mouvements élémentaires (translations–rotations) dans les modes de vibration. Le désaccord le plus important concerne la fréquence observée à 57.5 cm^{-1} (a_g) que l'on fait correspondre à la fréquence 12 cm^{-1} (tableau 1). Signalons d'autre part que l'on attribue la fréquence 57.5 cm^{-1} à deux vibrations de même type a_g. En effet au cours d'une étude en lumière polarisée, Rousset (11) a montré que deux modes a_g étaient superposés vers 57 cm^{-1}. Pour les autres attributions, l'accord est relativement bon, surtout si l'on remarque que nous avons négligé l'action des moments dipolaires électriques locaux dus aux halogènes comme l'avaient fait Ozora et coll. (20).

Dans les tableaux 1 et 2 nous avons indiqué les fréquences calculées par Reynolds et coll. (24), par Bonadeo et coll. (25) ainsi que celles de Burgos et Bonadeo (26).

V. Conclusion

Nous avons mis en évidence les modes de réseau de basse fréquence par l'étude de l'absorption dans l'infrarouge lointain d'une série de dérivés *p*-dihalogénés du benzène. Le calcul des fréquences des

modes de vibration de réseau effectué dans le cas du PDC, PDB et PDI permet de préciser la nature des modes observés par absorption infrarouge et par diffusion Raman. L'accord entre la valeur des fréquences calculées et observées est acceptable dans la mesure où nous nous sommes limités à un nombre réduit d'interactions entre atomes.

Mis à part le PDC dont les transitions de phase sont connues nous n'avons pas mis en évidence de transition de phase entre 300 et 80 K, dans la série de composés étudiés, contrairement à ce que nous avons observé lors du refroidissement des structures solides des dérivés dihalogénés du benzène liquide à température ambiante (1).

Crystal and molecular structure of bis[methyltris(1-pyrazolyl)gallato]nickel(II)

STEVEN J. RETTIG, ALAN STORR, AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2075 Wesbrook Mall, Vancouver, B.C., Canada V6T 1W5

Received February 2, 1979

STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **57**, 1823 (1979).

Crystals of bis[methyltris(1-pyrazolyl)gallato]nickel(II) are rhombohedral, $a = 9.6670(5)$, $c = 23.893(1)$ Å, $Z = 3$, space group $R\bar{3}$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to a final R of 0.030 and $R_w = 0.035$ for 925 reflections with $I \geq 3\sigma(I)$. The crystal structure consists of well separated molecules of $[MeGa(N_2C_3H_3)_3]_2Ni$ having exact $\bar{3}$ (S_6) symmetry and approximate D_{3d} symmetry. The coordination geometry about the nickel atom is octahedral with Ni—N = 2.109(2) Å, N—Ni—N = 90.65(6) and 89.35(6)°. The gallium atom has distorted tetrahedral coordination geometry with Ga—N = 1.939(2), Ga—C = 1.940(4) Å, N—Ga—N = 99.55(6), and N—Ga—C = 118.16(5)°.

STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **57**, 1823 (1979).

Les cristaux du bis[méthyltris(pyrazolyl-1) gallato] nickel(II) sont rhomboédriques, $a = 9.6670(5)$, $c = 23.893(1)$ Å, $Z = 3$, groupe d'espace $R\bar{3}$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de $R = 0.030$ et $R_w = 0.035$ pour 925 réflexions avec $I \geq 3\sigma(I)$. La structure cristalline est composée de molécules séparées de $[MeGa(N_2C_3H_3)_3]_2Ni$ de symétrie exacte $\bar{3}$ (S_6) et de symétrie approximative D_{3d}. La géométrie de coordination autour du nickel est octaédrique avec Ni—N = 2.109(2) Å, N—Ni—N = 90.65(6) et 89.35(6)°. La géométrie de coordination autour de l'atome de gallium est tétraédrique (déformée) avec Ga—N = 1.939(2), Ga—C = 1.940(4) Å, N—Ga—N = 99.55(6) et N—Ga—C = 118.16(5)°.

[Traduit par le journal]

Introduction

A series of complexes incorporating the anionic tridentate chelating ligand $[MeGa(N_2C_3H_3)_3]^-$ has been reported (1). An X-ray structural study on a molybdenum complex containing one of these ligands confirmed the denticity and chelating nature of the pyrazolyl gallate moiety (1). In that initial report a number of L_2M (where L = $MeGa(N_2C_3H_3)_3$, M = Mn → Zn) complexes were also characterized and the evidence collected at the time suggested an octahedral MN_6 core with incorporation of both the ligands as tridentate chelating moieties. The present account details the X-ray structure determination of one of these complexes, namely, $[MeGa(N_2C_3H_3)_3]_2Ni$.

Experimental

The title compound was prepared as previously described (1). The lilac crystals were indefinitely stable in air. A spherical crystal with a radius of 0.17 mm was mounted in a general orientation. Unit-cell parameters were refined by least squares on 2 sin θ/λ values for 30 reflections measured on a diffractometer with Mo K_α radiation (λ = 0.71073 Å). Crystal data (at 22°C) are:

$C_{20}H_{24}Ga_2N_{12}Ni$ fw = 630.64

Rhombohedral, $a = 9.6670(5)$, $c = 23.893(1)$ Å, $V = 1933.7(2)$ Å^3, $Z = 3$, $\rho_c = 1.625$ g cm^{-3}, $F(000) = 954$, μ(Mo K_α) = 29.4 cm^{-1}. Absent reflections: hkl, $-h + k + l \neq 3n$. Space group $R\bar{3}$ (C_{3i}^2, No. 148) from structure analysis.

Intensities were measured with graphite monochromatized Mo K_α radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–θ scan at 0.72–6.71° min^{-1} over a range of (0.45 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to $2\theta = 60°$. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within 2%. After data reduction, an absorption correction was applied (spherical crystal, $\mu R = 0.5$). Of the 1250 independent reflections measured, 925 (74%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = background count.

Laue symmetry $\bar{3}$ limits the possible space groups to $R3$ and $R\bar{3}$, the latter being assumed on the basis of the E-statistics. The structure was solved by direct methods, an E-map calculated from the best set of phases giving positions for all of the non-hydrogen atoms. After full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters to $R = 0.064$, a difference map gave the positions of the four unique hydrogen atoms which were included in all subsequent cycles of refinement with isotropic thermal parameters. The scattering factors of ref. 2 were used for non-hydrogen atoms and those of ref. 3 for hydrogen atoms. Anomalous scattering factors from ref. 4 were used for the Ga and Ni atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. Convergence was reached at $R = 0.030$ and $R_w = 0.035$ for 925 reflections with $I \geq 3\sigma(I)$. For all 1250 reflections $R = 0.050$ and $R_w = 0.038$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.009 and 0.15σ, respectively. The mean error in an observation of unit weight was 1.0158. A final difference map showed maximum fluctuations of ±0.4 e Å^{-3} in the vicinity of the Ga and Ni atoms and

The final positional and thermal parameters appear in Tables 1 and 2 respectively.[1] Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1] Bond lengths and angles are listed in Tables 3 and 4 respectively and intra-annular torsion angles are given in Table 5.

Results and Discussion

The crystal structure consists of discrete molecules of $[MeGa(N_2C_3H_3)_3]_2Ni$ separated by normal van der Waals distances. The molecule (Fig. 1) possesses crystallographic $\bar{3}$ (S_6) symmetry and approximate D_{3d} symmetry, the distortion from D_{3d} symmetry being a twist of the pyrazolyl rings with respect to the threefold axis (the angle between the c axis and the pyrazolyl mean plane, ideally 0°, is 4.8°). The nickel atom is bonded to six nitrogen atoms, three from each of the tridentate $MeGa(N_2C_3H_3)_3^-$ ligands. The coordination geometry about the nickel atom shows only a very small trigonal distortion from ideal octahedral geometry. The unique Ni—N distance is 2.109(2) Å and the intra- and interligand N—Ni—N angles are slightly, but significantly, different (90.65(6) and 89.35(6)° respectively). The gallium atom has trigonally distorted tetrahedral coordination geometry with Ga—N = 1.939(2), Ga—C = 1.940(4) Å, N—Ga—N = 99.55(6) and N—Ga—C = 118.16(5)°.

The related molecule $[HB(N_2C_3H_3)_3]_2Co$ (5) also has approximate D_{3d} symmetry, but has no crystallographically imposed symmetry. The trigonal distortion of the Co coordination sphere is more pronounced than in the present compound, with mean intra- and interligand N—Co—N angles of 85.5(6) and 94.5(21)° respectively. Although the M—N distances are similar in these two complexes (mean Co—N = 2.129(7) Å), the potential for steric crowding about the central metal is greater in the gallium complex (Ni...C(1) = 3.128(2) Å while the corresponding mean distance is 3.207 Å in $[HB(N_2C_3H_3)_3]_2Co$). This result is to be expected on the basis of previous spectroscopic (6) and structural (1) studies. The variation in the M...C(1) distances observed arises primarily from the different sizes of Ga and B atoms. The pyrazolyl N—N bonds are canted towards the boron atom in $[HB(N_2C_3H_3)_3]_2Co$ whereas they are nearly parallel to the threefold axis in $[MeGa(N_2C_3H_3)_3]_2Ni$, resulting in the closer approach of C(1) to the metal atom for the gallate ligand. In this regard it is possible to prepare 3,5-dimethyl substituted $[HB(N_2C_5H_7)_3]_2M$ compounds (7) whereas attempts to prepare $[MeGa(N_2C_5H_7)_3]_2M$ have so far failed.

TABLE 3. Bond lengths (Å) with estimated standard deviations in parentheses*

Bond	Distance	Bond	Distance
Ga —N(2)	1.939(2)	C(1) —C(2)	1.389(3)
Ga —C(4)	1.940(4)	C(2) —C(3)	1.359(3)
Ni —N(1)	2.109(2)	C(1) —H(1)	0.93(3)
N(1) —N(2)	1.360(2)	C(2) —H(2)	0.95(3)
N(1) —C(1)	1.331(3)	C(3) —H(3)	0.81(3)
N(2) —C(3)	1.349(3)	C(4) —H(4)	0.81(2)

*Here and in Tables 4 and 5 primed atoms have coordinates $-y, x-y, z$ and double primed atoms $y, y-x, -z$.

The Ni—N distance (2.109(2) Å) is similar to the Ni—N(pyrazolyl) distances of 2.085(3) and 2.097(6) Å observed for the *sym-fac-* and *mer* isomers of $[Me_2Ga(OCH_2CH_2NH_2)(N_2C_3H_3)]_2Ni$ (8) but is much longer than the mean Ni—N distance of 1.895(4) Å in the square planar complex $[Me_2Ga(N_2C_3H_3)_2]_2Ni$ (9). This has also been observed for the complexes $[HB(N_2C_3H_3)_3]_2Co$ (5), Co—N = 2.129(7) Å, and tetrahedral $[H_2B(N_2C_3H_3)_2]_2Co$ (10), Co—N = 1.967(12) Å. As pointed out in ref. 10, these differences in M—N bond lengths are probably due to changes in coordination number and steric requirements of the different ligands. The Ga—N distance in the tridentate gallate ligand (1.939(2) Å) is much shorter than the mean Ga—N distance of 1.977(1) Å in $[Me_2Ga(N_2C_3H_3)_2]_2Ni$ (9).

The relative strengths of the Ga—N and Ni—N bonds affect the internal geometry of the pyrazolyl ligand, resulting in significant differences between the pairs of C—C and C—N bonds (see Table 3). The pyrazolyl ring is planar to within ± 0.0007 Å (χ^2 = 0.26) with both Ni and Ga significantly displaced from the mean plane (by 0.0998(6) and −0.1800(5) Å respectively). The geometry of the ligand is very similar to that found for $[MeGa(N_2C_3H_3)_3]Mo$-

[1]The structure factor table and Table 2 (thermal parameters) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Use of XαSW calculations for parametrising the CNDO method for the heavier elements. II. Tests for the elements aluminium to sulphur

J. D. HEAD AND K. A. R. MITCHELL

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received December 12, 1978

J. D. HEAD and K. A. R. MITCHELL. Can. J. Chem. 57, 1826 (1979).

In Part I (Mol. Phys. **35**, 1681 (1978)) we used results from the Xα scattered wave (XαSW) method for guiding the parametrisation of the complete neglect of differential overlap (CNDO) method for clusters of silver, and we proposed the extension of this approach to other heavier elements for which CNDO schemes are not well developed. The main purpose of the present paper is to test this approach for the elements aluminium to sulphur for which more information is available. XαSW calculations have been made for the molecular clusters Al_7, Si_5H_{12}, and P_4, and comparisons made with experiment and with other calculations where possible. The charge distributions and transition-state energies, along with information obtained previously for S_8 by Salahub *et al.*, have been used to derive new parameters (designated CNDO/HM) for the elements aluminium to sulphur essentially following the procedure in Part I. Calculations using these parameters have then been tested against an XαSW calculation made here for an Al_{10} cluster (which simulates the (111) surface of aluminium), and against other calculations made previously for P_8, P_4S_3, SiH_4, PH_3, H_2S, and SO_2. Comparisons are also made with results from the CNDO/2 scheme. Generally the CNDO/HM procedure seems at least as successful as CNDO/2.

J. D. HEAD et K. A. R. MITCHELL. Can. J. Chem. **57**, 1826 (1979).

Dans le travail précédent 1 ère partie (Mol. Phys. **35**, 1681 (1978)) on a utilisé les résultats obtenus par la méthode des ondes diffractées Xα (ODXα) comme guide pour la paramétrisation de la méthode CNDO pour les agrégats d'argent et on a proposé une extension de cette approche à des éléments plus lourds pour lesquels aucun schéma CNDO n'a été développé. Le but du présent travail est de vérifier cette approche pour les éléments de l'aluminium au soufre pour lesquels plus d'informations sont disponibles. On a fait des calculs ODXα pour les agrégats Al_7, Si_5H_{12} et P_4 et l'on a effectué des comparaisons avec les données expérimentales et, si possible, avec d'autres calculs. On a utilisé les distributions de charge et les énergies des états de transition de même que les informations obtenues antérieurement pour le S_8 par Salahub et ses collaborateurs afin de dériver de nouveaux paramètres (désignés comme CNDO/HM) pour les éléments de l'aluminium au soufre en suivant essentiellement la méthode décrite dans le travail antérieur. On a évalué les calculs effectués à l'aide de ces paramètres par rapport aux calculs ODXα faits ici pour un agrégat de Al_{10} (qui simule la surface (111) de l'aluminium) et par rapport à d'autres calculs faits antérieurement pour P_8, P_4S_3, SiH_4, PH_3, H_2S et SO_2. On a aussi fait des comparaisons avec des résultats obtenus par le schéma CNDO/2. D'une façon générale, les calculs CNDO/HM semblent au moins aussi bons que les calculs CNDO/2.

1. Introduction

Although the complete neglect of differential overlap (CNDO) method has been used for a number of years for making routine, and reasonably reliable, calculations of wave functions for molecules formed by the lighter elements (1), this method has so far been less successful in general for the heavier elements, particularly for metals. Nevertheless, for the latter, there are continuing needs for computational methods that can give helpful assessments of molecular orbital levels, charge distributions, and energetics for large molecular systems and for clusters, such as those involved in catalytic and nucleation processes and those which model aspects of solids and solid surfaces (2). Satisfactory developments of the CNDO method for the heavier elements have been hindered by a scarcity of accurate non-empirical calculations for comparison; moreover those that are available are frequently restricted to diatomic species. An earlier study (3), which deduced improved CNDO parameters for Li and F for the purpose of investigating ionic LiF systems, used a near-Hartree–Fock wave function of diatomic LiF for comparison, but in general larger reference molecules appear advantageous for guiding the parametrisations. This is because polyatomic molecules both give more data for comparing with the CNDO calculations and they are more likely to contain atoms which manifest typical local stereochemical arrangements. On the other hand, the larger the reference molecule the less likely there will be calculations of near-Hartree–Fock quality with which to compare the CNDO results.

0008-4042/79/141826-13$01.00/0

Such considerations encouraged us earlier to use the Xα scattered wave (XαSW) method (4) for deducing CNDO parameters appropriate to silver (5). The XαSW method appears to offer a helpful compromise between successful calculations and computational tractability (6).

A potential advantage of the approach of deriving CNDO parameters from comparisons with results from the XαSW method is that it can be extended systematically and consistently to a wide range of elements including the transition elements. Part I of this series describes the determination of new CNDO parameters for some clusters of silver (5). However, before extending to other transition metal systems, it seemed prudent to assess the reliability of this approach by comparing for some elements for which CNDO schemes are better developed. The main purpose of the present paper therefore is to assess the use of XαSW calculations for deducing CNDO parameters for the elements aluminium to sulphur; a number of these second-row elements have already been investigated by CNDO schemes to a fair degree (7–10). This experience should be valuable in extending the basic approach used in Part I to other elements where CNDO procedures are at best poorly developed. An area of immediate importance is for clusters of transition metal atoms where, for investigating properties such as reaction profiles or for comparing different adsorption sites, the computational expense of the XαSW method can be appreciable, especially for systems of low symmetry. For such cases there would be great advantages in having faster and cheaper procedures which are useful for exploratory purposes, and in this category we include the CNDO method.

The four elements considered here range from a free-electron metal, through a semi-conductor to molecular solids in the cases of phosphorus and sulphur, and these differences in basic characteristics influence the particular molecular clusters considered for the purpose of parametrising the CNDO method. For phosphorus and sulphur, the molecular forms P_4 and S_8 seem natural choices. Silicon is represented by the molecule Si_5H_{12} since the local environment around the central silicon atom corresponds to that in the silicon lattice; also the presence of the hydrogen atoms limits effects associated with broken covalent bonds. For aluminium, we consider the clusters Al_7 and Al_{10} which have been chosen to provide relatively simple simulations of the (111) surface. For the parametrisations, it seems preferable that all the XαSW calculations are at corresponding levels of refinement. A problem here is that many XαSW calculations in the literature have been made only in the non-overlapping-spheres scheme, as in the earliest formulation of the method, although, at the present time, the XαSW approach has probably been most successful with the overlapping-spheres version (11). For this reason we have made new XαSW calculations for the Al_7 and Al_{10} clusters, and we have repeated and refined some earlier calculations made for Si_5H_{12} and P_4; for S_8 we have used results produced by Salahub *et al.* (12).

2. Calculational Methods

The XαSW calculations reported here for Al_7, Al_{10}, Si_5H_{12}, and P_4 involved standard procedures for solving the scattered wave equations (13) and for calculating transition-state energies (14). All these calculations used exchange-correlation parameters given by Schwartz (15) (except $\alpha = 0.77725$ for hydrogen (6)), and basis sets through to $l = 1$ for each atomic sphere of the second-row atom ($l = 0$ only for hydrogen) and to $l = 3$ for the outersphere. Generally the atomic spheres have been allowed to overlap as extensively as possible without introducing unrealistic features such as negative intersphere charges in some molecular orbitals. The actual degree of sphere overlap is specified below for each particular system, as well as the corresponding virial ratio since close satisfaction of the virial theorem has often been used for guiding the choice of absolute values of sphere overlap (11).

In the first instance, the CNDO calculations made here for the elements aluminium to sulphur use only *s* and *p* functions in the basis sets, although the extension to include *d* functions is considered later (section 6). We followed the basic scheme detailed by Santry and Segal (7) for this basis set, but for one minor difference. This concerns the expression for the resonance parameter

$$[1] \qquad \beta_{AB} = \tfrac{1}{2}K(\beta_A + \beta_B)$$

where the constant K is now kept equal to unity, whereas previously it had been taken as 0.75 if either A or B is an atom of the second row. Our initial choice of CNDO parameters is restricted to four for each element: (*i*) the exponents $\xi_s = \xi_p$ in the Slater-type orbitals which are used for evaluating the overlap and Coulomb integrals; (*ii*) the average of the ionisation energy and electron affinity for each member of the basis set, i.e. $\frac{1}{2}(I_s + A_s)$ and $\frac{1}{2}(I_p + A_p)$ which are used in the diagonal elements of the Fock matrix; and (*iii*) the bonding parameters $\beta_s = \beta_p$ which correspond to the terms on the right-hand-side of eq. [1] and which are used in the off-diagonal elements of the Fock matrix.

3. Selection of CNDO Parameters

Earlier we obtained new CNDO parameters for silver by comparing one-electron energies and charge distributions from CNDO calculations on silver clusters with the corresponding quantities calculated with the XαSW method (5). The one-electron energies were compared visually through total density of states (DOS) curves, and the charge distributions were compared by inspection of atomic populations and local DOS curves. In principle these comparisons would be easier to make, and perhaps less subjective, with the provision of a numerical index which measures the correspondence of one-electron energy levels and charge distributions from the two types of calculation. Previously we found new CNDO parameters for diatomic LiF (3) by minimizing a function of the type

$$[2] \quad R = \sum_i (\varepsilon_i^{\text{CNDO}} - \varepsilon_i^{\text{ref}})^2 + \sum_i (\mu_i^{\text{CNDO}} - \mu_i^{\text{ref}})^2$$

where the ε_i and μ_i represent one-electron energies and dipole moments from either the CNDO or reference calculations for the ith molecular orbital. Such a function seemed satisfactory for LiF, where the two types of properties compared make similar contributions to the value of R, but further experience has indicated that considerable care is needed for larger molecules since, with this type of function, either the charge distributions or the energies can be preferentially emphasized in the comparison.

In the present work, the one-electron charge distributions and the one-electron energy levels from the two sets of calculations are compared separately, and attempts have been made to assess those CNDO parameters which offer the best overall agreement. A simple function for the charge distributions is

$$[3] \quad R_q = \sum_i \eta_i \sum_j \omega_j (q_{ij}^{\text{CNDO}} - q_{ij}^{\text{X}\alpha\text{SW}})^2$$

where q_{ij}^{CNDO} and $q_{ij}^{\text{X}\alpha\text{SW}}$ represent populations (either total or alternatively the individual partial-wave populations) on the jth atom for the ith molecular orbital from the CNDO and XαSW calculations respectively. The populations from the CNDO calculations are derived using the analysis of Mulliken (16), and those from the XαSW calculations are obtained by allocating the intersphere and outersphere charges in the ratios of the component atomic sphere charges for each molecular orbital. In eq. [3], the η_i and ω_j are appropriate weight factors; in this study η_i has been taken as the occupation number of the ith molecular orbital, but, as discussed further below, the ω_j have been treated in various ways depending on the particular molecular system. That the two sets of populations are defined differently represents an unsatisfactory feature of this part of the comparison of XαSW and CNDO calculations; nevertheless some support for the use of [3] is provided by observations for P_4S_3 (17) where the CNDO/2 and XαSW calculations gave similar trends in charge distributions for corresponding molecular orbitals even though the ordering of the energy levels differed in some cases. The simplest index for comparing the distribution of energy levels is

$$[4] \quad R_\varepsilon = \sum_i \eta_i (\varepsilon_i^{\text{CNDO}} - \varepsilon_i^{\text{X}\alpha\text{SW}})^2$$

with an analogous notation to those used above. Our previous experience with the silver clusters (5) indicated that variations in some CNDO parameters (e.g. the values of $(I + A)/2$) cause primarily a shift in energy levels, whereas changes in other parameters (e.g. the values of β) cause mainly a change in scale. Such observations were confirmed in the present work, and as a result we found it convenient in practice to use a modified form of the function in eq. [4], namely

$$[5] \quad R_\varepsilon' = \sum_i \eta_i [R(\varepsilon_i^{\text{CNDO}} - S) - \varepsilon_i^{\text{X}\alpha\text{SW}}]^2$$

For a set of CNDO parameters that give a perfect match to the XαSW energy levels, it is clear that R_ε' is zero, the scale factor R is unity, and the energy shift S is zero. For matching the CNDO and XαSW energy levels our objective has been to find CNDO parameters that allowed the closest approach to these limiting values. Except for S_8, the values of $\varepsilon_i^{\text{X}\alpha\text{SW}}$ used in these analyses are transition state energies; then both $\varepsilon_i^{\text{CNDO}}$ and $\varepsilon_i^{\text{X}\alpha\text{SW}}$ represent approximations to ionisation energies.

The determination of new CNDO parameters for the elements aluminium to sulphur involved searching for minima of the correspondence functions, such as [3] and [5], by calculating these functions for many combinations of CNDO input parameters. The basic approach started with the parameters given for s and p basis functions by Santry and Segal (7). We considered first the effect of varying ξ over the range covered by the values given by Slater (18), Burns (19), and Clementi and Raimondi (20); this gave an improved value for the exponent. With this new value of ξ, β was then varied to minimize the correspondence functions, and the approach continued by varying ξ and β iteratively. Next $(I_s + A_s)/2$ was varied, and if the modification from the original CNDO value was substantial the values of ξ and β were reinvestigated. The value of $(I_p + A_p)/2$ was kept equal to the value used by Santry and Segal. By this means it was hoped that the parameters derived here for the second-row atoms should maintain a broad consistency with the

conventional parameters given for atoms of the first row in the CNDO/2 scheme (1). In cases where a range of CNDO parameters gave comparable overall levels of correspondence to the XαSW results, the final selection was completed by comparing calculated bond lengths with experimental values for some simple molecules. The values found from this procedure for the elements aluminium to sulphur are listed in Table 1; these parameters and the calculations made with them are designated in the following discussions by the label CNDO/HM. Further information for each reference molecular system is given in the next section, where comparisons are detailed between the XαSW, CNDO/2, and CNDO/HM calculations.

4. Particular Molecular Systems

4.1 Al_7 and Al_{10}

Results of the XαSW calculations for these two clusters are given here, although only those for Al_7 have actually been used for deriving the CNDO/HM parameters for aluminium in Table 1; results for Al_{10} are used for testing the CNDO/HM scheme in section 5. The clusters Al_7 and Al_{10} both have C_{3v} symmetry and they correspond to fragments of the bulk structure: Al_7 is composed of two layers of three atoms arranged around the C_3 symmetry axis and a lower atom on the C_3 axis as detailed previously for the corresponding cluster of silver (21). In Al_{10}, one plane involves seven atoms so that six are close packed around a central atom; the second plane has three atoms which occupy alternate three-fold sites below the first plane. The XαSW calculations were made with internuclear distances equal to the bulk value of 2.86 Å (22). For Al_7, the atomic spheres had radii 15% greater than those that just touch, and an outersphere of radius 4.51 Å was centred at the intersection of the C_3 axis with the plane containing the three atoms designated B in Table 3. For the XαSW calculation on Al_{10}, some negative intersphere charges required the sphere radii to be reduced to a 6% increase over the contact radius; the outersphere was centred on the central atom of the 7-atom layer and had a radius of 4.38 Å. The exchange parameter α was fixed at 0.72853 through all regions of both clusters.

TABLE 1. CNDO/HM parameters for aluminium, silicon, phosphorus, and sulphur

Parameter	Value			
	Al	Si	P	S
ξ	1.23	1.59	1.80	2.04
$\frac{1}{2}(I_s + A_s)$/eV	7.77	10.03	13.24	19.07
$\frac{1}{2}(I_p + A_p)$/eV	3.00	4.13	5.46	6.99

			$1e$	11.16
			$1a_1$	13.54

*$\varepsilon_{X\alpha SW}$ designates the XαSW one-electron energies and ε_{TS} the transition-state energies.
†The numbering scheme is for the valence orbitals only.

TABLE 3. Total *s,p* populations* for the valence shells of Al_7 and Al_{10}

Cluster	Calculation	q_A^s	q_A^p	q_B^s	q_B^p	q_C^s	q_C^p
Al_7	CNDO/2	1.17	1.85	1.21	1.77	1.35	1.66
	XαSW	1.60	1.51	1.66	1.38	1.64	0.94
	CNDO/HM	1.64	1.42	1.74	1.23	1.81	1.12
Al_{10}	CNDO/2	0.74	2.18	1.16	1.77	1.37	1.69
	XαSW	1.59	2.20	1.76	1.41	1.74	1.04
	CNDO/HM	1.11	2.08	1.68	1.34	1.74	1.22

*The atoms are designated A, B, C in order of decreasing coordination number; for Al_7 they correspond to atoms with coordination numbers 5, 4, and 3 respectively, and for Al_{10} they are for coordination numbers 9, 5, and 4 respectively.

The valence-shell one-electron energies ($\varepsilon_{X\alpha SW}$) are reported in Table 2 for Al_7 and Al_{10} where all orbitals, including those of the core, have been determined self-consistently. For Al_7, the highest-occupied level ($5a_1$) is singly occupied; in Al_{10} the highest-occupied level ($6a_1$) has a one-electron energy which is very close to that (−4.70 eV) of the first unoccupied level ($5e$). Transition state energies (ε_{TS}) for the occupied levels of Al_7 are also reported in Table 2, and charge distributions calculated for Al_7 and Al_{10} are included in Table 3. Local and total DOS from the XαSW calculation on Al_{10} are shown in Fig. 1. The virial ratio $-2T/V$ is 1.000354 for Al_7 and 1.000864 for Al_{10}.

Previous XαSW calculations for aluminium have been made for clusters with O_h symmetry to represent bulk atoms (23), and for clusters with C_{4v} symmetry for investigating the (100) surface and its adsorption of oxygen (24, 25). Salahub and Messmer (23) noted for some large clusters, e.g. Al_{25} and Al_{43}, a rough correspondence with the $E^{1/2}$ dependence expected for a free-electron metal, where E is measured from

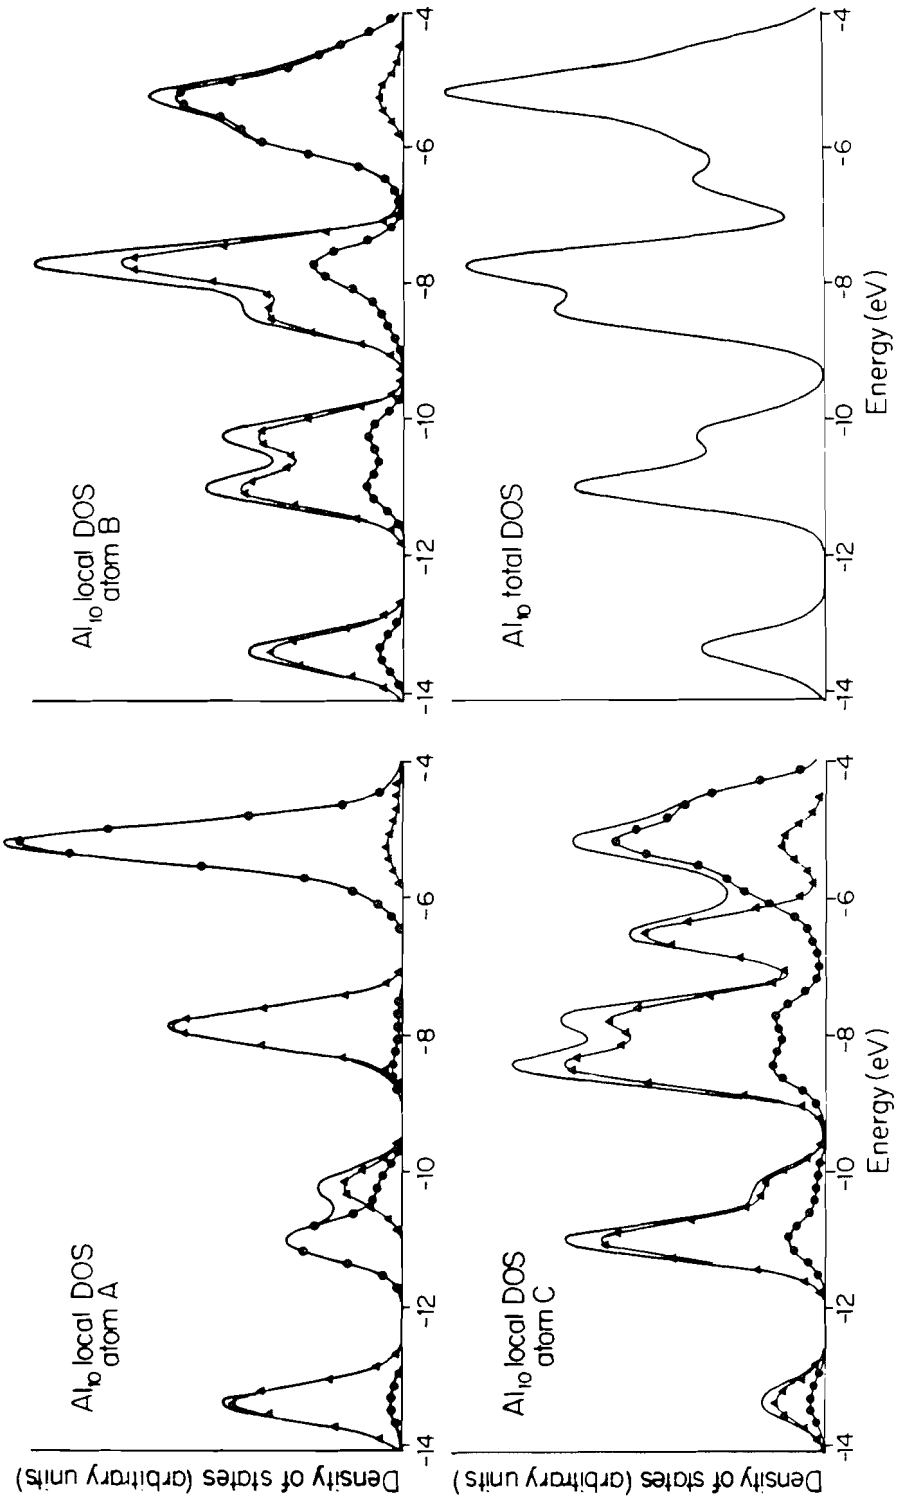

FIG. 1. Local and total DOS calculated with the XαSW method for Al_{10}. The curves designated by triangles and circles correspond to s and p components respectively.

the bottom of the valence band. We certainly find an increase in the total DOS with energy for both Al_7 and Al_{10}, but, as expected for small clusters, our results also bring out a substantial dependence on the local environment; this is apparent both in the local DOS for Al_{10} (see Fig. 1) and in the charge distributions (Table 3). Total sphere charges increase with coordination number, and the variations are associated especially with the populations of the *p*-functions. Indeed *s* to *p* promotion appears important for the bonding of the high-coordinate atoms in clusters of aluminium, and this relates to analogous effects in the corresponding clusters of silver (26). A dominant feature in the electronic structures of the silver clusters is the substantial localisation of the *d*-functions on those atoms of high coordination which are adjacent to atoms with appreciably lower coordination numbers. This depends on the reduced potential energy around the high-coordination atoms, and the small nearest-neighbour overlap for the relevant *d*-functions. This localisation is less marked for aluminium, in part because of the greater diffuseness of the atomic orbital functions of the valence shell.

In using the XαSW results of Al_7 for deriving CNDO/HM parameters of aluminium, the ω_j have been equated to the number of atoms in each unique set. Energy levels from the CNDO/2, XαSW, and CNDO/HM calculations are plotted in Fig. 2 and the separation between the lowest and highest occupied levels from each calculation is 26.54, 8.63, and 16.35 eV respectively. The separation between the $1a_1$ and $5a_1$ levels for CNDO/2 is therefore 3.07 times greater than that for the XαSW calculation; the corresponding ratio with the CNDO/HM parameters is reduced to 1.89. In choosing the final CNDO/HM parameters, the aim was to make the spread of levels as comparable as possible with that from the XαSW method while preserving the same ordering of the levels. The wide spread of the CNDO/2 levels relative to that from the XαSW calculation highlights the problem of defining a suitable numerical index for measuring overall improvements in the correspondence between the energy levels from the two sets of calculations. Thus, it is clear that in directly using eq. [4], starting with the CNDO/2 parameters, the comparisons would be overdominated by the differences for the $1a_1$ levels, and to a lesser extent from the $2a_1$ levels. These difficulties are reduced by including the scaling parameter *R* in the function defined by eq. [5].

Analysis of the *s* and *p* atomic populations for each valence orbital from the different calculations on Al_7 shows that the CNDO/HM calculation agrees with XαSW in that the lower levels essentially involve *s*

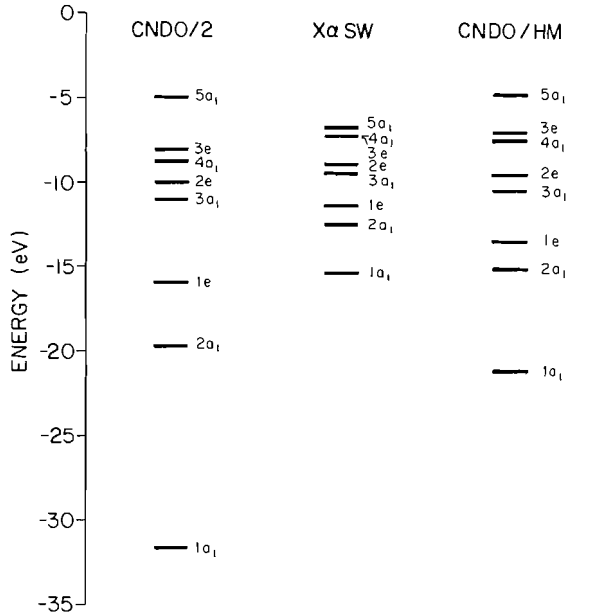

FIG. 2. Comparison by Al_7 of one-electron energies calculated with the CNDO/2 and CNDO/HM schemes and transition-state energies calculated with the XαSW method.

functions while the higher levels $4a_1$, $3e$, and $5a_1$ are largely associated with *p* functions. By contrast the CNDO/2 calculation indicates a high degree of *s* and *p* mixing; this has the effect of increasing the *p* populations at the expense of the *s* populations. Table 3 indicates that the CNDO/HM and XαSW calculations are in good agreement for the distribution of the total populations in Al_7.

4.2 Si_5H_{12}

The XαSW calculations made here for Si_5H_{12} have a number of features in common with those made previously by Cartling *et al.* (27). The main differences are that we use: (*i*) realistic Si—H distances; (*ii*) the overlapping-spheres version of the XαSW method; and (*iii*) exchange-correlation parameters appropriate to the H spheres. Our calculations were made for a model in which the central Si atom is surrounded tetrahedrally by the other four Si atoms, and the twelve H atoms are directed from the outergroup of four Si atoms towards where the next group of Si atoms would be in the actual silicon lattice. This molecule has T_d symmetry, and all Si—Si and Si—H distances are fixed equal to 2.35 and 1.47 Å respectively. The atomic sphere radii used are 1.29 Å for Si and 0.80 Å for H; these values were determined by Norman's procedure (11) for a 10% increase in radius for spheres which just touch in the silicon lattice. The outersphere was centred on the central Si atom with a radius equal to 3.96 Å (so making it just touch each of the H spheres).

Cartling *et al.* included vacancy spheres in their calculations, and it seemed worthwhile to investigate their value in this case, particularly in view of some recent discussion about their validity for this type of calculation (28). Vacancy spheres enable some of the intersphere potential to be spherically averaged rather than be reduced to a constant value. In these calculations the vacancy spheres were given the same radii as the Si spheres and were positioned tetrahedrally around the central Si atom so that their centres, and the centres of the four surrounding Si spheres, mark the corners of a cube. The exchange-correlation parameter for silicon ($\alpha = 0.72751$) is also used in the vacancy sphere, the outersphere, and the intersphere regions. Valence shell energies and charge distributions calculated with the XαSW method for Si_5H_{12} are shown in Tables 4 and 5 respectively; all orbitals, including those of the core, have been determined self-consistently. It is clear that the vacancy spheres have a negligible effect for this molecule; the population of the vacancy sphere comes almost entirely from the intersphere region. The virial ratios are 1.000436 and 1.000439 when the vacancy spheres are included and neglected respectively.

Some significant differences have been found from the results of Cartling *et al.* (27), and these are presumably associated with the differences noted above between the two sets of calculations. Surprisingly, Cartling *et al.* report the central Si sphere to contain 0.9 electron more than that in the neighbouring Si spheres; our XαSW calculations indicate a difference of 0.15 electron. Also the energy level structure is different from the two calculations; Cartling *et al.* report the $3t_2$ level to be just below $1e$ whereas we find $1t_1$, $1e$, and $2t_2$ to be close together and the $3t_2$ level nearly 3 eV higher in energy. According to our XαSW calculations, the lowest level $1a_1$ largely involves interactions between *s*-orbitals on the central and outer-Si atoms; $2a_1$ is concentrated especially on the *s*-orbital of the central-Si atom, and $1t_2$ corresponds to strong interactions between outer-Si *s*-orbitals and the neighbouring hydrogen 1*s*-orbitals. The band of levels $2t_2$, $1e$, and $1t_1$ involves basically Si3*p*–H1*s* interactions, while $3t_2$ corresponds to interactions between the central-Si 3*p* orbitals and those on the outer-Si atoms.

Although $Si(SiH_3)_4$ is known (29), its photoelectron spectrum does not seem to have been measured so far. The trends in structure (and their assignments) for photoelectron spectra of linear silanes (30) and permethylated silanes, including $Si[Si(CH_3)_3]_4$ (31), seem broadly consistent with the calculated transition state energies in Table 4. These latter values should be helpful for interpreting data from photoelectron spectroscopy for $Si(SiH_3)_4$.

TABLE 4. Valence-shell energies* (in eV) for Si_5H_{12}

Level†	Vacancy spheres included $-\varepsilon_{X\alpha SW}$	Vacancy spheres neglected $-\varepsilon_{X\alpha SW}$	Vacancy spheres neglected $-\varepsilon_{TS}$

TABLE 5. Total *s*,*p* populations* for the valence shell of Si_5H_{12}

Method	q_{Sic}^s	q_{Sic}^p	q_{Sio}^s	q_{Sio}^p	q_H^s
CNDO/2	1.05	3.09	1.05	2.54	1.12
XαSW	1.41	2.74	1.23	2.43	1.10
CNDO/HM	1.58	2.50	1.23	2.38	1.12

*Sic = central, Sio = outer Si atom.

In determining CNDO/HM parameters for silicon, we wished to minimize the possibility of the hydrogen charge distribution dominating the correspondence functions such as R_q; accordingly for this molecule the weight factors ω_j were taken equal to unity for each set of symmetrically equivalent atoms. The valence shell energy levels from the various calculations are plotted in Fig. 3. Although the highest-occupied to lowest-occupied separation is greater from the CNDO/HM calculation, compared with that from the XαSW calculation, by a factor of 1.31, this does represent an improvement over the CNDO/2 calculation for which the corresponding factor is 1.85. The CNDO/HM calculation reproduces the XαSW result that the orbitals $2t_2$, $1e$, and $1t_1$ are associated with Si3*p* orbitals bonding with the hydrogen atoms, but the CNDO/2 calculation also includes the $2a_1$ orbital in this category. The overall atomic populations from the XαSW calculation are reproduced fairly well with the CNDO/HM procedure (Table 5).

4.3 P_4

This molecular cluster has T_d symmetry, with all P—P distances equal to 2.21 Å. The XαSW calculations were made with atomic sphere radii equal to to 1.38 Å (corresponding to a 25% increase over the radii which just touch). The outersphere, with a radius of 2.73 Å, was centred at the centre of the

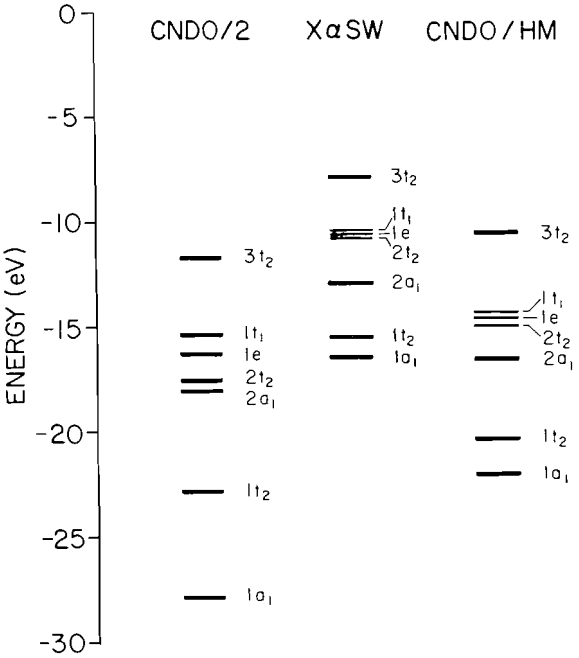

FIG. 3. Comparison for Si_5H_{12} of one-electron energies calculated with the CNDO/2 and CNDO/HM schemes and transition-state energies calculated with the XαSW method.

tetrahedron. The exchange correlation parameter was fixed equal to 0.72620 in all regions. On taking the calculations to the self-consistent limit, the calculated valence shell charges are 1.68 of *s* type and 2.80 of *p* type in each P sphere; the outersphere and intersphere charges being 0.99 and 1.11 respectively. The virial ratio was 1.000158.

Valence shell energies from this XαSW calculation are reported in Table 6, and comparisons are made with experimental ionisation energies and with previous calculations. Specifically for the latter we report transition state energies calculated in the non-overlapping sphere version of the XαSW method (32) and values using Koopmans' theorem (but reduced by a factor 0.92) from a non-empirical molecular orbital calculation with an *s,p* Gaussian basis set (33). The present XαSW calculations appear to provide a satisfactory level of agreement with the experimental ionisation energies.

The high symmetry and the smallness of this molecule combine to make it somewhat less than ideal for parametrising the CNDO method since all the atoms are equivalent and the number of different energy levels is restricted. A consequence of the high symmetry for the function R_q is that all the unique information is contained in the *s*-orbital populations. Minima in the functions R_q and R_ε' (eqs. [3] and [5]) could not be found simultaneously for a single combination of values of β and $(I_s + A_s)/2$; this type of problem was encountered previously by Santry (8). From the possible combinations of β and $(I_s + A_s)/2$, the final selection (Table 1) was made by ensuring that the calculated P—P distance was as close as possible to the experimental value.

The CNDO/HM and CNDO/2 level structures shown in Fig. 4 are in good agreement with those from the XαSW calculation, although the valence band is broader in both cases: by factors of 1.24 and 1.54 for the CNDO/HM and CNDO/2 calculations respectively. Information on the charge distributions from the different calculations is given in Table 7.

4.4 S_8

Overlapping-spheres XαSW calculations have been reported recently for this molecule (12); the D_{4d} symmetry ensures all sulphur atoms are equivalent. As for P_4, this restricts the amount of information for making the parametrisations, although for S_8 the number of different energy levels is greater. Again to make the final selection of CNDO/HM parameters for sulphur (Table 1), it was necessary to check the calculated values of the S—S bond length against the experimental value.

The energy levels from the different calculations are plotted in Fig. 5. The CNDO/HM calculation gives a good account of the separation of *s*-type and *p*-type molecular orbitals found with the XαSW

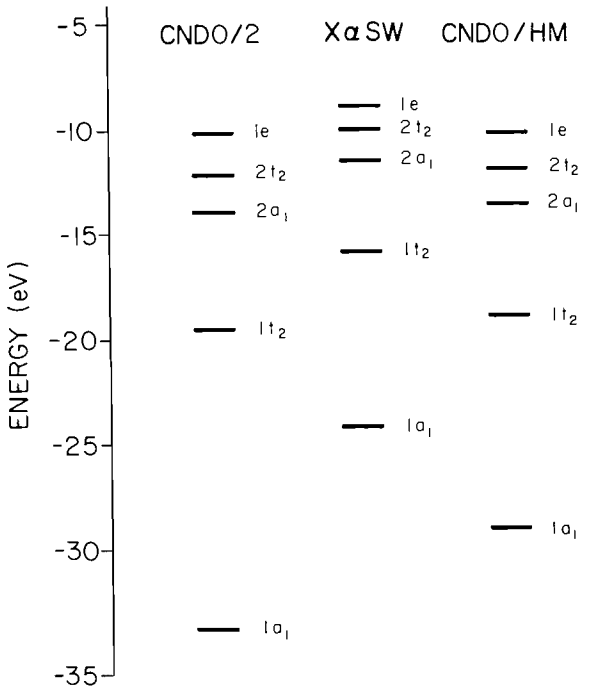

FIG. 4. Comparison for P_4 of one-electron energies calculated with the CNDO/2 and CNDO/HM schemes and transition-state energies calculated with the XαSW method.

TABLE 7. Individual and total *s* populations for the valence shell of P_4

Method	Population					Total
	$1a_1$	$2a_1$	$1e$	$1t_2$	$2t_2$	
CNDO/2	0.19	0.06	0	0.17	0.04	1.77
XαSW	0.17	0.04	0	0.20	0.02	1.73
CNDO/HM	0.20	0.05	0	0.20	0.02	1.83

method (i.e. the levels $1a_1$ to $1b_2$ are predominantly *s*-type while the upper levels are predominantly *p*-type), whereas the CNDO/2 calculation shows a degree of overlap between the *s* and *p* regions. Some differences in ordering of the levels in the *p* regions are found with both the CNDO/2 and CNDO/HM calculations compared with the XαSW calculation. These differences can be associated in part with the high density of states. Some errors within the CNDO procedures are inevitable; thus the approximations required for rotational invariance tend to blur some differences between orbitals with σ and π characteristics. The total atomic populations for *s* functions are 1.82, 1.95, and 1.91 for the CNDO/2, XαSW, and CNDO/HM calculations respectively.

