respectively.

KUMARDEV BOSE et KIRON K. KUNDU. Can. J. Chem. 57, 2476 (1979).

Opérant à 25°C et faisant appel à des mesures de solubilité de KPi, Ph_4AsPi et $KBPh_4$ (Pi = picrate) dans ces solvants, on a déterminé les énergies libres de transfert (ΔG_t^0) de l'électrolyte de référence, Ph_4AsBPh_4 (Ph = phényle), de l'éthylèneglycol à ses mélanges qui sont approximativement isodiélectriques avec de l'acétonitrile. Faisant l'hypothèse que $\Delta G_t^0(Ph_4As^+) = \Delta G_t^0(Ph_4B^-) = \frac{1}{2}\Delta G_t^0(Ph_4AsBPh_4)$, on a évalué les valeurs de ΔG_t^0 des ions individuels K^+, Pi^-, Ph_4As^+ et PhB^-. Ces valeurs, utilisées de concert avec les valeurs de ΔG_t^0 déterminées antérieurement pour MCl (M = Li, Na, K, Rb, Cs et H), KBr et KI permettent de déterminer les valeurs ΔG_t^0 des ions Cl^-, Br^-, I^- et M^+. On a interprété les valeurs de ΔG_t^0 ioniques en termes d'interactions spécifiques ion–solvant. On démontre que les contrastes entre les comportements de l'éthylèneglycol et l'acétonitrile vis-à-vis la solvatation ionique sont respectivement caractéristiques de types de solvants protiques et aprotiques dipolaires.

Introduction

The importance of isodielectric solvent systems is being increasingly recognized in thermodynamic studies of ion–solvent interactions. This is because while "Born-type" electrostatic contributions (1) to thermodynamic transfer parameters, e.g. the free energy of transfer (ΔG_t^0), of ions and electrolytes in non-isodielectric systems, being difficult to estimate and to correct for, mask the effect of "true" or short-range ion–solvent interactions, the ΔG_t^0 in isodielectric systems wholly reflects the extent of ion-stabilization through such short-range interactions since "Born-type" contributions are non-existent or negligibly small in the latter systems.

In addition, great interest lies in the study of binary solvent mixtures containing a protic and a dipolar aprotic component. Thus, with the progressive increase in the proportion of the dipolar aprotic solvent (DAS) in the mixture, the solvent character undergoes gradual but material change, with hydrogen-bond donating properties of the protic solvent (PS) weakening and giving way to radically different forces like soft–soft (2), dispersion (1) and π-overlap (3) interactions. In such a mixed solvent system, therefore, the modes of specificity in the solvation behaviour of the two components are expected to show up in sharp contrast.

In previous papers (4) we have indicated that the solvent system acetonitrile (ACN) + ethylene glycol (EG) constitutes a PS–DAS combination which is also approximately isodielectric and have determined the ΔG_t^0's of various electrolytes from EG to ACN + EG mixtures. These values, however, reflect the solvent effect on the sum of the interactions undergone by the ions with the solvent without revealing the nature of solvation of the individual ions. For a better understanding of the solvation of single ions, we now proceed to split the composite ΔG_t^0's into individual ionic contributions, using the most popular extrathermodynamic assumption (5–7):

$$[1] \quad \Delta G_t^0(Ph_4As^+) - \Delta G_t^0(Ph_4B^-) = \tfrac{1}{2}\Delta G_t^0(Ph_4AsBPh_4)$$

where Ph = phenyl.

Recently, Treiner (8) has calculated the ΔG_t^0 values for the Ph_4As^+ ion between water and several pure non-aqueous solvents using the scaled-particle theory (SPT) (9) according to which contribution to ΔG_t^0 comes from two parts — one due to solute–solvent interactions, ΔG_t^0(int), and the other due to cavity formation in the solvent, ΔG_t^0(cav). Thus,

$$[2] \quad \Delta G_t^0 = \Delta G_t^0(\text{int}) + \Delta G_t^0(\text{cav})$$

In calculating ΔG_t^0, a necessary approximation is to equate the relatively unknown ΔG_t^0(int) to zero. When theoretical and experimental (5*c*) values are compared, this approximation is shown to be generally invalid for DAS, the reason being correctly attributed to strongly increased ion–solvent interactions in passing from water to DAS and a corresponding large negative value for ΔG_t^0(int). However, it does not necessarily follow, as Treiner assumes (8), that with increasing strength of interaction with the solvent, the difference in solvation of the Ph_4As^+ ion and the Ph_4B^- ion becomes appreciable and hence that [1] becomes invalid. All that the SPT calculations reveal is the rather expected result that ΔG_t^0(int) values for these two large ions are highly negative. They cannot be used to make predictions about the equality or inequality of these values. Therefore, it seems unjustified to recommend, as Treiner does, against the use of [1]. Amidst the controversy raging over the "best" extrathermodynamic assumption (7*b*), [1] still remains one of the few most reliable assumptions for the determination of single ion ΔG_t^0 values. A recent paper by Kim (10) also strongly supports this contention.

ΔG_t^0 values at 25°C for the "reference electrolyte" Ph_4AsBPh_4 have been determined from [3]:

$$[3] \quad \Delta G_t^0(Ph_4AsBPh_4) = \Delta G_t^0(Ph_4AsPi) + \Delta G_t^0(KBPh_4) - \Delta G_t^0(KPi)$$

(where Pi = picrate) using the corresponding values for Ph_4AsPi, $KBPh_4$, and KPi obtained from solubility measurements.

Experimental

The purification of the solvents EG and ACN (4*a*) as well as the preparation of the salts KPi (11), Ph_4AsPi (12*a*), and $KBPh_4$ (12*b*) have been described. The concentration of water in the solvents determined by Karl Fischer titrations was found, as before (4*a*), to lie between 0.01 and 0.015 mol dm^{-3}. It was shown in an earlier paper (4*a*) that in presence of such small concentrations of water, even protons, which have normally a strong tendency to be hydrated, are preferentially solvated by EG. The possibility of selective solvation by water of the much larger and less hydrophilic ions presently under study was therefore considered to be remote.

For solubility measurements, small quantities of the salt was added with shaking to 25 mL of the solvent taken in a Jena bottle until no further visible dissolution occurred. Since prolonged contact with oxygen also affects its stability (12*b*), the dissolution of $KBPh_4$ as well as each subsequent withdrawal of its solution for analysis were performed under a flush of dry nitrogen. The solutions were thermostatted at 25 ± 0.05°C and allowed to equilibriate. At two-day intervals aliquots of each solution were withdrawn, appropriately diluted, and analyzed using a Beckmann DU-2400 model spectrophotometer. The solvents used for dilution and the pertinent λ_{max} and ε_{max} values are indicated below.

	Diluting solvent	Dilution	λ_{max} (nm)	ε_{max}
KPi (12*b*) and Ph_4AsPi (1*b*2)	Water	200–5000	355	1.44×10^4
$KBPh_4$ (7*a*)	ACN	100	266	3.2×10^3
			274	2.1×10^3

It may be noted that ε_{max} values of the samples when checked in the respective diluting solvents were found to lie within 1% of the literature values cited above. So was the solubility of $KBPh_4$ in pure ACN, which was found to be 0.0528 ± 0.0006 *M* compared to 0.0533 *M* reported by Popovych (7*a*). Saturation was reached 8–10 days after which the measured concentrations of the solutions showed no further change beyond the experimental error of about 1%. The reported concentrations (Table 1) are the mean of two sets of measurements agreed to within 1%.

Results

The thermodynamic solubility products of each of the salts on the molar scale were calculated by [4]:

$$[4] \quad pK_{sp}^c = -\log \{C(1-\alpha)y_\pm\}^2$$

where C is the observed concentration in mol dm^{-3}, α is the degree of association of the salt into ion-pairs, and $y_\pm$ is the mean molar activity coefficient of the salt. Values of α were calculated by [5]:

$$[5] \quad \alpha = \frac{(2CK_Ay_\pm^2 + 1) - (4CK_Ay_\pm^2 + 1)^{1/2}}{2CK_Ay_\pm^2}$$

using previously reported values (4*c*) of K_A, the association constant. $y_\pm$ values were obtained from [6] by interactive calculations with the help of B-6700 computer using FORTRAN programmes

$$[6] \quad -\log y_\pm = \frac{1}{2}\frac{A_0B_0d_s^{-1/2}C_1^{1/2}}{\ln 10} \times [(1 + a_0^+B_0d_s^{-1/2}C_1^{1/2})^{-1} + (1 + a_0^-B_0d_s^{-1/2}C_1^{1/2})^{-1}] + \log\left(1 + 0.002\frac{C_1M_s}{d_s}\right)$$

where $C_1 = C(1-\alpha)$ and the other parameters

TABLE 2. Single ion free energies of transfer from EG to ACN + EG mixtures at 25°C

	ΔG_t^0 (kJ mol^{-1})										
Wt.% ACN	H^+	Li^+	Na^+ t	K^+	Rb^+	Cs^+	Cl^-	Br^-	I^-	Pi^-	Ph_4As^+/Ph_4B^-
20	0.3	0.0	−0.4	−0.9	−1.1	−1.1	2.1	1.5	1.1	−0.5	−7.6
40	0.7	1.0	0.3	−0.6	−0.8	−0.9	4.3	3.7	2.5	−1.1	−11.0
60	1.7	2.8	1.3	0.4	0.0	−0.2	0.8	6.3	4.3	−1.3	−12.9
100	—	—	—	8.9	—	—	—	—	—	5.1	−10.9

carry their usual meaning (4*a*). The ion-size parameters, a_0^+ and a_0^-, for the cation and the anion respectively, were assumed to have the following values (7*a*):

$$a_0^{K^+} = a_0^{Pi^-} = 0.3 \text{ nm}$$

$$a_0^{Ph_4As^+} = a_0^{Ph_4B^-} = 0.5 \text{ nm}$$

Values of C, $y_\pm$, and pK_{sp}^c are listed in Table 1. Uncertainties in α values were obtained by using two sets of pK_A values as limited by their respective standard deviations, in the interactive calculations of α and $y_\pm$ values. Since the errors in the measured solubilities and those in the effective ionic concentrations $C_i = C(1 - \alpha)$ arising from the uncertainties in α values as well, lie within 2%, pK_{sp}^c values could be taken to be correct to within ±0.02 unit. pK_{sp}^c values for pure ACN computed from a previous work (7*a*) are also given. Free energies of transfer of each salt on the mole fraction scale (ΔG_t^0) were calculated using [7]

$$[7] \quad \Delta G_t^0 = (\ln 10)\, RT\, [(pK_{sp})_s^c - (pK_{sp})_g^c] + 2\,(\ln 10)\, RT \log M_g d_s / M_s d_g$$

where $T = 298.15$ K, and the subscripts g and s refer to EG and the mixed solvent respectively. ΔG_t^0 values reported in Table 1 are accurate to within ±0.1 kJ mol^{-1}.

Single ion free energies of transfer ΔG_t^0(i), estimated by means of the basic assumption [1] using [3], [8]–[11], are given in Table 2.

$$[8] \quad \Delta G_t^0(Pi^-) = \Delta G_t^0(Ph_4AsPi) - \Delta G_t^0(Ph_4As^+)$$

$$[9] \quad \Delta G_t^0(K^+) = \Delta G_t^0(KBPh_4) - \Delta G_t^0(Ph_4B^-)$$

$$[10] \quad \Delta G_t^0(X^-) = \Delta G_t^0(KX) - \Delta G_t^0(K^+)$$

$$[11] \quad \Delta G_t^0(M^+) = \Delta G_t^0(MCl) - \Delta G_t^0(Cl^-)$$

Values of ΔG_t^0(KX) (X = Br or I) and ΔG_t^0(MCl) (M = Li, Na, Rb, Cs, or H) were obtained from previous papers (4*a*, *b*).

Discussion

Plots of ΔG_t^0(i) against mol% of ACN are shown in Fig. 1. Certain distinct trends, each characterizing a group of ions, are observed and may be considered to reflect features peculiar to a protic + dipolar aprotic solvent system.

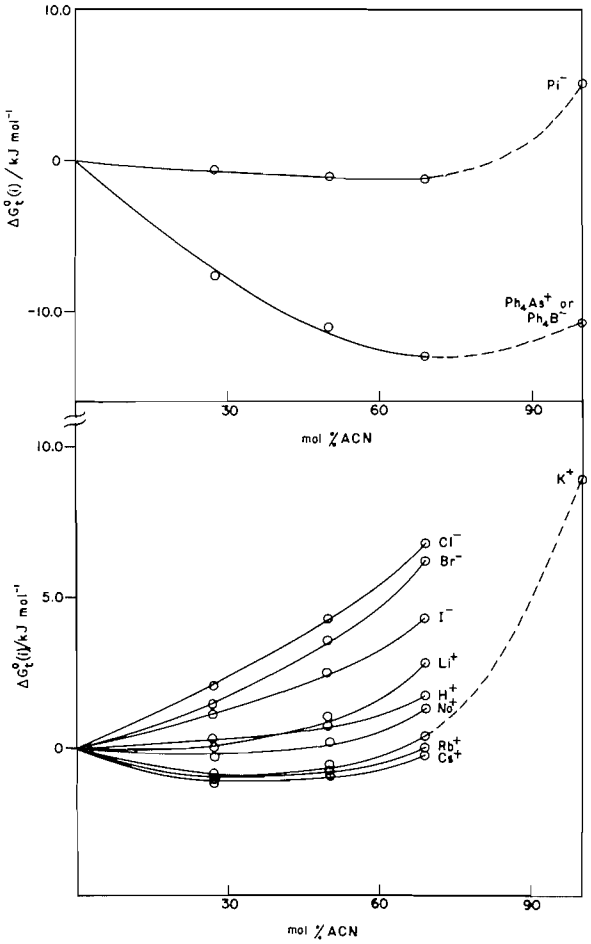

FIG. 1. Variation of ΔG_t^0(i) with solvent composition in ACN + EG mixtures at 25°C.

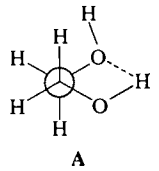
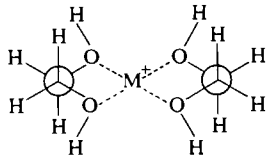
The simple anions, viz. the halide ions, are relatively strongly solvated by EG through hydrogen-bonding whereas their interaction with the very weakly acidic hydrogen atoms of ACN, although possible (13), is very weak. Increasing loss of hydrogen-bonded stability is seen reflected in the monotonic rise of $\Delta G_t^0(X^-)$ with increasing ACN content of the solvent. The observed order $\Delta G_t^0(Cl^-) > \Delta G_t^0(Br^-) > \Delta G_t^0(I^-)$ for any given solvent is the combined result of decreasing strength of H-bonded interaction (with EG) and increasing strength of "soft–soft" (2, 14) and dispersion interactions (5*c*, 15) (with ACN) with increasing anion size. A recent study (13*a*) indicates that steric requirements of H-bonding between X^- and ACN may also be partly responsible for this order: it has been suggested (13*a*) that the X^- ion approaches the ACN molecule along the C_3 axis of the latter and bonding occurs symmetrically through all three hydrogen atoms; and that therefore the overall strength of such H-bonds increases as the ion becomes larger and more accommodative.

The alkali metal cations have highly positive ΔG_t^0's between pure EG and pure ACN as typified by the behaviour of the K^+ ion. Apparently, in spite of its high dipole moment (16) and a considerable localization of negative charge density on its nitrogen atom (17), ACN is a poorer cation solvator compared to EG. This suggests an explanation in terms of ion–solvent interactions of a specific type, as outlined below.

The geometry of the EG molecule is such as to favour its functioning as a bidentate ligand towards alkali metal ions (M^+). Infrared studies (18) indicate that the predominant configuration of the EG molecule in the liquid state at room temperature is the *gauche* form with intramolecular H-bonding (**A**).



A

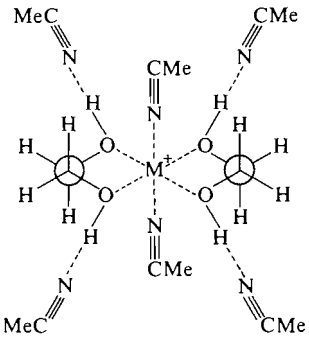


B

It may be assumed that the loss of stability accompanying the rupture of the H-bond during M^+ ion solvation is compensated by the possible formation of four essentially electrostatic bonds in solvates of the type $M(EG)_2^+$ (**B**). It should be apparent from a molecular model that when the four M—EG bonds in solvate (**B**) are coplanar, the eight-atom ring C—O—O—C—O—O—C surrounding the M atom is less puckered and hence more stable than when the M—EG bonds are not coplanar. The use of the Neumann projection (19) shows clearly that besides possessing reflection symmetry at the plane N, this solvate must also be centrosymmetric about M^+. Incidentally, for 1,2-dimethoxyethane, where the hydroxyl H atoms of EG have been substituted by CH_3 groups thereby making the O atoms more basic, alkali metal ions have been shown to be strongly solvated (20) and for cyclic ethers stable M^+ solvates have been isolated (21). The powerful solvation of M^+ by 1,2-dimethoxyethane has been believed to arise from its behaviour as a bidentate ligand (20*c*) through the electrostatic interaction of

the basic O atoms with the M^+ ion. In this light, to assume the existence of $M(EG)_2^+$ solvates, if only in solution, does not seem unreasonable. Such an assumption can moreover offer a plausible explanation for the interesting parts of the $\Delta G_t^0(M^+)$ curves: the noticeable minima for K^+, Rb^+, and Cs^+; $\Delta G_t^0(Li^+)$ has no minimum at all, and $\Delta G_t^0(Na^+)$ is a typical borderline case.

As indicated above, from symmetry and bond-strain considerations, the four M—EG bonds in the $M(EG)_2^+$ solvates may be expected to be more or less coplanar, so that in mixed solvents of low ACN content, ACN molecules approach the central ion from above and below the plane of the solvate and undergo ion–dipole and/or soft–soft interactions with the ion; an octahedral solvate (**C**) is thus



C

formed. Moreover, the well-known tendency of ACN to form hydrogen bonds with protic solvents (22–26) should lead to the stabilization of (**C**) through interaction of its "acidic" hydroxyl H atoms (1) with ACN molecules. An earlier study (27) involving the shift in ir stretching vibration frequencies has in fact indicated the formation of similar $M^+\cdots ODH\cdots N{\equiv}$ CMe associates in aqueous ACN solutions.

Note, however, that hexa-coordination of the M^+ ion in the above manner can be achieved only when its size is large enough, for example, in the case of K^+, Rb^+, and Cs^+. For Na^+, hexa-coordination would be possible but unfavourable; for Li^+ tetra-coordination is only just feasible while hexa-coordination is impossible from steric considerations. Apart from this, the increasing stability of **C** with increasing ionic size also stems from the fact that ACN, being a soft base (17), interacts more and more strongly with M^+ as its radius and hence its polarizability ("softness") increases. The two factors together explain the negative absolute magnitudes which increase in the order $K^+ < Rb^+ < Cs^+$. With increasing proportions of ACN, however, structure **C** should no longer be so stable. It is possible that EG, which, like water, has two donor centres for H-bonding (viz. its two hydroxyl hydrogen atoms) forms with ACN a H-bonded complex of the type EG·2ACN analogous to $H_2O{\cdot}2ACN$ which has been shown to exist in aqueous ACN solutions (23). The formation of such complexes probably forces structure **C** to fall apart "from both sides" with a resultant destabilization of the M^+ ion and an increase in $\Delta G_t^0(M^+)$ values. Above 70 mol% ACN, $\Delta G_t^0(M^+)$ rises sharply up to pure ACN where any tendency to establish ion–dipole interactions between M^+ and ACN is probably opposed by the formation of dimers of the type

$$H_3C{-}C{\equiv}N \quad (+\ -)$$
$$N{\equiv}C{-}CH_3 \quad (-\ +)$$

which ir studies in pure ACN have shown to exist (28, 29).

The Li^+ ion and the H^+ ion (and to a lesser degree, the Na^+ ion) behave similarly on transfer from EG to the mixed solvents. The uniform increases in ΔG_t^0 is indicative of a rather stable state of solvation in pure EG which is progressively broken up upon addition of ACN. As mentioned above, steric reasons oppose the entry of ACN molecules in the primary solvation zone of Li^+ and Na^+ ions, although H-bonding of the solvate **B** by ACN is still possible. This H-bonded stabilization of **B**, slowing down the initial rate of increase of $\Delta G_t^0(Li^+)$ and $\Delta G_t^0(Na^+)$ is rapidly overcome as further amounts of added ACN break up structure **B** in the manner described above and a rapid increase in ΔG_t^0 is observed. The relatively slower increase of $\Delta G_t^0(H^+)$ suggests that as in other amphiprotic solvents, the proton is "chemically" solvated by EG, and that this "glycolated" proton has a structure strong enough to retain its existence even in solvents rich in ACN.

The case of the Pi^- ion is in some ways similar to that of the larger M^+ ions. In pure EG, the Pi^- ion is stabilized by H-bonded solvation through all or some of its seven oxygen atoms, each of which has its share of the negative charge delocalized over the aromatic nucleus. The flat shape of the ion, however, allows the π-electron cloud of the nucleus to undergo dispersion interactions with an ACN molecule approaching in a perpendicular direction. Such interactions continue to stabilize the Pi^- ion till about 70 mol% ACN after which desolvation, caused by the rapid breakdown of the Pi^-—EG H-bonds, is probably more important than solvation through Pi^-—ACN dispersion interactions which are likely to reach saturation instead of increasing further in

strength. In pure ACN itself, the characteristic anion-desolvating property of ACN (1, 3, 15, 30) outweighs the effect of dispersion interactions and there occurs an overall destabilization of the Pi^- ion relative to pure EG or ACN + EG mixtures.

It is interesting to note, however, that the relative destabilization of the Pi^- ion in ACN-rich solvents is much less compared to that of the K^+ ion, although in general dipolar aprotic solvents are poorer solvators of anions than cations. This is certainly because the dispersion interactions of Pi^- with ACN are stronger than the "soft–soft" interactions of K^+ with ACN, a contention which is in agreement with the observation that $\Delta G_t^0(Pi^-)$ exhibits a more pronounced minimum than $\Delta G_t^0(K^+)$ at intermediate solvent compositions (1, 3).

Finally, the behaviour of $\Delta G_t^0(Ph_4As^+)$ or $\Delta G_t^0(Ph_4B^-)$ offers what looks like a straight case of solvation through dispersion interactions. With their four phenyl groups, such interactions with ACN must be very strong, whereas in pure EG these same groups effectively prevent any "classical" interactions with the ionic charge buried deep inside. This causes the very sharp and very large decrease of ΔG_t^0 upto 80% ACN after which saturation is probably reached and the inherent ion-desolvating tendency of ACN causes ΔG_t^0 to increase slightly from 80–100% ACN.

The thermal isomerisation of allyl isocyanide

MARSHA T. J. GLIONNA AND HUW O. PRITCHARD
Chemistry Department, York University, Downsview, Ont., Canada M3J 1P3

Received March 23, 1979

MARSHA T. J. GLIONNA and HUW O. PRITCHARD. Can. J. Chem. 57, 2482 (1979).

The thermal isomerisation of allyl isocyanide to allyl cyanide has been studied in the gas phase over the temperature range 130–200°C. The reaction is homogeneous and first order, and at high pressure (20 Torr) has an activation energy of 40.8 ± 0.6 (2sdm) kcal mol^{-1}; the corresponding range of frequency factor is $10^{14.77\pm0.30}$ s^{-1}.

MARSHA T. J. GLIONNA et HUW O. PRITCHARD. Can. J. Chem. 57, 2482 (1979).

Opérant en phase gazeuse, à des températures allant de 130 à 200°C, on a étudié l'isomérisation thermique de l'isocyanure d'allyle en cyanure d'allyle. La réaction est homogène et du premier ordre; à pression élevée (20 Torr), l'énergie d'activation est 40.8 ± 0.6 (2sdm) kcal mol^{-1} et le facteur de fréquence correspondant est $10^{14.77\pm0.30}$ s^{-1}.

Introduction

In our recent exploratory study of the reactions of methylene radicals with isocyanides (1), we noticed that allyl isocyanide appeared to be somewhat less readily isomerised than were methyl or ethyl isocyanides: since this isomerisation appears to take place through the insertion of the methylene radical into the R—NC bond, followed by its elimination, this might suggest that the R—NC bond in allyl isocyanide is slightly stronger than a normal aliphatic R—NC bond. The origin of such a strengthening could be rationalised in terms of some residual conjugation between the π-electrons in the C=C and N=C bonds and if this were the case, the activation energy for isomerisation to cyanide would be expected to be larger than normal: the activation energies for isomerisation at infinite pressure for methyl and ethyl isocyanides are both 38.4 kcal mol^{-1} (2, 3) whereas for vinyl isocyanide where there is full conjugation between the two π-electron systems, the activation energy for isomerisation is estimated to be about 70 or 80 kcal mol^{-1} (4).

On the other hand, allyl isocyanide could conceivably isomerise by a head-to-tail intramolecular mechanism, which would almost certainly have a lower activation energy than normal. Consequently, it is of some interest to determine the activation energy for the thermal isomerisation of allyl isocyanide to allyl cyanide.

Experimental

Allyl isocyanide was prepared from allylamine by standard methods (1) and was purified by preparative-scale gas chromatography. Allyl cyanide, required for calibration purposes, was prepared by carrying the thermal decomposition of a sample of our allyl isocyanide to completion: a commercial sample (Aldrich) appeared to be a mixture of two isomeric substances which we were unable to resolve sufficiently well to provide an analytical standard.

Reaction was carried out in a 100 mL spherical Pyrex bulb immersed in an oil bath; reaction was initiated by admitting a (nominal) pressure of 20 Torr of allyl isocyanide vapour into the bulb, already immersed in the bath, and was terminated by removing the bulb from the bath and quenching it. Auxiliary tests using fine thermocouples inside the reaction vessel showed that the maximum uncertainty in the measured reaction time was ±3 s; this is negligible, since the reaction times ranged from 3–4 days near 130°C to 15 min near 200°C.

Reaction temperature was measured by chromel–alumel thermocouple with a Digitemp digital display: the instrument was calibrated at 0, 100, and 327°C, and its linearity in the experimental interval was checked by comparison against a mercury in glass thermometer; the precision of the temperature control during any experiment was ±0.1°C, with an absolute accuracy of ±1°C.

Analysis of the reaction products was carried out by gas chromatography using a Pennwalt 223 column at 70°C and thermal conductivity detectors: due to the tailing of the isocyanide peak, the precision of these analyses was about ±5%, and this represents the major source of uncertainty in these experiments.

Results

The cleanliness of the reaction was demonstrated by the experiment, noted above, to prepare allyl cyanide from allyl isocyanide: apart from a trace of HCN, which is typical in these isomerisations (5, 6), there was about 1% of an unidentified product of retention time intermediate between that of the isocyanide and the cyanide; we cannot tell whether this was present in the original isocyanide, or whether it was a byproduct. Also, a separate series of experiments was undertaken at 175°C to show that the calculated rate constant, which we have assumed to be first order and at its high-pressure limit, was independent of the initial pressure, the

0008-4042/79/182482-02$01.00/0

TABLE 1. The thermal isomerisation of allyl isocyanide at 18 Torr in the temperature range 128.7–201.8°C

T (K)	Time (s)	% reaction	k_∞ (s^{-1})
401.9	2.55×10^{5}	0.96	3.8×10^{-8}
404.2	3.55×10^{5}	1.76	5.0×10^{-8}
415.3	7.75×10^{4}	1.51	2.0×10^{-7}
419.4	1.53×10^{5}	5.06	3.4×10^{-7}
422.5	6.36×10^{4}	2.85	4.6×10^{-7}
431.1	2.88×10^{4}	3.11	1.1×10^{-6}
440.3	1.35×10^{4}	3.87	2.9×10^{-6}
449.9	3.74×10^{3}	3.07	8.3×10^{-6}
458.2	3.73×10^{3}	7.63	2.1×10^{-5}
467.5	1.73×10^{3}	8.60	5.2×10^{-5}
475.0	9.43×10^{2}	8.69	9.6×10^{-5}

reaction time and the surface-to-volume ratio: all the rate constants fell within a range of $\pm6\%$, with no apparent trends, as would be expected for a well behaved reaction with the analytical precision attainable.

The results of a series of experiments to determine the activation energy, all made at the same pressure (18 Torr), are shown in Table 1; assigning equal weight to each determination, the least-squares treatment yields an activation energy of 40.81 kcal mol^{-1} with a standard deviation (7) of ±0.29 kcal mol^{-1}; the corresponding range in the frequency factor is $10^{14.77\pm0.15}$ s^{-1}.

The activation energy for the isomerisation of allyl isocyanide appears to be about 2.4 ± 1 kcal mol^{-1} greater than that for the analogous isomerisation of methyl isocyanide (2, 8) or than that for ethyl isocyanide (3). This supports the supposition that there may be a small enhancement of the strength of the R—NC bond in the allyl compound, and that the alternative head-to-tail intramolecular mechanism is not important: the latter conclusion is also supported by the relatively high value we find for the frequency factor, since the head-to-tail mechanism would require a cyclic transition state, and would probably have a rather lower frequency factor on this account. A definitive determination of the mechanism of this reaction could be made by using isotopically labelled allyl isocyanide; unfortunately, suitably deuteriated allyl compounds are not readily available.

Absolute rate constants for hydrocarbon autoxidation. 26. Rate constants for reaction of the *tert*-butylperoxy radical with 1-bromo-2-methylbutane and 1-bromo-3-methylbutane and some related substituted butanes[1]

J. A. HOWARD AND J. H. B. CHENIER

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received January 29, 1979

J. A. HOWARD and J. H. B. CHENIER. Can. J. Chem. 57, 2484 (1979).

Rate constants and Arrhenius parameters for reaction of the *tert*-butylperoxy radical with 1-bromo-2-methylbutane and 1-bromo-3-methylbutane in solution from 30–80°C have been estimated. The magnitude of these kinetic parameters are consistent with activation of the tertiary hydrogen vicinal to the bromine substituent and the involvement of a "bridged" transition state in the hydrogen atom transfer reaction.

Chloro, trimethylsilyl, and trimethylstannyl substituents also activate a vicinal tertiary hydrogen and activation increases in the order trimethylsilyl ~ trimethylstannyl < chloro < bromo.

J. A. HOWARD et J. H. B. CHENIER. Can. J. Chem. 57, 2484 (1979).

On a évalué les constantes de vitesse et les paramètres d'Arrhénius de la réaction du radical *tert*-butylpéroxy avec les bromo-1 méthyl-2 et bromo-1 méthyl-3 butanes en solution à des températures allant de 30 à 80°C. L'ordre de grandeur de ces paramètres cinétiques est en accord avec une activation de l'hydrogène tertiaire vicinal par rapport au brome et une implication d'un état de transition "ponté" dans la réaction de transfert de l'atome d'hydrogène.

Des substituants chloro, triméthylsilyle et triméthylstannyle activent aussi un hydrogène tertiaire vicinal et l'activation augmente dans l'ordre triméthylsilyle ~ triméthylstannyle < chloro < bromo.

[Traduit par le journal]

Introduction

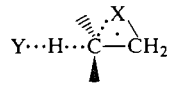
Several papers have appeared recently in support of the concept that rates of hydrogen atom abstraction by free-radicals ($Y^{\cdot}$) are enhanced by certain substituents (X) attached to the β-carbon of the substrate (reaction [1]) (for reviews dealing with anchimeric assistance, see ref. 1).

$$[1]\quad -\overset{|}{C}H—CH_2X + Y^{\cdot} \rightarrow -\overset{|}{\underset{\cdot}{C}}—CH_2X + YH$$

where Y is, for example, Br$^{\cdot}$ and t-$BuO_2^{\cdot}$ and X is Cl, Br, and I.

Thus Wagner and Sedon (2) have shown that δ-bromo and -iodo groups enhance the rate of triplet state γ-hydrogen abstraction during photolysis of δ-halovalerophenones while Everly, Schweinsberg, and Traynham (3) have concluded that a β-chloro substituent assists removal of a tertiary hydrogen by the bromine atom. Furthermore we have reported (4) that the tertiary hydrogen in 1-bromo-2-methylbutane is 2.6 times more reactive to the *tert*-butylperoxy radical at 30°C than the tertiary hydrogen in 3-methylpentane.

These enhanced rates have generally been rationalized in terms of an interaction between the neighbouring substituent and the reactive centre in the form of a bridged transition state.



I

The involvement of a bridged species such as **I** should be reflected in a decrease in both the enthalpy and entropy of activation for reaction because the bridged radical will have more resonance stabilization energy than the unbridged radical while the probability of forming **I** must be less than the probability of forming a transition state without bridging (5, 6). Unfortunately most of the work on anchimeric assistance by β-substituents has been performed at one temperature and the relation between rate enhancement and the activation parameters has not been generally established. Skell and co-workers (5, 6) have, however, reported that the enthalpy and entropy of activation for removal of a secondary hydrogen β to the bromo substituent in 1-bromobutane are ~3 kcal mol^{-1} and ~6 cal deg^{-1} mol^{-1} smaller than the corresponding parameters for removal of a secondary hydrogen from propane.

[1]NRCC No. 17535.

0008-4042/79/182484-07$01.00/0

Moreover, Cain and Solly (7) found that the activation energy for thermal ring opening of 1-bromomethyl-4-chlorobicyclo[2.2.0]hexane is 2.9 kcal mol^{-1} smaller than it is for 1-ethyl-4-chlorobicyclo [2.2.0]hexane although in this case the pre-exponential factors were identical within experimental error.

In the present paper we report a full kinetic and product study of the autoxidation of 1-bromo-2-methylbutane and its co-oxidation with 3-methylpentane, both reactions being performed in the presence of *tert*-butyl hydroperoxide. This work enables us to report kinetic parameters for abstraction of the tertiary hydrogen atom from 1-bromo-2-methylbutane by the *tert*-butylperoxy radical. These parameters will of course be influenced by deactivation by inductive electron withdrawal by the bromo substituent as well as activation by anchimeric assistance. Separation of these two effects has been achieved by comparing kinetic parameters for reaction of 1-bromo-2-methylbutane and 1-bromo-3-methylbutane with $t\text{-}BuO_2^{\bullet}$.

In addition we have investigated the effect of vicinal chloro, trimethylsilyl, and trimethylstannyl substituents on the rate of H-atom transfer to the *tert*-butylperoxy radical because β-chloro, β-trialkylsilyl, and β-trialkylstannyl-alkyl radicals are known to have a preferred conformation in which the heteroatom is eclipsed by the *p* orbital of the radical centre (8).

Experimental

Materials

1-Bromo-2-methylbutane (Chemical Procurement Labs. Inc.), *1-bromo-4-methylpentane* (Chemical Samples Co.), and *1-bromo-3-methylbutane* (Eastman) were purified by preparative gas chromatography to >99.9% *1-Chloro-2-methylbutane* and *1-chloro-3-methylbutane* (Chemical Samples Co.) were purified by distillation and were passed down a column of basic alumina before use.

2-Methyl-1-trimethylsilylbutane. 1-Bromo-2-methylbutane (61.1 g, 0.4 mol) in dry tetrahydrofuran (125 mL) was added dropwise with stirring to magnesium turnings (9.83 g) in dry THF (50 mL). After addition of the alkyl bromide the mixture was stirred and refluxed under argon for 1 h. Chlorotrimethylsilane (12.5 g, 0.4 mol) in dry THF (100 mL) was added dropwise and the reaction mixture was stirred for a further 16 h. Excess Grignard reagent was destroyed by the addition of water and dilute HCl was added until two layers were formed. The THF layer was washed three times with equal volumes of water and dried over anhydrous sodium sulphate. Distillation gave 15 g of 2-methyl-1-trimethylsilylbutane, bp 131–133°C.

2-Methyl-1-trimethylstannylbutane was prepared from 1-bromo-2-methylbutane and chlorotrimethylstannane by the method used for 2-methyl-1-trimethylsilylbutane.

1-Bromo-2-methylbutan-2-ol, *1-bromo-3-methylbutan-2-ol*, *1-chloro-2-methylbutan-2-ol*, and *1-chloro-3-methylbutan-2-ol* were prepared from 2-methylbut-1-ene and 3-methylbut-1-ene by the method of Suter and Zook (9).

Addition of the hypohalous acid to 2-methylbut-1-ene gave the expected 1-halo-2-methylbutan-2-ol whereas addition of hypobromous acid to 3-methylbut-1-ene gave 1-bromo-3-methylbutan-2-ol, 2-bromo-3-methylbutan-1-ol, and 1,2-dibromo-3-methylbutane and addition of hypochlorous acid to 3-methylbut-1-ene gave 1-chloro-3-methylbutan-2-ol and 2-chloro-3-methylbutan-1-ol. These products were separated by preparative gas chromatography and identified by mass spectrometry.

1,2-Dibromo-2-methylbutane and *1,2-dibromo-3-methylbutane* were prepared by reaction of molecular bromine with 2-methylbut-1-ene and 3-methylbut-1-ene.

Kinetic Procedure

Rate constants for reaction of the substituted butanes with the *tert*-butylperoxy radical were obtained either by the *direct* method which involved measuring substrate oxidizability in the presence of *tert*-butyl hydroperoxide (0.5–2 *M*) and 2,6-di-*tert*-butyl-4-methylphenol ($\sim 2 \times 10^{-4}$ *M*) or by the *indirect* method whereby relative reactivities were determined from competitive autoxidations in the presence of *tert*-butyl hydroperoxide using 3-methylpentane as the reference compound. More detailed experimental details for these two methods are given in previous publications in this series (10, 11).

Product Analysis

Oxidized samples were quantitatively reduced with a slight excess of triphenylphosphine and the products were analysed after distillation by gas chromatography employing a Varian 2800 chromatograph equipped with 12 ft × 1/8 in. OV-101 and FFAP on chromosorb W (60–80 mesh) columns and thermal conductivity and flame ionization detectors.

Alcohols were identified and their absolute and relative yields determined by comparing gas chromatographic retention times and integrated areas with those of authentic standard samples. When samples of the alcohols were not commercially available or readily synthesized they were separated from the reaction mixture by gas chromatography and identified by mass spectrometry. For example, the mass spectrum of 1-bromo-3-methylbutan-3-ol contained the following fragments with *m/e* values in order of decreasing intensity 59 ($m - CH_2CH_2Br$), 151 ($m - CH_3$), 153 ($m - CH_3$), 107 ($m - (CH_3)_2COH$), 109 ($m - (CH_3)_2COH$).

Results

1-Bromo-2-methylbutane (1)

1-Bromo-2-methylbutane (8.08 *M*) containing α,α′-azo-bisisobutyronitrile (0.18 *M*) absorbed oxygen slowly at 30°C and 720 Torr of oxygen and the kinetic chain length was ~3. The overall rate of autoxidation was 1.2 times faster at 100 Torr of oxygen suggesting the involvement of bromine atoms, produced by β-scission of 1-bromo-2-methylbutyl radicals (reaction [2]), in rate controlling propagation reactions (reaction [3]).

[a]All runs were performed in the presence of α,α′-azobisisobutyronitrile (0.18 M) and 2,6-di-*tert*-butyl-4-methoxyphenol (1×10^{-4} to 1×10^{-3} M).
[b]Total hydroperoxide concentration.
[c]Rate of free-radical chain initiation.
[d]Calculated from the rate expression $(-d[O_2]/dt)_{corr} = k_p^1[1]R_i^{1/2}/(2k_t)^{1/2}$.
[e]Solvent: *tert*-butylbenzene.

The kinetic chain length was about 10 times longer in the presence of *tert*-butyl hydroperoxide (0.5–2 M) and $-d[O_2]/dt$ was independent of the oxygen pressure. This means that although β-scission still occurred the accelerating effect bromine atoms had on the rate of propagation was eliminated by chain transfer with the hydroperoxide (12).

[4] $Br^{\cdot} + (CH_3)_3COOH \rightarrow HBr + (CH_3)_3COO^{\cdot}$

Kinetic data for autoxidation of 1-bromo-2-methylbutane are presented in Table 1 and the average oxidizability in the presence of *tert*-butyl hydroperoxide, $k_p^1/(2k_t)^{1/2}$, is $5.8 \pm 0.4 \times 10^{-4}$ $M^{-1/2}\,s^{-1/2}$ where k_p^1 is the *overall* rate constant for reaction of *t*-$BuO_2^{\cdot}$ with **1** and $2k_t$ is the termination rate constant for *t*-$BuO_2^{\cdot}$. The experimental value of $2k_t$ in this system was 1.4×10^3 $M^{-1}\,s^{-1}$ which is equal, within experimental error, to our best value of 1.2×10^3 $M^{-1}\,s^{-1}$ (13) indicating that *t*-$BuO_2^{\cdot}$ were the only radicals involved in rate controlling propagation and termination reactions. From the rate constant ratio $k_p^1/(2k_t)^{1/2}$, k_p^1 can be calculated to be $5.8 \times 10^{-4} \times (1.2 \times 10^3)^{1/2} = 0.02 \pm 0.002$ $M^{-1}\,s^{-1}$.

Product analyses established that >90% of the oxygen absorbed by 1-bromo-2-methylbutane gave 1-bromo-2-hydroperoxy-2-methylbutane. Interestingly 1,2-dibromo-2-methylbutane was formed in low yield and it probably arose by bromination of 2-methylbut-1-ene, formed in [2], with molecular bromine produced by reduction of the bromine atom formed in [2] to HBr followed by oxidation with excess *t*-BuOOH.

The high yield of products derived from abstraction of the tertiary hydrogen implies that the overall propagation rate constant should be equivalent to the rate constant for abstraction of the tertiary hydrogen

$$[5]\quad (CH_3)_3COO^{\cdot} + CH_3CH_2\overset{CH_3}{\overset{|}{C}}HCH_2Br \xrightarrow{k_p^1} (CH_3)_3COOH + CH_3CH_2\overset{CH_3}{\overset{|}{C}}CH_2Br$$

There was no evidence for the formation of secondary alcohols from **1** almost certainly because of deactivation of the secondary C—H bonds on C-1 and C-3 by the bromine substituent.

Co-oxidation of **1** (3.23 M) and 3-methylpentane (3.85 M) gave $k_p/(2k_t)^{1/2} = 2.9 \times 10^{-4}$ $M^{-1/2}\,s^{-1/2}$ where $k_p = ak_p^1 + bk_p^{ref}$(overall) and a and b are the mole fractions of **1** and 3-methylpentane and k_p^{ref}(overall) is the overall reactivity of 3-methylpentane to the *tert*-butylperoxy radical. Since k_p^{ref}(overall) = 0.008 $M^{-1}\,s^{-1}$ (11) $k_p^1 = 0.012$ $M^{-1}\,s^{-1}$. Oxygen (0.073 M) was absorbed to give 1-bromo-2-methylbutan-2-ol (0.041 M) and 3-methylpentan-3-ol (0.036 M) as the major reaction products indicating that k_p^1 (per *t*-C—H) = $1.35 \times 0.007 = 0.0094$ $M^{-1}\,s^{-1}$. Repetitive experiments at 30°C suggested that the tertiary hydrogen in **1** is 1.32 ± 0.16 times more reactive than the tertiary hydrogen in 3-methylpentane and k_p^1 (per *t*-C—H) = 0.009 ± 0.001 $M^{-1}\,s^{-1}$.

The value of k_p^1 obtained from these co-oxidation experiments is a factor of 2 smaller than the directly determined value from the autoxidation of **1** which is well outside our usual experimental error. At the present time we are inclined to favour the lower value because the errors involved in measuring $k_p/(2k_t)^{1/2}$ are greater than those involved in measuring ratios of alcohols.[2]

[2]We have previously reported a rate constant for reaction of *t*-$BuO_2^{\cdot}$ with 1-bromo-2-methylpropane at 30°C of 0.017_5 $M^{-1}\,s^{-1}$ determined by the direct method (12). Application of the co-oxidation method to this substrate gave the somewhat lower value of 0.013 $M^{-1}\,s^{-1}$. Interestingly the *t*-C—H

[a] 1-Bromo-2-methylbutan-2-ol.
[b] 3-Methylpentan-3-ol.

Co-oxidations of **1** and 3-methylpentane in the presence of *t*-BuOOH were performed from 30 to 80°C and the results are presented in Table 2. A least-squares treatment of the relative reactivities of these two substrates over this temperature range yielded the Arrhenius equation

$$\log (k_p^1/k_p^{ref}) = (-0.56 \pm 0.21) + (0.93 \pm 0.3)/\theta$$

where $\theta = 2.303RT$ kcal mol^{-1} and $k_p^{ref} = k_p$ (per *t*-C—H) for 3-methylpentane. This implies $\Delta S^{\ddagger}(ref) - \Delta S^{1\ddagger} \sim 2$ cal deg^{-1} mol^{-1} and $E_p^{ref} - E_p^1 \sim 900$ cal mol^{-1}, i.e., both the entropy and energy of activation are negative relative to the values for 3-methylpentane.

Incidentally the relative reactivity of 1-bromo-2-methylbutane and 3-methylpentane did not change when the oxygen pressure was increased from 1 to 100 atm. Relative reactivities of these substrates are, therefore, not influenced by reversal of the rate controlling propagation reaction (14).

1-Bromo-3-methylbutane, **2**, absorbed oxygen about 4 times slower than 1-bromo-2-methylbutane in the presence of *t*-BuOOH at 30°C. The oxidizability of **2**, $k_p^2/(2k_t)^{1/2}$, was 1.4×10^{-4} $M^{-1/2}$ s$^{-1/2}$ suggesting that k_p^2(overall) = 0.0048 M^{-1} s^{-1}. The principal reaction products, after reduction, were 1-bromo-3-methylbutan-3-ol and 1,2-dibromo-3-methylbutane, which were identified by their mass spectra. The relative concentration of these two products, [1-bromo-3-methylbutan-3-ol]/[1,2-dibromo-3-methylbutane] was ~15. There was also a low yield of 1-bromo-3-methylbutan-2-ol and at least 5 other products in very low yields with gas chromatographic retention times close to those for the major reaction products.

Production of 1,2-dibromo-3-methylbutane indicates abstraction of a secondary hydrogen from C-2 by the *tert*-butylperoxy radical followed by β-scission of the 1-bromo-3-methyl-2-butyl radical (reactions [6] and [7]).

[6] $t\text{-BuO}_2\cdot + (CH_3)_2CHCH_2CH_2Br \rightarrow t\text{-BuO}_2H + (CH_3)_2C\dot{C}HCH_2Br$

[7] $(CH_3)_2C\dot{C}HCH_2Br \rightarrow (CH_3)_2CHCH{=}CH_2 + Br\cdot$

Molecular bromine is evidently formed by autoxidation of **2** because reaction mixtures were usually yellowish-brown and became colorless immediately upon addition of $(C_6H_5)_3P$.

The rate of autoxidation of a mixture of **2** (4.95 *M*) and 3-methylpentane (2.15 *M*) in the presence of *t*-BuOOH (1 *M*) and the free radical initiator 2,2,3,3-tetraphenylbutane (0.0046 *M*) at 30°C gave $k_p/(2k_t)^{1/2} = 1.7 \times 10^{-4}$ $M^{-1/2}$ s$^{-1/2}$, a value consistent with the individual oxidizability of the substrates and their mole fraction. Oxygen (0.11 *M*) was absorbed in 10 days and the major reaction products were 3-methylpentan-3-ol (0.024 *M*), 3-methylpentan-2-ol (0.003 *M*), 1-bromo-3-methylbutan-3-ol (0.0085 *M*), and 1,2-dibromo-3-methylbutane (0.00064 *M*) to give a product yield of only 32% based on the oxygen absorbed. This extremely low yield of oxidation products is somewhat disturbing since we usually obtain yields in excess of 90% from most oxidations. There were, however, no major reaction products to account for this discrepancy.

bond in 1-bromo-2-methylpropane is ca. 1.4 times more reactive than the *t*-C—H bond in 1-bromo-2-methylbutane, perhaps because of a higher percentage of the rotomer with the substituent eclipsing the developing unoccupied orbital, i.e., the least favoured conformation.

[a]Oxidizability in the presence of *tert*-butyl hydroperoxide.
[b]Overall reactivity to *t*-BuO_2.
[c]Reactivity of the tertiary hydrogen relative to the tertiary hydrogen in 3-methylpentane.

If the concentrations of 1-bromo-3-methylbutan-3-ol, 1,2-dibromo-3-methylbutane, and 1-bromo-3-methylbutane-2-ol are used to calculate rate constants for **2**, we find that k_p^2(per *t*-C—H) = 0.001 $M^{-1}\ s^{-1}$ and k_p^2(per *s*-C—H on C-2) $\simeq 4 \times 10^{-5}$ $M^{-1}\ s^{-1}$ and k_p(overall) determined directly is 3 times larger than k_p^2 per (*t*-C—H) + $2k_p^2$(per *s*-C—H on C-2).

The results of co-oxidations of **2** and 3-methylpentane at various temperatures are gathered in Table 3 and yielded the following Arrhenius equation for the relative reactivities of the tertiary hydrogens of these substrates.

$$\log k_p^2(\text{per } t\text{-C—H})/k_p^{ref} = (0.75 \pm 0.4) - (2.3 \pm 0.6)/\theta$$

This equation implies that $\Delta S(\text{ref})^{\ddagger} - \Delta S_4^{\ddagger} \sim -3.5$ cal deg^{-1} mol^{-1} and $E_p^{ref} - E_p^2 \sim -2.3$ kcal mol^{-1}.

1-Chloro-2-methylbutane **3** and *1-chloro-3-methylbutane* **4** undergo autoxidation to give, after reduction, mainly 1-chloro-2-methylbutan-2-ol and 1-chloro-3-methylbutan-3-ol, respectively. Kinetic data obtained by the direct and indirect methods for **3** and **4** are summarized in Table 4.

2-Methyl-1-trimethylsilylbutane (5) and 2-Methyl-1-trimethylstannylbutane (6). Both these compounds in the presence of *t*-BuOOH absorb oxygen about 3 times faster than 3-methylpentane and $k_p^5/(2k_t)^{1/2} = 6.75 \times 10^{-4}\ M^{-1/2}\ s^{-1/2}$ and $k_p^6/(2k_t)^{1/2} = 6.1 \times 10^{-4}\ M^{-1/2}\ s^{-1/2}$ giving $k_p^5 = 0.023\ M^{-1}\ s^{-1}$ and $k_p^6 = 0.021\ M^{-1}\ s^{-1}$. 2-Methyl-1-trimethylsilylbutane is oxidized almost exclusively to 2-methyl-1-trimethylsilylbutan-2-ol and the indirect method gave $k_p^5 = 0.022\ M^{-1}\ s^{-1}$. We were unable to show that 2-methyl-1-trimethylstannylbutan-2-ol was the principal reaction product formed by oxidation of **6** and we could not confirm the value of k_p^6 by the indirect method. There is a slow reaction between **6** and *t*-BuOOH which probably accounts for the difficulties that we experienced in analyzing for the oxidation products of this compound.

Discussion

It is a little disturbing that the rate constants for reaction of *t*-$BuO_2^{\bullet}$ with 1-bromo-2-methylbutane and 1-bromo-3-methylbutane obtained directly and indirectly differ by as much as a factor of 3 whereas these two methods gave identical results for 3-methylpentane (11) and a variety of aralkanes (14). Since part of the aim of this work was to investigate the influence of a β-bromo substituent on absolute

reactivity towards t-$BuO_2^{\cdot}$ we have concluded that the *lower* rate constants obtained by the indirect method are more accurate than the directly determined values. There is some justification for this conclusion in that the errors involved in estimating relative rate constants by the direct method are greater than those involved in the indirect method.

With this limitation in mind, a tertiary hydrogen β to a bromine substituent is ~10 times more reactive than a tertiary hydrogen γ to this substituent ($k_p^1/k_p^2 = 0.009/0.0009$) whereas it would be less reactive if the substituent performs only in a deactivating capacity. The reactivity of a β position in the absence of anchimeric assistance relative to the tertiary position in 3-methylpentane can be estimated to be 0.03–0.07 from the rate constant for abstraction of the tertiary hydrogen from 1-bromo-4-methylpentane by t-$BuO_2^{\cdot}$ at 30°C (0.0017 M^{-1} s^{-1}) using the arguments of Shea, Lewis, and Skell (6). The magnitude of the anchimeric effect is, therefore, at least 30 if we consider that bridging can only occur for the radical derived from the thermodynamically least favoured rotomer.

A comparison of the activation parameters for 1-bromo-2-methylbutane and 1-bromo-3-methylbutane relative to those for 3-methylpentane reveals that the activation energy for 1-bromo-2-methylbutane is ~3 kcal mol^{-1} lower than activation energy for 1-bromo-3-methylbutane and $\Delta S^{2\ddagger} - \Delta S^{1\ddagger} =$ 4–5 cal deg^{-1} mol^{-1}. These parameters are quite consistent with the intermediacy of a "bridged" 1-bromo-2-methyl-2-butyl radical and a normal 1-bromo-3-methyl-3-butyl radical in the H-atom transfer reaction to a peroxy radical.

Deactivation by a β-chloro substituent overshadows activation by anchimeric assistance because the t-C—H in 1-chloro-2-methylbutane is ~0.5 times as reactive as the t-C—H in 3-methylpentane. There must, however, be activation by anchimeric assistance because the t-C—H in 1-chloro-2-methylbutane is slightly more reactive than the t-C—H in 1-chloro-3-methylbutane.

The secondary hydrogens on C-2 of 1-bromo-3-methylbutane are of course β to the bromo substituent and they will be deactivated by inductive electron withdrawal and may be activated by anchimeric assistance. We have previously estimated a rate constant for reaction of the secondary hydrogen on C-3 of 2-methylpentane = 1×10^{-4} M^{-1} s^{-1} (11) which, when compared with a value of 4×10^{-5} M^{-1} s^{-1} for **2** indicates that activation of a secondary hydrogen by a β-bromo substituent is overshadowed by deactivation.

The kinetic data reported in this paper suggest that the peroxy radical shows much less preference than the bromine atom for a tertiary position vicinal to bromo and chloro substituents. Thus a β-bromo substituent enhances the rate of abstraction of a tertiary hydrogen by the bromine atom by a factor of 8–27 at 30°C (6) whereas the rate enhancement for a peroxy radical is only 1.35 at this temperature. In addition a s-C—H bond β to a bromo substituent and a t-C—H bond β to a chloro substituent exhibit enhanced reactivity to Br· whereas these bonds are less reactive than the corresponding bonds in an alkane to $RO_2^{\cdot}$.

We have previously concluded that Br· and $RO_2^{\cdot}$ have approximately the same selectivity to aliphatic s-C—H and t-C—H bonds whereas rates of abstraction of benzylic hydrogens by Br· are more sensitive to meta and para electron donating and withdrawing substituents than the rates of reaction of the *tert*-butylperoxy radical with ring substituted toluenes (15). This latter difference has been attributed to the greater electron affinity of Br·. Similar polar effects can perhaps be invoked to explain the selectivity difference between $RO_2^{\cdot}$ and Br· towards C—H bonds vicinal to bromo and chloro substituents in alkanes.

In conclusion, trimethylsilyl and less unambiguously trimethylstannyl substituents activate vicinal tertiary hydrogens and these groups in an *overall* sense are more effective than bromine. Trimethylsilyl does not deactivate a vicinal hydrogen by inductive electron withdrawal and it can tentatively be concluded that bromine and almost certainly chlorine are better bridging groups than trimethylsilyl and trimethylstannyl.

Received February 5, 1979

MILJENKO PERIC, ROBERT J. BUENKER, and SIGRID D. PEYERIMHOFF. Can. J. Chem. **57**, 2491 (1979).

The potential surfaces for the X^2B_1 and A^2A_1 states of PH_2 are calculated by means of an *ab initio* CI method. These results are then used to obtain vibrational levels and wavefunctions for each electronic state in both PH_2 and PD_2, whereby a two-dimensional treatment of the associated bending modes is carried out; the resulting vibrational frequencies are found to agree with the corresponding experimental findings (where available) to within 25 cm^{-1} in each case. The discrepancy in the calculated 0–0 transition energy is 0.06 eV and the variation in $\Delta G_{v_2'+1/2}$ values parallels quite closely that obtained experimentally. Finally the electronic transition moment is calculated as a function of the internuclear angle and this information is combined with the above vibrational wavefunctions to describe the intensity distribution in this electronic system; a maximum intensity is obtained for $v_2' = 4$ in the bending mode for PH_2, in agreement with the observed findings, and is predicted to occur for $v_2' = 6$ in PD_2.

MILJENKO PERIC, ROBERT J. BUENKER et SIGRID D. PEYERMIHOFF. Can. J. Chem. **57**, 2491 (1979).

Faisant appel à une méthode CI *ab initio*, on a calculé les surfaces de potentiel des états X^2B_1 et A^2A_1 de PH_2. On a alors utilisé ces résultats dans le but obtenir les niveaux vibrationnels et les fonctions d'onde de chaque état électronique de PH_2 et PD_2 alors que l'on a effectué un traitement bi-dimentionnel des modes de vibrations associés; on note que les fréquences de vibration qui en résultent sont en bon accord avec les valeurs expérimentales correspondantes (lorsqu'elles sont disponibles) à 25 cm^{-1} dans chaque cas. La différence avec l'énergie de transition 0–0 calculée est de 0.06 eV et la variation dans les valeurs de $\Delta G_{v_2'+1/2}$ sont parallèlles à celles obtenues expérimentalement. Enfin on a calculé le moment de la transition électronique en fonction de l'angle internucléaire et on combine cette information avec les fonctions d'onde décrites plus haut afin de décrire la distribution d'intensité de ce systeme électronique; on obtient un maximum d'intensité pour $v_2' = 4$ dans le mode de déformation de PH_2 ce qui est en accord avec les valeurs observées; on prédit que ce maximum sera associé au $v_2' = 6$ dans le cas de PD_2.

[Traduit par le journal]

Introduction

The absorption spectrum of the free radical PH_2 was first observed by Ramsay (1) during flash photolysis of phosphine. It consists of a long progression of bands with complicated fine structure (eleven peaks have been found for PH_2 in the 3600–5500 Å region and 13 have been seen in the same energy range for PD_2) and the main features are attributed to excitation of successive quanta of the bending vibration v_2' of the upper state. Further studies (2) found that the solid state spectrum taken at 4.2 K corresponds closely to the spectrum in the gas phase and that the emission spectrum obtained from electrical discharges in PH_3 and PD_3 (3, 4) also shows the same pattern, whereby several progressions $(0v_2'0)$–$(0v_2''0)$ with $v_2' = 0$–5 and $v_2'' = 0$–9 could be identified.

In analogy to the situation in NH_2 (5, 6) the ground state electronic configuration of PH_2 is assigned as $^2B_1$, while the first excited state is taken to be of $^2A_1$ symmetry. Nevertheless, there is a major difference between the two radicals NH_2 and PH_2 since investigations (5, 7) of NH_2 clearly indicate a quasi-linear excited state conformation for NH_2, while the early experimental results (8, 9) for PH_2 already spoke in favor of a decidedly bent upper species.

A number of rotational analyses for the $(0v_2'0$–

0008-4042/79/182491-07$01.00/0

000) bands with v_2' running from 1 to 8 in the absorption spectrum (10, 11) and for the (000–020) and (000–030) bands of PH_2 in emission (12) have led to accurate predictions of various molecular constants; an internuclear angle of 91°40′ has been deduced in this manner for the $^2B_1$ electronic ground state and an opening of the internuclear angle upon excitation to 123° 4′ has also been extracted therefrom. Similar to the situation in NH_2 (7) numerous rotational perturbations are found in the excited state levels and it has been concluded (11) that these perturbations are caused by high vibrational levels of the ground state, since no other electronically excited PH_2 states are found below the A^2A_1 species.

Various new and refined experimental techniques (13–15) have been employed recently for the further study of the PH_2 free radical, whereby the greater emphasis was placed on its electronic ground state. Zittel and Lineberger (15) have observed a small peak in the photoelectron spectrum of PH_2^- at approximately 2270 ± 80 cm^{-1} relative to the (000) level of the ground state and have assigned this feature to the (100–000) transition, although they point out that this energy is similar to twice the PH_2 bending frequency ($\bar{\nu}_2' = 1102$ cm^{-1}). To our knowledge there are no experimental results available which allow a determination of the other vibrational frequencies $\bar{\nu}_3$ in PH_2 or $\bar{\nu}_1$ and $\bar{\nu}_3$ in PD_2.

In contrast to the numerous experimental investigations very few theoretical studies are available for this system; the most recent thereof is an *ab initio* SCF calculation (16) for the ground state of PH_2, but no *ab initio* treatment of the excited PH_2 states has appeared to our knowledge thus far. Hence it is the goal of the present paper to treat the PH_2 molecule in its X^2B_1 and $^2A_1$ excited states in a similar manner as has been undertaken recently for the related NH_2 molecule (17), whereby particular emphasis will be placed on the calculation of the vibrational features of the A^2A_1–X^2B_1 transition.

Technical Details of the Treatment

The AO basis set employed in the present calculations is similar to that used in a previous treatment of the PH_5 molecule (18): six *s* and four *p* groups in the contraction (6,2,1,1,1,1|4,2,1,2) given by Veillard (19) are employed to represent the P atom, in addition to two sets of cartesian *d* functions ($\alpha_1 = 0.85$, $\alpha_2 = 0.30$); the hydrogen atoms are described in the same manner as in NH_2 (17), i.e. by two *s* groups (20) with four and one components each (with a scaling factor of $\eta^2 = 2$) augmented by a single *p* function ($\alpha = 0.735$). Furthermore one *s* and one *p* function ($\alpha(s) = 0.14$ and $\alpha(p) = 0.18$) located in each of the PH bonds are added so that the entire AO basis consists of 48 contracted cartesian gaussian functions.

The configuration interaction treatment is of the standard MRD-CI type with configuration selection and energy extrapolation as described elsewhere (21, 22). A core of five MO's corresponding to the 1*s*, 2*s*, and 2*p* shells of phosphorous is kept doubly occupied in all configurations, the corresponding five complementary MO's with the highest orbital energies are entirely excluded from consideration; all other MO's are in principle allowed variable occupation. For both states, X^2B_1 and A^2A_1 only one reference species has been employed in order to generate the double-excitation configuration space since all other species appear with small coefficients (less than 0.3%) in the final CI expansion. This procedure led to configuration spaces of roughly 6000 symmetry-adapted functions (in C_{2v} symmetry), while the sizes of the secular equations actually diagonalized were in the order of 2000. It should be pointed out, however, that the respective SCF orbitals are always taken as the MO basis. The energy contribution of higher than double-excitation configurations is also estimated according to the formula (23), $\Delta E_{Quad} = (1 - C_0^2)(E_{SCF} - E_{CI})$, which upon addition to the corresponding CI result is referred to as the full-CI limit in the ensuing discussion.

The basic vibrational treatment has been discussed in detail recently (method 1 of ref. 24) for the examples HCN and O_2. A functional basis of Hermite polynomials is employed in order to form a matrix representation of the Schrödinger equation for the symmetric and antisymmetric stretching modes (generally 15 such basis functions), while harmonic oscillator functions of the form

$$[1a] \quad \psi(r, \phi) = e^{iK\phi}R(r)$$

whereby

$$[1b] \quad R_{v,K}(\rho) = N_{v,K}\, e^{-\beta\rho/2}(\beta\rho)^{K/2}L^K_{(v+K)/2}(\beta\rho)$$

are chosen for the corresponding description of the two-dimensional bending mode.[1] Since a large number of bending vibrational levels are of interest in the present study, a basis of 50 $R_{v,K}(\rho)$ functions is supplied for the treatment of this mode. In all

[1]In this notation *r* is directly proportional to the bending angle α and $\rho = r^2$ ($0 \le \rho \le \infty$), whereby $L^K_{(v+K)/2}$ are the associated Laguerre polynomials and the quantity β is used as a variational parameter. The bending Hamiltonian used explicitly in this case is of the form

$$\left\{-\frac{1}{2\mu}\left[\frac{\partial^2}{\partial r^2} + \frac{1}{r}\frac{\partial}{\partial r} + \frac{1}{r^2}\frac{\partial^2}{\partial\phi^2}\right] + V(r)\right\}\psi(r, \phi) = E\psi(r, \phi)$$

whereby a different potential energy function is used for each of the two electronic states.

cases cubic-spline fitting techniques are used to represent the *ab initio* potential energy data, as described in detail in ref. 24.

In essence the present treatment thus employs a matrix representation of the global Hamiltonian in terms of a basis set of conventional vibronic product functions. The calculations are carried out entirely within the Born–Oppenheimer framework, i.e. cross terms involving derivatives of electronic wavefunctions with respect to nuclear variables are neglected, so that the Renner effect is not considered in this work. It should be pointed out, however, that the vibrational functions of eq. [1*a*] already contain the factor $e^{iK\phi}$, where K is the total vibronic angular momentum quantum number. This procedure should be distinguished from that used in previous treatments of the bending vibration in triatomic molecules in which vibrational functions containing the factor $e^{il\phi}$ (l being a pure vibrational quantum number) are first obtained as eigenfunctions of a zeroth-order Schrödinger equation (one which uses the same potential energy function for both electronic states) for the bending mode, which are then multiplied with $e^{\pm i\Lambda\phi}$ (Λ being the pure electronic angular momentum quantum number) in order to give the final eigenfunctions of the form $e^{iK\phi}$.

Results and Discussion

Potential Energy Curves

The potential energy curves for HPH bending are obtained for angles of 180, 160, 140, 120, 100, 91.7, 80, 60, and 40 deg at the SCF and the CI (except at 40°) level and are presented in Fig. 1 together with the results corresponding to the full-CI limit in the given AO basis. The PH bond length is thereby held fixed at 2.67967 au, i.e. the experimental equilibrium value (11) for the PH_2 ground state. The total SCF energy for the ground state minimum is -341.85943 hartree compared to the best previous value in the literature (16) of -341.85720 hartree with a comparable AO basis set. The CI energy is -342.0016 hartree, while the contribution of higher excitation species is estimated to amount to roughly 0.01 hartree. From the overall appearance of the curves in Fig. 1 it is seen that the SCF treatment already gives a good approximation to the true potential curves, although a closer analysis shows that CI is more effective for the linear arrangement of nuclei (Δ(SCF,CI) is 0.1518 au at 180°, for example, and only 0.1407 au at 100° for the X^2B_1 state, while the corresponding differences are 0.1520 au and 0.1448 au for the $^2A_1$ excited species), thereby reducing the ground state barrier by about 2400 cm^{-1}. The curve for the estimated full-CI energy runs to a large extent parallel to the ground and excited state double-

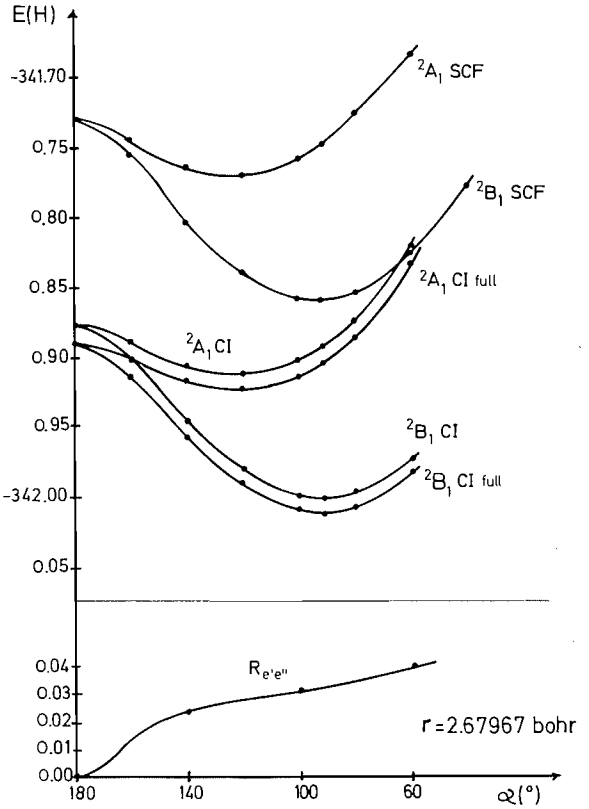

FIG. 1. Angular potential curves for the X^2B_1 and A^2A_1 electronic states of PH_2 obtained at various levels of treatment (see text for details); energy values are given in units of hartree (27.21 eV). The variation of the electronic transition moment (atomic units) between these two states is also given at the bottom of the figure.

excitation CI counterpart, although a small change in the same direction as the correction from SCF to CI can be noted (i.e. the difference between double-excitation CI and the full-CI estimate is 0.0136 au at 180° and only 0.0094 au at 100° for $^2B_1$, with the equivalent values of 0.0137 au and 0.0114 au for the $^2A_1$ species).

The calculated curves for the symmetric and asymmetric stretching mode of the PH_2 molecule are plotted in Figs. 2 and 3 respectively. In this case the $^2A_1$ upper state is treated at three different internuclear angles (91.7, 123, and 180 deg) in order to determine the coupling between the symmetric stretching and bending motion in this state, but the roughly parallel appearance of the curves indicates a relatively weak interdependence of the ν_1 and ν_2 modes in this instance. The calculations are again carried out at all three levels of treatment, but only the values corresponding to the full-CI estimate are given explicitly.

Finally, the various characteristic data for the $^2B_1$

[a]The calculated values are always obtained as the difference between $\varepsilon(v = 1)$ and $\varepsilon(v = 0)$.
[b]An alternative value of 1107.26 cm^{-1} (12) is also given for $\bar{\nu}_2$ from an extrapolation procedure.
[c]Alternative values given by other authors are 951 cm^{-1} (4) and 956 cm^{-1} (12).

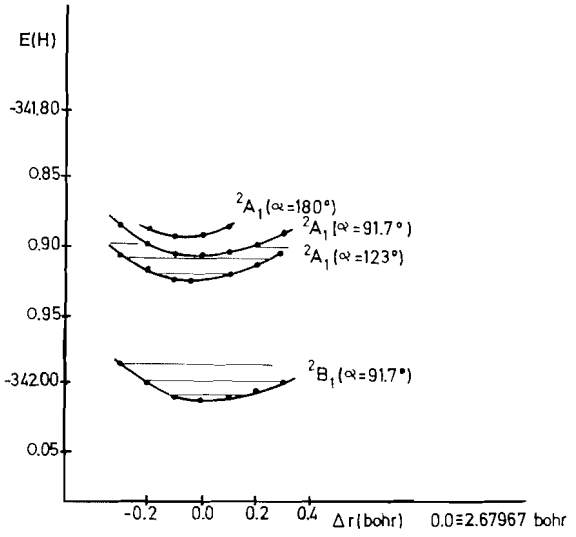

FIG. 2. Symmetric stretch potential curves and calculated vibrational levels for the X^2B_1 and A^2A_1 states of PH_2; in the upper state potential curves are shown for a series of three fixed internuclear angles (energy given in units of hartree).

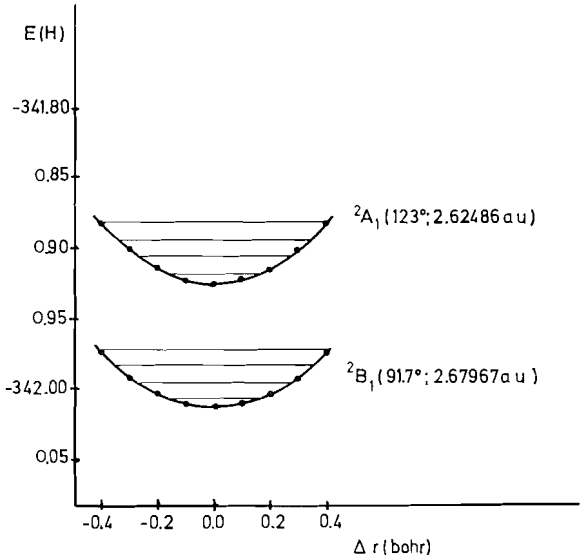

FIG. 3. Antisymmetric stretch potential curves and calculated vibrational levels for the X^2B_1 and A^2A_1 states of PH_2; results are obtained for fixed internuclear angle and average PH bond length, as given in parentheses (energy in hartree units).

and $^2A_1$ potential surfaces obtained by polynomial fits to the data points of Figs. 1–3 are collected in Table 1 and are compared with corresponding experimental data whenever available. It is seen that extremely good agreement between the structural data and the vibrational frequencies obtained from the *ab initio* potential energy surfaces and the corresponding quantities derived from experiments is achieved; discrepancies in the bond-angle determination are only 1.0 deg (or less), deviations in bond lengths are at most 0.01 Å, while experimental and theoretical vibrational frequencies agree to within 25 cm^{-1}.

The A^2A_1–X^2B_1 *Transition and Its Vibrational Structure*

The calculated energy difference between the two minima of the X^2B_1 and $^2A_1$ potential energy curves is $\Delta E_e = 18\,760\ cm^{-1}$. This value taken together

	$\nu_3' = 0$	$\nu_3' = 1$	$\nu_3' = 2$
$\nu_3'' = 0$	0.999	0.0	7.1×10^{-4}
$\nu_3'' = 1$	0.0	0.998	0.0
$\nu_3'' = 2$	7.1×10^{-4}	0.0	0.996

with the calculated frequencies for the zeroeth level of each vibrational mode yields an estimate for $\Delta E_{000,000}$ of 18 820 cm^{-1} (or 2.33 eV), which must be compared with the T_0 value of 18 276.6 cm^{-1} (25) or 18 272.6 cm^{-1} (26) (2.27 eV) deduced from experiment. Thus there remains a discrepancy of 0.06 eV.

The various calculated vibrational energy levels for the symmetric and asymmetric stretching modes[2] of PH_2 are also indicated for ground and excited states in Figs. 2 and 3. The calculated Franck–Condon factors (Table 2) support the qualitative conclusion which can be drawn from Figs. 2 and 3, namely that the 0–0 transition is by far the strongest in each of the two modes, so that one strong peak rather than a long progression in one of the stretching coordinates should be observed in the spectrum.

The calculated vibrational energy levels for the bending mode of PH_2 and PD_2 are contained in Figs. 4 and 5 respectively; the values for $K = 0$ (symmetric) and $K = 1$ (antisymmetric) are explicitly shown therein. It is seen that the K-type splitting is very small for the low-lying levels inside the potential well which exhibit the characteristic rotational structure; this splitting becomes a distinctive factor in the neighborhood of the potential maximum, however, and above this barrier the vibrational term pattern which is typical for a linear molecule becomes dominant. Levels corresponding to higher K values

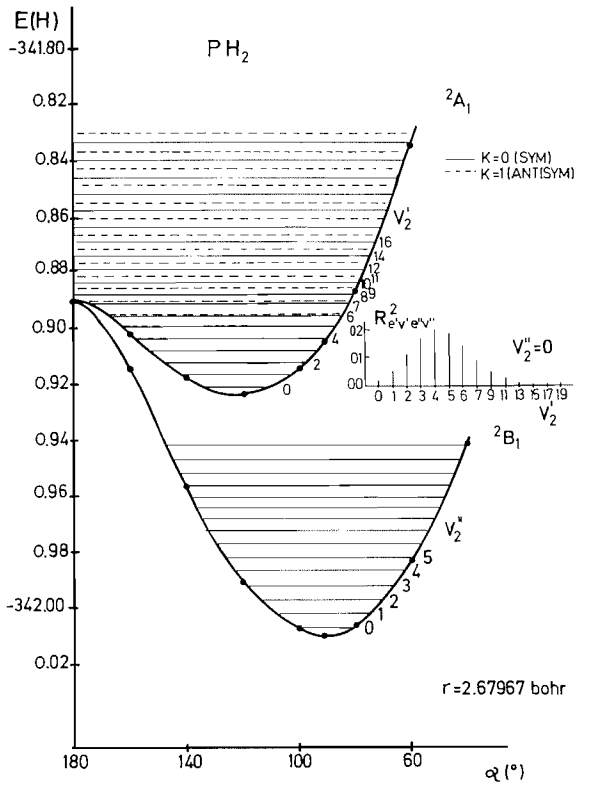

FIG. 4. Calculated CI angular potential curves and corresponding vibrational levels for the two lowest electronic states of PH_2; results are given for two different values of the rotational quantum number K in the upper state. The values of the square of the electronic moment connecting the various levels of the upper state with the $v_2'' = 0$ species of X^2B_1 are also given.

have also been calculated but are not plotted since they behave in the expected way (24).[3]

It is also interesting that the calculated differences ΔG between consecutive levels (of the same K quantum number) in the upper state decrease from (0–1) to (6–7) in PH_2 (and until (8–9) in PD_2), just as has been found in the observed ($K' = 1$) spectrum (see Fig. 6) (1), whereas the vibrational intervals increase thereafter with further increase in v_2'. Dixon (8) has interpreted this behavior as being caused by the barrier in the $^2A_1$ state potential function for the higher vibrations, and indeed Figs. 4 and 5 support this deduction quantitatively.

The intensity distribution for transitions between various vibrational levels of the $^2B_1$ and $^2A_1$ state has also been calculated and the resulting data,

[2]The potential energy curve for symmetric stretch is thereby represented via a fit with terms up to $(R - R_0)^5$, while the asymmetric curve is approximated by a polynomial of 4th order; 15 vibrational basis functions are chosen in each case.

[3]The calculated CI points have been supplemented by the spline technique so that the potential is represented by a polynomial of order 30; technical details are contained in ref. 24.

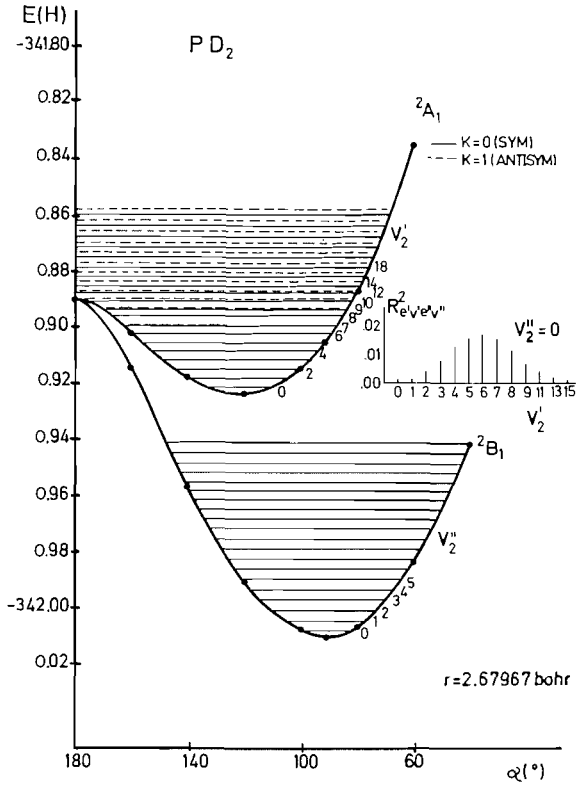

FIG. 5. Calculated CI angular potential curves and corresponding vibrational levels for the two lowest electronic states of PD_2; results are given for two different values of the rotational quantum number K in the upper state. The values of the square of the electronic transition moment connecting the various levels of the upper state with the $v_2'' = 0$ species of X^2B_1 are also given.

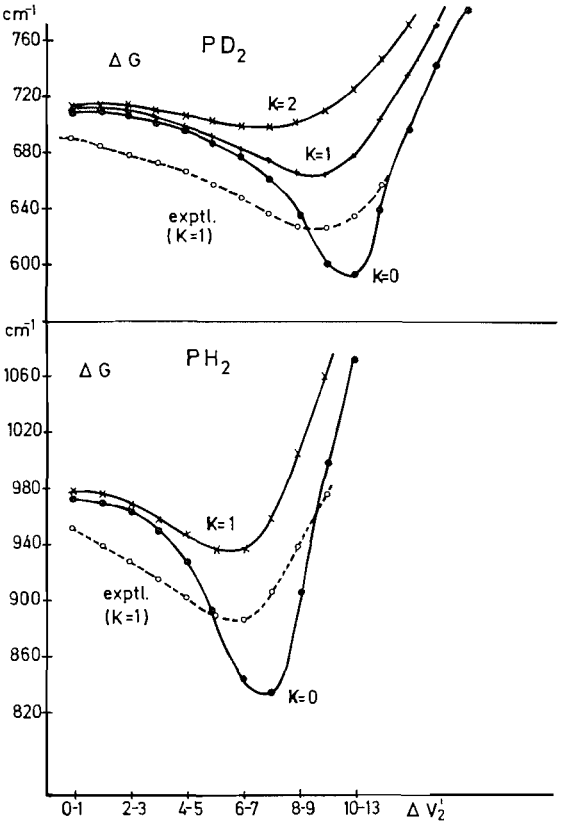

FIG. 6. Comparison of calculated and experimental ΔG values in cm^{-1} for the v_2' bending mode of the $^2A_1$ state of PH_2 (bottom) and PD_2 (top); theoretical results for several series with the same rotational quantum number K are given, while the experimental curve corresponds to $K = 1$ (for the vibrational numbering see Figs. 4, 5).

which correspond to the absorption spectrum of PH_2 and PD_2, are also plotted in Figs. 4 and 5. In this case simple Franck–Condon factors have not been evaluated but rather the actual expression

$$R^2_{e'v'e''v''} = [\int R_{v_2',K'}(\rho)\{\int \Psi_{e',\mu}\Psi_{e''}\,d\tau_e\}R_{v_2'',K''}(\rho)\,d\tau_v]^2$$

since the electronic transition moment $R_{e'e''}$ is found to depend strongly on the internuclear angle (Fig. 1). The intensity maximum for absorption is calculated to occur for $v_2' = 4$ in PH_2 in complete accord with known experiments (9); it is predicted to occur for $v_2' = 6$ in the PD_2 radical. In comparison to NH_2 the maximum occurs at much smaller quantum numbers (in NH_2 at $v_2' = 9$) because of the fact that the equilibrium internuclear angle is decidedly smaller (more bent) for the PH_2 $^2A_1$ state than for the (quasi-linear) NH_2 $^2A_1$ radical. Thus altogether it is seen that the calculations describe the long progression in the bending mode in an almost quantitative manner.

Summary and Conclusion

The present *ab initio* CI calculations have dealt with the calculation of the vibrational structure of the A^2A_1–X^2B_1 electronic transition of the PH_2 (and PD_2) radical. They predict the nuclear geometry of this system to within errors of 1.0 deg and 0.01 Å respectively in both electronic states, and also obtain the bending frequencies for both states and both isomers with deviations of less than 25 cm^{-1} from the corresponding experimental data. Furthermore they predict the frequencies for symmetric and asymmetric stretching vibrations of both ground and excited states, which have not yet been determined from experiments. Calculation of the vibrational intensity distribution shows that the 0–0 transitions in both symmetric and asymmetric stretch are highly favored over excitations to levels with higher quantum numbers. On the other hand, the long progression in the bending mode deduced from the observed

spectra is reproduced very satisfactorily by the calculations, both with respect to vibrational spacing and intensity distribution. Hence it is demonstrated that the fairly detailed structure of the PH_2 (or PD_2) electronic spectrum between 3600 and 5500 Å can be reproduced almost quantitatively by means of present-day *ab initio* CI calculations. The investigation of small perturbations of vibrational levels in the upper state, which are also observed in the measured spectrum and are thought to be caused by the presence of vibrational levels of the ground electronic state, i.e. effects of the Renner–Teller splitting or further terms not present in the Born–Oppenheimer approximation, would thus seem to be the next realistic step in upgrading the theoretical treatment of the molecular spectra of such systems.

Pentagonal pyramidal lead coordination in the crystal structure of dimeric diaquopyridine-2,6-dicarboxylatolead(II) pyridine-2,6-dicarboxylic acid monohydrate

K. A. BEVERIDGE AND G. W. BUSHNELL

Chemistry Department, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received December 22, 1978

K. A. BEVERIDGE and G. W. BUSHNELL. Can. J. Chem. 57, 2498 (1979).

The crystal structure of dimeric diaquopyridine-2,6-dicarboxylatolead(II) pyridine-2,6-dicarboxylic acid monohydrate, empirical formula and asymmetric unit $C_{14}H_{14}N_2O_{11}Pb$, has been solved and refined to $R = 0.081$, $R_w = 0.100$. The space group was $P\bar{1}$ with $a = 1073.8(3)$, $b = 1123.2(5)$, $c = 705.0(3)$ pm, $\alpha = 101.28(8)°$, $\beta = 95.42(6)°$, $\gamma = 92.80(7)°$, $\rho = 2.37$ g cm^{-3} (meas.). Measurements were done on an automatic 4-circle diffractometer ($MoK_{\bar{a}}$ radiation, $\lambda = 71.069$ pm), and corrected for absorption. The lead complex is dinuclear with an inversion point at the centre of the double bridging. Each lead atom has distorted pentagonal pyramidal coordination with a water molecule at the apex. The basal ligands are water and terdentate pyridine-2,6-dicarboxylate. The double bridging is by one of the coordinated carboxylic oxygen atoms and its inverse. The electron pair geometry is assumed to be pentagonal bipyramidal with a stereochemically active lone pair occupying considerable solid angle in an axial position. Bond lengths (±2 pm) are: Pb—OH_2 (apex), 259; Pb—OH_2 (basal), 273; Pb—O, 251, 258, 273; Pb—N, 259. The mean of the bond angles at Pb involving the apical oxygen is 77°. The unit cell contains two water and two dicarboxylic acid molecules of crystallisation which are involved in an H-bonding network with one bond for each hydrogen attached to oxygen in the structure.

K. A. BEVERIDGE et G. W. BUSHNELL. Can. J. Chem. 57, 2498 (1979).

On a résolu la structure cristalline du monohydrate dimère du diaquopyridinecarboxylato-2,6 plomb(II) acide pyridinedicarboxylique de formule empirique et unité asymétrique $C_{14}H_{14}N_2O_{11}Pb$ et on l'a affinée jusqu'à des valeurs de $R = 0.081$ et $R_w = 0.100$. Le groupe d'espace est $P\bar{1}$ avec $a = 1073.8(3)$, $b = 1123.2(5)$, $c = 705.0(3)$ pm, $\alpha = 101.28(8)°$, $\beta = 95.42(6)°$, $\gamma = 92.80(7)°$, $\rho = 2.37$ g cm^{-3} (mes). On a effectué les mesures sur un diffractomètre automatique à 4 cercles (radiation $MoK_{\bar{a}}$, $\lambda = 71.069$ pm) et elles sont corrigées pour l'absorption. Le complexe de plomb est dinucléaire avec un point d'inversion au centre du double pont. La coordination de chaque atome de plomb est assimilée à une pyramide pentagonale déformée portant une molécule d'eau à son sommet. Les ligands à la base de la pyramide sont l'eau et le pyridinedicarboxylate-2,6 tridentate. Le double pont est assuré par un des atomes d'oxygène du carboxylate coordonné et de son inverse. On fait l'hypothèse que la géométrie de la paire d'électrons est bipyramidale pentagonale et qu'elle porte une paire libre d'électrons active du point de vue stéréochimique qui occupe un angle solide important dans la position axiale. Les longueurs des liaisons (±2 pm) sont: Pb—OH_2 (sommet), 259; Pb—OH_2 (base), 273; Pb—O, 251, 258, 273; Pb—N, 259. L'angle de valence moyen autour du Pb impliquant l'oxygène au sommet est 77°. La maille unitaire contient deux molécules d'eau et deux molécules d'acide dicarboxylique de cristallisation qui sont impliquées dans un réseau de liaison H dans lequel il y a une liaison pour chaque hydrogène qui est attachée à un atome d'oxygène de la structure.

Introduction

Lead and its compounds are toxic and give rise to many serious industrial hazards. The smelting of lead produces metal fumes and flue dusts. In manufacturing processes nearly one million American workers are exposed to lead in various chemical forms. Some uses of lead compounds ensure that the element is widely distributed near to man, for example the inclusion of tetraethyllead in motor fuel formulations and the use of hydroxycarbonate as a white paint pigment. The toxicology of lead has been intensively studied (1). However, the structural chemistry of plumbous compounds which might be relevant to situations in living systems is relatively undeveloped. Existing X-ray crystallographic results indicate the variability of both the coordination number of the plumbous ion and its stereochemistry. The inert pair of electrons usually influences the stereochemistry, often by occupying one side of the lead atom opposite to the ligands.

The anion of pyridine-2,6-dicarboxylic acid (dipicolinate) is a ligand of some biochemical interest. It is produced by all bacterial spores and some fungi. The heat resistance and metabolic dormancy of the

0008-4042/79/182498-06$01.00/0

spores are thought to depend on the calcium salt of this acid. The crystal structures of calcium pyridine-2,6-dicarboxylate trihydrate (2) and strontium pyridine-2,6-dicarboxylate tetrahydrate (3) have been determined.

A recent series of papers on metal purpurate complexes (4) contains a summary of crystallographic studies on pyridine-2,6-dicarboxylates, and two eight coordinate Pb(II) purpurate complexes. The crystal structure of pyridine-2,6-dicarboxylic acid monohydrate has been published (5).

Experimental

A mixture of crystals was obtained by diffusion of aqueous solutions of lead nitrate into pyridine-2,6-dicarboxylic acid. The densities were found to be 3.16 g cm^{-3} for the flat lathes and 2.37 g cm^{-3} for the rods thus prepared. The mixture was separated by flotation in a carbon tetrachloride/1,1,2,2-tetrabromoethane solution. Analysis of the lathes gave: C 22.55, H 0.80, N 3.75%. Calculated for Pb dipic: C 22.58, H 0.81, N 3.76%. Analysis of the rods gave: C 26.8, H 2.19, N 4.68%. Calculated for Pb dipic·H_2 dipic·$3H_2O$: C 28.3, H 2.38, N 4.72. The structure of the rod shaped crystals is reported in this paper.

The crystal system is triclinic, space group $P\bar{1}$. The Delaunay reduced cell has parameters $a = 1073.8(3)$, $b = 1123.2(5)$, $c = 705.0(3)$ pm, $\alpha = 101.28(8)°$, $\beta = 95.42(6)°$, $\gamma = 92.80(7)°$, $V_{cell} = 0.8281(5)$ nm^3. The cell was refined by the method of least squares with Picker diffractometer centering measurements at $\pm 2\theta$ in pairs using $MoK_{\bar{\alpha}}$ radiation ($\lambda = 71.069$ pm). Formula $C_{14}H_{14}N_2O_{11}Pb$, $M = 593.47$, $n = 2$, ρ(calc) = 2.38 g cm^{-3}. Crystal dimensions 0.037, 0.041, 0.478 mm along x, y, z respectively; mounting direction, z. The absorption coefficient for $MoK_{\bar{\alpha}}$ was 96.9 cm^{-1}. Reflections were scanned in 50 steps of 0.04° in 2θ counting for 2 s at each step. Background counts were for 50 s at each extremity. Three standards were measured before each batch of 50 reflections. A total of 4156 measurements were made up to $2\theta = 50°$, ($h \geq 0$), and of these 2355 reflections (and 192 standards) had $I > 3\sigma(I)$. The crystal changed from colourless to pale smoky yellow in the X-radiation, and the intensities of the standards dropped approximately 12% during data collection. Lorentz, polarisation, and crystal decomposition/instrument variation factors were applied, and absorption corrections were done using a program derived from that of Coppens, Lieserowitz, and Rabinovich (6), and tested by the procedure of Cahen and Ibers (7). Transmission factors were in the range 0.65–0.72. After sorting the reflections and merging any duplicate or equivalent measurements 2206 intensities remained.

Structure Determination

The structure was solved by the Patterson function and heavy atom methods. The atomic scattering factors and the anomalous dispersion correction for Pb were taken from the International Tables (8). The light atoms were located by means of difference maps. The structure was refined uneventfully by minimising $\sum w(|F_o| - |F_c|)^2$ using full matrix least-squares. A weighting scheme devised to eliminate systematic variations of $w\Delta^2$ took the form $w = (A + Bx + Cx^2 + Dx^3)^{-1}$ where $x = |F_o|$, $A = 2.3208$, $B = -1.950 \times 10^{-2}$, $C = -6.4 \times 10^{-5}$, $D = 2 \times 10^{-6}$. The final agreement factors were $R = 0.081$, $R_w = 0.100$ where $R_w = (\sum w\Delta^2 / \sum w|F_o|^2)^{1/2}$. The final difference map had peaks and troughs

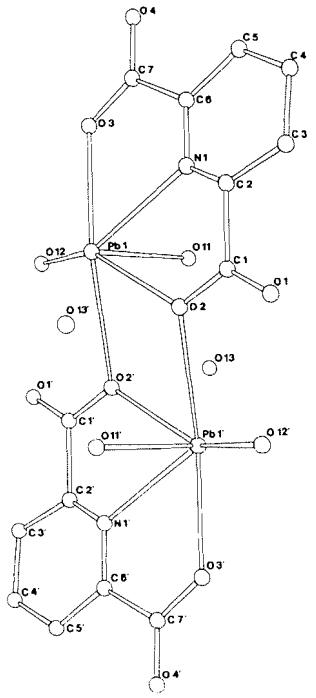

FIG. 1. The dimeric lead complex.

less than 2×10^{-6} e pm^{-3} except in the vicinity of Pb, where max = $+4.3 \times 10^{-6}$ e pm^{-3} and min = -3.2×10^{-6} e pm^{-3} both 105 pm from the metal atom.

The hydrogen atom peaks were poorly defined. Calculations were done using a set of programs supplied by Dr. B. R. Penfold of the University of Canterbury, Christchurch, New Zealand. The structure factor and other tables are in the Depository for Unpublished Data.[1]

Results and Discussion

The fractional atomic coordinates are given in Table 1. The asymmetric unit consists of half of the dimeric lead(II) complex shown in Fig. 1, a molecule of pyridine-2,6-dicarboxylic acid of crystallisation, and a water molecule containing O(13). The crystal packing is shown in Fig. 2. The numbering scheme of the free acid molecule can be derived by adding 7, 1, and 4 to the numbers of the corresponding C, N, and O atoms in Fig. 1. The only differences between the ligand and non-ligand molecules which are possibly significant are between the C—O bond lengths. In the ligand C(1)—O(2) = 128(3), C(1)—O(1) = 120(3), C(7)—O(3) = 128(3), C(7)—O(4) = 125(3) pm. The oxygen bound to Pb has the longer C—O length. The non-ligand has C(8)—O(6) = 119(3), C(8)—O(5) = 132(3), C(14)—O(7) = 128(3),

*Fractional atomic coordinates $\times 10^{-3}$ are given. U_{iso} values to be multiplied by 10 to give mean square amplitudes in pm². For Pb in pm²: $U_{11} = 278(5)$, $U_{22} = 191(5)$, $U_{33} = 544(7)$, $U_{12} = 64(4)$, $U_{23} = 117(4)$, $U_{31} = 120(4)$. Estimated standard deviations, given in parentheses, in units of the least significant digit.

C(14)—O(8) = 122(3) pm, showing asymmetry in the C(8) carboxyl group reversed with respect to that of the ligand. Hydrogen atoms on O(5) and O(7) are consistent with the hydrogen bonding scheme to be proposed. The mean C—C single bond length is 154 pm, and the mean O—C—O angle = 125°. Other bond lengths and angles of the pyridine groups are of little interest and have been deposited with the structure factor tables.

The lead atom is six coordinate with approximately pentagonal pyramidal geometry. The water molecule containing O(11) is at the apex of the pyramid. Interatomic distances are given in Table 2(*a*). The last three entries are distances from lead to its next nearest neighbours, and the bonding if present would be weak. We presume that the lone pair of electrons on the plumbous ion occupies the position below the pyramid base, opposite O(11). The electron pair geometry is thus pentagonal bipyramidal. As expected from valence shell electron pair repulsion theory, the lone pair occupies a greater solid angle than a bonding pair and the angles in Table 3(*a*) involving O(11) are all less than 85° (mean 77.0°). The bridging to an inverted pyramid is through O(2) and O(2′), an arrangement similar to that in calcium pyridine-2,6-dicarboxylate trihydrate (2). The centre of the bridge is a crystallographic inversion centre.

The hydrogen bonding scheme is illustrated in Fig. 3. Eight hydrogen bonds were found, one for each hydrogen attached to oxygen in the structure. The lengths of the hydrogen bonds are given in Table 2(*b*). The water molecule containing O(13) bridges the non-coordinated acid molecules in the y direction using hydrogen bonds to O(5) and O(8) which are at the extremities of these molecules. O(13) is also hydrogen bonded to O(11) at the apex of the pentagonal pyramid and lies beneath a neighbouring pyramid (not shown in Fig. 1) only 302(2) pm from its lead atom. O(4) at the end of the dimeric complex is hydrogen bonded to O(11) and O(12) of the next molecule in the y direction. The hydrogen bond to O(7) links the uncoordinated dicarboxylic acid and the dimeric unit. The distance O(11)—O(7) = 285(3) pm, but O(7) was rejected as an H atom receptor in favour of N(2), since angle O(4′)—O(11)—O(7) = 65°. The O(12)—O(1) hydrogen bond is intramolecular to the lead complex. O(6) is not involved in hydrogen bonding. The hydrogen atom attachments

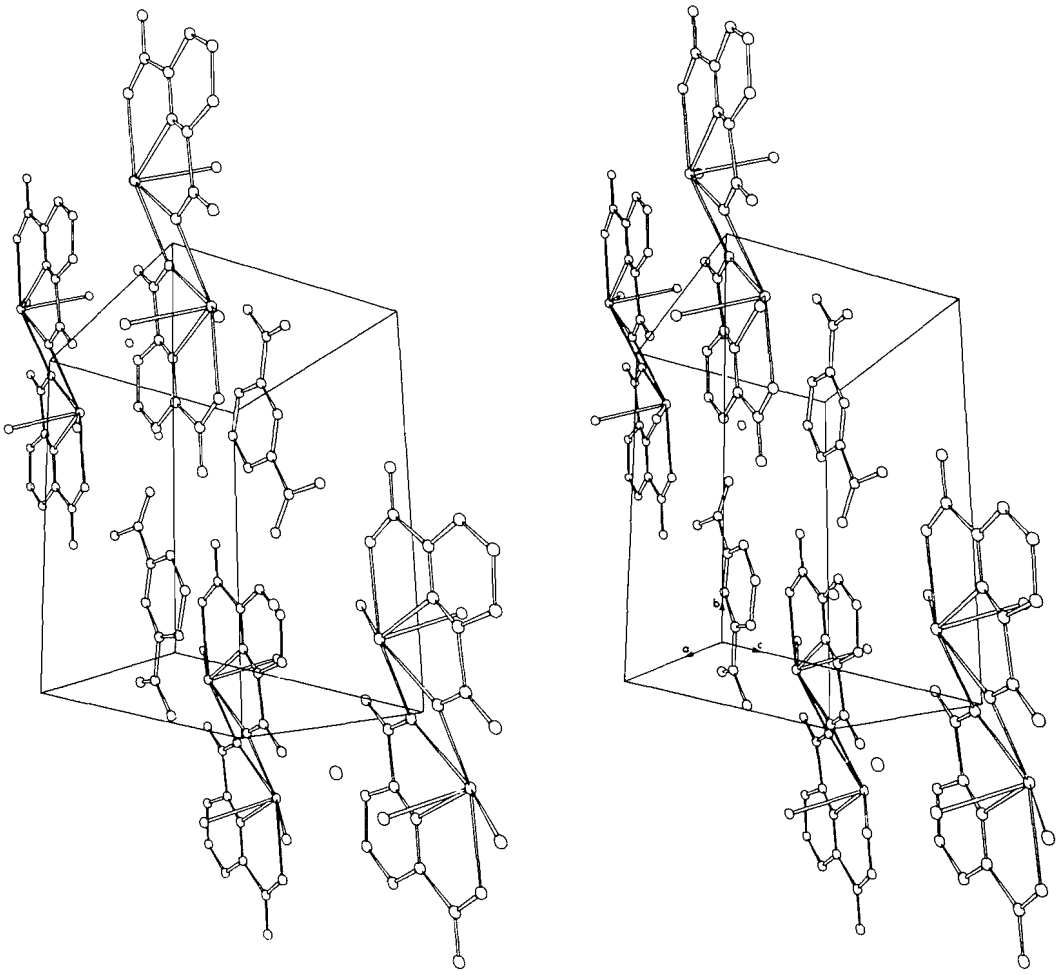

FIG. 2. The crystal packing diagram as a stereoscopic pair.

suggested in Table 2(*b*) were derived from the carboxyl C—O bond lengths, and are consistent with three water molecules and an undissociated dicarboxylic acid molecule in the asymmetric unit. Angles relevant to the hydrogen bonding scheme are given in Table 3(*b*).

The results of the mean plane calculations are given in Table 4. Both pyridine rings are planar. The carboxylate groups, particularly O(7) and O(8), are slightly out of the pyridine ring planes, which are mutually parallel. The coordination geometry of the lead atom is only approximately a pentagonal pyramid. The basal pentagon has significant deviations from planarity. The lead atom is at a perpendicular distance of 60.0 pm from the least-squares plane.

The pentagonal bipyramidal electron pair geometry has been found for two lead(II) complexes having sulfur atoms coordinated. In the crystal structure of tetraethylammonium tris(ethylxanthato)lead(II), $Et_4N^+[Pb(EtOCS_2)_3]^-$, the lead atom has an axial lone pair (9). Each ligand has one short (284–295 pm) and one long (312–313 pm) Pb–S bond. A next nearest neighbour lies at 368 pm from Pb. In the crystal structure of polymeric lead(II) *O,O'*-diisopropylphosphonodithionate, $\{Pb[(Pr^iO)_2PS_2]_2\}_\infty$, the lone pair position is equatorial (10). The axial lengths are 298.5 and 302.7 pm and the equatorial lengths are 276.1, 277.2, 317.5, and 323.2 pm, with the greater lengths adjacent to the lone pair. These two compounds establish the Pb—S lengths to be expected.

D-Penicillamine has been used in chelation therapy for lead poisoning. In the crystal structure of D-Penicillaminatolead(II) (11), the amino acid is a terdentate chelating ligand to one lead atom: Pb—O, 244 pm; Pb—N, 244 pm; Pb—S, 272 pm. Weaker interactions to two other lead atoms have lengths:

Pb—S, 316 and 348 pm; Pb—O, 277 pm. If the very long Pb—S bond is accepted, the electron pair geometry is distorted pentagonal bipyramidal with the lone pair equatorial, and adjacent to the long Pb—S bonds.

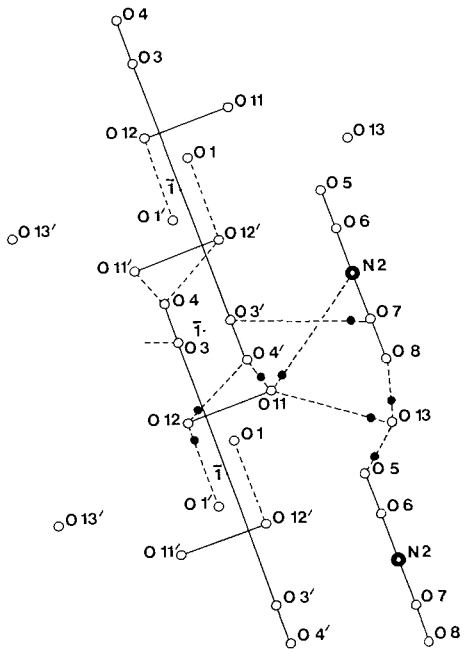

FIG. 3. The hydrogen bonding scheme.

The range of bond lengths in the literature for Pb(II) to N and O is wide with lengths from about 240 to 300 pm being common. The variability of the Pb(II) stereochemistry and the use of macrocyclic ligands are probable causes for this. Our bond lengths are near the middle of the range.

electrons on a Pb(II) ion cannot be taken for granted. In $(\pi\text{-}C_6H_6)Pb(AlCl_4)_2 \cdot C_6H_6$ the coordination geometry is pentagonal bipyramidal, with benzene occupying one site, and the lone pair position is not evident (12). In $[Pb(SCN)_2C_{12}H_{26}N_2O_4]$, containing the 1,7,10,16-tetraoxa-4,13-diazacyclooctadecane ligand, the Pb(II) ion is eight coordinate and the lone pair has only a minor stereochemical effect (13).

The crystal structure reported here establishes pentagonal pyramidal lead(II) with oxygen and nitrogen donors, in an interesting doubly bridged dimeric structure, the lone pair on each lead atom being stereochemically active.

The conformations of furanosides. A ^{13}C nuclear magnetic resonance study

NATSUKO CYR[1] AND ARTHUR S. PERLIN

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2A7

Received March 19, 1979

NATSUKO CYR and ARTHUR S. PERLIN. Can. J. Chem. 57, 2504 (1979).

A study of the conformations of 15 methyl aldohexo- and pentofuranosides in aqueous solution has been carried out, based primarily on measurements of coupling by ^{13}C-1 and ^{13}C-2 with protons of the five-membered ring. From these stereochemically-dependent data, and their correspondence with vicinal ^1H–^1H couplings, the conformation favored by each glycoside has been deduced. Although, in general, the coupling patterns exhibited by homologous pairs of hexoses and pentoses are closely similar, the α-*gluco* and α-*xylo* pair provide an exception: their data indicate that the latter favors the ^2E conformation, whereas the glucoside is characterized by interconverting E_4 and ^3E conformers. It appears that a *quasi*-equatorial exocyclic side chain and a *quasi*-axial C-1,O-1 bond (anomeric effect) are equally important stabilizing factors in furanosides. In a number of instances, the current findings differ from those obtained in earlier studies for configurationally-related furanose derivatives in organic media.

NATSUKO CYR et ARTHUR S. PERLIN. Can. J. Chem. 57, 2504 (1979).

On a effectué une étude des conformations de 15 aldohéxo- et pentofurannosides de méthyle en solutions aqueuses; cette étude est basée principalement sur des mesures de couplage entre les ^{13}C-1 et ^{13}C-2 avec les protons du cycle à cinq chaînons. A partir de ces données qui dépendent de la stéréochimie et de leur similitude avec les couplages vicinaux ^1H–^1H, on en déduit la configuration favorisée par chaque glycoside. Quoique, d'une façon générale, les couplages des paires homologues d'hexoses et de pentoses se ressemblent, la paire α-*gluco* et α-*xylo* correspond à une exception: leurs données indiquent que le dernier favorise une conformation ^2E alors que le glucoside est caractérisé par des conformères E_4 et ^3E en interconversion. Il semble qu'une chaîne latérale exocyclique *quasi*-équatoriale et une liaison C-1,O-1 *quasi*-axiale (effet anomère) soient aussi des facteurs stabilisants importants dans les furannosides. Dans un certain nombre de cas, nos résultats diffèrent de ceux obtenus au cours d'études antérieures effectuées sur les dérivés furannosides configurationnellement apparentés mais en solution dans des solvants organiques.

[Traduit par le journal]

Introduction

It has been known for many years that furanose sugars adopt conformations in which the five-membered ring is puckered. In 1947, an X-ray study by Beevers and Cochran (1) demonstrated that the D-fructofuranose residue in sucrose sodium bromide dihydrate has an envelope conformation in which C-4′ is displaced above the plane of the other four ring atoms. With developments in nucleic acid chemistry, extensive studies have been carried out on the solid state conformations of the ribo- and deoxyribofuranose moieties in these polymers and related nucleotides and nucleosides. Generally, either C-2′ or C-3′ of these compounds is displaced out of the plane of the furanose ring by 0.5–0.6Å, and a puckering angle in the vicinity of 35° is commonly observed (2, 3).

The conformations of diastereomeric furanoses and derivatives in solution are expected (4–8) to differ from each other in ways that reflect minimal non-bonded interactions between the ring substituents. However, for a given diastereomer (8, 9) there may be several pseudorotating envelope and twist conformations (10). Much of the evidence dealing with conformational isomerism in solution comes from the measurement of ^1H–^1H coupling constants (9, 11–17). For example, a small coupling constant (0–1 Hz) for vicinal *trans* protons is taken to indicate that the corresponding torsional angle is close to 90°, rather than 120°, whereas a large value of ^3J (~5 Hz) implies that the angle is closer to 180° than to 120°. However, less information is available as to the sense in which direction the ring is puckered from coupling data for vicinal *cis* protons, and the contributions to ^3J of factors other than torsional angle are difficult to assess. Hence many of the results available are tentative in nature.

In this study, we introduce an alternate criterion of furanose conformation, namely the stereochemical dependence of two-bond and three-bond ^{13}C–^1H coupling constants. Another aspect of the study con-

[1]Present address: Alberta Research Council, Edmonton, Alta.

0008-4042/79/182504-08$01.00/0

cerns the specific question of conformational isomerism in aqueous solution. That is, various methyl aldohexofuranosides and pentofuranosides in D_2O solution are dealt with here, whereas most of the earlier literature describes the characteristics of ester derivatives in organic solvents. We have also measured $^3J_{H,H}$ values for many of the glycosides which, in general, are shown to reinforce the conclusions based on the ^{13}C–^1H coupling data obtained.

Results and Discussion

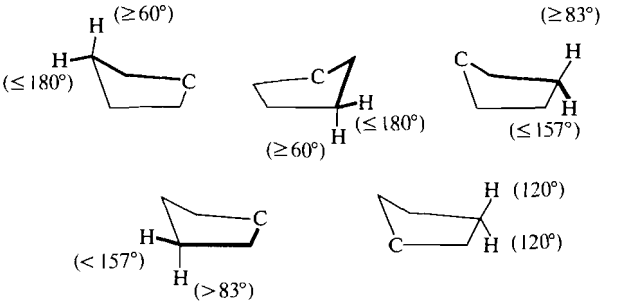
^{13}C–^1H Coupling Constants, and the Conformational Analysis of Furanosides

From the data available on saturated systems, the ^1H-coupled ^{13}C spectrum of an aldofuranoside is expected to exhibit spin–spin splitting due to coupling across one, two, or three bonds (^1J, ^2J, ^3J) but not four or more bonds. All of these couplings are stereochemically dependent (20, 21). Hence, in order to study the ring conformation, carbons-1 and -2 are of primary interest because the multiplicities of their signals are affected only by protons of the ring, whereas carbons-3 and -4 can couple with exocyclic protons (e.g., H-5) and thereby introduce the additional problem of side-chain conformations. Generally, therefore, only the C-1 and C-2 portions of ^{13}C spectra are described here. Since C-1 resonates far downfield of the other carbons (18, 19), its signal always can be examined readily, although the C-2 signal of most of the compounds examined (19) also proved to be adequately well separated from the others. It is noteworthy, as will be seen below, that many of the C-1 and C-2 signals have the appearance of simple multiplets. Aside from this indication that the contributing couplings involved are often of the same magnitude, another simplifying factor is likely to be the low limit of resolution obtainable over the many hours of accumulation time required.

Three-bond Coupling, ^3J

The relationship between $^3J_{CH}$ and torsional (dihedral) angle is expressed by a Karplus type curve (18, 20–23). However, only vicinal coupling >2–2.5 Hz is directly observable in ^1H-coupled ^{13}C spectra of carbohydrate derivatives (20, 24, 25), although it may be detected as line broadening. According to the data for $^3J_{CCCH}$ or $^3J_{COCH}$ available from studies on carbohydrates (20–22, 26–28), this means that the signal multiplicities due to ^3J reported here must arise from torsional angle relationships >120° associated with puckering of the furanose ring.

Considering envelope forms (for simplicity, a twist form may be regarded as a combination of two envelope forms) several different dihedral angles may be envisaged between ^{13}C—C (or ^{13}C—O) and



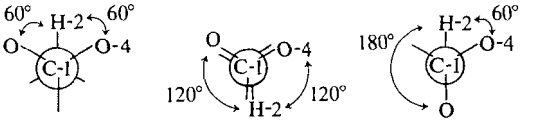
SCHEME 1. Dihedral angles between ^{13}C—C and C—^1H bonds in envelope conformations of furanosides. Heavy lines denote pathways expected to give rise to clearly observable values (~4–5 Hz) of $^3J_{CH}$.

C—^1H bonds under varying circumstances, as shown in Scheme 1. The maxima and minima listed are for extreme puckering of the ring (29), so that if the puckering is less pronounced the real angle would be be between 120° and the value given. Hence, only coupling pathways having the geometries represented by the heavy lines (Scheme 1) should be associated with an observable splitting (~4–5 Hz) of the C-1 or C-2 signal, due to interaction with H-3 and (or) H-4.

Two-bond Coupling, ^2J

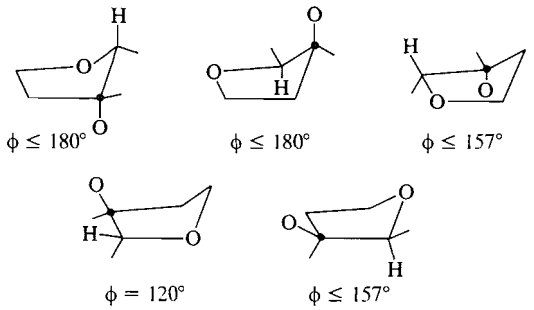
Coupling between ^{13}C and ^1H nuclei separated by two bonds also is stereochemically dependent (20, 21, 25, 30, 31). Three categories of ^2J involving C-1 and C-2 nuclei have been recognized (21, 30, 31), according to the number and disposition of proximal oxygen atoms.

(*a*) *C-1,H-2*—Coupling between C-1 and H-2 is observed (~4–5 Hz) when the torsional angle between the two anomeric C—O bonds and the C-2—H-2 bond are similar (as in **1** and **2**) but not, as in **3**, when the angles are very different. According to molecular models, the arrangement of nuclei in **1** can be attained only in a 1,2-*trans* anomer, through extreme puckering; for the arrangement in **2**, eclipsing in a 1,2-*cis* anomer is required.



1 **2** **3**

(*b*) *C-2,H-1*—Coupling between C-2 and H-1 may be as large as 8 Hz when the dihedral angle between the C-2—O-2 and C-1—H-1 bonds is close to 180°C, and decreases with decreasing angle size to a value of ~0 Hz at 60°. On this basis, there should be observable coupling for arrangements of nuclei illustrated in Scheme 2, which are confined to 1,2-*cis* isomers.



SCHEME 2. Orientations of C-1,^{1}H-1 and ^{13}C-2,O-2 bonds expected to give rise to clearly observable values (4–5 Hz) of $^2J_{CH}$ between ^{13}C-2 and ^{1}H-1 in furanosides.

(*c*) *C-2,H-3*—A coupling of ~5 Hz between C-2 and H-3 has been demonstrated when the angle between the ^{13}C-2—O-2 and C-3—^{1}H-3 bond is 60°, whereas ^2J is ~0 Hz when the angle is ≥ 120°. Therefore, if coupling between C-2 and H-3 is observed in a furanoside, O-2 and O-3 of that isomer must be close to *trans,gauche*.

Analyses of the ^{1}H-coupled Spectra of ^{13}C-1 and ^{13}C-2

Because $^1J_{CH}$ is large, each signal consists of two roughly equivalent segments separated by 150–175 Hz (24, 25). In a number of instances, only one of these segments could be examined because the second was obscured by overlap with other signals. Estimates of ^3J and ^2J were made from the spacings observed. Although some of these values could differ appreciably from the true J values, owing to second order effects (32), the discrepancies are assumed to be sufficiently small (32) so as not to invalidate the general conclusions reached. Furthermore, many of the spectra have been simplified, and the source of coupling confirmed, by the use of regioselectively deuterated glycosides.

Signal analyses for four methyl aldohexofuranosides are described below, as representative examples. The pentosides gave C-1 and C-2 signals closely resembling those of their six-carbon homologs, with one exception: the C-1 signal of methyl α-D-xylofuranoside was distinctly different from that of methyl α-D-glucofuranoside, and hence it is dealt with separately as a fifth example.

Methyl α-D-*Glucofuranoside (**4**)*

C-1 signal: (*a*) quintet, indicating coupling with one proton in addition to the three methyl protons; (*b*) a closely similar quintet was produced by the 4-deutero analog of **4**; (*c*) the 3-deutero analog of **4** produced a quartet. Therefore, C-1 couples with H-3; observed spacing, 4.5 Hz.

C-2 signal: (*a*) a triplet; (*b*) a closely similar triplet was produced by the 4-deutero analog of **4**; (*c*) the 3-deutero analog of **4** produced a doublet. Therefore, C-2 couples with H-2 and H-3; observed spacings, 4.0 Hz each.

Methyl α-D-*Mannofuranoside (**8**)*

C-1 signal: (*a*) broad septet, indicating coupling with two protons in addition to the methyl protons; confirmed by selective decoupling of latter protons, whereupon the signal became a triplet (centre peak broader than outside peaks); (*b*) quintet observed on selective decoupling of H-3; (*c*) quintet observed on selective decoupling of H-2 *plus* H-4 (overlapping signals); (*d*) selective decoupling, using the 3,5,6,6′-tetradeutero analog of **8** (33) showed that H-1 is coupled to C-4; in such circumstances, according to molecular models, there should not simultaneously be an observable coupling between C-1 and H-4.

Therefore, C-1 couples with H-2 and H-3; observed spacings, ~3 Hz and ~5 Hz, respectively.

C-2 signal: sharp singlet.

Therefore, C-2 does not couple with H-1, -3, or -4.

Methyl β-D-*Galactofuranoside (**11**)*

C-1 signal: quartet.

Therefore, C-1 does not couple with H-2, -3, or -4.

C-2 signal: doublet; according to Scheme 2, since O-2 and O-3 are *trans*, H-3 is suitably positioned for coupling (i.e., analogous to the *gluco* isomers).

Therefore, C-2 couples with H-3; observed spacing, 4.0 Hz.

Methyl α-D-*Allofuranoside (**6**)*

C-1 signal: (*a*) quintet, indicating coupling with one proton in addition to the methyl protons; (*b*) a closely similar quintet was produced by the 4-deutero analog; (*c*) the 3-deutero analog of **6** produced a quartet. Therefore, C-1 couples with H-3; observed spacing, 4.5 Hz.

C-2 signal: overlap with C-5 signal; appears to be sharp singlet.

Therefore, C-2 (probably) does not couple with H-1, -3, or -4.

Methyl α-D-*Xylofuranoside (**12**)*

C-1 signal: (*a*) quartet, attributable to coupling with methyl protons; (*b*) singlet produced by methyl-d_3 glycoside.

Therefore C-1 does not couple with H-2, -3, or -4.

Data obtained for 15 methyl furanosides, including values of $^1J_{CH}$, are presented in Tables 1 and 2.

Conformational Analysis of Furanosides

In selecting conformational possibilities consistent with the ^{13}C–^{1}H couplings observed and the various coupling pathways outlined in Schemes 1 and 2, the following procedure was adopted. For each of the ^3J

TABLE 1. ^{13}C-^{1}H coupling constants (Hz)[a] of methyl aldohexofuranosides

TABLE 3. Conformations of methyl β-allofuranoside (7) compatible with observed values of ^{13}C–^{1}H coupling

	^{3}J (Hz)	Possible conformations
C-1,H-3	0	$^{1}\underline{E}$, E_2, ^{3}E, E_4, ^{0}E, E_0
C-1,H-4	4.5	$^{1}\underline{E}$, E_3, ^{4}E, E_0
C-2,H-4	0	$^{1}\underline{E}$, E_2, ^{3}E, E_4, ^{0}E, E_1

values involving C-1 and C-2 (i.e., due to coupling of C-1 with H-3 and (or) H-4, and coupling of C-2 with H-4) all possible conformations were examined, and those consistent with all of the ^{3}J values were judged to be feasible conformations. Two-bond coupling of C-1 with H-2 and C-2 with H-1 was then evaluated, in a number of instances, as a cross check.[2] An example of the procedure is given for methyl β-D-allofuranoside **7** in Table 3, which shows that only the ^{1}E conformer (C-1 is displaced upwards from the plane) is consistent with all of the observations. This conclusion also is compatible with the fact that neither C-1 nor C-2 of **7** exhibited two-bond coupling.

[2]Applied to methyl β-D-mannofuranoside, this form of analysis also served to identify H-3 as a source of coupling with H-1; details are presented as an addendum to the Experimental section.

Conformational possibilities deduced in this way for each of the furanosides are listed in the second column of Table 4. More than one choice is given for most compounds, although it is noteworthy that each grouping contains only immediate E neighbors in the pseudorotational itinerary defined for furanose rings (8, 9). Hence energy barriers within each chosen group should be sufficiently small to allow for ready conformational interconversions.

To narrow the choice of possibilities further, corresponding vicinal ^{1}H–^{1}H coupling constants have been evaluated. The latter values, obtained from 220 MHz ^{1}H spectra (with the aid of computer simulation), are collected in Table 4 together with the pertinent vicinal ^{1}H–^{1}H projected angles (29). When the observed values of $^{3}J_{HH}$ are inconsistent with a conformation listed, the latter is regarded as less of a possibility. For example, an E_2 or ^{3}E conformation for methyl α-D-mannofuranoside (**8**) is not in accord with the intermediate value of 3.0 Hz found for $J_{1,2}$ (Table 4), because these conformations are characterized by relatively large H-1, H-2 torsional angles corresponding (34) to ^{3}J values of >5 Hz. By contrast, an E_4 conformer would be more consistent with all of the data for **9**. A similar process of selection leads to the conclusion that an E_4 conformation is not an important contributor to the pseudorota-

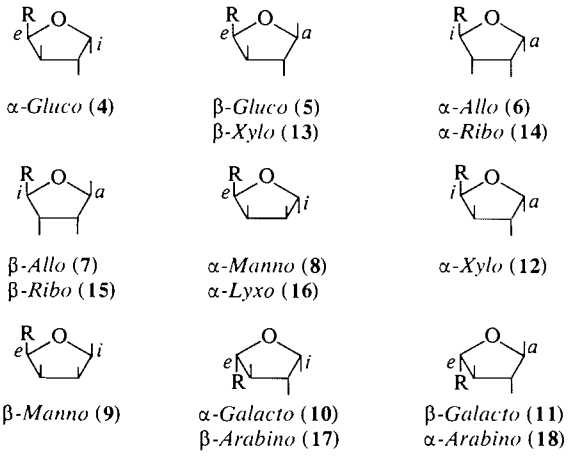
[b]These and other bracketed values are for peracetates.

tional itinerary of methyl β-D-glucofuranoside (**5**), and that this isomer is represented by interconverting E_2 and ^3E conformations.

An overall evaluation of our findings is presented in Scheme 3 in terms of the orientation of ring substituents in each of the furanosides. Two features are particularly prominent, i.e., very frequently the C-1—O-1 bond favours a *quasi* axial orientation, and the exocyclic C-4—C-5 bond a *quasi* equatorial orientation. Both of these features are consistent with well known stabilizing influences. The latter corresponds to the *quasi* equatorial preference of the methyl group of methylcyclopentane (4), and the former to operation of the anomeric effect (6–8, 35) which, in pyranoses, accounts for the stability of axial C-1—OR bonds. Noteworthy with respect to this general preference for a *quasi* axial orientation of the methoxyl function of the furanosides, is the fact (Table 1) that there is little variation in the magnitude of coupling between C-1 and H-1: all of the values are between 172 and 175 Hz. This is in contrast to the difference of ~10 Hz in $^1J_{C\text{-}1-H\text{-}1}$ that characterizes an axial, equatorial anomeric pair of pyranoses (20, 21, 36), and hence supports the conclusion above that the C-1 substituents of furanosides *tend* to be oriented in the same (axial) manner.

The process of ruling out certain conformational possibilities on the basis of the ^1H–^1H coupling data



SCHEME 3. Orientations favored by ring substituents in methyl D-aldohexo- and pentofuranosides; **17** and **18** are L-enantiomers. For hexosides **4–11**, R = $CHOHCH_2OH$; for pentosides **12–18**, R = CH_2OH. Axial (*a*), equatorial (*e*), isoclinal (*i*).

helped materially in arriving at an overall consistency. For example, an α-*gluco* E_4 conformation appears preferable to an E_2 because it would incorporate an equatorial C-5, whereas O-1 would be equatorial in the E_2 conformation. However, an E_2 conformation is a more attractive possibility for the β-glucoside because this would be more compatible with the anomeric effect.

Hexofuranoside vs. Pentofuranoside

In almost all instances, the coupling patterns exhibited by C-1 and C-2 of the 6- and 5-carbon homologs are closely similar. This is true also of their vicinal ^1H–^1H coupling characteristics. Therefore, it is valid to assume that the ring conformation of a pentoside is essentially the same as that of the configurationally-related hexoside. The α-*gluco* (**4**) and α-*xylo* (**12**) pair provide an exception to this consistent picture; whereas C-1 of the former shows coupling with H-3 the analogous interaction is not observed for the xyloside, and the ^1H spectra of the two differ strikingly also in the magnitude of $^3J_{2,3}$ and $^3J_{3,4}$. Consequently, these compounds have been depicted (Table 4 and Scheme 3) by geometries that are remote from each other in the conformational itinerary of the furanoside ring (8, 9), i.e., $E_4 \rightleftarrows {}^3E$ for **4** and ^2E for **12**. The latter is characterized by an axial O-1 substituent, and the former by an equatorial side chain.

By considering all 15 compounds, it is seen (Scheme 3) that 10 favor a conformation in which the exocyclic side chain is equatorial, and 9 compounds favour a conformation in which O-1 is axial, whereas the β-*galacto*,α-*arabino* and β-*gluco*,β-*xylo* pairs incorporate both features. Hence, neither of these stabilizing orientations is predominant in determining the conformations of furanosides. A related consideration is the fact that when C-5 and O-3 are *cis*, puckering of the ring so as to orient C-5 equatorially eliminates eclipsing at the 3,4-position; similarly, *cis*-1,2 substituents are staggered (*quasi a,e*) when O-1 is axial. The α-*gluco* and α-*xylo* pair is distinguished from the other pairs of hexo- and pentofuranosides in having *cis* arrangements of substituents at both the 1,2- and 4,5-positions. Either of the associated eclipsing arrangements may be alleviated by suitable puckering of the ring, but not both simultaneously. There is evidence (19) that the —$CHOHCH_2OH$ moiety of **4** introduces substantially greater steric crowding than does the —CH_2OH of **12**. That is, aldohexofuranosides in which C-5 and O-3 are *cis* exhibit notable C-5 and C-4 upfield shifts as compared with their pentose homologs. Conceivably, then, this difference is sufficient to favor an equatorial orientation and staggered 4,5-substituents in the α-glucoside whereas, on balance, the anomeric effect and concomitant staggering of the 1,2-substituents may be the overriding factor for the α-xyloside.

TABLE 5. A comparison of conformational choices proposed for aldopentofuranose derivatives in different studies

	Present study	Bishop and Cooper (5)	Stevens and Fletcher (15)	Hall and co-workers (9)
α-*Xylo*	^2E	$^2T_3$	$^2T_3$

β-*Arabino*	E_3, ^4E	E_2	$^1T_2$, E_2	
α-*Lyxo*	E_4	E_3	E_3	

The present findings may be compared with the results of ^1H nmr studies cited above. This is of interest particularly because the latter studies, in contrast to the current ones, have employed ester derivatives in organic media. The various data are compiled in Table 5; they deal only with aldopentofuranoses because hexose derivatives were not included in the earlier investigations. Also given in Table 5 are Bishop and Cooper's results of conformational analysis of methyl pentosides, based on thermodynamic data (5). All of the envelope (E) and twist (T) conformations represented in the Table appear within the following segment of the furanoid pseudorotational itinerary (8, 9); for simplicity, each T form is listed on the lower line between the two most closely related E forms:

$$\begin{array}{ccccccccccccccccccc} {}^4E & \rightleftarrows & E_0 & \rightleftarrows & {}^1E & \rightleftarrows & E_2 & \rightleftarrows & {}^3E & \rightleftarrows & E_4 & \rightleftarrows & {}^0E & \rightleftarrows & E_1 & \rightleftarrows & {}^2E & \rightleftarrows & E_3 \\ & & {}^4T_0 & & {}^1T_0 & & {}^1T_2 & & {}^3T_2 & & {}^3T_4 & & {}^0T_4 & & {}^0T_1 & & {}^2T_1 & & {}^2T_3 \end{array}$$

Since the various sets of data in Table 5 have all been obtained with different derivatives and (or) under different conditions, there is no reason a priori to expect general agreement as to the favored conformation associated with a given diastereomer. Nevertheless, a substantial number of consistencies are found. In four out of seven instances, the pentosides in water appear to adopt essentially the same conformations as do the corresponding ester derivatives examined by Stevens and Fletcher. Closely similar conclusions have been reached also for three out of the four diastereomers examined, as esterified glycosyl halides, by Hall and co-workers, and for four out of the seven evaluated by Bishop and Cooper. However, the degree of conformational variability for a given diastereomeric furanose is apparent from the fact that only the α-*ribo* species exhibits a consistent geometric preference throughout.

Experimental

Nuclear Magnetic Resonance Spectra

Proton-coupled ^{13}C spectra were recorded at 22.63 MHz with a Bruker WH-90 Ft spectrometer, using gated ^1H irradiation. The repetition time was ~2.5 s, the decouple time ~0.6 s, and the pulse width ~16 μs (~90°). Spectral widths of 1800–2400 Hz were used, giving a digital resolution of 0.5–0.6 Hz after Fourier transformation (4K real data points).

Proton nmr spectra were recorded at 220 MHz, by Dr. A. A. Grey of the Canadian 220 MHz NMR Centre.

Deuterium oxide was the solvent for unsubstituted compounds and $CDCl_3$ for their acetate derivatives, generally at concentrations of 0.2–0.4 g/mL.

Methyl Glycofuranosides

The preparation of these glycosides and monodeuterated analogs has been described earlier (19). Methyl-d_3 α-D-xylofuranoside was kindly furnished by Dr. J. E. Shin.

Assignment of ^{13}C–^1H Coupling in Methyl β-D-Mannofuranoside, and Conformational Analysis

The C-1 signal (downfield-half observed) was a quintet showing that, in addition to coupling with the methyl protons, C-1 couples (J = 4.5 Hz) with H-2, -3, or -4. These three possibilities (cases 1, 2, and 3) are associated in Table 6 with various envelope conformations of the glycoside. The additional fact that the C-2 signal (downfield-half observed) was a singlet, introduces two additional conditions to be satisfied. Complete correspondence is found only between the conformations in this latter group and those of case 1. Therefore, H-3 gives rise to the 4.5 Hz coupling with C-1 and, accordingly, the glycoside is expected to favor conformations E_2, ^3E, and (or) E_4, which are common to both sets.

Acknowledgments

Generous support by the Faculty of Graduate Studies and Research, McGill University, and by the National Research Council of Canada is gratefully acknowledged. The authors also express their thanks to Drs. R. G. S. Ritchie and J. E. Shin for valuable assistance, and to Dr. A. A. Grey for recording the 220 MHz ^1H spectra.

The normal and the retro-Boulton–Katritzky rearrangement of hydroxy- and nitro-substituted benzofuroxans

ERWIN BUNCEL, NOEMI CHUAQUI-OFFERMANNS, AND ALBERT R. NORRIS

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received April 16, 1979

ERWIN BUNCEL, NOEMI CHUAQUI-OFFERMANNS, and ALBERT R. NORRIS. Can. J. Chem. **57**, 2512 (1979).

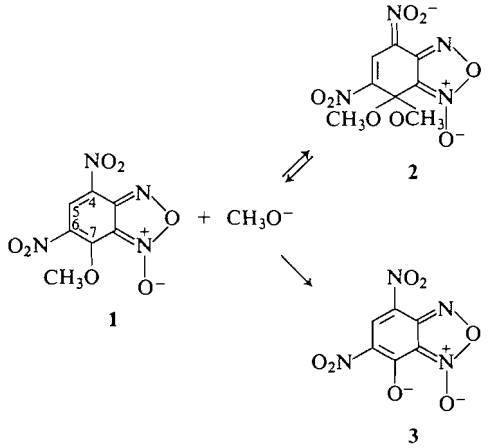
The demethylation of 7-methoxy-4-nitrobenzofuroxan by aqueous KOH gives rise to 7-hydroxy-4-nitrobenzofuroxan as well as 5-hydroxy-4-nitrobenzofuroxan, the latter being formed via a retro-Boulton–Katritzky rearrangement. The retro rearrangement also occurs on heating the potassium salt of 7-hydroxy-4-nitrobenzofuroxan in the solid state. In basic aqueous solution 5-hydroxy-4-nitrobenzofuroxan undergoes the normal Boulton–Katritzky rearrangement to yield 7-hydroxy-4-nitrobenzofuroxan. These processes are rationalized on the basis of a balance between electrostatic and steric interactions in the reactants and the products of rearrangement.

ERWIN BUNCEL, NOEMI CHUAQUI-OFFERMANNS et ALBERT R. NORRIS. Can. J. Chem. **57**, 2512 (1979).

La déméthylation du méthoxy-7 nitro-4 benzofuroxanne par le KOH aqueux conduit à l'hydroxy-7 nitro-4 benzofuroxanne aux côtés de l'hydroxy-5 nitro-4 benzofuroxanne; ce dernier composé se forme par une transposition retro-Boulton–Katritzky. La transposition rétro se produit aussi par chauffage du sel de potassium de l'hydroxy-7 nitro-4 benzofuroxanne à l'état solide. En solutions aqueuses basiques, l'hydroxy-5 nitro-4 benzofuroxanne subit la transposition normale de Boulton–Katritzky et conduit à l'hydroxy-7 nitro-4 benzofuroxanne. On rationalise ces processus en se basant sur un équilibre entre les interactions stériques et électrostatiques dans les réactifs et les produits de la transposition.

[Traduit par le journal]

During our study (1–3) of σ-complex formation and reactivity in the nitrobenzofuroxan series (see also refs. 4–7), we observed that the compound **1** reacts with methoxide ion in methanol solution by competitive attack at the aryl carbon to give the σ-complex **2**, and at the aliphatic carbon to give the displacement product **3**, Scheme 1 (1). In order to ascertain whether demethylation could also be effected in a less activated system, we have extended the study to the mononitro analog **4**. We have in fact identified conditions under which demethylation does occur readily with this compound. However, unexpectedly, we found that the demethylated product **7** undergoes a retro-Boulton–Katritzky rearrangement to yield **5**, while under other conditions **5** undergoes a normal Boulton–Katritzky rearrangement (8–14) to give **7**. The observations are unlike previous reports of the simultaneous occurrence of the normal and retro-Boulton–Katritzky rearrangement processes.

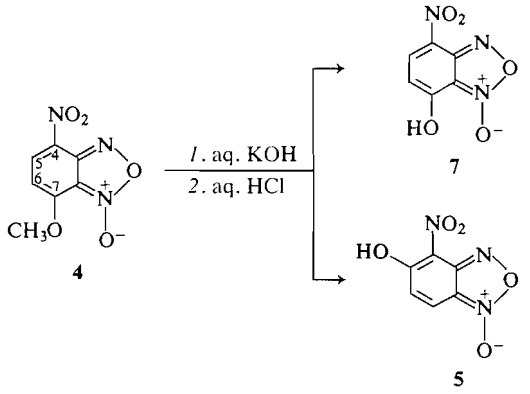


SCHEME 1

Results and Discussion

7-Methoxy-4-nitrobenzofuroxan (**4**) on heating at 55°C with aqueous KOH for 45 min, followed by acidification to pH 1, yielded a suspension consisting of a red solid and an orange colored solution. The separated red solid, after treatment with chloroform to remove traces of orange material, was recrystallized from water to yield a red crystalline material which was shown to be the potassium salt of 7-hydroxy-4-nitrobenzofuroxan (**7**). The orange filtrate was further acidified, extracted with chloroform, and worked up to yield a yellow solid shown to be 5-hydroxy-4-nitrobenzofuroxan (**5**). The following evidence was obtained as structure proof for the reaction scheme given in

0008-4042/79/182512-04$01.00/0



SCHEME 2

Scheme 2 (details of analytical data, etc. are given in the Experimental).

7-Hydroxy-4-nitrobenzofuroxan (7) and its Potassium Salt (7-K)

The red solid obtained as above exhibited in the nmr spectrum (Table 1) in DMSO-d_6 resonances (δ ppm), H_A 8.10 (d), H_B 5.60 (d), J_{AB} 10 Hz, assignable respectively to the protons adjacent to the NO_2 and O^- functions of **7**-K. For a series of 7-substituted 4-nitrobenzofuroxans the differences in the chemical shifts between the A and B protons, Δ_{AB}, has been found to range between 1.5 and 2.0 ppm (10). In the present system, the larger difference of 2.5 ppm is attributed to the greater shielding effect of the O^- function compared to the uncharged substituents examined in previous work (10). Acidification of the solution of the potassium salt in DMSO-d_6 with CF_3CO_2D led to a shift in the resonances, that is H_A 8.47 (d), H_B 6.52 (d), J_{AB} 9 Hz. The Δ_{AB} value of 1.95 ppm is now quite comparable to that (1.77 ppm) observed in **4** and related compounds and is in accord with the acid conversion of **7**-K to **7**. On treatment of the solution of the potassium salt in DMSO-d_6 with methyl iodide and monitoring by nmr, the characteristic spectrum of 7-methoxy-4-nitrobenzofuroxan (**4**) gradually evolved, that is H_A 8.61 (d), H_B 6.84 (d), J_{AB} 9 Hz, CH_3O 4.13 (s), thus providing definitive proof of structure.

5-Hydroxy-4-nitrobenzofuroxan (5)

The nmr spectral characteristics of the yellow solid in DMSO-d_6/CF_3COOD are given in Table 1. The assignment of the 7.88 resonance to H-7 and of the 7.24 resonance to H-6 of **5** is in accord with results in the literature for a number of 5-substituted 4-nitrobenzofuroxans (10). The difference in chemical shifts for the A and B protons, Δ_{AB} 0.64 ppm, compares with corresponding literature values of 0.3–0.8 ppm (10) reported for similar compounds. The reduced Δ_{AB} value in **5** compared with **7** can be accounted for by the weaker deshielding effect of the N(O) function relative to NO_2. The ir spectrum of **5** (KBr) presents the characteristic stretching absorption for intramolecular hydrogen-bonded hydroxyl at 3400–3600 cm^{-1}.

The Rearrangement Processes

The most plausible and consistent explanation of our experimental findings is that demethylation of **4** occurs by direct nucleophilic displacement to yield **7**, which then undergoes a retro-Boulton–Katritzky rearrangement to yield **5**. The possibility that a prior rearrangement of **4** had occurred to yield 5-methoxy-4-nitrobenzofuroxan can be discounted by the work of Ghosh (10), who showed that this compound readily undergoes the normal Katritzky–Boulton rearrangement at ambient temperature.

Interestingly, Ghosh observed (10) that 7-anilino-4-nitrobenzofuroxan (**6**) on heating above 150°C in the dry state changed, without melting, into the isomeric 5-anilino-4-nitrobenzofuroxan (**8**) (eq. [1]).

[1] 
The compound **6** provided the only case of the retro-Boulton–Katritzky rearrangement in the course of examination of about a dozen 7-substituted 4-nitrobenzofuroxan derivatives. Ghosh suggested that the likelihood of a stronger NH···O_2N hydrogen bond in **8** compared with **6** (NH···ON distance 1.9 Å in **8** versus 2.3 Å in **6**) would compensate for the increased steric interactions in **8** compared with **6**. In accord with this explanation, the normal Boulton–Katritzky rearrangement (**8** → **6**) was found to occur in DMSO, which can act as a hydrogen bond acceptor (15, 16), but not in protic solvents (10).

In view of these proposals and the dearth of information concerning the factors which promote the retro-Boulton–Katritzky rearrangement (10), as well as current interest in the limits of the normal Boulton–Katritzky rearrangement (14), we decided to investigate further the interconversion of **5** and **7**.

When the solid potassium salt **7**-K was heated at 50°C under *vacuo* for 24 h, a color change from red to deep orange was observed. The uv–visible absorption spectrum of the resulting material was identical to that of the oxyanion of **5** (i.e., **5**-K), indicating the occurrence of the retro-Boulton–Katritzky rearrange-

TABLE 1. Nuclear magnetic resonance spectral characteristics of the hydroxy- and nitro-substituted benzofuroxans and their anions

Compound	H_A δ (ppm)	H_B δ (ppm)	Δ_{AB} δ (ppm)	J_{AB} (Hz)	Solvent
7-K 	8.10	5.60	2.50	10.0	DMSO-d_6
7[a] 	8.47	6.52	1.95	9.0	DMSO-d_6/CF_3CO_2D (80/20 v/v)
5-K[b] 	7.25	6.46	0.79	9.6	DMSO-d_6
5 	7.88	7.24	0.64	9.7	DMSO-d_6/CF_3COOD (80/20 v/v)

[a]Spectrum recorded following acidification of solution of 7-K in DMSO-d_6.
[b]Spectrum of material obtained from retro-Boulton–Katritzky rearrangement of 7-K (see text). A pure sample of 5-K, dissolved in DMSO-d_6 at room temperature, rapidly yields an equilibrium mixture of 5-K and 7-K in which 7-K is present in approximately 10-fold excess over 5-K.

[2] 7-K 5-K

ment (eq. [2]). The nmr data for **5**-K are included in Table 1 and are in accord with the structural formulation of the rearranged material. It is noteworthy that this rearrangement could be brought about ~100° below the temperature required in the case of the transformation **6** → **8** (10).

As a contrasting experiment, it was of interest to examine the behaviour of the rearrangement product in aqueous solution. Thus a solution of **5** in a buffer of pH 10.3 was found to undergo the spectral changes which are illustrated in Fig. 1. These changes are characteristic of the conversion **5** → **7** (i.e., **5**-K → **7**-K, at pH 10.3) and indicate that a normal Boulton–Katritzky rearrangement is occurring. It is recalled that the anilino compound **8** showed no spectral changes in solutions of protic solvents (10).

The experiments described above show that we are dealing here with a reversible system, **7**-K ⇄ **5**-K, representing a retro- and a normal Boulton–

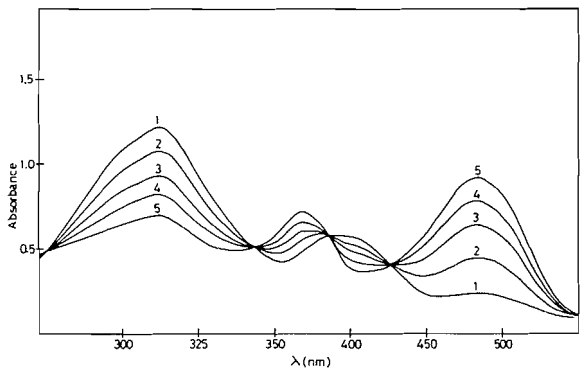

FIG. 1. Spectral scans of a solution of 5-hydroxy-4-nitrobenzofuroxan (7.14×10^{-5} *M*) at pH 10.3, 25°C, showing the transformation to 7-hydroxy-4-nitrobenzofuroxan. Scan times: (*1*) 1 min; (*2*) 30 min; (*3*) 75 min; (*4*) 135 min; (*5*) 16 h.

Katritzky rearrangement in the forward and reverse directions, respectively. Our present results can be explained by invoking electrostatic interactions as having a major influence on the type of process which occurs. In the solid state, the increased electrostatic attraction between K^+ and the two oxygen atoms in **5**-K, compared with the situation in **7**-K, will tend to overcome the unfavorable steric interactions in the former, so that the retro-Boulton–Katritzky rearrangement, **7**-K → **5**-K, is favored. In aqueous solution the free oxy anion will no longer be

TABLE 2. Ultraviolet–visible absorption spectral characteristics of hydroxy-nitrosubstituted benzofuroxans and their anions

Species	Medium	λ_{max} (ε), nm (L mol^{-1} cm^{-1})		
7	8*M* HCl	435 (7 370)	320 (5 630)	300 sh (5 600)
7-K	pH 10.3	484 (11 700)	371 (8 300)	312 (8 100)
5	7*M* HCl	402 (7 300)	320 (7 200)	277 (5 950)
5-K	pH 10.3	394 (6 720)	—	312 (15 500)

subject to influence from the potassium counterion, thus allowing the normal Boulton–Katritzky rearrangement, **5**-K → **7**-K, to occur. This explanation of the importance of electrostatic interactions is similar in principle to that invoked by Ghosh (10), even though in that system the normal Boulton–Katritzky rearrangement was not observed in aqueous solution, unlike the present case. We intend to study the kinetics of the rearrangement processes in these systems in order to shed more light on the normal as well as the retro-Boulton–Katritzky rearrangement.

Experimental

7-Methoxy-4-nitrobenzofuroxan (0.5 g, 2.4 mmol), prepared as described previously (3), was heated with 31 mL of 0.1 *N* KOH (3.2 mmol) at 55°C for 45 min. Cooling to 0°C, acidification with 1 *N* HCl to pH 1, and filtration yielded a red precipitate and an orange colored filtrate. The filtrate was further acidified with concentrated HCl, extracted with chloroform, the solvent evaporated, and the solid recrystallized from chloroform to yield **5** as yellow crystals, mp 170–172°C (dec.), *m/e* 197. *Anal.* calcd. for $C_6H_3N_3O_5$: C 36.57, H 1.53, N 21.32; found: C 36.56, H 1.51, N 21.17. The nmr data (Bruker 60 MHz HFX-60, with tetramethylsilane as internal standard) are given in Table 1.

The red solid obtained above was agitated with chloroform, to remove residual **5** as well as any unreacted **4**, and recrystallized from water to yield the potassium salt of **7**, i.e., **7**-K, as red crystals of the monohydrate, mp 275–277°C (dec.). *Anal.* calcd. for $C_6H_2N_3O_5K \cdot H_2O$: C 28.46, H 1.59, N 16.60, K 15.44; found: C 28.96, H 1.74, N 16.32, K 13.17.

For the methylation of **7**-K the red solid (0.066 mmol) was placed in an nmr tube, dissolved in 0.4 mL DMSO-d_6, treated with methyl iodide (0.12 mmol), and the nmr spectrum monitored with time. After 6 days at room temperature the characteristic resonances of **4** appeared (3) and a precipitate of potassium iodide was formed.

The uv–visible absorption spectra of **5** and **7** were obtained for the neutral and anionic forms. The spectral characteristics are given in Table 2. The *n*-butylamine/HCl buffer solution used in the experiment shown in Fig. 1 was prepared according to procedures outlined in ref. 17.

Subtilisin Carlsberg, a chiral catalyst: an organic co-solvent

JOHN F. BECK AND JOHN F. MCMULLAN

Department of Chemistry, St. Francis Xavier University, Antigonish, N.S., Canada B2G 1C0

Received May 22, 1979

JOHN F. BECK and JOHN F. MCMULLAN. Can. J. Chem. 57, 2516 (1979).

The kinetics of subtilisin Carlsberg catalyzed hydrolyses of typical substrates in the presence of isopropanol indicate that this secondary alcohol could serve as a suitable organic co-solvent in synthetic applications of this enzyme.

JOHN F. BECK et JOHN F. MCMULLAN. Can. J. Chem. 57, 2516 (1979).

La cinétique d'hydrolyse de substances typiques catalysées par la subtilisine Carlsberg en présence d'alcool isopropylique indique que cet alcool secondaire peut servir de co-solvant organique idéal lorsque cet enzyme est utilisé en synthèse.

[Traduit par le journal]

The use of an enzyme as an asymmetric catalyst in an organic reaction sequence is contingent on the predictability of that enzyme acting on a foreign substrate, under conditions required to solubilize the substrate in the aqueous medium of the enzyme. Data providing this predictability are currently available for only a few enzymes, notably some mammalian hydrolases and various alcohol dehydrogenases (1, 2). The bacterial serine hydrolases, the subtilisins, possess a constitutional specificity which is potentially broader than all of the mammalian serine hydrolases (1), and have displayed a greater organic solvent stability while retaining a high degree of stereospecificity (3, 4). Because its reaction rates are higher than the other subtilisins (4, 5) we chose to investigate subtilisin Carlsberg as a potential organic reagent. We found that although data have begun to accumulate as to its action on foreign substrates (4–9), the organic co-solvents employed in these studies were either DMSO, dioxane, or primary alcohols. These are effective inhibitors of the enzyme (6, 10) and in the case of the alcohols, transesterification has also been shown to occur (4). Isopropanol being a secondary alcohol does not lead to transesterification due to steric factors and has, in fact, been reported to enhance the activity of the enzyme (4). Moreover, it has good solubilizing characteristics and can be easily purified and easily separated from the reaction products (compare DMSO).

The reaction kinetics of the subtilisin Carlsberg mediated hydrolyses of *N*-acetyl-L-tyrosine ethyl ester (NATEE) and of α-*N*-benzoyl-L-arginine ethyl ester (BAEE) were determined employing pH-stat methods (6) at pH 8 and 25°C. All reaction solutions were 0.1 *M* with respect to KCl and 0.02 *M* or 0.04 *M* NaOH solutions were used as titrants. Enzyme concentrations of about 1.8×10^{-8} *M* and 3.6×10^{-8} *M* were used for NATEE and BAEE respectively, while the substrate concentrations varied from 5.0×10^{-4} *M* to 9×10^{-3} *M*. Four isopropanol concentrations (1%–20% v/v) were compared to the essentially alcohol free conditions. The Michaelis–Menten constants were obtained using Lineweaver–Burke and least-squares regression analyses. All experiments were duplicated.

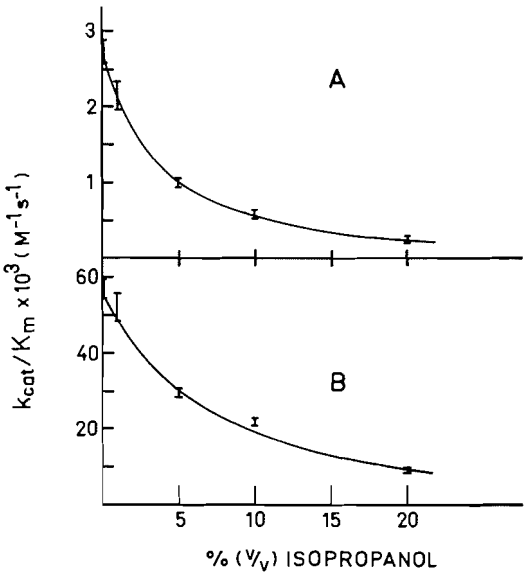

FIG. 1. k_{cat}/K_M (m^{-1} s^{-1}) versus isopropanol concentration (% v/v), pH 8, 25°C, 0.1 *M* KCl; (*A*) BAEE, (*B*) NATEE.

The results, presented in Fig. 1, indicate that the susceptibility (1) of both the NATEE and the BAEE

0008-4042/79/182516-02$01.00/0

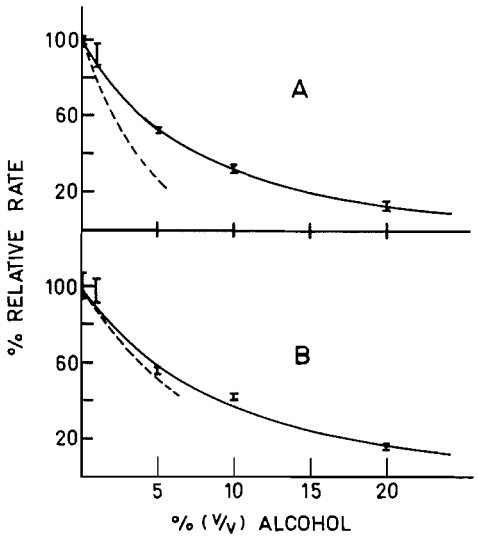

FIG. 2. % Relative rate versus alcohol concentration (% v/v) at a substrate concentration of 2.5×10^{-3} *M*, pH 8, 25°C, 0.1 *M* KCl. (*A*) BAEE with isopropanol (—); *p*-tosyl-argine methyl ester with methanol or ethanol (---) (10), (*B*) NATEE with isopropanol (—), with methanol or ethanol (---) (10).

to enzyme catalysis decreases as the isopropanol concentration increases. The effect over the range studied is greater for the more polar BAEE (ca. 11-fold decrease) compared to the less polar NATEE (ca. 6.4-fold decrease). This is due largely to a greater increase in K_M for BAEE (2.7-fold) than for NATEE (1.2-fold) and compares favourably with previous reports (10, 11) which conclude that the substrate binding forces in subtilisin Carlsberg are primarily hydrophobic in nature. As the alcohol concentration rises the solvation of these hydrophobic substrate binding sites (12) by the isopropanol stabilizes the enzyme, hindering substrate interactions (13). The NATEE competes more effectively with the isopropanol than does the BAEE, hence the above results.

The only published compilation (10) of solvent effects on subtilisin Carlsberg activity employing conditions similar to those used here is limited to reporting the relative rates versus solvent concentration. The primary alcohols are the least inhibitory solvents (10) and in order to compare the effects of isopropanol the reaction rates at a substrate concentration of 2.5×10^{-3} *M*, taken as a percent of the aqueous medium rates, were plotted versus alcohol concentration (Fig. 2). As is evident for NATEE, the isopropanol effects the catalysis somewhat less than the methanol or ethanol, which are the least inhibitory of the primary alcohols (10). In the case of the arginine derivatives the effects are more dramatic but it must be borne in mind that the interaction of the *p*-tosyl-arginine methyl ester will differ from that of the BAEE at the amide binding region (14) of the enzyme. This binding dissimilarity will account (1) for some of the observed difference in the rate profiles. Nevertheless, the more polar substrate displays a relative rate profile very similar to that of the less polar one, which is not the case for subtilisin Carlsberg inhibited by primary alcohols (10).

It would thus appear that the use of isopropanol with subtilisin Carlsberg offers the advantages of an organic co-solvent which is less inhibitory than the primary alcohols, but will not lead to transesterification (4) and is somewhat of a better solvent than ethanol or methanol.[1]

Variable-temperature Raman spectroscopy as a probe of the supermolecular structure of ionomers

A. NEPPEL, I. S. BUTLER, AND A. EISENBERG
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received May 24, 1979

A. NEPPEL, I. S. BUTLER, and A. EISENBERG. Can. J. Chem. 57, 2518 (1979).

Raman spectroscopy has been used for the first time to show the presence of multiplets and clusters of ion pairs in ethyl acrylate – sodium acrylate and styrene – sodium methacrylate ionomers and to determine the relative concentrations of ion pairs in these two different kinds of sites.

A. NEPPEL, I. S. BUTLER et A. EISENBERG. Can. J. Chem. 57, 2518 (1979).

La spectroscopie Raman a été utilisée pour la première fois dans le but de montrer d'une part, la présence de multiplets et des groupes de paires d'ions dans les ionomères suivants; acrylate d'éthyle – acrylate de sodium, et styrène – méthacrylate de sodium, et pour déterminer d'autre part la concentration relative des paires d'ions dans ces deux différentes sortes de sites.
[Traduit par le journal]

The state of aggregation of the ions in ion-containing polymers such as the copolymers of acrylic and methacrylic acid salts with ethylene, butadiene, and styrene is known to have a strong influence of the mechanical and rheological properties of the polymers (1, 2). Ion pairs are thought to be formed between the ionic sites on the polymer chains and the metal ions, and these ion pairs are further believed to conglomerate into groups of a few ion pairs called *multiplets* and into somewhat larger entities called *clusters* (3). Evidence for multiplet and cluster formation in styrene-based ionomers has come from such measurements as small angle X-ray scattering (4), water saturation experiments (5), dynamic mechanical (4) and dielectric loss studies (6), and far-infrared spectroscopy (7). We report here the first use of Raman spectroscopy to show the presence of multiplets and clusters in ionomers and, more importantly, how Raman intensity data can be used to determine the relative concentrations of ion pairs in the two different kinds of sites. This latter information is of importance in the designed synthesis of ionomers with specific properties and is not readily available by any other method.

The Raman spectra of powdered samples of ethyl acrylate – sodium acrylate and styrene – sodium methacrylate ionomers containing various mol% of ionic component have been investigated in the 22–250°C temperature range. Both series of ionomers exhibit characteristic weak Raman bands at ~ 250 and $\sim 170\ cm^{-1}$ which are not present in the spectra of the homopolymers and which, on the basis of previous far-infrared work on the styrene samples (7), can be assigned to multiplets and clusters of ion pairs, respectively. Unlike the infrared bands where it was impossible to measure their intensities because of strong overlapping with bands due to the polymer backbones, the intensities of the Raman bands could be readily determined. These intensities were obtained by measuring the areas of the two peaks and then correcting these areas for instrument response by comparison to suitable reference peaks of the host polymer. The Raman measurements were made on a Jarrell-Ash 25-300 spectrometer using 488.0 nm Ar^+ laser excitation (~ 85 mW at the samples) and the intensities of the bands at ~ 250 and $\sim 170\ cm^{-1}$ were determined for all the samples at 22, 150, 200, and 250°C.

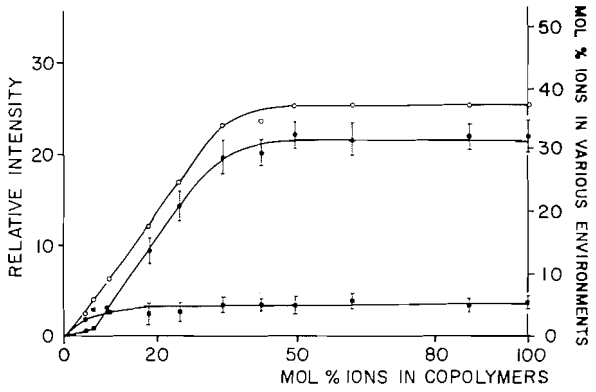

FIG. 1. Plots of the relative Raman intensities of the multiplet (■) and cluster (●) bands, and their sum (○), in the series of ethyl acrylate – sodium acrylate copolymers investigated at 22°C vs. mol% sodium acrylate.

In the case of the ethyl acrylate – sodium acrylate copolymers, at all four temperatures, the intensities of the multiplet and cluster Raman bands increase steadily with increasing sodium acrylate content up

0008-4042/79/182518-02$01.00/0

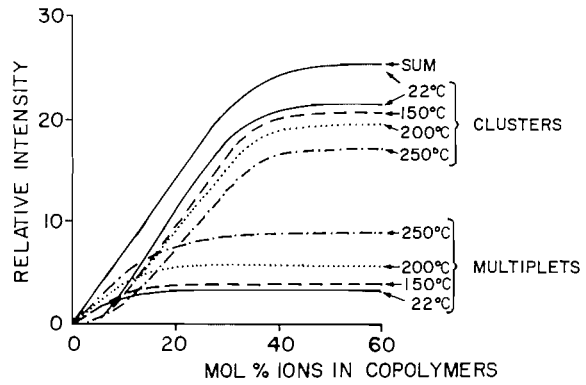

FIG. 2. Plots of the relative Raman intensities of the multiplet and cluster bands in the ethyl acrylate – sodium acrylate copolymers at four different temperatures vs. mol% sodium acrylate. Since their sum is essentially the same at all four temperatures, only that at 22°C is shown. The graphs follow the same monotonous trends from 60 to 100 mol% ions in the copolymers.

to about 10 and 35 mol%, respectively (Fig. 1). With increasing temperature, the multiplet band intensity increases while the cluster band intensity decreases for the complete composition range investigated (Fig. 2). This behaviour is in qualitative accord with earlier theoretical predictions (3) but has not been verified experimentally before the present study. The quantitative relations between the peak areas and the ion contents assumed in the above analysis can be deduced from the following considerations. As is seen in Fig. 1, the sum of the relative intensities of the multiplet and cluster bands between 0 and ~30 mol% gives an excellent linear correlation ($\bar{r}$ = 0.992) with the total ion content. This suggests that all the ions are accounted for by this technique. Furthermore, since in Raman spectroscopy the band intensities are directly proportional to the ion contents, and since the sums correlate so well with the total ion content, the individual band intensities are expected to show the same relation.

Throughout the temperature range investigated, the intensities of the multiplet and cluster Raman bands in the styrene – sodium methacrylate ionomers are essentially invariant to changes in temperature. Moreover, the intensity data reveal that at comparable total ion contents at room temperature the total number of ion pairs in multiplets is greater in the ethyl acrylate ionomers than in the styrene ones. For the ethyl acrylate ionomers, the multiplet saturation limit is reached at ~5 mol% of ionic groups, while for the styrene ionomers this limit is reached at ~2 mol%. Clearly, the multiplet solubility limit is a function of the host polymer and is most probably a direct consequence of the dielectric constant of the polymer backbone (poly(ethyl acrylate): ε = ~4.0; polystyrene: ε = ~2.5 (8)).

The sum of the relative intensities of the multiplet and cluster bands in the ethyl acrylate – sodium acrylate ionomers remains essentially constant above about 35–40 mol% of ionic groups. This suggests that at this approximate total ion content the matrix becomes saturated with clusters, just as it became saturated with multiplets at ~10 mol% of ionic groups. It appears, therefore, that above ~10 mol% ionic concentration, any additional ion pairs go into clusters, and that above the cluster solubility limit (~40 mol%), all further ionic groups go into a hitherto unsuspected third type of structure which has not as yet been detected by Raman spectroscopy.

In conclusion, Raman spectroscopy is an extremely useful technique for studying the supermolecular structure of ionomers and we are currently investigating the spectra of several other types of these industrially important copolymers.

Solution structures of dimeric methylpyrazolyl and indazolyl dimethyl-derivatives of boron, gallium, and indium from ^{1}H nuclear magnetic resonance data

LOUIS K. PETERSON[1]

Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

AND

KWAT I. THÉ

Departmento de Quimica, Universidade Federal da Paraiba, Joao Pessoa, Paraiba, Brazil

Received April 3, 1979

LOUIS K. PETERSON and KWAT I. THÉ. Can. J. Chem. **57**, 2520 (1979).

Trimethylboron and trimethylgallium react with 3-methylpyrazole to yield isomer pairs of dimeric products $[Me_2E(Mepz)]_2$ (E = B, Ga; Mepz = 3-methylpyrazolyl), in the approximate ratios 4:3 (E = B) and 9:1 (E = Ga), while trimethylindium gives a single species. Reactions of indazole with trimethylgallium and trimethylindium also yield a single structural isomer of the dimer $[Me_2Eind]_2$ (E = Ga, In; ind = indazolyl). Solution structures were interpreted on the basis of ^{1}H nmr data.

LOUIS K. PETERSON et KWAT I. THÉ. Can. J. Chem. **57**, 2520 (1979).

Le triméthylbore et le triméthylgallium réagissent avec la méthyl-3-pyrazole pour donner des paires d'isomères de produits dimères $[Me_2E(Mepz)]_2$ (E = B, Ga; Mepz = méthyl-3 pyrazolyle) dans les rapports approximatifs de 4:3 (E = B) et 9:1 (E = Ga), alors que le triméthylindium donne des espèces monomères. Les réactions de l'indazole avec le triméthylgallium et le triméthylindium donnent également un seul isomère structural du dimère $[Me_2Eind]_2$ (E = Ga, In; ind = indazolyle). L'attribution des structures a été faite sur la base des données de la rmn du proton.

[Traduit par le journal]

There is considerable interest in the coordination properties of the pyrazolyl derivatives of the Group III elements (1–7). The neutral, coordinatively saturated dimeric species $[R^1{}_2E(R_2pz)]_2$ (E = B, Al, Ga; R^1 = hydrogen, alkyl, aryl, or halogen; R = H, in pyrazolyl, or R = CH_3, in 3,5-dimethylpyrazolyl) are readily converted to monoanions $R^1{}_2E(R_2pz)_2^-$ which function as chelating ligands in a wide variety of metal complex systems (1–11). Structurally, the species $[R^1{}_2E(R_2pz)]_2$ and $[R^1{}_2E(R_2pz)_2M]$ (M = metal atom or ion plus associated ligands) contain a central, six-membered $[E(N—N)_2E]$ or $[E(N—N)_2M]$ metallocycle with representative structures ranging from relatively flexible boat configurations to planar or even shallow chair conformations (4, 12) for the six atoms.

We report here the preparation of $[Me_2E(Mepz)]_2$ (E = B, Ga, and In; Mepz = 3-methylpyrazolyl) and $(Me_2Eind)_2$ (E = Ga, In; ind = indazolyl) by the reaction of 3-methylpyrazole or indazole with the appropriate trimethyl–Group III derivative (see Experimental section).

The boron and gallium derivatives $[Me_2E(Mepz)]_2$ were obtained as isomeric pairs of products, in the approximate ratios 4:3 (E = B) and 9:1 (E = Ga), as determined from ^{1}H nmr spectra. Only one isomer of $[Me_2In(Mepz)]_2$ was observed.

The largest mass spectral fragment observed for all three $[Me_2E(Mepz)]_2$ compounds was M − 15, corresponding to the loss of one methyl group from the parent ion. A similar loss of a single alkyl group from the parent ion of $(Me_2Gapz)_2$ and $(Et_2Gapz)_2$ (6) and $(Me_2Inpz)_2$ has been observed,[2] and details of the fragmentation of 1-pyrazolylboranes (pyrazaboles) have been published (13).

From ^{1}H nmr evidence (see Table 1) the pseudoaxial and pseudoequatorial methyl—E groups of the more abundant isomer **1** of $[Me_2E(Mepz)]_2$ (E = B, Ga) are magnetically equivalent. In addition, the pairs of groups 3-Me/3′-Me, 4-H/4′-H, and 5-H/5′-H are equivalent. Consequently, the rapidly inverting structure A is assigned to isomer **1**. An alternative inverting chair structure would also satisfy the nmr evidence, but seems less likely on account of an independent X-ray crystal structure analysis which indicates a boat form for isomer **1** of $[Me_2Ga(Mepz)]_2$ (5). The boat inversion process in $(Me_2Gapz)_2$ has been shown to be rapid on the nmr time scale, even at −100°C (6).

Structure B is assigned to the less abundant isomer

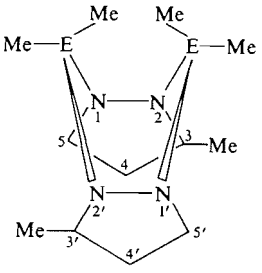
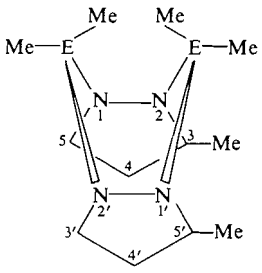
9.95s	9.72s	7.58s	3.83d[h]	2.50d[h]

[a]Spectra were run in $CDCl_3$, and data quoted are τ values relative to internal TMS, τ = 10.0.
[b]Mepz = 3-methylpyrazolyl.
[c]$J_{4,5}$ = 2.2 Hz.
[d]$J_{4,5}$ = 2.1 Hz.
[e]J = 2.0 Hz.
[f]The Me_2Ga resonances occurred at τ 10.03 and 10.18. Other ^{1}H resonances were not resolved from those of isomer **1** for $[Me_2Ga(Mepz)]_2$.
[g]τ 9.95 is assigned to the Me_2B protons proximal to the 3-Me and 5′-Me groups; τ 9.72 is assigned to Me_2B proximal to 3′-H and 5-H.
[h]$J_{4,5} = J_{3,4}$ = 2.2 Hz.



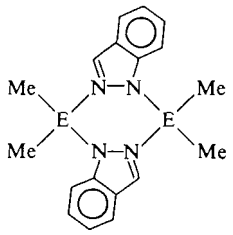
Structure A



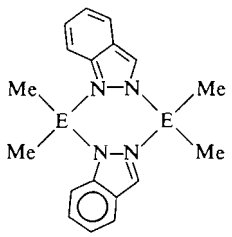
Structure B

2 of $[Me_2E(Mepz)]_2$ (E = B, Ga), on the basis of the observed magnetic distinction between the two sets of Me_2E groups. The six protons of the pairs of methyl groups are equivalent, however, by virtue of rapid inversion of boat forms, as are the pairs of groups 3-Me/5′-Me, 4-H/4′-H, and 5-H/3′-H. For isomer **2** of $[Me_2B(Mepz)]_2$, the more upfield resonance (at τ 9.95) is assigned to the Me_2B group proximal to the electron-releasing 3-Me and 5′-Me groups, while the second resonance (at τ 9.72) is due to Me_2B proximal to 5-H and 3′-H. The Me_2Ga groups of isomer **2** of $[Me_2Ga(Mepz)]_2$ are distinguished in a similar fashion. The chemical shift for the twelve equivalent Me_2E protons of structure A is the mean of the two distinct shifts for the protons of the two different Me_2E groups of structure B.

While structure A satisfies the ^{1}H nmr data obtained for the unique form of $[Me_2In(Mepz)]_2$, a



Structure C



Structure D

completely planar $[In(N—N)_2In]$ bimetallocycle cannot be ruled out. Planar or near planar metallocycles have been found or proposed for $[Et_2B(4\text{-}Brpz)]_2$ (1), $[Me_2Ga(Me_2pz)]_2$ (4), $[Me_2Ga(Me_2pz)_2\text{-}Cu]$ (9), $[(pz)HBpz]_2$ (12), and $[(\phi_2PCH_2CH_2P\phi_2)\text{-}Pt(pz)_2\ Ni]^{2+}$ (14). It appears that boat configurations are generally preferred because of favourable bond angles about the Group III atom, and maximized delocalization of the π-electrons of the planar pyrazolyl rings in these structures (4). The flattening of the boat configuration is a function of the nature of the metal atoms within the metallocycle, and the need to minimize intramolecular steric repulsions (1, 4, 5, 12).

In principle, six structures are possible for the indazolyl derivatives $(Me_2Eind)_2$ (E = Ga, In), viz., boat, chair, and planar metallocycle configurations based upon structures C and D. In fact, the ^{1}H nmr solution spectra of the gallium and indium derivatives $(Me_2Eind)_2$ showed that the twelve Me—E protons were equivalent, thus eliminating structures based on D, and indicating a rapidly inverting boat or chair configuration C, or planar C. Of these possibilities, the chair conformation is least preferred, since the pyrazolyl rings would lose planarity to some extent, with a consequent loss of π-electron delocalization energy (4). In the solid phase, an independent X-ray diffraction study has shown that $(Me_2Gaind)_2$ adopts a boat configuration, based on structure C (5).

Experimental

All materials were handled using a high vacuum system or a nitrogen-filled drybox. 3-Methylpyrazole and indazole (K & K) were dried and sublimed before use. Me_3B (15) was made from BCl_3 (K & K), and Me_3In (16) from $InCl_3$ (K & K), according to published methods. Solvents were dried and distilled under nitrogen before use (17).

Analyses for C, H, and N were performed by the Departmental analyst, Simon Fraser University. Melting points were measured on samples in sealed capillaries, using a Gallenkamp instrument, and are uncorrected. In several cases, samples softened several degrees before melting, in a manner already described in the literature (18, 19). Mass spectra were determined with a double focusing RMU-6E Hitachi Perkin-Elmer instrument, and nmr spectra with the Varian XL100 spectrophotometer.

Preparation of $[Me_2E(Mepz)]_2$ *(E = B, Ga, In)*[3]

Reactions between 3-methylpyrazole (~1.5 mmol) and Me_3E (E = B, Ga, In; ~3 mmol) were carried out in sealed tubes, using ether as solvent in all cases except Me_3B. Reaction temperatures (and times) were: Me_3B, 100°C (~24 h); Me_3Ga, 80°C (3 days); Me_3In, 40°C (~24 h). Products were separated on a vacuum line. The derivatives $[Me_2E(Mepz)]_2$ were purified by sublimation under high vacuum, and were identified by elemental analysis, mass spectra, ^1H nmr (see Table 1), and ir spectroscopy.

$[Me_2B(Mepz)]_2$, yield, 90%. *Anal.* calcd. for $C_{12}H_{22}B_2N_4$: C 59.1, H 9.08, N 23.0; found: C 59.3, H 9.30, N 23.2.

$[Me_2Ga(Mepz)]_2$, yield, 80%, mp (isomer **1**) 47–48°C. *Anal.* calcd. for $C_{12}H_{22}B_2N_4$: C 39.8, H 6.09, N 15.5; found: C 40.1, H 6.20, N 15.2. Isomer **1** was obtained pure by repeated crystallization (from hexane) and repeated sublimation.

$[Me_2In(Mepz)]_2$, yield, 90%, mp 58–61°C. *Anal.* calcd. for $C_{12}H_{22}In_2N_4$: C 31.9, H 4.87, N 12.4; found: C 32.2, H 4.90, N 12.3.

Preparation of $[Me_2Eind]_2$ *(E = Ga, In)*

The procedure was similar to that described above, except that indazole was used in place of 3-methylpyrazole, and reaction temperatures were: Me_3Ga, 110°C; Me_3In, 80°C. Products were purified by sublimation under vacuum.

$[Me_2Gaind]_2$, yield, 90–100%, mp 125–128°C. *Anal.* calcd. for $C_{18}H_{22}Ga_2N_4$: C 49.8, H 5.08, N 12.9; found: C 49.9, H 5.03, N 13.0. ^1H nmr spectrum (in $CDCl_3$), τ 10.90 (s, 12H, Me—Ga), and a multiplet of ring protons (10H), centred at τ 3.17.

$[Me_2Inind]_2$, yield, 90–100%, mp 108–110°C. *Anal.* calcd. for $C_{18}H_{22}In_2N_4$: C 41.2, H 4.20, N 10.7; found: C 41.1, H 4.10, N 10.7. ^1H nmr spectrum (in $CDCl_3$), τ 10.77 (s, 12H, Me—In), and a multiplet (10H), centred at τ 3.17, for the ring protons.

[3]Reaction between 3-methylpyrazole and Me_3Al gave $[Me_2Al(Mepz)]_2$, sublimable when freshly prepared but rapidly becoming non-volatile. The product did not melt sharply, and analyses for C, H, and N were poor.

Preparation of $[Me_2E(Mepz)]_2$ *(E = B, Ga, In)*[3]

Reactions between 3-methylpyrazole (~1.5 mmol) and Me_3E (E = B, Ga, In; ~3 mmol) were carried out in sealed tubes, using ether as solvent in all cases except Me_3B. Reaction temperatures (and times) were: Me_3B, 100°C (~24 h); Me_3Ga, 80°C (3 days); Me_3In, 40°C (~24 h). Products were separated on a vacuum line. The derivatives $[Me_2E(Mepz)]_2$ were purified by sublimation under high vacuum, and were identified by elemental analysis, mass spectra, ^1H nmr (see Table 1), and ir spectroscopy.

$[Me_2B(Mepz)]_2$, yield, 90%. *Anal.* calcd. for $C_{12}H_{22}B_2N_4$: C 59.1, H 9.08, N 23.0; found: C 59.3, H 9.30, N 23.2.

$[Me_2Ga(Mepz)]_2$, yield, 80%, mp (isomer **1**) 47–48°C. *Anal.* calcd. for $C_{12}H_{22}B_2N_4$: C 39.8, H 6.09, N 15.5; found: C 40.1, H 6.20, N 15.2. Isomer **1** was obtained pure by repeated crystallization (from hexane) and repeated sublimation.

$[Me_2In(Mepz)]_2$, yield, 90%, mp 58–61°C. *Anal.* calcd. for $C_{12}H_{22}In_2N_4$: C 31.9, H 4.87, N 12.4; found: C 32.2, H 4.90, N 12.3.

Preparation of $[Me_2Eind]_2$ *(E = Ga, In)*

The procedure was similar to that described above, except that indazole was used in place of 3-methylpyrazole, and reaction temperatures were: Me_3Ga, 110°C; Me_3In, 80°C. Products were purified by sublimation under vacuum.

$[Me_2Gaind]_2$, yield, 90–100%, mp 125–128°C. *Anal.* calcd. for $C_{18}H_{22}Ga_2N_4$: C 49.8, H 5.08, N 12.9; found: C 49.9, H 5.03, N 13.0. ^1H nmr spectrum (in $CDCl_3$), τ 10.90 (s, 12H, Me—Ga), and a multiplet of ring protons (10H), centred at τ 3.17.

$[Me_2Inind]_2$, yield, 90–100%, mp 108–110°C. *Anal.* calcd. for $C_{18}H_{22}In_2N_4$: C 41.2, H 4.20, N 10.7; found: C 41.1, H 4.10, N 10.7. ^1H nmr spectrum (in $CDCl_3$), τ 10.77 (s, 12H, Me—In), and a multiplet (10H), centred at τ 3.17, for the ring protons.

[3]Reaction between 3-methylpyrazole and Me_3Al gave $[Me_2Al(Mepz)]_2$, sublimable when freshly prepared but rapidly becoming non-volatile. The product did not melt sharply, and analyses for C, H, and N were poor.

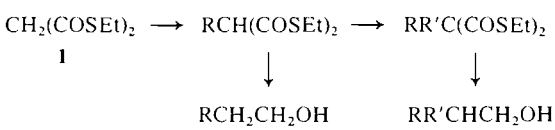
We recently observed that β-keto thiolesters undergo facile dealkylthiocarbonylation reaction when treated with Raney nickel under virtually neutral conditions (1).[1] An extrapolation of these results suggested that treatment of a 1,3-dithiol ester with Ra-Ni could induce the removal of one thiolester group with concomitant reduction of the other to the aldehyde or the alcohol level (2). On this basis, a general procedure has been developed for the introduction of a hydroxyethyl function, a process which is of considerable importance in organic synthesis. The overall transformation can be considered as the replacement of one or two β-protons of ethyl alcohol by electrophile(s) involving no more than three operationally simple steps using *S,S'*-diethyl dithiomalonate (**1**) as a latent ethanol carbanion according to the following general scheme.



S,S'-Diethyl dithiomalonate (**1**), bp 105–106°C/3 Torr (lit. (3) bp 135°C/10 Torr), was readily prepared in 95% yield by the reaction of malonyl dichloride and ethanethiol (1.5 equiv.) in ether at room temperature for 16 h.[2] Dithiomalonate **1** was shown to react cleanly with a variety of alkyl halides[3] in the presence of sodium hydride in 1,2-dimethoxyethane (Table 1). Monoalkylation (Entries 1–4) could be achieved using one equivalent of base. When dialkylation with two identical substituents (Entry 5) or ring formation (Entry 6) are desired, substitution could be accomplished in one operation by using two equivalents of base. The incorporation of two different substituents (Entries 7–9) was best done via isolation and purification of the intermediate monosubstituted material followed by the second alkylation step. Electrophiles other than electrophilic carbon can also be used.[4] For example, treatment of the carbanion derived from dithiomalonate **2** with benzoyl peroxide in benzene produced the benzoyloxy derivative **4** in 97% yield (Entry 9).

Table 1 also summarizes the results of the reactions of the dithiomalonates with W-2 Ra-Ni[5] (9), all of which were carried out in benzene solution at room temperature under an atmosphere of nitrogen. In all cases, the dithiomalonate function was effectively reduced to a hydroxyethyl group and ethanol derivatives were obtained in good yields. Two especially noteworthy examples are the reductions of the dithiomalonates **3** and **4**. In each case, the reduction occurred smoothly with the *O*-ester group intact.

The preparation of 3-phenyl-1-propanol shown below illustrates the general procedure used.

To a suspension of sodium hydride (50% oil dispersion; 48 mg, 1 mmol) in 1,2-dimethoxyethane (5 mL) was added a solution of *S,S'*-diethyl dithiomalonate (192 mg, 1 mmol) in 1,2-dimethoxyethane (3 mL). The reaction mixture was stirred at room temperature under a nitrogen atmosphere for 10 min and a solution of benzyl chloride (163 mg, 1.3 mmol) in 1,2-dimethoxyethane (3 mL) was introduced. The resulting mixture was refluxed for 6 h. After cooling to room temperature, it was poured into ice-cold 1 *N* aqueous hydrochloric acid and extracted with ether. Column chromatography of the crude product obtained after the usual work-up of the extracts on silica gel with *n*-hexane elution resulted in the removal of the mineral oil from sodium hydride. Further elution with benzene–*n*-hexane (1:1) gave dithiomalonate **2** (244 mg, 87% yield): ir (neat) 1697, 1668 (thiolester), 1602, and 1585 (phenyl) cm^{-1}; nmr (CCl_4) δ: 7.13 (t, 5H, C_6H_5), 3.91 (t, 1H, CH), 3.15 (d, 2H, benzylic CH_2), 2.82 (q, 4H, $J = 8$ Hz, $COSCH_2$), and 1.23 (t, 6H, $J = 8$ Hz, CH_3); ms M^+: 282.0749 (calcd. for $C_{14}H_{18}O_2S_2$: 282.0749). To a solution of dithiomalonate **2** (95 mg, 0.34 mmol) in benzene (5 mL) was added 1 mL (settled volume) of W-2 Raney nickel suspended in benzene (5 mL). After stirring at room temperature under a nitrogen atmosphere for 1 h, the mixture was filtered and the residue washed thoroughly with benzene. Concentration of the filtrate gave an oil which was purified by column chromatography on silica gel. Elution with a solution of 30% ether in benzene afforded 35 mg (76% yield) of 3-phenyl-1-propanol.

In an attempt to extend the method to the direct synthesis of aldehydes, we examined the reaction of dithiomalonate **2** with Ra-Ni which had been

[1] We have since found that β-keto thiolesters readily undergo *C*-alkylation, and the dealkylthiocarbonylation of fully substituted β-keto thiolesters is equally effective. Results will be published elsewhere.

[2] For other methods, see refs. 3–5.

[3] Alkylation of dithiomalonate **1** has been previously studied using sodium in pyridine (6). Dithiomalonate **1** is also known to undergo Michael additions with ethyl acrylate and acrylonitrile (5) as well as reactions with diazomethane (5), aldehydes (7), and acid chlorides (8).

[4] See ref. 5 for bromination of dithiomalonate **1**.

[5] The rate of reduction was found to be sensitive to the quality of the Raney nickel. Slight variation of the procedure for preparation of the catalyst or storage of the catalyst for a period of time gave decreased reaction rates, however the reaction yields were unchanged.

TABLE 1. Substitution and reduction of dithiomalonates

		Substitution[a]				Reduction[b]		
Entry	Malonate	Reagent	Time (h)	Product[c]	(% yield)	Time (h)	Product[c]	(% yield)
1	**1**	$C_6H_5CH_2Cl$	6[d]	$C_6H_5CH_2CH(COSEt)_2$ **2**	(87)	1	$C_6H_5(CH_2)_3OH$	(76)
2	**1**	$C_6H_5CH_2Br$	20	**2**	(76)	—	—	—
3	**1**	$CH_3(CH_2)_4CH_2I$	48	$CH_3(CH_2)_5CH(COSEt)_2$	(78)	1	$CH_3(CH_2)_7OH$	(84)
4	**1**	$BrCH_2COOEt$	4	$EtOOCCH_2CH(COSEt)_2$ **3**	(90)	12	$EtOOC(CH_2)_3OH$	(77)
5	**1**	$C_6H_5CH_2Br$[e]	16	$(C_6H_5CH_2)_2C(COSEt)_2$	(100)	1.5	$(C_6H_5CH_2)_2CHCH_2OH$	(79)
6	**1**	$Br(CH_2)_5Br$[f]	48[d]		(91)	16		(84)
7	**2**	CH_3I	6		(100)	1		(66)
8	**2**	$(CH_3)_2CHI$	48[d]		(61)	1		(81)
9	**2**	$(C_6H_5COO)_2$[g]	24	 **4**	(97)	3		(72)

[a]Unless otherwise specified, substitution reactions were carried out at room temperature in 1,2-dimethoxyethane using 1 equiv. of NaH and 1.3 equiv. of the reagents listed.
[b]Without exception, reductions were performed in benzene at ambient temperature using ca. 10 mL (settled volume) of Ra-Ni (W-2)/g of substrate.
[c]All new compounds were adequately characterized by spectroscopic methods and by exact mass measurement and (or) elemental analysis.
[d]The reaction was carried out in refluxing 1,2-dimethoxyethane.
[e]2.2 equiv. of NaH and 2.4 equiv. of the reagent were used.
[f]2 equiv. of NaH was used.
[g]Benzene was used as a solvent.

deactivated with acetone (2) to various degrees (room temperature reflux for 0.5–3 h). However the results were unpromising; the best obtained was a 2:3 mixture of 3-phenylpropanal and the corresponding alcohol.

Ipso nitration XXI.[1] Nitration of *p*-tolylalkanoic acids and derivatives: spiro adducts

ALFRED FISCHER, DAVID R. A. LEONARD, and ROLF RÖDERER
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received March 2, 1979

ALFRED FISCHER, DAVID R. A. LEONARD, and ROLF RÖDERER. Can. J. Chem. **57**, 2527 (1979).

Nitration of 4-(*p*-tolyl)butyric acid and of 3-(*p*-tolyl)propionic acid in acetic anhydride gives good yields of the diasteriomeric spiro lactone adducts **1** and **12**, respectively. Nitration of methyl 4-(*p*-tolyl)butyrate, 4-(*p*-tolyl)butanol, and 4-(*p*-tolyl)butyl acetate gives nitronium acetate adducts but does not give spiro adducts.

ALFRED FISCHER, DAVID R. A. LEONARD et ROLF RÖDERER. Can. J. Chem. **57**, 2527 (1979).

La nitration de l'acide (*p*-tolyl)-4 butyrique et de l'acide (*p*-tolyl)-3 proprionique dans l'anhydride acétique conduit avec de bons rendements aux spiro lactones diastéréoisomères **1** et **12**. La nitration du (*p*-tolyl)-4 butyrate de méthyle, du (*p*-tolyl)-4 butanol et de l'acétate de (*p*-tolyl)-4 butyle conduit aux adduits acétates de nitromium mais non pas aux adduits spiro.
[Traduit par le journal]

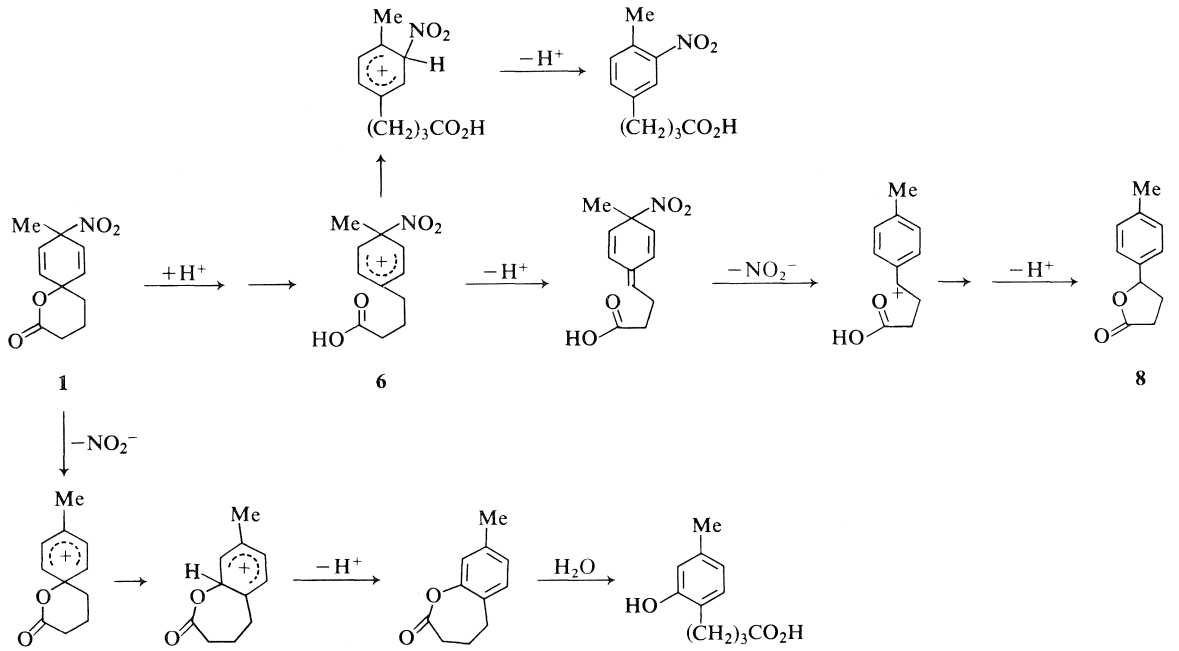
Nitration, in acetic anhydride, of aromatic compounds containing an activated *ipso* position, leads to the formation of nitronium acetate adducts (1–5). Such adducts are formed in particularly high yield from *p*-xylene and other *p*-dialkylbenzenes (6–11). The compounds studied in the present work: 4-(*p*-tolyl)butyric acid, methyl 4-(*p*-tolyl)butyrate, 4-(*p*-tolyl)butan-1-ol, 4-(*p*-tolyl)butyl acetate, 3-(*p*-tolyl)-propionic acid, and *p*-tolylacetic acid may be regarded as side-chain derivatives of dialkylbenzenes. Formation of significant amounts of adducts is therefore to be expected from these substrates.

Results and Discussion

Nitration of 4-(*p*-tolyl)butyric acid in acetic anhydride gave a crude product which contained 65% of dienes. Recrystallization gave one diastereoisomer of the lactone of 4-(1′-hydroxy-4′-methyl-4′-nitrocyclohexa-2,5-dienyl)butyric acid (**1***a*) and the other diastereoisomer **1***b* was obtained on chromatography. Formation of the adduct 4-(4′-acetoxy-4′-methyl-1′-nitrocyclohexa-2,5-dienyl)butyric acid (**2**) also apparently occurred since a diene with a methyl peak at δ 1.45 ppm was evident in a late (polar) column fraction. The higher field methyl group is typical of a methyl *ipso* to acetate (10). In **1***a* and **1***b* the methyl groups (*ipso* to nitro) are at lower field, δ 1.78 and 1.72 ppm. The methyl peak at 1.45 ppm was also evident in the spectrum of the crude reaction product, as was another smaller peak at 1.32 ppm (possibly from a diastereoisomer). The 1.45 ppm peak was ca. one third of the height of the peaks at 1.72 and 1.78 ppm and thus nitration *ipso* to the methyl group is favoured over nitration *ipso* to the butyric acid side-chain. Nitration *ipso* to the methyl was found to be preferred to nitration *ipso* to other alkyl groups (8–10), a result attributed to the increase of steric hindrance with size of the alkyl group. A similar explanation is applicable in the present case. Formation of the lactone **1** in preference to nitronium acetate adduct **4** shows that in the intermediate cyclohexadienyl cation **6** the carboxylic acid group competes effectively with the external nucleophile (acetic acid or acetic anhydride) in adding to the tertiary carbonium ion centre. Other reaction products include the expected 4-(4′-methyl-2′-nitrophenyl)-butyric acid and its 3′-nitro isomer and the lactone of 4-hydroxy-4-(*p*-tolyl)butyric acid

[1]For Part XX, see ref. 5.

0008-4042/79/192527-06$01.00/0

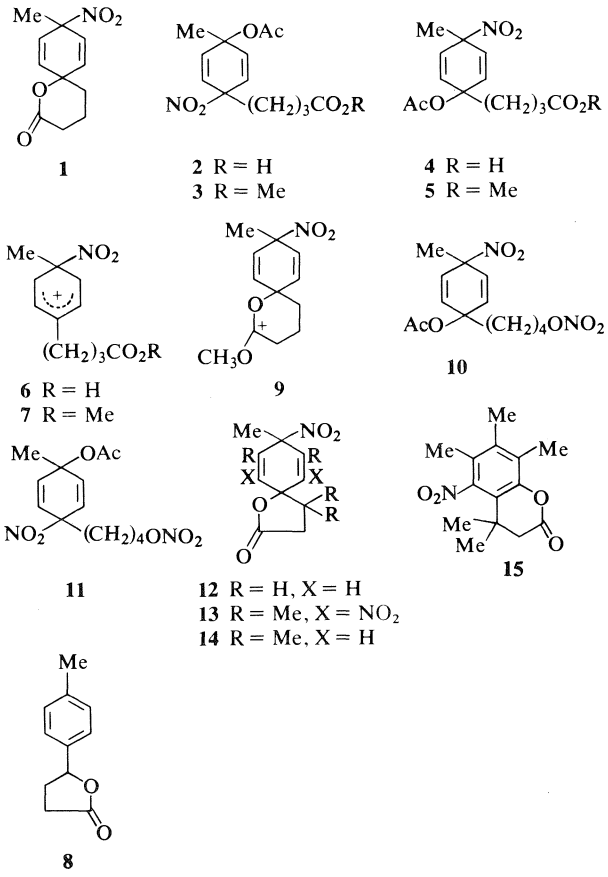


SCHEME 1. Reactions of lactone **1**.

(**8**). Formation of lactone **8** is a parallel to the reactions leading to side-chain derivatives commonly observed accompanying the nitration of polymethylbenzenes containing *para* alkyl groups (12). The probable mechanism is shown in Scheme 1, **6** → **8**.

Nitration of methyl 4-(*p*-tolyl)butyrate gave 40% of diene adducts. Four isomers appeared to be present in the crude reaction product, two with lower field methyl groups (δ 1.77 and 1.70 ppm) which are assigned as the diastereoisomers of **5** with nitro *ipso* to methyl, and two with higher field methyl groups (δ 1.46 and 1.48 ppm), presumably the diastereoisomers of **3**. Dienes **5** were present in greater amount. The dienes were partially separated by chromatography but only one of them, one diastereoisomer of **5**, was able to be crystallized and thus obtained pure. In this case the nitronium acetate adduct is formed in preference to the lactone **1** and it appears that the methoxy carbonyl function is not able to compete effectively with the solvent nucleophile in adding to the tertiary cation centre of **7**. However, it is also possible that ring closure by the ester function of **7** is fast but that demethylation of the resulting cation **9** is slow relative to its reversion to **7** and eventual reaction of the latter with solvent.

Nitration of 4-(*p*-tolyl)butanol followed a similar pattern to that of the butyrate ester in that adducts were obtained with nitro *ipso* to methyl in the predominant pair of diastereoisomers and with nitro *ipso* to the tetramethylene side-chain in the minor



pair of diastereomers (Table 1). No spiro ether product resulting from ring closure in the nitrocyclohexadienyl cation was observed. This observation does not necessarily mean that the intramolecular addition of hydroxyl to the cationic centre is not competitive with the attack by the solvent nucleophile, since the alcohol function was converted into the nitrate ester in the course of the reaction and this may have preceded the addition of nitronium ion to the aromatic ring.

Nitration of 4-(*p*-tolyl)butyl acetate gave ~60% of diene adducts. Only partial separation of the diene adducts was achieved on chromatography. However, it was possible to recognise at least three different dienes in the various fractions. Two of the dienes had nitro *ipso* to methyl since the methyl peak in each was at lower field, δ 1.77 and 1.71 ppm, respectively. The third, with a methyl peak at δ 1.48 ppm, evidently had nitro *ipso* to the butyl acetate side-chain and acetate *ipso* to methyl. All of the fractions exhibited two peaks in the acetate region (δ 1.96 and 2.02 ppm) and there was no evidence for the formation of spiro product.

Nitration of 3-(*p*-tolyl)propionic acid gave ~70% of diene adducts. The diastereoisomeric diene lactones **12***a* and **12***b* were isolated from the reaction mixture. The mother liquid remaining after isolation of the dienes was heated with acetic acid to decompose any residual dienes. From this the normal nitration products, 3-(4′-methyl-2′-nitrophenyl)propionic acid and 3-(4′-methyl-3′-nitrophenyl)propionic acid were isolated and, in addition, a compound tentatively assigned as 7-methyldihydrocoumarin. The last is the product that would be expected to be obtained on solvolysis of diene **12**, by analogy with the solvolytic conversion of the adduct of *p*-xylene to 2,5-dimethylphenyl acetate. Shinoda and Suzuki (13) obtained lactone **13** on nitration of methyl 3-methyl-3-(3′,4′,5′-trimethylphenyl)butyrate and proposed lactone **14** as an intermediate in the formation of the dihydrocoumarin **15** which is also obtained in the nitration (14).

TABLE 1. Dienes from nitration of 4-(*p*-tolyl)butanol

Diene[a]	Yield[b] (%)	^{1}H nmr (CCl_4) δ/ppm[c]
11*a*	12	1.43, 1.91, 4.37, 6.01, 6.06
10*a*	50	1.75, 1.92, 4.35, 5.95, 6.00
11*b*	8	1.48, 1.93, 4.36, 6.11, 6.12
10*b*	30	1.68, 1.93, 4.36, 6.16, 6.17

[a]Dienes listed in order of elution.
[b]Percentage of total diene product formed.
[c]Peaks from left to right are assigned as (1′ or 4′)-CH_3(s), $OCOCH_3$(s), CH_2ONO_2(s), 2′-*H*, 3′-*H*, 5′-*H*, and 6′-*H* (q, J = 10 Hz). The peaks of 2-CH_2, 3-CH_2, and 4-CH_2 were not clearly resolved.

Nitration of *p*-tolylacetic acid gave a low yield (~20%) of diene products which were not further investigated.

Shift reagent studies using tris(1,1,1,2,2,3,3-heptafluoro-7,7-[$^2H_6$]dimethyl-4,6-[$^2H_3$]octanedionato)europium(III)(Eu([$^2H_9$]fod)$_3$) with the diene lactones **1***a*, **1***b*, **12***a*, and **12***b* gave the results shown in Table 2. Studies with secondary acetate adducts have been useful in assigning the stereochemistry of adducts (15). However, in the case of tertiary acetate adducts (from 1-methyl-4-alkylbenzenes), the shifts of the 4-methyl protons in the diastereoisomers are closely similar and it has not been possible to assign the stereochemistry (7, 8). The shifts of the 4′-methyl protons in the lactones **1***a* and **1***b*, and also in the lactones **12***a* and **12***b*, are similar and the differences between them are not larger than those between other pairs of corresponding protons. Nevertheless, a tentative stereochemical assignment can be proposed. The *a* isomers in each case exhibit a smaller relative gradient for the 4′-methyl protons than the *b* isomers. The *a* isomers were eluted first in chromatography and the *a* isomers have higher melting points than the *b* isomers. In the nmr spectra the 3-(or 4-)methylene and the 4′-methyl protons are lower field in the *a* isomers than in the *b* isomers. The chemical shift difference between the 2′- and 3′-protons is smaller in the *a* isomers than in the *b* isomers. These parallels strongly suggest that the *a* isomers have the same stereochemistry and, correspondingly, the two *b* isomers have the same stereochemistry opposite to that of the *a* isomers. The consistent smaller shift gradient of the 4′-methyl protons in the *a* isomers indicates that these have the europium *trans* to methyl, i.e., *cis* nitro and lactone groups, and thus the *b* isomers have *trans* nitro and lactone functions.

Rearomatization of lactone **1** was studied under both acidic and solvolytic (aqueous acetic acid) conditions. Lactone **8** was formed under both acidic and solvolytic conditions. It was the only product in acetic acid containing acetic anhydride and sulfuric acid and the major product in deuteriochloroform containing borontrifluoride etherate. It was a minor

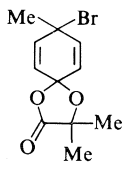
TABLE 2. Relative gradients (gradient 2-CH_2 = 1.00) of proton chemical shifts for diene lactones from the addition of Eu([$^2H_9$]fod)$_3$

Lactone	3-H[a]	2′-H	3′-H	4′-CH_3
1*a*	0.33	0.35	0.15	0.103
1*b*	0.32	0.37	0.18	0.121
12*a*	0.41	0.37	0.20	0.117
12*b*	0.40	0.42	0.18	0.130

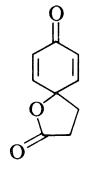
[a]The 3-CH_2 and 4-CH_2 groups in **1***a* and **1***b* were not resolved from each other.

product in aqueous acetic acid. The major products were a mixture of acids which were not further identified but which appeared (nmr spectrum) to include nuclear nitro-substituted 4-*p*-tolylbutyric acid(s) and phenolic acid(s). Nuclear magnetic resonance absorptions in the δ 6.5–7.0 ppm region suggested the presence of the phenol derivatives. The mechanism proposed for formation of lactone **8** is depicted in Scheme 1 (centre). A 1,2 migration of the nitro group in the *ipso* cation **6** would, after deprotonation, give 4-(4′-methyl-3′-nitrophenyl)butyric acid (Scheme 1, upper). Expulsion of the nitro group as nitrite anion followed by migration of the carboxylate group, deprotonation, and hydrolysis of the resulting lactone would give 4-(2′-hydroxy-4′-methylphenyl)butyric acid (Scheme 1, lower). Parallels for these reactions exist in the reactions of adducts obtained from alkylbenzenes (4, 7, 16, 17).

Electrophilic addition at an *ipso* position coupled with internal nucleophilic participation was first noted by Corey *et al.* They obtained the bromolactone **16** on bromination of the salt of α-*p*-tolyloxyisobutyric acid (18). If the carbonyl group is accepted as a two-membered ring then there are many other (and earlier) examples of electrophilic addition coupled with internal nucleophilic participation provided by the nitration and halogenation of *p*-cresol and its derivatives to form *ipso*-nitro- and halocyclohexadienones (19–22). The spirolactone **17** is ob-



16



17

tained on both chemical oxidation (23) and electrooxidation (24) of 3-(*p*-hydroxyphenyl)propionic acid. On treatment with acid, **17** gives a mixture of 6- and 7-hydroxydihydrocoumarins in which either isomer can be made to predominate depending upon the conditions. Migration of the carboxylate function to give the 7-hydroxydihydrocoumarin is not intramolecular but apparently involves an initial Michael-like addition of a solvent nucleophile to the dienone system (23). It is possible that solvolysis of **12** could also involve a competition between the migration of the methylene group (to form 6-methyldihydrocoumarin) and the formal migration of the carboxylate group (to form 7-methyldihydrocoumarin), i.e., the compound tentatively identified above as 7-methyldihydrocoumarin could be the 6-isomer or a mixture of the two. In this connection it should be noted that the facile migration of an acetate group in the solvolysis of nitrocyclohexadienyl acetates is not necessarily a good analogy for the migration of the carboxylate group in either **12** or **1** (Scheme 1). In the case of the dienyl acetates the carbonyl oxygen can bond to the neighbouring carbon atom allowing the acetate to migrate via a cyclic transition state. An analogous transition state is impossible for the diene lactones.

Experimental

General experimental methods have been described previously (7).

*Nitration of 4-(*p*-Tolyl)butyric Acid*

A solution of nitric acid (15.7 g, 0.25 mol) in acetic anhydride (100 cm^3) at −78°C was added to a stirred mixture of 4-(*p*-tolyl)butyric acid (17.8 g, 0.1 mol) in acetic anhydride (200 cm^3) at −50°C. The temperature was maintained between −45 and −50°C for 1.5 h, the mixture becoming homogenous after 20 min. The solution was then added to ether (1.5 dm^3) at −78°C and quenched with ammonia, keeping the temperature below −60°C. Excess ammonia was aspirated and the ethereal solution washed with water, dried, and the ether evaporated to yield the crude product (12.1 g) containing 65% of dienes by nmr. Recrystallization from acetone–ether yielded one diastereomer of the lactone of 4-(1′-hydroxy-4′-methyl-4′-nitrocyclohexa-2′,5′-dienyl)butyric acid (**1***a*, 2.2 g) as colourless needles, mp 138.0–138.5°C; ir (Nujol): 1730, 1240 (δ-lactone), 1555 (NO_2) cm^{-1}; nmr ($CDCl_3$) δ: 1.78 (s, 3, C*H*$_3$), 1.95 (m, 4, 3-C*H*$_2$, 4-C*H*$_2$), 2.60 (m, 2, 2-C*H*$_2$), 6.17 (s, 4, 2′-*H*, 3′-*H*, 5′-*H*, 6′-*H*) ppm, on addition of Eu([$^2H_9$]fod)$_3$ the 6.17 ppm singlet split into a quartet, J = 10 Hz. *Anal.* calcd. for $C_{11}H_{13}NO_4$: C 59.18, H 5.87, N 6.28; found: C 59.26, H 6.21, N 6.14.

Chromatography of the mother liquor residues from the recrystallizations on neutral alumina (400 g deactivated with 10% (w/w) water), at −45°C and elution with ether–pentane and then ether gave the *lactone* of *4-hydroxy-4-(*p*-tolyl)butyric acid* (**8**, 0.38 g), mp 71–72.5°C (lit. (25) mp 72–73°C); ir (Nujol): 1765 (γ-lactone) cm^{-1}; nmr ($CDCl_3$) δ: 2.34 (s, 3, C*H*$_3$), 2.6 (m, 4, C*H*$_2$C*H*$_2$), 5.42 (t, 1, J = 7 Hz, C*H*CH$_2$), 7.18 (s, 4, Ar*H*) ppm; ms (70 eV) *m/e* (relative intensity): 176 (33, M), 161 (23, M − CH_3), 121(52), 119(43), 117(43), 115(20), 91(68), 28(100).

Further elution with ether afforded diene **1***a*, and then mixtures of the diastereomers **1***a* and **1***b* in approximately equal proportions. Elution with dichloromethane gave a further amount of the mixture of diastereomers. The mixtures were combined (2.1 g) and recrystallized from chloroform–pentane to give colourless prisms of the second diastereomer of the *lactone* of *4-(1′*-hydroxy-4′-methyl-4′-nitrocyclohexa-2′,5′-dienyl)butyric acid (**1***b*), mp 113.5–114.0°C (dec.); ir (Nujol): 1730 (δ-lactone), 1545 (NO_2) cm^{-1}; nmr ($CDCl_3$) δ: 1.72 (s, 3, C*H*$_3$), 1.87 (m, 4, 3-C*H*$_2$ and 4-C*H*$_2$), 2.60 (m, 2, 2-C*H*$_2$), 6.20 (nq, 2, J = 10 Hz, 2′-*H* and 6′-*H*), 6.27 ppm (nq, 2, J = 10 Hz, 3′-*H* and 5′-*H*). *Anal.* calcd. for $C_{11}H_{13}NO_4$: C 59.18, H 5.87, N 6.28; found: C 58.76, H 6.18, N 6.07.

Elution with methanol gave a mixture of 4-(nitro-*p*-tolyl)butyric acids and dienes (4.0 g). This appeared to contain a third diene, presumably 4-(4′-acetoxy-4′-methyl-1′-nitrocyclohexa-2,5-dienyl)butyric acid, but the mixture was not further resolved.

The aqueous washings were acidified with hydrochloric acid and extracted with methylene chloride to yield a mixture (4.2 g) containing 4-(nitro-*p*-tolyl)butyric acids; ir: 1705 (CO), 1525 (NO_2) cm^{-1}; nmr δ: 7.25, 7.75 ppm. Another component

present was probably 4-(hydroxy-*p*-tolyl)butyric acid; nmr δ: 6.85, 7.0, 7.05 ppm. Chromatography on silica did not resolve the mixture and it did not crystallize.

*Nitration of Methyl 4-(*p*-Tolyl)butyrate*

A solution of nitric acid (15.8 g, 0.25 mol) in acetic anhydride (100 cm^3) at −78°C was added to a slurry of methyl 4-(*p*-tolyl)butyrate (19.2 g, 0.1 mol) in acetic anhydride (100 cm^3) also at −78°C. The mixture was warmed to −50°C and stirred for 2 h. After quenching with ammonia and work-up the product contained 40% of dienes, by nmr. On chromatography at least four different dienes could be recognized in various fractions but only that obtained in largest amount could be crystallized and obtained pure. Methyl 4-(1′-acetoxy-4′-methyl-4′-nitrocyclohexa-2′,5′-dienyl)butyrate (**5**) was recrystallized from ether–pentane, m.p. 62–63°C; ir (Nujol): 1740, 1240 ($OCOCH_3$), 1735, 1180 ($COOCH_3$) 1540 (NO_2) cm^{-1}; nmr ($CDCl_3$) δ: 1.74 (m, 4, 3-CH_2 and 4-CH_2), 1.77 (s, 3, CH_3), 1.97 (s, 3, $OCOCH_3$), 2.29 (t, 2, J = 6 Hz, 2-CH_2), 3.62 (s, 3, OCH_3), 6.04, and 6.07 ppm (q, 4, J = 10 Hz). *Anal.* calcd. for $C_{14}H_{19}NO_6$: C 56.56, H 6.44, N 4.71; found: C 56.35, H 6.41, N 4.51.

*Nitration of 4-(*p*-Tolyl)butanol*

Nitric acid (6.3 g, 0.1 mol) in acetic anhydride (50 cm^3) was added to a stirred solution of the alcohol (8.2 g, 0.05 mol) in acetic anhydride (50 cm^3) at −40°C. After 2.5 h the solution was quenched and worked up yielding an oil (13.7 g) which contained 20% of starting material and 55% of dienes, by nmr. Repeated chromatography at low temperature on 5 and 3% aqueous deactivated neutral alumina afforded fractions containing four isomers of 4-(1′ or 4′)-acetoxy-4′-methyl(4′ or 1′)-nitrocyclohexa-2′,5′-dienyl)butyl nitrate (**11** and **10**, Table 1). Only the major isomer, 4-(1′-acetoxy-4′-methyl-4′-nitrocyclohexa-2′,5′-dienyl)butyl nitrate (**10***a*) was clearly separated from the others, as an oil; ir (film): 1740, 1240 ($OCOCH_3$), 1630, 1280 (ONO_2), 1545 (NO_2) cm^{-1}; nmr (CCl_4) δ: 1.70 (m, 6, 2-CH_2, 3-CH_2, 4-CH_2), 1.75 (s, 3, 4′-CH_3), 1.92 (s, 3, $OCOCH_3$), 4.35 (t, 2, J = 6 Hz, CH_2ONO_2), 5.95, 6.00 (q, 4, J = 10.4 Hz, 2′-*H*, 3′-*H*, 5′-*H*, 6′-*H*) ppm.

*Nitration of 3-(*p*-Tolyl)propionic Acid*

A solution of nitric acid (1.98 cm^3, 47 mmol) in acetic anhydride (9 cm^3) was added to a solution of 3-(*p*-tolyl)propionic acid (5 g, 30 mmol) in acetic anhydride (9 cm^3) at −78°C and the mixture warmed to 0°C. Evaporation of the solvent under reduced pressure gave a residue containing 70% of (two) dienes and 30% of aromatic compounds, by nmr. Crystallization from acetone–pentane gave one diastereomer of the lactone of 4-(1′-hydroxy-4′-methyl-4′-nitrocyclohexa-2′,5′-dienyl)propionic acid (**12***a*) which, after recrystallization from chloroform, had mp 138–139°C (dec.); ir (Nujol): 1790, 1180 (γ-lactone), 1530 (NO_2) cm^{-1}; nmr ($CDCl_3$) δ: 1.78 (s, 3, 4′-CH_3), 2.24 (t, 2, J = 7 Hz, 3-CH_2), 2.68 (t, 2, J = 7 Hz, 2-CH_2), 6.14 (nq, 2, J = 10.7 Hz, 2′-*H* and 6′-*H*), 6.20 (nq, 2, J = 10 Hz, 3′-*H* and 5′-*H*) ppm; ms (chemical ionization, methane) *m/e* (relative intensity): 192 (15, M − OH), 165 (15), 164 (100), 163 (80). Recrystallization of the residue from acetone–ether gave the second diastereomer of the dienyl lactone **12***b* which had mp 82–84°C (dec.); ir (Nujol): 1775, 1190 (γ-lactone), 1540 (NO_2) cm^{-1}; nmr ($CDCl_3$) δ: 1.71 (s, 3, 4′-CH_3), 2.15 (t, 2, 3-CH_2), 2.66 (t, 2, 2-CH_2), 6.08 (nq, 2, J = 10 Hz, 2′-*H* and 6′-H), 6.30 (nq, 2, J = 10 Hz, 3′-*H* and 5′-*H*) ppm; ms (chemical ionization, methane) *m/e* (relative intensity): 192 (15, M − OH), 165 (15), 164 (100), 163 (100).

The mother liquor from which the dienyl lactones had been crystallized was heated with acetic acid on the steam bath and, after work-up, chromatographed on silica gel using ether–pentane (20:80) for elution. The early fractions contained a component tentatively assigned the structure of 7-methyldihydrocoumarin; ms *m/e*: 162 (95, M) 134 (90, M − CO), 119 (65), 91 (100, $C_7H_7^+$), 77 (35), 39 (56). Later fractions contained mixtures of 3-(4′-methyl-3′-nitrophenyl)propionic acid and its 2′-nitro isomer with the former being present in greater amount in the final fractions. Recrystallization of the fractions and hand sorting of the crystals obtained gave 3-(4′-methyl-2′-nitrophenyl)propionic acid, nmr ($CDCl_3$) δ: 2.39 (s, CH_3), 2.74 (t, J = 7 Hz, 2-CH_2), 3.17 (t, J = 7 Hz, 3-CH_2), 7.28 (nq, J = 8 Hz, 6′-*H*), 7.34 (nq, J = 8 Hz, 5′-*H*), 7.76 (b s, 3′-*H*) ppm; and 3-(4′-methyl-3′-nitrophenyl)propionic acid, nmr ($CDCl_3$) δ: 2.54 (s, CH_3), 2.69 (t, J = 7 Hz, 2-CH_2), 2.99 (t, J = 7 Hz, 3-CH_2), 7.28 (nq, J = 8 Hz, 5′-*H*), 7.35 (nq, J = 8 Hz), 7.83 (b s, 2′-*H*) ppm.

The dienyl lactones were also isolated by neutralization of the nitration mixture with ammonia at low temperatures followed by extraction with ether and low temperature chromatography of the extract.

Nitration of p*-Tolylacetic Acid*

A solution of nitric acid (1.26 g, 20 mmol) in acetic anhydride (5 cm^3) was added to *p*-tolylacetic acid (1.5 g 10 mmol) in acetic anhydride (5 cm^3) at 0°C and the mixture stirred for 2 h. The nmr of the reaction mixture indicated that most of the *p*-tolylacetic acid had reacted and ca. 20% of diene products had been formed. A reaction carried out in which methylene chloride (10 cm^3) was added to increase the solubility of the *p*-tolylacetic acid gave a similar yield of dienes.

Rearomatization of Lactone **1***a*

A solution of lactone **1***a* (90 mg) in $CDCl_3$ (0.2 cm^3) at −78°C was treated with boron trifluoride etherate (0.4 cm^3) and warmed to ambient temperature. After work-up, ir and nmr showed that the product was mainly the lactone of 4-hydroxy-4-(*p*-tolyl)butyric acid (**8**). The minor product appeared to be 4-(4′-methyl-3′-nitrophenyl)butyric acid (δ 7.75 ppm).

Reaction, at 0°C, of lactone **1***a* with a solution of acetic anhydride in acetic acid (1:9 v/v) containing 0.05% sulfuric acid gave only lactone **8**.

Reaction, at 100°C of lactone **1***a* with aqueous acetic acid (1:9 v/v) gave a mixture of lactone **8** and carboxylic acids. The reaction was repeated on a 1 mmol scale. The carboxylic acids (~0.7 mmol) were extracted with aqueous bicarbonate and appeared to consist of a mixture of 4-(4′-methyl-3′-nitrophenyl)butyric acid (δ 7.25, 7.75 ppm) and 4(4′-methyl-2′-hydroxyphenyl)butyric acid (δ 6.85, 7.0, 7.05 ppm). The neutral fraction was lactone **8** (0.3 mmol).

Lactone **1***a* was recovered unchanged on refluxing for 1 h in benzene and also in methanol.

Enzymes in organic synthesis 17.[1] Oxidoreductions of alcohols, aldehydes, and ketones using chemically modified horse liver alcohol dehydrogenase

J. BRYAN JONES AND DAVID R. DODDS

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received April 12, 1979

J. BRYAN JONES and DAVID R. DODDS. Can. J. Chem. **57**, 2533 (1979).

The substrate specificity of acetimidylated (A-HLADH) and hydroxybutyrimidylated horse liver alcohol dehydrogenase (HB-HLADH) has been evaluated for the ethanol–acetaldehyde, *trans*-2-hexenol – *trans*-2-hexenal, furfural – furfuryl alcohol, benzaldehyde – benzyl alcohol, cyclobutanol–cyclobutanone, cyclopentanol–cyclopentanone, cyclohexanol–cyclohexanone, and cycloheptanol–cycloheptanone substrate couples. The pH-optima of A- and HB-HLADH are similar to that of native enzyme (~pH 7) for the reduction mode, but are displaced from the broad ~8–10.5 range for the native enzyme to ~11.8 for the modified enzymes in the oxidative mode. However, because of coenzyme instability, the practical pH optimum for oxidations remains 9 for both native and modified HLADH's. The modified enzymes provide limited synthetic advantages for the substrates evaluated.

J. BRYAN JONES et DAVID R. DODDS. Can. J. Chem. **57**, 2533 (1979).

On a évalué la spécificité de la déshydrogénase d'alcool extraite du foie de cheval à laquelle on a fixé des groupes acétymidyle (A-HLADH) et hydroxybutyrimidyle (HB-HLADH) vis-à-vis les systèmes de substrat éthanol/acétaldéhyde, hexène-2 ol-*trans*/hexène-2 al-*trans*, alcool furfurylique/furfural, alcool benzylique/benzaldéhyde, cyclobutanol/cyclobutanone, cyclopentanol/cyclopentanone, cyclohexanol/cyclohexanone et cycloheptanol/cycloheptanone. Les pH optima des A- et HB-HLADH sont semblables à celui (~pH = 7) de l'enzyme naturel pour le mode de réduction mais ils sont déplacés, dans le mode oxydant, de la large région ~8–10.5 applicable à l'enzyme naturel vers ~11.8 pour les enzymes modifiés. Toutefois due à l'instabilité du coenzyme, le pH optimum pratique pour les oxydations demeure 9 tant pour l'enzyme naturel que pour ses modifications. Les enzymes modifiés fournissent des avantages synthétiques limités pour les substrats évalués.

[Traduit par le journal]

The practicality of exploiting the chiral catalytic properties of enzymes for effecting asymmetric syntheses of broad organic chemical interest is well recognised (1, 2). Alcohol dehydrogenases are among the synthetically most useful enzymes, with the best documented of this group being the enzyme from horse liver, HLADH.[2] HLADH is a commercially available NAD^+/H-dependent alcohol dehydrogenase which catalyzes $CH(OH) \rightleftharpoons C{=}O$ oxidoreductions for a broad spectrum of substrates (1, 2). The oxidoreductions generally proceed via the ordered Theorell–Chance pathway, as represented in eq. [1] (3*a*). For many good substrates, E.NAD/H

$$[1]\quad E + NAD^+ \rightleftharpoons E.NAD^+ + S_{OH} \rightleftharpoons E.NAD^+.S_{OH} \rightleftharpoons E.NADH.S_{CO} \rightleftharpoons S_{CO} + E.NADH \rightleftharpoons E + NADH$$

dissociation is the rate-determining step (1*b*, 3*a*).

Although HLADH is one of the most versatile enzymes of proven practical value, experimental problems are encountered during preparative-scale oxidoreductions of slowly transformed substrates. Such reactions can take many days to go to completion, during which time extensive degeneration of the enzyme, the nicotinamide coenzymes, and the coenzyme recycling systems (1*b*) may occur. This can add considerably to the amounts of the biological materials which must be used in order to achieve complete conversion of a poor substrate to the desired product.

Some of the substrates of most organic chemical interest fall into the poor substrate category. In fact, many are oxidoreduced so slowly that preparative-scale reactions are currently impractical. Clearly the value of HLADH as an asymmetric synthetic catalyst would be greatly enhanced if the catalytic activity of the enzyme towards slow substrates could be increased. The enhanced catalytic activities observed by Plapp and co-workers (4) for chemically modified HLADH presented an attractive possibility in this regard. Accordingly, we have carried out a comparative study of A-HLADH[2]- and HB-HLADH[2]-catalyzed oxidoreductions of a selected structural

[1]For Part 16, see ref. 1*a*.

[2]Abbreviations used: HLADH, horse liver alcohol dehydrogenase; NAD^+ and NADH, oxidized and reduced forms respectively of nicotinamide adenine dinucleotide; S_{OH}, alcohol substrate; S_{CO} carbonyl substrate; A-HLADH, acetimidylated HLADH; HB-HLADH, hydroxybutyrimidylated HLADH.

0008-4042/79/192533-06$01.00/0

range of acyclic and cyclic alcohols, aldehydes, and ketones.

Results

A-HLADH and HB-HLADH were prepared by modification of native HLADH with ethyl acetimidate and 4-bromobutyramide respectively (4*b*, *d*, *f*). The modified enzymes were found to possess 7-fold (A-HLADH) and 19-fold (HB-HLADH) the activity of native HLADH with respect to catalysis of ethanol oxidation.[3] The modified enzymes were somewhat less stable than native HLADH when stored at 4°C in 0.05 *M* Tris/HCl buffer pH 7.4. Both A- and HB-HLADH lost up to 35% of their activity during 1 week under these conditions, as determined by acetaldehyde reduction and ethanol oxidation assays at pH 7 and 9 respectively. The stabilities of the modified enzymes were not improved by the addition of up to 0.5 m*M* EDTA. The loss of activity was slightly greater when phosphate buffer was used. However, when A-HLADH stored as described above at pH 7.4 for 3 weeks was assayed in its oxidation mode at pH 11, >90% of activity was retained.

The pH-profiles were determined for both modified enzymes using acetaldehyde and ethanol as substrates. The results are summarized in Fig. 1.

The kinetics of oxidoreduction of the alcohol, aldehyde, and ketone substrates selected for study were determined at pH 7 for reduction and pH 9 for oxidation. The results obtained with each enzyme are summarized in Tables 1 and 2.

Discussion

A wide selection of reagents has been used to modify HLADH (4, 5–11). In contrast, the range of substrates used to evaluate the oxidoreduction properties of the modified enzymes has been restricted to those of the ethanol ⇌ acetaldehyde, benzyl alcohol ⇌ benzaldehyde, and cyclohexanol ⇌ cyclohexanone reactions. A more extended structural specificity data base was clearly needed in order to evaluate the organic synthetic advantages of the modified enzymes. With this aim in mind, structurally more diverse substrates encompassing a representative range of acyclic and cyclic aliphatic and aromatic structures (Tables 1 and 2) were selected for examination. Achiral compounds only were considered at this stage, leaving the important question of the effect of the enzyme modifications on stereospecificity to be examined subsequently with appropriate chiral substrates.

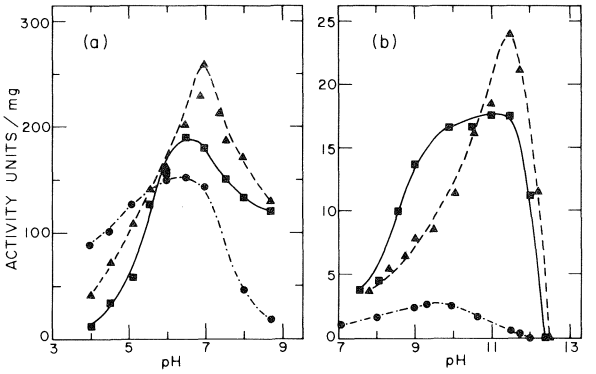

FIG. 1. pH Profiles for HLADH (●), A-HLADH (▲), and HB-HLADH (■)-catalyzed (*a*) reduction of acetaldehyde and (*b*) oxidation of ethanol. Close to optimum substrate concentrations[3] were used for each profile.

Various degrees of activation, or inactivation, can be induced by different chemical modifications of HLADH (4, 5–11). The highest activation levels are achieved by imidylation of the ε-amino group of Lys-228 (4*c*). Acetimidylation and hydroxybutyrimidylation were selected as two simply effected activations permitting comparisons of the consequences of introducing both a small (A) group and a larger, conformationally flexible, one (HB). Such modifications effect activation of HLADH by increasing the velocity of the, for many substrates, rate-limiting dissociation of coenzyme from the E.NAD/H binary complex (4).

The activations were performed in triethanolamine–HCl buffer pH 8 (4*b*, *d*).[4] The 7- and 19-fold[3] levels of activation achieved for A-HLADH and HB-HLADH respectively were in accord with the literature values (4*f*). Modifications performed at pH 10 (12) in phosphate buffer were less satisfactory, giving ≤3-fold activations only. In our hands, the modified enzymes were less stable than previously reported (4*d*). In contrast to native enzyme, which is unaffected by ≥2 weeks storage at pH 7.4 at 4°C, both A- and HB-HLADH lost up to 5% of their activity every 24 h under the same storage conditions. Accordingly, all kinetic data for the modified enzymes were obtained with freshly prepared, <1 day old, A- and HB-HLADH.

[3]The assays were performed as recommended (4*a*) under conditions favourable to the modified enzymes, i.e., with [EtOH] at 550 m*M*. Native HLADH is subject to substrate inhibition at this EtOH level, and retains only 40% of its activity in the standard assay, in which [EtOH] is 9 m*M* (3*b*). The activation levels of the modified enzymes relative to native HLADH would therefore be ~3-fold (A-HLADH) and ~7.5-fold (HB-HLADH) if the activity of each under its individual optimum assay conditions were used as the basis of comparison.

[4]HLADH modifications performed in phosphate buffer of the same pH in the absence of triethanolamine gave a 60%-*deactivated* enzyme preparation. B.V. Plapp (personal communication) has also found phosphate alone to be a poor buffer.

TABLE 1. Kinetic data for HLADH-, A-HLADH-, and HB-HLADH-catalyzed reductions[a]

Substrate	K_m (mM)			k_{cat} (s^{-1})		
	HLADH[b]	A-HLADH[c]	HB-HLADH[c]	HLADH[b]	A-HLADH[c]	HB-HLADH[c]
CH_3CHO	0.33	1.18	2.24	132.3	136.7	175.9
$CH_3(CH_2)CH{=}CHCHO$	0.16	0.61	1.24	20.0	35.8	44.3
Furfuraldehyde	0.20	13.8	2.25	110.8	209.5	37.6

[a]Determined at 25°C in 0.1 M glycine–NaOH buffer pH 9.0.
[b][NAD^+] 0.5 mM, [S] 0.01–10.0 mM.
[c][NAD^+] 2.0 mM, [S] 0.01–10.0 mM.

The rate of loss of activity on storage was found to be sensitive to the pH at which the assays were performed. For example, A-HLADH kept at pH 7.4 at 4°C for three weeks lost only 10% of its activity with respect to ethanol oxidation at pH 11. This observation, and the fact that HB-HLADH showed a monotonic increase in activity up to pH 9.9 with benzyl alcohol as substrate (4*h*), prompted the pH-activity profile study summarized in Fig. 1 for the acetaldehyde $\rightleftharpoons$ ethanol substrate couple. The results for both oxidation and reduction are remarkable in that the modified enzymes show much higher activities at elevated pH's than does the native enzyme. The oxidation mode is the more noteworthy, with the pH-optima for A- and HB-HLADH occurring at ~11.8. The data at pH > 10 required increasingly large corrections for the pseudo-base reaction of NAD^+ (13).[5] At pH > 12, the rate of this reaction became the limiting factor, and the apparent loss of activity at pH ≥ 12.5 is due to the effectively instantaneous conversion of NAD^+ to its pseudo-base under these conditions. As a result, the practical pH-maximum for routine assays or preparative-scale reactions remains 9 for both native and modified HLADH.

For the reductive mode (Fig. 1*a*), the inflection points of each curve occur at about the same pH's, viz. ~6.4 and ~7.8 (14). This implies that the ionizing groups responsible for the characteristic pK_a's of HLADH-catalyzed reduction of acetaldehyde (4*g–i*, 10*a*, 14–17) are not affected by Lys-228 imidylation, and that the modified Lys-228 does not exert any electronic effects during reduction. This is in accord with the conclusion that the imidylated HLADH's continue to follow the mechanistic pathway outlined in eq. [1] (4*a*,*f*). On the other hand, the pH profile of ethanol oxidation (Fig. 1*b*) shows a large shift to higher pK_a for the modified enzymes, from ~6.3 for the native enzyme (14) to ~9 for HB-HLADH and ~10 for A-HLADH. The current data are insufficient to enable the reasons for these shifts to be identified. Electronic effects due to the conversion of the lysine residues of the native enzyme

[5]At pH 10.5, the half-life of NAD^+ under our assay conditions was ≤4 h.

($pK_a \sim 10.5$) to guanidine-like groups ($pK_a \sim 12$ (18)) on imidylation, together with accompanying conformational, isomerization, and steric changes (4*e–h*, 8, 11, 18–21) may all contribute. In addition, these factors may also account collectively for the need to increase [NAD^+] in oxidations involving modified HLADH's (Table 2). For reductions, all the pH-profiles have the same form and no corresponding [NADH] increase is required when assaying the modified enzymes (Table 1).

The kinetic constants of Tables 1 and 2 do not follow a simple pattern. Under reductive mode conditions (Table 1) only two of the substrates, acetaldehyde and furfuraldehyde, have k_{cat} values consistent with NAD^+ dissociation from the E.NAD^+ complex (eq. [1]) being rate-determining in native enzyme-catalyzed reductions (3*a*). HLADH-mediated reductions of the other substrates are significantly (up to 400-fold) slower, presumably reflecting the fact that the hydride transfer step, or product–alcohol dissociation (22), have become at least partly rate-limiting.

With the exception of the 41-fold increased k_{cat} of A-HLADH-catalyzed reduction of cyclopentanone, fairly modest rate increases only are observed for modified enzyme-mediated reductions of the Table 1 substrates. In fact, for several substrates the k_{cat} values are more or less the same for all three enzymes and, in one or two cases, for example HB-HLADH-catalyzed reductions of cyclohexanone and benzaldehyde, the modified enzymes are slightly less effective than HLADH itself.

The situation with respect to oxidation is quite different. In contrast to their Table 1 carbonyl counterparts, the alcohol substrates of Table 2 are generally significantly more efficiently oxidized in the presence of the imidylated HLADH preparations than with the native enzyme. The only exceptions are cyclobutanol and cyclopentanol, both of which are poor substrates of unmodified HLADH also. The increases in oxidative mode k_{cat} values with modified HLADH's are greatest for alcohols such as ethanol, *trans*-2-hexenol, cyclohexanol, and cycloheptanol, which are also good substrates for native HLADH. This is as expected since E.NADH dissociation is rate-limiting for good substrates of this kind, and the imidylation of the Lys-228 residue in the A- or HB-modifications of HLADH has been shown to increase the rate of this limiting dissociation step (4). For the remaining Table 2 alcohols, all of which are somewhat poorer substrates than the four mentioned above, the normal k_{cat} values are augmented to a smaller degree by A- or HB-modification of HLADH. This is again as expected since the rates of hydride-transfer or substrate-diffusion steps become dominant for poorer substrates (3*a*, 4*f*, 11*c*, 16*b*, 19, 20), thus reducing, or even eliminating, the impact of Lys-228 modifications, which have their greatest impact on the E.NADH dissociation step.

For all the carbonyl and alcohol substrates examined, the K_m values are higher, often considerably so, for the modified enzyme oxidoreductions than for the corresponding native enzyme-catalyzed reactions. While the K_m values recorded in the Tables are not Michaelis constants as usually defined (23), they are considered to reflect relative binding affinities of the substrates under the saturating coenzyme concentration conditions employed in the assays. Each substrate is clearly less well bound by A- and HB-HLADH than by the native enzyme (4*e*, *f*, *h*).

While many of the kinetic questions arising from the current study remain to be answered, the results obtained do provide a clear perspective with regard to our main objective of assessing the preparative potentials of the modified enzymes.

In both reduction and oxidation modes, the modified HLADH's can be expected to show significant rate enhancements for good substrates where E.NAD/H dissociation (eq. [1]) remains rate determining. Primary alcohols and aldehydes, and many cyclic six- and seven-membered ring alcohols, will be in this category. For poorer substrates, into which group most alcohols and ketones of organic chemical interest will fall, modest rate enhancements may be anticipated in the oxidation mode. At present, A- or HB-HLADH do not appear to offer any significant advantages over the native enzyme for effecting reductions of slower substrates of this kind.

Experimental

HLADH (EC 1.1.1.1) is commercially available from Worthington or Boehringer. NAD^+ (>99% purity) and NADH (>98% purity) were purchased from Sigma. All substrates were obtained from Aldrich or Fisher and were purified prior to use.

Preparation of A-HLADH and HB-HLADH

A-HLADH

The general procedure of Plapp and co-workers (4*b*, *d*) was used. Ethyl acetimidate (1 g (24)) in water (2 mL) was brought to pH 8.0 with concentrated aqueous sodium hydroxide to a final volume of 4 mL of a 2.1 *M* solution. An aliquot (100 μL) of this solution was added every 15 min to HLADH (5 mg) dissolved in triethanolamine–HCl buffer (2 mL, 0.5 *M*, pH 8.0) at 25°C. (It is recommended that the ethyl acetimidate solution be freshly made up prior to each addition.) After four additions (1 h), the mixture was passed through a Sephadex G-50 (1.5 cm × 30 cm) column and eluted with 0.05 *M* Tris-HCl buffer, pH 7.4. The protein-containing fractions were monitored at 280 nm, with an OD of 0.455 taken as 1 mg/mL. The A-HLADH obtained consistently assayed (4*a*) for 6.5–7.0 μ/mg. This corresponds to ~7-fold activation

with respect to native enzyme, which showed 0.92 μ/mg activity under these modified enzyme assay conditions. The modified enzyme was stored as its pH 7.4 solution at 4°C.

HB-HLADH

The procedure described above was used, with 4-bromobutyramide (45 mg (4*d*)) added all at once and using a reaction period of 2 h. The HB-HLADH obtained consistently showed activity of 17.5–18.0 μ/mg, corresponding to ~19-fold activation. It was stored as for A-HLADH at 4°C.

Kinetic Studies

Reductions

Kinetic runs were carried out at 25°C in 0.1 *M* phosphate buffer pH 7.0 with [NADH] 0.2 m*M*. The reactions were initiated by the addition of 10–40 μL of enzyme solution having an OD of 0.400 at 280 nm to make a final volume of 3.0 mL in a 1 cm-pathlength quartz cuvette. This was up-ended briefly to ensure mixing and the absorbance change at 340 nm measured using a Unicam SP 1800 spectrophotometer. The initial rates at each substrate concentration were analyzed in a Lineweaver–Burk manner by the least squares method. Correlation coefficients were ≥0.995 in each case. The k_{cat} values were obtained taking the molecular weight of HLADH as 80 000 and the extinction coefficient of NADH as 6 220. The substrate concentration ranges used, for HLADH, A-HLADH, and HB-HLADH, respectively, were (in m*M*): acetaldehyde (0.04–0.3; 0.6–1.5; 0.3–2.7), *trans*-2-hexenal (0.03–0.4; 0.06–1.5; 0.3–2.0), furfuraldehyde (0.012–0.036; 0.006–0.33; 0.03–0.33), benzaldehyde (0.013–0.13; 0.006–0.14; 2.0–20.0), cyclobutanone (1.5–11.0; 4.0–40.0; 4.0–40.0), cyclopentanone (1.3–9.0; 10.0–100.0; 10.0–180.0), cyclohexanone (1.3–7.5; 0.6–5.5; 0.6–6.0), 4-methylcyclohexanone (0.3–5.0; 1.5–10.5; 0.6–11.0), and cycloheptanone (0.3–3.3; 4.0–30.0; 1.3–9.3). The results obtained are recorded in Table 1.

Oxidations

The procedures described above were applied using 0.1 *M* glycine–NaOH buffer pH 9.0. [NAD^+] was 0.5 m*M* for HLADH and 2.0 m*M* for A- and HB-HLADH. The substrate concentration ranges used, in m*M*, for HLADH, A-HLADH, and HB-HLADH, respectively, were: ethanol (0.03–0.6; 0.3–6.0; 0.1–2.0), *trans*-2-hexenol (0.01–0.08; 0.02–1.2; 0.02–1.2), furfuryl alcohol (0.01–0.25; 0.01–0.15; 0.016–0.5), benzyl alcohol (0.007–0.07; 0.016–0.4; 0.03–0.33), cyclobutanol (0.007–0.1; 0.01–0.06; 0.016–0.1), cyclopentanol (0.01–0.13; 0.13–2.3; 0.03–0.3), cyclohexanol (0.06–1.0; 0.09–11.0; 0.3–4.0), *cis*-4-methylcyclohexanol (0.06–1.0; 0.1–0.7; 0.1–1.5), *trans*-4-methylcyclohexanol (0.01–0.16; 0.1–1.0; 0.1–2.5), and cycloheptanol (0.06–0.6; 0.16–2.0; 0.06–0.17). The results obtained are recorded in Table 2.

pH-Profiles

The pH-profiles were determined using the standard assay procedure (3*a*) with 0.1 *M* phosphate buffer for the pH range 4.0–8.7 and 0.1 *M* glycine–NaOH for pH >7.5. Acetaldehyde and ethanol were used as substrates for the reductive and oxidative modes respectively. The substrate concentrations were 9 m*M* for HLADH and 550 m*M* for the modified enzymes. The corresponding coenzyme concentrations employed were: reductions, [NADH] 0.2 m*M*; oxidations, [NAD^+] 0.5 m*M* with HLADH, 2.0 m*M* with A- and HB-HLADH.

Acknowledgements

Support of this work by NSERC is gratefully acknowledged. We also express our gratitude to Hoffmann-La Roche for additional financial aid and for a generous gift of enzyme, and to Ogilvie Flour Mills Ltd. for the award of a Kenneth Armstrong Memorial Fellowship (to D.R.D.).

MICHEL BELLETÊTE and GILLES DUROCHER. Can. J. Chem. **57**, 2539 (1979).

Fluorescence and phosphorescence spectra of a few *p*-substituted benzylideneaniline (BA) molecules have been obtained in the EPA solvent. Results show that the ϕ_p/ϕ_f ratio increases regularly with an increase in the static dipole moment of the molecules except for the most polar molecule where the fluorescence is much more intense.

Moreover, it has been shown that the interaction of the BA molecules with aprotic polar solvents is solvatochromic in origin, meaning that no specific solute–solvent interactions had been detected. It has been shown that the BA molecules behave like the D—Ar—A molecular type as far as the photophysical aspect is concerned.

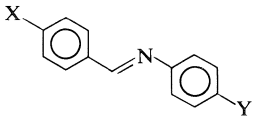
MICHEL BELLETÊTE et GILLES DUROCHER. Can. J. Chem. **57**, 2539 (1979).

Les spectres de fluorescence et de phosphorescence de quelques molécules de benzylideneaniline (BA) *para*-substituées ont été obtenus dans l'EPA utilisé comme solvant. Les résultats démontrent que le rapport ϕ_p/ϕ_f augmente régulièrement en fonction du moment dipolaire de l'état fondamental des molécules de BA étudiées à l'exception de la molécule de BA la plus polaire où la fluorescence est plus intense.

Il est de plus démontré qu'un effet solvatochrome normal explique l'interaction entre les BA et un solvant polaire aprotique. Aucune interaction spécifique soluté–solvant n'a pu être mise en évidence dans ces solvants. Il est démontré que le comportement photophysique des BA est semblable à celui des molécules plus connues du type D—Ar—A.

Introduction

The absorption spectroscopy of the para-substituted benzylideneaniline (BA) molecules has been studied in recent years and for a review of the literature we refer the reader to parts I and II of this series of papers (1, 2). Very few papers exist on the emission spectroscopy of these molecules (3–6). In order to carry on our work on the intramolecular charge transfer states in these kind of molecules, we had to investigate their emission properties. The purpose of this paper is two-fold; first of all, we would like to establish the conditions where molecular emissions can be detected and secondly, we would like to propose a mechanism by which the highly polar excited states in those molecules interact with polar solvents. The molecules studied here are the following using the same notation as described in an earlier paper (2):



6: X = $N(CH_3)_2$, Y = NO_2
5: X = OCH_3, Y = NO_2
3: X = H, Y = NO_2
2: X = OCH_3, Y = H
4: X = OCH_3, Y = OCH_3

Experimental

The BA molecules have been synthesized and purified as described previously (1, 2). The EPA solvent (5:5:2 mixture of diethyl ether, isopentane, and ethanol) was prepared in the laboratory. Diethyl ether and ethanol were purified as described previously (2). Isopentane (pure grade from Phillips Petroleum Co.) was distilled over concentrated sulfuric acid, washed with triply distilled water, and distilled again over sodium. Methylcyclohexane (pure grade from Phillips Petroleum Co.) was distilled over concentrated sulfuric acid, washed with distilled water, distilled again over sodium, then chromatographed on a 5 ft silica gel column and stored in the dark. Acetonitrile and dimethylformamide (DMF) (reagent grade, Anachemia Chemicals Ltd.) were purified as described previously (2).

The emission spectra (fluorescence and phosphorescence) were measured with a Fluorispec Baird Atomic Model SF-1 spectrofluorometer modified to accommodate a 1000 W Xenon arc lamp at the entrance of the excitation monochromator (7). The fluorescence spectra have been recorded with all samples at room temperature and at 77 K and the phosphorescence spectra have been recorded with all samples at liquid nitrogen temperature. The EPA solvent was used for the latter and the sample concentrations were of the order of 5×10^{-5} *M*.

Results and Discussion

Among the *p*-substituted BA molecules studied earlier (2), only those molecules with substituents favoring an electron migration from X to Y, that is to say stabilizing the intramolecular charge transfer state, have been shown to give any measurable emission: fluorescence or phosphorescence.

*Following ref. 2.
†Only indicative of the limiting value.

Results are given in Table 1 in which the phosphorescence to fluorescence quantum yield ratios (ϕ_p/ϕ_f) have been obtained through excitation in the first absorption peak maximum of each solute molecule and by further correction for the sensitivity of the emission monochromator–PM system versus the emission wavelength. Results show clearly that the ϕ_p/ϕ_f ratio increased regularly with an increase in the static dipole moment of the molecules except for molecule **6** where the fluorescence is much more intense than for other molecules and the phosphorescence has hardly been observed. McGlynn *et al.* obtained the same kind of behavior in their study of the luminescence of polar molecules of the type D—Ar—A (8). The dipole moment of the ground states of these molecules varies as *p-* > *m-* > *o-*. The low energy highly polar excited states of these molecules are referred to as "charge transfer" states and the phosphorescence intensity as well as the S_1–T_1 intersystem crossing efficiency vary in the order *p-* > *m-* > *o-*. In less polar aniline derivatives, the intersystem crossing is apparently not quite as efficient and weak fluorescence can be observed. Moreover, *N*-methylation of *p*-nitroaniline by lowering the effective ionization potential of the amino group (makes it a better electron donor and increases the dipole moment of the molecule) has a pronounced effect on the luminescence behavior of *p*-nitroaniline. The efficiency of intersystem crossing seems to decrease to a point where fluorescence again is observable.

The intramolecular charge transfer states in the benzylideaniline molecules seems to have the same photophysical behavior as the smaller aniline derivatives. Substitution effect greatly alters the energies and the polarities of the various electronic excited states which in turn are responsible for the various non-radiative probabilities between the excited states and the ground state.

Are there any specific interactions between the excited BA molecules and polar solvents? In view of the fact that the excited dipole moments of the BA molecules are quite large (2), exciplex formation with highly polar solvents may be possible at room temperature (9). Molecule **6** which possesses the highest static dipole moment in the ground state was dissolved in methylcyclohexane (MCH) and their absorption and fluorescence peak maxima were studied with various amounts of ethanol, acetonitrile, and DMF added to the MCH solution.

The fluorescence peak maxima of molecule **6** dissolved in a non-polar solvent like MCH is at 21 300 cm^{-1} compared to 19 200 cm^{-1} when it is dissolved in EPA which is a 5:5:2: mixture of ether, isopentane, and ethanol. Since no fluorescence could have been detected when molecule **6** is dissolved in ether alone, we can say that ethanol is the solvent responsible in EPA for the fluorescence observed. When ethanol is added to a MCH solution of molecule **6**, a red shift in the fluorescence peak maximum is observed but no new fluorescence emission which might be assigned to an exciplex (9) could be detected. Moreover, the fluorescence intensity does not change much with the addition of ethanol. On the other hand the relation of Lippert–Mataga on the solvatochromic shift does not hold (10–12).

Since the polarizability function $F(D,n)$ in the Lippert–Mataga equation (10–12) is about the same for ethanol, acetonitrile, and DMF, it would be interesting to compare the effect of adding the last two solvents to a MCH solution of molecule **6**.

Results for DMF are reported in Table 2. The absorption peak maximum of molecule **6** is not much influenced by these small amounts of DMF added to the MCH solution.

Table 2 shows that the fluorescence intensity at the peak maximum markedly increases with the amount of DMF added. This behavior is contrary to that observed when exciplex formation is present in that there is normally a quenching of the fluorescence and appearance of a new emission band at lower energies (9). McGlynn *et al.* (8) also observed an increase in the fluorescence intensity of the D—Ar—A type of molecules they have studied. Table 2 also shows that the fluorescence is red-shifted for the relatively small amounts of DMF added.

In order to verify whether this shift is solvato-

TABLE 2. Effect of small amounts of DMF added to the MCH solution of 4-dimethylaminobenzylidene-4′-nitroaniline (**6**) on the first electronic absorption and fluorescence peak maxima

%DMF (V/V)	$\bar{\nu}_A$ (cm^{-1})	$\bar{\nu}_F$ (cm^{-1})	I_F (r. unit)	$\bar{\nu}_A - \bar{\nu}_F$ (cm^{-1})	$F(D,n)$

4.15	26 000	19 000	92	7 000	0.213

chromic in nature, we have calculated the excited state dipole moment of molecule **6** using the method proposed by Lippert (10) and Mataga *et al.* (11, 12). The slope of the graph, $\bar{\nu}_A - \bar{\nu}_F$ vs. $F(D,n)$ $[\equiv (D-1)/(2D+1) - (n^2-1)/(2n^2+1)]$, where D and n are respectively the dielectric constants and the refraction index of the medium, gives access to the excited state dipole moment when the ground state dipole moment along with the cavity radius of the solute molecule are known (2, 10–12). From the results contained in Table 2, an excited state dipole moment of 39 D has been calculated. This value is in very good agreement with that of 38 D already published by Lippert *et al.* (10). So, the red-shifted fluorescence observed when molecule **6** is dissolved in DMF is only due to a normal solvatochromic effect (10–12). Exactly the same behavior has been observed with acetonitrile. We take this as another proof, apart from the fluorescence intensity behavior, to conclude that no specific interaction exists between the highly polar benzylideneaniline molecules and the aprotic polar solvents. Ethanol does not behave like aprotic solvents and work is still in progress in order to be sure that some specific interactions do exist with the BA molecules.

Conclusions

The emission spectroscopy of the *p*-substituted BA molecules with substituents favoring an electron migration from X to Y seems to be similar in many respects to the spectroscopy of polar molecules of the type D—Ar—A in that the photophysical behavior seems to be the same and, moreover, the interaction of the BA molecules with aprotic polar solvents seems to be solvatochromic in origin.

Osmotic and activity coefficients of lithium chloride in water from 50 to 150°C

ALAN N. CAMPBELL AND OM N. BHATNAGAR

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received April 18, 1979

ALAN N. CAMPBELL and OM N. BHATNAGAR. Can. J. Chem. **57**, 2542 (1979).

The activity coefficients of lithium chloride in aqueous solution at temperatures of 50, 75, 100, 125, and 150°C and concentrations varying from 0.5 to 3 *m* have been determined. The method used was the application of the Gibbs–Duhem theorem, i.e., the activity of the solvent water was the quantity actually determined. The experimental determination was that of the vapour pressure of the solution using a differential manometer. At all temperatures the activity coefficient passes through a minimum and then increases progressively.

ALAN N. CAMPBELL et OM N. BHATNAGAR. Can. J. Chem. **57**, 2542 (1979).

On a déterminé les coefficients d'activité de solutions aqueuses de chlorure de lithium à 50, 75, 100, 125 et 150°C et à des concentrations allant de 0.5 à 3.0 *m*. On a fait appel à une méthode basée sur le théorème de Gibbs–Duhem c'est à dire que l'on a déterminé de fait l'activité de l'eau agissant comme solvant. On a déterminé expérimentalement la tension de vapeur de la solution en utilisant un manomètre différentiel. A toutes les températures, le coefficient d'activité passe par un minimum avant de croître d'une façon progressive.

[Traduit par le journal]

Introduction

It is not necessary to stress the importance of osmotic and activity coefficients in the study of solutions of electrolytes. Because of this importance a wealth of data has accumulated since the concept of activity was first introduced some seventy years ago. Most of these data, however, were obtained at room temperature (say 25°C). Knowledge of activity at elevated temperatures is perhaps even more important than at room temperature but the amount of such data is small. The reason obviously lies in the experimental difficulty of the work at temperatures above 100°C.

Some thermodynamic work has been done at higher temperatures (1, 2) but in many instances the data lack precision. Osmotic coefficients for NaCl solutions have been reported up to 270°C by Gardner and co-workers (3, 4). In their admirable work, Liu and Lindsay (5, 6) carried out a detailed and systematic study of osmotic and activity coefficients of aqueous sodium chloride solutions up to 300°C and from a concentration of 0.1 *m* to saturation. These workers also investigated to a limited extent salts such as LiCl, CsCl, $MgCl_2$, $MgSO_4$, etc. Their technique was essentially that of the present study, viz. determination of the vapour pressure of the solvent or, more correctly, the difference between the vapour pressure of solvent in solution and in the pure state. Application of the Gibbs–Duhem theorem then yields the activity of the electrolyte.

Soldano and co-workers (7–10) have reported the osmotic coefficients of a number of electrolytes at temperatures up to 165°C in the concentration range 0.5 up to 8 *m* using the isopiestic method.

The whole study of the thermodynamic properties of electrolytic solutions above 100°C is in a fragmentary state, and it seemed to us that systematic work should be done on these properties as functions of temperature and concentration. We have chosen to study the osmotic and activity coefficients of 1:1, 1:2, and 2:2 electrolytes. Our first report deals with lithium chloride at temperatures from 50 to 150°C and over a concentration range from 0.5 to 3.0 *m*.

Experimental

Analytical grade lithium chloride was used without further purification. The concentrations of the solution were determined by gravimetric analysis as silver chloride. The solvent was triply distilled conductance water. To avoid contact with air, the solutions were prepared by the method of Lindsay and Liu (11). The vapour pressures of the solutions were measured by means of a differential manometer (Fig. 1), one limb of which contained the solution and the other pure water or, in the case of concentrated solutions, a solution of lithium chloride or sodium chloride, whose vapour pressure had previously been determined. The latter procedure was inevitable because, with concentrated solutions, the difference in vapour pressure from that of pure water was so great that it exceeded the pressure range of the manometer. The liquids in the manometer were degassed by freezing in liquid nitrogen, pumping down, melting, refreezing, and so on.

The differential manometer was enclosed in a stainless steel pressure bomb, with windows of pressure resistant glass. The glass used for these windows was obtained from Corning Glass Works, Corning, NY. Effectually to remove the manometer itself from high pressure, pure water was always placed at the bottom of the bomb. Thus, the only high pressure developed was that on the interior of the bomb.

0008-4042/79/192542-04$01.00/0

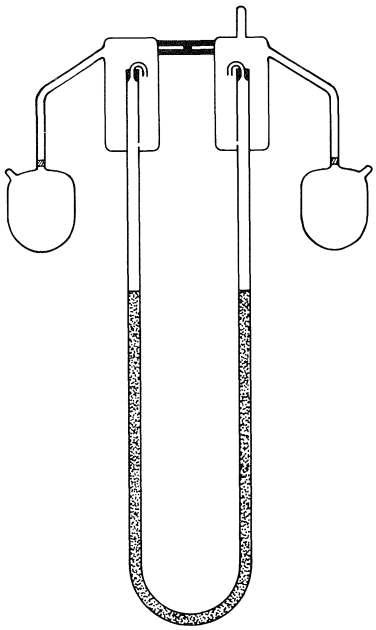

FIG. 1. Differential manometer.

The bomb, which was very heavy, was raised by means of a crane and lowered into a large oil bath, also furnished with glass windows, and containing about 25 gallons of oil.[1] The bath was stirred by two stirrers. Temperature control was obtained by means of a Sargent Thermonitor, model ST, temperature control unit. The temperature of the oil bath was constantly monitored using multijunction thermocouples. An exploration with a thermocouple at different points in the bath showed that the temperatures at different points did not differ by more than ± 0.05°C. The temperature was constant to ± 0.05 up to 100°C, and to ± 0.1°C between 100 and 150°C. In order to check the reproducibility of our equipment and technique, we measured the vapour pressure of 1 *m* NaCl at 75 to 150°C. Our values of osmotic coefficients were within 1% of those reported by Liu and Lindsay (5) for 1 *m* NaCl solutions.

Results

At each temperature several readings of vapour pressure were taken, over a time period of a few hours, after equilibrium had been reached. For each temperature, the readings were taken twice, once after the temperature had been raised and once after cooling from a higher temperature. If the two readings did not agree within 1%, the results were rejected. Otherwise, the two readings were averaged to give the pressure difference (ΔP). The manometric liquid was mercury throughout and the ΔP values were corrected to the density of mercury at 0°C. The solutions were analyzed after each experiment, and it was these concentrations which were used in the calculations. These concentrations were then corrected to the appropriate temperature, as suggested by Lindsay and Liu (11).

The osmotic coefficients were calculated from the following:

$$[1]\quad \phi = \frac{1000}{\nu m M_1 RT}\left[RT \ln \frac{P^0}{P} - \int_P^{P^0} \xi \mathrm{d}p - V_1{}^0(\mathrm{l})\Delta P\right]$$

where ϕ is the osmotic coefficient, T is the absolute temperature, R the gas constant, M_1 the molecular weight of the solvent water, m the molality, ν the number of ions resulting from the complete ionisation of one molecule, P^0 the vapour pressure of pure water, and P the vapour pressure of the solution (solute assumed non-volatile).

The first term in the brackets gives the osmotic coefficient at low vapour pressures, the second term gives the corrections for the deviations of the vapour from the perfect gas law, and the third term is an adequate approximation for the isothermal compression of the solution from its own vapour pressure to that of pure water. The integrand, ξ, was calculated using the equation given by Smith, Keyes, and Gerry (12). $V^0(\mathrm{l})$, the molar volume of pure water and P^0 were calculated from the equations given in ref. 12. As usual, $V^0(\mathrm{l})$ is used instead of $\bar{V}_1(\mathrm{l})$, the partial molar volume of water, because under these conditions the difference is negligibly small. The osmotic coefficients obtained from eq. [1] are listed in Table 1.