5. Applications to Other Molecules

In this section CNDO/HM calculations, using the parameters of Table 1, are applied to a number of

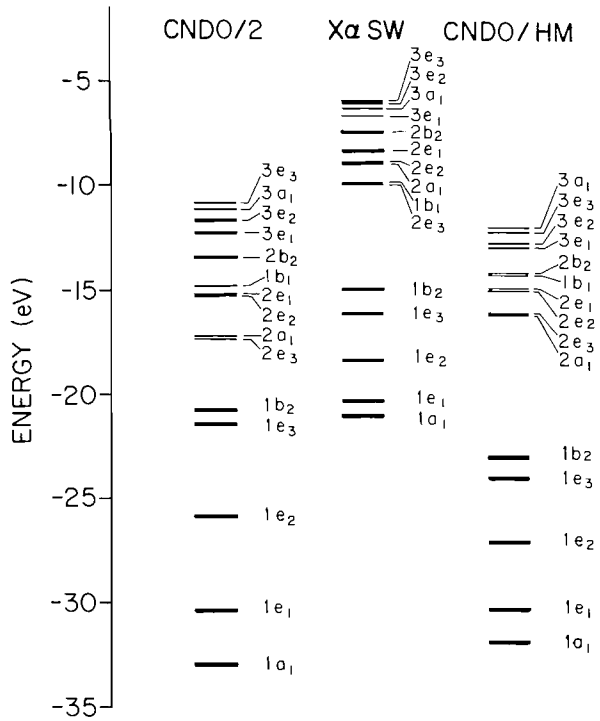

FIG. 5. Comparison for S_8 of one-electron energies calculated with the CNDO/2, CNDO/HM, and XαSW methods. The XαSW results are from ref. 12.

other molecules and molecular clusters formed by the elements aluminium to sulphur; the objective is to assess how the parameters derived for the particular reference molecules transfer to other molecules. First we check for some homonuclear clusters which are larger than those used in deriving the CNDO/HM parameters. Figure 6 compares valence-shell energy levels from the three types of calculation on Al_{10}. The separation between the highest- and lowest-occupied levels is much greater from CNDO/2 than from the XαSW calculation, and there are some differences in the ordering of the higher levels. The total energy separation from the CNDO/HM calculation is intermediate, but the ordering and relative positions of the levels are in better agreement with those from the XαSW method; the $5a_1$ and $4e$ levels are reversed but these two levels have very similar energies from both calculations. The charge distributions in each molecular orbital from CNDO/HM agree better with the XαSW distributions than do those from the CNDO/2 calculation; the total populations over the occupied levels are included in Table 3. Figure 7 compares valence-shell energy levels from the various calculations for the hypothetical P_8 molecule; again the CNDO/HM scheme appears to give a better account of the XαSW level structure (32) than does the CNDO/2 method.

Next an assessment is made of the applicability of

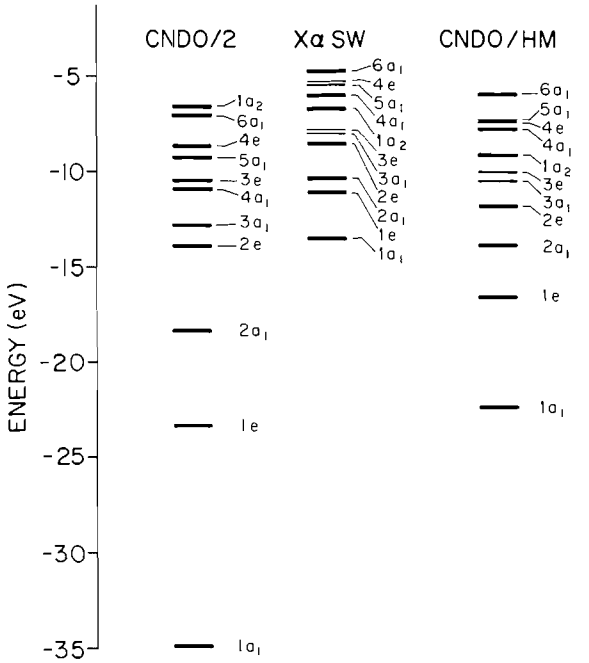

FIG. 6. Comparison for Al_{10} of one-electron energies calculated with the CNDO/2, CNDO/HM, and XαSW methods. The transition-state energies should be about 2 eV lower than the one-electron energies from the XαSW method.

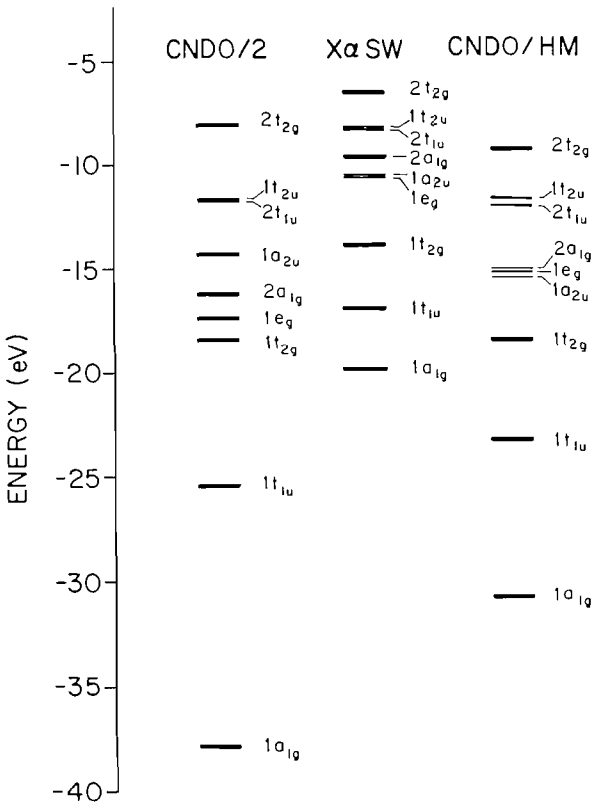

FIG. 7. Comparison for P_8 of one-electron energies calculated with the CNDO/2, CNDO/HM, and XαSW methods. The transition-state energies should be about 3 eV lower than the one-electron energies from the XαSW method (from ref. 32).

the CNDO/HM parameters for the hydrides SiH_4, PH_3, and H_2S. The calculated energy levels are given in Table 8. Compared with the XαSW calculations, the CNDO calculations show rather greater separations between the lowest and highest occupied levels. In the CNDO/HM calculation for H_2S the separation between $1b_2$ and $2a_1$ seems too small, but overall the CNDO/HM calculations show reasonable levels of agreement for the energy levels of these hydrides. The charge distributions from the CNDO/HM scheme correspond very closely to those from CNDO/2; it is satisfying that the atomic charges vary smoothly over the series of molecules, for example according to CNDO/HM the net charges on the H atoms are -0.134, -0.047, and $+0.036$ for SiH_4, PH_3, and H_2S respectively. The overall similarity in the results from CNDO/HM and CNDO/2 for these hydrides may perhaps suggest that there is a certain flexibility in choosing the CNDO parameters, particularly for molecules containing just a single second-row atom. However, our experience with the larger clusters suggests this flexibility is reduced for molecules containing several second-row atoms.

Valence-shell energies for P_4S_3 from six different calculations encompassing the XαSW, CNDO/2, and CNDO/HM procedures are given in Fig. 8 and information on the atomic charges is in Table 9. The XαSW calculation (designated *A*) includes *d* waves in the atomic spheres; some consideration of an extension of the basis set to include *d* functions for the CNDO-type calculations is given below. The entries in Fig. 8 and Table 9 designated *B* and *D* to correspond respectively to the CNDO/2 and CNDO/HM calculations for an *s,p* basis. It is immediately apparent that the CNDO/HM scheme accounts better

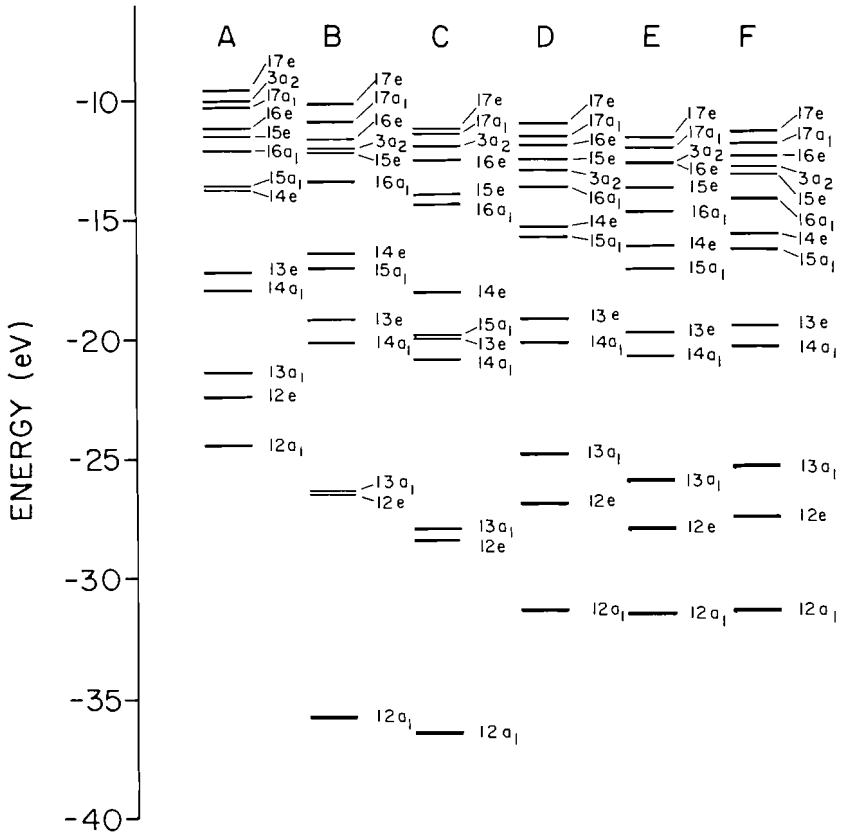

FIG. 8. Comparison of valence-shell energy levels for P_4S_3. The designations are: *A*, transition state energies from XαSW calculation including *d* waves (17); *B*, one-electron energies from CNDO/2 calculation with *s,p* basis: *C*, as *B* but *s,p,d* basis; *D*, one-electron energies from CNDO/HM calculation with *s,p* basis; *E*, as *D* but *s,p,d* basis with $\beta_d = \beta_s = \beta_p$; *F*, as *E* except the β_d values are -5 eV for P and -9 eV for S.

than the CNDO/2 procedure for the energy separation between the highest and lowest occupied valence levels given by the XαSW calculation, although both CNDO calculations interchange the closely-spaced levels $14e$ and $15a_1$, and they depress the $3a_2$ level compared with the XαSW calculation. The charge distributions in the individual molecular orbitals show that the CNDO/HM calculations, unlike the CNDO/2 calculations, follow the XαSW calculation in characterizing the orbitals as predominantly *s*-type and predominantly *p*-type (17). Associated with this is an observation from Table 9 that the CNDO/HM calculations indicate slightly higher *s* populations than do the CNDO/2 calculations. The experience here for P_4S_3 and the hydrides suggests that the CNDO/HM parameters extend satisfactorily to some molecules involving different types of atoms, even though these parameters were deduced primarily for homonuclear molecules.

6. Inclusion of *d* Orbitals

For many years there have been frequent discussions about the extent of the involvement of *d* orbitals in the bonding of molecules containing second-row atoms (37, 38). Generally this involvement seems greatest for atoms in high valence states, but even for the low valence states (e.g. divalent S, trivalent P) *d* orbitals can be needed in computational schemes either as polarisation functions or to take up deficiencies associated with other aspects of the calculations. In extending the CNDO/2 method to the second row, Santry and Segal (7) considered three basis sets: a simple *s,p* basis, an *s,p,d* basis where the *d* functions are included in an analogous way to the *s* and *p* functions, and a basis corresponding to an intermediate involvement of the *d* functions. In extending the basis set to include *d* orbitals in the present work, consideration was given to various values for the parameters ξ_d, $(I_d + A_d)/2$ and β_d. However, this examination indicated that a satisfactory approach involved the *d* exponent being given the same value as used for the corresponding *s* and *p* orbitals with $\frac{1}{2}(I_d + A_d)$ kept at the value used by Santry and Segal. The final parameter to be fixed is then the bonding parameter β_d. In the calculations for P_4S_3 designated *C* and *E* (Fig. 8 and Table 9), β_d

*Pa = apical, Pb = basal P atom.
†*A* = XαSW calculation where *d* waves are included in the atomic spheres (17); *B* = CNDO/2 calculation with *s,p* basis; *C* = CNDO/2 calculation with *s,p,d* basis; *D* = CNDO/HM calculation with *s,p* basis; *E* = CNDO/HM calculation with *s,p,d* basis where $\beta_d = \beta_s = \beta_p$; *F* = CNDO/HM calculation where the β_d values are reduced, namely −5 eV for P and −9 eV for S.

has been given the same value as for the *s* and *p* functions; *C* corresponds to the CNDO/2 calculation and it is apparent from the atomic populations that the *d* populations are too large. These are reduced somewhat in the CNDO/HM scheme, although the *d* populations are still about twice those from the XαSW calculation. We find a similar situation for other molecules referred to in sections 4 and 5; thus usually the orderings of the energy levels are essentially unchanged when *d* functions are included within the CNDO/HM procedure, but the *d* populations can be as large as 0.5 electron per atom. (Inclusion of *d* orbitals in the CNDO/HM scheme does change the orbital orderings in the *p* region for S_8, but this is not surprising in view of the relatively high density of states.) Santry and Segal (7) proposed that the *d* populations should be reduced to more plausible values by reducing the β_d value. Table 9 shows that the CNDO/HM calculation for P_4S_3 gives a rather good account of the XαSW populations when the β_d values are reduced to −5 eV for P and −9 eV for S (entry *F*), although the corresponding energy level structure (Fig. 8) is seen to be changed only marginally from those for the calculations designated by *D* and *E*.

Figure 9 compares the valence level structures for SO_2 from a number of different calculations. The XαSW calculation included *d* waves in the sulphur sphere (39), and it is clear that the inclusion of *d* orbitals in the CNDO calculations affects the ordering of the upper levels. Again the CNDO/HM calculations appear somewhat more successful than the CNDO/2 calculations at matching up the orderings and relative spacings found from the XαSW calculation; the two CNDO/HM calculations which include *d* orbitals (designated *E* and *F* in Fig. 9) seem equally successful in this regard although, compared with the XαSW results, the $3a_1$ level seems too low and the $2b_2$ level too high.

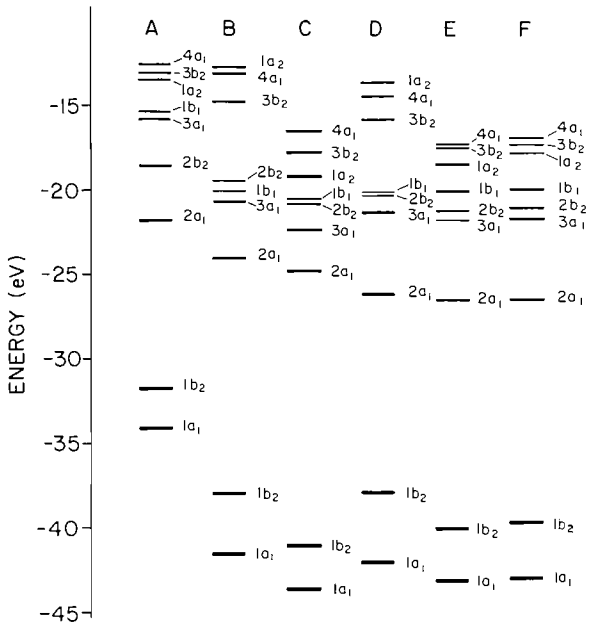

FIG. 9. Comparison of valence-shell energy levels for SO_2. The designations are: *A*, transition-state energies from XαSW calculation including *d* waves (39); *B*, one-electron energies from CNDO/2 calculation with *s,p* basis; *C*, as *B* but *s,p,d* basis for S; *D*, one-electron energies from CNDO/HM calculation with *s,p* basis; *E*, as *D* but *s,p,d* basis for S with $\beta_d = \beta_s = \beta_p$; *F*, as *E* except $\beta_d = -9$ eV.

7. Concluding Remarks

The new XαSW calculations reported here relate to three neighbouring atoms in the second row, and as expected the populations of the valence shell *p*-functions increase with atomic number through the clusters considered. For P_4, the occupied levels show a clear separation into *s*-type orbitals ($4a_1$ and $5t_2$) and *p*-type orbitals ($5a_1$ to $2e$), and this has been reported previously from molecular orbital calculations on P_4 (33) and from XαSW calculations on P_4S_3 (17) and S_8 (12). For Al_7 and Al_{10}, on the other hand, there is a greater mixing of *s*- and *p*-characteristics in the individual molecular orbitals; a somewhat intermediate situation is indicated for the silicon atoms in Si_5H_{12}. The calculated XαSW one-electron energies reported in this paper for Al_7, Si_5H_{12}, and P_4 show closely linear relationships to the corresponding transition state energies. Indeed we assumed this relationship extends to S_8 since only one-electron

energies were available for deducing CNDO/HM parameters from the XαSW calculation on this molecule (12).

Within the limits of our present experience, the CNDO/HM parameters given in Table 1 for the elements aluminium to sulphur seem at least as sucessful as the conventional CNDO/2 parameters for simple molecules containing a single second-row atom, and these parameters appear more successful for molecules containing a number of second-row atoms. The main objective here has been to check that the CNDO/HM procedure can give broadly consistent results in relation to the basic CNDO/2 scheme. At present we have not addressed ourselves to comparing CNDO/HM calculations with the several variations of CNDO that have been used previously for these second-row elements, nor do we claim that the parameters in Table 1 are optimal for all situations for these elements. Although the band widths are generally better with the CNDO/HM procedure than with the CNDO/2 procedure, it is clear that the former are still often too large compared with those from the XαSW calculations. The band widths calculated with CNDO/HM could no doubt be improved with a double-zeta basis set; that is one refinement that may be needed in making systematic extensions to transition metal systems. The approach used here attempts to find a balance between matching band widths and matching orderings of levels. Both of course are important, and ultimately the suitability or otherwise of this CNDO scheme must be judged by its ability to guide interpretations of experimental measurements. For the present, we feel that the observations made in this paper do not discourage the possibility of the CNDO/HM approach providing a helpful route for getting CNDO parameters for systems of the heavier elements for which alternative procedures are hindered by the unavailability or sparsity of both near-Hartree–Fock calculations and suitable experimental data.

Acknowledgements

We are grateful for support by the National Research Council of Canada, and for helpful guidance on the XαSW method by Dr. L. Noodleman. We also thank Dr. D. R. Salahub for providing detailed results for the XαSW calculations on S_8 in ref. 12.

Received December 28, 1978

PABLO J. BRUNA, GERHARD HIRSCH, SIGRID D. PEYERIMHOFF, and ROBERT J. BUENKER. Can. J. Chem. 57, 1839 (1979).

Potential curves are reported for the ground and various valence and Rydberg excited states of HOCl and HClO using *ab initio* SCF and CI methods. The states of HOCl are found to be generally favored over their counterparts in HClO, but the calculations indicate that small barriers nevertheless exist for angular interconversion between at least some pairs of such states; they also show that dissociation processes involving ClO bond breaking are universally favored for both HOCl and HClO. Additional calculations for the ions have also been carried out, from which the heat of formation of $HOCl^+$ is calculated to be 237 kcal/mol and it is pointed out that a previous estimate for the corresponding HOCl quantity has subsequently been substantiated by experiment; the relative energies of the first four states of $HOCl^+$ are found to be in good agreement with experiment as well.

PABLO J. BRUNA, GERHARD HIRSCH, SIGRID D. PEYERIMHOFF et ROBERT J. BUENKER. Can. J. Chem. 57, 1839 (1979).

On rapporte les courbes de potentiel pour les états fondamentaux, divers états de valence et pour des états excités Rydberg du HOCl et du HClO évaluées par des méthodes SCF et CI. On a trouvé que les états de HOCl sont généralement favorisés par rapport à leurs contreparties de HClO mais les calculs indiquent toutefois qu'il existe de faibles barrières à l'interconversion angulaire entre au moins quelques-uns de ces états; ils montrent aussi que le processus de dissociation impliquant le bris de la liaison ClO est universellement favorisé pour HOCl et HClO. On a effectué des calculs additionnels sur ces molécules et l'on peut en déduire que la chaleur de formation de $HOCl^+$ est égale à 237 kcal/mol et l'on signale que l'évaluation antérieure de la quantité correspondante pour HOCl a depuis été confirmée expérimentalement; on a trouvé que les énergies relatives des quatre premiers états du $HOCl^+$ sont aussi en bon accord avec les valeurs expérimentales.

1. Introduction

In a previous study[1] (1) the relative stability of the HOCl molecule with respect to the HClO nuclear arrangement and the various fragments H + ClO, OH + Cl, O + HCl, and H + Cl + O has been investigated by means of *ab initio* configuration interaction treatments. The first four low-lying excited states of HOCl were also studied in I, and it has been found, as confirmed in a similar study by Jaffe and Langhoff (2), that population of all these species promotes dissociation of the molecule into OH and Cl.

Interest in the HOCl molecule has increased considerably in the past few years because of its possible role as an intermediate in the chlorine chemistry of the troposphere and stratosphere (3, 4). Furthermore, in view of the large stability difference found between HClO in I additional interest of a more theoretical nature has arisen, especially since isomerization energies for HAB systems composed exclusively of first-row atoms have quite generally been found to be much smaller. It thus becomes important to understand what differences in electronic structure cause the HOCl arrangement to be so preferred in nature and furthermore to establish whether a similar situation exists for the excited states of these systems.

For part of the present work only the SCF level of treatment is employed since potential energy curves obtained for ground and pertinent low-lying excited states in this approximation are often satisfactory for gaining information on the general structural behavior of the system under various nuclear displacements. These calculations are supplemented by CI treatments at various key points along the potential energy surfaces when necessary in

[1]Hereafter referred to as I.

0008-4042/79/141839-13$01.00/0

order to obtain information of quantitative significance. At the same time the original study (I) is extended in order to predict the location of additional excited states of valence and Rydberg character and their possible role in photochemical reactions of this system.

2. Technical Details

The HOCl system is placed in the xy plane for the present investigations. The AO basis set chosen is of double-zeta plus polarization quality and for the majority of calculations consists of 48 contracted cartesian gaussian functions (basis A of I). The (4, 2) oxygen contraction is thereby taken from Dunning (5) and a (6,4) chlorine set is adopted from the work of Veillard (6), while a (2,1) set with scaling factor $\eta^2 = 2.0$ is centered at the hydrogen site (1). Polarization is taken into account by bond functions of s, p, and d type centered in the ClO bond and an s species located between hydrogen and the respective heavier atom. Long-range functions of s and p_x, p_y, p_z type ($\alpha = 0.015$) are also located at the center of the ClO bond in order to represent the first members of corresponding Rydberg series. In addition for a few cases which are critical for destruction of the Cl—O bond the d bond functions are replaced by a set of d functions centered at each of the heavy atoms O and Cl.

The CI procedure employed is of the multi-reference double-excitation (MRD-CI) type with configuration selection and energy extrapolation (7); it is wholly analogous to the treatment in I and maintains a core of 12 electrons (corresponding to the K and L shells in chlorine and the K shell in oxygen) uncorrelated.

3. Comparison of the HOCl Structures

A. Orbital Characteristics

The experimental (8) structural data for HOCl are: OH = $1.83a_0$, ClO = $3.194a_0$, and $\angle$HOCl = 102.4° while those determined by calculations in I for HOCl are: OH = $1.876a_0$, ClO = $3.220a_0$, and $\angle$HOCl = 104.0°, and for HClO: HCl = $2.48a_0$, ClO = $3.10a_0$, and $\angle$HClO = 104.4°. The orbital energies obtained for both isomers in the same basis are contained in Table 1 and these data show that the charge distribution around the respective oxygen and chlorine atoms in the two species are markedly different from one another; the distinctly higher inner-shell orbital energy for chlorine ($1a'$) in HOCl compared to HClO reflects the larger negative charge around the chlorine atom when it is in the terminal position than what is found when it is located in the middle; similarly the lower $2a'$ energy in HOCl indicates that oxygen is less negative in HOCl than in HClO. Both observations taken together show that the more negatively charged atom is preferred at the terminal position in each case, a finding which is quite consistent with what has been observed generally in other triatomic systems, including molecules of A_3 type (9).

TABLE 1. Orbital energies (in hartree) for HOCl and HClO in their equilibrium nuclear arrangements (basis A of I)

ε	HOCl	HClO
$1a'$	−104.9041	−104.9785
$2a'$	−20.6489	−20.5593
$3a'$	−10.6045	−10.6797
$4a'$	−8.08093	−8.15586
$5a'$	−8.07827	−8.15428
$6a'$	−1.41331	−1.32464
$7a'$	−1.05870	−1.10042
$8a'(\pi)$	−0.71491	−0.70503
$9a'(\sigma)$	−0.59538	−0.56702
$10a'(\pi^*)$	−0.46619	−0.45642
$1a''$	−8.07805	−8.15371
$2a''(\pi)$	−0.61110	−0.59456
$3a''(\pi^*)$	−0.44231	−0.42776

Similarly large differences in the valence orbital energies are obvious from the results of Table 1. A comparison of the various charge density contour diagrams shows that the $6a'$ is to a large extent the $\sigma_g(2s + 3s)$ type MO in both systems, while the $7a'$ is the antibonding $\sigma_u(2s - 3s)$ counterpart and the $9a'$ can be looked upon as the $\sigma_g(p\sigma)$ bonding orbital (Fig. 1). The $8a'$ and $10a'$ species correspond to π and π^* respectively with a typical hydrogen admixture. It is interesting that in the bent equilibrium geometry the σ-type orbital $9a'$ lies between the π and π^* species (for both in-plane and out-of-plane components), in contrast to the situation for the linear HOCl geometry, for which the energy order is $\sigma(\varepsilon = -0.695$ hartree), $\pi(\varepsilon = -0.577)$, and $\pi^*(\varepsilon = -0.430)$.

The lowest unoccupied MO ($11a'$) is of σ^* type, as can also be seen from Fig. 1. It is strongly Cl—O antibonding and shows a definite preference for the linear nuclear arrangement, as will become clear from consideration of the geometrical characteristics of electronic states which occupy this species. Finally the out-of-plane MO's (Fig. 2) exhibit clear differences in charge distribution; in HOCl oxygen character is dominant in the $2a''$ (π-type MO) and that of chlorine is more important in the antibonding $3a''$ MO while the situation is reversed in HClO.

A localized MO representation (10) indicates quite clearly that the ClO bond is stronger in the more stable HOCl species (Fig. 3), since the charge distribution is much more evenly distributed between

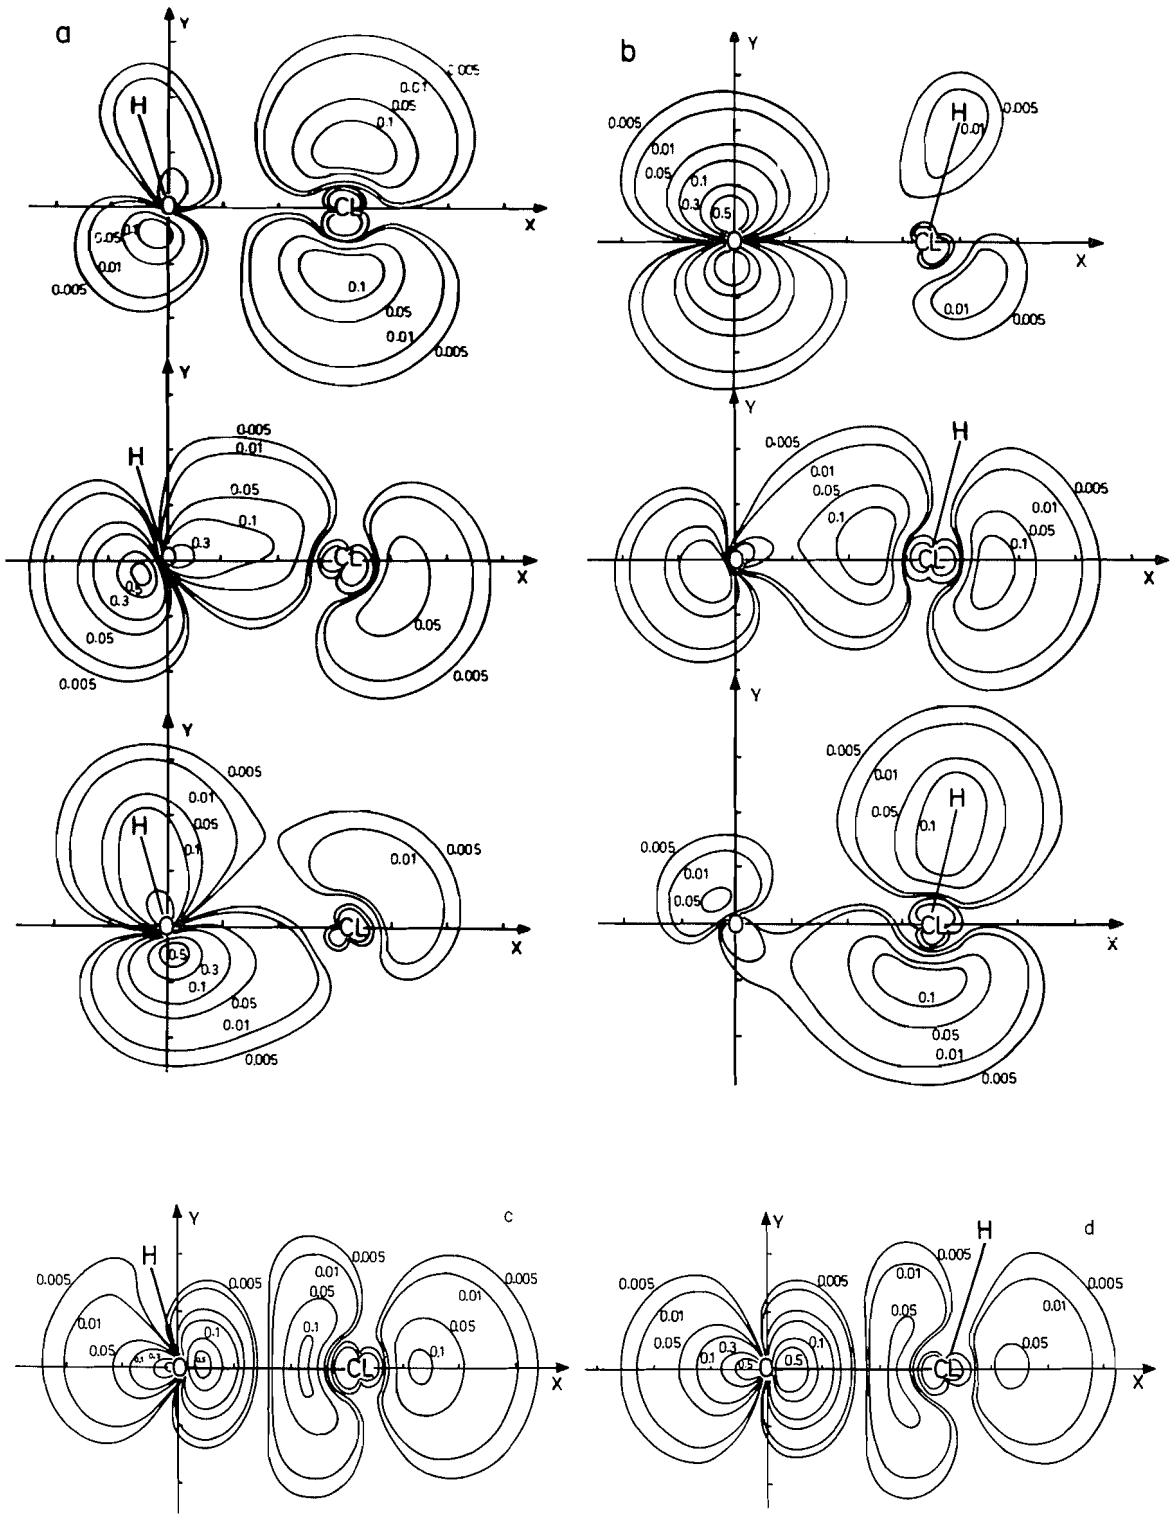

FIG. 1. Canonical orbital charge density contours for the three highest occupied a' MO's ($8a'$ to $10a'$ from bottom to top) of (*a*) HOCl and (*b*) HClO in their respective ground state equilibrium geometries, and for the lowest unoccupied (σ^*) MO in the same systems, (*c*) and (*d*).

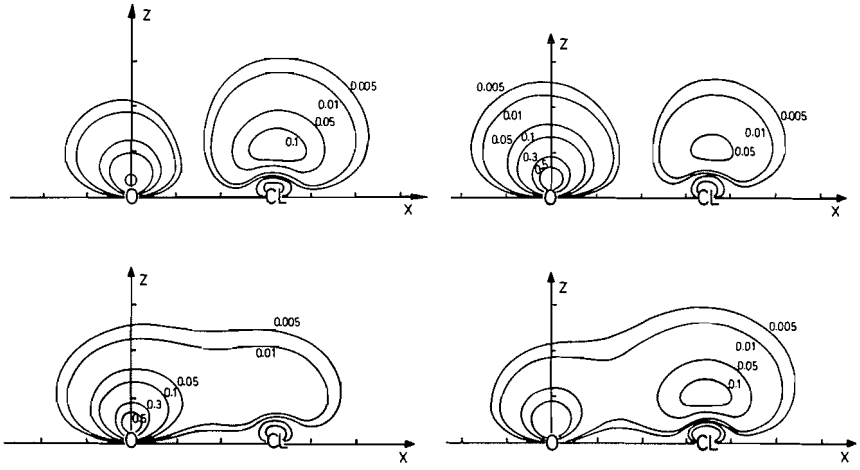

FIG. 2. Canonical orbital charge density contours for the π and π^* MO's of HOCl (left) and HClO (right) respectively.

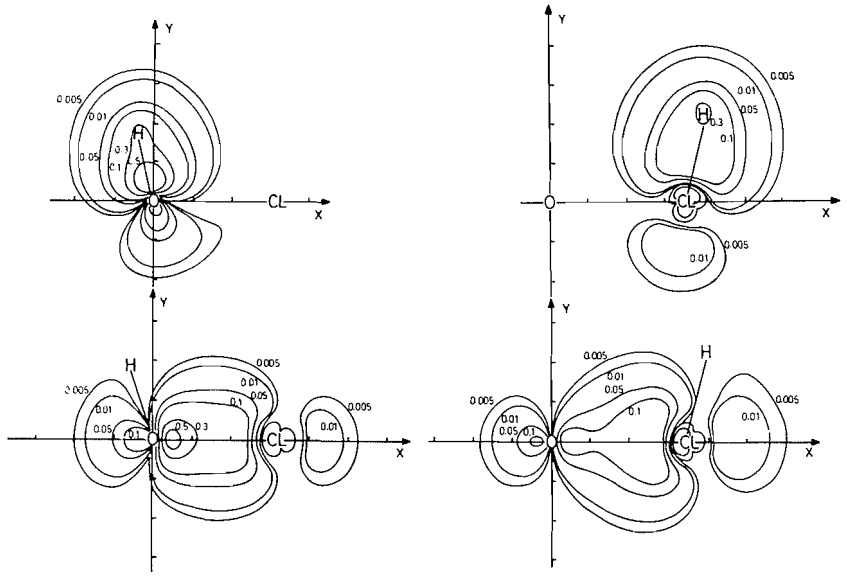

FIG. 3. Localized orbital charge density contours for the OH and ClO bonds in HOCl (left) and for the HCl and ClO bonds of HClO (right).

the two nuclei in the corresponding orbital than in its HClO counterpart. Since the respective dissociation products (OH + Cl and HCl + O) are known (11, 12) to be nearly isoenergetic, the difference in ClO bond strengths is essentially equal to the stability difference of the two systems, which has been calculated to be 60 kcal/mol in I. The localized OH and ClH bonding orbitals (also in Fig. 3) show quite normal behavior; their relation to the canonical MO's is given in Table 2 and shows that there are always four MO's which contribute to the localized bonds. The σ_g-type species $6a'$ and $9a'$ (Fig. 1) contribute in the main to the ClO bond, while the OH species gains its dominant character from the $6a'$ and $8a'$ canonical MO's and the $7a'$ and $8a'$ MO's predominate in forming the HCl bond.

B. Angular Potential Energy Curves

A series of SCF calculations is carried out at various internuclear angles for all low-lying electronic states of HClO and HOCl which are accessible via the Roothaan procedure, and the results are summarized in Fig. 4; the various bond lengths are held constant thereby at their optimal values in the respective equilibrium conformations.

The correlation between the various states is obvious for the ground and those states resulting from $\pi^* \rightarrow \sigma^*$ ($11a'$) excitation; the relation between

TABLE 2. Expansion coefficients for the localized orbitals representing the H—X and Cl—O bonds in the basis of the canonical MO's

	Bond	$6a'$	$7a'$	$8a'$	$9a'$	$10a'$
HOCl	O—H	0.56	0.36	0.71	—	−0.21
	Cl—O	0.55	−0.30	−0.33	−0.69	—
HClO	Cl—O	−0.52	−0.11	+0.30	−0.79	—
	Cl—H	0.36	0.52	0.76	—	−0.10

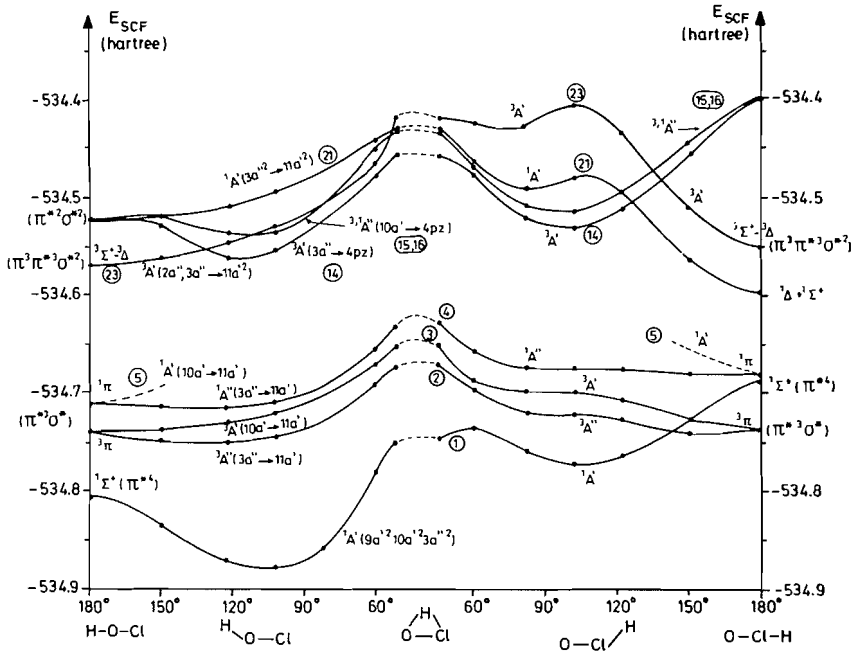

FIG. 4. SCF potential curves for the angular interconversion of HOCl and HClO in ground and various excited states (OH = $1.83a_0$ and ClO = $3.194a_0$ for HOCl and HCl = $2.48a_0$ and ClO = $3.10a_0$ for HClO). The enumeration of the potential curves is made according to the notation of Table 3. The $10a' \rightarrow 11a'\,^1A'$ state has not been treated in the SCF calculations but an estimate of the nature of its potential curve (as indicated with a dashed line) is given, based on subsequent CI calculations.

the various species in different symmetry and the abbreviations used in the figure are indicated in Table 3, along with details of the corresponding CI calculations. The SCF potential energy curves show that all the states under discussion are higher in energy in the less stable HClO form than in HOCl, and CI calculations (Fig. 5) carried out for the four representative points, linear HOCl, equilibrium HOCl, equilibrium HClO, and linear HClO, demonstrate that the relative spacing and form of the SCF curves is not unrealistic in this case (HOCl and HClO vertical transition energies are given in Table 4). A barrier for interconversion from HClO to HOCl is indicated for each state, however, but optimization of the various structural parameters is expected to reduce these quantities relative to Fig. 4 and probably eradicate them entirely in some instances. On the other hand, in states such as the $^{3,1}A'$ $(10a' \rightarrow 11a')$ pair (curves *4* and *5*) which strongly prefer the linear nuclear arrangement in HClO it is quite unlikely that the corresponding barriers disappear upon optimization of the internuclear distances at each bond angle. Nonetheless since the HClO ground state is considerably more stable in the bent geometry it is possible that no barrier to angular interconversion is actually present in this important case. In this connection it is interesting that a substantial barrier for HNC → HCN interconversion (of the order of 35 kcal (13)) and also for $HOC^+ \rightarrow HCO^+$ (14) is found in calculations, while only a very small barrier results for the related HSiN → HNSi process (of the order of 4 kcal (15))

TABLE 3. Characterization of HOCl states treated and technical details of the CI calculations. The corresponding HClO states are treated in a similar manner

$^3A'$	23	11.24	10.32				

[a]The numbering refers to the states given in Table 3.
[b]Since the singlet–triplet splitting is very small in Rydberg states, generally only one multiplet is calculated explicitly.
[c]This value is misprinted in I (8.92 instead of 9.92).

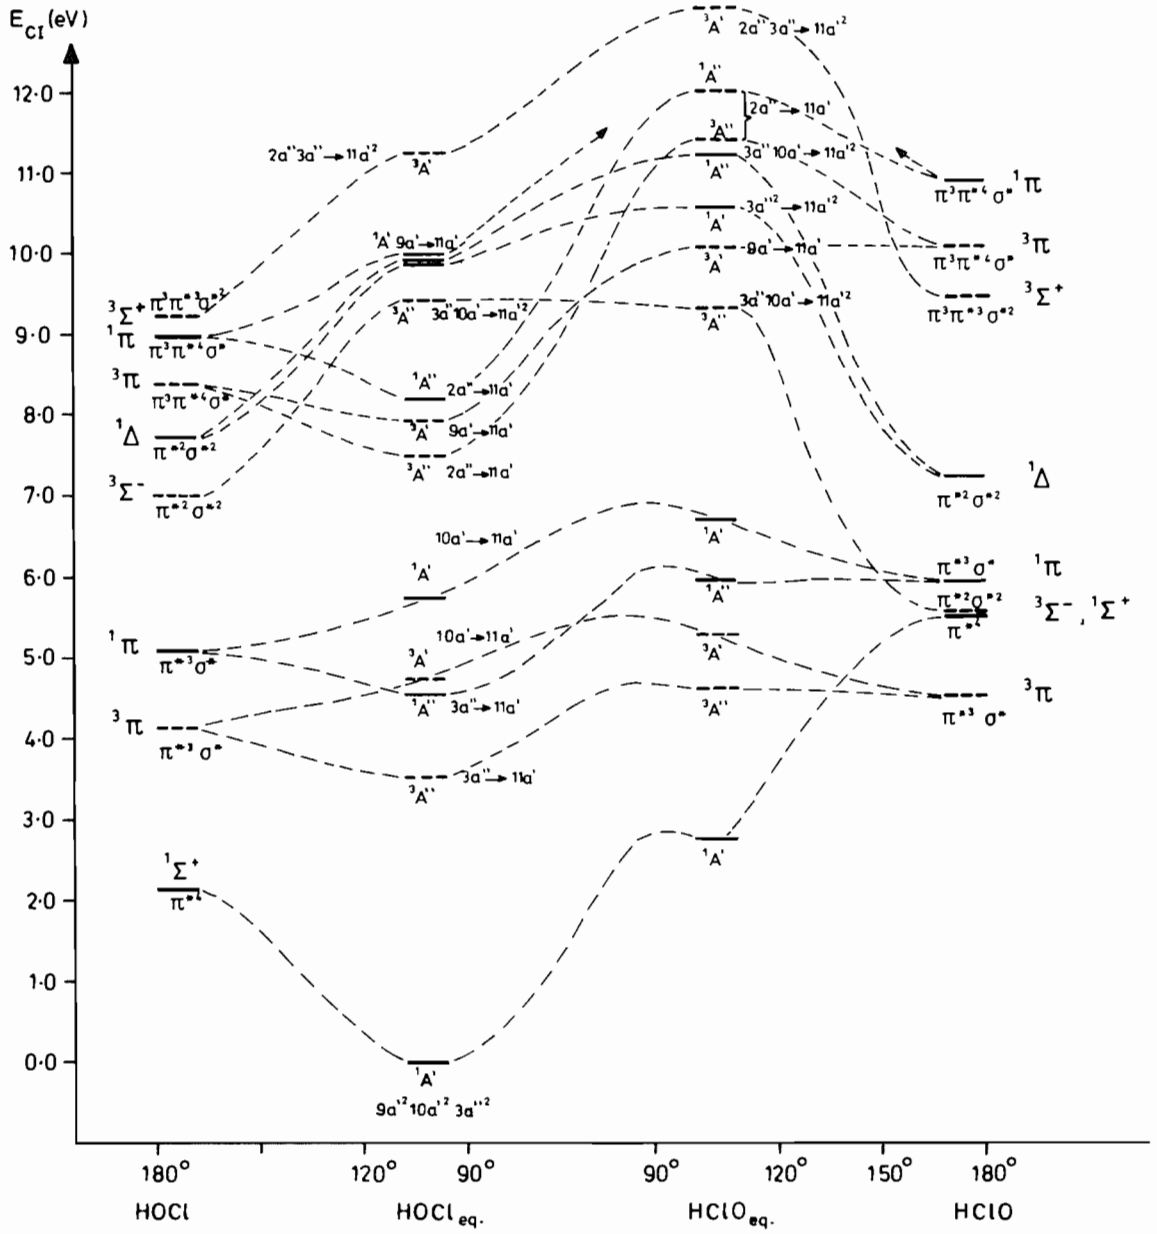

FIG. 5. Comparison of calculated CI energy levels for the ground and lowest-lying valence excited states of bent and linear HOCl and HClO. The dashed lines connect states of equivalent electronic configuration in each case (avoided crossings are not taken into account).

and no barrier at all for the HCS^+–HSC^+ pair (16), whereby HCS^+ is calculated to be the more stable by 110 kcal/mol.

One further observation (Figs. 4 and 5) is the finding that for linear HClO it is the $^3\Pi$ state which has the lowest energy and not the $^1\Sigma^+$; in addition there is another low-energy state $^3\Sigma^-$ ($\pi^{*2}\sigma^{*2}$) in close proximity to the $^1\Sigma^+$. This result can be traced back to the decidedly less stable σ MO in HClO[2] compared to HOCl (Fig. 1, *a* and *b*) and consequently its less antibonding (more stable) σ*

[2]The orbital energies of the π MO's are very similar: $\varepsilon(\pi) = -0.5764$, $\varepsilon(\pi^*) = -0.4303$ in the $^1\Sigma^+$ state of linear HOCl and $\varepsilon(\pi) = -0.5893$, $\varepsilon(\pi^*) = -0.4453$ in linear HClO, while the σ energies are −0.6946 and −0.6621 hartree respectively for $^1\Sigma^+$ of linear HOCl and HClO.