The mean ionic activity coefficients, $\gamma\pm$, were calculated using the osmotic coefficients of Table 1 from eq. [2].

$$[2]\quad \ln \gamma\pm = -2\int_0^{m^{1/2}} \frac{1-\phi}{m^{1/2}} \mathrm{d}m^{1/2} - (1-\phi)$$

The Debye–Hückel limiting values were used to evaluate the above integral in the dilute region; the integration was done graphically. The results for mean ionic activity coefficients are also given in Table 1.

In Fig. 2, we have plotted our results for osmotic coefficients vs. the square root of concentration. Our values from 1 *m* lithium chloride at 125 and 150°C are in good agreement with those of Lindsay and Liu (11). The results of Soldano *et al.* refer to temperatures of 99.6 and 151.4°C (7, 10). Our values for 100 and 150°C are in reasonable agreement at lower concentrations, but, at higher concentrations the agreement with Soldano is poor.

In all cases, the osmotic coefficients increase with

concentration and with temperature up to about 100°C, after which temperature they decrease. Similar behaviour is observed with sodium chloride (5) although here the temperature of the maximum is about 65°C.

We are unable to understand Soldano's curves in the lower part of his Fig. 1 (10) for 151.4°C since it is necessary for all such curves to have their origin at $\phi = 1.0000$, at $m = 0$.

Discussion

In Fig. 3 (a comparison of the osmotic coefficients of lithium chloride and of sodium chloride at 75 and at 150°C) it appears that the difference in the osmotic coefficients of the two salts becomes small at 150°C. When ϕ is plotted against $m^{1/2}$, the results of Soldano show the curves for LiCl at 151.40 intersecting but our results show no intersection up to 3.2 m at 150°C.

Lindenbaum *et al.* (13) reported the osmotic coefficients of a number of ternary alkyl ammonium salts. They found the order of magnitude to be $(C_4H_9)_4NCl > (C_3H_7)_4NCl > (CH_3)_4NCl$ at 25°C,

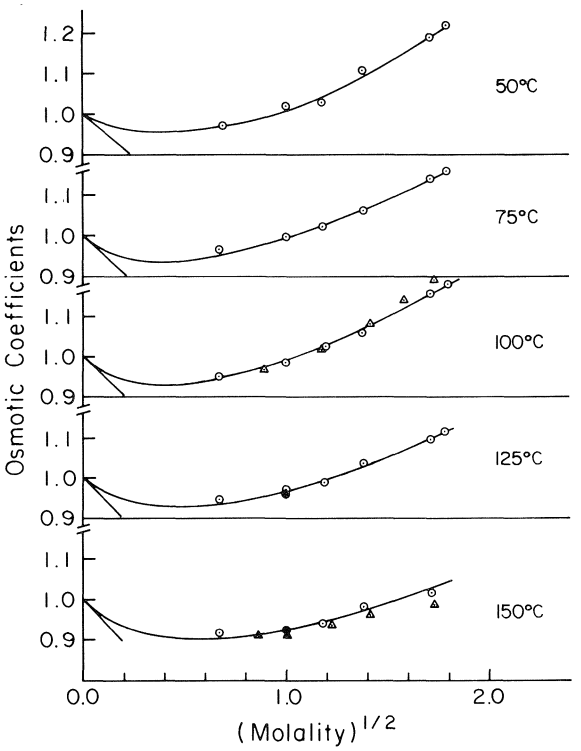

FIG. 2. Osmotic coefficient (ϕ) vs. (molality)$^{1/2}$: ○, present work; ●, data from ref. 11; △, data from refs. 7, 10 at 99.6 and 151.4°C.

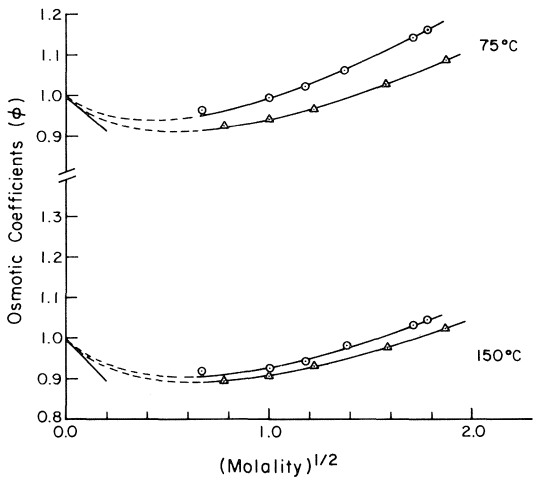

FIG. 3. Osmotic coefficients of NaCl (△) ref. 11, LiCl (○) in water.

i.e., the osmotic coefficient increased with increasing molecular weight, while the order was reversed at 65°C. On the other hand, they found that the osmotic coefficient of $(CH_3)_4NI$ is greater than that of $(C_3H_7)_4NI$ both at 25 and 65°C. It is perhaps unreasonable to draw conclusions from the tetraalkyl ammonium salts since the ion-solvent interaction

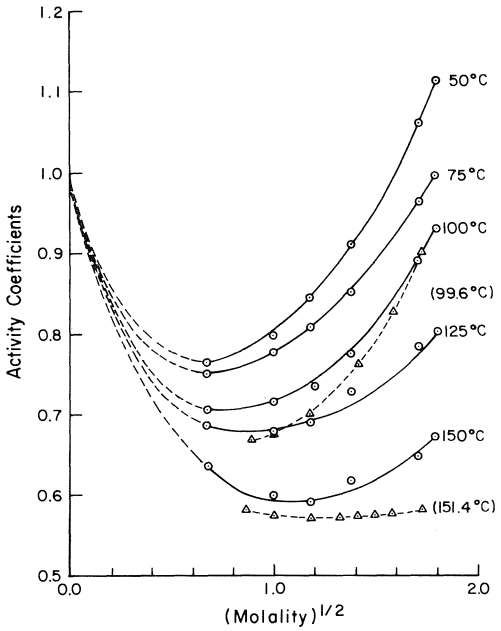

FIG. 4. Activity coefficients of LiCl in water; ○, present work; △, calculated from the osmotic coefficient data from refs. 7 and 10.

must be very different from that of the alkali halides, but it is significant that the osmotic coefficient of lithium chloride is always greater than that of sodium chloride at 25 to 150°C.

The activity coefficients of lithium chloride are in general much lower than those of sodium chloride at corresponding temperatures and concentrations. Figure 4 reproduces the activity coefficients calculated as above. By way of comparison, we have calculated the activity coefficients from the results of Soldano for osmotic coefficients at 99.6 and 151.4°C. At 100°C, our results are generally larger than those of Soldano, while the agreement at 150°C is very poor, even allowing for the slight difference in temperature. Our results show a considerable concentration dependence, similar to the behaviour of sodium chloride, as reported by Lindsay and Liu (6). No such concentration dependence is exhibited by Soldano's results, at 151.4°C.

Åkerlöf (13) has reported the activity coefficients of lithium chloride in water–methanol mixtures at 25°C. Addition of methanol to water lowers the dielectric constant progressively. Similarly, raising the temperature of water lowers its dielectric constant in much the same way. A 50% mixture of water–methanol has almost the same dielectric constant (55.9) as water at 100°C (56). The plot of activity coefficient vs. the square root of molality in water–methanol mixtures is quite similar to that reported by us for water at 100°C although the $\gamma\pm$ values for LiCl are much lower than in water having the same dielectric constant (at 100°C). This seems to show that, in addition to ion association and solvation processes, the activity coefficient is also dependent on some other factor or factors.

Acknowledgments

Analysis of trace metal impurities in phthalocyanine pigments

RAFIK O. LOUTFY AND CHENG-KUO HSIAO

Xerox Research Centre of Canada, 2480 Dunwin Drive, Mississauga, Ont., Canada L5L 1J9

Received April 24, 1979

RAFIK O. LOUTFY and CHENG-KUO HSIAO. Can. J. Chem. **57**, 2546 (1979).

An analytical procedure was developed to determine the content of metallic impurities in metal-free phthalocyanine (H_2Pc) pigments. The technique involves dissolving the pigment in concentrated sulfuric acid, followed by oxidative degradation using hydrogen peroxide. Phthalimide was the only organic oxidation product. The remaining trace metals in the solution were determined using plasma atomic emission. The trace metals content in a commercial α polymorph of phthalocyanine pigment (ICI-Monolite Fast Blue GS) was monitored as a function of purification processes. Experiment showed that Monolite Fast Blue contains 2500 ppm Na; 350 ppm Ca, and 370 ppm Fe. Purification of this material by extraction with hot dimethylformamide gave β-H_2Pc, which contained 300 ppm Na, 110 ppm Ca, and 310 ppm Fe. Sulfuric acid purification (acid pasting) reduced the content of non-transition elements, but inincreased the content of transition metals.

These results were compared to the trace metal content in H_2Pc pigment which were synthesized.

RAFIK O. LOUTFY et CHENG-KUO HSIAO. Can. J. Chem. **57**, 2546 (1979).

On a développé une méthode analytique permettant de déterminer les quantités d'impuretés métalliques contenues dans des pigments de phtalocyanine (H_2Pc) sans métaux. La technique implique la dissolution du pigment dans de l'acide sulfurique concentré suivie d'une dégradation oxydante faisant appel au peroxyde. La phtalimide est le seul composé organique résiduel. On détermine les traces métalliques résiduelles à l'aide d'émission atomique des plasmas. On a déterminé les quantités de métaux à l'état de trace de la forme polymorphe α d'un pigment phtalocyanine commercial (ICI-Monolite Fast Blue GS) en fonction des méthodes de purification. L'expérience montre que le Monolite Fast Blue contient 2500 ppm de Na, 350 ppm de Ca et 370 ppm de Fe. La purification de ce produit par extraction avec de la diméthylformamide à l'ébullition conduit à la β-H_2Pc qui contient 300 ppm de Na, 110 ppm de Ca et 310 ppm de Fe. Une purification par de l'acide sulfurique (formation de pate acide) augmente le contenu en éléments de transition mais diminue les quantités des autres éléments.

On compare ces résultats à ceux obtenus relativement aux quantités de métaux à l'état de trace contenus dans des pigments H_2Pc obtenus par synthèse.

Introduction

Phthalocyanine and its metal complexes possess unique semiconducting (1), photoconducting (2), and dielectric properties (3) and have found many practical applications in electrophotographic imaging systems (4). These materials have the potential to replace inorganic semiconductors and photoconductors in many applications. Metal-free phthalocyanine (H_2Pc) is now known to exist in three distinct polymorphic forms. The face centred monoclinic β-H_2Pc, the tetragonal α-H_2Pc, and the hexagonal *x*-H_2Pc have substantially differing dielectric conductivity and photoactivities (3). These phthalocyanines are normally prepared by methods involving reductive condensation of phthalonitrile. Seldom has a commercial phthalocyanine been found to be electrically useful. Extensive purification was always required to produce materials which possess these semiconducting and photoconducting properties. Workers (1, 2) often assume that extensive solvent extraction, acid pasting, or sublimation procedures will yield high purity materials and thus neglect to measure the nature, concentration, and distribution of any remaining impurity. Therefore, the differences and irreproducible electrical results reported in the literature are not surprising.

Often, insufficient attention is paid to the chemical purity of organic semiconductors. Many investigators (1–3) have used phthalocyanine, purified in different ways, without an exact determination of the amount and nature of the impurities present, even though impurities are known to greatly influence the measured electrophysical properties.

The aim of this work is to describe a method which was developed for the analysis of trace metal impurities in phthalocyanines. We have chosen for this investigation all the three polymorphs of metal-free phthalocyanines (α, β, and *x*-H_2Pc), the commercial

precursor material (ICI Monolite Fast Blue GS) and a synthesized *x*-H_2Pc. Full details of the method and the results are described below.

Methodology

Phthalocyanine pigments, in particular the metal-free compounds, are highly intractable materials insoluble in most common solvents. This renders analytical examination for trace impurities difficult. Metal-free phthalocyanines are soluble in concentrated H_2SO_4 although the resulting solutions are quite viscous. Because of the high viscosity it is difficult to analyze for trace metals by plasma emission spectroscopy where nebulization of the solution is required. On dilution with water, the phthalocyanine and its metal complexes precipitate. In order to resolve this dilemma, we decided to oxidize the phthalocyanine with peroxides before dilution. In this way, all the trace metals will remain in the solution, but the macrocyclic tetrazoporphin ring system will suffer oxidative degradation. The following general procedure was used.

(a) Sample Test Solution

Metal-free phthalocyanine (5 g) was dissolved in 16.7 mL concentrated sulfuric acid (36 *N*, BDH Aristar 98%). This was followed by drop-wise addition of hydrogen peroxide (30 Volume, Baker) to the cooled solution until the colour of the solution changed from dark green to pale yellow (~10 mL H_2O_2). The volume of the solution was then brought up to 50 mL using dionized water. N.B.: all the glassware was washed with (1:1) dilute nitric acid, deionized water, and dried. The product of the oxidation, phthalimide (3.45 g, 60%), identified using infrared spectroscopy and mixed melting point, precipitated on cooling.

The solution was filtered before plasma emission analysis.

(b) Blank Solution

A blank solution was prepared, which contained the same volume of sulfuric acid, hydrogen peroxide, and deionized water as the test solution. This solution was used to determine and cancel the background atomic emission level.

(c) Standard Solution

The standard solutions were prepared using the same amount of sulfuric acid (16.7 mL), hydrogen peroxide (10 mL), and a known volume of BDH standard metal ion solution: 5 mL of 1000 ppm iron, 0.5 mL of 1000 ppm each of calcium, sodium, magnesium, aluminum, copper, zinc, manganese, cobalt, and barium, The total volume was brought up to 50 mL using deionized water to give a standard solution of 100 ppm Fe, 10 ppm of Ca, Na, Al, Mg, Cu, Zn, Mn, Co, and Ba.

Plasma Emission Analysis

The trace metal analysis was carried out using a Spectrametrics Incorporated (Boston), model Spectrospan III, DC Argon plasma atomic emission instrument. The standard solution was nebulized into the argon ion plasma and the strongest atomic emission line of the particular element under investigation was selected using the instrument echelle grating. The slit position and width, photomultiplier sensitivity and wavelength were optimized to give the best signal/noise ratio. Then the microprocessor was activated to optimize the signal output and to accept it as the high standard 100 ppm for iron and 10 ppm for other metals. This was followed by nebulizing the blank solution at exactly the same rate and instrument setting, thus allowing the microprocessor to accept the emission signal output as background which is used for normalization. The test solution was then nebulized and the atomic emission signal (accumulation time 10 s, average of two runs) was processed by the microprocessor in reference to the high standard and blank samples to directly give the metallic content of the sample in ppm. For each element an average of three to four runs were performed. A linear curve resulted using the method of standard additions.

Results and Discussion

In the present work trace metal impurities in a number of metal-free phthalocyanines were determined using the procedure described above. Results are given in Table 1. The relative precision of the determination is 2–3%, which is much better than that reported by Kiryukhin and co-workers (6).

Table 1 shows that the unpurified commercial material, α-H_2Pc Monolite Fast Blue GS, contains large amounts of sodium (2500 ppm) and lesser amounts of the commonly used metals (Fe, Ca, Mg). This material was probably synthesized using the ICI-patented phthalonitrile – sodium amylate – amyl-alcohol method (7).

Monolite Fast Blue GS was purified by extraction with hot dimethylformamide solvent. Three extractions were required to remove all soluble organic

contaminants. During this treatment the material was converted to the β polymorph. The product was washed twice with isopropanol, dried, then preground to submicron size. This purification procedure reduced the sodium and calcium content significantly to 300 ppm and 110 ppm, respectively, as indicated by the trace metal analysis.

The α-H_2Pc polymorph was prepared by dissolving β-H_2Pc in cold, concentrated sulfuric acid and slowly reprecipitating the phthalocyanine by adding the solution to a large volume of ice water. The resulting α-H_2Pc, after filtering, was washed successively with ammonia and methanol, and then dried at 70°C. Several batches of α-H_2Pc were prepared from β-H_2Pc using the acid pasting process. A dramatic difference in the content of metallic impurities between these batches was noted. The greatest differences are in the content of the transition metals such as iron and the alkaline earths such as calcium. These differences were attributed to the purity and quantity of the sulfuric acid used in the acid pasting process.

The attempts to purify phthalocyanine by reprecipitation from concentrated sulfuric acid reduce only the labile metals such as sodium. However, the content of the heavy metals, Fe, Cu, Zn, and Mn, and organic impurities (decomposition products), are usually increased. The difficulty of eliminating many metals is associated with the fact that phthalocyanine complexes are formed in the synthesis together with the main product. Furthermore, these complexes possess very similar physiochemical properties. The most important effect of the acid pasting process is the morphological change in the pigment structure and in the particle size.

x-H_2Pc polymorph was prepared by dry milling α-H_2Pc-11 with flint stones for a week, followed by a methanol wash to remove organic impurities which are either formed by or released during grinding. The final product is microcrystalline material, submicron in size (1000 Å particles). The metallic content in *x*-H_2Pc is shown in Table 1. The most abundant metal is iron (600 ppm) followed by calcium (110 ppm) and lesser amounts of a variety of other metals.

Synthesized *x*-H_2Pc was prepared using Brach's methods (8) which involves heating phthalonitrile in 2-dimethylaminoethanol (DMAE) at 140°C for 1 h. When the temperature of the reaction mixture reached 130°C, 3% by weight of *x*-H_2Pc was added as seed, then the temperature was raised to 140°C and maintained for 1 h. The dark blue solution was filtered while hot, and the product was washed repeatedly with hot DMF, then with isopropanol, then dried, to yield 44% of crystalline material. The crystal structure was determined to be *x*-H_2Pc using visible and ir spectroscopy and from X-ray powder diffraction methods (5). The mean particle size was 36 μm.

Trace metal analysis of synthesized *x*-H_2Pc indicated that this material is very pure. This *x*-H_2Pc contained 50 ppm iron, originating from DMAE (contains 50 ppm Fe) and ~10 ppm Al, originating from the phthalonitrile, and very little of other metals.

In conclusion, tests showed that the content of metallic impurities in phthalocyanine pigments is highly dependent on the synthetic route and the purification procedures. High purity metal-free phthalocyanine can be obtained by reductive condensation of purified phthalonitrile in dimethylaminoethanol.

The presence of metallic impurities — most likely as metal phthalocyanines — could greatly influence the electrical properties of phthalocyanines. Impurities may act as exciton or carrier traps. The influence of these impurities would be observed in charge-carrier generation, carrier mobility, electron spin resonance signals and perhaps in other spectroscopic measurements, such as fluorescence emission and singlet exciton lifetime. We are at present studying the effect of these impurities on the electrical and photoelectrical properties of metal-free phthalocyanines.

Insertion of an acetylene into the platinum–iodide bond

N. CHAUDHURY AND R. J. PUDDEPHATT[1]

Donnan Laboratories, The University of Liverpool, P.O. Box 147, Liverpool L69 3BX, U.K.

N. CHAUDHURY and R. J. PUDDEPHATT. Can. J. Chem. **57**, 2549 (1979).

Reaction of [PtIMe(2,2′-bipyridine)], **I**, with $MeO_2CC{\equiv}CCO_2Me$ gives first a 5 co-ordinate π-complex [PtIMe($MeO_2CC{\equiv}CCO_2Me$)(bipy)], **II**, and then the product of insertion into the PtI bond [PtMe{$C(CO_2Me){=}C(CO_2Me)I$}(bipy)], **III**. A study of the kinetics of dissociation of **II** to **I** and free alkyne shows that reaction occurs largely by dissociation of iodide followed by loss of alkyne from the resulting cationic alkyne complex. Formation of **III** may involve nucleophilic attack by I^- on the co-ordinated alkyne of this cationic intermediate.

N. CHAUDHURY et R. J. PUDDEPHATT. Can. J. Chem. **57**, 2549 (1979).

La réaction du [PtIMe(bipyridine-2,2′)], **I**, avec le $MeO_2CC{\equiv}CCO_2Me$ conduit en premier lieu à un complexe π penta coordonné [PtIMe($MeO_2CC{\equiv}CCO_2Me$)(bipy)], **II**, puis au produit d'insertion dans la liaison PtI [PtMe{$C(CO_2Me){=}C(CO_2Me)I$}bipy], **III**. Une étude de la cinétique de la dissociation de **II** en **I** et en alcyne libre montre que la réaction se produit en grande partie par une dissociation de l'iodure suivie par une perte de l'alcyne par le complexe alcyne cationique qui en résulte. La formation de **III** peut impliquer une attaque nucléophile par le I^- sur l'alcyne coordonné de cet intermédiaire cationique.

[Traduit par le journal]

Introduction

There has been considerable interest in insertion reactions of alkenes and akynes into the Pt—X bond where X = H, CH_3, or Cl (1–7). Generally such reactions involve intermediates in which the alkene or alkyne and the group X are in mutually *cis* co-ordination sites in a square planar molecule, for then migration of X to the co-ordinated alkene or alkyne is particularly favorable (1) Such reactions give *cis* addition to alkynes. However, attack by external nucleophiles on co-ordinated alkenes or alkynes is also possible and *trans* addition then occurs (8–10). During investigations of alkyl(2,2′-bipyridine)platinum(II) complexes with alkenes and alkynes (4, 5, 11), a reaction was discovered in which an alkyne underwent insertion into a Pt—I bond of [PtIMe(bipy)], bipy = 2,2′-bipyridine, rather than into the PtMe bond as was expected. This paper describes an investigation into the mechanism of this reaction.

Results

Characteristics of Products

Yellow solutions of [PtIMe(bipy)], **I**, in acetone, benzene, or methanol were rapidly decolorised by addition of $MeO_2CC{\equiv}CCO_2Me$, and the almost colorless adduct [PtIMe($MeO_2CC{\equiv}CCO_2Me$)(bipy)], **II**, could be isolated after short reaction times. However, in acetone or benzene the solutions became yellow in color after a few minutes at room temperature and from such solutions the yellow product [PtMe{$C(CO_2Me){=}C(CO_2Me)I$}(bipy)], **III**, could be isolated.[2]

Many 5 co-ordinate platinum–alkyne complexes analogous to **II** are now known and characterisation was straight-forward (11–17). The infrared spectrum contained a strong band at 1818 cm^{-1} due to ν(C≡C) of the co-ordinate alkyne as well as ν(CO) stretching vibrations at 1700 cm^{-1}. The uv–visible spectrum of a freshly-prepared solution contained no MLCT band in the region 400–500 nm, and this is typical of 5 co-ordinate alkene or alkyne complexes or of (2,2′-bipyridine)platinum(IV) complexes; 2,2′-bipyridine complexes of platinum(II) with square planar stereochemistry have a prominent band in this region due to excitation of an electron from a filled 5*d*-orbital of platinum to a π*-orbital of 2,2′-bipyridine (18). However, dissociation of the alkyne occurred readily and the characteristic MLCT band of **I** was observed after a short time. Attempts to record the ^1H nmr spectrum of **II** in $CDCl_3$ were unsuccessful due to dissociation to **I** (δ(MePt) 1.22 ppm, ^2J(PtH) 78 Hz) and free alkyne (δ(MeO) 3.81 ppm). However, a spectrum was obtained by adding excess alkyne to a solution of **I** in $CDCl_3$, when a methylplatinum resonance appeared (δ(MePt) 0.58 ppm, ^2J(PtH) 68 Hz) due to **II**. The decrease in the coupling constant $^2J(PtCH_3)$ is typical of such com-

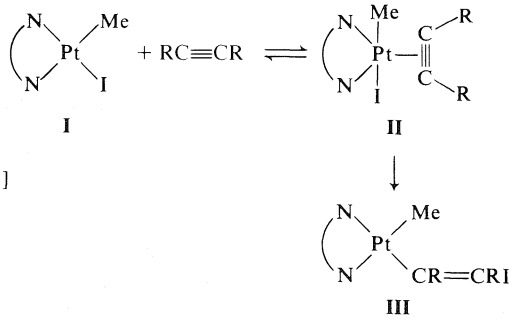
[1]To whom all correspondence should be addressed. Present address: Department of Chemistry, The University of Western Ontario, London, Ont., Canada N6A 5B7.

[2]In methanol this product was not formed and the observed product was an oil which could not be purified. Nuclear magnetic resonance studies suggested that a methoxy group from the solvent was incorporated.

0008-4042/79/192549-06$01.00/0

pounds (19, 20). The resonances due to the equilibrium mixture of **I** and **II** then slowly decayed as further reaction to give **III** occurred.

The ^{1}H nmr spectrum of **III** contained a methylplatinum resonance (δ(MePt) 0.84 ppm, ^2J(PtH) 82 Hz) characteristic of square planar methyl(2,2′-bipyridine)platinum(II) complexes (18, 21), and two equal intensity methoxy resonances (δ 3.80 ppm, J(PtH) 3 Hz; δ 3.65 ppm). The low-field methoxy resonance with distinct coupling to ^{195}Pt is assigned to the CO_2Me group α to a platinum (6, 7, 20). The uv–visible spectrum contained an MLCT band with typical dependence of energy on solvent polarity (390 mn in CH_3CN, 402 and 414 nm in acetone, 422 and 436 nm in benzene). The presence of this MLCT band indicates that the product is a square planar platinum(II) complex. The infrared spectrum gave strong peaks due to ν(CO) at 1700 cm^{-1}, but no peaks due to a co-ordinated alkyne. A band at 568 cm^{-1} was assigned to ν(PtMe) but the expected weak band at around 1550 cm^{-1} due to ν(C≡C) was not observed and was presumably obscured by a strong band due to the ligand 2,2′-bipyridine in this region. Unfortunately, the spectroscopic data cannot distinguish between the *cis* and *trans* orientations of the CO_2Me groups about the C≡C bond of **III**, and attempts to grow single crystals suitable for X-ray structural determination have been unsuccessful due to crystal twinning. Overall the reaction of **I** with $MeO_2CC{\equiv}CCO_2Me$ can be represented by reaction [1] where N⌒N = bipy, R = CO_2Me.



[1]

Kinetic Studies

Complex **II** decomposed quantitatively to **I** and free alkyne when dissolved in organic solvents, and we have studied the kinetics of this process using uv–visible spectrophotometry. Thus the growth of the MLCT band due to **I** can be used to monitor the reaction rate. A typical uv–visible spectrum is shown in Fig. 1. The reactions followed first-order kinetics in benzene, tetrahydrofuran, and acetone solvents. The rates were higher in the more polar solvents as measured by Reichardt's E_T parameter of solvent polarity (Table 1), suggesting a polar reaction intermediate (22). In acetone solution the reaction was retarded by addition of free iodide (Table 1). Concentrations of I^- were calculated from the concentrations of Bu_4NI added after allowing for ion-pairing using the equilibrium constant given by Winstein and co-workers (23). A graph of k_{obs} vs. $1/[I^-]$ gave an intercept at $1/[I^-] = 0$ of approximately 1.7×10^{-3} s^{-1}, indicating that there was a component of the reaction rate which was independent of the concentration of iodide. Good agreement was obtained using the expression for k_{obs}:

$$k_{obs} = k_1 + 1/(a[I^-] + b)$$

or

$$1/(k_{obs} - k_1) = a[I^-] + b$$

The constants $k_1 = 1.53 \times 10^{-3}$ s^{-1}, $a = 3.85 \times 10^5$ L mol^{-1} s, and $b = 21$ s were then determined (24).

The above results strongly support the mechanism of Scheme 1 (11).

If the stationary state approximation is made for

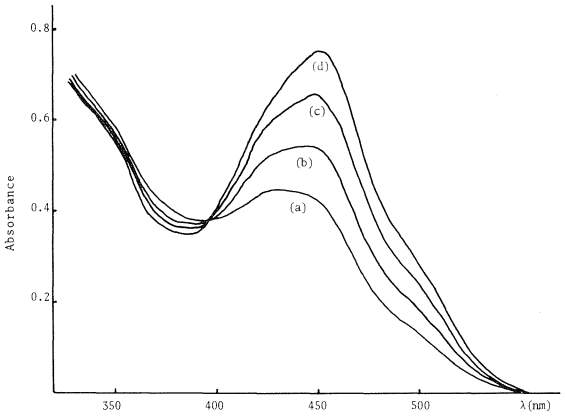


FIG. 1. Ultraviolet–visible spectra recorded during the decomposition of **II** → **I** in tetrahydrofuran at 40°C. Spectra recorded after: (*a*), 3 min; (*b*), 8 min; (*c*), 17 min; (*d*), 40 min.

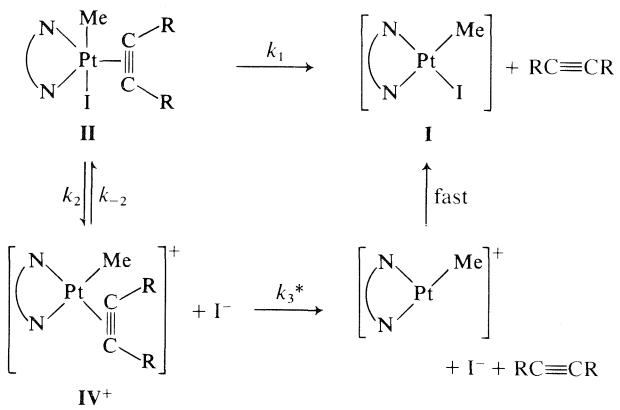
TABLE 1. First order rate constants for the thermal decomposition of **II** at 40°C

Solvent	E_T	10^3 [$Bu_4N^+I^-$] (M)	$10^3 k_{obs}$ (s^{-1})
Benzene	34.1	0	2.0
Tetrahydrofuran	37.4	0	2.3
Acetone	42.4	0	6.3
		1.25	3.3
		2.50	2.8
		5.00	2.2
		10.0	2.0
		20.0	1.8



SCHEME 1. N⌒N = bipy, R = CO_2Me. The k_3 step is written as a dissociative step (for which precedents are known (25)) but could well involve displacement of alkyne by solvent. The reverse reaction **I** → **II** is negligible under the experimental conditions, and hence the reaction proceeds essentially to completion as shown

the ionic intermediate **IV** then the expected rate expression is:

$$-d[\mathbf{II}]/dt = [\mathbf{II}][k_1 + k_2k_3/(k_{-2}[I^-] + k_3)]$$

This is consistent with all the experimental data and the values $k_1 = 1.53 \times 10^{-3}$ s^{-1}, $k_2 = 4.77 \times 10^{-3}$ s^{-1}, and $k_{-2}/k_3 = 1.8 \times 10^3$ L mol^{-1} can be calculated for the reaction in acetone solution at 40°C. We were unable to obtain reliable kinetic data for the reverse reaction leading to formation of **II** from **I**, but this must involve the same intermediates.

Examination of typical uv–visible spectra obtained after addition of $MeO_2CC{\equiv}CCO_2Me$ to a solution of **I** again leads to the conclusion that reaction proceeds in two separate steps (Figs. 2 and 3). The first rapid step leads to decay of the MLCT band of **I** as the rapid equilibrium with **II** is achieved (graphs (*a*)–(*c*) in Figs. 2 and 3). It was not possible to obtain reliable kinetic data for this step since it was too rapid, but approximate values of the equilibrium constants for π-complex formation were obtained; the mean values were 4.1 ± 0.5 L mol^{-1} in acetone and 5.4 ± 0.6 L mol^{-1} in benzene. The second stage of reaction leads to growth of a new MLCT band due to **II** and clear isosbestic points are observed during this reaction. The formation of **III** from the quilibrium mixture of **I** and **II** followed good first order kinetics in solvents benzene, acetone, and methylcyanide and rate constants in these solvents with a fixed concentration of alkyne are given in Table 2. There is a significant increase in rate with solvent polarity suggesting a polar intermediate or transition state. The rate of reaction in benzene or acetone solution increased with concentration of alkyne, reaching

a limiting value at high alkyne concentration. The data gave good agreement with the expression

$$k_{obs} = [RCCR]/(a + b[RCCR])$$

or

$$1/k_{obs} = a/[RCCR] + b$$

Thus graphs of $1/k_{obs}$ vs. 1/[RCCR] gave good linear plots (Fig. 4) and the parameters resulting are given in Table 3.

Attempts to study the kinetics of formation of **III** in the presence of free I^- were unsuccessful since different, unidentified products were formed under these conditions. The rate was not affected by the

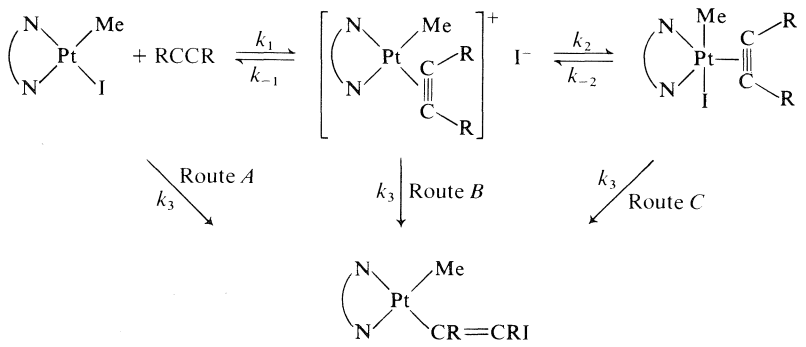
presence of free 2,2′-bipyridine, indicating that dissociation of 2,2′-bipyridine at an intermediate stage does not occur. This type of ligand dissociation was observed in the reaction of diethyl(2,2′-bipyridine)-platinum(II) with methyl acrylate (5).

Discussion

The kinetic data for dissociation of alkyne from **II** shows clearly that the dominant pathway involves preliminary reversible dissociation of I^- to give a cationic intermediate **IV**, which then releases the alkyne as shown in Scheme 1. The mechanism is strongly supported by the retardation of the reaction by free iodide and is also supported by the increased rate in more polar solvents. There is also a component of the reaction for which the rate is independent of the concentration of free iodide. This could involve simple dissociation of the alkyne from **II**, or could involve the intermediacy of a tight ion pair $\mathbf{IV}^+I^-$, or could involve the direct displacement of alkyne from $\mathbf{IV}^+$ by I^-.

The mechanism by which the product of insertion of the alkyne into the Pt—I bond, **III**, is formed is more difficult to elucidate, particularly because other reactions occurred in the presence of free I^- and hence the dependence of the reaction rate on $[I^-]$ could not be determined. The observed rate dependence on the concentration of alkyne is consistent with any one of the routes *A*, *B*, or *C* shown in Scheme 2. Route *A* involves direct insertion of the alkyne into the Pt—I bond of **I**, route *B* involves nucleophilic attack by I^- on the co-ordinated alkyne of $\mathbf{IV}^+$ while route *C* involves intramolecular migration of co-ordinated iodide to the co-ordinated alkyne of **II**. If the equilibrium between **I** and **II** is established rapidly compared with the rate of formation of **III** and, in the case of route *B*, if the stationary state approximation is made for $\mathbf{IV}^+$, then each route will give an expression for k_{obs} of the general form observed experimentally, and in each case the ratio of parameters b/a should give an independent measure of the equilibrium constant, K, for formation of **II** from **I** and RCCR. The relevant data are given in Table 3 and satisfactory agreement is found between the values of the equilibrium constants measured directly and those deduced from the kinetic data.

The considerable increase in rate of formation of **III** in more polar solvents strongly suggests a polar intermediate or transition state and this can be taken as evidence in favor of route *B* above. This would be expected to give a product with *trans* stereochemistry about the C=C bond. We were unable to determine this stereochemistry, but insertion of $MeO_2CC{\equiv}CCO_2Me$ into a PtCl bond of



SCHEME 2. This scheme shows the possible mechanisms of the formation of **III**. The mechanism of interconversion of **I** ⇌ **II** has been simplified for clarity (see Scheme 1 for details)

$[Pt(CO)_2Cl_2]$ is known to give this *trans* stereochemistry although it was suggested that the *cis* isomer might be formed first followed by rapid isomerisation (6). Curiously, the reaction of [PtClMe(bipy)] with $MeO_2CC{\equiv}CCO_2Me$ gives the adduct $[PtClMe(MeO_2CC{\equiv}CCO_2Me)(bipy)]$ but this does not readily rearrange to give the product of insertion into either the PtMe or PtCl bond. Slow reaction does occur, but there is always an induction period in solvents acetone, CH_2Cl_2, or tetrahydrofuran and a free-radical process, perhaps like that discovered by Clark and co-workers (20), appears to operate. This reaction gave a mixture of products which were difficult to identify, and the kinetics were not reproducible. It was therefore not studied further. The difference in reactivity could be due to the greater nucleophilicity of iodide than of chloride.[3]

Experimental Section

[PtIMe(COD)], COD = 1,5-cyclo-octadiene, was prepared by the literature method (21). ^1H nmr spectra were recorded at 60 MHz using a Perkin-Elmer R12B instrument. Ultraviolet–visible spectra were recorded using a Unicam SP8000 spectrophotometer, with an electrically heated thermostatted (to ±0.2°C) cell compartment.

Iodo(methyl)(2,2′-bipyridine)platinum(II) [PtIMe(COD)] (0.316 g) and 2,2′-bipyridine (0.196 g) were each dissolved in benzene (5 cm^3). The solutions were mixed and heated under reflux for 2 h, then cooled to 0°C for several hours. The orange crystals of the product were filtered off, washed with ether, and dried under vacuum. Yield 0.314 g; mp 255–264°C (dec.). *Anal.* calcd. for $C_{11}H_{11}IN_2Pt$: C 26.80, H 2.33; found: C 26.85, H 2.39. Nmr ($CDCl_3$) δ(CH_3Pt) 1.22 ppm, ^2J(PtH) 78 Hz.

[PtIMe(MeO₂CC≡CCO₂Me)(2,2′-bipyridine)]

[PtIMe(2,2′-bipyridine)] (0.205 g) was dissolved in the minimum volume of warm acetone (~50 cm^3). This solution was then cooled in ice and $MeO_2CC{\equiv}CCO_2Me$ (0.2 cm^3) was added. The mixture was allowed to react at 0°C for 15 min and the solvent was then evaporated under high vacuum. The product was washed with ether and dried *in vacuo*. Yield 0.2374 g, mp 160°C (dec.). *Anal.* calcd. for $C_{17}H_{17}IN_2O_4Pt$: C 32.20, H 2.68, Pt 30.70; found: C 32.06, H 2.97, Pt 31.30. The pure product is almost colourless, and can also be prepared conveniently in methanol solution.

[PtMe{C(CO₂Me)=C(CO₂Me)I}(2,2′-bipyridine)]

[PtIMe(2,2′-bipyridine)] (0.110 g) was dissolved in warm acetone (25 cm^3) and $MeO_2CC{\equiv}CCO_2Me$ (0.115 g) was then added. The solution was stirred for 3 h at room temperature. The yellow crystals which formed were filtered off, washed with ether, and dried under vacuum. Yield 0.054 g; mp 173–183°C (dec.). *Anal.* calcd. for $C_{17}H_{17}IN_2O_4Pt$: C 32.20, H 2.68, I 20.00, Pt 30.70; found: C 32.13, H 2.74, I 20.12, Pt 30.77.

Kinetic Studies

(a) Decomposition of Complexes II

The complex **II** (0.002–0.003 g) was dissolved in the required solvent and the volume was made up to 25 cm^3 in a volumetric flask. The solution was rapidly transferred to the 1 cm quartz uv cell held in the thermostatted cell compartment of the spectrophotometer. Spectra were recorded at intervals as the reaction proceeded. Naturally some decomposition occurred before the first spectrum could be recorded but this does not affect the form of the kinetics. Absorbance changes were taken at 465 nm in benzene, 450 nm in tetrahydrofuran, and 432 nm in acetone solution, these values being close to the maximum absorbance due to the MLCT band of [PtIMe(bipy)] in these solvents.

(b) Kinetics of Formation of III

$MeO_2CC{\equiv}CCO_2Me$ (0.04–0.5 g) was weighed accurately into a 5 cm^3 volumetric flask. [PtIMe(bipy)] (0.0015 g) was weighed out separately, dissolved in the required solvent, and the volume made up to 25 cm^3. This solution was added to the volumetric flask containing the alkyne and the volume was made up to 5 cm^3. The solution was mixed and transferred rapidly to the 1 cm quartz uv cell held in the thermostatted cell compartment of the spectrophotometer. Spectra were then recorded at intervals as the reaction proceeded.

Structure of a new crystalline modification of dithiocyanato(triphenylphosphine)-mercury(II)

RAMESH C. MAKHIJA, ROLAND RIVEST, AND ANDRÉ L. BEAUCHAMP[1]

Département de Chimie, Université de Montréal, C.P. 6210, Succ. A, Montréal (Qué.), Canada H3C 3V1

Received April 4, 1979

RAMESH C. MAKHIJA, ROLAND RIVEST, and ANDRÉ L. BEAUCHAMP. Can. J. Chem. **57**, 2555 (1979).

Crystals of the β-form of the title compound are monoclinic, space group $P2_1/c$, a = 21.071(5), b = 17.716(5), c = 11.285(3) Å, β = 101.66(5)°, and Z = 8. The structure was refined on 2741 independent observed reflections to an R factor of 0.042.

The crystals consist of two types of infinite chains with backbones of thiocyanate-bridged mercury atoms. In chain 1, mercury shows the same (3 + 2) coordination as observed in the α-form. It is bound to P of triphenylphosphine (Hg—P = 2.429(4) Å) and two S-bonded thiocyanate ligands (Hg—S = 2.491(5), 2.519(5) Å) in the equatorial plane of a distorted trigonal bipyramid. The axial positions are occupied by weakly-bonded N atoms from adjacent units (Hg—N = 2.74(1), 2.89(1) Å). Chain 2 contains four-coordinated mercury with an approximate tetrahedral geometry. A bridging SCN group links successive Hg atoms in the chain by moderately strong Hg—S (2.648(5) Å) and Hg—N (2.40(1) Å) bonds. The coordination sphere also includes phosphorus (Hg—P = 2.432(4) Å) and a unidentate S-bonded thiocyanate group (Hg—S = 2.454(5) Å). The chains are held together by normal van der Waals contacts.

RAMESH C. MAKHIJA, ROLAND RIVEST et ANDRÉ L. BEAUCHAMP. Can. J. Chem. **57**, 2555 (1979).

Les cristaux de la forme β du composé étudié appartiennent au système monoclinique, groupe d'espace $P2_1/c$, a = 21.071(5), b = 17.716(5), c = 11.285(3) Å, β = 101.66(5)° et Z = 8. La structure a été affinée au moyen de 2741 réflexions observées indépendantes jusqu'à un facteur R de 0.042.

Les cristaux sont constitués de deux sortes de chaînes infinies dans lesquelles les atomes de mercure sont reliés par des ponts thiocyanates. Dans la première sorte de chaîne, le mercure possède la même coordination (3 + 2) que dans la forme α. Il s'y trouve entouré du phosphore de la triphénylphosphine (Hg—P = 2.429(4) Å) et de deux groupes SCN liés par le soufre (Hg—S = 2.491(5), 2.519(5) Å) dans le plan équatorial d'une bipyramide triangulaire déformée. Les sites axiaux sont occupés par des atomes d'azote faiblement liés appartenant à des motifs voisins (Hg—N = 2.74(1), 2.89(1) Å). L'autre sorte de chaîne renferme du mercure tétracoordiné selon une géométrie à peu près tétraédrique. Un groupe SCN relie deux atomes de mercure successifs par des liaisons Hg—S (2.648(5) Å) et Hg—N (2.40(1) Å) moyennement fortes. La sphère de coordination comprend aussi un atome de phosphore (Hg—P = 2.432(4) Å) et un groupe SCN monodentate lié par le soufre (Hg—S = 2.454(5) Å). Les chaînes sont retenues normalement par des forces de van der Waals.

Introduction

In a previous paper, we have shown that mercury has a (3 + 2) trigonal bipyramid coordination in the 1:1 adduct of $Hg(SCN)_2$ with triphenylarsine (1). The three strongly-bonding equatorial positions are occupied by the soft donors (2 S and 1 As), whereas the apical sites are filled with two weakly-bonded N atoms from SCN groups acting as bridging ligands. Recently, the crystals obtained from a 1:1 mixture of $Hg(SCN)_2$ and triphenylphosphine (Ph_3P) in *ethanol* (referred to hereafter as the α-form) were shown to be isomorphous with the As analog (2). These results seemed to disagree with those of Plane and coworkers (3), who interpreted the ir spectrum of $Hg(SCN)_2 \cdot Ph_3P$ in terms of both bridging and nonbridging SCN groups. However, when the compound was prepared from *acetone* as originally described by Plane *et al.* (3), its composition remained unchanged but it was crystallographically different. The crystal structure of this new modification (the β-form) is described in the present paper.

Experimental Section

Preparation

$Hg(SCN)_2$ and triphenylphosphine (1:1 ratio) were mixed in acetone. Crystals suitable for X-ray work were obtained by slow evaporation at room temperature.

Crystal Data

Crystallographic Measurements

The crystal selected for X-ray work was an elongated plate with the following distances between pairs of opposite faces: 0.10 mm (100 and $\bar{1}00$), 0.17 mm ($1\bar{1}0$ and $\bar{1}10$), and 0.47 mm (011 and $0\bar{1}\bar{1}$). Space group $P2_1/c$ was unambiguously determined from a set of precession photographs. The crystal was mounted on an Enraf-Nonius CAD4 diffractometer and the cell parameters were obtained from least-squares fit of the setting angles for 25 reflections centered in the counter aperture. Intensity data were collected using the ω/2θ scan technique. A fixed slit of 4 × 4 mm^2 was used and the scan range (ω) was (1.0 + 0.347 tan θ)° extended 25% on either side for backgrounds. Scan speed between 16.7 and 1.0 deg min^{-1} was automatically selected to make $I/\sigma(I)$ = 100, but maximum scan time was limited to 120 s. Prescans at 10° min^{-1} were made and all reflections having $I/\sigma(I) < 1$ were labeled "weak" and not remeasured. Three standard reflections used as a check on instrument and crystal stability showed only random fluctuations. Crystal orientation was checked every 100 reflections by recentering three axial reflections. If a difference > 0.2° was found between any scattering vector and the corresponding direction deduced from the orientation matrix, a new matrix was defined.

A total of 5401 independent hkl and $\bar{h}kl$ reflections (2θ ≤ 45°) were measured using Enraf–Nonius option FLAT, a procedure to measure intensity at the ψ position where absorption is minimum. Net intensity I was calculated from $I = (P - 2B)S$ where P is the peak count, B is the total background counted during one half of scanning time, and S is the scan rate. The standard deviation was obtained from $\sigma^2(I) = (P + 4B)S^2 + (0.04I)^2$. A set of 2741 reflections with $I > 2.5\sigma(I)$ was retained for structure determination. An absorption correction was applied (Gaussian integration, grid 10 × 10 × 10, Program NRC-3, Ahmed and Singh). For 95% of the data, the transmission factor was in the range 0.25–0.50, but factors as low as 0.12 were found in the remaining 5% of the data for which diffractometer geometry did not permit measurement at the most favorable ψ angle. The data were finally corrected for Lp.

Structure Determination

The structure was solved by the heavy-atom method and refined by full-matrix least-squares in the early stages. Both independent Hg atoms were positioned from a Patterson synthesis and the remaining nonhydrogen atoms were located from a subsequent Fourier synthesis. Isotropic refinement using unit weights led to $R = \sum ||F_o| - |F_c||/\sum |F_o| = 0.076$. Refinement was continued using block-diagonal least-squares. Anisotropic temperature factors were refined for all nonhydrogen atoms. Hydrogens were held fixed at the calculated positions (assuming sp^2 hybridization and a C—H distance of 0.95 Å) with isotropic temperature factors U of 0.076 Å^2 (B = 6.0 Å^2), and their coordinates were recalculated after each cycle. Individual weights based on counting statistics $w = 1/\sigma^2(F)$ were applied in the last least-squares cycles. Anisotropic refinement of all nonhydrogen atoms, together with scale factor and isotropic extinction coefficient (g = −5.4(4) × 10^3) converged to R = 0.042 and $R_w = [\sum w(|F_o| - |F_c|)^2/\sum w|F_o|^2]^{1/2}$ = 0.046. The goodness-of-fit ratio was 1.55. The general background in the final ΔF map was 0.5 e Å^{-3}, except around mercury, where a few peaks of 0.7–1.2 e Å^{-3} were left.

The form factors used were those of Cromer and Waber (4), except for hydrogen (5). Anomalous dispersion terms f' and f'' were used for Hg, S, and P (6).

The refined coordinates are listed in Table 1. Anisotropic temperature factors and hydrogen coordinates are part of the unpublished material.[2]

[2]The supplementary material includes lists of temperature factors, structure factors, interatomic distances and bond angles in the triphenylphosphine ligands and hydrogen coordinates. Complete set of data is available, at a nominal charge, from the Depositiory of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

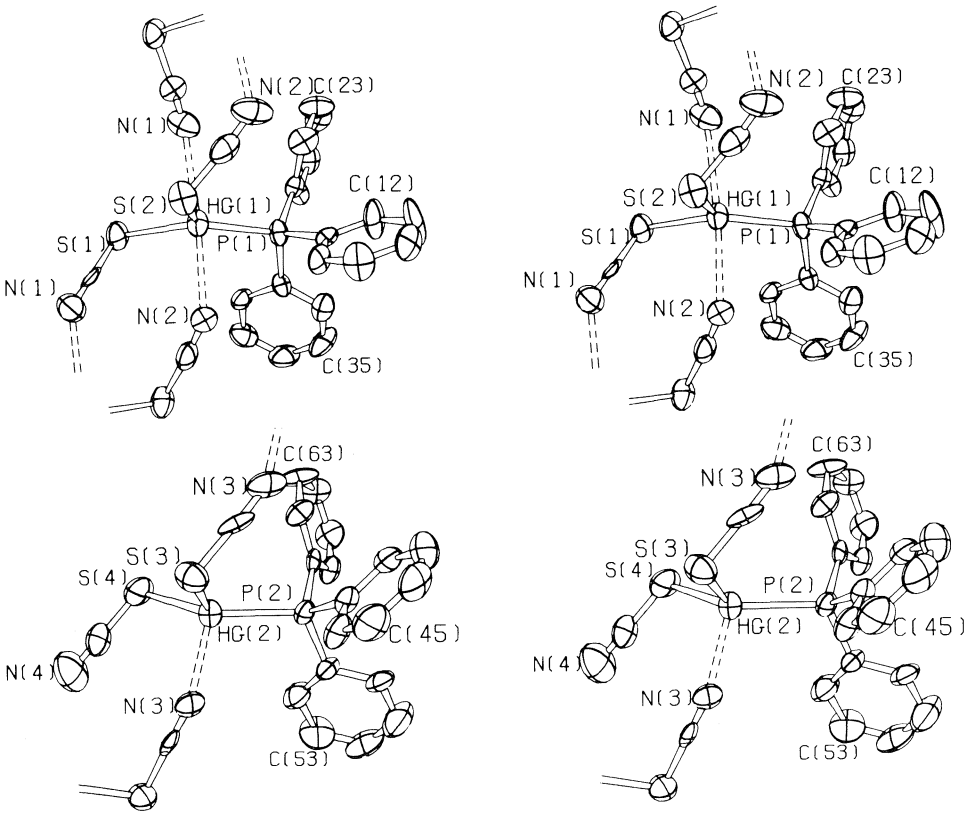

FIG. 1. Stereoscopic view of the two non-equivalent $Hg(SCN)_2$(triphenylphosphine) units and their surroundings. Dashed sticks represent chain-propagating Hg—N bonds. The ellipsoids correspond to 50% probability.

Description of the Structure and Discussion

Figure 1 shows both non-equivalent $Hg(SCN)_2 \cdot Ph_3P$ units. Selected interatomic distances and bond angles are listed in Table 2.

Mercury Coordination

The environment of Hg(1) is essentially the same as in the α-form of $Hg(SCN)_2 \cdot Ph_3P$ (2): a (3 + 2) trigonal bipyramid in which the equatorial positions are filled with three strongly-bonded soft donors. Hg(1) is only 0.02 Å above the PSS plane and the Hg—S (2.491(5), 2.519(5) Å) distances are normal. The Hg—P distance (2.429(4) Å) is slightly smaller than in the α-form (2.461 Å), but both of these bonds are longer than those of $(Hg(NO_3)_2 \cdot Ph_3P)_n$ (7) and $(Hg(NO_3)_2(\text{tricyclohexylphosphine}))_2$ (2.359 Å) (8), where hard nitrate groups act as anions. The S(1)—Hg(1)—S(2) angle (106.4(2)°) is much smaller than the S—Hg—P angles (132.5(2), 121.1(1)°) as a consequence of steric hindrance from phenyl groups. Two weak axial Hg—N bonds (2.74(1), 2.89(1) Å) are approximately perpendicular to the HgS_2P plane (Table 2).

In contrast with the above unit, where both SCN groups are bridging, there is only one bridging SCN group attached to Hg(2) which is four-coordinated with a distorted tetrahedral geometry. The Hg(2)—P(2) distance (2.432(4) Å) is the same as above, but the Hg(2)—S(4) bond length with the unidentate SCN group is shorter (2.454(5) Å). The nitrogen end of the bridging group is much more strongly bonded to mercury (2.40(1) Å) at the expense of the Hg(2)—S(3) bond which is considerably lengthened (2.648(5) Å). A similar type of coordination has been observed in the $[Ph_4P]^+$ salt of $[Hg(SCN)_3]^-$, with the difference that Ph_3P is replaced by another unidentate S-bonded SCN group (9). As in the present case, a bridging SCN group forms a moderately strong Hg—N bond and weakened Hg—S bond. The shortest intermolecular Hg(2)...N(4) contact with the other SCN group is >3.4 Å.

The Ligands

The S—C (ave. 1.65(2) Å) and C—N (ave. 1.14(2) Å) distances are normal and the angles at sulfur are around 100° as usual (Table 2). The angles at nitrogen are 132(1)° and 138(1)° for weak bridging. It is noteworthy that the most strongly bonded nitrogen is the one with the C—N—Hg angle (152(1)°) closest to 180°. The P—C bond lengths (ave.

TABLE 2. Selected interatomic distances and bond angles

Bond	Length (Å)	Bonds	Angle (deg)

[a] x, $1/2 - y$, $1/2 + z$.
[b] x, $1/2 - y$, $-1/2 + z$.
[c] x, $3/2 - y$, $1/2 + z$.

1.80(2) Å) are the same as in Ph_3P itself (10). The Hg—P—Ring angles average 111.5(5)° and the Ring—P—Ring angle (ave. 107.4(7)°) are larger than in Ph_3P (103.0°), where the lone pair is free. Phenyl rings have normal geometry within experimental errors.[2]

Packing

Figure 2 shows the two varieties of chains running along the *c* direction. All mercury atoms in a given chain are of the same type and chain propagation is consequently achieved by the same bridging pattern. Interchain interactions are restricted to van der Waals contacts, none of which are unusually short.

Discussion

Chain propagation by single bridging involves strong bonding from both donor atoms of the SCN group. In the doubly-bridged chain, mercury interacts with one extra donor, but the N ends of both ligands are only weakly bonded. These bridging patterns presumably do not greatly differ in energy, because they result from only slight changes in preparative conditions and they coexist within the same crystal.

A few years ago, Plane and co-workers (3) reported for $Hg(SCN)_2 \cdot Ph_3P$ infrared results that could not be satisfactorily interpreted with our crystallographic results on the α-form. The β-form, which is most likely the one used by these authors, is more consistent with their results. Two bands were observed in the C—S stretching region: one at 680 cm^{-1} is typical of unidentate S-bonded ligands and another at 760 cm^{-1} can be assigned to bridging groups (11). The C—N stretching region was not so clear, but the presence of a many-component band pointed to more than one type of SCN groups. Crystals of the β-form contain one unambiguously recognizable bridging group (# 3) and one unidentate S-bonded group (# 4). Because the N end of the two remaining ligands (# 1 and # 2) interact only weakly with mercury, we expect them not to differ greatly from unidentate ligands in the ir spectrum. Indeed, similarly weak intermolecular Hg—N contacts (2.80 Å) exist in $Hg(SCN)_2$ itself (12), and there is no evidence of bridging in its ir spectrum (13).

The simple dimeric structure proposed by Plane and co-workers (3) incorporated all structural features deduced from ir spectra. However, the present work shows more complicated patterns which have also been found in other compounds

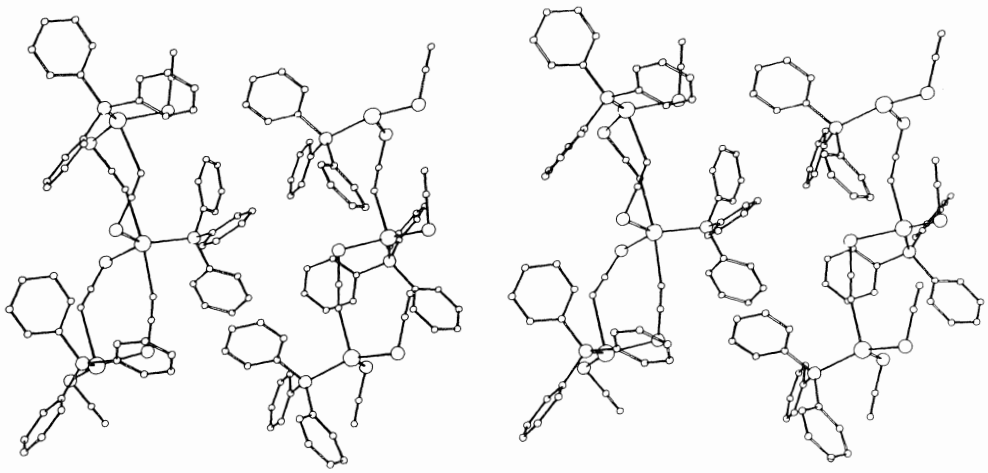

FIG. 2. Stereoscopic view of the two types of infinite chains in crystals of $Hg(SCN)_2$(triphenylphosphine), β-form. The chains are oriented along the *c* axis. The plane represented here goes through the origin and bisects the γ angle.

(1, 2, 9). Therefore, it is quite possible that other 1:1 adducts of $Hg(SCN)_2$ believed to be dimeric, also form in the solid state infinite chains similar with those observed in the present compound.

Received March 14, 1979

HÉLIO C. CHAGAS. Can. J. Chem. **57**, 2560 (1979).

Electrosorption at the platinum rotating disc electrode in sulfuric acid solutions of selenite, selenate, selenide, and tellurite gives rise to isopotential points in the potential range where oxidation of platinum occurs. The data are analyzed with the framework of the model put forward by Untereker and Bruckenstein. Since similar behavior is observed for the selenite, selenate, and selenide systems, it is tentatively inferred that a common electrosorbed species, possibly selenium itself, may be involved in these systems.

HÉLIO C. CHAGAS. Can. J. Chem. **57**, 2560 (1979).

L'électrosorption sur une électrode de platine à disque tournant dans des solutions sulfuriques de sélénite, de sélénate, de sélénure et de tellurite donne lieu à des points isopotentiels dans l'écart de potentiel où l'oxydation du platine se produit. On analyse les données dans le cadre du modèle proposé par Untereker et Bruckenstein. Puisque l'on observe des comportements semblables avec les systèmes sélénite, sélénate et sélénure, on en déduit provisoirement qu'il existe peut être une espèce électrosorbée commune, possiblement du sélénium lui-même, dans tous ces systèmes.

[Traduit par le journal]

Introduction

The occurrence of isopotential points in a family of current–potential curves facilitates detection and analysis of surface processes at solid electrodes. Such isopotential points (IP) are the electrochemical counterparts of isobestic points in absorption spectrophotometry. The relevant parameters are: the current (or charge) passed at the electrode, the potential, and a factor related to the nature of the temporal dependence of the potential variation (e.g., the sweep rate in linear voltammetry).

The model developed by Untereker and Bruckenstein (1) to rationalize the occurrence of IP is applicable when the following experimental conditions hold: (*a*) all the current–potential curves of a given family correspond to the same electrode potential – time program; (*b*) the electrode surface, at the onset of potential–time program is covered with at least one electrosorbed or electrodeposited species in quantities which differ for each curve of the family; (*c*) the electrode surface behaves as if it were composed of at least two electrochemically independent regions of areas A_1 and A_2 whose sum remains constant throughout the entire period during which the potential sweep is applied.

The existence of IP was verified in studies of the electrodeposition of metals at platinum (1, 2) and gold (3) rotating disc electrodes and of electrosorption of species such as sulfite on the platinum rotating disc electrode (RDE) (1).

In the present work, we report an investigation of the electrosorption of selenite, selenate, selenide, and tellurite at the platinum RDE in sulfuric acid medium, taking advantage of information derived from the occurrence of IP in the systems.

This electrosorption process is of special interest in view of the technological importance of these substances as additives for improving the current yield in electrodeposition of manganese (4–6). Moreover, the electrosorption of selenium has been employed to increase the activity of platinum electrodes in studies of oxidation processes of organic compounds (7).

Experimental

Apparatus

The potentiostat used to control the electrode potential, the potential programmer, and the electromechanical system which controls the electrode rotation rate have been previously described (8, 9). A Pyrex cell with volume of ca. 200 mL was employed throughout. Electrical contact between the SCE reference electrode and the electrolytic solution was achieved by means of a Luggin capillary situated near the working electrode. All potentials were referenced against the saturated calomel electrode (SCE).

Materials

Electrolytic solutions were prepared with triple-distilled water. The supporting electrolyte was 0.2 *M* H_2SO_4 (Baker Reagent grade) in all experiments. Sodium selenite was prepared by careful neutralization of a water solution of SeO_2 (BDH A.R. grade) with reagent grade sodium hydroxide; sodium selenate was prepared in a similar fashion using an aqueous selenic acid solution (10). Sodium selenide (K & K

0008-4042/79/192560-04$01.00/0

Lab., Inc.) was used as received. Sodium tellurite was prepared by the method of Brauer (11). The final concentration of all stock solutions was $5 \times 10^{-4} M$.

All solutions were deaerated by purging with purified nitrogen and all electrochemical measurements performed under a nitrogen atmosphere.

Methods

Prior to all experiments the platinum RDE was polished by hand with 0.05 μm alumina powder and subjected to an electrochemical pretreatment in the supporting electrolyte solution. This pretreatment consisted of repeated cycling of the potential of the working electrode between +1.40 and −0.25 V and maintaining the electrode rotation frequency (36 Hz) and the potential sweep rate (200 mV/s), until reproducible current–potential curves were obtained (10–20 cycles). Following this treatment, appropriate aliquots of the stock solution of the electroactive species of interest were added to the supporting electrolyte solution already in the electrolytic cell.

Families of current–potential curves were obtained utilizing a potential program of the type $E(t) = E_i + vt$, where E_i represents the initial potential and $v = dE/dt$ the (constant) sweep rate. The sign of v was reversed at the extremes of the potential sweep, i.e., at +1.40 and −0.25 V. The quantity of the chemical species under investigation electrosorbed at the electrode surface was varied by maintaining the electrode at a potential $E_i = 0$ V and a rotation frequency of 9 Hz for different periods of time. At the end of this electrosorption period, the electrode was swept from $E_i = 0$ V to a more cathodic potential up to a potential of −0.25 V, at which point the sweep was reversed to the anodic direction. Between each successive curve, the electrode was oxidized for 60 s at a potential of +1.30 V. At the end of this oxidation, the electrode potential was jumped to $E_i = 0$ V for a new electrosorption. The initial fractional coverage θ_R of the electrode surface by the electrosorbed species was calculated from the relative decrease in the area of the hydrogen desorption peaks in the presence and absence of the electrosorbed species according to the general procedure of Untereker and Bruckenstein (1).

Results and Discussion

Figure 1 exhibits a family of current–potential curves for a 3.3×10^{-6} M solution of sodium selenite in 0.2 M H_2SO_4. Each curve corresponds to the oxidation of a different quantity of the electrosorbed species at the electrode surface. Of particular importance is the presence of an isopotential point IP-I at $E_{IP\text{-}I} = 0.75$ V, i.e., in the potential range where oxidation of platinum occurs. Indeed, the electrode surface may be considered to consist of two independent electrochemical regions; one of area A_1 corresponding to the platinum itself and a second of area A_2 corresponding to a submonolayer of the electrosorbed species. Thus, the relevant Faradaic processes occurring in the potential range around IP-I are: (*a*) the oxidation of platinum in area A_1

[1] $Pt \rightarrow PtO_x + n_1e$

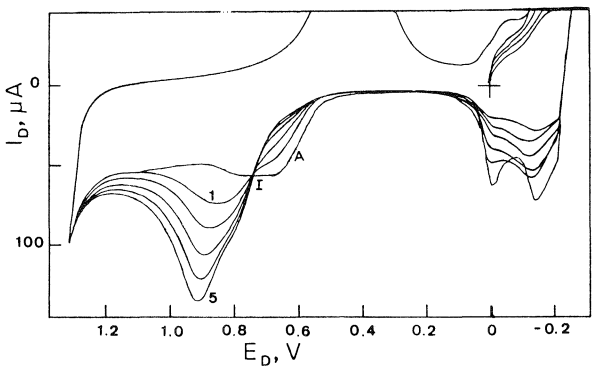

FIG. 1. *I–E* curves for oxidation of various quantities of the electrosorbed species at the platinum rotating disc electrode in the selenite system: $[SeO_3^{2-}] = 3.3 \times 10^{-6}$ M, $[H_2SO_4] = 0.2$ M, $f = 9$ Hz, $v = 200$ mV/s, $E_{IP\text{-}I} = 0.75$ V/SCE, electrode area = 0.162 cm². Fractional monolayer coverages of electrosorbed species at the electrode surface for *I–E* curves are: (*1*) 0.14, (*2*) 0.22, (*3*) 0.37, (*4*) 0.49, (*5*) 0.61; *A* = absence of SeO_3^{2-}.

and (*b*) oxidation of the electrosorbed species, represented as $R(H_2SeO_3)$, in area A_2.

[2] $R(SeO_3^{2-}) \rightarrow Ox_2 + n_2e$

That the species $R(SeO_3^{2-})$ is electrosorbed at both the weakly and strongly bound hydrogen atom electrosorption sites is indicated by the corresponding decrease of both current peaks characteristic of hydrogen desorption with increasing fraction of coverage θ_R.

Families of current–potential curves for 3.3×10^{-6} M sodium selenate and 3.75×10^{-6} M sodium selenide in 0.2 M H_2SO_4 are presented in Figs. 2 and 3, respectively. As in the case of selenite, isopotential points (IP-II at $E_{IP\text{-}II} = 0.75$ V in Fig. 2 and IP-III at $E_{IP\text{-}III} = 0.75$ V in Fig. 3) are observed in the potential range where oxidation of platinum occurs. Thus the faradaic processes associated with these IP may be represented by equations entirely analogous to [1] and [2]. In the hydrogen desorption potential range, the electrosorbed species $R(Se^{2-})$ of Fig. 3 exhibits roughly equal preference for the hydrogen binding sites; on the other hand, the electrosorbed species $R(SeO_4^{2-})$ of Fig. 2 exhibits a slight preference for the sites corresponding to strong binding of hydrogen. Curve *A* of Fig. 2, obtained for the supporting electrolyte in the absence of the electroactive species, fails to pass through the point IP-II observed in the presence of the electroactive species. This departure from the expected behavior is most readily interpretable in terms of a small constant amount of "irreversible" electrosorption of a nonoxidable species at the electrode surface resulting in

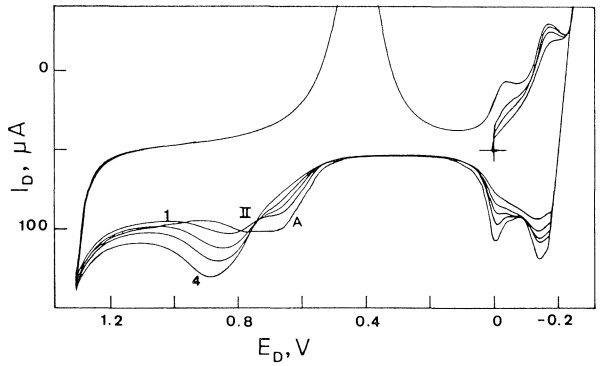

FIG. 2. *I–E* curves for oxidation of various quantities of the electrosorbed species at the platinum rotating disc electrode in the selenate system: $[SeO_4^{2-}] = 3.3 \times 10^{-6}$ *M*, $[H_2SO_4]$ = 0.2 *M*, *f* = 9 Hz, *v* = 200 mV/s, $E_{IP\text{-}II}$ = 0.75 V/SCE, electrode area = 0.162 cm². Fractional monolayer coverages of electrosorbed species at the electrode surface for *I–E* curves are: (*1*) 0.15, (*2*) 0.18, (*3*) 0.24, (*4*) 0.35; *A* = absence of SeO_4^{2-}.

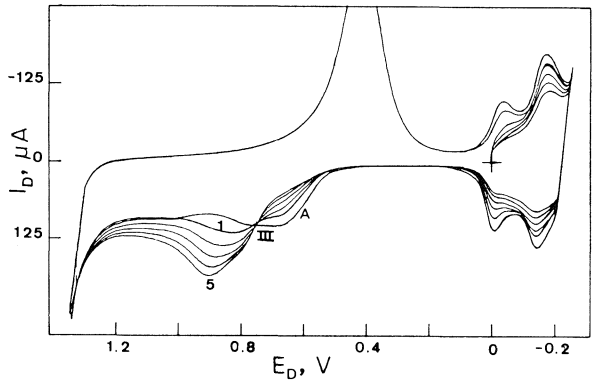

FIG. 3. *I–E* curves for oxidation of various quantities of the electrosorbed species at the platinum rotating disc electrode in the selenide system: $[Se^{2-}] = 3.75 \times 10^{-6}$ *M*, $[H_2SO_4]$ = 0.2 *M*, *f* = 9 Hz, *v* = 200 mV/s, $E_{IP\text{-}III}$ = 0.75 V/SCE, electrode area = 0.280 cm². Fractional monolayer coverages of the electrosorbed species at the electrode surface for *I–E* curves are: (*1*) 0.09, (*2*) 0.19, (*3*) 0.27, (*4*) 0.33, (*5*) 0.42; *A* = absence of Se^{2-}.

a net reduction of the available electrode surface in the presence of selenate. This phenomenon is much less pronounced for the selenite and selenide systems (Figs. 1 and 3 respectively).

Families of current–potential curves similar to those of Figs. 1–3 were obtained in experiments carried out under the same conditions but with different potential sweep rates. The dependence of the current density at the potential points (IP-I, IP-II, and IP-III) on the potential sweep rate (*v*) for each of these three systems is shown in Fig. 4. Linear dependences are observed with slopes of 1.74, 1.62, and 1.77 μA s/(cm² mV) for selenite, selenate, and selenide systems, respectively. The potential (E_{IP}) at

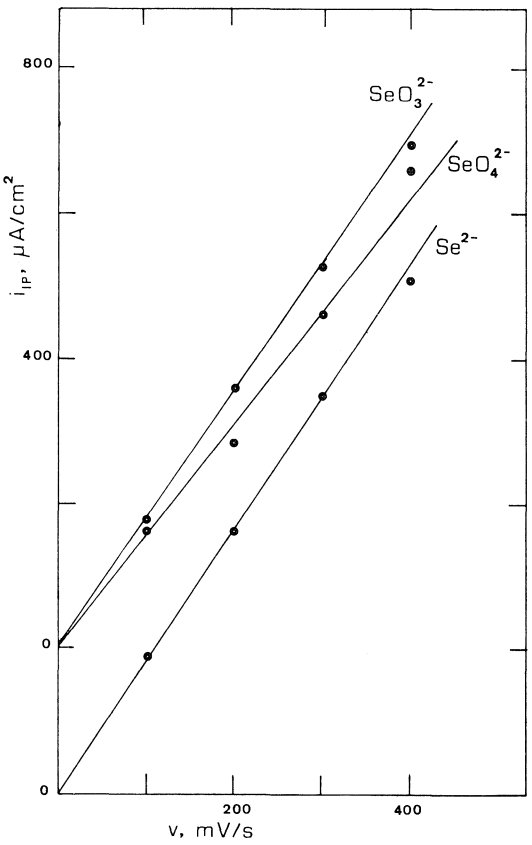

FIG. 4. Plot of the current density at the isopotential points versus potential sweep rate for selenite, selenate, and selenide systems.

which the points IP-I to IP-III occur varies very little (<2%) over the range of potential sweep rates (*v*) employed.

Figure 5 exhibits a family of current–potential curves for 3.3×10^{-6} *M* sodium tellurite in 0.2 *M* H_2SO_4. In this case, the current peaks corresponding to oxidation of electrosorbed species occur at a less anodic potential and are much sharper than those observed for selenium systems.

For the tellurite we don't observe isopotential points. In the potential range for hydrogen desorption this system exhibits the same behavior as the selenite and selenide systems.

Conclusions

The currents are sufficiently high at the experimental isopotential points for the selenite, selenate, and selenide systems ($I_{IP\text{-}I}$ to $I_{IP\text{-}III}$) that we may conclude that these points result from equal current densities for oxidation of platinum (i_{Pt}^0) in area A_1 and oxidation of a submonolayer of electrosorbed species (i_k^0) in area A_2.

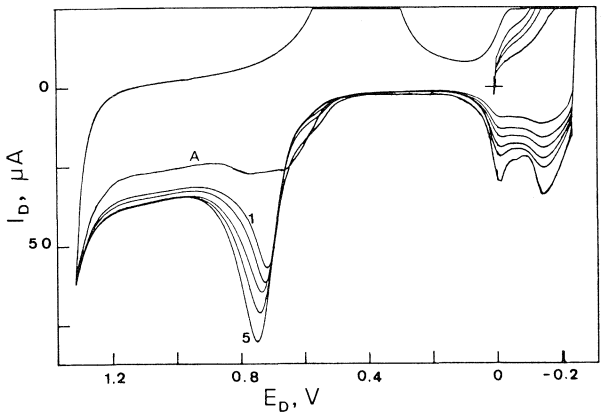

FIG. 5. *I–E* curves for oxidation of various quantities of the electrosorbed species at the platinum rotating disc electrode in the tellurite system: $[TeO_3^{2-}] = 3.3 \times 10^{-6}$ *M*, $[H_2SO_4] = 0.2$ *M*, $f = 9$ Hz, $v = 100$ mV/s, electrode area = 0.162 cm². Fractional monolayer coverages of the electrosorbed species at the electrode surface for *I–E* curves are: (*1*) 0.16, (*2*) 0.24, (*3*) 0.36, (*4*) 0.48, (*5*) 0.63; *A* = absence of TeO_3^{2-}.

According to the theory of Untereker and Bruckenstein (1), this current I_{IP} may be expressed as

$$[3] \quad I_{IP} = A|(\partial Q_k/\partial E)_t v + (\partial Q_k/\partial t)_E|$$

where A is the total area of the electrode and

$$Q_k = \int_0^\tau i_k^0 \, dt$$

represents the charge density necessary for oxidation of platinum or of the electrosorbed submonolayer during the time interval 0–τ (or, for a linear potential sweep, between two potentials). The observation of a linear relationship between $i_{IP} = I_{IP}/A$ and v for the three selenium systems (Fig. 4) permits us to conclude from [3] that

$$(\partial Q_k/\partial E)_t v \gg (\partial Q_k/\partial t)_E$$

The corresponding slopes thus furnish values of $(\partial Q_k/\partial E)_t$ for the two Faradaic processes responsible for the existence of the isopotential points. These slopes are comparable for the selenite and selenide systems. In addition, the potentials E_{IP} for these two systems, as well for selenate system, are quite similar. In this regard, the overall similarity of the families of current–potential curves for the three systems (Figs. 1–3) is noteworthy. These considerations lead us to infer that the species R electrosorbed at the electrode surface may well be the same, and possibly selenium itself, in all three cases, particularly in the selenite and selenide systems. This inference, though still tentative in the absence of additional corroborating evidence, is supported by the standard potentials (12) for the reactions

$H_2SeO_3 + 4H^+ + 4e = Se(0) + 3H_2O$	$E^0 = 0.74$ V
$H_2SeO_3 = H^+ + HSeO_3^-$	$k = 2.7 \times 10^{-3}$
$HSeO_3^- = H^+ + SeO_3^{2-}$	$k = 2.5 \times 10^{-7}$
$SeO_4^{2-} + 4H^+ + 2e = H_2SeO_3 + H_2O$	$E^0 = 1.15$ V
$HSeO_4^- = H^+ + SeO_4^{2-}$	$k = 8.9 \times 10^{-3}$
$Se(0) + 2H^+ + 2e = H_2Se$	$E^0 = -0.40$ V

which suggest that, in acid medium, the reductions Se(IV) → Se(0) and Se(VI) → Se(IV) → Se(0) and the oxidation Se^{2-} → Se(0) should be possible.

Stereoselectivity in Diels–Alder reactions

MASATOSHI KAKUSHIMA

Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 5A3

Received March 30, 1979

MASATOSHI KAKUSHIMA. Can. J. Chem. **57**, 2564 (1979).

Two competing effects, secondary attractive interactions and closed-shell repulsions, provide the main control of *endo–exo* stereoselectivity of Diels–Alder cycloadditions.

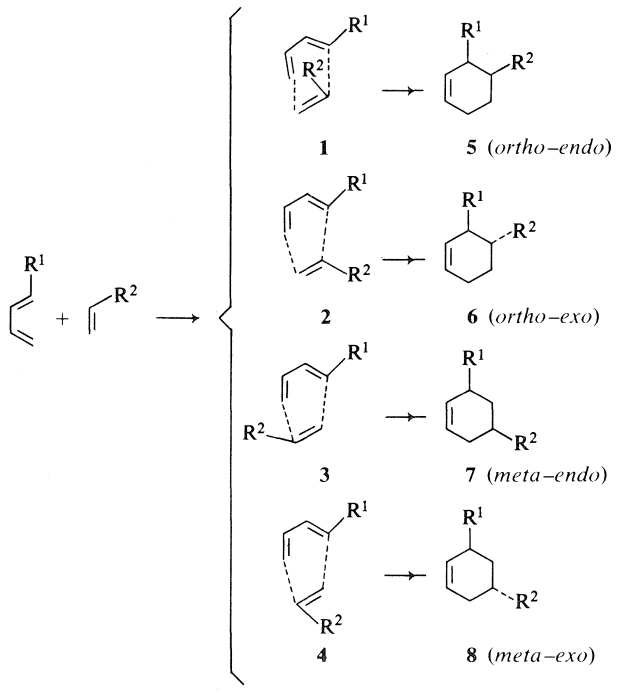
MASATOSHI KAKUSHIMA. Can. J. Chem. **57**, 2564 (1979).

Deux effets compétitifs, les interactions attractives secondaires et les répulsions des couches complètes d'électrons, procurent le contrôle principal de la stéréosélectivité *endo–exo* des cycloadditions de Diels–Alder.

[Traduit par le journal]

In the course of our endeavors in the total synthesis of natural products, some results from our concurrent studies on the Diels–Alder reaction (1, 2, 3) have enabled us to systematize several factors which we believe may contribute to a better understanding of the regio- and stereoselectivity of this reaction (4, 5).

In the schematic Diels–Alder reaction shown in Scheme 1, four isomeric adducts are possible. Examples of the reaction between some 1-substituted dienes and acrylates are presented in Table 1. The *ortho* isomers **5** and **6** are predominant or exclusive in all cases (6). Frontier molecular orbital (FMO) theory using terminal (7, 8) and secondary (9) attractive interactions has been applied to rationalize these phenomena. For example, an electron-donating substituent at C-1 of the diene increases the difference in the magnitudes of the terminal HOMO coefficients (C-1 and C-4) of the diene (Table 2), resulting in a high regioselectivity in the reaction (Table 1).



SCHEME 1

However, controversy has arisen on the subject of the importance of secondary overlap on the stereochemical outcome of the reaction (8, 9, 10). Experimental results show that an alkoxycarbonyl group on the dienophile fails to control *endo* stereoselectivity in reactions with highly electron-rich 1-substituted dienes (Table 1). As shown in Table 2, an electron-donating substituent at C-1 of the diene not only increases the difference in the magnitudes of the secondary HOMO coefficients (C-2 and C-3), but also increases the exclusion shell[1] (the gross orbital charge of $2P_z^2$) at C-2. The *ortho–endo* isomer **5** must be favored through increased secondary attractive interactions (9), while at the same time the same isomer **5** must be disfavored through increased closed-shell repulsions (3). Clearly, both for preparative and for theoretical reasons, it is important to assess the relative magnitudes of these two opposing interactions.

In order to examine the balance between secondary attractive interactions and closed-shell repulsions more closely, we have focused on the reaction between some 1-substituted dienes and dimethyl fumarate (**9**) (Scheme 2), because in this case ter-

[1]The larger the π charge density on an atom, the larger the size of the "exclusion shell" into which other electrons are forbidden to penetrate (11).

[2]Since the coefficients of $2P_z$ orbitals are discussed for attractive interactions by FMO theory (7, 8, 9), the gross orbital charges of $2P_z$ orbitals should be considered for repulsive interactions.

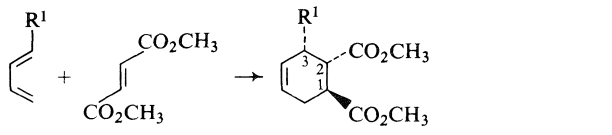
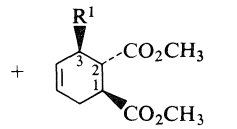
minal interactions can be ignored due to the symmetric nature of this dienophile (Table 3). The difference in the magnitudes of the secondary HOMO coefficients (C-2 and C-3) of *E*-1-methoxybutadiene



9 **10***a*: $R^1 = CH_3$; **10***b*: $R^1 = OCOCH_3$; **10***c*: $R^1 = OCH_3$



11*a*: $R^1 = CH_3$; **11***b*: $R^1 = OCOCH_3$; **11***c*: $R^1 = OCH_3$

SCHEME 2

is much larger than that in the magnitudes of the secondary HOMO coefficients (C-2 and C-3) of *E*-piperylene (*E*-penta-1,3-diene) (Table 2); as a result, the selectivity (**10**:**11**) in the addition of *E*-1-methoxybutadiene to **9** should be greater than that in the addition of *E*-piperylene to **9**. However, a very small difference in the selectivity of these reactions is observed (Table 4), which suggests that the increase in secondary attractive interactions must be counteracted by a nearly equal increase in closed-shell repulsions. Interestingly, Fleming *et al.* (10) have reported that the addition of 1-methoxycyclohexa-1,3-diene (**12**) to **9** or **13** produces the isomer of type **10** as the minor adduct (Scheme 3), which indicates that in these cases the secondary attractive interactions fail to overcome the closed-shell repulsions due to the large exclusion shell at C-2 of **12**. The exclusion shell at C-2 of **12** is similar to that at C-2 of *E*-1-methoxybutadiene, while the difference in the magnitudes of the secondary HOMO coefficients (C-2 and C-3) of **12** is smaller than the difference in

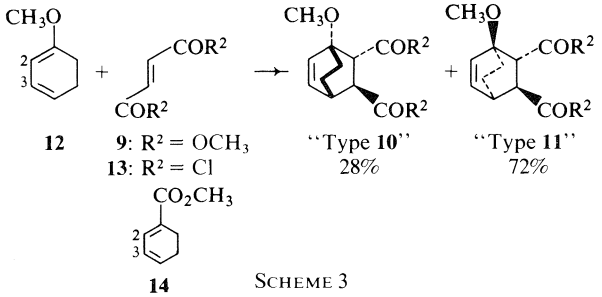

SCHEME 3

the magnitudes of the secondary HOMO coefficients (C-2 and C-3) of *E*-1-methoxybutadiene.[3]

A simple prediction can be made to test this explanation: the addition of a diene such as **14** to **9** should produce the isomer of type **10** as the major adduct. The methoxycarbonyl group of **14** should significantly decrease the exclusion shell at C-2 of **14**, while retaining a larger secondary HOMO coefficient at this carbon.[4]

A quantitative assessment of the two opposing effects considered above is clearly difficult. It is hoped, however, that experimental results and MO calculations of the type reported here together with further predictions and their testing will make it possible to achieve better stereo-control of Diels–Alder cycloadditions in the future.

Experimental

The ir spectra were recorded in CCl_4 solution on a Perkin-Elmer 457 ir spectrophotometer. The nmr spectra were recorded in $CDCl_3$ solution using TMS as an internal standard on a Varian T-60 spectrometer. The 220 MHz nmr spectra were obtained from the Canadian 220 MHz NMR Centre, University of Toronto. Proton chemical shifts (ppm) are expressed relative to TMS. The high resolution mass spectra were obtained from the Department of Chemistry, University of Alberta.

Chromatographic columns were packed with Merck silica gel H (type 60) under a positive nitrogen pressure, and Merck precoated silica gel 60 F-254 plates (0.25 mm) were used. *E*-Piperylene (99%) and *E*-1-methoxybutadiene (practical grade) were purchased from the Aldrich Chemical Co. and were used without purification. Dimethyl fumarate (Eastman Kodak Co.) was washed with an aqueous $NaHCO_3$ solution, extracted with benzene, dried over anhydrous K_2CO_3, concentrated, and recrystallized. Ethyl acetate and hexanes were distilled. Toluene was distilled from $LiAlH_4$. $Eu(fod)_3$ was purchased from the Aldrich Chemical Co. Diels–Alder reactions were performed under a nitrogen atmosphere in the presence of hydroquinone (catalytic amount) in a 200 mL pressure bottle. The adducts were concentrated *in vacuo* and passed through a chromatographic column using the solvent system of ethyl acetate–hexanes (1:9). Conditions and product ratios (**10**:**11**) are summarized in Table 4. The product ratios were found to be constant at temperatures from 40 to 140°C. Prolonged heating of the isomers (**10***c* and **11***c*) at 140°C for 90 h did not affect the ratio.

Analysis of Diels–Alder Adducts

Compounds **10***a* and **11***a* ($R^1 = CH_3$) gave values for ir: 1735, 1195, 1175, and 1162 cm^{-1}; *m/e* (% int.): 181.0859(31) ($M^+ - CH_3O$, $C_{10}H_{13}O_3$ requires 181.0865); 180.0787(39) ($M^+ - CH_3OH$, $C_{10}H_{12}O_3$ requires 180.0786); 152.0836(49) ($M^+ - CO_2CH_3-H$, $C_9H_{12}O_2$ requires 152.0837). The product ratio (**10***a* and **11***a*) was determined by comparison of the 220 MHz nmr spectrum of the adducts with that of the authentic sample (**10***a*:**11***a* = 11:5), which was prepared from the adducts of *E*-piperylene with methyl *E*-4-oxobutenoate (2, 3). Nuclear magnetic resonance for **10***a* δ: 2.87 (J = 12, 11.5, 5 Hz, C1—H), 3.03 (J = 12, 6 Hz, C2—H), 2.70 (multiplet, C3—H), 0.88 (J = 7 Hz, C3—CH_3); for **11***a* δ: 1.05 (J = 7 Hz, C3—CH_3).

For compounds **10***c* and **11***c* ($R^1 = OCH_3$), ir: 1735, 1195, 1175, and 1160 cm^{-1}; *m/e* (% int.): 196.0735(100) ($M^+ - CH_3OH$, $C_{10}H_{12}O_4$ requires 196.0736); 168.0788(70) ($M^+ - CO_2CH_3-H$, $C_9H_{12}O_3$ requires 168.0787). The nmr spectrum of the product (adducts **10***c* and **11***c*; 54 mg) with $Eu(fod)_3$ (67 mg) shows two sets of three methyl singlets, the integration of which indicates that the product ratio is approximately 2:1. The integration of the product (54 mg) when combined with an authentic sample (**10***c*:**11***c* = 5:1; 52 mg) indicates that the major isomer in the product is **10***c*. The authentic sample was prepared from the adducts of *E*-1-methoxybutadiene with methyl *E*-4-oxobutenoate (3).

Acknowledgements

The author would like to express his sincere appreciation to Professor Z. Valenta for his encouragement, helpful suggestions, and ample financial support. He also thanks Professor F. Grein, University of New Brunswick, for helping him with the computations, and Dr. I. Fleming, Cambridge University, and Mr. D. J. Burnell of this Department, for several enlightening discussions concerning FMO theory. Miss J. P. Smolinski, a senior student in this Department, has helped with computations.

[3]The computed data for the diene ($R^1 = OCH_3$; R^2, $R^3 = CH_3$) are used for the description of **12** (Table 2).

[4]The computed data for the diene ($R^1 = CO_2CH_3$; R^2, $R^3 = CH_3$) are used for the description of **14** (Table 2). The LUMO (diene)/HOMO (dienophile) secondary attractive interactions also predict the formation of the isomer of type **10** as the major adduct.

The occurrence of ergosterol and (22*E*,24*R*)-24-ethylcholesta-5,7,22-trien-3β-ol in the unicellular chlorophyte *Dunaliella tertiolecta*[1]

JEFFREY L. C. WRIGHT

Atlantic Regional Laboratory, National Research Council of Canada, 1411 Oxford St., Halifax, N.S., Canada B3H 3Z1

Received May 7, 1979

JEFFREY L. C. WRIGHT. Can. J. Chem. **57**, 2569 (1979).

Using ^{13}C nuclear magnetic resonance spectroscopy the major sterols of the unicellular chlorophyte *Dunaliella tertiolecta* were found to be ergosterol and a closely related C_{29} trienol. Apparently the absence of a cell wall in *D. tertiolecta* does not significantly affect the type of sterol produced since other unicellular chlorophytes which possess a cell wall produce similar sterols containing an unsaturated side chain and a 24[*R*]-alkyl substituent.

JEFFREY L. C. WRIGHT. Can. J. Chem. **57**, 2569 (1979).

Faisant appel à la rmn ^{13}C, on a trouvé que les principaux stérols du chlorophyte monocellulaire, *Dunaliella tertiolecta*, sont l'ergostérol et un triénol en C_{29} qui lui est intimement apparenté. Il semble que l'absence de paroi cellulaire dans le *D. tertiolecta* n'affecte pas beaucoup le type stérol produit puisque d'autres chlorophytes monocellulaires possédant une paroi cellulaire fournissent des stérols semblables portant une chaîne latérale qui n'est pas saturée et un substituant alkylé [*R*] en 24.

[Traduit par le journal]

Introduction

The distribution of sterols in marine algae is of phylogenetic interest to phycologists (1–4). Although patterns have emerged for major sterols within certain phyla (e.g., cholesterol in Rhodophyceae; fucosterol in Phaeophyceae) there is much variety among the Chlorophyceae. It arises through biogenetic alkylation at C-24 and modification of the tetracyclic ring system. Thus a range of Δ^5, Δ^7, and $\Delta^{5,7}$ compounds with methyl or ethyl substituents at C-24 have been reported as major sterols in Chlorophyceae (1, 4). Recently we used ^{13}C nmr spectroscopy to determine the structure and C-24 configuration of several alkyl sterols (5). This technique has now been applied in a study of the sterols of *Dunaliella tertiolecta* Butcher, a unicellular chlorophyte which is unusual in lacking a cell wall.

Results and Discussion

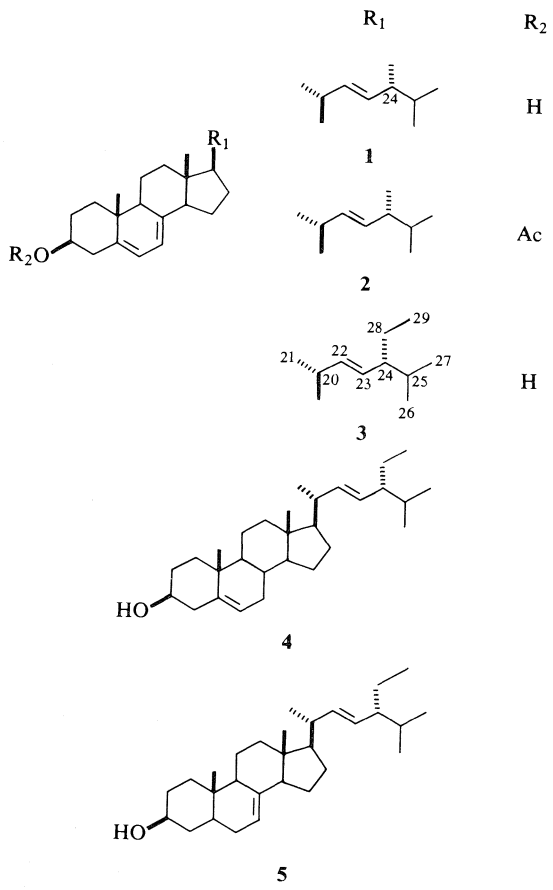
Sterols were separated from the non-saponifiable fraction of *D. tertiolecta* by silica gel chromatography. Gas–liquid chromatographic analysis (1.5% OV-17) of the combined sterol fractions showed two major components (Peaks B and E) and five minor ones. (Peaks A, C, D, F, and G). When the sterol mixture was acetylated the minor sterols were eluted together, before the two major sterols, from a silver nitrate – silica gel column. The major sterols, although freed from the minor components, could not be separated from each other by repeated argentation chromatography either as the parent compounds or as their acetates. The uv absorption of the mixture indicated that at least one contained an ergosterol-type nucleus. The smaller component (Peak B) had the same gas–liquid chromatography (glc) retention time as ergosterol (**1**) or its C-24 epimer. Gas chromatography – mass spectral (gc–ms) analysis of the acetate gave a mass spectrum identical (6) with that of ergosterol acetate (**2**) and high resolution mass spectral data of the free sterol established the molecular formula as $C_{28}H_{44}O$.

The glc retention time of the more abundant component (Peak E) corresponded with that for a C_{29} sterol (7), and the high resolution mass spectrum indicated a molecular formula of $C_{29}H_{46}O$. The gc–ms analysis of the acetate gave a mass spectral fragmentation pattern like that of ergosterol acetate but with the most abundant ions above *m/e* 355 at 14 mass units higher. Ions at *m/e* 392 and 377 correspond to loss of acetic acid and additional loss of methyl, but further cleavage yielded fragments at *m/e* 355, 341, 281, and 253, as found in ergosterol acetate. The striking similarity in mass spectral fragmentation patterns of the two sterol acetates including the common ion at *m/e* 253 which arises through loss of the complete side chain (6) indicates that the compounds differ only by an extra carbon in the side chain.

The ^{13}C nmr spectrum of the free sterol mixture contained 39 signals of varying intensity (Table 1). The sixteen most intense signals could be assigned to C-1 through C-19 of an ergosterol nucleus (8), though the signals for C-15, C-16, and C-17 appeared

[1]NRCC No. 17601.

0008-4042/79/192569-03$01.00/0



as pairs with components in the approximate ratio 1:2. Thus, both sterols share a common ergosterol-type nucleus but differences in the side-chain cause a perturbation of some resonances in ring D.

The seven least intense signals in the spectrum (δ_c 135.62, 132.05, 40.44, 33.13, 19.97, 19.67, and 17.64) can be assigned to an ergosterol side chain (Table 1). Resonances for C-21, (δ_c 21.16) and C-24 (δ_c 42.88) overlap with those for C-11 and C-13. The characteristic shift at δ_c 17.64,[2] assigned to C-28, establishes the configuration at C-24 as *R* (5) and hence ergosterol (**1**) as a major sterol of *D. tertiolecta*. The ten remaining resonances (δ_c 138.05, 129.66, 51.27, 40.73, 31.86, 25.41, 21.35, 20.94, 18.98, and 12.44) are accommodated by a Δ^{22} unsaturated side-chain containing an ethyl substituent at C-24 (Table 1). In this case the chemical shifts of C-28 (δ_c 25.41) and C-29 (δ_c 12.44)[3] indicate that the configuration at C-24 is also *R* (5), and thus identify (22*E*,24*R*)-24-ethylcholesta-5,7,22-trien-3β-ol (**3**) as the second major sterol. A similar trienol has been reported as a minor constituent in the prokaryotic blue-green alga *Phormidium luridum* (9), the unicellular chlorophyte *Chlamydomonas reinhardi* (10), and the unicellular chrysophyte *Ochromonas danica* (11), though in all cases the configuration at C-24 was not established.

The occurrence of ergosterol in *D. tertiolecta* and other Chlorophyceae (1) is interesting, since it is more generally recognised as a major sterol of fungi and yeast (12). However, the latter organisms biosynthesize it via a 24-methylene derivative (12) (Scheme 1, *a*) whereas the Chlorophyceae use an alternative route (e.g., Scheme 1, *b*) which may not include an unsaturated intermediate (2, 13, 14). The occurrence of (**1**) and (**3**) as major sterols in *D. tertiolecta* corresponds to the distribution in other unicellular chlorophytes (1, 4) of (**1**), poriferasterol (**4**), and chondrillasterol (**5**) which all possess a Δ^{22} side-chain and a 24[*R*]-alkyl substituent. Clearly the absence of a cell wall in *D. tertiolecta* does not drastically affect the

TABLE 1. ^{13}C nuclear magnetic resonance chemical shift data (δ_c TMS) for *D. tertiolecta* sterols, ergosterol (**1**), ergosterol acetate (**2**), and poriferasterol (**4**) in C^2HCl_3

type of sterol produced. Phylogenetically it is interesting that ergosterol and related $\Delta^{5,7}$ sterols have not been reported in multicellular species of green algae which, in fact, usually produce isofucosterol (1, 4).

Experimental

Gas–liquid chromatographic analysis was carried out with a Hewlett-Packard model 5750 chromatograph equipped with a flame-ionization detector and a packed column (3 m × 0.4 mm id) containing 1.5% OV-17 on Gas Chrom Q. The injector port was at 260°C, the detector at 260°C, the oven at 240°C; helium carrier gas was at 22 psi, flow 15 mL/min. The gc-ms analysis was performed with a Finnigan Model 4000; glc conditions: glass column (2 m × 0.4 mm id) containing 3% OV-1 on Gas Chrom Q, injector port 180°C, oven 250°C, He carrier gas, flow 30 mL/min. Mass spectral conditions: glass jet separator, probe at 250°C, 70 eV; ionising energy, scan limits 60 to 500 amu. Mass spectra were obtained with a DuPont model 21-110B double-focusing spectrometer used in the electrical detection mode; 8 kV accelerating voltage, 70 eV ionising energy. Accurate mass measurements were made by peak matching against a perfluorokerosene reference. ^{13}C nuclear magnetic resonance spectra were recorded with a Varian XL 100/15 Fourier transform spectrometer under the conditions already described (5). Sample concentration was 5–15 mg/mL in C^2HCl_3. Ultraviolet and infrared absorption spectra were recorded with GCA McPherson Series 700 and Perkin-Elmer model 237 spectrophotometers respectively.

Dunaliella tertiolecta Butcher (15) was maintained in an enriched seawater medium containing (per L) $NaNO_3$ 850 mg, NaH_2PO_4 7.66 mg, P–I metals (16) 10 mL, EDTA (Na Salt) 541 mg, ferric citrate 28.6 mg, $MgSO_4 \cdot 7H_2O$ 116 mg, at 25°C with constant illumination. Cultures were transferred every two weeks. For production one to two week old cultures (100 mL) were added to the above medium (30 L) in a sterilised glass culture tank designed and constructed in this laboratory.[4] The culture was grown aseptically at 25°C for five days with constant illumination (16 fluorescent tubes, 100 W) and pH was maintained at 7.6 by buffering with CO_2. The cells were harvested by centrifugation, freeze dried (14 g), saponified under reflux in methanol:water (3:7) containing 10% KOH for 2 h and the lipid fraction extracted with ether to yield a yellowish oil (286 mg.) Chromatography on a silica gel column (1.2 cm × 25 cm) using hexane and hexane–ether mixtures yielded a sterol fraction (35 mg) which by glc analysis showed peaks A, B, C, D, E, F, and G in the proportion 1, 27, 4, 15, 37, 5, and 11. Chromatography of the sterol acetates (pyridine and acetic anhydride, 16 h) on a 25% silver nitrate – silica gel column eluted with hexane–benzene mixtures yielded a fraction which glc analysis showed to contain five components corresponding to peaks A, C, D, F, and G of the original mixture and another fraction with two components corresponding to peaks B and E of the original mixture. The gc–ms analysis gave the following data: *m/e* (relative intensity) for peak B: 378 (13), [*M* − 60], 363 (6.6) [*M* − (60 + 15)], 355 (5) [*M* − 83], 341 (5) [*M* − 97], 281 (30) [*M* − (97 + 60)], 253 (23) [*M* − (125 + 60)]; peak E: 392 (15) [*M* − 60], 377 (10) [*M* − (60 + 15)], 355 (5) [*M* − 97], 341 (6.6) [*M* − 111], 281 (31.6) [*M* − (111 + 60)], 253 (30) [*M* − (139 + 60)]. Accurate mass measurement of the free sterol mixture: peak B, 396.3379 (M^+, calculated for $C_{28}H_{44}O$, 396.3392); peak E, 410.3545 (M^+, calculated for $C_{29}H_{46}O$, 410.3548); 392.3436 (*M* − H_2O, calculated for $C_{29}H_{44}$, 392.3443); λ_{max} (EtOH) 215.6, 271.6, 282.2, 293.8 nm; ν_{max} (KBr disc) 3600–3100, 1450, 1370, 1050, 1033, 965, and 830 cm^{-1}.

RATREMANIAINA ZO ANDRIAMIALISOA, NICOLE LANGLOIS, YVES LANGLOIS, PIERRE POTIER et PETER BLADON. Can. J. Chem. **57**, 2572 (1979).

La nor-5 catharanthine **3** est préparée à partir de la catharanthine **5**. Le couplage du N_b-oxyde correspondant **10** avec la vindoline **4**, dans les conditions de la réaction de Polonovski modifiée, conduit à deux dimères sans fragmentation du squelette.

L'obtention de nor-5 desméthoxycarbonyl-16 catharanthine **20** par clivage d'un des produits de couplage (**18**) de la vindoline **4** et du N_b-oxyde de desméthoxycarbonyl-16 catharanthine **17** corrobore la structure **18** qui avait été assignée à ce dimère dans notre laboratoire.

RATREMANIAINA ZO ANDRIAMIALISOA, NICOLE LANGLOIS, YVES LANGLOIS, PIERRE POTIER, and PETER BLADON. Can. J. Chem. **57**, 2572 (1979).

5-Norcatharanthine **3** was prepared from catharanthine **5**. The coupling of the corresponding N_b-oxide **10** with vindoline **4**, under modified Polonovski reaction conditions, led to two dimers without breaking the structural framework.

The isolation of 5-nor-16-demethoxycarbonylcatharanthine **20** by cleavage of one of the coupling products (**18**) of vindoline **4** and the N_b-oxide of 16-demethoxycarbonylcatharanthine **17** corroborates the structure **18** which was assigned to this dimer by our laboratory.

[Journal translation]

L'application de la réaction de Polonovski modifiée (2) au N_b-oxyde d'anhydrovinblastine **1**[3] se traduit par une compétition entre l'élimination d'un proton en C21′ et une fragmentation de la liaison C5′—C6′ (3). Cette dernière s'effectue avec participation de l'atome d'azote indolique ($N_{a'}$) et conduit, après hydrolyse des intermédiaires, perte de formol et cyclisation (Schéma 1) à la nor-5′ anhydrovinblastine **2** (3). L'accès, par cette méthode, à de nouveaux composés bis-indoliques du type norvinblastine nous a incités à étendre aussi ces résultats à la préparation des dérivés nor d'alcaloïdes monoindoliques. En particulier, il nous a semblé intéressant d'obtenir la nor-5 catharanthine **3** et d'étudier le couplage de ce nouveau composé avec la vindoline **4**.

Nous avons déjà montré (4) que la chaîne tryptaminique du N_b-oxyde **6** de la catharanthine **5** et d'autres composés du même type se fragmente dans les conditions de la réaction de Polonovski proprement dite (5) pour conduire, après addition d'un nucléophile en C6 tel qu'un ion acétate et cyclisation, à des composés tels que **8**, comportant l'enchaînement N_a—CH_2—N_b (Schéma 2).

Les essais d'hydrolyse du bis-immonium **7** impliqué dans cette réaction n'ont pas permis d'obtenir directement la nor-5 catharanthine **3**. En effet, la cyclisation $N_a \rightarrow C5$ s'effectue plus facilement que l'addition d'un hydroxyle sur le carbone 5 suivie de perte de formol et seul le composé **9** est obtenu.

Toutefois, des conditions acides plus énergiques (HCl 10%, 110°C) provoquent rapidement la réouverture de ce cycle et la nor-5 catharanthine **3** s'obtient alors avec 66% de rendement. Il est possible que le bis-immonium **7** soit régénéré au cours de cette réaction avec participation de l'azote N_b selon le Schéma 2, mais on ne peut pas exclure l'éventualité d'une protonation de l'azote N_b suivie de la participation de l'azote indolique qui conduirait au même résultat.

L'analyse spectrale de **3** prouve la structure indiquée. En particulier, l'analyse en haute résolution de l'ion moléculaire $M^{+\cdot}$ à *m/e* 322.1634 en spectrométrie de masse ($C_{20}H_{22}N_2O_2$), l'identification de tous les signaux en rmn du ^1H à haut champ (6) et en rmn du ^{13}C où le déplacement chimique du C6 se situe à 50.0 ppm (appariccine δ C6 = 54.3 ppm (7))

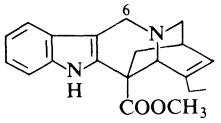
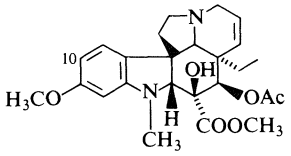
et celui du C16 à 45.1 ppm (catharanthine δ C16 ~ 55.5 ppm (8, 9)).

Le N_b-oxyde de nor-5 catharanthine **10** en présence d'anhydride trifluoroacétique et de vindoline **4** (10) n'évolue que très lentement à basse température (−70°C). Si la même réaction est effectuée à 0°C, la



3



4 vindoline

formation de deux composés est détectée en ccm avant l'addition de borohydrure de sodium, ce qui indique l'absence d'immonium en fin de réaction. L'analyse des deux dimères obtenus permet de leur attribuer respectivement les structures **12** et **14**, ce qui corrobore le fait précédent. Le dimère **12** résulte de l'addition de la vindoline **4** sur l'immonium **11** formé par élimination inhabituelle d'un des protons en C3 (Schéma 3, I) comme en témoignent, en particulier, la composition de l'ion *a* (35%) à *m/e* 562.2890 en spectrométrie de masse, et la présence d'un système AB attribuable à un méthylène de type gramine dans le spectre de rmn du ^1H. L'élimination d'un des protons en C6, en α de l'indole, conduit à l'immonium **13**, précurseur du dimère **14** (Schéma 3, II). Pour ce composé également, le spectre de masse (composition de l'ion *b* (100%) à *m/e* 668.2958) et le spectre de rmn du ^1H (absence de système AB vers

SCHÉMA 2

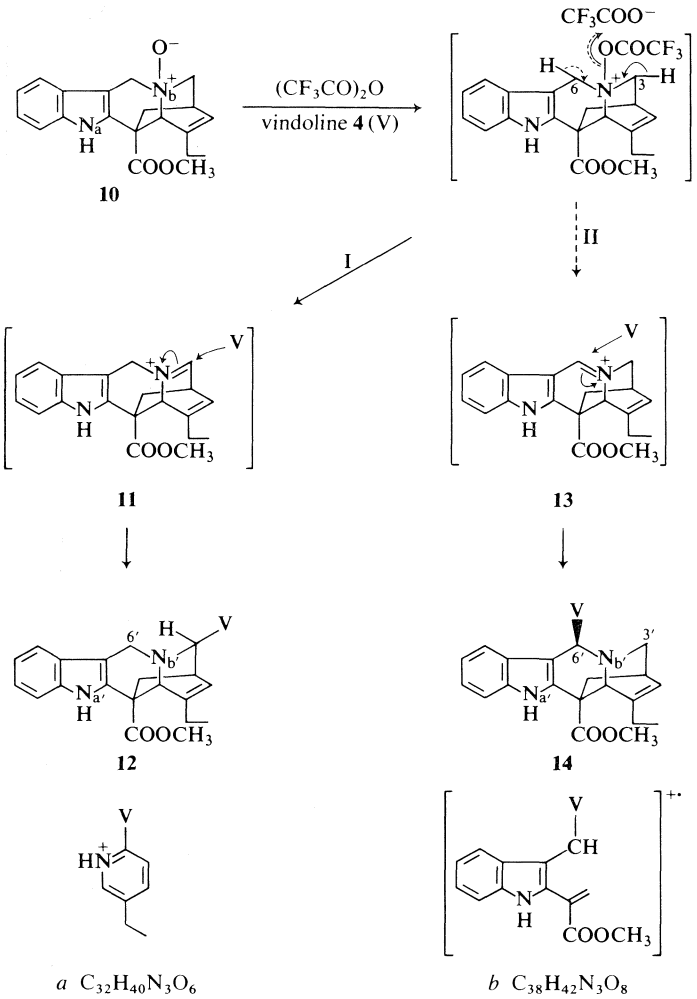

SCHÉMA 3

4 ppm et présence d'un singulet d'un proton à 5.58 ppm attribué à C6′—H) sont les plus caractéristiques. L'examen des modèles moléculaires est en faveur des configurations respectives en 3′ et 6′ indiquées sur les formules.

Aucun dimère résultant de la fragmentation C16—C21, majoritaire dans le cas du N_b-oxyde de catharanthine **6** (10, 11), n'a été observé. Dans le composé **10**, la rupture de cette liaison qui fait partie d'un cycle à 6 atomes est donc très défavorisée.

Lors du couplage de la vindoline **4** et du N_b-oxyde de catharanthine **6** dans les conditions de la réaction de Polonovski modifiée, la fragmentation décrite dans le Schéma 2 constitue une réaction secondaire (4%) conduisant au "dimère" **15** (10*b*). Avec certains dérivés de **6** comme le N_b-oxyde **17** de la desméthoxycarbonyl-16 catharanthine **16** (12), cette réaction est plus importante et le dimère **18** est obtenu avec un rendement d'environ 16% (13). Nous avons établi sa structure par analyse spectrale (13, 14). Cette structure **18** est très différente de celle (**19**) assignée par Kutney et collaborateurs, qui ont préparé un dimère présentant les mêmes caractéristiques en appliquant notre méthode de couplage (11). Leur argument principal reposait notamment sur l'identification du produit obtenu par coupure en milieu acide à la desméthoxycarbonyl-16 catharanthine **16**.

La possibilité de fragmenter en milieu acide les composés à enchaînement $—N_a—CH_2—N_b—$ tels que **8** et **9** (Schéma 2) nous a conduits à reproduire l'expérience de clivage du dimère **18** dans les conditions décrites par ces auteurs (11). Le seul composé indolique isolé de cette réaction s'est révélé différent de **16** en ccm et ses données spectrales sont en accord avec la structure nor-5 desméthoxycarbonylcatharanthine **20**. On observe en particulier dans le spectre de rmn du ^1H enregistré à 400 MHz[4] le système AB engendré par le méthylène de type gramine (C6—H_2)

à 4.44 et 4.11 ppm. Ceci corrobore la structure **18** que nous avions attribuée au dimère précurseur.

Contrairement au N_b-oxyde de catharanthine **6**, le N_b-oxyde de nor-5 catharanthine **10** ne subit pas de fragmentation C16—C21 dans les conditions de la réaction de Polonovski modifiée en présence de vindoline **4** mais on observe une compétition entre l'élimination d'un proton en C3 et C6. Les deux dimères obtenus seront soumis aux tests systématiques pour évaluer leur rôle éventuel d'inhibiteur de polymérisation de la tubuline (15).

Partie expérimentale

Les points de fusion ont été pris sur bloc Kofler et sont corrigés. Les pouvoirs rotatoires ont été mesurés au moyen du polarimètre électronique Perkin-Elmer 141 MC. Les spectres ir (ν cm^{-1}, $CHCl_3$, sauf indication contraire) ont été enregistrés sur spectromètre Perkin-Elmer 257, les spectres uv (EtOH, λ_{max} nm (ε)) sur appareil Bausch et Lomb Spectronic 505 et les courbes de dc [EtOH, λ_{max} nm (Δε)] sur dichrographe Roussel-Jouan. Les spectres de rmn (sauf mention contraire dans $CDCl_3$, avec le TMS comme indicateur interne δ = 0 ppm) ont été effectués, pour le ^1H sur appareils IEF 240 MHz (6) ou 400 MHz[4] (les constantes de couplage sont exprimées en Hz, les lettres s, d, t, dd et m désignent respectivement les singulets, doublets, triplets, doublets de doublets et multiplets), et, pour le ^{13}C sur appareil Brüker HX 90 E ou Caméca 250 MHz. Les spectres de masse ont été enregistrés sur spectrographe AEI type MS 9, MS 50 ou MS 902. Les chromatographies sur couches épaisses (cce) ont été effectuées avec le Kieselgel HF 254 + 366 Merck.

Préparation de la nor-5 catharanthine **3**

A une solution de N_b-oxyde de catharanthine (200 mg, 0.57 mmol) préparé comme décrit (10*b*), dans 25 mL de chlorure de méthylène sec, maintenue à 0°C sous atmosphère inerte, on ajoute 2.5 mL d'anhydride acétique. Le mélange est agité à température ambiante pendant 1.5 h. Le solvant et l'excès de réactif sont évaporés sous vide. Une solution du résidu dans 40 mL d'acide chlorhydrique aqueux à 10% est ensuite chauffée sous argon à 110°C pendant 10 min. Le milieu réactionnel refroidi à 0°C est alcalinisé par NH_4OH concentrée et extrait par du chloroforme. Après séchage (Na_2SO_4) et évaporation du solvant sous pression réduite (traitements habituels), on obtient la nor-5 catharanthine **3** (180 mg) qui est purifiée par cce de silice (éluant: acétate d'éthyle, cuve saturée de NH_3), 120 mg (66%); $[\alpha]_D$ 0° (*c* 0.69, $CHCl_3$); chlorhydrate $[\alpha]_D$ −17° (*c* 0.63, CH_3OH); ir: 3400, 2950, 1730 cm^{-1}; uv (CH_3OH): 228(34 000), 276(ep 10 800), 284(11 000), 291(9700); uv (CH_3OH–HCl): 224-(31 800), 260(12 100), 272(ep 11 600), 288(9500); dc (CH_3OH): 230 (+1.5), 275 (+1.1); sm pics à *m/e* (%): 322.1634 (33), $C_{20}H_{22}N_2O_2$ calc.: 322.1629; 214(100); 154.0659 (42), $C_{11}H_8N$ calc.: 154.0659; 131.0740 (13), C_9H_9N calc.: 131.0741; 121.0911 (3), $C_8H_{11}N$ calc.: 121.0913; 109.0891 (57), $C_7H_{11}N$ calc.: 109.0891; 108.0819 (51), $C_7H_{10}N$ calc.: 108.0820. N_b-oxyde de nor-5 catharanthine ***10***

A une solution de nor-5 catharanthine **3** (48 mg, 0.15 mmol) dans du chlorure de méthylène anhydre (2 mL) maintenue sous argon, on ajoute à 0°C et sous agitation 30 mg (0.17 mmol) d'acide *m*-chloroperbenzoïque. Après 5 min d'agitation à 0°C, le milieu réactionnel est alcalinisé par une solution aqueuse de Na_2CO_3 à 10%, puis extrait par du chloroforme. Après traitements habituels, le N-oxyde de nor-5 catharanthine **10** est purifié par cce de silice (éluant: chloroforme–méthanol 94:6, sat. NH_3), on isole 31 mg (rdt 62%) de N_b-oxyde **10**.

Infrarouge: 3400, 2950, 1740 cm^{-1}; uv: 225, 276, 286, 292; inchangé en milieu acide; sm *m/e*: 338 ($M^{+\cdot}$), 322, 294, 234, 214 (100%), 158, 154, 130, 109, 108; rmn du ^1H (Varian 60 MHz) δ: 9.10 (s, 1H, N_a—H), 7.53–7.0 (m, 4H aromatiques), 6.33 (m, 1H, C15—H), 4.83 (m, 2H, C6—H), 4.50 (s élargi, 1H, C21—H), 3.80 (s, 3H, CO_2CH_3), 1.13 (t, 3H, *J* = 7.0, C18—H).

Couplage du N_b-oxyde de nor-5 catharanthine ***10*** *avec la vindoline* ***4***

A une solution de N_b-oxyde **10** (310 mg, 0.92 mmol) et de vindoline **4** (450 mg, 0.98 mmol) dans du CH_2Cl_2 anhydre (2.5 mL) maintenue sous argon à 0°C, on ajoute, sous agitation, l'anhydride trifluoroacétique (0.345 mL, 2.4 mmol). Le mélange est agité à 0°C pendant 45 min, puis le solvant et l'excès d'anhydride sont évaporés sous vide. Le résidu en solution dans du méthanol (20 mL) est réduit par un excès de $NaBH_4$. Après 10 min, le milieu réactionnel est dilué par de l'eau distillée et extrait par du chloroforme. Après traitements habituels, on obtient 700 mg de résidu qui est chromatographié sur cce de silice (éluant: acétate d'éthyle – méthanol 99.25:0.75, 2 migrations de 20 cm). On isole le dimère **12** (200 mg, 0.26 mmol, rdt 28%), la vindoline **4** (200 mg, 44%), la nor-5 catharanthine **3** (40 mg, 13%) et le dimère **14** (160 mg, rdt 23%).

Dimère ***12*** *(vindolinyl-3′ nor-5 catharanthine)*

*Desméthoxycarbonyl-16 catharanthine **16***

Une solution d'acide catharanthinique (350 mg, 1.09 mmol préparé quantitativement à partir de **5** (3, 13)) dans de l'acide trifluoroacétique (30 mL) est agitée sous argon à température ordinaire pendant 30 min. Après évaporation sous pression réduite à la même température et alcalinisation par une solution aqueuse de Na_2CO_3, la desméthoxycarbonyl-16 catharanthine **16** est extraite par du chloroforme et purifiée par cce de silice (éluant éther–cyclohexane–méthanol 70:20:10). On obtient 273 mg de desméthoxycarbonyl-16 catharanthine **16** (rdt 90%) déjà connue (12).

Infrarouge: absence de carbonyle; uv: 228(16 500), 284(7500), 292(5700); dc(CH_3OH): 230 (+1.4), 240(−3.1), 305 (−0.2); sm *m/e*: 278, 170, 156, 143, 135(100%), 122, 121, 107; rmn du ^1H δ: 7.80 (s, 1H, N_a—H), 7.4–7.0 (aromatiques), 5.80 (d large, 1H, $J_{14,15}$ = 8, C15—H), 3.17 (m, 1H, C21—H), 2.14 (m, 2H, C19—H), 1.87 (m, 1H, C16—H), 0.90 (t, 3H, $J_{18,19}$ = 7, C18—H); rmn du ^{13}C (13).

*Dimère **18***

Le dimère **18**, préparé comme décrit (11, 13, 14) présente les caractéristiques suivantes: $[\alpha]_D$ −26° (*c* 0.33); ir: 1745, 1620 cm^{-1}; uv: 214 (45 200), 222 (épaulement 36 700), 254 (13 000), 286 (9000), 295 (8500), 304 (épaulement 7000); dc: 250 (+16.9), 295 (+0.2), 305 (+0.4); sm pics à *m/e*: 732 ($M^{+\cdot}$), 673, 672, 624, 573, 571, 465, 464, 357, 343, 324, 282, 178, 135 (pic de base), 122, 121; rmn du ^1H (240 MHz) δ: 7.43–7.03 (m, 4H aromatiques), 6.53 (s, 1H, C9—H), 6.12 (s + m, 2H, C12—H et C15′—H), 5.82 (dd, 1H, $J_{14,15}$ = 10 et $J_{3,14}$ = 3.5, C14—H), 5.40 (s, 1H, C17—H), 5.20 (d, 1H, $J_{14,15}$ = 10, C15—H), 5.18 (d, 1H, J_{AB} = 12.8, C5′—H_a), 4.94 (d, 1H, J_{AB} = 12.8, C5′—H_b), 3.90 et 3.80 (2s, 6H, C11—OCH_3) et C16—CO_2CH_3), 2.71 (s, 3H, N_a—CH_3), 2.11 (s, 3H, $OCOCH_3$), 1.13 (t, 3H, $J_{18',19'}$ = 7, C18′—H), 0.27 (t, 3H, $J_{18,19}$ = 7, C18—H).

*Clivage du dimère **18***

Le dimère **18** (60 mg, 0.08 mmol) est traité par de l'acide chlorhydrique à 10% en présence d'étain et de chlorure d'étain comme décrit (11).

La séparation des produits obtenus par cce de silice (acétate d'éthyle – méthanol 96:4, cuve saturée de NH_3) permet d'isoler, à côté de vindoline **4**, de son dérivé désacétylé, de dimère **18** qui n'a pas réagi et de produits polaires, la nor-5 desméthoxycarbonyl-16 catharanthine **20** (10 mg, 46%).

Infrarouge: 3400, 2950; uv (CH_3OH): 228, 276, 282, 290; sm *m/e*: 264, 182, 156 (100), 154, 149, 139, 110, 108; rmn du ^1H (400 MHz) δ: 8.15 (m, 1H, N_a—H), 7.4–7.0 (m, 4H aromatiques), 6.15 (d élargi, 1H, $J_{14,15}$ ~ 5, C15—H), 4.44 (d, 1H, $J_{6a,6b}$ = 15, C6—H_a), 4.11 (d, 1H, $J_{6a,6b}$ = 15, C6—H_b), 1.10 (t, 3H, $J_{18,19}$ = 7, C18—H).

Remerciements

Nous remercions la Ligue Nationale Française contre le Cancer pour l'attribution d'une bourse (R. Z. Andriamialisoa), le Dr. J. Y. Lallemand (École Normale Supérieure, Paris) pour l'enregistrement de spectres de RMN sur Caméca (250 MHz), C. Marazano pour des discussions concernant les spectres de masse et les Laboratoires Eli Lilly pour la fourniture de catharanthine.

Polar radicals XIII.[1] A reinvestigation of the polar effects reported for the hydrogen transfer reactions of the 1-ethylpentyl radical

DENNIS D. TANNER, ROBERTO HENRIQUEZ,[2] AND DARWIN W. REED

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received March 23, 1979

DENNIS D. TANNER, ROBERTO HENRIQUEZ, and DARWIN W. REED. Can. J. Chem. **57**, 2578 (1979).

The relative kinetics obtained from the decomposition products of *tert*-butyl-2-ethylperhexanoate, BEPH, (0.1 *M*) in mixtures of toluene and carbon tetrachloride were reinvestigated. Relative reactivities calculated from the ratios of heptane to 3-chloroheptane formed from BEPH decompositions in a variety of substituted toluenes, with added carbon tetrachloride, gave a similar Hammett correlation to that previously reported, but with a rather poor correlation coefficient ($r = 0.88$, $\rho = 0.68$).

From a material balance of the products formed it was determined that very few if any of the 1-ethylpentyl radicals formed ultimately abstract a benzylic hydrogen from toluene or a substituted toluene. The small amounts of heptane found (<0.7%) at any of the kinetically meaningful ratios of substrates, $ArCH_3/CCl_4$ 2.1 to 16.3, could have potentially arisen from radical disproportionation. No appreciable amount of aromatic substitution product could be detected under these conditions.

Decompositions of BEPH carried out in neat toluene only yielded small amounts (~0.4%) of addition product; however, the absolute amounts of heptane produced in reactions run in *p*-cyanotoluene were less than those formed in reactions carried out in toluene. These observations do not argue strongly for the authenticity of a relatively large positive ρ value (previously reported, +0.7) arising either from benzylic abstraction, or from addition to the aromatic ring.

DENNIS D. TANNER, ROBERTO HENRIQUEZ et DARWIN W. REED. Can. J. Chem. **57**, 2578 (1979).

On a étudié les cinétiques relatives à partir des produits de décomposition de l'éthyl-2 perhexanoate de *tert*-butyle, EPHB (0.1 *M*), dans des mélanges de toluène et de tétrachlorure de carbone. Les réactivités relatives calculées à partir des rapports d'heptane: chloro-3 heptane formés par décomposition de EPHB dans des toluènes substitués auxquels on a ajouté du tétrachlorure de carbone conduisent à des corrélations de Hammett semblables à celles rapportées antérieurement; le coefficient de corrélation est toutefois médiocre ($r = 0.88$, $\rho = 0.68$).

En se basant sur un bilan pondéral des produits formés, on peut déterminer que les radicaux éthyl-1 pentyles formés n'enlèvent que peu d'hydrogènes benzyliques du toluène ou des toluènes substitués. Les faibles quantités de pentane trouvées (<0.7%) à tous les rapports de substrat présentant une signification cinétique $ArCH_3/CCl_4$: 2.1 à 16.3, pourraient provenir d'une dismutation du radical. Dans ces conditions on n'a pas pu détecter des quantités appréciables de produits de substitution aromatique.

Les décompositions du EPHB effectuées dans le toluène pur ne conduisent qu'à de faibles quantités, ~0.4%, de produit d'addition; toutefois les quantités absolues d'heptane produites lors de réactions effectuées dans le *p*-cyanotoluène sont plus faibles que celles obtenues lorsque les réactions sont effectuées dans le toluène. Ces observations ne correspondent pas beaucoup à une valeur de ρ relativement très positive (rapportée antérieurement à +0.7) provenant soit de l'enlèvement benzylique ou d'une addition au noyau aromatique.

Introduction

Substituent effects observed in the hydrogen transfer reactions of substituted toluenes have generally been explained as arising from the contribution of dipolar structures to the stabilities of the transition states for these reactions, i.e., polar effects (1).

Several years ago an interesting alternative proposal for these substituent effects was proposed by Zavitsas and Pinto (2). These authors suggested that polar effects were unnecessary considerations in rationalizing the relative rates of these reactions, but that the effects observed could be explained solely on the basis of the effect of the substituent on the bond dissociation energy of the benzylic carbon–hydrogen bond. Since a large number of radical abstraction reactions from substituted toluenes had been shown to have negative Hammett ρ values, it followed from their proposal that only negative ρ values could be obtained from these abstraction

reactions since the nature of the abstracting species could not affect the ordering of the bond dissociation energies.

Evidence against the Zavitsas proposal was subsequently reported (3, 4), but the most convincing arguments against these ideas were the publication of the positive ρ values obtained from the kinetic studies of a number of alkyl radicals, undecyl (5, 6) (ρ, +0.5), isopropyl (7) (ρ, +0.8), 1-ethylpentyl (8) (ρ, +0.7), and *tert*-butyl (7, 9) (ρ, +1.0), generated in the presence of a series of substituted toluenes. The validity of the reported ρ value for the primary undecyl radical has been seriously questioned by Zavitsas (10). In a reinvestigation of the ρ value obtained for the *tert*-butyl radical, the ρ value previously reported was shown to be an artifact of a competing reaction, cage disproportionation, since the production of the isobutane formed from the radicals was governed by the viscosity of the toluene (solvent) in which the radical source, 2,2′-azoisobutane, was decomposed (11).

In order to substantiate whether any authentic positive ρ values have been determined for alkyl radicals it has become necessary to reinvestigate the reaction previously reported for the two still unchallenged, secondary radicals. The study of the isopropyl radical (7) was carried out in a manner similar to that for *tert*-butyl, and its reactions are presently being reinvestigated. The results of the reinvestigation of the 1-ethylpentyl radical is the subject of this report.

The method used by the previous author was to generate the 1-ethylpentyl radical (R·) by the thermolysis, at 80°C, of *tert*-butyl-2-ethylperhexanoate (BEPH) in a mixture of a toluene (QH) and carbon tetrachloride (8).

$$\text{Perester} \rightarrow \text{R}\cdot \text{ and other products}$$

$$\text{R}\cdot + \text{QH} \xrightarrow{k_H} \text{RH} + \text{Q}\cdot$$

$$\text{R}\cdot + \text{CCl}_4 \xrightarrow{k_{Cl}} \text{RCl} + \text{CCl}_3\cdot$$

The values for k_H/k_{Cl} were obtained from plots of [RH]/[RCl] vs. [QH]/[CCl_4] and from these values, assuming that k_{Cl} is constant with different QH toluenes, the relative values of k_H/k_H^0 could be determined. The method assumes that the only source of RH is from abstraction by the 1-ethylpentyl radical (R·) from a substrate toluene.

Results and Discussion

Although Henderson did not report the [QH]/[CCl_4] ratios used in his kinetic studies (8) it became immediately apparent, upon the repetition of the reported reactions, that the range that could conceivably have been used must have been quite limited. When the BEPH decompositions were carried out in substrate mixtures having ratios of [QH]/[CCl_4] of 2.13 (QH, toluene) very little heptane, <0.5%, could be detected ([RH]/[RCl], 8.3×10^{-3}), while at a larger [QH]/[CCl_4] ratio, 16.3, the value of [RH]/[RCl] that was determined, 11.0×10^{-3}, did not appear to change appreciably from those obtained at the lower ratio. Even at the larger ratio only 0.75% of heptane (RH) was formed during a typical decomposition carried out in toluene and carbon tetrachloride (0.5 *M*), see Table 1.

At the larger [QH]/[CCl_4] ratio, 16.3, a material balance was obtained (QH, toluene) which accounted for 98% of the products resulting from the BEPH decomposition, see Table 1.

The small values of [RH]/[RCl] found in the perester decompositions were expected and are predictable, since the competitive abstraction reactions of 1-hexyl radicals from substrate mixtures of toluene and carbon tetrachloride had previously been reported by DeTar and Wells (12). These authors carried out the decomposition reactions of *n*-heptanoyl peroxide in mixtures of toluene and carbon tetrachloride, [QH]/[CCl_4], ranging from 4.17–0.265 and found, for the less selective primary 1-hexyl radical, values of [RH]/[RCl] of from 59×10^{-3} to 25×10^{-3}. From these values the relative rates of transfer between toluene and carbon tetrachloride, k_H/k_{Cl}, could be approximated, after an estimated correction for cage disproportionation had been applied, to be $6 \times 10^{-2} \pm 10^{1}$. The smaller values obtained for the more selective 1-ethylpentyl radical, 6.6×10^{-4}, are not unreasonable in light of the small value previously reported for the 1-hexyl radical.

Reactions carried out at the higher [QH]/[CCl_4] ratio, 16.3, with a variety of QH solvents gave simi-

larly small ratios of [RH]/[RCl], 11×10^{-5} to 23×10^{-3}, over the entire range of substrates previously used by Henderson (substituted toluenes with σ values of -0.17 to 0.63) (8) (see Table 2). The yield of heptane in these reactions ranged from 0.75–1.4%. The relative rates calculated from the [RH]/[RCl] ratios obtained from these reactions, although very reproducible, gave a poor fit to the Hammett equation, $\rho = 0.56$, $r = 0.88$ (see Table 3).

The Hammett parameters, however, are quite similar to those reported by Henderson (8), $\rho = 0.70 \pm 0.09$ ($r = 0.94$). The supposition that the heptane was produced solely by radical abstraction from toluene must be questioned since accompanying the heptane were three products arising from hydrogen transfer reactions, 2-heptene, 3-heptene, and a substituted stilbene. The ratio of olefinic products to heptane in the reaction run in toluene was 10.7 (see Table 1). Similar values, >7.2–12.8, were obtained for the reactions run in the other substrates; amounts of substituted stilbenes were not included in these calculations, as only stilbene itself was determined quantitatively (see Table 2).

An average material balance of 99 ± 2% was obtained for the radicals produced from the decomposition of the BEPH in all solvents.

From an analysis of the products formed from the decomposition of BEPH in the toluene–carbon tetrachloride mixture a reasonable picture can be formulated for the decomposition of the perester and for the subsequent reactions of its radical products.

A plethora of reactions must be considered due to the complexity of the reaction mixture (see Fig. 1). The formation of heptane by disproportionation as well as abstraction, need be considered (see reactions [12]–[14]); however, heptane's disproportionation partner, heptene (reaction [14]), cannot only be formed external to the solvent cage (reactions [14] and [15]) but within the solvent cage (reaction [2]). In order to establish the potentiality of disproportionation (reaction [14]) as a source of the small

amounts of heptane, the cage yield of heptene (and conceivably heptane) was examined. Since carbon tetrachloride appears to be such a good transfer agent, decompositions carried out in pure carbon tetrachloride should scavenge a large fraction of the radicals which escape cage reaction. As expected only traces, $1.4 \times 10^{-3}\%$, of 2- and 3-heptene and heptane, $6 \times 10^{-2}\%$, were formed when the decomposition of BEPH (0.1 *M*) was carried out in pure carbon tetrachloride. It is clear from these results that a major amount (>90%) of the 2- and 3-heptene as well as the *cis*- and *trans*-stilbenes found in the kinetic runs were formed external to the solvent cage by radical disproportionation and, therefore, could act as potential sources of hydrogen for the formation of heptane.

Another potential hydrogen donor that need be considered is the cyclohexadienyl radical resulting from the addition of the 1-ethylpentyl radical to the aromatic ring. Since homolytic aromatic substitution has been suggested to be the genesis of the positive ρ value observed in the reactions of undecyl radicals with a series of substituted toluenes (10), it became necessary to obtain an estimate of the relative bimolecular rate constants, k_{ad}/k_{ab}, for the reactions of 1-ethylpentyl radicals with toluene. When the decomposition of BEPH (0.1 *M*) was carried out in neat toluene both the products of addition and abstraction were obtained; however, the yield of addition products was found to be negligible, about 0.4%, compared to the heptane (63%) produced (see Table 4). The ratio of the yield of addition products to heptane was therefore calculated to be 6×10^{-3} and k_{ad}/k_{ab} must be somewhere between 6×10^{-3} and 8×10^{-3} (after a correction for possible disproportionation to form olefins (see Table 4)). It was obvious from these small values for the relative rates of addition vs. abstraction that for the reactions carried out in carbon tetrachloride and toluene, which

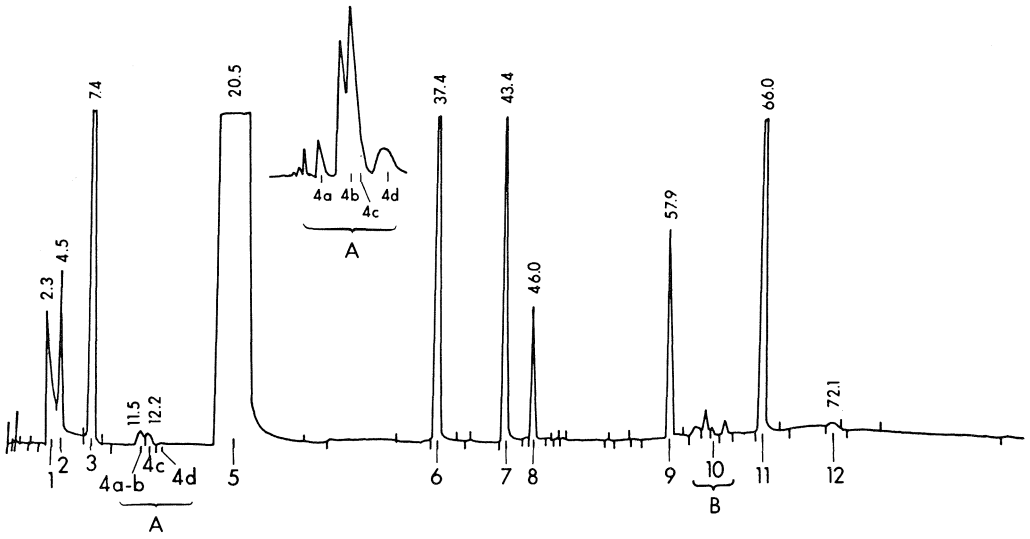

FIG. 1. Glc chromatogram and peak assignments for the reaction mixture from the thermolysis (80°C) of BEPH (0.1 *M*) in a mixture of toluene and carbon tetrachloride (0.5 *M*). The chromatogram was obtained using the SE-30 column, while the insert portion (A) was obtained using the Carbowax 400 column. **1**, *tert*-Butanol; **2**, chloroform; **3**, carbon tetrachloride; **4***a*, heptane; **4***b*, 2-heptene; **4***c*, 3-heptene; **4***d*, —; **5**, toluene; **6**, 3-chloroheptane; **7**, benzyl chloride; **8**, *tert*-butyl-3-heptyl ether; **9**, 1,1,1-trichloro-2-phenylethane; **10**, 3-benzylheptane; **11**, bibenzyl; **12**, *t*-stilbene.

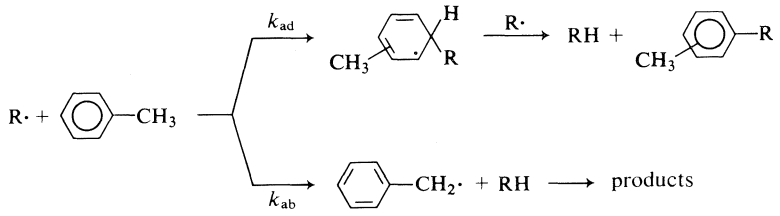

showed so little abstraction, no detectable amount of addition would be found.

When BEPH (0.1 *M*) was thermolyzed (80°C) in neat *p*-cyanotoluene the absolute amount of heptane (40.8%) formed in the BEPH decompositions carried out in the supposedly more hydrogen donating solvent, *p*-cyanotoluene, was less than 2/3 that formed when the decomposition was carried out in toluene.

TABLE 4. Products from the thermolysis (80°C) of BEPH (0.1 *M*) in toluene

Products	Yield (mol/mol BEPH)[a]	%
Heptane	0.632±0.035	63.2

Conclusion

Toluene (or a substituted toluene) as a donor of benzylic hydrogen appears to compete quite poorly with carbon tetrachloride, as a transfer reagent, at all practical concentrations, for reaction with secondary alkyl radicals. Kinetic methods based on these competitive rates have very little possibility of being definitive since other sources of hydrogen, kinetically more favorable, are available to the alkyl radicals. In kinetic runs the formation of disproportionation products, olefins, far outweighs the heptane produced. The olefinic products produced in the reaction were shown to be formed, primarily, external to the solvent cage, and thus their precursor radicals are established as a potential source of hydrogen for the formation of heptane.

Decompositions of BEPH carried out in pure toluene demonstrated that addition to the aromatic ring is negligibly competitive with benzylic abstraction. Addition products only accounted for the reaction of ca. 0.4% of the 1-ethylpentyl radicals that were produced, while the absolute amount of heptane

produced in the reaction was less for the reactions run in *p*-cyanotoluene than the reactions carried out in toluene. These observations do not argue strongly for a relatively large, $\rho = +0.7$, positive ρ value caused either from benzylic abstraction (8), or from addition to the aromatic ring (10).

A calculation of the relative rates of reaction of the substituted toluenes obtained using the competitive method of Henderson (8) gave relative rate constants which showed a poor correlation with their Hammett substitution constants ($r = 0.88$, $\rho = +0.66$). Since under the most favorable conditions the yield of heptane amounts to only from <0.5–0.75% of the 3-ethylpentyl radicals produced, and since under these reaction conditions it was not experimentally possible to determine the genesis of this small amount of heptane, the nucleophilicity (8) or electrophilicity (10) of a secondary alkyl radical has not as yet been experimentally demonstrated.

Experimental

Materials

Toluene and *p*-xylene (Phillips 66, research grade, >99.9%) were used without further purification. *m*-Xylene and *m*-chlorotoluene (Eastman Chemical Co.) were fractionally distilled (24 in. teflon spinning band column) before use. *p*-Cyanotoluene and *p*-chlorotoluene (Aldrich Chemical Co.) were purified by repeated low temperature fractional recrystallization followed by fractional distillation, using a 24 in. teflon spinning band column. Carbon tetrachloride (Baker Chemical Co., spectral grade), was fractionally distilled before use. All these materials were shown by glpc (10 ft × 1/4 in. 10% QF-1 on 60/80 Chromosorb P AW DMCS, glass column) to be >99.9% pure.

tert-Butyl-2-ethylperhexanoate (BEPH) was prepared according to an adaptation of the method reported in the literature for *tert*-butyl perpivalate (13). The perester was purified by column chromatography on activated alumina at 0°C, using dry ether as eluent. *Anal.* calcd. for $C_{12}H_{24}O_3$: C 66.63, H 11.18; found: C 66.83, H 11.02.

3-Chloroheptane (**6**) was prepared using the general method for preparation of secondary halides with thionyl chloride and 3-heptanol in pyridine as solvent (14). The chloride was fractionally distilled through a 24 in. teflon spinning band column and shown to be one compound by glpc (7.5% SE-30 Chromosorb PAW 60/80 10 ft × 1/4 in. column and on the QF-1 column); bp 144°C/751 Torr. *Anal.* calcd. for $C_7H_{15}Cl$: C 62.42, H 11.22; found: C 62.53, H 11.37.

tert-Butyl-3-heptyl ether (**8**) was prepared according to the method of Henry (15); bp 164–166°/740 Torr. Its glpc (SE-30, column) retention time and mass spectral cracking pattern (*m/e* 143 M^+, base peak 57, $C_4H_9^+$) and ir spectra were identical to those obtained from the product (assigned this structure) which was formed in the perester decomposition reaction.

1-(3-Heptyl)-4-methylbenzene, 1-(3-heptyl)-3-methylbenzene, and 3-benzylheptane (**10**) were synthesized by the hydrogenation of the olefins obtained from the dehydration of the alcohols which were obtained from the reaction of 3-heptanone with the appropriate Grignard reagent (16).

Thermolysis of tert*-Butyl-2-ethylperhexanoate (BEPH)*

Aliquot solutions of BHP (0.1 *M*), the appropriate toluene (7–8 *M*), and carbon tetrachloride (0.5–0.6 *M*) were placed in Pyrex ampoules, degassed by the freeze–thaw method, and sealed. The sealed ampoules were thermostated at 80 ± 0.1°C for 76 h.

One of the reactions was carried out in an ampoule fitted with a break seal. After the reaction the ampoule was opened to a vacuum line and the CO_2 produced in reaction was fractionated, measured, and identified by its glpc retention time and mass spectrum, all in the manner previously described (13). The decomposition was found to have proceeded essentially to completion since 98.8% of the theoretical carbon dioxide was isolated.

After thermolysis the ampoules were opened and a weighed amount of internal standard (*p*-nitrotoluene) was added and the mixture was then subjected to glpc analysis using the SE-30 column. A typical chromatogram (toluene as substrate) is given in Fig. 1. The glpc chromatogram indicated the presence of a large number of products. The identity of the products (compounds **1**–**4***b*, **5**–**8**, and **10**–**12**) was established by a comparison of their glpc retention times, mass spectral cracking patterns, and ir spectra with those of authentic samples. The structure of the compound corresponding to **4***c* (see Fig. 1), 3-heptene, was tentatively assigned on the basis of the following observations. In the course of the synthesis of 3-chloroheptane several olefinic products are formed. One of these corresponded (identical glpc retention time and mass spectral cracking pattern) to 2-heptene, while the other olefin corresponded to the compound assigned the structure 3-heptene. The products with lower retention times, heptane, 2-heptene, and 3-heptene, were analysed by glpc using a second column (10% Carbowax 400 Diotoport WAW 60-80 mesh 20 ft × 1/8 in. ss column) (see insert A in Fig. 1).

An aliquot of the reaction mixture (with toluene as substrate) was treated with a small amount of bromine in the absence of light for about 5 min; glpc analysis using both the SE-30 and Carbowax 400 columns showed the disappearance of the peaks corresponding to 2-heptene, 3-heptene, and *trans*-stilbene.

The identity of the chromatographic peak corresponding to 3-heptene was assigned on the basis of the reaction of the compound with molecular bromine and because of the similarity of its mass spectral cracking pattern with that of its isomer 2-heptene. Analysis by glpc–ms showed ions at *m/e* 98 (M^+, 20.4%) and 55 ($M^+ - C_3H_7$, 100%), while 2-heptene gave *m/e* 98 (M^+, 22.9%) and 41 ($M^+ - C_4H_9$, 100%).

The structure of 1,1,1-trichloro-2-phenylethane (**9**) was assigned according to its mass spectral cracking pattern, which showed weak intensity parent ions, *m/e* 212, 210, 208 (M^+) whose relative intensities were consistent with the ratios produced for three chlorine atoms (calcd. 0.01, 0.13, 0.42, 0.43; found: 0.0, 0.12, 0.42, 0.45), base peak *m/e* 91 corresponding to $C_7H_7^+$, and its ir spectra which showed aromatic absorption at 3080, 3040, 705, and 768 cm^{-1}, and CH_2 absorption at 2940 and 1460 cm^{-1}.

The chromatographic peaks on either side of **10** (see section B, Fig. 1) did not compare (ir, mass spectral cracking pattern, or glpc retention times) with either of the two substitution products, 1-(3-heptyl)-4-methylbenzene or 1-(3-heptyl)-3-methylbenzene. The first peak (section B, Fig. 1) had the same retention time as the two substitution products, but ir and mass spectra were different than those of the authentic materials.

The thermolyses of BEPH in neat solvents, carbon tetrachloride, toluene, and *p*-cyanotoluene were carried out in the same manner as the reactions that were run in the mixed substrates. The products identified (see Table 4) were assigned the structures listed on the basis of a comparison of their glpc retention times, SE-30 and Carbowax 400 columns, and their mass spectra with those of authentic samples.

Gas–Liquid Partition Chromatographic Analyses

The quantitative glpc analyses were carried out using both the SE-30 and Carbowax 400 columns (see Fig. 1). The area ratios of the product and an added standard were obtained using a HP-3380A integrator. The mole ratios of products were determined using standard calibration curves obtained using known mixtures of the authentic materials. For the compounds listed below, the authentic materials were not available and the calibration factors obtained from model compounds were used: 3-heptene (model compound 2-heptene); 1,1,1-trichloro-2-phenylethane (calibration factor 1).

Gas–Liquid Partition Chromatographic – Infrared Analyses

The glpc–ir analyses were carried out on kinetic reaction mixtures from the reaction of 0.1 *M* BEPH and 0.5 *M* carbon tetrachloride in toluene. The spectrum for each compound was obtained using a Nicolet 7199 FT-IR interfaced to a Nicolet series 7000 gas chromatograph fitted with a 6 ft × 1/8 in. OV-1, 3%, ss column. The spectrum of each component was compared with that of the authentic material.

Acknowledgements

The authors wish to thank the National Research Council of Canada and the University of Alberta for their generous support of this work. We would further like to express our appreciation to Dr. R. L. Julian of the Nicolet Instrument Corporation for carrying out the gc–ir analyses in their laboratory.

The partial molal volumes $\bar{V}^0$ in carbon tetrachloride at 25°C of 13 ketones, 18 alcohols, and 17 mono- or poly-functional ethers, all acyclic, have been determined. Results are in reasonable agreement with $\bar{V}^0$ calculated from an equation developed previously, using previous parameters plus the following: increments (in mL mol^{-1}) of 8.72 for carbonyl, 6.1 for hydroxyl, 4.4 for oxygen in a monofunctional ether, and 5.8 for oxygen in a polyfunctional ether; decrements δ (in mL mol^{-1}) of -1.68 for $g_{C-C}^{CO/C}$, -2.22 for $g_{C-C}^{O/C}$, -0.90 for $g_{C-C}^{O/O}$, -3.27 for $g_{O-C}^{C/C}$, and -1.93 for $g_{O-C}^{C/O}$. The increments for carbonyl and hydroxyl are smaller than the van der Waals volumes of these groups, and indicate some degree of complexation to carbon tetrachloride. Only a roughly linear relation is found between $\bar{V}^0$ of alcohols in water and $\bar{V}^0$ in carbon tetrachloride, possibly because of the intrusion of additional effects such as structure-promotion in water.

JOHN T. EDWARD, PATRICK G. FARRELL et FEREIDOON SHAHIDI. Can. J. Chem. **57**, 2585 (1979).

On a déterminé le volume molaire partiel, $\bar{V}^0$, dans le tétrachlorure de carbone à 25°C, de 13 cétones, 18 alcools, et de 17 éthers mono ou polyfonctionnels, tous acycliques. Les résultats sont raisonnablement en accord avec $\bar{V}^0$ calculé à partir des équations développées antérieurement en utilisant les paramètres déjà mentionnés, ainsi que les suivants: des incréments (en mL mol^{-1}) de: 8.72 pour le carbonyle, 6.1 pour l'hydroxyle, 4.4 pour l'oxygène des éthers monofonctionnels, et 5.8 pour l'oxygène des éthers polyfonctionnels; des décréments δ (en mL mol^{-1}) de: -1.68 pour $g_{C-C}^{CO/C}$, -2.22 pour $g_{C-C}^{O/C}$, -0.90 pour $g_{C-C}^{O/O}$, -3.27 pour $g_{O-C}^{C/C}$ et -1.93 pour $g_{O-C}^{C/O}$. Les incréments pour le carbonyle et l'hydroxyle sont plus petits que les volumes de van der Waals de ces groupes et indiquent quelque degré de complexation au carbone du tétrachlorure. On a seulement trouvé une grossière relation linaire entre $\bar{V}^0$ des alcools dans l'eau et $\bar{V}^0$ dans le tétrachlorure de carbone, probablement à cause de l'intrusion d'effets additionnels, telle l'accroissement de structure dans l'eau.

[Traduit par le journal]

Introduction

The partial molal volumes $\bar{V}^0$ of straight- and branched-chain alkanes (1) and alkyl halides (2) in carbon tetrachloride at 25°C may be calculated with reasonable accuracy using the equation

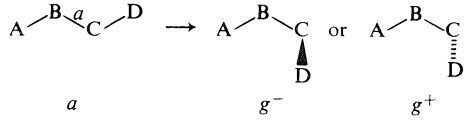
$$[1] \quad \bar{V}^0 = V_c + \sum_1^m n^k I^k + \sum_1^n Z_g{}^l \delta^l$$

where V_c is a covolume of 11.61 mL mol^{-1}, n^k is the number of atoms or groups of type k and I^k is the volume increment associated with this type, Z_g^l is the mol fraction of *gauche* interactions of type l found in the solute molecules (3) and δ^l is the decrement associated with this interaction. In the present paper we test the validity of [1] for 13 aliphatic ketones, 18 alcohols, and 17 ethers, whose $\bar{V}^0$ values we have determined and listed in Tables 1, 4, and 5.

To calculate $\bar{V}^0$, we must first calculate Z_g^l, following the procedure described by Mann (3) for straight- and branched-chain alkanes. For the compounds discussed in this paper, particularly ethers, the calculations become complex, and so are described in some detail.

Calculation of Z_g

Following Flory (4), we adopt the extended, all *anti* (*a*) conformation[2] as the reference state of A—B—C—D. Rotation about the B—C bond can convert this conformation into either of two chiral *gauche* conformations, g^- and g^+:



Accompanying the change $a \rightarrow g$ is an enthalpy change $\Delta H_{g(B-C)}^{A/D}$ and a change in partial molal

[1]Present address: Lash Miller Chemical Laboratory, University of Toronto, 80 St. George Street, Toronto, Ont., Canada M5S 1A1.

[2]Flory uses the term *trans* instead of *anti*; our usage is that preferred by most stereochemists (5*a*).

SCHEME 1

volume $\delta^{A/D}_{(B-C)}$: the superscripts and subscripts define completely the nature of the *gauche* arrangement.

As an illustration of the calculation of Z_g^l of a ketone, let us consider 2-pentanone (**3** in Table 1). The stable conformations of ketones are those in which the carbonyl double bond is eclipsed by a neighbouring C—H or C—C bond (5*b*, 6, 7), so that we can write down the five staggered conformations A—E of Scheme 1. Various lines of evidence (6) indicate the *anti–anti* (*aa*) conformation A to be the most stable. The *anti–gauche* (*ag*$^+$) arrangement B should be less stable because of *gauche* interaction between the C(2) (carbonyl) and the C(5) (methyl) carbons, denoted $g^{CO/C}_{C-C}$. The enthalpy difference $\Delta H^{CO/C}_{g(C-C)}$ between *a* and $g^{CO/C}_{C-C}$ is discussed below. (The enantiomeric *ag*$^-$ conformation will have the same enthalpy as *ag*$^+$.) The *g*$^-$*a* conformation C will be less stable than A because of a *gauche* interaction $g^{C/C}_{C-C}$ between the C(1) methyl and the C(4) methylene carbons. The enthalpy difference between C and A will approximate $\Delta H^{C/C}_{g(C-C)}$ between *gauche* and *anti* alkanes (700 cal mol^{-1} (1, 3)). (It may be slightly smaller because of the different geometry of methylene (sp^3) and carbonyl (sp^2) carbons.) Accompanying C is an enantiomeric *g*$^+$*a* conformation. Next, enantiomeric *g*$^-$*g*$^-$ (D) and *g*$^+$*g*$^+$ conformations are possible. As before (1–3) we assume that ΔH of D is given by the sum of $\Delta H^{C/C}_{g(C-C)}$ for each individual *gauche* interaction. This assumption however fails for *g*$^-$*g*$^+$ (E) and *g*$^+$*g*$^-$ arrangements, which are of excessively high enthalpy (1–3) because of the close approach of the terminal methyl groups. Conformations containing such arrangements form a very small proportion of the molecular population and may be ignored.

We estimate the $\Delta H^{CO/C}_{g(C-C)}$ recorded in Table 2 from ΔH (1360 cal mol^{-1}) for the *cis* to *trans* epimerization of 3,5-dimethylcyclohexanone (5*c*, 8), which results in two additional *gauche* interactions (one $g^{C/C}_{C-C}$, one $g^{CO/C}_{C-C}$). This compares with 1700

TABLE 2. Enthalpy (ΔH_g) and volume (δ) effects associated with first-order interactions in acyclic ethers and alcohols

Interaction	ΔH_g (cal mol^{-1})	δ (mL mol^{-1})

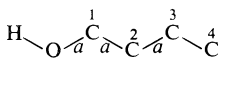
*From ref. 1.
†From ref. 4.

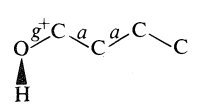
cal mol^{-1} for the change from equatorial to axial methyl in cyclohexane (5*d*), due to two additional $g^{C/C}_{C-C}$ interactions. Assuming additivity of conformational effects, this indicates ΔH = 850 cal mol^{-1} for $g^{C/C}_{C-C}$ and 500 cal mol^{-1} for $g^{CO/C}_{C-C}$.[3]

Using these ΔH values, the mol fraction γ of the conformations *aa*, ag^+, g^+a, and g^+g^+ may be calculated in the usual way (1–3) (taking account of the different multiplicities of A, B, C, and D). Values of γ are shown in Scheme 1, along with the numbers of *gauche* interactions z^l_g of type *l* in each conformation. The mole fractions of *gauche* conformation of each type are then given by $Z^l_g = \Sigma\gamma\, z^l_g$, and are recorded in Table 1. Also recorded are Z^l_g values for the other twelve ketones, which were calculated in a similar way.

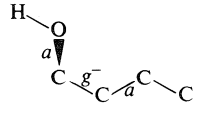
Rotation about the C—O bond of alcohols encounters a three-fold barrier (10, 11), so that in alcohols three kinds of *gauche* arrangements are possible, illustrated in the conformations G, H, and I of 1-butanol:



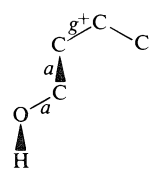
F



G



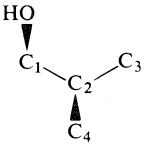
H



I

For reasons discussed below, we ignore *gauche* arrangements of the type found in G, and consider only those found in H and I. We assume that in alcohols, as in ethers (4), the enthalpy of the $g^{O/C}_{C-C}$ arrangement in H is 200 cal mol^{-1} lower than that of the *anti* arrangement in F (see Table 2). (Probably for similar reasons, the *gauche* form of *n*-propyl fluoride is more stable than the *anti* (5*e*); oxygen and fluorine have similar van der Waals radii (12).)

The superior stability of the *gauche* form in H is possible because attractive and repulsive forces between O---C_3 can be brought into balance by a small increase above 60° in the O—C1/C2—C3 dihedral angle, with only a small increase in torsional strain. This is not possible in isobutyl alcohol in the conformation J; the rotation about C1—C2 to relieve the O---C_3 repulsion would only increase the O---C_4 repulsion (cf. ref. 5*f*), and this conformation with two *gauche* arrangements (O/C3, O/C4) should be less stable than the alternative conformations with only one *gauche* (O/C3 or O/C4) arrangement.[4] The published data for isobutyl chloride (5*f*) show that this "isobutyl effect" results in an increase



J

of 540 cal mol^{-1} over that calculated from the simple addition of ΔH_g values as prescribed by Mann (3). We have adopted the same value for the isobutyl effect in alcohols, although because of the different dimensions of oxygen and chlorine (5*g*) it is likely to be too high.

Gauche interactions are an example of first-order interactions, the interacting groups A/D being separated by three bonds. Second-order interactions can occur between groups separated by four bonds (4). In alkane sequences g^+g^+ or g^-g^-, second-order interactions are negligible (1, 3), and ΔH for such sequences is approximately $2\Delta H_g$. However, sequences g^+g^- or g^-g^+ (I in Table 3) bring the methyl or methylene carbons intolerably close together (~2.54 Å), so that ΔH for such sequences is very much higher than $2\Delta H_g$; the additional enthalpy ΔH_ω due to the second-order interaction is about 2200 cal mol^{-1} (4). However, the smaller size of oxygen as compared with methyl or methylene causes the second-order interaction II of Table 3 to

[3]The $g^{C/C}_{C-C}$ interactions for axial methyl in cyclohexane are evidently of higher energy than $g^{C/C}_{C-C}$ interactions in flexible chain alkanes, probably because in the latter, but not the former, minor torsional adjustments are possible to reduce torsional strain (9). It is accordingly possible that $\Delta H_g{}^{CO/C}_{(C-C)}$ of 500 cals mol^{-1} is slightly too high for flexible chain molecules. However, this will be compensated to some extent by having $\delta^{CO/C}_{C-C}$ (see below) also slightly too high.

[4]A similar argument applies to cyclohexanol, which is more stable in the equatorial than in the axial conformation (5*d*), in spite of the fact that the latter has two *gauche* O/C arrangements.

TABLE 3. Enthalpy (ΔH_ω) associated with second-order interactions

Interaction	Structure	ΔH_ω (cal mol^{-1})
I $g^{+C/C}_{C-C}\ g^{-C/C}_{C-C}$		~2200
II $g^{+O/C}_{C-C}\ g^{-C/C}_{C-C}$		340
III $g^{+C/C}_{O-C}\ g^{-O/C}_{C-C}$		>2200
IV $g^{+C/C}_{C-O}\ g^{-C/C}_{O-C}$		>2200
V $g^{+O/C}_{C-O}\ g^{-C/C}_{O-C}$		350
VI $g^{+O/O}_{C-C}\ g^{-C/C}_{C-O}$		350
VII $g^{+O/C}_{C-C}\ g^{-C/O}_{C-C}$		250
VIII $g^{+C/O}_{O-C}\ g^{-O/C}_{C-O}$		>2200

be no longer prohibitively crowded, so that ΔH_ω is modest. Consequently, such arrangements must be taken into account in calculations of Z_g. The value of ΔH_ω for II shown in Table 3 is taken from Flory (4) (who was considering the conformations of ethers).

The mol fractions $Z^{O/C}_{g(C-C)}$ and $Z^{C/C}_{g(C-C)}$ of the simpler *n*-alkanols were calculated from these ΔH_g and ΔH_ω values by usual methods and are listed in Table 4. Calculations of $Z^{C/C}_{g(C-C)}$ of the *n*-alkanols **3**, **5**, **8**, and **15** showed that it varied with the number n of carbon atoms according to the equation (cf. ref. 1):

$$Z^{C/C}_{g(C-C)} = 0.5 + 0.29(n - 3)$$

and hence this equation was used to obtain $Z^{C/C}_{g(C-C)}$ for **16**, **17**, and **18**, for which computations otherwise would be tedious. For 1-butanol and higher alcohols $Z^{O/C}_{g(C-C)}$ remained constant at 0.72.

Ethers have been shown by extensive investigations (summarized by Flory (4)) also to have a threefold rotational barrier about the C—O bond, and so they also exist in various staggered conformations. Examination of these conformations reveals many more types of *gauche* arrangements ($g^{O/O}_{C-C}$, $g^{C/C}_{O-C}$, $g^{C/O}_{O-C}$) when we consider the various mono- and polyfunctional ethers of Table 5. The mol fractions Z_g of these various types have been calculated using ΔH_g values in Table 2 and ΔH_ω values in Table 3. Four of the ΔH_g values and seven of the ΔH_ω values are from Flory (4); ΔH_ω for the second-order interaction V of Table 3 represents our guess. This is likely to be not grossly in error, because ΔH_ω values have about the expected magnitude when account is taken of (*a*) the van der Waals radius of oxygen, which is smaller than that of methyl or methylene (12), and which accounts in part for the much smaller ΔH_ω of II as compared with I; (*b*) the length of the C—O bond (smaller than C—C) and the size of the C—O—C bond angle (smaller than C—C—C), which accounts for the more severe methyl/methylene interactions in III, IV, and VIII as compared with I; and (*c*) the electrostatic repulsion between oxygen atoms, which causes ΔH_ω of VII to be only slightly smaller than ΔH_ω of II, in spite of much smaller van der Waals repulsions. (Explanation of the first-order effects of Table 2 is less straightforward. The low ΔH_g of $g^{O/O}_{C-C}$ is a manifestation of the "*gauche* effect" (15), and of $g^{C/O}_{O-C}$ of the anomeric effect (16).)

Results and Discussion

Using the values of Z_g listed in Table 1, and increments (Table 6) and decrement $\delta^{C/C}_{C-C}$ (Table 2) already reported (1), the increment I of the carbonyl group (Table 6) and the decrement $\delta^{CO/C}_{C-C}$ (Table 2) were obtained by a least-squares fitting of the experimental data of Table 1 to [1]. It was then possible to calculate $\bar{V}^0$ of the ketones of Table 1 by this equation. Agreement between calculated and experimental values is good considering the various approximations necessary. Thus $\bar{V}^0$ values calculated for the isomeric ketones $C_7H_{14}O$ (**8**–**13** of Table 1) reproduce at least qualitatively the trends in $\bar{V}^0$ found by experiment. Any of the other purely additive schemes in vogue at present ignore conformational as well as more subtle effects (e.g., variation in the volume of primary, secondary, and tertiary hydrogen (1)), and would yield identical values of $\bar{V}^0$ for all six ketones **8**–**13**.

A similar procedure yielded the increments for hydroxyl and ether oxygen (Table 6) and the decrements for the various *gauche* arrangements found in alcohols and ethers (Table 2). An increment of 5.57 mL mol^{-1} for ether oxygen was established by a least-squares fitting of all of the experimental data of Table 5 to [1]. However, the values of $\bar{V}^0$ calculated using this value of I tended to be systematically high for monoethers (compounds **1**–**8** of

*Using I = 4.40 mL mol^{-1} for ether O.
†Using I = 5.80 mL mol^{-1} for ether O.

Table 5) and systematically low for polyethers (compounds **9**–**17** of Table 5). Consequently we have adopted I = 4.40 mL mol^{-1} for monoethers and I = 5.80 mL mol^{-1} for polyethers (see Table 6).

Results for eighteen alcohols are given in Table 4. $\bar{V}^0$ values for twelve have been reported in the literature,[5] and we have checked eleven of them, with generally fair agreement; $\bar{V}^0$ values for six alcohols are (to our knowledge) reported for the first time. If we ignore the small molecules **1**, **2**, **4**, and **7**, agreement between calculated and experimental $\bar{V}^0$ is astonishingly good, and often within experimental error. Particularly impressive is the agreement for the seven isomeric alcohols $C_5H_{11}OH$ (**8**–**14**).

The agreement between calculated and experimental $\bar{V}^0$ for ethers is considerably poorer. If we scrutinize the series of isomeric ethers $C_5H_{12}O$ (**2**, **3**, and **4** in Table 5), we see that [1] gives values of $\bar{V}^0$ following only roughly the experimental values. The

[5]The values reported by Longsworth (14) are in fact for apparent molal volumes ϕ of the alcohols in very dilute (0.1–0.5 *m*) solution. At this dilution the difference between ϕ and $\bar{V}^0$ is small, as shown by comparison with values in Table 1.

same is true for the isomers $C_6H_{14}O$ (**5**, **6**, **7**), $C_4H_{10}O_2$ (**10**, **11**), and $C_5H_{12}O_2$ (**12**, **13**).

Several possible reasons for the less regular behaviour of ethers present themselves. Second-order interactions are of negligible importance for alkyl but not for ether chains. Hence ethers can suffer more extensive folding, which may affect $\bar{V}^0$. The dipole moments of the ether groups may tend to cancel out in some polyethers, so that the interaction with the induced dipole of the solvent may be less for polyethers than monoethers. (This would account fot different I values.) Finally, because there are many different types of *gauche* conformations, the δ values of Table 2 are based on a small number of experimental values for each different type, and become more liable to experimental error.

It accordingly seems possible that [1] may not apply too well to certain classes of polyfunctional compounds. This has already been found true for 1,2-, but not 1,3-dibromoalkanes (2). However, the same defects will be found *a fortiori* in other additive schemes for calculating molecular volumes.

Relation of Increments to van der Waals Volumes

We now consider the relation of the increments I listed in Table 6 for carbonyl, hydroxyl, and ether oxygen to their van der Waals volumes. The loose packing of the roughly spherical molecules of carbon tetrachloride results in a molar volume of the liquid 84% greater than the van der Waals volume V_w at 25°C. This additional volume has been termed *empty volume* (V_e) by Bondi (17). The introduction of one mol of solute into a very large volume of carbon tetrachloride increases the volume by $\bar{V}^0$, part made up by the van der Waals volume V_w of N (Avogadro number) solute molecules, part by an increase in $V_e \equiv Nv_e$ which depends on how closely the solvent molecules pack about N solute molecules; v_e would be expected to be proportional to the area A (12) of the solute molecule, and hence to A of the groups making it up (18). This expectation is fulfilled for methyl, methylene, and methine groups, for which an approximate value of I may be calculated by

$$[2] \quad I_{calc} = V_w + 5.9 \times 10^{-9} A$$

as shown in Table 6.[6] However, the experimental increment I for bromine and ether oxygen (Table 6) is less than I_{calc}, although still greater than V_w. Attractive forces due to dipole-induced dipole effects evidently lead to closer packing of carbon tetrachloride molecules about bromine and oxygen than about alkyl groups, so that V_e and thence I are diminished.

For carbonyl and hydroxyl groups I actually becomes smaller than V_w. Such a decrease is greater than can be accounted for by dipole-induced dipole effects, and points to some degree of complexation of these groups with carbon tetrachloride (19). Such complexation has already been indicated for dinonyl ketone by thermodynamic studies (20), and for a large number of alcohols by a variety of techniques (21–27).

Complexation of the hydroxyl group with the bulky carbon tetrachloride molecule would tend to bias conformations about the O—C bond towards *anti* (e.g., F) and away from *gauche* (e.g., G) arrangements, which was our reason for ignoring possible effects of $g_{O-C}^{H/C}$ (e.g., G) conformations. The smaller values of $\bar{V}^0$ found for the smaller alcohols **1**, **3**, **4**, and **7** of Table 4, in which the proportion of OH to inert hydrocarbon is higher, and which would consequently be more effective in hydrogen-bonding, can be explained by either (*a*) stronger hydrogen-bonding to carbon tetrachloride, or (*b*) stronger self-association by hydrogen-bonding, so that even in the most dilute solutions studied some methanol (**1**), etc., is in the form of dimers. It is noteworthy that

[6]Close agreement between I and I_{calc} cannot be expected, because we have ignored small differences in attractive forces between solvent and CH_3, CH_2, and CH (1). These should affect v_e and hence I.

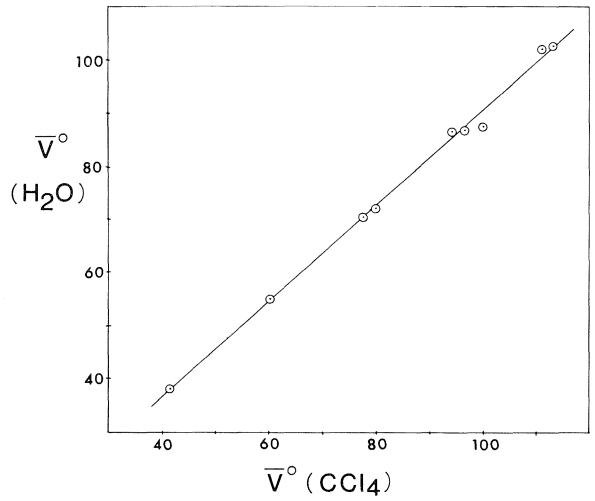

FIG. 1. Relation between the partial molal volumes $\overline{V}^0$ (in mL mol^{-1}) of alcohols **1–9** of Table 4 in carbon tetrachloride and in water. Straight line given by [3].

Duboc's $\overline{V}^0$ for methanol (13), found by fitting excess volumes to a polynomial function of concentration, is close to our calculated value.

Partial Molal Volumes of Alcohols in Water

While our preliminary studies show that [1] is successful with other organic solvents, it seems likely that it will be less successful with water as solvent. This is shown by our studies of $\overline{V}^0$ of alcohols **1–14**[7] in water at 25°C. These $\overline{V}^0$ values prove to be roughly linearly related to $\overline{V}^0$ in carbon tetrachloride, as shown for alcohols **1–9** by the straight line of Fig. 1, which is defined by

[3] $\overline{V}^0(H_2O) = 0.90\ \overline{V}^0(CCl_4)$

The smaller volumes in water may be explained by the greater internal pressure (29) or cohesive energy density (30, 31) of this solvent. However, while [3] serves as a rough guide to correlate $\overline{V}^0$ (H_2O) and $\overline{V}^0$ (CCl_4), its limitations are shown in Fig. 2, in which the data for the seven isomeric alcohols $C_5H_{11}OH$ (**8–14** of Table 4) are plotted on a larger scale. It would seem that factors other than those accommodated in [1] (perhaps solvent structure-making or structure-breaking[8]) obtrude in water.

[7]Values of $\overline{V}^0$ (in mL mol^{-1}) of alcohols **1–14** in water at 25°C were obtained from ref. 28, except for the following, which were determined for this work: **8**, 102.1; **9**, 102.5; **11**, 101.3; **12**, 101.7; **13**, 100.5.

[8]These factors have occasionally been invoked (cf. ref. 32) to explain different $\overline{V}^0$ values of isomeric alcohols in water. It is apparent from the results in this paper that at least a part, probably the major part, of such differences arises from structural (I) and constitutional (Z_g) factors, and that only when these have been accounted for should the residual effects be explained in terms of solvent perturbation.

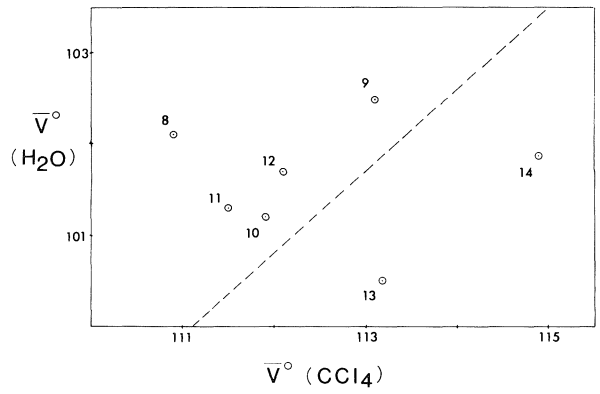

FIG. 2. Relation between partial molal volumes $\overline{V}^0$ (in mL mol^{-1}) of alcohols **8–14** of Table 4 in carbon tetrachloride and in water. Straight line given by [3].

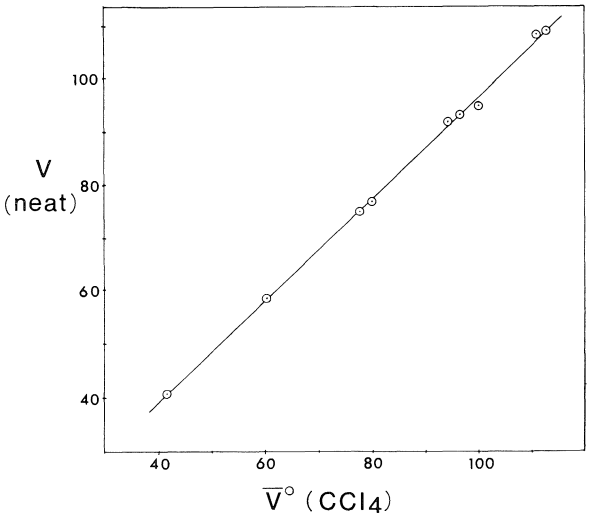

FIG. 3. Relation between molar volumes V of neat alcohols **1–9** (Table 2) and their partial molal volumes $\overline{V}^0$ in carbon tetrachloride, both in mL mol^{-1}. Straight line given by [4].

The same is likely to be true for molar volumes V of the neat alcohols (calculated from data in ref. 33), as shown by deviations from linearity in the plot in Fig. 3. The straight line is defined by

[4] $V = 0.968\ \overline{V}^0(CCl_4)$

the slope being closer to unity because the internal pressures (30–32) of the various alcohols are not so far removed from that of carbon tetrachloride as is the internal pressure of water.[9]

Experimental

Materials

The ketones, alcohols, and ethers were all commercial

[9]The success of Mann's treatment (3) for the neat hydrocarbons probably arises from the fact that all of them have low and comparable internal pressures.

products, for the most part from Aldrich Co. They were distilled before use, and the middle fraction retained for experimental work. Purification of carbon tetrachloride and the procedure for density measurements using a Paar digital precision density meter have been described previously (1). Densities were determined at 8–21 different concentrations, ranging usually from about 0.03 to 0.20 *M*. Plots of the apparent molal volume ϕ_v against concentration were linear, and $\overline{V}^0$ was obtained by extrapolation to zero concentration.[10]

Cyanoethylation of the salts of cyanoguanidine in aprotic solvents

PIOTR ALEKSANDROWICZ, MARIA BUKOWSKA, MIECZYSŁAW MACIEJEWSKI, AND JAN PREJZNER[1]

Institute of Organic Chemistry and Technology, Warsaw Technical University, 75 Koszykowa St., 00-662 Warsaw, Poland

Received March 13, 1979

PIOTR ALEKSANDROWICZ, MARIA BUKOWSKA, MIECZYSŁAW MACIEJEWSKI, and JAN PREJZNER. Can. J. Chem. **57**, 2593 (1979).

The reactions of lithium or sodium salts of cyanoguanidine (**1**) with acrylonitrile in aprotic solvents result in the rapid formation of *N,N*-bis(2-cyanoethyl)-*N'*-cyanoguanidine (**3**) followed by a slower intramolecular cyclization of **3** leading to 4-amino-1-(2-cyanoethyl)-5,6-dihydro-2-pyrimidinylidenecyanamide (**4**). A tentative assignment of the tautomeric forms to the cyclic derivatives of (β-cyanoethyl) cyanoguanidines and the products of their hydrolysis is described.

PIOTR ALEKSANDROWICZ, MARIA BUKOWSKA, MIECZYSŁAW MACIEJEWSKI et JAN PREJZNER. Can. J. Chem. **57**, 2593 (1979).

L'addition de sels de lithium et de sodium de la cyanoguanidine (**1**) sur l'acrylonitrile en milieu non protique conduit à la formation rapide de la *N,N*-bis(cyano-2 ethyl)cyanoguanidine (**3**) qui subit une cyclisation intramoléculaire plus lente pour donner l'amino-4 cyanimino-2-(cyano-2 ethyl)-1 dihydro-5,6 pyrimidine (**4**). Les formes tautomères de dérivés cycliques de (cyano-2 ethyl)cyanoguanidines et de produits de leur hydrolyse sont discutées.

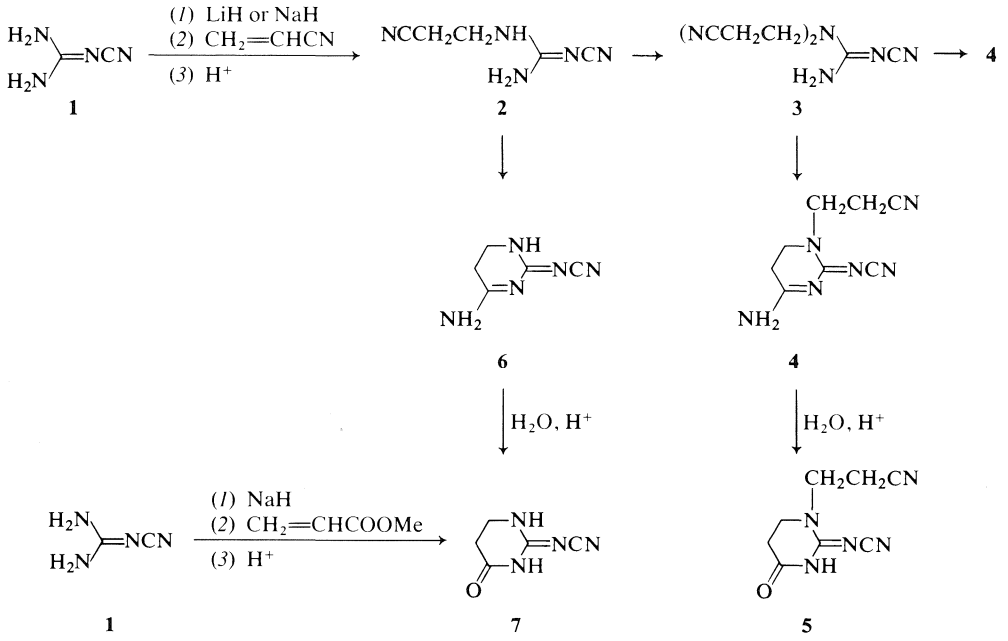
The present investigations have been made in consideration of cyanoguanidine derivatives as monomers to make them available for polyguanamine synthesis (1).

The reaction of cyanoguanidine with acrylonitrile in the presence of strong alkaline bases such as sodium hydroxide was employed to prepare syrups suitable for the impregnation of textiles (2). All our attempts to isolate or identify distinct products of this reaction were unsuccessful; complex reaction mixtures resulted apparently from several competitive and consecutive reactions such as conjugate additions, inter- and intramolecular cyclizations, etc. On the basis of preliminary experiments it appeared to us that the cyanoethylation process should be favored with respect to others by a high concentration of cyanoguanidine anion providing the reaction time was sufficiently short. To confirm this prediction we have carried out the cyanoethylation of lithium and sodium salts of **1** in dipolar aprotic solvents. Cyanoguanidine, a weak acid of $pK_a^{25} = 12$ (3), was converted into its lithium or sodium salt by reaction with lithium or sodium hydride, respectively, in dimethylformamide or dimethyl sulfoxide. Upon rapid addition of an equimolar amount of acrylonitrile an exothermic reaction occurred which subsided after 1–2 min; stirring was continued for another 8–13 min, followed by quenching the reaction with an equimolar amount of an acid. A crude product was proved to consist only, apart from starting material, of the 1:2 adduct **4** of cyanoguanidine (**1**) and acrylonitrile. The same reaction brought about under milder conditions resulted in a main product **3** of the same molecular weight but for which both the melting point and spectra were quite different from those for **4**. On the basis of spectra and chemical behaviour **3** was identified as *N,N*-bis(2-cyanoethyl)-*N'*-cyanoguanidine. The ir spectrum of **3** shows four intense bands in the N—H stretching vibration region. The strong sharp band at 3438 cm^{-1} is likely related to the NH_2 group. If this is so, the strong band at 1660 cm^{-1} which disappears on deuteration will be the NH_2 scissoring band. Two weak absorptions at 2258 and 2249 are due to the C≡N stretching vibration in the cyanoethyl group, although the nature of this splitting is not clear. The strong band at 2174 with a shoulder at 2185 cm^{-1} is undoubtedly due to the stretching vibration of the =N''—CN grouping and may be compared to the similar bands in **1**; similarly, the NCN' and NCN'' asymmetric vibrations may be tentatively assigned to a broad strong band with maxima at 1554 and 1523 cm^{-1} (4). A proper choice of structure **3** among three possible bis(2-cyanoethyl)-cyanoguanidines was confirmed by treatment of **3** with barium hydroxide. The resulting monobarium salt of iminodipropionic acid was converted into monoammonium salt which was identical with the product of the independent synthesis (5).

Before discussing the nmr spectrum of **3**, which is not contradictory with the proposed structure, it seems that the nmr spectra of cyanoguanidine and 5,6-dihydropyrimidine derivatives described in this paper merit some general comment. Unlike the nmr spectra of some 5,6-dihydropyrimidine derivatives (6), so far as we know, those of cyanoguanidines have

[1]To whom all correspondence should be addressed.

0008-4042/79/192593-06$01.00/0

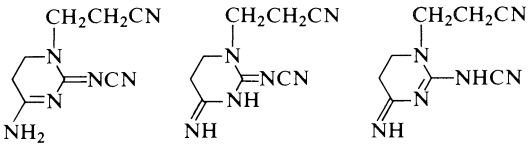


SCHEME 1

not been studied yet. It seems, generally, that for both cyanoguanidines and dihydropyrimidines a N—H proton exchange in aprotic solvents is slow on the nmr time scale, and this is probably due to both low acidity and basicity of these compounds. On the other hand, quadrupolar relaxation appears to be rather efficient, leading to relatively narrow signals of the N—H resonances in these types of compound unless the NH group is adjacent to a carbonyl function, and therefore, in some cases to a splitting of these resonances resulting from coupling to α-carbon protons (7). In the course of another investigation it was found, e.g., that the N—H protons in *N*-(methyloxymethyl)-*N'*-cyanoguanidine in $(CD_3)_2SO$ show a triplet at 7.64 ppm and a singlet at 6.98 ppm which correspond to the —NH— and $—NH_2$ groups, respectively. The N—methylene resonance appears as a doublet resulting from coupling to the NH proton which itself, therefore, constitutes a triplet.[2]

The nmr spectrum of **3** in $(CD_3)_2SO$ reveals a single peak at 7.36 ppm due to two protons of the NH_2 group and pair of triplets at 3.63 and 2.74 ppm due to the CH_2N and CH_2CN groups, respectively, coupled to each other (J = 6.9 Hz).

A close relationship between **3** and **4** was established by the observation that **3** was easily converted to **4** on being heated above its melting point. In the infrared spectrum of **4**, in addition to strong bands at 3403 and 1665 cm^{-1} due to the NH_2 group, the high intensity doublet at 2172 and 2189 cm^{-1} related to the N''—CN grouping, and the medium-weak intensity band at 2255 cm^{-1} due to the aliphatic nitrile, there are several additional strong bands in the region 1300–1600 cm^{-1}. Some of these bands may be assigned to a dihydropyrimidine ring although this assignment must still be regarded as tentative. The above data suggest that **4** is the product of intramolecular cyclization in which the amino and cyano groups are involved. The cyclic product **4** could, in principle, exist in three tautomeric forms, **4***a*–**4***c*, but it appears that its infrared spectrum rules out, at least in the solid state, **4***b* and **4***c* (Scheme 2).



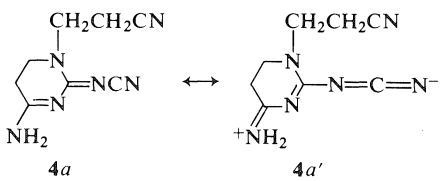
SCHEME 2

In the nmr spectrum of **4** there are two pairs of triplets in the methylene region. Assuming that the cyclization does not affect essentially the chemical shifts of methylenes in the cyanoethyl group in **4** with respect to those in **3** we have assigned the triplets at 3.62 and 2.76 ppm to the CH_2N and CH_2CN groups, respectively, in the cyanoethyl group. Some support for this assignment has been obtained from the observation that the addition of a drop of trifluoroacetic acid does not affect these

[2]M. Bukowska and M. Maciejewski. Unpublished results.

resonances. The other two triplets at 3.42 and ca. 2.5 ppm we have assigned to the CH_2N and $CH_2C{=}$ groups of the 5,6-dihydropyrimidine ring. The fact that these resonances appear as triplets instead of as more complex multiplets due, e.g., to an AA′BB′ system might be perhaps explained on a stereochemical basis as has been done for dihydrouracil (6). In the NH region there are two singlets at 8.05 and 8.34 ppm ($w_{1/2}$ ca. 6 Hz) each integrating for one proton. If **4** had structure **4***b* or **4***c* it would be difficult to explain this relatively high deshielding of an imine proton, for it is known that in somewhat similar structures the imine proton resonances occur at ca. 6 ppm (8, 9). On the other hand, structure **4***a* can be assigned from its nmr spectrum, assuming that the nonequivalence of the two amino protons results from hindered rotation about the C—NH_2 bond owing to its partial double bond character. Both the restricted rotation and the relatively high deshielding of the amino protons can be attributed to a marked contribution of structure **4***a*′ to a resonance hybrid. Nuclear magnetic resonance temperature variation experiments and uv spectra support also the structure of 4-amino-1-(2-cyanoethyl)-2(1*H*)-pyrimidinylidenecyanamide (**4***a*) (*vide infra*).

Several runs performed with variation of molar ratio of reactants, time, and temperature led us to the supposition that (cyanoethyl)cyanoguanidine anion resulting from addition of the guanidine anion to acrylonitrile undergoes addition to another molecule of acrylonitrile, with the formation of the asymmetric derivative **3**, at a rate much higher than that of the first step. The subsequent intramolecular cyclization reaction evidently occurs more slowly than the cyanoethylation reaction under these conditions. Analysis by nmr spectroscopy of samples withdrawn at various reaction times offered some support for this assumption. The nmr spectrum of a sample taken after 3 min (starting with the addition of acrylonitrile at room temperature, molar ratio 1:1) revealed in the NH region, apart from the cyanoguanidine peak, three signals at 6.9, 7.0, and 7.4 ppm which might be attributed to the NH resonances of bis(2-cyanoethyl)- and probably (2-cyanoethyl)cyanoguanidine (**2**) (Scheme 1). The lack of cyclic products in this earlier stage of the reaction was also shown in the methylene region where there were only two multiplets centered at 3.67 and 2.79

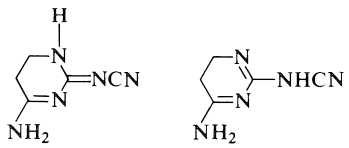


4*a* **4***a*′

SCHEME 3

ppm. On continuing the reaction (7–17 min) the above mentioned NH resonances disappeared and the new ones appeared in the 8 ppm region; also in the methylene region there appeared two pairs of triplets as those in **4**. Longer reaction times (45 min and more) led to substantial changes in both the NH and methylene regions of the nmr spectrum, and gave unidentifiable syrups.

Isolation of cyanoethylation products was generally difficult due to their low solubility in common solvents and to the unstable nature of the cyclic products to hydrolysis (*vide infra*). All our attempts to isolate *N*-(2-cyanoethyl)-*N*′-cyanoguanidine (**2**) failed. In the course of the laborious and tedious process of multiple crystallizations the NH signals of the supposed monocyanoethyl derivative **2** disappeared and new signals in the 8 ppm region appeared. In fact, we have only been able to obtain a very small amount of crystalline product, presumably a side effect of the isolation procedure, assigning to it structure **6**. Microanalysis and mass spectrometric measurement show a molecular composition for **6** consistent with that of a 1:1 adduct of **1** and acrylonitrile. The ir spectrum of **6** displays no band in the aliphatic nitrile region and, therefore, indicates clearly the absence of the cyanoethyl group in the molecule. The strong bands at 3435 and 1666 cm^{-1}, disappearing on deuteration, indicate the presence of the amino group and this suggests that **6**, at least in the solid state, is similar to **4** and exists in the tautomeric form with the amino group at C-4. This excludes from further considerations two of four possible tautomeric forms, and the choice between the other two, the cyanoimino **6***a* and the cyanoamino form **6***b* may also be made tentatively by



6*a* **6***b*

SCHEME 4

means of its ir spectrum. The former appears to be the more likely, based on the observed low frequency of a high intensity band at 2165 cm^{-1} due to the —NC≡N grouping as compared with an expected higher frequency of the —NHC≡N group, reinforced by a cross-conjugation in **6***b* (10, 11). The uv spectra of **4** and **6** are consistent with structures **4***a* and **6***a* in that a strong absorption at ca. 250 nm may provide evidence for the presence of a conjugated cyanoguanidine chromophore in their molecules. Indicative of a more conjugated system in **4** than in its open-chain precursor **3** is a bathochromic shift

of the wavelength maximum, $\Delta\lambda = 32$ nm, in the ultraviolet spectrum after cyclization.

The nmr spectrum of **6** reveals a pair of triplets at 2.44 and 3.22 ppm which we have assigned to the $CH_2C{=}$ and CH_2N groupings, respectively. The NH protons give rise to three peaks at 8.32 ($w_{1/2}$ ca. 14 Hz), 8.07 ($w_{1/2}$ ca. 14 Hz), and 7.84 ($w_{1/2}$ ca. 7 Hz), each with an area due to one proton. The two lower field peaks are attributable, by analogy to **4**, to two protons of the amino group with hindered rotation due to partial double bond character in structure **6***a*. The different nature of these protons with respect to that at 7.84 ppm can be shown by temperature variation experiment. The two lower field resonances coalesce in $(CD_3)_2SO$ at around 80°C, while the higher field peak may be distinctly seen even at 110°C. Similarly, the NH proton resonances in **4** coalesce at about 80°C. Some ambiguity remains in assignment of the higher field NH peak and, therefore, in the choice between structures **6***a* and **6***b* for this compound in a DMSO solution. First of all, tautomeric structure **6***a* might be expected to reveal coupling between H-1 and H-6, and the lack of splitting of the CH_2N resonance due to this coupling, if not fortuitous, might show evidence for **6***b*. On the other hand, the NHCN proton resonance in **6***b* might be expected to occur at lower field than that experimentally determined. Since, intuitively, chemical resonance in **6***b* does not seem to be sufficiently significant to hinder a rotation of the amino group, we have tentatively assigned structure **6***a* to this compound in the DMSO solution too.

A striking difference between the cyanoethyl derivative of cyanoguanidine **3** and the cyclic products of cyanoethylation, **4** and **6**, can be seen in their hydrolytic behaviour. Compounds **4** and **6** are rapidly converted into the 4-pyrimidinone derivatives, **5** and **7**, respectively, under the influence of dilute mineral acid. In contrast, **3** is quite stable under these conditions. The labile nature of **4** and **6** is likely attributable to a facile protonation of N-3 resulting in some increase of positive charge at C-4. This, consequently, would facilitate the attack of a water molecule at C-4. This suggestion may be somewhat substantiated by the nmr spectrum of **4** in which, upon the addition of a drop of trifluoroacetic acid to its $(CD_3)_2SO$ solution, the NH_2 doublet collapses into a broad singlet and the $CH_2C{=}$ resonance is shifted a little downfield. Both **5** and **7** show a strong carbonyl band at ca. 1730 cm^{-1} which is only slightly shifted towards the lower frequency on deuteration. The relatively high values of the C=O and N—C≡N stretching frequencies in **5** and **7** could be likely attributed to a cross-conjugation between the carbonyl and cyanoguanidine moieties in these compounds. Their uv spectra are consistent with that conclusion. In contrast to **4** and **6** which exhibit only one band at λ_{max} ca. 250 nm due to a conjugation of cyanoguanidine chromophore, **5** and **7** display two bands at λ_{max} ca. 215 and 240 nm.

The cyclic structure of **5** and **7** was also confirmed chemically by the reaction of the sodium salt of **1** with methyl acrylate (12) resulting in a product which was identical with that obtained by acid hydrolysis of **6** (Scheme 1).

The nmr spectrum of **5** exhibits in the methylene region two pairs of triplets integrating for eight protons; these centered at 3.74 ($J = 7.0$ Hz) and 2.67 ppm we have assigned to NCH_2 and CH_2CO of the 5,6-dihydro-4-pyrimidinone ring, respectively, and the other two centered at 3.64 and 2.82 ppm ($J = 6.7$ Hz) to NCH_2 and CH_2CN, respectively, of the cyanoethyl group. A broad band at 10.9 ppm integrating for one proton can be attributed to the N-3 proton adjacent to the C=O and C=NCN groups. This accounts for a marked deshielding of this proton. The nmr spectrum of **7** shows a pair of triplets at 3.42 (3H, $J = 7$ Hz) and ca. 2.5 ppm partly obscured by residual DMSO due to the CH_2N and CH_2CN groups respectively. In the NH region there is a broad featureless resonance at 10.65 and the other at 8.72 ($w_{1/2} = 20$ Hz), each integrating for one proton, assigned to the N-3 and N-1 protons, respectively. Although a tentative choice between the cyanoimimo- and cyanoamino tautomer in favour of the former was based on the ir and uv spectra, some ambiguity persists in that the N-1 proton is more strongly deshielded than might be expected as compared with similar structures, and in the lack of splitting of the NCH_2 resonances due to coupling to this proton.

Experimental

All melting points are uncorrected. Dimethylformamide and dimethyl sulfoxide were dried by refluxing over calcium hydride and distilled *in vacuo* in an argon atmosphere. Acrylonitrile was distilled just before use. Reagent grade cyanoguanidine was used without further purification.

Ultraviolet spectra were measured in water with a Cary Model 118 C spectrophotometer. Infrared spectra were recorded on a Perkin-Elmer Model 577 spectrometer. Proton magnetic resonance spectra were recorded with a JEOL JMN-MH 100 spectrometer in δ values with $(CD_3)_2SO$ as solvent and tetramethylsilane as an internal reference standard. Mass spectra were determined with a LKB-9000 instrument (70 eV, direct inlet system). The elemental analyses were made on an Elemental Analyser Perkin-Elmer CHNO 240.

Preparation of the Lithium Salt of Cyanoguanidine

A solution of 0.1–0.2 mol of **1** in 50 cm^3 of DMSO or DMF was added to a suspension of an equimolar amount of lithium hydride in 50 cm^3 of the same solvent. The mixture was stirred and heated at 50–60°C under argon until no further evolution of hydrogen was observed.

Preparation of the Sodium Salt of Cyanoguanidine

A solution of 0.1–0.2 mol of **1** was added with stirring and cooling to a solution of an equimolar amount of the sodium salt of dimethyl sulfoxide prepared from DMSO and sodium hydride by heating at 70°C in an argon atmosphere. The sodium salt of **1** was prepared prior to use.

4-Amino-1-(2-cyanoethyl)-5,6-dihydro-2(1H)-pyrimidinylidene-cyanamide (4)

A. Acrylonitrile (5.3 g, 0.1 mol) was added rapidly to 50 cm^3 of a DMSO solution of 0.1 mol of the lithium salt of **1** with stirring and water cooling under an argon atmosphere. The temperature rose immediately to 67°C and began rapidly to fall. After 10–15 min the reaction mixture was poured into 150 cm^3 of ice-chilled tetrahydrofuran. The resulting slurry mixture was centrifuged to remove an amorphous precipitate. Tetrahydrofuran and most of the dimethyl sulfoxide were distilled off *in vacuo*. A semisolid residue was triturated with ethanol yielding 6.5 g of crystalline product **4**, mp 226–229°C (yield 68%).

B. Acrylonitrile (10.6 g, 0.2 mol) was added rapidly to 50 cm^3 of a DMSO solution containing 0.1 mol of the sodium salt of **1**. The temperature rose to 86°C. After 10 min the reaction mixture was subject to the same work-up as described in *A*, yielding **4** in 86% yield. Crystallization from water gave an analytical sample of mp 233–234°C; ir (KBr) ν_{max}: 3403 (NH_2), 3340, 3165 (NH), 2255 (C≡N), 2172 and 2189 (N—C≡N), 1665 (NH_2) cm^{-1}; uv λ_{max} (log ε): 255 (4.42); ms *m/e*: 190 (M^+); nmr δ: ca. 2.5 (CH_2C=), 3.42 (t, 2H, J = 7 Hz, ring CH_2N), 2.76 (t, 2H, J = 6.6 Hz, CH_2CN), 3.62 (t, 2H, J = 6.6 Hz, CH_2N), 8.05 (s, $w_{1/2}$ = 6.6 Hz, 1H, NH), 8.34 (s, $w_{1/2}$ = 6.6 Hz, 1H, NH). *Anal.* calcd. for $C_8H_{10}N_6$: C 50.52, H 5.30, N 44.18; found: C 50.85, H 5.45, N 43.59.

N,N-*Bis(2-cyanoethyl)*-N′-*cyanoguanidine (3)*

To a stirred solution of 0.118 mol of the lithium salt of **1** in 100 cm^3 of dimethylformamide at 3°C under argon was added dropwise 12.5 g (0.236 mol) of acrylonitrile in 30 cm^3 of DMF. The reaction mixture was stirred for 1 h at around 3°C, and then poured into 200 cm^3 of chilled tetrahydrofuran with 0.06 mol of sulfuric acid. After centrifuging an amorphous solid and evaporating the solvents *in vacuo*, a semisolid residue was triturated with 100 cm^3 of acetone yielding 18.6 g of **3** (yield 82%). Crystallization from water gave an analytical sample of mp 166–167°C; ir (KBr) ν_{max}: 3438, 3320 (NH_2), 3192, 3164 (NH), 2258, 2249 (C≡N), 2174, 2185 (sh N—C≡N), 1660 (NH_2), 1554, 1523 cm^{-1}; uv λ_{max} (log ε): 223 (4.29) nm; nmr δ: 2.74 (t, 2H, J = 6.9 Hz, CH_2CN), 3.63 (t, 2H, J = 6.9 Hz, CH_2N), 7.36 (s, 2H, NH_2); ms *m/e*: 190 (M^+). *Anal.* calcd. for $C_8H_{10}N_6$: C 50.52, H 5.30, N 44.18; found: C 50.49, H 5.26, N 44.30.

4-Amino-5,6-dihydro-2(1H)-pyrimidinylidenecyanamide (6)

To a stirred solution of 0.08 mol of the salt of **1** in 35 cm^3 of dimethyl sulfoxide was added dropwise 4.27 g (0.08 mol) of acrylonitrile. Throughout the addition the mixture was cooled in a water bath and the temperature did not rise above 30°C. When the exothermic reaction subsided the mixture was removed from the water bath, stirred for 30 min at room temperature, and then poured into a chilled solution of 0.08 mol of sulfuric acid in 80 cm^3 of acetone. A crystalline material was recrystallized from water yielding 3.4 g of **4**. The filtrate was concentrated *in vacuo* yielding a material which was found to be a mixture of **1**, **3**, **4**, and an alleged monocyanoethyl derivative **2** (see the text). The multiple crystallizations from acetone gave, apart from **3** and **4**, a small amount (60 mg) of **6**, mp 250–252°C; ir (KBr) ν_{max}: 3455 (NH_2), 3235, 3145 (NH), 2165, 2170 (sh, N—C≡N), 1666 (NH_2) cm^{-1}; uv λ_{max} (log ε): 253 (4.31) nm; nmr δ: ca. 2.44 (CH_2C=), 3.22 (t, 2H, J = 7 Hz, CH_2N), 7.84 (s, $w_{1/2}$ = 9 Hz, 1H, NH), 8 07 (s, $w_{1/2}$ = 14 Hz, 1H, NH), 8.32 (s, $w_{1/2}$ = 14 Hz, 1H, NH); ms *m/e*: 137 (M^+). *Anal.* calcd. for $C_5H_7N_5$: C 43.79, H 5.14, N 51.07; found: C 43.56, H 5.17, N 50.77.

Conversion of 3 into 4

One hundred milligrams of **3** was heated above its melting point. After several seconds the liquid substance began to resolidify yielding 100 mg of a crystalline product which was proved to be identical with **4**.

Hydrolysis of 3 with Barium Hydroxide

A mixture of 0.58 g (0.003 mol) of **3** and 3 g of barium hydroxide octahydrate in 20 cm^3 of water was heated under reflux until the evolution of ammonia ceased. The mixture was saturated with carbon dioxide and the precipitate was filtered off. The filtrate was evaporated *in vacuo* to dryness. The resulting monobarium salt was dissolved in a small amount of water and treated with an equivalent amount of ammonium sulfate. After filtering off barium sulfate the filtrate was concentrated and diluted with methanol. The precipitate was recrystallized twice from aqueous methanol yielding a crystalline product, mp 178–179°C, which was proved to be identical with the ammonium salt of β,β′-iminobispropionic acid obtained by alkaline hydrolysis of β,β′-iminobispropanenitrile.

Hydrolysis of 6

An equivalent amount of hydrochloric acid was added dropwise, as it was consumed, to a stirred suspension of 0.027 g (2×10^{-4} mol) of **6** in 3 cm^3 of water at 40°C. The addition was continued until a slight excess of hydrochloric acid was present. The colorless crystals were filtered off and washed with water yielding 0.024 g of tetrahydro-4-oxo-2(1*H*)-pyrimidinylidenecyanamide (**7**), mp 273–274°C; ir (KBr) ν_{max}: 3200, 3095, 3060 (NH), 2200, 2185 (sh, N—C≡N), 1725 (C=O) cm^{-1}; uv λ_{max} (log ε): 216 (4.22), 239 (4.17) nm; nmr δ: ca. 2.5 (CH_2CO), 3.42 (t, 2H, J = 7 Hz, CH_2N), 8.72 (s, $w_{1/2}$ ca. 20 Hz, 1H, NH), 10.65 (br s, 1H, NHCO); ms *m/e*: 138 (M^+). *Anal.* calcd. for $C_5H_6N_4O$: C 43.48, H 4.38, N 40.56; found: C 43.28, H 4.65, N 40.46.

Hydrolysis of 4

Compound **4** (0.19 g) was hydrolysed in a similar way to that described above for **6** yielding 0.17 g of 1-(2-cyanoethyl)-tetrahydro-4-oxo-2(1*H*)-pyrimidinylidenecyanamide (**5**), mp 148–149°C; ir (KBr) ν_{max}: 3175 (NH), 2256 (C≡N), 2196 (N—C≡N), 1731 (C=O) cm^{-1}; uv λ_{max} (log ε): 218 (4.16), 244(4.17) nm; nmr δ: 2.67 (t, 2H, J = 6.6 Hz, CH_2CO), 3.74 (t, 2H, J = 6.6 Hz, CH_2N ring), 2.82 (t, 2H, J = 6.7 Hz, CH_2CN), 3.64 (t, 2H, J = 6.7 Hz, CH_2N), 10.92 (br s, 1H, NH); ms *m/e* 191 (M^+). *Anal.* calcd. for $C_8H_9N_5O$: C 50.26, H 4.75, N 36.63; found: C 50.31, H 4.71, N 36.44.

Characterization of autohydrolysis aspen (*P. tremuloides*) lignins. Part 2. Alkaline nitrobenzene oxidation studies of extracted autohydrolysis lignin

MORRIS WAYMAN AND MIRANDA G. S. CHUA

Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A4

Received February 19, 1979

MORRIS WAYMAN and MIRANDA G. S. CHUA. Can. J. Chem. **57**, 2599 (1979).

Alkaline nitrobenzene oxidation of the lignins extracted from extractive-free aspen wood meal after autohydrolysis at 195°C for periods varying from 5 min to 2 h indicated that these lignins were structurally more condensed in terms of an increase in new carbon–carbon bonds than aspen milled wood lignin. The degree of condensation generally increased with longer autohydrolysis times. It is postulated that condensation involved materials from both the carbohydrate and lignin components of the wood which were generated during the autohydrolysis. The molar ratio of syringaldehyde to vanillin of extracted lignin on oxidation was observed to decrease with increasing autohydrolysis time. It is suggested that syringyl units are preferentially extracted as low molecular weight material.

MORRIS WAYMAN et MIRANDA G. S. CHUA. Can. J. Chem. **57**, 2599 (1979).

L'oxydation par le nitrobenzène alcalin de lignines extraites de sciures de bois de tremble sans principes extractifs et soumises à une autohydrolyse à 195°C pour des périodes allant de 5 min à 2 h indiquent que ces lignines sont, du point de vue structural, plus condensées en termes d'une augmentation de nouvelles liaisons carbone–carbone que la lignine de bois de tremble broyé. Le degré de condensation augmente généralement en fonction des temps d'autohydrolyse. On suppose que la condensation implique des substances provenant autant de la portion carbohydrate que de la lignine qui est générée au cours de l'autohydrolyse. On a observé que les rapports molaires de syringaldéhyde à vanilline obtenus par oxydation des lignines extraites diminuent lorsque le temps d'autohydrolyse augmente. On suggère que les unités syringyles sont extraites d'une façon préférentielle sous forme de substances de bas poids moléculaires.

Introduction

Alkaline nitrobenzene oxidation of wood and of extracted lignin has been widely used for characterizing protolignin, as well as for studying the effects of isolation procedures on the structure of lignin (1–3). The composition and quantity of the aromatic aldehydes obtained reflect the structural features of the side chain and the extent of carbon–carbon linkages present in the lignin (4). Studies of model compounds (5–7) have indicated that lignin structures which are condensed gave lower aromatic aldehyde yields. In this alkaline nitrobenzene oxidation study of the lignins extracted from aspen wood meal after autohydrolysis at 195°C for periods varying from 5 min to 2 h, a decrease in aromatic aldehyde yield is attributed mainly to condensation reactions and only to a minor extent to modification of the side chain of the lignin. Condensation also adequately explains the changes in the chemical composition and molecular weight distribution of the extracted lignins (8). Kratzl and co-workers (9–11) showed that even after only a short pretreatment with water at elevated temperature and pressure, the total aldehyde yield from wood on alkaline nitrobenzene oxidation was considerably decreased, which has been attributed to condensation.

Results

Alkaline nitrobenzene oxidation of aspen milled wood lignin (MWL) and extracted lignin (XL) was modified in the determination of vanillin and syringaldehyde according to the procedure of Stone and Blundell (12) i.e., by simultaneous spectrophotometric analysis (13). The reproducibility of the yields of vanillin and syringaldehyde by the modified procedure is shown in Table 1. The autohydrolysis XL have lower yields of vanillin and syringaldehyde than MWL, the reference protolignin, except for XL-5 which has a slightly higher syringaldehyde yield. This apparent increase in syringaldehyde for XL-5 can probably be attributed to a lower value of uncondensed syringyl units determined for MWL than originally present in wood. After 40 min of autohydrolysis, the vanillin yield remained constant but the syringaldehyde yield fluctuated $\pm 12\%$ of that of XL-40.

As shown in Table 2, at longer autohydrolysis times, the decrease in aromatic aldehyde yield was small,

XL-120	2.341	2.311	2.334	2.329	+0.5 to −0.8

*% yield by weight, based on lignin on a carbohydrate-free basis.

TABLE 2. Total yield and molar ratio of vanillin and syringaldehyde

Sample	Total (V + S)*	Molar ratio S/V
MWL	15.89	1.32
XL-5	14.36	2.07
XL-10	11.79	1.65
XL-20	8.21	1.39
XL-30	6.96	1.34
XL-40	3.67	1.16
XL-60	3.52	1.08
XL-90	4.02	1.31
XL-120	3.91	1.23

*% yield by weight, based on lignin on a carbohydrate-free basis.

and after going through a minimum at about 60 min, the S/V ratio increased to that of MWL.

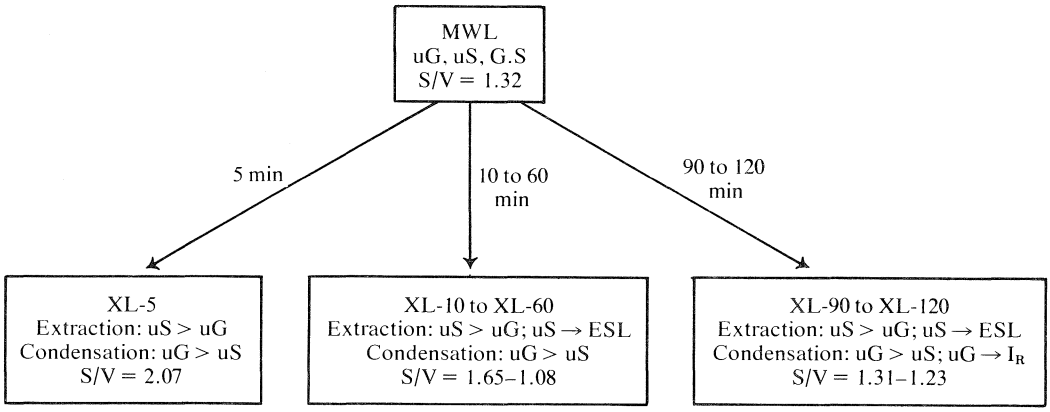
Discussion

The observed marked decreasing yield of aromatic aldehyde from the XL with increasing autohydrolysis time is attributed mainly to condensation reactions involving the formation of new carbon–carbon bonds, resulting in a lignin structure which is much less amenable to oxidation to phenolic aldehydes. Chang and Allen (4) have suggested that the yields and nature of the oxidation products may be determined by the structural features of the aliphatic side chains. This possibility may contribute to the observed decreased yields of aromatic aldehydes, but it is difficult to relate it to the syringyaldehyde to vanillin molar ratio trends and molecular weight distribution patterns (8).

A lower yield of aromatic aldehyde can also be partly attributed to physical or chemical incorporation of non-lignin materials such as carbohydrate degradation products. It is highly probable that these reaction intermediates, namely furfural and its precursors, participate in the lignin condensation reactions (14), resulting in the formation of new carbon–carbon bonds, thereby contributing to the condensed nature of XL.

The methoxyl content of MWL was 21.54%, 1.47 MeO/C_9 unit, which represents a syringyl-to-guaiacyl ratio, taking into account both condensed and uncondensed units, of 1:1. The S/V ratio found after oxidation, 1.32:1, indicates more uncondensed syringyl than guaiacyl, and conversely preferential condensation of guaiacyl units in the protolignin.

Our explanation for the variation in S/V ratio for XL is depicted in Scheme 1. The observed high S/V ratio after 5 min of autohydrolysis is due to preferential condensation of guaiacyl units and preferential extraction of syringyl units during autohydrolysis. From studies of the reactivity of the aromatic sites in lignin (15–17), it has been established that acid-catalyzed condensation reactions proceed most rapid-



SCHEME 1. Explanation of variation of S/V ratio with autohydrolysis time; uG = uncondensed guaiacyl; uS = uncondensed syringyl; G.S = condensed guaiacyl/syringyl; S/V = molar ratio of syringaldehyde-to-vanillin; ESL = ether-soluble extracted lignin; I_R = reactive intermediate.

ly at the C-6 position (structures **1**, **2**, and **3**). The syringyl unit because of the additional methoxyl group at the C-5 position would represent a configuration sterically hindered to condensation at C-6. This would also account for the preferential extraction of syringyl units during lignin fragmentation. Stone (18) and Marth (19) in their alkaline nitrobenzene oxidation studies of the spent sulphite pulping liquors and pulps of aspens found that the ratio of syringaldehyde-to-vanillin in the liquor continually increased during the heating, whereas the syringaldehyde-to-vanillin ratio of the pulp decreased. These results support the suggestion that syringyl-containing units of lignin are more easily extracted. The observed decrease in syringyl units for XL-10 to XL-60 may be attributed to the removal of syringyl units into the ether-soluble fraction during purification of the lignin, which is supported by the high methoxyl content of 23.1% found for this fraction.

After 60 min of autohydrolysis the S/V ratio increased. At this stage of autohydrolysis, lignin and non-lignin degradation products, termed reactive intermediates, are becoming prominent. These reactive intermediates are postulated to be Hibbert ketones (20), *p*-hydroxybenzoic acids (21, 22), syringic acid (23), vanillic acid (23), and furfural, hydroxymethyl furfural, and their precursors (14). From molecular weight distribution studies (8), XL-90 and XL-120 are essentially low molecular weight materials but are highly condensed in the sense of having high proportions of carbon–carbon bonds, as indicated by the very low aromatic aldehyde yield on alkaline nitrobenzene oxidation. An explanation for the increase in S/V ratio is that remaining uncondensed guaiacyl can react with the reactive intermediates resulting in new carbon–carbon bonds and consequently contributing to the increase in S/V ratio.

Experimental

Preparation of Autohydrolysis Extracted Lignin (XL)

For details refer to ref. 8. Extractive-free aspen wood meal was autohydrolysed at 195°C for periods varying from 5 min to 2 h. The lignocellulosic residue was then extracted with 90% dioxane at 70°C and the extracted lignin purified and recovered by precipitation into ether, followed by subsequent washings with benzene and petroleum ether.

Alkaline Nitrobenzene Oxidation of Autohydrolysis Extracted Lignin

The modified procedure is described in detail in ref. 13. It consisted essentially of subjecting the extracted lignin to alkaline nitrobenzene oxidation at 180°C for 2 h, recovering the oxidation products by paper chromatography, and determining the vanillin and syringaldehyde contents by simultaneous spectrophotometric analysis.

Characterization of autohydrolysis aspen (*P. tremuloides*) lignins. Part 3. Infrared and ultraviolet studies of extracted autohydrolysis lignin

MIRANDA G. S. CHUA AND MORRIS WAYMAN

Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A4

Received February 19, 1979

MIRANDA G. S. CHUA and MORRIS WAYMAN. Can. J. Chem. **57**, 2603 (1979).

Infrared and ultraviolet studies of the lignins extracted from extractive-free aspen wood meal after autohydrolysis at 195°C for periods varying from 5 min to 2 h indicated that these lignins were functionally modified and different from aspen milled wood lignin. The extracted lignins changed from a guaiacyl–syringyl type lignin to a syringyl-deficient type lignin with increasing autohydrolysis time. Extracted lignins were also observed to contain unconjugated β-ketone groups and conjugated carboxylic acid groups. It is proposed that the unconjugated β-ketone groups resulted from the depolymerization reactions of the lignin macromolecule under acidic conditions which formed monomeric, dimeric, and oligomeric/polymeric lignin fragments with Hibbert's ketone side chains. The conjugated carboxylic acid group observed to be present was attributed to *p*-hydroxybenzoic acid. *p*-Hydroxybenzoic acid has been postulated as contributing to the extractability of aspen lignin by acting as a blocking agent in the repolymerization of lignin fragments to form insoluble lignin.

MIRANDA G. S. CHUA et MORRIS WAYMAN. Can. J. Chem. **57**, 2603 (1979).

Des études infrarouge et ultraviolette de lignines extraites de sciures de bois de tremble sans principes extractifs et soumises à une autohydrolyse à 195°C pour des périodes allant de 5 min à 2 h indiquent que ces lignines sont modifiées du point de vue fonctionnel et sont différentes de la lignine de bois de tremble broyé. Si l'autohydrolyse se prolonge, les lignines extraites changent d'un type guaiacyl–syringyle à un type déficient en syringyle. On a aussi observé que les lignines extraites contiennent des groupes β-cétoniques qui ne sont pas conjugués et des groupes carboxyliques conjugués. On suggère que les groupes β-cétoniques qui ne sont pas conjugués proviennent de réactions de dépolymérisation de la macromolécule de lignines sous l'influence des conditions acides qui forment des fragments de lignines monomères, dimères et oligomère/polymère avec des chaînes latérales cétoniques de Hibbert. On attribue le groupe acide carboxylique conjugué observé à la présence d'acide *p*-hydroxybenzoique. On suppose que l'acide *p*-hydroxybenzoique contribue à la facilité d'extraction de la lignine de tremble en agissant comme agent qui bloque la repolymérisation des fragments de lignine conduisant à de la lignine sous forme insoluble.

Introduction

During autohydrolysis (steaming) of wood, the reactions that occur in the lignin fraction, as well as in the hemicellulose and cellulose components of wood, are a result of the prevailing acidic condition and the high temperature. In many respects, the effects of autohydrolysis on the lignin fraction are similar to those obtained on acidolysis (1–3) and ethanolysis (4–8). As reported in an earlier paper (9), the changes in elemental composition and decrease in methoxyl content of the lignin extracted from extractive-free aspen wood meal autohydrolysed at 195°C for periods varying from 5 min to 2 h were similar to those observed for aspen lignin on acidolysis. Alkaline nitrobenzene oxidation studies suggested that the extracted autohydrolysis lignins were condensed in structure which was in accordance with the molecular weight changes observed for extracted lignin (9). Acidolysis lignin has also been found to have undergone condensation (10, 11). Lundquist in a comprehensive study of acidolysis (12–18) using spruce and birch Bjorkman milled wood lignins and model compounds has, by identifying the reaction products of the acid-catalyzed degradation, proposed cleavage mechanisms which have proved useful in the elucidation of the structure of lignin. Autohydrolysis at elevated temperatures, although lower in acidity (pH of liquor approximately 3.0), is more drastic in terms of cleavage of lignin–lignin and lignin–carbohydrate bonds than mild acidolysis due to the higher temperatures involved. In addition, in autohydrolysis, the depolymerized lignin fragments remain in the proximity of condensation sites in the wood matrix, and are more liable to recondense than in acidolysis, where degradation products go into solution. Klemola (19) obtained only the more stable Hibbert ketones in the degradation products on steam hydrolysis of birch at 185°C for 2 h. Nimz (20, 21) on mild hydrolysis of finely powdered wood with percolating water at 100°C succeeded in

TABLE 1. Assignment of infrared absorption bands in the region 800 cm^{-1} to 2000 cm^{-1} for aspen milled wood lignin (MWL) and for extracted autohydrolysis lignins (XL)

MWL (cm^{-1})	XL (cm^{-1})	Overall trend in XL	Comment
845	845	Decreases	Aromatic C—H out-of-plane deformation, attributed to the presence of 1,2,3,5-tetrasubstituted aromatic rings, i.e., uncondensed syringyl units
920	915	Increases	Aromatic C—H out-of-plane deformation of syringyl units
1035	1035	Decreases	Aromatic C—H in-plane deformation, assigned as characteristic of uncondensed guaiacyl units
1128	1125–1115	Decreases	Aromatic C—H in-plane deformation, attributed to contribution from both guaiacyl and syringyl units
1225	1215	Constant (Variation ±10%)	Ring breathing with C—O stretching in syringyl and guaiacyl units
1270	1270	Decreases	Ring breathing with C—O stretching in uncondensed guaiacyl units
1325	1325	Decreases	Ring breathing with C—O stretching in syringyl unit
1420	1425	Decreases	Aromatic skeletal vibrations. Strongly coupled by C—H in-plane deformation and sensitive to the nature of ring substituents
1460	1460	Decreases	Asymmetric C—H deformation in methyl and methylene groups, apparently considerably affected by methoxyl groups
1505	1510	Constant	Aromatic skeletal vibrations. Found to have minimal intensity variation with structure, therefore used as internal standard
1590	1595–1605	Decreases	Aromatic skeletal vibrations. Affected by aromatic C—O stretching mode and by conjugation with α-carbonyl groups
1670	—	—	Stretching of conjugated aryl carbonyl, i.e., aryl—C(=O^{α})—C—, aryl—C=C—C(=O)—
1720	1710–1705	Increases	Carbonyl stretching of unconjugated β-ketone, i.e., aryl—C—C(=O^{β})—C— and conjugated acids/esters, i.e., aryl—C(=O^{α})—O— in the lignin unit
1735	—	—	Attributed to unconjugated acids/esters, i.e., aryl—C—C(=O^{β})—O—

hydrolysing specifically the more labile benzyl ether linkages, and reduced recondensation reactions and rearrangements in the aliphatic side chain.

The purpose of these infrared and ultraviolet studies of the extracted autohydrolysis lignin was to follow the changes in functional groups taking place during the acid-catalyzed degradation of lignin. Thus, together with the results obtained from the earlier studies and also supplemented by the findings of the above-mentioned researchers, insight can be gained into the mechanisms involved in lignin reactions during autohydrolysis.

Results

Infrared Spectra of Aspen Milled Wood Lignin (MWL) and Extracted Lignin (XL)

The positions and assignments for the infrared absorption bands for aspen MWL and XL are tabulated in Table 1. The assignments in Table 1 follow essentially those summarized by Hergert (22, 23) supplemented by the work of Sarkanen and Chang (24–26).

Comparing the spectra of XL with MWL as shown in Fig. 1, significant differences are observed. The spectra of MWL indicated absorption at 1720 cm^{-1} with a shoulder at 1735 cm^{-1} attributed to unconjugated acids/esters and a band at 1670 cm^{-1} due to α-carbonyl groups.

In XL, a sharp increase in the 1705–1710 cm^{-1} band with increasing autohydrolysis time is observed, which because of its broadness (1650–1720 cm^{-1}) may indicate some absorption at 1670 cm^{-1}. The 1705–1720 cm^{-1} band may be attributed to unconjugated ketone carbonyl groups and conjugated acids/esters (23, 27–31). To evaluate the nature of the absorption in this region, the lignins were reduced with sodium borohydride under mildly alkaline conditions and the percentage decrease in the 1705–1720 cm^{-1} tabulated in Table 2. The results show that MWL contains unconjugated acids/esters (elimination of 1735 cm^{-1} band) and conjugated acids/esters (1720 cm^{-1} remaining after reduction), but no unconjugated ketones. The 1670 cm^{-1} band in MWL attributed to conjugated

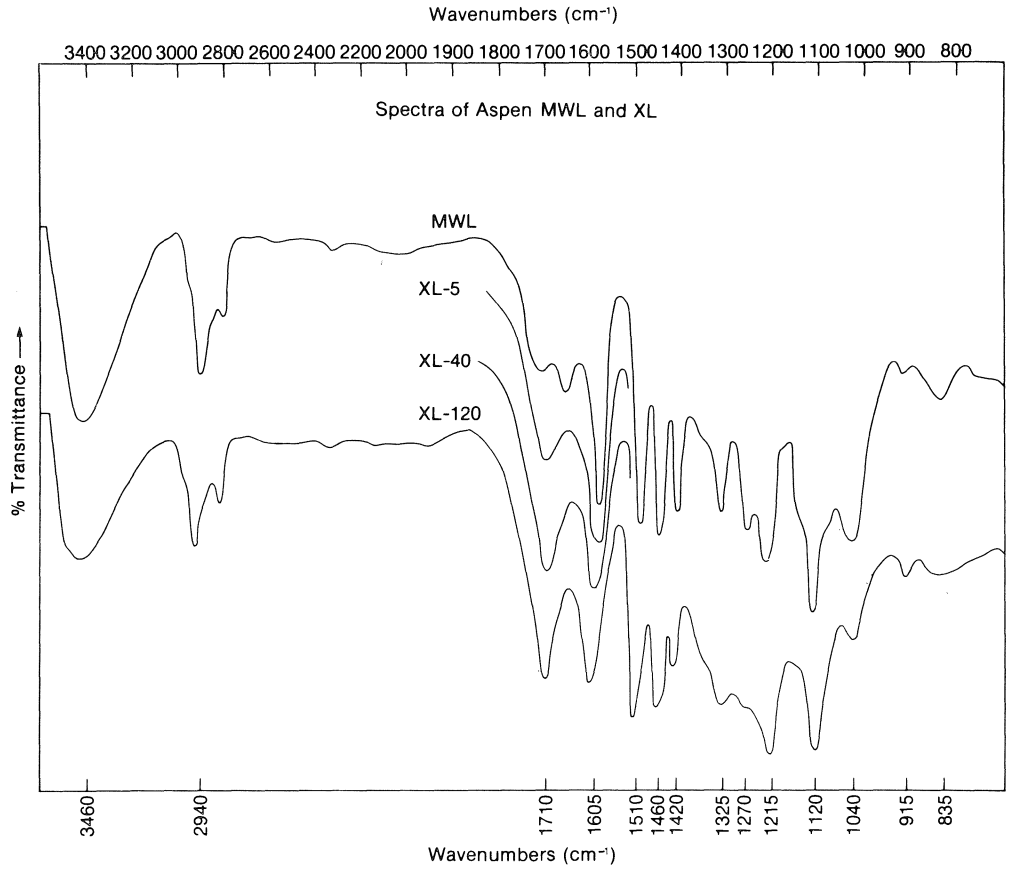

FIG. 1. Spectra of aspen MWL and XL.

TABLE 2. Analyses of infrared spectra of sodium borohydride reduced aspen MWL and XL

Sample	%Change after $NaBH_4$ reduction		
	1590–1610 cm^{-1}	1705–1720 cm^{-1}	1670 cm^{-1}
Reduced MWL	Small	Significant change in 1735 cm^{-1} region Insignificant change in 1720 cm^{-1} region	−12.2
Reduced XL-5	+11.9	−27.0	Absent
Reduced XL-40	+16.1	−47.6	Absent
Reduced XL-120	+23.8	−60.0	Absent

carbonyl groups was decreased by only 12% on reduction. The XL is seen to contain both unconjugated carbonyl structures (reduced portion) as well as conjugated acids/esters (unreduced portion). The band remaining after reduction is more likely to be due to carboxylic acid groups than esters, since the labile ester bonds would have been cleaved by the prevailing hydrolytic conditions. On saponification, the XL could only be precipitated at pH 4 or below and the infrared spectra of the saponified XL showed a decrease in the 1705–1720 cm^{-1} band. This is indicative of carboxylic acid groups.

There is also observed a shift from a lower to a higher frequency of absorption from MWL to XL in the aromatic skeletal vibrations, from 1420–1425 cm^{-1}, 1505–1710 cm^{-1}, and 1590–1605 cm^{-1}, corresponding to a change from a guaiacyl–syringyl type lignin (MWL) to a syringyl-deficient type lignin (XL) (ref. 22, p. 272). This transition is also substantiated by the ratio of absorptivities of the 1600–

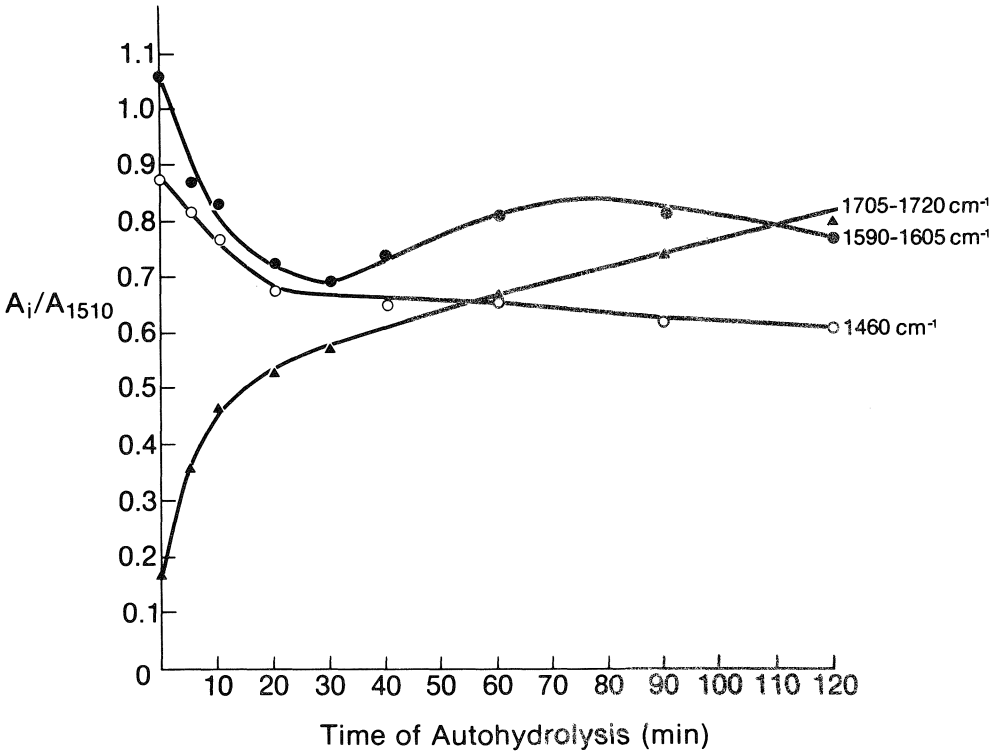

FIG. 2. Trends for absorption bands at 1705–1720 cm^{-1}, 1590–1605 cm^{-1}, and 1460 cm^{-1} for MWL and XL.

1500 cm^{-1} band, which decreases from 1.05 for MWL to approximately 0.8 for XL. The former value is characteristic of hardwood (guaiacyl–syringyl) lignin and the latter softwood (guaiacyl) unit. Furthermore, the band at 1460 cm^{-1} affected by absorption of methoxyl groups (25, 32, 33) is observed to decrease with increasing autohydrolysis time, supporting the observation that XL is tending towards a softwood lignin structure. Figure 2 shows in greater detail the increase in the 1705–1720 cm^{-1} band and the decrease in the 1600 and 1460 cm^{-1} bands.

Ultraviolet Spectra of Aspen Milled Wood Lignin (MWL) and Extracted Lignin (XL)

Aspen lignin has been found by many researchers (26, 34, 35) to give abnormally high ionization difference absorption ($\Delta\varepsilon_i$) due to the presence of *p*-hydroxybenzoate groups. For this reason, the $\Delta\varepsilon_i$ (ionization difference) and $\Delta\varepsilon_r$ (borohydride reduction difference) curves obtained for MWL and XL will be qualitatively interpreted only.

The presence of a maximum at 360 nm for MWL and 366 nm for XL shown in Fig. 3 indicates that both contain phenolic hydroxyls conjugated to α-carbonyl groups, carbon–carbon double bonds, or biphenyl groups. The shift in frequency indicates that the type and proportion of these conjugated structures differ for MWL and XL. From Fig. 4, the phenolic hydroxyl content increases with increasing autohydrolysis time as indicated by the increase in $\Delta\varepsilon_i$ at 255 nm and 296 nm. However, the absorption at these wavelengths is affected by conjugation. Sodium borohydride reduced samples, $\Delta\varepsilon_r$, were run but the trends obtained were difficult to explain, although still indicative of higher phenolic hydroxyl content. It can also be concluded from the 366 nm absorption that increasing amounts of conjugated phenolic structures are being formed on autohydrolysis. From the reduction difference spectra, $\Delta\varepsilon_r$, it appears that only a portion of the conjugated structures can be reduced by sodium borohydride, and this implies the presence of both conjugated carbonyl groups (reduced portion) and conjugated ethylenic group and conjugated acid/esters (unreduced portion).

Discussion

In order to explain the results of the infrared and ultraviolet studies and to relate these to the earlier work on molecular weight distribution (9) and degree of condensation of XL,[1] the possible mechanisms of lignin depolymerization and repolymerization proposed are outlined in Scheme 1.

Scheme 1 shows all possible cleavages of ether

[1]Part 2 in this series of papers.

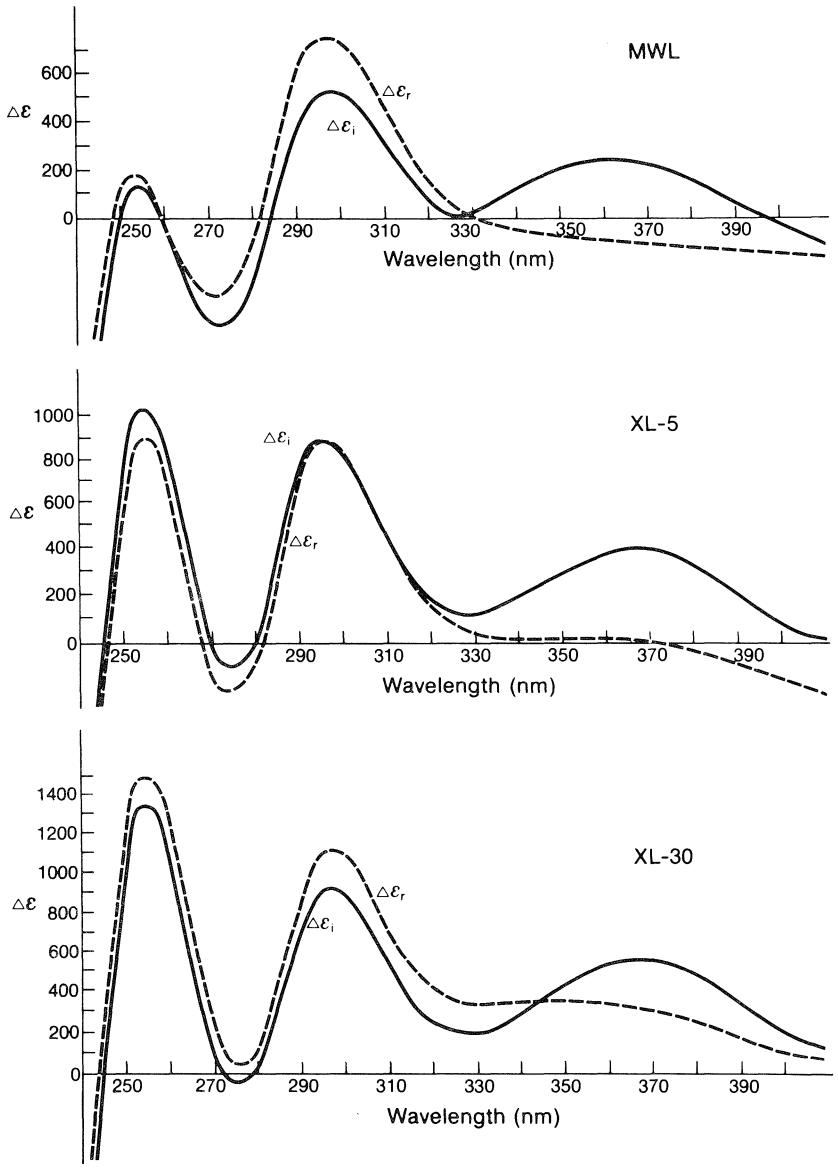

FIG. 3. Ultraviolet ionization ($\Delta\varepsilon_i$) and reduction ($\Delta\varepsilon_r$) curves for MWL and XL.

linkages under acidic conditions of a representative portion of beech hardwood lignin structure as proposed by Nimz (36), with generation of monomeric aromatic (**I***a* and **I***b*) and monomeric aliphatic (**I***c*), dimeric (**II***a* and **II***b*) and oligomeric/polymeric (**III***a* and **III***b*) lignin degradation products. Legend 1 explains the groupings and the subsequent products obtained under the prevailing acidic conditions after the initial hydrolysis.

The depolymerization scheme in Scheme 1 shows that on acidic hydrolysis the monomeric, dimeric, and also oligomeric/polymeric products formed contain aliphatic side chains similar to Hibbert's ketones, namely, with carbonyl and hydroxyl groups. The presence of these compounds is supported by the infrared studies which showed increasing formation of unconjugated β-ketones in the XL, from the 1705–1720 cm^{-1} band with increasing autohydrolysis time. Also the ultraviolet studies have indicated the presence of α,β-diketone, and conjugated ethylenic groups, which may be indicative of phenylcoumarone and stilbene structures. Klemola (19) has also found the more stable Hibbert's ketones and guaiacyl and syringyl derivatives with 3 or less carbon side chain compounds such as acetoguaiacone, acetosyringone, guaiacol, and syringol, in the low molecular weight

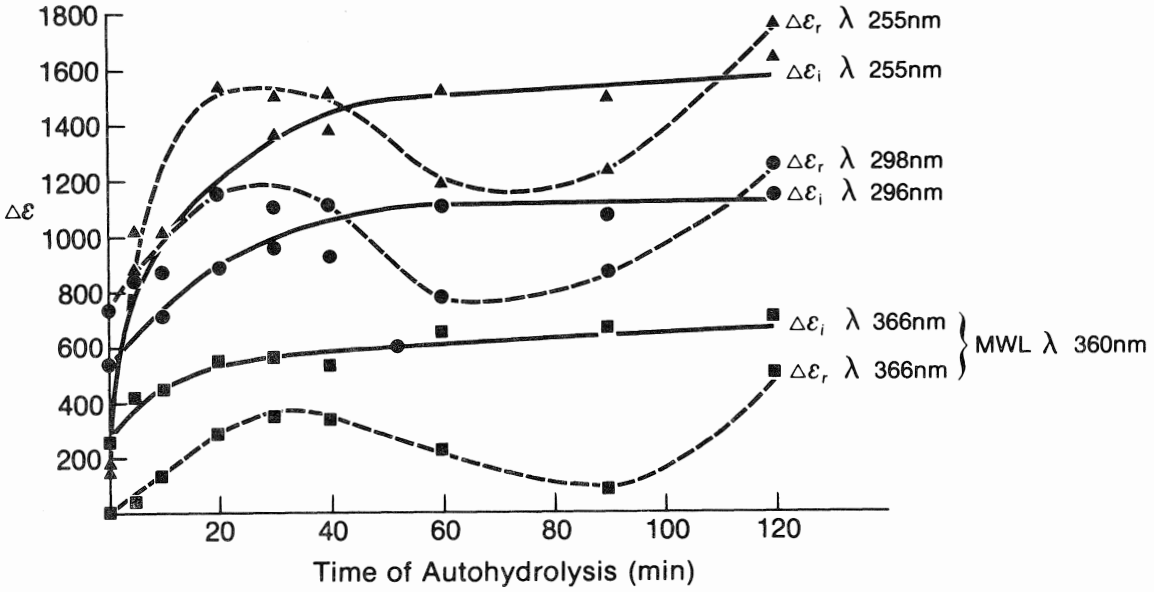

FIG. 4. Trends in ionization ($\Delta\varepsilon_i$) and reduction ($\Delta\varepsilon_r$) curves for MWL and XL.

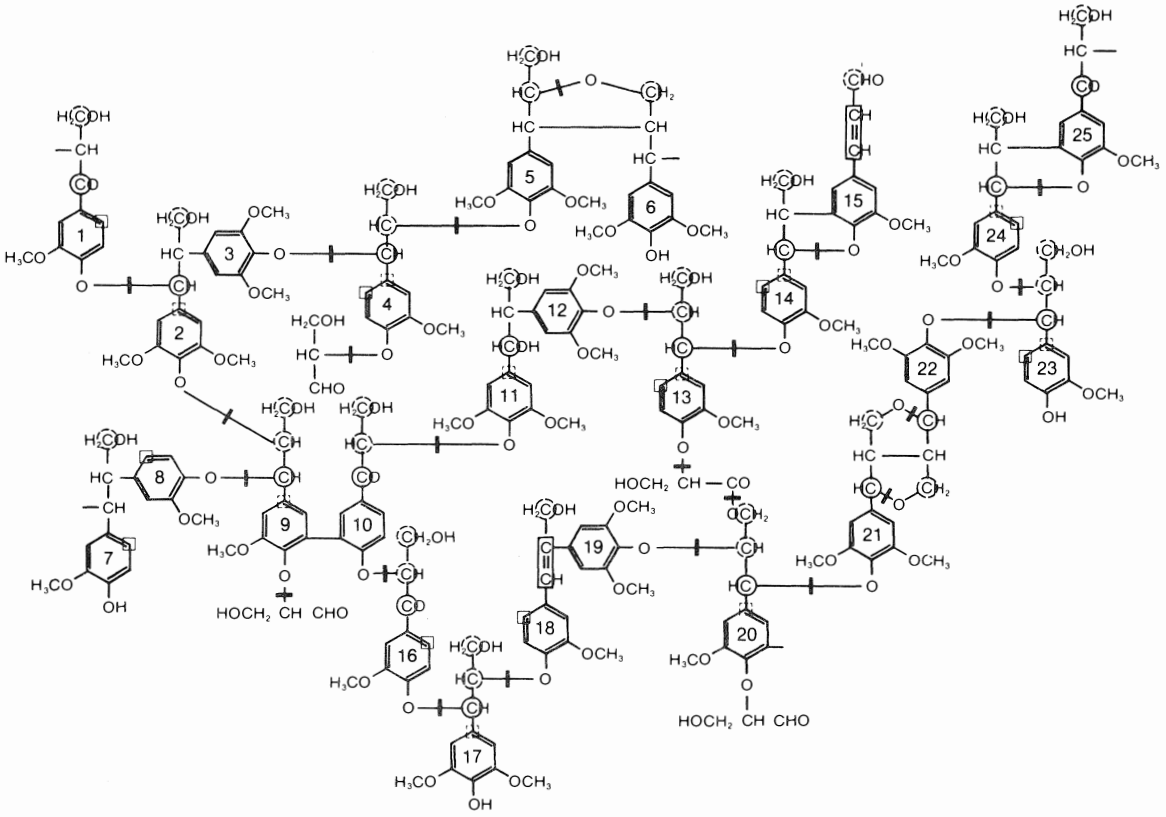

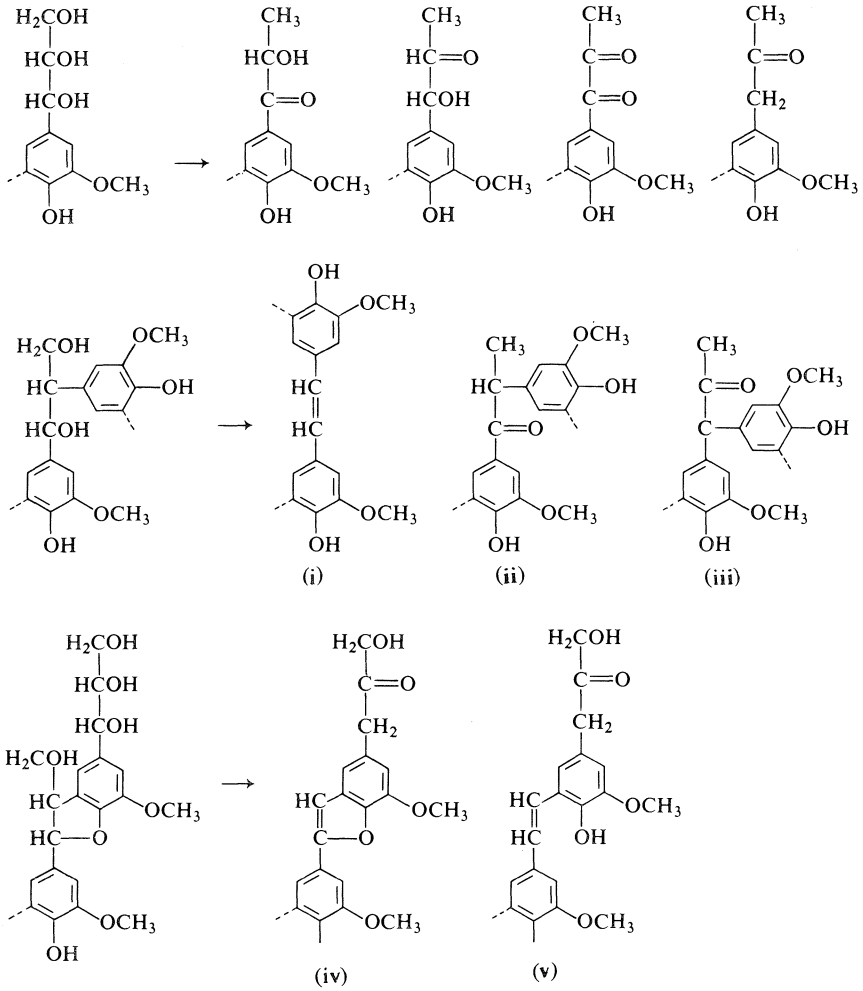

SCHEME 1. Schematic representation of (*a*) depolymerization and (*b*) repolymerization of a representative portion of hardwood lignin under acidic conditions.

(*a*) Depolymerization (indicated by bond cleavage (/)): aromatic ring number → lignin degradation products are 1 → I*a* or III; 2/3 → III*a*; 4 → I*b*, I*c*; 5/6 → II*b* or III; 7/8 → II*b* or III; 9/10 → I*c*, II*b*; 11/12 → II*a*; 13 → I*b*, I*c*; 14/15 → II*b*; 16 → I*a*; 17 → I*b*; 18/19 → II*b*; 20 → I*c*, III*a*; 21/22 → II*b*; 23 → I*b*; 24/25 → II*b* or III.

I*a* = Monomeric guaiacyl and syringyl derivatives with 3 or less carbon atom aliphatic side chains, carrying C=C double bond, carbonyl or hydroxyl groups.

I*b* = Guaiacylglycerol and syringylglycerol structures, which from acidolysis studies are known to form Hibbert's ketones under acidic conditions.

I*c* = Monomeric aliphatic compounds. Lundquist (13) has found pyruvaldehyde, formaldehyde, and methanol in acidolysis liquor.

II*a* = 1,2-Bisguaiacyl-1,3-propandiol and 1,2-bissyringyl-1,3-propandiol structures, which from acidolysis studies have been found to form the following compounds: 4,4′-dihydroxy-3,3′-dimethoxy stilbene (**i**), 1,2-bisguaiacyl-1-propanone (**ii**), and 1,1-bisguaiacyl-2-propanone (**iii**) (or their syringyl analogues).

II*b* = Dimeric guaiacyl or syringyl structures originating from dimers present in the lignin, for example, phenylcoumaran and pinoresinol type of structures (or their syringyl analogues). From acidolysis studies it has also been shown that phenylcoumaran structures which on hydrolysis have a glyceryl side chain form dimeric products with Hibbert's ketone side chains: phenylcoumarone ketone (**iv**) and *o,p*′-dihydroxystilbene (**v**).

III = These represent oligomeric/polymeric products which are not degraded to monomers or dimers because of carbon–carbon linkages.

III*a* = Oligomeric/polymeric products with Hibbert's ketone side chains which on hydrolysis contain glyceryl side chains.

III*b* = Repolymerization (indicated by reactive centres): electrophilic sites ◯, strong; ◌, weak; nucleophilic sites □, strong; ⬚, weak.

fraction on steam hydrolysis of birch. Kratzl *et al.* (37), Sears *et al.* (38), and Goldschmid (39) in their prehydrolysis studies have found besides the Hibbert's ketones, aldehydes such as vanillin *p*-coumaraldehyde and coniferylaldehyde. Stanek (40) in his hydrolysis studies of aspen has found vanillic, syringic, and *p*-hydroxybenzoic acids, the latter in larger amounts than the former two. Smith (27) has found that *p*-hydroxybenzoate groups are present in aspen, up to 10% by weight, which on hydrolysis of the ester linkages form *p*-hydroxybenzoic acid. Furthermore, Nakano and co-workers (41) have shown that at least a part of the *p*-hydroxybenzoate groups are located at the α-position of the lignin side chain. It is also worth stressing that during autohydrolysis the hemicellulose fraction is also being hydrolysed, followed by subsequent dehydration of the sugars to generate reactive furfural, hydroxymethylfurfural, and their precursors. Sugars, furfural, and 5-hydroxymethylfurfural, evidently derived from the carbohydrate constituents of the wood, have been found together with the monomeric lignin degradation products in the hydrolysis liquor of hemlock at 175°C by Goldschmid (39).

The cleavage of lignin linkages under the acidic conditions of autohydrolysis is viewed as only one of two types of opposing reactions occurring simultaneously. Hydrolytic degradation results in depolymerization of lignin, which accounts for its subsequent extractability by various solvents, and condensation reactions result in repolymerization of the lignin fragments and insolubility.

Condensation reactions in lignin under acidic conditions involve an electrophile reacting with a nucleophile to form carbon–carbon bonds. In Scheme 1, part *b*, strong and weak electrophilic and nucleophilic sites have been marked and these represent positions of condensation in the lignin macromolecule. Lignin electrophiles are essentially carbonium ions generated as a result of the cleavage of ether bonds or aliphatic side chain carbon with hydroxyl or carbonyl groups capable of forming carbonium ions. Lignin nucleophiles are the unsaturated aromatic rings with a high electron density at C-6 and C-1 and the unsaturated aliphatic side chains. It is further suggested that some of the lignin degradation products **I**, **II**, and **III**, are also reactive electrophiles and nucleophiles and recondense with the reactive centres in the lignin macromolecule. In addition, furfural, hydroxymethylfurfural, and their precursors, because of the aldehyde group and C=C double bonds in the furan ring, are electrophilic and can also participate extensively in lignin condensation reactions. All these condensations result in the formation of higher molecular weight lignin, leading eventually to the formation of insoluble residual lignin. In aspen lignin, it is proposed that the formation of insoluble residual lignin has to a large extent been prevented, as is seen by the ease of extractability of aspen lignin compared with other hardwoods, by the action of *p*-hydroxybenzoic acid acting as a blocking agent. *p*-Hydroxybenzoic acid acting as a nucleophile reacts at the position *ortho* to the phenolic hydroxyl with electrophilic lignin carbonium ions, thus preventing further condensation towards the formation of insoluble lignin. This is substantiated by these infrared studies, which have indicated the presence of conjugated carboxylic acid in the XL.

Experimental

Preparation of Autohydrolysis Extracted Lignin (XL)

For details refer to ref. 9. Extractive-free aspen wood meal was autohydrolysed at 195°C for periods varying from 5 min to 2 h. The lignocellulosic residue was then extracted with 90% dioxane at 70°C and the extracted lignin purified and recovered by precipitation into ether, followed by subsequent washings with benzene and petroleum ether.

Infrared Spectra

Infrared spectra of milled wood lignin (MWL) and extracted autohydrolysis lignin (XL) were determined in potassium bromide pellets on the Beckman IR-9. Lignin samples and spectrophotometric-grade potassium bromide were dried before use to ensure moisture-free pellets. Lignin (1 mg) was mixed and thoroughly ground with 300 mg of potassium bromide to reduce particle size and to obtain uniform dispersion of the sample in the pellet. The lignin sample was then determined against a pure potassium bromide pellet on the IR-9 operated on a double-beam mode.

Borohydride-reduced MWL and XL were prepared (26) by dissolving 60 mg of lignin in a mixture of 2.0 mL of ethanol and 1.0 mL of 0.1 *N* sodium hydroxide in a nitrogen atmosphere. To the mixture 20 mg of sodium borohydroxide was added, followed by 2.0 mL of water. After 7 days, the solution was acidified to pH 4 with dilute hydrochloric acid, and the precipitated lignin collected by centrifugation. The reduced lignin samples were washed twice with water, dried in a vacuum desiccator, and the infrared spectra determined as in the previous procedure.

XL's were saponified (26) by dissolving 200 mg of lignin in 5% NaOH in a nitrogen atmosphere at room temperature. After 24 h, the solution was acidified to pH 4 with dilute hydrochloric acid. The precipitated lignin was recovered by centrifugation, washed twice with water, dried in a vacuum desiccator, and the infrared spectra determined.

Ultraviolet Spectra

For the determination of ultraviolet spectra (26) of MWL and XL, 5 mg of lignin was dissolved in 7.5 mL of methylcellosolve and diluted with 95% ethanol to 25 mL. The neutral solution was prepared by diluting 10 mL of this solution to 50 mL with 95% ethanol. The alkaline solution was prepared by adding 5 mL of 1 *N* NaOH to 10 mL of the initial solution and diluting to 50 mL with distilled water. The alkaline-neutral difference spectra, $\Delta\varepsilon_i$, were determined by running the alkali solution against the neutral solution. Similarly the reduction difference spectra, $\Delta\varepsilon_r$, were determined as in the above procedure using sodium borohydride reduced MWL and XL.

Acknowledgements

The authors wish to thank the National Research Council of Canada for both the award of an NRCC postgraduate scholarship to one of them (M.G.S.C.) and for a research grant which supported this investigation. The authors also wish to thank Mr. J. H. Lora for the sample of milled wood lignin used in this work, and for helpful discussion of the results.

Characterization of autohydrolysis aspen (*P. tremuloides*) lignins. Part 4. Residual autohydrolysis lignin

MORRIS WAYMAN AND MIRANDA G. S. CHUA

Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A4

Received March 21, 1979

MORRIS WAYMAN and MIRANDA G. S. CHUA. Can. J. Chem. **57**, 2612 (1979).

Lignocellulosic residue remaining after autohydrolysis of extractive-free aspen wood meal at 195°C for periods of time varying from 5 to 120 min followed by extraction with 90% dioxane was subjected to enzymatic hydrolysis to obtain residual lignin. Infrared studies indicated that in the early stages of autohydrolysis residual lignin resembles protolignin, but as autohydrolysis proceeds it changes to resemble more and more the extracted lignin. Residual lignin was found to be higher in carbon but lower in hydrogen and oxygen than aspen milled wood lignin. The methoxyl content was also lower than the reference lignin. From alkaline nitrobenzene oxidation, residual lignin is seen to become more condensed with increasing autohydrolysis time. The insolubility of residual lignin is attributed to the existence of strong bonds between this lignin and carbohydrate.

MORRIS WAYMAN et MIRANDA G. S. CHUA. Can. J. Chem. **57**, 2612 (1979).

On a soumis le résidu lignocellulosique provenant d'une autohydrolyse de sciures de bois de tremble sans principes extratifs à 195°C pour des périodes allant de 5 à 120 min et suivie d'une extraction par du dioxanne à 90%, à une hydrolyse enzymatique dans le but d'en retirer la lignine résiduelle. Des études infrarouges indiquent qu'au début de l'autohydrolyse la lignine résiduelle ressemble à la protolignine, mais au fur et à mesure que l'autohydrolyse progresse la lignine se transforme pour resembler de plus en plus à la lignine extraite. On a trouvé que la lignine résiduelle contient plus de carbone et moins d'hydrogène et d'oxygène que la lignine de bois de tremble broyé. La quantité de méthoxyle est aussi plus faible que la lignine de référence. En se basant sur l'oxydation alcaline par le nitrobenzène, on observe que la lignine résiduelle devient plus condensée lorsque le temps d'autohydrolyse augmente. On attribue l'insolubilité de la lignine résiduelle à l'existence de la présence de liaisons fortes entre cette lignine et les hydrates de carbone.

Introduction

Studies of the protolignin in wood and the reactions of lignin during various pulping processes have centred mainly on the lignin which is extractable. Characterization of these isolated lignins, for example, milled wood lignin, kraft lignin, and lignosulphonate, have enabled lignin researchers to achieve some understanding of lignin structure and to postulate the mechanisms involved in lignin reactions. Recently however, interest is being focussed on the non-extractable lignin fraction, the residual lignin, as indicated by investigations (1, 2) into the characterization of the residual lignin in kraft and NSSC pulps.