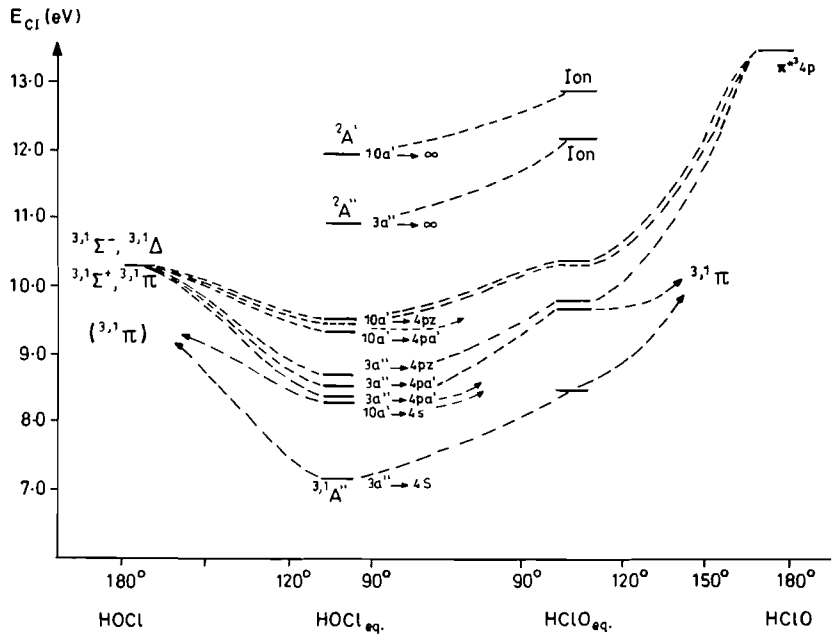

FIG. 6. Comparison of calculated CI energy levels for the lowest-lying Rydberg states and ions of bent and linear HOCl and HClO (fixed bond lengths of the same magnitudes as in Fig. 4). Estimated appearance of the corresponding angular potential curves is indicated in the figure with dashed lines; note that fewer states have actually been treated for the less stable HClO conformer.

species (Fig. 1*c*), whereby the π and π^* MO's exhibit very similar stability in both linear conformers. This situation, on the other hand, is not unusual since similar observations have been made in related molecule pairs such as HNO–HON (17, 18) or HCO^+–HOC^+ (14), for example, in which an exchange of singlet and triplet ground states or the reverse ordering of (π,π^*) and (σ,π^*) states in the respective pairs of isomeric forms has also been noted.

The end result of the various changes in relative orbital stability in the two systems is that the vertical transition energies of stable HOCl are generally much higher than for HClO, as can be seen in Table 4 as well as in Fig. 5. A similar but even more extreme example of this phenomenon has been found in the study of the HNSi–HSiN pair (15, 19), for which the lowest excited state becomes nearly isoenergetic with the closed shell ground state in the less stable (HSiN) form. Since as mentioned above there is at most a small barrier for angular interconversion of the HClO ground state to the much more stable HOCl species it is doubtful whether this clear distinction between these two systems can be observed experimentally. In this connection it should be noted, however, that there is still an open question concerning the HOCl spectrum, as observed by Fergusson *et al.* (20, 2). Although the first strong experimental band at 5.64 eV is quite plausibly assigned as the $2^1A'$–$^1A'$ transition of HOCl (calculated at 5.75 eV; Table 4), a second weaker system with an absorption maximum at 3.87 eV does not fit in well at all with any other dipole-allowed species for this system. The analogous ($2^1A'$–$^1A'$) transition in HClO does lie in the proper range (3.92 eV; Table 4), as does the $^3A''$–$^1A'$ HOCl species (3.50 eV), but it is certainly unclear whether either of these transitions is in any way related to the above experimental findings.

The analysis of the more highly excited states involving the π MO or double substitutions from π and π^* is more difficult since a number of states lying in the same energy region are mixed (in the CI or already at the SCF level of treatment) because of the lower C_s symmetry of the bent molecule. There is also the additional complication that although σ ($8a'$) and π ($9a'$,$2a''$) are energetically well separated in the linear nuclear framework, the in-plane $8a'$ and $9a'$ components can mix so that for the equilibrium bent structure (see Fig. 1, *a* and *b*) it is the $9a'$ MO which possesses σ character in both isomers while the $8a'$ is predominantly an in-plane π orbital; hence identification of the dominant configuration in a given state must be coupled with the knowledge of the specific character of the MO's in order to allow for a proper microscopic description of the state.

A relatively clear pattern is present for the lowest members of the Rydberg states (Fig. 6). All first

singlet members for the most stable equilibrium form of HOCl are treated by CI calculations ($3a'' \rightarrow 4s$, $4p_x$, $4p_y$, and $4p_z$ and $10a' \rightarrow 4s$, $4p_x$, $4p_y$, $4p_z$), while calculation of the corresponding triplet species (with the exception of the $10a' \rightarrow 4p_z$) is not undertaken because of the well-known small triplet–singlet separation for such Rydberg states. The typical features of Rydberg states are obvious: the $4s$ state is found well below the $4p$ species, of which all spatial components lie very close in energy; furthermore the energy difference between the series originating from the $3a''$ and the $10a'$ MO and their respective ionic limits is very similar (approximately 30 000 cm^{-1} for the s series). The pattern of Rydberg levels for the other arrangements of nuclei is equivalent (even though not all states have been treated explicitly in CI calculations), especially once it is realized that $3a''$ and $10a'$ become degenerate in the linear molecular geometry.

The Rydberg states lying in the energy range between 7 and 13 eV might possibly mix with valence states (21) of the proper symmetry and energy (Fig. 5), although this feature has not been explicitly treated in the present work. On the other hand, such mixing is already partially accounted for in the SCF data of Fig. 4, and as a result the corresponding potential curves exhibit a rather unconventional form with several minima in some areas.

The valence-shell states involving higher than $\pi^* \rightarrow \sigma^*$ transitions are also calculated for HOCl and HClO in the CI treatment and the results are collected in Fig. 5 and Table 4. Correlation with corresponding states in the four nuclear conformations is shown, while crossing of states is only indicated; details concerning the various states are contained in Table 3. It is generally seen that the higher valence-shell states prefer a linear structure, while the Rydberg states (Fig. 6) are generally more stable in the bent nuclear arrangement (as are the corresponding ions), leading to the interactions of various states mentioned above.

4. The Molecules HOCl and HClO and their Fragments

In order to investigate the possible destruction of HOCl into its various components or formation therefrom, potential energy curves connecting the different partners in a number of electronic states are calculated and will be discussed in what follows.

A. HOCl and its Components HO + Cl

The calculated SCF curves for separation of HOCl into OH and a Cl atom are contained in Fig. 7 while the CI values for the pertinent end points are given in Fig. 8. It is obvious that the first valence states

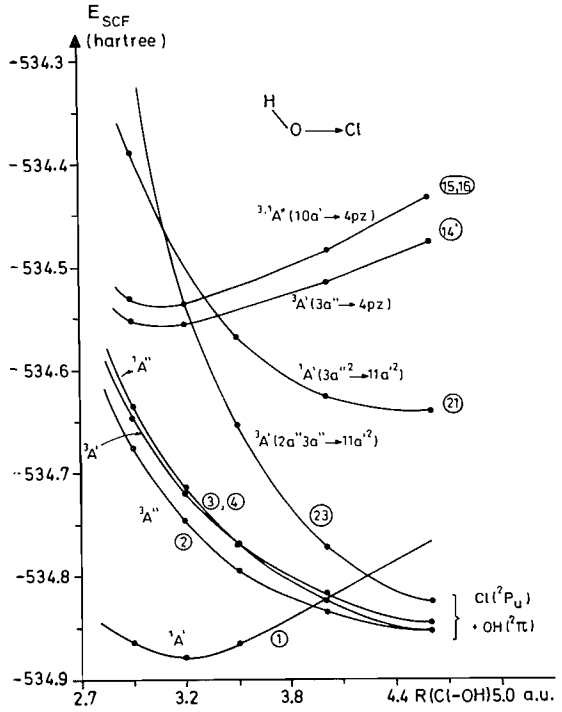

FIG. 7. SCF potential curves for Cl—O stretch in ground and various excited states of HOCl.

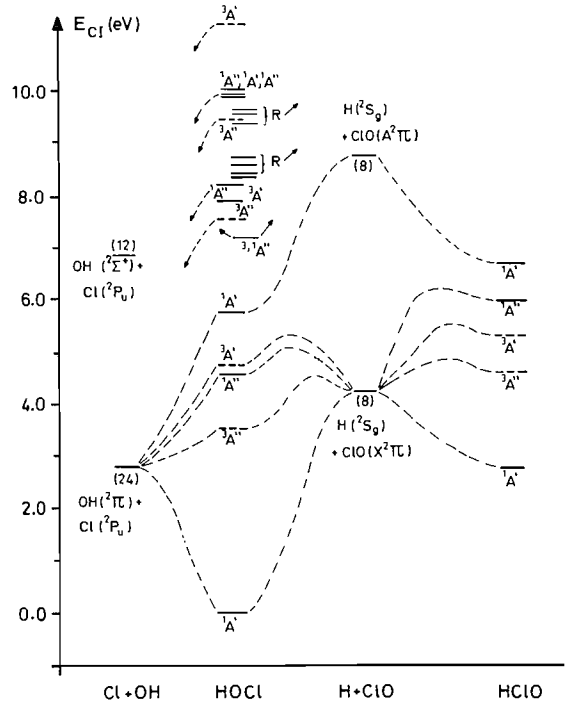

FIG. 8. Comparison of calculated CI energy levels of HOCl and HClO in ground and various excited states with those of the dissociation products H + ClO and OH + Cl respectively. (The degeneracies of the various fragment energy levels are given in parentheses in each case.)

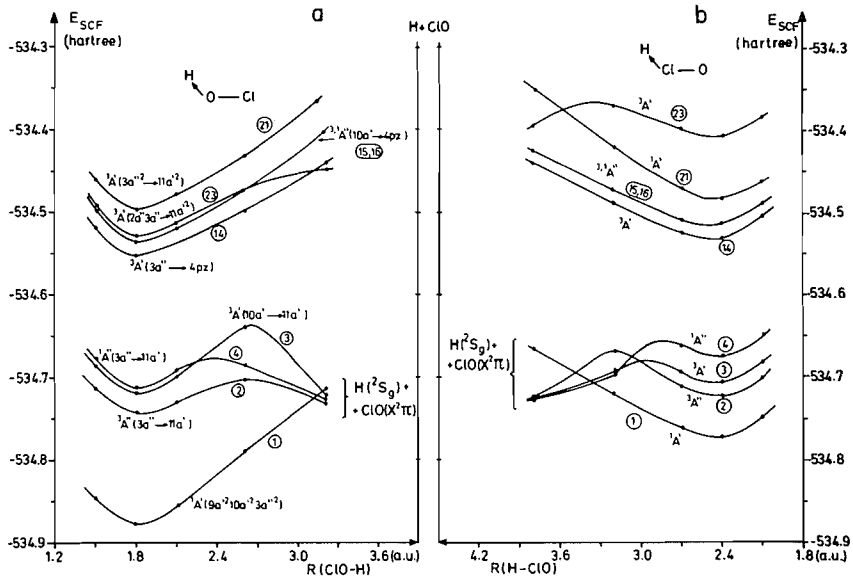

FIG. 9. SCF potential curves for hydrogen removal of (*a*) HOCl and (*b*) HClO in ground and various excited states (calculated equilibrium values for the ClO bond length and corresponding bond angle are used in each case).

$^{3,1}A'$ and $^{3,1}A''$ arising from $\pi^* \rightarrow \sigma^*$ excitations promote immediate decomposition into $OH(^2\Pi)$ and $Cl(^2P_u)$ as a consequence of populating the strongly ClO antibonding σ^* orbital, as has been pointed out earlier in I, as well as by Jaffe and Langhoff (2). The Rydberg states (Figs. 7 and 8) are not repulsive and show potential curves similar to that of the positive ion, i.e. they prefer a somewhat smaller Cl—O bond length than does the ground state, which is also stable with respect to Cl + OH separation. Various high-energy states (Figs. 7 and 8) populating the antibonding σ^* twice are strongly repulsive and furnish the remaining curves leading to the ground state products (Fig. 8). The conclusion from these results is that any excitation of HOCl below the first Rydberg species (7 eV) will immediately lead to fragmentation into OH and Cl (calculated fragment total energies are given in Table 5 of I for comparison with the HOCl vertical excitation energies in Table 4).

B. Hydrogen Removal Processes

The calculated SCF potential energy curves for hydrogen removal HOCl → H + ClO and HClO → H + ClO are contained in Fig. 9, *a* and *b*; the corresponding CI data are also presented in Fig. 8. Both ground state curves show the typical behavior of a bound state with one minimum[3], and approximately 95 kcal/mol must be added to the system in order to remove the hydrogen atom from HOCl in its ground state (Table 5 of I).[4] All excited states in Fig. 9 *a* and *b* with minima in the same general energy range as the ground state fragments H (^2S_g) + ClO ($^2\Pi$) exhibit a potential barrier for larger hydrogen distances. Although the calculated barriers in Fig. 9 *a* and *b* will most probably be reduced considerably when relaxation of the ClO bond is taken into account in the process, it is still likely that a small barrier remains in each case in analogy to what is found for similar states in HCO, HN_2, or HNO (for example see ref. 24). All potential energy curves involving HOCl or HClO Rydberg states correlate with electronically excited fragments and the SCF calculations of Fig. 9 again suggest that substantial energy is required before dissociation into H + ClO can take place via these states.

Finally consideration of Fig. 8, which shows the realistic relative positions of the various energy levels, makes it clear that loss of hydrogen in any of the HOCl states treated is extremely unlikely, especially since in the excited states dissociation into $OH(^2\Pi)$ + $Cl(^2P_u)$ can take place so easily instead. Similarly formation of the molecule in its ground state from $H(^2S_g)$ + $ClO(^2\Pi)$ is probably not

[3]The long-range SCF part must be corrected in the standard way to obtain a realistic description of the bond-breaking process involving the open-shell fragments.

[4]The measurement of a heat of formation for HOCl of −18 kcal/mol by Molina and Molina (22) and of −19 kcal/mol by Timmons (private communication, value of R. Timmons transferred to authors by D. Phillips (NASA)) as compared to the predicted value for this quantity in I of −19.2 ± 3.9 kcal, gives at least some indication of the overall reliability of the present *ab initio* results.

favored since the excess energy of this reaction would readily promote dissociation into OH and Cl. Furthermore although the OH + Cl destruction channel is not directly open to the HClO isomer, consideration of Fig. 5 suggests that a small supply of energy in the bending vibrational mode might favor interconversion from the HClO excited states into HOCl (not even considering the HCl + O pathway), which again would be followed by fragmentation into OH + Cl rather than dissociation from the excited HClO states into H + ClO.

C. HClO and the Components O + HCl

The SCF potential energy curves connecting the fragments O and HCl with the system HClO are given for various states in Fig. 10 (whereby the internuclear angle of 102.4° is held constant) while the complementary CI data are contained in Fig. 11. In this case the adiabatic correlation of states is especially simple since all low-lying triplet HClO states correlate with $O(^3P_g)$ + $HCl(^1\Sigma^+)$, while the corresponding singlet species must be connected with $O(^1D_g)$ + $HCl(^1\Sigma^+)$. It is seen that except for that of the ground state the low-energy curves are all

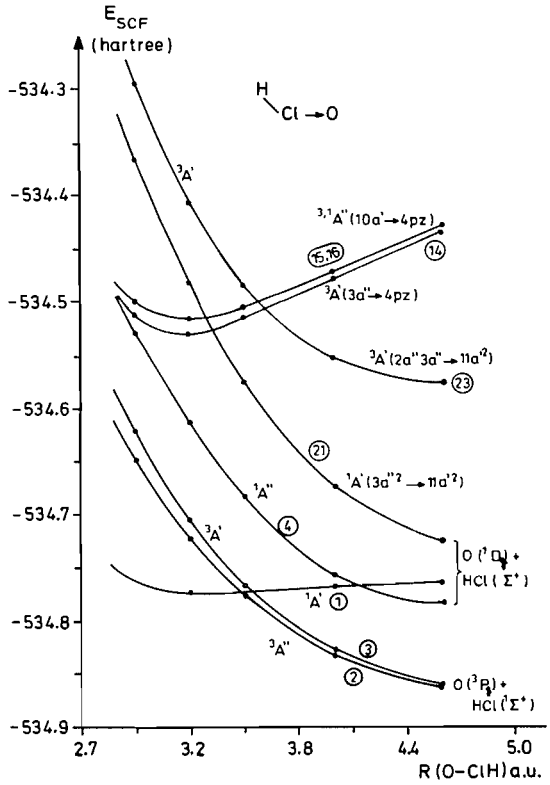

FIG. 10. SCF potential curves for Cl—O stretch in ground and various excited states of the HClO system (calculated equilibrium values for the H—Cl bond length and HClO bond angle are assumed throughout).

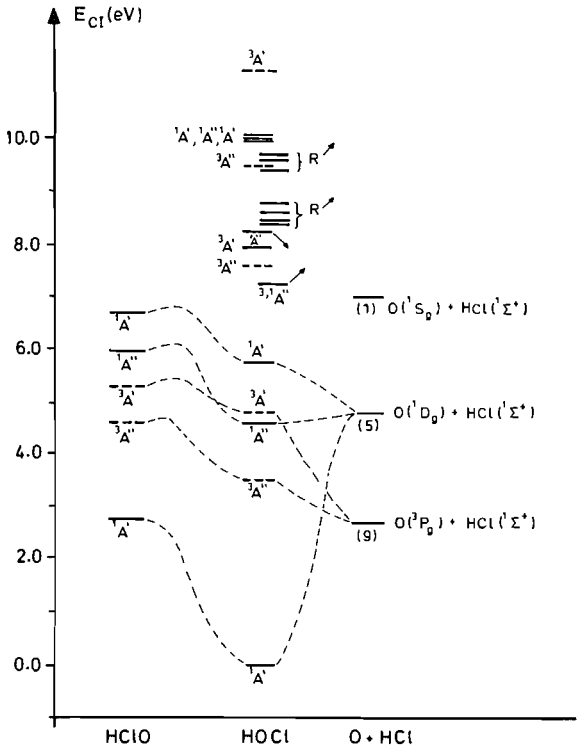

FIG. 11. Comparison of calculated CI energy levels of HOCl and HClO with those of various O + HCl dissociation products. (The degeneracies of the various fragment energy levels are given in parentheses in each case.)

repulsive, favoring dissociation into O + HCl in a manner quite similar to the HOCl dissociation (Fig. 7) into OH + Cl.

The reaction $O(^1D_g)$ + HCl has been studied experimentally (25) and it has been found to yield the products OH + Cl rather than ClO + H. According to the present study this reaction could proceed with very little activation energy (if any) in a favorable geometrical position via the lowest excited $^1A''$ state (which is essentially isoenergetic with $O(^1D_g)$ + HCl $(^1\Sigma^+)$ if the oxygen inserts to give the HOCl arrangement; see Fig. 11), which has been shown to be strongly repulsive with respect to the OH + Cl fragments. Reaction via the ground state HClO–HOCl surface could lead to an HOCl entity provided the high excess energy of this reaction can be set free appropriately. Again, as discussed earlier (Fig. 8), dissociation into OH + Cl is preferred over that in H + ClO in any of the low-energy HOCl states, in accordance with experimental observation (2, 25).

The rate of the corresponding triplet reaction $O(^3P_g)$ + $HCl(^1\Sigma^+)$ → $OH(^2\Pi)$ + $Cl(^2P_u)$ has been investigated by various experimental techniques (11, 26–29) and an activation barrier of approximately 0.25 eV (11, 25) has been estimated. From

the overall experimental evidence there is an indication (25, 30), although not conclusive (11), that this reaction proceeds via a non-adiabatic transition from the triplet to the lowest-lying singlet surface, as discussed by Nikitin and co-workers (30, 31). Furthermore the absence of vibrational to translational and rotational energy transfer is taken as an indication (28) that the representative pathway cuts the corner of the potential energy surface and does not penetrate into the deep HOCl equilibrium well.

According to the present potential energy curves a pathway involving the $^3A''$ state is only conceivable with a low activation energy of a few kcal/mol if the hydrogen migration occurs for large O—Cl distances and requires very little energy for such structures; since the corresponding potential energy surfaces (Figs. 4 and 5) are only calculated for structures close to equilibrium, the present study cannot support or discard this possibility. Because of the strongly repulsive nature of the $^3A''$ curve an intersection with the corresponding singlet to yield a stable HOCl molecule via a spin–orbit curve crossing must also occur at quite large O—Cl distances, unless (as in the previous case) the repulsive nature changes considerably with the angle of approach of oxygen to HCl, a situation which is unlikely to occur. A curve crossing is found in CI calculations for $\angle HClO = 140°$, $HCl—O = 3.45a_0$, for example, but this point is already 1.0 eV above the initial products, so that a study of this phenomenon must involve larger HCl—O separations.

5. Vertical Ionization of HOCl and HClO

The ground state for both the $HOCl^+$ and $HClO^+$ isomers is a $^2A''$ species, arising from the loss of an electron from the corresponding $3a''$ MO in the respective neutral system. Because of the nodal characteristics of the latter orbital it can be predicted from Walsh's rules that little change in equilibrium geometry accompanies ionization in this instance. Hence it is expected that the values for the vertical minimum IP for both HOCl and HClO will be only slightly higher than for the corresponding adiabatic quantities. The lowest ionization potential of HOCl has recently been measured experimentally to be 11.22 eV (32), in good agreement with the present calculated value of 10.90 eV (Table 4), as well as with another theoretical result given in the literature (33). Furthermore because of the above geometrical considerations for such ions it is possible to identify the energy difference between lowest and higher vertical IP's with the vertical transition energies of the ion itself. In the case of $HOCl^+$ the results obtained in this manner (1.08, 3.62, and 4.55 eV) correspond to transitions into the $3a''$ MO from the $10a'$, $2a''$, and $9a'$ orbitals respectively and are found to be in good agreement with experimental values for these quantities (32).

If the lowest adiabatic IP is taken to be 11.1 eV (32) the heat of formation of $HOCl^+$ can thus be estimated to be in the order of 237 kcal/mol, based on the ΔH_f^0 value for HOCl of -19 kcal/mol discussed earlier (1, 22). The $HOCl^+$ heat of formation can then be combined with known ΔH_f^0 values for possible dissociation fragments of this system to obtain predictions of its bond strengths. For example, heats of reaction of the order of 100 kcal/mol each are thereby indicated for decomposition into both $Cl^+(^3P_g) + OH(^2\Pi)$ and $Cl(^2P_u) + OH^+(^3\Sigma^-)$. Comparison of these results with the corresponding value for the neutral reaction, $HOCl \rightarrow Cl(^2P_u) + OH(^2\Pi)$, of 57 kcal/mol leads to the conclusion that the ClO bond is some 43 kcal/mol stronger in $HOCl^+$ than in neutral HOCl; such a finding is clearly consistent with the ClO antibonding characteristics of the $3a''$ (π^*) species from which ionization takes place. On the other hand, similar calculations indicate that the OH bond strength is very nearly the same (95 kcal/mol) before and after the $3a''$ ionization, as again seems quite reasonable based on the lack of H-atom character in this molecular orbital.

Analogous calculations can be made for the $HClO^+$ system, for which a ΔH_f^0 value of 260 ± 5 kcal/mol results. Taking the difference between these two ΔH_f^0 values leads to an estimate for the isomerization energies of $HOCl^+$ and $HClO^+$ of 22 ± 5 kcal/mol, markedly less than for the corresponding neutral systems. By comparison the isomerization energy for the HSO–SOH pair of the same number of electrons as the ions has been calculated at a similar level of CI treatment (23) to be 12 kcal/mol, again with the system containing the second-row atom in the terminal position indicated to be the more stable. Finally it is found that the Cl—O bond of $HClO^+$ should be 75 kcal/mol stronger than in HClO, while its H—Cl counterpart should be about 35 kcal/mol stronger than in the neutral system.

6. Conclusion

The present study has investigated various points of the potential energy surface of the HOCl–HClO system in ground and a number of excited states in connection with interconversion of the two isomeric forms and their fragmentation into (or formation from) OH, Cl, H, ClO, HCl, $O(^3P_g)$, and $O(^1D_g)$. It is found that the ground state and the four lowest singlet and triplet states occupying the σ^* MO can be followed very easily from products to various fragments, while higher excited species, including the

Rydberg states, will generally change their energy ordering among one another upon structural deformations so that no definite reaction channels will be preferred in the higher-energy range of fragments and products.

The calculations indicate further that isomer conversion into the more stable HOCl form is likely in the ground state without substantial activation barrier, but that in at least some of its excited states HClO prefers a linear nuclear arrangement and should not be easily converted into HOCl in these cases. In general the antibonding π^* and σ^* MO's in these systems are found to be relatively more stable in HClO than in HOCl, while the opposite is true for the corresponding bonding orbitals. As a result the vertical transition energies in the less stable HClO conformer are often markedly smaller than for the corresponding excitations in HOCl.

All four first excited states $^{3,1}A''$ and $^{3,1}A'$ (and also higher species) exhibit strongly repulsive potential energy curves and hence decidedly favor dissociation into $OH(^2\Pi) + Cl(^2P_u)$ as soon as one of these excited states is populated. Since furthermore this fragment energy is considerably lower than that of $H(^2S_g) + ClO(X^2\Pi)$, decomposition into OH + Cl is preferred over hydrogen removal; in addition it is found that barriers towards hydrogen removal are present even in the excited states, as has been observed in related systems, and this eventuality makes such processes even less likely. Dissociation of HOCl in its first two triplet excited states also seems possible via repulsive energy curves into $O(^3P_g) + HCl(^1\Sigma^+)$, i.e. fragments which are practically isoenergetic with $OH(^2\Pi) + Cl(^2P_u)$; on the other hand, crossing with the ground state singlet curve might introduce (via spin–orbit coupling) some complications. Decomposition of HOCl in its first two singlet states into $O(^1D_g) + HCl(^1\Sigma^+)$ via repulsive potential energy surfaces is also conceivable, although the energetically more favorable channel OH + Cl is probably preferred in this case.

9-Oxobenzomorphans. I. General syntheses of dihydrobenz[*e*]indolines as key intermediates

GERRY KAVADIAS,[1] STEPHAN VELKOF, AND BERNARD BELLEAU

Bristol Laboratories of Canada, 100 Industrial Boulevard, Candiac, P.Q., Canada J5R 1J1

Received December 20, 1978

GERRY KAVADIAS, STEPHAN VELKOF, and BERNARD BELLEAU. Can. J. Chem. **57**, 1852 (1979).

Various 5,9b-dihydrobenz[*e*]indolines were synthesized by three general methods: (*a*) by alkylation with the appropriate alkyl halide of 1,2,4,5-tetrahydro-1*H*-benz[*e*]indoles, themselves obtained by alkylation with bromochloroethane of enamines derived from 7-alkoxy-2-tetralones; (*b*) from 1-alkylaminoethyl-2,2-ethylenedioxy-1,2,3,4-tetrahydronaphthalenes by acid hydrolysis, and (*c*) by reduction of 2-oxo-2,3,5,9b-tetrahydro-1*H*-benz[*e*]indoles which in turn were obtained from ethyl 2-oxo-1,2,3,4-tetrahydro-1-naphthalene acetates by reaction with methylamine followed by dehydration. These substances are key intermediates in the synthesis of 9-oxobenzomorphans.

GERRY KAVADIAS, STEPHAN VELKOF et BERNARD BELLEAU. Can. J. Chem. **57**, 1852 (1979).

On a synthétisé diverses dihydro-5,9b benz[*e*] indolines par trois méthodes générales: (*a*) par alkylation, à l'aide d'un halogénure d'alkyle approprié, de tétrahydro-1,2,4,5 1*H*-benz[*e*] indoles, eux mêmes obtenus par alkylation avec du bromochloroéthane des ènamines provenant d'alkoxy-7 tétralones-2; (*b*) par hydrolyse acide d'alkylaminoéthyl-1 éthylènedioxy-2,2 tétrahydro-1,2,3,4 naphtalènes et (*c*) par réduction des oxo-2 tétrahydro-2,3,5,9b 1*H*-benz[*e*] indoles qui sont obtenus à partir des oxo-2 tétrahydro-1,2,3,4 naphtalènes acétates d'éthyle-1 par réduction avec de la méthylamine suivie par une déshydratation. Ces substances sont des intermédiaires clés dans la synthèse des oxo-9 benzomorphanes.

[Traduit par le journal]

As part of our continuing search for medicinally useful analgesics, it became necessary to have ready access to variously substituted 9-oxobenzomorphans. The best known method for their synthesis is the one described by Murphy *et al.* (1) more than 20 years ago. This process involves as the ultimate step the pyrolysis of a quaternary salt such as the methiodide of 2′-methoxy-2,5-dimethyl-9-oxo-6,7-benzomorphan and accordingly its applicability is limited to compounds that can survive the vigorous pyrolytic conditions. A new general process for the synthesis of 9-oxo-benzomorphans was therefore developed and after our work was completed, Takeda *et al.* (2) described an approach which is conceptually similar. However, in our hands, the process described by these authors was not generally applicable and led to low yields of product. In this paper we wish to describe three general methodologies (Schemes 1–3) which provide for ready accessibility to 5,9b-dihydrobenz[*e*]indolines **5***a–h* (Fig. 1) as key intermediates in the synthesis of the desired 9-oxobenzomorphans (see accompanying papers).

Treatment of the 2-tetralones **1***a,b* with the appropriate amines according to published procedures (3, 4) afforded the enamines **2***a–d* in 96–99% yields (Scheme 1).

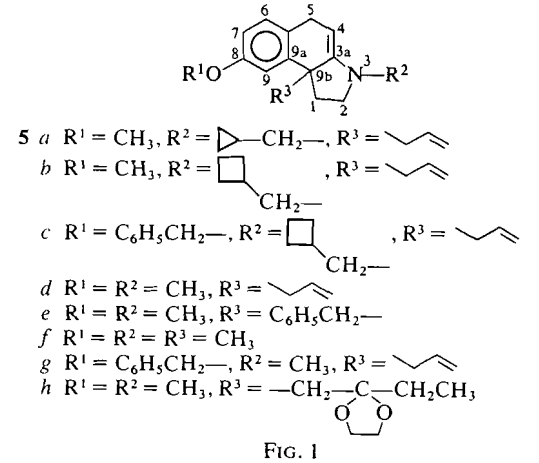

FIG. 1

Applying a procedure similar to that previously described by Evans *et al.* (4) for the synthesis of 3-methyl-1,2,4,5-tetrahydro-3*H*-benz[*e*]indole, the enamines **2***a–d*, after conversion to 'bidendate' nucleophiles with isopropyl magnesium chloride, were reacted with bromochloroethane to give **3***a–d* in 95–99% yields. The nmr spectra of these products lacked any olefinic proton resonances in the region δ 3.3–6.3, thus ruling out the formation of the isomeric enamines with the double bond unconjugated with the benzene ring (5). The benz[*e*]indolines **3***a–d* were alkylated with the appropriate alkyl halides to

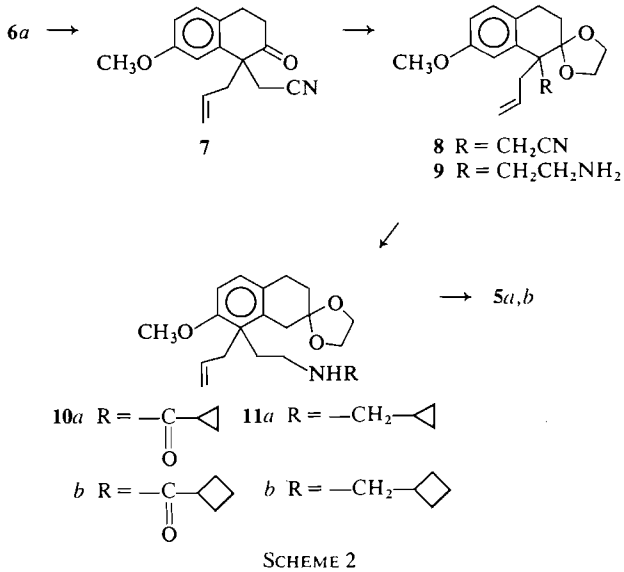
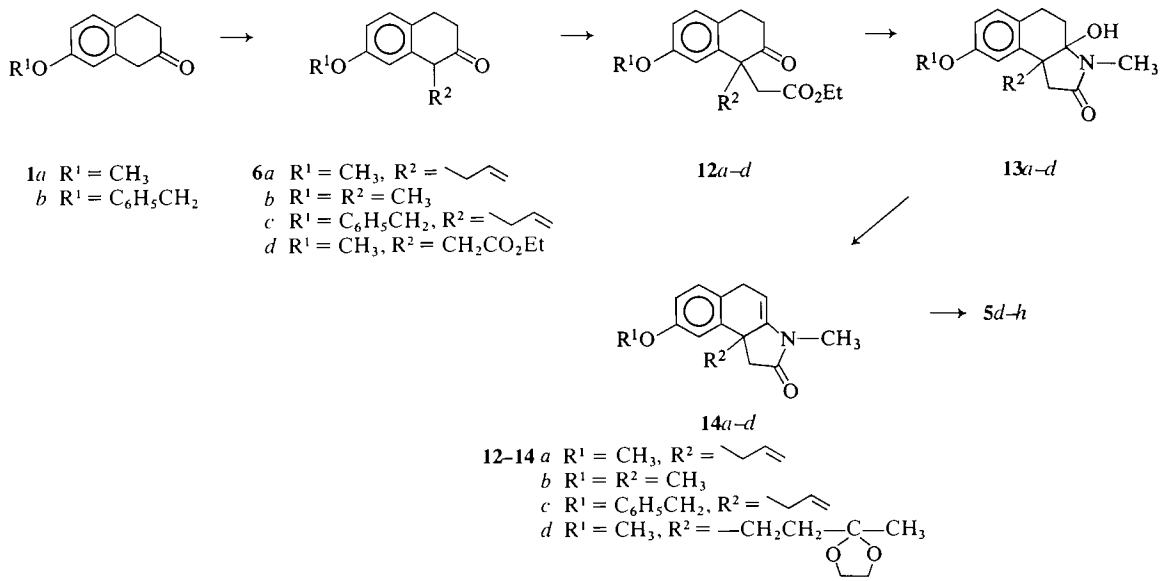
produce **4***a–e*. To some extent *N*-alkylation was a competing reaction and the ratio of the desired *C*-alkylated products to *N*-alkylated compounds varied with the alkylating agent and the solvent (6). Thus, alkylation of **3***a–c* with allyl bromide in acetonitrile proceeded mainly to give *C*-alkylation. The expected products **4***a–c* (X = Br) were thus obtained in 60–63% yields in pure crystalline form. Alkylation of **3***d* with allyl bromide in the same solvent produced the *C*-alkylated product, isolated as the picrate salt **4***d*, in 76% yield. The yields of **4***a–d* were approximately 10% lower when benzene was used as the solvent in place of acetonitrile. The effect of solvent was more pronounced when benzyl chloride was employed as the alkylating agent. For instance, reaction of **3***d* with benzyl chloride in solvents such as benzene, dioxane, or acetonitrile produced the *C*-alkylated product **4***e*, isolated as the picrate salt in yields of 10, 39, and 46%, respectively. Alkylation of **3***d* with methyl iodide in benzene or acetonitrile provided the methiodide of **3***d* as the major product (82–92%). The salts **4***a–e* were stable and could be conveniently stored at room temperature for several months. When treated with base they were quantitatively converted to the oxygen-sensitive benz[*e*]indolines **5***a–e*.

An alternative synthesis of **5***a* and **5***b* is outlined in Scheme 2. Alkylation of the sodium enolate of **6***a* with chloroacetonitrile in DMF afforded **7** in good yield (76%). The conversion of **7** into **8** was carried out without difficulty. Reduction of the ketal nitrile **8** with lithium aluminium hydride in ether produced the ketal amine **9** in quantitative yield. Acylation of **9** with the appropriate acyl halides gave the amides **10***a,b* which after reduction with lithium aluminium hydride afforded the ketal amines **11***a,b*. Acid hydro-



SCHEME 2



SCHEME 3

lysis of **11***a* produced the dihydrobenz[*e*]indoline **5***a* in 92% yield which was identical in every respect with the product obtained according to Scheme 1. Analogously, the ketal amine **11***b* was converted to **5***b* (98%) which was also identical to the product obtained above by Scheme 1.

A third process for the synthesis of 5,9b-dihydrobenz[*e*]indolines is shown in Scheme 3 and was applied to the preparations of **5***d–h*. Alkylation of the 2-tetralones **1***a,b* with the appropriate alkyl halides by Stork's enamine procedure (1*a*, 3), produced **6***a–d* in 67–94% yields. The subsequent alkylation of the sodium enolates of **6***a–d* with ethyl bromoacetate in dimethylformamide afforded the 1,1-disubstituted products **12***a–d* in good yields (66–88%). Treatment of **12***a–d* with excess methyl amine in ethanol produced the hydroxy lactams **13***a–d* (80–86% yields) in crystalline form, except for **13***d* which was a syrup. Evidence for their assigned structures was provided by elemental analysis and ir spectroscopy. The ir spectra of **13***a–d* showed absorption bands for hydroxyl (3300–3500 cm^{-1}) and lactam-carbonyl groups (1670–1690 cm^{-1}), but no absorption bands for ketone-carbonyl. The hydroxy lactams **13***a–d* are relatively stable in crystalline forms and in solution at temperatures below 40°C. At higher temperatures, water is eliminated and they are quantitatively converted to the unsaturated lactams **14***a–d*. The conversion to **14***a–d* was preferably carried out by heating a solution of **13***a–d* in benzene or toluene with a catalytic amount of *p*-toluenesulfonic acid. Reduction of the unsaturated lactams **14***a–d* with lithium aluminium hydride in ether provided the corresponding dihydrobenz[*e*]-indolines **5***d–h* in 90–95% yield as air-sensitive oils.

The structures assigned to the products **5***a–h* are supported by ir and nmr spectroscopy. The ir spectra showed strong C=C absorption at 1670 cm^{-1}. The nmr spectra showed a one proton band in the area of δ 4.4 either as a doublet of doublets (X part of ABX system, J_1 = 5.5, and J_2 = 2.5 Hz) for **5***d–f* or as an unresolved band for **5***a–c*.

In view of the air sensitivity of the products **5***a–h* and of the intermediate enamines **2** and **3**, it was clearly advantageous to carry out the reactions and all other operations (such as extractions, filtrations, and evaporations) under an atmosphere of nitrogen. This precaution minimized air oxidation of the unstable products and led to comparatively good yields. Storage of **5***a–h* required conversion to stable salts such as hydrobromides and picrates from which they were quantitatively regenerated by treatment with base.

Experimental

The melting points were determined on a Mel-Temp melting point apparatus and are uncorrected. The ir spectra were recorded on a Unicam Sp-200G grating ir spectrometer. The nmr spectra were recorded on a Varian A-60A spectrometer using deuteriochloroform as the solvent. The chemical shifts are expressed in δ values using tetramethylsilane as internal reference. Microanalyses were performed by Micro-Tech Laboratories Inc., Skokie, IL, U.S.A. All experiments involving enamines, and work-up processes such as filtration, extraction, and release of vacuum after evaporation, were performed under a nitrogen atmosphere.

2-N-Cyclopropylmethylamino-7-methoxy-3,4-dihydronaphthalene (2a)

Into a three-neck round-bottomed flask fitted with mechanical stirrer, a Soxhlet extractor packed with molecular sieves (50 g, type 3A), a condenser, and a nitrogen inlet tube, was added 10.75 g (100 mmol) cyclopropylmethylamine hydrochloride, 0.75 mL water (to solubilize the salt), and 10.1 g (100 mmol) triethylamine. After stirring for 10–15 min to liberate the cyclopropylmethylamine, a solution of 12.30 g (70 mmol) of 7-methoxy-2-tetralone (**1***a*) in 100 mL benzene was added and the mixture (under nitrogen) was heated under reflux while stirring for 5 h. After cooling to room temperature, the solids (triethylamine hydrochloride) were filtered off quickly and washed with ether (50 mL). The combined filtrates and washings were evaporated to dryness to give 15.8 g (99%) of **2***a* as a pale yellow air-sensitive liquid; ir (neat): 3420 (NH), 1635 cm^{-1} (C=C—N); nmr δ: 0.15–1.15 (m, 5H, cyclopropyl), 2.15 (m, benzylic), 2.63–2.95 (m, 4H, allylic and N-CH_2), 3.40 (broad, 1H, NH), 3.75 (s, 3H, OCH_3), 5.18 (s, 1H, C-1H), 6.63–7.0 (m, 3H, ArH). *Anal.* calcd. for $C_{15}H_{19}NO$: C 78.57, H 8.35, N 6.11; found: C 78.93, H 8.41, N 6.03.

2-N-Cyclobutylmethylamino-7-methoxy-3,4-dihydronaphthalene (2b)

Employing the procedure described above for the synthesis of **2***a*, 7-methoxy-2-tetralone (70.4 g, 400 mmol) was reacted with cyclobutylmethylamine (generated *in situ* from 62.7 g (516 mmol) of its hydrochloride by treatment with an equimolar amount of triethylamine and 4.0 mL of water) in benzene (300 mL) to provide 93.4 g (96.5%) of **2***b* as a pale yellow air-sensitive syrup; ir (neat): 3420 (NH), 1635 cm^{-1} (C=C—N); nmr δ: 3.70 (s, 3H, OCH_3), 5.15 (s, 1H, C-1H), 6.25–6.90 (m, 3H, ArH). *Anal.* calcd. for $C_{16}H_{21}NO$: C 78.97, H 8.69, N 5.75; found: C 79.26, H 8.73, N 5.65.

7-Benzyloxy-2-N-cyclobutylmethylamino-3,4-dihydronaphthalene (2c)

In a manner analogous to that given for **2***a*, 7-benzyloxy-2-tetralone (36.5 g, 145 mmol) was reacted with cyclobutylmethylamine (generated *in situ* from 22.7 g (187 mmol) of its hydrochloride by treatment with an equimolar amount of triethylamine and 1.5 mL water) in benzene (110 mL) and the product isolated as above to yield 46.28 g (99%) of **2***c* as a pale yellow, air-sensitive syrup; ir (neat): 3420 (NH), 1635 cm^{-1} (C=C—N); nmr δ: 4.98 (s, 2H, $ArCH_2O$), 5.15 (s, 1H, C-1H), 6.35–7.40 (m, 8H, ArH). *Anal.* calcd. for $C_{22}H_{25}NO$: C 82.83, H 7.89, N 4.38; found: C 82.87, H 7.79, N 4.23.

7-Methoxy-2-N-methylamino-3,4-dihydronaphthalene (2d)

This compound was prepared according to the procedure described by Evans *et al.* (4) for the synthesis of 2-*N*-methylamino-3,4-dihydronaphthalene. Thus, into a dry, nitrogen-purged, 500 mL three-neck flask fitted with mechanical stirrer, dropping funnel, and nitrogen inlet tube was added a solution of 14.3 g (460 mmol) methylamine in anhydrous ether (100 mL) and a solution of 20.0 g (113.5 mmol) of 7-methoxy-2-tetralone in the same solvent (100 mL), and the solution was blanketed with nitrogen and cooled to −18°C (ice–methanol). A solution of 11.56 g (61 mmol) titanium tetrachloride in pentane (50 mL) was added dropwise while stirring over a 30 min period. After the addition was completed, the reaction mixture was stirred at room temperature for 1 h and then rapidly filtered. The solid residue was washed with ether (50 mL) and the filtrate and washings were combined. Removal of the solvent *in vacuo* gave 20.6 g (96%) of **2***d* as an oxygen-sensitive oil which crystallized on standing; ir (neat): 3430 (NH), 1630 cm^{-1} (C=C—N); nmr δ: 2.15 (m, 2H, benzylic), 2.55 (m, 2H, allylic), 2.70 (s, 3H, NCH_3), 3.15 (broad, NH), 3.70 (s, 3H, OCH_3), 5.13 (s, 1H, C-1H), 6.25–6.90 (m, 3H, ArH). *Anal.* calcd. for $C_{12}H_{15}NO$: C 76.15, H 7.99, N 7.40; found: C 75.44, H 7.92, N 7.19.

3-Cyclopropylmethyl-8-methoxy-1,2,4,5-tetrahydro-3H-benz[e]indole (3a)

This compound was prepared according to the procedure described by Evans *et al.* (4) for the synthesis of 3-methyl-1,2,4,5-tetrahydro-3*H*-benz[*e*]indole as follows. Into a dry, nitrogen-filled, 1 L three-neck flask fitted with reflux condenser, septum cap, dropping funnel, and magnetic stirrer, was added a solution of 38.55 g (167.9 mmol) of **2***a* in dry tetrahydrofuran (50 mL) under nitrogen. A 2.20 *M* solution of isopropylmagnesium chloride in THF (96.1 mL, 211.7 mmol) was added slowly with a syringe at such a rate as to maintain gentle reflux. After the addition was completed (15 min), 30.72 g (214.2 mmol) of bromochloroethane was added to the warm reaction mixture at a rate sufficient to maintain gentle reflux. After addition of the alkyl halide was completed, an additional 52.3 mL (115 mmol) of the Grignard reagent was added at a controlled rate. The reaction mixture was cooled in an ice-bath and 270 mL of 1 *M* aqueous solution of ethylenediaminetetraacetic acid tetrasodium salt was added slowly (with stirring) followed by 600 mL 1:1 ether–benzene. The organic layer was separated and the aqueous phase was extracted with ether. The combined extracts were washed with water (2 × 100 mL), dried ($MgSO_4$), and the solvent evaporated to yield 43.0 g (99%) of **3***a* as a pale yellow oxygen-sensitive oil; ir (neat): 1635 cm^{-1} (C=C—N). *Anal.* calcd. for $C_{17}H_{21}NO$: C 79.96, H 8.29, N 5.48; found: C 79.86, H 8.35, N 5.41.

3-Cyclobutylmethyl-8-methoxy-1,2,4,5-tetrahydro-1H-benz[e]indole (3b)

Employing the procedure described above for the preparation of **3***a*, compound **2***b* (93.4 g) was converted to **3***b* (98.0 g, 94.5%), a pale brown oxygen-sensitive oil; ir (neat): 1635 cm^{-1} (C=C—N). *Anal.* calcd. for $C_{18}H_{23}NO$: C 80.25, H 8.60, N 5.19; found: C 80.15, H 8.71, N 5.09.

8-Benzyloxy-3-cyclobutylmethyl-1,2,4,5-tetrahydro-1H-benz[e]indole (3c)

Employing the procedure described above for the preparation of **3***a*, compound **2***c* (46.0 g) was converted to **3***c*; yield 48.0 g (98%); ir ($CHCl_3$): 1635 cm^{-1} (C=C—N). *Anal.* calcd. for $C_{24}H_{26}NO$: C 83.43, H 7.87, N 4.06; found: C 83.72, H 7.77, N 3.96.

3-Methyl-8-methoxy-1,2,4,5-tetrahydro-1H-benz[e]indole (3d)

In a manner analogous to that given for **3***a*, compound **2***d* (19.0 g) was converted to **3***d* in 96% yield; ir (neat): 1635 cm^{-1} (C=C—N); nmr δ: 2.62 (s, 3H, NCH_3), 3.75 (s, 3H, OCH_3), 6.6–7.1 (m, 3H, ArH). A sample was converted to the picrate salt; mp 108.5–110°C (acetone–ether). *Anal.* calcd. for $C_{20}H_{21}N_4O_8$: C 53.93, H 4.75, N 12.58; found: C 53.79, H 4.65, N 12.68.

9b-Allyl-3-cyclopropylmethyl-8-methoxy-5,9b-dihydrobenz[e]indole (5a) and Its Hydrobromide Salt 4a

(a) Preparation from 3-Cyclopropylmethyl-8-methoxy-1,2,4,5-tetrahydro-3H-benz[e]indole (3a)

A solution of 43.0 g (167.9 mmol) of **3***a* and 25.0 g (206 mmol) of allyl bromide in dry benzene (120 mL) was heated under reflux while stirring under a nitrogen atmosphere for 10 h. An oily precipitate formed. After cooling to room temperature, the supernatant was decanted and the residue

treated with acetone (50 mL) to give a crystalline precipitate which was collected to give 36.3 g (57.5%) of **4***a* (X = Br), mp 160–165°C. An analytical sample was obtained by recrystallization from acetone–ether, mp 172–174°C. *Anal.* calcd. for $C_{20}H_{26}BrNO$: C 63.84, H 6.94, Br 21.24; found: C 63.94, H 6.94, Br 21.13.

The yield of crystalline **4***a* was 67% when acetonitrile was used as the solvent in place of benzene in the above procedure.

Benz[*e*]indoline **5***a* was quantitatively obtained from the hydrobromide **4***a* by treatment with 10% aqueous sodium hydroxide and extraction with ether; ir (neat): 1670 cm^{-1} (C=C—N); nmr δ: 3.77 (s, 3H, OCH_3), 4.35 (broad, 1H, NC=CH), 4.75–5.91 (m, 3H, olefinic), 6.5–7.1 (m, 3H, ArH).

(b) Preparation from **11***a*

To a solution of 30.4 g (85 mmol) of **11***a* in ethanol (125 mL) was added a solution of 4% hydrochloric acid (125 mL). The reaction mixture was stirred at room temperature overnight (16 h) and then concentrated under vacuum to about half its volume. It was made basic with 10% sodium hydroxide and extracted with ether (2 × 100 mL). The combined extracts were washed with water (2 × 80 mL), dried ($MgSO_4$), and the solvent evaporated *in vacuo* to give 23.0 g (92%) of **5***a*, which was identical to the material prepared in part (*a*) above.