The problems associated with the study of residual lignin are two-fold. First, residual lignin is generally insoluble in most solvents, or if it dissolves under more drastic conditions there is inadvertent modification of the lignin structure. This has limited the characterization of residual lignin to methods which utilise the lignin in the solid form. The second factor contributing to the difficulties involved in analysing residual lignin is the strong association of lignin with carbohydrate in wood (3–11) and wood-pulp (12–17), making it impossible to obtain residual lignin free of carbohydrate or conversely a carbohydrate fraction free of lignin. This has led to the prevailing concept of the existence of lignin–carbohydrate bonds and the presence of lignin–carbohydrate complexes in wood.

In our study of the effects of autohydrolysis on the lignin in wood to elucidate the mechanism whereby lignin becomes solvent-soluble during autohydrolysis, there is the need to account for the inextractability of the residual lignin.

Extractive-free aspen wood meal was autohydrolyzed at 195°C for periods of time varying from 5 to 120 min, and the soluble lignin extracted with 90% dioxane at 70°C.[1] The extracted lignocellulosic residue (ER) was then treated with cellulase enzyme to recover the residual lignin (RL), which was analysed for elemental composition and methoxyl content, for infrared absorption, and subjected to alkaline nitrobenzene oxidation.

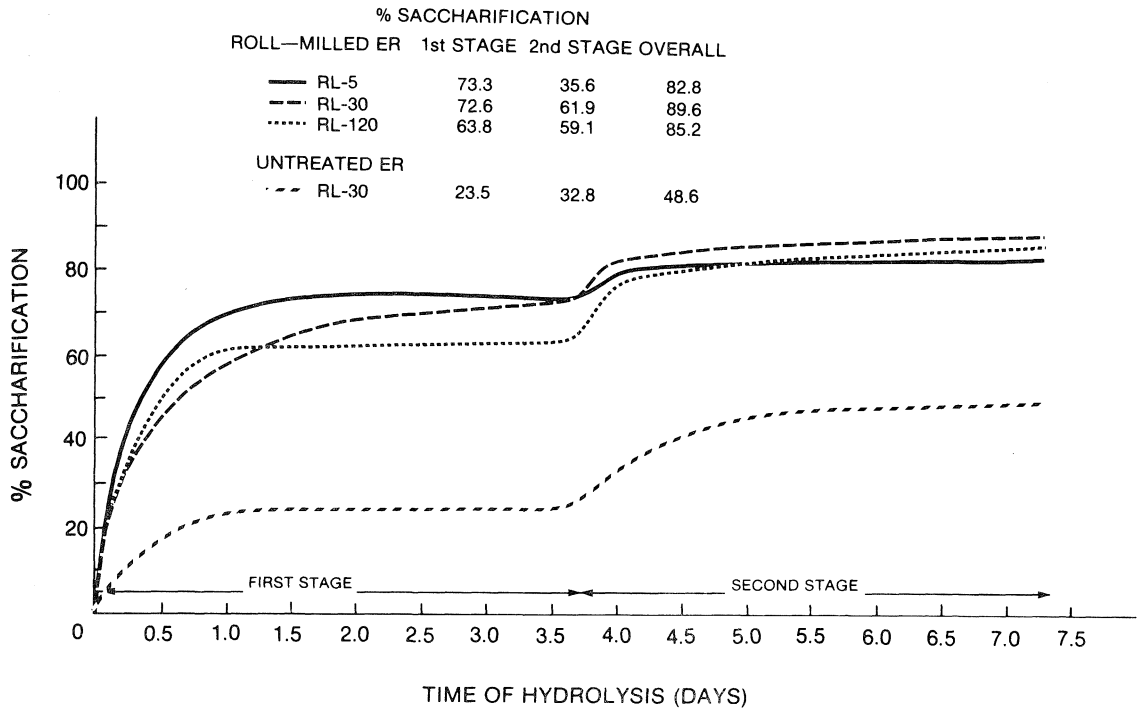

FIG. 1. Enzymatic hydrolysis of extracted lignocellulosic residue (ER) to obtain residual lignin (RL) (based on sugars in liquor after post-hydrolysis).

Results

Saccharification of Extracted Lignocellulosic Residue (ER)

The two-stage saccharification of the extracted lignocellulosic residue (ER) by cellulase enzyme, as shown in Fig. 1, resulted in saccharification yields of 83–90% based on the sugar in the liquor after post-hydrolysis. A mechanical pretreatment of the ER before hydrolysis affected greatly the percentage saccharification, as seen from the untreated ER and roll-milled samples. The effectiveness of mechanical pretreatment in enhancing reactivity of cellulosic materials is due to the alteration of the cellulose crystalline structure thereby increasing accessibility of the cellulose to enzyme or chemicals (19). By comparison, the saccharification yields calculated from Klason lignin determinations of ER and RL were between 92–97%. The higher saccharification yields were attributed to the solubilization under the concentrated acid conditions of Klason analysis of the carbohydrate portion which is not hydrolyzable by cellulase enzyme. The RL contained between 12–34% carbohydrate.

Elemental Analyses of Residual Lignin (RL)

The elemental composition of residual lignin (RL), shown in Table 1, indicated that RL has higher carbon content and lower hydrogen and oxygen contents than aspen milled wood lignin (MWL). Similar changes in C, H, and O were observed for the extracted lignin (XL) (18). These changes suggest that condensation reactions with formation of carbon–carbon bonds and elimination of water have taken place in the lignin in wood during autohydrolysis. The low oxygen content of RL-5 is attributed to the hydrolysis of *p*-hydroxybenzoate groups in MWL with subsequent removal of *p*-hydroxybenzoic acid ($C_7H_6O_3$) with its high oxygen content.

The observed decrease in OCH_3/C_9 unit for RL with increasing autohydrolysis time was quantitatively very similar to that for XL (18). It can be attributed to demethoxylation, inclusion of non-lignin components such as carbohydrate degradation products, and to variation of the proportion of syringyl to guaiacyl units.

Alkaline Nitrobenzene Oxidation of Residual Lignin (RL)

As shown in Table 2, the total aromatic aldehyde yield on alkaline nitrobenzene oxidation of RL decreased with increasing autohydrolysis time

TABLE 1. Elemental analyses of residual lignin (RL) (carbohydrate-free-basis)*

Sample	Carbohydrate in RL (%)	Analysis (%) C	H	O	OCH_3	C_9 formula	Molecular weight C_9 unit
MWL	2.5	59.50	6.25	34.25	21.54	$C_9H_{8.70}O_{3.05}(OCH_3)_{1.47}$	211.2
RL-5	18.2	62.29	6.09	31.62	21.49	$C_9H_{7.93}O_{2.57}(OCH_3)_{1.39}$	200.2
RL-20	25.4	60.54	6.19	33.27	18.51	$C_9H_{8.81}O_{3.00}(OCH_3)_{1.21}$	202.5
RL-30	34.5	61.07	6.09	32.84	18.24	$C_9H_{8.56}O_{2.93}(OCH_3)_{1.18}$	200.1
RL-40	16.5	62.07	6.02	31.91	18.32	$C_9H_{8.25}O_{2.76}(OCH_3)_{1.16}$	196.5
RL-90	14.3	62.08	5.75	32.17	15.54	$C_9H_{8.10}O_{2.91}(OCH_3)_{0.97}$	192.7
RL-120	12.8	62.55	5.64	31.81	15.77	$C_9H_{7.79}O_{2.83}(OCH_3)_{0.97}$	191.5

*Elemental composition for extracted lignin (XL) at corresponding autohydrolysis time is found in ref. 18.

TABLE 2. Alkaline nitrobenzene oxidation of residual lignin (RL)*

Sample	Vanillin (V)† (%)	Syringaldehyde (S)† (%)	Total (V+S) (%)	Molar ratio S/V
MWL	6.15	9.74	15.89	1.32
RL-5	6.74	10.22	16.96	1.27
RL-40	2.07	2.67	4.74	1.08
RL-120	1.42	1.39	2.81	0.80

*Alkaline nitrobenzene oxidation yields for extracted lignin (XL) at corresponding autohydrolysis time is found in Part 2 of this series.
†% yield by weight, based on lignin on a carbohydrate-free basis.

suggesting that RL became increasingly more condensed in structure as autohydrolysis proceeded. Very similar results were obtained for the XL of the same autohydrolysis periods. The slightly higher aromatic aldehyde yield of RL-5 than for MWL is attributed to modification during MWL preparation. The total aromatic aldehyde yield on alkaline nitrobenzene oxidation of aspen wood meal has been found to be much higher than our value of 15.9% for MWL (20).

The decreasing molar ratio of syringaldehyde to vanillin (S/V) for RL with increasing autohydrolysis time is attributed to the preferential removal of syringyl units as low molecular weight compounds into the ether-soluble fraction during purification. The ether-soluble fraction has a high methoxyl content of 23.1%. This trend of decreasing S/V ratio with increasing autohydrolysis time was also observed for the extracted lignin.[2]

Infrared Spectra of Residual Lignin (RL)

The infrared spectra of RL shown in Fig. 2 will be only qualitatively treated because of the presence of carbohydrate in RL. This is indicated in the spectra of RL-30, which had the highest carbohydrate content, by the two peaks at 1060 cm^{-1} and 1165 cm^{-1} attributed to C—O and C—O—C stretching vibrations respectively, in cellulose and hemicellulose (11, 15, 21–23).

In the region 1600–1800 cm^{-1}, the 1670 cm^{-1} band attributed to α-conjugated carbonyl group is present for RL-5 to RL-40, whereas the 1705–1715 cm^{-1} band attributed to β-unconjugated ketone group is present in RL-90 and RL-120. The 1670 cm^{-1} band is present in MWL spectra whilst the 1705–1715 cm^{-1} band is observed to increase prominently with increasing autohydrolysis time for extracted lignin (XL).[3]

A prominent band at 810 cm^{-1} is observed to be present in the spectrum of RL-120 only but absent from the other RL and XL spectra. The presence of furans or furan-related compounds cannot explain the observed 810 cm^{-1} band, because although 2-methylfurfural and furfuryl alcohol show strong absorption around 810 cm^{-1}, the 730 cm^{-1} band associated with the ring deformation of the furan nucleus is absent (24, 25). It was also noted that the 675 cm^{-1} band is present in the spectra of all XL and RL-5 to RL-40, but absent from RL-90 and RL-120.

Discussion

In the early stages of autohydrolysis RL resembles MWL (or protolignin) but as autohydrolysis proceeds it is seen to resemble more and more extracted lignin. This is clearly suggested from the infrared studies by the presence of the 1670 cm^{-1} band (present in MWL[3]) and the absence of the 1705–1715 cm^{-1} band (present in XL) in the spectra of RL-5 to RL-40, whereas for the samples at longer autohydrolysis times, RL-90 and RL-120, the reverse is true. The elemental analyses also show this tran-

[3]Part 3 of this series.

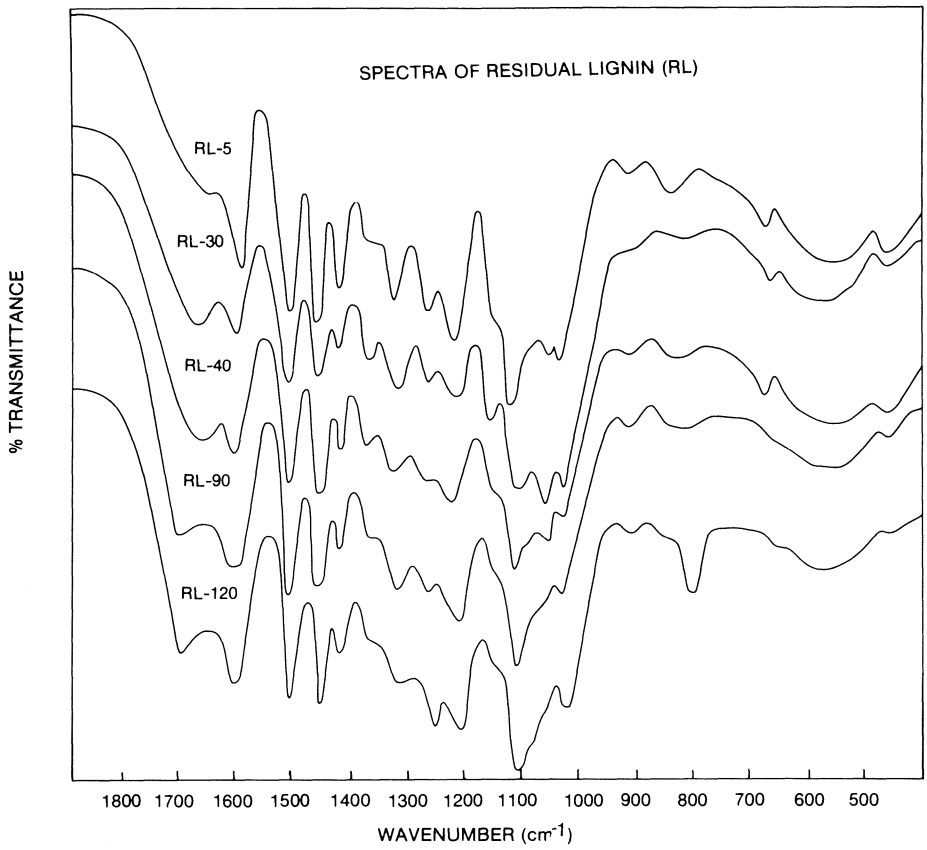

FIG. 2. Spectra of residual lignin (RL).

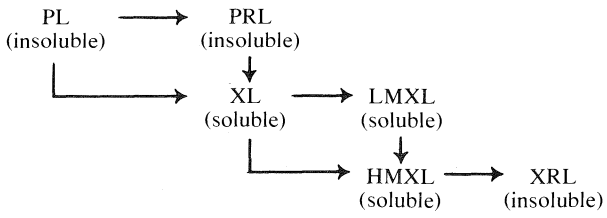
sition from a protolignin-type residual lignin to an extracted lignin-type residual lignin, as is indicated by the composition of RL-120 being more similar to XL-120 (18) than to MWL.

Alkaline nitrobenzene oxidation has proved to be most illuminating with regard to the concept of simultaneous depolymerization and repolymerization. It has shown that during autohydrolysis besides depolymerization, resulting in extractable lignin, condensation has also taken place even as early as during the first 5 min of autohydrolysis. In addition, condensation is observed to be taking place to almost the same extent in the RL and in the XL of the same autohydrolysis time, as indicated by their similar total aromatic yield.

The mechanism of the reactions of lignin in wood during autohydrolysis may be viewed as in Scheme 1. It shows that on autohydrolysis the original insoluble protolignin (PL) in wood was depolymerized resulting in formation of extracted lignin (XL) and leaving a protolignin-type residual lignin (PRL) presumably firmly bound to the carbohydrate. The XL was shown from molecular weight distribution studies (18) to consist of low and high molecular weight lignins (LMXL and HMXL). The soluble LMXL repolymerizes to form soluble HMXL. For the first 40 min of autohydrolysis, the yield of PRL decreased resulting in formation of more extracted lignin (XL). As a result of condensation and also of reaction with carbohydrates and their degradation products as autohydrolysis proceeded, most of the lignin became insoluble as observed by the increase in yield of extracted lignin-type residual lignin (XRL). This increase in XRL is seen to correspond to a decrease in soluble HMXL, which is postulated to be the intermediate in a succession of condensa-



SCHEME 1. Formation of residual lignin and extracted lignin: PL = insoluble protolignin, PRL = protolignin-type residual lignin, LMXL = low molecular weight extracted lignin from XL, HMXL = high molecular weight extracted lignin from XL, XRL = extracted lignin-type residual lignin.

tion reactions of lignin fragments leading eventually to the formation of insoluble lignin (18).

From the saccharification studies, the presence of a portion of carbohydrate which is not saccharified by cellulase enzyme suggests the existence of strong lignin–carbohydrate linkages. The insolubility of residual lignin during autohydrolysis is attributed to these strong bonds between this lignin and carbohydrate.

Experimental

Residual Lignin (RL) from Extracted Lignocellulosic Residue (ER)

The extracted lignocellulosic residue (ER) which remained after extraction of autohydrolysed extractive-free aspen wood meal at 195°C for periods varying from 5 min to 2 h with 90% dioxane (18), was subjected to cellulase hydrolysis to recover the residual lignin (RL). For most experiments, ER was mechanically pretreated before enzymatic hydrolysis, by passing through a two roll mill 3 times for 1-min cycles (processed by the U.S. Army Natick Development Laboratory, Natick, MA) as this was found to enhance cellulose saccharification. Cellulase enzyme (*Trichoderma reesei*) supplied by courtesy of Dr. C. Massey of Natick Laboratory with an activity of 0.125 IU/mg was used for the hydrolysis.

Following the Natick procedure, 5 g of substrate (ER) in 95 mL of citrate buffer pH 4.8 was hydrolysed using 0.7 g of cellulase (enzyme activity in solution was 1 IU per mL) in 250 mL shake flasks at 50°C. Samples of the solution (5 mL) were withdrawn at various time intervals and analysed for sugar content after post-hydrolysis by the dinitrosalicylic acid method of Miller (26) as modified by Natick Laboratory (27). Post-hydrolysis consisted of subjecting the hydrolysis solution to 4% H_2SO_4 in an autoclave at 16 psig for 1 h to ensure that oligomers or dimers are completely hydrolysed to glucose. The difference between the glucose content determined before and after posthydrolysis was less than 6%. The hydrolysis was stopped after 3.5 days, the remaining substrate centrifuged, washed thoroughly with distilled water, and subjected to a second hydrolysis. After another 3.5 days, the solid remaining from the 2-stage hydrolysis, termed residual lignin (RL) was recovered by centrifugation, washed thoroughly with distilled water, and freeze-dried.

Elemental Analyses, Methoxyl Determination of Residual Lignin and % Carbohydrate in the Residual Lignin

Lignin samples were analysed for C, H, and methoxyl content by Schwarzkopf Microanalytical Laboratory, Inc., New York.

The % carbohydrate in the residual lignin was determined by measuring the amount of sugar present in the final hydrolysis liquor after Klason analysis by the dinitrosalicylic acid method.

Alkaline Nitrobenzene Oxidation

The modified procedure for alkaline nitrobenzene oxidation is described in detail in ref. 28.

Infrared Spectra

Infrared spectra of residual lignin were determined in potassium bromide pellets on the Beckman IR-9. Lignin (1 mg) was mixed and thoroughly ground with 300 mg of potassium bromide to reduce particle size and to obtain uniform dispersion of the sample in the pellet. The lignin sample was then determined against pure potassium bromide on the Beckman IR-9.

Acknowledgments

The authors wish to thank the National Research Council of Canada for both the award of an NRCC postgraduate scholarship to one of them (M.G.S.C.) and for a research grant which supported this investigation. The authors also wish to thank Mr. J. H. Lora for the sample of milled wood lignin used in this work, and for helpful discussion of the results.

Electrochemical oxidation of trifluoroacetic acid anion. IV. Synthesis and stereochemistry of products of trifluoromethyl radical addition to some mono- and disubstituted olefins[1]

ROGER N. RENAUD, PHILIPPE J. CHAMPAGNE,[2] AND MARC SAVARD[3]

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received September 18, 1978[4]

ROGER N. RENAUD, PHILIPPE J. CHAMPAGNE, and MARC SAVARD. Can. J. Chem. **57**, 2617 (1979).

The trifluoromethylation of mono- and disubstituted ethylene molecules was performed in good yields via the electrochemical oxidation of sodium trifluoroacetate. The relative quantities of monomeric and dimeric products are a function of the concentration of the substrate.

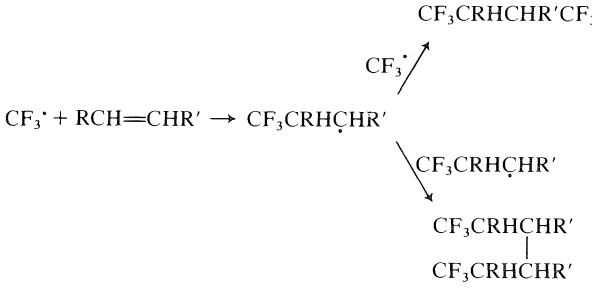
The stereoisomers of the products were separated and identified and, when possible, their stereochemistry was determined by Hnmr and Fnmr spectroscopies.

ROGER N. RENAUD, PHILIPPE J. CHAMPAGNE et MARC SAVARD. Can. J. Chem. **57**, 2617 (1979).

La trifluorométhylation par voie électrochimique de molécules d'éthylène mono et disubstituées fut étudiée. A partir de radicaux trifluorométhyles formés par oxydation anodique d'acétate de sodium, il est démontré qu'il est possible de trifluorométhyle la double liaison en bons rendements. La quantité relative des produits monomériques et dimériques formés est en fonction de la concentration du substrat dans le milieu réactionnel.

Les stéréoisomères des produits formés furent séparés et identifiés, et, dans quelques cas, la stéréochimie fut établie par spectroscopie de rmn du proton et du fluor.

Trifluoromethylation of olefinic compounds via the photolysis of trifluoroiodomethane (1) or hexafluoroazomethane (2) has been the subject of very extensive studies. The results showed that only monotrifluoromethylated products were obtained. More recently, trifluoromethylation of olefins by electrochemical oxidation of trifluoroacetic acid anion gave bis-trifluoromethylated monomeric and dimeric products (3–5) according to Scheme 1.



SCHEME 1

The present paper concerns the electrochemical trifluoromethylation of a few monosubstituted, disubstituted, and heterocyclic olefinic compounds (**1–5**) in order to study the generality of the reaction.

The stereoisomers of the products were separated and their physical properties were determined. In some cases the stereochemistry of the isomers was also determined. These results were compared with those obtained for the equivalent methylation reactions (6).

Experimental

All starting compounds were commercially available and were further purified by fractional distillation or sublimation. The Pr-optishift-II nmr reagent was obtained from Willow Brook Labs Inc. All melting points are uncorrected. The electrolytic cell has been shown before (6). Gas–liquid chromatographic analyses were done on a Fisher/Victoreen apparatus Series 4400 and preparative glc was carried out using an Aerograph Autoprep model A-700 with a 20 ft × 3/8 in. column, 30% SE30 on 45/60 chromosorb P. A LKB 7000 Ultrorac Fraction collector was utilized for the silica gel chromatographic column separation. Proton magnetic resonance spectra were taken in deuteriochloroform on a Varian Associates spectrometer model EM 360 and are reported in the δ scale. Fnmr spectra were obtained in $CHCl_3$, unless otherwise noted, on a Varian Associates XL 100A spectrometer equipped with a Nicolet Instrument TT 100A FT accessory. The spectra are reported in ppm using $CFCl_3$ as reference. The mass spectra were obtained either from a Finnigan 4000 GC-MS or a Hitachi Perkin-Elmer RMU-6D mass spectrometer.

Electrolysis of Sodium Trifluoroacetate in the Presence of the Olefinic Substrate (General Procedure)

A solution of NaOH (6 g) in TFA (45 mL) was added to the anodic compartment containing a mixture of acetonitrile (180 mL) and water (75 mL). The cathodic compartment was charged with a 1.0 *M* solution of NaOH in water. A current of 1.8 A was passed through the solution for a period of 15 min. The temperature of the reaction mixture was maintained at 22°C using a cold ethanol bath. Then the substrate (0.01 to 0.1 mol) was added and the electrolysis was continued for 7 h at a current of 1.8 A, which is equivalent to a current density of 0.15 A/cm^2.

Purification and Physical Properties of the Products

*(A) From Methyl Vinyl Ketone (**1**)*

The solution after electrolysis of 0.1 mol of freshly distilled methyl vinyl ketone was poured into water (600 mL), a heavy brown oil separating from the aqueous phase. The mixture was extracted with three 75 mL portions of methylene chloride. After the evaporation of the solvent on a rotary evaporator, a brown oil (6.3 g) was obtained. This crude oil was distilled under reduced pressure (10^{-2} Torr) at 50°C into a liquid N_2 trap. The analytical vpc of the distillate showed a mixture of at least six minor peaks and one major one. This mixture was fractionally distilled first under reduced pressure (10^{-2} Torr) at room temperature and the colorless high vapor pressure distillate, collected in a liquid N_2 trap, corresponded to impure 1,2-bis(trifluoromethyl)ethyl methyl ketone. Fnmr: 94.60 (d), 96.55 (t). The ketone could not be obtained pure as it turned dark brown on standing for a few hours at 5°C.

The low vapor pressure fraction, which distilled at 50°C, was collected in an ice trap. The semi-solid distillate proved to be a 1:1 stereoisomeric mixture of *meso*- and *dl*-3,4-bis(βββ-trifluoroethyl)hexane-2,5-dione (3.3 g; 24%). A final purification of the mixture was done on the preparative glc. Fnmr: −68.26 (t), −68.10 (t). *Anal.* calcd. for $C_{10}H_{12}F_6O_2$: C 43.19, H 4.32; found: C 42.57, H 4.36. The solid phase was separated from the above mixture either by centrifuge in a Craig tube or by a simple washing with ether. The oil could not be obtained absolutely free from the solid isomer. The Fnmr showed the presence of about 5% of the solid isomer. The melting point of the white solid isomer was 86–87°C. Fnmr −68.00 (t). *Anal.* found for $C_{10}H_{12}F_6O_2$: C 43.29, H 4.28.

*(B) From Vinyl Acetate (**2**)*

Freshly distilled vinyl acetate (0.1 mol) was trifluoromethylated as described above. The anodic solution was concentrated on a rotary evaporator and the remaining 75 mL was poured into water (600 mL). The resulting aqueous solution was extracted 4 times with 75 mL of methylene chloride. The residue after the evaporation of the solvent was distilled under a pressure of 10^{-2} Torr into a liquid N_2 trap. A yellowish oil (2.8 g) was obtained and shown by analytical vpc to be a mixture of at least three minor and three major compounds. The oil was fractionally distilled at 50°C in a Späth bulb under a pressure of 10^{-2} Torr. The colorless high vapor pressure distillate collected in a liquid N_2 trap was so unstable that it turned dark blue as it warmed up to room temperature. The colorless oil collected in the bulb at room temperature corresponded to a nearly pure 1:1 stereoisomeric mixture of *meso*- and *dl*-3,4-diacetyl-1,1,1,6,6,6-hexafluorohexane (1.6 g; 13.5%). The large difference in retention times of the isomers on the preparative glc allowed them to be separated in pure form. The compound corresponding to the first peak was an oil at room temperature. Fnmr −67.23 (t). *Anal.* calcd. for $C_{10}H_{12}F_6O_4$: C 38.71, H 3.87; found: C 38.62, H 3.96. The second fraction was a solid melting at 61–62°C. Fnmr −67.43 (t). *Anal.* found for $C_{10}H_{12}F_6O_4$: C 38.74, H 4.04.

*(C) From Diethyl Fumarate (**3**)*

The solution after electrolysis of 0.1 mol of substrate was poured into water (600 mL) and the heavy oil that separated was collected (22.5 g). This oil was washed once with water (200 mL) and fractionally distilled at 10^{-2} Torr in a vacuum manifold. Two main fractions were collected as follows:

High Vapor Pressure Fraction

This fraction which was distilled at room temperature and was collected in a liquid N_2 trap consisted of almost pure *meso*- and *dl*-diethyl-2,3-bis(trifluoromethyl)succinate (14.5 g; 47%); Hnmr 1.32 (6H, 2t, methyls), 3.86 (2H, m, methines), 4.27 (4H, q, methylenes); Fnmr −68.10 (d), −68.79 (d); ms *m/e* 310 $(M)^+$, 283 $(M - C_2H_3)^+$ (7), 265 $(M - OC_2H_5)^+$, 237 $(M - CO_2C_2H_5)^+$. *Anal.* calcd. for $C_{10}H_{12}F_6O_4$: C 38.71, H 3.87; found: C 39.32, H 4.12.[5]

The two stereoisomers, obtained in a ratio of 2:1, were separated and identified by the following procedure. The mixture was placed in a Craig tube and cooled to 0°C for 12 h. Under these conditions one of the isomers crystallized out. The cold mixture was then centrifuged in order to separate the two phases. The solid phase (4.7 g) melted at 56–58°C and was nearly pure *meso* isomer according to vpc analysis and nmr spectroscopy: Hnmr 1.34 (6H, t, methyls),[6] 3.80 (2H, m, methines), 4.26 (4H, q, methylenes);[6] Fnmr −68.80 (d).[7] *Anal.* found for $C_{10}H_{12}F_6O_4$ (after recrystallization and sublimation): C 38.40, H 3.83. The liquid phase obtained from the separation of the solid phase by centrifuge still contained about 6% of the *meso* isomer. A purity of over 98% was attained after a second treatment in the Craig tube. The yield of this isomer (shown below to be the *dl* isomer)[8] was 9.3 g; Hnmr 1.32 (6H, t, methyls), 3.78 (2H, m, methines), 4.23 (4H, q, methylenes);[9] Fnmr −68.10 (d).[10] *Anal.* found for $C_{10}H_{12}F_6O_4$: C 38.68, H 3.89.

Low Vapor Pressure Fraction

This fraction was distilled at 100°C (10^{-2} Torr) and was determined by vpc analysis and nmr spectroscopy to be nearly pure 1,4-bis(trifluoromethyl)-1,2,3,4-tetracarboethoxybutane (6.4 g; 26.6%):[11] Fnmr (series of doublets of unequal intensities indicating a mixture of isomers). *Anal.* calcd. for $C_{18}H_{24}F_6O_8$: C 44.81, H 4.98; found: C 44.89, H 5.07. When the isomeric mixture was cooled in a Craig tube for 24 h some crystals were formed. These were separated from the liquid phase by centrifuge and were shown by Fnmr spectroscopy to contain only one of the stereoisomers (mp 68–69°C): Fnmr −69.10 (d). *Anal.* found for $C_{18}H_{24}F_6O_8$: C 44.88, H 4.98.

---

[5]The elemental analysis is a little over the acceptable limit. However, it is introduced in order to indicate that even after a simple distillation the compound is nearly pure.

[6]The triplet and the quartet shifted upfield in the presence of Pr-optishift-II nmr reagent but remained as a triplet and a quartet indicating the presence of the *meso* isomer.

[7]The doublet remained a doublet in the presence of optishift reagent, which also indicates the presence of the *meso* isomer.

[8]A sample of the *dl* isomer in the presence of a trace of triethylamine epimerized into a 1:1 *meso*:*dl* isomeric mixture after 1 min.

[9]The quartet split into two quartets in the presence of optishift reagent indicating the presence of the *dl* isomer.

[10]Some splitting of this doublet could be seen due to long range coupling. The doublet split into two doublets in the presence of the optishift reagent. This result also indicates the presence of the *dl* isomer.

[11]The dimeric product was nearly eliminated by reducing the initial concentration of diethyl fumarate to 0.01 mol.

(D) From Diethyl Maleate (3)

Essentially the same result as with diethyl fumarate was obtained using diethyl maleate as the trifluoromethyl radical acceptor.

(E) From N-*Ethylmaleimide (4)*

The solution obtained from the electrolysis of 0.02 mol of substrate was concentrated on a rotary evaporator and the residue was poured into water (600 mL). The aqueous solution was extracted three times with 75 mL of methylene chloride. The organic solution on concentration gave a colorless oil which was fractionally distilled at 10^{-2} Torr. The fraction which distilled slowly at room temperature (2.5 g) was collected in a liquid N_2 trap and determined by vpc analysis and nmr spectroscopy to be a mixture of 85% of *trans*-2,3-bis(trifluoromethyl)-*N*-ethylsuccinimide[12] and 3% of a peak which was attributed to the *cis* isomer[13] and 12% of starting material. Pure 2,3-bis(trifluoromethyl)-*N*-ethylsuccinimide (mp 29–30°C) was obtained from preparative glc separation. Hnmr 1.20 (3H, t methyl), 3.62 (4H, 2 unresolved q, methylene and methines). Fnmr −71.32 (d, J = 7.36 Hz);[14] ms *m/e* 263 $(M)^+$, 248 $(M - CH_3)^+$, 236 $(M - C_2H_3)^+$ (7), 220 $(M - NCH_2CH_3)^+$. *Anal.* calcd. for $C_8H_7F_6NO_2$: C 36.50, H 2.66, N 5.32; found: C 36.62, H 2.87, N 5.73.

(F) From 2,5-Dihydrothiophene-1,1-dioxide (5)

Freshly sublimed 2,5-dihydrothiophene-1,1-dioxide (0.02 mol) was trifluoromethylated as described above. After concentration of the anodic solution on a rotary evaporator, the residue (≈ 75 mL) was poured into water (600 mL) and the solution was extracted with four 75 mL portions of methylene chloride. A viscous oil was obtained on evaporation of the solvent. The crude material (3.0 g) was distilled at 65°C under a pressure of 10^{-2} Torr into a liquid N_2 trap leaving an unidentified sticky oil in the distilling flask (0.4 g). The analytical vpc of the distillate showed three peaks, one of which corresponded to the starting compound. The Fnmr spectrum of this distillate in acetone showed the presence of four fluorinated compounds whose absorptions were centered at −72.09, −70.76, −68.59, and −67.50 in a ratio of 0.5:1:0.2:0.9 respectively. On heating an aliquot of the mixture at 160°C for 2 min, the peak corresponding to the starting compound on the vpc and the broad singlet at −68.59 in the Fnmr spectrum disappeared. This singlet corresponds most likely to 3-trifluoromethyl-2,5-dihydrothiophene-1,1-dioxide.

The distillate obtained above was dissolved in boiling ether and allowed to cool to 0°C in a Craig tube. The white solid that precipitated was separated by centrifuge. This product, melting at 135–136°C, corresponded to one of the two stereoisomers of 3,4-bis(trifluoromethyl)tetrahydrothiophene-1,1-dioxide. Fnmr −67.50 (2d, J = 4.13 and 4.45 Hz); ms *m/e* 256 $(M)^+$, 207 $(M - HSO)^+$, 192 $(M - SO_2)^+$. *Anal.* calcd. for $C_6H_6F_6O_2S$: C 28.13, H 2.34, S 12.50; found: C 28.34, H 2.45, S 12.34.

The residual oil from above was subjected to column chromatography on silica gel. Elution of the column with a 4:1 hexane – ethyl acetate mixture afforded three main fractions. The first fraction was a solid (0.82 g; 16%) subliming on melting at 104–108°C. It corresponded to the other stereoisomer of 2,3-bis(trifluoromethyl)tetrahydrothiophene-1,1-dioxide. Fnmr −70.72 (broad s); ms *m/e* 256 $(M)^+$. *Anal.* found for $C_6H_6F_6O_2S$: C 28.37, H 2.47, S 12.39. The second fraction corresponded to the same compound obtained from the crude mixture in ether (total yield 0.79 g; 15.4%). The third fraction was an oil (0.49 g; 13%) corresponding to 3-trifluoromethyl-4,5-dihydrothiophene-1,1-dioxide. Hnmr 3.35 (m, 2H, methylene), 3.91 (m, 1H, methine), 6.63 and 6.90 (2H, m, CH=CH). Fnmr −72.10 (d, J = 8.91 Hz); ms *m/e* 186 $(M)^+$. *Anal.* calcd. for $C_5H_5F_3O_2S$: C 32.26, H 2.67, S 17.20; found: C 32.38, H 2.78, S 17.03.

[12]The *trans* isomer was detected by Hnmr analysis. In the presence of optishift reagent, the quartet for the methylene protons split into two quartets as expected for the *trans* isomer.

[13]The compound corresponding to the minor peak was not isolated but showed a doublet in Fnmr at −71.93 ppm. It disappeared after 15 min at room temperature in the presence of trimethylamine presumably by epimerization to the more stable *trans* isomer.

[14]The doublet split into two doublets in the presence of optishift reagent, indicating the presence of the *trans* isomer.

Results and Discussion

The trifluoromethylation of activated ethylene molecules by the electrochemical technique was found to give, in most cases, good yields of 1,2-bis(trifluoromethyl) derivatives and, under certain experimental conditions such as high concentration of the substrate, to give acceptable yields of dimeric products.

The behaviour of the two monosubstituted substrates was similar to that observed previously for ethyl acrylate (4) but in both cases the monomeric products were too unstable to allow them to be isolated in pure form. The dimers, however, are stable. The yields of 3,4-bis(βββ-trifluoroethyl)hexane-2,5-dione and 3,4-diacetyl-1,1,1,6,6,6-hexafluorohexane are acceptable for a one step reaction. The stereoisomers were separated but their configurations were not determined.

Both diethyl fumarate and diethyl maleate give rise to a mixture of *meso* and *dl* isomers in a ratio of 1:2 respectively. Efforts to change this ratio either by varying the current densities or by varying the concentration of the substrate even by a factor of ten were unsuccessful. In order to determine whether epimerization of the products was occurring under the conditions of electrolysis, a run was carried out in which diethyl fumarate was replaced by pure *dl*-diethyl-2,3-bis(trifluoromethyl)succinate. The *dl*-succinate compound was quantitatively recovered unchanged. Therefore, it can be concluded that no epimerization occurred after the product formation. Furthermore, the thermodynamic ratio was found to be 1:1 (*meso*:*dl*) in the presence of triethylamine.

The trifluoromethylation of *N*-ethylmaleimide gives practically only *trans*-*N*-ethyl 2,3-bis(trifluoromethyl)succinimide. The small amount of product which was attributed to the *cis* isomer epimerized readily in the presence of triethylamine to the thermodynamically more stable of the two possible isomers. A slow acid-catalyzed epimerization might also be occurring during the electrolysis, but this fact can only be clarified with the availability of the *cis* isomer.

The trifluoromethylation of 2,5-dihydrothiophene-

1,1-dioxide is an example of a radical addition to an unactivated double bond. The *cis* and *trans* stereoisomers of the 3,4-bis(trifluoromethyl)tetrahydrothiophene-1,1-dioxide, obtained in a ratio of 1:1, were separated and identified but their stereochemistry was not determined. This work is in progress. Important quantities of Δ^2 and Δ^3 unsaturated monotrifluoromethylated products were also obtained. The Δ^2 compound behaves in a similar fashion to the starting compound in that it decomposes on heating to 160°C, presumably to SO_2 and 2-trifluoromethylbutadiene, whereas the Δ^3 isomer is stable at this temperature.

The yields from methylation of olefins activated by electron withdrawing groups (6) are consistently higher than the yields from trifluoromethylation, while the methyl radical did not react at all with the unactivated double bond in 2,5-dihydrothiophene-1,1-dioxide under the present conditions. This can be explained in terms of the much stronger electrophilicity of the trifluoromethyl radical over the slightly nucleophilic methyl radical (8). The CF_3 radical, therefore, reacts more slowly with electron poor olefins and more quickly with electron rich olefins than does the methyl radical.

Received April 12, 1979

J. L. HOLMES, D. L. MCGILLIVRAY, and D. YUAN. Can. J. Chem. 57, 2621 (1979).

The gas phase pyrolyses of *exo*-2-norbornyl chloride and cyclopentyl chloride were studied in the temperature range 570–670 K. The results obtained show that these compounds behave as typical secondary halides insofar as the kinetics of their hydrogen chloride elimination reactions are concerned. Labelling experiments showed that in the formation of *both* norbornene and cyclopentene, a *cis*-1,2 elimination with a deuterium isotope effect of ~3 was involved. Nortricyclene also was produced from *exo*-2-norbornyl chloride, via a *trans* 1,3 elimination; this process is analogous to a fragmentation of the ionized molecule. No gas phase Wagner–Meerwein rearrangement was involved in the formation of either norbornene or nortricyclene.

J. L. HOLMES, D. L. MCGILLIVRAY et D. YUAN. Can. J. Chem. 57, 2621 (1979).

On a étudié dans l'intervalle de température 570–670 K la pyrolyse en phase gazeuse des chlorures de *exo*-norbornyl-2 et de cyclopentyle. Les résultats obtenus montrent que ces composés se comportent comme des halogénures secondaires typiques dans la mesure ou les cinétiques de leur réactions d'élimination de chlorure d'hydrogène sont impliqués. Les expériences de marquage isotopique montrent que dans la formation des *deux* produits: norbornène et cyclopentène, une élimination *cis* 1,2 est impliquée avec un effet isotopique du deutérium d'environ 3. Par une élimination *trans* 1,3, on aboutit au nortricyclène à partir du chlorure de *exo*-norbornyl-2; ce procédé est analogue à une fragmentation de la molécule ionisée. Aucun réarrangement de Wagner–Meerwein en phase gazeuse n'est impliqué lors de la formation du norbornène ou du nortricyclère.

[Traduit par le journal]

Introduction

The nature of the transition state in the unimolecular gas phase elimination of hydrogen halide from halogen substituted hydrocarbons has been investigated for many years. No direct experimental test has been made as to whether the process occurs as a *cis* or *trans* 1,2 elimination. Maccoll's (1) ion pair theory would allow both a *cis* and a *trans* process, while Benson's semi-ion pair theory (2) would not permit the latter.

We have investigated this mechanistic problem by studying the gas phase pyrolyses of *exo*-2- norbornyl chloride and cyclopentyl chloride using compounds specifically labelled with deuterium.

exo-2-Norbornyl chloride was chosen for this investigation because of its rigid structure and in the belief that the only hydrocarbon product was norbornene.

The gas phase pyrolysis of *exo*-2-norbornyl chloride has been mentioned by Herndon *et al.* (3, 4). They also reported (5) that norbornene rapidly underwent a retro-Diels–Alder reaction yielding ethylene and cyclopentadiene; they measured the kinetics of this reaction in the temperature range 573 K to 673 K.

The gas phase pyrolyses of specifically deuterium labelled cyclopentyl chlorides were also studied in the present work for comparison with the more complex pyrolysis of *exo*-2-norbornyl chloride. The gas phase pyrolysis of the former has been described by Swinbourne (6) who presented the rate expression for the elimination of hydrogen chloride in the temperature range 582 K to 649 K. Herndon *et al.* (3, 4) showed that the rates of elimination of hydrogen chloride from the cyclopentyl compound were similar to those for cyclohexyl chloride.

Experimental

Materials

Hydrogen chloride, deuterium chloride, and deuterium oxide, norbornene, norcamphor, 5-norbornene-2-ol, cyclopentanol, cyclopentanone, and cyclopentyl chloride were obtained commercially.

We have previously reported (7) the preparation of *exo*-2-norbonyl chloride, a mixture of 56% *exo*-3-d_1 and 44% *syn*-7-d_1 *exo*-2-norbornyl chloride and *exo*-2-norbornyl chloride-3,3-d_2. *exo*-2-Norbornyl chloride-*exo*-5-*exo*-6-d_2 was obtained by treating the corresponding alcohol (8) with triphenyl-phosphine as described by Downie and Lee (9). The extent and location of the deuterium was determined by mass spectrometry (7, 10) and nmr analysis (11). Nortricyclene was

[1]Present address: Chemistry Department, University of Victoria, Victoria, B.C., Canada V8W 2Y2.

0008-4042/79/192621-05$01.00/0

prepared by a Bamford-Stevens reaction on the tosyl-hydrazone of norcamphor (12).

Cyclopentyl chloride-*cis*-2-d_1 was prepared by chlorination of the brosylate of cyclopentyl alcohol-*trans*-2-d_1 with tetramethylammonium chloride in dimethyl sulphoxide. Cyclopentyl alcohol-*trans*-2-d_1 was obtained by $LiAlD_4$ reduction of cyclopentene oxide, prepared from cyclopentene and *meta*-chloroperoxybenzoic acid in ether. Using the same method of chlorination, cyclopentyl alcohol-*cis*-2-d_1, prepared from cyclopentene and hexa-deuterodiborane plus hydrogen peroxide in alkaline solution, was converted to cyclopentyl chloride-*trans*-2-d_1. The mono-labelled compounds (95% d_1) were purified by gas chromatography. Repeated deuteration of cyclopentanone with anhydrous sodium acetate in deuterium oxide, followed by $LiAlH_4$ reduction and chlorination by triphenylphosphine dichloride in dimethylformamide gave cyclopentyl chloride-2,2,5,5-d_4 (94%), purified by trap-to-trap distillation. The deuterium content of the labelled compounds was determined from mass spectra obtained at low ionising electron energies.

Apparatus and Procedures

The decompositions were studied in a static Pyrex glass vacuum system of conventional design. The gas chromatographic apparatus consisted of a Gowmac thermal conducitivity detector and a 1 m column containing 10% by weight of di-isodecylphthalate on chromosorb P; helium was used as carrier gas.

A typical pyrolysis was carried out by expanding a vaporised sample into the reaction vessel and measuring the initial pressure using a null glass-diaphragm gauge. The reaction was studied by continually monitoring the pressure of the reaction mixture. In the case of *exo*-2-norbonyl chloride the extent of reaction was also followed by titration of the hydrogen chloride produced and by gas chromatography of the reaction products.

The pyrolysis products of the labelled norbornyl chlorides were trapped as they left the glc column. The olefins produced from the mono-labelled cyclopentyl chlorides were removed from undecomposed starting material by means of two cold traps. The deuterium content of the products was determined by mass spectrometry.

Results and Discussion

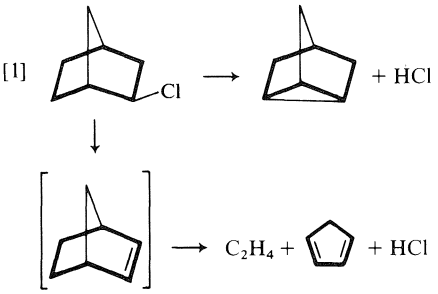
Kinetics

(a) exo-*2-Norbornyl Chloride*

The production of hydrogen chloride and cyclopentadiene (and ethylene) in the pyrolysis of *exo*-2-norbornyl chloride were found to follow first order kinetics. If any free radical reactions were present they would be inhibited by the cyclopentadiene produced (13). The first order rate coefficients were independent of pressure (range 10–80 Torr) and the homogeneity of the reaction was established by comparing the rate of formation of HCl in unpacked (s/v 1:1 cm^{-1}) and packed (s/v 5:1 cm^{-1}) reaction vessels (see Table 1). The rate of formation of cyclopentadiene, which is equal to the rate of formation of norbornene (because the rate of the retro-Diels–Alder reaction (5) is very much faster than the rate of formation of norbornene) is shown in Table 1 for the temperature range 573 K to 643 K. The results yield the Arrhenius equation $k_{HCl} = 13.79 \pm 0.70 \exp(-208 \pm 8)/RT\ s^{-1}$, for $C_5H_6(C_7H_{10})$ $\log A = 12.97 \pm 0.70$ and E_a was the same as for the HCl production.

The discrepancy between the rates of formation of the two products is due to the presence of another primary elimination product, nortricyclene. Its presence was confirmed by comparing the gc retention time and mass spectrum of a synthetic sample with that of the pyrolysis product. That the two C_7H_{10} isomers, nortricyclene and norbornene, do not intercovert under pyrolysis conditions was shown as follows. A sample of norbornene placed in the reaction vessel was observed to produce a very rapid pressure increase due to the fast retro-Diels–Alder reaction (5); the reaction products contained *only* ethylene and cyclopentadiene. A sample of nortricyclene similarly treated produced *no* pressure change with or without HCl, and the recovered material contained *only* nortricyclene.

Thus, the gas phase pyrolysis of *exo*-2-norbornyl chloride can be represented as shown below



At each temperature it was observed that the rate of formation of cyclopentadiene was a constant fraction of the rate of formation of hydrogen chloride (see Table 1). Owing to the solubility of nortricyclene in *exo*-2-norbornyl chloride and the difficulty of completely sweeping excess chloride into the gas chromatograph, it was not possible to measure accurately the absolute rate of formation of nortricyclene. This was therefore determined indirectly, from the difference in the rates of formation of hydrogen chloride and cyclopentadiene at each temperature. The Arrhenius parameters for nortricyclene generation are $k = 13.29 \pm 0.70 \exp(-207 \pm 8)/RT\ s^{-1}$.

For a similar system, *endo*-2-bornyl chloride, the results have been interpreted as involving appreciable surface induced reactions (14). However, surface catalyzed eliminations of hydrogen halide have much lower activation energies (ca. 85 kJ mol^{-1}) (15) than that observed here for the nortricyclene production. We therefore propose that this reaction is indeed homogeneous.

It is not possible to determine the rates of the

2,2,5,5-d_4	4.07 (1)	30.9 (1)	105 (1)	218.5	14.96

[a]Rate constants at 613, 643, and 663 K from Swinbourne (6) were 15.5, 100, and 309 $\times$ 10^{-5} s^{-1}, respectively.
[b]The values in parentheses are the variation of rate ratios with temperature. The rate for the 2,2,5,5-d_4 compound has been taken as unity at each temperature.

individual reactions from the pressure data alone. However, using the rates of formation of hydrogen chloride, cyclopentadiene, and nortricyclene from Table 1 and assuming the norbornene concentration to be negligible, pressure changes were calculated using the equation appropriate for two first order concurrent reactions. Calculated and observed pressure changes agreed to within 10% over conversion ranges from ~10 to 40%.

(b) Cyclopentyl Chloride

The variation of the rate coefficients with temperature and the Arrhenius parameters are shown in Table 2 together with the ratios of the pyrolysis rate coefficients for unlabelled and labelled cyclopentyl chlorides. The results can be explained by invoking an isotope effect of 3 for the elimination of HCl at 613 K; the magnitude of the isotope effect decreases slightly with increasing temperature. This isotope effect is similar to that reported by Blades *et al.* (16, 17) who found an isotope effect of 2.20 for the elimination of HCl from ethyl chloride compared with that of DCl loss from deuterium labelled ethyl chloride at 773 K, and a value of 2.17 for the corresponding process in ethyl bromide. The results show that deuterium in the *trans* position is not involved in the elimination, that in the *cis* position being specifically lost. Thus the pyrolysis of cyclopentyl chloride proceeds by a *cis*-1,2 unimolecular elimination of hydrogen chloride via a four-centered transition state.

Analyses for the deuterium content of the olefin produced from several pyrolyses at low conversions of *trans* and *cis*-2-d_1-cyclopentyl chlorides at temperatures of 613 K and 663 K are shown in Table 3. The isotope content of the olefin produced in the pyrolysis of the *cis* isomer agreed with that calculated assuming an exclusively *cis* elimination. These

trans-2-d_1	95.0	5.0	95.0	5.0
cis-2-d_1	69.5	30.5	67.4	32.6

[a]The compounds were 95%-d_1, 3.0 was taken as the isotope effect at 613 K and 2.65 at 663 K. Calculation based on the assumption that the pyrolysis proceeded solely via a *cis*-elimination.

results confirm retention of label in the *trans* isomer, proving that *trans* elimination does not occur to greater than 5%.

Labelling Experiments with exo-*2-Norbornyl Chloride*

The extent of *cis* or *trans* elimination in the formation of norbornene can directly be determined by placing a deuterium atom in the *exo* or *endo*-3 position of the halide and measuring the deuterium content of the cyclopentadiene. Similarly, by pyrolysing appropriately labelled compounds and then measuring the deuterium content of the nortricyclene, it should be possible to determine which hydrogen atom(s) is involved in its formation. However, first it was necessary to show whether a Wagner–Meerwein rearrangement took place under pyrolysis conditions. *exo*-2-Norbornyl chloride-3,3-d_2 was prepared and analyzed both for deuterium content and the positional integrity of the label atoms by a specific mass spectrometric method previously reported by ourselves (7, 8). It was found that 11.5% Wagner–Meerwein reaction had occurred during the preparation of the compound and that the deuterium content of the halide was 92% d_2, 8% d_1. This compound was then pyrolyzed and the deuterium content of the products determined mass spectrometrically; the results are shown in Table 4. The deuterium content of the cyclopentadiene was then calculated (assuming a *cis* elimination) using the deuterium content and the Wagner–Meerwein analysis of the starting material. An isotope effect of 3 was assumed for the relative elimination rates of HCl and DCl. For the 3,3-d_2 compound the calculated deuterium contents of the cyclopentadiene products were d_2 = 24%; d_1 = 73%; d_0 = 3% in very good agreement with the experimental results 24%, 71%, and 5% respectively (see Table 4). Thus, only the hydrogen atoms on C-3 are involved in the elimination of hydrogen chloride which yields norbornene. This therefore rules out the involvement of any Wagner–Meerwein rearrangement in the pyrolysis system. The nortricyclene formed in the above pyrolyses was found to have the same deuterium content as the parent chloride indicating that the hydrogen atoms on C-3 were *not* involved in its formation viz.:

[2] 
exo-2-Norbornyl chloride, prepared by the addition of deuterium chloride to norbornene (shown by metastable peak analysis (7, 10) to contain 56% *exo*-2-norbornyl chloride-*exo*-3-d_1 and 44% *exo*-2-norbornyl chloride-*syn*-7-d_1), was pyrolyzed and the deuterium content of the products is also shown in Table 4. The deuterium content of the cyclopentadienes, calculated in the same manner as above, were d_1 = 65% and d_0 = 35%. This agrees well with the experimental results (see Table 4) and again is compatible with a *cis* elimination of HCl in the formation of norbornene. Furthermore, the deuterium content of the nortricyclene was again the same as that of the parent compound showing that hydrogen atoms in the *exo*-3 and *syn*-7 positions were not involved in the formation of nortricyclene.

In order to determine whether the *exo* and *endo*-6 hydrogen atoms are involved in nortricyclene formation, the pyrolysis of *exo*-2-norbornyl chlorine-*exo*-5-*exo*-6-d_2 was similarly studied. These results are

[3] 
TABLE 4. Deuterium content of the pyrolysis products of various labelled *exo*-2-norbornyl chlorides

Compound	Label %	Wagner–Meerwein in syntheses %	Pyrolysis products	Label %
	92 d_2 8 d_1	11.5	Cyclopentadiene Ethylene Nortricyclene	24 d_2, 71 d_1, 5 d_0 0 d_2, 2.5 d_1, 97.5 d_0 92 d_2, 5 d_1, 3 d_0
	94 d_1 6 d_0	44	Cyclopentadiene Ethylene Nortricyclene	62 d_1 38 d_0 0 d_1, 100 d_0 94 d, 6 d_0
	30 d_2 40 d_1 30 d_0	0	Cyclopentadiene Ethylene Nortricyclene	0 d_2, 0 d_1, 100 d_0 31 d_2, 40 d_1, 29 d_0 28 d_2, 41 d_1, 31 d_0
	72 d_2 22 d_1 6 d_0	15[a]	Cyclopentadiene Ethylene Nortricyclene	4 d_2, 7 d_1, 89 d_0 63 d_2, 24 d_1, 13 d_0 57 d_2, 34 d_1, 10 d_0

[a]From metastable peak analysis of the chloride it is clear that some 5% of the label is in the 2 and 3 positions. A Wagner–Meerwein rearranged reactant would contain a further 5% deuterium in the 1 and 7 positions. These factors contribute to the discrepancy in the results.

also given in Table 4. The ethylene produced had the same deuterium content as the parent chloride showing that the hydrogen atoms on the *exo*-5 and *exo*-6 positions were *not* involved in the formation of norbornene. The deuterium content of the nortricyclene was the *same* as that of the chloride. We therefore propose that *only* the *endo*-6 hydrogen atom is involved in the formation of nortricyclene; i.e. that a *trans* elimination takes place in this reaction. This pyrolysis was repeated using a sample of *exo*-2-norbornyl chloride – *exo*-5-*exo*-6-d_2 which was richer in deuterium and these results are given in Table 4. They agree with the previous results.

Additional support for the above proposal comes from our study of the elimination of a chloroethyl radical from the molecular ion of *exo*-2-norbornyl chloride (10), where it was shown that the reaction specifically involved the *endo*-6 H atom.

Electron scattering cross sections of gaseous pentanes and hexanes[1]

GORDON R. FREEMAN, ISTVÁN GYÖRGY, AND SAM S.-S. HUANG
Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received May 15, 1979

GORDON R. FREEMAN, ISTVÁN GYÖRGY, and SAM S.-S. HUANG. Can. J. Chem. **57**, 2626 (1979).

Electron scattering cross sections σ_v have been estimated as functions of electron velocity v for six gaseous pentanes and hexanes. The scattering cross section of each compound has a minimum in the vicinity of $v = (2\text{–}3)\ 10^7$ cm/s, corresponding to an electron energy of 0.1–0.2 eV. For the pentanes, the scattering cross sections on the low energy side of the minimum increase with increasing sphericity of the molecules, while the minimum tends to shift to higher energies. The same is true of the hexanes.

GORDON R. FREEMAN, ISTVÁN GYÖRGY et SAM S.-S. HUANG. Can. J. Chem. **57**, 2626 (1979).

Les sections transversales σ_v de diffusion électronique sont évaluées comme étant des fonctions de la vitesse v de l'électron pour six pentanes et hexanes à l'état gazeux. Pour chaque composé la section transversale de diffusion a un minimum, au voisinage de $v = (2\text{–}3)\ 10^7$ cm/s, correspondant à une énergie électronique de 0.1–0.2 eV. Pour les pentanes, du côté de basse énergie du minimum, les sections transversales de diffusion augmentent avec le sphéricité des molécules, pendant que le minimum tend à glisser vers de plus grandes énergies. On observe la même tendance pour les hexanes.

[Traduit par le journal]

The effects of density and temperature on thermal electron transport in gaseous and liquid hexanes (1) and pentanes (1, 2) have recently been reported. The treatment of electron scattering by molecules in the low density limit involved the assumption that the scattering cross section σ_v for electrons of velocity v could be approximated by eq. [1] over the limited range of velocities used.

$$[1] \quad \sigma_v = A_\alpha v^{-\alpha}$$

where A_α is a constant whose value depends on α. It has been found that for some of the butenes eq. [1] is inadequate to describe the behavior over the temperature range 300–500 K (3). The pentane and hexane results have therefore been subjected to a more detailed numerical analysis, using trial and error to extract σ_v as a function of v from plots of mobility against temperature. The cross section of each compound has a minimum in the vicinity of $v = (2\text{–}3)\ 10^7$ cm/s, corresponding to an electron energy of 0.1–0.2 eV. The same result had been found earlier for simpler alkanes (4).

When the velocity distribution is Maxwellian and scattering is mainly elastic,[2] the low density limit of the mobility μ_{1d} (cm^2/V s) may be represented (3, 5) by eq. [2].

$$[2] \quad \mu_{1d} = (5.23 \times 10^{-14}/nT^{2.5}) \times \int_0^\infty (v^3/\sigma_v) \exp(-3.30 \times 10^{-12} v^2/T)\, dv$$

where n (molecule/cm^3) is the gas density and T (K) is the temperature.

A first approximation to σ_v as a function of v was obtained using eq. [1] in the manner described previously (1, 2). A plot of σ_v against v thus obtained was then adjusted to improve the agreement of values of μ_{1d} calculated numerically from eq. [2] with those observed over a range of temperatures.

The mobilities normalized for gas density, $n\mu_{1d}$, are shown as functions of temperature in Fig. 1. The experimental data for each compound display curvature towards the T axis, with the exception of those for n-pentane and neopentane. We believe that curvature in the n-pentane results is obscured by the experimental scatter.

Cross sections derived from the mobilities are

[1]Assisted financially by the National Science and Engineering Research Council and the International Atomic Energy Agency.

[2]At the low energies involved in the present work, the magnitude of the elastic scattering cross section is much greater than that of the inelastic scattering cross section (see, for example, ref. 4). The mobility is restricted by collisions that change the direction of flight of the electrons. The flight direction is changed by both elastic and inelastic collisions, but under the present conditions the former dominate. The amount of energy exchanged during the elastic collisions is small, however, and the relatively infrequent inelastic collisions govern the electron energies in the present systems (2). This explains the conclusion that "... the electrons are cooled predominantly by inelastic collisions with the hydrocarbons, in contrast to the behavior with the monatomic molecules of xenon" (1), that had been derived from consideration of the ratio v_d(threshold)/c_0.

0008-4042/79/192626-03$01.00/0

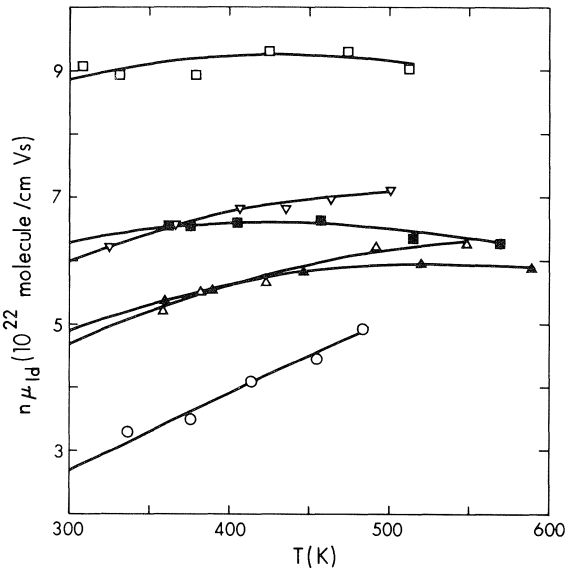

FIG. 1. Temperature dependence of density normalized mobilities $n\mu_{1d}$ of thermal electrons in low density pentane and hexane gases. □, *n*-pentane; ▽, isopentane; ○, neopentane; △, cyclopentane; ■, *n*-hexane; ▲, cyclohexane. Mobilities from ref. 2 were decreased by a factor of 1.21 and those from ref. 1 were increased by a factor of 1.08 (hexanes) or 1.03 (cyclopentane) to correct for errors in measurement of the gap between the electrodes. The lines represent the mobilities calculated from the cross sections displayed in Fig. 2.

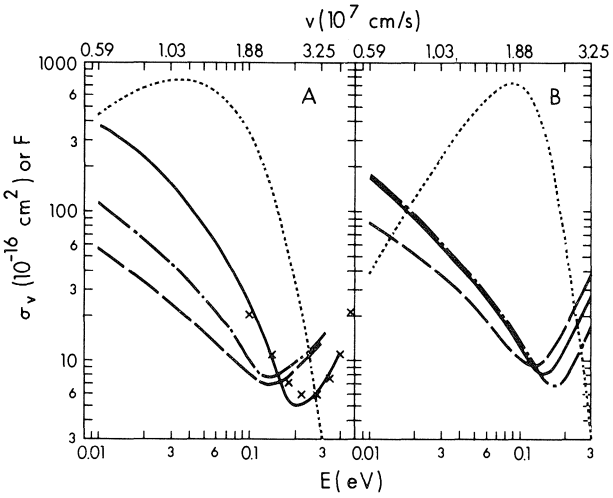

FIG. 2. Electron scattering cross sections σ_v of pentane and hexane molecules, as functions of electron velocity v or energy E. *A*: ---, *n*-pentane; ·····, isopentane; —, neopentane; ×, neopentane cross sections from ref. 7; ··· Maxwellian E and v distribution at 400 K, $F = (1.36 \times 10^{-7} v^2/T^{1.5}) \exp(-3.3 \times 10^{-12} v^2/T)$. *B*: ---, *n*-hexane; ·····, cyclopentane; —, cyclohexane; ···, scattering probability distribution for *n*-hexane at 400 K, $F = 2 \times 10^{-33}(v^3/\sigma_v) \exp(-3.3 \times 10^{-12} v^2/T)$. The factors F are the true values multiplied by 10^{10} in *A* and 2×10^{-33} in *B* to fit the displayed scale.

given in Fig. 2. Mobilities calculated from these cross sections are represented by the lines in Fig. 1.

To designate the energy region of main interest, the Maxwellian distribution of electron velocities and energies at 400 K is shown in Fig. 2*A*, and the scattering probability distribution for *n*-hexane at 400 K is given in Fig. 2*B*. The energy region of greatest sensitivity in the curve fitting procedure is in the vicinity of the maximum in the scattering probability curve (Fig. 2*B*). Under the present conditions the region ranges from about 0.04–0.14 eV for *n*-hexane and *n*-pentane to about 0.05–0.22 eV for neopentane. The cross section curves become progressively more uncertain with increasing distance from this region.

The most accurate portion of each σ_v curve in Fig. 2 lies on the low energy side of the minimum. The scattering cross sections of the pentanes in this region increase with increasing sphericity of the molecules, while the minimum tends to shift to higher energies. The same is true of the hexanes. The reason for the correlation between the scattering properties and molecular sphericity is not known. The correlation for the low density gases is different from that for the normal liquids of the same compounds (2, 6).

The cross sections for neopentane are in satisfactory agreement with those reported recently by McCorkle *et al.* (7), in the region of overlap.

When scattering cross sections derived from mobilities are averaged for comparison of one molecule with another, the appropriate weight is placed on the most sensitive region of velocities by using eq. [3].

[3] $$\sigma_{ave} = \langle v \rangle / \langle v/\sigma_v \rangle = 4.59 \times 10^{22} T^2 \Big/ \int_0^\infty (v^3/\sigma_v) \exp(-3.30 \times 10^{-12} v^2/T)\, dv$$

The simple average $\langle \sigma_v \rangle$ is commonly used, but it tends to emphasize the larger values of σ_v, where the curve fitting is least accurate.

[4] $$\langle \sigma_v \rangle = 4\pi (m/2\pi kT)^{3/2} \int_0^\infty \sigma_v v^2 \exp(-mv^2/2kT)\, dv$$

$$= 1.35 \times 10^{-17} T^{-1.5} \int_0^\infty \sigma_v v^2 \exp(-3.30 \times 10^{-12} v^2/T)\, dv$$

TABLE 1. Average scattering cross sections at 300 K[a]

Molecule	σ_{ave}[b]	$\langle\sigma_v\rangle$[c]
n-C_5H_{12}	15.7	31.8
	(15.1[d])	(23.2[d])
i-C_5H_{12}	23.2	60.5
neo-C_5H_{12}	52.0	200.0
c-C_5H_{10}	29.6	91.0
n-C_6H_{14}	22.1	48.6
	(21.2[d])	(31.0[d])
c-C_6H_{12}	28.4	86.0

[a]From Fig. 2 unless otherwise noted. In units of 10^{-16} cm^2.
[b]Equation [3]. Recommended.
[c]Equation [4]. This type of average is not recommended when σ_v has been estimated from mobility data.
[d]Using eq. [1] with $\alpha = 1.0$, inserted in eq. [2].

The difference between σ_{ave} and $\langle\sigma_v\rangle$ is illustrated in Table 1. The mobilities in *n*-pentane and *n*-hexane over the present range of temperatures can be reproduced moderately well by using eq. 1 for σ_v with $\alpha = 1.0$. The values of σ_{ave} so obtained are nearly the same as those obtained from Fig. 2 (see Table 1). However, the values of $\langle\sigma_v\rangle$ are greatly different for the two forms of σ_v (Table 1). The average scattering powers of molecules should be compared through σ_{ave}, not through $\langle\sigma_v\rangle$, when σ_v has been estimated from mobility data.

On a effectué des réactions de *C*- et *O*-alkylations, de sulphénylations et d'additions de Michael facilitées par des liaisons hydrogènes en faisant appel à l'ion fluorure immobilisé sur des résines échangeuses anioniques fortement basiques.

[Traduit par le journal]

Introduction

We have previously shown that the fluoride ion is capable of behaving as an electron source in hydrogen bonds formed with a wide variety of protic organic compounds (1). From a chemical reactivity point of view, the nucleophilicity of the electron acceptors in these H-bonds is enhanced. This prompted us to investigate a number of alkali metal fluoride and tetraalkylammonium fluoride assisted organic reactions carried out under heterogeneous and homogeneous conditions including *C*-alkylations (2, 3), *O*-alkylations (1, 4–6), *N*-alkylations (1), sulphenylations (7), and Michael additions (3, 8). The results of these investigations clearly demonstrated the fluoride ion method to be a viable alternative to more conventional base-assisted processes.

In the last few years, functionalized insoluble polymers have been developed for a variety of sequential and one-step organic syntheses (9–11). These include a number of reactions using polymer supported phase transfer catalysts often prepared from Merrifield type DVB crosslinked chloromethylated polystyrene resin (12–18). One recent article on this subject described the fluoride ion assisted preparation of Merrifield resin ester (19). The realization that strongly basic ion exchange resins are simply insoluble quaternary ammonium salts led us to investigate the possibility of carrying out typically fluoride-ion mediated reactions in the presence of commercial strongly basic anion exchange resins converted to their fluoride form (20*a*). Another communication published during the writing of this paper describes the synthesis of phthalimidomethyl esters of *N*-protected amino acids using the strongly basic anion exchange resin, Amberlyst A-26, containing fluoride ions (20*b*).

Other reported examples of the synthetic use of anion exchange resins include the synthesis of nitrites (21), the *C*-alkylation of malonic esters and related compounds (22), fluorinations (23, 24), alkylations (25, 26), and reductions (27). Our preliminary work (20*a*) showed that while the fluoride forms of commercial analytical type resins such as Amberlite[4] IRA-400 and Dowex[5] 1-X8 and lower crosslinked resins such as Dowex 1-X2 were not particularly effective, the fluoride forms of Dowex MSA-1 macroporous resin and Amberlyst A-26 and A-27 macroreticular resins, which are designed for use in non-aqueous solvents, gave satisfactory results. We now report our detailed results for H-bond assisted reactions using the fluoride forms of these resins. The results have been optimized in terms of the resin, solvent, temperature, and regenerative capability of the resin.

[a]Yields were determined by ^1H nmr peak intensities for products and starting material and by gc peak areas. Known compounds were identified by ^1H nmr and gc/ms.
[b]Characteristics of the commercial strongly basic anion exchange resins in their chloride forms taken from manufacturer's literature (see Table 1(*b*)).
[c]Resin was regenerated from used resin.
[d]Only 15 mL resin used.
[e]Resin was previously used in a Michael addition reaction.

Experimental

^1H nmr spectra were recorded in $CDCl_3$ on a Varian A60 (60 MHz) spectrometer ($SiMe_4$ internal standard). Mass spectra were obtained on a AEI MS-30 double beam double focussing mass spectrometer interfaced to a Pye 104 G.C. via a Biemann separator. Samples were introduced either via a solids probe or via the gas chromatograph (6 ft × 1/4 in. column, 3% SE30 on Chromosorb W).

The resins were converted to their fluoride forms by the following general procedure. The resins were obtained in their chloride forms and were first treated with an excess of 10% sodium bicarbonate followed by at least five bed volumes of 10% NaOH solution over a period of 1.25 h to convert the resins to their hydroxide forms. The resins were washed with water until neutral and in order to determine the capacity of the resin, a sample was washed with acetone and ether, dried, and weighed. The sample was then reacted with excess 1.000 *M*

HCl, filtered off, and washed. The resulting solution was back-titrated with 1.000 *M* NaOH to a bromothymol blue end point. The calculated capacities of the Amberlyst resins were between 0.83 and 0.97 meq/cm^3 of moist resin. The hydroxide resins were converted to their fluoride forms with 1 *M* HF solution, a slight excess of acid being used. It was also possible to convert the chloride form of the resin to the fluoride form by direct exchange with a KF solution although we preferred the more quantitative neutralization procedure. Once in the fluoride form, the resin was washed with water until neutral, followed by several bed volumes of methanol, then washed with the solvent that was to be used in the proceeding reaction. Regeneration of used resins followed a similar procedure. The A-26 resin appeared to be particularly easy to regenerate whereas the A-27 resin appeared to break down, at least physically, after some of the reactions.

In an attempt to determine the extent of resin fluorination after a typical conversion, samples of dried resin were reacted with α-bromoacetophenone, α-fluoroacetophenone being the expected product. Some chloroacetophenone was also produced, suggesting that some unconverted chloride resin was also present. Typical F/Cl ratios were 9:1.

In a typical reaction, 2,4-pentanedione (0.01 mol) was added to 40 cm^3 of A-27 F^- resin (ca. 0.035 mol F^-) in 50 cm^3 THF. After stirring for several minutes, iodomethane (0.01 mol) was added and reaction was allowed to proceed with stirring, at room temperature for 24 h. At the end of this time, the resin was filtered off and washed with several portions of diethyl ether. The combined filtrates were evaporated yielding 0.95 g of material which was shown by nmr and gc/ms to be the starting diketone (20–25 mol%) and the 3-methyl derivative (75–80 mol%). This corresponds to a yield of 65% based on diketone used. Somewhat better yields could be obtained by using a 10% excess of iodomethane.

Results and Discussion

The results of our detailed investigations into the efficiency of fluoride resins in some typically base-assisted organic reactions are summarized in Table 1. There are essentially three important aspects of these results to be considered: the relative efficiencies of the resins used, the loss in efficiency on using a regenerated resin, and the choice of solvent.

Overall, there does not seem to be one particular resin which consistently gives the best yields although some definite trends are apparent. In particular, MSA-1 F^- resin seems to be a particularly effective catalytic resin in that it is clearly the best choice for both Michael additions and sulphenylations. The latter reactions are especially sensitive to the choice of resin in that only the MSA-1 F^- resin gives a satisfactory yield. In an attempt to isolate the cause of this apparent anomaly, we attempted to convert the thiolalone to the disulphide in the presence of the A-26 F^- resin and found that 100% reaction occurred within 24 h at room temperature. This leads us to believe that the efficiency of the A-26 and A-27 F^- resins may be impaired by the presence of water (produced in the thiol oxidation step) and we are presently investigating the possibility as part of a general project into the effect of water on fluoride ion mediated reactions.

While the MSA-1 F^- resin is superior for catalytic reactions, alkylations (where the resin undergoes chemical reaction), and in particular *C*-alkylation, are best carried out using A-26 and A-27 F^- resins. IRA-900 F^- resin gave moderate yields of product in *C*-alkylation experiments. We found that IRA 938 resin and Whatman DE32 ion exchange cellulose were only converted to their F^- forms with considerable difficulty and we did not attempt any reactions with them.

In most reactions, a 2- to 4-fold excess of resin was used. Doubling the quantity of resin did not significantly affect the yields for *C*- and *O*-alkylations. In the absence of resin or in the presence of resin in its Cl^- form, no *C*- or *O*-alkylation was observed although some reaction did occur in the Michael additions.

We have found that with regard to the reusability and efficiency of regeneration of the F^- resins, the A-26 is superior and we report *C*-alkylation yields

using regenerated resin and resin that was previously used in a (catalytic) Michael addition (Table 1). While the regenerated resin is of comparable efficiency to the fresh sample, the previously used resin gives noticeably lower product yields which implies significant loss in activity but not appreciable physical degeneration on reaction.

With regard to the choice of solvent, it would seem that those reactions which proceed smoothly at or near room temperature are best carried out in THF whereas the higher boiling DMF is preferred for those reactions requiring higher temperatures. Reaction times were usually kept at 24 h although where reaction monitoring was attempted, optimum yields seemed to occur at 12 h or less.

Analysis of the product mixtures did reveal the presence of some side-products, in particular the disulphide (strictly an intermediate) in the sulphenylations and Michael additions and also the olefin dimer for the latter reactions.

In general, the yields reported here are comparable or slightly poorer than those obtained using soluble tetraalkylammonium fluoride (2, 3, 6–8), silica supported tetraalkylammonium fluoride (28), or KF supported on Celite (29). One possible explanation for some of the low yields obtained in reactions with the F^- resins is that it is often difficult to ensure complete extraction of products from the resin. Despite such shortcomings, the overall success of the method, demonstrated here and by independent research (20*b*), suggests that fluoride resins are useful and inexpensive aids to the synthetic chemist.

Rare-gas sensitized radiolysis of gaseous isobutene: ionic processes

JAN A. HERMAN

Département de chimie et Centre de Recherches sur les Atomes et les Molécules, Université Laval, Québec (Qué.), Canada G1K 7P4

Received May 3, 1979

JAN A. HERMAN. Can. J. Chem. **57**, 2633 (1979).

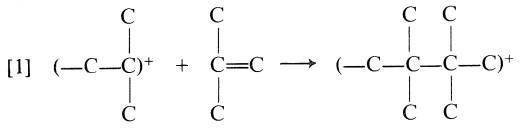
Irradiation of isobutene at low pressure in the presence of suitable scavengers or mixed with the rare gases Ar, Kr, and Xe shows that 2-methyl-but-2-ene is partially formed in ionic processes. These processes involve polymeric ions of isobutene formed in "head-to-head" reactive encounters with neutral isobutene. The resulting ionic species, which have internal structural tension, can isomerize with a subsequent elimination of ethylene, or decompose to give 2-methyl-but-2-ene. The rare-gas sensitized radiolysis confirms the already established reaction channels for formation of the main products.

JAN A. HERMAN. Can. J. Chem. **57**, 2633 (1979).

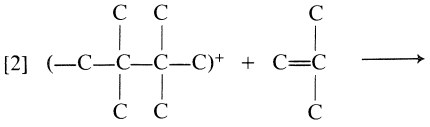
L'irradiation de l'isobutylène à basse pression et présence d'intercepteurs adéquats, de même que la radiolyse sensibilisée aux gaz nobles Ar, Kr et Xe, de ce même composé, indique que le 2-méthyl-butène-2 est formé en partie par voie ionique. Ce processus est la conséquence de réaction "tête-à-tête" entre les ions polymériques et l'isobutylène neutre. L'intermédiaire ainsi formé peut, soit isomériser avec élimination de l'éthylène, soit se décomposer en donnant du 2-méthyl-butène-2. La radiolyse sensibilisée aux gaz nobles confirme les voies réactionnelles déjà établies de formation des produits principaux.

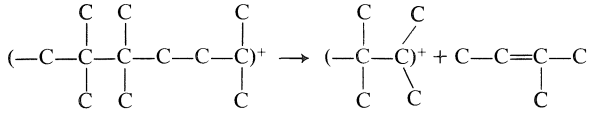
Introduction

In a recent mass-spectrometric investigation of ion/molecule reactions in gaseous isobutene it was assumed that the condensed ionic species formed during the polymerization processes may decompose to give neutral ethylene and branched pentenes, as depicted in Scheme 1 (1). Such decomposition processes result from "head-to-head" bonding between the condensed ion and the tertiary carbon of the neutral isobutene, giving rise to the formation of a species with internal structural strain,

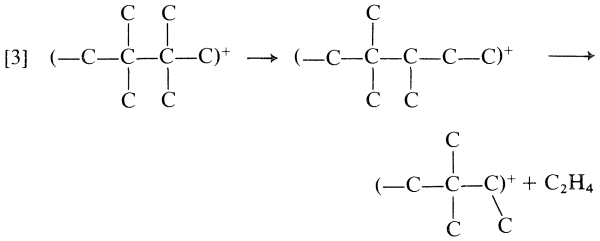


This ion decomposes on reactive encounter,





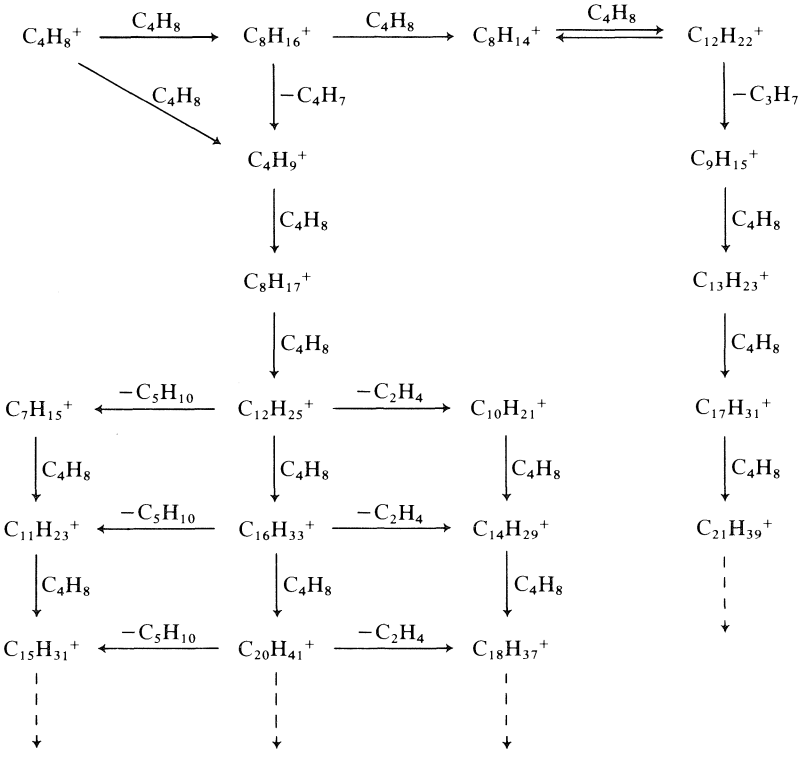
or isomerizes with the subsequent elimination of an ethylene molecule,



On the other hand, radiolysis experiments on gaseous isobutene with added nitric oxide as radical scavenger suggested that all condensed C_5 products were formed by radical processes (2). However, the choice of NO as a radical scavenger is not unambiguous, because of the possibility of charge transfer between ionized isobutene (ionization potential, IP = 9.23 eV) and/or its fragmentary ions and the NO molecule (IP = 9.26 eV) (3), even if this process is known to be a slow one (4). Therefore, it seems useful to investigate again the possibility of the formation of ethylene and pentenes in ionic processes, using this time a radical scavenger for which the charge transfer process from iso-$C_4H_8^+$ is not allowed.

The mass-spectrometric investigations of ion/molecule reactions were conducted in systems at low pressure (< 3 Torr) and normally the γ-ray radiolysis should also be carried out at these pressures in order to avoid doubtful extrapolation of results from high to low densities of gas. However, the γ-ray doses needed for accumulation of reasonable amounts of products in low pressure isobutene samples were

0008-4042/79/192633-07$01.00/0



SCHEME 1

unduly long for the available ^{60}Co γ-ray irradiator. Therefore, only a few radiolyses of pure isobutene at 10 Torr or less were performed, most of the irradiations being done on high-pressure samples of rare gases containing small amounts of iso-C_4H_8 ($\simeq 1\%$); under these conditions the irradiation time was shortened to only several hours. Besides this practical aspect of the rare-gas sensitized radiolysis, there is another feature of this kind of experiment that is useful to the comprehension of the observed behaviour of the irradiated system. In the rare-gas sensitized radiolysis the spread of the energy transferred from the excited or ionized noble gas atom to the molecule of interest is much narrower, limited usually to the energy of the metastable states and the fundamental ionic state of the rare gas atom or molecular ion (ref. 5, part 4, p. 211). Under these conditions one can expect that the extent of fragmentation of parent ions is limited to only a few fragment ions as compared to the direct radiolysis, and that the identification of reaction paths for products originating in ionic processes might be less ambiguous (6).

Experimental

Matheson Co. C.P. Grade isobutene (minimum purity 99.0%) was gas-chromatographically purified and the remaining impurities consisted of isobutane (<0.01%) and butene-1 (0.31%). Oxygen (99.995%) from Union Carbide and ammonia (99.99%) from the Matheson Co. were used without further purification. Matheson rare gases, Ar, Kr, and Xe (minimum purity 99.995%), were dried and deoxygenated on pulverised metallic sodium for at least 24 h prior to mixing with isobutene in the reaction cell.

Pyrex irradiation cells were spherical with a volume of 270 ± 10 mL. Break seals allowed the gases to be recovered after irradiation.

The products of radiolyses were analyzed by gas-chromatography equipped with a flame ionization detector. The products were separated on a 9 m squalane or on a 6 m Ucon column.

The samples were irradiated at room temperature (~25°C) in a Gammacell 220 irradiator (Atomic Energy of Canada Ltd) at a dose-rate of approximately 2.21×10^5 rad/h. The total doses absorbed ranged between 2.8×10^{17} eV ($\sim 10^{21}$ eV mol^{-1}) for low-pressure pure isobutene samples and 1.3×10^{19} eV ($\sim 10^{22}$ eV mol^{-1} of rare gas) in rare-gas sensitized radiolysis experiments. The dosimetry was carried out by measuring the acetylene formed in irradiated ethylene at 600 Torr, whose radiolytical yield is 3.6 (7).

Results

Partial results for direct radiolysis and rare-gas sensitized irradiations are presented in Table 1. The radiolytic yields are expressed in $G(X)$ values, which represent the number of molecules X formed per 100 eV of energy absorbed by the system. The only correction made for energy absorbed directly by iso-C_4H_8 in the rare-gas sensitized radiolysis consists of subtracting the yields of products formed in pure

iso-C_4H_8 at 1 Torr irradiated for the same length of time. This correction is actually very small, being less than 1%. The results in Table 1, with the exception of Xe-sensitized irradiations, are mean values of several experiments. They are reproducible within 12% for the main compounds.

In Table 1 are shown yields for these products which are relevant for the discussion. The following products are not indicated: propane (whose yield is around 0.1), *cis*- and *trans*-butene-2, butene-1, 1,2-butadiene ($G \simeq 0.04$), and some minor unsaturated C_6, whose $G < 0.01$. All these compounds, with the exception of the butenes, are scavenged completely by oxygen. The yields of methane in krypton-sensitized irradiations were less reproducible than in other experiments, as indicated by the range of variation of the G-value. Special care was undertaken in the analyses by gc of the C_5 condensation products. The reported yields for these compounds in the presence of oxygen and ammonia, although very low, correspond to measurable amounts and are meaningful (Tables 1 and 2). In the radiolysis of isobutene at low pressure (without or with oxygen) the radiochemical yields of 2-methyl-but-2-ene (2MB2) are not very reproducible, the likely reason being that neither isobutene nor oxygen was thoroughly dried and traces of water vapor introduced into the system appear to affect the polymerization yield (8).

In rare-gas sensitized irradiations the presence of additives, oxygen and/or ammonia, diminishes the G-values of products formed from isobutene because of the partitioning of transferred energy from the rare gas, among the components of the mixture. This effect is shown by the G-values of allene in Table 2 (11th row). On the other hand, it is well established that allene and propyne are formed with yields which are independent of radical scavenger concentrations (8–10). Therefore, at constant pressure the yield of allene, as well as that of propyne, can be used as an internal reference for calculation of the amount of energy transferred from the rare-gas atom to isobutene. This property is used to estimate the relative yields of products formed in the presence of ammonia and oxygen in the rare-gas sensitized radiolysis as a function of G(allene); the results are presented in Table 2.

Inspection of Table 2 shows that the presence of oxygen has a strong effect on the yields of methane, ethane, isobutane, 2,2-dimethylpropane, and the methyl-butenes. The simultaneous presence of oxygen and ammonia almost completely suppresses the formation of isobutane and 2MB2, and influences strongly the yields of ethylene and propene in the case of the Ar-sensitized radiolysis.

Discussion

The radiochemical yields for irradiations of pure iso-C_4H_8 or iso-C_4H_8 + O_2 mixtures at 10 Torr or

lower pressure are those expected from extrapolation of G-values already published (2, 9, 10). They are strongly pressure dependent, decreasing with increasing density of the gas.

Ionic Processes

As established by Sieck and Ausloos (12), the formation of isobutane in an ionic process (accounting for approximately 50% of all iso-C_4H_{10} formed in irradiation of pure isobutene) consists of a H_2 transfer from the $(C_8H_{16})^+$ ion to neutral isobutene,

[4] $C_8H_{16}^+ + \text{iso-}C_4H_8 \rightarrow C_8H_{14}^+ + \text{iso-}C_4H_{10}$

Our results are consistent with this mechanism, as shown by the action of oxygen and ammonia (Tables 1 and 2). Here ammonia acts as a proton or charge acceptor from the ionic species formed in the iso-C_4H_8 system, in competition with ion/molecule reaction of hydrocarbon ions leading to ionic isobutane (13). However, one can see that the addition of NH_3 in an amount corresponding to 10% of that of iso-C_4H_8 at 10 Torr is not sufficient to inhibit completely the formation of the $(C_8H_{16})^+$ species, which react very efficiently with neutral iso-C_4H_8 (reaction [4]). In the rare-gas sensitized radiolysis, where the relative concentrations of isobutene and ammonia are similar, one can see that isobutane is almost completely scavenged when O_2 and NH_3 are both present in the system (Table 2).

The new result of this study, as compared to ref. 2, is the proof that 2MB2 is partially formed in ionic processes. This observation is particularly evident from the data obtained by irradiation of isobutene at low pressure in the presence of oxygen (acting as a radical scavenger) and ammonia (acting as a proton acceptor). Assuming that $G_{ion}(2MB2) = 0.29$ represents the yield of 2-methyl-but-2-ene formed at 10 Torr in the detachment process form successive condensation ion products,

[5] $[C_4H_9(C_4H_8)_n]^+ \rightarrow [C_7H_{15}(C_4H_8)_{n-2}]^+ + C_5H_{10}$

one can compare this yield with the extrapolated yield of $[C_7H_{15}(C_4H_8)_p]^+$ ($p = 0, 1, 2, \ldots$) at 10 Torr from mass-spectrometric measurements (1). Taking $W = 23.8$ eV (14) as the energy required for the formation of one pair of ions in gaseous isobutene, the total radiochemical yield for ion species should be G_{total} (ion) = 4.2. The yield G_{ion} (2MB2) = 0.29 constitutes 7% of the G_{total} (ion), which is in very good agreement with the extrapolated percentage of $[C_7H_{15}(C_4H_8)_p]^+$ ions observed by mass-spectrometry (1).

The formation of only 2MB2 in the ionic process [5], with the exclusion of the two other methylbutenes (2MB1 and 3MB1) indicates that the reactive site is on the methylene position of the neutral isobutene, which is in accordance with a polymerization mechanism.

Following the reaction Scheme 1, some of the ethylene should be formed by the reactions

[6] $[C_4H_9(C_4H_8)_n]^+ \rightarrow [C_{10}H_{21}(C_4H_8)_{n-2}]^+ + C_2H_4$

The mass-spectrometric investigation shows that the

corresponding ion species $[C_{10}H_{21}(C_4H_8)_q]^+$ ($q = 0$, 1, 2, ...) account for $\sim 2\%$ at 3 Torr of the total ion concentration, which corresponds to a $G_{ion}(C_2H_4) \simeq 0.08$ (1). This yield seems to be pressure independent (or very nearly) and its value is probably unchanged at 10 Torr. There is actually a small decrease in $G(C_2H_4)$ in irradiated isobutene at 10 Torr in the presence of O_2 and NH_3 (Table 1). However, this decrease is within the limits of the experimental errors, and, on the basis of the present data, reaction [6] cannot be confirmed.

The rare-gas sensitized irradiations confirm the occurrence of ionic reactions leading to the 2MB2 formation. However, the dilution of the reacting hydrocarbon makes this reaction path less effective; only around 25% of the 2MB2 is formed in reaction [5], compared to $\sim 60\%$ in the case of pure isobutene. If this lower effectiveness to ionic polymerization of isobutene in rare gases is real, then the formation of C_2H_4 in reaction [6] should be even more difficult to establish, as suggested by inspection of Table 2.

Rare-gas Sensitized Radiolysis

A general view of how the energy of excited or ionized isobutene is disposed after the energy transfer processes from the rare gas metastable and ionic species can be inferred from the sum of the radiochemical yields, $\sum G$, for unscavenged radiolysis experiments (Table 1). Even if the quoted $\sum G$ values do not include yields of isomerization and polymerization processes, the general trend is maintained, and, as expected, $\sum G$ increases with increasing IP and/or metastable-state energy of the noble gas atoms.

In rare-gas sensitized radiolysis experiments the occurrence of less exothermic charge-transfer reactions from dimer rare-gas ions must be taken into account, when added compound is present at low concentration. To what extent dimerization of rare-gas ion, X^+, via

[7] $X^+ + 2X \rightarrow X_2^+ + X$

occurs at pressures of 100 Torr and higher in the presence of added compound whose concentrations are around 1%, can be estimated from the rate coefficients of reaction [7] for Ar, Kr, and Xe (15–17). With a typical value of $k = 10^{-31}$ cm^6 s^{-1} at a pressure of 100 Torr, a positive atomic ion is converted to a molecular ion with a frequency of approximately 10^6 s^{-1}. On the other hand, the frequency of collision of an atomic ion, X^+, with iso-C_4H_8 at 1 Torr is roughly 10^7 s^{-1}. Therefore, it can be assumed that the contribution of molecular rare-gas ions, X_2^+, in charge transfer reaction on isobutene,

[8] $X_2^+ + \text{iso-}C_4H_8 \rightarrow \text{iso-}C_4H_8^+ + 2X$

is not very important in the present experiments.

The Hornbeck–Molnar process

[9] $X^{**} + X \rightarrow X_2^+ + e$

is another possibility of formation of molecular rare-gas ions. (The appearance potentials of X_2^+ (X = Ar, Kr, Xe) species in HM process (ref. 5, p. 196) or the ionization potentials of X_2 van der Waals molecules (19) are the same within 0.1 eV. Their values are within ± 0.1 eV: $AP(Ar_2^+) = 14.6$ eV, $AP(Kr_2^+) = 12.9$ eV, and $AP(Xe_2^+) = 11.2$ eV.) It is difficult to assess the importance of HM processes in the present experiments. A kinetic study of associative excitation in argon indicates that the limiting quantum yields for reaction [9] are rather less than unity, because evidence was found for a competitive quenching (20)

[10] $X^{**} + X \rightarrow X^+ + X$

However, reaction [10] can occur with states X** that lie very close (~ 0.1 eV) to the ionization continuum, but the HM region extends to 1 eV or more from the continuum. On the other hand, theoretical calculations of the contribution of HM processes to the W-value of pure Ar, Kr, and Xe indicate that they account for less than 10%, as estimated on the basis of the optical approximation (21). Based on this information we shall neglect the formation of X_2^+ species in the HM process under the present experimental conditions, and we shall assume that their contribution to reaction [8] seems not to be important in the radiolysis.

Therefore, we assume that the charge transfer only from atomic rare-gas ions

[11] $X^+ + \text{iso-}C_4H_8 \rightarrow \text{iso-}C_4H_8^+ + X$

contributes to the formation of the isobutene ions. The iso-$C_4H_8^+$ ions can also be formed in Penning reactions involving the metastable states of the rare-gas atoms,

[12] $X^* + \text{iso-}C_4H_8 \rightarrow \text{iso-}C_4H_8^+ + e + X$

Assuming that the lowest metastable states of rare-gas atoms are participating in the energy exchange reaction [12], only the $^3P_2(Ar) = 11.5$ eV and the $^3P_2(Kr) = 9.9$ eV states contribute to the parent ion formation.

The iso-$C_4H_8^+$ ions formed either in reaction [11] or [12] carry away an excess energy which is approximately equal to the differences $[IP(X^+) - IP(\text{iso-}C_4H_8^+)]$ or $[^3P_2(X) - IP(\text{iso-}C_4H_8^+)]$. (The exoergicity of reactions [11] and [12] is carried away solely by the iso-$C_4H_8^+$ ions, if the electrons formed have zero energy. However, Penning electron

spectroscopy shows that the electrons can carry away some of the exoergicity.)

The excited parent ion can be collisionally deactivated or, if it contains enough energy to overcome the internal-potential barriers, it can isomerize or decompose. The fragment ions formed in the monomolecular decomposition of iso-$C_4H_8^+$ species having the lowest AP are $C_4H_7^+$ (AP = 11.41 eV), $C_3H_5^+$(AP = 11.45 eV) (22), and $C_2H_4^+$(AP = 12.0 ± 0.25 eV) (23). As already established, the allyl ion, $C_3H_5^+$, leads to propene formation by an H^- transfer reaction (10),

[13] $C_3H_5^+ + \text{iso-}C_4H_8 \rightarrow C_3H_6 + C_4H_7^+$

In photolysis experiments at 8.4 eV (where photoionization does not occur) and at 11.6–11.8 eV (where the photoionization quantum yield = 0.31) the ratios of yields $r_1 = \phi(C_2H_4)/\phi(\text{allene}) = 0.10 \pm 0.03$ and $r_2 = \phi(C_3H_6)/\phi(\text{allene}) = 0.16 \pm 0.03$ seem to be independent of the photon energy (11). This suggests a non-ionic origin of ethylene and propene formation. In the rare-gas radiolyses the similar ratios are higher and they increase with the IP of the rare gases: $r_1^{Xe,Kr,Ar} = 1.0, 1.0, 1.47$ and $r_2^{Xe,Kr,Ar} = 0.8, 0.9$, and 1.47, respectively. These differences in behaviour in photolysis and rare-gas irradiations suggest strongly that an important fraction of both propene and ethylene originates in ionic reactions, such as [13] and [14]

[14] $C_4H_7^+ + \text{iso-}C_4H_8 \rightarrow C_5H_9^+ + C_3H_6$

in the case of C_3H_6 (24). Ethylene is formed probably in charge-exchange reaction of the $C_2H_4^+$ fragmentary ion with neutral isobutene

[15] $C_2H_4^+ + \text{iso-}C_4H_8 \rightarrow C_2H_4 + \text{iso-}C_4H_8^+$

a very efficient reaction, as measured by Abramson and Futrell (24). For each rare gas used the transferred energy in process [11] is sufficient to decompose the isobutene parent ion into fragmentary ions, $C_4H_7^+$, $C_3H_5^+$, and $C_2H_4^+$, which can undergo ion/molecule reactions (13–15).

The decrease of $G^{Ar}(C_2H_4)$ in the presence of oxygen and ammonia in Ar-sensitized irradiations suggests an additional ionic reaction channel of formation of this molecule, involving a fragmentary ion, which is not formed in Xe- and Kr-sensitized radiolyses.

The formation of allene and propyne proceeds from excited neutral isobutene through splitting of the β(C—H) bond or the α(C—C) bond, respectively,

[16] $\text{iso-}C_4H_8^{**} \rightarrow H + CH_2{-}C(CH_3){=}CH_2^*$

[16a] $\downarrow \quad CH_2{=}C{=}CH_2 + CH_3$

[17] $\text{iso-}C_4H_8^{**} \rightarrow CH_3 + CH_3{-}C{=}CH_2^*$

[17a] $\downarrow \quad CH_3{-}C{\equiv}CH + H$

The ratio β(C—H)/α(C—C) is equal to 1.3 ± 0.1, as found by Collin (24) in the photolysis of the butene isomers at 8.4 eV (xenon resonance line) and this value is in agreement with the experimental ratio of photochemical yields: φ(allene)/φ(propyne) = 1.53 (11) at this wavelength. The ratio of radiochemical yields G(allene)/G(propyne) is 1.5 for Xe-sensitized irradiations, indicating that the same mechanisms of formation of allene and propyne are involved in both cases, the required energy of excitation coming from 8.4 eV photons or through $^3P_2$(Xe) metastable state atoms. When transferred energy originates from higher metastable states of Kr and Ar, the ratio G(allene)/G(propyne) decreases to 1.4 and 1.0, respectively. This result suggests that other excited states of neutral isobutene may be involved in α(C—C) splitting with increasing excitation energy. The decrease of the $G(CH_4)$ value in Kr- and Ar-sensitized radiolysis in the presence of both O_2 and NH_3 is probably due to the competition of NH_2· radicals with oxygen for methyl radicals.

The Raman and infrared spectra of crystalline methyl 3,6-dideoxy-β-D-*ribo*-hexopyranoside monohydrate in the O—H stretching region have been studied at room temperature and lower temperatures. Four bands have been identified and correlated with the corresponding O...O distances of the four distinct hydrogen bonds obtained from X-ray data. The assignments were substantiated by a deuterium isotopic dilution study.

On a étudié, à la température ambiante et à de plus basses températures, les spectres Raman et infra rouge du méthyle 3,6-didésoxy-β-D-*ribo*-hexopyranoside monohydrate cristalline dans la région d'élongation du O—H. On a identifié 4 bandes et on les a relié aux distances O...O correspondantes de 4 liaisons hydrogènes distinctes obtenues à partir des données des rayons X. On a corroboré ces assignations par l'étude de dilution isotopique du deutérium.
[Traduit par le journal]

Introduction

The 3,6-dideoxyhexoses are characteristic cell wall components of Gram-negative bacteria (1, 2), and immunodominant sugars of O-antigens.

The crystal structure of such a 3,6-dideoxyhexose, methyl 3,6-dideoxy-β-D-*ribo*-hexopyranoside (methyl paratoside) monohydrate has been recently published by two of the present authors (3). The crystals are monoclinic, belonging to the space group $P2_1$; the unit cell contains two molecules of sugar and two water molecules. There are four distinct intermolecular hydrogen bonds whose O...O distances range from 2.652 to 2.960 Å. The relation between hydrogen bonded O...O distances and the corresponding O—H stretching frequencies has been investigated by several authors (4–9). Since this crystalline sugar monohydrate has four distinct O...O distances, its OH vibrational spectra should be particularly amenable to analysis using such a relationship.

In this study we measured the Raman and infrared spectra; the results obtained at room temperature and at lower temperatures are discussed in relation to the individual hydrogen bond distances.

Experimental

Materials

Methyl 3,6-dideoxy-β-D-*ribo*-hexopyranoside was synthesized and crystallized as described elsewhere (3, 10). For the isotopic dilution experiment, 500 mg of methyl paratoside were dissolved in 5 mL of water containing 10% v/v of deuterium oxide. The solution was evaporated to dryness at 40°C under reduced pressure and then treated once more with the 10% deuterium oxide solution. The crystalline mass was then dissolved in 5 mL of ethyl acetate and seeded (3) with a single crystal of methyl paratoside. After 2 h at room temperature the resulting colourless crystals were filtered, washed with ethyl acetate, and dried under a stream of dry nitrogen.

Spectra

For Raman measurements, a single crystal with dimensions of 5 × 3 × 1 mm was attached to the end of a glass rod with epoxy cement. It was mounted in a variable temperature cell (11) such that the *b* (5 mm) axis was parallel to the direction of the incident beam. Raman scattering was obtained using 400 mW of 488.0 nm radiation from a Spectra Physics model 166-03 argon ion laser. Polarized spectra were recorded at a spectral resolution of about 4 cm^{-1} using a Jarrell-Ash 25-102 double monochromator, a cooled RCA C31034 photomultiplier, and a photon counting system.

For infrared measurements, a flurolube mull was prepared between NaCl plates using a stream of dry nitrogen to prevent further hydration. It was mounted in a liquid nitrogen cooled low temperature cell. The partially deuterated sample was investigated as a KBr pellet. Spectra were recorded using a Perkin–Elmer 180 spectrophotometer, with resolution better than 2.8 cm^{-1}.

Results and Discussion

O—H Stretching Bands

Figure 1 shows Raman spectra in the O—H stretching region of the single crystal of methyl paratoside. In the spectrum taken at room temperature there are two bands clearly evident at 3442 and 3216 cm^{-1} and a weaker feature at 3530 cm^{-1}. In Table 1, the correlation diagram for the methyl paratoside crystal is given. Each of the four distinct OH stretching vibrations (two of free methyl paratoside and two of free water) split into a pair of

components having A and B symmetry under the factor group C_2^2. All of these are active in both the Raman and infrared spectra. For the Raman spectra shown in Fig. 1, the electric vectors of both the incident and scattered light were parallel to the γ axis, which lies in the *ac* plane. Therefore, the scattering geometry can be identified as $b(\gamma\gamma)\perp\gamma$. Since the *b*-axis is perpendicular to the γ axis, the *ab* or *bc* components will not be observed; and the spectra will consist of bands belonging only to the A species of the factor group C_2^2.

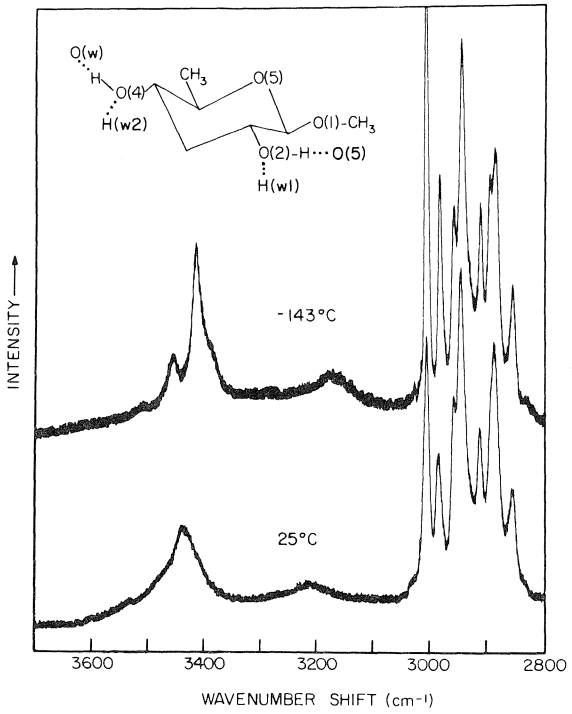

FIG. 1. Polarized Raman spectra of a single crystal of methyl paratoside at two different temperatures: polarization $b(\gamma\gamma)\perp\gamma$. The γ-axis is in the *ac*-plane and the spectrum thus consists of the (*aa*), (*cc*), and (*ac*) components.

Since all four OH vibrations have components of A symmetry, each of them should be observable under our experimental conditions. However, differences in the inherent scattering activity for the four bands will make some easier to observe than others. Also, since the properties of each type of OH bond are actually the average of those of a distribution of bonds, the vibrational band due to a given OH species will be broadened to an extent dependent on the range of the distribution associated with that bond.

These distributions are expected to sharpen at reduced temperatures, so, in order to try to observe spectral features associated with each type of OH bond, the Raman spectrum was recorded at a reduced temperature. The resulting spectrum is also shown in Fig. 1. The strongest feature in the OH region of the low temperature spectrum is a narrow band at 3413 cm^{-1}. However, because this band is so sharp, we prefer to identify it with a combination band which becomes more evident at reduced temperatures due to a decrease in bandwidth. Similar enhancement of combination bands at reduced temperature has been observed previously (12, 13). In addition to the 3413 cm^{-1} band, the low temperature OH stretching region consists of (*i*) a weak band at 3508 cm^{-1} (corresponding to the feature at 3530 cm^{-1} in the room temperature spectrum), (*ii*) a band at 3454 cm^{-1} which may be identified with the high frequency shoulder (at about 3470 cm^{-1}) of the 3442 cm^{-1} band in the room temperature spectrum of Fig. 1, (*iii*) a 3405 cm^{-1} shoulder on the strong 3413 cm^{-1} peak associated with the room temperature feature at 3442 cm^{-1}, and (*iv*) the broad feature centered at 3170 cm^{-1}. The observed OH stretching frequencies are collected in Table 2.

Other polarized components of the Raman spectrum were also measured; however, the band intensities were weaker and the spectra thus noisier. Bands of B symmetry were observed at 3437, 3198,

and 3160 cm^{-1} corresponding to *A* symmetry components at 3442, 3216, and 3170 cm^{-1}, respectively.

In order to confirm the Raman results, infrared spectra were run at room temperature and at a reduced temperature. In the room temperature spectrum in Fig. 2, there are two broad features centered at 3439 and 3196 cm^{-1}. In the low temperature infrared spectrum, we observe bands at 3503(I), 3439(II), 3404, ~3395(III), and 3130(IV) cm^{-1}, corresponding to the Raman bands at 3508(I), 3454(II), 3414, 3405(III), and 3170(IV) cm^{-1}. A careful re-examination of the room temperature infrared spectrum reveals shoulders at 3527 and ~3467 cm^{-1}, corresponding to the 3503(I) and 3439(II) cm^{-1} features in the low temperature infrared spectrum. These frequencies are all included in Table 2. The discrepancies between the frequencies observed in the Raman and infrared spectra are likely due to the fact that modes transforming to both the *A* and *B* symmetry species are observed in the infrared spectra of the polycrystalline sample. Since the *A* and *B* species bands for the individual transitions are broad, they are not resolved in the observed spectra, but act only to shift the peak frequencies. In addition, for the low temperature spectra, these frequency discrepancies are also associated with the difference in the sample temperature. The OH stretching frequencies were observed to decrease with decreasing temperature, e.g. as has been reported for *l*-ascorbic acid (14).

In spectra taken at intermediate temperatures, the 3404 cm^{-1} band sharpens with decreasing temperature and remains almost unchanged in frequency, in contrast to the shifts of the bands I–IV. This feature is thus assigned to a combination band, the ir counterpart of the 3413 cm^{-1} Raman feature. The very weak band at 3285 cm^{-1} in the low temperature infrared spectrum is presumably another combination band corresponding to a feature at 3270 cm^{-1} in the low temperature Raman spectrum. The shoulder band at about 3180 cm^{-1} in the low temperature infrared spectrum is probably also a combination band. The assignment of this feature as an *A* species band corresponding to the *B* species band at 3130 cm^{-1} is unlikely in view of the observed frequency separation of 10 cm^{-1} for those bands in the polarized Raman spectra of the single crystal.

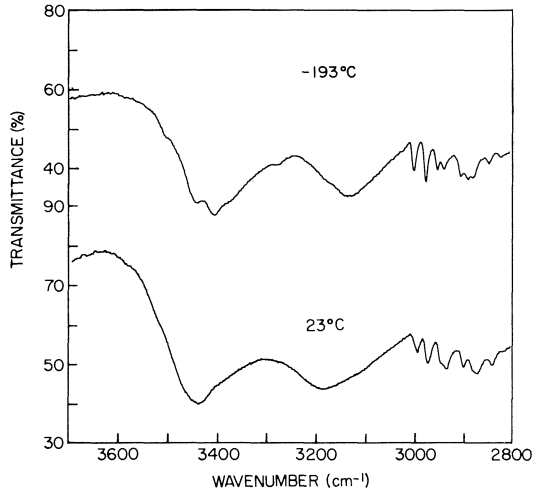

FIG. 2. Infrared spectra of polycrystalline methyl paratoside monohydrate (fluorolube mull) at two temperatures.

O—D Stretching Bands

Since there was some uncertainty in the identification of the OH stretching bands, infrared spectra of the OD stretching region of a 10% v/v deuterated sample were recorded at room temperature and at a reduced temperature (Fig. 3). The three strong bands at 2553, 2502, and 2399 cm^{-1} in the room temperature spectrum shift to 2531, 2479, and 2364 cm^{-1}, respectively, at low temperature. These frequency shifts are characteristic of OH stretching bands as previously stated. Thus, these bands are easily identified with bands II, III, and IV, respectively, in the undeuterated compound (see Table 2). As shown in Table 2, the ratios of the OH/OD frequencies for this assignment agree fairly well for the two temperatures. They also agree quite well with the average

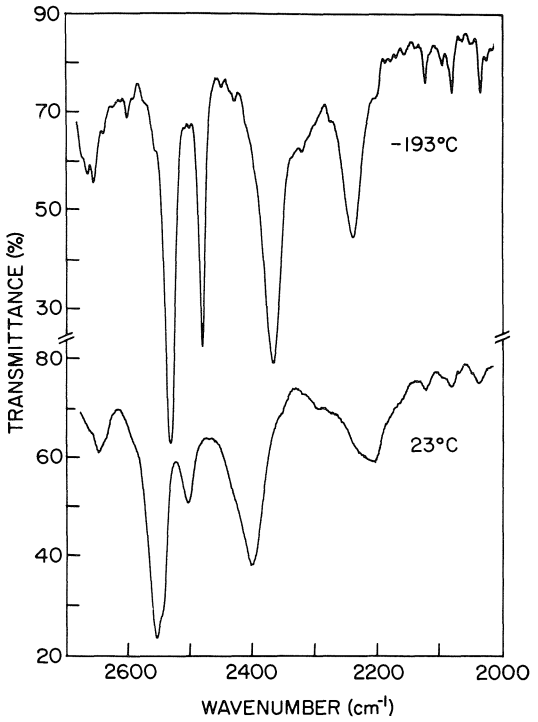

FIG. 3. Infrared spectra of partially deuterated (10% v/v deuterium) polycrystalline methyl paratoside monohydrate (KBr pellet) at two temperatures.

value of 1.355 obtained from a large collection of data, mainly ices and hydrates.[2]

The broad band at 2210 cm^{-1} cannot be assigned to an OD stretching mode since it shifts to 2236 cm^{-1} at low temperature, contrary to the expected behaviour. Furthermore, this band appears in the undeuterated methyl paratoside spectrum, and consequently may be assigned as a combination band whose intensity compares to that of the OD stretching bands because of the dilute deuterium concentration.

It is important to note that there is no feature in the OD stretching region corresponding to the strong band in the OH spectrum identified as a combination band. That assignment thus appears to be justified.

It remains to identify a feature in the OD spectrum corresponding to band I. For shoulders at 2592 cm^{-1} at room temperature and 2575 cm^{-1} at low temperature, an agreement is found for the OH/OD frequency ratios at two temperatures, similar to the behaviour of these ratios for the bands II, III, and IV. Other weak features in the room temperature spectrum shift to higher frequencies, if they shift at all, and are due to combination bands; in particular, the shoulder at 2544 cm^{-1} in the room temperature spectrum shifts to 2556 cm^{-1} at low temperature. We are thus led to the above tentative assignment of band I in the isotopically diluted sample. However, this weak band is clearly identified in the Raman and ir spectra of the undeuterated methyl paratoside.

[2]M. Falk. Private communication.

Correlation of OH/OD Stretching Frequencies with O...O Distances

For an identification of the individual stretching frequencies with specific OH bonds in the crystal, we have considered the available correlations between hydrogen bonded O...O distances and OH frequency shifts (5–7). It has been found that in all cases the OH frequency shifts monotonically to lower frequencies as the O...O distance is decreased, i.e., as the hydrogen bond strength increases. In our case, the frequencies of the two types of isolated OH bonds (alcoholic and aqueous) are close enough that we may initially consider the four bonds on the same basis. The frequency of the free aqueous OH bond is taken to be that of HOD vapour, 3707 cm^{-1} (15), and that of the free alcoholic bond as that of methanol vapour, 3682 cm^{-1} (16). In this case, the observed frequencies may be related to individual OH bonds on the basis of their associated $R_{O...O}$ distances. This has been done in Table 2, where the notation is that of ref. 3, and the atoms involved are identified in the insert to Fig. 1.

From the O...O distance correlation, it is obvious that the alcoholic OH modes should have frequencies at the extremes of the allowed range. This suggests that the $\nu_{O(4)—H}$ frequency should be the highest one observed (band I). For an $R_{O...O}$ distance of 2.652 Å, however, previously proposed relations predict that $\nu_{O(2)—H}$ should be observed at 3075 cm^{-1} (7) or even at 2830 cm^{-1} (5). This would then suggest that $\nu_{O(2)—H}$ is overlapped with CH stretching modes and that band IV may not be ascribed to that OH vibration. However, this possibility is readily eliminated by the isotopic dilution results, since the ν_{OH}/ν_{OD} value for the above assignment is clearly consistent with the corresponding ratios for the other bands. Furthermore, we can find no strong band ascribable to the OD stretching modes in the region below 2399 cm^{-1}. The assignment of bands I and IV, which differ so much in intensity, to the two alcoholic modes is reasonable in light of previous findings that intensities of the OH stretching bands increase significantly with increasing hydrogen bond length (14).

This assignment of the alcoholic OH(OD) stretching modes leads us to the conclusion that bands II and III are due to aqueous OH(OD) stretching modes. In the general case of a hydrated crystal (17–20) water is treated as a vibrationally distorted molecule. For a water molecule which occupies an asymmetric site,

the concept of symmetric and antisymmetric stretching modes breaks down and the two OH stretching modes become partially decoupled. Then the maximum separation between the two modes would be appreciably less than in the fully coupled case. There, e.g., in water vapour, the frequency separation is $\nu_3 - \nu_1 = 3756 - 3654 = 102\ cm^{-1}$ (21, 22). Thus we expect the frequencies of the aqueous OH stretching modes in methyl paratoside to differ by significantly less than this amount. In fact, the frequency separation between bands II and III ranges from 28 to 49 cm^{-1} (about 50 cm^{-1} for the isotopically diluted sample). This confirms the identification of bands II and III with the aqueous OH stretching modes, with band II being associated with the OH bond having the large O...O distance. The alternate assignment of band I to one of these modes is less reasonable because of the difference in intensities between that band and band II or III.

As stated above, there have been several studies of the relationship between the hydrogen bonded O...O distance and OH stretching frequencies obtained from vibrational spectra (4–9). The best correlation was found for isotopically dilute samples, where coupling between adjacent OH bonds is eliminated (8). As deduced from theoretical arguments (5), it is preferable to correlate the O...O distance with the shift in OH stretching frequency from that for the corresponding free OH bond.

We have made such a correlation for the present case. From the free aqueous and alcoholic frequencies given above and our observed Raman data (room temperature and using the average frequencies for *A* and *B* symmetry species, when available), we have calculated $\Delta\nu_{OH} = (\nu_{OH,free} - \nu_{OH,bonded})$. These are plotted against the O...O distance in Fig. 4. Also included in Fig. 4 are $\Delta\nu_{OH}$ frequencies calculated from the room temperature ν_{OD} data, using the relation $\Delta\nu_{OH} = 1.355\Delta\nu_{OD}$.[2] For comparison, we have also included three of the correlations previously presented in the literature. One of these (9) was given in terms of $\Delta\nu_{OD}$, and we converted it to $\Delta\nu_{OH}$ using the relation given above.

The present data points fall close to the previously derived relation; it must be pointed out that the latter curves are the average of data which were scattered due to the diversity of the systems studied. Further, the frequencies for methyl paratoside are likely to be affected by interactions within the crystal including coupling between adjacent OH bonds.

It is clearly more appropriate to correlate the O—H stretching frequencies directly with O—H bond lengths rather than with O...O distances in an O—H...O hydrogen bond. However, hydrogen positions obtained from X-ray analyses are poorly

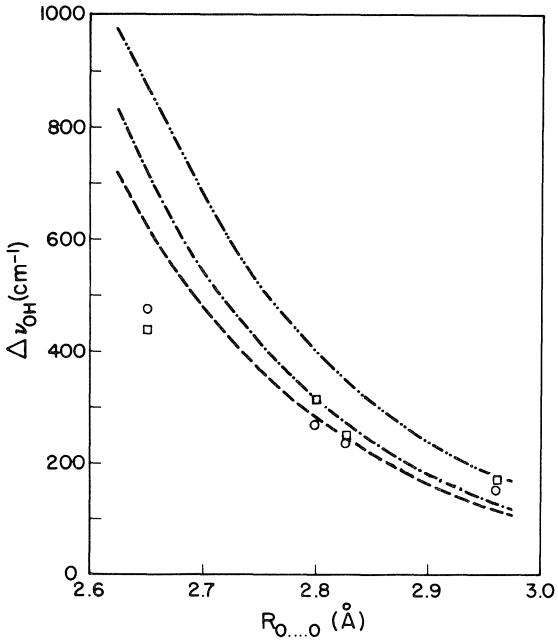

FIG. 4. Correlation between the O...O distance and $\Delta\nu_{OH}$ ($\nu_{OH,free} - \nu_{OH,bonded}$) in crystalline methyl paratoside monohydrate (○, from observed OH spectra; □, converted from observed OD spectra), in comparison with similar correlations proposed by Lippincott and Schroeder (-··) ref. 5, Bellamy and Owen (---) ref. 7, and Falk (-·) ref. 9.

defined; O—H distances so derived are an order of magnitude less precise than corresponding O...O distances. Furthermore, the O—H...O angle may deviate appreciably from linearity. In the case of the four hydrogen bonds of methyl paratoside monohydrate (3), these deviations range from 2 to 16°, but they can be as large as 40° (23). Accurate O—H distances are obtainable from neutron diffraction, but the number of such studies is as yet relatively small. A comparison between neutron diffraction and corresponding X-ray data has been reviewed recently for a number of carbohydrate crystals (24). Unfortunately, neutron diffraction studies have not been made for many compounds which have been well characterized spectroscopically, and vice versa. As more such data become available, the direct correlation of O—H stretching frequencies with O—H distances will have to be reinvestigated.

The mechanism of the solvolysis of *p*-methoxybenzyl chloride in aqueous acetone containing pyridine or thiourea. Evidence for concurrent substitution by unimolecular and bimolecular processes

ALAN QUEEN

Parker Chemical Laboratory, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received December 20, 1978

ALAN QUEEN. Can. J. Chem. **57**, 2646 (1979).

The overall rate of reaction of *p*-methoxybenzyl chloride with 70% aqueous acetone is increased by the addition of pyridine but the rate of hydrolysis is decreased. Comparison of these data with those for benzhydryl chloride under the same conditions shows that the rate of hydrolysis of *p*-methoxybenzyl chloride is less than the rate of ionisation. These results are discussed in terms of concurrent operation of the S_N1 mechanism and a bimolecular process. Similar results are obtained when thiourea is used instead of pyridine.

ALAN QUEEN. Can. J. Chem. **57**, 2646 (1979).

La vitesse globale de la réaction du chlorure de *p*-méthoxybenzyle avec l'aceétone aqueux à 70% est augmentée par l'addition de pyridine, mais la vitesse d'hydrolyse est diminuée. La comparaison de ces résultats avec ceux du chlorure de benzhydryle dans les mêmes conditions montre que la vitesse d'hydrolyse du chlorure de *p*-méthoxybenzyle est plus faible que celle d'ionisation. On discute de ces résultats en termes de l'opération concurrente d'un mécanisme S_N1 et d'un processus bimoléculaire. On a obtenu des résultats semblables quand on utilise la thiourée au lieu de la pyridine.

[Traduit par le journal]

Introduction

During the last few years considerable attention has been given to the mechanisms of nucleophilic displacement reactions of substituted benzyl compounds (1–3). Kohnstam has presented evidence that benzyl chloride hydrolyses in aqueous solvents by the S_N2 mechanism (4) that *p*-methoxybenzyl chloride solvolyses by the S_N1 route and that a progressive change from the bimolecular mechanism to the unimolecular pathway is observed as the para-substituent is changed in the order NO_2, Cl, H, CH_3, CH_3O (1, 5). The intermediate situation for *p*-methylbenzyl chloride is sometimes referred to as "borderline" solvolysis and several possibilities have been proposed. Kohnstam (1) has argued that S_N1 and S_N2 processes occur side by side. Although it is difficult to demonstrate this for purely solvolytic reactions, evidence has been presented that azide attack on *p*-methoxybenzyl chloride involves concurrent operation of the two mechanisms (6). Other workers have preferred some sort of intermediate mechanism involving either a "loose" S_N2 type of transition state (7) or ion-pairs (8, 9). The extreme view of the situation has been that of Sneen (10, 11) who has proposed that all nucleophilic substitutions proceed through a single ion-pair intermediate. Although this view has been accepted by some workers (12–14), it has been criticized by others (15–17). Reviews of the S_N1–S_N2 borderline region have been published (18–20).

Graczyk and Taylor (21) have measured the effect of azide ions on the chlorine isotope effect for the reaction of *p*-methoxybenzyl chloride in aqueous acetone. They concluded that their results support Sneen's mechanism. Although this interpretation has not been specifically discarded, it seems to have been modified in a recent paper (22) to admit concurrent substitution through a free carbocation.

The present trend in dealing with solvolytic reactions is to discuss them in terms of the mechanism (scheme [I]) originally proposed by Winstein *et al.* (23) for solvolytic reactions in acetic acid.

[I] $RX \rightleftharpoons |R^+ \ X^-| \rightleftharpoons R^+ // X^- \rightleftharpoons R^+ + X^-$

intimate ion-pair; external ion-pair; free carbocation

Products

Aronovitch and Pross (24) have applied the concept of reactivity–selectivity relationships (25, 26) to the solvolyses of benzyl compounds in aqueous ethanol and have concluded that a truncated form of the Winstein scheme, which excludes the kinetic involvement of the free carbocation, can account for the behaviour of all these systems.

TABLE 1. The effects of electrolytes on the rates of solvolysis of *p*-methoxybenzyl chloride in aqueous ethanol

T (°C)	Solvent	Salt	[Salt] (M)	$10^4 k$ (s^{-1})	$k/k^{0\,b}$
19.44	80% ethanol	None		7.125 ± 0.031^a	
		NaCl	0.5470	7.133 ± 0.024	1.001
		$NaClO_4$	0.04971	8.610 ± 0.034	1.210
10.03	70% ethanol	None		6.734 ± 0.024	
		NaCl	0.05580	6.711 ± 0.024	0.997
		$NaClO_4$	0.05767	8.043 ± 0.029	1.169

[a] $k = k^0$.
[b] Calculated for 0.05 M salt.

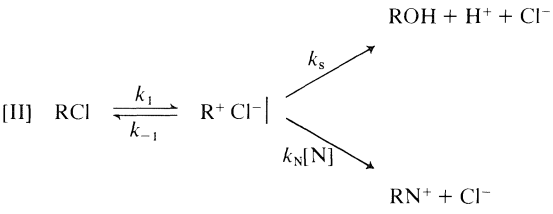
It is our view that the conclusions of these two sets of workers are not correct for the case of *p*-methoxybenzyl chloride. Both ignore the well documented retardation of the rate of solvolysis of this compound by chloride ions in aqueous acetone (1, 6). This effect strongly supports the participation of the free carbocation in the solvolytic reaction (18, 27). It seems unlikely that solvent would be able to react with any form of ion-pair and yet be unreactive towards the free carbonium ion. The magnitude of the common ion rate depression is the same as that for the corresponding reaction of benzhydryl chloride, a classical S_N1 case (28, 29). Support for the view that the rate decrease in the presence of chloride ion is a mass-law effect is provided by the observation that similar retardations are observed for the solvolyses of substituted benzhydryl chlorides and that the effect increases as the electron releasing capacity of the substituent increases (30). While it is true that common-ion retardation of solvolysis has not been previously reported for the reaction of benzyl compounds in aqueous ethanol, the data in Table 1 show similar features to those reported for aqueous acetone. The very large differences in the effects of sodium chloride and sodium perchlorate indicate, in the absence of contrary evidence, that carbonium ions are formed in the solvolysis of *p*-methoxybenzyl chloride in aqueous ethanol.

If free carbocations are present in the reaction mixtures, any discussions of mechanism which ignore them would seem to be incomplete. Further information about nucleophilic substitutions in aqueous organic media can often be obtained by adding competitive nucleophiles to the reaction mixtures and measuring the rates of formation of the various products. A number of such studies have been carried out using ionic reagents but little data is available for nonionic nucleophiles. A notable exception has been the use of thiourea as a competitive nucleophile to study the supposedly borderline reactions of 2-octyl mesylate. The results are entirely consistent with reaction by the S_N2 mechanism (31).

This paper presents data for the reaction of *p*-methoxybenzyl chloride with 70% aqueous acetone containing either pyridine or thiourea.

Results and Discussion

The ion-pair scheme [II] was proposed by Sneen and Larsen (10) as a unifying mechanism for all nucleophilic substitution reactions.



The overall rate of reaction is defined by eq. [III] and the rate of hydrolysis by eq. [IV]

$$[III] \quad d[Cl^-]/dt = k_{Cl}[RCl]$$

$$[IV] \quad d[H^+]/dt = k_H[RCl]$$

The experimental instantaneous rate constants are:

$$[V] \quad k_{Cl} = \frac{k_1(1 + m[N])}{1 + x + m[N]}$$

$$[VI] \quad k_H = \frac{k_1}{1 + x + m[N]}$$

where $x = k_{-1}/k_s$; $m = k_N/k_s$. In the absence of added nucleophile, but in the presence of an appropriate amount of non-nucleophilic salt or non-electrolyte, depending on the nature of the nucleophile used, a rate constant k_{NA} can be defined by eq. [VII]:

$$[VII] \quad k_{NA} = k_1/(1 + s)$$

[a] $k = k^0$.