9b-Allyl-3-cyclobutylmethyl-8-methoxy-5,9b-dihydrobenz[e]*indoline (***5***b) and Its Hydrobromide Salt* **4**b

(a) Preparation from 3-Cyclobutylmethyl-8-methoxy-1,2,4,5-tetrahydro-1H-benz[e]*indole (***3***b)*

A solution of 18.0 g (67 mmol) of **3***b* and 10.5 g (87 mmol) of allyl bromide in dry acetonitrile (60 mL) was heated under reflux under nitrogen for 16 h. After removal of the solvent *in vacuo*, the residue was treated with acetone (50 mL) and the crystalline product collected to give 15.5 g (59%) of **4***b*, mp 168–170°C. *Anal.* calcd. for $C_{21}H_{28}BrNO$: C 64.61, H 7.23, Br 20.47; found: C 64.38, H 7.25, Br 20.35.

The yield of crystalline **4***b* was 49% when benzene was used as the solvent in place of acetonitrile in the above procedure.

Benz[*e*]indoline **5***b* was quantitatively obtained from the hydrobromide **4***b* by treatment with sodium hydroxide and extraction with ether; ir (neat): 1670 cm^{-1} (C=C—N); nmr δ: 3.75 (s, 3H, OCH_3), 4.36 (broad, 1H, NC=CH), 4.75–5.9 (m, 3H, olefinic), 6.5–7.1 (m, 3H, ArH).

(b) Preparation from the Ketal Amine **11**b

Compound **11***b* (33.7 g) was treated with hydrochloric acid in aqueous ethanol and the product isolated as in the case of **5***a* (part (*b*)) to give 27.5 g (98%) of **5***b*, identical with the material obtained in part (*a*) above.

9-Allyl-8-benzyloxy-3-cyclobutylmethyl-5,9b-dihydrobenz[e]*indoline (***5***c) and Its Hydrobromide Salt* **4**c

A mixture of 48.0 g (139 mmol) **3***c* and 21.9 g (181 mmol) of allyl bromide in dry acetonitrile (140 mL) was heated under reflux under nitrogen for 16 h. After removal of the solvent by evaporation, the residue was treated with acetone (150 mL) and the crystalline material collected to give 40.0 g (63%) of **4***c* (X = Br), mp 181–183.5°C. An analytical sample was obtained by recrystallization from ethanol; mp 183–184°C. *Anal.* calcd. for $C_{27}H_{32}BrNO$: C 69.52, H 6.91, N 3.00, Br 17.13; found: C 69.56, H 6.92, N 2.90, Br 16.96.

The benz[*e*]indoline **5***c* was quantitatively obtained from the hydrobromide **4***c* by treatment with sodium hydroxide and extraction with ether; ir (neat): 1670 cm^{-1} (C=C—N); nmr δ: 4.40 (broad, 1H, NC=CH), 5.07 (s, 2H, $ArCH_2O$), 4.73–5.90 (m, 3H, olefinic), 6.75–7.5 (m, 8H, ArH).

9b-Allyl-8-methoxy-3-methyl-5,9b-dihydrobenz[e]*indoline (***5***d) and Its Picrate Salt* **4**d

(a) Preparation from **3**d

A solution of 5.04 g (23.4 mmol) **3***d* and 3.70 g (30.5 mmol) of allyl bromide in dry acetonitrile (20 mL) was heated under reflux for 16 h under nitrogen. Removal of the solvent *in vacuo* left a sticky residue of **4***d* (X = Br) which was purified by conversion to the picrate salt as follows: The hydrobromide **4***d* (X = Br) was dissolved in water (100 mL) and extracted with ether (2 × 50 mL) to remove neutral material. The aqueous phase was made alkaline with 10% sodium hydroxide (30 mL) and extracted with ether (2 × 70 mL). The ethereal solution was washed with water (3 × 30 mL), dried ($MgSO_4$), and the solvent removed *in vacuo*. The liquid residue (5.1 g) was dissolved in ethanol (20 mL) and added to a solution of 6.8 g picric acid in hot ethanol (50 mL) and allowed to crystallize at room temperature. The crystalline product was filtered to give 8.6 g (76%) of **4***d* (X = picrate ion), mp 143–147°C. An analytical sample was obtained by recrystallization from ethanol–acetone (1:15), mp 147–148°C. *Anal.* calcd. for $C_{23}H_{24}N_4O_8$: C 57.02, H 5.00, N 11.56; found: C 57.15, H 5.35, N 11.61.

The yield of the picrate **4***d* was 66% when benzene was used in place of acetonitrile in the above procedure.

The benz[*e*]indoline **5***d* was regenerated from the picrate **4***d* as follows: A mixture of finely powdered **4***d* (10 mmol), 1 *N* aqueous lithium hydroxide (50 mL), ethanol (20 mL), and ether (100 mL) in a separatory funnel was shaken until all the picrate had dissolved. The ether phase was washed with water and, after drying, was evaporated to dryness to give **5***d* in quantitative yield as a pale yellow and air-sensitive liquid; ir (neat): 1670 cm^{-1} (N—C=C); nmr δ: 2.60 (s, 3H, NCH_3), 3.68 (s, 3H, OCH_3), 4.60 (d of d, 1H, NC=CH, J_1 = 5.5, J_2 = 2.5 Hz), 4.63–5.98 (m, 3H, olefinic), 6.43–7.0 (m, 3H, ArH).

(b) Preparation from **14**a

To a suspension of 5.8 g (155 mmol) of lithium aluminium hydride in 190 mL dry ether was added dropwise under a slow stream of nitrogen and while stirring a solution of 28.19 g (104.8 mmol) of **14***a* in 190 mL dry ether at such a rate as to maintain gentle refluxing. Following the addition (20 min), stirring at room temperature was continued for 2 h. The reaction mixture was cooled in an ice-bath and treated successively with 5.9 mL water, 4.4 mL 20% aqueous sodium hydroxide, and 20.6 mL water (7) to provide a granular precipitate which was filtered under nitrogen and rinsed with ether. The combined filtrate and washings were evaporated to dryness under reduced pressure. After removal of the solvent was complete, the flask containing the product was filled with nitrogen. The compound **5***d* thus obtained was a pale yellow syrup, 26.2 g (98%), and was identical to that obtained in part (*a*) above. A sample was converted to picrate **4***d*, mp 147–148°C.

9b-Benzyl-8-methoxy-3-methyl-5,9b-dihydrobenz[e]*indoline (***5***e) and Its Picrate Salt* **4**e

A solution of 27.3 g (127 mmol) of **3***d* and 25.0 g (197 mmol) of benzyl chloride in 130 mL dry acetonitrile was heated under reflux under nitrogen for 18 h. Removal of the solvent *in vacuo* left a residue (**4***e*, X = Br) which resisted crystallization. The residue was dissolved in water (150 mL), extracted with ether (2 × 100 mL) to remove neutral material, and the aqueous phase treated with 10% sodium bicarbonate (200 mL) and extracted with ether (3 × 100 mL). The combined ethereal extracts were washed with water (2 × 100 mL), dried, and the solvent removed *in vacuo* to give 30 g (78%) of **5***e* as a light brown syrup. The purity of this material was approximately 90% as estimated by nmr. The crude benz[*e*]indoline **5***e* was treated with picric acid as in the case of **5***d* above to give 28.5 g (42% based on **3***d*) of the picric acid salt **4***e*, mp 123–126°C (ethanol–acetone, 1:4). *Anal.* calcd. for $C_{27}H_{26}N_4O_8$: C 60.66, H 4.90, N 10.48; found: C 59.99, H 4.93, N 10.52.

The benz[*e*]indoline **5***e* was quantitatively regenerated from

the picrate **4***e* by the procedure described above for **5***d*; ir (neat): 1670 cm^{-1} (C=C—N); nmr δ: 2.65 (s, 3H, NCH_3), 2.80 (s, 2H, $ArCH_2$), 3.72 (s, 3H, OCH_3), 4.37 (d of d, 1H, NC=CH, J_1 = 5.5, J_2 = 2.5 Hz), 6.50–7.35 (m, 8H, ArH).

In another experiment, where dioxane was used as the reaction solvent instead of acetonitrile, the yield of the crude **5***e* was 60% and the yield of the picrate salt was 39%.

The yield of crude **5***e* was 10%, where benzene was used as the reaction solvent in the above procedure.

3,9b-Dimethyl-8-methoxy-5,9b-dihydrobenz[e]*indoline (***5***f)*

To a stirred suspension of 3.40 g (89.4 mmol) of lithium aluminium hydride in 110 mL dry ether under a slow stream of nitrogen was added dropwise a solution of 14.65 g (60.2 mmol) of crude **14***b* in 500 mL of dry ether and at such a rate as to maintain gentle refluxing. After the addition was completed (25 min) stirring was continued at room temperature for 1.5 h. The product was isolated as in the case of **5***d* (part (*b*)) above to give 13.42 g (98%) of the air-sensitive **5***f* as a pale brown liquid; ir (neat): 1670 cm^{-1} (N—C=CH); nmr δ: 1.20 (s, 3H, CH_3), 2.67 (s, 3H, NCH_3), 3.74 (s, 3H, OCH_3), 4.30 (d of d, 1H, NC=CH, J_1 = 5.5, J_2 = 2.5 Hz). *Anal.* calcd. for $C_{15}H_{19}NO$: C 78.56, H 8.35, N 6.10; found: C 78.06, H 8.24, C 5.93.

When the reduction of **14***b* was carried out in ether–THF, a sticky product was obtained which contained very little **5***f* as evidenced by nmr.

9b-Allyl-8-benzyloxy-3-methyl-5,9b-dihydrobenz[e]*indoline (***5***g)*

This compound was prepared by reduction of the crude **14***c* with lithium aluminium hydride in ether by the method described above for **5***d* (part (*a*)); yield, 95%; ir (neat): 1670 cm^{-1} (NC=C); nmr δ: 2.70 (s, 3H, NCH_3), 4.36 (d of d, 1H, NC=CH, J_1 = 5.5, J_2 = 2.5 Hz), 4.73–5.90 (m, 3H, olefinic), 5.08 (s, 2H, $PhCH_2O$), 6.25–7.53 (m, 8H, ArH).

9b-(3-Ethylenedioxy)butyl-8-methoxy-3-methyl-5,9b-dihydrobenz[e]*indoline (***5***h)*

To a suspension of 0.5 g (13 mmol) lithium aluminium hydride in 50 mL dry ether was added portionwise, under nitrogen and while stirring, 3.43 g (10 mmol) of crystalline **14***d*. After the addition was completed (15 min), the mixture was heated under reflux under nitrogen for 45 min; 30 mL ether was added and heating continued while stirring for a total of 2.5 h under nitrogen. The reaction mixture was cooled in an ice-bath and the excess lithium aluminium hydride decomposed by the dropwise addition of water (0.6 mL). After stirring for 45 min the mixture was filtered under nitrogen and the solids washed with ether. The ether solution was dried and evaporated to dryness to give 3.1 g (94%) of **5***h* as a pale yellow syrup; ir (neat): 1670 cm^{-1}; nmr δ: 1.20 (s, 3H, CH_3), 2.65 (s, 3H, NCH_3), 3.80 (s, 7H, OCH_2CH_2O and OCH_3), 4.41 (d of d, 1H, NC=CH, J_1 = 5.5, J_2 = 2.5 Hz).

*1-Allyl-3,4-dihydro-7-methoxy-2(1*H*)-naphthalenone (***6***a)*

To a solution of 104.1 g (0.59 mol) of **1***a* in 110 mL dry benzene was added 62.5 g of pyrrolidine (0.88 mol) dropwise under nitrogen while stirring at room temperature. After the addition was completed (10–15 min), the reaction mixture was heated under reflux for 2.5 h with azeotropic removal of water and then cooled to room temperature. The enamine solution was added dropwise to 143.8 g (1.19 mol) of allyl bromide while stirring at a rate sufficient to maintain gentle refluxing. A heavy precipitate formed. Benzene (50 mL) was added to facilitate stirring and heating continued for 4 h; 700 mL of water was then added and heating resumed. After 2 h, the reaction mixture was cooled to room temperature and diluted with 100 mL benzene. The benzene layer was separated and the aqueous phase extracted with benzene (2 × 100 mL). The combined extracts were washed with water (2 × 100 mL) and dried (Na_2SO_4). After evaporation of the solvent, the residue was distilled to give 113.5 g (89%) of **6***a*, bp 114–118°C/0.1–0.05 Torr (lit. (8) bp 118–120°C/0.05 Torr); ir (neat): 1715 cm^{-1}; nmr δ: 2.40–3.10 (m, 6H, allylic and alicyclic), 3.45 (t, 1H, C-1H, J = 6.5 Hz), 3.75 (s, 3H, OCH_3), 4.8–6.1 (m, 3H, olefinic), 6.7–7.2 (m, 3H, ArH).

*3,4-Dihydro-7-methoxy-1-methyl-2(1*H*)naphthalenone (***6***b)*

This compound was prepared in 84% yield by the method described in the literature (1*a*); bp 110–112°C/0.3–0.4 Torr (lit. (1*a*) bp 110–115°C/0.3–0.4 Torr); nmr δ: 1.43 (d, 3H, CH_3, J = 7.0 Hz), 3.68 (s, 3H, OCH_3), 6.65–7.20 (m, 3H, ArH).

*1-Allyl-7-benzyloxy-3,4-dihydro-2(1*H*)-naphthalenone (***6***c)*

To a mixture of 22.7 g (90 mmol) **1***b* and 50 mL of dry benzene was added dropwise at room temperature a solution of 9.6 g (135 mmol) of pyrrolidine in 50 mL benzene while stirring under nitrogen. After the addition was completed (10 min), the reaction mixture was heated under reflux with azeotropic removal of water for 3 h and then cooled to room temperature. A solution of 22.0 g (181 mmol) of allyl bromide in 25 mL benzene was added dropwise (10 min) and then heating under reflux continued. Benzene (100 mL) was added to facilitate stirring and heating continued for 4 h. Water (200 mL) was added and reflux continued for another 2 h. After the reaction mixture had cooled to room temperature, the benzene phase was separated and the aqueous phase was extracted first with benzene (50 mL) and then with ether (100 mL). The combined extracts were washed with water (100 mL), dried (Na_2SO_4), and evaporated to dryness to give 24.8 g (94%) of liquid **6***c*; ir ($CHCl_3$): 1715 cm^{-1}; nmr δ: 5.15 (s, 2H, $PhCH_2O$), 4.8–6.1 (m, 5H, olefinic and $PhCH_2O$), 6.80–7.50 (m, 8H, ArH). *Anal.* calcd. for $C_{20}H_{20}O_2$: C 82.14, H 6.89; found: C 80.72, H 6.75.

This material was used in the next step without further purification.

*Ethyl-7-methoxy-2-oxo-1,2,3,4-tetrahydro-1-naphthaleneacetate (***6***d)*

This compound was prepared in 78% yield according to a described procedure (9).

*1-Allyl-7-methoxy-2-oxo-1,2,3,4-tetrahydro-1-naphthaleneacetonitrile (***7***)*

Compound **6***a*, (256.5 g or 1.186 mol) in 250 mL dry DMF was added dropwise to a stirred, cold (ice-bath) suspension of 24.86 g (1.186 mol) of sodium hydride (or 49.92 g of a 57% dispersion in oil washed with benzene) in 350 mL DMF under nitrogen. After the addition was completed (1 h), the reaction mixture was stirred at room temperature for 2 h and then cooled in an ice-bath. A solution of 89.54 g (1.186 mol) of chloroacetonitrile in 300 mL dry DMF was added over a period of 1 h, then the cooling bath removed, and stirring continued at room temperature overnight. Water (1500 mL) and ether (300 mL) were added and while stirring a crystalline material precipitated. It was collected to give 210 g of **7**. The organic phase of the filtrate was separated and the aqueous phase was extracted with benzene (4 × 200 mL). The combined extracts were washed with water (3 × 150 mL), dried, and evaporated to dryness. The syrupy residue was triturated with ether (200 mL) and on cooling it crystallized to give an additional 40.0 g of product **7**. The two crystalline crops were combined (250 g) and recrystallized from 1:1 ethanol–ether to give 231.0 g (76%) of **7**, mp 90–96°C. A sample was distilled at 150–160°C/0.1 Torr and the distillate was crystallized from EtOH to give an analytical sample, mp 94–96°C; ir ($CHCl_3$): 2250 (CN), 1715 cm^{-1} (CO); nmr δ: 3.77 (s, 3H, OCH_3), 4.75–5.65 (m, 3H, $CH=CH_2$), 6.65–7.15 (m, 3H, ArH). *Anal.*

calcd. for $C_{16}H_{17}NO_2$: C 75.26, H 6.71, N 5.48; found: C 74.85, H 6.97, N 5.54.

*1-Allyl-2,2-ethylenedioxy-7-methoxy-1,2,3,4-tetrahydro-1-naphthaleneacetonitrile (**8**)*

A round bottomed flask fitted with a Soxhlet extractor packed with molecular sieves 3A (80 g), a condenser, and magnetic stirrer was charged with 71.5 g (200 mmol) of crude 7 (mp 90–96°C), 90 mL ethylene glycol, 1.0 g *p*-toluenesulfonic acid and 250 mL of dry toluene. The mixture was heated under reflux while stirring and at intervals (8–10 h) the sieves were replaced with fresh ones. After refluxing for 48 h, the reaction mixture was cooled to room temperature and diluted with 10% aqueous sodium bicarbonate (100 mL). The organic phase was separated and the aqueous phase extracted with benzene (2 × 50 mL). The combined extracts were washed with water, dried, and the solvent evaporated. Trituration of the residue with ethanol (60 mL) gave 64.0 g (76%) of compound **8**, mp 82–85°C. A sample recrystallized twice from the same solvent melted at 85–86°C; ir ($CHCl_3$): 2250, 1615, 1505 cm^{-1}; nmr δ: 3.75 (s, 3H, OCH_3), 4.06 (s, 4H, OCH_2CH_2O), 4.85–6.0 (m, 3H, olefinic), 6.6–7.15 (m, 3H, ArH). *Anal.* calcd. for $C_{18}H_{21}NO_3$: C 72.21, H 7.07, N 4.68; found: C 72.23, H 7.10, N 4.50.

*1-Allyl-2,2-ethylenedioxy-7-methoxy-1-(2-aminoethyl)-1,2,3,4-tetrahydronaphthalene (**9**)*

A solution of 33.2 g (111 mmol) of **8** in 480 mL of dry ether was added dropwise under nitrogen and while stirring to a suspension of 8.43 g (222 mmol) of lithium aluminium hydride in 210 mL dry ether. After the addition was completed (30 min), stirring at room temperature was continued for 48 h. The reaction mixture was cooled in an ice-bath and the excess hydride and salts decomposed by the dropwise consecutive addition of 8.5 mL water, 6.4 mL 20% sodium hydroxide, and 29.5 mL water (7). The granular inorganic precipitate was collected, rinsed with ether (100 mL), and the ether solution dried ($MgSO_4$). Removal of the solvent *in vacuo* afforded 33.5 g (100%) of **9** as a syrup. The ir spectrum of the reduction product and tlc (alumina, CH_2Cl_2) established the absence of any unreduced nitrile. A sample was purified by chromatography on aluminium oxide; elution with methylene chloride at first removed some impurities; subsequent elution with ethanol removed the product; nmr δ: 1.05 (s, 2H, NH_2), 3.70 (s, 3H, OCH_3), 3.91 (s, 4H, OCH_2CH_2O), 4.73–6.0 (m, 3H, olefinic), 6.5–7.0 (m, 3H, ArH). *Anal.* calcd. for $C_{18}H_{25}NO_3$: C 71.25, H 8.30, N 4.61; found: C 70.74, H 8.35, N 4.50.

*1-Allyl-1-(2-cyclopropanecarboxamidoethyl)-2,2-ethylenedioxy-7-methoxy-1,2,3,4-tetrahydronaphthalene (**10**a)*

To an ice cold solution of 10.8 g (35.7 mmol) of **9** and 8.3 mL (60 mmol) triethylamine in 25 mL methylene chloride was added dropwise while stirring a solution of 4.18 g (40 mmol) of cyclopropanecarbonyl chloride in 15 mL of methylene chloride. After stirring for 1 h in the cold and 2 h at room temperature, it was washed with water and 10% aqueous sodium bicarbonate and dried (Na_2SO_4). Evaporation of the solvent and trituration of residue with ether (50 mL) gave 10.5 g (79.5%) of crystalline **10***a*, mp 94–95°C, solidified and remelted at 114–115°C; ir ($CHCl_3$): 3320 (NH), 1650, and 1555 (CO) cm^{-1}; nmr δ: 0.3–0.8 (m, 5H, cyclopropyl), 3.75 (s, 3H, OCH_3), 4.0 (s, 4H, OCH_2CH_2O), 4.75–6.0 (m, 3H, olefinic), 6.50–7.10 (m, 3H, ArH). *Anal.* calcd. for $C_{22}H_{29}NO_4$: C 71.13, H 7.87, N 3.77; found: C 71.10, H 8.03, N 3.67.

*1-Allyl-1-(2-cyclobutanecarboxamidoethyl)-2,2-ethylenedioxy-7-methoxy-1,2,3,4-tetrahydronaphthalene (**10**b)*

Reaction of **9** with cyclobutanecarbonyl chloride as described above for the preparation of **10***a* provided an 83% yield of **10***b*, mp 99–101°C (benzene–ligroin); nmr δ; 3.81 (s, 3H, OCH_3), 4.06 (s, 4H, OCH_2CH_2O), 4.86–6.05 (m, 3H, olefinic), 6.6–7.1 (m, 3H, ArH). *Anal.* calcd. for $C_{23}H_{31}NO_4$: C 71.66, H 8.10, N 3.63; found: C 71.60, H 8.21, N 3.42.

*1-Allyl-1-[2-(N-cyclopropylmethylamino)ethyl]-2,2-ethylenedioxy-7-methoxy-1,2,3,4-tetrahydronaphthalene (**11**a)*

To a suspension of 3.0 g (81 mmol) lithium aluminium hydride in dry ether (160 mL) was added dropwise while stirring a solution of 14.8 g (40 mmol) of **10***a* in dry THF (160 mL) at a rate such as to maintain gentle refluxing. After stirring at room temperature for 48 h, the reaction mixture was cooled in an ice-bath and the excess hydride and complexes were decomposed (7) by the consecutive dropwise addition of water (3.0 mL), 20% sodium hydroxide (2.25 mL), and water (10.5 mL). The inorganic precipitate was collected and rinsed with ether (50 mL). The combined filtrate and washings were dried ($MgSO_4$) and evaporated to dryness to give 14.0 g (98%) of **11***a* as a syrup; nmr δ: 3.71 (s, 3H, OCH_3), 3.95 (s, 4H, OCH_2CH_2O), 4.7–6.0 (m, 3H, olefinic), 6.5–7.0 (m, 3H, ArH). *Anal.* calcd. for $C_{22}H_{31}NO_3$: C 73.91, H 8.74, N 3.91; found: C 73.38, H 8.89, N 3.76.

*1-Allyl-1-[2-(N-cyclobutylmethylamino)ethyl]-2,2-ethylenedioxy-7-methoxy-1,2,3,4-tetrahydronaphthalene (**11**b)*

Compound **11***b* was obtained in 95% yield by reduction of **10***b* according to the above procedure for the preparation of **11***a*; nmr δ: 3.76 (s, 3H, OCH_3), 4.0 (s, 4H, OCH_2CH_2O), 4.8–6.0 (m, 3H, olefinic), 6.60–7.10 (m, 3H, ArH). *Anal.* calcd. for $C_{23}H_{33}NO_3$: C 74.35, H 8.95, N 3.77; found: C 74.36, H 9.13, N 3.56.

*Ethyl-1-allyl-7-methoxy-2-oxo-1,2,3,4-tetrahydro-1-naphthaleneacetate (**12**a)*

Into a flame-dried, 500 mL three-neck flask equipped with a mechanical stirrer, a dropping funnel, and a nitrogen inlet tube was placed 4.21 g of sodium hydride (55% dispersion in oil, 100 mmol) while maintaining a nitrogen atmosphere. The mineral oil was washed out with benzene (3 × 30 mL), then 40 mL of dry DMF was added, and the suspension stirred while cooling in an ice-bath. A solution of 21.6 g (100 mmol) **6***a* in 10 mL DMF was added dropwise (10 min), the cooling bath removed, and stirring at room temperature continued until the evolution of gas ceased (2 h). The brown-colored reaction mixture was cooled (ice-bath) and a solution of 16.7 g (100 mmol) of ethyl bromoacetate in 40 mL DMF was added dropwise while keeping the reaction temperature below 25°C. After the addition was completed (15–20 min), stirring in the cold was continued for 1 h and then overnight at room temperature. Water (300 mL) was added and the mixture extracted with ether (3 × 100 mL). The combined ether extracts were washed with water (2 × 100 mL), dried ($MgSO_4$), the solvent removed by evaporation, and the residue distilled to give 26.0 g (86%) of **12***a*, bp 145–150°C/0.05–0.01 Torr; ir (neat): 1740, 1715 cm^{-1}; nmr δ: 1.05 and 3.92 (triplet and quartet for OCH_2CH_3), 3.75 (s, 3H, OCH_3), 4.65–6.0 (m, 3H, $CH{=}CH_2$), 6.55–7.15 (m, 3H, ArH). *Anal.* calcd. for $C_{18}H_{22}O_4$: C 71.50, H 7.33; found: C 71.27, H 7.28.

*Ethyl-7-methoxy-1-methyl-2-oxo-1,2,3,4-tetrahydro-1-naphthaleneacetate (**12**b)*

Compound **6***b* (28.23 g, 148 mmol) was reacted with ethyl bromoacetate by the above method to yield 36.0 g (88%) **12***b*, bp 138–140°C/0.1 Torr; ir (neat): 1740 cm^{-1} (unresolved ketone and ester bands); nmr δ: 1.05 and 3.93 (triplet and quartet for $CO_2CH_2CH_3$), 1.37 (s, 3H, CH_3), 3.80 (s, 3H, OCH_3), 6.6–7.3 (m, 3H, ArH). The distillate crystallized on

standing. A sample recrystallized from ethanol melted at 55–55.5°C. *Anal.* calcd. for $C_{16}H_{20}O_4$: C 69.54, H 7.29; found: C 69.75, H 7.33. The distilled product was used as such in the next step.

*Ethyl-1-allyl-7-benzyloxy-2-oxo-1,2,3,4-tetrahydro-1-naphthaleneacetate (**12**c)*

Compound **6c** (22.9 g, 78.5 mmol) was reacted with ethyl bromoacetate by the method described above for the preparation of **12***a* to yield 25.5 g (87%) crystalline **12***c*. Recrystallization from ethanol gave 19.5 g (66%), mp 83–85°C; ir ($CHCl_3$): 1725, 1710 (ketone and ester) cm^{-1}; nmr δ: 1.05 and 3.96 (triplet and quartet for OCH_2CH_3), 4.8–5.8 (m, 5H, olefinic and $PhCH_2O$), 5.15 (s, 2H, $PhCH_2O$), 6.80–7.55 (m, 8H, ArH). *Anal.* calcd. for $C_{24}H_{26}O_4$: C 76.16, H 6.92; found: C 76.09, H 6.96.

*Ethyl-1-(3-ethylenedioxy)butyl-7-methoxy-2-oxo-1,2,3,4-tetrahydro-1-naphthaleneacetate (**12**d)*

This compound was prepared in 87% yield from **6***d* according to a described procedure (9) and was used without purification in the next step.

*9b-Allyl-3a-hydroxy-8-methoxy-3-methyl-2-oxo-2,3,3a,4,5,9b-hexahydro-1H-benz[e]indole (**13**a)*

Methylamine (gas) (6.80 g, 220 mmol) was dissolved in ethanol (25 mL) and the solution added to 21.2 g (70 mmol) of **12***a*. After standing at room temperature for 24 h a crystalline product formed and was collected to give 12.5 g (62%) of **13***a*, mp 146–149°C. After evaporation of the filtrate (35°C) and treatment of the residue with ether (50 mL), an additional 3.8 g of **13***a*, mp 147–150°C, was obtained, increasing the yield to 81.5%; ir ($CHCl_3$): 3500, 1690, 1615, 1505 cm^{-1}; nmr δ: 2.88 (s, 3H, N—CH_3), 3.92 (s, 3H, OCH_3), 4.62 (broad singlet, OH), 4.9–6.1 (m, 3H, olefinic), 6.8–7.3 (m, 3H, ArH). *Anal.* calcd. for $C_{17}H_{21}NO_3$: C 71.05, H 7.37, N 4.87; found: C 70.90, H 7.38, N 4.67.

*3,9b-Dimethyl-3a-hydroxy-8-methoxy-2-oxo-2,3,3a,4,5,9b-hexahydro-1H-benz[e]indole (**13**b)*

A solution of 22.0 g (79.7 mmol) of **12***b* and 7.5 g (240 mmol) of methylamine in 25 mL of ethanol was left at room temperature for 24 h. The crystalline precipitate which formed was collected to give 15.5 g (74.5%) of **13***b*, mp 182–186°C. After evaporation (35°C) of the filtrate and treatment of the residue with ether, another 1.0 g of **13***b* was obtained to give a total yield of 79.5%; ir (Nujol): 3300 (OH), 1670 (lactam) cm^{-1}; nmr ($CDCl_3$–DMSO) δ: 1.48 (s, 3H, CH_3), 2.82 (s, 3H, N—CH_3), 3.78 (s, 3H, OCH_3), 6.6–7.1 (m, 3H, ArH). *Anal.* calcd. for $C_{15}H_{19}NO_3$: C 68.94, H 7.32, N 5.36; found: C 68.74, H 7.30, N 5.53.

*9b-Allyl-8-benzyloxy-3a-hydroxy-3-methyl-2-oxo-2,3,3a,4,5,9b-hexahydro-1H-benz[e]indole (**13**c)*

A mixture of 63.0 g (167 mmol) of **12***c*, 31.0 g of methylamine, and 200 mL of 1:1 ethanol–dioxane was stirred at room temperature for 3 days. The reaction mixture was concentrated by evaporation (35–40°C) to half its volume and diluted with 200 mL of ether to give **13***c* as a crystalline product weighing 51.0 g (86%); mp 188–190°C; ir (Nujol): 3250, 1665, 1615, 1505 cm^{-1}. *Anal.* calcd. for $C_{23}H_{25}NO_3$: C 76.00, H 6.93, N 3.85; found: C 75.89, H 6.87, N 3.90.

*9b-Allyl-8-methoxy-3-methyl-2-oxo-2,3,5,9b-tetrahydro-1H-benz[e]indole **14**a*

A solution of 14.0 g (48.7 mmol) of **13***a* and 24 mg *p*-toluenesulfonic acid in 100 mL benzene was heated under reflux for 2 h with azeotropic distillation of water. After cooling to room temperature, the solution was washed with water and dried. Evaporation of the solvent gave 13.0 g (100%) of **14***a* as a pale yellow syrup;[2] ir (neat): 1725, 1685, 1615, 1505 cm^{-1}; nmr δ: 2.24 (d, 2H, allylic, J = 7.0 Hz), 2.75 (s, 2H, CH_2CO), 2.94 (s, 3H, NCH_3), 3.34 (m, 2H, benzylic), 3.75 (s, 3H, OCH_3), 4.75–5.85 (m, 4H, olefinic), 6.5–7.2 (m, 3H, ArH). *Anal.* calcd. for $C_{17}H_{19}NO_2$: C 75.80, H 7.11, N 5.20; found: C 75.93, H 7.10, N 5.19.

*3,9b-Dimethyl-8-methoxy-2-oxo-2,3,5,9b-tetrahydro-1H-benz[e]indole (**14**b)*

A solution of 11.25 g (43.2 mmol) of **13***b* and 25 mg *p*-toluenesulfonic acid in 100 mL toluene was heated under reflux for 2 h with azeotropic removal of water. After cooling to room temperature, the solution was washed with water and dried (Na_2SO_4). Removal of the solvent *in vacuo* and trituration of the residue with ether (20 mL) gave 9.5 g (90%) of crystalline **14***b*, mp 106–108°C; ir ($CHCl_3$): 1725, 1685 cm^{-1}; nmr δ: 1.27 (s, 3H, CH_3), 2.72 and 2.76 (s, 2H, CH_2CO), 2.95 (s, 3H, NCH_3), 3.34 (m, 2H, benzylic), 3.78 (s, 3H, OCH_3), 5.14 (d of d, 1H, NC=CH, J_1 = 5.0, J_2 = 3.5 Hz), 6.7–7.3 (m, 3H, ArH). *Anal.* calcd. for $C_{15}H_{17}NO_2$: C 74.04, H 7.04, N 5.75; found: C 74.28, H 7.06, N 5.89.

*9b-Allyl-8-benzyloxy-3-methyl-2-oxo-2,3,5,9b-tetrahydro-1H-benz[e]indole (**14**c)*

This compound was obtained quantitatively from **13***c* by the procedure described in the preparation of **14***a* and was used in the next step without further purification; ir (neat): 1725, 1685, 1610, 1505 cm^{-1}; nmr δ: 2.26 (d, 2H, allylic, J = 7.0 Hz), 2.78 (s, 2H, CH_2CO), 3.0 (s, 3H, HCH_3) 3.41 (m, 2H, benzylic), 4.8–5.8 (m, 5H, olefinic, $PhCH_2O$), 6.7–7.6 (m, 8H, ArH).

*9b-(3-Ethylenedioxy)butyl-8-methoxy-3-methyl-2-oxo-2,3,5,9b-tetrahydro-1H-benz[e]indole (**14**d)*

To a solution of 15.0 g (0.5 mol) of methylamine in 50 mL of ethanol was added 30.0 g (80 mmol) of **12***d* and the solution allowed to stand at room temperature for 49 h. Evaporation of the solvent, addition of benzene, and re-evaporation left **13***d* as a dark brown syrup. The crude product was dissolved in toluene, 50 mg *p*-toluenesulfonic acid was added, and the mixture heated under reflux for 1 h with azeotropic removal of water. The solvent was evaporated and the residue dissolved in ethanol (25 mL), the solution diluted with ether (120 mL), and the product allowed to crystallize at room temperature. The crystalline **14***d* was collected and weighed, 7.0 g. Evaporation of the filtrate left a residue which was dissolved in a small amount of methylene chloride and the solution passed through a sintered glass funnel packed with silica (6 cm long × 9.5 cm id). After washing with 4% ethanol – methylene chloride and evaporation of the eluate, the dark brown residue (14.0 g) was dissolved in ether (50 mL) and the product allowed to crystallize at room temperature. The crystalline precipitate was collected to give an additional 5.0 g of **14***d*. The mother liquor, after cooling to 0°C overnight, deposited an additional 1.0 g of **14***d*. The above crystalline crops were combined to provide a total of 13.0 g (48%) of **14***d*. Thin layer chromatography on silica (4% EtOH–CH_2Cl_2) showed one major spot and a trace of another with lower R_f value. Recrystallization from ethanol (35 mL) – ether (20 mL) gave 10.0 g of analytically pure **14***d*, mp 143–145°C; ir ($CHCl_3$): 1725, 1680, 1610, 1505 cm^{-1}; nmr δ: 1.18 (s, 3H, CH_3), 2.80 (s, 2H, CH_2CO), 3.0 (s, 3H, NCH_3), 3.80 (s, 7H, OCH_2CH_2O and

[2]On several occasions, this product developed a dark brown color on standing at room temperature. This could be prevented by washing an organic solution of the product with 3% aqueous HCl, an operation which led to discoloration.

OCH_3), 5.25 (d of d, 1H, NC=CH, J_1 = 3.5 and J_2 = 5.0 Hz), 6.70–7.35 (m, ArH). *Anal.* calcd. for $C_{20}H_{25}NO_4$: C 69.94, H 7.33, N 4.07; found: C 69.45, H 7.67, N 4.29.

9-Oxobenzomorphans. II. A versatile process for the synthesis of 9-oxo-6,7-benzomorphans

GERRY KAVADIAS,[1] STEPHAN VELKOF, AND BERNARD BELLEAU

Bristol Laboratories of Canada, 100 Industrial Boulevard, Candiac, P.Q., Canada J5R 1J1

Received December 20, 1978

GERRY KAVADIAS, STEPHAN VELKOF, and BERNARD BELLEAU. Can. J. Chem. **57**, 1861 (1979).

The synthesis of 5-allyl-2′-methoxy-2-methyl-9-oxo-, 2′-methoxy-2,5-dimethyl-9-oxo-, 5-allyl-2-cyclopropylmethyl-2′-methoxy-9-oxo-, and 5-(3-ethylenedioxy)butyl-2′-methoxy-3-methyl-9-oxo-6,7-benzomorphans (**5***a–d*) by an improved process is described. It involves bromination of the 5,9b-dihydrobenz[*e*]indolines to the bromoiminium bromides, followed by hydrolysis with ammonium bicarbonate which converted them to 4-bromo-5,9b-dihydrobenz[*e*]indolines (in a fast step). These underwent hydration (in a slow step) followed by rearrangement to **5***a–d*. The course of these reactions was different when sodium, potassium, and ammonium hydroxides were substituted for ammonium bicarbonate.

GERRY KAVADIAS, STEPHAN VELKOF et BERNARD BELLEAU. Can. J. Chem. **57**, 1861 (1979).

On décrit la synthèse, par un procédé amélioré, des allyl-5 méthoxy-2′ méthyl-2 oxo-9, méthoxy-2′ diméthyl-2,5 oxo-9, allyl-5 cyclopropylméthyl-2 méthoxy-2′ oxo-9 et (éthylènedioxy-3)-butyl-5 méthoxy-2′ méthyl-3 oxo-9 benzo-6,7 morphanes (**5***a–d*). Le procédé implique la bromation des dihydro-5,9b benz[*e*] indolines en bromures des bromoiminium, suivie par une hydrolyse à l'aide du bicarbonate d'ammonium qui les transforme en bromo-4 dihydro-5,9b benz[*e*] indolines (étape rapide). Celles-ci subissent une hydratation (étape lente) qui est suivie par une transposition en **5***a–d*. La nature des produits de ces réactions varie si l'on remplace le bicarbonate d'ammonium par des hydroxydes de sodium, de potassium ou d'ammonium.

[Traduit par le journal]

In the course of our studies on the synthesis of new analgesics structurally related to benzomorphans and morphinans, 9-oxo-6,7-benzomorphans with various substituents at 2-, 2′-, and 5-positions were needed. At the inception of this work, the best known method for the synthesis of such compounds was that developed by Murphy *et al.* (1, 2) as applied to the synthesis of 2′-methoxy-2,5-dimethyl-9-oxo-6,7-benzomorphan (**5***b*). This process involves in the ultimate step the pyrolysis of a quaternary salt such as the methobromide of **5***b*, and therefore the process is limited to the synthesis of substances that can survive the vigorous pyrolytic conditions. Furthermore, the method is limited to the synthesis of *N*-methyl substituted-9-oxobenzomorphans, and the substitution of *N*-methyl by other groups is a tedious task. The procedures employed in the benzomorphan series for the conversion of *N*-methyl benzomorphans to other *N*-substituted analogs involve demethylation of the parent compound by a variety of methods (3) followed by acylation and reduction (4, 5). This methodology cannot readily be applied to 9-oxocompounds.

Our need for 9-oxobenzomorphans carrying such substituents as allyl, benzyl, 3-ethylenedioxybutyl at the 5-position, as well as *N*-substituents such as methyl, cyclopropylmethyl, and cyclobutylmethyl, prompted us to develop a new synthetic methodology. The present report describes the synthesis of the desired compounds **5***a–d* by a process involving bromination of the indolines **1***a–d* to bromoiminium bromides **2***a–d*, followed by hydrolysis (Scheme 1).

After the completion of this work (in 1972), Takeda *et al.* (6) described a parallel approach to the synthesis of 9-oxobenzomorphans. However, in our hands, the process described by these authors was not generally applicable and led to low yields of products.

The 5,9b-dihydrobenz[*e*]indolines (enamines) **1***a–d* were prepared by our previously published methods (see Part I of this series (7)) and used immediately after their preparation. As expected on the basis of literature precedents (8), bromination of **1***a–d* yielded the bromoiminium bromides **2***a–d*. However, the yields and purity of the products were influenced by such factors as solvent, reaction temperature, and mode of mixing of the reagents. Thus, bromination of **1***a* in ether at −40°C by a described procedure (9) yielded a mixture of **2***a* and the hydrobromide salt of **1***a*, as evidenced by elemental analysis (low bromine content) and by the fact that the corresponding free base (after bicarbonate treatment) exhibited nmr absorption at δ 4.3 which is attributed to the proton at position-4 of **1***a*. Chlorinated solvents such as

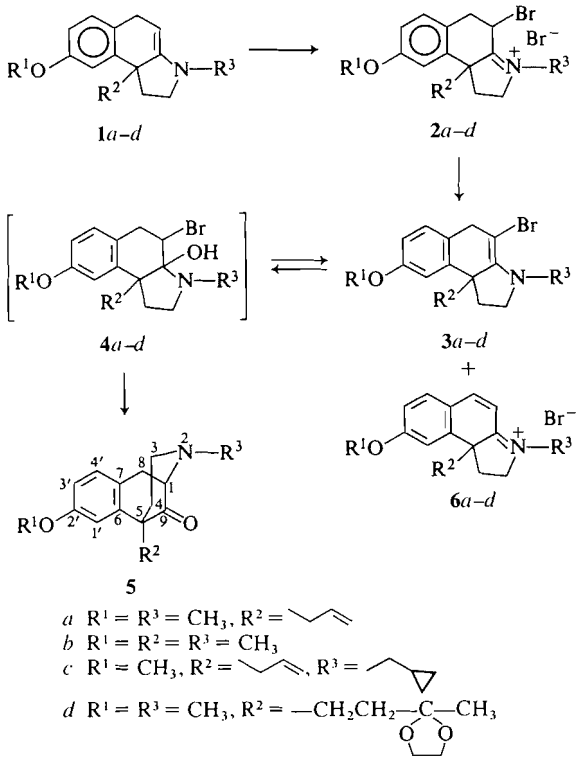
0008-4042/79/141861-05$01.00/0



SCHEME 1

carbon tetrachloride and chloroform gave good results but methylene chloride proved to be the solvent of choice for this bromination reaction. The best results were obtained when a solution of **1***a* in methylene chloride was rapidly added (in one portion) to a solution of bromine in the same solvent at −60°C. This procedure was followed for the bromination of **1***a–d*. Fast reversed mixing of the reagents at −60°C also gave good results. But if the bromine solution in methylene chloride was added dropwise to a solution of **1***a* in the same solvent the product was contaminated with the hydrobromide of **1***a*. Bromination of **1***b* in methylene chloride, by the above recommended procedure for the preparation of **2***a*, afforded crystalline **2***b* in quantitative yield. In an analogous manner, **1***c* was brominated to give crystalline **2***c* in 98% yield; under the same conditions, **1***d* afforded **2***d* as a syrup in 97% yield.

The structures of **2***a–d* which can be deduced from simple mechanistic considerations were confirmed by elemental analysis, and by nmr and ir spectroscopy. The parent enamines **1***a–d* exhibited nmr resonances at δ 4.3 for the proton at the 4-positions; these bands were eliminated after bromination. The ir spectra of **2***a–d* showed double bond absorption at 1660 cm^{-1} which was more intense and at a lower frequency than for the parent enamines **1***a–d* (1670 cm^{-1}), in agreement with previous observations with analogous compounds (10). There are two possible isomeric forms for each compound of the **2***a–d* series and apparently both are formed. Since both isomers can be converted to the corresponding 9-oxobenzomorphan (see mechanism below), no attempt was made to fractionate the mixtures although this was possible in certain cases.

The conversion of the bromoiminium salts **2***a–d* to 9-oxobenzomorphans **5***a–d* will now be discussed. It was anticipated that basic hydrolysis of **2***a–d* would initially form the carbinolamine A (Fig. 1) which could rearrange directly to **5***a–d* or rearrange via an intermediate bromoketone B (Fig. 1) followed by ring closure. The reported (11) conversion of α-bromoiminium bromides to α-aminoketals and α-aminoaminals by reaction with alkoxides and secondary amines respectively (eq. [1]) favors the first mechanistic possibility.

Treatment of **2***a* in aqueous ethanol with sodium, potassium, or ammonium hydroxide gave a product which contained only traces of **5***a* as evidenced by tlc and ir spectroscopy. When sodium or ammonium bicarbonate were used, **5***a* was produced in 35–65%

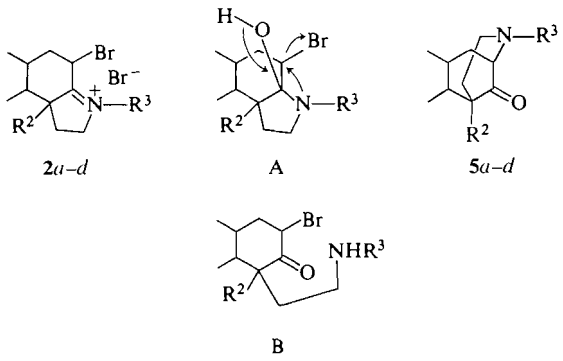


FIG. 1

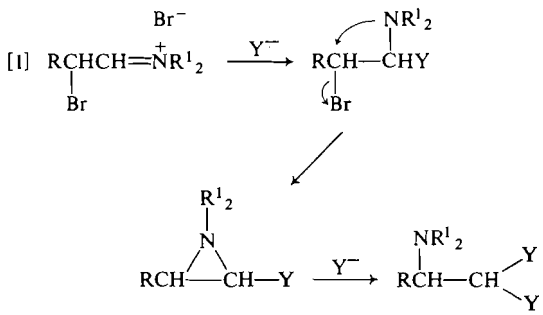
yields. A thorough investigation of the reaction conditions for maximum yields of **5***a* was therefore undertaken. The following variables were examined: the nature of the base (alkali hydroxides, carbonates, and bicarbonates), the mode of addition of the base,



the nature of the solvent, and finally the effects of temperature. The best yields (~64%) of **5***a* were obtained when an aqueous solution of 1 equiv. of ammonium bicarbonate was added slowly (1.5 h) to a solution of **2***a* in 95% ethanol at −10°C followed by stirring at room temperature for 24 h. This procedure was adopted for the conversion of compounds **2***a–d* to **5***a–d*. Thus, treatment of **2***b* with ammonium bicarbonate by this procedure produced **5***b*, isolated as the oxalate salt, in 58% yield. Similar treatment of **2***c* gave **5***c* (as the oxalate salt) in 50% yield. In an analogous manner, **2***d* was converted to **5***d* in 35.5% yield.

In the early stage of the basic hydrolysis reaction of **2***a–d* the bromoenamines **3***a–d* precipitated out, but gradually dissolved as the reaction progressed. The bromoenamine **3***a* was a crystalline solid and on one occasion it was isolated in 47% yield by rapid filtration under nitrogen. Compound **3***a* was very sensitive to air oxidation but could be stored under nitrogen for 2–3 days at room temperature before decomposing. The structural assignment for bromoenamine **3***a* was based on its solubility properties, its nmr and ir spectra, and its chemical behavior. It was soluble in ether and insoluble in water, unlike **2***a*. Its nmr spectrum lacked the band at δ 4.3 which is characteristic of the proton at the 4-position of enamine **1***a*; the ir spectrum showed strong C=C absorption at 1670 cm^{-1}. Furthermore, it gave rise to **5***a* when in contact with aqueous solvents.

Treatment of **2***a* with excess aqueous sodium bicarbonate gave **3***a* (55%) as an ether-soluble fraction together with a water-soluble compound extractable with chloroform. This latter fraction gave a positive test for bromide ion and showed strong C=C absorption in the ir at 1650 cm^{-1}. Treatment of this material with aqueous solvents did not produce **5***a*. On that basis, it would appear that **6***a* represents the structure of the secondary product. Accordingly, base treatment of **2***a–d* not only produces the bromoenamines **3***a–d*, which are the precursors of **5***a–d*, but also leads to dehydrohalogenation products **6***a–d* which are not convertible to **5***a–d*. The proportions of the two types of products depend on the nature of the base, strong ones yielding **6***a–d* as the major products. This may explain the low yields of **5***a* from **2***a* following treatment with sodium, potassium, or ammonium hydroxides.

It should be pointed out at this point that the results of Takeda *et al.* (6) on the conversion of **2***b* to **5***b* by treatment with ammonium hydroxide are at variance with our own observations. We therefore repeated this reaction under the exact conditions reported by these authors, but in our hands the yield of **5***b* was only 21% and isolation required chromatographic procedures. In the case of **5***a* the yield was vanishingly small.