It can be seen that eqs. [V] and [VI] lead to eq. [VIII]:

$$[\text{VIII}] \quad k_{Cl}/k_H = 1 + m[N]$$

Table 4 gives values of m calculated from the data for the reaction of *p*-methoxybenzyl chloride with pyridine (Table 3). The values of m increase markedly with the concentration of pyridine. Since comparatively large amounts of this reagent were used, the water content of the solvent was also considerably decreased and the changes in m are in the expected direction.

Equations [V] and [VII] can be combined to give eq. [IX]:

$$[\text{IX}] \quad \frac{k_{Cl}}{k_{NA}} = \frac{(1 + x)(1 + m[N])}{1 + x + m[N]}$$

Unfortunately, values of k_{NA} cannot be obtained directly. Sneen, for his work with ionic nucleophiles, carried out model experiments with non-nucleophilic salts and assumed that the salts had non-specific effects. This is not justified (32, 33). The results shown in Tables 2 and 3 show that different inert solvents and non-ionic reagents also have specific effects on the rates of hydrolysis of both *p*-methoxybenzyl chloride and benzhydryl chloride. On the other hand, these non-nucleophilic adducts have very similar effects on the rates of hydrolysis of the

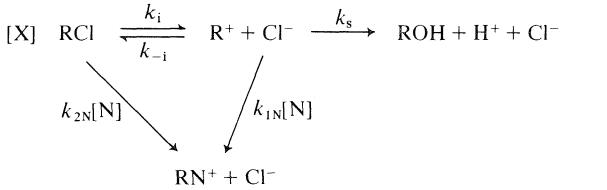
[Pyridine] (M)	$10^4 k_{Cl}$ (s^{-1})	$10^4 k_H$ (s^{-1})	m	$10^4 k_i$ (s^{-1})	$10^4 k_{2N}$ ($M^{-1} s^{-1}$)
0	2.507±0.018	2.507±0.018		2.507±0.018	
0.2472	2.573±0.020	2.172±0.021	0.747±0.022	2.399±0.035	0.704±0.040
0.4942	2.606±0.019	1.865±0.020	0.804±0.023	2.275±0.030	0.670±0.036
0.7420	2.660±0.020	1.611±0.017	0.878±0.024	2.187±0.030	0.637±0.036

two chlorides. Kohnstam and co-workers (6) have used the salt effects of nucleophiles on the rate of solvolysis of benzhydryl chloride to estimate the corresponding effects for the reactions with *p*-methoxybenzyl chloride. There is considerable justification for this approach from the observation that both reactions are equally affected by non-nucleophilic acids and salts, by changes in water content of the solvent and by the addition of chloride ions (1, 6). On the other hand, the application of this method to [II] requires either that m is the same for both reactions or that $m = 0$ for benzhydryl chloride. The data in Tables 2 and 3 show that neither condition is satisfied. In fact, it is not possible to adequately test eq. [IX] with any data available at the present time. The same problems apply to the studies carried out using thiourea as the nucleophile. McLennan (31) used the inert substance urea to obtain the medium effects for his reactions. Since these effects were very small for his reactions, this method was probably justified. The data in Table 2 show that this is not the case in the present studies.

Since the ion-pair mechanism cannot be adequately tested, a different approach has been used. This attempts to see if the results are consistent with the operation of two independent mechanisms. It is justified by the fact that common-ion rate depression of the rate of solvolysis indicates the presence of reactive free carbocations in the reaction mixture. Moreover, there is at least one case (34) where the strongly nucleophilic azide ions react bimolecularly with an organic chloride in 70% aqueous acetone even though the hydrolysis follows the S_N1 route.

The solvolytic reactions of benzhydryl chloride and *p*-methoxybenzyl chloride show a number of similarities. Mass law and salt effects have already been mentioned. The ratio $\Delta C_p^{\neq}/\Delta S^{\neq}$ for both reactions are the same and the values are much larger than those for bimolecular solvolyses (1). Many studies have shown that benzhydryl chloride is sterically hindered to bimolecular attack, even by powerful reagents such as azide ions (35). On the other hand, although the solvolytic reactions of *p*-methoxybenzyl chloride follow an S_N1 route, more powerful reagents may be able to react by a bimolecular process. The simplest reaction scheme, which uses only the S_N1 and S_N2 pathways, is shown in [X].



As before, overall substitution can be measured by the rate constant, k_{Cl}, and hydrolysis, by k_H. A complete treatment of mechanism [X] leads to eq. [XI], where $\alpha = k_{-i}/k_s$ and $\beta = k_{1N}/k_s$.

$$[XI] \quad k_{Cl} = \frac{k_i(1 + \beta[N])}{1 + \alpha[Cl^-] + \beta[N]} + k_{2N}[N]$$

When the concentration of the substrate is low, $\alpha[Cl^-] \ll (1 + \beta[N])$, so that eq. [XI] reduces to eq. [XII]:

$$[XII] \quad k_{Cl} = k_i + k_{2N}[N]$$

The rate constant for hydrolysis is given by eq. [XIII]

$$[XIII] \quad k_H = \frac{k_i}{1 + \alpha[Cl^-] + \beta[N]} \approx \frac{k_i}{1 + \beta[N]}$$

In the absence of strong nucleophiles, $k_{Cl}^0 = k_H^0 = k_i^0$. Equations [XII] and [XIII] may be combined to give eq. [XIV].

$$[XIV] \quad k_{Cl}/k_i = 1 + k_{2N}[N]/k_i$$

The ratio k_{Cl}/k_i is the analogue of the term k_{Cl}/k_{NA} used by Sneen, but in this case it is possible to correct k_i^0 for medium effects in order to obtain k_i. The evidence for this will be discussed for the reactions in the presence of pyridine.

Pyridine has a low polarity and dielectric constant compared to water. Thus, its addition to aqueous acetone would be expected to decrease the ionising power of the solvent and the rates of S_N1 reactions should be less than those in the pure solvent. This expectation is confirmed for the reaction of benzhydryl chloride in 70% aqueous acetone (Table 2). This compound is known to react less rapidly as the water content of aqueous organic solvents is

TABLE 5. The effect of thiourea on the rate of reaction of *p*-methoxybenzyl chloride in 70% aqueous acetone at 19.44°C

[Thiourea] (M)	$10^4 k_{Cl}$ (s^{-1})	$10^4 k_H$ (s^{-1})	m	$10^4 k_i$ (s^{-1})	$10^4 k_{2N}$ ($M^{-1} s^{-1}$)

decreased (1, 28). The effects of benzene, ethanol, and 2,6-lutidine on the rate of reaction of benzhydryl chloride are also shown in Table 2.

Table 3 lists results obtained for the corresponding reactions of *p*-methoxybenzyl chloride under the same conditions. For every case except those involving pyridine, the rate of reaction is decreased by the addition of a non-ionic material to the solvent. The reactions with 2,6-lutidine are particularly interesting because this compound, apart from the large amount of steric hindrance around the nucleophilic nitrogen atom, is structurally similar to pyridine. Thus, although it would be a poor nucleophile compared to water or pyridine, its medium effects should be similar in type to those of pyridine. It can be seen that 2,6-lutidine decreases the rates of solvolysis of benzhydryl chloride and *p*-methoxybenzyl chloride to the same extent. These results indicate that experiments with benzhydryl chloride and pyridine provide a very close measure of the rate of ionisation of *p*-methoxybenzyl chloride under the same conditions.

In contrast to the results obtained with 2,6-lutidine, the overall rate of reaction of *p*-methoxybenzyl chloride is increased by the addition of pyridine to the reaction mixture, despite the decrease in ionising power and water content. Consequently, pyridine must be able to react by a pathway that does not involve the free carbocation. If S_N1 substitution by pyridine also occurs, the rate of hydrolysis, $k_H[RCl]$, will be less than the rate of ionisation, $k_i[RCl]$. The value of k_i can be obtained from model experiments with benzhydryl chloride in the presence of pyridine, as described in the last paragraph. Table 4 shows that the rate of hydrolysis is indeed less than that of ionisation.

A plot of k_{Cl}/k_i against pyridine concentration is linear, as required by eq. [XIV]. The values of k_{2N} are given in Table 4. They show an apparent drift of about 20%, but this is within the combined experimental errors. The results are, therefore, consistent with the concurrent operation of unimolecular and bimolecular mechanisms for the reaction of pyridine with *p*-methoxybenzyl chloride.

The data for reaction in the presence of thiourea also support the concurrent operation of two mechanisms. The data in Table 2 show that both urea and thiourea increase the rate of reaction of benzhydryl chloride, but to different extents. On the other hand, urea has very nearly the same effects on the rates of hydrolysis of benzhydryl and *p*-methoxybenzyl chlorides. This indicates that the reactions of benzhydryl chloride can be used to obtain the medium effects for the reactions *p*-methoxybenzyl chloride with thiourea. The results of these calculations are listed in Table 5. Thiourea is much more nucleophilic than pyridine and lower concentrations of this nucleophile could be used. The m values for the ion-pair scheme increase with thiourea concentration whereas k_{2N} values for scheme [X] are constant. In addition, the values of k_H are less than those of k_i, indicating that thiourea also reacts with the free carbocation.

It is concluded that at least two independent pathways of substitution are concurrently involved in the reaction of *p*-methoxybenzyl chloride with pyridine and thiourea. One of these routes involves a free carbocation and corresponds to the classical S_N1 mechanism. The other may involve one or more ion-pair intermediates and/or the undissociated substrate. The literature contains many conflicting views concerning the importance of ion-pairs and unionised substrates in bimolecular processes. The present results do not resolve the difficulties of the problem. At the present time it seems to be necessary to consider nucleophilic substitution reactions in terms of the full Winstein mechanism. The actual species involved in a particular reaction will depend on the solvent and the nucleophiles involved.

Experimental

Solvents

Aqueous acetone (70%) was made up using 30 volumes of water and 70 volumes of acetone, as previously described (36). Ethanol was Fisher Certified Reagent which was used without further purification. Benzene and petroleum ether (60–80°C) were washed several times with concentrated sulphuric acid and 5% sodium carbonate solution. They were dried over anhydrous magnesium sulphate and fractionally distilled from sodium. Pyridine, bp 115°C and 2,6-lutidine, bp 144–145°C were fractionally distilled from potassium hydroxide.

Weighed samples of the non-electrolytes were accurately made up to volume with 70% aqueous acetone.

Kinetics

Solvolytic rate constants were determined in two ways. The first method involved titration of acid with 0.01 *M* sodium hydroxide solution using lacmoid as indicator. An equivalent method involved titration of chloride ions using a glass electrode and a silver electrode attached to a sensitive pH meter. Samples were drawn from the reaction mixtures at intervals throughout at least three half-lives and the reaction quenched with an excess of dry, neutral acetone. The second method used a conductance technique (37). Reaction cells were calibrated individually by measuring the resistance of a large number of solutions of known composition and concentration of completely reacted benzhydryl chloride. Large scale graphs of resistance against concentration were drawn.

For reactions involving pyridine and 2,6-lutidine, the rates were also determined in two ways. Quenched samples of the reaction mixtures in dry acetone were potentiometrically titrated for acid and chloride ions using a glass electrode and silver electrode as described above. When only the total rate or reaction was required, the reactions were monitored by the conductance method.

In the reactions with thiourea, samples (10 mL) of the reaction mixture were quenched by adding them to ice-cold petroleum ether (50 mL) and water (5 mL). After thoroughly shaking, the aqueous layer was isolated. Separate samples (5 mL) were titrated with 0.01 *M* sodium hydroxide solution using a mixed methylene blue, methyl red indicator. One of the samples was titrated without further treatment while the other was first passed through a column of amberlite IR 120 resin to remove cations.

Thermostats were controlled at 20°C to within $\pm 0.01°$, as measured by a platinum resistance thermometer.

Rate Constants

Overall rate constants are defined by eq. [XV] and integrated values were obtained in the usual way from the integrated form of this equation. Hydrolysis rate constants were obtained from eq. [XVI] by numerical integration.

$$[XV] \quad d[Cl^-]/dt = k_{Cl}[RCl] = k_{Cl}([Cl^-]_\infty - [Cl^-]_t)$$

$$[XVI] \quad d[H^+]/dt = k_H[RCl] = k_H([Cl^-]_\infty - [Cl^-]_t)$$

Substituent effects on the zero-field splitting parameters of diarylmethylene. Evidence for merostabilization in appropriately substituted diphenylmethylenes[1]

ROBERT W. R. HUMPHREYS AND DONALD R. ARNOLD[2]

The Photochemistry Unit, Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received March 20, 1979

ROBERT W. R. HUMPHREYS and DONALD R. ARNOLD. Can. J. Chem. **57**, 2652 (1979).

An analysis of the temperature dependence (4–30 K) of the electron spin resonance (esr) spectra of substituted diphenylmethylenes (e.g. *para*-, *para'*-; methoxy, cyano, dimethylamino, and nitro) indicates all of these species have a triplet ground state. The variation in the zero-field splitting parameter D for this series of methylenes provides evidence that the average separation of the unpaired electrons is greatest for the unsymmetrically substituted derivatives, those having a strong *para*-electron-withdrawing substituent and a strong *para'*-electron-donating substituent. This result is explained in terms of a favourable contribution of charge-separated valence-bond structures, i.e., merostabilization.

ROBERT W. R. HUMPHREYS et DONALD R. ARNOLD. Can. J. Chem. **57**, 2652 (1979).

Une analyse de la relation entre la température (4–30 K) et les spectres de résonance paramagnétique électronique des diphénylméthylènes substitués (i.e. *para*-, *para'*-; méthoxy, cyano, diméthylamino et nitro) indique que toutes ces espèces ont un état fondamental triplet. Pour ces séries de méthylènes, la variation du paramètre D de dédoublement du champ zéro fournit la preuve que la séparation moyenne des électrons non appariés est plus grande pour les dérivés substitués d'une façon dissymétrique en particulier ceux ayant en *para* un substituant fortement électroattracteur et en *para'* un substituant fortement électrodonneur. On explique ces résultats en termes d'une contribution favorable de structure, de liaison de valence dont les charges sont séparées, i.e. mérostabilisation.

[Traduit par le journal]

Introduction

It has been recognized for some time that radicals which are appropriately substituted with strong resonance electron-withdrawing and -donating groups exhibit unusual spectral properties and stability when compared to the unsubstituted systems. The first explanation for these observations was provided by Walter (1), who classified radicals as "S" or "O" based on whether electron-withdrawing and donating substituents have the same or opposite effects on the spectral properties of the radical in question. Katritzky and co-workers (2) classified as "merostabilized" those radicals for which favourable, charge-separated resonance structures can be drawn by virtue of the appropriate substitution of the radical with a strong electron-withdrawing and a strong electron-donating group. The predictive value of the approach of Katritzky and co-workers was exemplified by the design and synthesis of new, stable radicals (2*b*).

Both of these classification systems are based on simple resonance theory and concepts of radical stabilization through three-electron bonding. Illustrative examples of merostabilized radicals are Kosower's radical, nitroxides, and diphenylpicrylhydrazyl. The importance of delocalization to the stability of these radicals becomes evident on examination of Kosower's radical and related systems. For instance, 4-carbomethoxy-1-methylpyridinyl (**1**) dimerizes very slowly in solution at room temperature, whereas 4-carbomethoxy-1,3,5-trimethylpyridinyl (**2**) dimerizes very rapidly under identical conditions (3). Delocalization involving charge-separated resonance structures is possible only in the former in which the carbonyl and pyridinyl π-systems can approach coplanarity (Fig. 1). These charge-separated canonical forms are important in the overall resonance description of merostabilized radicals.

Increased delocalization should result in a change in the spin density distribution in merostabilized radicals compared to similar systems lacking such stabilization. This effect has been observed in the electron spin resonance (esr) of *para*-substituted α-carbomethoxy-α-cyanobenzyl radicals (4).

While it is now generally accepted that resonance involving charge-separated structures and three-electron bonding can play an important part in both the spectral properties and stability of free radicals,

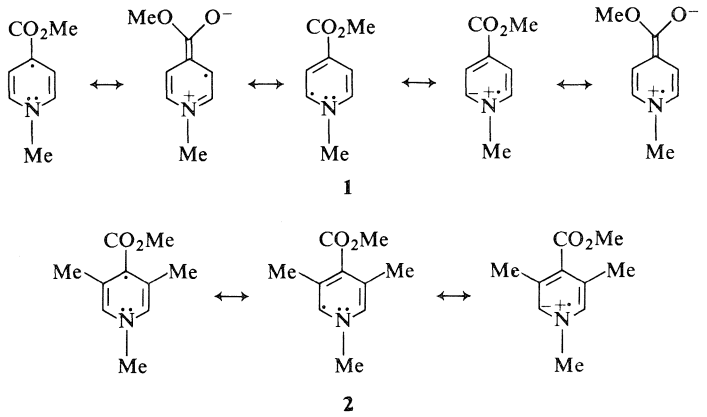

FIG. 1. Merostabilization and increased delocalization.

these concepts had not been applied to other electron deficient species containing unpaired electrons. It occurred to us that diphenylmethylene should be an appropriate system for the investigation of the effects of merostabilization in divalent carbon species. Electron spin resonance (5) and visible and fluorescence spectroscopic studies (6) have shown that the diphenylmethyl radical provides a reasonable model for the electronic structure of diphenylmethylene. Both molecules possess a 13-π-electron odd-alternant hydrocarbon system and exhibit absorption and emission spectra in accord with this structure. The other unpaired electron in diphenylmethylene occupies an orbital (the σ-orbital) situated in the plane of the molecule and the nodal plane of the π-system.

Examination of diphenylmethyl in light of the arguments of Walter and Katritzky leads to the prediction that substitution of this molecule with a strong *para*-electron-donating group and a strong *para'*-electron-withdrawing group should lead to a merostabilized system. Similar substitution in diphenylmethylene should result in a significant redistribution of the unpaired electron spin density of the π-system. This effect is shown in Fig. 2 for (*p*-dimethylaminophenyl) - (*p* - nitrophenyl)methylene (**3***l*). It can be seen that, by virtue of the favourable charge-separated resonance structures, the unpaired electron in the π-system can be delocalized into positions *ortho* to the substituents, that is, *meta* to the divalent carbon.

The experimental verification of this change in spin density distribution in appropriately substituted (merostabilized) diphenylmethylenes should be possible by examination of the magnitude of the zero-field splitting (ZFS) parameter *D* as a function of substitution. *D* can be calculated from the esr spectrum of the diphenylmethylene triplet and it can be shown that the magnitude of *D* is related to the inverse of the cube of the distance between the unpaired electrons in the triplet (7). Any effect which increases the average distance between the unpaired electrons in the triplet causes a corresponding decrease in *D*. The increased delocalization in appropriately substituted (merostabilized) diphenylmethylenes should lead to an increased separation between the unpaired electrons with a concomitant decrease in *D* (see Discussion for further details).

We have studied the esr spectra of an extensive series of *para*- and *para,para'*-substituted diphenylmethylenes and, in this paper, we report the first examples of significant and predictable substituent effects on the ZFS parameter *D* of diphenylmethylene. These effects can be explained in terms of the simple resonance theory discussed above. The diphenylmethylenes studied are listed in Table 1.

In addition, we have a continuing interest in the ground state multiplicity of diphenylmethylene as a function of substitution. It has been suggested recently that the separation between the ground state triplet and first excited singlet state of diphenylmethylene may be as small as 3 kcal mol^{-1} (8). We felt that an energy separation of this magnitude might be significantly affected by appropriate substituents, possibly to the extent that the singlet would become the ground state of the system. The rationale behind this hypothesis has been dealt with in detail in a previous publication (9*a*) in which it was shown that the ground state of the diphenylmethylenes **3***a–f* is the triplet. Although the effects of *p*-methoxy and *p*-cyano-substituents were not large enough to invert the order of states in diphenylmethylene, we were reluctant to abandon this objective. Therefore, we have determined the ground state multiplicity of diphenylmethylenes **3***g–o* substituted with the stronger resonance electron-withdrawing and -donating groups nitro and dimethylamino, respectively, by temperature dependent esr studies and application of the Curie law.

Results

Diphenylmethylenes **3***a–o* were generated by irradiation of the corresponding diazo compounds. The substituted diphenyldiazomethanes (**4**) (Table 2) were prepared by one of two general methods. The first method involved the oxidation of the corresponding benzophenone hydrazone with yellow mercuric oxide in the presence of base in a manner previously described (9, 10). This procedure was found to be quite satisfactory for diphenyldiazomethanes **4***a–i*.

Diphenyldiazomethanes **4***j–o* were prepared by the thermal decomposition of the potassium salt of the tosylhydrazone of the corresponding benzophenone. This was essentially a modification of the general procedure of Bamford and Stevens (11) and was adopted because of difficulties encountered in the preparation and/or oxidation of the hydrazone precursors to **4***j–o*. The tosylhydrazone salts could be prepared in large quantities and were stable when stored in a refrigerator. The diazo compounds were generally prepared by allowing the solid salt to stir in the dark at room temperature in *n*-pentane or diethyl ether. In most cases, the decomposition of the salt was a slow process and accumulation of significant amounts of the diazo compound required a considerable period of time (up to one week). The tosylhydrazone salts of *p*-dimethylamino-*p'*-nitrobenzophenone and *p*-cyano-*p'*-dimethylamino-benzophenone decomposed rapidly and reasonable amounts of the diazo compounds could be accumulated overnight.

The diphenyldiazomethanes **4***a–o* were characterized by ir, ^{1}Hmr, and visible spectroscopy. The long-wavelength visible absorption band was particularly useful for the proof of structure of these compounds. A good correlation was found between the position of the visible absorption maximum and the Hammett substituent parameter $\sum\sigma_p$. The visible absorption maxima along with $\sum\sigma_p$ values are listed in Table 2 and the Hammett plot is shown in Fig. 3. The λ_{max} values for the nitro compounds **4***j–n* are plotted in ranges of 10 nm. The long-wavelength absorption for these compounds occurs as a shoulder on a far more intense band and, thus, the exact position is difficult to estimate. The line drawn in Fig. 3 is the least-squares line obtained by using the midpoint of the 10 nm range for **4***j–n*, and the points for the other compounds. The utility of this relationship in identifying the diazo compounds, particularly the less stable ones, should be obvious. A similar correlation has been reported between the diazo stretching frequency in the infrared and Hammett σ_p^+ (12, 13).

The preparations of the diphenyldiazomethanes **4***a–f* have been described elsewhere (9*a*). The preparations of diphenyldiazomethanes **4***g–o* are described in the Experimental section. All of the tosylhydrazones and their salts are new compounds, as are the diphenyldiazomethanes **4***i*, *l*, *n*, and *o*. The preparation of bis(*p*-nitrophenyl)diazomethane has been reported previously (13), but the hydrazone of the corresponding benzophenone is required, for

which a preparation was not described. The preparation of this hydrazone is apparently not straightforward (14).[3]

Generation of diphenylmethylenes **3***a–i* in the esr cavity at ca. 5 K was performed by irradiating the appropriate diazo precursor in a rigid glass with a high pressure mercury arc lamp (1 kW). Once generated, these diphenylmethylenes seemed to be stable to further irradiation. A variety of precursors was used to generate diphenylmethylenes **3***j–o*. In an initial experiment, it was found that the esr spectrum of diphenylmethylene could be generated by irradiating the solid potassium salt of benzophenone tosylhydrazone at 77 K. Based on this result, **3***j–o* were generated and characterized by irradiating the corresponding tosylhydrazone salt under similar conditions. This procedure was found to be unsuccessful for **3***k* and *l*. Prolonged irradiation of the salts of these tosylhydrazones produced no signals which could be assigned to **3***k* or *l* at either liquid nitrogen or liquid helium temperatures. Thus, attempts to generate **3***k* and *l* by this method were abandoned in favour of the diazo precursors.

Methylene triplet signals were assigned in terms of the Hamiltonian

$$[1] \quad \hat{H} = g\beta \boldsymbol{H} \cdot \hat{S} + D(\hat{S}_z^2 - \tfrac{1}{3}\hat{S}^2) + E(\hat{S}_x^2 - \hat{S}_y^2)$$

The ZFS parameters were obtained from the observed spectra by employing an iterative computer program and are summarized in Table 3. Accurate field positions for all diphenylmethylenes were obtained by employing the esr field standard $[Cr(NH_3)_5Cl]Cl_2$ diluted in $[Co(NH_3)_5Cl]Cl_2$ (15) (see Experimental for details).

The ZFS parameters for **3***a–f* were obtained by irradiating the diazo compound in a rigid glass (4:1 methylcyclohexane:isopentane). The ZFS parameters for **3***g–o* were obtained in a number of matrices and at varying temperatures. The field positions for **3***l* were obtained in a tetrahydrofuran (THF) matrix at liquid helium temperature. This low temperature was required because of the difficulty in generating even moderately strong signals for this species at liquid nitrogen temperature. It should be noted that although THF does not form a glass, spectra of diphenylmethylenes obtained in a matrix of this solvent did conform to those expected for randomly oriented triplets (i.e., rotating the sample caused no noticeable shift in field positions).

For diphenylmethylenes generated from the tosylhydrazone salt, a powdered salt was used in all cases and the spectra obtained again conform to those of randomly oriented triplets; the ZFS parameters for all diphenylmethylenes except **3***l* were obtained at 77 K.

For **3***a–g* and **3***k*, spectra were intense enough that four lines could be observed (H_{z_1}, H_{x_2}, H_{y_2}, H_{z_2}). For the other diphenylmethylenes, the H_{z_2} line was not observed or was so weak and broad that assignment of the field position was impossible.

Temperature dependence studies were carried out on diphenylmethylenes **3***g–o* using the H_{x_2} line in every case. The experiments were performed in the same glass or matrix used to obtain the ZFS parameters. Temperatures were varied over the range of 5–30 K. The temperature was monitored by using the

[3]Preparation of *p,p'*-dinitrobenzophenone hydrazone required prior preparation of the thioketone P_2S_5 (14).

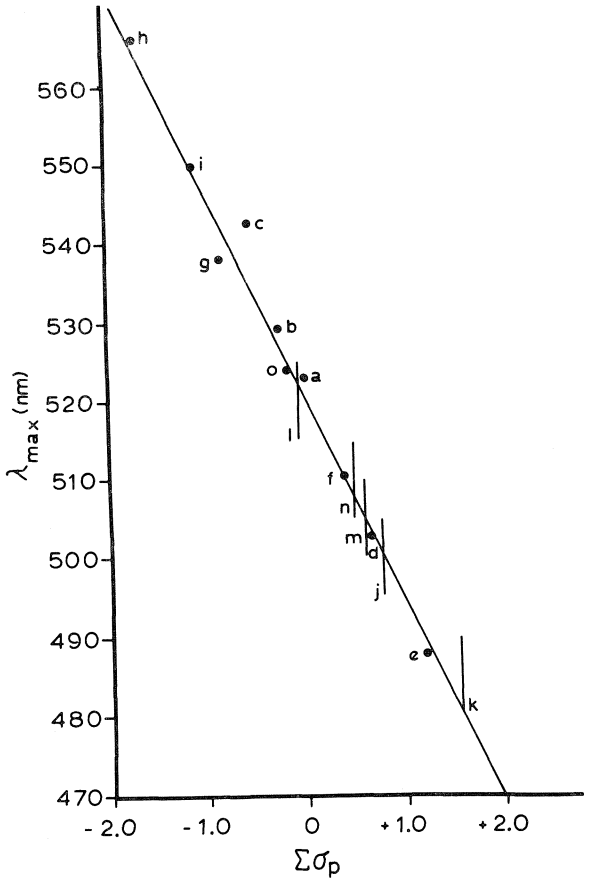

FIG. 3. Graph of λ_{max} (nm) vs. $\Sigma\sigma_p$ for diphenyldiazomethanes (4).

high field line of phenylnitrene as an internal standard in a manner described previously (16).

The observed signal intensity (peak-to-peak height of the H_{x_2} line) as a function of temperature for two of the diphenylmethylenes (**3***h*, *k*) is shown in Fig. 4. As can be seen, the plots are linear over the entire temperature range. These results were typical of those for all of the diphenylmethylenes listed in Table 1.

Discussion

In a simple model, the ZFS parameters D and E for a triplet depend on the distance between electrons with parallel spins as given by eq. [2]:

$$[2a] \quad D = \tfrac{3}{4}g^2\beta^2\left\langle\frac{r^2 - 3z^2}{r^5}\right\rangle$$

$$[2b] \quad E = \tfrac{3}{4}g^2\beta^2\left\langle\frac{y^2 - x^2}{r^5}\right\rangle$$

where the angular brackets imply an average value (7). These equations assume that any spin–orbit coupling contribution to D and E is small and thus, that D and E arise from a predominantly dipolar interaction between the two unpaired electrons. D is essentially a measure of the interaction between the two unpaired electrons along the z-magnetic axis of the molecule while E is a measure of the x,y-interaction. E is relatively small for the methylenes measured here and, although the approximation is crude, it facilitates the discussion somewhat if D is assumed to be related to $1/r^3$ (i.e., cylindrical symmetry is assumed and E is ignored).

Two trends become obvious when the D-values for **3***a–o* are compared (Table 3). First, substitution generally causes a decrease in D over that in the parent molecule **3***a*. Second, the decrease in D is largest when the diphenylmethylene is substituted with one *para*-electron-withdrawing group and one *para'*-electron-donating group. The decrease in D in these unsymmetrically disubstituted diphenylmethylenes is always larger than that predicted by taking the sum of the effects in the mono-substituted derivatives (e.g., compare **3***g*, **3***j*, and **3***l*).

The substituent effects on D are not large, but an explanation can be formulated for the observed trends. The ZFS parameters are directly related to the spin density distribution in the molecule. In the accepted model for diphenylmethylene, one unpaired electron is localized at the divalent carbon atom in the σ-orbital, which means that the spin density at the divalent carbon due to this unpaired electron is essentially one. Obviously, then, any change in D due to substitution must result from a change in the spin density distribution in the π-system containing the other unpaired electron.

The D values in Table 3 indicate that mono- and symmetrical disubstitution both cause a decrease in D and that the effect of disubstitution is greater than (but not double) that of monosubstitution by the same substituent in all cases. The small substituent effect on D was predictable based on the results obtained for the substituent effects on the esr hyperfine splittings of substituted benzyl radicals. For all substituents, the hyperfine splitting constant of the benzyl protons was found to be similar and, thus, substitution has little effect on the spin density at the benzyl carbon (17). A similar conclusion was reached from INDO calculations on the diphenylmethylene system (14). The calculations indicate that substituents had very little effect on the spin density at the divalent carbon and that any change in D was due to a spin density change in other regions of the molecule. Unfortunately, only mono- and symmetrically disubstituted systems were investigated, but the results agree with those in this study for similar systems.

The effect on D of disubstitution of diphenylmethylene with a strong electron-withdrawing group

[b]Previously reported values, ref. 5*a*.

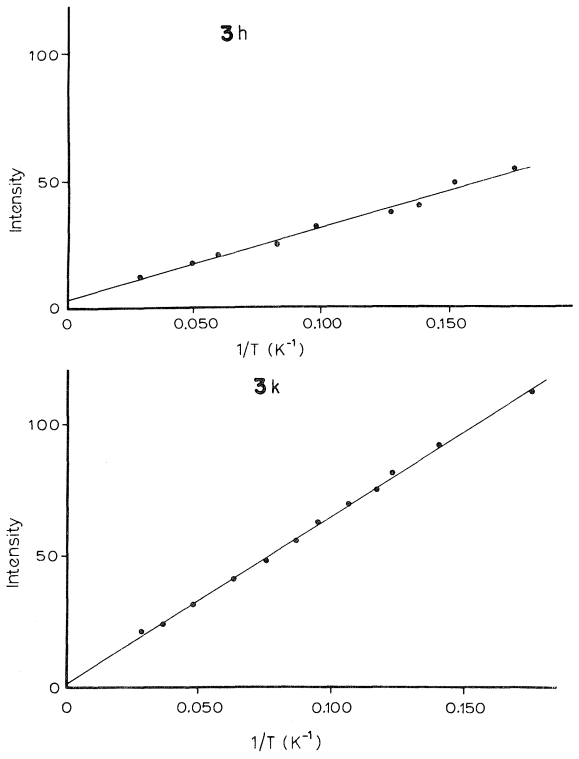

FIG. 4. Curie law plots for the diphenylmethylenes 3*h* and 3*k*.

and a strong electron-donating group can be explained in a different way. For all of the diphenylmethylenes which fall into this class (3*f*, *l*, *m*, *n*, *o*), the D value is smaller than that predicted by taking the sum of the effects in the mono-substituted systems. A simple explanation involving resonance theory allows these results to be explained and is illustrated in Fig. 2 for 3*l*. The appropriate substitution leads to systems which, by Katritzky's definition, can be classified as merostabilized. It should be obvious from Fig. 2 that this type of resonance interaction in symmetrically disubstituted or monosubstituted diphenylmethylenes leads to canonical forms of type "*c*" which would be of relatively high energy. Such canonical forms contribute very little to the overall resonance description of these symmetrically substituted systems. However, for diphenylmethylenes disubstituted with a strong *para*-electron-withdrawing and a strong *para'*-electron-donating group, canonical forms of type "*c*" should contribute significantly to the overall resonance description of these systems. The result is increased delocalization of the unpaired electron occupying the π-system of these diphenylmethylenes. The experimental result is a significant decrease in D compared to systems lacking merostabilization.

The increased delocalization of the *p*-electron in these diphenylmethylenes will result in a spin density

redistribution throughout the π-system. From Fig. 2, it can be seen that merostabilization of diphenylmethylene should result in a significant decrease in the negative spin density at positions *ortho* to the substituents compared to the parent molecule. Unfortunately, the large linewidths (ca. 80 G) of the esr spectra of these randomly oriented triplets preclude the resolution of the appropriate proton hyperfine coupling constants. Nevertheless, the concept of merostabilization is completely consistent with the observed trends in D as a function of substitution.

Although the ZFS parameters for a number of *para*-substituted diphenylmethylenes have been reported (*5a*), the substituents were chosen in a random fashion and no consistent trend in D as a function of substitution was apparent. In addition to providing a clear picture of the effects of substitution on D, this work indicates the importance of resonance and merostabilization in the interaction between the unpaired electrons of a triplet species such as diphenylmethylene.

The temperature dependence studies indicate that the intensity of the esr signals for the diphenylmethylenes **3***g–o* follow the Curie law over the entire temperature range studied. Therefore, **3***g–o* have triplet ground states and the singlet state is not populated to any significant extent at the maximum temperature of the experiment for any of the systems studied. An alternative possibility is that the singlet is the ground state of these species and it is separated by such a small energy from the upper triplet (< 5 cal mol^{-1}) as to be in thermal equilibrium with this upper state even at the lowest temperature studied. The latter explanation seems highly unlikely for **3***g–o*.

Temperature dependence studies have been carried out on the parent molecule (*8a*) and there is no doubt that this molecule has a triplet ground state. Although the chemistry of diphenylmethylene at room temperature seems to involve both the singlet and the triplet states (19), no spectroscopic observation of the singlet state has been reported. From the studies described in this paper, it is not possible to place a lower limit on the triplet–singlet energy separation for any of the diphenylmethylenes **3***g–o* because of the experimental difficulty in detecting deviations from Curie law behaviour due to population of an upper singlet state (16). It is possible that the triplet–singlet separation was lowered significantly in some of the derivatives and that this effect was not detected. It can, however, be concluded that the effects of *p*-methoxy, *p*-cyano, *p*-nitro, and *p*-dimethylamino substituents are not large enough to invert the order of states in diphenylmethylene.

Experimental

General

[1]Hmr spectra were obtained on a Varian T-60 spectrometer, usually in deuterochloroform, and are reported in units of δ ppm relative to tetramethylsilane as an internal standard. Infrared spectra were obtained on a Beckman IR-5A, Beckman "Acculab 4", or Perkin-Elmer 621 Grating Infrared Spectrometer and were calibrated with a polystyrene film. Infrared spectra were obtained in chloroform or carbon tetrachloride in potassium bromide solution cells and are quoted in μm. Visible and ultraviolet spectra were obtained on a Cary 118 spectrometer using quartz cuvettes. Melting points were obtained on a Sybron Corporation Thermolyne melting point apparatus and are corrected.

Electron spin resonance spectra were obtained from a Varian E-12 esr spectrometer. Temperature dependence studies were performed with an Air Products Model LTD-3-110 "Heli-tran" liquid helium Dewar and transfer system. Samples were placed in Suprasil esr tubes and were irradiated with a Hanovia 1 kW high-pressure mercury arc lamp.

Sample preparation varied and depended on the precursor used to generate the methylene. When the diazo compound was used as the precursor, 10–20 mg was dissolved in 1 mL of the appropriate solvent. If the diazo compound was stable, degassing was carried out by the freeze–pump–thaw method. If the diazo compound was unstable, no attempt was made to degas the sample.

In some cases, the potassium salt of the tosylhydrazone of the corresponding benzophenone was used as a convenient precursor for the generation of the methylene. Usually, the solid salt was packed in an esr tube to the appropriate height. In some cases, it was found that only the outer surface of the salt was irradiated under these conditions, and thus the salt was added to an esr tube as a slurry in dry THF and was quickly placed in the esr cavity and frozen before settling could occur. This procedure allowed more complete irradiation to occur and, thus, produced larger signals.

Phenylazide was added to samples used in temperature dependence studies. When the diazo compound was used as the methylene precursor, about 6–8 mg phenylazide was added to the esr sample. When the tosylhydrazone salt was used, a solution of about 40 mg phenylazide in 1 mL methylcyclohexane was added to the salt in the esr tube and was allowed to mix with the salt.

Irradiations in the esr cavity were generally carried out through a Corning O-53 (≥ 280 nm) or O-54 (≥ 300 nm) filter. Under these conditions, large methylene (and nitrene) signals could be produced quickly from either precursor.

Temperature dependence studies on all diarylmethylenes were carried out using a procedure identical to that described previously (9, 16, 20). Temperature measurement at liquid helium temperatures was carried out by including phenylazide in the sample and monitoring the nitrene signal intensity as a function of temperature.

Zero-field Splitting Parameters

Accurate field positions for the diphenylmethylenes **3***a–o* were determined by employing the inorganic field standard $[Cr(NH_3)_5Cl]Cl_2$ as a 2% mixture in $[Co(NH_3)_5Cl]Cl_2$ (15). Accurate field positions for this standard have been provided, along with the appropriate microwave frequency corrections.

Calculations of the zero-field splitting parameters from the esr field positions were performed by employing an iterative computer program described previously (16). The line position was taken as the maximum, minimum, or midpoint, depending on the line shape (21).

Preparation of the Diphenyldiazomethanes

The preparation of **4***a–f* has been described in full (9). The general procedure for **4***g–i* involved the preparation of the corresponding benzophenone hydrazone (10) from the ketone, and subsequent oxidation with yellow mercuric oxide in the presence of base. **4***j–o* were prepared by decomposition of the tosylhydrazone salt.

The visible absorption maxima for the diazo compounds are listed in Table 2.

Preparation of the Hydrazones

A 100 mL round-bottom flask equipped with a magnetic stirring bar, reflux condenser, nitrogen inlet tube, and bubbler was purged with nitrogen. The ketone (ca. 2.0 g) and hydrazine hydrate (50 mL) were added and the contents were heated to reflux using an oil bath. Vigorous stirring was employed. After heating at reflux overnight, the reaction mixture was cooled. An oil settled to the bottom of the flask and solidified and crystals formed in the hydrazine hydrate. The solid was collected by vacuum filtration. The hydrazine hydrate was extracted with chloroform (100 mL) and the chloroform was removed on a rotary evaporator to give an oil. This oil was combined with the solid and solidified on standing.

p-*Dimethylaminobenzophenone Hydrazone*

The ^{1}Hmr spectrum showed that both *E* and *Z* isomers were present (yield = 2.0 g, 99%). ^{1}Hmr ($CDCl_3$): δ 2.80, 2.86 (s, 6H total); δ 5.10, 5.27 (2 br. s, 2H total); δ 6.60 (m, AA′BB′, 4H); δ 7.18 (m, 5H).

*Bis-(*p*-dimethylamino)benzophenone Hydrazone*

The product was recrystallized from absolute alcohol to give yellow needles, mp 150–152°C. ^{1}Hmr ($CDCl_3$): δ 2.84 (s, 3H); δ 2.92 (s, 3H); δ 5.07 (s, br., 2H); δ 6.86 (m, 8H); ir ($CHCl_3$): 2.90, 3.31, 6.20, 6.60, 6.75, 6.91, 7.37, 8.39, 8.47, 9.40, 10.57, 12.17.

p-*Dimethylamino*-p′-*methoxybenzophenone Hydrazone*

The product was recrystallized from absolute alcohol to give light yellow needles, mp 166–170°C. ^{1}Hmr ($CDCl_3$): δ 2.86, 2.92 (2s, 6H); δ 3.72, 3.80 (2s, 3H); δ 5.20, 5.32 (2s br., 2H); δ 6.92 (m, 8H); ir ($CHCl_3$): 2.92, 3.31, 3.56, 6.19, 6.60, 7.33, 7.43, 7.97, 8.49, 9.62, 11.90, 12.12.

Anal. calcd. for $C_{16}H_{19}N_3O$: C 71.34, H 7.11; found: C 71.12, H 7.06.

Oxidation of the Hydrazone

The hydrazone (ca. 1.0 g), anhydrous ether (60 mL), anhydrous sodium sulfate (3.0 g), yellow mercuric oxide (3.3 g, 15 mmol) and saturated ethanolic potassium hydroxide (3 mL) were placed in a 150 mL round-bottom flask equipped with a magnetic stirring bar and drying tube. The mixture was allowed to stir in the dark at room temperature for 11 h. After filtering by gravity into a round-bottom flask covered with aluminum foil, the solvent was removed on a rotary evaporator with the water bath at room temperature.

*(*p*-Dimethylaminophenyl)phenyldiazomethane (***4***g)*

A purple solid was obtained, the ^{1}Hmr, ir, and visible spectra of which were consistent with **4***g*. ^{1}Hmr (CCl_4): δ 2.92 (s, 6H); δ 6.83 (m, AA′BB′, 4H); δ 7.10 (m, 5H); ir ($CHCl_3$): 3.38, 4.93, 6.23, 6.61, 6.71, 6.93, 7.73, 9.58.

*Bis-(*p*-dimethylaminophenyl)diazomethane (***4***h)*

As above, with the exception that dry tetrahydrofuran was substituted for anhydrous ether; **4***h* was obtained as a grey-blue solid. ^{1}Hmr (CH_2Cl_2): δ 2.90 (s, 12H); δ 6.78 (m, AA′BB′, 8H); ir ($CHCl_3$): 3.31, 4.91, 6.20, 6.60, 6.92, 7.35, 12.24.

*(*p*-Dimethylaminophenyl)(*p*-methoxyphenyl)diazomethane (***4***i)*

As above, with the exception that *n*-pentane was substituted for anhydrous tetrahydrofuran. A deep blue solid was obtained. ^{1}Hmr (CD_2Cl_2): δ 2.96 (s, 6H); δ 3.83 (s, 3H); δ 6.96 (m, 8H); ir ($CHCl_3$): 3.31, 3.50, 4.93, 6.19, 6.61, 8.00, 8.26, 9.62.

p-*Cyano*-p′-*dimethylaminobenzophenone*

This compound was prepared by a modification of the procedure of Shah, Deshpande, and Chaubal (22). Phosphorus oxychloride (11.8 mL, 0.13 mol), *N*,*N*-dimethylaniline (36 mL, 0.28 mol) and *p*-cyanobenzanilide (21 g, 0.095 mol) were placed in a 1 L round-bottom flask equipped with a reflux condenser and thermometer with the bulb extending below the surface of the reaction mixture. The flask was placed in an oil bath and the bath was heated slowly. At about 120°C, an exothermic reaction began and the flask was cooled in ice-water as soon as the temperature reached 180°C. A thick brown syrup was obtained. After adding 10% HCl (700 mL), the mixture was heated on a steam bath and the brown product was hydrolyzed. The resulting yellow solid was collected by vacuum filtration and recrystallized several times from absolute alcohol. Yellow plates (3.0 g, 20%) of *p*-cyano-*p*′-dimethylaminobenzophenone were obtained, mp 178–179°C. ^{1}Hmr ($CDCl_3$): δ 3.07 (s, 6H); δ 7.07 (m, 4H); δ 7.63 (m, 4H); ir ($CHCl_3$): 3.32, 4.37, 6.00, 6.20, 6.40, 7.20, 7.48, 7.65, 8.65, 10.69, 11.66, 12.03.

Anal. calcd. for $C_{16}H_{14}N_2O$: C 76.78, H 5.64; found: C 76.68, H 5.48.

p-*Nitrobenzophenone Tosylhydrazone*

A mixture of *p*-nitrobenzophenone (23) (5.0 g, 0.022 mol), *p*-toluenesulfonhydrazide (8.2 g, 0.044 mol), and benzene (200 mL), in a 500 mL round-bottom flask equipped with a reflux condenser, was heated at reflux for 3 days. The solution was cooled and the benzene was removed on a rotary evaporator to give a yellow oil containing some solid. Methanol (50 mL) was added and the mixture was warmed to dissolve the oil and then cooled in ice. Crystals were collected in a sintered glass funnel and recrystallized by dissolving in benzene, adding ethanol, and boiling off most of the solvent. A total of 4.0 g (46%) *p*-nitrobenzophenone tosylhydrazone was obtained, mp 130–138°C. ^{1}Hmr ($CDCl_3$): δ 2.45 (s, 3H); δ 7.75 (m, 14H); ir ($CHCl_3$): 3.03, 3.23, 6.24, 6.58, 6.91, 7.20, 7.73, 7.60, 8.58, 9.38, 10.19, 11.42, 11.72, 11.80.

Anal. calcd. for $C_{20}H_{17}N_3O_4S$: C 60.75, H 4.33; found: C 60.92, H 4.44.

p-*Methyl*-p′-*nitrobenzophenone Tosylhydrazone*

Light yellow needles (1.18 g from 1 g of the ketone (24), 70%) mp 130–200°C (dec.) were obtained after recrystallization from benzene–alcohol. ^{1}Hmr ($CDCl_3$): δ 2.30, 2.40 (2s, 6H); δ 7.47 (m, 13H); ir ($CHCl_3$): 3.04, 3.28, 3.41, 6.26, 6.61, 7.24, 7.45, 7.62, 8.61, 9.38, 10.21, 11.41, 11.63, 12.16.

Anal. calcd. for $C_{21}H_{19}N_3O_4S$: C 61.61, H 4.68; found: C 61.42, H 4.62.

p-*Methoxy*-p′-*nitrobenzophenone Tosylhydrazone*

Yellow crystals (3.0 g from 4.0 g of the ketone (18), 45%), mp 191–192°C were obtained after recrystallization from chloroform–methanol. ^{1}Hmr ($CDCl_3$): δ 2.40 (s, 3H); δ 3.72, 3.83 (2s, 3H total); δ 7.50 (m, 13H); ir ($CHCl_3$): 3.03, 3.27, 3.39, 3.52, 6.22, 6.60, 7.39, 7.62, 7.96, 8.60, 10.19, 11.63.

Anal. calcd. for $C_{21}H_{19}N_3O_5S$: C 59.29, H 4.50; found: C 59.51, H 4.82.

p,p′-*Dinitrobenzophenone Tosylhydrazone*

Yellow needles (1.17 g from 1.0 g of the ketone, 84%), mp 198–201°C (dec.) were obtained after recrystallization from benzene–ethanol. ^{1}Hmr (acetone-d_6): δ 2.39 (s, 3H); δ 7.74 (m, 13H); ir ($CHCl_3$): 3.03, 3.30, 6.25, 6.58, 7.44, 7.63, 8.60, 9.35, 10.21, 11.41, 11.64, 11.88.

Anal. calcd. for $C_{20}H_{16}O_6N_4S$: C 54.55, H 3.66; found: C 54.30, H 3.72.

p-*Dimethylamino*-p′-*nitrobenzophenone Tosylhydrazone*

Benzene (250 mL), *p*′-dimethylamino-*p*′-nitrobenzophenone (24) (20 g, 0.074 mol), and *p*-toluenesulfonylhydrazide (16.6 g, 0.089 mol, 20% excess) were placed in a 500 mL round-bottom flask equipped with a reflux condenser, Dean–Stark trap, and drying tube. The reaction mixture was heated at reflux for 3 days, during which time approximately 1 mL water accumulated in the D–S trap. The reaction mixture was allowed to cool and the benzene was removed on a rotary evaporator to give a thick, dark orange oil. Absolute alcohol (100 mL) was added and the mixture was warmed on a steambath until the oil had dissolved. A light orange solid precipitated. After cooling in ice, the orange solid was collected by vacuum filtration. After recrystallization from tetrahydrofuran – absolute alcohol, orange crystals (17.2 g, 53%) of *p*-dimethylamino-*p*′-nitrobenzophenone tosylhydrazone were obtained.

Recrystallization from benzene – petroleum ether (30–60) resulted in two crystal forms; one, dark red cubes, and the other, an orange powder. The ^{1}Hmr spectra indicated that the two crystalline forms were composed of different ratios of *E* and *Z* isomers of the tosylhydrazone. ^{1}Hmr ($CDCl_3$): δ 2.40 (s, 3H); δ 3.00 (s, 6H); δ 7.24 (m, 13H); ir ($CHCl_3$): 3.05, 3.41, 6.23, 6.60, 7.45, 7.63, 8.61, 9.40, 10.24, 11.41, 11.64, 11.77, 12.22.

Anal. calcd. for $C_{22}H_{22}N_4O_4S$: C 60.27, H 5.06; found: C 60.15, H 5.21.

p-*Cyano*-p′-*dimethylaminobenzophenone Tosylhydrazone*

Yellow crystals (435 mg from 500 mg of the ketone, 52%), mp 178–179°C, were obtained from benzene–alcohol. ^{1}Hmr ($CDCl_3$): δ 2.42 (s, 3H); δ 3.03 (s, 6H); δ 7.30 (m, 13H); ir ($CHCl_3$): 3.04, 3.51, 4.48, 6.21, 6.93, 7.33, 7.61, 8.57, 9.35, 10.21, 11.41, 11.83, 12.21.

Anal. calcd. for $C_{23}H_{22}N_4O_4S$: C 66.01, H 5.30; found: C 65.84, H 5.43.

(p-*Dimethylaminophenyl*)-(p-*nitrophenyl*)*diazomethane* (**4**l)

In a 250 mL Erlenmeyer flask equipped with a magnetic stirring bar, *p*-dimethylamino-*p*′-nitrobenzophenone tosylhydrazone (760 mg, 1.74 mmol) and anhydrous diethyl ether (100 mL) were placed and the mixture was stirred for several minutes to allow as much as possible of the tosylhydrazone to dissolve. Potassium *tert*-butoxide (215 mg, 1.91 mmol, 10% excess) was added and the colour of the ether changed slowly from light orange to a deep red-orange. The flask was loosely corked and the reaction mixture was allowed to stir for 1 h in the dark. The red potassium salt of the tosylhydrazone was separated from the ether by gravity filtration, giving an orange ether solution and a deep red solid in the filter paper. The red salt was washed back into the Erlenmeyer flask with *n*-pentane and a total of 200 mL *n*-pentane was added. The flask was corked lightly and allowed to stir at room temperature in the dark. After 5 h, the mixture was filtered by gravity into a round-bottom flask covered with aluminum foil, giving an orange pentane solution and leaving the red salt behind in the filter paper. The pentane was removed on a rotary evaporator using a cold water bath. A red orange solid was obtained, the ir and visible absorption spectra of which indicated the presence of the desired (*p*-dimethylaminophenyl)-(*p*-nitrophenyl)diazomethane. The diazo compound was stored in a freezer at ca. −20°C. The potassium salt was washed back into the Erlenmeyer flask and more *n*-pentane (200 mL) was added. This process could be repeated until all of the salt had decomposed. However, since only small amounts of the diazo compound were required for the esr experiments and since **4***l* was found to be unstable, the salt decomposition was never carried to completion.

The purity of the (*p*-dimethylaminophenyl)-(*p*-nitrophenyl)-diazomethane was checked by both ^{1}Hmr and thin layer chromatography (tlc). The ^{1}Hmr spectrum showed one large singlet for the methyls of the dimethylamino group of the diazo compound and two much smaller singlets at approximately the same chemical shift, assigned to impurities. The purity was checked by tlc using alumina plates and benzene elution. The diazo compound in *n*-pentane, before solvent removal, showed one dark orange spot which moved rapidly and faded to pale yellow when exposed to room light. A faint spot with a much smaller R_f was also observed. The dark orange spot was assigned to the diazo compound. The red-orange solid obtained after removal of the pentane was also tested by tlc under identical conditions. Again, a dark orange spot with large R_f was observed. Two lighter spots of lower R_f, one visible only under uv light, were also observed. However, the diazo compound was the major spot. Based on ^{1}Hmr and tlc results, the diazo compound was estimated to be ca. 80% pure. ^{1}Hmr (CH_2Cl_2): δ 2.83 (s, 6H); δ 7.30 (m, 8H); ir ($CHCl_3$): 3.28, 3.40, 4.90, 6.22, 6.30, 7.43, 7.51, 8.35, 8.89.

Bis-(p-*nitrophenyl*)*diazomethane* (**4**k)

In a 25 mL round-bottom flask equipped with a magnetic stirring bar and drying tube, *p*,*p*′-dinitrobenzophenone tosylhydrazone (1.00 g, 2.27 mmol) and dry tetrahydrofuran (7 mL) were placed and the tosylhydrazone was allowed to dissolve. The solution was stirred slowly and potassium *tert*-butoxide (0.28 g, 2.5 mmol) was added. The solution turned deep orange immediately and an orange precipitate formed. After approximately 5 min, the orange potassium salt of the tosylhydrazone was collected in a Buchner funnel and washed with anhydrous ether. The salt was transferred to a 250 mL Erlenmeyer flask covered with aluminum foil and equipped with a magnetic stirring bar, anhydrous ether (200 mL) was added and the flask was loosely corked and allowed to stir at room temperature. After stirring overnight, the reaction mixture was filtered by gravity into a round-bottom flask covered with aluminum foil, giving a light yellow ether solution and leaving the orange salt in the filter paper. The ether was removed on a rotary evaporator to give a small amount of an orange solid, the ir of which showed a strong diazo stretching band at ca. 4.9 μm (2040 cm^{-1}). The salt was rinsed back into the Erlenmeyer flask, more ether was added, and the process was repeated. This procedure was continued until enough bis-(*p*-nitrophenyl)-diazomethane was accumulated for the experiments of interest to be performed. ^{1}Hmr (CH_2Cl_2): δ 7.83 (m, AA′BB′); ir ($CHCl_3$): 3.31, 4.85, 6.28, 6.58, 7.41, 7.50, 8.95, 11.75.

(p-*Nitrophenyl*)*phenyldiazomethane* (**4**j)

In a 100 mL round-bottom flask equipped with a magnetic stirring bar and drying tube, *p*-nitrobenzophenone tosylhydrazone (1.00 g, 2.52 mmol) and dry tetrahydrofuran (10 mL) were added and the tosylhydrazone was allowed to dissolve. The solution was stirred slowly and potassium *tert*-butoxide (0.31 g, 2.9 mmol) was added. The reaction mixture immediately turned deep red and, after a few minutes, the potassium salt of the tosylhydrazone began to precipitate. After about 10 min, anhydrous ether (60 mL) was added. The salt precipitated completely and was collected in a Buchner funnel and washed several times with anhydrous ether. The orange salt was transferred to a 250 mL Erlenmeyer flask equipped with a magnetic stirring bar and covered with aluminum foil. Anhydrous ether (150 mL) was added, the flask was loosely corked, and the mixture was allowed to stir at room temperature. After stirring overnight, the reaction was filtered by gravity to yield a light yellow ether layer. The ether solution was placed in a round-bottom flask covered with aluminum foil and the solvent was removed on a rotary evaporator with the water bath at room temperature. A small amount of orange solid was obtained, the ir spectrum of which showed a diazo stretching band at 4.88 μm as the strongest band in the spectrum.

The salt was rinsed from the filter paper back into the Erlenmeyer flask. More ether was added and the entire process was repeated until enough diazo compound was accumulated to perform the desired experiments. ^{1}Hmr (CD_2Cl_2): δ 7.14 (m, 5H); δ 7.62 (m, AA′BB′, 4H); ir ($CHCl_3$): 3.28, 4.88, 6.29, 6.62, 7.49, 8.31, 9.00.

*(*p*-Methylphenyl)-(*p*-nitrophenyl)diazomethane (4*m*)*

This compound was prepared by a method similar to that used to prepare **4***i*. ^{1}Hmr (CD_2Cl_2): δ 2.30 (s, 3H); δ 7.19 (s, 5H); δ 7.56 (m, AA′BB′, 4H); ir ($CHCl_3$): 3.33, 3.46, 4.87, 6.27, 6.61, 7.50, 8.32, 8.98.

*(*p*-Methoxyphenyl)-(*p*-nitrophenyl)diazomethane (4*h*)*

The same procedure was used as for **4***i*. ir ($CHCl_3$): 3.30, 3.50, 4.89, 6.29, 6.63, 7.50, 8.01, 9.00, 9.67.

*(*p*-Cyanophenyl)-(*p*-dimethylaminophenyl)diazomethane (4*o*)*

In a 125 mL Erlenmeyer flask equipped with a magnetic stirring bar, 400 mg (0.96 mmol) *p*-cyano-*p*′-dimethylaminobenzophenone tosylhydrazone and 15 mL dry tetrahydrofuran were added and the tosylhydrazone was allowed to dissolve. The solution was stirred slowly and 118 mg (1.05 mmol, 10% excess) potassium *tert*-butoxide was added. The solution slowly changed from light yellow to a deep yellow. After 15 min stirring, 50 mL *n*-pentane was added. The potassium salt of the tosylhydrazone precipitated and the yellow solid was allowed to settle. The solvent was decanted and the salt was washed once with 50 mL anhydrous ether. The Erlenmeyer flask was covered with aluminum foil and 100 mL anhydrous ether was added. The flask was loosely corked and the reaction mixture was allowed to stir at room temperature for 3 h. The reaction mixture was filtered by gravity into a round-bottom flask covered with aluminum foil, giving a light pink ether solution. The ether was removed on a rotary evaporator, using a cold water bath. A purple solid was obtained by the above procedure. The ir and uv spectra confirmed the formation of **4***o*. This compound was found to be comparatively unstable and was kept in a freezer until needed (ca. −20°C). ir ($CHCl_3$): 3.34, 3.49, 4.49, 4.90, 6.24, 6.60, 8.25.

Some thermodynamic aspects of dissolution of solid solutions of hydroxylapatites of phosphorus and arsenic

T. S. B. NARASARAJU[1] AND U. S. RAI

Department of Chemistry, Banaras Hindu University, Varanasi-221005, India

Received March 20, 1979

T. S. B. NARASARAJU and U. S. RAI. Can. J. Chem. 57, 2662 (1979).

The solubility equilibria of synthetic samples of hydroxylapatite, its arsenic isomorph, and a series of their solid solutions, spread over the entire compositional range, were investigated at 37°C in the pH range 5.0 to 7.6 in buffered systems through microanalytical determinations of calcium, phosphorus, and arsenic in their saturated solutions. From the ionic products of the samples so determined their stoichiometric dissolution was established and their free energies of solution evaluated.

T. S. B. NARASARAJU et U. S. RAI. Can. J. Chem. 57, 2662 (1979).

Opérant à 37°C, à des pH allant de 5.0 à 7.6 dans des systèmes tamponnées et faisant appel à des déterminations microanalytiques du calcium, du phosphore et de l'arsenic dans leurs solutions saturées, on a étudié les équilibres de solubilité d'échantillons de synthèse de l'hydroxylapatite, de son isomorphe contenant de l'arsenic et d'une série de leurs solutions solides variant sur toute l'échelle de composition. Sur la base des produits ioniques déterminés pour ces échantillons, on a établi leur dissolution stoechiométrique et on a évalué leurs énergies libres de solution.

Introduction

Phosphorus hydroxylapatite (PHA), $Ca_{10}(PO_4)_6(OH)_2$, the principal inorganic constituent of human bones and teeth (1), undergoes several anionic and cationic substitutions, significant among which from the point of view of arsenic poisoning (2, 3) being the replacement of PO_4^{3-} by AsO_4^{3-} resulting in the formation of its isomorph, arsenic hydroxylapatite (AsHA). It is evident that incomplete progress of such a substitution leads to the formation of a series of solid solutions of these isomorphs as shown by Montel and co-workers (4). Since bone processes, calcification and resorption, the deposition and dissolution respectively of PHA at the bone/body-fluid interface are controlled by its solubility, it was considered desirable to investigate the pH-dependence of solubilities of PHA, AsHA, and a series of their solid solutions over the entire compositional range under simulated biological conditions to throw light on the mechanism of arsenic incorporation and its likely reversal. The present paper which deals with such a series of investigations in the pH range 5.0 to 7.6 adopts a new approach towards the evaluation of their solubility products from which their free energies of solution have been calculated.

Experimental

The experimental details of preparation, characterization, and determination of solubilities of PHA, AsHA, and a series of their solid solutions were reported elsewhere (5–10), particular attention being paid to provide evidence for the homogeneity of the solid solutions based on the validity of Vegard's law. The solubility of each one of the samples was determined by analyses of its saturated solution at a few chosen pH values in the range 5.0 to 7.6, using suitable buffer combinations (10), the final pH of each system being measured using a pH meter (PHM 29, Radiometer, Copenhagen). To overcome the complications involved in the microdetermination of the products of dissolution of the samples of apatites, three different analytical procedures were adopted for the analyses of the saturated solutions of (*i*) PHA, (*ii*) AsHA, and (*iii*) solid solutions of (*i*) and (*ii*). While the method adopted for (*i*) is the same as that reported earlier (11, 12), solutions of (*ii*) could be analysed by an extension of method (*i*) to a combination of calcium and arsenic instead of calcium and phosphorus, the only difference being that the reduction of the corresponding heteropoly acid to molybdenum blue was by heating the solution for about 15 min over a water bath since the process is considerably slower for arsenic than for phosphorus at ordinary temperatures.

While saturated solutions of PHA and AsHA could be analysed for calcium and phosphorus or arsenic as described above, complications arose in the case of systems involving the solid solutions. Consequent upon the similarity in the behaviour of phosphorus and arsenic towards their spectrophotometric determination based on the formation of molybdenum blue, a combined determination of the two elements in the saturated solution of the systems involving the solid solutions of PHA and AsHA was attempted. Concentration of arsenic was then obtained by subtracting the phosphorus content determined by masking (13) of arsenic as mentioned above from the combined value. Such an indirect procedure had to be adopted for the analysis of the systems of the solid solutions since alternative techniques were not available for the purpose.

Results and Discussion

The weight percent errors in the quantitative

determinations of calcium, phosphorus, and arsenic when present together were found to be ± 0.6, ± 1.7, and ± 2.5 respectively. The details of the analytical data of Ca^{2+}, PO_4^{3-}, and AsO_4^{3-}, the associated calculations (6) as well as the pH range used, leading to the evaluation of the ionic product, K_{ip} (represented as pK_{ip}, equal to $-\log K_{ip}$) and the free energy of solution, ΔG_{soln}, of each sample have been included in the Depository of Unpublished Data.[2] From the average pK_{ip} values of the samples obtained from the analysis of their saturated solution, values of ΔG_{soln} were calculated; a consolidated account of these two sets of values is given in columns 3 and 4 respectively of Table 1. The details of the theoretical implications involved in considering the ionic products of these solutes to be synonymous with their corresponding solubility products have been mentioned earlier (14, 15).

The present investigations could establish that the solubilities of PHA, AsHA, and their solid solutions increased with increasing hydrogen ion concentration of the medium of dissolution.[2] This could be justified on the basis of the establishment of a series of simultaneous equilibria in the saturated solutions of these samples and their dependence (15) on the H_3O^+ ion activity of the medium. It may be mentioned that the set of equilibria operative in the case of AsHA is analogous to that of PHA while both sets are established in the case of their solid solutions.

It can be concluded from the pK_{ip} values given in column 3 of Table 1 that the solubilities of the samples increased with an increase in the proportion of AsHA. This could be explained on the basis of the higher dissociation constants (6, 10) of H_3AsO_4 ($K_1 = 4.0 \times 10^{-3}$, $K_2 = 1.0 \times 10^{-7}$, and $K_3 = 3.2 \times 10^{-12}$) over the corresponding values of H_3PO_4 ($K_1 = 7.51 \times 10^{-3}$, $K_2 = 6.33 \times 10^{-8}$, and $K_3 = 4.73 \times 10^{-13}$). An additional theoretical substantiation of this experimental finding can be made on the basis of alterations in lattice and solvation energies of ionic crystals brought about by anionic replacement, the rest of the ions being left undisturbed. The tetrahedral covalent radius (16) of AsO_4^{3-} (1.18 Å) being higher than that of PO_4^{3-} (1.10 Å) the lattice of AsHA can be supposed to be less firmly bound than that of PHA. Solvation energies of the constituent ions of the two lattices being nearly the same, loose packing associated with the lattice of AsHA can account for its higher solubility. That AsHA is relatively less stable than PHA is evident from the experimental ΔG_{soln} values given in column 4 of Table 1. The reported (17) increase in the solubilities of sodium halides in the order NaF, NaCl, NaBr, and NaI may be suggested to justify this observation. However, solubilities of RbF and RbI do not follow this sequence. It is evident that ΔG_{soln} depends exclusively on the balance of entropy and enthalpy terms and hence the above argument does not merit a generalization.

In accordance with the earlier observations (15, 18–21) the analytical data of the saturated solutions of the samples could establish stoichiometric dissolution on the basis of the proximity of the Ca/(P or As or both) values to the theoretical value of 1.67 (as indicated by materials in the Depository of Unpublished Data). In addition, as is to be expected from the variation in lattice energies of the samples with a replacement of PO_4^{3-} by AsO_4^{3-}, a fairly systematic gradation of ΔG_{soln} values with increase in the proportion of PHA could be observed, absence of regularity in this gradation being attributed to the fluctuations in the determination of pK_{ip} values which amount to about $\pm$ 1.5. Since the difference in the ΔG_{soln} values of the end members (PHA and AsHA) is about 20, which is much above the limits of fluctuation, the above conclusion can be justified.

TABLE 1. Ionic products and free energies of solution of hydroxylapatites of phosphorus and arsenic and their solid solutions*

Sample Number	Molecular formula of the sample	Average pK_{ip}	ΔG_{soln} (kcal/mol)
1	$Ca_{10}(PO_4)_6(OH)_2$	107.8	153.9
2	$Ca_{10}(PO_4)_{5.4}(AsO_4)_{0.6}(OH)_2$	107.9	154.1
3	$Ca_{10}(PO_4)_{4.8}(AsO_4)_{1.2}(OH)_2$	108.1	154.3
4	$Ca_{10}(PO_4)_{4.2}(AsO_4)_{1.8}(OH)_2$	107.9	154.1
5	$Ca_{10}(PO_4)_{3.6}(AsO_4)_{2.4}(OH)_2$	105.6	150.8
6	$Ca_{10}(PO_4)_{3.0}(AsO_4)_{3.0}(OH)_2$	105.1	150.1
7	$Ca_{10}(PO_4)_{2.4}(AsO_4)_{3.6}(OH)_2$	102.0	145.6
8	$Ca_{10}(PO_4)_{1.8}(AsO_4)_{4.2}(OH)_2$	99.9	142.6
9	$Ca_{10}(PO_4)_{1.2}(AsO_4)_{4.8}(OH)_2$	98.9	141.2
10	$Ca_{10}(PO_4)_{0.6}(AsO_4)_{5.4}(OH)_2$	96.6	137.9
11	$Ca_{10}(AsO_4)_6(OH)_2$	94.5	134.9

*Details of analytical data of Ca^{2+}, PO_4^{3-}, and AsO_4^{3-}, the associated calculations as well as the pH ranges used have been included in the Depository of Unpublished Data.

Thermochemistry of tantalum(V) bromide

ALAN D. WESTLAND

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received May 8, 1979

ALAN D. WESTLAND. Can. J. Chem. 57, 2665 (1979).

The enthalpy of formation of crystalline $TaBr_5$ is found by solution calorimetry to be -142.9 ± 0.4 kcal mol^{-1}. Estimates of entropies and heat capacities lead to thermochemical quantities for the liquid and gaseous compound as well.

ALAN D. WESTLAND. Can. J. Chem. 57, 2665 (1979).

On a trouvé, par calorimétrie en solution, que l'enthalpie de formation du composé cristallin $TaBr_5$ est de -142.9 ± 0.4 kcal mol^{-1}. Des évaluations des entropies et des capacités calorifiques permettent de déduire les quantités thermochimiques des composés à l'état liquide et à l'état gazeux.

[Traduit par le journal]

In the course of measuring the bromide ion affinity of gaseous $TaBr_4$ it was necessary to obtain the standard enthalpy of formation of the compound and this in turn required a knowledge of the enthalpy of formation of the pentabromide. The literature contains two values which are not in good agreement. The present work was undertaken in order to resolve the question.

Shchukarev *et al.* reported a value of -145.6 ± 1.0 kcal mol^{-1} for the enthalpy of formation of $TaBr_5$ which was based upon measurement of the enthalpy of hydrolysis of the compound (1). When their value is revised by making use of the most recent auxiliary data (2) a value of -147.0 kcal mol^{-1} is obtained. Gross *et al.* subsequently determined the enthalpy of formation by direct combustion and obtained the value -142.96 kcal mol^{-1} (3). The combustion measurements carried out on other systems by the latter workers have been of generally high quality. However, in favour of the Russian work is the accuracy of their value of ΔH_f^0 for $TaCl_5$ which they reported in the same publication (1) and which was based in part on some of the same data which led to the pentabromide value. Moreover, we have found that if the combustion of tantalum is momentarily inefficient, a refractory tribromide is formed which does not subsequently brominate easily to $TaBr_5$. McCarley and Boatman reported a similar finding (4). Gross *et al.* indeed found the reaction with bromine to be so sluggish that it was necessary to operate the calorimeter at 110°C and correct the value so obtained to 298 K with the aid of estimated heat capacities.

It was decided to employ an independent method based on the dissolving of $TaBr_5$ and tantalum metal in aqueous hydrofluoric acid. The procedure devised by Schäfer and Kahlenberg and used by them to examine the pentachloride (5) was followed exactly. In following Schäfer and Kahlenberg it was possible to verify some of their data for partial processes common to the chloride and bromide thermal cycles and this served to minimize some of the uncertainty associated with solution calorimetry where many terms may have to be added in the cycle.

Experimental

Calorimeter

The calorimeter consisted of a Dewar vessel and attachments which was immersed in a water thermostat maintained at 25.00 ± 0.05°C. The Dewar volume was 600 cm^3. The top of the calorimeter had five inlets which contained respectively a spiral stirrer, a thermistor, a calibration heater, a sample container, and a cooling well. All glass surfaces were coated with a wax composed of 90% paraffin and 10% butyl rubber sealant (Lepage's Ltd).

The thermistor (Sargent-Welch Model S81750-12) was immersed in oil in a thin-walled well. The thermistor resistance was measured by means of a Sargent-Welch Model 81601 thermometric bridge connected to a Wheelco 1 mV recorder. The sensitivity was ±0.001°C. Non-linearity of the thermistor was compensated for by calibrating after each run over the same temperature interval as in the dissolution process. This was achieved by evaporating small quantities of liquid nitrogen in the cooling well by which means the calorimeter could be brought back to its original temperature before the electrical heating was begun.

The heater was a spiral of No. 30 constantan wire which was immersed in oil. Its resistance was 4.160 ± 0.003 ohms. The leads were No. 22 gauge copper wire. Current for the heater was drawn from a large 2 V accumulator. The current was measured by means of a potentiometer (Derritron Electronics Model No. E4224) connected across a 0.2 ohm standard resistance.

Solid samples were contained in thin-walled quartz bulbs which were crushed on a silver spike mounted in a plastic housing. The exterior surface of the bulbs was coated with wax. A blank experiment showed that the operation of crushing the bulb generated negligible heat (≤ 0.2 cal).

In order to measure the enthalpy of dilution of concentrated hydrofluoric acid solutions, the bulb-breaking device was re-

0008-4042/79/192665-04$01.00/0

placed by a cylindrical silver vessel (2.5 × 11 cm) mounted on a Teflon sleeve. The bottom of this cup was affixed with wax and could be knocked out in order to allow the contained liquid to mix with the outer liquid. When the concentrated acid contained platinum, the silver cup was also coated with wax.

Reaction periods lasted no longer than 2 min. Errors in the corrections for heat loss or gain during the reaction period were estimated to be no greater than 0.1%. The operation of the calorimeter was checked by measuring the heat of neutralization of tris(hydroxymethyl)aminomethane (THAM) (6). This indicated that the electrical circuitry and timer were correctly calibrated to ±0.2%.

Materials

Tantalum Pentabromide

Tantalum foil (99.95%) was supplied by Fansteel Metals, Inc. The bromide was prepared by heating the metal in purified bromine vapour in a previously evacuated, sealed system. The product was handled in a dry nitrogen atmosphere and stored in sealed ampoules. Bromine in the samples was determined by totally hydrolyzing the compound in a closed container with aqueous hydroxide and completing the determination by the Volhard method. *Anal.* calcd. for $TaBr_5$: Br 68.83; found: Br 68.73.

Hydrofluoric Acid

Two solutions were prepared from the concentrated acid (Analar). The concentrations were established by alkalimetric titration of weighed portions. A standardized burette was employed. (*a*) Hydrofluoric acid containing 26.97 ± 0.04% w/w HF. The 40.00 g portions of this acid used later contained 0.5391 mol HF and 1.621 mol H_2O. (*b*) Hydrofluoric acid containing 3.47 ± 0.01% w/w HF. A 349.7 g portion of this was used as a solvent for $TaBr_5$. This portion contained 0.6064 mol HF and 18.74 mol H_2O.

Hydrobromic Acid

A dilute solution which contained 0.7285 ± 0.0003% w/w HBr was used as a calorimeter liquid in the study of partial process [II] (*vide infra*). A 306.9 g portion contained 0.02763 mol HBr and 16.91 mol H_2O.

H_2PtCl_6-solution

A platinum catalyst solution identical to that used by Schäfer and Kahlenberg was prepared (5).

The Partial Processes

A thermal cycle analogous to that described by Schäfer and Kahlenberg was employed (5). The first step of this cycle involves the dissolving of tantalum metal in aqueous HF. This was done by Schäfer and Kahlenberg who employed 1.0 g of 6 μm thick foil. In order that the previous authors' value for the heat of solution of tantalum could be used in the present work, acids of the same concentration were used throughout.[1] The following list of partial processes therefore corresponds to that of the German workers.

Reactions [II] to [IV] were examined experimentally in this laboratory. The enthalpy of reaction [I] was taken from ref. 5. The enthalpies of reactions [V] to [VIII] were obtained from standard literature sources (2, 7).

The quantities shown in the following reactions refer to 1 mol of tantalum. The quantities contained in braces denote solution compositions in terms of moles of the solutes and the solvent water. The quantities used in the actual calorimeter runs are given in the details which follow these equations.

[I] $Ta(c) + \{109.7; 0.00165H_2PtCl_6; 331.7H_2O\} \xrightarrow{\Delta H_1} \{TaF_5; 104.7HF; 0.0369HCl; 331.7H_2O\} + 0.00615Pt + (2.5\text{–}0.0123)H_2(g)$

[II] $\{TaF_5; 104.7HF; 0.0369HCl; 331.7H_2O\} + \{5.00HBr; 3060H_2O\} \xrightarrow{\Delta H_2} \{TaF_5; 104.7HF; 5HBr; 0.0369HCl; 3391.7H_2O\}$

[III] $\{TaF_5; 104.7HF; 5.00HBr; 0.0369HCl; 3391.7H_2O\} \xrightarrow{\Delta H_3} TaBr_5(c) + \{109.7HF; 0.0369HCl; 3391.7H_2O\}$

[IV] $\{109.7HF + 3390.06H_2O\} \xrightarrow{\Delta H_4} \{109.7HF; 330.06H_2O\} + 3060H_2O\,(l)$

[V] $2.5H_2(g) + 2.5Br_2(l) + 3060H_2O(l) \xrightarrow{\Delta H_5} \{5.00HBr; 3060H_2O\}$

[VI] $\{0.0369HCl; 1.64H_2O\} + 0.00615Pt \xrightarrow{\Delta H_6} \{0.00615H_2PtCl_6; 1.64H_2O\} + 0.0123H_2(g)$

[VII] $\{109.7HF; 330.06H_2O\} + \{0.00615H_2PtCl_6; 1.64H_2O\} \xrightarrow{\Delta H_7} \{109.7HF; 0.00615H_2PtCl_6; 331.7H_2O\}$

[VIII] $\{109.7HF; 0.0369HCl; 3391.7H_2O\} \xrightarrow{\Delta H_8} \{0.0369HCl; 1.64H_2O\} + \{109.7HF; 3390.06H_2O\}$

The sum of these partial processes yields

$$Ta(c) + 2.5\,Br_2(l) = TaBr_5(c)$$

for which

$$\Delta H_f^0(TaBr_5(c)) = \sum_1^8 \Delta H_i$$

Process [I]: Dissolving of Tantalum in Hydrofluoric Acid

Schäfer and Kahlenberg (5) dissolved 1.000 g tantalum foil in a mixture of 45.00 g hydrofluoric acid (0.6065 mol HF +

[1]This was done for economy. A quotation of $200 per g for 10 μm foil led us to abandon our intention to repeat the measurements for the first process.

1.824 mol H_2O) with 0.170 cm^3 of H_2PtCl_6 solution (34×10^{-6} mol H_2PtCl_6 + 9.05×10^{-3} mol H_2O). Their mean value was $\Delta H_1 = -99.66 \pm 0.1$ kcal/mol. This value includes a correction for the heat of evaporation of the hydrofluoric acid caused by the evolution of hydrogen. The platinum catalyzes the reaction.

Process [II]: Dilution of the Tantalum Solution from Process [I]

In the present work, tantalum solutions {TaF_5; 104.7HF; 0.0369HCl; 331.7H_2O} were prepared from 0.1 mm thick tantalum foil. The dissolving process was too slow with foil of this thickness for a calorimetric study. The metal (0.889 g) was dissolved in 40.00 g of 26.97% HF to which was added 0.15 g of the H_2PtCl_6-solution. After the solution had been allowed to stand for 2 days[2] it was thoroughly mixed and a 41.04 g portion diluted in the calorimeter with 272.8 g of 0.7285% hydrobromic acid. The mean of three values of the enthalpy of dilution gave $\Delta H_2 = -22.7 \pm 0.2$ kcal based on 1.0 mol of tantalum.

Process [III]: Dissolving of Tantalum(V) Bromide

Owing to the extreme moisture sensitivity of $TaBr_5$, the product was inevitably hydrolyzed to a slight extent. The enthalpies of solution were corrected by dividing by the purity where purity = observed % Br/calculated % Br. This assumes that a given quantity of moisture totally hydrolyzes an equivalent amount of the halide:

$$n\mathrm{TaBr_5} + 5\mathrm{H_2O} \rightarrow \mathrm{Ta_2O_5} + (n-2)\mathrm{TaBr_5} + 10\mathrm{HBr}$$

This is perhaps an oversimplification.

It was not convenient to work with exactly 3.208 g portions of $TaBr_5$ as indicated by the ideal partial reaction [III]. Instead, various quantities were dissolved in 3.47% hydrofluoric acid and the mean value chosen. The data shown in Table 1 indicate that enthalpies of solution are independent, within experimental error, of the quantity of $TaBr_5$ taken; thus, the compound behaves in solution as if it were infinitely dilute. The results give $\Delta H_3 = +96.04 \pm 0.12$ kcal mol^{-1}.

The solution so obtained, when referred to 1 mol of tantalum, must still be mixed with the solution {0.0369HCl; 0.7H_2O} in order for the above reaction to correspond to partial process [III]. This would entail a negligible heat of mixing (< 0.1 kcal).

Process [IV]: Dilution of Hydrofluoric Acid

Portions (40.00 g) of 26.97% hydrofluoric acid were diluted with 270.8 g portions of water. The mean of four determinations gave $+27.9 \pm 0.2$ kcal. This is 0.1 kcal less than the value reported by Schäfer and Kahlenberg. A possible reason for this difference may be the presence of silica in the acid used in the former work. It was common for acid to contain silica. The acid used in the present study was reported by the manufacturer to contain 0.1% SiF_4. In any case, the error would appear also in ΔH_2 with a reversed sign. Thus $\Delta H_2 + \Delta H_4 = 5.2$ kcal in both the present and the former work of Schäfer and Kahlenberg.

Process [V]: Enthalpy of Formation of Hydrobromic Acid

Interpolation of the literature data (2) gives $\Delta H_5 = -144.68$ kcal. The preamble to ref. 2 suggests that the uncertainty in this figure is no greater than ± 0.10 kcal.

[2]Although Schäfer and Kahlenberg report that foil of 6 μm thickness dissolved rapidly to form Ta(V), we found that the thicker metal led to the formation of brown–yellow solutions which became colourless only after several hours. Schäfer and Kahlenberg observed such an effect with niobium (8). The coloured species was believed to be metal in the 3+ oxidation state.

TABLE 1. Enthalpy of solution of $TaBr_5$

Sample weight (g)	$-\Delta H$ (kcal mol^{-1})
0.6480	96.22
1.0244	96.06
1.2059	96.03
1.3128	95.88
2.5335	96.01
	Mean 96.04 ± 0.12

TABLE 2. Enthalpies of partial processes

Enthalpy	Value
ΔH_1	-99.66 ± 0.15
ΔH_2	-22.7 ± 0.2
ΔH_3	$+96.04 \pm 0.12$
ΔH_4	$+27.9 \pm 0.2$
ΔH_5	-144.68 ± 0.15
ΔH_6	$+0.43 \pm 0.02$
ΔH_7	-0.23
ΔH_8	~ 0

Process [VI]: Reduction of the H_2PtCl_6-solution

The literature data yield the value $\Delta H_6 = -0.43 \pm 0.02$ kcal (2).

Process [VII]: Enthalpy of Dilution

We neglect the small H_2PtCl_6 content. The enthalpy of dilution of the hydrofluoric acid is then $\Delta H_7 = -0.23$ kcal (2).

Process [VIII]: Enthalpy of Mixing

The literature does not contain data for the mixing of hydrochloric and hydrofluoric acids. However, Schäfer and Kahlenberg (5) have bracketed the value and find $\Delta H_8 < 0.1$ kcal.

The partial process enthalpies are summarized in Table 2. The sum of the partial enthalpies gives:

$$\Delta H_f^0(\mathrm{TaBr_5(c)}\ 298\ \mathrm{K}) = -142.9 \pm 0.4\ \mathrm{kcal\ mol^{-1}}$$

It is possible to estimate the quantities shown in Table 3.

Estimates of entropies and heat capacities were based on data for similar reference compounds which are available in standard compilations (2, 6). The heat capacities were derived from $ZrBr_4$(c) and $TiBr_4$(g) by an application of Kopp's Law. The halogen contribution was obtained by subtracting the heat capacities of the metals at 298 K. The heat capacity of tantalum metal was then added to the halogen contribution extrapolated to five atoms of bromine.

The entropies of crystalline compounds likewise obey an additivity law which is a corollary of Kopp's Law. The related compounds $TaCl_5$, UCl_4, UCl_5, UBr_4, and $ThBr_4$ permit us to infer the standard entropies of $TaBr_5$ by making use of the following approximate principles: (*i*) The contribution of the halogen in a pentahalide is taken to be 5/4 that for a tetrahalide. (*ii*) Given the value of S_{298}^0 for a chloride, the increment in entropy which would result by replacing Cl by Br is the same in all analogous compounds, e.g. in UCl_4 and UBr_4.

The heat of fusion, 10.9 kcal mol^{-1} (9, 10), affords the value of ΔH_f^0 for the liquid. Two sets of workers have measured the sublimation pressures of $TaBr_5$(c) over a range of temperature extending from 453 to 540 K (10, 11). These data lead to enthalpies of sublimation of 25.4 and 25.8 kcal mol^{-1} respectively. We estimate from the heat capacities given in Table 3 a correction of +1.3 kcal mol^{-1} in converting from 498 K to

TABLE 3. Thermochemical data for $TaBr_5$ at 298 K

State	ΔH_f^0 (kcal mol^{-1})	S^0 (eu)	ΔG_f^0 (kcal mol^{-1})	C_p
Crystalline	-142.9 ± 0.4	67 ± 2	-133	$29+19\times10^{-3}T$
Liquid	-132.0 ± 0.4			
Gaseous	-116.0 ± 0.6	115 ± 3	-120	$31-2\times10^{5}T^{-2}$

298 K. We thus propose ΔH(subl. 298 K) = 26.9 kcal mol^{-1}. From the same vapour pressure data we obtain ΔS(subl. 498 K) = 44.0 cal deg^{-1} mol^{-1}. The heat capacity correction (+3.5 cal deg^{-1} mol^{-1}) therefore gives ΔS(subl. 298 K) = 47.5 cal deg^{-1} mol^{-1}.

The empirical formula of Geiseler (12) gives the value $S^0(TaBr_5(g)$ 298 K) = 116.9 cal deg^{-1} mol^{-1} which agrees well with the estimate recorded in Table 3.

Hill, Worsley, and Hepler have provided estimates of entropies which are very close to ours (13).

Photochemical ring expansion of a bridged cyclobutanone. Crystal and molecular structure of the photoproduct acetal

TREVOR J. GREENHOUGH, JOHN R. SCHEFFER, JAMES TROTTER, AND LEUEEN WALSH

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received December 8, 1978

TREVOR J. GREENHOUGH, JOHN R. SCHEFFER, JAMES TROTTER, and LEUEEN WALSH. Can. J. Chem. **57**, 2669 (1979).

The photochemistry of the bridged cyclobutanone system 1,3,4,6,8,9-hexamethyltricyclo-[4.4.0.0^{3,10}]decane-2,5-dione has been studied. Irradiation in methanol leads to a single ring-expanded cyclic acetal whose structure was determined by X-ray crystallography. The reaction represents the first example of oxacarbene formation in a bridged cyclobutanone. Rationalization of the observed regioselectivity on the basis of alkyl substitution effects on radical stability following α-cleavage is inappropriate since the starting cyclobutanone bears equal α and α′ substitution. An alternative explanation involving alkyl radical angle strain and hyperconjugation effects is advanced.

TREVOR J. GREENHOUGH, JOHN R. SCHEFFER, JAMES TROTTER et LEUEEN WALSH. Can. J. Chem. **57**, 2669 (1979).

On a étudié la photochimie du système cyclobutanone ponté hexaméthyl-1,3,4,6,8,9 tricyclo[4.4.0.0^{3,10}] décanedione-2,5. L'irradiation dans le méthanol conduit à la formation d'un seul acétal cyclique, résultant d'une extention de cycle dont la structure a été déterminée par diffraction des rayons-X. Cette réaction correspond au premier exemple de formation du oxacarbène dans une cyclobutanone pontée. Il ne serait pas approprié de rationaliser la régiosélectivité observée en utilisant les effets de substitution alkyle sur la stabilité des radicaux provenant d'un clivage α puisque les substituants en α et en α′ de la cyclobutanone de départ sont semblables. On propose une autre explication impliquant la tension angulaire alkyl-radical et des effets d'hyperconjugaison.

[Traduit par le journal]

Introduction

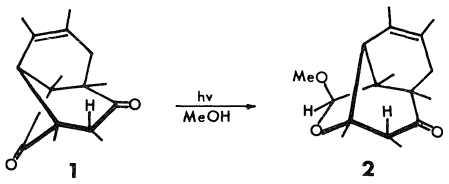
The photochemistry of cyclobutanones is a subject of continuing interest and investigation (1–3). For monocyclic or fused bicyclic cyclobutanones, three major photochemical pathways have been identified, (*a*) reverse 2 + 2 fragmentation (cycloelimination) to yield ketenes and olefins, (*b*) decarbonylation, and (*c*) ring expansion via oxacarbenes to afford (in alcoholic solvents) cyclic acetals.

This latter process is favored by increasing alkyl substitution at the α-carbon atoms of the four membered ring as well as by substituents (e.g., β-cyclopropyl) which increase the cyclobutanone internal angle strain. Also effective in directing reaction toward this pathway are cyclobutanone substituents which electronically stabilize the product oxacarbene, for example α-ethylenic and α-cyclopropyl moieties.

Both biradical (initial alkyl–acyl cleavage) and concerted mechanisms have been considered in oxacarbene formation owing to the fact that the reaction exhibits features characteristic of each. For example, oxacarbene formation is regiospecific, the major product generally (but not always (4)) being explicable in terms of formation of the more stable of the two possible biradical intermediates. On the other hand (and consistent with a concerted process), oxacarbene formation is generally found to be stereospecific (1–3), the reaction proceeding with retention of configuration at the cyclobutanone α-carbon atom. To accommodate these and other experimental observations, Morton and Turro (1) have suggested a "biradical-like" transition state (and not a freely rotating acyl–alkyl biradical) as the direct precursor of the oxacarbene species.

Perusal of the literature reveals that oxacarbene formation has never been observed for cyclobutanone systems which are *bridged* across positions 2 and 4. Of the few substrates of this type which have been irradiated, one undergoes decarbonylation (ref. 5, as quoted in ref. 1, footnote 89), one takes part in unsaturated aldehyde formation (6), and the others (which are bridged β,γ-unsaturated cyclobutanones) either rearrange via 1,3-acyl shifts (7), decarbonylate (7*a*), or undergo cyclo-elimination (8). The source of this avoidance of oxacarbene formation is not apparent, and in order to clarify the situation, we have undertaken a study of the photochemistry of the bridged cyclobutanone 1,3,4,6,8,9-hexamethyltricyclo[4.4.0.0^{3,10}]decane-2,5-dione (**1**, Scheme 1). The present paper describes the high yield formation of an oxacarbene-derived product from irradiation of **1**

0008-4042/79/192669-08$01.00/0



SCHEME 1

in methanol and summarizes the elucidation of the photoproduct structure via X-ray crystallography.

Results

Cyclobutanones having the basic tricyclo-[4.4.0.0^{3,10}]decane-2,5-dione structure of **1** are readily available through irradiation ($\lambda > 340$ nm) of Diels–Alder adducts between duroquinone and acyclic 1,3-dienes (9); the substrate **1** is derived from the 2,3-dimethylbutadiene–duroquinone adduct (9*a*). Photolysis of cyclobutanone **1** (uv n $\rightarrow \pi^*\lambda_{max}^{MeOH}$ 300 nm, ε 66) in methanol solvent through Pyrex rapidly and cleanly afforded a single major photoproduct in 70–80% yield. More than a dozen minor photoproducts could be detected by flame ionization glc but were present in amounts too small to permit isolation.

The photoproduct is isolated as a colorless solid, mp 49.5–51.5°C, ir, (KBr) 5.89 (C=O) μ; nmr (270 MHz, $CDCl_3$) δ 1.03 (d, 3H, J = 7 Hz), 1.05 (s, 3H), 1.36 (s, 3H), 0.92 (s, 3H), 1.64 (broad s, 3H), 1.79 (broad s, 3H), 2.12 and 1.69 (calculated) (AB q, J = 18.5 Hz), 2.41 (q, 1H, J = 7 Hz), 2.44 (s, 1H), 3.32 (s, 3H), and 4.40 (s, 1H); mass spectrum parent (70 eV) *m/e* 278.

These data clearly indicate that the photoproduct has an oxacarbene-derived cyclic acetal structure. They do not, however, allow one to distinguish between the structure **2** and its "opposite" in which the cyclic ether oxygen atom and the methoxyl bearing carbon atom are interchanged. In addition the data do not permit a definitive assignment of the stereochemistry at the methoxyl bearing carbon. For these reasons a direct method X-ray crystal structure investigation was undertaken. The results of this study, the details of which are given below, unequivocally identify **2** as the structure of the major photoproduct.

X-ray Crystal Structure Determination

Crystallization of the photoproduct **2** from hexane afforded well-formed colorless plates suitable for X-ray examination. Initial unit cell parameters and the space group were established from a series of precession photographs. A crystal of dimensions ca. 0.18 × 0.18 × 0.09 mm was mounted with the normal to (10$\bar{1}$) approximately parallel to the φ axis of the goniometer. Accurate unit-cell dimensions were obtained by a least-squares analysis of the setting angles of 25 reflections ($60 < 2\theta < 80°$) automatically located and centered in the counter of an Enraf Nonius CAD-4F diffractometer using Ni filtered CuK_α radiation.

Crystal data for 1α,4,5α,7α,9,10-hexamethyl-2β-methoxy-3-oxatricyclo[5.4.0.0^{4,11}]undec-9-ene-6-one (**2**):

$C_{17}H_{26}O_3$ fw = 278.4
Monoclinic, a = 13.9190(8), b = 8.5880(12), c = 13.6506(7) Å, β = 105.02(1)°, V = 1576.0(1) Å^3, Z = 4, ρ_c = 1.173 g cm^{-3}, $F(000)$ = 608 (22°C, CuK_α, λ = 1.5418 Å, μ = 5.9 cm^{-1}). Absent reflections: 0k0, $k \neq 2n$, and h0l, $l \neq 2n$, space group $P2_1/c$ (C_{2h}^5, No. 14).

Diffractometer data provided a total of 3252 independent reflections out to $2\theta_{max}$ = 150° using an ω–2θ scan with variable scan width and scan speed. The ω scan angle was set to (1.10 + 0.5 tan θ)°, the midpoint being calculated using the average wavelength $(\lambda\alpha_1 + \lambda\alpha_2)/2$, with a 25% extension each side for background determination. The scan speed for each reflection was determined by a prescan using a speed of 20.0116/NPIPRE deg/min with NPIPRE set to 2. This prescan gives I_{net} = INT − 2(BGL + BGR) and $\sigma(I_{net})$ = (INT + 4(BGL + BGR))$^{1/2}$ where INT is the scan total and BGL and BGR are the left and right background count totals. For reflections giving more than 30 000 counts/s the reflected beam was attenuated (factor 26.92) and the scan repeated at the same speed; for all other reflections the final scan speed was determined by SIGPRE, SIGMA, and ITMAX. SIGPRE, the prescan acceptance parameter, was set to 0.5 so that reflections giving $\sigma(I_{net})/I_{net} > 0.5$ were considered unobserved; SIGMA was set to 0.05 leading to acceptance of the prescan data when $\sigma(I_{net})/I_{net} \leq 0.05$. All other reflections were rescanned at speeds determined by these parameters and ITMAX, the maximum scan time which was set to 120 s. The final scan speed of 20.0116/NPI was determined from NPI = NPIPRE((σ(I_{net})/I_{net})/SIGMA)^2 with NPI_{max} calculated from NPI_{max} = ITMAX/3(SCAN ANGLE). Thus, using the prescan information, reflections more than 20σ above background were collected at 2°/min, very strong intensities being attenuated, those less than 2σ above background were considered unobserved, and those in between were collected at speeds inversely proportional to the relative σ(I)/I down to a minimum of NPI = 23 or 0.91°/min. The intensities of three check reflections remained constant to within ±3% throughout the data collection, and reorientation, set to take place

when a deviation of 0.05° or more from the calculated position of the scattering vectors of any of three orientation control reflections occurred, was not required.

Lorentz and polarization corrections were applied in the usual manner along with check reflection scaling, and the derived structure amplitudes were corrected for absorption by the Gaussian integration method using the program BICABS, which gave maximum and minimum transmission factors for the correction of F^2 of 0.9088 (15,2,4) and 0.8048 ($0,\bar{2},\bar{16}$). Of the 3252 reflections measured, 1305 had $I < 3\sigma(I)$ where $\sigma^2(I) = S + B + (0.07S)^2$ with S = scan count and B the time averaged background count.

Structure Analysis

The structure was solved by direct methods. A total of 449 $|E|$-values greater than 1.5 was used to determine eight sets of signs by Sayre relationships in an iterative procedure (10). One set of signs was outstanding with a consistency index of 0.77, and an E map computed from the 216 positive and 233 negative values of E in this set contained twenty large peaks which accounted for the non-hydrogen atoms. Three cycles of isotropic followed by three cycles of anisotropic full-matrix least-squares refinement of the C and O atoms gave $R = 0.10$ using unit weights, and a subsequent difference-Fourier synthesis allowed 19 of the 26 hydrogen atoms to be located. After further refinement including the hydrogen positional parameters, R was 0.067 and the outstanding hydrogen atoms were located from a difference-Fourier synthesis. The final cycles of least-squares refinement included the isotropic thermal parameters of the hydrogen atoms and an isotropic extinction parameter g (11) and gave the final R-index of 0.043 for 1943 observed reflections. The function minimized was $\sum w(|F_o| - |F_c|)^2$ where F_c is extinction corrected. The chosen weights were $1/\sigma^2(F)$ and weighting analyses confirmed their suitability, the final value of $R_w = [\sum w(|F_o| - |F_c|)^2/\sum w|F_o|^2]^{1/2}$ being 0.058 and the standard deviation of an observation of unit weight (σ_1) 1.04. A difference-Fourier synthesis calculated after the final cycle of refinement showed maximum fluctuations of ± 0.25 e/Å^3, the greatest parameter shift being 0.176σ and the average 0.008σ on the final cycle. Atomic scattering factors for C and O were taken from ref. 12 and those for H from ref. 13. The final positional and thermal parameters are given in Tables 1 and 2[1] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

Thermal Motion Analysis and Molecular Geometry Correction

The thermal motion of the molecule was analyzed in terms of rigid-body translation (**T**), libration (**L**), and screw motion (**S**) (14) using the computer program RIGIDB. Different sets of atoms contributing to the assumed rigid body were inspected, omitting hydrogen atoms. Approximating the whole molecule to a rigid-body gave rms $\Delta U_{ij} = 0.0040$ Å^2 com-

[1]The structure factor table and Tables 2 and 3 (thermal parameters) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

pared to the rms deviation in U_{ij} of 0.0012 Å^2. The agreement between observed and calculated U_{ij} for this model was particularly poor for C(101) and O(61), and omitting these atoms from the model gave rms ΔU_{ij} = 0.0026 Å^2, indicating a reasonable rigid body approximation. The analysis results are given in Table 3.[1] **T** is roughly isotropic and the principal axes of **L** are oriented 4° from the C(5)—C(2) vector (L_1), 14° from O(3)—O(61) (L_2) and 16° from O(3)—C(1) (L_3).

Bond distances corrected for libration (15) using shape parameters q^2 of 0.08 for all atoms are included in Table 4 along with the uncorrected distances. The libration corrections are all less than twice the esd of the uncorrected bond length and bond distances referred to in the discussion are the uncorrected values.

Discussion of the X-ray Crystal Structure

Figure 1 shows a stereoscopic view of the molecule and the atomic numbering scheme. Bond lengths and angles are given in Tables 4 and 5. Selected dihedral angles are given in Table 6. The structure analysis shows that the major photoproduct has the tricyclic acetal structure **2** (Scheme 1).

The six-membered ring containing the carbonyl group is in the chair conformation with C(1), C(4), C(5), and C(7) in plane and C(6) and C(11) displaced above and below the plane by 0.51 and 0.89 Å, respectively. The carbonyl group is slightly nonplanar, with O(61) displaced by 0.012 Å (6σ) from the C(5) to C(7) plane. The methyl group C(51) is in the equatorial configuration with respect to this ring, consistent with maximizing intramolecular contact distances in this molecular conformation.

The other six-membered ring, C(1) and C(7) to C(11), is in a half-chair conformation with C(8) to C(11) in plane and C(1) and C(7) on opposite sides of the plane displaced by 0.59 and 0.17 Å, respectively. The torsion about the C(9)=C(10) double bond is 1.1(2)°. The five-membered ring is in a slightly twisted envelope conformation (see Table 6) with C(11) displaced by 0.65 Å from the mean plane of C(1), C(2), O(3), C(4).

The bond lengths generally agree well with expected values, with mean C(sp^3)—C(sp^3) 1.533 and

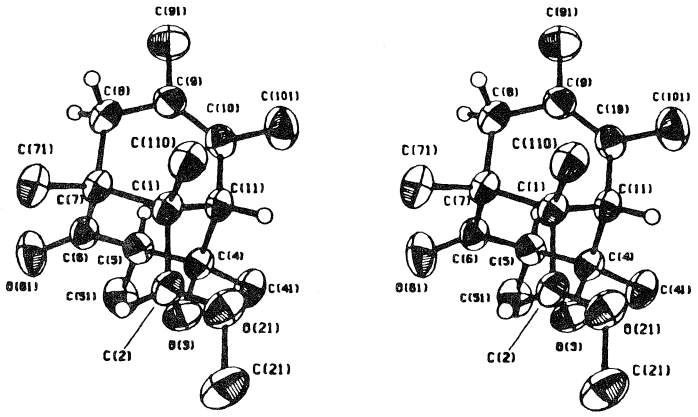

FIG. 1. Stereoscopic view of photoproduct **2**. The methyl hydrogen atoms have been omitted for clarity.

		C(6)—C(7)	−44.2(2)
		C(7)—C(1)	−49.7(2)

mean C(sp^2)—C(sp^3) 1.509 Å compared to normal values of 1.534 (16) and 1.510 Å (17), respectively; C=C is 1.332(3), C=O 1.213(3), and mean C—H 0.98 Å. The lengthening of the C(1)—C(7) distance, 1.560(3) Å, is possibly due to the intramolecular crowding (see Table 7); the bond lengths and angles in general do not indicate a large amount of strain in the molecule. The C(sp^3)—O bond distances average 1.427 Å with C(21)—O(21) as expected at 1.427(3) Å (17) and C(4)—O(3), O(3)—C(2), and C(2)—O(21) at 1.458(3), 1.411(2), and 1.412(2) Å, differing by +0.031, −0.016, and −0.015 Å from the mean value. It is interesting that the variations in the C—O bond distances are similar to those observed in the methyl acetal groups of methyl α-pyranoses such as methyl α-D-galactopyranoside monohydrate and methyl α-D-altopyranoside (18), where the bond distances comparable to C(4)—O(3), O(3)—C(2), and C(2)—O(21) are 1.439, 1.418, 1.405 and 1.440, 1.416, 1.405 Å respectively. A shortening of −0.016 Å for the two C—O bonds associated with the anomeric carbon in methyl α-pyranoses has

TABLE 7. Selected intra- and intermolecular* contacts

C(1)···O(21)	2.400(2)	C(110)—H(711)[3]	2.99(3)
O(3)···C(11)	2.344(3)	H(113)—H(82)[4]	2.39(5)
O(3)···O(21)	2.321(2)	H(102)—H(2)[5]	2.50(5)
C(2)···C(11)	2.349(3)		
C(6)···C(8)	2.477(3)		
C(7)···C(11)	2.487(3)		
C(7)···C(2)	2.533(3)		
O(3)···H(2)	1.97(2)		
C(6)···H(5)	1.97(2)		
O(21)···H(2)	1.94(2)		

*X—X < 3.5 Å, X—H < 3.0 Å, H—H < 2.5 Å (X = C, O). Superscripts refer to atoms at positions [1] $-x, -y, -z-1$; [2] $1-x, 1/2+y, 1/2-z$; [3] $-x, 1-y, -z$; [4] $x, 1/2-y, z-1/2$; [5] $x, y-1, z$.

been predicted (19). In the β-pyranoses the predicted shortening is −0.009 (in ring) and −0.041 Å (equatorial anomeric C—O), in general agreement with observed values such as those in methyl β-cellobioside-methanol (20). In the oxolane ring, described as intermediate between envelope and twist, of the tricyclic photoproduct $C_{15}H_{24}O_3$ (21) the torsion angles and C—O bond distances are similar to those found here, with the equivalents of C(4)—O(3), O(3)—C(2), C(2)—O(21), and O(21)—C(21) at 1.435(4), 1.417(5), 1.403(6), and 1.430(5) Å. The fact that C(4)—O(3) here (1.458(3) Å) is significantly longer than those compared above may be due to the same intramolecular steric effects which give the C(1)—C(7) distance of 1.560(3) Å (see Table 7).

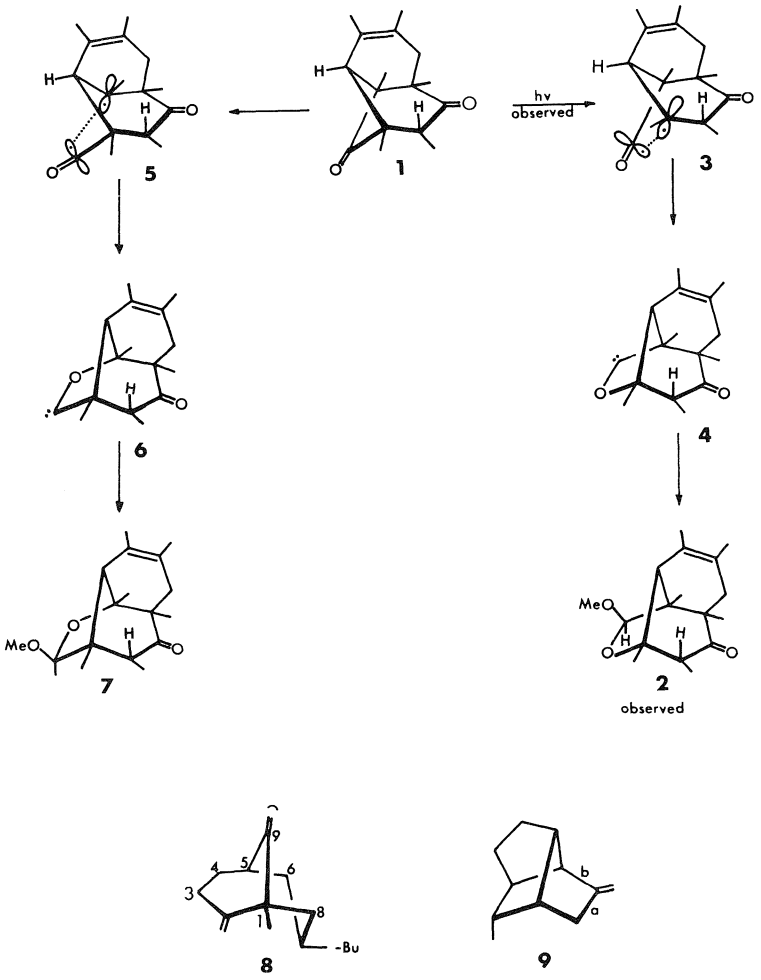
The C(1)—C(2)—O(21)—C(21) torsion angle is 174.1° with C(21) *trans* to C(1) corresponding to the preferred orientation in methyl glycosides (18) and to that predicted for this group in the 2-alkoxyhydropyrans (22). The bond angles at C(1), C(11), and C(4) within the five-membered ring are all well below tetrahedral values at 100.4(1), 101.0(2), and 102.8(2)°, respectively. Selected intermolecular contact distances, which correspond to van der Waals interactions, and intramolecular non-bonded distances are given in Table 7.

Discussion of the Photochemical Results

The present photochemical results indicate that there is no inherent difference in photochemical reactivity between bridged cyclobutanones and their fused or monocyclic counterparts and that all can take part in oxacarbene formation. The observation of a *single* ring-expanded cyclic acetal in the case of cyclobutanone **1** is, however, intriguing and worthy of further comment.

There are at least three possible explanations for the preference for formation of cyclic acetal **2** rather than its regioisomer **7** (Scheme 2). In order to discuss these possibilities we adopt Morton and Turro's (1) notion of an acyl–alkyl biradical-like transition state (**3** and **5**) as leading to the two possible intermediate oxacarbenes **4** and **6** respectively. (*A*) We first consider the possibility that the relative amounts of **2** and **7** could be governed by the rates of reaction of methanol with oxacarbene intermediates **4** and **6** respectively. This explanation appears unlikely, however, in view of the close structural similarities between these latter two species. (*B*) Secondly, the possibility exists that oxacarbene intermediate **6** could be reverting to **1** faster than the analogous return of oxacarbene **4** to **1**. While we cannot at present rigorously rule this possibility out, we deem it unlikely since there is good reason to believe (*vide infra*) that the forward process **1** → **3** → **4** is associated with a lower activation energy than the **1** → **5** → **6** sequence. Microscopic reversibility plus the realization that **4** and **6** should have very nearly equal energies thus renders explanation (*B*) improbable. (*C*) It thus appears most likely that the relative amounts of final products **2** and **7** are controlled by the relative rates of rearrangement of photoexcited **1** to oxacarbenes **4** and **6**, i.e., by the relative energetics of biradicaloid transition states **3** and **5** respectively.

It should be noted at the outset that the standard explanation of preferential α-cleavage of the more highly substituted acyl–alkyl carbon–carbon bond does not suffice in the case of cyclobutanone **1**; both carbon atoms α to the four-membered ring carbonyl group of **1** are equally substituted with two ring residues and one methyl group. However, one obvious difference between biradicaloids **3** and **5** involves the location of the alkyl radical portion in



SCHEME 2

each. In **5** it is situated on the one-carbon bridge of a bicyclo[3.3.1]nonyl system whereas in species **3** the developing *p*-orbital is located on one of the three-carbon bridges. We suggest that one significant factor involved in favoring transition state **3** over transition state **5** concerns the angle strain experienced by the incipient alkyl radical centers in each. While the requirement for trigonal, planar geometry is less stringent for free radicals as compared to carbocations, it does seem reasonable to suggest that **3** will be able to approach this favorable arrangement more easily than **5**. This idea is borne out by X-ray crystal structure data on bicyclo[3.3.1]nonyl systems. A good example is provided by diketone **8** (23) (Scheme 2) in which the C(1)—C(9)—C(5) angle (112.5°, model for transition state **5**) is considerably distorted from the ideal of 120° relative to the C(1)—C(2)—C(3) angle (116.7°, model for transition state **3**). Analogous effects are presumably involved in the preference for oxacarbene formation via cleavage of bond (*a*) rather than bond (*b*) in the photolysis of ketone **9** (24) (Scheme 2).

A second important factor which favors transition state **3** over transition state **5** involves the extra stabilization afforded **3** by hyperconjugation of the alkyl radical center with its adjacent non-methyl β-hydrogen atom. Such delocalization is of course not possible in biradicaloid **5** due to the bridgehead nature of the relevant β-hydrogen atom involved. The existence of radical hyperconjugation is clearly indicated by esr measurements on alkyl radicals bearing β-hydrogen atoms which show large β-hyperfine coupling constants (25).

One final point concerns the stereoselectivity of the reaction of methanol with the intermediate oxacarbene **4**. It could be argued that such stereoselectivity indicates approach of methanol from the *exo* face with concerted insertion of the carbene into the oxygen–hydrogen bond. Such an interpretation, while speculative, is in accord with (*a*) the preferred

direction of approach of most reagents to the bicyclo[2.2.1] system (incorporated in the oxacarbene portion of **4**) and (*b*) the singlet nature of the photochemical oxacarbene-forming reactions of cyclobutanones (1, 3).

Experimental

Photolysis of Cyclobutanone 1

Cyclobutanone **1** was prepared as described in ref. 9*a*, uv $n \rightarrow \pi^* \lambda_{max}^{MeOH}$ 300 nm, ε 66. A solution of 101 mg of **1** in 170 mL of methanol containing 1.4 g of sodium carbonate (to avoid acid-catalyzed reactions) was irradiated through Pyrex using a 450 W medium pressure mercury lamp and immersion well apparatus. The reaction was monitored by glc (5 ft × 1/8 in. stainless steel column packed with 5% OV-17 on 80/100 Chromosorb W, column temperature 175°C) which showed the buildup of one major photoproduct and at least a dozen minor products. After 10.7 h of photolysis the mixture consisted of 53% of photoproduct **2** and 25% of starting material **1**; none of the other photoproducts was present in amounts greater than 7% (product percentages are estimated without use of internal standards and are approximate only). Cyclic acetal **2** was isolated by preparative glc (5 ft × 1/4 in. stainless steel column packed with 5% OV-17 on 80/100 Varaport 30 operating at 160°C) and exhibited the physical and spectroscopic data outlined in the text. Large clear single crystals were grown from concentrated hexane solutions. *Anal.* calcd. for $C_{17}H_{26}O_3$: C 73.35, H 9.41; found: C 73.29, H 9.56.

COMMUNICATION

Thermal explosions of methyl isocyanide: a re-examination of the data

HUW O. PRITCHARD

Chemistry Department, York University, Downsview, Ont., Canada M3J 1P3

Received June 4, 1979

HUW O. PRITCHARD. Can. J. Chem. 57, 2677 (1979).

By the use of an improved interpolation method for the rate constants for the thermal isomerisation of methyl isocyanide, it is found that a pattern emerges in the previously unexplained scaling behaviour of the critical explosion parameter (δ_c). At low Rayleigh number (where δ_c should be constant) the ratio $(\delta/Ra)_c$ for a fixed temperature is approximately constant for seven spherical vessels of volumes 0.3 to 5 L. Also, in the limit of very large vessels, or very high temperatures, it appears that the Arrhenius temperature coefficient of $(\delta/Ra)_c$ tends to the activation energy of the reaction.

HUW O. PRITCHARD. Can. J. Chem. 57, 2677 (1979).

L'emploi d'une méthode améliorée d'interpolation des constantes de vitesse dans l'isomérisation thermique de l'isocyanure de méthyle a permis de faire la lumière sur la tendance à l'augmentation, non expliquée précédemment, du paramètre d'explosion critique (δ_c). Pour des valeurs faibles des nombres de Rayleigh (où δ_c doit être constant) le rapport $(\delta/Ra)_c$ à température donnée est approximativement constant pour sept récipients sphériques dont le volume varie de 0.3 à 5 L. Dans le cas limite de très grand récipients ou de très hautes températures, il apparait également que la valeur du coefficient de température d'Arrhénius $(\delta/Ra)_c$ tend vers l'énergie d'activation de la réaction.

[Traduit par le journal]

In the two existing studies of the thermal explosions of methyl isocyanide vapour (1, 2) the rate constants for the isomerisation reaction in the explosion temperature range were estimated by extrapolation procedures: in the former study, the rough-and-ready assumption was made that the shape of the unimolecular fall-off curve for 230°C could be taken as constant and used to estimate the rate constants in the range 280–350°C; in the latter study, empirical extrapolation formulae were generated (3) from conventional static and flow experiments at lower temperature. Tyler (4) has shown that near 280°C, such extrapolated values are in error by some 25%, and we have found that the formulae of ref. 3 do not give monotonically varying rate constants above 300°C. However, it is known (3, 5) that at infinite pressure and in the absence of self-heating, the rate constant for the isomerisation of methyl isocyanide is strict-Arrhenius in form. Moreover, we are now able to calculate unimolecular fall-off from these infinite-pressure rates with considerable confidence (5); hence all the required rate constants have been recalculated in this way, and the results are shown in Table 1. Also shown in this table are the recalculated values of the critical explosion parameter δ_c and the Rayleigh number Ra: the thermal conductivity data used in these calculations are our own (2), the viscosity data are those of Vines and Bennett (6) for methyl cyanide extrapolated linearly into the interesting temperature range; the heat capacity, likewise, is that of methyl cyanide.

Apart from some alterations to the actual numbers,[1] the pattern of the δ_c values differs little from

[1]The data from ref. 1 are not included in Table 1 since, in general, they do not fall at the tabulated temperature values. The revised rate constants and values of δ_c and Ra, recalculated from newer enthalpy and thermal conductivity data (2), and values of $(\delta/Ra)_c$, are as follows

T (°C)	10^2k (s^{-1})	δ_c	Ra	$(\delta/Ra)_c$
285	1.18	13.9	(2540)	(6)
292	1.56	11.6	(1087)	(11)
300	2.08	11.1	(612)	(18)
312	3.39	11.1	240	46
323	5.04	11.1	119	93
335	7.47	10.8	55	195
344	9.60	10.1	32	319
351	12.0	10.2	22	468

At an earlier stage (2), we suspected that there could be a temperature discrepancy between the works of refs. 1 and 2: for example, an error in the temperature of 2°C would change δ_c by about 10%, and these values of δ_c seem to be 10–20% below those for the 1.0 L vessel in Table 1. However, the values of $(\delta/Ra)_c$ of 93 and 319 at $T = 323$ and 344°C respectively are not out of line with the values in Table 1 of about 80 and about 260 at 320 and 340°C respectively, so that, despite appearances, both sets of data could be quite consistent.

	(4210	**1**)	416	**6**	123	**23**	36	**80**	8	**240**	5	**610**

*The rate constants are calculated from the infinite-pressure data of Collister and Pritchard (3) viz. $A_\infty = 10^{13.35}$ s^{-1}, $E_\infty = 38.2$ kcal/mol, together with the procedures of Yau and Pritchard (5); the entries in parentheses have Ra significantly greater than 400, see final paragraph of Discussion section.

that already published in Table 1 of ref. 2, and the conclusions remain the same, i.e., (*i*) for a given vessel, and provided that Ra is below 400–500, δ_c is independent of temperature, but there is some considerable scatter, well outside the limits of the precision of the experiments. (*ii*) with the exception of the 5 L vessel, for which δ_c appears to be a little lower than the theoretical value for a sphere (7) of about 3.75, all the values of δ_c are very much higher than expected.

The fourth number for each tabular entry in Table 1 is the ratio $(\delta/Ra)_c$ and it can be seen that, for a fixed temperature, this ratio is remarkably constant, if one excludes points with $Ra \gg 400$; the data for $T = 320$°C are particularly impressive.

It appears that there are two regimes in these thermal explosions. The first is a high-pressure regime for which $Ra > 400$: below this Rayleigh number, the critical temperature rise ΔT_c is correctly predicted by standard theory, but above this value, the temperature profiles cease to be uniform (8) and the observed values of ΔT_c fall considerably below the theoretical values (1, 8). However, in the low-pressure regime, the critical explosion conditions are defined, not by δ_c = constant for all r and T, but by $(\delta/Ra)_c$ = constant for all r (r being the radius of the vessel).

In normal circumstances, it is conventional to plot $R \ln p_c/T^3$ vs. T^{-1} whence[2] the slope is the activation energy E of the reaction (9): for the data described here (cf. Table 1 of ref. 2) the slopes lie in the range 20–23 kcal/mol, fortuitously (?) close to the value of Q, the exothermicity of the reaction. On the other hand, plots of $R \ln (\delta/Ra)_c$ vs. T^{-1} are reasonable straight lines, with slopes in the range 36–39 kcal/mol. The reason for this is fairly clear at high temperature or for large volumes: in this temperature range $Ra \sim$ constant $\times r^3 p_c^2/\lambda T^4$ (the extra power of T arises because the viscosity $\sim cT$) and $\delta_c \sim$ constant $\times r^2 p_c k/\lambda T^3$ (where k is the rate constant and λ is the thermal conductivity); thus $(\delta/Ra)_c \sim$ constant $\times k r^{-1} p_c^{-1} T^{-1}$. Now, for very large vessels or for very high temperatures, the explosion pressure changes very little with temperature, so that for fixed r, the temperature coefficient of $(\delta/Ra)_c$ is dominated (especially since p_c and T vary in opposite senses) by that of the rate constant k itself, i.e., E, the activation energy, which is about 36 kcal/mol at these low pressures (5).

It is not clear at the present time why it should be that standard explosion theory can predict the correct temperature rise in these systems, provided Ra is low, but that it cannot predict the critical explosion pressure. If the present correlation of δ_c with Ra is significant, then clearly we have to consider other as yet unsuspected energy transport mechanisms which alone, or severally, cause an inhibition of the explosion in small vessels, but perhaps also make the explosion somewhat easier in very large vessels. It does not seem likely that the fault lies in the neglect of convection, as might be signalled by the correlation of δ_c with Ra: the onset of convective effects, which destroy the ideal temperature profiles above $Ra = 400$, are clearly seen both in this system (1) and in others (8). It seems more likely that the

[2]This relationship assumes that the thermal conductivity is independent of temperature: since λ is roughly proportional to T, this will introduce a small difference of the order of RT.

present correlation of δ_c with Ra is accidental in the sense that the hitherto unsuspected mechanism is not convection, but some other transport process which when taken together with the thermal conductivity gives a net transport rate which appears to scale roughly with the Rayleigh number.

I have chosen, for the time being, to exclude from consideration those results for which Ra $\gg$ 400 for two reasons: one, that the principal problem at the moment is to understand the explosion behaviour in the range Ra $<$ 400 where δ_c should be constant; two, that in the convective explosions when Ra $\gg$ 400, the calculation of Ra itself (using for example, as in ref. 1, a constant value of ΔT_c) is a considerable oversimplification. However, when one considers that the values of Ra in parentheses in Table 1 and in footnote 1 are somewhat too large, it is not entirely impossible that all the values of $(\delta/\mathrm{Ra})_c$ conform to a single pattern — compare the value for 285°C (in footnote 1) with that for 280°C (in Table 1), or the five values for $T = 300$°C.

Ketone or diazoalkane formation from Δ^3-1,3,4-oxadiazolin-2-ones. Details of two competing thermolysis mechanisms[1]

ANTHONY JAMES PAINE[2] AND JOHN WARKENTIN[2]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received April 5, 1979

ANTHONY JAMES PAINE and JOHN WARKENTIN. Can. J. Chem. **57**, 2681 (1979).

The title compounds thermolyse at 50–100°C in a variety of solvents via two (and only two) competing unimolecular pathways, one producing a diazoalkane and carbon dioxide, the other a ketone, carbon monoxide, and dinitrogen. Diazoalkane formation is favoured by polar solvents and electron-donating substituents, with a Hammett ρ of −1.93 for seven *p*-substituted 5-methyl-5-phenyloxadiazolinones. Moderate solvent polarity effects, secondary kinetic isotope effects (2.1 ± 0.3% per D for **2***b*-d_6), the Hammett ρ, and Frontier Molecular Orbital Theory, all support concerted diazoalkane formation through a transition state with non-synchronous bond rupture.

Neither decomposition mode shows any correlation with Taft steric parameters, E_s, and ketone formation does not correlate with inductive parameters. The enthalpy change during the exothermic three piece fragmentation was calculated to be only -30 ± 2 kcal mol^{-1}, precluding chemiluminescence. A vigorous search for intermediates by esr, ms, CIDNP, trapping, and racemization experiments leads to the conclusion that ketone formation must also be concerted.

A new oxidation procedure using lead tetraacetate in the presence of five equivalents of trifluoroacetic acid was useful in the synthesis of oxadiazolinones from ketone semicarbazones which would not cyclize under normal LTA oxidation conditions.

ANTHONY JAMES PAINE et JOHN WARKENTIN. Can. J. Chem. **57**, 2681 (1979).

Les composés mentionnés subissent la thermolyse à 50–100°C dans différents solvants par l'intermédiaire de deux (et seulement deux) processus unimoléculaires compétitifs. L'un de ces processus fournit un diazoalcane et du dioxyde de carbone, l'autre produit une cétone, du dioxyde de carbone et de l'azote. La formation du diazoalcane est favorisée par les solvants polaires et les substituants électrodonneurs, avec un paramètre de Hammett ρ = −1.93 pour sept méthyl-5 phényl-5 oxadiazolinones substituées en position *para*. Tous les facteurs suivants: l'effet des solvants modérément polaires, l'effet cinétique isotopique (2.1 ± 0.3% par D pour **2***b*-d_6), le paramètre ρ de Hammett et la théorie des orbitales moléculaires frontières militent en faveur de la formation concertée du diazoalcane par l'intermédiaire d'un état de transition impliquant une rupture asynchrone de la liaison.

Aucune méthode de décomposition ne correspond aux paramètres stériques de Taft, E_s, et la formation de la cétone ne correspond pas aux paramètres d'induction. La réaction de fragmentation en trois parties est exothermique et la faible valeur de $\Delta H = -30 \pm 2$ kcal mol^{-1} obtenue par les calculs exclut la possibilité d'une réaction chimiluminescente. Une recherche approfondie des intermédiaires au moyen de diverses techniques d'analyse, telles la rpe, la spectrométrie de masse, la CIDNP, l'isolation des produits et la racémisation, a permis de conclure que la formation de la cétone est également concertée.

Un nouveau processus d'oxidation qui utilise du tétraacétate de plomb en présence de cinq equivalents d'acide trifluoroacétique a aidé à la synthèse d'oxydiazolinones à partir de semicarbazones de cétone qui ne se cyclisent pas sous des conditions normales d'oxidation par tétraacetate de plomb (TAP).

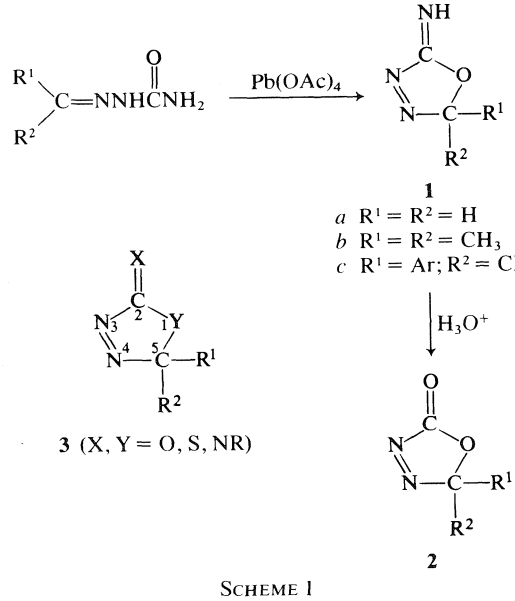
Introduction

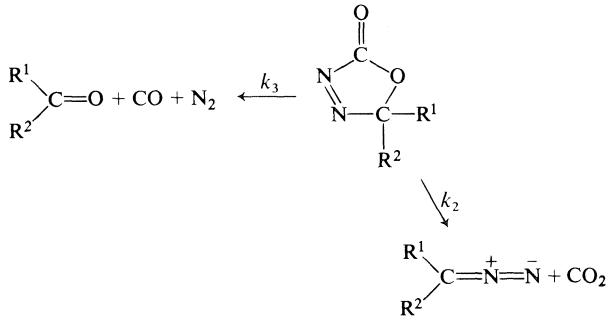
Δ^3-1,3,4-Oxadiazolin-2-ones (**2**, Scheme 1) are the most reactive of a series of heterocyclic compounds of general structure **3** under study in this laboratory. The ring system **3** is characterized by two possible thermolysis modes, one generating $R_1R_2C{=}Y$, together with N_2 and $:C{=}X$, and another producing a diazoalkane ($R_1R_2C{=}\overset{+}{N}{=}\overset{-}{N}$) concomitant with $X{=}C{=}Y$. The former reaction has been shown to produce carbon monosulfide from 5,5-dimethyl-1-phenyl-Δ^3-1,3,4-triazolin-2-thione (**3**; X = S, Y = NPh) (1). Generation of diazoalkanes bestows synthetic utility upon the two piece fragmentation, and thermolyses of oxadiazolinones (**2**) as well as phenyliminooxadiazolines (**3**; X = NPh, Y = O) have recently been exploited, the first as a good alternative method for the conversion of α,β-epoxyketones to acetylenic carbonyl compounds (2) and the second as an alternative route to oxindoles, hydantoins, and related heterocycles (3).