In summary then, we have shown that the bromoiminium bromides **2***a–d* upon treatment with an appropriate weak base are rapidly converted to the expected bromoenamines **3***a–d* which react more slowly with water to give via intermediates **4***a–d* the desired and difficultly accessible 9-oxobenzomorphans **5***a–d* in fair to good yields.

Experimental

The melting points were determined on a Mel-Temp melting point apparatus and are uncorrected. The ir spectra were recorded on a Unicam Sp-200G grating spectrometer. The nmr spectra were recorded on a Varian A-60A spectrometer using deuteriochloroform as the solvent. The chemical shifts are expressed in δ values using tetramethylsilane as internal reference. Microanalyses were performed by Micro-Tech Laboratories Inc., Skokie, IL, U.S.A.

*9b-Allyl-4-bromo-8-methoxy-2,4,5,9b-tetrahydro-1*H*-benz*[e]*indole Methobromide (***2***a)*

To a stirred solution of 5.84 g (36.4 mmol) of bromine in 360 mL methylene chloride, previously cooled to −60°C (acetone – dry ice bath) under nitrogen, was added all at once a solution of 9.28 g (36.4 mmol) of the enamine **1***a* in 40 mL methylene chloride. After stirring at −60°C for 5 min, the cooling bath was removed and stirring continued for 20 min. Evaporation of the solvent gave 15.0 g (99%) of **2***a* as a sticky syrup which resisted crystallization; ir (Nujol): 1660 cm^{-1}. *Anal.* calcd. for $C_{17}H_{21}Br_2NO$: C 49.18, H 5.10, N 3.37, Br 38.49; found: C 51.79, H 5.53, N 3.69, Br 36.74.

This product was unstable at room temperature and was used without delay.

A sample of **2***a* was dissolved in water, sodium bicarbonate was added, and the solution extracted with ether. After drying and evaporation of the extract to dryness, **3***a* was obtained as a syrup; its nmr spectrum showed it to be free of the enamine **1***a* (no absorption at δ 4.3), thus showing that **2***a* was free of the hydrobromide salt of **1***a*.

Reverse rapid mixing of the reagents (bromine added in methylene chloride to the enamine solution in the same solvent at −60°C) also produced **2***a* uncontaminated by **1***a* hydrobromide.

In another experiment a 1 *M* solution of bromine in methylene chloride was added dropwise over a 20 min period to a 0.1 *M* solution of **1***a* in the same solvent at −60°C. After stirring at −60°C for 10 min and at room temperature for 15–20 min, the solvent was removed *in vacuo* to give **2***a*. Treatment of the crude **2***a* with sodium bicarbonate and extraction with ether gave **3***a* as a syrup contaminated to the extent of 15–20% with **1***a* as evidenced by nmr spectroscopy (small band at δ 4.3). This shows that **2***a* as obtained by this procedure was contaminated by **1***a* hydrobromide.

In another experiment, a 1 *M* solution of bromine in ether was added dropwise over a 5–10 min period to a 0.1 *M* solution of **1***a* in the same solvent at −40°C. The product thus obtained was an approximately 1:1 mixture of **2***a* and **1***a* hydrobromide as evidenced by elemental analysis (low bromine content) and by nmr spectroscopy (band at δ 4.3 for enamine **1***a*).

*4-Bromo-9b-methyl-8-methoxy-2,4,5,9b-tetrahydro-1*H*-benz*[e]*-indole Methobromide (***2***b)*

To a stirred solution of 9.4 g (58.6 mmol) of bromine in

600 mL methylene chloride at −60°C under nitrogen was added all at once a solution of 13.4 g (58.6 mmol) of the enamine **1***b* in 60 mL methylene chloride. After stirring at −60°C for 10 min the cooling bath was removed and stirring continued for another 20 min. Removal of the solvent by evaporation and trituration of the syrupy residue with ether gave 22.8 g (100%) of **2***b* as a crystalline mass. The analytical sample was prepared by recrystallization from ethanol; mp 125–127°C (lit. (6) mp 124–125°C); ir (Nujol): 1660 cm^{-1}. *Anal.* calcd. for $C_{15}H_{19}Br_2NO \cdot \frac{1}{2}H_2O$: C 45.24, H 5.06, Br 40.13, N 3.54; found: C 45.37, H 5.10, Br 39.15, N 3.51.

*9b-Allyl-4-bromo-8-methoxy-2,4,5,9b-tetrahydro-1*H*-benz*[e]*indole Cyclopropylmethobromide (2*c*)*

To a stirred solution of 11.9 g (74.5 mmol) of bromine in 750 mL methylene chloride at −60°C under nitrogen was added all at once a solution of 22.06 g (74.5 mmol) of the enamine **1***c* in 50 mL of the same solvent and the mixture stirred at −60°C for 10 min and at room temperature for 20 min. Removal of the solvent by evaporation left a solid residue which was triturated with ether (100 mL) and collected to give 33.0 g (98.5%) of **2***c*, mp 112–117°C; ir (Nujol): 1660 cm^{-1}. *Anal.* calcd. for $C_{20}H_{25}Br_2NO$: C 52.76, H 5.53, Br 35.10; found: C 52.65, H 5.48, Br 34.96.

This material was used as such in the next step.

An analytical sample was obtained by recrystallization from ethanol, mp 133–134°C. *Anal.* found: C 52.68, H 5.79, Br 35.05.

*9b-(3-Ethylenedioxy)butyl-4-bromo-8-methoxy-2,4,5,9b-tetrahydro-1*H*-benz*[e]*indole Methobromide (2*d*)*

Following the above procedure for **2***c*, treatment of the enamine **1***d* (3 g, 9.1 mmol) with bromine (1.46 g, 9.1 mmol) in methylene chloride gave 3.6 g (97%) of **2***d* as a solid which turned sticky when exposed to air; ir (Nujol): 1660 cm^{-1}. This material was used as such in the next step.

9b-Allyl-4-bromo-8-methoxy-3-methyl-5,9b-dihydrobenz[e]*indoline (3*a*) and Compound 6*a

To a stirred solution of 3.75 g (9.05 mmol) of **2***a* in 55 mL of 95% ethanol at −10°C under nitrogen was added dropwise 20 mL of a 0.5 *M* aqueous ammonium bicarbonate solution. After addition of the ammonium bicarbonate solution was completed (45 min), stirring at −10°C was continued for 30 min. The crystalline precipitate was collected by rapid filtration under a blanket of nitrogen, placed in a flask previously dried under high vacuum, and filled with nitrogen. The yellowish crystalline **3***a* thus obtained weighed 1.4 g (47%) and had mp 50–60°C (dec.); ir ($CHCl_3$): 1670 cm^{-1} (strong N—C=C); nmr ($CDCl_3$) δ: 1.85–2.35 (m, 4H, allylic and CH_2), 3.14 (s, 3H, NCH_3), 3.76 (s, 3H, OCH_3), 3.14–3.76 (m, 4H, benzylic and NCH_2—), 4.70–5.80 (m, 3H, olefinic), 6.50–7.15 (m, 3H, ArH).

Compound **3***a* was very sensitive to air oxidation and had to be kept under nitrogen. It was stable at room temperature for 2–3 days.

In another experiment, 3.4 g (8.2 mmol) of **2***a* was treated with 30 mL of 10% aqueous sodium bicarbonate and the mixture extracted with ether (5 × 40 mL). The ether extracts were dried and were evaporated to give 1.5 g (55%) of **3***a*, identical (ir and nmr) to the material obtained above.

The dark brown aqueous phase was extracted with chloroform (4 × 40 mL), the extracts dried and evaporated to give 1.0 g of a sticky dark brown residue; ir ($CHCl_3$): 1650 cm^{-1}. A test for bromine was positive.

*5-Allyl-2′-methoxy-2-methyl-9-oxo-6,7-benzomorphan (5*a*)*

A 250 mL three-neck flask fitted with mechanical stirrer, dropping funnel, and nitrogen inlet and outlet tubes, was charged with a solution of 8.05 g (19.4 mmol) of **2***a* in 170 mL of 95% ethanol, placed under a slow stream of nitrogen, and cooled to −10°C. To this stirred solution was added dropwise over a period of 1.5 h a solution of 1.58 g (20 mmol) of ammonium bicarbonate in 42 mL of water. A pale yellow crystalline precipitate (**3***a*) formed and after the addition of the ammonium bicarbonate solution was completed, the mixture was stirred in the cold for 2 h and at room temperature for 24 h under nitrogen. The dark brown mixture was concentrated *in vacuo* to about 50 mL, basified with 10% aqueous sodium bicarbonate (50 mL), and extracted with ether (3 × 50 mL). The combined extracts were washed with water (3 × 50 mL), dried, and evaporated to give 4.2 g of **5***a* as a syrup. It exhibited strong carbonyl absorption at 1730 cm^{-1} and a small band at 1670 cm^{-1} (enamine). The crude syrup **5***a* was dissolved in 20 mL dry acetone and added to a solution of 2.0 g anhydrous oxalic acid in 20 mL dry ether and the solution allowed to deposit crystals first at room temperature and then at 0°C overnight. The product was collected to give 4.12 g (58.5%) of **5***a* oxalate, mp 156–159°C. Recrystallization from 94% ethanol gave an analytical sample of the oxalate monohydrate, mp 115–120°C, resolidified and melted at 160–161°C (lit. (12) mp 160–161°C). *Anal.* calcd. for $C_{19}H_{23}NO_6H_2O$: C 60.15, H 6.64, N 3.69; found: C 60.09, H 6.68, N 3.56.

The yield of **5***a* was 64% after purification by chromatography on alumina (activity II) (methylene chloride as eluent).

The free base **5***a* was regenerated from its oxalate salt by base treatment and extraction with ether; ir (neat): 1730 cm^{-1}; nmr ($CDCl_3$) δ: 2.42 (s, 3H, NCH_3), 3.75 (s, 3H, OCH_3), 4.70–6.15 (m, 3H, olefinic), 6.60–7.15 (m, 3H, ArH).

The yield of **5***a* was not lowered appreciably when sodium bicarbonate or ammonium carbonate were used.

In other experiments the solution of sodium or ammonium bicarbonate was added all at once to the solution of **2***a*. This caused the yield of **5***a* to drop to 30–35%.

In DMSO–H_2O or DMF–H_2O as the solvents and ammonium bicarbonate as the base, the yields of **5***a* were 40–45%.

When sodium hydroxide was used as the base and aqueous ethanol as solvent **5***a* was formed in only trace amounts.

With ammonium hydroxide as the base using conditions described in the literature (6) for the preparation of **5***b*, the yield of **5***a* was negligible.

*2′-Methoxy-2,5-dimethyl-9-oxo-6,7-benzomorphan (5*b*)*

*(*a*) Using the Procedure Described Above for the Preparation of 5*a

A solution of 7.78 g (20 mmol) of **2***b* in 175 mL of 95% ethanol was treated with a solution of 1.64 g (20.6 mmol) of ammonium bicarbonate in 42 mL water. After stirring at room temperature for 24 h, the mixture was concentrated *in vacuo* to a small volume (~50 mL), treated with 10% aqueous sodium bicarbonate (50 mL), and extracted with ether (5 × 50 mL). The combined extracts were washed with water (2 × 50 mL), dried, and evaporated to give a syrupy residue (3.46 g) which was dissolved in 10 mL dry acetone and the solution added to a solution of 2.0 g anhydrous oxalic acid in 10 mL acetone. Crystals separated first at room temperature and then at 0°C overnight. The product was collected, washed with acetone (20 mL), and dried to give 3.91 g (58%) of the oxalate salt of **5***b*, mp 140–142°C. The free base **5***b* was quantitatively regenerated from its oxalate salt by treatment with ammonium hydroxide followed by extraction with chloroform; ir (neat): 1730 cm^{-1}; nmr ($CDCl_3$) δ: 1.36 (s, 3H, CH_3), 2.32 (s, 3H, NCH_3), 3.65 (s, 3H, OCH_3), 6.5–7.1 (m, 3H, ArH).

A sample of **5***b* in ether was treated with an ethereal solution of hydrogen chloride to give the hydrochloride salt of **5***b*. Recrystallization from 95% ethanol gave the hydrochloride of

the ethanol hemiacetal adduct of **5***b* (no C=O absorption in the ir; ethoxy absorption in the nmr spectrum); mp 122°C; resolidified and melted at 186–188°C. When the hydrochloride of **5***b* was recrystallized from aqueous acetone it gave the hydrochloride monohydrate, mp 130–132°C (lit. (6) 130–132°C).

(b) By the Process Described in the Literature (6)

Following the procedure given by Takeda *et al.* (6), 3.89 g (10 mmol) of **2***b* in methylene chloride was treated with aqueous ammonium hydroxide and the product isolated as described and purified by chromatography on alumina to give 0.51 g (21%) of **5***b*.

5-Allyl-2-cyclopropylmethyl-2'-methoxy-9-oxo-6,7-benzomorphan (5c)

The procedure described above for the preparation of **5***a* was used. Thus, a solution of 9.1 g (20 mmol) of **2***c* in 95% ethanol (170 mL) was treated with a solution of 1.7 g (21.5 mmol) ammonium bicarbonate in 21 mL of water. Initially, **3***c* precipitated as an oil. After stirring at room temperature for 48 h the oil had dissolved and the reaction mixture was concentrated *in vacuo* to a small volume (~50 mL), basified with 10% aqueous sodium bicarbonate (50 mL), and extracted with ether (4 × 50 mL). The combined extracts were washed with water, dried, and evaporated to give 4.6 g of **5***c* as a syrup. Thin layer chromatography on alumina (ether) showed one major spot with R_f 0.78 (**5***c*) and a minor one with R_f 0. The syrup **5***c* was dissolved in acetone (10 mL) and treated with a solution of 2.0 g anhydrous oxalic acid in acetone (10 mL) and the resulting solution diluted with dry ether (10 mL). The crystalline product was collected to give 4.0 g (50%) of the oxalate salt of **5***c*, mp 148.5–150°C. *Anal.* calcd. for $C_{22}H_{27}NO_6$: C 65.82, H 6.78, N 3.48; found: C 65.57, H 7.08, N 3.40.

The free base **5***c* was quantitatively regenerated from its oxalate salt by treatment with sodium hydroxide and extraction with ether; ir (neat): 1730 cm^{-1}.

The yield of **5***c* was reduced to 30% when the ammonium bicarbonate solution was added all at once to the solution of **2***c*.

5-(3-Ethylenedioxy)butyl-2'-methoxy-3-methyl-9-oxo-6,7-benzomorphan (5d)

The procedure described above for the preparation of **5***a* was followed. The bromoiminium bromide **2***d* (9.1 mmol) was treated with ammonium bicarbonate in 95% ethanol and after stirring at room temperature for 30 h the product was isolated as described above and purified by chromatography on silica using ether as the eluent to give 1.1 g (35.5%) of **5***d* as an oil; ir (neat): 1730 cm^{-1}; nmr ($CDCl_3$) δ: 1.40 (s, 3H, CH_3), 2.47 (s, 3H, NCH_3), 3.84 (s, 3H, OCH_3), 3.98 (s, 4H, OCH_2CH_2O), 6.7–7.2 (m, 3H, ArH). *Anal.* calcd. for $C_{20}H_{27}NO_4$: C 69.54, H 7.88, N 4.05; found: C 69.02, H 7.63, N 4.03.

9-Oxobenzomorphans. III. Synthesis of derivatives with various substituents at 2-, 2′-, and 5-positions

GERRY KAVADIAS,[1] STEPHAN VELKOF, AND BERNARD BELLEAU

Bristol Laboratories of Canada, 100 Industrial Boulevard, Candiac, P.Q., Canada J5R 1J1

Received December 20, 1978

GERRY KAVADIAS, STEPHAN VELKOF, and BERNARD BELLEAU. Can. J. Chem. 57, 1866 (1979).

5-Allyl-2-cyclobutylmethyl-2′-methoxy-, 5-allyl-2′-benzyloxy-2-methyl-, 5-benzyl-2′-methoxy-2-methyl-, and 5-allyl-2′-benzyloxy-2-cyclobutylmethyl-9-oxo-6,7-benzomorphans were prepared by a previously described process. The process involves bromination of the 5,9b-dihydrobenz[*e*]indolines to β-bromoiminium bromides followed by treatment with a weak base in aqueous organic solvents. Ammonium bicarbonate and aluminium oxide are effective bases for the conversions of the β-bromoiminium salts to 9-oxobenzomorphans **5***a–g*. The mechanism of the reaction involves formation of the bromoenamines (fast step) followed by hydration of the latter (slow step) and rearrangement to **5***a–g*.

GERRY KAVADIAS, STEPHAN VELKOF et BERNARD BELLEAU. Can. J. Chem. 57, 1866 (1979).

On a préparé par un procédé décrit antérieurement, les allyl-5 cyclobutylméthyl-2 méthoxy-2′, allyl-5 benzyloxy-2′ méthyl-2, benzyl-5 méthoxy-2′ méthyl-2 et allyl-5 benzyloxy-2′ cyclobutylméthyl-2 oxo-9 benzo-6,7 morphanes. Le procédé implique la bromation des dihydro-5,9b benz[*e*] indolines en bromures des β-bromoiminium suivie par une réaction avec une base faible dans des solvants organiques aqueux. Le bicarbonate d'ammonium et l'oxyde d'aluminium sont des bases efficaces pour la transformation des sels des β-bromoiminium en oxo-9 benzomorphanes **5***a–g*. Le mécanisme de la réaction implique la formation des bromoènamines (étape rapide) suivie par une hydratation de ces dernières (étape lente) et une transposition en **5***a–g*.

[Traduit par le journal]

The preceding papers of this series (1, 2) described the preparation of 9-oxo-6,7-benzomorphans by a process which involves bromination of the indolines **1** to bromoiminium bromides **2** followed by hydrolysis with aqueous ammonium bicarbonate (Scheme 1). The present paper is an extension of that work and describes the synthesis of the new 9-oxo-benzomorphans **5***a–d* by the same process. It also describes a novel and efficient way of converting the bromoiminium salts **2** to 9-oxobenzomorphans **5**, namely, by treatment with aluminium oxide.

The 5,9b-dihydrobenz[*e*]indolines (cyclic enamines) **1***a–g* were prepared as previously described (see Part I of this series (1)) and used without delay.

Bromination of the enamines **1***a–d* to the bromoiminium salts **2***a–d* was performed by the procedure previously developed (see Part II of this series (2)) and involves rapid mixing of a solution of the enamine in methylene chloride with a solution of an equimolar amount of bromine in the same solvent at −60°C. Thus, bromination of **1***a* produced crystalline **2***a* in 91% yield (Scheme 1). Bromination of **1***b* afforded **2***b* in quantitative yield as a syrup. Bromination of **1***c* and **1***d* gave **2***c* and **2***d* as crystalline products in 93% and 90% yields respectively. The structures of **2***a–d* as β-bromoiminium salts were confirmed by elemental analyses and by ir and nmr spectroscopy. The ir spectra of **2***a–d* showed strong C=C absorption at 1660 cm^{-1}, a frequency which is lower than that of the analogous absorption (1670 cm^{-1}) of the parent enamines **1***a–d* as would be expected (2, 3). The nmr spectra showed an absence of the signal at δ 4.3 which is characteristic for the proton at C-4 in the parent enamines **1***a–d*.

The conversion of the bromoiminium salts **2***a–c* to **5***a–c* was accomplished by the procedure described earlier (2) and involved treatment of **2***a–e* with ammonium bicarbonate in aqueous ethanol. More specifically, treatment of a solution of **2***a* in 95% ethanol with an aqueous solution of ammonium bicarbonate, first at −5 to 0°C for 2 h and then at room temperature for 48 h (method *A*), produced the 9-oxobenzomorphan **5***a* isolated in 55% yield as the oxalate salt. In an analogous manner, **2***b* was converted to **5***b* which was similarly isolated in 42% yield. Intermediate **2***c* was also converted to **5***c* which was separated by chromatography on alumina and obtained in 30% yield. As previously observed (2) in the early stage of the conversion of **2***a–c* to **5***a–c*, the bromoenamines **3***a–c* initially precipitated followed by slow dissolution as the hydration progressed to give **5***a–c*.

An effective alternative procedure for the conversion of the bromoiminium salts **2***a–g* to 9-oxoben-

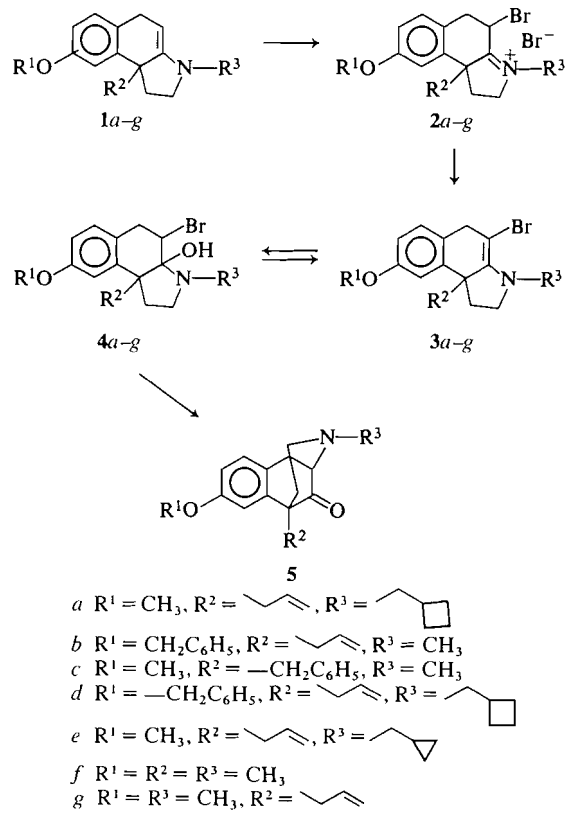

SCHEME 1

zomorphans **5***a–g* involved treatment of the salts with alumina in aqueous organic solvents at room temperatures for 24–48 h (method *B*). For instance, stirring a mixture of **2***e* and alumina (Merck, type E) (5 g Al_2O_3/g of **2***e*) in DMSO–water (3:1) for 24 h at room temperature produced **5***e* isolated in 66% yield as the oxalate salt. The yields at **5***e* were sensitive to solvent volume and the proportion of alumina. Similar treatment of the bromoiminium salts **2***c–g* with alumina under the same conditions gave the 9-oxobenzomorphans **5***c–g* in fair to good yields that were comparable to those obtained by the ammonium bicarbonate method (Table 1). The role of the aluminium oxide in this process is to convert the bromoiminium salts **2***a–g* to the bromoenamines **3***a–g* which then react with a mole of water to give ketones **5***a–g* via intermediates **4***a–g*. In fact, when a solution of **2***e* in chloroform was stirred with aluminium oxide for 5 min followed by rapid filtration under nitrogen, the intermediate bromoenamine **3***e* was produced in 80% yield as an air-sensitive oil. The same product was obtained when **2***e* was treated with sodium bicarbonate followed by extraction with ether. In the ir, compound **3***e* showed strong C=C absorption at 1670 cm^{-1} and when dissolved in DMSO–water was converted to **5***e*.

TABLE 1. Yields obtained by methods *A* and *B*

9-Oxobenzomorphan	Yield	
	Method *A*	Method *B*
5*a*	55[a]	
5*b*	42[a]	
5*c*	30[b]	25[b]
5*d*		51[a]
5*e*	50[a]	66[a]
5*f*	58[a]	58.5[a]
5*g*	58.5[a]	55[a]

[a]Isolated as the oxalate salt.
[b]Purified by chromatography.

Experimental

The melting points were determined on a Mel-Temp melting point apparatus and are uncorrected. The ir spectra were recorded on a Unicam Sp-200G grating ir spectrometer. The nmr spectra were recorded on a Varian A-60A spectrometer using deuteriochloroform as the solvent. The chemical shifts are expressed in δ values using tetramethylsilane as internal reference. Microanalyses were performed by Micro-Tech Laboratories Inc., Skokie, IL, U.S.A. All experiments with enamines (work-up, filtration, extraction, release of vacuum after evaporation, etc.) were carried out under a nitrogen atmosphere.

*9b-Allyl-4-bromo-8-methoxy-2,4,5,9b-tetrahydro-1H-benz[e]indole Cyclobutylmethobromide (***2a***)*

To a stirred solution of 5.18 g (32.4 mmol) of bromine in 325 mL of methylene chloride at −60°C under nitrogen was added all at once a solution of 10 g (32.4 mmol) of the enamine **1***a* in 40 mL methylene chloride. After stirring at −60°C for 5 min, the cooling bath was removed and the reaction mixture stirred for an additional 20 min. The solvent was evaporated and the solid residue recrystallized from acetone–ether (1:2, 75 mL) to give 13.8 g (91%) of **2***a*, mp 117–120°C; ir (Nujol): 1660 cm^{-1}. *Anal.* calcd. for $C_{21}H_{26}Br_2NO$: C 53.86, H 5.59, Br 34.12, N 2.99; found: C 53.88, H 5.85, Br 34.24, N 2.86.

*9b-Allyl-8-benzyloxy-4-bromo-2,4,5,9b-tetrahydro-1H-benz[e]indole Methobromide (***2b***)*

Following the above procedure for the preparation of **2***a*, the enamine **1***b* (51.2 g, 154 mmol) was reacted with bromine in methylene chloride to give 75.5 g (100%) of crude **2***b* as a syrup. The crude **2***b* was used in the next step without delay.

*9b-Benzyl-4-bromo-8-methoxy-2,4,5,9b-tetrahydro-1H-benz[e]indole Methobromide (***2c***)*

Following the preceding method for the preparation of **2***a*, the enamine **1***c* (14.0 g, 46.8 mmol) was reacted with bromine (7.4 g, 46 mmol) in methylene chloride (500 mL) at −60°C. Evaporation of the solvent and trituration of the residue with acetone–ether (60 mL, 1:1) gave 19.2 g (93%) of **2***c*, mp 103–106°C; ir (Nujol): 1660 cm^{-1}. *Anal.* calcd. for $C_{21}H_{23}Br_2NO$: C 54.21, H 4.98, Br 34.35; found: C 54.46, H 5.01, Br 34.08.

*9b-Allyl-8-benzyloxy-4-bromo-2,4,5,9b-tetrahydro-1H-benz[e]indole Cyclobutylmethobromide (***2d***)*

The enamine **1***d* (30.1 g, 78.2 mmol) was reacted with bromine (12.5 g, 160 mmol) in methylene chloride (850 mL) at

−60°C by the procedure described for **2***a*. Evaporation of the solvent left a solid residue which was triturated with acetone–ether (100 mL, 1:1) and collected to give 37 g (90%) of **2***d*, mp 109–112°C. A sample recrystallized twice from ethanol–ether (1:8) had mp 114–115°C; ir (Nujol): 1660 cm^{-1}. *Anal.* calcd. for $C_{27}H_{31}Br_2NO$: C 59.46, H 5.72, Br 29.30, N 2.56; found: C 59.64, H 5.88, Br 29.12, N 2.57.

*5-Allyl-2-cyclobutylmethyl-2′-methoxy-9-oxo-6,7-benzomorphan (***5***a). Method* A

5*a* was obtained from **2***a* by treatment with ammonium bicarbonate according to the previously described procedure (see Part II). To a stirred solution of 46.9 g (100 mmol) of **2***a* in 1 L 95% ethanol at −5° to 0°C under nitrogen was added dropwise over a 90 min period a solution of 8.5 g (108 mmol) of ammonium bicarbonate in 100 mL of water. After the addition was complete the reaction mixture was stirred in the cold for 2 h and then at room temperature for 48 h under nitrogen. In the early stage of the reaction, the bromoenamine **3***a* precipitated as an oil which slowly dissolved as the reaction progressed. The solvent was evaporated, the residue treated with 8% aqueous sodium bicarbonate (300 mL), and the mixture extracted with ether (4 × 200 mL). The combined extracts were washed with water, dried, and evaporated to give a residue which after chromatography on alumina (activity II) using methylene chloride as the eluent gave 20 g of **5***a* as an oil. It was dissolved in 60 mL dry acetone and the solution added to a solution of 10 g anhydrous oxalic acid in the same solvent (50 mL) and diluted with 40 mL of anhydrous ether. The crystalline product was collected, washed with acetone, and dried to give 23 g (55%) of the oxalate salt of **5***a*, mp 182–182.5°C. *Anal.* calcd. for $C_{23}H_{29}NO_6$: C 66.48, H 7.03, N 3.37; found: C 66.72, H 6.99, N 3.25.

The free base was regenerated from the oxalate salt by treatment with sodium hydroxide and extraction with ether; ir (neat): 1730 cm^{-1}; nmr ($CDCl_3$) δ: 3.75 (s, 3H, OCH_3), 4.85–6.15 (m, 3H, olefinic).

*5-Allyl-2′-benzyloxy-2-methyl-9-oxo-6,7-benzomorphan (***5***b)*

Following the procedure described above for the preparation of **5***a* (method *A*), crude **2***b* (17.2 g, 35 mmol) was treated with ammonium bicarbonate in aqueous ethanol and the product isolated as above to yield **5***b* (10.7 g) as an oil. This crude material was dissolved in anhydrous ether and treated with a solution of anhydrous oxalic acid in the same solvent. The oxalate salt thus obtained was recrystallized from ethanol (10 mL) – acetone (40 mL) to yield 6.7 g (42%) of the oxalate monohydride salt of **5***b*, mp 104–107°C. *Anal.* calcd. for $C_{25}H_{27}NO_6 \cdot H_2O$: C 65.91, H 6.41, N 3.07; found: C 65.15, H 6.41, N 2.89.

The free base **5***b* was regenerated from its oxalate salt by treatment with sodium hydroxide and extraction with ether; ir (neat): 1730 cm^{-1}; nmr ($CDCl_3$) δ: 2.40 (s, 3H, NCH_3), 4.90 (s, 2H, $PhCH_2O$), 4.85–6.15 (m, 3H, olefinic), 6.60–7.30 (m, 8H, ArH).

*5-Allyl-2-cyclopropylmethyl-2′-methoxy-9-oxo-6,7-benzomorphan (***5***e). Method* B

5*e* was obtained from **2***e* by treatment with aluminium oxide. To a solution of 5 g (11 mmol) of **2***e* in DMSO–water (3:1) (50 mL) was added 25 g aluminium oxide G (Merck, type E), the mixture blanketed with nitrogen, and stirred at room temperature. After 24 h the mixture was filtered and the alumina washed first with ethanol (2 × 15 mL) and then with water (2 × 20 mL). The filtrate and washings were combined, diluted with water (50 mL), treated with 8% aqueous sodium bicarbonate (50 mL), and extracted with ether (4 × 50 mL). The combined extracts were washed with water (3 × 50 mL) dried, and evaporated to give 2.7 g of **5***e* as a syrup. It was dissolved in 20 mL dry acetone, treated with a solution of 1.2 g anhydrous oxalic acid in 5 mL of the same solvent, and the solution diluted with 15 mL dry ether. The crystalline precipitate was collected to give 2.72 g (62%) of the oxalate salt of **5***e*, mp and mixture mp with an authentic sample (Part II of this series) 148–150°C.

On a larger scale experiment (43 g of **2***e*) the above procedure led to the oxalate salt of **5***e* in 58% yield.

When the amount of aluminium oxide was reduced (2 g of Al_2O_3/g of **2***e*) the yield of the oxalate salt of **5***e* was 53%, whereas an increase in solvent volume to 20 mL/g of **2***e* raised the yield to 66%.

The free base of **5***e* was quantitatively regenerated from its oxalate salt (sodium hydroxide – ether) and was identical in all respects to an authentic sample (Part II of this series).

*5-Benzyl-2′-methoxy-2-methyl-9-oxo-6,7-benzomorphan (***5***c)*

(a) From **2***c by Treatment with Ammonium Bicarbonate (Method* A*)*

Following the above method for the preparation of **5***a* (method *A*), a solution of 6.97 g (15 mmol) of **2***c* in 200 mL of 95% ethanol was treated with a solution of 1.28 g (16.2 mmol) of ammonium bicarbonate in 20 mL water and the reaction mixture stirred at room temperature for 72 h. At first, the bromoenamine **3***c* precipitated and gradually dissolved as the reaction progressed. Work-up of the mixture as described for **5***a* gave 2.4 g of crude **5***c* as a syrup, which after chromatography on alumina (activity II) using 1% ethanol in methylene chloride as the eluent gave 1.4 g (30%) of **5***c*, mp 136.5–137.5°C (ethanol); ir ($CHCl_3$): 1730 cm^{-1}; nmr ($CDCl_3$) δ: 2.40 (s, 3H, NCH_3), 3.35 (s, 2H, $ArCH_2$), 3.65 (s, 3H, OCH_3), 6.6–7.2 (m, 3H, ArH). *Anal.* calcd. for $C_{21}H_{23}NO_2$: C 78.47, H 7.21, N 4.36; found: C 78.42, H 7.28, N 4.30.

(b) From **2***c by Treatment with Aluminium Oxide (Method* B*)*

Following method *B* above for the preparation of **5***e*, a mixture of 4.65 g (10 mmol) of **2***c* and 23 g aluminium oxide in 90 mL 85% DMSO–water was stirred at room temperature for 48 h. The crude product (2.7 g) was chromatographed on alumina (as in part *a* above) to give 0.8 g (25%) of **5***c* identical in every respect with the product obtained above (Method *A*).

*5-Allyl-2′-benzyloxy-2-cyclobutylmethyl-9-oxo-6,7-benzomorphan (***5***d). Method* B *Above*

To a solution of 5.45 g (10 mmol) of **2***d* in 115 mL of DMSO–water (3:1) was added 25 g aluminium oxide and the mixture stirred under nitrogen at room temperature for 72 h. The mixture was filtered and the solids washed with ethanol (2 × 15 mL) and with water (2 × 20 mL). The combined filtrate and washings were diluted with 250 mL of water, the solution basified with 8% aqueous sodium bicarbonate (50 mL), and extracted with ether (5 × 60 mL). The combined extracts were washed with water (3 × 60 mL), dried, and evaporated to give 3.0 g of **5***d* as a syrup. It was dissolved in dry acetone (10 mL), a solution of 1.2 g anhydrous oxalic acid in the same solvent (20 mL) was added, and the solution diluted with dry ether (30 mL). The crystalline product was collected to give 2.5 g (51%) of the oxalate salt of **5***d*, mp 165–167°C.

The free base **5***d* was quantitatively regenerated from its oxalate salt by treatment with sodium hydroxide and extraction with ether; ir (neat): 1730 cm^{-1}; nmr ($CDCl_3$) δ: 5.05 (s, 2H, $ArCH_2O$), 5.85–6.15 (m, 3H, olefinic), 6.85–7.50 (m, 8H, ArH).

The hydrobromide salt of **5***d* had mp 198–199°C (ethanol–ether). *Anal.* calcd. for $C_{27}H_{31}NO_2 \cdot HBr$: C 67.21, H 6.68, N 2.90; found: C 67.07, H 6.83, N 3.01.

2′-Methoxy-2,5-dimethyl-9-oxo-6,7-benzomorphan (5f). (Method B for 5e)

A mixture of 3.89 g (10 mmol) of **2***f* and 23 g aluminium oxide in 90 mL DMSO–water (3:1) was stirred under nitrogen for 24 h, filtered, the solids washed with ethanol (2 × 15 mL) and then water (2 × 20 mL). The combined filtrate and washings were diluted with water (250 mL), basified with 8% aqueous sodium bicarbonate (50 mL), and extracted with ether (7 × 50 mL). The combined extracts were washed with water (2 × 50 mL), dried, and evaporated to give a liquid residue (1.74 g) which was dissolved in 5 mL dry acetone and a solution of 1.0 g anhydrous oxalic acid in 5 mL acetone added. The crystalline product was collected to give 1.97 g (58.5%) of the oxalate salt of **5***f*, mp and mixture mp with an authentic sample (Part II of this series), 130–132°C.

5-Allyl-2′-methoxy-2-methyl-9-oxo-6,7-benzomorphan (5g). (Method B for 5e)

A mixture of 3.78 g (9.08 mmol) of **2***g* and 20 g of aluminium oxide in 40 mL DMSO–water (3:1) was stirred at room temperature under nitrogen for 24 h. Work-up as in **5***e* gave 1.7 g of **5***g* as a syrup which was dissolved in 10 mL dry acetone and a solution of 1.0 g anhydrous oxalic acid in 10 mL dry ether added. The crystalline precipitate was collected to give 1.8 g (55%) of the oxalate salt of **5***g*, mp and mixture mp with an authentic sample (2) 156–159°C.

9b-Allyl-4-bromo-8-methoxy-3-cyclopropylmethyl-5,9b-dihydrobenz[e]indoline (3e)

(a) From 2e by Treatment with Ammonium Bicarbonate

To a solution of 1.0 g (2.2 mmol) of **2***e* in 15 mL water was added 10 mL of 8% aqueous sodium bicarbonate and the solution extracted quickly with ether (3 × 20 mL) under nitrogen. Removal of the solvent *in vacuo* gave 0.5 g (61%) of the air-sensitive **3***e*; ir (neat): 1670 cm^{-1}.

(b) From 2e by Treatment with Alumina

To a solution of 1.0 g (2.2 mmol) of **2***e* in 50 mL chloroform was added 10 g of alumina (activity II) and the mixture stirred for 5 min under nitrogen followed by filtration under a blanket of nitrogen. Evaporation of the solvent left 0.65 g (80%) of **3***e* as an air-sensitive light brown liquid; ir (neat): 1670 cm^{-1}. When left in DMSO–water (3:1) or 95% ethanol at room temperature for 24 h, **3***e* was converted to 9-oxobenzomorphan **5***e*.

Aminocyclitols. III. Synthesis of diaminocyclohexanediols

GERRY KAVADIAS[1] AND ROBERT DROGHINI

Bristol Laboratories of Canada, 100 Industrial Boulevard, Candiac, P.Q., Canada J5R 1J1

Received December 1, 1978

GERRY KAVADIAS and ROBERT DROGHINI. Can. J. Chem. **57**, 1870 (1979).

Reaction of *N,N'*-diethoxycarbonyl-2,5-dideoxystreptamine (**1***b*) with thionyl chloride produced the iminoether dihydrochloride **8** which, upon simple treatment with water gave the di-*N,O*-carbonyl compound **9**. Acidic hydrolysis of **9** yielded the aminocyclitol **2***a*. Alternatively, **2***a* was prepared from *N,N'*-dibenzoyl-2,5-dideoxystreptamine (**1***c*) via the oxazoline **10** followed by acidic hydrolysis. Treatment of **1***c* with triethyl orthoacetate in the presence of boron trifluoride etherate produced the oxazoline **11** and the latter product was hydrolyzed to give **3***a*. By the same reaction sequence, **1***e* and **1***h* were converted to the oxazolines **12** and **13** which upon acidic hydrolysis provided the enantiomeric aminocyclitols **4** and **5**. Ring-opening reactions of *cis*- and *trans*-1,4-diepoxycyclohexanes (**14** and **16**) with sodium azide to the diazido compounds **15** and **17**, followed by reduction, afforded the aminocyclitols **6** and **7**.

GERRY KAVADIAS et ROBERT DROGHINI. Can. J. Chem. **57**, 1870 (1979).

La réaction de la *N,N'*-diéthoxycarbonyldidéoxy-2,5 streptamine (**1***b*) avec le chlorure de thionyle fournit le dichlorure de l'iminoéther (**8**) qui, par un traitement simple avec de l'eau, conduit au composé di-*N,O*-carbonyle **9**. Une hydrolyse acide de **9** fournit l'aminocyclitol **2***a*. On peut préparer **2***a* par une autre voie à partir de la *N,N'*-dibenzoyl didéoxy-2,5 streptamine (**1***c*) par l'intermédiaire de l'oxazoline **10** après une hydrolyse acide. Si l'on traite **1***c* par de l'orthoacétate de triéthyle en présence de l'éthérate de trifluorure de bore on obtient l'oxazoline **11** qui, par hydrolyse, conduit à **3***a*. Par la même suite de réaction, on a pu transformer **1***e* et **1***h* en oxazolines **12** et **13**, qui, par hydrolyse acide, donnent respectivement naissance aux aminocyclitols énantiomères **4** et **5**. Les réactions d'ouverture de cycle des diépoxy-1,4 cyclohexanes *cis* et *trans* (**14** et **16**) par l'azoture de sodium fournissent les diazotures **15** et **17** qui, par réduction, conduisent aux aminocyclitols **6** et **7**.

[Traduit par le journal]

In the previous papers of this series (1, 2) we have reported the syntheses of several aminocyclitols and their derivatives to be used as substrates in chemical and biochemical studies related to the synthesis of novel aminocyclitol antibiotics.

The present paper describes the syntheses of the aminocyclitols **2**–**7** (Fig. 1) and their derivatives and provides evidence for their assigned structures.

The readily available 2,5-dideoxystreptamine (**1***a*) (1) served as the starting material for the preparations of the aminocyclitols **2**–**5**. Thus, treatment of **1***a* with ethyl chloroformate in aqueous methanol, in the presence of sodium bicarbonate, gave *N,N'*-diethoxycarbonyl-2,5-dideoxystreptamine (**1***b*) in high yield. Reaction of **1***b* with an excess of thionyl chloride at the reflux temperature for 2 h produced the iminoether dihydrochloride **8** which on simple treatment with water gave a 74% yield of di-*N,O*-carbonyl-(1,3,4,6/0)-4,6-diamino-1,3-cyclohexanediol (**9**). Acidic hydrolysis (acetic acid – hydrochloric acid) of **9** afforded the dihydrochloride salt of (1,3,4,6/0)-4,6-diamino-1,3-cyclohexanediol (**2***a*) in 90% yield (Scheme 1). Alternatively, **2***a* was prepared from *N,N'*-dibenzoyl-2,5-dideoxystreptamine (**1***c*) via the oxazoline **10** and acidic hydrolysis. Thus, treatment of **1***c* with thionyl chloride by our previously described procedure (2), afforded a 72% yield of the oxazoline **10**. When **10** was treated with a dilute acid solution for a short period of time and the product neutralized with base, (1,3,4,6/0)-4,6-dibenzamido-1,3-cyclohexanediol (**2***b*) was obtained in 90% yield. Treatment of **10** with a concentrated acid solution (acetic acid – hydrochloric acid 1:1) at the reflux temperature, afforded a 49% yield of **2***a* dihydrochloride. Structural assignment to **2***a* was based on mechanistic considerations (two independent syntheses) and was further confirmed by ^{1}Hmr spectroscopy. The ^{1}Hmr spectrum of **2***a* dihydrochloride exhibited a two-proton eight-line multiplet at δ 3.60 with coupling constants of 10.5, 6, and 3 Hz which were ascribed to the magnetically equivalent N—C—H protons. The coupling pattern and the coupling constant magnitudes show that the two N—C—H protons are axially oriented and each one coupled with a neighboring axial and two neighboring equatorial protons. It also showed a two-proton five-line multiplet at δ 4.20 with coupling constants of 6, 6, and 3 Hz, assigned to the magnetically equivalent O—C—H protons, thus indicating that these protons are equatorially oriented and each coupled with

[1]To whom correspondence should be addressed.

0008-4042/79/141870-07$01.00/0

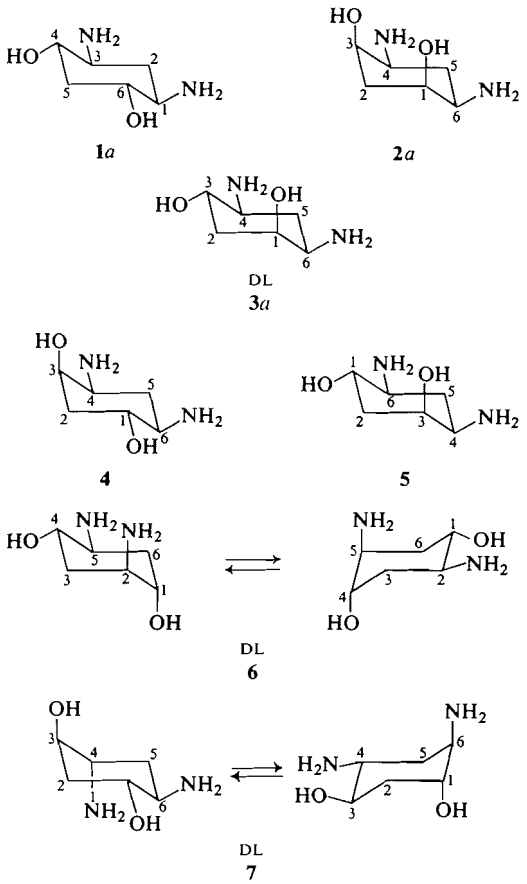

FIG. 1

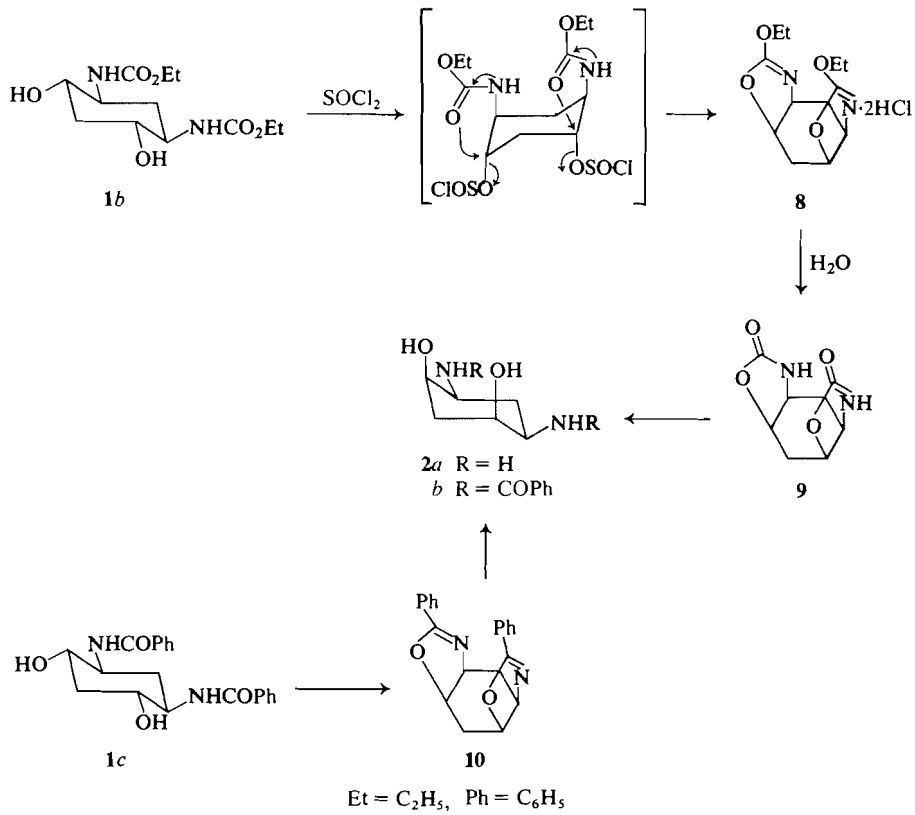
two axial and one equatorial adjacent protons. This spectral data confirms the all-*cis*-configuration for **2***a* dihydrochloride and further indicates that the preferred conformation of the molecule is the one where the two amino groups are in equatorial and the two hydroxyls in axial orientations, with little or no ring inversion.

DL-(1,4,6/3)-4,6-Diamino-1,3-cyclohexanediol (**3***a*) and the enantiomers **4** and **5** were prepared by the reaction sequences outlined in Scheme 2. Treatment of *N*,*N*′-dibenzoyl-2,5-dideoxystreptamine (**1***c*) with triethyl orthoacetate in dimethylformamide in the presence of boron trifluoride etherate by the procedure we have previously described (2) produced the oxazoline **11** in 75% yield. Upon mild acidic hydrolysis, the oxazoline **11** was converted to DL-(1,4,6/3)-4,6-dibenzamido-1,3-cyclohexanediol (**3***b*) in 90% yield. When **11** was refluxed in a concentrated acid solution (AcOH–HCl), an 85% yield of **3***a* dihydrochloride was obtained. The stereochemical assignment to **3***a* was supported by ^{1}Hmr spectroscopy. The ^{1}Hmr spectrum of **3***a* dihydrochloride exhibited signals due to the four nonequivalent ring methine protons which were interpretable by a first-order method. Thus, a double triplet at δ 3.26 having coupling constants of 11, 11, and 4 Hz was ascribed to the axial H-4 proton (N—C—H) indicating that this proton was coupled with two axial and one equatorial adjacent protons. An eight-line multiplet at δ 3.57 with coupling constants of 12, 5, and 3 Hz was ascribed to the axial H-6 proton (N—C—H), coupled with one axial and two equatorial neighboring protons. The spectrum also showed a double triplet at δ 4.06 ($J_{2a,3} = J_{3,4} = 11$ Hz, $J_{2e,3} = 5$ Hz) due to the axial H-3 (O—C—H) and a five-line multiplet at δ 4.26 ($J_{1,2a} = J_{1,6} = 5$ Hz, $J_{1,2e} = 3$ Hz) due to the equatorial H-1 proton. This spectral data is in complete accord with the 1,4*N*,6*N*/3 stereochemistry of **3***a*. Attempts to resolve racemic **3***a* were unsuccessful.

The optical isomers **4** and **5** were prepared as follows. 1-*N*-Ethoxycarbonyl-2,5-dideoxystreptamine (**1***d*) of known absolute configuration (1), was *N*-benzoylated to produce 3-*N*-benzoyl-1-*N*-ethoxycarbonyl-2,5-dideoxystreptamine (**1***e*). Treatment of **1***e* with triethyl orthoacetate in DMF containing boron trifluoride etherate gave a 78.5% yield of the oxazoline **12** (2) which, on acidic hydrolysis, produced (1*R*,3*R*,4*S*,6*R*)-4,6-diamino-1,3-cyclohexanediol (**4**) dihydrochloride in 72% yield. In a similar manner, 3-*N*-ethoxycarbonyl-2,5-dideoxystreptamine (**1***f*) (1) (the enantiomer of **1***d*) was *N*-benzoylated and the product **1***h* was treated with triethyl orthoacetate in DMF in the presence of boron trifluoride etherate to produce the oxazoline **13** (88%). Acidic hydrolysis of **13** gave a 75% yield of (1*S*,3*S*,4*R*,6*S*)-4,6-diamino-1,3-cyclohexanediol (**5**) dihydrochloride, identical with **4** dihydrochloride in all respects except optical activity. The ^{1}Hmr spectra of **4** and **5** were identical to that of the racemic products **3***a* discussed above, thus confirming the stereochemical assignments to these products.

The preparation of the aminocyclitols **6** and **7** was carried out via ring-opening of the diepoxides **14** and **16** with sodium azide to the diazido compounds **15** and **17**, followed by reduction (Scheme 3). Thus, treatment of *cis*-1,4-diepoxycyclohexane **14** with an excess of sodium azide in a DMSO–water mixture in the presence of *p*-toluenesulfonic acid at 70°C for 22 h, gave a 67% yield of (1,4/2,5)-2,5-diazido-1,4-cyclohexanediol (**15**). Catalytic hydrogenation of **15** with palladium on carbon afforded (1,4/2,5)-2,5-diamino-1,4-cyclohexanediol (**6**) in 84% yield. The assignment of the 1,4/2*N*,5*N* stereochemistry to **6**, was based upon the mechanism of the reactions involved in its synthesis and the ^{1}Hmr spectrum of this material. Since *trans* opening of the epoxide rings by



SCHEME 1

nucleophiles is assumed, the *cis* diepoxide **14** should produce (via respective diazido compounds) the isomeric aminocyclitols **6** and (or) the known product **1***a*. The physical and spectral properties exhibited by **6** were different from those of **1***a* and therefore its structure could be deduced by elimination. The ^{1}Hmr spectrum of **6** exhibited a two-proton quartet at δ 2.93 with a coupling constant of 6 Hz assigned to the two equivalent N—C—H protons. It also showed a two-proton quartet at δ 3.66 with a coupling constant of 6 Hz assigned to the two equivalent O—C—H protons. The appearance of both the N—C—H and O—C—H signals as quartets was taken as evidence for time averaging of the axial and equatorial protons in these positions by ring inversion and confirmed the assigned structure to this product. Treatment of *trans*-1,4-diepoxycyclohexane (**16**) with sodium azide, as described above for the preparation of **15**, gave a 70% yield of (1,4/3,6)-4,6-diazido-1,3-cyclohexanediol (**17**) which upon catalytic reduction afforded (1,4/3,6)-4,6-diamino-1,3-cyclohexanediol (**7**) in 82% yield. The ^{1}Hmr spectrum of **7** revealed a two-proton quartet at δ 3.71 for the O—C—H protons, both with coupling constants of 6 Hz. These spectral data indicate a time averaging of the axial and equatorial protons in these positions as a result of rapid ring inversion and confirms the 1,4*N*/3,6*N* stereochemistry for **7**.

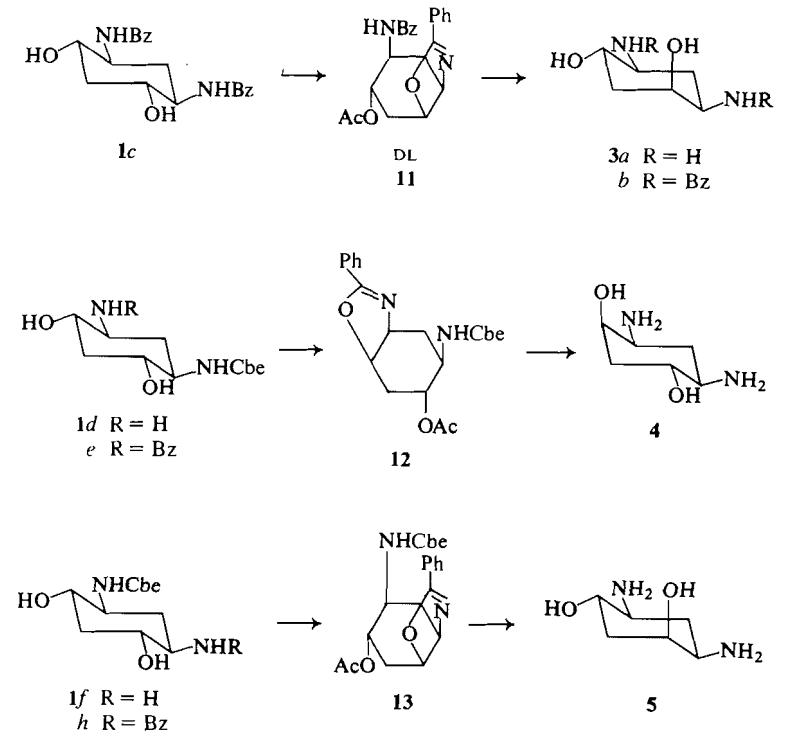
The ring-opening reactions of the *cis*- and *trans*-diepoxides **14** and **15** with sodium azide to the diazido products **15** and **17**, respectively, are in accord with previous reports on the stereochemical course of the ring-opening reactions of these compounds with other nucleophiles and confirm the *trans* and diaxial opening (3, 4).

Experimental

The melting points were determined on a Mel-Temp melting point apparatus and are not corrected. The ir spectra were recorded on a Unicam SP-200G grating ir spectrometer. The ^{1}Hmr spectra were taken with a Varian EM-360A 60 MHz spectrometer. The chemical shifts are expressed in δ values using tetramethylsilane (for solutions other than deuterium oxide) and sodium 4,4-dimethyl-4-silapentane-1-sulfonate (for solutions of deuterium oxide) as internal standards. Thin-layer chromatography (tlc) was carried out on microscope slides coated with silica gel. Optical rotations were measured with a Perkin-Elmer model 141 polarimeter. The analyses were performed by Micro-Tech Laboratories, Skokie, IL.

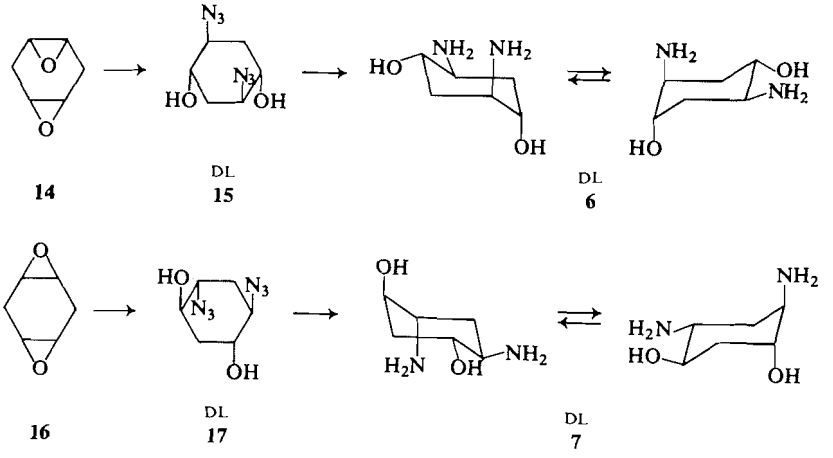
N,N′-*Diethoxycarbonyl-2,5-dideoxystreptamine* (*1b*)

A solution of 24.6 g (150 mmol) of 2,5-dideoxystreptamine monohydrate (**1***a*) (1) and 46 g (0.55 mol) of sodium bicar-



Ac = $COCH_3$, Bz = COC_6H_5, Cbe = $CO_2C_2H_5$, Ph = C_6H_5,

SCHEME 2



SCHEME 3

bonate in 500 mL of water was diluted with 30 mL of methanol and cooled in an ice-bath while stirring. Ethyl chloroformate (54 g or 0.5 mol) was added dropwise and at a rate to maintain the solution temperature below 20°C. After completion of the addition (5 min), stirring was continued at 4–6°C for 30 min and then at room temperature for 3 h. The reaction mixture was evaporated and the residue was dissolved in water (400 mL) and extracted continuously with ethyl acetate until all the product **1***b* was extracted (48 h). Compound **1***b* crystallized in the ethyl acetate extract and was collected by filtration to give 40.9 g (94%), mp 197–199°C. The analytical sample was obtained by recrystallization from ethanol, mp 204–205°C; ir (Nujol): 3320, 1695, 1545 cm^{-1}. *Anal.* calcd. for $C_{12}H_{22}N_2O_6$: C 49.64, H 7.64, N 9.65; found: C 49.58, H 7.70, N 9.61.

N,N′-*Dibenzoyl-2,5-dideoxystreptamine (1c)*

To an ice-cold solution of 17.8 g (122 mmol) of 2,5-dideoxystreptamine (**1***a*) and 35 g (330 mmol) of sodium carbonate in 210 mL water and 70 mL methanol was added dropwise

(15 min), with stirring, a solution of 44.4 g (305 mmol) of benzoyl chloride in 70 mL of dry acetone. After stirring at 0°C for 30 min and at room temperature for 1 h, the reaction mixture was diluted with water (400 mL). The resulting precipitate was collected by filtration, washed successively with water (2 × 130 mL), ethanol (100 mL), and ether (2 × 130 mL), and dried to give 40.8 g of **1***c*, mp 278–282°C. This product was stirred in boiling ethanol and filtered to give 39.0 g (90%) of **1***c*, mp 280–282°C (dec.). This material was used in the next reaction. The analytical sample was prepared by recrystallization from DMF–EtOH (1:1); mp 283–285°C, resolidified and melted at 294–295°C; ir (Nujol): 3400, 3300, 1625, 1615, 1575, 1565 cm^{-1}. *Anal.* calcd. for $C_{20}H_{22}N_2O_4$: C 67.78, H 6.25, N 7.90; found: C 67.70, H 6.26, N 8.03.

*3-N-Benzoyl-1-N-ethoxycarbonyl-2,5-dideoxystreptamine (**1**e)*

To a solution of 7.81 g (35.6 mmol) of 1-*N*-ethoxycarbonyl-2,5-dideoxystreptamine (**1***d*) and 5.04 g (60 mmol) of sodium bicarbonate in 40 mL water was added 40 mL of acetone and 5 mL of methanol and the mixture was cooled in an ice-bath while stirring. A solution of 7.03 g (50 mmol) of benzoyl chloride in 15 mL of dry acetone was added dropwise. After the addition (15 min), the reaction mixture was stirred at room temperature for 1.5 h and then evaporated *in vacuo*. The residue was treated with water (50 mL) and the solid product collected by filtration, washed with water (2 × 30 mL) and ether (50 mL), and dried first at room temperature, then at 100°C, to give 8.90 g of **1***e*, mp 254–256°C. The aqueous filtrate was extracted continuously with ethyl acetate to give 2.2 g of **1***e*, mp 254–256°C. The two crops were combined to a total of 11.1 g (96.5%). A sample was recrystallized from ethanol–ether (1:3), mp 240–245°C, resolidified and melted at 254–256°C; $[\alpha]_D^{25}$ −18.6 (*c* 0.8, EtOH); ir (Nujol): 3350, 1700, 1650, 1550 cm^{-1}. *Anal.* calcd. for $C_{16}H_{22}N_2O_5 \cdot \frac{1}{2}H_2O$: C 57.99, H 6.99, N 8.45; found: C 57.66, H 6.90, N 8.19.

*1-N-Benzoyl-3-N-ethoxycarbonyl-2,5-dideoxystreptamine (**1**h)*

3-*N*-Ethoxycarbonyl-2,5-dideoxystreptamine (**1***f*) was *N*-benzoylated by the procedure described above for the synthesis of **1***e* to give a 91% yield of **1***h*, mp 244°C; resolidified and melted at 254–256°C; $[\alpha]_D^{25}$ +17.6 (*c* 0.8, EtOH); ir (Nujol): 3350, 1700, 1650, 1550 cm^{-1}. *Anal.* calcd. for $C_{16}H_{22}N_2O_5$: C 59.61, H 6.88, N 8.69; found: C 59.65, H 7.01, N 8.70.

*Di-N,O-carbonyl-(1,3,4,6/0)-4,6-diamino-1,3-cyclohexanediol (**9**)*

To 35 g (120 mmol) of powdered *N,N'*-diethoxycarbonyl-2,5-dideoxystreptamine (**1***b*) in a 1 L round-bottomed flask was added portionwise 120 mL of thionyl chloride. After the reaction had subsided, the reaction mixture was refluxed until the evolution of gasses ceased (2 h) and then evaporated to dryness. The residue was evaporated with toluene to remove traces of thionyl chloride and the product was cooled in an ice-bath. Water (100 mL) was slowly added to it and after the material had dissolved 100 mL of ether was added. The crystalline precipitate that was formed was collected by filtration, washed with ether, and dried to give 12.7 g of **9**, mp 254–256°C (dec.). The aqueous phase of the filtrate was separated, neutralized with an anion exchange resin (Rexyn 201, in the OH form, from Fisher Scientific Co.), and evaporated to dryness. The solid residue was treated with ethanol (15 mL) and filtered to give 4.8 g of **9**, mp 255–257°C (dec.). The two fractions were combined to give a total of 17.5 g (73.5%) of **9**; ir (Nujol): 3300, 1750 cm^{-1}; ^{1}Hmr (DMSO-d_6): 1.46–2.25 (m, 4H, CH_2), 3.85 (m, 2H, N—C—H), 4.70 (octet, 2H, O—C—H, J_1 = 10 Hz, J_2 = 8 Hz, J_3 = 5.5 Hz), 7.4 (s, 2H, NH). *Anal.* calcd. for $C_8H_{10}N_2O_4$: C 48.48, H 5.08, N 14.23; found: C 48.21, H 5.07, N 14.08.

*Bisoxazoline (**10**)*

Powdered *N,N'*-dibenzoyl-2,5-dideoxystreptamine (**1***c*) (20.0 g, 56.4 mmol) was added to 100 mL of thionyl chloride and the mixture was stirred at room temperature for 3 min and then heated on a steambath for 3 min. The solution was cooled in an ice-bath and then evaporated to dryness at 30°C. The residue, on trituration with ether (150 mL), solidified. The ether phase was decanted and the crystalline oxazoline dihydrochloride was treated with 6% aqueous sodium hydroxide (250 mL) and extracted with chloroform (250 mL). The chloroform solution, after drying, was evaporated to dryness to give 15.3 g of crude **10**. Thin-layer chromatography (10% ethanol–chloroform) showed, under uv, one major spot of R_f 0.23 (**10**) and four minor spots of R_f 0, 0.37, 0.43, and 0.50. The crude product was boiled and stirred with 70 mL acetone (5–10 min) and then cooled in an ice-bath and filtered to give 12.8 g (72%) of the bisoxazoline **10**, mp 191–195°C. Thin-layer chromatography showed one major spot (R_f 0.23) and a trace of the spot with R_f 0.37. This material was used in the next reaction. The analytical sample was obtained by recrystallization from ethanol (twice); mp 196–198°C; ir ($CHCl_3$): 1650, 1585, 1500 cm^{-1}. *Anal.* calcd. for $C_{20}H_{18}N_2O_2$: C 75.45, H 5.70, N 8.80; found: C 75.68, H 5.75, N 8.69.

*(1,3,4,6/0)-4,6-Diamino-1,3-cyclohexanediol (**2**a)*

Method A

2*a* was obtained from the dicarbamate **9** by acidic hydrolysis. A solution of 6.0 g (30.3 mmol) of the dicarbamate **9** in 15 mL of 20% hydrochloric acid was heated under reflux for 24 h. The solution was filtered and the filtrate evaporated to dryness. The solid residue was stirred with cold ethanol (50 mL), collected by filtration, washed with ethanol (2 × 20 mL), and dried to give 5.5 g of the dihydrochloride salt of **2***a*, mp 315°C (decomposition starts at 290°C). The filtrate and washings were combined, evaporated to dryness, and the residue was crystallized from ethanol (30 mL) to give 0.4 g more of the dihydrochloride salt of **2***a*. The two fractions were combined to a total of 5.9 g (89.5%). Thin-layer chromatography on silica plates with H_2O–NH_4OH–MeOH–$CHCl_3$ (1:1:4:1) as eluent showed a single spot of R_f 0.18; ^{1}Hmr (D_2O): 1.63–2.53 (m, 4H, two CH_2), 3.60 (octet, 2H, H-4 and H-6, $J_{4,5a}$ = $J_{5a,6}$ = 10.5 Hz, $J_{3,4}$ = $J_{1,6}$ = 6 Hz, $J_{4,5e}$ = $J_{5e,6}$ = 3 Hz), 4.20 (five-line multiplet, 2H, H-1 and H-3, $J_{1,2a}$ = $J_{2a,3}$ = $J_{3,4}$ = $J_{1,6}$ = 6 Hz, $J_{1,2e}$ = $J_{2e,3}$ = 3 Hz). *Anal.* calcd. for $C_6H_{14}N_2O_2 \cdot 2HCl$: C 32.89, H 7.36, Cl 32.36, N 12.79; found: C 32.85, H 7.44, Cl 32.34, N 12.95.

The free base **2***a* was quantitatively regenerated from its dihydrochloride salt by treatment with an anion exchange resin (Rexyn 201, OH form); mp 119–121°C.

Method B

2*a* was obtained from the bis-oxazoline **10** by acidic hydrolysis. A solution of 0.4 g (1.26 mmol) of the bis-oxazoline **10** in 20 mL of acetic acid – concentrated hydrochloric acid mixture (1:1) was heated under reflux for 36 h. After removal of the solvent by evaporation, the residue was dissolved in water and the solution extracted with ether (to remove benzoic acid). The aqueous phase was evaporated. The solid residue was boiled with ethanol (5 mL) and after cooling to room temperature, the crystalline product was collected to give 0.136 g (49%) of the dihydrochloride of **2***a* identical in all respects with the product above.

*(1,3,4,6/0)-3,6-Dibenzamido-1,3-cyclohexanediol (**2**b)*

To a solution of the bis-oxazoline **10** (0.5 g or 1.57 mmol) in 90% ethanol (15 mL) was added concentrated hydrochloric acid (0.5 mL) and the reaction mixture was heated under reflux for 15 min and then evaporated. The residue was dissolved

in 25 mL of 1 *N* sodium hydroxide solution in aqueous ethanol (1:1) and the solution stirred at room temperature for 1 h. Removal of the solvent *in vacuo* left a residue to which 20 mL of water was added, stirred for 5 min, and then the aqueous phase decanted. The residue, on trituration with ether, solidified. The solid product was suspended in water (20 mL) and the mixture was stirred for a few minutes. The crystalline product was collected by filtration, washed with water and ether, and dried to give 500 mg (90%) of **2***b*, mp 224–228°C. Recrystallization from ethanol–ether gave an analytical sample, mp 227–228°C. *Anal.* calcd. for $C_{20}H_{22}N_2O_4$: C 67.78, H 6.25, N 7.90; found: C 67.72, H 6.24, N 7.90.

Oxazoline ***11***

To a suspension of 14.2 g (40 mmol) of *N,N'*-dibenzoyl-2 2,5-dideoxystreptamine (**1***c*) in 80 mL dry DMF was added 30 mL of triethyl orthoacetate and 10 mL of boron trifluoride etherate and the mixture, protected from moisture, was stirred at room temperature for 24 h. The reaction mixture was poured into a cold solution of 8% sodium bicarbonate (500 mL) and the precipitate was collected and washed with water (3 × 100 mL). After drying, the crystalline product was dissolved in chloroform (200 mL), filtered to remove some insoluble matter, and the filtrate evaporated to dryness. The solid residue was treated with a 1:1 ether – petroleum ether solution (60 mL) and filtered to give 12.1 g, mp 186–189°C. Recrystallization from ethanol (200 mL) gave 10.2 g of **11**, mp 189–190°C. A further 1.1 g of **11** were recovered from the mother liquor after evaporation and recrystallization from ethanol (30 mL). The two crops were combined to a total of 11.3 g (75%); ir (Nujol): 3350, 1740, 1660, 1530 cm^{-1}. *Anal.* calcd. for $C_{22}H_{22}N_2O_4$: C 69.83, H 5.85, N 7.40; found: C 69.80, H 5.86, N 7.34.

DL-*(1,4,6/3)-4,6-Diamino-1,3-cyclohexanediol (3*a*) Dihydrochloride*

A solution of 2 g (5.3 mmol) of the oxazoline **11** (racemic) in 20 mL of a 1:1 acetic acid – concentrated hydrochloric acid mixture was heated under reflux for 16 h. The reaction mixture was evaporated, the residue dissolved in water (50 mL), and the solution extracted with ether (3 × 20 mL) to remove benzoic acid. The aqueous solution was evaporated and the residue was refluxed with 20 mL of ethanol. After cooling to room temperature, the solid precipitate was collected to give 0.99 g (85.5%) of **3***a* dihydrochloride. Thin-layer chromatography on silica plates with H_2O–NH_4OH–MeOH–$CHCl_3$ (1:1:4:1) as eluent showed a single spot of R_f 0.25. Recrystallization from water (1 mL) – ethanol (5 mL) gave the analytical sample, mp 305–307°C; ^{1}Hmr (D_2O): 1.42–2.49 (m, 4H, two CH_2), 3.26 (dt, 1H, H-4, $J_{3,4} = J_{4,5a} = 11$ Hz, $J_{4,5e} = 4$ Hz) 3.57 (octet, 1H, H-6, $J_{5a,6} = 12$ Hz, $J_{5e,6} = 3$ Hz, $J_{1,6} = 5$ Hz), 4.06 (dt, 1H, H-3, $J_{2a,3} = J_{3,4} = 11$ Hz, $J_{2e,3} = 5$ Hz), 4.26 (five-line multiplet, 1H, H-1, $J_{1,2a} = J_{1,6} = 5$ Hz, $J_{1,2e} = 3$ Hz). *Anal.* calcd. for $C_6H_{14}N_2O_2 \cdot 2HCl$: C 32.89, H 7.36, N 12.78; found: C 32.81, H 7.29, N 12.79.

DL-*(1,4,6/3)-4,6-Dibenzamido-1,3-cyclohexanediol (3*b*)*

A mixture of 1.14 g (3 mmol) of the oxazoline **11** with 15 mL of 90% ethanol and 0.5 mL of concentrated hydrochloric acid was heated under reflux for 15 min while stirring. The reaction mixture was evaporated and the residue dissolved in a 1 *N* sodium hydroxide solution in aqueous ethanol (1:1, 25 mL) and the resulting solution stirred at room temperature for 1 h. The solvent was removed by evaporation and replaced with 20 mL of water. The mixture was stirred for 5 min and the crystalline precipitate that was formed was collected by filtration, washed with water and with ether, and dried to give 0.95 g (90%) of **3***b*, mp 232–233°C; ir (Nujol): 3350, 1650, 1560 cm^{-1}. *Anal.* calcd. for $C_{20}H_{22}N_2O_4$: C 67.78, H 6.25, N 7.90; found: C 67.95, H 6.32, N 7.97.

Oxazoline ***12***

To a solution of 37.1 g (112 mmol) of **1***e* in dry DMF (110 mL) was added 50 mL triethyl orthoacetate and 15 mL boron trifluoride etherate and the solution, protected from moisture, was stirred at room temperature for 20 h. The mixture was then poured into a cold solution of 8% sodium bicarbonate (1 L) and extracted with ether (4 × 350 mL). The ether solution was washed with water (2 × 250 mL), dried, and evaporated to dryness to yield a syrup which crystallized on trituration with ether to give 31.2 g (78.5%) of **12**, mp 108–112°C. Thin-layer chromatography with 5% ethanol–ether showed, under uv, a major spot of R_f 0.54 (**12**) and a minor one of R_f 0.85. This material was used in the next experiment without further purification. A small sample was recrystallized from ethyl acetate – petroleum ether (1:3), mp 111–113°C; $[\alpha]_D^{25}$ −64.2 (*c* 1.0, EtOH); ir (Nujol): 3350, 1730, 1690, 1660, 1640, 1540 cm^{-1}. *Anal.* calcd. for $C_{18}H_{22}N_2O_5$: C 62.41, H 6.40, N 8.09; found: C 62.54, H 6.43, N 7.95.

Oxazoline ***13***

Compound **1***h*, (6.0 g, 18.2 mmol) was reacted with triethyl orthoacetate (9 mL) and boron trifluoride etherate (2.0 mL) in dry DMF (19 mL), as described in the preparation of **12**, to give 5.5 g (88%) crude **13** as a solid. Thin-layer chromatography with 5% ethanol–ether showed one major spot of R_f 0.53 and a minor one of R_f 0.90. This material was used in the next reaction. The analytical sample was obtained after three recrystallizations from ethyl acetate (1.5 mL/g) – petroleum ether (6 mL/g), mp 111–113°C; one spot on tlc: $[\alpha]_D^{25}$ +63.7 (*c* 1.0, EtOH); ir (Nujol): 3350, 1745, 1700, 1655, 1550 cm^{-1}. *Anal.* calcd. for $C_{18}H_{22}N_2O_5$: C 62.41, H 6.40, N 8.09; found: C 62.35, H 6.43, N 8.09.

*(1*R*,3*R*,4*S*,6*R*)-4,6-Diamino-1,3-cyclohexanediol (4) Dihydrochloride*

A mixture of 2.23 g of the oxazoline **12** and 20 mL of 1:1 acetic acid – concentrated hydrochloric acid solution was refluxed for 18 h and the reaction mixture was then evaporated. The residue was dissolved in water (20 mL) and extracted with ether (3 × 20 mL) to remove benzoic acid. The aqueous solution was evaporated and the solid residue (1.43 g) was recrystallized from 90% ethanol (20 mL) – ether (7 mL) to give 1.0 g (71.5%) of **4** dihydrochloride, mp 312–314°C (dec.). Thin-layer chromatography on silica with H_2O–NH_4OH–MeOH–$CHCl_3$ (1:1:4:1) showed a single spot of R_f 0.31; $[\alpha]_D^{25}$ −44.4 (*c* 1.0, H_2O); ^{1}Hmr (D_2O) was identical to that of the racemic product **3***a* dihydrochloride. *Anal.* calcd. for $C_6H_{14}N_2O_2 \cdot 2HCl$: C 32.89, H 7.36, N 12.79; found: C 32.82, H 7.13, N 12.75.

*(1*S*,3*S*,4*R*,6*S*)-4,6-Diamino-1,3-cyclohexanediol (5) Dihydrochloride*

In a manner analogous to that given above for the preparation of **4**, acidic hydrolysis of 1.73 g of **13** gave 1.07 g of crude product. Recrystallization from 90% ethanol (20 mL) – ether (7 mL) afforded 0.82 g (75%) of **5** dihydrochloride, mp 312–314°C (dec.); $[\alpha]_D^{25}$ +44.0 (*c* 1.0, H_2O); tlc on silica with H_2O–NH_4OH–MeOH–$CHCl_3$ (1:1:4:1) showed a single spot of R_f 0.31; ^{1}Hmr (D_2O) was identical to that of the racemic product **3***a* dihydrochloride. *Anal.* calcd. for $C_6H_{14}N_2O_2 \cdot 2HCl$: C 32.89, H 7.36, N 12.79; found: C 32.85, H 7.32, N 12.72.

(1,4/2,5)-2,5-Diazido-1,4-cyclohexanediol (15)

cis-1,4-Diepoxycyclohexane (**14**) (6.7 g or 60 mmol) was reacted with hydrazoic acid (generated *in situ* from 14.6 g sodium azide and 30.4 g *p*-toluenesulfonic acid in DMSO–

water) as in the procedure given below for the preparation of **17**. After the reaction was complete (22 h) the reaction mixture was diluted with water (100 mL) and continuously extracted with ether (5 h). The ethereal extract, after drying ($MgSO_4$), was evaporated to dryness. The solid residue was recrystallized from acetone (15 mL) – benzene (50 mL) mixture to give 6.0 g of **15**, mp 138–141°C. The mother liquor was evaporated to dryness, the residue was triturated with benzene (25 mL), and the crystalline product was collected by filtration to give 3.0 g of **15**, mp 137–140°C, which was combined with the above fraction to give a total of 9.0 g product. Recrystallization from acetone – petroleum ether (1 : 1, 50 mL) gave 8.0 g (67%) of **15**, mp 142–143°C; ir (Nujol): 3350 (OH), 2110 (N_3) cm^{-1}. *Anal.* calcd. for $C_6H_{10}N_6O_2$: C 36.36, H 5.08, N 42.41; found: C 36.32, H 4.99, N 42.66.

*(1,4/3,6)-4,6-Diazido-1,3-cyclohexanediol (**17**)*

To a solution of 14.6 g (220 mmol) of sodium azide in 60 mL 1 : 1 DMSO–water mixture was added 30.4 g (160 mmol) *p*-toluenesulfonic acid monohydrate and the solution was stirred at room temperature for 30 min, *trans*-1,4-diepoxycyclohexane (**16**) (6.70 g or 60 mmol) was added, and the reaction mixture was heated at 75°C with stirring for 22 h. After cooling to room temperature, the reaction mixture was diluted with water (100 mL) and extracted with ether (6 × 60 mL). The ethereal solution, after drying over magnesium sulfate, was evaporated to dryness to give 9.0 g of crystalline product. Recrystallization from benzene (45 mL) afforded 8.0 g of **17**, mp 93–95°C. The aqueous phase was extracted continuously with ether, and the ethereal extract was evaporated to dryness. The residue was recrystallized from benzene to give an additional 0.5 g of **17**, mp 93–95°C, which was combined with the first fraction to give a total of 8.5 g (70%) of product. A sample was recrystallized from benzene–ether mixture (1 : 1) to give the analytical sample, mp 96–97°C; ir (Nujol): 3350 (OH), 2110 (N_3) cm^{-1}. *Anal.* calcd. for $C_6H_{10}N_6O_2$: C 36.36, H 5.08, N 42.41; found: C 36.44, H 5.07, N 42.57.

*(1,4/2,5)-2,5-Diamino-1,4-cyclohexanediol (**6**)*

Reduction of the azide **15** (5 g, 25.2 mmol) by the procedure described below for the preparation of **7** gave 3.1 g (84%) of **6**, mp 212–213.5°C (dec.); ^{1}Hmr (D_2O) δ: 1.6–1.9 (m, H, CH_2), 2.93 (q, 2H, N—C—H, J = 6 Hz, band intensities ratio 1 : 3 : 3 : 1), 3.66 (q, 2H, O—C—H, J = 6 Hz, band intensities ratio 1 : 3 : 3 : 1). *Anal.* calcd. for $C_6H_{14}N_2O_2$: C 49.30, H 9.65, N 19.16; found: C 49.25, H 9.61, N 19.06.

*(1,4/3,6)-4,6-Diamino-1,3-cyclohexanediol (**7**)*

A solution of 1.98 g (10 mmol) of **17** in 50 mL of ethanol and 0.1 g of 10% Pd/C was shaken under hydrogen in a Paar apparatus at room temperature and an initial pressure of 50 psi for 4 h. The catalyst was removed by filtration and the filtrate was evaporated to dryness. The solid residue (1.42 g) was recrystallized from ethanol–ether (14 mL, 1 : 1) to give 1.2 g (82%) of **7**, mp 155–157°C; ^{1}Hmr (D_2O) δ: 1.61–1.96 (m, 4H, CH_2), 2.88 (q, 2H, N—C—H, J = 6 Hz, band intensities ratio 1 : 3 : 3 : 1), 3.71 (q, 2H, O—C—H, J = 6 Hz, band intensities ratio 1 : 3 : 3 : 1). *Anal.* calcd. for $C_6H_{14}N_2O_2$: C 49.30, H 9.65, N 19.16; found: C 49.24, H 9.63, N 18.98.

Solvent-induced changes in ^2J(H, F) for fluoroform via van der Waals interactions. Non-contact contributions to spin–spin coupling constants involving a proton?

TED SCHAEFER, HAROLD M. HUTTON, AND SALMAN R. SALMAN[1]

The spin–spin coupling between the proton and the fluorine nuclei, ^2J, in fluoroform varies by 1% in a range of solvents. It is argued that ^2J decreases algebraically as the van der Waals solute–solvent interactions increase in magnitude. Such a decrease is also observed for coupling constants which likely contain a substantial positive orbital contribution. If the van der Waals interactions perturb the spin–orbital term in J, then ^2J in fluoroform may well contain orbital contributions, as recently calculated for ^2J in methyl fluoride. In that event, the large discrepancies between observed ^2J(H,F) values and those calculated by semiempirical theories of the contact term may be partially attributed to the neglect of orbital terms.

TED SCHAEFER, HAROLD M. HUTTON et SALMAN R. SALMAN. Can. J. Chem. 57, 1877 (1979).

Le couplage spin–spin entre le proton et le fluor, ^2J, du fluoroforme varie par 1% dans divers solvants. On suggère que ^2J diminue d'une façon algébrique au fur et à mesure d'une augmentation des interactions de van der Waals soluté-solvant. On observe aussi une telle diminution des constantes de couplage qui contiennent probablement une contribution orbitalaire positive importante. Si les interactions de van der Waals perturbent le terme orbitalaire du spin de J, il est possible que la valeur ^2J du fluoroforme puisse contenir des contributions orbitalaires semblables à celles calculées récemment pour le ^2J du fluorure de méthyle. Alors, on pourrait attribuer en partie les grandes différences observées entre les valeurs de ^2J(H,F) observées et calculées par des théories semi-empiriques au fait que des termes orbitalaires ont été omis.

Introduction

The theory of Barfield and Johnston (1) accounts rather well for the medium dependence (2, 3) of a variety of spin–spin coupling constants, J. It is a one-electron theory, based on an INDO MO FPT formulation (4), and implies that solvent effects on coupling constants involving a proton arise from electrostatic (polarization) perturbations of the contact interaction. It has usually been accepted (5) that couplings involving at least one proton are adequately described in terms of the contact term in Ramsey's formulation of J (6).

Barfield and Johnston recognize (1) that dispersion (van der Waals) effects on coupling constants could be important if orbital contributions to J were to exist. There exists experimental evidence that couplings involving heavier nuclei than protons are sensitive to dispersion interactions with neighbouring molecules (7–10). Furthermore, recent *ab initio* MO calculations (11–13) indicate the presence of sizeable orbital contributions to couplings between nuclei, one or both of which are protons.

The purpose of the measurements reported here is to present evidence for a van der Waals dependence of a coupling to a proton in a molecule in which the coupled nuclei are contained in atoms on the periphery of the molecule. For this purpose, CHF_3 was chosen. The one-electron theory has been used to calculate the solvent dependence of $^1J(^{13}C,H)$, $^1J(^{13}C,F)$, and ^2J(H,F) in this molecule, reasonable agreement with experiment being found for the one-bond couplings (1). On the other hand, the predicted increase of ^2J(H,F) as the solvent polarity (or dielectric constant) increases (1) apparently disagrees with experiment (14, 15), which finds ^2J(H,F) as largely solvent independent.

Again, the extensive work on solvent effects on the proton chemical shift of methane (16–18) has allowed Rummens and co-workers to establish reliable shift parameters characterizing its van der Waals interactions with a variety of solvents. The site factors (16, 17) for methane and fluoroform are rather similar so that these solvent parameters can possibly be used to establish a correlation between ^2J(H,F) and van der Waals fields (perhaps attractive and (or) repulsive[2]) from dipole–dipole interactions.

[1]On sabbatical leave from the Department of Chemistry, University of Baghdad, Iraq.

[2]Short-range, repulsive interactions dominate the local arrangements of molecules in simple liquids (19). Thus, the local structures of liquid CH_3CN and CS_2 resemble one another (19) because the molecular shapes are very similar. The molecular shapes of CH_4 and CHF_3 are also similar, as are their polarizabilities (2.6 and 2.8 $\times$ 10^{-24} cm^3, respectively) but, of course, not their dipole moments.

[c]Dielectric constant.
[d]Data taken from ref. 15.
[e]At 295 K.

Furthermore, if van der Waals interactions perturb the orbital contribution to J, it is intuitive that short-range solvent molecule interactions with fluorine atom orbitals should perturb the orbital terms in J more than would solvent interactions with the hydrogen orbitals. The high ratio of fluorine to hydrogen in fluoroform is therefore an advantage if perturbations of orbital contributions are sought; although, of course, fluoroform is not very polarizable and observed changes in ^2J(H,F) may therefore be small.

Experimental

Using a vacuum line, CHF_3 (Matheson) was transferred to thick-walled 5 mm od sample tubes containing solvent and enough TMS to provide an internal lock. As little as 0.4 mol% and as much as 3 mol% of CHF_3 was present in different solutions, as judged by a comparison of appropriate peak intensities from solute and solvent protons. Sample tubes were flame-sealed on a vacuum rack. ^{1}H nmr spectra were recorded on DA60I and HA100 spectrometers at probe temperatures of 301 and 305 K, respectively. Calibrations were performed in the frequency-sweep mode, at sweep rates of 0.02 Hz/s and a dispersion of 1 Hz/cm, by reading sweep and manual oscillator frequencies of calibration lines placed about each peak. The values of ^2J(H,F) in these first-order spectra are thought to be accurate to at least 0.05 Hz, about twice the standard deviations of the measured peak frequencies. Some samples were examined in both spectrometers. For example, in DMSO solution ^2J(H,F) was 79.12 ± 0.02 Hz at 60 MHz and was 79.09 ± 0.03 Hz at 100 MHz.

Results and Discussion

Table 1 presents the values of ^2J(H,F) in CHF_3 for 21 solvents, the last datum being taken from ref. 15. Included are the proton chemical shifts relative to internal TMS, δ_H, and the approximate dielectric constant of the solvent, when known. ^2J(H,F) varies by 1%, from 79.68 Hz in neat CHF_3 to 78.90 Hz in CH_2I_2 solution (~0.4 mol% in CHF_3).

Dependence of ^2J(H,F) on van der Waals Interactions

Perusal of the data in Table 1 leads to the following observations.

(*i*) The polar properties of the solute and solvent are not the main determinants of the variation in ^2J(H,F). For example, ^2J(H,F) is 79.68 Hz in neat CHF_3 and is 79.64 Hz in C_6F_6 solution. CHF_3 has a dipole moment of 1.65 D (20), whereas the dipole moment of C_6F_6 is probably insignificant (its quadrupole moment is nonzero, of course). Again, the dielectric constants of CH_3CN and of 1,3,5-trifluorobenzene (*s*-$C_6H_3F_3$) differ by about 35, yet ^2J(H,F) is the same in the two solutions.

(*ii*) The variation in ^2J(H,F) is apparently more closely related to the polarizability of the solvent molecules than to the dielectric constant of the solvent. For example, the dielectric constants of $CHCl_3$ and $CHBr_3$ are almost the same, yet ^2J(H,F) differs by 0.2 Hz (25% of its variation) in the two solutions. Again, ^2J(H,F) is smallest in CH_2I_2 solution and largest in neat CHF_3. The polarizabilities of these two molecules span those of the molecules in Table 1, being 2.8×10^{-24} cm^3 for CHF_3 (21) and 12.9×10^{-24} cm^3 for CH_2I_2 (17). These observations suggest that van der Waals interactions dominate the medium dependence of ^2J(H,F).

(*iii*) Rummens finds parameters which measure the van der Waals term in the solvent-induced proton chemical shifts of methane. This term can be written as a product of two factors, one characterizing the solute molecule[3] and the other characteristic

[3]The similar molecular radii of CH_4 and CHF_3 (17, 22) and the fact that in liquid CHF_3 the reorientational motion of the CHF_3 molecule is effectively isotropic (23) suggest that the cavity radii and possibly also the site factors of the two molecules will be closely related, so that the solvent parameters, derived by Rummens (17) and possibly model dependent, can still be sensibly used in the manner proposed here.

of the solvent (see eq. [2] in refs. 16, 17). In Fig. 1, ^2J(H,F) is plotted versus the medium shifts of methane, σ_m, as measured in ref. 18 at 303 K and corrected for bulk susceptibility by Rummens (16). A similar plot of ^2J(H,F) versus σ_w, as determined in (17) for a set of solvents somewhat different from that in Fig. 1, agrees with Fig. 1 in indicating that the medium dependence of ^2J(H,F) is indeed related to the van der Waals interactions of CHF_3 with the solvent and is not strongly influenced, for example, by dipole–dipole interactions between solute and solvent. Thus, ^2J(H,F) is essentially the same in CS_2 and DMSO solutions, and is large in acetone and smallest in CH_2I_2 solutions (see points 6, 16, 18 in Fig. 1).

(*iv*) The solvent effects on ^2J(H,F) in CHF_3 are reminiscent of those found for ^1J(F,Si) in SiF_4 (24). Raynes (25) shows that the solvent dependence of ^1J(F,Si) in halomethane solvents is reproduced by the following bond parameters assigned to the solvents: j(C—F) = 0.18, j(C—H) = 1.23, j(C—Cl) = 1.98 Hz. The small value for C—F bonds is striking, particularly as ^1J(F,Si) varies by as much as 8 Hz. Comparison of ^2J(H,F) magnitudes in Table 1 for CHF_3, C_6H_6, *s*-$C_6H_3F_3$, and C_6F_6 solvents, for example, emphasizes the similarity of the behaviour of solvent C—F bonds in perturbing J in the two solute molecules. In fact, because the variation of ^2J(H,F) in CHF_3 is so small, the value of ^2J(H,F) in the gas phase at low pressure is probably very close to the 79.69 Hz measured in the gas phase at 313 K (Table 1), just above the critical temperature of 306 K (the critical pressure is 47 atm).

The Coupling Mechanism for ^{2}J(H,F) in CHF_3

Polarization (electrostatic) models predict an algebraic *increase* in ^2J(H,F) in CHF_3 when dissolved in a polar solvent (1), arising from an increase in the magnitude of the contact contribution. Now, it is interesting that coupling constants for which the presence of orbital components are not disputed display an algebraic *decrease* as the solute molecule is subjected to van der Waals interactions. For example, ^1J(F,Cl) in FCl is +840 Hz in the gas phase (26) and is 770 Hz in the liquid phase (27). Again, ^1J(F,P) is very likely negative in PF_3 (28), and its magnitude is 1404 Hz in the gas phase and 1423 Hz in CCl_4 solution (29). Similar remarks apply to ^1J(F,Si) in SiF_4 (7, 24, 25).

Furthermore, ^2J(F,F) in 1,1-difluoroethene also decreases algebraically as the polarizability of the solvent increases (9). Again, in cyclopropane derivatives (30), ^2J(F,F) decreases algebraically as the intramolecular mean square fields increase in magnitude. ^2J(F,F) is calculated to contain a large positive orbital component (12).

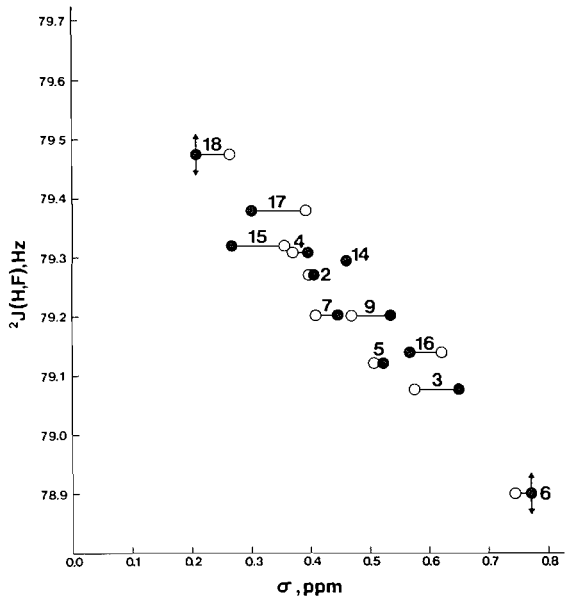

FIG. 1. The coupling constant, ^2J(H,F), in fluoroform is plotted versus the gas-to-medium proton shift, σ_m, of methane from ref. 18, as corrected for bulk susceptibility in ref. 16. The open circles refer to the van der Waals shift, σ_w, as calculated in ref. 16. Point 14 refers to benzene (numbering of solvents as in Table 1) and only σ_w is plotted because σ_m undoubtedly contains a large anisotropy contribution.

If van der Waals interactions act to decrease the magnitude of orbital contributions, as might be anticipated if intermolecular mean square electric fields interfere with spin-induced orbital currents in the solute molecule, and if the orbital components are positive as calculated for ^1J(H,F) in HF (11), for ^2J(H,F) in CH_3F (13), and for ^2J(F,F) in $CF_2{=}CH_2$ (12), then it seems reasonable to attribute the observed algebraic decrease in ^2J(H,F) in CHF_3 to a solvent-induced reduction in the magnitude of its orbital component. Of course, an increase in ^2J(H,F) from the contact term cannot be excluded on the basis of the data in Table 1. However, such an increase must be masked by other interactions.

It is also of interest that INDO MO FPT calculations of ^2J(H,F), although remarkably successful for many coupling constants, disagree badly with observation (4). Such calculations take only the contact term into account.

For all the molecules discussed in this section, at least one of the heavy atoms containing a coupled nucleus lies on the periphery of the molecule. In tetramethyltin, ^2J(H,Sn) *increases* algebraically as the van der Waals interactions with the solvent molecules become larger (8). Tetramethyltin differs from the molecules above in that the heavy atom lies at the center of the molecule and therefore it is the hydrogen atom orbitals which are primarily exposed to buffeting by the solvent molecules, suggesting

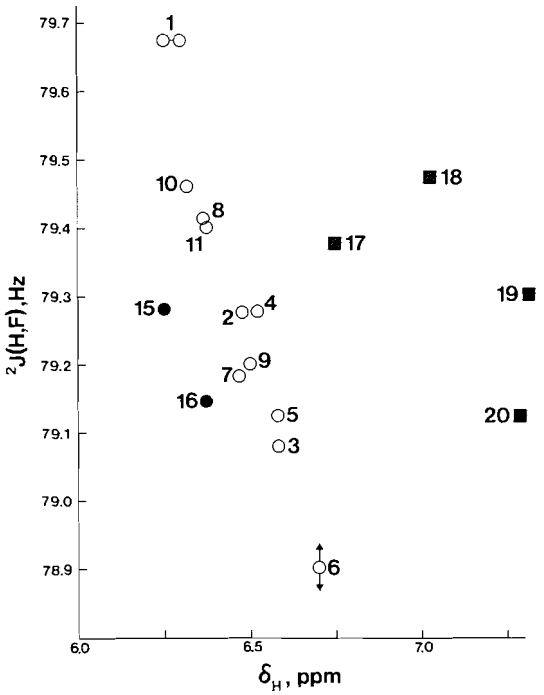

FIG. 2. ^2J(H,F) is plotted versus δ_H from Table 1. Open circles refer to halomethane solvents. Solid squares refer to solvents with which specific (hydrogen bonding) solute–solvent interactions are thought to occur.

perhaps that the electrostatic theory (1) is applicable here.

The Proton Chemical Shift of CHF_3

The proton and fluorine chemical shifts of CHF_3 in 11 solvents have been discussed (15). Fig. 2 displays a plot of ^2J(H,F) versus δ_H, the shift to low field from internal TMS for many of the solvents in Table 1. Referencing to internal TMS removes only some of the van der Waals contributions to δ_H. In the figure, open circles refer to halomethane solvents. If changes in ^2J(H,F) are indeed determined mainly by van der Waals interactions, it appears that δ_H in these solvents is also dominated by such interactions. On the other hand, solvents like DMSO or acetone, for which specific interactions of the polar C—H bond in CHF_3 with the carbonyl or sulfoxide bond may well occur, do not display a correlation between δ_H and ^2J(H,F), the latter being dominated by van der Waals effects (Fig. 1). In particular, δ_H in benzene solution is 5.26 ppm and does not fall on the figure scale at all. In such respects, CHF_3 behaves like $CHCl_3$, for which hydrogen bonding to acetone or to the π electrons of the benzene molecules apparently occurs (31).