The title oxadiazolinones are easily prepared from ketone semicarbazones by oxidative cyclization with lead tetraacetate (LTA), followed by acid hydrolysis (Scheme 1) (4). When both R groups are alkyl, isolated yields of oxadiazolinones are near 80%, based on semicarbazone, but if aldehyde semicarbazones are used, tautomerization of the intermediate iminooxadiazoline (**1**) prevents the desired reaction (5).

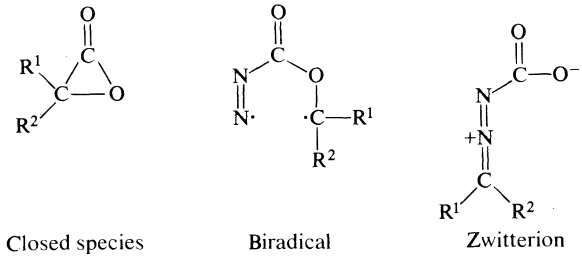
The oxadiazolinone ring system undergoes competing unimolecular fragmentations at modest temperatures (less than 100°C). One of these produces diazoalkane by carbon dioxide loss, the other ketone



SCHEME 1



Some possible intermediates—



Closed species Biradical Zwitterion

SCHEME 2

by carbon monoxide and nitrogen extrusion (Scheme 2) (6).

A preliminary kinetic study (6) suggested that the balance between the two decomposition modes is dependent on solvent polarity, for the yield of diazoalkane increased on changing solvent from carbon tetrachloride to methanol. Solvent effects on the individual rate constants were qualitatively assessed in terms of a nonpolar ketone-forming transition state and a polar diazoalkane-forming transition state. We now wish to report the results of more detailed mechanistic studies which provide considerable insight on the transition state structures for these reactions. By exposing the underlying factors controlling the balance between the rates of these competing reactions, comprehensive mechanistic information permits partial control of the diazoalkane-forming reaction for synthetic purposes. In addition, it illuminates one example of a relatively rare chemical phenomenon — a three piece fragmentation to stable molecules.

Methods, Results, and Discussion

There are several, a priori, mechanistic alternatives for these thermolyses. Either one or both reactions could be completely concerted, for both thermal reactions are symmetry allowed. Diazoalkane and carbon dioxide are produced by what is formally a 1,3-dipolar cycloreversion, while ketone, carbon monoxide, and nitrogen arise from a $\sigma 2s + \sigma 2s + \sigma 2s$ cycloreversion (7). Among stepwise alternatives, there exists a plethora of possibilities because either

of the two bonds broken during diazoalkane formation could be broken in the rate determining step, while any one or two of three bonds broken in the ketone formation might be broken in the slow step. The possible alternatives may be grouped according to the type of intermediate involved. As Scheme 2 exemplifies, these might include zwitterions (such as that from O1—C5 bond heterolysis) or biradicals (for example, from homolysis of the N4—C5 bond) or even closed-shell molecules. It is important to remember that these two competing decomposition modes each have several possible intermediates of each of the three types in Scheme 2 from which a choice must be made; those structures in the Scheme are only a few reasonable examples.

The kinetic analysis of this reacting system is straightforward. From the disappearance of the starting oxadiazolinone, as monitored by its uv absorption at 360 nm (azo n $\rightarrow \pi^*$) or its ir carbonyl stretch at 1835 cm^{-1}, excellent concentration-independent, first order plots for the total rate constant, $k_T = k_2 + k_3$, are obtained. To dissect this further into the two individual rate constants, the product distribution is required. Since the diazoalkane formed on thermolysis is usually subject to several different fates (none of which ultimately produce ketone), only the time infinity ketone yield was quantitatively analysed by calibrated gas chromatography or infrared spectroscopy. From the fraction of ketone formed, k_3 is easily calculated, and hence k_2 by difference.

That only two primary processes occur can be verified by trapping the diazoalkane with a few percent trifluoroacetic acid (TFA). In these experiments, monitored by nmr, only ketone and trifluoroacetic acid ester are observed, indicating that the other, often unidentified, products formed in the absence of TFA, arose from subsequent reactions of diazoalkane, usually with itself or with solvent. Furthermore, even though only ketone was quantitatively assayed, better linear-free energy relationship correlations (*vide infra*) were always obtained for diazoalkane formation. Had an unknown third process been operative, large systematic errors would have surfaced in the diazoalkane correlations.

Product Distributions

Relevant to the synthetic potential of oxadiazolinones as diazoalkane precursors are the data pictorialized in Fig. 1. The two lines show how the delicate balance between the two competing decomposition routes is affected by solvent polarity. To facilitate comparison to current literature on cycloaddition and cycloreversion reactions, the polarity parameter used here is Dimroth's E_T value

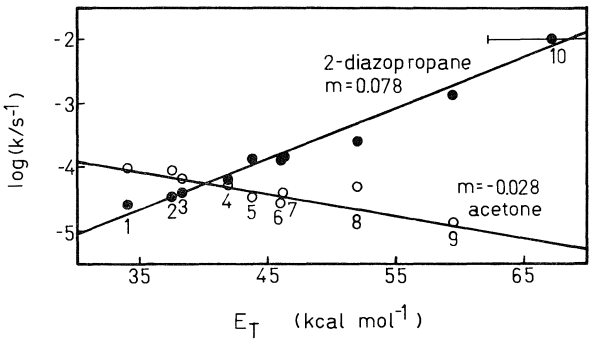


FIG. 1. Effect of solvent polarity on rates of 2-diazopropane (k_2) and of acetone (k_3) formation from **2***b* at 85.0°C. The solvents are: 1 (toluene), 2 (chlorobenzene), 3 (DME), 4 (DCE), 5 (DMF), 6 (acetonitrile), 7 (nitromethane), 8 (acetic acid), 9 (TFE), and 10 (TFA). The E_T value for TFA is estimated in Appendix I. Product composition as a function of E_T can be estimated for untried solvents from this plot. For example, it is 50:50 at the E_T value where the regression lines intersect, and 91:9, or 9:91 at the E_T values for which the ordinates of the two lines differ by one log unit. The slopes of the lines are given by *m*.

(see ref. 8 for an excellent review of solvent polarity parameters). An E_T value for TFA was estimated from correlations with other polarity parameters (see Appendix I). For the 5,5-dimethyl compound, the diazoalkane yield increases from about 20% in toluene, up through chlorobenzene, 1,2-dimethoxyethane (DME), 1,2-dichloroethane (DCE), nitrobenzene, dimethylformamide (DMF), nitromethane, acetonitrile, acetic acid, and 1,1,1-trifluoroethanol (TFE) to TFA where one obtains diazoalkane exclusively.

The effect of substituent polarity, as measured by the Hammett σ parameter, on the product distribution from *para*-substituted 5-phenyl-5-methyloxadiazolinones, can be determined from Fig. 2. Even weak electron donors such as methyl and phenyl strongly favour the diazoalkane route, although a relatively polar solvent, acetonitrile, was used to obtain these data. Note also that these compounds were thermolysed at 50°C compared to 85°C for the 5,5-dialkyl oxadiazolinones. These are unstable compounds indeed, and many could only be purified by column chromatography at Dry Ice temperatures.

Substituted acetophenone semicarbazones, in which the *para*-substituent is strongly electron withdrawing (NO_2, CN, or CF_3) would not cyclize under normal oxidation conditions (LTA in methylene chloride at room temperature, 2 h). For these compounds and for other semicarbazones especially insoluble in methylene chloride (e.g., *p*-C_6H_5), addition of five equivalents of trifluoroacetic acid boosted the oxidative capability and a rapid reaction

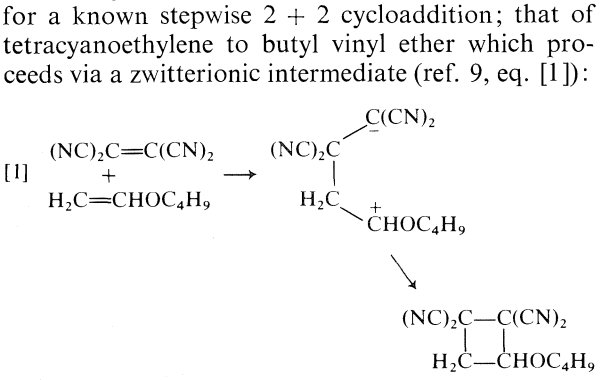
occurred at lower temperatures. This mixed oxidizing system gave unique results not observed with lead tetratrifluoroacetate itself. For details see the Experimental section.

Kinetic Investigations

Solvent Effects (Table 5)

The degree of charge separation at the transition state, as reflected in solvent effects on the reaction rate, is a particularly useful mechanistic probe. In Fig. 1, the log of an individual rate constant for diazopropane or acetone formation, from 5,5-dimethyloxadiazolinone, is plotted against the E_T parameter: toluene is on the low E_T end and TFE and TFA are on the high E_T end. It is noteworthy that a similar plot of log k_T (the total rate constant) is not at all linear, but shows an overall U-shape. That the dissection of k_T into two competing processes gives linear correlations supports the contention that these are independent primary processes and that both products do not originate from a common intermediate, produced in the rate determining step, whose subsequent product determining steps are solvent sensitive.

The slopes of the solvent correlation lines are small. The sign of the slope means that the transition state for diazopropane formation is more polar than the starting material, while that for ketone is less polar. The actual respective values of 0.08 and -0.03 mol kcal^{-1} may be compared to the very much larger value of $+0.29$ observed by Huisgen for a known stepwise 2 + 2 cycloaddition; that of tetracyanoethylene to butyl vinyl ether which proceeds via a zwitterionic intermediate (ref. 9, eq. [1]):



From the data in Fig. 1, oxadiazolinone decomposition in either mode via zwitterionic intermediates is ruled out.

Thermochemistry and Activation Parameters (Tables 1 and 2)

A brief look at the thermochemistry of these two processes is in order inasmuch as it relates to the position of the transition state on the reaction coordinate and is germane to discussion of the activation parameters. The heat of combustion of 5,5-dimethyloxadiazolinone was measured and used to calculate its heat of formation in the gas phase at room temperature (see Experimental). With a crude estimate for the entropy, data from standard tables, and the additivity principles of Benson (10), changes in the thermodynamic variables were calculated for each process. These are summarized in Table 1. From the lower part of the table, it is plain that the thermodynamic entropy changes, ΔS^0, are quite large; about $+26$ and $+58$ entropy units for the two and three piece fragmentations, respectively. The calculated free energy changes of -7 and -48 kcal mol^{-1} differ by 41 kcal. This may be contrasted with the difference in the free energies of activation, a difference of about 1 kcal mol^{-1} in the nonpolar solvent, toluene.

A further consequence of the thermodynamic estimates from Table 1 is that, exothermic as it is, fragmentation to the three very stable products — acetone, carbon monoxide, and nitrogen — is not sufficiently exothermic to populate excited states of any products. The lowest available electronically excited state would be the acetone $n\pi^*$, with respective singlet and triplet energies of 85 and 78 kcal mol^{-1} above the ground state (11). Dioxetane thermolysis produces triplet acetone (with a few percent singlet) whose phosphorescence (and minor fluorescence) can be observed in degassed samples (11). Using a single photon counting apparatus, we observed no chemiluminescence in the thermolysis of **2***b*. Based on that experiment, an upper limit to the yield of excited state acetone was set at 10^{-7} to 10^{-8}% (see Experimental section for details).

Historically, activation parameters have often been employed as a guide to the mechanism of similar unimolecular fragmentations (7, 12). It is not uncommon for concerted cycloreversions (for example, the retro-Diels–Alder reaction) to show small or even negative entropies of activation as bonds are only partially broken at the transition state. For ketone formation, very little of the large positive thermodynamic entropy change of $+58$ entropy units is realized at the transition state: $\Delta S^{\ddagger}$ varies from $+2$ to $+10$ eu (Table 2). Although the entropy of activation is expected to be positive if the reaction proceeds through a floppy biradical intermediate, it should not be as large as the ΔS^0 for the whole fragmentation process. It is impossible to say, a priori, where, in the range $0 < \Delta S^{\ddagger} < +58$ eu, the borderline between a concerted mechanism and a stepwise alternative, via a biradical intermediate, would lie. For this reason, we sought other types of evidence.

For diazoalkane formation, the activation entropies (-5 to -10 eu) have neither the sign nor the

[a]Data for acetone, CO, N_2, and CO_2 from ref. 36. Units are kcal mol^{-1} (ΔH, ΔG) or cal mol^{-1} K^{-1} (ΔS, S) throughout.
[b]$\Delta H_f^0(Me_2CNN) = \Delta H_f^0(H_2CNN) + \Delta H_f^0(Me_2CO) - \Delta H_f^0(H_2CO) = 71 \pm 5 - 51.7 + 27.7 = 47.0 \pm 5$ kcal mol^{-1} (10).
[c]Analogous to footnote [b], for $S_{298}^0 = 58.1 + 70.5 - 53.7 = 74.9$ cal mol^{-1} K^{-1} (10).
[d]Compare to S_{298}^0(cyclopentane) = 70.0, (1,1-dimethylcyclopentane) = 85.4, and (cyclopentene) = 69.2 cal mol^{-1} K^{-1} (10).
[e]Energy difference between transition state and products at 85°C, assuming $\Delta H^{\ddagger}$ and $\Delta G^{\ddagger}$ for toluene (Table 2) apply to the gas phase.

TABLE 2. Activation parameters for thermolysis of 5,5-dimethyloxadiazolinone over the temperature range 50–95°C[a]

	Diazopropane formation		Acetone formation	
Solvent	$\Delta H^{\ddagger}$	$\Delta S^{\ddagger}$	$\Delta H^{\ddagger}$	$\Delta S^{\ddagger}$
Toluene	27.1 ± 0.4	-4.7 ± 1.0	30.3 ± 0.3	7.4 ± 0.9
Acetonitrile	25.1 ± 1.0	-6.3 ± 2.7	29.3 ± 1.7	1.8 ± 4.7
Trifluoroethanol	23.4 ± 0.15	-6.6 ± 0.4	32.3 ± 1.5	8.5 ± 4.3
Trifluoroacetic acid	20.8 ± 0.5	-9.9 ± 1.4	—	—

[a]Crude data found in Table 6. All errors are those returned by linear least-squares analysis. Units are kcal mol^{-1} and cal mol^{-1} K^{-1} for ΔH and ΔS, respectively.

magnitude of the thermodynamic value of +28 eu. Here, the increasingly negative values of $\Delta S^{\ddagger}$, as solvent polarity increases, could be interpreted as arising from increased ordering of the solvent shell around the moderately polar transition state for this process. In this case, biradicals could not account for the trend.

Secondary Deuterium Kinetic Isotope Effects (Table 7)

The β-deuterium kinetic isotope effects measured for **2***b*-d_6 were 2.1 ± 0.3 and 1.3 ± 0.4% per deuterium for diazopropane-d_6 and acetone-d_6 formation, respectively. Although small, these values are significant (13) and imply that a bond involving C5 is broken in the rate-determining step of each process. These would be the O1—C5 and N4—C5 bonds, respectively. There are no reasonable transition states which do not involve rupture of a bond to C5 but which could account for this isotope effect. Steric or ponderal effects of isotopic substitution are ruled out by the absence of an alkyl steric effect on either process (*vide infra*).

Alkyl Substituent Effects (Table 8)

There is no correlation of rate constants for nine 5,5-dialkyl substituted oxadiazolinones with Taft steric parameters, E_s (14), for either ketone formation or diazoalkane formation. The reason for the scatter plots obtained is that some of the data are much better fitted by inductive parameters, σ^*, for the alkyl substituents. For diazoalkane formation, $\rho^* = -1.27 \pm 0.06$ ($r = 0.993$), but there is no significant correlation of the rate of ketone formation with σ^* — much like the Hammett plot for that reaction.

Aryl Substituent Effects (Table 3)

For the seven *para* substituted 5-aryl-5-methyloxadiazolinones studied, both electron withdrawing and electron donating substituents mildly accelerate ketone formation. The range of rate is only a factor of two, and the rho value is not significantly different from zero: -0.13 ± 0.12 ($r = -0.402$). This erratic behaviour is not unlike that observed from bis-(phenylmethyl)diazene fragmentation to benzyl radicals (15) and could be interpreted as suggesting that ketone formation involves rate determining creation of a radical centre at C5. On the other hand, scatter plots are to be expected from any mechanism if the isokinetic temperature lies in the range studied (50–85°C).

In complete contrast, diazoalkane formation gives an excellent fit to inductive parameters. A rho value of −1.93 is obtained with log k plotted against a

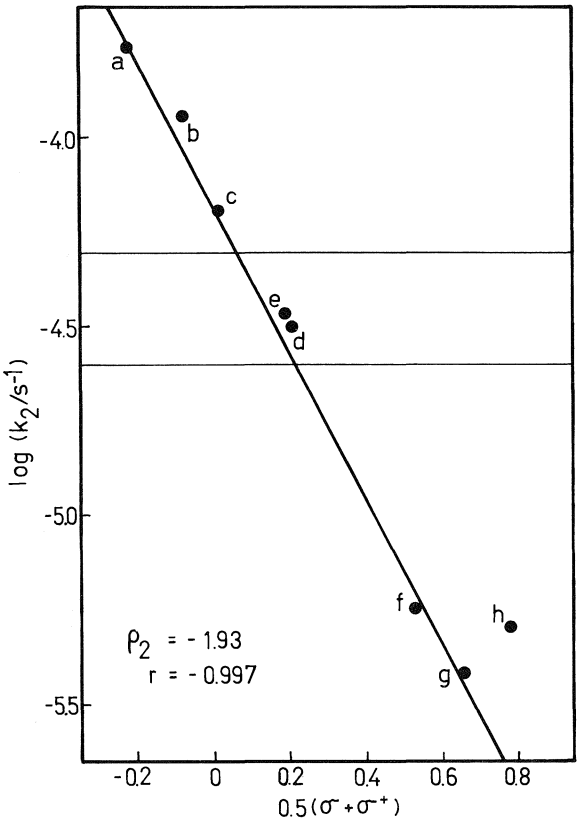

FIG. 2. Hammett plot for diazoalkane formation from *p*-substituted 5-methyl-5-phenyloxadiazolinones (**2***c*) thermolysed at 50.0°C in acetonitrile. Substituents are X = CH_3 (a), C_6H_5 (b), H (c), Br (d), Cl (e), CF_3 (f), CN (g), NO_2 (h). The horizontal band corresponds to the range of rate constants for ketone formation (which do not correlate with σ, σ^+, or the "improved" $\sigma^\cdot$ (40)). From this band, and the regression line, product compositions may be estimated for untried substituents, by a procedure analogous to that of Fig. 1.

50/50 mixture of sigma and sigma plus (Fig. 2). The utility of blending the sigma parameters in cases where a full positive charge is not achieved in the products has been discussed elsewhere (16).

Mechanism of Diazoalkane Formation

At first sight, a build-up of positive charge at C5 of the transition state is quite difficult to rationalize as CNDO calculations (see Experimental) confirm that the corresponding carbon of the diazoalkane is most definitely negative in net charge density relative to C5 of the oxadiazolinone. For the hypothetical **2***a* in Scheme 1, the calculations give a net charge density of +0.17 at C5 (17) while in diazomethane, the same carbon is −0.26 in net charge. Notwithstanding the fact that the calculations only refer to gas phase molecules, a rho value of −1.93 measured in acetonitrile must surely mean that the net charge on C5 increases and passes through a value greater than +0.17 at the transition state. This is only consistent with some degree of O1—C5 bond heterolysis at the transition state. Both the solvent effects and the intermediate size of this Hammett rho rule out a zwitterionic intermediate sporting a full positive charge at C5. The reaction must therefore be concerted with more O1—C5 than C2—N3 cleavage at the transition state (Fig. 3).

Consideration of the reverse of fragmentation, cycloaddition, tends to confirm this deduction. Fragmentation to give carbon dioxide and diazoalkane is formally a retro-1,3-dipolar cycloaddition. Thanks to the work of Fukui (18), Houk (19), and Huisgen (20), the stereoselectivity of the cycloaddition reaction is understandable in terms of Frontier Molecular Orbital (FMO) theory and a concerted mechanism.

Examination of the frontier orbitals of CO_2 and diazomethane shown in Fig. 3 predicts that their major cyclization product (path *a*) would be the wrong regioisomer (**4**), resulting from the largest orbital extension between the two biggest lobes, on the carbon atoms. However, by the Principle of Microscopic Reversibility, the fragmentation in question must share the same transition state as the cyclization to give that regioisomer (path *b*). Now the greatest frontier density is found between the CO_2 carbon and the terminal nitrogen, predicting a transition state with more C2—N3 than O1—C5 bond formation, in precise agreement with the experimental deduction of transition state structure. We conclude, therefore, that diazoalkane formation occurs via a non-synchronous but concerted mechanism.

Mechanism of Ketone Formation

A large number of possible mechanisms are still consistent with the information presented so far. A few reasonable alternatives to a fully concerted mechanism are: prior loss of one of the three stable fragments to give either a biradical or a closed shell species which rapidly decays to products; or a pre-equilibrium one bond scission to give a biradical.

Even at ambient temperature (ca. 50°C) and low ionizing voltages (ca. 10 eV), the mass spectrum of **2***b* shows no evidence for fragment ions at P − 28 (loss of N_2 or CO), nor any metastables for P → P − 28. A parent ion is also not observed. Like the parent ion, if such intermediates occur, their lifetimes must be of the order of a microsecond (21). If they do not occur for ionized oxadiazolinone at 10^{-5} Torr in the gas phase, it seems unlikely they could be significant in the solution thermolysis of oxadiazolinones.

Both a stepwise process via reasonable biradicals like **5** or **6** or a concerted mechanism would be con-

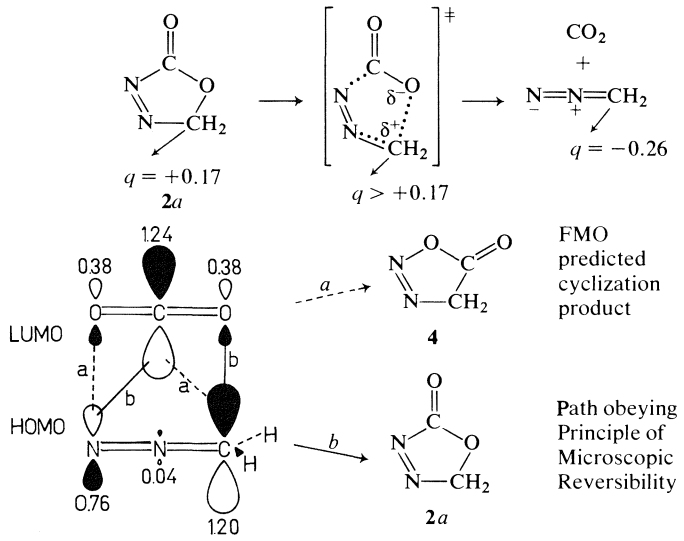

FIG. 3. Charge densities (q) and Frontier MO's for cycloaddition. Frontier densities are given by $2\sum C_{\mu i}^2$.

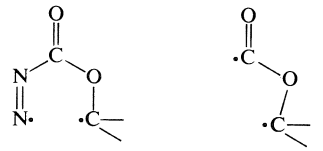
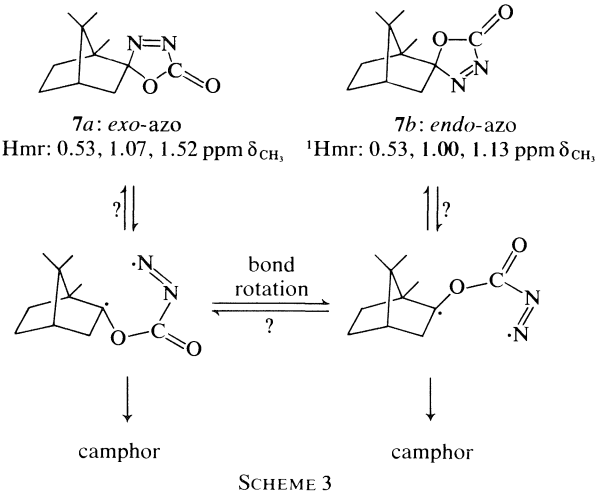
sistent with the observed solvent effects and β-deuterium kinetic isotope effect. The Hammett plot misbehaviour slightly favours a biradical, while the low activation entropies tend to favour a concerted mechanism. No esr signals attributable to intermediate radicals or biradicals were observed when **2***b* was thermolysed in the presence or absence of nitrosobenzene. Furthermore, chemically induced dynamic nuclear polarization (CIDNP) effects (22) were not observed in decompositions performed in either chlorobenzene or methylene iodide solvent (heavy atoms expected to enhance singlet–triplet mixing (25)), even in ^{13}C spectra obtained during decomposition of 90% C5 labelled substrate.



5 **6**

Most reasonably, any diradical formed in thermolysis would be born singlet, and would, therefore, have to intersystem cross and then fragment to triplet products for CIDNP to be observed. In the fifteen year history of the phenomenon, CIDNP from 1,5-biradicals has only been reported for biradicals born as triplets (23–25). However, the singlet 1,5-biradical **5** has unusual potential to display CIDNP effects by intersystem crossing and fragmentation, because one of the products (ketone) has a low-lying triplet state. When both C5 substituents are methyl, the thermochemistry suggests that there is actually insufficient energy for formation of triplet ketone. Nevertheless, other heterocyclic ring systems which do show chemiluminescence might be a source for this, as yet unrecognized, type of CIDNP from thermally generated biradicals. Photo-CIDNP may be more likely if 1,5-biradicals are intermediates in the photodecomposition of oxadiazolinones.

If the biradical **5** were reversibly formed, racemization might occur during decomposition of starting material optically active at C5. To this end, the two oxadiazolinones, **7** (Scheme 3), were prepared from the semicarbazone of *d*-camphor. Their stereochemistry was assigned on the basis of a large downfield shift of the signal corresponding to the *syn* methyl group at C7 of the *exo*-azo isomer, **7***a*. Models show that these protons spend time in the deshielding region of the azo pi bond and so absorb at an extra 0.5 ppm downfield from the analogous protons in the *endo*-azo isomer, **7***b* (see Appendix



SCHEME 3

II). If biradicals were formed reversibly and if bond rotation (and inversion, for a non-planar radical centre) competed with decomposition, interconversion of *exo*-azo and *endo*-azo isomers could occur during decomposition (Scheme 3). Such interconversion was not observed by ^{1}Hmr during thermolysis of the pure *exo*-azo isomer, suggesting that rotation/inversion *with* return does not occur, although either rotation/inversion *or* return might occur.[3]

Finally, it is instructive to consider the effect of phenyl substitution on k_3. From the activation parameter data reported in Table 2, k_3 for **2***b* in acetonitrile at 50°C is computed to be 2.54×10^{-7} s^{-1}. Thus, $k_3(\mathbf{2}c)/k_3(\mathbf{2}b) = 170$, corresponding to $\Delta\Delta G^{\ddagger} = -3.3$ kcal mol^{-1}. For comparison, values of $\Delta\Delta G^{\ddagger}$ of -5.8, -6.3, and -5.8 kcal mol^{-1} per phenyl group replacing a methyl group may be calculated for two sets of symmetrical *trans*-diazenes and one set of *trans*-3,5-disubstituted pyrazolines.[4] If thermolyses of these three model diazene sets are assumed to involve concerted nitrogen loss to form two radical centres, then the $\Delta\Delta G^{\ddagger}$ per phenyl group for the models is twice as large as for oxadiazolinone. If the model extrusions were stepwise (one CN bond ruptured at the transition state), then the oxadiazolinone effect would be even more discrepant!

Clearly, ketone formation does not behave like these classical radical forming reactions and, after eliminating all other mechanistic alternatives and failing to detect (or even infer the existence of) possible intermediates in numerous experiments, a concerted mechanism is compellingly implicated.

Experimental

General

Melting points were determined on a Thomas Hoover capillary melting point apparatus and are uncorrected. Infrared (ir) spectra (CCl_4 solutions unless otherwise noted) were obtained on a Perkin-Elmer model 283 spectrophotometer. ^{1}Hmr and Cmr spectra were taken on Varian EM-390 and Brüker WH-90 instruments, respectively, all with TMS internal reference unless otherwise indicated. Mass spectra (ms) were recorded on either a CEC-21-110B spectrometer at 70 eV or an Hitachi Perkin-Elmer RMU-6A instrument at lower ionizing voltages. Ultraviolet–visible (uv–vis) measurements were obtained from a Cary 14 instrument. Gas chromatographic (glc) analyses were performed on a column (10 ft × 1/4 in.) packed with 20% Carbowax 20M on 60–80 mesh Chromosorb P, using a Varian Aerograph model 920 gas chromatograph equipped with thermal conductivity detection and model 485 digital integration. Chlorocarbon extracts were dried over anhydrous sodium sulfate and diethyl ether or light petroleum extracts over anhydrous magnesium sulfate. Light petroleum refers to the fraction boiling between 30–45°C; pentane to "Fisher Certified, IR Spectranalysed" *n*-pentane; hexane to "Baker Analysed" reagent, bp 68.5–69.3°C.

Materials

Because of an aqueous decomposition mechanism,[5] good first order kinetics could not be obtained using wet solvents. 1,2-Dimethoxyethane (DME) and toluene were each fractionated at high reflux ratio (ca. 5:1) from calcium hydride and a two-thirds centre cut stored over fresh 4 Å molecular sieves. The following solvents were fractionated from Drierite ($CaSO_4$, Hammond Co.) and the centre cut stored over molecular sieves: chlorobenzene, 1,2-dichloroethane (DCE), and trifluoroethanol (TFE); acetonitrile and nitromethane were each pretreated by passage through a column of neutral alumina (30 g L^{-1}); nitrobenzene and dimethylformamide (DMF) were fractionated at reduced pressure (10–20 Torr). Trifluoroacetic acid (TFA) and acetic acid (HOAc) were each fractionated prior to use and ca. 1% of the respective anhydride added to keep them dry. In all cases, glc analysis showed water to be less than 0.05%.

Lead tetraacetate (LTA) refers to the material stabilized with 10% acetic acid, as sold by Ventron Corp.

Synthesis

General Procedure for LTA Oxidation of Dialkyl Ketone Semicarbazones (Method A)

LTA (10.0 g, 0.021 mol) was added in one portion to a stirred suspension of the semicarbazone (0.020 mol) in dry CH_2Cl_2 (150 mL) at 0°C. There was an immediate development of a yellow colour. The ice bath was then removed for a period of 0.5–2 h during which time the solution gradually became colourless and a white precipitate formed. The ice bath was returned and a mixture of 2.4 *N* HCl (50 mL) and ice (150 g) was added. After 15 min the reaction mixture was filtered through Celite (Johns-Manville Ltd.), the organic phase was separated, and the aqueous phase extracted with ice cold CH_2Cl_2 (3 × 50 mL). The organic extracts were com-

[3]A referee has pointed out that the isomerization of **7***a* to **7***b* is inherently unlikely because bicycloheptyl radicals are known to react preferentially from the *exo* side (see, for example, ref. 37). There are three reasons why we expect that preference to be unimportant in the present case. First, the reclosure to either **7***a* or **7***b* is a radical coupling reaction rather than a chain transfer step. *Exo* preference has been established for chain transfer steps, which must have a higher activation energy, and presumably greater *exo*/*endo* selectivity, than coupling reactions. Second, reclosures to either **7***a* or **7***b* are intramolecular steps with a restricted approach angle for attack at C2 of the bicycloheptyl skeleton, because the new ring formed is 5-membered. Intramolecularity should reduce the normal *exo* preference because the more severely hindered approach avenues from the *endo* side (which cut down bimolecular *endo* rate constants) are irrelevant to intramolecular closure. Third, the presence of the C7 methyl group should mitigate potential *exo* preference. The alternative test, isomerization from **7***b*, could not be performed because pure **7***b* was unavailable. Also, it is noteworthy that no Δ^1-pyrazoline has ever demonstrated internal return with isomerization (38, 39).

[4]$\Delta G^{\ddagger}$ values, in kcal mol^{-1}, computed at 50°C from ln (k/T) vs. T^{-1} plots of the original kinetic data are: di-*t*-butyldiazene (37.0); dicumyldiazene (25.4); diisopropyldiazene (42.3); bis(α-phenylethyl)diazene (29.6); *trans*-3,5-dimethyl-Δ^1-pyrazoline (37.5); and *trans*-3,5-diphenyl-Δ^1-pyrazoline (25.9) (refs. 41–46, respectively).

[5]Manuscript in preparation.

$CH(CH_3)_2$	$CH(CH_3)_2$	Oil	0.91 and 1.06 (both d, J = 6.9 Hz, 12H, diastereotopic CH_3) 2.72 (septet, J = 6.9 Hz, 2H, 2CH)

[a] CCl_4 solution, except where noted.
[b] $CDCl_3$ solvent.

bined and washed with a cold, saturated solution of sodium bicarbonate (50 mL), and with water (3 × 50 mL). Drying and removal of the solvent under reduced pressure gave crude oxadiazolinone in about 80–90% yield.

The crude material was purified by one or more of the following three methods. Dimethyl- and methyl-*t*-butyl-oxadiazolinones were twice sublimed at 0.01 Torr from 0°C to a Dry Ice/acetone cold finger. The methylbenzyl and dibenzyl compounds were recrystallized from light petroleum. All other alkyl-substituted substrates were distilled at 0.01 to 0.001 Torr at room temperature (higher temperatures lead to decomposition), then repeatedly recrystallized from pentane at low temperature (ca. −20 to −80°C) until magnified ir spectra of the carbonyl region showed less than 0.5% of ketone impurity. Overall yields at the end of the first purification step were 70 to 80%, in most cases. Table 3 lists the melting points and ^{1}Hmr data obtained for this series.

Isotopically labelled dimethyloxadiazolinones (5-^{13}C and perdeutero-) were synthesized from the semicarbazones of acetone-2-^{13}C (90% enriched, Merck, Sharpe and Dohme Ltd.) and acetone-d_6 (99+% D, Aldrich Co.). The deuterium content of the latter oxadiazolinone was taken to be identical to that measured for the semicarbazone (98.4 ± 0.2% D by ms comparison to unlabelled material).

LTA Oxidation of Semicarbazones of p-*Substituted Acetophenones (Method B)*

As Table 4 summarizes, Method A was successfully used to synthesize the *p*-H, Br, Cl, and CH_3 substituted 5-methyl-5-phenyloxadiazolinones. Although a change of oxidation solvent (to light petroleum) permitted ir observation of the oxadiazolinone from *p*-methoxyacetophenone, evaporation of the solvent was followed by rapid decomposition to the corresponding diazoalkane and subsequent products. Method B was used in cases where Method A was not successful because the semicarbazones would not cyclize at low temperature and the oxidation products were unstable if oxidation was attempted at higher temperatures.

An oxidizing mixture of 0.21 *M* Pb(IV) containing approximately 1:1 acetate and trifluoroacetate was prepared by dissolving lead tetraacetate (90%, 102.5 g) and TFA (76 mL) in dry CH_2Cl_2 (1 L). Qualitatively, this solution gave the best results: more TFA led to more decomposition, less meant incomplete cyclization. No effort was made to determine if

the enhanced oxidation rate was due to increased semicarbazone solubility or to formation of a mixed acetate/trifluoroacetate Pb(IV) species of higher oxidizing power. Lead tetratrifluoroacetate (LTTFA) (26) in either CH_2Cl_2 or TFA/TFAA did not result in oxidative cyclization, even though the latter solution was completely homogeneous.

In a typical experiment, three separate solutions were cooled to −15°C for 0.5 h in an ice/salt or ice/alcohol bath: a stirred slurry of semicarbazone (0.010 mol) in dry CH_2Cl_2 (50 mL) in a stoppered flask (250 mL); oxidizing solution (50 mL, 0.0105 mol) in a stoppered flask; and 2.4 *N* HCl (50 mL). The oxidant was rapidly added to the semicarbazone slurry and the now-homogeneous reaction mixture stirred 3–5 min before the aqueous acid was added. Hydrolysis times of about 1 min were adequate and filtration through Celite followed by ice-cold workup was identical to that in Method A above. ^{1}Hmr spectra of the crude reaction product indicated that oxadiazolinone accounted for more than 50% of this material (yields of crude products, Table 4).

Purification of the crude material was done as follows. For the *p*-NO_2, $CONH_2$, and CN compounds, the crude solid was extracted from a residue of unreacted semicarbazone with a minimum of CH_2Cl_2, then recrystallized from $CHCl_3$. The separation of the oxadiazolinones bearing *p*-CH_3, C_6H_5, H, Cl, Br, and CF_3 substituents from their decomposition products formed in synthesis, mostly ketone and trifluoroacetic acid ester, could only be achieved without further decomposition by low temperature column chromatography. In an evacuated, Dry Ice/acetone filled, jacketting Dewar, a column of 2.5 cm × 30 cm was packed with silica gel (Baker, 60–300 mesh, ca. 90 g for one gram of crude material). Generally, 15–20% diethyl ether in light petroleum was used as the eluant. In spite of problems inherent in this technique — trying to keep things dry, low solubility (gumming of the sample at the top of the column), and rapid elution — magnified ir spectra of the carbonyl region for each fraction allowed selection of a small cut of reasonably clean material. In all cases but the *p*-C_6H_5, an oil was obtained which could not be further purified. 5-Methyl-5-*p*-biphenylyloxadiazolinone was recrystallized from diethyl ether/hexane.

Because none of the acetophenone oxadiazolinones was very pure, each was assayed by low temperature (−30°C) ^{1}Hmr in CCl_4 or acetone-d_6 by careful integration of the methyl group against anisole as internal standard. This information is also contained in Table 4. The assay was applied as a correction factor, f_{oxa}, when determining starting oxadiazolinone concentrations for product analysis. Fortunately, the reaction rates were independent of any impurities remaining in these samples after the above purification step. All samples (neat or CH_3CN solution) were stored in the freezer (−25°C) prior to use, and none was kept for more than 10 days after preparation.

LTA Oxidation of d-*Camphor Semicarbazone*

The crude reaction product obtained using Method A contained about 60% ketone and 40% oxadiazolinones (ir). This material was chromatographed at −20°C on silica gel (Baker, 60–300 mesh, 50 g per gram), from which it was eluted with 1% diethyl ether in light petroleum. Although the two isomeric oxadiazolinones (**7***a* and **7***b*) were completely separated from the ketone, they were not well separated from each other. Fractions containing more than 75% *exo*-azo isomer (**7***a*; by ^{1}Hmr, see Appendix II) were combined and the white solid fractionally crystallized five times from pentane to give **7***a* (ca. 0.1 g, mp 83–84°C) in 1.5% overall yield. The *endo*-azo isomer (**7***b*) remained an oil and further attempts to isolate it from its contaminant (30% of **7***a*) were unsuccessful.

Kinetics

General

Rate constants k_3 and k_2, respectively, for ketone and diazoalkane formation, were determined by applying the product assay for fraction of ketone formed (see below) to the total rate constant for disappearance of starting material, $k_T = k_2 + k_3$. Each value of k_T was measured in triplicate and the results averaged. The bath temperature was maintained to ±0.10°C or better and the average k_T had a typical standard deviation of the mean of less than 1%.

Ultraviolet Method

A kinetic method employing uv analysis of removed aliquots was utilized for the solvent effects (Table 5), activation parameters (Tables 2 and 6), β-deuterium kinetic isotope effect (Table 7), and alkyl substituent effect studies (Table 8) in all but TFE and TFA. After a warming period of 20 min, aliquots of 6 mL (3–5 m*M* in oxadiazolinone) were withdrawn by syringe from capped 100 mL volumetric reaction flasks and quenched in liquid N_2. Two time infinity (10 half-lives) samples were taken for each run and then all 12–14 samples were allowed to warm to room temperature for uv–vis analysis of absorption at λ_{max} of the azo $n \rightarrow \pi^*$ transition (ca. 360–380 nm, slightly solvent variable, $\varepsilon_{max} \sim 200$–$400\ M^{-1}\ cm^{-1}$).

[a]Temperatures measured by National Research Council of Canada calibrated thermometer (°C, ±0.1°).
[b]Total first-order rate constant, k_T (s^{-1}).
[c]Errors are estimated standard deviations of the mean, usually from triplicates.
[d]Calibrated gas chromatography with internal standard.
[e]Not measurable; put at 0.4 ± 0.25.

The data were treated by a standard linear least-squares procedure and the calculated total first order rate constants (k_T) were obtained with typical correlation coefficients of 0.999 for up to 5 or more half-lives. Increasing the concentration by a factor of 20 or adding 1% aniline had no effect on the measured rate constants. TFE and TFA runs were done using 0.5 mL aliquots individually sealed in glass tubes and uv analysis was accomplished in cells of 0.1 cm path length.

The β-deuterium kinetic isotope effect, k_H/k_D, for each process was measured at 85.0°C in toluene and acetonitrile by the uv method. For labelled and unlabelled **2***b*, k_T was simultaneously determined, each in duplicate to eliminate possible errors arising from minor temperature variations. Duplicate k_T's for 3 half-lives agreed within their estimated standard deviations ($\lesssim 0.3\%$). Product analysis by calibrated glc employed acetone-d_6 in a fashion analogous to that described below. Although the total isotope effects, $k_T(H)/k_T(D)$ were nearly the same for both solvents (1.1 for all 6D), only k_H/k_D for ketone formation in toluene and for diazoalkane formation in acetonitrile are ultimately reported since the propagated error for the minor pathway in each case renders the value of k_H/k_D for that pathway unreliable (see Table 7).

Infrared Method

The uv method was unsuitable for the *para*-substituted 5-methyl-5-phenyloxadiazolinones because a pink to red colouration develops during decomposition, presumably from the diazoalkane. Oxadiazolinone (ca. 0.050 g) was carefully

[d]Total first-order rate constant, k_T (s^{-1}).

weighed and dissolved in dry CH_3CN (10.00 mL). Portions of about 0.2 mL were transferred by syringe to glass tubes (12 cm long by 2 mm id), filling about 45 of them to a depth of 5 cm. This amount of sample was exactly sufficient to fill a 0.5 mm CaF_2 ir solution cell. The tubes were quickly sealed and stored in the freezer at −25°C until used for either kinetics or product analysis.

In a typical kinetic run, 12 to 16 sample tubes were withdrawn from the bath at intervals calculated to give roughly equal concentration differences up to 3 to 5 half-lives. The reaction was quenched by cooling with liquid N_2. For the ir analysis, the spectrophotometer was operated in the absorbance mode on a very slow scan speed and a large wavelength expansion setting at 1835 cm^{-1}. Calibration plots using ketones showed that measured absorbances were a linear function of concentration, and first order fits of the disappearance of ν_{co} of oxadiazolinone gave correlation coefficients typically better than 0.9995 (see Table 4).

Product Analysis

Diazoalkanes generated in oxadiazolinone thermolyses often react in a variety of ways to give several products, some incorporating solvent (^{1}Hmr, glc). The addition of a few drops of TFA per mL of solvent effectively traps the diazoalkane as the trifluoroacetic acid ester, the only other product observed by ^{1}Hmr and glc being ketone. Under the reaction conditions employed in these thermolysis studies, neither diazopropane nor any of its subsequent reaction products (principally acetone azine) were hydrolysed or otherwise converted to the ketone. This means that accurate determination of the product distribution may be inferred from quantitative assay of ketone only.

For the solvent effects (Table 5), activation parameters (Table 6), and β-deuterium kinetic isotope effects (Table 7) (cases where very pure starting material was available), the time infinity acetone concentration was measured by integrated glc, calibrated against internal standard 2-butanone. Typically 8–15 injections of each of several calibrant solutions and reaction mixtures were used to obtain an average of the fraction of ketone formed in each case, f_{co}, and this result had an estimated standard deviation of the mean of about 1–2%.

Ketone measurements by ir carbonyl absorption for dialkyl and acetophenone oxadiazolinones were obtained under conditions of slow scan speed and large wavelength scale magnification. Seven to ten calibration solutions of twice recrystallized or redistilled ketone demonstrated excellent linearity between absorbance and concentration. By measuring the time infinity ketonic carbonyl absorption and correcting for any ketonic impurity at time zero, the concentration, and hence the fraction, f_{co}, of ketone formed was computed. From a knowledge of the nmr purity assay, f_{oxa} (see above), a correction to the starting concentration of acetophenone oxadiazolinone was made:

$$f_{co} = \frac{([\text{ketone}]_\infty - [\text{ketone}]_0) \times MW_{oxa} \times Vol}{\text{weight}_{oxa} \times f_{oxa}}$$

For alkyl substituted oxadiazolinones, f_{oxa} was taken to be unity though it may have been as low as 0.95 in rare cases.

The product distribution in nitrobenzene was obtained by ^{1}Hmr.

For the camphor oxadiazolinones, the product ratios (ir) were obtained as a function of the *exo*/*endo* ratio (^{1}Hmr) in seven mixtures. Least-squares analysis gave $f_{co}(exo) = 8.4 \pm 0.4\%$ and $f_{co}(endo) = 26.2 \pm 1.1\%$.

Thermochemistry: $\Delta H_f^0(oxa)_g$

At 25°C, the energy released by combustion of 1 g pellets of 5,5-dimethyloxadiazolinone was measured in a Parr Oxygen Bomb Calorimeter and found to be 526.0 ± 0.2 kcal mol^{-1}. An enthalpy of combustion was computed from the stoichiometry,

$$C_4H_6N_2O_{2(s)} + 4\tfrac{1}{2}O_{2(g)} \rightarrow 4CO_{2(g)} + N_{2(g)} + 3H_2O_{(L)}$$

then corrected for the ca. 2% nitrogen combustion (27). This gave $\Delta H_c^0 = -525.1 \pm 0.4$ and $\Delta H_f^0(oxa)_s = -56.05 \pm 0.4$ kcal mol^{-1}. Determination of the gaseous heat of formation necessitated approximating the heat of sublimation, ΔH_s^0, to a crude estimate for the heat of vaporization, ΔH_v^0, obtained from Benson's empirical formula (10):

$$\Delta H_v^0(298\ K) = 22(1.76 \times 10^{-3} \times T_b(°C) + 0.253)$$

Although the boiling point, T_b, of dimethyloxadiazolinone is unknown, it is a reasonably volatile solid of mp 39.5–40.0°C, so a bracketted guesstimate of $40 < T_b < 100$°C generated error limits in $\Delta H_v^0 = 8.3 \pm 1.2$ kcal mol^{-1}. With $\Delta H_s^0 \sim 8.3 \pm 2.0$, $\Delta H_f^0(oxa)_g = -47.7 \pm 2.0$ kcal mol^{-1}. Admittedly, several very crude assumptions are involved in the value chosen for ΔH_s^0, and hence $\Delta H_f^0(oxa)_g$, but very generous error limits appended to the final value do reflect the uncertainty.

Chemiluminescence

Attempts to observe chemiluminescence employed a single photon counting apparatus calibrated with luminol (28). Event signals from a 14 stage Amperex 56 DUVP/03 photomultiplier tube in a PRA-510 housing operated at −1990 V were run through an ORTEC 9301 fast preamp to an ORTEC 454 timing filter and out to a Hewlett-Packard 60 MHz frequency counter. The dark current was 13 Hz.

A solution of dimethyloxadiazolinone in hexane (0.3 *M*) was degassed in a cylindrical quartz tube by three freeze–pump–thaw cycles and heated to 100–110°C in an oil bath for three min prior to transferral to the sample chamber of the single photon counting apparatus. Counting was initiated immediately. In only a few minutes, the sample had cooled to ca. 50°C, but at no time was any chemiluminescence apparent. No signal above background dark current was observed. The experiment was repeated in the presence of anthracene with identical results. Another sample, 0.02 *M* in 5-methyl-5-(*p*-chlorophenyl)-Δ^3-1,3,4-oxadiazolinone, also gave no additional counts. A detection limit of a 20% increase over background counts would have meant the fraction of acetone excited states formed near 50°C had been $\sim 2 \times 10^{-10}$.

CNDO/2 Calculations

The computer program and method have been described previously (17). The following structural parameters were used: CO_2 (29), $r_{CO} = 1.162$ Å; diazomethane (30), $r_{CH} = 1.08$, $r_{CN_1} = 1.32$, $r_{N_1N_2} = 1.12$, all in Å, and $\angle HCH = 127°$. Eight of twelve CNDO/2 LCAO orbitals for carbon dioxide are occupied, giving rise to zero order net charge densities of +0.536 and −0.268 on the carbon and each oxygen, respectively. A pair of degenerate HOMO's with π symmetry at −15.70 eV have a node on carbon and coefficients of ±0.707 on the oxygens. The LUMO is also a degenerate pair of π-type orbitals, at 5.14 eV, each with coefficients: C(+0.795), O(−0.429). The Frontier orbital densities of Fig. 3 are calculated for atom A in orbital *i* as $2 \sum_{\mu}^{on\ A} C_{\mu i}^2$.

In the case of diazomethane, eight of fourteen LCAO orbitals are occupied, and net charge densities computed to be: H(+0.045), C(−0.261), N_1(+0.306), N_2(−0.136). At −11.05 eV, the HOMO has π symmetry, with orbital coefficients: C(−0.780), N_1(−0.125), N_2(+0.613). The LUMO, at 4.35 eV, is found to have σ symmetry, but the π-type NLUMO at 4.45 eV has orbital coefficients: C(+0.506), N_1(−0.704), N_2(+0.499). In cycloaddition reactions, the regiochemistry is very often controlled by the HOMO–LUMO interaction of smallest energy gap (18), which would be HOMO(CH_2N_2) − LUMO(CO_2), at 16.19 eV. The calculations predict the HOMO(CO_2) − NLUMO(CH_2N_2) gap to be 20.15 eV.

Electron Spin Resonance

Electron spin resonance signals were not observed during thermolysis of degassed chlorobenzene solutions 0.5 *M* in dimethyloxadiazolinone at a temperature of 100°C in the probe of a JEOL JES-3BS-X spectrometer. When the experiment was repeated in the presence of doubly sublimed nitrosobenzene, the esr spectrum of diphenyl nitroxide was obtained (a_N = 10.0 g; a_H = 0.9 g). The same spectrum was observed from nitrosobenzene in the absence of oxadiazolinone, and the splitting parameters agree with those in the literature (31).

Chemically Induced Dynamic Nuclear Polarization

In a biradical of structure **5**, formed from 5,5-dimethyloxadiazolinone, coupling of the methyl protons to the unpaired electron at C5 might produce enhanced absorption or emission in the ^{1}H nmr during decomposition, but such effects were not observed at ca. 100°C in chlorobenzene.

In some cases, ^{13}C nmr is more sensitive to CIDNP phenomena (e.g., ref. 24*b*), but with as much as 0.25 g of sample, the carbonyl carbons of oxadiazolinone and product acetone could not be detected above baseline noise because too few scans were accumulated during the key minutes of the reaction. To overcome this problem, 90% enriched 5,5-dimethyl-Δ^3-1,3,4-oxadiazolin-2-one-5-^{13}C was synthesized from acetone-2-^{13}C (Merck, Sharpe and Dohme of Canada Ltd.). Even though C5 and acetone carbonyl could be easily observed from 0.050 g of the labelled oxadiazolinone, the thermolysis at 100°C in either chlorobenzene or methylene iodide failed to generate emission or enhanced absorption in the Cmr spectrum. The CIDNP experiment was negative.

Proton Magnetic Resonance Test of Interconversion of **7**a *and* **7**b

The sample of pure **7***a* was assayed by 90 MHz ^{1}Hmr to contain ≤0.2% **7***b*. This detection limit was determined from scans of the 0.6 to 1.1 ppm region under conditions which did not saturate signals (low rf power and moderate scan speed). Excellent Gaussian lineshapes were always obtained. Cut-and-weight integration procedures established for assay of mixtures of **7***a* and **7***b* proved that a peak of 0.5% of the total intensity in this region was easily measured. Hence, a detection limit of about 40% of this level was inferred as reasonable.

Oxadiazolinone **7***a* (0.030 g) in dry CCl_4 (0.5 mL) was sealed into a tube and thermolysed at 85°C for 80 min (ca. 30% decomposition). The sample was cooled, transferred to an nmr tube, and the ^{1}Hmr obtained. To the high field side of the *anti*-C7 methyl protons of **7***a* (1.07 ppm), a complex series of absorptions obscured one possible C7 methyl of the *endo* isomer, **7***b* (1.00 ppm). However, the low field side of the **7***a* absorption was remarkably clear and revealed no observable change in baseline attributable to the 1.13 ppm methyl in **7***b*. On this evidence, interconversion of **7***a* and **7***b* was ruled out.

Appendix I. Estimation of an E_T Value for TFA

Protonating solvents remove the solvatochromic absorption band of the pyridinium *N*-phenolbetaine used to define the E_T scale. In order to include trifluoroacetic acid in the reported solvent polarity correlations, an E_T value was estimated from linear correlations with other solvent polarity parameters (8).

Solvolysis data on 2-adamantyl tosylate ($k_{2\text{-AdOTs}}$) in TFA, TFE, HCOOH, HOAc, EtOH, MeOH, and $(CF_3)_2CHOH$ (33) were correlated with the solvent polarity parameter called log k_{ion} (8) to estimate a value of log k_{ion}(TFA), and then that value was plugged into a correlation of log k_{ion} with E_T:

$$\log k_{2\text{-AdOTs}} = (2.193 \pm 0.096) \log k_{ion} - (2.269 \pm 0.154) \qquad r = 0.990$$

$$\log k_{ion} = (0.195 \pm 0.016)E_T - (13.17 \pm 0.75) \qquad r = 0.964$$

$$\log k_{2\text{-AdOTs}}(\text{TFA}) = -3.05$$

Therefore E_T(TFA) = 65.7 ± 6.6.

In spite of the necessary use of two correlations, instead of one (because log $k_{2\text{-AdOTs}}$ data are available only for very few solvents with measured E_T

values), the error propagation suggests quite reasonable confidence limits. The same procedure converts log $k_{2\text{-AdOTs}}$(TFE) = −5.821 (33) to an E_T(TFE) = 59.2 ± 6.2, only 0.3 units below the measured value (8*b*).

Appendix II. Nuclear Magnetic Resonance Assignment of Stereochemistry in the Diastereomers of *d*-Camphor Oxadiazolinones

Selective decoupling of the methyl protons at 0.53 ppm of either isomer of **7** caused collapse of the quartet at 8.6 or 9.4 ppm in the Cmr spectrum (see Table 9), indicating that the upfield protons were on C10. In both isomers, these protons spend time in the shielding region above the plane of the azo pi bond and appear about 0.5 ppm upfield of their usual position at ca. 1 ppm. The opposite downfield shift of the C8 methyl protons to 1.52 ppm in one isomer cannot be due to the oxygen lone pairs nor to the carbonyl group since such an effect is absent in borneol and isoborneol acetates (Table 9). Models show that free rotation of the C8 methyl group of 7*a* permits the protons to spend time in the deshielding region in the plane of the azo pi bond. In the *endo*-azo isomer, this effect is not possible and the C8 methyl hydrogens appear in their usual position, at about 1 ppm.

Synthesis of 1,3-dihydro-2*H*-benzo-1,4-diazepin-2-ones and 1,2-dihydropyrazin-2-ones via iminophosphoranes. Mass spectra of 1,5-disubstituted-1,2-dihydropyrazin-2-ones[1,2]

Received February 15, 1979

JACK ACKRELL, EDVIGE GALEAZZI, JOSEPH M. MUCHOWSKI, and LASZLO TÖKÉS. Can. J. Chem. **57**, 2696 (1979).

The azido ketones **4***c–e* and **10***a–d* reacted with triphenylphosphine under mild conditions to give the benzo-1,4-diazepin-2-ones **7***c–e* and the 1,2-dihydropyrazin-2-ones **12***a–d*, respectively.

The electron impact induced fragmentation of the 1,5-disubstituted-1,2-dihydropyrazin-2-ones was shown to occur by extensive skeletal rearrangement. The 1,5-diaryl derivatives **12***a–c* fragmented via 1,4-diarylimidazole species produced by the expulsion of CO from the molecular ion. In contrast, the 1-cyclohexyl-5-phenyl derivative **12***d* fragmented almost entirely via a 2-hydroxypyrazine intermediate derived from the molecular ion by McLafferty cleavage.

JACK ACKRELL, EDVIGE GALEAZZI, JOSEPH M. MUCHOWSKI et LASZLO TÖKÉS. Can. J. Chem. **57**, 2696 (1979).

Les azido cétones **4***c–e* et **10***a–d* réagissent, dans des conditions douces, avec la triphénylphosphine pour conduire respectivement aux benzodiazépine-1,4 ones-2 **7***c–e* et aux dihydro-1,2 pyrazinones-2 **12***a–d*.

On a montré que, pour les composés dihydro-1,2-pyrazinones-2 disubstitués en positions 1,5, la fragmentation induite par impact électronique se produit avec une transposition profonde du squelette. Les dérivés diary-1,5 **12***a–c* se fragmentent par l'*intermédiaire* d'une espèce diaryl-1,4 imidazole produite par l'élimination du CO de l'ion moléculaire. A l'opposé le dérivé cyclohexyl-1 phényl-5, **12***d* se fragmente presqu'entièrement via un intermédiaire pyrazinol-2 provenant de l'ion moléculaire selon un clivage de McLafferty.

[Traduit par le journal]

Iminophosphoranes, the isoelectronic analogues of phosphonium ylids, have been known (1) for sixty years, and the chemistry of this class of compounds has been investigated extensively. Whereas the intermolecular synthesis of imines from iminophosphoranes and aldehydes or ketones is well known (1–3), examples of the intramolecular version of this reaction are rare. The synthesis (4) in low yield (11%) of the alkaloid nigrifactine **2** from the azido ketone **1** and triphenylphosphine is one instance of a reaction which may proceed in the above manner. In contrast, Nomura *et al.* (5) have shown that *N*-(2-acylphenyl)iminophosphoranes did not cyclize to benzazetes. Recently (6), the synthesis of diazepam **7***a* and nitrazepam **7***b* from the azidoacetanalides **4***a* and **4***b* and triphenylphosphine or triethylphosphite (Scheme 1) was described in a patent. Our work, which had been carried out independently, confirms and extends the observations published in a recent patent (6).

The intramolecular reaction between an iminophosphorane and a carbonyl moiety was first applied to the synthesis of benzo-1,4-diazepines. Thus, the addition of a slight excess of triphenylphosphine to a toluene solution of 2-azidoacetamidobenzaldehyde **4***c* (see Table 1) caused the occurrence of an exothermic reaction and the rapid precipitation of 1,3-dihydro-2*H*-benzo-1,4-diazepin-2-one **7***c* in greater than 50% yield. The other benzo-1,4-diazepines **7***d*, *e* were prepared (see Table 2) in a similar way from the azides **4***d*, *e*, but in these cases the intermediate iminophosphoranes **5** could be detected as polar intermediates by thin layer chromatography (tlc). Indeed, in one instance (**5***e*), the iminophosphorane was stable at room temperature and could be isolated as the hydrochloride salt. The transformation of this substance into **7***e* could then be effected at a higher temperature after liberation from its salt with sodium hydride.

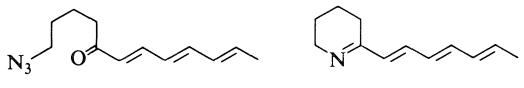
SCHEME 1

A process analogous to that described above when applied to the azidoketone **10***a* (Scheme 2 and Table 1), derived from the corresponding phenacyl amine **8***a*, gave 1,5-diphenyl-1,2-dihydropyrazin-2-one **12***a* (35% yield) and not the expected tetrahydropyrazin-2-one **11***a*. The oxidation which took place was not aerial in nature (7) because the dihydro compound **12***a* was also formed (40% yield) when the reaction was effected in a nitrogen atmosphere. Indeed, a careful examination of the course of the reaction by tlc revealed only the presence of the unstable, but isolable, intermediate iminophosphorane, the product **12***a*, and triphenylphosphine oxide. The other 1,5-disubstituted-1,2-dihydropyrazin-2-ones **12***b–d* (Table 2) were likewise formed in 34–54% yields from the azidoketones **10***b–d*.[4] Although unexceptional, these yields are not worse than those obtained when dihydropyridazin-2-ones are synthesized by the ammonolysis of the bromoacetamides of α-aminoketones (7).

The mildness and formal neutrality of the intramolecular Schiff base synthesis described herein make this a highly attractive process for the construction of nitrogen containing cyclic systems.



1 2

[4]These compounds were examined for general central nervous system depressant activity but did not possess significant activity in this regard.

Compounds **12***a–d* were characterized by their elemental analysis and spectral characteristics. The nmr spectra had the expected (8) low field absorption (δ 8.15 ± 0.05) for H-3 which was long range coupled ($J \approx 1.5$ Hz) to H-6. The mass spectra (see Table 3), in addition to the expected molecular ions, possessed several interesting and notable features which are discussed in detail below.

The electron impact induced behaviour of the 1,5-diaryl-1,2-dihydropyrazin-2-ones **12***a–c* is typified by the mass spectrum of the diphenyl derivative **12***a* (Fig. 1). These compounds exhibited extensive skeletal rearrangements during the course of fragmentation and the major cleavage patterns, the supporting metastable ion measurements, as well as some mechanistic considerations are summarized in Scheme 3.[5]

The primary fragmentation of **12***a–c* occurs by the expulsion of CO from the molecular ion (a process which has analogy in the mass spectra of pyridazones and phthalazones (12*a*)) to yield the 1,4-diarylimid-

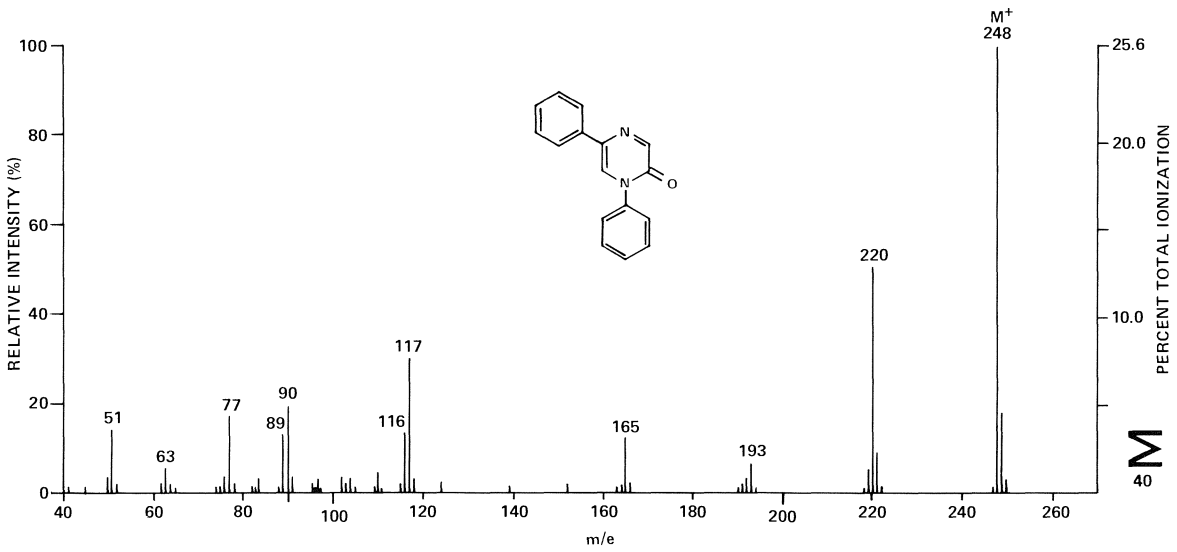

FIG. 1. Mass spectrum of 1,5-diphenyl-1,2-dihydropyrazin-2-one (**12***a*).

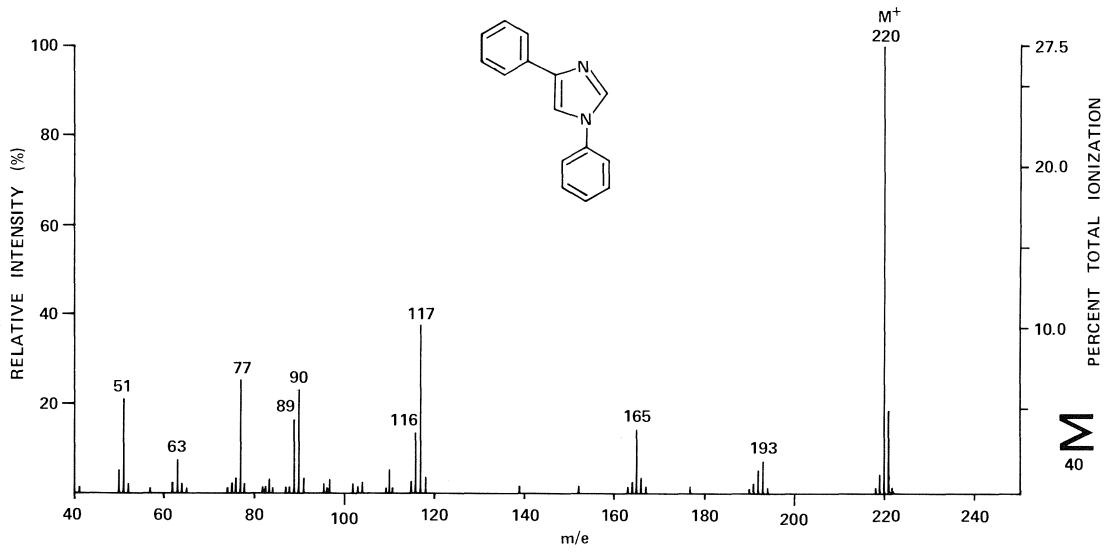

FIG. 2. Mass spectrum of 1,4-diphenylimidazole.

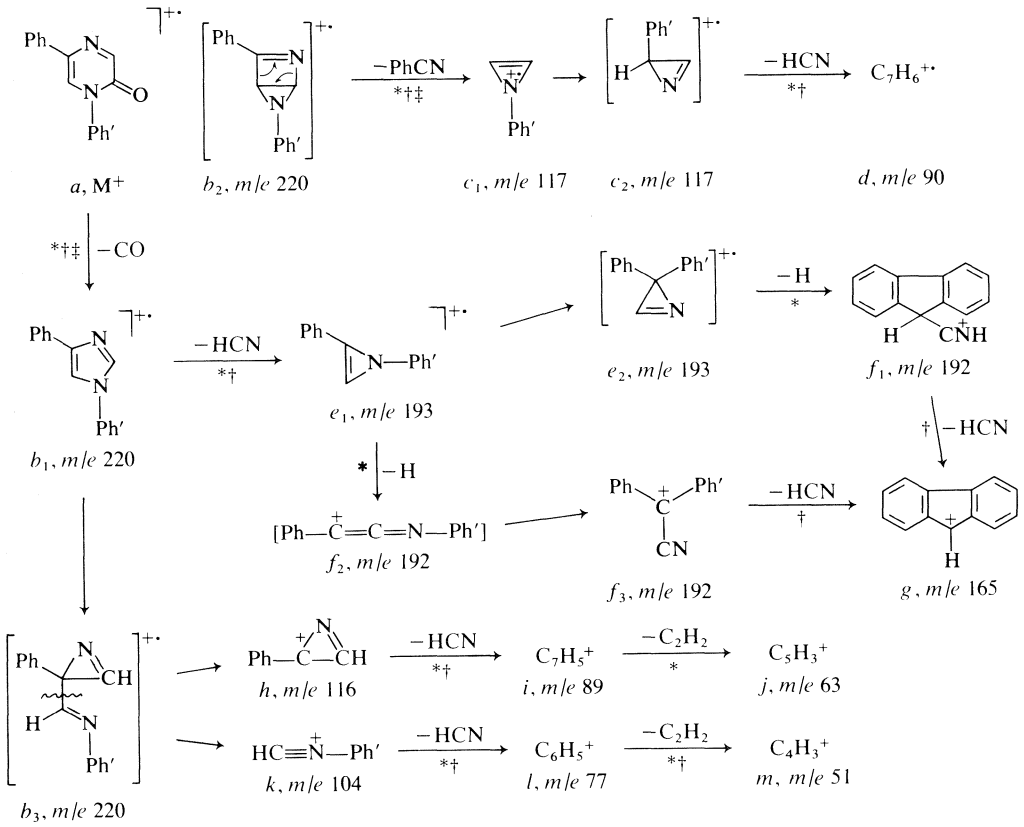
azole ion b_1. The structure assignment of this ion is based on the observation that the spectrum from this point (i.e., *m/e* 220) downward is identical to that of authentic (13) 1,4-diphenylimidazole (cf. Figs. 1 and 2). The predominant mode of fragmentation of b_1 is the loss of benzonitrile, presumably via a valence isomer such as b_2. The ion c_1, thus produced, retains the *N*-aryl substituent in **12***b* and **12***c* and the deuterium labels in 1,4-diphenylimidazole-2,5-d_2. Ion c_1 then undergoes a 1,2-shift of the phenyl group from nitrogen to carbon and loss of HCN (from c_2) to give the $C_7H_6^{+\cdot}$ species (*d*). This pathway is only partially responsible for the genesis of *d* because the spectra of **12***b* and **12***c* contain the $C_7H_6^{+\cdot}$ species as well as the expected substituted ions (i.e., *m/e* 104 and 124, respectively; see Table 3).

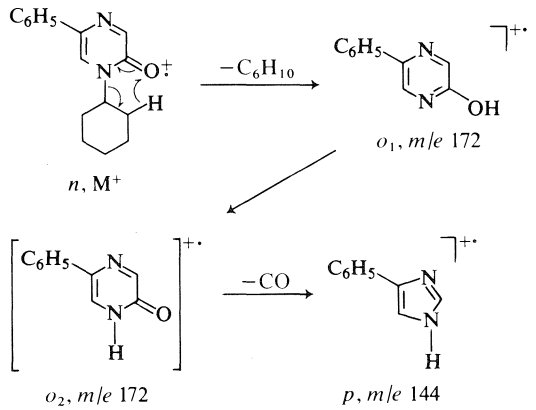
Another important fragmentation of the 1,4-diarylimidazole species b_1 takes place by the loss of HCN to give an ion the most probable structure of which is e_1. This type of cleavage is common to both unsubstituted (12*b*, 14) and substituted (15) imidazoles and the site specificity thereof is dependent on the substitution pattern of the imidazole moiety (12*b*). The fragmentation behaviour of the diphenylazirine radical ion e_1 is very complex. Thus, when derived from **12***a* or **12***b* a hydrogen radical is lost,



SCHEME 3

whereas either a hydrogen or the *meta* chloro group is liberated from the ion which stems from **12***c*. The species obtained via hydrogen elimination (i.e., f_1 or f_3) then lose HCN, which indicates that this fragmentation process involves a 1,2-migration of the nitrogen substituent to the carbon atom bearing the phenyl group. The $C_{13}H_9^+$ fragment (*m/e* 165) obtained in this way from **12***a*, and for which the fluorenyl cation structure has been suggested, has also been observed for several other diphenyl substituted heterocyclic systems containing two heteroatoms (16, 17). Other fragmentation pathways, in addition to the two shown, contribute to the formation of *g* from e_1. Thus, the *m/e* 165 species is also formed from **12***b* and **12***c*, and furthermore, metastable ion measurements indicate that it is, in part, formed directly from *e*. For **12***b* and **12***c*, this requires the loss of HCN and the substituent from the 1-aryl group instead of an *ortho* hydrogen involved in $e \rightarrow g$. In addition, about 50% of one of the deuterium atoms is retained in the *m/e* 165 ion derived from 1,4-diphenylimidazole-2,5-d_2, an observation which implicates exchange of the imidazole and phenyl hydrogens prior to fragmentation of the diheteroatomic system (17).

The formation of the other fragment ions in these systems do not require the invervention of skeletal rearrangements. The genesis thereof can be rationalized in terms of simple cleavages of valence isomer b_3 of the diarylimidazole. The fragmentation modes $h \rightarrow i$–j and $k \rightarrow l$–m (Scheme 3) are supported by the expected mass shifts in the spectrum of 1,4-diphenylimidazole-2,5-d_2 and by metastable ion measurements on **12***a*–*c*, although the parent ions of



SCHEME 4

h and *k* could not be identified. It is noteworthy, however, that the aryl cation *l* is derived almost entirely from the *N*-aryl groups, an observation which may be of value for structure elucidation purposes.

The mass spectrum of the 1,5-disubstituted-1,2-dihydropyrazin-2-ones changes completely when the nitrogen substituent is a cyclohexyl group as in **12***d* (see Table 3). It is suggested that the fragmentation of this compound can be rationalized in terms of an initial McLafferty cleavage of the molecular ion as shown in Scheme 4. The expulsion of CO does take place to a significant extent, but only after the McLafferty cleavage has occurred (i.e., $n \rightarrow o_1 \rightarrow o_2$–$p$)

Experimental

The melting points were determined in a Mel-Temp apparatus and are corrected. The ir spectra were measured with a Perkin-Elmer model 237 grating infrared spectrophotometer. The nmr spectra were recorded with a Varian T-60 spectrometer. The low resolution mass spectra were measured on Varian-MAT CH-7 and AEI MS-9 mass spectrometers at 70 eV ionizing voltage. The high resolution analyses and metastable ion measurements were carried out on a Varian-MAT 311A mass spectrometer at 70 eV ionizing voltage, 10 000 resolution (10% valley), and ±2 ppm accuracy.

*Preparation of the Chloroacetamido Compounds **3** and **9***

These compounds were prepared by the method of Petersen and Lakowitz (18) except that dioxan was used as the solvent instead of chloroform. Compounds **3***d* (19) and **3***e* (10) have been described previously. The yields, melting points, etc. for the unknown chlorides are given in Table 1.

*Synthesis of the Azidoamides **4** and **10***

These compounds were synthesised from the chlorides and sodium azide by the method of Petersen and Lakowitz (18) except that dimethylsulfoxide was used as the solvent and the reaction was conducted at room temperature. The yields, melting points, etc. for these compounds are compiled in Table 1.

*Synthesis of the 1,3-Dihydro-2*H*-benzo-1,4-diazepin-2-ones **7***

To a stirred solution of the azide (1 equiv.) in anhydrous toluene (20–100 mL/g of the azide) was added triphenylphosphine (1.1 equiv.). Agitation was continued for the times and at the temperatures specified below. The progress of the cyclizations was followed by tlc.

Synthesis of 7c

The addition of triphenylphosphine to a toluene solution of the azide **4***c* caused an exothermic reaction to take place and a solid separated from solution. The mixture was kept at room temperature for 0.5 h (reaction apparently complete at this time) and at reflux temperature for 2.5 h.

Synthesis of 7d

The reaction was complete after 4 h at room temperature.

Synthesis of 7e *and Isolation of the Iminophosphorane* 5e

The solution was stirred at room temperature for 1 h and at reflux temperature for 18 h at the end of which time the iminophosphorane was no longer present.

To isolate the iminophosphorane hydrochloride, the solution obtained after 1 h at room temperature was evaporated to dryness *in vacuo*, and a 10% hydrochloric acid solution was added to the residue. The aqueous solution was decanted from the gummy residue, and the addition of ethyl acetate to this material caused crystallization to occur. The solid was collected by filtration, washed with water, and dried *in vacuo*. Crystallization of this substance from chloroform – ethyl acetate gave a white solid (83%) with mp 217–219°C dec. Recrystallization from ethyl acetate gave the analytical specimen, mp 222–224°C dec. *Anal.* calcd. for $C_{33}H_{26}ClN_2O_2P{\cdot}HCl$: C 67.69, H 4.65, N 4.79; found: C 67.85, H 4.51, N 4.76; ir ($CHCl_3$) ν_{max}: 3330, 2730, 2640, 2440, 1695, 1650 cm^{-1}; nmr ($CDCl_3$) δ: 3.73 (d, CH_2N, J_{PH} = 14.4 Hz), 7.15–8.05 (m, aromatic H's), 9.35 (s, HNP, W_H = 16 Hz, exchanged with D_2O), 10.93 (s, NHCO, W_H = 4 Hz, exchanged with D_2O).

To cyclize the iminophosphorane, an equimolar amount of the hydrochloride and sodium hydride was stirred at room temperature with anhydrous toluene (60 mL toluene/g of iminophosphorane hydrochloride) until hydrogen evolution had ceased. The mixture was stirred at reflux temperature for 4 h, during which period only a slight conversion to the cyclized material had occurred. At this time, 0.1 molar equivalents of triphenylphosphine (the catalytic effect of triphenylphosphine is not understood) was added, and stirring at reflux temperature was continued for 18 h. The reaction was worked up as described below to give a 96% yield of the crude (homogeneous by tlc) benzodiazepinone **7***e*. One crystallization of this material from ether–hexane gave the pure product mp 214–215°C (67%).

The isolation of the benzodiazepinones was carried out in the manner described below.

Compound **7***c* was very insoluble in toluene. When the reaction mixture had cooled to room temperature, this substance was collected by filtration and dried.

To isolate the other benzodiazepinones, the solvent was removed *in vacuo*, the residue was dissolved in ethyl acetate, and this solution was extracted with 10% hydrochloric acid. The acidic extract was cooled, made alkaline with 20% sodium hydroxide solution, and the product was extracted into ethyl acetate. The extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The residue was crystallized from an appropriate solvent.

The yields, melting points, etc., of the benzodiazepinones are compiled in Table 2. The identity of these compounds was ascertained from their characteristic nmr spectra (20) and from the good agreement of the observed melting points with those recorded in the literature. In addition, the ir spectrum of compound **7***c* was identical to that of an authentic specimen, and the mixture mp's of **7***d* and **7***e* with authentic samples were undepressed.

*Synthesis of the 1,2-Dihydropyrazin-2-ones **12***

*Synthesis of **12***a–c

A solution of the azide (1 equiv.) and triphenylphosphine (1.2 equiv.) in anhydrous toluene (10 mL/g of azide) was stirred at room temperature for 20 h. The solvent was removed *in vacuo* and the residue was then purified as described below.

Compound **12***a* was obtained pure by tlc of the mixture on silica gel using chloroform–acetone (95:5) as the developing solvent.

Compound **12***b* was separated from the reaction mixture by column chromatography on Florisil (100 g, for a 7.7 mmol scale reaction). The column was developed (100 mL fractions) with hexane (200 mL), hexane – ethyl acetate, 95:5 (400 mL), and hexane – ethyl acetate, 90:10 (600 mL). The product was contained in fractions 8–10.

Compound **12***c* was also purified by column chromatography on Florisil (50 g, for a 3.1 mmol scale reaction). The column was developed (100 mL fractions) in exactly the same

manner as described for **12***b*. The product was found in fractions 9–11.

Synthesis of **12**d

The synthesis of **12***d* was effected without purification of any of the intermediates.

Cyclohexylamine (5.8 mL, 50 mmol) was added, at −10°C, to a stirred solution of phenacyl bromide (5.0 g, 25 mmol) in anhydrous dichloromethane (100 mL) maintained in a nitrogen atmosphere. The reaction temperature was allowed to rise to 15°C and the mixture was stirred at this temperature for 1 h 40 min. The mixture was filtered, and chloroacetyl chloride (4.6 mL, 60 mmol) was added to the filtrate at room temperature. After a few minutes the solution was concentrated to a small volume *in vacuo*, water was added, and the mixture was extracted with ethyl acetate. The extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The residue was dissolved in benzene, the solution was washed with aqueous sodium carbonate solution, and then with water. The solution was dried, evaporated *in vacuo*, and the residue was chromatographed on alumina (250 g, Act. II, 200 mL fractions). The column was eluted with hexane (600 mL), hexane – ethyl acetate, 95:5 (1000 mL), hexane – ethyl acetate, 90:10 (100 mL), and hexane – ethyl acetate, 85:15 (2200 mL). The chloroamide **9***d* (2.25 g, 32% overall) was isolated as an oil from fractions 17–23. This substance had ν_{max} ($CHCl_3$): 1708, 1650 cm^{-1}, and was used directly in the next step.

The chloroamide was converted into the azido amide **10***d* in the manner described previously. The crude, oily azide (ν_{max} ($CHCl_3$): 2075, 1708, 1655 cm^{-1}) was obtained in 98% yield and was used immediately in the next step.

The azido compound was transformed into the corresponding pyrazin-2-one in the manner described above. The crude product was chromatographed on alumina (100 g for a 6.6 mmol reaction; Act II, 100 mL fractions). The column was eluted with hexane (300 mL) and hexane – ethyl acetate, 95:5 (1400 mL). The product was contained in fractions 8–12.

The 1,5-diaryl-1,2-dihydropyrazin-2-ones showed four intense ir ($CHCl_3$) bands at 1672 ± 2, 1616 ± 2, 1605 ± 3, and 1595 ± 5 cm^{-1}. Compound **12***d* had ν_{max} ($CHCl_3$): 1657, 1595 cm^{-1}. The yields, melting points, etc., for these compounds are compiled in Table 2.

2,5-Diphenylimidazole-2,5-d_2

A solution of 1,4-diphenylimidazole (10 mg) (13) in methanol-OD (5 mL, 99% d_1) containing sodium methoxide (prepared from sodium (50 mg)) was boiled under reflux for three days (nitrogen atmosphere) the progress of the exchange being followed by gc–ms analysis of periodically removed aliquots (0.1 mL). The solution was poured onto a mixture of ice and ether, the ether phase was washed with water, dried over sodium sulfate, and evaporated *in vacuo*. The crystalline residue exhibited 17% d_1 and 83% d_2.

When the exchange was carried out in MeOD–D_2O (9:1), in the presence of NaOD, the first deuterium was incorporated in ca. 20 h, presumably at position 2 (21). The exchange of the second hydrogen took place much more slowly.

Acknowledgements

We are grateful to Dr. H. Yamamoto, Sumitomo Chemical Co. Ltd., Osaka, Japan, for the ir and nmr spectra of **7***c*, and Dr. W. E. Scott, Hoffmann-La Roche Inc., Nutley, New Jersey, for a generous gift of compounds **7***d* and **7***e*. Also, we thank Dr. D. H. Smith, Stanford University, for recording the AEI MS-9 mass spectra. Finally, the skillful technical assistance of P. Demaree, H. Schären, and D. K. Cho of this Institute is gratefully acknowledged.

Phase transformation studies on $K_2Cr_2O_7$

MAHADEVA NATARAJAN AND ETALO A. SECCO[1]

Chemistry Department, St. Francis Xavier University, Antigonish, N.S., Canada B2G 1C0

Received June 6, 1979

MAHADEVA NATARAJAN and ETALO A. SECCO. Can. J. Chem. 57, 2703 (1979).

The phase transformations occurring in $K_2Cr_2O_7$ have been examined by differential thermal analysis (DTA), differential scanning calorimetry (DSC), specific heat measurements, electrical conductivity technique, and X-ray diffractometry. The results show that the polymorphic behavior of $K_2Cr_2O_7$ is very sensitive to the thermal and preparative history of the sample.

MAHADEVA NATARAJAN et ETALO A. SECCO. Can. J. Chem. 57, 2703 (1979).

A l'aide des méthodes suivantes: l'analyse thermique différentielle (DTA) la calorimétrie par balayage différentiel (DSC) les mesures de chaleur spécifique, la technique de conductivité électrique et la diffraction par rayons X, on a examiné les transformations de phase se produisant dans le $K_2Cr_2O_7$. Les résultats montrent que le comportement polymorphique du $K_2Cr_2O_7$ est très sensible au mode de préparation de l'échantillon et aux conditions thermiques utilisées.

[Traduit par le journal]

Introduction

Polymorphism in $K_2Cr_2O_7$ has been the subject of a number of studies (1–5). The room temperature (RT) stable structure of $K_2Cr_2O_7$ is triclinic (6) space group $P\bar{1}$ with cell constants $a = 13.376$ Å, $b = 7.376$ Å, $c = 7.445$ Å, $\alpha = 90.75°$, $\beta = 96.21°$, and $\gamma = 97.96°$.[2]

The triclinic form A transforms at ~270°C to a monoclinic form C, space group $P2_1/n$; the cell parameters reported (4) at 300°C are $a = 13.45$ Å, $b = 7.52$ Å, $c = 7.55$ Å, and $\beta = 91.68°$. Below 240°C monoclinic C transforms to a metastable monoclinic form B, probable space group $C2/c$, with lattice constants $a = 13.06$ Å, $b = 7.37$ Å, $c = 7.43$ Å, and $\beta = 91.85°$. The B → C transition was noted to occur at 255°C. However, the existence of a distinct monoclinic B phase in $K_2Cr_2O_7$ is questioned (5).

Our interest in phase transformation phenomena (7, 8) prompted us to investigate the polymorphic changes occurring in $K_2Cr_2O_7$. This paper presents the results of such an investigation using differential thermal analysis, differential scanning calorimetry, X-ray diffractometry, electrical conductivity, and infrared techniques.

Experimental

Certified ACS potassium dichromate (Fisher Scientific, ≥99.95% purity) was used in this work. The stock material was passed through a standard sieve (0.297 mm mesh) to obtain samples of uniform particle size for this study.

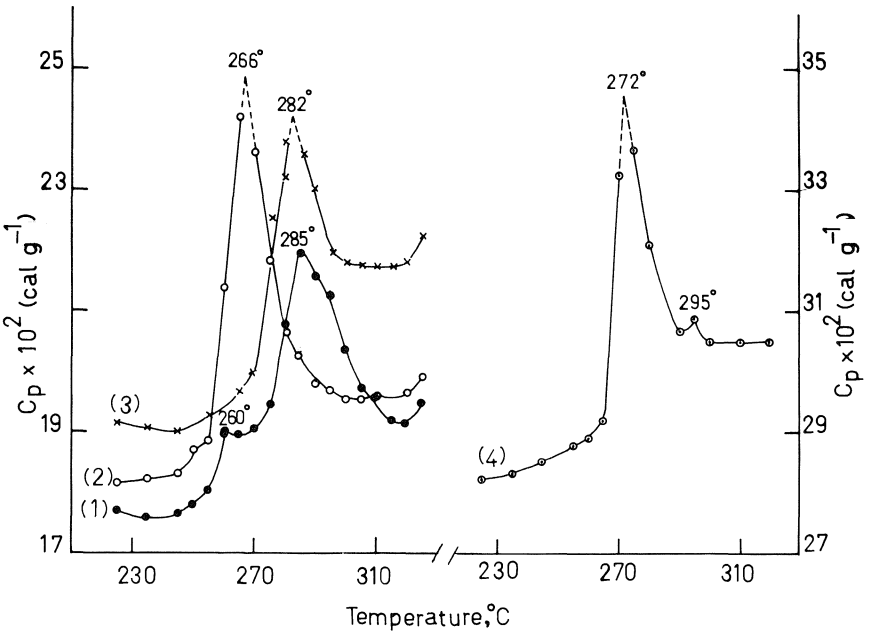

FIG. 2. Specific heat plots: *1*, stock triclinic $K_2Cr_2O_7$ fused and cooled to RT; *2*, reheat residue from *1*; *3*, $K_2Cr_2O_7$ precipitated slowly from aqueous solution; *4*, $K_2Cr_2O_7$ by heating aqueous solution to dryness.

Differential thermal analysis (DTA) and differential scanning calorimetric (DSC) traces were recorded on a duPont Model 990 Thermal Analyzer module with the appropriate attachments (9). Al_2O_3 was used as the reference material and the heating rate was 10° min^{-1}. The transition enthalpies were evaluated using the enthalpy of fusion for Sn as standard (ΔH_f = 14.14 mcal mg^{-1} at 231.9°C). Specific heat measurement traces with the DSC attachment used sapphire crystal as calibration standard.

X-ray diffraction patterns were recorded using a Norelco diffractometer, calibrated with Si standard, using CuK_α radiation (λ = 1.5418 Å) as previously described (10).

The procedure for the electrical conductivity measurements on compressed polycrystalline discs using General Radio impedance bridge GR-1608A has already been described (7, 11). Heating rate was 20° h^{-1}.

The infrared spectra of samples were recorded in the 4000–250 cm^{-1} region on Perkin-Elmer Model 180 spectrophotometer using the standard disc technique with KBr or KCl as matrix.

Results and Discussion

DTA traces are presented in Fig. 1. Curve *1* represents the heat mode for stock triclinic $K_2Cr_2O_7$ undergoing a sharp transition to stable monoclinic structure at 272°C; the enthalpy for this A → C transition was determined to be 385 ± 10 cal mol^{-1}. Curve *2* represents the cool mode of the fused product from curve *1*; the weak exotherm at 226°C assigned to the C → B transition corresponds to an enthalpy of 30 ± 5 cal mol^{-1}. Immediate reheating of this residue, curve *3*, yields a weak endotherm at 255°C with an enthalpy of 30 ± 5 cal mol^{-1}. After remaining at RT for 2 h, the sample gave curve *4* in the heat mode with the endotherm at 260°C and curve *5* in the cool mode with the exotherm at 232°C. Curves *6* and *7* represent heat and cool modes of the sample, respectively, after remaining at RT for 48 h — standing at RT sharpens the thermal effects and shifts the peak temperatures.

Curve *8* represents stock triclinic $K_2Cr_2O_7$ heated to 350°C, identical thermal effect as curve *1*. Curve *9* represents the cool mode of the product from curve *8* with an exotherm extending over the temperature range 202–238°C; the broad exotherm suggests a slow C → B transformation rate. Reheating the residue, curve *10*, produces the endotherm at 259°C and re-cooling the sample yields curve *11*; further heat–cool cycles do not alter significantly the DTA traces of this sample.

The transition enthalpy at 270°C for well-powdered (ground in mortar) stock triclinic $K_2Cr_2O_7$ was determined to be 180 ± 10 cal mol^{-1} in contrast to 385 cal mol^{-1} for "as bottled" sample; the enthalpy of this sample attains the value of 380 cal mol^{-1} after repeated heat–cool cycles. The lower enthalpy indicates that a partial conversion of form A to form C had occurred on grinding. Since the three forms of $K_2Cr_2O_7$ have been correlated (1) with different layer arrangements of the basic Cr_2O_7 unit it is most probable that the A → C transition, occurring via a displacive mechanism is effected by the grinding shear energy.

The specific heat curves *1–4*, Fig. 2, clearly show

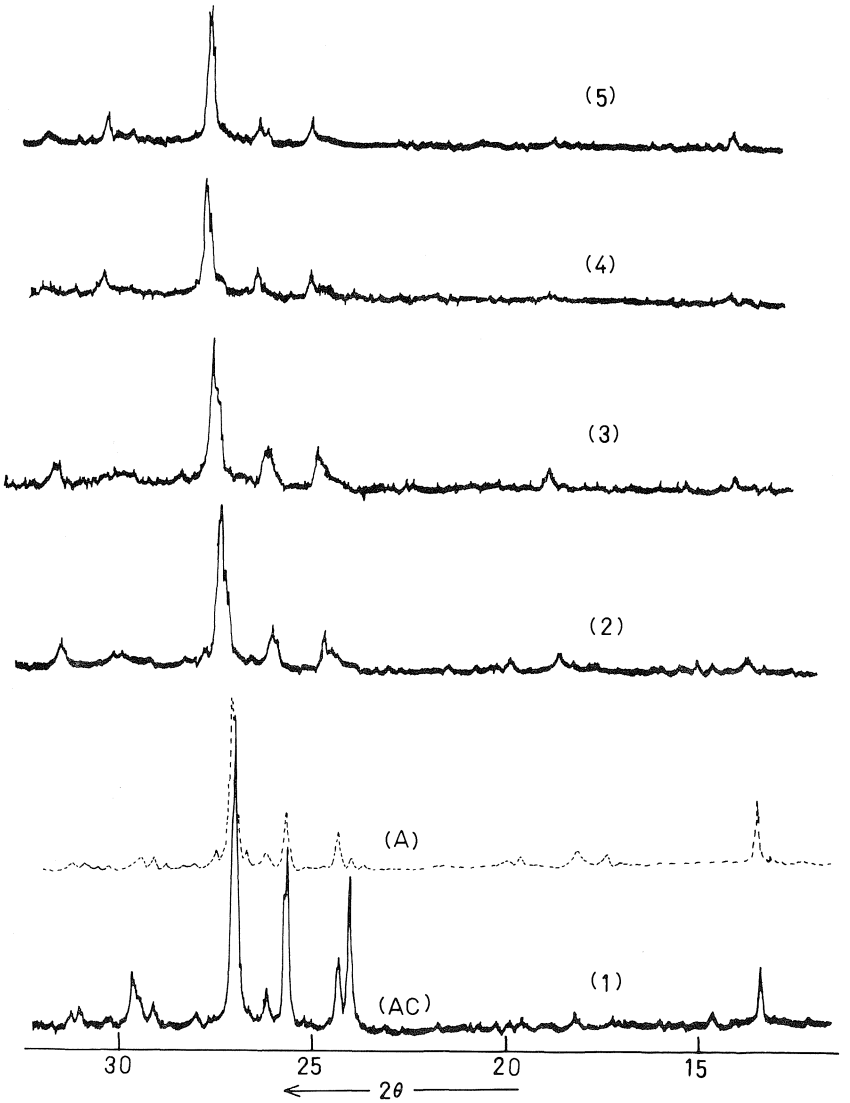

FIG. 3. X-ray diffractograms at RT: A, stock triclinic $K_2Cr_2O_7$; AC, well powdered stock $K_2Cr_2O_7$; *1*, identical to AC; *2*, after heating *1* to 300°C; *3*, after remaining 3 h at RT; *4*, after reheating *3* to 300°C; *5*, after remaining 17 h at RT.

distinct features of the different samples.[3] Curve *1*, stock sample fused and cooled to RT, exhibits a weak anomaly at 260 ± 2°C interpreted as a small fraction of B transforming to C with an intense anomaly at 285°C assigned to triclinic A conversion to monoclinic C. Reheating this cooled sample revealed a single sharp anomaly at 266 ± 2°C, curve *2*, interpreted as the pure A → C transition. The specific heat behavior of $K_2Cr_2O_7$ precipitated slowly from aqueous solution, curve *3*, produces a single sharp anomaly at 282°C. On the other hand, $K_2Cr_2O_7$ obtained by gently heating an aqueous solution to dryness, curve *4*, reveals an intense anomaly at 272 ± 2°C along with a very weak one at 295°C.

The X-ray diffractograms of $K_2Cr_2O_7$ exposed to specific anneal conditions are presented in Fig. 3. The stock sieved sample produces pattern A, with peaks characteristic of triclinic A, whereas the well-powdered stock sample gives pattern AC, with peaks characteristic of both triclinic A and monoclinic C forms. The sequence of X-ray diffractograms, curves *1–5*, shows the progress of the characteristic peaks as a function of anneal and storage variables.

[3]Comment added in proof: The additional contribution to the specific heat of sample 4, Fig. 2, relative to samples 1–3 could originate with an ionic complex, e.g. $(CrO_4 \cdot CrO_3)^{2-}$?

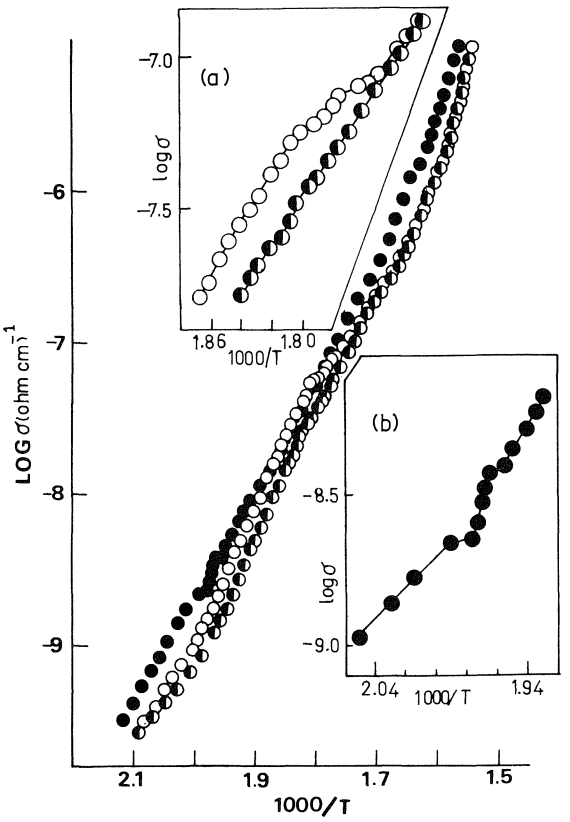

FIG. 4. Logarithm of conductivity, σ, versus $10^3/T$ K plots at reduced pressure, $\sim 10^{-2}$ Torr: ○, stock well-powdered $K_2Cr_2O_7$ in heat mode; ●, heated product in cool mode; ◐, quenched $K_2Cr_2O_7$ in heat mode.

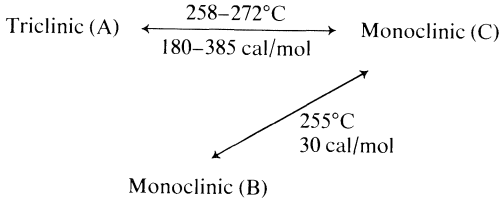
Figure 4 presents the conductivity versus temperature plots for $K_2Cr_2O_7$. The conductivity for stock well-powdered $K_2Cr_2O_7$ (unfilled circles) in the heat mode shows a break from linearity in the temperature region 279–288°C, inset (*a*). The conductivity behavior in the cool mode (filled circles) shows a discontinuity over the temperature range 240–230°C, inset (*b*), with higher conductivity values. The conductivity data for a quenched sample in the heat mode (half-filled circles) are lower for lower temperature region but merge with the stock sample data at elevated temperatures — a barely discernible break occurs in the region 276–282°C, inset (*a*). All the conductivity data are reproducible well within the limits of the bridge sensitivity and therefore, the discontinuities are to be viewed with a high degree of confidence.

Since the infrared spectra of all samples were identical no additional structural correlation was evident.

DTA traces obtained on single crystals of $K_2Cr_2O_7$, grown by slow evaporation (10 days) of aqueous solutions, exhibited non-reproducible extraneous thermal effects in the heat mode, including an exotherm. The extraneous effects, most likely due to lattice strain energy, were absent after the single crystal had been powdered.

In summary, this study shows that the polymorphic behavior in $K_2Cr_2O_7$ is not straightforward and very sensitive to the thermal and preparative history of the sample as evident by the results from DTA, calorimetry, specific heat, electrical conductivity, and X-ray diffraction. The phase relationships with transition temperature ranges and transition ΔH values are presented below:



The coexistence of mixed A and C phases produces a range in transition temperatures and ΔH values. Although monoclinic B exists at RT it does not transform to RT stable triclinic directly but only via monoclinic C. The low transition ΔH values observed for $K_2Cr_2O_7$ relative to Na_2SO_4 (8) suggest that the $K_2Cr_2O_7$ phases are energetically quite similar.

J. KORPPI-TOMMOLA and H. F. SHURVELL. Can. J. Chem. 57, 2707 (1979).

Complex formation between pentachlorophenol-OD (PCP-OD) and acetone and acetone-d_6 in CCl_4 solution has been studied. Digitized infrared spectra in the O—D stretching region ν(OD) of PCP-OD and the C—O stretching region ν(CO) of acetone have been recorded from solutions of various concentrations. The present results are compared with previous work on complex formation between PCP and the same acceptor molecules.

In the ν(OD) region, factor analysis (principal component analysis) and a concentration study of the areas of the resolved band components suggest that two (1:1) complexes occur in solution. The equilibrium constant obtained for one of the complexes shows an isotope effect due to deuteration of the proton donor. In the ν(CO) region, only one band due to complexed species was resolved. Equilibrium constants calculated using the results from the ν(OD) and ν(CO) regions are in good agreement with each other.

J. KORPPI-TOMMOLA et H. F. SHURVELL. Can. J. Chem. 57, 2707 (1979).

On a étudié, en solution dans le CCl_4, la formation de complexe entre le pentachlorophénol-OD (PCP-OD) et l'acétone, et l'acétone-d_6. A partir de solutions à différentes concentrations, on a enregistré les spectres numériques ir dans la région d'élongation du O—D ν(OD) du PCP-OD et la région d'élongation du C—O ν(CO) de l'acétone. On a comparé ces résultats à ceux de travaux antérieurs sur la formation de complexes entre le PCP et les mêmes molécules "accepteurs".

Dans la région ν(OD), le facteur d'analyse (analyse du constituant principal) et l'étude de concentration des surfaces des bandes résolues des constituants suggérent que deux complexes (1:1) se forment en solution. La constante d'équilibre obtenue pour l'un de ces complexes montre un effet isotopique due à la deutération du donneur de proton. Dans la région ν(CO) seule une bande due à l'espèce complexe a été résolue. Les constantes d'équilibre calculées en utilisant les résultats obtenus à partir des régions de ν(OD) et ν(CO) sont en parfait accord avec l'une et l'autre.

[Traduit par le journal]

Introduction

Self-association of alcohols and phenols and complex formation with other proton acceptors in solution have been studied extensively by infrared spectroscopy. In earlier work (1, 2), equilibrium constants have been obtained from the concentration dependence of the monomer hydroxyl stretching band only, while the band due to association or complex formation was usually ignored. The application of factor analysis (principal component analysis) to digitized infrared spectra leads to the determination of the number of absorbing components in a complex band (3). Subsequent band resolution and the calculation of band areas and molar absorption coefficients allows various models of complex formation to be tested and equilibrium constants to be calculated (3, 4). Additional quantities such as wavenumber maxima and half-widths of bands assigned to complexed species can be obtained. These quantities, together with the equilibrium constants, provide a qualitative as well as quantitative picture of association or complex formation in solution and utilize fully the data recorded in a given spectral region.

Fundamental bands associated with the vibrations of the functional groups involved in hydrogen bonding are subject to both frequency and intensity changes in the vibrational spectrum. In some cases, direct study of the hydrogen-bond stretching modes is possible (5). Several matrix-isolation infrared self-association studies have shown that hydrogen bonding manifests itself in all three vibrational modes of the hydroxyl group in alcohols (6, 7). When complex formation occurs between alcohols or phenols and ketones, both the ν(OH) band and the ν(CO) band show concentration dependencies (4). In principle, any band in the vibrational spectrum, which undergoes changes due to hydrogen bonding can be used to calculate the equilibrium constants. One purpose of the present study was to compare the calculated parameters of the bands due to complexed species and the equilibrium constants obtained from studies of two separate regions of the infrared spectrum.

In our recent study of complex formation between PCP and acetone in CCl_4 solution (4), conflicting results were obtained from factor analysis and band

0008-4042/79/202707-07$01.00/0

resolution. In the ν(OH) region, factor analysis indicated three absorbing components, whereas the band resolution procedure gave a better fit when four components were used. It was therefore of interest to see if this conflict would also arise in the ν(OD) region of the spectra of PCP-OD/acetone mixtures.

We have recorded infrared spectra of pentachlorophenol-OD (PCP-OD) and acetone and PCP-OD and acetone-d_6 in CCl_4 solution in the O—D stretching region of PCP-OD and in the carbonyl stretching region of acetone. The spectra were digitized and factor analysis and band resolution were carried out. The molar absorption coefficients were calculated for each set of solutions and equilibrium constants were then calculated. The results are compared to those obtained earlier for normal PCP/acetone and acetone-d_6 complexes (4) and to those reported previously for phenol and phenol-OD/acetone complexes (8–10).

Experimental

Deuterated pentachlorophenol (PCP-OD) was synthesized by shaking a warm PCP/carbon tetrachloride solution with D_2O and re-crystallizing the deuterated phenol, which precipitates on cooling. The procedure was repeated several times until deuteration was better than 90%. Samples were contained in Beckman- R.I.I.C. variable pathlength cells and the spectra were recorded on a Perkin-Elmer 180 spectrometer. Pathlengths were determined using the fringe method from 0.05 to 0.2 mm and linearity of micrometer readings with pathlength was assumed over the range used in this work. When recording the spectra in the ν(OD) region the spectrometer was flushed with nitrogen gas to minimize absorption by carbon dioxide. The same solutions were used in both ν(OD) and ν(CO) regions, with the pathlengths adjusted accordingly. Concentrations were corrected for the thermal expansion of CCl_4 due to heating of the sample by the infrared beam of the spectrometer.

A spectrum of PCP-OD in CCl_4 solution was recorded and areas of the ν(OH) and ν(OD) bands were measured. These areas were used to estimate the isotopic concentration ratio k, given by:

$$[1] \qquad k = \frac{C_{OD}}{C_{OH} + C_{OD}} = \frac{A_{OD}}{A_{OD} + (\varepsilon_{OD}/\varepsilon_{OH})A_{OH}}$$

where C_{OD} and C_{OH} are the concentrations of PCP-OD and PCP and A_{OD} and A_{OH} are the areas of the ν(OD) and ν(OH) bands respectively. The observed spectra were digitized at 2.5 cm^{-1} intervals in the ν(OD) region giving 281 data points, while in the ν(CO) region the digitization inverval was 1.0 cm^{-1} giving 151 data points per spectrum. The digitizing procedure and the further computational processing of the data are reported in detail in ref. 4. The details of the solutions and the pathlengths are not given here, but these are available from the authors on request.

PCP is unusual in that it does not undergo self association in CCl_4 solution (11). Thus no complication of the spectra in the OD stretching region is expected from self association and any absorption in addition to the free ν(OD) band must be due to formation of complexes.

The possibility of interference from water in the phenol, or the solvents has been considered. Independent experiments indicate that small added amounts of moisture do not significantly perturb the OH stretching band. Nevertheless, as a precaution, all solvents were stored over molecular sieves and all manipulations, except weighing, were carried out in a dry box.

Chemical Equilibrium

Our previous results in the ν(OH) region of PCP (4) and the present results in the ν(OD) region of PCP-OD suggest that there are two 1:1 pentachlorophenol–acetone complexes in CCl_4 solution. In the PCP-OD case, the solutions always contain some of the non-deuterated phenol and its complexes. The calculation of the equilibrium constants accordingly becomes somewhat complicated. The total initial concentration of donor OH or OD groups (C_d^T) is distributed among six species at equilibrium as follows:

$$[2] \qquad C_d^T = C_d^{OH} + C_d^{OD} + \sum_{i=1}^{4} C_{11}{}^i$$

where C_d^{OH} and C_d^{OD} are the equilibrium concentrations of uncomplexed donor species PCP and PCP-OD and $C_{11}{}^i$ is the concentration of the ith 1:1 complex (either a PCP-OD or a PCP complex). Using the Beer–Lambert law:

$$[3] \qquad A = \varepsilon C l$$

where A = absorbance, ε = molar absorption coefficient, and l = pathlength. We can rewrite eq. [2] as:

$$[4] \qquad C_d^T = \frac{A_{OD}}{\varepsilon_{OD} l} + \frac{A_{OH}}{\varepsilon_{OH} l} + \sum_{i=1}^{4} \frac{A_i}{\varepsilon_i l}$$

where A_i and ε_i are the absorbance and molar absorption coefficients respectively of the ith 1:1 complex (either a PCP-OD or a PCP complex).

The concentration (C_a) of the uncomplexed acceptor species (acetone) at equilibrium is given by:

$$[5] \qquad C_a = C_a^T - \sum_{i=1}^{4} C_{11}{}^i$$

and from eq. [2] we obtain:

$$[6] \qquad C_a = C_a^T - C_d^T + C_d^{OH} + C_d^{OD}$$

Using the isotopic concentration ratio k from eq. [1] we can write:

$$[7] \qquad C_a = C_a^T - C_d^T + C_d^{OD}/k$$

Again using the Beer–Lambert law eq. [7] becomes:

$$[8] \qquad C_a = C_a^T - C_d^T + A_{OD}/\varepsilon_{OD} k l$$

For the equilibrium between PCP-OD and acetone we can write:

$$[9] \qquad K_{11}{}^i = C_{11}{}^i / C_d^{OD} C_a$$

where i = 1 or 2 for the first or second 1:1 complex respectively.

Finally, eq. [9] can be written as

$$[10] \qquad K_{11}{}^i = A_i \varepsilon_{OD} / A_{OD} \varepsilon_i C_a$$

In the ν(CO) region, the calculations were made in the same way, except that only one complex band was assumed to occur in solution and the monomeric donor concentration (C_d^{OD}) was considered as an unknown in eq. [6] instead of the monomeric acceptor concentration. For comparison, 1:1 equilibrium constants were also calculated using the areas of the monomer ν(OD) band.

Results and Discussion

Typical concentration behaviour of the ν(OD) band is seen in Fig. 1. For a fixed PCP-OD initial concentration the sharp monomer band at 2608 cm^{-1} decreases in intensity relative to the broad complex band on the lower frequency side as the acetone concentration is increased. For the PCP-OD/acetone complex band shown in Fig. 1 there are no interfering ν(CH) bands and the concentration dependence is similar to that of the PCP/acetone complex bands in ref. 4. On the other hand, it is seen in Fig. 2 that the concentration behaviour in the ν(CO) region is reversed. The monomer band at 1718 cm^{-1} increases in intensity relative to the complex band which appears as a shoulder on the lower frequency side as the acetone concentration is increased. This kind of behaviour is expected, since at fixed PCP-OD concentration a decreasing proportion of acetone molecules forms complexes as the acetone concentration is increased.

Factor Analysis

In the ν(OD) region, factor analysis (principal component analysis) indicates three absorbing components for both sets of solutions studied (i.e. for PCP-OD/acetone and PCP-OD/acetone-d_6 in CCl_4). Three absorbing components were also found previously for non-deuterated PCP/acetone solutions in the ν(OH) region. To illustrate the method, the results of the factor analysis are given here for the PCP-OD/acetone system. Similar results were obtained for the PCP-OD/acetone-d_6 system.

The number of absorbing components NC in a complex band is taken as the number of statistically non-zero eigenvalues of the matrix $\mathbf{Q} = \mathbf{A}^T\mathbf{A}$ (3), where $\mathbf{A}$ is the absorbance matrix for all solutions studied and $\mathbf{A}^T$ is its transpose. Details of four statistical tests to determine the number of non-zero eigenvalues of $\mathbf{Q}$ are given in ref. 3.

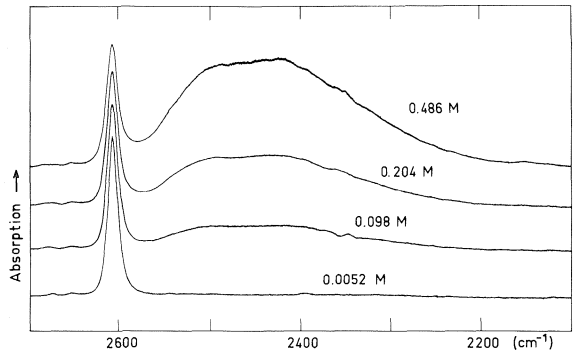

FIG. 1. Infrared spectra in the ν(OD) region of various solutions of PCP-OD/acetone in CCl_4. Acetone concentrations are shown on the figure. The PCP-OD concentration was 0.045 *M*.

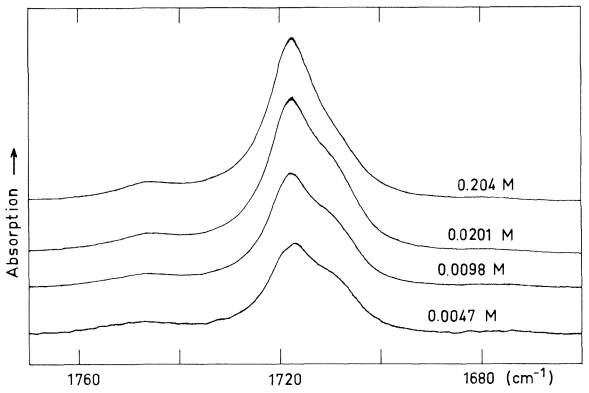

FIG. 2. Infrared spectra in the ν(CO) region of various solutions of PCP-OD/acetone in CCl_4. Acetone concentrations are shown on the figure. The PCP-OD concentration was 0.045 *M*.

The matrix $\mathbf{A}$ is an NW by NS matrix, where NW is the number of digitized points in the spectrum and NS is the number of solutions studied. The results of two statistical tests are given in Table 1. When the residual standard deviation (S_k) is calculated using two eigenvalues, then S_2 is greater than the experimental error in the absorbance measurements (DA). On the other hand, S_3 is less than DA. This indicates that NC = 3. There is also a leveling off of the eigenvalues below the third entry. The square root of the estimated variance criterion also indicates that NC is three, since the variance of the fourth eigenvalue is more than three times larger than the eigenvalue itself.

Table 2 summarizes the results of a regeneration of the absorbance matrix using m eigenvectors ($m = 1, 2, \ldots, NS$) for DA = 0.01. The smallest number of eigenvectors to give a satisfactory fit with the experimental A is equal to NC. When three eigenvectors are used to regenerate the absorbance matrix, only 72 points out of 2529 deviate by more

9	2529	0	0	0	0	0	0	0

[a]Experimental absorbance error DA = 0.01.

than two standard deviations from the experimental values. Adding the fourth eigenvector does not markedly improve the fit. Thus, it is concluded that NC = 3. A final criterion is the calculation of χ_m^2 using from one to nine eigenvectors of **Q** and comparing these with the expectation values, given by $(NW - m)(NS - m)$. It is seen that χ_3^2 is smaller than the corresponding expectation value, while χ_2^2 is larger, which indicates that NC = 3.

In the ν(CO) region, factor analysis indicates again three absorbing components. However, the interpretation here is different. There are two monomer bands and only one complex band in the spectra, as indicated by the concentration study. It can be seen in Fig. 2 that there is a broad shoulder on the high frequency side of the main ν(CO) peak. The intensity of this shoulder increases with increasing acetone concentration. In acetone-d_6 a Fermi doublet (12, 13) is observed, while the complex band is found as an asymmetry on the lower frequency side. These features are illustrated in Fig. 3, where CALCOMP plots of the various resolved components are shown.

Band Contour Resolution

A band resolution programme (PC 116) originally written by Jones *et al.* (14) was modified to perform the calculations in absorbance units. Baseline subtraction and band area computation subroutines have been added to the program. Three Gauchy–Gauss product functions were used to reproduce the experimental spectrum in the ν(OD) region. Plots of typical resolved spectra are shown in Fig. 4.

When the number of components NC is not known, components are added sequentially to an initial trial fit, at the position of greatest difference between observed and calculated contours, until an acceptable fit is obtained. The criterion of an

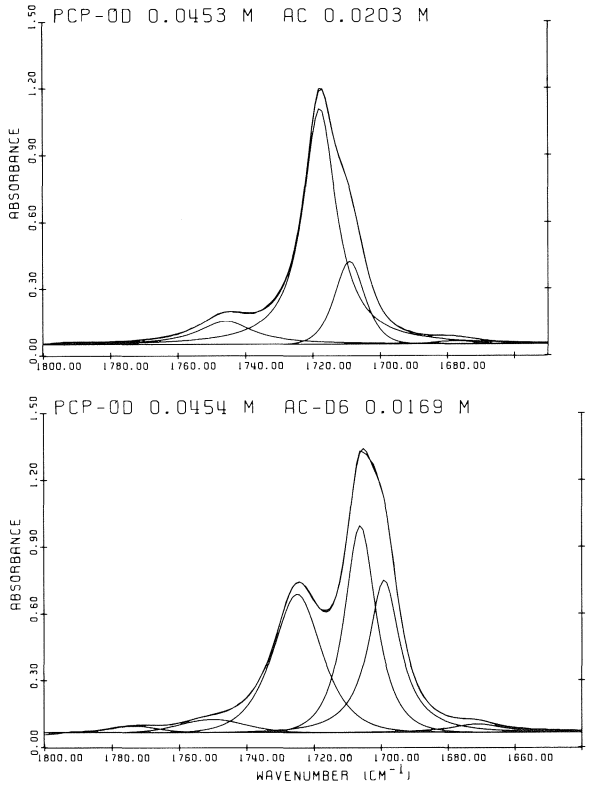

FIG. 3. Resolution of a typical ν(CO) band of PCP-OD/acetone (upper) and of PCP-OD/acetone-d_6 in CCl_4 (lower).

acceptable fit is found from the sum of the squares of the differences between experimental and computed absorbance values at each of the NW points in the digitized spectrum. When this sum is approximately equal to $S_A^2 \cdot NW$ (where S_A is the standard deviation in the absorbance measurements) then the fit is good. Addition of further components would improve the fit beyond experimental error. For the

band fitting program, it is assumed that all bands are symmetric and in the present case it is also assumed that only the OD stretching modes of the species present contribute to the overall contour. However, in the presence of extraneous absorption, due perhaps to weak overtone or combination bands, or an asymmetry in one or more of the component bands, which could arise from the presence of "hot" bands,[1] the criterion for a good fit may not be satisfied by only NC components. In such cases additional components will improve the fit but may not be reasonable from the point of view of the chemistry of the system under study. The OD stretching band of solutions of PCP-OD with acetone in CCl_4 provides an example of this problem. The three band fits shown in Fig. 4 give a sum of squares of errors greater than $S^2 \cdot NW$, whereas addition of a fourth component gives an excellent fit with the experimental spectrum, as may be seen in Fig. 5. For a four-band fit, the areas of the three resolved bands due to complexed species each show a linear relationship to the area of the monomer ν(OD) band. This result requires that three (1:1) complexes be present in solution. However, we reject this conclusion for several reasons. First, factor analysis clearly indicates that only three components contribute to the absorption in the ν(OD) region. Secondly, it was not possible to obtain a consistent set of molar absorption coefficients for the four-component model and finally, it is difficult to find chemically reasonable structures for three 1:1 complexes. We therefore believe that the three-component fit for the ν(OD) band is correct.

Average wavenumber maxima and half-widths of the resolved bands of the three-band fit are given in Table 3. The standard deviations indicate that the monomer ν(OD) bands have an excellent wavenumber position and half-width consistency.

Four- and six-component fits were carried out in the ν(CO) regions of acetone and acetone-d_6, respectively. These fits are illustrated in Fig. 3. However, only the three main components, as suggested by factor analysis, were used to calculate the equilibrium constants. In the ν(CO) region the wavenumber maxima and half-width consistency of the resolved band components are also excellent, as is seen in Table 3.

To illustrate the frequency changes typical of the modes involved in hydrogen bonding, we have tabulated Δν values in Table 4 ($\Delta\nu = \nu_0 - \nu_i$, where ν_0 and ν_i are the wavenumbers of bands due to the free and the *i*th complexed species, respectively).

[1] "Hot" bands arise from transitions for which the lower state is not the ground state.

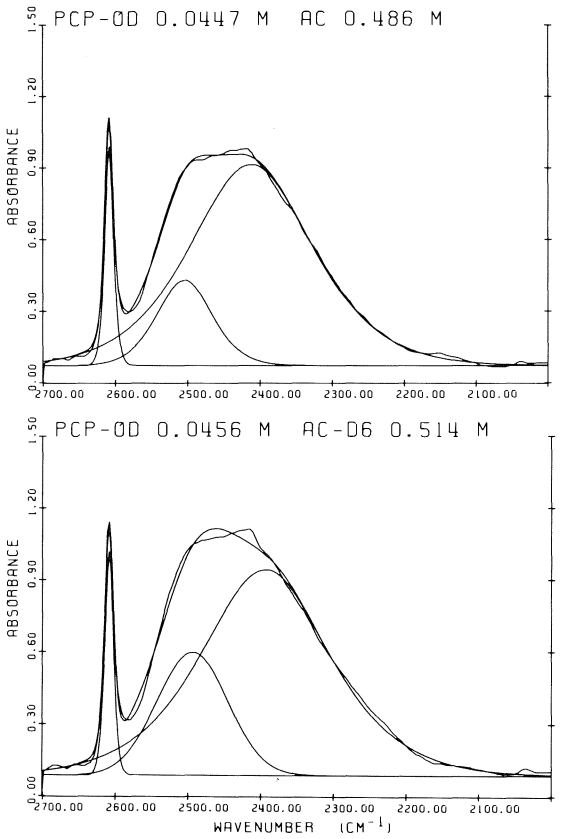

FIG. 4. Resolution using a three-component fit of a typical ν(OD) band of PCP-OD/acetone in CCl_4 (upper) and of PCP-OD/acetone-d_6 (lower).

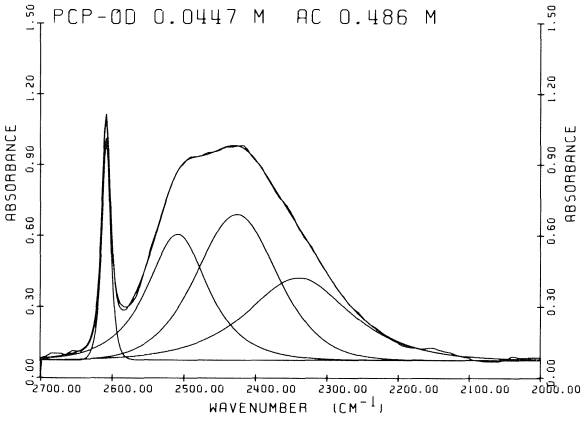

FIG. 5. Resolution using a four component fit of a typical ν(OD) band of PCP-OD/acetone in CCl_4.

Relative wavenumber perturbations $\Delta\nu/\nu_0$ and half-widths in each complex band studied are also included in Table 4. Our Δν values for the two (1:1) complexes in the PCP/acetone and PCP-OD/acetone systems in the hydroxyl stretching region are higher

[b]These results are from ref. 4. The frequency of the monomer band is ν_0.

than those reported for phenol/acetone (135 and 235 cm^{-1}) and phenol-OD/acetone (90 and 160 cm^{-1}) respectively (9). Larger Δν values in PCP complexes could be interpreted as an indication of stronger complexing of acetone with the chlorinated proton donor.

The isotopic frequency ratio ν_{OH}/ν_{OD} for the monomer band of PCP is 1.350, while for the bands due to complexes, ν_{OH}/ν_{OD} is ~1.335. Using eq. [3] from p. 20 of ref. 7, it appears that for PCP/acetone complexes, O—H···O bonding is slightly stronger than O—D···O bonding. This result is independent of the deuteration of acetone. In the ν(CO) region the Δν values are larger for acetone/PCP complexes than for acetone-d_6/PCP complexes, independent of PCP deuteration. The values of Δν are compared in Table 4.

The relative frequency perturbation ($\Delta\nu/\nu_0$) in the ν(OH) region seems to be higher than that in the ν(OD) region. A similar result has been reported previously for some phenol complexes (15). From Tables 3 and 4 it can be seen that for the bands in the ν(CO) region, changes in half-width on complex formation as well as $\Delta\nu/\nu_0$ are an order of magnitude less than corresponding quantities in the hydroxyl stretching regions. This observation indicates that hydrogen bonding results in a considerable perturbation of the hydroxyl stretching mode of the proton donor, while the influence on the ν(CO) mode of the proton acceptor is small, but not negligible.

It seems reasonable to conclude that the hydrogen-bond energy originates mainly from the functional group of the proton donor.

Equilibrium Constants

Before proceeding to calculate the molar absorption coefficients by a linear regression program, the band resolution was carried out for a second time. A chemical requirement, that each of the complexes should absorb at a particular wavenumber independent of its concentration in the solution, was introduced into the calculation by fixing the wave-

[b]These data are from ref. 4.

numbers of the monomer and the resolved complex bands to the average wavenumbers obtained previously for each set of solutions (Table 3). Only the peak height and band shape parameters were allowed to change in the second iteration process. The fixing of the wavenumbers resulted in slightly worse fits, but more consistent sets of band areas were obtained for each set of solutions, especially at low complex concentrations. The linear regression method, used to calculate the molar absorption coefficients, seemed to be very sensitive to the actual values of the band areas, as is indicated by fairly large standard deviations of the values of ε in Table 3. In each set of solutions the complex-band areas showed a linear relationship with the corresponding monomer-band areas, indicating that only (1:1) complexes occur in solution. According to our assignments, we have two (1:1) complexes in solution. Individual bands for each of these complexes have been obtained in the ν(OD) region, and from the areas of these bands, equilibrium constants $K_{11}^{(1)}$ and $K_{11}^{(2)}$ can be calculated for the formation of the two complexes labelled $(1:1)^1$ and $(1:1)^2$. The calculated values of $K_{11}^{(1)}$ and $K_{11}^{(2)}$ are given in Table 5.

Only one complex band can be resolved in the ν(CO) region and from the concentration dependence of the area of this band a combined equilibrium constant, K_{11}, can be calculated. This implies that there is no difference, from the point of view of the ν(CO) band of the acceptor molecule, between the two (1:1) complexes. A calculation of K_{11} can also be made using the concentration dependence of the free ν(OD) band. The results of these calculations are shown in the last two columns of Table 5.

From the algebraic expressions for $K_{11}^{(1)}$ and $K_{11}^{(2)}$, it follows that $K_{11} = K_{11}^{(1)} + K_{11}^{(2)}$. By adding the values of $K_{11}^{(1)}$ and $K_{11}^{(2)}$ from columns 2 and 3 of Table 5 and comparing these sums with the corresponding values of K_{11} in columns 4 and 5, it is seen that this simple relationship does appear to hold.

Conclusions

The calculated equilibrium constants $K_{11}^{(1)}$, $K_{11}^{(2)}$, and K_{11} show standard deviations of less than 20%, which gives a rough picture of the accuracy of the method used. The equilibrium constants in the hydroxyl stretching region show two isotopic effects. The value of $K_{11}^{(1)}$ increases slightly when PCP is deuterated for complex formation with either acetone or acetone-d_6. On the other hand, the value of $K_{11}^{(1)}$ is lowered when deuterated acetone replaces normal acetone as the acceptor. The value of $K_{11}^{(2)}$ is either almost unchanged or slightly lowered when PCP is deuterated. Examination of the ratio $K_{11}^{(2)}/K_{11}^{(1)}$ leads to the conclusion that the $(1:1)^2$ complex is favoured by deuteration of acetone, while the $(1:1)^1$ complex is favoured by deuteration of PCP.

PF_3 and CO react with $CuAsF_6$ in SO_2 solution to form 1:1 addition compounds, the vibrational spectra of which are consistent with the formulations $[CuPF_3]^+[AsF_6]^-$ and $[CuCO]^+[AsF_6]^-$. The latter has a ν[CO] stretch at 2180 ± 5 cm^{-1}, the highest yet observed for a monocarbonyl.

C. David Desjardins, D. Brian Edwards et Jack Passmore. Can. J. Chem. **57**, 2714 (1979).

La trifluorophosphine et le monoxyde de carbone réagissent avec l'hexafluoroarsenate de cuivre dans une solution de bioxyde de soufre pour conduire aux composés d'addition 1:1. Les spectres de vibration de ces produits d'addition permettent de conclure à la formation de composés de type: $[CuPF_3]^+[AsF_6]^-$ et $[CuCO]^+[AsF_6]^-$. Ce dernier a une élongation ν[CO] à 2180 ± 5 cm^{-1} la plus grande valeur observée jusqu'à présent pour un composé monocarbonylé.
[Traduit par le journal]

We previously described the preparation of $CuAsF_6$ containing the Cu^+ ion in a very weakly basic environment (1). In such an environment Cu^+ and related transition metal ions are potentially powerful electron acceptors towards a variety of ligands (2, 3). In general, $[Cu^IL]^+$ complexes are unstable unless other ligands are present. For example, although complexes containing phosphorus ligands are well known (4–6), no simple $[CuPF_3]^+$ complexes have been reported. Also, the ready formation of $[Cu^I(am)_3CO]^+$ complexes (am_3 = ammine ligand(s) occupying 3 coordination sites (7)) is in contrast to the simple triatomic $[CuCO]^+$, known so far only in $[Cu^ICO]^+[CF_3CO_2]^-$ (8) in which there is likely to be strong cation–anion interaction. We report below the preparation of $[CuPF_3]^+[AsF_6]^-$ and $[CuCO]^+[AsF_6]^-$.