Received December 4, 1978

TED SCHAEFER, WALTER NIEMCZURA, WERNER DANCHURA, and TIMOTHY A. WILDMAN. Can. J. Chem. **57**, 1881 (1979).

The long-range spin–spin coupling constants over six bonds, $^6J_p^{H,CH}$ and $^6J_p^{F,CH}$, in 3,5-dibromodiphenylmethane and 4,4′-difluorodiphenylmethane, respectively, imply that the ground state conformations of these molecules have C_{2v} symmetry (gable conformations). In terms of a hindered rotor model which assumes a twofold barrier to internal rotation about the exocyclic carbon–carbon bond, the barrier in the dibromo derivatives is 1.1 ± 0.3 kcal/mol. A satisfactory fit to the temperature dependence of $^6J_p^{F,CH}$ is found for a gable conformation. If the conformational properties of these molecules and of diphenylmethane are determined mainly by steric interactions between *ortho* C—H bonds on neighbouring phenyl groups, it seems likely that the results above are a first approximation to the conformational behaviour of diphenylmethane. Some molecular orbital calculations are in semiquantitative agreement with the conclusions based on coupling constants.

TED SCHAEFER, WALTER NIEMCZURA, WERNER DANCHURA et TIMOTHY A. WILDMAN. Can. J. Chem. **57**, 1881 (1979).

Les constantes de couplage spin–spin à longue distance à travers six liaisons, $^6J_p^{H,CH}$ et $^6J_p^{F,CH}$, dans les dibromo-3,5 diphénylméthane et difluoro-4,4′ diphénylméthane, impliquent respectivement que la symétrie des conformations, dans l'état fondamental, de ces molécules est C_{2v} (conformations gables). Si l'on utilise comme modèle un rotor empêché qui implique une barrière binaire à la rotation interne autour de la liaison carbone–carbone exocyclique, la barrière dans les dérivés dibromés est de 1.1 ± 0.3 kcal/mol. On trouve une corrélation satisfaisante pour la relation entre la température et la valeur de $^6J_p^{F,CH}$ dans le cas d'une conformation "gables". Si les propriétés conformationnelles de ces molécules et du diphénylméthane sont principalement déterminés par des interactions stériques entre les liaisons C—H *ortho* des groupes phényles voisins, il semble que les résultats rapportés ci-dessus correspondent à une première approximation du comportement conformationnel du diphénylméthane. Quelques calculs d'orbitales moléculaires sont en accord semi-quantitatif avec des conclusions basées sur les constantes de couplage.

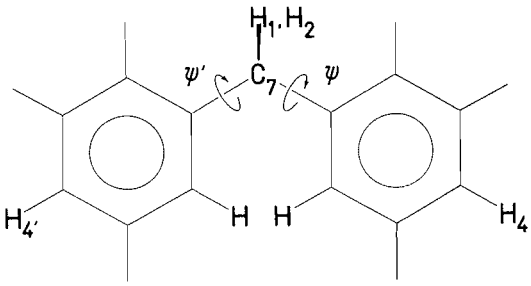
Introduction

The most stable conformation of and the barrier to internal rotation in diphenylmethane are uncertain. Kerr constants in CCl_4 solution (1) at 298 K suggest a structure in which both benzene planes are rotated by 41° out of a planar conformation, **1**. Because of steric hindrance between *ortho* C—H bonds on neighbouring phenyl groups, it is assumed here[1] that these rotations correspond to $\psi = -\psi' = 41°$. Such a conformation would be chiral.

In the crystal, the conformation of 3,3′-dichloro-4,4′-dihydroxydiphenylmethane (2) is defined by $\psi = -\psi' = 52°$. Intermolecular hydrogen bonding forces a layered arrangement of molecules and the C—C_7—C angle is apparently as large as 120°.



1

Raman scattering data (3) demonstrate that the reorientation of the phenyl groups in diphenylmethane is slower than in toluene.

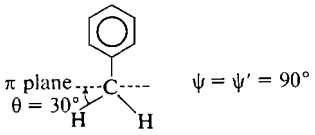
In this paper, the conformational properties of some diphenylmethane derivatives are discussed in terms of **1** ($\psi = \psi' = 0°$), **2** ($\psi = \psi' = 90°$), **3** ($\psi = 0°$, $\psi' = 90°$), **4** ($\psi = \psi' = 60°$), and of **5** ($\psi = -\psi' = 60°$). Conformation **1** is unstable, of

[1]In **1**, positive ψ values correspond to clockwise rotation viewed along the H_4—C_7 direction, whereas a positive ψ' value corresponds to anticlockwise rotation viewed along the $H_{4'}$—C_7 direction. $\psi = \psi' = 0°$ means that the phenyl groups are coplanar.

0008-4042/79/141881-06$01.00/0

course, because of strong nonbonded repulsions between *ortho* C—H bonds on neighbouring phenyl groups and will not be significantly populated at the temperatures involved in the present set of experiments.

Conformation **2**, here called the gable conformation and of C_{2v} symmetry, can be represented as shown (viewed along the C_7—H_4 axis of one phenyl group while projecting the sidechain into a plane perpendicular to this phenyl group). Distances between *ortho* hydrogen atoms on neighbouring phenyl groups in **2** are well beyond the sum of their van der Waals radii, so that **2** is a candidate for a low-energy conformer.

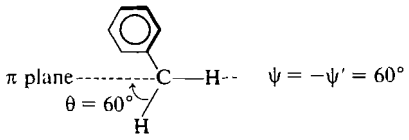


2

Conformer **3** can be derived from **2** by rotation by 90° of the explicitly depicted phenyl group in **2**, yielding C_s symmetry. It is unlikely that **3** is of low energy, because one *ortho* hydrogen must penetrate the π cloud of the neighbouring ring, and will not be discussed further.

Conformation **4** has C_s symmetry also and one methylene C—H bond lies in a plane with each phenyl group. Again, because of strong repulsion between one set of *ortho* C—H bonds on neighbouring rings, **4** is considered to have relatively high energy.

Finally, **5** has a skew conformation of C_2 symmetry in which one methylene C—H bond is in the plane of one phenyl group and the second methylene C—H bond lies in the plane of the other phenyl group. This conformer has a structure rather similar to that found for a derivative in the solid state (3). **5** does not possess a rotation–reflection axis and is chiral.



5

It seems that **2** and **5** are candidates for the most stable conformation of diphenylmethane. Note that their structural formulae are here depicted on the assumption that the methylene carbon is sp^3 hybridized. The one-bond spin–spin coupling constant, $^1J(^{13}C,H)$, in diphenylmethane is 126.0 Hz (4, 5), very close to its value in methane (6) and in toluene (4, 6). In the absence of polar substituents (7–11) on the methylene carbon atom, this result strongly suggests minor deviations from tetrahedral geometry at the methylene carbon.

As recently discussed in considerable detail (12), the long-range spin–spin coupling constant over six bonds, $^6J_p^{H,CH}$, between a sidechain proton and a ring proton in the *para* position can be written as

$$[1] \qquad {}^6J_p^{H,CH} = -1.24\langle\sin^2\theta\rangle \text{ Hz}$$

Equation [1] holds in benzyl-X, for example, if the electronegativity of the substituent X is not high (CH_3 or SH groups). The angle θ measures the deviation from coplanarity of the sidechain C—H bond and the benzene ring. Thus, θ is 30° for both methylene C—H bonds in **2** and is 60° and 0° for the C—H bonds in **5**. Again, $\langle\sin^2\theta\rangle$ is the value of $\sin^2\theta$ averaged over the motion about the exocyclic C—C bond. For a twofold barrier, V_2, a hindered rotor treatment yields $\langle\sin^2\theta\rangle$ as a function of temperature, of the magnitude of V_2, and of the reduced moment of inertia about the internal rotation axis. Such a treatment has been successful in the determination of the stable conformations and of internal rotational barriers in molecules such as ethylbenzene (13), phenylcyclopropane (14), phenylcyclohexane (12), and benzyldimethylarsine (12).

Determination of $^6J_p^{H,CH}$ in diphenylmethane is beyond the applicability of current high-resolution nmr techniques. However, $^6J_p^{H,CH}$ can be reliably determined for the substituted ring in 3,5-dibromodiphenylmethane, **6**. If, as seems very likely, the stable conformation and the internal rotational barrier in diphenylmethane are primarily determined by interactions between *ortho* C—H bonds on neighbouring phenyl groups, then substitution at the *meta* positions may well represent a minor perturbation. Certainly, the stable conformation and the barrier about the sp^2–sp^3 carbon–carbon bond in 3,5-dibromophenylethane measured by means of [1] agree exactly with recent low-resolution microwave (15) and heat capacity data (16) on phenylethane.

Cross-conjugation in 4,4′-difluorodiphenylmethane, **7**, is apparently slight (17). In addition, it seems that $^6J_p^{F,CH}$ (fluorine on the ring) can be used in a way similar to $^6J_p^{H,CH}$ by writing (18)

$$[2] \qquad {}^6J_p^{F,CH} = 2.24\langle\sin^2\theta\rangle$$

Because $|^6J_p^{F,CH}| \sim 2|^6J_p^{H,CH}|$, the possibility arises that the temperature dependence of $^6J_p^{F,CH}$, and therefore of $\langle\sin^2\theta\rangle$, is experimentally accessible (at least for a favorable magnitude of V_2) and that some of the deductions based on $^6J^{H,CH}$ in **6** can be verified by a study of $^6J^{F,CH}$ in **7**. A comparison (18) of barrier magnitudes deduced from $^6J^{H,CH}$ and $^6J^{F,CH}$ for a

number of benzyl-X compounds (X = CN, Cl, Br), suggests that V_2 values derived from $^6J^{F,CH}$ data are somewhat higher than those derived from $^6J^{H,CH}$ data, although the correct preferred conformations are given by both types of coupling constants. In view of the extensive discussion in (18), it appears that $^6J^{H,CH}$ data are more reliable indicators of V_2. Nevertheless, the temperature dependence of $^6J^{F,CH}$ may provide valuable confirmation of conformational conclusions based on $^6J_p^{H,CH}$.

Experimental

A 5 mol% solution of 4-aminodiphenylmethane (K&K) in toluene-d_8, a 5 mol% solution of 3,5-dibromodiphenylmethane (prepared from the amino compound by a standard procedure) in toluene-d_8, and a 10 mol% solution of 4,4′-difluorodiphenylmethane (Aldrich) in toluene-d_8 were degassed by the freeze–pump–thaw technique and flame-sealed into 5 mm od sample tubes containing small amounts of tetramethylsilane (TMS).

The ^{1}H nmr spectra of the substituted phenyl groups in the first two compounds were calibrated on an HA100 spectrometer at a probe temperature of 305 K. Calibrations were performed in the frequency-sweep mode by repeated measurements of sweep and manual oscillator frequencies of markers placed at ca. 5 Hz intervals, at sweep rates of 0.02 Hz/s and a spectral dispersion of 1 Hz/cm.

The ^{19}F nmr spectra of 4,4′-difluorodiphenylmethane were recorded on a WH-90 spectrometer in the FT mode at 84.69 MHz and at probe temperatures as measured by the thermocouple supplied with the spectrometer. The ring proton internal chemical shifts are very small, so that the ^{19}F nmr spectrum is complex. However, decoupling of the ring protons (coherent mode) yielded a 1:2:1 triplet for the ^{19}F nmr spectrum, the splitting arising from $^6J_p^{CH_2,F}$. This triplet was recorded at four temperatures between 250 and 370 K. In these experiments, the pulse width was 2.8 μs (tip angle ~40°), the spectral width was 500 Hz, the acquisition time was ca. 32 s, and 32 K of data storage was employed. The ring proton spectrum spreads over 10 Hz only, so that the amplitude of the decoupling field could be kept small enough to prevent off-resonance decoupling of the methylene protons, resonating 2.7 ppm to high field of the ring protons. The amplitude of the decoupling field was kept well below a value at which off-resonance perturbations of the methylene proton transitions were noticeable in the ^{19}F nmr spectrum.

Results and Discussions

Spectral Analysis

The computer program LAME (19, 20) gave the results in Table 1. The analysis of the ^{1}H nmr spectrum of the substituted ring in 4-aminodiphenylmethane as a six-spin system (four ring and two methylene protons) demonstrated insignificant cross-ring coupling constants. Iterations could be carried out only on ring proton transition frequencies because the methylene protons are coupled to all ring protons. The ^{1}H nmr spectrum of **6** was treated as part of a five-spin system, the presence of the bromine substituents ensuring sufficient dispersion of the chemical shifts of the protons in different phenyl groups.

Figure 1 displays the ^{19}F spectrum of **7** at 370 K under conditions in which the ring protons are decoupled.

The Model for Internal Rotation

Because of the structure of diphenylmethane and of **6** and **7**, it is reasonable to assume that the main component of the barrier to internal rotation about the exocyclic C—C bond will be twofold in character. In terms of the hindered rotor model (21, 22), a vanishing barrier implies that $\langle \sin^2 \theta \rangle = 0.5$ and, from [1], that $^6J_p^{H,CH}$ is 0.5×-1.24 or -0.62 Hz. If **2** is of lowest energy, a relatively large barrier implies $\langle \sin^2 \theta \rangle \sim 0.25$ because $\theta \sim 30°$, so that $^6J_p^{H,CH}$ becomes -0.31 Hz, as observed, for example, in 2,6-dichlorophenylethane (23). A small barrier entails $0.3 < |^6J_p^{H,CH}| < 0.6$. Similarly, from [2], $0.56 < |^6J_p^{F,CH}| < 1.12$ in **7**. The other plausible

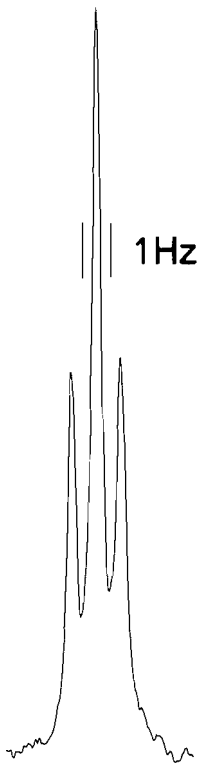

FIG. 1. The ^{19}F spectrum of 4,4′-difluorodiphenylmethane as a ca. 10 mol% solution in toluene-d_8 recorded at 84.69 MHz at 370 K under conditions in which the ring protons are decoupled. The spectral dispersion is 0.975 Hz/cm. The triplet spacings are both 0.87_9 Hz, as determined from cursor readings for a 32 K transform of a region corresponding to 500 Hz. Some of the peak width may be caused by incomplete decoupling and (or) by nonambient temperature conditions.

low-energy conformation, **5**, implies that $^6J_p^{H,CH}$ and $^6J_p^{F,CH}$ lie between 0.375 and 0.5 of -1.24 Hz and 2.24 Hz, respectively.

It is a simple matter to compute (21, 22) $\langle \sin^2 \theta \rangle$ for a range of reduced moments of inertia, of V_2 values, and of temperatures. A grid of V_2 and T values can be chosen such that linear interpolations between $\langle \sin^2 \theta \rangle$ values are valid for a given reduced moment of inertia about the assumed internal rotation axis. Observed J values are then matched to this grid.

Conformation and Barrier in **6** *Based on* $^6J_p^{H,CH}$

$^6J_p^{H,CH}$ is -0.49_8 Hz in **6**, yielding $\langle \sin^2 \theta \rangle$ as $0.49_8/1.24 = 0.40_2$. For a reduced moment of inertia of 2×10^{-38} g cm^2 ($\langle \sin^2 \theta \rangle$ versus V_2 curves are insensitive to changes by a factor of two in the reduced moment of inertia, thereby obviating complications caused by variations introduced by the rotational motion), the assumption of **2** as the low-energy form implies a V_2 of 1.1_1 kcal/mol. Allowance for errors in ^6J suggests that $V_2 = 1.1 \pm 0.3$ kcal/mol is a reasonable estimate.

If **5** were the low-energy conformer, then a ^6J of $-1.24(\sin^2 60° + \sin^2 0°)/2 = -0.46_5$ Hz should be observed for a 'rigid' conformer, that is, for a V_2 of greater than about 4 kcal/mol. The observed ^6J of -0.49_8 Hz is compatible with a situation in which the barrier is then about 3 kcal/mol. However, models of phenylethane, where V_2 is 1.2 kcal/mol (13, 16) and of diphenylmethane suggest that a large V_2 in the latter molecule is unrealistic.

Barrier and Conformation Based on $^6J_p^{F,CH}$

$^6J_p^{F,CH}$ in **7** is 0.80_8 Hz at 250 K, rising to 0.87_9 Hz at 370 K. In Fig. 2 calculated and observed ^6J values are plotted versus temperature for an assumed ground-state conformation **2** and a V_2 of 1.5_5 kcal/mol, using [2]. A realistic error estimate suggests $V_2 = 1.5_5 \pm 0.25$ kcal/mol. Again, $^6J_p^{F,CH}$ at room temperature is compatible with a large V_2 and a stable conformer **5**. However, a large V_2 would not lead to the temperature dependence plotted for ^6J in Fig. 2.

It may be noted that the value of V_2 is one for which a maximum dJ/dT is expected for a hindered rotor model at practical temperatures and that, even here, a 120° temperature range leads to only a 0.07 Hz change in J, i.e., $dJ/dT \sim 7 \times 10^{-4}$ Hz/K.

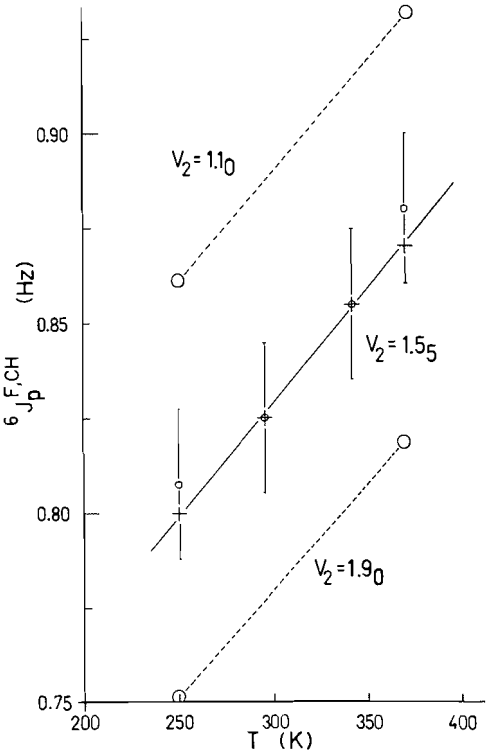

FIG. 2. The calculated (crosses) and observed (circles) values of $^6J_p^{F,CH}$ in 4,4′-difluorodiphenylmethane are plotted versus temperature for an assumed twofold internal rotational barrier of 1.55 kcal/mol, and a ground state conformer **2**.

As noted above, V_2 values for benzyl derivatives derived from $^6J_p^{H,CH}$ are somewhat lower than those based on $^6J_p^{F,CH}$, while the deductions about the low energy conformations are the same. Because of the factors which may influence $^6J^{F,CH}$ (18), the barrier based on $^6J_p^{H,CH}$ is the more reliable one. However, the combined experimental error overlaps both values. It is clear from Fig. 2 that the temperature dependence of $^6J_p^{F,CH}$ is compatible also with the barrier based on $^6J_p^{H,CH}$. The observed temperature dependence supports the gable conformation as the stable form. Of course, the present results do not prove that diphenylmethane behaves in the same manner. If, however, the ground state conformation and the origins of V_2 of all three molecules are determined by steric interactions between *ortho* C—H bonds, the results for **6** and **7** are compatible and do perhaps imply very similar conformational properties in diphenylmethane.

Long-range Couplings over Four and Five Bonds

It is fairly certain that $^4J_o^{H,CH_2}$ and $^5J_m^{H,CH_2}$ in 4-amino- and in 3,5-dibromophenylmethane contain both σ and σ–π electron contributions (24). Their conformational dependence is not as simple as that of $^6J_p^{H,CH_2}$. However, a rough empirical correlation between V_2 and $^4J_o^{H,CH_2}$ apparently occurs for some benzyl derivatives (25). In such a correlation, the $^4J_o^{H,CH_2}$ values in Table 1 agree with the derived V_2 value for 3,5-dibromodiphenylmethane to within experimental error.

Theoretical Calculations

Diphenylmethane is too large for *ab initio* calculations at the STO 3G level of molecular orbital theory, at least as used in this laboratory. However, INDO MO computations (26), using a standard geometry (27) and a 370/168 IBM system, gave **3** and **5** respectively as 1.99 and 1.07 kcal/mol less stable than **2**, in qualitative agreement with the conclusions above.

Molecular mechanics calculations on diphenylmethane are not feasible because of an unknown crucial torsional potential.[2]

Conclusions

It seems probable that the gable conformation, **2**, of diphenylmethane is the stable conformer in solution and that the twofold barrier to rotation about the exocyclic C—C bond is 1.3 ± 0.4 kcal/mol. Confirmation of this likelihood by other means is desirable.

Manipulation of models and considerations of the molecular symmetry emphasize, of course, that the actual motion about the C—C bond is more complex than would be inferred from a simple twofold potential and, therefore, that higher terms in a Fourier series expansion of the potential barrier may be significant. The present data allow no estimate of such terms. However, the strong indication of **2** as the ground state may be of help in future attempts to characterize the internal rotation more fully by vibrational and (or) rotational spectroscopies (28). The present implication, that the methyl and phenyl groups are similar in their steric demands during rotation in phenylethane and diphenylmethane, has its counterpart in other compounds (29).

Tetraethylammonium fluoride in dimethylformamide promotes the alkylation of phenols with alkyl iodides and benzyl chloride to provide good yields of alkyl phenyl ethers. A number of phenols have been investigated including examples of sterically hindered phenols, phenols containing anion stabilising groups, and intramolecularly hydrogen bonded phenols, the majority of which react smoothly and efficiently in the fluoride system.

JACK M. MILLER, K. H. SO et JAMES H. CLARK. Can. J. Chem. 57, 1887 (1979).

Le fluorure de tétraéthylammonium dans le diméthylformamide favorise l'alkylation des phénols par les iodures d'alkyles et le chlorure de benzyle conduisant à des phénoxyalcanes. On a étudié un certain nombre de phénols, y compris des phénols stériquement empêchés, des phénols contenant des groupes stabilisant l'anion et des phénols comportant des liaisons hydrogène; ces composés réagissent généralement facilement et d'une manière efficace dans le système au fluorure.

[Traduit par le journal]

Introduction

The preparation of alkyl phenyl ethers is an important synthetic reaction which is usually accomplished by the alkylation of the phenoxide ion although numerous modifications of the familiar Williamson synthesis have been developed (1) including those employing diazomethane (for methylations) (2), phase-transfer catalysis (3), tetraalkylammonium phenoxides (4), sodium hydride (5), and anion-exchange resins (6).

We now wish to report results on the use of fluoride ion as the base in the alkylation of a variety of phenols with alkyl halides. The simplicity and efficiency of the fluoride ion method has been demonstrated for many typically base-assisted reactions (7–13) and it is desirable to test its effectiveness in the synthesis of alkyl phenyl ethers. Furthermore, the role of the fluoride ion has been shown to often depend on its ability to behave as a powerful hydrogen bond electron donor (7–9) and the importance of hydrogen bonding in controlling the course of phenol alkylations is well established (14, 15).

Experimental

^{1}H nmr spectra were recorded in $CDCl_3$ with a Varian A60 (60 MHz) spectrometer ($SiMe_4$ standard). Mass spectra were determined with an AEI MS-30 double beam mass spectrometer. Infrared spectra were recorded on Perkin Elmer 237B and 735 spectrophotometers.

A solution of tetraethylammonium fluoride was prepared by neutralisation of 20% aqueous tetraethylammonium hydroxide with 48% aqueous hydrofluoric acid. The phenols and alkyl halides were commercial grade samples used without further purification.

Reactions

The technique used in each reaction was the same. Most of the reactions were carried out at room temperature (see Table 1). All products are known compounds and gave ^{1}H nmr, ir, and mass spectra consistent with their structure and, where reported data is available, consistent with those reported in the literature. Details of a representative preparation are given below.

Preparation of Benzyl 2-Nitro Phenyl Ether

An aqueous solution of tetraethylammonium fluoride (0.02 molar equiv.) was placed in a round-bottomed flask immersed in a boiling water-bath and connected via a splash-head, tap, and trap to an efficient water pump. The system was maintained at 10–20 Torr for ca. 0.5 h or until a white solid hydrate formed and no further ebullition was evident. 2-Nitrophenol (0.01 mol in 10 cm^3 dimethylformamide) was added and the mixture was returned to the boiling water bath and kept under reduced pressure (10–20 Torr) for a further 10 min. Benzyl chloride (0.01 mol in 20 cm^3 dimethylformamide) was added and the resulting solution stirred in a closed flask for approximately 3 h at room temperature (ca. 20°C) at which point sampling and ^{1}H nmr analysis showed no starting material remaining. Diethyl ether (200 cm^3) and water (100 cm^3) were added to the reaction mixture and after vigorous shaking, the aqueous layer was washed with ether (2 × 100 cm^3) and the combined ethereal layers were then washed with equal volumes of water (3 ×) so as to remove the dimethylformamide, dried over anhydrous $MgSO_4$ and

[1]To whom all correspondence should be addressed.

0008-4042/79/141887-03$01.00/0

evaporated on a rotary evaporator to give a yellow liquid. Purification on a basic alumina column using pentane as eluent gave benzyl 2-nitrophenyl ether (1.9 g, 0.0083 mol, 83%) oil; (lit. (16) mp 25°C); ^{1}H nmr δ: ~7.5 (4H, m, ring CH), 7.45 (5H, m, Ph), and 5.25 ppm (2H, s, CH_2); ir ν_s: 1520, 1350 (NO_2), 1250 (Ar—O—C asym.) and 1010 cm^{-1} (Ar—O—C sym.); ms *m/e* 229 (M^+).

Results and Discussion

The ability of the fluoride anion to behave as a powerful hydrogen bond electron donor is well known and its strong association with a variety of H-bond electron acceptors including HF (17), carboxylic acids (18, 19), amines (7), and thiols (7) has been described. In a recent article (7) it was shown that phenol and fluoride formed a strong H-bond together resulting in a large shift of the hydroxyl stretching band in the ir ($\Delta\nu_s$(OH) ~ 1000 cm^{-1}). The strongly H-bonded fluoride-carboxylic acid systems have been shown to behave as powerful sources of the carboxylate anion (20) and it seemed reasonable to assume that fluoride-phenol systems might behave in a similar manner. On treating phenol-tetraethylammonium fluoride with methyl iodide, ethyl iodide, or benzyl chloride in dimethylformamide solution, reaction occurs generally at room temperature to produce the corresponding alkyl phenyl ether. Yields are generally good (Table 1) and compare favourably with those obtained by classical and more recent methods. There is no evidence for the formation of any side products in the listed reactions and the isolation of pure products is simple and straightforward. The tetraethylammonium iodide or chloride, bifluoride and any unreacted fluoride may be recovered in aqueous solution and the whole regenerated into the fluoride form by passing through an ion-exchange column.

It was of interest to extend the utility of the present method to the etherification of isomeric nitrophenols and of highly hindered phenols.

Alkylation methods involving initial formation of the phenoxide ion may prove unsatisfactory in the cases of 2- and 4-nitrophenols because of resonance stabilisation in the nitrophenoxide anions effectively lowering the nucleophilicity of those ions. The direct alkylation of phenols by the use of phase-transfer catalysis does not suffer from this drawback (3). We have found that the times required for alkylation of these nitrophenols using tetraethylammonium fluoride are comparable or less than those required for alkylation of unsubstituted or methyl substituted phenols. The results of the alkylation of 2- and 4-nitrophenols using Et_4NF/DMF (ca. 3 h, 70–83%) would seem to be comparable to those using $NaOH/R_4NBr/CH_2Cl_2/H_2O$ (2–12 h, 79–83%—only methylations reported) (3).

2-Naphthol	$PhCH_2Cl$	85

[a]All of the reactions were carried out in dimethylformamide using ca. 0.01 molar equiv. of phenol, 0.01 molar equiv. alkyl halide, and 0.02 molar equiv. tetraethylammonium fluoride at room temperature (unless otherwise noted) and were complete in 2–24 h.
[b]Isolated yield.
[c]At 100°C.

The esterification of 2-hydroxyacetophenone was also found to proceed rapidly in the fluoride system. Indeed the reactions with methyl and ethyl iodide were complete in less than 2 h, precipitation of tetraethylammonium iodide being evident on addition of the alkyl iodide to the DMF–phenol-fluoride solution. This phenol fails to react with the powerful methylating agent, diazomethane (21), and this has been explained as being due to intramolecular H-bonding between the hydroxyl and carbonyl groups (22). The fluoride anion is a considerably more powerful H-bond electron donor than the carbonyl group and should readily break the intramolecular H-bond (23) enabling rapid alkylation.

Attempted alkylation of the 2,6-disubstituted sterically hindered phenols shown in Table 1 failed to give satisfactory yields at room temperature; however, on raising the temperature of the reaction mixture, good yields were obtained.

As with 2- and 4-nitrophenols, attempted alkylation of such sterically hindered phenols by initial generation of the phenoxide ion may provide less

than satisfactory results and more direct methods such as phase-transfer catalysis are preferred (3). Our method would again appear to offer a reasonable alternative.

In the reactions of 2,6-di-*tert*-butylphenol with alkyl halides in the presence of fluoride, products resulting from *O*-alkylation, *C*-alkylation, and phenol oxidation were recovered. Kornblum and Seltzer observed comparable mixtures in their investigations of the alkylation of the potassium salt of this phenol (24). These were the only reactions that we investigated where other than *O*-alkylation occurred. Further work on the nature of these reactions, in particular with special reference to the autoxidations, is underway and will be discussed elsewhere.

Application of photoelectron spectroscopy to substituent effects. Conformational analysis of some flexible allylic ethers and alcohols

R. S. BROWN, R. W. MARCINKO, AND A. TSE

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received January 22, 1979

R. S. BROWN, R. W. MARCINKO, and A. TSE. Can. J. Chem. **57**, 1890 (1979).

He(I) photoelectron (pe) spectroscopy is applied to determine the preferred gas phase conformations of a limited number of flexible allylic ethers and alcohols. Based on earlier observations that the π-ionization energy is increased more when the allylic C—O bond is coplanar (with the π-system) than when it is perpendicular, the pe spectrum of *cis* and *trans*-4-*tert*-butyl-2-cyclohexanol and their corresponding ethers, and 5α-hydroxy(and methoxy)-10α-Δ^3-octalin have been determined. The results indicate that when a coplanar arrangement of the allylic C—O bond can be attained, it is preferred, leading to a favored conformation of the allylic alcohol or ether.

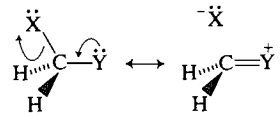
R. S. BROWN, R. W. MARCINKO et A. TSE. Can. J. Chem. **57**, 1890 (1979).

On a appliqué la spectroscopie photoélectronique (pe) He(I) pour déterminer les conformations privilégiées en phase gazeuse d'un nombre limité d'alcools et d'éthers allyliques flexibles. On a déterminé les spectres pe des *tert*-butyl-4 cyclohexène-2 ols *cis* et *trans* et de leurs éthers correspondants ainsi que ceux des hydroxy (et méthoxy)-5α 10α-octaline-Δ^3. Des observations antérieures permettant de prédire que l'énergie d'ionisation π est plus élevée lorsque la liaison C—O allylique est coplanaire (avec le système π) que lorsqu'elle est perpendiculaire, on peut déduire de nos résultats que s'il est possible, l'arrangement coplanaire est préféré et qu'il en résulte une conformation privilégiée pour l'alcool ou de l'éther.

[Traduit par le journal]

Introduction

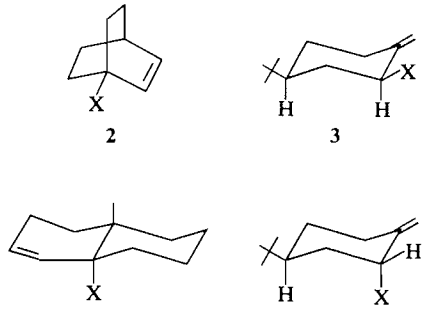
For some time we have been interested in applying the techniques of photoelectron spectroscopy (pes) to substituent effects (1). Prompted by calculations (2) which suggest that molecules of the type X—CH_2—Y (**1**) are stabilized by a bond – no bond resonance form



1

when X and Y are electronegative groups such as OR, OH, NH_2, F, and Cl, we set out to determine whether this phenomenon was experimentally observable by pes. Two important consequences of structures such as **1** require that (*a*) the 'lone pair' and the C—X bond be coplanar for maximum effect and (*b*) the pair of electrons on Ÿ should be more difficult to ionize when coplanarity is achieved than when the C—X bond is orthogonal. We first sought to probe the ionization energy (ip) of a π-bond (group Ÿ) as a function of the orientation of a single electronegative allylic group (X).

From the models in which the allylic substituent is orthogonal (or nearly so) to the π-bond (**2** and **3**) changing from *a* to *b* or *c* within a series stabilized[1] the π-bond considerably less than in the models in which the allylic C—X bond was coplanar with the π-system (**4** and **5**) (1*a*). Because there seemed to be a



2 **3**

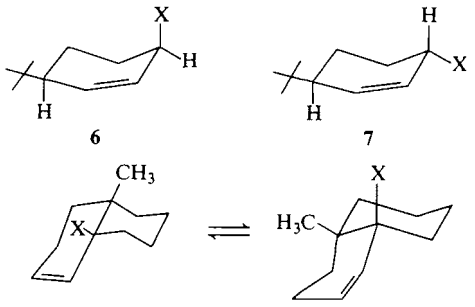
4 **5**

a X = H, *b* X = OH, *c* X = OCH_3

clear orientational effect it appeared possible that one might be able to use the technique to determine the orientations of similar substituents in systems which were not as conformationally rigid as **2**–**5** provided suitable model compounds were available. Compounds **6** and **7** which contain an anchored cyclohexene with an allylic pseudo-axial and pseudo-equatorial (*vide infra*) substituent and octalin **8** which can potentially exist in two conformations having the allylic C—X bond coplanar with (**8**) and orthogonal to (**8′**) the π-bond came to mind. The following reports the findings of this study.

[1]In this context the term 'stabilized' means an increase in ionization energy (3).

0008-4042/79/141890-07$01.00/0



6 7

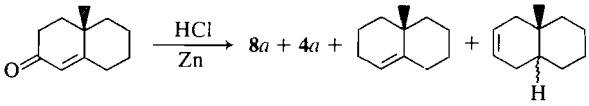
8 8′

a X = H, *b* X = OH, *c* X = OCH_3

Results

Compounds **6** and **7** can be prepared in routine fashion (see Experimental) and are easily characterized. An attempt to establish the dihedral angle between the allylic methine hydrogen and adjacent vinyl hydrogen in **6***b*,*c* and **7***b*,*c*, and by inference the dihedral angle between the π-bond and C—OR by ^{1}H nmr coupling constants, proved fruitless and no solution or gas phase data on this problem appear available.

Octalin **8***a* (X = H) is to our knowledge an unreported material, and since it serves as a key parent compound with which to compare **8***b* and **8***c*, it is important that its structure be on firm ground. Its method of synthesis via a Clemmensen reduction (4) of the corresponding α,β-unsaturated ketone (**9**) (5) could potentially have given **8***a*, **10** (*cis* or *trans*), **11**, and **4***a* (which was produced in 10% yield and identified by comparison with an authentic sample prepared by an independent route (1*a*)) (Scheme 1).



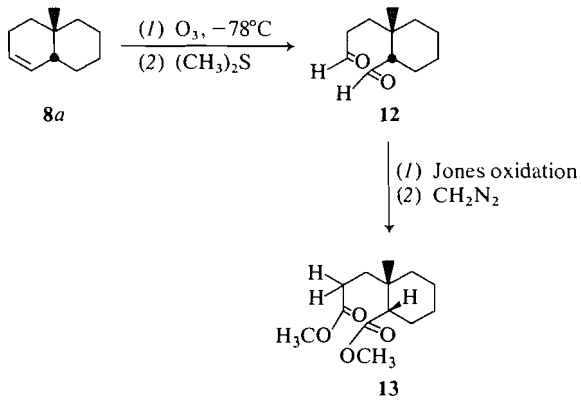
9 **11** **10**

SCHEME 1

^{1}H nmr data for the major olefinic fraction showed two vinyl hydrogens centred at δ 5.52 (inconsistent with **11**) and ambiguously supported **8***a*. ^{13}C nmr spectroscopy indicated that the two vinyl carbons were separated by about 7 ppm (132.09 and 125.34 ppm respectively in $CDCl_3$) and appeared as doublets when proton coupled, again inconsistent with **11**. The large chemical shift difference for the vinyl carbons is more appropriate for **8***a* than **10** (6) but independent proof was sought by chemical degradation according to Scheme 2.

Ozonolysis of **8***a* (7) followed by Jones oxidation of the presumed dialdehyde intermediate **12** and finally treatment with diazomethane gave, after chromatography over silica gel, diester **13** in good yield. Integration of the α-hydrogens in **13** (which are well separated from the aliphatic resonances) relative to the methoxyl singlets clearly indicated a ratio of 1:2 as expected if the starting olefin had been **8***a*.[2]

The vertical ionization energies as well as the appropriate assignments for compounds **6**–**8** and for comparison purposes **3**–**5** (1*a*) are presented in Tables 1 and 2. Table 3 lists the same data for the saturated counterparts which were prepared as an aid to assignment. Photoelectron spectra of selected examples **3***c* and **5***c* and **6***c* and **7***c* are displayed in Figs. 1 and 2, while Fig. 3 illustrates the observations



8*a* **12** **13**

SCHEME 2

for **8***a*–*c*. The assignments for **3**–**5** have been described (1*a*) and those for **6**–**8** were made analogously. Assignment of the $n_{\ddot{O}R}$ peaks in the allylic alcohols and ethers were made on the basis of which band moved markedly to lower binding energy on substitution of a CH_3 for H; the remaining band was assigned to the π-ionization. Comparison of the spectra of the saturated and unsaturated analogues confirmed the assignments.

A *general*[3] observation in these and related systems (8) is that two electronegative groups have increased ip's when they are together than when they are inde-

[2]A small sample of a mixture of **4***a* and **8***a* when ozonolized according to the route in Scheme 2 gave two isomeric diesters, one the same as **13** and one very slightly different in terms of its 200 MHz ^{1}H nmr spectrum.

[3]Conjugative and inductive effects operate simultaneously to produce the observed spectra. For a system of two interacting non-degenerate orbitals centred on electronegative groups, the lower lying orbital experiences reinforcing conjugative and inductive effects, while the upper orbital may be stabilized inductively but destabilized conjugatively by through-space or bond mechanisms. The $n_{\ddot{O}R}$ orbitals of **4***c* and **8***c* are cases in point when compared with their saturated analogues in Table 3.

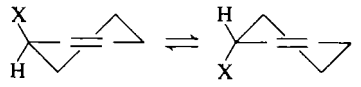
[a]Values are reported to a precision of ±0.02 eV and are averages of at least three runs.
[b]Δip = ipπ(compound) − ipπ(parent olefin).
[c]Reference *1a*.

pendent; each group apparently stabilizes the other but not necessarily by equivalent amounts.

Discussion

It has been determined that for 3-substituted cyclohexenes in the half-chair conformation (**14**)



14

electronegative groups such as OH and OAc (9) (for a different interpretation see ref. 10), Cl (11), and Br (11, 12) tend to favor a pseudo-axial form in contrast to their well-known equatorial preference in the cyclohexane series (13). A similar preference for axial over equatorial orientations exists in cases where an electronegative group occupies the 2-position of a tetrahydropyran and has been termed the anomeric effect (14). Explanations for the effect in terms of dipole–dipole interactions (14*a*,*g*) and more recently electron-delocalization of n (or π) electrons into the adjacent electronegative X—C σ*-orbital

TABLE 3. Vertical ionization energies for the $n_{\ddot{O}R}$ orbitals of saturated analogues of compounds **4**, **6**, **7**, and **8**

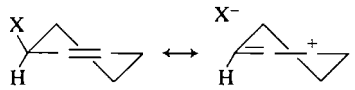
(2*b*,*c*, 12, 15) have been advanced. Recently Lessard *et al.* (12) have determined a preference for a pseudo-axial conformation of the electronegative substituent in some cyclohexenes and methylene cyclohexanes and interpreted their data in terms of a double bond – no bond resonance form as illustrated in **15**.



15

Model compounds **3***c* and **5***c* are anchored in a single chair conformation (16) and orient the allylic OCH_3 group so it is nearly[4] orthogonal to (in **3***c*) and coplanar with (in **5***c*) the π-bond. Correspondingly the pe spectra (Fig. 1) and data (Table 1) indicate the π-bond in the *trans* isomers (**5***b*,*c*) is markedly stabilized[1] relative to the parent (**3***a*) while that in the *cis* isomers (**3***b*,*c*) shows only a small stabilization (**3***b*) and net destabilization (**3***c*). Analogously, cyclohexenes **6** and **7** (Fig. 2) show similar trends in that the pseudo-axial substituent in **7***b*,*c* stabilizes the π-bond far more than it does when it is pseudo-equatorial (**6***b*,*c*). Although the term 'pseudo' does not allow a quantitative measure of the dihedral angles (θ and φ in **16** and **17**), molecular models seem to indicate that θ is likely to be smaller than φ,

[4]From Dreiding models the C—OR bond in **3** is some 10° from orthogonality while in **5** it is roughly 20–30° from coplanarity with the π-bond. Conjugative interactions are proportional to the overlap $S_{\pi-\sigma*}$ which is itself dependent on the cosine of the dihedral angle. A 30° distortion from coplanarity still leads to 87% of the maximum conjugation (17).

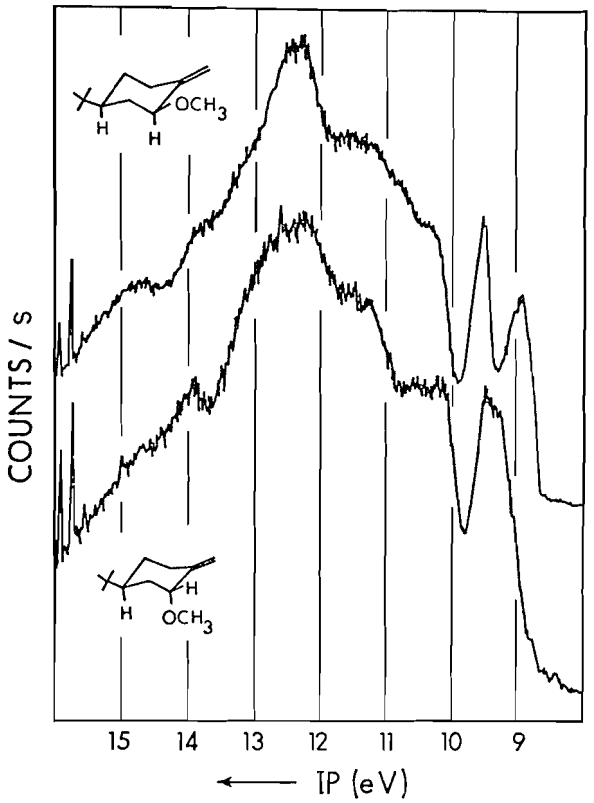


FIG. 1. The pe spectra of *cis*- and *trans*-2-methoxy-4-*tert*-butylmethylenecyclohexane (**3***c* and **5***c*) using argon as an internal calibrant.

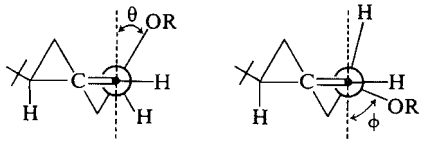
allowing a better overlap between the C—OR σ*-orbital and π in **16**. The models clearly cannot account for torsional and subtle non-bonded effects but the similarity of the pe spectral data between the anchored models (**3** and **5**) and flexible systems (**6** and



16 **17**

7) to us indicates that the dihedral angles must be similar in the two comparison series.

A more interesting example comes to light in the examination of the pe spectra of **8***a*–*c* shown in Fig. 3. Temperature dependent ^{13}C nmr spectra of **8***a* reveal a roughly 1:1 ratio of **8***a* and **8***a*′ (18) and the observed gas phase pe spectrum is probably a resultant of some equilibrium distribution of the two. The sharpness of the π-ionization for **8***a*, however, suggests that even if both conformations are present, their pe spectra must be very similar. The quoted value in Table 2 for the π-ionization energy of the *trans*

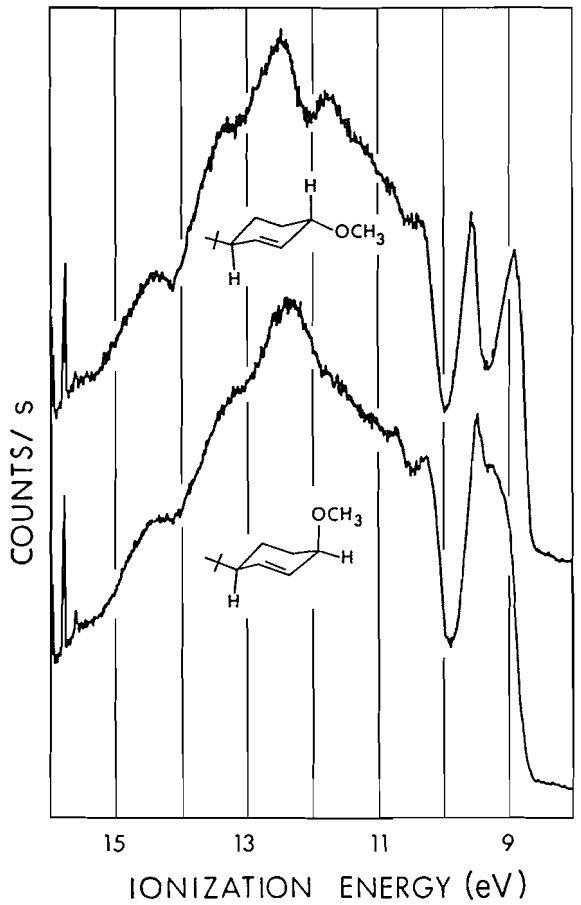


FIG. 2. The pe spectra of *cis*- and *trans*-3-methoxy-6-*tert*-butylcyclohexene (**7***c* and **6***c*) using argon as an internal calibrant.

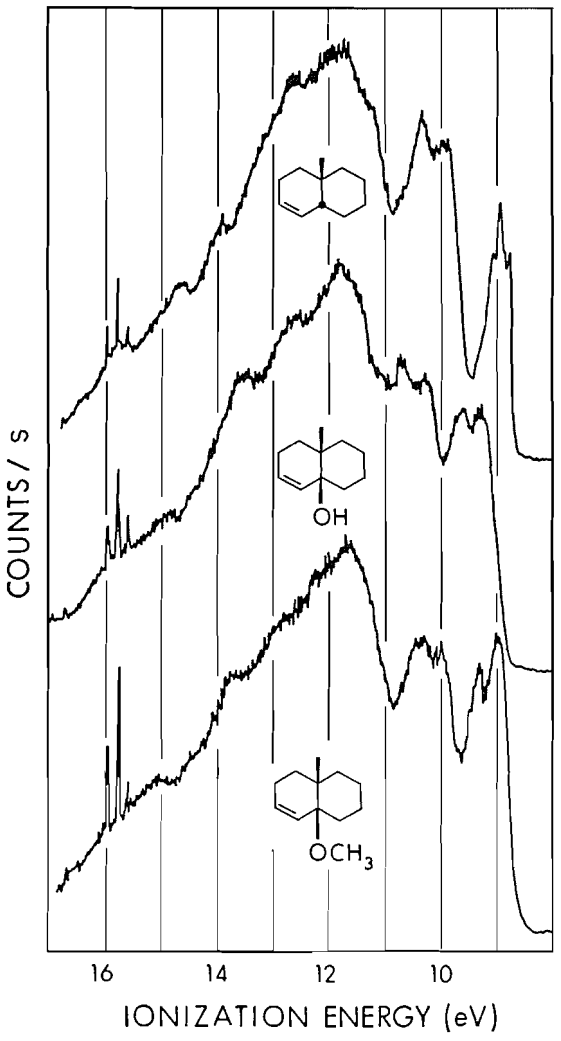

FIG. 3. The pe spectra of 5α-substituted-10α-methyl-Δ^3-octalins (**8***a–c*) using argon as an internal calibrant.

isomer **4***a* is identical to that of the *cis* isomer and indicates that the π-ionization energy is not very sensitive to the orientation of an allylic H, or alkyl substituent.