Experimental Section

Chemicals, experimental procedures, and the preparation of $CuAsF_6$ have been described (1). Phosphorous trifluoride (Pfaltz and Bauer) and carbon monoxide (Matheson, 99.5%) were used directly. Analytical results were obtained from Alfred Bernhardt Microanalytical Laboratories. A Raman spectrum of $CuAsF_6 \cdot PF_3$ was obtained by use of a Spex Industries 1400 spectrometer and a Spectra-Physics 140 Argon-ion laser at liquid nitrogen temperatures.

Preparation of $CuAsF_6 \cdot PF_3$

In a typical reaction $CuAsF_6$ (2.2 g, 8.7 mmol) was dissolved in sulphur dioxide (ca. 5 g) and then reacted with excess PF_3 (1.5 g, 17.0 mmol) in a glass vessel (ca. 80 mL) equipped with a medium glass fritted disc and a "Rotaflo" valve. On warming to room temperature from −196°C, the reddish brown $CuAsF_6$ solution immediately became colourless. After 1 h, all volatiles were removed under dynamic vacuum leaving a solid white product (2.79 g) which corresponds to formation of a 1:1 adduct. Analytical results obtained (*Anal.* calcd. for $CuAsF_6 \cdot PF_3$: F 50.22, Cu 18.67, As 22.01, P 9.10; found: F 50.43, Cu 18.51, As 21.70, P 9.24) support this formulation. The ir spectrum showed peaks, in addition to those of Nujol, at 960(sh), 919(s), 714(s, br), 587 (w), 519(s), 389(m, br) cm^{-1}. The Raman spectrum gave peaks at 940(m), 715(m), 680(s), 577(w), 373(w), 245(w), 145(m), 122(s), 104(s) cm^{-1}. An X-ray powder diffraction photograph of $CuAsF_6 \cdot PF_3$ indicated that neither unreacted $CuAsF_6$ nor elemental copper were present. Reaction times exceeding 1 h resulted in disproportionation (i.e. the solution changed to light brown with formation of a brown unidentified precipitate). This result may parallel that obtained by Dean and Ibbott (2) who observed disproportionation of Hg_2^{2+} in the presence of excess ligand (i.e. $PPh_3:Hg^{2+} > 1$). Reactions completed without solvent at low pressures of PF_3 (ca. 2–3 atm) gave varying product ratios due to incomplete reaction. Unreacted $CuAsF_6$ was observed in the X-ray powder diffraction photographs of these products. Adducts containing higher ratios of $PF_3:CuAsF_6$ (i.e. $2PF_3:CuAsF_6$) were obtained at low temperatures (i.e. −78°C) in SO_2 solution but these higher adducts slowly lost PF_3 on warming and were not further investigated. $CuPF_3^+AsF_6^-$ did not change on storage in a sealed vessel for several weeks at room temperature.

Preparation of $CuAsF_6 \cdot CO$

In a reaction similar to that described above, $CuAsF_6$ (1.33 g, 5.27 mmol) was dissolved in SO_2 (ca. 6 g) and an excess of CO was added. The reactants were warmed to room temperature. After a day, the volatiles were removed and the remaining solid was ground, and pumped to dryness yielding a yellow solid. Analytical results obtained (*Anal.* calcd. for $CuAsF_6 \cdot CO$: C 4.28, F 40.64, Cu 22.66, As 26.71; found: C 4.31, F 40.36, Cu 22.99, As 26.83) were consistent with formation of a 1:1 adduct. An ir spectrum of the adduct excluding peaks due to Nujol gave a CO stretch at 2180 ± 5 cm^{-1} and peaks attributable to AsF_6^- (700, 389 cm^{-1}). Solid $CuAsF_6 \cdot CO$ stored under anhydrous conditions changed colour slowly indicating either decomposition or disproportionation.

Results and Discussion

PF_3 Adduct

PF_3 reacted with $CuAsF_6$ in SO_2 solution at room temperature to form a 1:1 adduct. The vibrational spectrum is consistent with the presence of AsF_6^- (ir 714, 389 cm^{-1}; Raman 715, 680, 577, 373 cm^{-1}), although the symmetry is less than octahedral (9), and coordinated (approximately C_{3v}) PF_3 (ir 919ν_{as}, 519δ_s; Raman 940ν_s). The increase in the P—F stretching frequency relative to PF_3 itself (892ν_s, 860ν_{as}) (10) is consistent with other related PF_3 adducts (i.e. $Hg_2PF_3^{2+}$ (2), $AgPF_3^+$ (2), and $M(PF_3)_x$ (M = Ni, Pd, Pt, etc. (6, 11))) but not as marked as that for $AsF_5 \cdot PF_3$ (12) (953ν_s, 1003, and 1027ν_{as}). Presumably arsenic pentafluoride is a better acceptor than the copper(+1) cation and back donation is absent in $F_3P \cdot AsF_5$. The vibrational spectra, reaction stoichiometry, and solubility of the product in SO_2 indicate the presence of a $[CuPF_3]^+$ ion (though this may be fluorine bridged to a neighbouring AsF_6^- (or to SO_2 in solution)). However, a formulation such as $(CuPF_3^+)_x(AsF_6^-)_x$ (or $(CuCO^+)_x(AsF_6^-)_x$) cannot be totally excluded.

CO Adduct

The reaction of $CuAsF_6$ with CO at room temperature results in the formation of a 1:1 adduct. The most noteworthy property of the $[CuCO]^+[AsF_6]^-$ complex is the extremely high ν(CO) stretch, 2180 $\pm$ 5 cm^{-1}, the highest yet observed for a monocarbonyl (free carbon monoxide has ν(CO) at 2143 cm^{-1} (13), $[CuCO][CF_3CO_2]$ at 2155 cm^{-1} (8), $CuCO^+$ at 2168 cm^{-1} in H_2SO_4–BF_3–H_2O solution (14), $Cu_4(F_3C_2O_2)_4 \cdot 4CO$ at 2120 cm^{-1} (15), $BH_3 \cdot CO$ at 2165 cm^{-1} (10), and normal $[Cu(am_3)(CO)]^+$ complexes have νCO at 2080 cm^{-1} (7)).

The increase in ν(CO) stretching frequency (relative to free CO) may be attributed to a kinematic effect, the donation of the slightly antibonding lone pair (16) towards the cuprous ion, and to an increase in positive charge on carbon which results in an increase in CO bond order. Presumably there is only weak back donation in $CuCO^+$.

Density and temperature effects on electron mobilities in gaseous butene isomers[1]

TOSHINORI WADA AND GORDON R. FREEMAN

Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received June 4, 1979

TOSHINORI WADA and GORDON R. FREEMAN. Can. J. Chem. **57**, 2716 (1979).

The density normalized mobilities μn at low electric field strengths in the low density gases fall in the order *trans*-2- > *cis*-2- > 1- > isobutene. The respective values in the saturated vapors at 297 ± 1 K were 10.7, 4.4, 3.8, and 1.84 (10^{22} molecules/cm V s). The scattering cross section σ_v has a Ramsauer–Townsend-like minimum at an electron energy of 0.085 eV in *trans*-2-butene, 0.13 eV in *cis*-2-butene, 0.12 eV in 1-butene, and 0.16 eV in isobutene. The mobilities in the last three isomers increase with increasing temperature (300–500 K) and field strength ($\gtrsim$ 1 Td). Temperature and field effects were smaller in *trans*-2-butene. The ratio of the field effect threshold drift velocity to the speed of sound in the low density gas is 14, 19, 20, and > 50 in iso-, 1-, *cis*-2-, and *trans*-2-butene, respectively, at 297 K. The electrons are de-energized mainly by inelastic collisions. Quasilocalization occurs to a similar extent in each of the isomers at densities $\gtrsim 1 \times 10^{21}$ molecules/cm^3 and temperatures near the coexistence curve. Quasi-localization is characterized by large, negative values of ΔH and ΔS, and a small value of ΔG over a small temperature range.

TOSHINORA WADA et GORDON R. FREEMAN. Can. J. Chem. **57**, 2716 (1979).

Les mobilités normalisées pour la densité μn à de faibles champs électroniques pour les gaz de faible densité, décroissent dans l'ordre 2-*trans* > 2-*cis* > 1- > isobutène. Les valeurs respectives pour les vapeurs saturées à 297 ± 1 K sont 10.7, 4.4, 3.8 et 1.84 (10^{22} molécules/cm V s). La section efficace σ_v de diffusion passe par un minimum de Ramsauer–Townsend à une énergie électronique de 0.085 eV pour le produit 2-*trans*, de 0.13 eV pour le 2-*cis*, de 0.12 eV pour le 1- et de 0.16 eV pour l'isobutène. Les mobilités des trois derniers isomères augmentent avec la température (300–500 K) et la force du champ ($\gtrsim$ 1 Td). Les effets de la température et du champs sont plus faibles pour le butène-2 *trans*. Les rapports entre la vitesse de dérivé du seuil d'effet de champ et la vitesse du son dans les gaz de faible densité, à 297 K sont respectivement 14, 19, 20 et > 50 pour les dérivés iso-, 1-, 2-*cis* et butène-2 *trans*. Les électrons subissent principalement une perte d'énergie à cause de collisions non élastiques. Une quasi-localisation se produit d'une manière similaire dans chacun des isomères à des densités $\gtrsim 1 \times 10^{21}$ molécules/cm^3 et à des températures voisines de la courbe de concomitance. La quasi-localisation est caractérisée par une grande valeur négative de ΔH et ΔS et une faible valeur de ΔG dans une zone de température assez limitée.

[Traduit par le journal]

Introduction

The mobilities of electrons in the liquid isomeric butenes are vastly different from each other at room temperature (1), but they are similar near the melting points and in the critical fluids (2). At temperatures near the critical temperature and pressures equal to the vapor pressure, the mobilities are more affected by the changing fluid density than by the changing temperature (2). It was therefore desirable to extend the study to the gas phase, with densities ranging from the critical to the dilute gas. The results are reported herein.

Experimental

Materials and Apparatus

The Phillips Research Grade butenes were further purified under vacuum as described earlier (2).

The conductance cell was of the heavy walled type which could contain a pressure of 60 bar (3). The gap between the parallel electrodes was $l = 0.32$ cm. The purified butene was distilled into the cell at 77 K and sealed under a vacuum of 10^{-4} Pa.

The sample was placed in a well grounded Faraday cage and irradiated by a 110 ns pulse of X rays, which delivered 7×10^9 eV/g to the gas. The pulse shape is shown in Fig. 1*a*. A dc voltage was applied to the high voltage electrode by a Fluke (up to 6 kV) or Spellman (up to 30 kV) power supply through low pass filters. The electron conductance transient (ECT, Fig. 1*b*) was measured using amplifier #8 (4) and a Tektronix 7623 oscilloscope; a 7A22 plug-in was used for decay times > 50 μs and a 7A13 for shorter times.

The temperature control system and other experimental procedures were the same as in refs. 2 and 3.

Physical Properties of the Fluids

The densities n (molecules/cm^3) of the saturated vapors were calculated from the law of rectilinear diameters (6) and the liquid densities (5, 6). The critical constants listed in refs. 5–7 were averaged (Table 1). Dipole moments were taken from ref. 8.

Determination of the Electron Mobility μ

The mobility was determined from the flight time of the

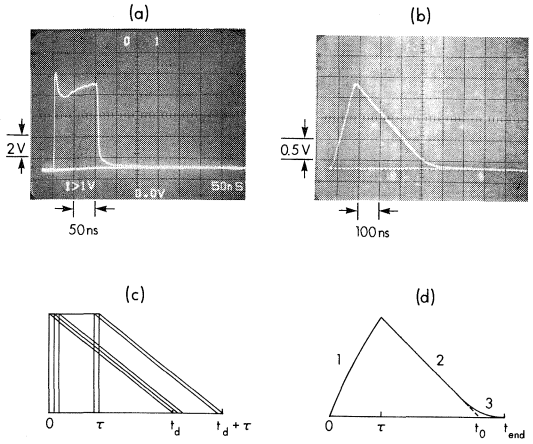

FIG. 1. (*a*) Pulse shape, measured using a 7A24 plug-in with 350 MHz bandwidth. (*b*) ECT signal in *cis*-2-butene, $E = 31$ kV/cm, $n = 2.06 \times 10^{21}$ molecules/cm^3. (*c*) Growth and decay of signal from small portions of a pulse. (*d*) Sum of the portions in part *c*.

electrons between parallel electrodes, using eq. [1].

$$[1] \qquad \mu = l^2/Vt_d$$

where l is the distance between the electrodes, V is the applied voltage, and t_d is the time required for the electrons to drift the distance l. An ECT obtained at a high field strength is shown in Fig. 1*b*. This ECT is composed of three parts; (*i*) the rising part during the radiation pulse, (*ii*) the linear decay part, and (*iii*) the tail for which it is not easy to determine the real end. The length of the tail is similar to the pulse width. To determine the drift time t_d, we divide the square radiation pulse width τ into many narrow parts. Each part produces a small individual ECT which decays linearly for the drift time t_d (Fig. 1*c*). The whole ECT obtained by summation of the small ECT's is shown in Fig. 1*d*, which is very similar to the experimental ECT in Fig. 1*b*. For $\tau < t_d$ the electron current during the three portions of the ECT is: (*i*) $ct(1 - [t/2t_d])$, $t \leq \tau$; (*ii*) $c\tau(t_d + [\tau/2] - t)/t_d$, $\tau \leq t \leq t_d$; (*iii*) $c(t_d + \tau - t)^2/2t_d$, $t_d < t < t_d + \tau$; c is a constant that depends on the energy absorption rate by the sample and the free ion yield. The drift time may be determined experimentally from eq. [2] or [2′].

$$[2] \qquad t_d = t_0 - (\tau/2)$$

$$[2'] \qquad t_d = t_{end} - \tau$$

where t_0 is the time when an extension of the linear decay crosses the base line, and t_{end} is the time when the ECT actually reaches zero. Equation [2] was used to obtain t_d because t_0 is more accurately determined than t_{end}.

At sufficiently low fields and large values of t_d, the decay of the ECT was no longer linear. Random diffusion of the electrons during the drift to the collecting electrode spreads the tail of the ECT. This effect is taken into consideration by replacing l in eq. [1] with $(l + \Delta x)$, where Δx is the mean distance of diffusion opposed to the field direction during the time t_d and is given by $(2Dt_d)^{1/2}$. It is assumed that the diffusion coefficient D of the electrons is represented by the Einstein relation $D = (kT/e)\mu$, and eq. [1] is used as a zero order approximation of the mobility. The corrected electron mobility is then:

$$[3] \qquad \mu = l^2[1 + (2kT/eV)^{1/2}]/Vt_d$$

where k is Boltzmann's constant, T is the absolute temperature, and e is the electron charge. For an ECT measured at $V = 10$ V and $T = 500$ K the correction for the diffusion is $(2kT/eV)^{1/2} = 0.09$.

Results

Electron mobilities were measured as functions of electric field strength, temperature, and vapor density. The range of the density-normalized electric field strength E/n was 0.03 – 4 Td (Td = 10^{-17} V cm^2/molecule). The saturated vapors were measured from room temperature to the critical temperature T_c, with densities from $0.025n_c$ to the critical n_c. The gases were further heated above the coexistence curves at several fixed densities.

Low Density

The density normalized mobilities μn at low fields fell in the order *trans*-2-butene > *cis*-2-butene > 1-butene > isobutene (Fig. 2). The respective values at 297 ± 1 K in the saturated vapors were 10.7, 4.4, 3.8, and 1.84 (10^{22} molecules/cm V s).

The mobilities in three of the saturated vapors increased with field strength at $E/n \gtrsim 1$ Td as shown in Fig. 2. The drift velocity at the threshold of the field dependent region was 3 km/s in isobutene, and 4 km/s in 1-butene and *cis*-2-butene. The experimental arrangement did not have sufficient time resolution to permit measurement of the threshold in *trans*-2-butene.

Increasing the temperature of isobutene vapor at constant density increased the electron mobility and the threshold of the field effect (Fig. 3). The same was true in *cis*-2-butene vapor (Fig. 4). Temperature and field effects were smaller in low density *trans*-2-butene and 1-butene (see below).

Effect of Density

Along the coexistence curve. The increasing density of the saturated vapor with increasing temperature resulted in a decrease of mobility (half filled points in Figs. 5–8). The density normalized mobility μn decreased gently with increasing density over most of the vapor range (Fig. 9). However, as the critical density was approached μn either increased (isobutene and *cis*-2-butene) or decreased more sharply (1-butene and *trans*-2-butene). The liquid phase results from ref. 2 are included in Fig. 9 for completeness. The curve for *trans*-2-butene plunges through the curves for the other compounds in the vicinity of the critical region.

Electron mobilities in the critical fluids were 17,

On the temperature coefficient at constant density. In low density *trans*-2-butene vapor the Arrhenius temperature coefficient was nearly zero. The coefficient was slightly positive near the coexistence curve and

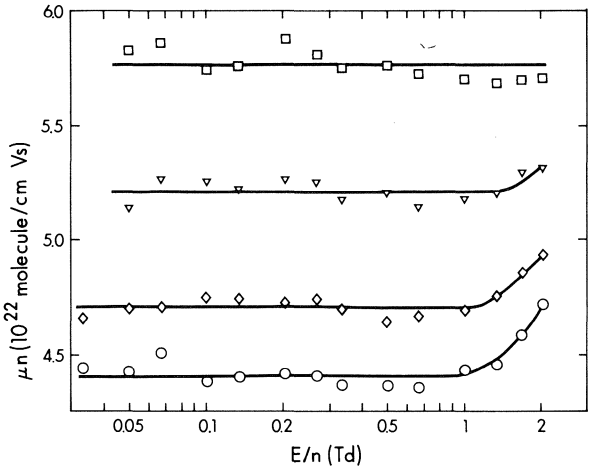

FIG. 4. Effect of E/n on μn in low density *cis*-2-butene vapor at different temperatures $n = 9.3 \times 10^{19}$ molecule/cm^3. ○, 317 K; ◇, 347 K; ▽, 417 K; □, 518 K.

slightly negative at high temperatures (Fig. 5). At high densities the coefficient was more positive.

In the other isomers the temperature coefficients were positive at all temperatures at low density, and increased with density (Figs. 6–8). At each density the coefficient tended to decrease with increasing temperature.

The temperature coefficients at a given n/n_c and T/T_c were in the order iso- $\gtrsim$ *cis*-2- > 1- > *trans*-2-butene. For example, at $n/n_c = 1.00$ and $T/T_c = 1.01$ the respective Arrhenius temperature coefficients are 0.69, 0.69, 0.56, and 0.48 eV. Although at very low densities the Arrhenius model is not appropriate, to indicate the magnitude of the change of temperature coefficient with density, at $n/n_c = 0.03$ and just above the coexistence temperature the respective coefficients are 0.024, 0.020, 0.011, and 0.008 eV.

On the field effect. In the saturated vapors of 1-, *cis*-2-, and *trans*-2-butene the field effect remained essentially the same from low densities up to the critical. The uncertainty in the threshold values of E/n was about 30%. In isobutene the threshold remained at ~1.5 Td up to $n/n_c = 0.2$, but decreased at higher densities and reached ~0.7 Td at $n/n_c = 1.0$.

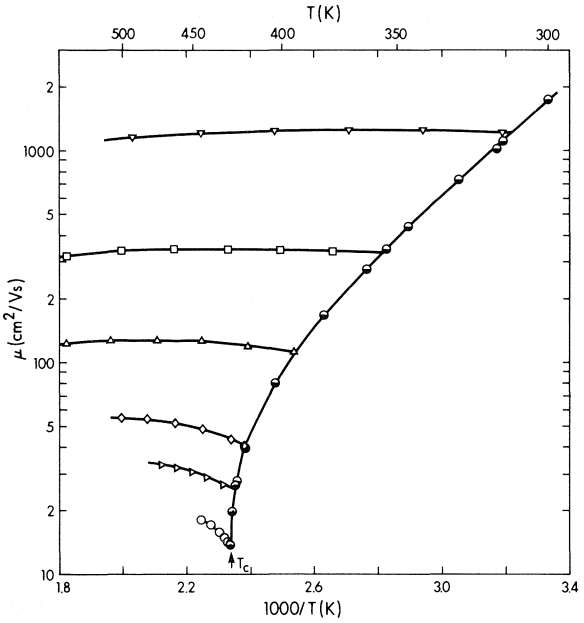

FIG. 5. Arrhenius plots of electron mobilities in *trans*-2-butene vapor at different densities n (10^{20} molecule/cm^3). ▽, 0.90, the curve was calculated by eq. [6] with cross sections from Fig. 11; □, 2.91; △, 6.98; ◇, 14.4; ▷, 20.2; ○, n_c = 25.6; ◒, coexistence vapor.

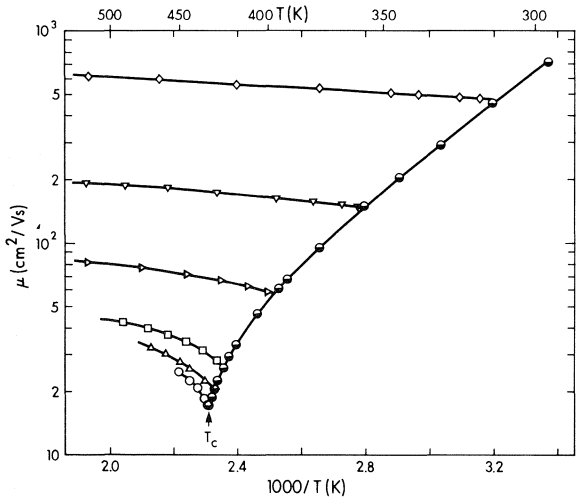

FIG. 6. Arrhenius plots of electron mobilities in *cis*-2-butene vapor at different densities n (10^{20} molecules/cm^3). ◇, 0.93, the curve was calculated by eq. [6] with cross sections from Fig. 11; ▽, 2.95; ▷, 7.32; □, 14.4; △, 18.8; ○, n_c = 25.7; ◒, coexistence vapor.

In the supercritical gases at $n/n_c = 1.00$ and $T/T_c = 1.04$ the magnitudes of the field effects at 1.0 Td in 1-, iso-, and *cis*-2-butene were somewhat smaller than those in the critical fluids. In the corresponding supercritical *trans*-2-butene the mobility decreased gently at $E/n > 0.07$ Td, so the field effect

has the opposite sign to those in the other butenes (Fig. 10).

Discussion

Low Density

Electrons gain energy by acceleration in the field and lose it by collisions with molecules. At low field strengths the average amount of energy gained be-

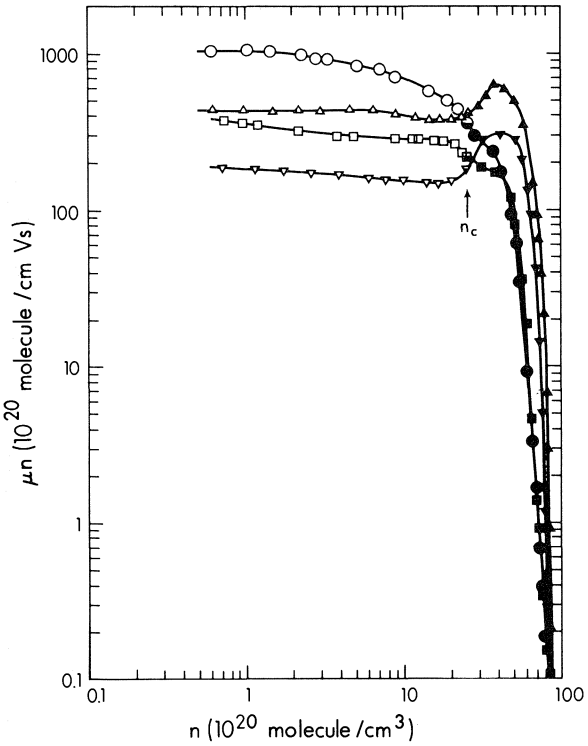

FIG. 9. Plots of μn against n in the coexistence fluids. ○, *trans*-2-butene; △, *cis*-2-butene; □, 1-butene; ▽, isobutene. Open symbols, vapors; filled symbols, liquids (ref. 2); half-filled symbols, critical fluids.

tween collisions is less than that normally exchanged during a collision, so the electrons remain in thermal equilibrium with the medium. At moderate field strengths the electrons gain more energy between collisions than they normally exchange, so they increase in velocity until a new steady state is reached. If the electron collision frequency changes as a result of the increased velocity, the mobility changes.

The velocity also increases with temperature, so the field effect at moderate field strengths is in the same direction as the temperature effect.

The mobility μ_{ld} at low densities can be expressed as (9–11):

$$[4] \quad \mu_{ld} = -\frac{4\pi}{3}\frac{e}{mn}\int_0^\infty \frac{v^2}{\sigma_v}\frac{df_0}{dv}\,dv$$

where e and m are the charge and mass of the electron, respectively, σ_v is the scattering cross section of the molecules for electrons of velocity v, and f_0 is the spherically symmetric term in the series expansion of the electron velocity distribution function. For a Maxwellian distribution one has

$$[5] \quad f_0 = (m/2\pi kT)^{3/2}\exp(-mv^2/2kT)$$

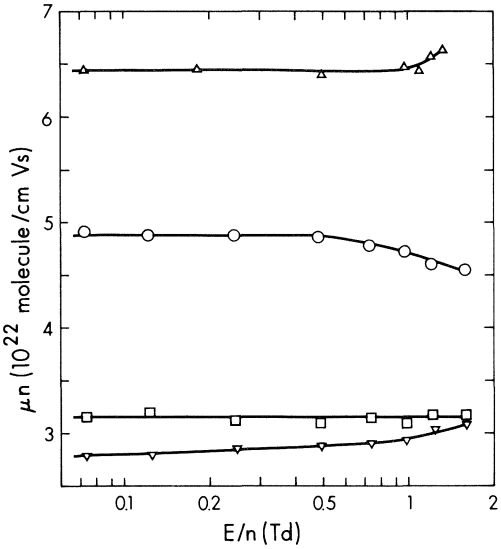

FIG. 10. Effect of E/n on μn in the supercritical gases at $n = n_c$ and $T/T_c = 1.04$. ○, *trans*-2-butene; △, *cis*-2-butene; □, 1-butene; ▽, isobutene.

and

$$[6] \quad \mu_{ld} = (5.23 \times 10^{-14}/nT^{2.5})\int_0^\infty (v^3/\sigma_v) \times \exp(-3.30 \times 10^{-12}v^2/T)\,dv$$

where k is Boltzmann's constant.

Scattering Cross Sections

The value of σ_v as a function of v was determined for each butene by fitting eq. [6] to the mobilities in the uppermost curve in each of Figs. 5–8. Equation [6] was integrated numerically, using 22 logarithmic steps between $v = 5.9 \times 10^6$ and 3.2×10^7 cm/s, which was the sensitive range (0.01–0.3 eV). An initial estimate of σ_v was made by assuming $\sigma_v \approx A_\alpha v^{-\alpha}$, which gives eq. [7].

$$[7] \quad \mu_{ld} \approx \left[1.32 \times 10^{15}\left(1 + \frac{\alpha}{2}\right)!/nA_\alpha\right] \times (3.03 \times 10^{11}T)^{(\alpha-1)/2}$$

The values of α and A_α were obtained from the slope and intercept of a plot of log μ_{ld} against log T. A plot of log σ_v against log v was then made and adjusted to give the best agreement with the array of experimental (μ_{ld}, T) values, through iterative calculations with eq. [6]. The cross sections so obtained are displayed in Fig. 11, plotted against energy in the traditional manner. Cross sections estimated earlier (12) for 1-butene are shown for comparison; mobilities had been measured at only two temperatures.

The Maxwellian distribution of E and v is indi-

cated in Fig. 11*a*. The energy range of greatest sensitivity in the curve fitting procedure is that near the maximum in the scattering probability curve, which ranges from about 0.04–0.20 eV in isobutene (Fig. 11*b*) to about 0.03–0.13 eV in *trans*-2-butene. The accuracy of the estimated cross section decreases with increasing distance from this central region.

The density normalized mobilities $n\mu_{ld}$ in the low density gases are plotted on an expanded scale in Fig. 12 to show the extent to which the values calculated from eq. [6] with the cross sections in Fig. 11 match those determined experimentally.

When cross sections σ_v that have been derived from mobilities are averaged to compare values for different molecules, the appropriate weight is placed on the most sensitive region of velocities by using eq. [8] (13, 14).

$$[8] \quad \sigma_{ave} = \langle v \rangle / \langle v/\sigma_v \rangle$$

For a Maxwellian distribution of velocities eq. [8] becomes

$$[9] \quad \sigma_{ave} = 4.59 \times 10^{22} T^2 \Big/ \int_0^\infty (v^3/\sigma_v) \times \exp(-3.30 \times 10^{-12} v^2/T)\, dv$$

It may be noted that multiplying eq. [6] by

$$1 = 4.59 \times 10^{22} T^2 \Big/ \sigma_{ave} \int_0^\infty (v^3/\sigma_v) \times \exp(-3.3 \times 10^{-12} v^2/T)\, dv$$

from eq. [9] gives [10].

$$[10] \quad \mu_{ld} = 2.40 \times 10^9 / nT^{1/2} \sigma_{ave}$$

This is equivalent to the expression derived by Lorentz using a cross section that was independent of v (15).

The values of σ_{ave} fall in the order *trans*- < *cis*- $\lesssim$ 1- < isobutene (Table 2). The molecular electric dipole moments lie in the same order (Table 1). One may therefore suggest that the scattering power of a butene molecule contains contributions from a stiff central core and the dipolar electric field.

The simple model of electron scattering by the induced dipole (16) is not adequate for the central core component, because the value of σ_{ave} predicted by the model for the nonpolar *trans*-2-butene is seventeen times larger than the observed value. The repulsive interaction between the projectile electron and the imperfectly polarizable molecular electrons cancels most of the attractive interaction between the charge and the induced dipole.

For scattering by a point-dipole potential $(-eD/r^2)$

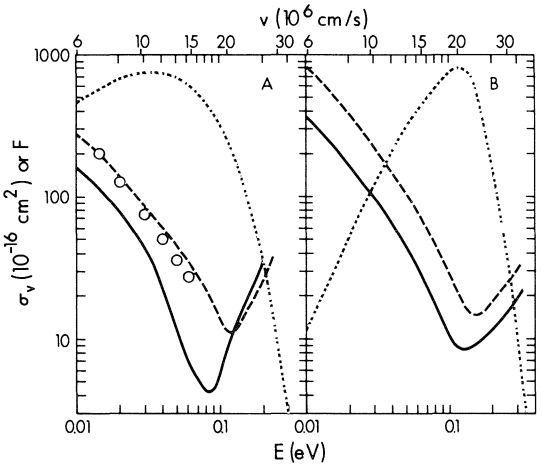

FIG. 11. Scattering cross sections σ_v of the low density vapors as functions of electron energy E or velocity v. *A*:—, *trans*-2-butene; ---, 1-butene; ○, 1-butene from ref. 12; ···, Maxwellian distribution of E and v at 400 K, $F = (1.36 \times 10^{-7}\ v^2/T^{1.5}) \exp(-3.30 \times 10^{-12}\ v^2/T)$; *B*: —, *cis*-2-butene; ---, isobutene; ···, scattering probability distribution for isobutene at 400 K, $F = 6 \times 10^{-33}\ (v^3/\sigma_v) \exp(-3.30 \times 10^{-12}\ v^2/T)$. The factors F are the true values multiplied by 10^{10} in *A* and 6×10^{-33} in *B* to fit the displayed scale.

$\times \cos\theta$, the Born approximation model of Altshuler (17) gives:

$$[11] \quad \sigma_v(\text{Alt}) = (8\pi/3)(eD/\hbar v)^2$$

where D is the dipole moment and $h = 2\pi\hbar$ is Planck's constant. The cross section averaged over a Maxwellian distribution in the manner of eq. [8] is:

$$[12] \quad \sigma_{\text{Alt},T} = 2.86 \times 10^{24} D^2/T$$

Values of $\sigma_{\text{Alt},300\text{ K}}$ are given in Table 2. They are roughly three-fold smaller than the observed cross sections for the polar butenes. Taking σ_{ave} of *trans*-2-butene to represent the contribution of the stiff core for each of the butenes, and making the crude assumption that contributions of two processes are approximately additive when one does not completely dominate the other, the net ratio $[(\sigma_{ave} - 12.5)/\sigma_{Alt}]_{300\text{ K}}$ is still greater than unity (Table 2). The dipole field makes a significant contribution to scattering by the polar butenes, but some other force is greater. The dipole field tends to dominate only for molecules with $D \gtrsim 1.0 \times 10^{-18}$ esu cm (18).

An additional factor in scattering by the butenes is the as yet unexplained effect of the degree of sphericity of the molecules. The scattering cross section for low energy electrons increases with increasing sphericity of isomeric hydrocarbons (19). The degrees of sphericity of the butenes are in the order *trans*- < 1- < *cis*- < isobutene, and the cross sections tend to

TABLE 2. Electron scattering parameters of the gaseous butenes

Parameter	Value			
	trans-Butene	*cis*-Butene	1-Butene	Isobutene
n (10^{19} molecules/cm^3)	9.0	9.3	7.8	7.5
$\sigma_{ave,300\ K}$ (10^{-16} cm^2)	12.5	33	38	75
$\sigma_{ave,500\ K}$ (10^{-16} cm^2)	10.3	19	24	39
$\sigma_{Alt,300\ K}$ (10^{-16} cm^2)	0	8.6	11.0	24
$[(\sigma_{ave} - 12.5)/\sigma_{Alt}]_{300\ K}$	—	2.3	2.3	2.6
$E_{\sigma min}$ (eV)	0.085	0.13	0.12	0.16

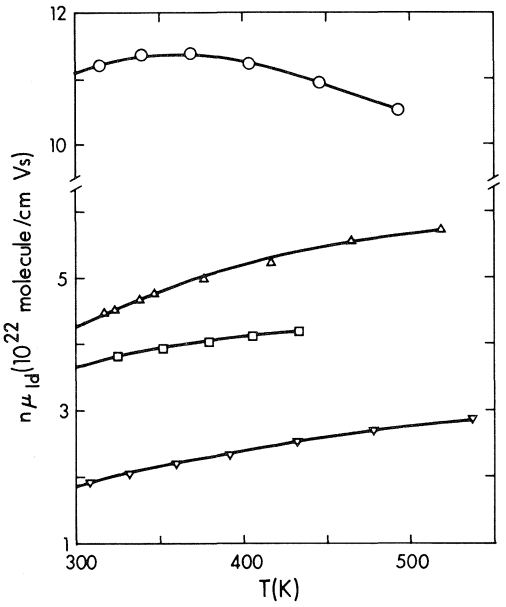

FIG. 12. Comparison of the calculated and experimental values of the density normalized mobilities $n\mu_{td}$ in the low density gases at different temperatures. ○, *trans*-; △, *cis*-; □, 1-; ▽, isobutene. The lines were calculated by eq. [6] with cross sections from Fig. 11.

increase in the same order (Table 2). This rationalizes the apparent anomaly that the butene with the largest dipole moment, isobutene, has a value of $[(\sigma_{ave} - 12.5)/\sigma_{Alt}]$ larger than those of the other polar butenes (Table 2). For a dipole field superimposed upon a stiff core, the ratio might have been expected to be closest to unity for the isomer with the largest dipole moment.

In terms of the less accurate but simpler eq. [7], the sphericity effect displays itself as a larger value of α for more spherelike molecules. The present results for the low density butene gases give $\alpha \approx 0.7$, 1.6, 2.0, and 2.5 for *trans*-, 1-, *cis*-, and isobutene, respectively, which is in the same order as the degree of sphericity estimated visually from space-filling molecular models. Similarly, for the isomeric pentanes the values of α were 1.1, 1.5, and 3.2 for *n*-, iso-, and neopentane, respectively (13).

The sphericity effect includes a tendency for the minimum in σ_v to lie at a higher energy for a more sphere-like isomer (Fig. 11 and Table 2). In the pentane isomers the value of $E_{\sigma min}$ was 0.13 eV for *n*- and isopentane and 0.21 eV for neopentane (19).

Simple models of electron scattering by induced or permanent dipoles (9, 16, 17) do not fit scattering by hydrocarbons. A better interpretation of the results might involve the Ramsauer–Townsend effect or transient negative ion states. However, it is not yet known how to interpret the sphericity effect in those terms.

Field Dependence Thresholds

Elastic scattering of electrons by individual molecules in the gas is kinetically equivalent to scattering by phonons (20, 21). The effective mass M^* of a phonon is given by:

$$[13] \quad M^* c_0^2 = kT$$

where c_0 is the velocity of low frequency sound. In the low density gas $c_0 = (\gamma kT/M)^{0.5}$, where γ is the heat capacity ratio and M is the molecular mass (22). One therefore obtains $M^* = M/\gamma \approx 0.9\,M$ in the low density butenes (5). When elastic scattering is the dominant process that moderates the electron energy, the electron drift velocity v_d should become nonlinear with field strength when $v_d \approx c_0$ (20). The velocity of sound is therefore a useful parameter in assessing electron scattering processes even in the single scatterer regime.

The value of c_0 in the low density butene vapors at 297 K is 221 m/s. The threshold drift velocities, v_d(threshold), for field dependent mobilities were 3.1, 4.2, 4.4, and >11 km/s in iso-, 1-, *cis*-2-, and *trans*-2-butene, respectively (Fig. 2). The respective values of the ratio v_d(threshold)/c_0 are 14, 19, 20, and >50 at 297 K. These large values imply that the electrons in the butenes are cooled predominantly by inelastic collisions. Values of the ratio in other gases are: xenon, 0.7 (4); methane, 1.0 (23); neopentane, 5 (13); cyclopentane, 11 (14); isopentane, 15 (13); *n*-pentane, >100 (13). The ratio increases with decreasing sphericity of the molecules. We conclude

that the sphericity contribution to electron scattering tends to be an elastic process.

The values of v_d(threshold) in iso- and *cis*-2-butene increase with increasing temperature (Figs. 3 and 4). So do the values of c_0 and v_d(threshold)/c_0. At 530 K the values in both gases are v_d(threshold) > 11 km/s, $c_0 = 290$ m/s and v_d(threshold)/$c_0 > 40$. The higher electron energies at the higher temperature enhance the contribution of inelastic collisions. The higher vibrational–rotational states of the molecules in the hotter gas might also be better energy sinks than the lower states for inelastic collisions with low energy electrons.

Effect of Density

The effects of density on μn in the coexistence vapor and liquid of 1-butene are similar to those in *trans*-2-butene; each curve contains a negatively sloped inflection near 3×10^{21} molecules/cm^3 (Fig. 9). The density effects in isobutene are similar to those in *cis*-2-butene; each curve contains a shallow minimum near 2×10^{21} molecules/cm^3 and a maximum near 4×10^{21} molecules/cm^3 (Fig. 9). The plots for *cis*- and *trans*-2-butene cross near the critical region, as do those for iso- and 1-butene. A detailed description of the behaviors in *cis*- and *trans*-2-butene will therefore apply qualitatively to those in iso- and 1-butene as well.

The temperature coefficient of the mobility in the high density gas varies with the density and the temperature. The coefficient is taken as $\theta_{n,T} = (\partial \log \mu/\partial \log T)_{n,T}$; values are plotted against n for two fixed temperatures, T_c and $1.05T_c$, in Fig. 13. The value of $\theta_{n,T}$ becomes independent of n and T at low n, where an electron interacts with only one molecule at a time. The low density limit of θ is related to the α in eq. [7] through the relation $\theta = (\alpha - 1)/2$. As the density is increased above about 7×10^{20} molecules/cm^3, θ_{n,T_c} increases rapidly, becoming roughly proportional to n^2. Heating the vapor to $1.05T_c$, an increase of only 21 K, greatly reduces the temperature coefficient at high densities (Fig. 13); the reduction is by a factor of 3.4 in *trans*-2-butene at n_c, while the mobility itself increases by only a factor of 1.3 (Fig. 5).

The great difference between the temperature dependence of the *mobility* and that of the *temperature coefficient of the mobility* indicates that the extent of localization is relatively small. The electrons are only shallowly trapped and the temperature coefficient is associated mostly with the concentration of trapping sites, that is, with the density fluctuations in the fluid. The process is termed quasilocalization (4, 13, 14, 24).

Values of μn at several values of constant T are plotted against n for *trans*- and *cis*-2-butene in Figs. 14 and 15, respectively. Moderate heating of the gas at constant density greatly decreases the degree of quasilocalization, and at $1.15T_c$ it is virtually destroyed in both gases. At this temperature μn increases with density at $n > 7 \times 10^{20}$ molecules/cm^3

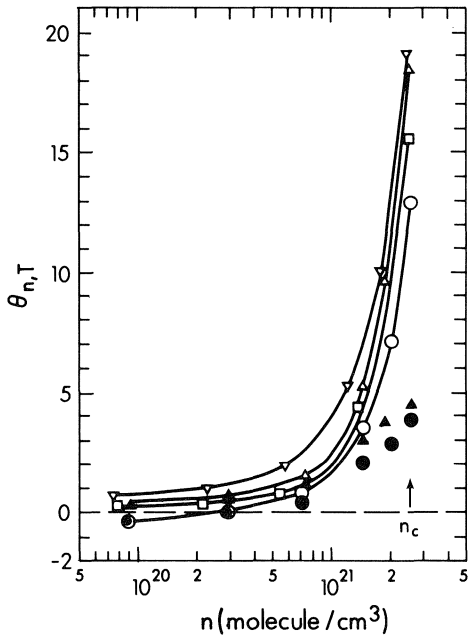

FIG. 13. Effect of density on the temperature coefficient of mobility at temperature T. $\theta_{n,T} \equiv (\partial \log \mu/\partial \log T)_{n,T}$. ▽, isobutene; △, ▲, *cis*-2-butene; □, 1-butene; ○, ●, *trans*-2-butene. FIG. 16. Plot of $(n\mu_n^0)^{-1}$ against density in *trans*-2-butene vapor at $1.15T_c = 492$ K.

in *cis*-2-butene, while in the *trans* isomer it decreases at $n > 2 \times 10^{20}$ molecules/cm^3. The increase in *cis*-2-butene is due to the mutual partial cancellation of long range scattering interactions, such as charge–dipole and charge – induced dipole, by the several molecules that interact simultaneously with an electron. *trans*-2-Butene is nonpolar, but the mutual inference of the charge – induced dipole interactions would still tend to make μn increase at high densities. The observed decrease must have a different cause, probably transient anion formation (25, 26).

$$[14] \quad e_{qf}^- + M \underset{\tau^{-1}}{\overset{\nu_1}{\rightleftharpoons}} M^-$$

where e_{qf}^- represents a quasifree electron. The attachment rate is represented by $\nu = \nu_1 n$, and the anion ionization lifetime by τ. The forward and reverse reactions have orders that differ by one, which might be either 2 and 1 or 3 and 2, respectively.

The mobility μ_{qf} of a quasifree electron is much greater than that of an anion, so reaction [14] leads to eq. [15].

$$[15] \quad n\mu_n^0 = n\mu_{qf}/(1 + \nu_1\tau n)$$

where μ_n^0 refers to the mobility in the absence of quasilocalization (see later) in the fluid of density n. In Fig. 16 the reciprocal of $n\mu_n^0$ at $1.15T_c$ is plotted against n. The relation is linear for $n < 0.8n_c$, with $n\mu_{qf} = 1.08 \times 10^{23}$ molecules/cm V s and $\nu_1\tau = 2.6 \times 10^{-22}$ cm^3/molecule.

The forward and reverse rates of [14] depend on the energies of the species. The energy dependence of the attachment cross section is probably different from that of the total scattering cross section. However, taking the average attachment cross section as a fraction κ of the average scattering cross section σ_{ave} one obtains

$$[16] \quad \nu_1 \approx \kappa\sigma_{ave}\langle v\rangle$$

Thus, for *trans*-2-butene at $n < 0.8n_c$ and $T = 1.15T_c$, with $\langle v\rangle = 1.2 \times 10^7$ cm/s and $\sigma_{ave} = 1.04 \times 10^{-15}$ cm^2 one obtains

$$[17] \quad \tau \approx 2.1 \times 10^{-14}/\kappa$$

At $n > 0.8n_c$, the mobility decreases more rapidly than is suggested by [14] and [15]. Higher order processes contribute at high densities.

The present results support the suggestion that transient anions are the lower energy state in the two-state electron transport mechanism in liquid *trans*-2-butene (2).

Quasilocalization is a different process than the transient attachment represented by [14]. The former is much more sensitive to temperature and occurs over a narrower density range than the latter. At vapor densities and temperatures near the coexistence curve van der Waals clusters of molecules form, some of which can temporarily capture an electron. In general, the clusters may be considered as density fluctuations in the fluid. A fluctuation of appropriate depth and width is a possible localization site for an electron.

$$[18] \quad \text{Medium} \rightleftarrows \text{site}$$

$$[19] \quad e_{qf}^- + \text{site} \rightleftarrows e_{loc}^-$$

The density normalized mobility at any value of n and T is:

$$[20] \quad \mu n = n\mu_n^0 f$$

where

$$[21] \quad f = [e_{qf}^-]/([e_{qf}^-] + [e_{loc}^-]) = (1 + [\text{site}]K_{19})^{-1}$$

where [site] is the concentration of sites and K_{19} is the equilibrium constant of reaction [19]. One may write

$$[22] \quad [\text{Site}] = \exp(\Delta S_{18}^0/R)\exp(-\Delta H_{18}^0/RT)$$

[23] $K_{19} = \exp(\Delta S_{19}^0/R)\exp(-\Delta H_{19}^0/RT)$

and

[24] $(n\mu_n^0/\mu n) - 1 = \exp(\Delta S'/R)\exp(-\Delta H'/RT)$

where $\Delta S' = \Delta S_{18}^0 + \Delta S_{19}^0 \approx \Delta S_{18}^0$ and $\Delta H' = \Delta H_{18}^0 + \Delta H_{19}^0 \approx \Delta H_{18}^0$ (see below).

The density fluctuations, and hence the concentration of sites, are largest in the coexistence vapor. They diminish as the gas is heated at constant density.

It may be shown that the Arrhenius temperature coefficient of mobility, E_μ, is related to $\theta_{n,T}$ by[2]

[25] $E_\mu = kT\theta_{n,T}$

The Arrhenius temperature coefficient in *trans*-2-butene at n_c and just above T_c is 0.47 eV, or 46 kJ/mol. However, the value of μn in the critical fluid is 0.5 of $n_c\mu_{n_c}^0$ and is 0.3 of the low density limit $n_c\mu_{qf}$. The total amount of localization by both [14] and [19] is relatively small and the localization free energy is in each case a bit less than kT, ~3 kJ/mol. Thus ~6% of the temperature coefficient is due to [19] and ~94% is attributable to [18].

A plot of the log of the left side of eq. [24] against $1/T$ is given in Fig. 17 for *trans*-2-butene, using $n_c\mu_{n_c}^0 = 7 \times 10^{22}$ molecules/cm V s. The slope at $1.002T_c$ gives $\Delta H' = -85$ kJ/mol and the extrapolated intercept indicates $\Delta S' = -198$ J/mol K. Thus $\Delta G' \approx 0$ kJ/mol at 429 K, corresponding to the relatively small extent of quasilocalization.

The values of $\Delta H'$ and $\Delta S'$ decrease rapidly in magnitude with increasing temperature away from the coexistence curve. For $n = n_c$ and $T = 1.04T_c$, $\Delta H' = -47$ kJ/mol and $\Delta S' = -110$ J/mol K. These are only 55% of the values at $T = 1.002T_c$.

The quasilocalization behavior is similar in each of the isomers. For electron transport in the high density gas near the coexistence curve, the enthalpy and entropy changes associated with quasilocalization are large and negative and are due to step [18], while the energy and extent of [19] are small.

Returning now to the behavior of μn as a function of n in the coexistence vapor and liquid of *trans*-2-butene (Fig. 9), at $n > n_c$ there is an inflection in the curve. The inflection is attributed to a tendency of interactions of the several molecules interacting simultaneously with an electron to partially counteract each other at the distances in question. In the more globular hydrocarbons, such as *cis*-2- and isobutene, this tendency causes μn to increase (Fig. 9). Finally, at $n/n_c > 1.5$ in *trans*-2-butene μn plunges, due to the formation of increasingly stable localized states. The greater stability is caused by the existence of deeper traps in the denser fluid and by the concomitant lower temperature of the liquid with higher n.

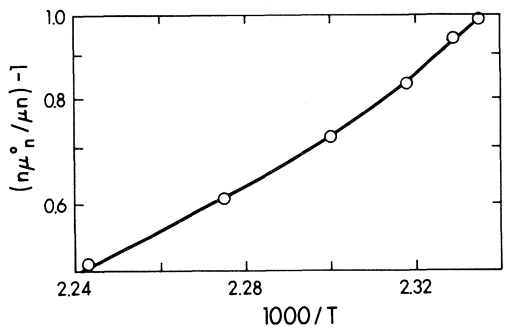

FIG. 17. Plot of eq. [24] for *trans*-2-butene at n_c, with $n\mu_n^0 = 7 \times 10^{22}$ molecules/cm V s.

The rapid plunge of μn occurs at $n/n_c > 1.5$ in *trans*-2-, 1.8 in 1-, and 2.0 in iso- and *cis*-2-butene (Fig. 9). This correlates with the degree of sphericity of the molecules and the associated difficulty of forming a stable localized state of the electron in the liquid.

Quasilocalization and Molecular Structure

The quasilocalization process does not reflect differences in molecular structure as much as do the processes in the dilute gases or normal liquids. For a series of substances ranging from xenon (4) and methane (23) to *n*-pentane (13) and 1-butene, quasilocalization occurs to a similar extent in the dense, coexistence vapors, independent of whether in the normal liquids of the same substances the electrons become quasifree or more deeply trapped.

Reactions of 4-phenyl-3*H*-1,2,4-triazole-3,5 (4*H*)-dione with alcohols and amines

LÊ H. DAO[1] AND DONALD MACKAY

The Guelph–Waterloo Centre for Graduate Work in Chemistry, Waterloo Campus, Department of Chemistry, University of Waterloo, Waterloo, Ont, Canada N2L 3G1

Received April 20, 1979

LÊ H. DAO and DONALD MACKAY. Can. J. Chem. **57**, 2727 (1979).

Two equivalents of the title compound (**1**) react with one equivalent of primary alcohols to give good yields of nitrogen and 1-alkoxycarbonyl-2-*N*-phenylcarbamoyl-4-phenyl-1,2,4-triazolidine-3,5-diones (**3**). With secondary alcohols or benzyl alcohol the major products are the ketone or benzaldehyde, while **3** are minor products. The latter can, however, be made the major products if pyridine is used to catalyze the reaction. Compound **3***a* dissociates on heating or in pyridine solution into the 1-methoxycarbonyltriazolidinedione **4**.

If alcohols are absent **1** is converted by pyridine or other tertiary amines into nitrogen and the bicyclic compound **9**; if diethyl azodicarboxylate is present in the reaction compound **13** can be trapped.

Primary and secondary amines react very rapidly with **1** to give nitrogen and complex products. It is likely that these are 1,2-dicarbamoyl-4-phenyltriazolidine diones, analogous to **3**, and that they are very prone to dissociate in solution.

LÊ H. DAO et DONALD MACKAY. Can. J. Chem. **57**, 2727 (1979).

Deux équivalents du composé (**1**) réagissent avec un équivalent d'alcools primaires pour conduire, avec de bons rendements, à l'azote et à l'alkoxycarbonyl-1-*N*-phénylcarbamoyl-2-phényl-4-triazolidine-1,2,4,diones-3,5 (**3**). Avec les alcools secondaires ou l'alcool benzylique, les produits principaux sont la cétone ou la benzaldéhyde, tandis que **3** sont des produits secondaires. Cependant, ces derniers peuvent devenir des produits principaux si on utilise la pyridine comme catalyseur de la réaction. Par chauffage ou dans une solution de pyridine, le composé **3***a* se dissocie en méthoxycarbonyl-1-triazolidinedione **4**.

S'il n'y a pas d'alcools, **1** est transformé par la pyridine ou d'autres amines tertiaires en azote et en composé bicyclique **9**; si l'azodicarboxylate de diéthyle est présent dans la réaction, le composé **13** peut être isolé.

Les amines primaires et secondaires réagissent très rapidement avec **1** pour conduire à l'azote et à des produits complexes. Il est probable que ces produits soient des dicarbamoyl-1,2-phényl-4-triazolidine diones semblables à **3** et qu'ils aient une grande tendance à se dissocier en solution.

[Traduit par le journal]

As a class the 4-substituted 3*H*-1,2,4-triazole-3,5(4*H*)-diones[2] are probably the most powerful dienophiles known, but they show a wide range of other reactivity as well. A large variety has now been synthesized, though the 4-phenyl derivative **1** has been the most widely studied, references to it outnumbering those to all others combined.

As well as Diels–Alder additions many other reactions of compound **1** with unsaturated substrates have been investigated. Among these are "ene" reactions with alkenes (1), dienes (2), and primary enamines (3), insertion reactions in tropolone (4), cycloaddition to alkenes (5, 6), formation of reactive dipoles with vinyl ethers (7), vinyl azides (8), vinyl esters (6, 9, 10), and diazoacetic ester (11), addition to 1,3-dipoles (12), and insertion in N—H in pyridones (13). It has also been shown to oxidize alcohols to carbonyl compounds (14).

Despite its great reactivity to such a range of substrates, **1** is remarkably stable to strong acids, as its synthesis from the 4-phenylurazole **2** with N_2O_4 attests (15). It is unaffected by atmospheric exposure for long periods, and its solutions in chlorinated or saturated hydrocarbon solvents remain deeply colored and free of precipitate almost indefinitely. We noticed, however, that its solutions in methanol rapidly decolorized. In concentrated solution the reaction was exothermic with the formation of a precipitate. We expected this to be the urazole **2**, formed by oxidation of the alcohol. In fact it was a product $C_{17}H_{14}N_4O_5$ resulting from the reaction of one molecule of methanol and two molecules of **1** with loss of one molecule of nitrogen.

In view of the proven ability of **1** to oxidize secondary alcohols (14) we decided to examine its reaction with a range of representative alcohols: methanol, ethanol, 1-butanol, 2-propanol, cyclopentanol, and benzyl alcohol. Some of our results have been published in a preliminary form (16), and are now

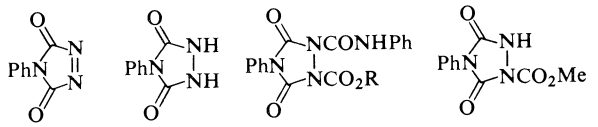
0008-4042/79/202727-07$01.00/0

presented in more detail along with other related reactions of **1**.

The identity of the product from methanol as **3***a* followed from its spectra, its reactions, and its rational synthesis. The ^{1}Hmr spectrum included a MeO singlet at 5.95τ and one exchangeable proton. The ir spectrum (Nujol) had an NH absorption at 3398 and an intense broad complex absorption in the CO region with maxima at 1828, 1760, and 1700 cm^{-1}. It had no well defined mp, decomposing between 180 and 187°C to a solid and a liquid. The solid was readily identified as **4** by comparison with an authentic sample made from **2** by treatment with sodium hydride or pyridine, followed by methyl chloroformate. If **2** was treated with one equivalent of sodium hydride, and then in turn with phenyl isocyanate and methyl chloroformate, **3***a* was produced in a good yield. The liquid was phenyl isocyanate identified as ethyl *N*-phenylcarbamate. The latter was also formed when **3***a* was refluxed in ethanol. The behaviour of **3***a* in solution was examined by ^{1}Hmr spectroscopy. In benzene-d_6 or chloroform-*d* there was no evidence of decomposition, but in pyridine-d_5 the equilibrium in eq. [1] was rapidly established. (K_{eq} = 0.75 for a 0.17 *M* solution of **3***a*.) Addition of chloroform-*d* reversed the reaction, which could be moved in either direction by varying the proportions of chloroform and pyridine. Examples of such urethane–isocyanate equilibria have been noted previously (17).

[1] **3***a* ⇌ **4***a* + PhNCO



1 **2** **3** **4**

a R = Me
b R = Et
c R = *n*-Bu
d R = *i*-Pr
e R = *c*-C_5H_{10}
f R = $PhCH_2$

In general compounds **3***a–f* were prepared by stirring equimolar amounts of **1** and the alcohol (0.1 *M* each) in benzene at room temperature for 2 days. Alternatively a large excess of the alcohol was used in methylene chloride as solvent, in which case the reaction was much more rapid (~30 min). In either case the reaction mixture was evaporated and the residue treated with chloroform to remove traces of insoluble polymer or the urazole **2**. The chloroform-soluble material was worked up to give **3**, purified by conventional crystallization techniques.

The isolated yields were close to the actual in those cases where the latter were determined by gas–liquid chromatography (glc); glc was also used to analyze for benzaldehyde and cyclopentanone. The determination of other carbonyl compounds was made by ^{1}Hmr analysis.

The yields of products, and the melting points, spectroscopic properties, and elemental analyses are shown in Table 1. The yields of **3** are seen to be good to excellent for the oxidation of primary alcohols; aldehydes were not detected. From benzyl alcohol and both secondary aliphatic alcohols examined the yields of **3** were low, benzaldehyde or the ketone being the major product.

The mechanism for the oxidation reactions of **1** with alcohols is not certain, though initiation through α-hydrogen atom abstraction by the azo group seems likely. Other instances of oxidation of 2-propanol to acetone by carbonylazo compounds have been noted (18, 19). In the case of benzoylphenyldiimine (18) the intervention of radicals by homolysis of the intermediate phenyldiimine was clearly established.

For the formation of compounds **3** we propose (Scheme 1) an initial addition of alcohol at the carbonyl group, followed by deprotonation to the nucleophilic species **5** (or its *N*-acyl anion equivalent if loss of nitrogen precedes further reaction of **5**). Attack on a second molecule of **1** to give **6**, cyclization to **7**, and cleavage of the C to N—Ph bond completes the reaction. The sequence **6** to **7** to **3** in effect transposes the methoxycarbonyl group from one nitrogen to another. Migrations of this general type to a nucleophilic centre have been reviewed (20). The resonance stabilized amide anion is predictably a better leaving group from **7** than is alkoxide ion. We tried to synthesize compound **8**, the protonated form of **6** (R = Me) to test whether the 1,4-shift of methoxycarbonyl to give **3** occurred under the reaction conditions. *N*,*N*-Dimethoxycarbonylaniline was treated with the anion of the urazole **2**, but neither NaH nor KO*t*-Bu was able to effect the condensation to **8** in a variety of solvents. This failure is perhaps not surprising since it requires the displacement of methoxide by amide anion.

Pyridine had a strong catalytic effect on the reac-

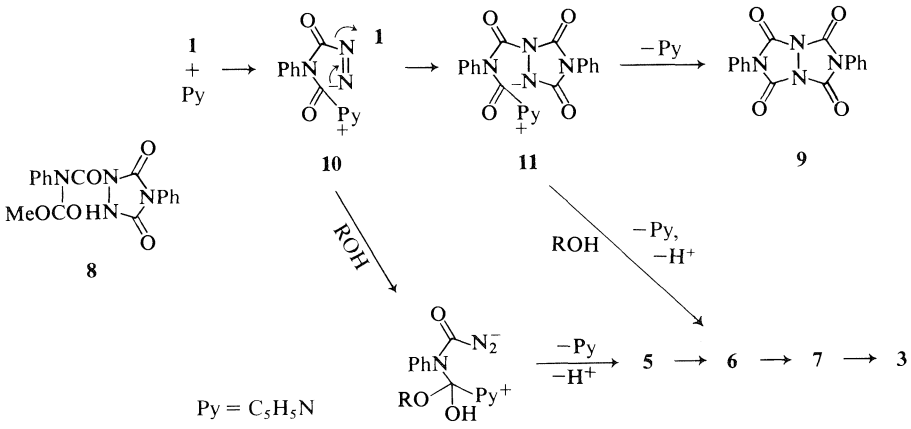
[a]Based on the reaction of 1 mol of **1** with 1 mol of alcohol.
[b]Based on the reaction of 1 mol of **1** with 0.5 mol of alcohol.
[c]Analysis by ^{1}Hmr (±4%).
[d]Analysis by glc (±2%).
[e]Isolated.
[f]The unreacted alcohol was measured by glc. The balance of the alcohol was assumed to be the yield of **3**.
[g]In all cases accompanied by decomposition. Compound **3***d* re-solidified above its mp; melting occurred again between 260–290°C.
[h]Recrystallization from $CHCl_3$.
[i]Recrystallization from C_6H_6.
[j]Recrystallization from C_6H_6–isooctane.
[k]Recrystallization from CCl_4.
[l]The NH absorption was variable, but in general occurred between 0.0 and 1.0 τ.
[m]The phenyl protons absorbed in general as a broad multiplet, dominated by a strong singlet, each containing 5H.



SCHEME 2

tion of **1** with alcohols. Thus when benzene solutions were made 1 *M* in pyridine, as well as in **1** and in methanol, decolorization was complete within minutes, **3***a* being again formed in an excellent yield. Likewise attack on benzyl alcohol and the secondary alcohols to give compounds **3** was accelerated, much more so than the oxidation reaction. The results are also shown in Table 1, from which it is clear that the conversion of alcohols in general into compounds **3** can be made the dominant reaction by inclusion of pyridine where necessary. A series of reactions in 2-propanol (Table 1) showed that the yields of **3***d* and acetone were almost independent of pyridine concentration over the range 0.5 to 10 *M*.

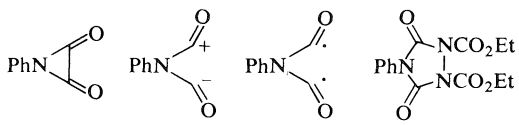
In the absence of alcohols, solutions of **1** containing pyridine, or alternatively triethylamine or 1,5-diazabicyclo[4.3.0]nonene-5, still reacted readily with evolution of nitrogen to give a sparingly soluble solid in good yield. This product, which was not observed in the alcohol reactions,[3] was shown to be the tetrazabicyclo[3.3.0]octane derivative **9**. It is the pyrolysis product of **1**, first obtained by Stollé (21). It has also been made by reaction of **2**, either with phenyl isocyanate (22) or with **1**, in what has been interpreted as a radical chain process (23).

The role of the pyridine was examined on a somewhat more quantitative basis by visible spectroscopy. A solution in methylene chloride 0.02 *M* in each of **1** and pyridine[4] had a half life (measured at the λ_{max} of **1** at 550 nm) of 40 min at 30°C. When a similar solution was also made 0.04 *M* in methanol the half life was reduced to 23 min. The uncatalyzed reaction of **1** (0.02 *M*) and methanol (0.04 *M*) is relatively very much slower with a half life of 1–1.5 days.

The formation of **3** or **9** in the presence of pyridine can be accounted for by a variation of the uncatalyzed reaction in which nucleophilic attack by pyridine leads to the ring-opened species **10** (Scheme 2), analogous to **5**. In the absence of alcohol the reaction proceeds through **10** to **11** to **9**. When alcohol is present it may attack **10** to give **5**, or **11** to give **6**, and thence compound **3** in either case, a reaction faster than the sequence leading to **9**. The latter is *not* an intermediate in the formation of **3**, control reactions showing that it is not opened by, for example, methanol alone or methanol and pyridine.

Bicyclic structures of type **9** are recognized thermal decomposition products of 5-membered cyclic azodicarbonyl compounds. They have been found with other triazolinediones (21, 24), while pyrazolinediones also give analogous products (25).

Formally **9** is the result of cycloaddition of **1** to 2-phenylaziridinedione or an open dipolar or diradical equivalent of it (**12***a*, *b*, *c*). We examined the possibility of other cycloadditions of **12**. Treatment of **1** with an excess of diethyl azodicarboxylate gave an isolated yield of 28% of **13**, whose identity was proven by its synthesis from the urazole **2** with 2 equiv. of sodium hydride and ethyl chloroformate. No reaction was detected with dimethyl maleate or stilbene, only compound **9** being produced; dimethyl acetylenedicarboxylate gave a methoxy-containing polymer, as well as **9**.



a *b* *c*

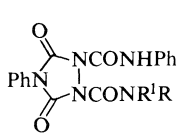
12 **13**

[3]It was a minor product in the pyridine-catalyzed reactions of the *sec* alcohols.

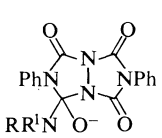
[4]The lower concentrations, one tenth that used in the preparative runs, were necessary for the spectrophotometric experiment. Methylene chloride, rather than benzene, was chosen as solvent since separation of solid products in the cell only occurred in the late stages of the reaction.

The greater reactivity towards the azo bond than towards -ene or -yne bonds may reside in the greater ability of nitrogen than carbon to stabilize negative charge in the product precursor, as in **11**. Azo adducts must also benefit from the stabilization inherent in the creation of two amide groups.

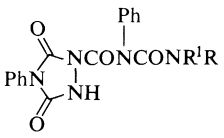
The reaction of **1** with primary and secondary amines was also examined to see if compounds **14** (R^1 = H or R^1 = R) might be formed, analogous to **3** from alcohols. With *tert*-butylamine, pyrrolidine, or dimethylamine, decomposition of **1** was fast and exothermic, but work-up led to intractable gums. Compound **9** was evidently not a product. The reaction of **1** with dimethylamine in C_6D_6 was followed by ^{1}Hmr spectroscopy, but the methyl signals were at all times broad and complex.



14



15



16

An intermediate like **15** does not have the special bias towards cleavage of the C to N—Ph bond found in **7**. Cleavage to **16** must also compete with that to **14**. Furthermore the amines presumably catalyze the dissociation of **14** (cf. pyridine and compound **3**) to PhNCO and, when R^1 = H, to RNCO. These, on recombination with the urazole ring system can lead to multiplication of products. Compound **16** may similarly dissociate when R^1 = H.

Experimental

The following spectrometers were used: for ir a Beckman IR 10, all values given being determined in Nujol mulls; for uv a Unicam SP 800 B; for ^{1}Hmr a Varian T-60. Melting points are uncorrected.

*1-Alkoxycarbonyl-2-*N*-phenylcarbamoyl-4-phenyl-1,2,4-triazolidine-3,5-diones (3)*

Uncatalyzed Reactions

(*a*) The deep red solution of the azo compound **1** (15) (1.75 g, 10 mmol) and the alcohol (10 mmol) in benzene (100 mL) was stirred for about 2 days at room temperature, by which time the color had faded to a pale yellow. The benzene was evaporated under reduced pressure and the pasty residue treated with chloroform (5 mL). A small amount of undissolved material (the urazole **2** or polymer) was filtered off. The solution was evaporated till crystallization occurred or otherwise to dryness. In the latter case the residue was crystallized from an appropriate solvent.

(*b*) To a solution of **1** (10 mmol) in methylene chloride (10 mL) was added a large excess of the alcohol (10 mL). The reaction was exothermic, vigorous evolution of nitrogen was observed, and after about 30 min the red had given place to a straw color. The solution was evaporated and the residue worked up as before.

To confirm the absence of aldehyde (methanol, ethanol, 1-butanol reactions) and to determine the yield of acetone in the 2-propanol reaction, the alcohol and **1** (0.1 mmol each) were dissolved in C_6D_6 (0.3 mL) in an nmr tube. When the reaction was complete toluene was added as an internal standard and the peaks for it and the carbonyl compound were integrated (±4%).

To estimate the amounts of benzaldehyde and cyclopentanone produced, and of benzyl alcohol and cyclopentanol unreacted, solutions of alcohol and **1** (1.0 mmol each) in benzene (3 mL) were allowed to react and then analyzed by glc (6 ft × 1/8 in., 10% SE 30, 90°C), using mesitylene as internal standard (±2%). From the amount of reacted alcohol the yields of **3***e* and *f* (and in one case **3***d*) were determined. The latter were only slightly higher than the isolated yields obtained in the work-up. Gas–liquid chromatography (70°C) was similarly used as an alternative for measuring the yields of acetone.

The melting points, solvents of crystallization, yields, and elementary analyses of **3**, as well as the yields of aldehyde or ketones, are listed in Table 1.

Pyridine-catalyzed Reactions

These experiments were in general done on a 1 mmol scale as described above for the glc analyses. One equivalent of pyridine (in the case of the 2-propanol reaction variable amounts, see Table 1), the alcohol, and **1** reacted rapidly in benzene, decolorization being complete within one hour.

The work-up and the determination of yields were carried out as described above. Compound **9** (see below) was a minor insoluble product in the reaction with 2-propanol or cyclopentanol.

The yields of **3** and of the corresponding carbonyl compounds are also given in the table.

Kinetics

The disappearance of the chromophore at 550 nm in 0.02 *M* solutions of **1** in methylene chloride (1 cm quartz cell, 30°C) was followed in each of the following experiments by repeated scanning of the visible region: (*i*) 0.04 *M* in methanol, $t_{1/2}$ = 1–1.5 days; (*ii*) 0.02 *M* in pyridine, $t_{1/2}$ = 40 min; (*iii*) 0.04 *M* in methanol, 0.02 *M* in pyridine, $t_{1/2}$ = 23 min.

1-Methoxycarbonyl-4-phenyl-1,2,4-triazolidine-3,5-dione (4)

(a) From **3**a

When **3***a* (100 mg) was heated just above its mp in a small test tube it decomposed to a solid and a liquid which condensed on the upper walls. Careful washing out of this liquid and treatment of it with ethanol gave ethyl *N*-phenylcarbamate, identified by comparison with an authentic sample. The solid was identified as **4** by crystallizing it from ethanol.

Alternatively, when **3***a* was refluxed in ethanol for 30 min and the solution concentrated and cooled, compound **4** separated out. Ethyl *N*-phenylcarbamate was identified in the mother liquor.

Equilibrium between **3**a *and* **4**

Solutions of **3***a* in chloroform-*d* showed no evidence of the presence of **4** when examined by ^{1}Hmr spectroscopy. Addition of pyridine-d_5 caused the appearance of compound **4**. In neat C_5D_5N the equilibrium constant for **3***a* ⇌ **4** was 0.75 (**3***a* and **4** having τ for OMe at 3.82 and 3.92 ppm respectively) but it could be reduced by the addition of $CDCl_3$.

(b) By Synthesis from **2**

To a suspension of 50% sodium hydride – mineral oil (0.50 g, 11 mmol) in dry tetrahydrofuran (40 mL) was added **2** (1.77 g, 10 mmol) followed by methyl chloroformate (0.91 g, 10 mmol). After one hour the mixture was evaporated and the residue washed free of oil with hexane. Decomposition with water gave **4** (1.98 g, 84%), purified by crystallization from ethanol, mp 229–230°C.

Pyridine could also be used in place of sodium hydride.

Compound **4** had ν: 3350 (NH), 1800, 1754 (C=O) cm^{-1}; τ(CD_3COCD_3): 2.45 (m, 5H phenyl), 6.05 (s, OMe) ppm.

Anal. calcd. for $C_{10}H_9N_3O_4$: C 51.07, H 3.86, N 17.87; found: C 51.03, H 3.99, N 17.61.

Synthesis of **3***a from* **2**

Addition of **2** (1.77 g, 10 mmol) to a suspension of 50% sodium hydride – mineral oil (0.50 g, 11 mmol) in dry tetrahydrofuran (40 mL) caused vigorous effervescence. Phenyl isocyanate (1.19 g, 10 mmol) and then methyl chloroformate (0.91 g, 10 mmol), each in tetrahydrofuran (5 mL), were added and the mixture kept for 1 h at room temperature. Addition of water (30 mL) gave a colorless solid which was washed with water and ether and then dried (80%). It was identified as **3***a* by comparison with the product from the reaction of **1** with methanol.

*3,7-Diphenyl-1,3,5,7-tetrazabicyclo[3.3.0]octan-2,4,6,8-tetraone (***9***)*

Pyridine (3 mL) was added to a solution of **1** (1.75 g, 10 mmol) in methylene chloride (10 mL). Decolorization was rapid, nitrogen was copiously evolved, and a solid separated. Filtration and washing with cold alcohol gave **9** (1.30 g, 80%) in high purity, mp 234–235°C. It could be recrystallized on a small scale from a large volume of ethanol. It was identical with material prepared by pyrolysis, as described by Stollé (21); ν (Nujol): 1790, 1757 (C=O) cm^{-1}.

Triethylamine or 1,5-diazabicyclo[4.3.0]nonene-5 in place of pyridine also led to **9** in high yields.

Stability of **9** *to Methanol and Pyridine*

A suspension of **9** (50 mg) in methanol (10 mL) was refluxed for 12 h and evaporated to dryness. The ir spectrum of the residue was identical with that of starting material.

Pyridine (2 mL) containing **9** (50 mg) was brought to its boiling point and methanol (2 mL) was added. The milky suspension was then kept at room temperature for 4 h and the solvents completely removed. The residue was pure **9**.

*1,2-Diethoxycarbonyl-4-phenyl-1,2,4-triazolidine-3,5-dione (***13***)*

(a) By Trapping with **1** *in the Presence of Pyridine*

To a suspension of **1** (1.75 g, 10 mmol) and diethyl azodicarboxylate (8.7 g, 50 mmol) in dry ether (30 mL) was added pyridine (10 mL). The mixture was stirred until the azo color had disappeared and evolution of nitrogen had stopped. The ethereal suspension was washed with water, hydrochloric acid (2 *N*), water again, and dried. Evaporation of the ether gave an oil which was chromatographed on silica gel with benzene as eluent, affording **13** as a colourless solid (0.9 g, 28%) identical with material synthesized in (*b*) below.

(b) Direct Synthesis

Compound **2** (1.77 g, 10 mmol) and a 50% sodium hydride – mineral oil suspension (0.92 g, 20 mmol) were stirred in dry dimethoxyethane (50 mL) for 4 h at room temperature. Ethyl chloroformate (2.16 g, 20 mmol) was added dropwise and the mixture was stirred for 12 h. Work-up as in (*a*) gave a residue which readily crystallized (2.0 g, 62%). It was recrystallized from benzene–iso-octane as needles, mp 120–120.5°C; ν (Nujol): 1767, 1734 (C=O) cm^{-1}; τ($CDCl_3$): 2.58 (5H phenyl, s), 5.58 ($2OCH_2$, q, J = 7.2 Hz), 8.65 ($2CH_3$, t) ppm. *Anal.* calcd. for $C_{14}H_{15}N_3O_6$: C 52.34, H 4.71, N 13.08; found: C 52.46, H 4.68, N 12.88.

Attempted Trapping Experiment with **1** *in the Presence of Pyridine*

Solutions of **1** (0.175 g, 1 mmol) in methylene chloride (5 mL) were treated with 1 mmol of either stilbene, dimethyl maleate, or dimethyl acetylenedicarboxylate, followed in each case by pyridine (1 mL). When nitrogen evolution had ceased the solvent was removed. The stilbene reaction produced only unreacted stilbene and compound **9**. The involatile residue from the dimethyl maleate reaction was devoid of methoxy-containing material (^{1}Hmr). In the acetylene ester reaction the residue contained material which gave a broad methoxy signal in the ^{1}Hmr spectrum, suggesting that polymeric material had been produced. Compound **9** was the major product.

Reaction with Amines

(a) tert-*Butylamine*

A solution of the amine (73 mg, 1 mmol) in methylene chloride (5 mL) was slowly added to a solution of **1** (175 mg, 1 mmol) in methylene chloride (5 mL). The reaction was highly exothermic and deep colors developed through light to deep purple and then to brown. Evaporation to a sticky residue and trituration with cold ether – methylene chloride gave a tan solid (200 mg) which was sparingly soluble in $CDCl_3$; τ: 2.3–2.9 (Ph), 4.4–5.1 (NH), and 8.7–9.0 (*tert* Bu) ppm, all very broad and in the approximate ratios of 5:2:9.

(b) Pyrrolidine

Solutions of pyrrolidine (51 mg, 1 mmol) and **1** (175 mg, 1 mmol), each in methylene chloride (5 mL), were mixed. There was immediate decolorization of the azo compound. The residue on evaporation was a gum soluble in $CDCl_3$; τ: 2.1–3.1 (5H phenyl), 6.0 (1H, broad), 6.5 (3H, slightly broadened q), 8.1 (3H, broad), 8.8 (2H, t) ppm. Attempted purification gave fractions of increased complexity in their ^{1}Hmr spectra.

(c) Dimethylamine

Equimolar solutions (0.3 mmol) of the amine and **1** were mixed as in (*b*) in a total of 5 mL of methylene chloride. The brown residue obtained on evaporation was mostly soluble in $CDCl_3$; τ: 2.3–3.0 (Ph), 6.37, 6.60, 6.83, 6.93, 7.04, 7.62 (Me and ? NH, 6 singlets of widely varying intensity, 1.2 times area of Ph peak) ppm.

The reaction was followed by ^{1}Hmr spectroscopy in C_6D_6 by gradually adding **1** to a solution of the amine. The Me region was complex before and after the stoichiometric point.

La réaction des diaryl-1,3 propène-2 ones-1 avec la thiourée en présence d'éthylate de sodium fournit les diaryl-4,6 dihydro-3,4 1*H*-pyrimidinethiones-2 (**5**) qui par déshydrogénation par 3 mole d'éthylate de sodium en milieu éthanolique conduisent aux diaryl-4,6 1*H*-pyrimidine thiones-2 (**9**) correspondantes. On a aussi préparé les dérivés *N*-acétylés des thiones. On rapporte et discute les données spectrales ir, rmn et uv des composés préparés.

[Traduit par le journal]

Introduction

The reaction of acetylenic ketones with thiourea and its derivatives has been known to give 4,6-diarylpyrimidine-2(1*H*)thione derivatives (1, 2). The condensation of 1,3-diaryl-2-propen-1-ones with thiourea in the presence of sodium ethoxide under reflux for 10 h has been reported to give the corresponding 4,6-diaryl-5,6-dihydropyrimidine-2(1*H*)thiones (3).

The present work was intended to study the reaction of 1,3-diaryl-2-propen-1-ones **1** with thiourea and to account for the manipulated methods and reasoning in establishing the mechanism of the reaction as well as the structure of the products.

Experimental

Infrared (ir) spectra were measured on a Perkin Elmer 577 spectrophotometer (KBr). Nuclear magnetic resonance (nmr) spectra were measured on a JEOL-PMX 60 spectrometer using TMS as internal standard. Ultraviolet spectra (uv) were measured on a Beckman spectrophotometer ACTA MVI (ethanol). The purity of the analytical samples was checked by thin-layer chromatography (tlc) (silica gel). Melting points were taken in a BÜCHI 510 melting point in open capillary tubes and are uncorrected. Microanalyses for N, S, and Cl were determined by the Chemical Analytical Laboratory (KISR), however, C and H were determined by Alfred Bernhardt, West Germany. All evaporations were performed on evaporators *in vacuo*.

*Reaction of 1,3-Diaryl-2-propen-1-one **1** with Thiourea*

General Procedure

1,3-Diaryl-2-propen-1-one **1** (0.03 mol) and thiourea (0.03 mol) were added successively to a solution of sodium ethoxide (0.03 mol) in absolute ethanol (100 mL). The reaction mixture was heated under reflux for 1 h. The solvent was evaporated and the residue was dissolved in water (150 mL). The alkaline solution was acidified with acetic acid (10 mL) and the precipitated solid was separated by filtration. Crystallization of the crude products from suitable solvents gave the corresponding 4,6-diaryl-3,4-dihydropyrimidine-2-(1*H*)thione **5** as colorless crystals. The results are reported in Table 1. Heating of the thiones **5***a–f* with 3 mol of sodium ethoxide in absolute ethanol for 2 h afforded the corresponding 4,6-diarylpyrimidine-2(1*H*)thione **9***a–f* approximately in quantitative yield (mp, mixed mp, and ir spectra).

The thiones **5***a–c* are insoluble in both hot and cold NaOH solutions. All the attempts to prepare the *N*-methyl, *S*-methyl, or the disulfide derivatives from the corresponding thiones **5***a–l* were unsuccessful.

*1-Acetyl-4,6-diaryl-3,4-dihydropyrimidine-2(1*H*)thiones **8**a–l*

General Procedure

The thione **5** (2.0 gm) was heated with acetic anhydride (3 mL) on a boiling water-bath for 30 min. The product, which precipitated on addition of cyclohexane, was crystallized from a suitable solvent to give the corresponding 1-acetyl derivative which upon heating for 5 min with 3 mol of sodium ethoxide in ethanol gave the corresponding thione **5** (mp, mixed mp, and ir spectra). However, when the heating was continued for 2 h, it gave the corresponding 4,6-diarylpyrimidine-2(1*H*)thione **9**. The results are reported in Table 2.

Results and Discussion

When 1,3-diaryl-2-propen-1-ones **1***a–l* were refluxed with thiourea in the presence of sodium ethoxide in ethanol for one hour, they gave the corresponding 4,6-diaryl-3,4-dihydropyrimidine-2-(1*H*)thiones **5***a–l* and not 4,6-diaryl-5,6-dihydropyrimidine-2(1*H*)thione **4**, as described previously by Sammour *et al.* (3). The reaction proceeds either by (*i*) 1:2-addition or (*ii*) 1:4-addition of the anion (A) to the ketone, followed by cyclization of the intermediates **2** and **3** (Scheme 1). Route (*ii*) seems more

likely by analogy to the reaction of α,β-unsaturated ketones with nitrogen compounds (1, 4) and an active methylene group (5, 6).

The structure of the above products was established spectroscopically and chemically. Thus, the ir spectra of these compounds (Table 3) were devoid of ν SH, which excluded structures **6** and **7**. The presence of a broad band in the region 3360–3140 cm^{-1} (ν NH) and a strong band in the region 1180–1155 cm^{-1} (ν C=S) (7) indicated that these compounds have structure **5**. The nmr spectra of these compounds reflect a strong evidence for the suggested structure (Table 3). They show a multiplet or two doublets in the region δ 5.22–5.07 correlated to the neighbouring methine and methylene protons. The spectra also show a broad signal attributed to two NH protons exchangeable with D_2O. This fact was established by running the nmr spectrum of **5***j* in $CDCl_3$, $CDCl_3$/DMSO-d_6 1:3, and DMSO-d_6, respectively (cf. Fig. 1), in which the broad signal was split into two broad ones, exchangeable with D_2O, and the distance between them depends on the ratio of the more polar solvent added. Natural abundance ^{13}C nmr spectra for the thiones (**5***a*, *f*) gave further support for the reported structure. They show signals attributable for CS, $\geqslant$CH, and =CH— (Table 4). Further evidence for the structure of these compounds was obtained from their uv spectra. They show absorption bands which can be attributed to π–π* transition of the styrene moiety (6). Also the uv spectra of these compounds in polar and non-polar solvents such as ethanol, chloroform, and carbon tetrachloride (cf. Table 5) show that the red shift in the position of the absorption bands varies inversely with the polarity of the solvent. This may be attributed to the stabilizing influence of the hydrogen bonding on the thione form **5**; however, in the non-polar solvents the other form (thiol form, **6** or **7**) is favoured, similar to the phenomenon observed in the case of pyrimidine-2(1*H*)thione (1) and β-diketones (8). The ms spectrum of **5***f* affords an additional support for the assigned structure, since it shows peaks at the following *m/e* (relative intensity): 296 (63.2)]M]$^+$, 219 (27.2) [M − C_6H_5]$^+$, 194 (17.2) [M − $C_6H_5C{\equiv}CH$]$^+$, and 77 (100) [C_6H_5]$^+$.

Chemical behaviour of these compounds gives further evidence for the assigned structure. Thus, compounds **5***a–g* gave, upon refluxing for 2 h with 3 mol of sodium ethoxide in methanol, the corresponding 4,6-diarylpyrimidine-2(1*H*)thiones **9** (Scheme 2) approximately in quantitative yield identical with the products separated from the reaction of acetylenic ketones with thiourea (2). Acetylation of the thiones **5***a–l* with acetic anhydride afforded the corresponding *N*-acetyl derivatives **8***a–l*. The structure of the latter compounds was established by their ir, nmr, uv, and ms spectra (Table 6). Thus, their ir spectra (KBr) show a strong band in the region 1660–1650 cm^{-1} (ν $NCOCH_3$) and two broad bands in the region 3370–3140 cm^{-1} (ν NH) (Table 6). When the ir spectrum of **8***a* was run in chloroform solution, a sharp band at 3410 cm^{-1} (free NH) was obtained. Their nmr spectra (Table 5), however, show two doublets in the regions δ 6.33–6.19 and δ 5.91–5.71 (J = 7 Hz) attributable to the neighbouring methine and olefinic protons. These assignments were con-

firmed by double irradiation experiments, e.g., on irradiation at the frequency of the olefinic proton, the doublet of the methine proton collapsed to a singlet. The differences in the proton shifts for the methine and olefinic protons in the compounds **5***a–l* as compared with the acetylated products **8***a–l* are due to the fact that the NH group possesses more +R effect than the $-NCOCH_3$ group, accordingly it will increase the electron density on the olefinic CH more than the $NCOCH_3$ group, i.e., it will cause a decrease in the δ-value (upfield shift) (cf. Scheme 3). These structures show, in addition, a singlet signal in the region δ 2.83–2.75 (3,$COCH_3$) and a broad signal at δ 8.82–8.42 (1,NH) exchangeable with D_2O. The ^{13}C nmr spectra for **8***a*,*f* (Table 4) show signals attributable to CS and $COCH_3$ groups. The uv spectra of these compounds are identical, which reflects their structural analogy (Table 6). Further support for the assigned structure was gained from the ms spectrum **8***f* which shows peaks at the following *m*/*e* (relative intensity): 338 (13.15) $[M]^+$, 323 (3.28) $[M - CH_3]^+$, 295 (98) $[M - COCH_3]^+$, and 236 (100) $[M - C_6H_5C{\equiv}CH]^+$. The absence of the $[M - SCOCH_3]^+$ peak in the spectrum gave further evidence for the structure. All the spectral data of these compounds show that structure **8**(A) is more probable than the other one **8**(B) because the

The $AlCl_3$-promoted reaction of methyl 2,5-dimethylpyrrole-1-carboxylate **1** with dimethyl acetylenedicarboxylate affords under certain conditions a low yield of 2,5-dimethyl-2-tricarbomethoxyvinyl-2*H*-pyrrole **3**. The structure of the latter was established on the basis of detailed ^1H and ^{13}C nmr studies, and confirmed by conversion to dimethyl 5-methyl-5-(3-oxobutyl)-3-pyrrolin-2-one-3,4-dicarboxylate **4**.

R. A. F. MATHESON, A. W. MCCULLOCH, A. G. MCINNES et D. G. SMITH. Can. J. Chem. 57, 2743 (1979).

La réaction du diméthyl-2,5-pyrrole carboxylate de méthyle-1 (**1**) avec l'acétylène dicarboxylate de méthyle catalysée par $AlCl_3$ conduit sous certaines conditions avec un faible rendement au diméthyl-2,5-tricarbométhoxyvinyl-2-2*H* pyrrole **3**. La structure de ce dernier est établie à partir d'études détaillées en rmn du proton et du ^{13}C, et confirmée par sa transformation en méthyl-5-(3-oxobutyl)-5-pyrrolin-3-one-2-dicarboxylate de méthyle-3,4 (**4**).

[Traduit par le journal]

Introduction

We have previously reported the $AlCl_3$-promoted Diels–Alder addition of 1-carbomethoxy-2,5-dimethylpyrrole **1** to dimethyl acetylenedicarboxylate (DMAD) to give trimethyl 1,4-dimethyl-7-azabicyclo-[2.2.1]2,5-heptadiene-2,3,7-tricarboxylate **2** (1). Further investigation of the reaction between **1** and DMAD (see Experimental) led to the isolation of an additional product (max. yield 15%). In this note we describe the structural elucidation of this new compound, which has been identified as 2,5-dimethyl-2-tricarbomethoxyvinyl-2*H*-pyrrole **3**.

Results and Discussion

Mass spectral analysis of **3** established the molecular formula $C_{14}H_{17}NO_6$, indicating a 1:1 product. The ^1H nmr spectrum (Table 1) showed that the seventeen hydrogens were accounted for by resonances for three chemically non-equivalent carbomethoxy methyl groups, two chemically non-equivalent methyl groups, both on quaternary carbons, and two olefinic hydrogens which were vicinally coupled to one another (J = 4.8 Hz). Irradiation of the low-field *C*-methyl (δ 2.14) caused a 14% nuclear Overhauser enhancement of the signal for the high-field olefinic hydrogen, whereas irradiation of the high-field methyl (δ 1.39) caused a 19% enhancement of the signal for the olefinic hydrogen at low field. These results established that each olefinic hydrogen was vicinal to a methyl group.

When 1-carbomethoxy-3,4-dideutero-2,5-dimethylpyrrole was substituted for **1** in the reaction with DMAD, the product obtained had ^1H nmr resonances for five methyl groups identical to those of **3**, but had no olefinic signals. Thus the olefinic hydrogens of **3** are derived directly from the comparable hydrogens (H-3 and H-4) of **1**. In other words, the intact carbon chain of the 2,4-hexadiene moiety of **1** is incorporated into **3**, as suggested by the nOe experiments.

Further evidence for structure **3** was derived from ^{13}C nmr measurements (Table 2).[3] On the basis of characteristic chemical shifts, multiplicities, and $^1J_{CH}$ values it was possible to unequivocally assign resonances due to the two methyl, six carbomethoxyl, and two olefinic methine carbons. The remaining four resonances were all for quaternary carbons. The chemical shift (δ 82.06) of one of these indicated a saturated carbon (C-2) deshielded by an attached nitrogen, while the low-field shift (δ 173.60) of a second was characteristic of an imino carbon (C-5) forming part of a cyclic structure (cf. ref. 2). Single frequency decoupling experiments (irradiation in

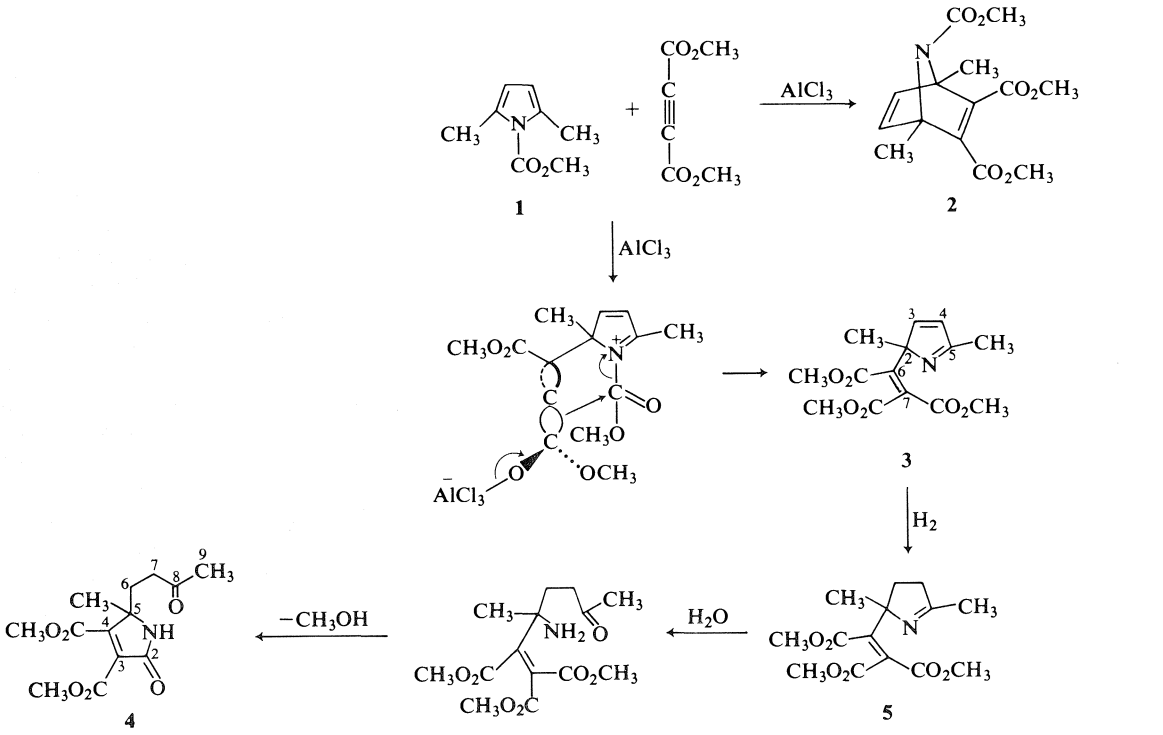
[a]Using a 5% solution of **3** in degassed DMSO-d_6, the following nuclear Overhauser enhancements were observed (irradiated hydrogens in parentheses): H-3 (CH_3 at C-2) 19%, H-4 (CH_3 at C-5) 14%, H-3 (CH_3 at C-5) 0%, H-4 (CH_3 at C-2) 0%.

turn of each olefinic hydrogen and of the hydrogens of each *C*-methyl group) established that each of C-2 and C-5 was directly bonded to a methyl group and *trans* ($^3J_{CH}$ = 11.5 Hz) to an olefinic hydrogen. The combined evidence, together with the high $^1J_{CH}$ values observed for C-3 and C-4 (3), is consistent with a 2-substituted 2,5-dimethyl-2*H*-pyrrole moiety.

The only possible arrangement of the three carbomethoxyl groups and two unassigned quaternary olefinic carbons is as a tricarbomethoxyvinyl group, which must therefore be the C-2 substituent. The carbon resonating at δ 147.02 was coupled ($^3J_{CH}$ = 4.1 Hz) only to the hydrogens of the methyl group at C-2 and can thus be readily assigned to C-6. As expected, C-7 (δ 124.98), which is bonded to and



SCHEME 1

geminal to quaternary centers, showed no discernible coupling. For similar reasons no coupling other than that with the methoxyl hydrogens ($^3J_{CH} \sim 4$ Hz) would be expected or was observed in any of the three carbonyl carbon resonances.

Chemical confirmation of the structure of **3** was provided by its conversion to the pyrrolinone **4**. Catalytic reduction of **3** afforded the sensitive 3,4-dihydro derivative **5**, which was not fully characterized. During chromatography **5** underwent imine hydrolysis; spontaneous cyclization of the resulting aminoketone (not isolated) gave **4**.

The ^{1}H nmr spectrum of **5** (Table 1) showed signals for two chemically non-equivalent methyl groups attached to quaternary centers, four methylene hydrogens, and three chemically non-equivalent methoxyl groups, but none for olefinic hydrogens. The spectrum of **4** was similar except that there were signals for only two chemically non-equivalent methoxyl groups, and there was now an NH signal.

Mass measurement of **4** established the molecular formula $C_{13}H_{17}NO_6$ and also the facile cleavage of the 3-oxobutyl side-chain. The ^{13}C nmr spectrum of **4** (Table 2) contained signals for the carbons of two methyl, two methylene, and two carbomethoxyl groups, and for two quaternary olefinic carbons. The three remaining resonances could be readily assigned to a saturated carbon (C-5; δ 63.27) deshielded by nitrogen, and to amide (C-2; δ 166.60) and ketone (C-8; δ 207.43) carbonyls. The high-resolution ^{13}C data are compatible only with structure **4**. The lack of coupling in the two carbomethoxyl carbonyls once again indicated that both these carbons were bonded to and geminal to quaternary carbons. Couplings of the amide proton with the adjacent carbonyl ($^2J_{CH}$ 2.3 Hz) and with the ring carbon C-3 ($^3J_{CH}$ 7.2 Hz) were confirmed by running the spectrum after exchange of the NH with deuterium.

The formation of **3** involves a novel 1,3-migration of an intact carbomethoxyl group from nitrogen to carbon. Although migrations of ester groups to nucleophilic centers have been observed (4), this appears to be the first example of such a migration from nitrogen to carbon. A plausible intramolecular transfer pathway is shown (Scheme 1). An alternative mechanism would be an intermolecular process involving methyl chloroformate: we were, however, unable to detect the latter in the reaction mixture or products.

Experimental

The ^{1}H nmr spectra of **4** and **5** were recorded in $CDCl_3$ on a Varian A-60A spectrometer; spectra of **3** (in $CDCl_3$ and DMSO-d_6) were obtained using a Varian HA-100D spectrometer.

The ^{13}C spectra of **1**, **2**, and **4** were recorded in $CDCl_3$ on a Varian XL-100-15 spectrometer under the following condi-

tions: frequency 25.16 MHz; acquisition time 0.8 or 1.6 s (data accuracy ± 0.6 or ± 0.3 Hz); spectral width 5120 Hz (5400 Hz in case of **4**); flip angle 30°; internal ^{2}H lock to solvent; temperature about 30°C. ^{1}H irradiation at 100 MHz: (*a*) $\gamma H_2/2\pi$ ca. 3800 Hz, broadband irradiation by 0–180° phase modulation at 150 Hz; (*b*) as for *a*, but irradiation only applied for 1.6 s between data acquisition periods (high-resolution spectrum with retained nOe). ^{13}C spectra of **3** (100 mg/0.4 mL $CDCl_3$) were recorded on a Varian FT 80 spectrometer under the following conditions: frequency 20 MHz; acquisition time 0.99 or 1.98 s (data accuracy ± 0.5 or ± 0.25 Hz); spectral width 4132 Hz; flip angle 25° or 50°; internal ^{2}H lock to solvent; temperature about 35°C. ^{1}H irradiation at 80 MHz: (*a*) $\gamma H_2/2\pi$ ca. 4000 Hz, bandwidth 2000 Hz (broadband decoupling); (*b*) $\gamma H_2/2\pi$ ca. 2900 Hz, bandwidth 1000 Hz, field applied for 2 s between data acquisitions to retain nOe (high-resolution spectrum); (*c*) as for *b*, but with additional constant ^{1}H irradiation $\gamma H_2/2\pi$ 196 Hz at frequencies of individual ^{1}H resonances (single frequency decoupling with nOe retained at all resonances).

Infrared absorptions were measured on Perkin-Elmer 521 or 180 spectrometers. High-resolution mass spectral measurements were made with a Dupont-CEC 21-110B double-focussing mass spectrometer, using electrical detection for mass measurements.

2,5-Dimethyl-1,3,4-trideuteropyrrole

A solution of concentrated H_2SO_4 (400 mg) in D_2O (100 mL) was added directly to 2,5-dimethylpyrrole (20 g) and the mixture stirred for 30 min at room temperature. An excess of solid K_2CO_3 was then added and the mixture extracted with benzene. Evaporation of solvent from the dried (Na_2SO_4) extract afforded an oily residue which was distilled. The product (71%) was obtained as a colorless oil; ^{1}H nmr analysis indicated 93% of the title compound.

1-Carbomethoxy-2,5-dimethylpyrrole ***1***

This compound was prepared in the manner described by Gabel (5). Its 3,4-dideutero derivative was similarly prepared from 2,5-dimethyl-1,3,4-trideuteropyrrole.

*2,5-Dimethyl-2-tricarbomethoxyvinyl-2*H*-pyrrole* ***3***

A solution of **1** (1.53 g, 0.01 mol) in CH_2Cl_2 (50 mL) was added dropwise with stirring to a mixture of DMAD (2.90 g, 0.02 mol) and $AlCl_3$ (1.40 g, 0.01 mol) in CH_2Cl_2 (100 mL). The mixture was refluxed for 30 min. The dark red reaction mixture was then washed with ice water. The organic layer was dried and evaporated to give a dark red oily residue (4.26 g) which was chromatographed (200 g SiO_2; $CHCl_3$ as eluant). This gave (*a*) DMAD (1.93 g), (*b*) trimethyl 1,4-dimethyl-7-azabicyclo[2.2.1]2,5-heptadiene-2,3,7-tricarboxylate **2** (0.09 g) (1), and (*c*) slightly contaminated **3**. Fraction (*c*) was subjected to preparative tlc (2 mm SiO_2; 70% petroleum ether/ethyl acetate as eluant). This afforded **3** (0.45 g, 15%) as a cream-colored solid, mp 77–79°C. Repeated tlc raised the mp to 82–84°C. Molecular ion at *m/e* 295.1056 ($C_{14}H_{17}NO_6$ requires 295.1057). Infrared ν_{max} ($CHCl_3$): 1722, 1636, 1613 cm^{-1}.

A similar experiment was conducted using 1-carbomethoxy-3,4-dideutero-2,5-dimethylpyrrole in place of **1**. The same work-up procedure gave 3,4-dideutero-2,5-dimethyl-2-tricarbomethoxyvinyl-2*H*-pyrrole.

An estimated (from ^{1}H nmr) 10% yield of **3** was obtained by reacting **1**, DMAD, and $AlCl_3$ (molar ratio 1:1:5) in CH_2Cl_2 for 30 min at −10°C.

Care must be exercised during the work-up of **3**, particularly when high concentrations of $AlCl_3$ are used. The compound is sensitive to aqueous acid and the reaction mixture must therefore be quenched cautiously with ice. Compound **3**, in addition, deteriorates on standing, even under refrigeration.

Gas chromatography (Perkin-Elmer 910; OV-101; capillary column 25 m × 0.27 mm id; column temp. 40°C) did not show any methyl chloroformate in either the reaction or products.

*3,4-Dihydro-2,5-dimethyl-2-tricarbomethoxyvinyl-2*H*-pyrrole* ***5***

A sample (170 mg) of **3** in methanol (75 mL) was hydrogenated over 5% Pd/C (90 mg) for 5 min only. Filtration and evaporation gave **5** as a pale yellow oil (166 mg). It was important to restrict uptake of H_2 to only one mole.

Dimethyl 5-methyl-5(3-oxobutyl)-3-pyrrolin-2-one-3,4-dicarboxylate ***4***

The crude **5** (166 mg) obtained above was applied to two 20 cm × 20 cm × 2 mm prep. tlc plates, which were then eluted twice with 5% MeOH/$CHCl_3$. Extraction of the major band (R_f 3) afforded **4** as an almost colorless oil (102 mg, 62% overall from **3**), which crystallized on standing at 0°C. Recrystallization from ethyl acetate/petroleum ether gave colorless needles, mp 104.5–106°C. Molecular ion at *m/e* 283.1055 ($C_{13}H_{17}NO_6$ requires 283.10559); base peak at *m/e* 180.0293 ($C_8H_6NO_4$ requires 180.02968); strong ion at *m/e* 212.0565 ($C_9H_{10}NO_5$ requires 212.05590). Infrared ν_{max} (liq. film): 3270 (br), 1740 (sh), 1700 (br), 1645 (sh) cm^{-1}.

Acknowledgements

We wish to thank Mrs. M. G. Flack for her valuable technical assistance. We also thank D. J. Embree for the mass spectra and P. F. Seto for infrared measurements. The assistance of Dr. J. A. Walter with the single-frequency decoupling experiments is gratefully acknowledged.

A new semiquantitative method has been developed for measuring the relative acidities of methanol, ethanol, isopropyl alcohol, and *tert*-butyl alcohol in mixed hydroxylic solvents. A solution of the alkoxides of two alcohols in an excess of the two alcohols is allowed to react with *n*-butyl bromide to form a mixture of two ethers. The composition of the ether mixture is a measure of the "competitive reactivity" of the two alkoxides. This can be measured directly, and in theory can be factored into two components: the relative nucleophilicity and the relative basicity of the two alkoxides. Relative nucleophilicities are determined by using solutions in which phenol is one component. Knowing the competitive reactivities and nucleophilicities, the relative acidities of methanol, ethanol, isopropyl alcohol, and *tert*-butyl alcohol in alcoholic media are shown to be 4.4, 1.0, 0.24, and 0.21, respectively. The relative nucleophilicities of hydroxide, methoxide, ethoxide, isopropoxide, *tert*-butoxide, phenoxide, and *m*-cresoxide are 0.08, 0.82, 1.0, 0.4, 0.04, 0.46, and 0.57 respectively.

WILKINS REEVE, CHARLES M. ERIKSON et PATRICK F. ALUOTTO. Can. J. Chem. **57**, 2747 (1979).

On a développé une nouvelle méthode semi-quantitative pour mesurer les acidités relatives du méthanol, de l'éthanol, des alcools isopropylique et tertiobutylique dans un mélange de solvants hydroxyliques. On a fait réagir une solution d'alkoxydes de deux alcools en présence d'un excès de ces alcools avec le bromure de *n*-butyle pour obtenir un mélange de deux éthers. La composition du mélange d'éther est une mesure de la "réactivité compétitive" des deux alkoxydes. Ceci peut être mesuré directement et en théorie peut être décomposer en deux composantes: la nucléophilie et la basicité relative des deux alkoxydes. Les nucléophilies relatives sont déterminées en utilisant des solutions où le phénol est un constituant. Connaissant les réactivités compétitives et les nucléophilies, les acidités relatives du méthanol, de l'éthanol et des alcools isopropylique et tertiobutylique sont établies respectivement à 4.4, 1.0, 0.24 et 0.21. Les nucléophilies relatives des méthoxyde, isopropoxyde, *tert*-butoxyde, phenoxyde et *m*-crésoxyde sont respectivement: 0.08, 0.82, 1.0, 0.4, 0.04, 0.46 et 0.57.

[Traduit par le journal]

There has been much interest recently in the relative acidities of alcohols in the gas phase (1), but little progress has been made in developing new methods for determining acidities of alcohols in protic solvents. We report here a new, semi-quantitative method for measuring the relative acidities of methanol, ethanol, isopropyl alcohol, and *tert*-butyl alcohol in mixtures of these alcohols. The presence of small amounts of water does not affect the results, but it does not follow that the acidity values reported here necessarily apply to dilute aqueous solutions where the three dimensional structure of pure water might have an effect.

During the past fifty years, many investigators have studied the acidities of methanol and ethanol and, to a lesser extent, some secondary and tertiary alcohols. The alcohols are weak acids and the methods used to measure their acidities often gave conflicting results (2). It is recognized that new independent approaches are needed to determine acidity values more accurately, and to provide independent evidence as to the correctness of the acidity values measured by the different methods (3).

We have now developed a new method for measuring the proton-transfer acidities of alcohols. It depends upon the determination of what we call the competitive reactivity (C.R.) of two alkoxides, and also the relative nucleophilicity (R.N.) of these two alkoxides. These properties are related by the simple equation:

$$[1] \quad C.R._{RO^-/R'O^-} = (R.N._{RO^-/R'O^-}) \times (\text{Relative acidities of ROH/R'OH})$$

where the competitive reactivity of two alkoxides, RO^- and $R'O^-$, is measured with respect to a certain substrate, and the relative nucleophilicity of the two alkoxides is also measured with respect to the same substrate. Knowing the C.R. and the R.N., the

0008-4042/79/202747-08$01.00/0

relative acidities of the two alcohols can be calculated. We will now discuss our method for determining competitive reactivities and relative nucleophilicities in detail.

Competitive Reactivity

Consider an experiment in which an atom of sodium is dissolved in a mixture of 10 mol of methanol and 10 mol of ethanol to yield the two alkoxides, each in equilibrium with each other and with the two alcohols, which are present in large excess.

[2] $CH_3OH + C_2H_5O^- \rightleftarrows CH_3O^- + C_2H_5OH$

[3] $K = [CH_3O^-][C_2H_5OH]/[CH_3OH][C_2H_5O^-]$

We will show later that the equilibrium constant, K, has a value of 4.4, and we therefore say that methanol is 4.4 times as strong an acid as ethanol and the concentration of methoxide anion will be 4.4 times as great as the concentration of ethoxide anion in a solution prepared as described above. Our definition of acidity in this work is as above. If a mole of *n*-butyl bromide is now added to the solution, the two alkoxide anions will competitively react with it to form a mixture of methyl *n*-butyl ether and ethyl *n*-butyl ether. If the two alkoxide anions had identical nucleophilicities, the methyl and ethyl ethers would be formed in the same ratio as the concentrations of the two alkoxide anions. However, methoxide is only 0.82 times as nucleophilic as ethoxide (as we will show later) so the amount of methyl *n*-butyl ether formed is reduced by this amount. Accordingly, the competitive reactivities of methoxide versus ethoxide in the above experiment is 4.4 times 0.82 which equals 3.6. Experimentally, the ratio in which these ethers are formed can be determined by analyzing a sample of the reaction mixture by glc.

We see from the above discussion that competitive reactivity is a measure of how two nucleophiles, in the presence of their conjugate acids, compete with each other for a common substrate. Experimentally it can be measured directly, and in theory it can be factored into two components, relative nucleophilicity of the alkoxides and the relative acidity of the alcohols. For this approach to be theoretically sound, the reactions with the substrate must be irreversible so that kinetic control is in effect. It follows that the molar ratio of the final products is also the ratio of the reaction rates by which they are formed.

The experimental results in Table 1 were obtained using *n*-butyl bromide as substrate. In all cases the alcohols were present in seven-fold to thirty-fold excess over the corresponding alkoxide concentrations. The initial concentration of the *n*-butyl bromide was the same or a little less than that of the initial total alkoxide concentration. The reactions were carried out at 26°C, and 25 h were required for 50% of the *n*-butyl bromide to react. Less than 3% of the *n*-butyl bromide is converted to 1-butene, and this has no effect on the product ratios. In the absence of base, there was no measurable reaction.

All of the competitive reactivity values given in Table 1 are the averaged values of at least duplicate experiments, and are accurate to at least 10%. The internal consistency of the data is striking. Changing the ratios of the alcohols caused little change in the measured competitive reactivities if a concentration term was included so as to give the following equation which corrects for mass action.

[4] $C.R._{RO^-/R'O^-} = (\text{mole ratio ROBu/R'OBu}) \times (\text{mole ratio R'OH/ROH})$

The concentration term in eq. [4] is a valid correction as long as the alcohols are present in large excess relative to the base. On varying the ratios of allyl alcohol to methanol over a fifteen-fold range (#5, 6, 7 in Table 1), the measured competitive reactivities were constant within experimental error. Furthermore, the same value was obtained in a mixture containing three alcohols (#11), and the addition of 20% of water (#12) had no effect. This strongly indicates that the influence of ion-pairing, changes in the dielectric constant, and other solvent effects are small. In any case, the concentrations used are characteristic of practical synthetic work, so the results obtained do have practical significance.

Since competitive reactivities are ratios of rate constants, it is possible to multiply or divide one by another and obtain a new competitive reactivity. Thus, dividing the allyloxide/ethoxide competitive reactivity value by the allyloxide/methoxide value gives 4.4 as the value for the methoxide/ethoxide competitive reactivity, and this is in reasonable agreement with the more accurate value of 3.6 obtained by a direct comparison of methoxide and ethoxide anions. Multiplying the nominal competitive reactivity of *t*-BuO^-/*i*-PrO^- by that of *i*-PrO^-/EtO^- gives the nominal competitive reactivity of *t*-BuO^-/EtO^- equal to (0.11) (0.11) or 0.012.

The comparison of ethanol with isopropyl alcohol and of isopropyl alcohol with *tert*-butyl alcohol are special cases in that the 0.2 mol of minor alcohol in each mixture was in only two-fold excess of the metal (0.1 atom of metal was used in runs 3 and 4), whereas normally there was a five- to ten-fold excess of the minor alcohol. In the first case, after correcting for

[e]Allyloxide anion.

the amount of alcohol converted to the alkoxide by using eq. [3] and acidity values calculated later, the ratio of the two neutral alcohols present at the beginning of the reaction was calculated to be 11.17 instead of the nominal 10.0. At the end of the reaction, the ratio was 12.78 because an appreciable fraction of the minor alcohol was consumed in product formation. Using an average value of 11.97 in eq. [4], the C.R. was recalculated to be 0.0917. A similar treatment of the isopropyl alcohol in *tert*-butyl alcohol data changes the nominal C.R. of 0.11 to 0.097. A more detailed explanation is in the Experimental section.

Benzyl bromide has also been studied as a substitute for the *n*-butyl bromide substrate (4), and the results are in Table 2. The time for 50% reaction with the benzyl bromide was approximately 15 min.

The agreement between the various competitive reactivity ratios using *n*-butyl bromide and benzyl bromide is outstanding. Benzyl bromide is known to be capable of reacting by either the S_N1 or S_N2 mechanism, but the experimental conditions employed here (good nucleophile in non-aqueous solvent) favors the S_N2 mechanism (5), and so both substrates are reacting by the S_N2 pathway.

Relative Nucleophilicity

Nucleophilicity relates to the kinetics of covalent bond formation. We have used only *n*-butyl bromide as a substrate, so relative nucleophilicity (R.N.) in our studies is the ratio of the rates with which two nucleophiles enter into an S_N2 displacement reaction with *n*-butyl bromide. Consider an experiment in which 0.1 mol *n*-butyl bromide is added to an ethanol solution containing 0.1 mol sodium ethoxide and 0.1 mol sodium phenoxide. Since phenol is a million times stronger as an acid than ethanol, all of the phenol in the reaction mixture will always be present as phenoxide and we therefore know the ratio of the concentrations of the two nucleophiles at the start of the reaction. As the reaction proceeds, *n*-butyl ethyl ether and *n*-butyl phenyl ether are competitively formed by S_N2 attack of ethoxide and phenoxide on the *n*-butyl bromide, and the ratio of the ethers formed, determined by glc analyses, is a measure of the R.N. of the two nucleophiles.

In the above experiment, the moles of the butyl ethyl ether and butyl phenyl ether present at the completion of the reaction was 0.063 and 0.037 respectively. Ethoxide is clearly the better nucleophile, but one must consider the relative amounts of

TABLE 2. Competitive reactivities of some alkoxides with benzyl bromide at 26°C

[a]Allyloxide anion.

the two nucleophiles present during the course of the reaction before a R.N. is calculated. At the start of the reaction, the nucleophiles were present in equal amounts, but the amounts present at the end of the reaction were 0.037 mol for ethoxide and 0.063 mol for phenoxide due to the two ethers being formed in unequal amounts. An approximate R.N. can be calculated using average concentrations of the nucleophiles present during the course of the reaction to correct for the effects of mass action, but an exact solution follows.

$$[5] \quad EtO^- + BuBr \xrightarrow{k_1} EtOBr$$

$$[6] \quad PhO^- + BuBr \xrightarrow{k_2} PhOBu$$

let x = [EtOBu], and y = [PhOBu] at any time, t. The values for [EtO^-] and [PhO^-] at $t = 0$ will be A_0 and B_0.

$$[7] \quad dx/dt = k_1[EtO^-][BuBr]$$

$$[8] \quad dy/dt = k_2[PhO^-][BrBr]$$

Dividing, substituting, and rearranging terms gives

$$[9] \quad \frac{dx}{[A_0 - x]} = \left(\frac{k_1}{k_2}\right)\left(\frac{dy}{[B_0 - y]}\right)$$

Integrating between $x = 0$ and $x = x_{final}$ gives

$$[10] \quad \frac{k_1}{k_2} = \frac{\log \dfrac{[\text{initial } EtO^-]}{[\text{final } EtO^-]}}{\log \dfrac{[\text{initial } PhO^-]}{[\text{final } PhO^-]}}$$

For the experiment described, R.N. = k_1/k_2 = 2.14.

In the above manner, nucleophilicities of methoxide, ethoxide, isopropoxide, and *tert*-butoxide were determined relative to phenoxide. Methoxide and ethoxide were also measured against *m*-cresoxide, and phenoxide and *m*-cresoxide in ethanol were also compared directly. The results are in Table 3. As before, all runs were at least in duplicate and most were repeated several times. Standard deviations were calculated for all glc analyses and were usually under 2%. The error in the final calculated R.N. is believed not to exceed 5%. The time for 50% of the *n*-butyl bromide to react was approximately 20 h at

5.[c] PhO^-/*m*-CrO^-	24:29	0.77

[a]Reaction mixture consisted of 0.1 mol sodium phenoxide or *m*-cresoxide, 0.1 mol sodium alkoxide, and 0.1 mol *n*-butyl bromide in 1.8 to 2.7 mol of the alcohol corresponding to alkoxide.
[b]Potassium salts used.
[c]Three nucleophiles (0.1 mol *m*-cresoxide, 0.1 mol phenoxide, 0.1 mol ethoxide) competing for 0.1 mol *n*-butyl bromide in 2.65 mol of ethanol solvent.

25°C, and the reactions were allowed to run for about 2 weeks.

An experiment was devised to demonstrate that the composition of the ether mixture is dependent on the relative concentrations of the alkoxides present, that is, that the nucleophile which forms the new oxygen–carbon bond is the alkoxide ion itself rather than solvating neutral molecules clustered around the alkoxide ion. Two moles of ethanol were allowed to react with 0.1 atom of sodium; 0.11 mol of phenol was then added, and finally 0.10 mol of *n*-butyl bromide. This mixture should consist initially of essentially 100% phenoxide ion, solvated with ethanol, since phenol is 10^6 more acidic than alcohol. The ether mixture obtained was 98% *n*-butyl phenyl ether and 2% *n*-butyl ethyl ether. The small amount of the latter shows the neutral alcohol molecules interfere to only a minor extent; less than the 5% error observed in measuring the relative nucleophilicities. A similar experiment substituting methanol for ethanol gave 96% *n*-butyl phenyl ether and 4% *n*-butyl methyl ether. Again this error is within the experimental limits. If these side reactions are treated as competitive side reactions and the data recalculated, the relative nucleophilicities of MeO^-/PhO^- and EtO^-/PhO^- given in Table 3 are decreased from 1.90 to 1.70 and 2.20 to 2.10 respectively. These changes are within the experimental error and are too small to affect the subsequent calculations of acidity appreciably.

Since relative nucleophilicities are ratios of reaction rates, they can be combined by multiplication or division and new ratios obtained, some of which cannot be measured directly. In Table 4, the validity of this approach is demonstrated with the *m*-CrO^-/PhO^- ratio which is calculated from two different sets of data and compared with the value obtained by direct measurement.

Relative Acidity

Knowing the competitive reactivities and the relative nucleophilicities of the alkoxides, the relative acidities of the alcohols in mixed hydroxylic solvents can be calculated using eq. [1]. We believe these relative acidities are valid for the conditions under which they are measured, namely, in alcoholic media with the ionic strength in the range of 0.5 to 1.5. Table 5 gives the results and summarizes the C.R. and R.N. data from Tables 1, 3, and 4.

Comparisons with Prior Data

Alet and England (8) compared the rates of the S_N2 reaction of hydroxide, methoxide, and ethoxide with methyl iodide in various dioxane–alcohol mixtures, and extrapolated the results to pure dioxane to calculate relative nucleophilicities of 0.21, 0.64, and 1.0 respectively. They also summarized the earlier work of others on the MeO^- in MeOH vs. EtO^- in EtOH ratios of individual reaction rate constants against a variety of substrates; the ratios varied from 0.1 to 0.5. Murto (9) has made a thorough study of the rates of competitive displacement reactions of hydroxide, methoxide, and ethoxide with methyl iodide, as well as other substrates in solvents of varying composition, and has calculated the reaction rate constants for these reactions by a lengthy mathematical analysis of his data. The relative nucleophilicities with methyl iodide substrate were calculated to be 0.08:0.6:1.0 respectively. It is apparent both of these earlier studies are in agreement with our work (0.08:0.82:1.0) in that hydroxide was found to be a weak nucleophile relative to ethoxide and that methoxide was intermediate in nucleophilicity. We believe our results are more accurate, in part because ours is a more simple and direct approach. Data on many studies of the reactions of phenoxide and ethoxide with alkyl halides have been summarized by Streitwieser *et al.* (10). Again there is qualitative agreement with our work in that the ratio of the reaction rate constants in the literature indicate the PhO^-/EtO^- relative nucleo-

TABLE 4. Calculated relative nucleophilicities

Comparison	Calcd. from Table 3, runs #	Relative nucleophilicity
m-CrO^-/PhO^-	5	1.30
m-CrO^-/PhO^-	1/6	1.40

[c]Reference 7.

philicity has an average value of 0.2 for methyl iodide substrate, 0.5 for ethyl iodide, and 0.6 for *n*-propyl iodide, all in ethanol solution. For *n*-butyl bromide, we found the relative nucleophilicity to be 0.46.

Although there is a voluminous literature on the acidity and basicity of organic compounds in general (3, 11), there are only eight quantitative studies on the acidity of methanol (6, 9, 12–15, 20, 21), ten on ethanol (6, 9, 14–21), four on isopropyl alcohol (6, 15, 20, 21), and three on *tert*-butyl alcohol (15, 20, 21). All investigators now agree that methanol is more acidic than water by a factor of two- (12) to seven- (13) fold. Unmack's 1928 work (12), based on conductivity, solubility, freezing points, and reaction rate data, suggested methanol was three to five times more acidic than water, but emf measurements suggested it was less than twice as acidic. The most accurate work appears to be that of Hine and Hine (6) who established their acidity scale in isopropyl alcohol by the indicator method using *p*-nitrodiphenylamine. The pioneering work with an indicator (etioporphyrin) was done by McEwen (15), and his work is still often cited in textbooks. He took methanol as his standard and assigned it a pK_a of 16 based on the work of Unmack (12). The conductivity method of Ballinger and Long (14) established the pK_a scale relative to water.

Ethanol has been studied thoroughly by emf (16), conductivity (14, 17), indicator (6, 15, 18), titration (19, 20), and reaction-kinetic methods (9). Caldin and Long's indicator procedure (18) gave ethanol as either 2 or 0.2 times as strong an acid as water depending on whether their data were extrapolated to pure ethanol or water, respectively. Their data as recalculated by Murto (ref. 9; p. 29) give ethanol 0.56 as acidic as water. Again, the most reliable work appears to be that of Hine and Hine (6) who studied water, methanol, ethanol, and other alcohols by their indicator method. The reaction-kinetic method used by Murto (9) represents a new approach. Methods based on emf measurements or titration data give erratic results. Ballinger and Long could not measure the acidity of ethanol directly by their conductivity method, and extrapolation of their data using a σ^* relationship was necessary (14).

Arnett and Small (21) have measured the heat of deprotonation of alcohols in dimethyl sulfoxide and calculated the following pK_a values: water, 27.5; methanol, 27.9; ethanol, 28.2; isopropyl alcohol, 29.3; and *tert*-butyl alcohol, 29.4. This corresponds to relative acidities of 2:1:0.08:0.063 for these alcohols in this aprotic solvent. Comparisons between our results in protic solvents and these results in an aprotic solvent must be made very cautiously, but it is noteworthy that methanol here also is more acidic than ethanol, and *tert*-butyl alcohol is only a little less acid than isopropyl alcohol.

There is remarkably good agreement between our work and that of Hine and Hine (6), Murto (9), and Long and Ballinger (14), with respect to the relative acidities of methanol and ethanol, especially in view of the four different experimental approaches. Our measured acidity of *tert*-butyl alcohol relative to ethyl or isopropyl alcohols is surprising, but the only values our data can be compared against are those of McEwen (15) and Arnett and Small (21). Perhaps the common belief that *tert*-butyl alcohol is much less acidic than isopropyl alcohol arises from the low nucleophilicity of the *tert*-butoxy anion (see Table 5).

Streitwieser *et al.* (22) have shown that a plot of Taft's σ^* values (23) against the pK_a values of a series of 9-alkylfluorenes yields a straight line for the methyl, ethyl, and isopropyl members of this series, but not for *tert*-butyl and hydrogen. A plot of our pK_a values (see Table 6) against the σ^* values gives a plot similar to that of Streitwieser *et al.*, and reinforces our belief in the validity of our data.

Experimental Section

The alcohols were pure as measured by glc. Reference samples of the ethers were prepared by standard procedures

TABLE 6. Comparison of relative acidities with literature values

Compound	This work: Relative value	This work: pK_a[a]	McEwen[b] pK_a	Hine and Hine[c] relative values	Long[d] pK_a	Murto[f] relative values
Water	—	15.74	—	1.27	15.74	1.27

and used to determine the instrumental response factor for the mixtures analyzed. Gas–liquid chromatographic analyses were carried out on either a F and M model 300 with a thermistor detector (used for the competitive reactivity work) or a Hewlett-Packard 5750 instrument with flame ionization (used for runs 3 and 4 in Table 1 and for the relative nucleophilicity work), using 2 m columns packed with 10% isodecyl phthalate, 20% Lutensol (an oxyethylation product of nonylphenol manufactured by Supelco Inc., Supelco Park, Bellefonte, PA), or Apiezon-L (for the benzyl ethers). Programs and retention times are in the thesis of C.M.E. Erratic results were avoided by using a syringe which minimized blow-by (Glenco Micro Syringe, Glenco Scientific, Houston, Texas).

Typical Competitive Reactivity Determination

To a mixture of 40.4 mL (1 mol) of methanol and 58.2 mL (1 mol) of ethanol was added 1.4 g (0.06 g-atom) of freshly cut sodium. Following the dissolution of the sodium, 5.4 mL (0.05 mol) of *n*-butyl bromide was added, and the mixture was allowed to stand for a month in a stoppered flask at 26 ± 1°C. Samples of the reaction mixture were then directly and repeatedly analyzed by glc and the area ratios of the two ethers measured. Application of the response factor gave the ether compositions listed in Table 1, and the competitive reactivities were calculated by eq. [4]. With benzyl bromide, the reaction is complete in a few hours, but the mixtures were allowed to stand for 3 weeks.

The *i*-PrO^-/EtO^- C.R. ratio (run #3 in Table 1) differed from the others in that the two alcohols were employed in a nominal 10:1 ratio with the more acidic alcohol being the minor component, and with 0.1 atom of metal per 0.2 mol of minor alcohol. The data were treated initially in the usual way and the relative acidity of *i*-PrOH to EtOH was calculated to be 0.282 from the C.R. value of 0.11 divided by the R.N. value of 0.39 (Table 5). Equation [3] was then set up as follows:

$$\text{Acidity of } i\text{-PrOH/EtOH} = 0.282 = [PrO^-][EtOH]/[PrOH][EtO^-] = [PrO^-][0.2 - EtO^-]/[2 - PrO^-][EtO^-]$$

Knowing $[EtO^-] + [i\text{-}PrO^-] = 0.1$, the equation was solved to give $[i\text{-PrOH}] = 1.925$ and $[EtOH] = 0.1755$, or a ratio of these alcohols of 10.98 at the start of the reaction. No base is left at the completion of the reaction, and the ratio of the two alcohols can be calculated from the initial concentrations of 2.0 and 0.2 minus what was consumed by formation of the two ethers. These concentrations are calculated to be 1.948 and 0.1524 or a ratio of 12.78. Accordingly the average ratio of the two alcohols present during the course of the reaction is 11.9. If this value is used in eq. [4] the C.R. changes from its first calculated value of 0.11 to 0.0925, and the relative acidity changes from 0.282 to 0.237. Repeating the calculations again using the new relative acidity causes little change; a new C.R. value of 0.0917 is obtained, from which a new relative acidity of 0.236 is calculated.