On the other hand solution phase ^{13}C nmr data reveal that the ratio of **8***b*:**8**′*b* and **8***c*:**8**′*c* is 5:1 and 6:1 respectively (18); in other words when the electronegative substituent is present, the conformation adopted is the one which aligns the π- and C—OR bonds. The large stabilization of the π-bond in **8***b* and **8***c* of 0.34 and 0.42 eV respectively (relative to **8***a*) is reminiscent of that observed in the rigid colinear *trans* series **4***a* → **4***b* → **4***c* and supports a dominant colinear conformation in the gas phase. Were the dominant conformation really **8**′*b* (**8**′*c*), a much smaller π-stabilization (or perhaps even destabilization) would have been observed (1*a*).

The present examples seem to indicate that in cases where one has an allylic alcohol or ether, interaction between π and σ* (C—OR) is sufficient to stabilize one of the possible conformations, perhaps due to a hyperconjugative interaction which requires coplanarity of the orbitals (12, 15). For example, according to models, the pseudo-axial and equatorial orientations (**16** and **17**) can attain similar dihedral angles with little effort,[5] and yet a stabilizing π–σ* interaction in **16** could favor a 'more' axial orientation leading to the observed pe spectrum. In order for the pseudo-equatorial isomer (**17**) to maximize the stabilizing π–σ* interaction, the molecule is forced to assume an unfavorable twist boat conformation.

Several literature examples seem to indicate that the pe observations may be general. For example, when compared with propene (π_{ip} = 9.88 eV (19)),

[5]Dreiding models obviously cannot assess torsional and nonbonded interactions which contribute to the stability of the adopted conformation.

allyl fluoride, chloride, and bromide show π_{ip}'s of 10.56, 10.34, and 10.18 eV respectively (19). Allyl fluoride and chloride have been said to exist preferentially in conformations which align the C—X bond with the π-system (20), although conflicting data for the fluoride have been reported (21). The pe observations are consistent both with electronegativity arguments and a hyperconjugative π–σ^* interaction, but only the latter explanation requires coplanarity.

Allyl alcohol also adopts a preferred conformation in which the C—OH bond is nearly coplanar with the π-system (22). Photoelectron data show the π_{ip} (10.22 eV (23)) to be 0.34 eV greater than the parent propene (19), close to the stabilization found for the coplanar alcohols found in Tables 1 and 2.

Conclusions

For these selected flexible allylic alcohols and ethers, pe spectroscopy indicates that in the gas phase the molecules prefer to adopt a conformation which aligns the π and adjacent C—OR σ-bond.

Experimental

Photoelectron spectra were determined using a MacPherson 36 ESCA spectrometer and were calibrated using argon or nitrogen as an internal calibrant. The resolution on the argon $2P_{1/2}$–$2P_{3/2}$ lines was commonly 25–35 meV during operation. Linearity of the spectrometer for electron kinetic energies between 17 and 7 eV was ensured by independent runs using argon and methyl iodide and was found to vary no more than 0.01 eV. Spectra are computer stored in 1006 channels for a 10 eV scan and peak positions were determined from an intensity vs. channel number listing. Each value reported is an average of at least three independent runs, and has a precision of ±0.02 eV unless otherwise noted. Routine ir and ^{1}H nmr spectra were recorded on a Nicolet 7199 FT-IR spectrophotometer and a Varian Associates HA-100 spectrometer. Melting and boiling points are uncorrected.

cis *and* trans-*4*-tert-*Butyl-2-cyclohexen-1-ol (7*b *and* 6*b)*

Seven grams of a 3:7 mixture of **7***b* and **6***b* (24) were chromatographed over 350 g of grade III alumina as published (25) to give 0.9 g of pure **7***b*, mp 51–54°C (from petroleum ether) (lit. (21) mp 44–49°C) and 6 g of mixture. The *trans* isomer (**6***b*) was obtained by a published procedure (26) from 9 g of a 3:7 mixture of **7***b* and **6***b* to give 2.5 g of **6***b*, mp 32–34°C (lit. (26) mp 31–32°C).

cis-*2-Methoxy-6-*tert-*butylcyclohexene (7*c*)*

Alcohol **7***b* (0.25 g, 1.49 × 10^{-3} mol) was methylated (27) to give after final microdistillation (70–80°C/14 Torr) 0.170 g (63%) of **7***c*; ^{1}H nmr ($CDCl_3$) δ: 0.89 (s, 9H), 1.20–2.20 (m, 5H), 3.32 (s, 3H), 3.44–3.70 (m, 1H), 5.78 (s, 2H). *Anal.* calcd. for $C_{11}H_{20}O$: C 78.57, H 11.90; found: C 78.43, H 11.99.

trans-*3-Methoxy-6-*tert-*butylcyclohexene (6*c*)*

Methylation (27) of 0.5 g (2.98 × 10^{-3} mol) **6***b* gave after microdistillation (80°C/12 Torr) 0.40 g (74%) of **6***c*; ^{1}H nmr ($CDCl_3$) δ: 0.88 (s, 9H), 1.12–2.40 (m, 5H), 3.36 (s, 3H), 3.60–4.00 (m, 1H), 5.78 (b s, 2H). *Anal.* calcd. for $C_{11}H_{20}O$: C 78.57, H 11.90; found: C 78.51, H 12.11.

*10-Methyl-*cis*-3-octalin (8*a*)*

Five grams (0.03 mol) of 10-methyl-4-octalin-3-one (**9**) (5) was added to amalgamated zinc (prepared from 6.1 g (0.03 mol) of granular zinc) in a solution of water (6.1 mL) and concentrated hydrochloric acid (6.4 mL) according to the procedure of Davis and Woodgate (4). After refluxing for 3.5 h, the mixture was cooled and extracted with ether which was subsequently dried ($MgSO_4$), filtered, and evaporated to yield 4.0 g (88% crude yield) of viscous brown oil which proved to be a mixture of **8***a* and its *trans* isomer **4***a* in a 10:1 ratio. Preparative glpc (16 ft × 3/8 in. – 20% DEGS on Chrom. WAW-DMCS (80–100 mesh)) gave first the major isomer (**8***a*) which was collected and microdistilled (50°C, 5.0 Torr) to give a clear liquid; ^{1}H nmr ($CDCl_3$) δ: 0.94 (s, 3H, 10-CH_3); Fourier transform ir (Ftir) (cast film): 3005, 2920, 2850, 1450, 1378, and 775 cm^{-1}. *Exact Mass* calcd. for $C_{11}H_{18}$: 150.1409; found: 150.1405.

*Degradation of 8*a *to Diester 13*

Twenty-five milligrams (1.67 × 10^{-4} mol) of olefin **8***a* was collected by preparative glpc as described above and ozonized (7) in 25 mL dry CH_2Cl_2 at −78°C until the solution turned blue. After flushing the solution with O_2 to remove excess ozone, 1 mL of dimethyl sulfide was added and the mixture stirred 2 h at 25°C. The mixture was then extracted with H_2O, dried over Na_2SO_4, and evaporated. The residue in 5 mL acetone was oxidized by the addition of Jones reagent, worked up by the addition of H_2O, and extracted with CH_2Cl_2 which was subsequently dried over Na_2SO_4. Evaporation produced a second residue which was methylated with CH_2N_2 in ether, and after ether removal, the residue was chromatographed over silica gel using 19:1 petroleum ether – ether to yield 11.4 mg of diester; 200 MHz, ^{1}H nmr ($CDCl_3$) δ: 0.95 (s, 3H), 2.12–2.40 (m, 3H, (α-H's)), 3.64 (s, OCH_3), 3.66 (s, OCH_3); Ftir (cast film): 1739 cm^{-1}. *Exact Mass* calcd. for $C_{13}H_{22}O_4$: 242.1518; found: 242.1511.

*5α-Hydroxy-10α-methyl-3-octalin (8*b*)*

A mixture of **8***b* and its *trans* isomer **4***b* was prepared as described (1*a*) and separated by preparative tlc (silica gel (1 mm), pentane–ether, 4:1) and the band of higher R_f value collected. Microdistillation (90°C/1 Torr) gave a clear liquid; ^{1}H nmr ($CDCl_3$) δ: 1.00 (s, 3H, 10-CH_3) 5.6 (m, 2H, olefinic H); Ftir (cast film): 3445, 3010, 2920, 2850, and 1445 cm^{-1}. *Exact Mass* calcd. for $C_{11}H_{18}O$: 166.1358; found: 166.1356.

5α-Hydroxy-10α-methyldecalin

Hydrogenation of 115 mg of **8***b* (50 mL dry ether, 5 drops triethylamine, 400 mg 5% Pd–C) at 50 psi for 120 h followed by work-up (as described for its *trans* isomer (1*a*)) yielded after microdistillation (100°C/3 Torr) 97 mg (83%) of a clear liquid; ^{1}H nmr ($CDCl_3$) δ: 0.97 (s, 3H, 10-CH_3), 1.4 (m, 17H); Ftir (cast film): 2930, 2860, and 1449.7 cm^{-1}. *Exact Mass* calcd. for $C_{11}H_{20}O$: 168.1509; found: 168.1514.

*5α-Methoxy-10α-methyl-3-octalin (8*c*)*

Methylation (27) of a mixture (1.0 g, 9 × 10^{-3} mol) of **8***b* and its *trans* isomer (**4***b*) yielded after work-up 0.95 g (88%) of a viscous yellow oil containing both allylic ethers. Preparative glpc (16 ft × 3/8 in., 10% polyphenyl ether on Chrom. WAW-DMCS (80–100 mesh)) gave as a major component having a longer retention time **8***c* which was collected and microdistilled (95°C/7 Torr) to give a clear liquid; ^{1}H nmr ($CDCl_3$) δ: 0.97 (s, 3H, 10-CH_3), 3.19 (s, 3H, 5-OCH_3), 5.7 (m, 2H, vinyl H); Ftir (cast film): 2930, 1377, 1277, 1085 cm^{-1}. *Exact Mass* calcd. for $C_{12}H_{20}O$: 180.1515; found: 180.1513.

5α-Methoxy-10α-methyldecalin

Hydrogenation of **8***c* (100 mg, 5.5 × 10^{-4} mol) in 40 mL

dry ether containing 6 drops of triethylamine and 400 mg of 5% Pd–C was carried out at 50 psi over a period of 5 days. Work-up (similar to that reported for the *trans* isomer (1*a*)) and microdistillation (80°C/5 Torr) gave 95 mg (94%) of liquid; ^{1}H nmr ($CDCl_3$) δ: 0.94 (s, 3H, 10-CH_3), 1.5 (s, 16H, methylene protons), 3.09 (s, 3H, 5-OCH_3). *Exact Mass* calcd. for $C_{12}H_{22}O$: 182.1672; found: 182.1671.

3-tert-*Butylcyclohexene (7a)*

Prepared by the published procedure (28).

cis *and* trans-*4*-tert-*Butylcyclohexanol*

Seven grams of commercially available material (4:1, *trans*:*cis*) was separated as reported (29) to give 1.2 g *cis*, mp 82–83°C (lit. (29) mp 81–82°C) and 2.6 g *trans*, mp 81–82°C (lit. (29) mp 80–81°C) as well as 3 g of mixture.

Polymerisation of the 3-halogenomethyl-5-methyl(or 5-phenyl)-3′(5′)-methyl-1,5′(3′)-dipyrazolylmethane. Synthesis of new macrocyclic systems

ALAIN FRUCHIER, ABDELKRIM RAMDANI, AND GEORGES TARRAGO[1]

Laboratoire de Synthèse et d'Etudes Physicochimiques d'Hétérocycles Azotés, Université des Sciences et Techniques du Languedoc, Place Eugène Bataillon, 34060 Montpellier Cedex, France

Received December 22, 1978

ALAIN FRUCHIER, ABDELKRIM RAMDANI, and GEORGES TARRAGO. Can. J. Chem. **57**, 1897 (1979).

The study of the polymerisation of the 3-halogenomethyl-5-methyl(or 5-phenyl)-3′(5′)-methyl-1,5′(3′)-dipyrazolylmethane allowed the isolation of five new macrocyclic compounds with four or six pyrazole rings. Their structures have been determined by mass spectrometry and proton nmr spectroscopy.

A scheme is proposed which takes into account the different possible orientations of this reaction.

ALAIN FRUCHIER, ABDELKRIM RAMDANI et GEORGES TARRAGO. Can. J. Chem. **57**, 1897 (1979).

L'étude de la polymérisation de l'halogénomethyl-3-méthyl (ou phényl)-5-méthyl-3′(5′)-dipyrazolyl-1,5′(3′)-méthane nous a permis d'isoler cinq nouveaux composés macrocycliques comportant 4 ou 6 noyaux pyrazoliques. Leurs structures ont été déterminées par spectrométrie de masse et de rmn protonique.

Un schéma réactionnel, rendant compte des différentes orientations possibles de cette réaction, est proposé.

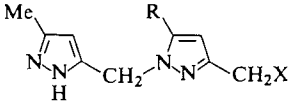
Introduction

We described in a preceding paper (1) the synthesis of a new macrocyclic compound of the 1,6,11,16-tetraazaporphyrinogen type by polymerization of a halogenomethyldipyrazolylmethane.

Nevertheless, the poor yield (about 15%) with which we obtained the first compound led us to study the other products formed during this reaction.

Experimental

The polymerisation has been effected by heating for 2 h at 100°C the 3-halogenomethyl-3′,5′-dimethyl-1,5′-dipyrazolylmethane, **1***a*, and the 3-halogenomethyl-3′-methyl-5-phenyl-1,5′-dipyrazolylmethane, **1***b*, in dimethylformamide in the presence of potassium iodide. After solvent concentration, the residue was chromatographed on alumina. Physical properties of isolated compounds are given in Table 1. Their structures have been determined essentially by 100 MHz proton nmr analysis.



1*a* R = methyl
1*b* R = phenyl

Mass spectra were recorded by M. Guiraud on the JEOL JMS-D-100 spectrometer of the Laboratoire de Mesures Physiques of U.S.T.L. in Montpellier.

Proton nmr spectra were obtained in the same laboratory using a Varian HA-100 spectrometer. Concentrations were about 10% by weight in deuteriochloroform and the chemical shifts are expressed in δ units from TMS. When they have been measured, coupling constants are given, in hertz, in parentheses.

Results

In the polymerisation of each of **1***a* and **1***b*, the compound with the largest R_f has an *m/e* value corresponding to a macrocyclic ring with six pyrazole rings (Table 1). Theoretically, four isomers of this type can be obtained but only two of them were isolated.

The first compound, when R = methyl, shows two methyl signals of equal intensities which indicate a symmetric structure. The signal at 2.10 ppm belongs to a 5-methyl group of a pyrazole ring (2) coupled (J = 0.6 Hz) with the close H_4 whose signal appears at 5.82 ppm. The other methyl signal at 2.17 ppm shows no measurable coupling and is characteristic of a 3-methyl pyrazolic group, the corresponding H_4 signal being at 5.79 ppm. Two methylene signals are also observed (5.23 and 5.34 ppm) but their assignment is not possible. This spectrum is only compatible with the symmetric structure **2***a*.

When R = phenyl, only one methyl signal is observed at 2.14 ppm which belongs to 3-methylpyrazolic groups (no measurable coupling but the signal is broadened), with the corresponding H_4 signal at 5.58 ppm. The signal of the H_4 close to 5-phenyl groups (narrow multiplet at 7.36 ppm) appears at 6.14 ppm and those of methylenes at 5.35 and 5.46 ppm. Thus it is clear that this spectrum corresponds to structure **2***b*.

*The residues are formed by non-identified polymers for which the yields are under 4%.

The second type of macrocycle with six pyrazole rings which has been isolated has a spectrum indicating a non-symmetric structure.

When R = methyl, four methyl signals (1.78 (0.5), 2.01 (0.5), 2.11, 2.24 ppm, the last two being twice as intense as the others), five methylene signals (4.71, 4.95, 5.10 (4H), 5.14, 5.26 ppm), and five H_4 pyrazolic signals (5.30 (2H), 5.39, 5.76, 5.87, 6.09 ppm) are observed. When three drops of deuteriobenzene are added to this solution, six methyl signals become clearly visible, four of which bear a coupling constant of 0.6 Hz while two are broadened.

This spectrum can be attributed to the structure **3***a* which has two pyrazole rings with 3-methyl groups and four with 5-methyl groups.

These results are confirmed by the compound **3***b* (R = phenyl). Its spectrum has three methyl signals (2.00 (0.6), 2.12 (broadened), 2.20 (broadened)) but only the first one belongs to a 5-methyl group. Six methylene signals (4.93, 4.96, 5.00, 5.20, 5.25, 5.34 ppm) and six 4-pyrazolic protons (5.31 and 5.86 (pyrazole with a 3-methyl group), 5.76 (pyrazole with a 5-methyl group), 5.72, 5.99, 6.03 (pyrazole with 5-phenyl group)) are also observed.

Also isolated are three further types of macrocycles showing *m/e* corresponding to four pyrazole rings (Table 1) which is the same number of isomers as predicted. The results of their nmr analysis are collected in Table 2. To facilitate comparisons between them, we have adopted for **4** and **5** a numerotation similar to the conventional one used for compound **6** (Fig. 1).

When R = methyl, the identification of compounds **4***a*, **5***a*, and **6***a* presents no difficulty. One of them has a very simple spectrum with three signals of relative intensities 3:2:1. Only the structure **6***a* has a symmetry compatible with this spectrum. On the contrary, structure **5***a* has no symmetry and its spectrum bears four signals of each type (methyl, methylene, and pyrazolic protons). The signals at 5.00 and 5.02 ppm can be assigned to the 10- and 15-methylene groups which have an environment similar to the methylenes in **6***a* (signal at 4.98 ppm). Likewise, the 5- and 20-methylenes in **5***a* can be compared to the 5,15- and 10,20-methylenes in **4***a* respectively. The structure **4***a* has a C_2 axis which leads the 2,12- and the 7,17-methyl groups, the 3,13- and the 8,18-protons, the 5,15- and the 10,20-methylene groups being equivalent respectively. The coupling constant (0.7 Hz) between the 7,17-methyl groups and the 8,18-protons allows the assignment of their signals.

When R = phenyl, the structure **6** loses its C_4 axis which is replaced by a C_2 axis. Then **6***b* and **4***b* should have similar spectra. Effectively, spectra are of the same type and, at first sight, the major difference is the appearance of the phenyl signal. Again, the identification is made on the basis of the coupling constant between the methyl group and the adjacent pyrazolic proton. The value is 0.7 Hz in **6***b* (methyl in position 5 of a pyrazole ring) and is not measurable in **4***b* (methyl in position 3).

Discussion

Some comments can be made about these results.

(*1*) In structure **1**, the pyrazole ring unsubstituted on nitrogen presents, owing to the well known prototropy in such systems, two nucleophilic centers localised on the nitrogens.

(*2*) Generally, the *N*-alkylation site of a pyrazole ring is directed by steric factors involving the substituents close to the nitrogens (3). This is observed when the substituents are alkyl or aryl, but not if one of them contains a lone electronic pair adequately situated (as in structure **1**). In this case, we have shown (4) that the lone pair play a great part in the orientation of the reaction: the alkylation of the β site is then favoured even against an eventual steric hindrance of this site.

(*3*) When the final macrocycle is not (or only

FIG. 1. Polymerisation reaction scheme (percentages indicated are theoretical ones based on final experimental yields). *a*, R = methyl; *b*, R = phenyl. P = non-isolated degradation and polymerisation products. None of them should have yield over 3%. Q = products which could be obtained from the cyclisation of the intermediate compound **D**. Nevertheless, the global yield of **D** cannot be over 6%. Thus the yield of each Q product is under 3% and explains why they have not been isolated.

1

slightly) strained, the intramolecular cyclisation occurs more rapidly than the intermolecular substitution. This is observed when the compound **A** (Fig. 1) gives the macrocycle **6** only, by cyclisation. We demonstrated this point in a preceding paper (1) where we described the isolation, with a good yield, of a compound of type **6** from the cyclisation of an analog of **A** (all pyrazole rings having one phenyl substituent) unequivocally synthesised. In the case of the intermediate compound **B** (Fig. 1), a competition exists between the cyclisation which gives **4** and **5** and the intermolecular reaction giving the intermediate compounds **C** and **D**.

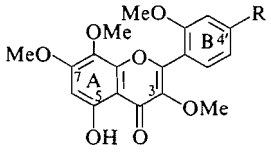
Les structures dihydroxy-4′,5 tétraméthoxy-2′,3,7,8 flavone et hydroxy-5 pentaméthoxy-2′,3,4′,7,8 flavone ont été attribuées à deux flavonoïdes nouveaux isolés d'un exsudat farineux de *Notholaena affinis*; ce résultat découle de l'analyse des spectres uv, sm et rmn des produits naturels et de leurs dérivés.

MAURICE JAY, JEAN FAVRE-BONVIN, and ECKHARD WOLLENWEBER. Can. J. Chem. **57**, 1901 (1979).

The structures 4′,5-dihydroxy-2′,3,7,8-tetramethoxyflavone and 5-hydroxy-2′,3,4′,7,8-pentamethoxyflavone have been attributed to two new compounds isolated from a farinose exudate of *Notholaena affinis*; this result is derived from uv, ms, and nmr spectra of the natural products and their derivatives.

Introduction

Dans le cadre de nos recherches biochimiques sur les processus d'excrétion chez les végétaux vasculaires et plus particulièrement ici chez les Fougères (1), nous venons d'isoler d'un exsudat farineux de fronde de *Notholaena affinis* (Mett.) Moore deux méthyl-3 flavonols dont les structures ont été établies après analyse spectrale comme dihydroxy-4′,5 tétraméthoxy-2′,3,7,8 flavone **1** et hydroxy-5 pentaméthoxy-2′,3,4′,7,8 flavone **2**. Il s'agit de constituants mineurs au sein du pool flavonique de cette farine et d'espèces moléculaires nouvelles pour la littérature flavonique.



1 R = OH
2 R = OMe

Résultats et discussion

Les spectres uv dans le MeOH laissent supposer une parenté structurale entre les deux composés qui montrent en effet les mêmes λ_{max} (I = 264 nm, II = 354 nm) et le même profil original des spectres avec une dissymétrie très accusée entre les bandes I et II (30% et 100% respectivement). En outre, au vu du λ_{max} de la bande I et de la fluorescence violette en chromatographie sur papier, l'hypothèse d'un flavonol méthylé en position 3 peut être retenue. Les réactifs classiques en spectrophotométrie de flavonoïdes (2) conduisent aux conclusions structurales suivantes: les deux composés ont des OH bloqués en position 7 (pas de déplacement bathochrome de la bande II en présence de NaOAc), des OH libres en position 5 (+55 nm sur la bande I en présence de $AlCl_3$ + HCl par rapport au MeOH); ils ne possèdent sur leur squelette aucun groupement *ortho*-dihydroxylé (pas de déplacement hypsochrome entre $AlCl_3$ et $AlCl_3$ + HCl sur la bande I); en position 4′, la substitution est de type hydroxyle pour le composé **1** (+30 nm sur la bande I en présence de NaOH par rapport au MeOH, sans diminution d'intensité du pic), et de type méthoxyle pour le composé **2** (très faible déplacement bathochrome sur la bande I avec diminution d'intensité du pic).

La formule chimique brute obtenue par mesure de masse à haute résolution permet de reconnaitre en **1** ($C_{19}H_{18}O_8$) une tétraméthoxy, dihydroxy-flavone, et en **2** ($C_{20}H_{20}O_8$) une pentaméthoxy, monohydroxy-flavone. L'étude des fragments selon le mécanisme proposé par Audier (3) permet de préciser la distribution des substituants entre les noyaux A et B du squelette flavone: pour les deux composés un ion-fragment apparait à 197 ($C_9H_9O_5$) témoignant d'un noyau A diméthoxylé et monohydroxylé; un second ion-fragment donne pour le composé **1** un pic *m/e* 151 ($C_8H_7O_3$) caractéristique d'un noyau

0008-4042/79/141901-02$01.00/0

B monométhoxylé et monohydroxylé, pour le composé **2** un pic *m/e* 165 ($C_9H_9O_3$) typique d'un noyau B diméthoxylé.

En première conclusion, il apparait que ces deux composés flavoniques ont le même noyau A, le même hétérocycle et des noyaux B qui diffèrent par la nature de leurs substituants. La position relative de ces derniers est déterminée par rmn de ^1H; en effet, la figure de résonance observée dans la région des protons aromatiques est très significative: pour le composé **2**, nous notons deux protons couplés en *ortho* (H-6′ et H-5′), le plus blindé des deux (H-5′) étant lui-même couplé en *méta* avec un troisième proton (H-3′); les deux substituants du noyau B sont donc portés par les carbones 2′ et 4′ (soit diméthoxy-2′,4′); les attributions ont été faites en tenant compte des δ, les protons H-2′ et H-6′ étant toujours les plus déblindés chez les composés flavoniques, ce qui dans ce cas exclut une substitution de type 2′,5′. Pour le composé **1** où la figure de résonance est voisine, le noyau B est monométhoxylé en 2′ et monohydroxylé en 4′ (voir uv).

En ce qui concerne le noyau A commun aux deux composés, la spectrophotométrie uv a permis de localiser un hydroxyle en 5 et un méthoxyle en 7; il ne reste à placer que le second groupement méthoxyle pour lequel deux hypothèses se présentent: OMe-6 ou OMe-8. Le spectre de rmn ne permet pas de trancher entre les deux termes de l'alternative, car le signal singulet relatif au proton libre résonne à une valeur de champ qui peut être le fait aussi bien d'un H-6 que d'un H-8 (2). Le spectre de masse des produits naturels dans lequel nous relevons un pic de base correspondant à l'ion $M - 15$, oriente vers une structure méthoxy-8 flavonoïde (4); cette hypothèse est d'ailleurs confirmée après méthylation du groupement OH-5, le spectre de masse montrant alors un M^+ pic de base (5); il a en effet été démontré (4, 5) que les spectres de masse des OH-5 diOMe-7,8 flavones, flavonols et méthyl-3 flavonols présentent un pic moléculaire inférieur au pic $M - 15$ (pic de base), et que cette figure spectrale s'inverse pour les dérivés triOMe-5,7,8.

Conclusions

Les deux composés flavoniques isolés de *Notholaena affinis* se voient attribuer les structures suivantes: dihydroxy-4′,5 tétraméthoxy-2′,3,7,8 flavone (**1**), monohydroxy-5 pentaméthoxy-2′,3,4′,7,8 flavone (**2**). Ces deux flavonoïdes naturels nouveaux sont proches au plan structural de quatre autres composés précédemment isolés de la farine de *Notholaena affinis*; ces derniers montraient en effet un noyau B disubstitué en 2′ et 4′, mais possédaient un noyau A tétrasubstitué en 5, 6, 7 et 8 (6).

Partie expérimentale

Matériel végétal

Les frondes de *Notholaena affinis* ont été récoltées au Costa Rica (Prov. Gabacaste, Dec. 1976); un échantillon d'herbier est conservé au Museo nacional de Costa Rica à San José (LDG 4725).

Isolement des flavonoïdes

L'exsudat foliaire de 98 g de frondes est dissous par lavage avec Me_2CO et C_6H_6; il représente environ 6% du poids sec. Après élimination par filtration des cristaux du flavonol majeur (environ 2 g) (7), 1.2 g d'extrait initial est adsorbé sur poudre de polyamide MN SC6; le fractionnement est réalisé sur colonne (3 × 30 cm) du même adsorbant élué avec du C_6H_6 enrichi progressivement en MeCOEt et MeOH (8). Les fractions alors collectées, ici 3 (15 mg) et 7 (26 mg) sont purifiées en CCM préparative de polyamide MN DC 11 dans les systèmes solvants: C_6H_6: petrol 100–140: MeCOEt: MeOH 60:26:7:7, 60:60:7:7 et 30:60:5:5. Finalement 2.5 mg du composé **1** et 4.5 mg du composé **2** sont récupérés.

Dihydroxy-4′,5 tétraméthoxy-2′,3,7,8 flavone (1)—uv λ_{max} nm: MeOH (254), 264, 354; NaOAc (254), 264, 380; NaOAc + H_3BO_3 (256), 266, 356; $AlCl_3$ 272, 306, 346, 412; $AlCl_3$ + HCl 272, 340, 418; NaOMe 264, 384 stable; sm (70 eV) *m/e*: 374 (M^+, 75%, 374.0997, calculé pour $C_{19}H_{18}O_8$ 374.1002), 359 ($M - 15$, 100%), 346 ($M - CO$, 7%), 343 ($M -$ OMe, 6%), 197 (ion D selon Audier, 5%, 197.0441, calculé pour $C_9H_9O_5$ 197.0450), 151 (ion C selon Audier, 10%, 151.0393, calculé pour $C_8H_7O_3$ 151.0397); rmn, 100 MHz (DMSO) (δ en ppm/TMS): 3.71 (3H, s, OMe), 3.73 (3H, s, OMe), 3.79 (3H, s, OMe), 3.93 (3H, s, OMe), 6.57 (3H, m, H-3′, H-5′, H-6), 7.35 (1H, d, $J = 8.5$ Hz, H-6′).

Hydroxy-5 pentaméthoxy-2′,3,4′,7,8 flavone (2)—uv λ_{max} nm: MeOH 264, 352; NaOAc 266, 350; NaOAc + H_3BO_3 264, 350; $AlCl_3$ 272, 340, 412; $AlCl_3$ + HCl 270, 340, 408; NaOMe 268, 360 stable avec diminution d'intensité de BI; sm (70 eV) *m/e*: 388 (M^+, 71%, 388.1151, calculé pour $C_{20}H_{20}O_8$ 388.1158), 373 ($M - 15$, 100%), 357 ($M -$ OMe, 6%), 197 (ion D selon Audier, 5%, 197.0442, calculé pour $C_9H_9O_5$ 197.0450), 165 (ion C selon Audier, 10%, 165.0553, calculé pour $C_9H_9O_3$ 165.0552); rmn, 100 MHz (DMSO) (δ en ppm/TMS): 3.73 (6H, s, deux OMe), 3.85 (3H, s, OMe), 3.89 (3H, s, OMe), 3.93 (3H, s, OMe), 6.64 (1H, s, H-6), 6.72 (1H, dd, $J = 2.5$ et 8.5 Hz, H-5′), 6.78 (1H, s, H-3′), 7.48 (1H, d, $J = 8.5$ Hz, H-6′); sm après méthylation au diazométhane de **2**: 402 (M^+, 100%), 387 ($M - 15$, 50%).

Remerciements

Synthesis of some alkoxyfluorophosphoranes and alkoxyfluorophosphines and characterization by ^{1}H, ^{19}F, and ^{31}P nuclear magnetic resonance spectroscopy[1]

ALEXANDER F. JANZEN AND LEONARD J. KRUCZYNSKI

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received December 27, 1978

ALEXANDER F. JANZEN and LEONARD J. KRUCZYNSKI. Can. J. Chem. **57**, 1903 (1979).

The preparation of phosphoranes $C_6H_5PF_2HOR$ by the oxidative addition of alcohols to $C_6H_5PF_2$, followed by elimination of HF to give phosphines C_6H_5PFOR (R = CH_3, CH_2CH_3, CH_2CF_3, $CH(CF_3)_2$, $CH(CF_3)C_6H_5$, $C(CH_3)_3$), is described. All products were characterized by ^{1}H, ^{19}F, and ^{31}P nmr spectroscopy. The ^{31}P nmr spectrum of $C_6H_5PFOCH(CF_3)C_6H_5$ confirms the presence of diastereomers. Rapid ligand exchange in phosphoranes $C_6H_5PF_2HOR$ occurs upon addition of a base such as pyridine.

ALEXANDER F. JANZEN et LEONARD J. KRUCZYNSKI. Can. J. Chem. **57**, 1903 (1979).

L'addition oxydante d'alcools à du $C_6H_5PF_2$ conduit aux phosphoranes $C_6H_5PF_2HOR$ qui par élimination de HF conduisent aux phosphines C_6H_5PFOR(R = CH_3, CH_2CH_3, CH_2CF_3, $CH(CF_3)_2$, $CH(CF_3)C_6H_5$, $C(CH_3)_3$). On a caractérisé tous les produits par spectroscopie rmn ^{1}H, ^{19}F et ^{31}P. Le spectre rmn ^{31}P du $C_6H_5PFOCH(CF_3)C_6H_5$ confirme la présence de diastéréoisomères. L'échange rapide du ligand des phosphoranes $C_6H_5PF_2HOR$ se produit par addition d'une base comme la pyridine.

[Traduit par le journal]

Phosphines undergo oxidative addition reactions with alcohols, amines, thiols, hydrogen halides, or halogens to give five-coordinate phosphoranes (see, for example, ref. 1). We have prepared a variety of phosphoranes $C_6H_5PF_2HOR$ by the oxidative addition reaction of $C_6H_5PF_2$ with alcohols and studied their conversion to phosphines C_6H_5PFOR by the elimination of HF.

The reaction of $C_6H_5PF_2$ with alcohols occurred under mild conditions, typically at -10 to $+10$°C within 5 to 30 min in an nmr tube (eq. [1]).

[1] $$C_6H_5PF_2 + HOR \longrightarrow C_6H_5P(F)(H)(OR)(F)$$

1–6

1 R = CH_3
2 R = CH_2CH_3
3 R = CH_2CF_3
4 R = $CH(CF_3)_2$
5 R = $CH(CF_3)C_6H_5$
6 R = $C(CH_3)_3$

The products were characterized by ^{1}H, ^{19}F, and ^{31}P nmr (Table 1) and the nmr data are in agreement with trigonal bipyramidal phosphoranes in which fluorines occupy axial sites. The phosphoranes were stable at temperatures below $+10$°C in the absence of pyridine or excess $C_6H_5PF_2$.

The synthesis of $C_6H_5PF_2HOC(CH_3)_3$ (**6**) was carried out at $+5$°C in the presence of a small amount of pyridine; attempts to prepare **6** at $+25$°C resulted in the formation of $(CH_3)_3CF$ (85%), $(CH_3)_2C{=}CH_2$ (15%), $C_6H_5P(O)HF$, and HF.

Conversion of $C_6H_5PF_2HOR$ to C_6H_5PFOR

At temperatures above $+10$°C, HF elimination occurred and the phosphoranes were converted to phosphines C_6H_5PFOR **7–12** which were characterized by ^{1}H, ^{19}F, and ^{31}P nmr (Table 2). The presence of $C_6H_5PF_2$ favours the conversion to C_6H_5PFOR because HF is then removed as $C_6H_5PF_3H$.

react slowly with $C_6H_5PF_2$, any unreacted $C_6H_5PF_2$ will favour the conversion of $C_6H_5PF_2HOR$ to C_6H_5PFOR; on the other hand, for reactive alcohols such as CH_3OH or C_2H_5OH, $C_6H_5PF_2$ is consumed before it seriously affects the conversion to C_6H_5PFOR.

The phosphines **7**–**12** have a chiral center at phosphorus which leads to magnetically nonequivalent CF_3 groups in **10** (2). An additional chiral center at carbon is found in **11** and the ^{31}P nmr spectrum of **11** clearly shows the presence of diastereomers with the coupling constant $^4J_{POCCF}$ differing by a factor of 2 in the isomers (Fig. 1).

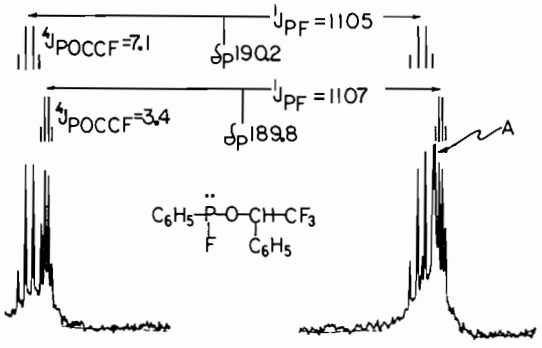

FIG. 1. The ^{31}P nmr spectrum (proton decoupled) of $C_6H_5PFOCH(CF_3)C_6H_5$ (**11**) showing the presence of diastereomers. Peak A is due to unreacted $C_6H_5PF_2$.

HF, H_2O, Base Catalysts, and Ligand Exchange

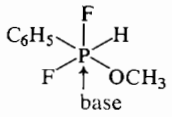
As a continuation of previous work (3, 4), we briefly investigated the effect of HF, H_2O, and base catalysts on exchange processes. It was found that addition of a small amount of H_2O to $C_6H_5PF_2$ resulted in an instantaneous reaction to give, mainly, $C_6H_5P(O)HF$ and $C_6H_5PF_3H$ (eq. [3]).

[3] $C_6H_5PF_2 + H_2O \longrightarrow C_6H_5P(O)HF + HF$

$C_6H_5PF_2$ ↓

$C_6H_5PF_3H$

Addition of HF to $C_6H_5PF_3H$ produced only very slow fluorine exchange, on the nmr time scale,[2] unlike the situation in the $CH_3SiF_4^-$–HF system (4). Unreacted alcohols gave separate nmr peaks in the presence of phosphoranes $C_6H_5PF_2HOR$; however, addition of a base such as pyridine produced rapid ligand exchange in the $C_6H_5PF_2HOR$–HOR system. Presumably, the function of the base catalyst is to produce a six-coordinate phosphorus



species as the first step towards rapid ligand exchange and chemical reaction, as suggested previously for analogous phosphorus and silicon compounds (3, 4). A more detailed study of intra- and intermolecular ligand exchange in $C_6H_5PF_3H$ and $C_6H_5PF_2HOCH_3$ is in progress.[2]

Experimental

General

Tetramethylene sulfone (Aldrich), $C_6H_5PCl_2$ (Aldrich), and SbF_3 (Fisher) were used without further purification. DL-Phenyltrifluoromethyl carbinol (Burdick and Jackson Laboratories) and $(CF_3)_2CHOH$ (Aldrich) were stored over molecular

[2]R. K. Marat and A. F. Janzen. Unpublished results.

sieve. CH_3OH, C_2H_5OH, CF_3CH_2OH, and $(CH_3)_3COH$ were distilled from sodium prior to use. Conventional vacuum line techniques were used for handling volatile materials.

Fluorine and proton nmr spectra were recorded on a Varian A-56/60A spectrometer at 56.4 and 60 MHz for fluorine and proton, respectively; phosphorus nmr spectra were recorded on a Bruker WH90 spectrometer at 36.44 MHz. ^{31}P chemical shifts are reported with respect to external 85% H_3PO_4. Temperatures were calibrated by the method of Van Geet (6).

$C_6H_5PF_2$ was prepared most conveniently from $C_6H_5PCl_2$ and NaF in tetramethylene sulfone according to the method of Schmutzler (7). It was also prepared from SbF_3 (27 g, 0.15 mol) in tetramethylene sulfone (200 mL) by adding $C_6H_5PCl_2$ dropwise at room temperature (8). A slightly exothermic reaction occurred immediately and volatile $C_6H_5PF_2$, along with about 5–10% $C_6H_5PF_4$, was condensed into the vacuum line. Enough pyridine was added to complex out $C_6H_5PF_4$:py and the volatile $C_6H_5PF_2$ was condensed into a reaction flask at 22°C and 10^{-3} Torr. $C_6H_5PF_2$ was prepared in yields of 80–90% (lit. yield 14% (8)). On standing for several weeks, $C_6H_5PF_2$ decomposed to $(C_6H_5P)_5$ and $C_6H_5PF_4$ (5, 8), therefore samples of $C_6H_5PF_2$ were used within several days of redistillation.

Preparation of Phosphoranes $C_6H_5PF_2HOR$

In a typical reaction, $C_6H_5PF_2$ (5.0 mmol) and ROH (5.0 mmol) were condensed into a 5 mm nmr tube containing C_6D_6 (1 mL). The reactions were generally very slow below −10°C, as monitored by nmr, but proceeded at a reasonable rate between 0 and +20°C. For example, $C_6H_5PF_2HOCH_3$ was formed in 90% yield at 0°C for 30 min and in quantitative yield at +10°C for 10 min. $C_6H_5PF_2HOCH_2CH_3$ was formed quantitatively within 2 h at +18°C and $C_6H_5PF_2HOCH(CF_3)C_6H_5$ was formed within 5 min at 0°C. All phosphoranes $C_6H_5PF_2HOR$ were stable indefinitely at temperatures below +10°C; above this temperature decomposition occurred; for example, only 30% of $C_6H_5PF_2HOCH_3$ remained after 2 days at +22°C.

Preparation of $C_6H_5PF_2HOC(CH_3)_3$

Initial attempts to prepare $C_6H_5PF_2HOC(CH_3)_3$ were unsuccessful. Reaction of $C_6H_5PF_2$ with $(CH_3)_3COH$ is very slow below +10°C; however, attempts to increase the rate of reaction by increasing the temperature to +25°C resulted in complete decomposition to give $(CH_3)_3CF$ (85%), $(CH_3)_2C{=}CH_2$ (15%) and $C_6H_5P(O)HF$. Eventually, it was observed that pyridine catalyzed the formation of phosphorane; hence, $C_6H_5PF_2HOC(CH_3)_3$ was prepared from $C_6H_5PF_2$ (5.0 mmol) and $(CH_3)_3COH$ (5.0 mmol) plus pyridine (0.4 mmol) in C_6D_6 (1 mL) at +5°C.

Conversion of Phosphorane $C_6H_5PF_2HOR$ to Phosphine C_6H_5PFOR

The presence of excess $C_6H_5PF_2$ resulted in the conversion of phosphorane $C_6H_5PF_2HOR$ to phosphine C_6H_5PFOR plus $C_6H_5PF_3H$. The phosphines C_6H_5PFOR could therefore be produced in two ways: either by adding $C_6H_5PF_2$ to $C_6H_5PF_2HOR$, or by mixing $C_6H_5PF_2$ and alcohol in a 2:1 molar ratio. In a typical reaction, $C_6H_5PF_2$ (5.0 mmol) and CF_3CH_2OH (2.5 mmol) in C_6D_6 (1 mL) were mixed at +25°C. After several hours, nmr examination showed an equilibrium mixture of $C_6H_5PF_2HOCH_2CF_3$, $C_6H_5PF_2$, $C_6H_5PFOCH_2CF_3$, and $C_6H_5PF_3H$. The ^1H, ^{19}F, and ^{31}P nmr spectra of phosphines C_6H_5PFOR are shown in Table 2.

COMMUNICATION

Interaction of the unusual bonds in cyclopropane with an extra electron in the dense fluid[1]

NORMAN GEE AND GORDON R. FREEMAN

Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received April 9, 1979

NORMAN GEE and GORDON R. FREEMAN. Can. J. Chem. **57**, 1906 (1979).

An unexpectedly strong interaction between electrons and closely packed cyclopropane molecules has been discovered through measurement of electron mobilities in the liquid and gas phases. In the low density vapors the mobilities fell in the expected order cyclopropane > propane > propene; at STP they were 9000, 6000, and 2040 cm^2/V s, respectively. In the liquids the order was propane > propene > cyclopropane; at 273 K the mobilities were 1.4, 0.12, and 0.017 cm^2/V s, respectively. The abnormally low mobility in liquid cyclopropane is attributed to the formation of transient dimeric anions. The reaction is only significant at densities greater than about 0.4 times the critical density.

NORMAN GEE et GORDON R. FREEMAN. Can. J. Chem. **57**, 1906 (1979).

A la suite de mesures de mobilités électroniques en phases liquide et vapeur, on a découvert une interaction particulièrement forte entre des électrons et des molécules de cyclopropane bien tassées. A des densités de vapeur faibles, les mobilités diminuent dans l'ordre attendu: cyclopropane > propane > propène; aux conditions NTP, elles sont respectivement 9000, 6000 et 2040 cm^2/V s. Dans les liquides, l'ordre est: propane > propène > cyclopropane; à 273 K, les mobilités sont respectivement 1.4, 0.12 et 0.017 cm^2/V s. On attribue la mobilité anormalement faible dans le cyclopropane liquide à la formation d'anions dimères transitoires. La réaction n'est toutefois significative qu'à des densités qui sont plus grandes que 0.4 fois la densité critique.

[Traduit par le journal]

The magnitude of the diffusion coefficient (cm^2/s) or mobility (cm^2/V s) of thermal electrons in a fluid is an indicator of the interactions between the electrons and the fluid. In a low density gas an electron interacts with one molecule at a time, in which case the mobility provides a measure of the electron–molecule scattering cross section (1). If the density of the gas is increased along the vapor/liquid coexistence curve, van der Waals clusters of molecules become an important component of the gas (2–5). At densities greater than about 10% of that of the normal liquid, electron interactions with the clusters are detectable (6, 7). In the liquid phase, the electron interacts continuously with several molecules at once, which can either enhance (6) or diminish (6, 7) the scattering, depending on the nature of the molecules and the density of the fluid. Molecules that possess a permanent dipole moment or an anisotropic polarizability, such as methanol (8) or ethane (9), provide sufficiently large potential fluctuations in the liquid that an extra electron can become localized in a potential minimum. Molecules that are nearly spherical in shape and are isotropically polarizable, such as methane and neopentane, present a relatively constant potential to the electron throughout the liquid; electrons do not form localized states in these liquids to a large extent (9–13).

For the low density gas phase of the C_3 hydrocarbons, considerations of molecular dipole moment (14) and size (reflected in the mean polarizability (15), see Table 1) lead one to expect that electron mobilities would fall in the order cyclopropane > propane > propene. This order has been observed (1). For the liquid phase, the relative anisotropies of polarizability (Table 1) lead one to expect (16) that the mobilities would fall in the order propane > cyclopropane > propene. However, the observed order was propane > propene > cyclopropane (9).

0008-4042/79/141906-03$01.00/0

The mobility in liquid cyclopropane was anomalously low. To learn more about the behavior of electrons in these fluids we have measured mobilities in each of the three compounds over a 100-fold range of densities.

As expected from theory, in each dilute gas the mobility was inversely proportional to the gas density. At STP the values of the mobilities in cyclopropane, propane, and propene were respectively 9000, 6000, and 2040 cm^2/V s. In the liquids at 273 K the respective mobilities were 0.017, 1.4, and 0.12 cm^2/V s. The mobility in liquid cyclopropane is two orders of magnitude lower than that in liquid propane, and at least one order of magnitude lower than expected on the basis of the relative anisotropies of polarizability. The low mobility means that a localized state of electrons is especially stable in liquid cyclopropane.

The localized state could be either a solvated electron or an anion. One might suggest that the solvation energy of electrons is greater in cyclopropane than in propene, due to the greater density of the former liquid.[2] However, the permanent dipole moment and anisotropy of polarizability are larger for propene (Table 1), which would tend to make the solvation energy greater in that liquid. We therefore suggest that anions are formed.

Monomeric anions would be expected to form more readily in propene than in cyclopropane, by addition to the double bond, producing a lower mobility for the negative charge in the former liquid.

The high degree of symmetry of the molecular orbitals in cyclopropane (17–19), and the relatively small amount of steric hindrance to packing the molecules together,[2] lead one to suggest that transient dimeric anions are formed in the liquid. The extra electron would occupy the lowest unoccupied molecular orbitals of adjacent molecules. The shared orbitals probably occur along edges of the molecules (17–19), but the detailed configuration is difficult to predict.

[1] $$e_s^- + 2(CH_2)_3 \rightarrow [(CH_2)_3]_{2,s}^-$$

The subscripts s in reaction [1] indicate solvation. The possibility of trimeric anions would depend upon attainment of a favorable geometry and cannot be excluded.

At 294 K the mobility of electrons in liquid cyclopropane, $\mu = 0.04$ cm^2/V s, is even smaller than that in benzene, $\mu = 0.12$ cm^2/V s (20). Transient anion formation was postulated to explain the relatively high temperature coefficient of mobility in benzene (20).

[2] $$e_s^- + C_6H_6 \rightleftarrows C_{6,s}H_6^-$$

The temperature dependence of the mobility in liquid cyclopropane indicates that the binding energy of the electron in the ion would be ~ 0.1 eV greater than that in a solvation site. Ion formation is apparent only in the high density fluid, so the electron affinity of an isolated pair of cyclopropane molecules (van der Waals dimer) would be negative. The slight stability of the anion in the dense fluid would be gained through polarization of the surrounding solvent.

The crossover of the electron mobilities in propane and cyclopropane occurs in the saturated vapors at 1.3×10^{21} molecules/cm^3, which is 0.4 of the critical density. This can be taken to be near the lower limit of the density at which the special nature of cyclopropane need be considered. The mobilities at this density are 95 cm^2/V s, in the regime of gas phase transport modified by interaction with van der Waals clusters.

[2]The density of liquid cyclopropane at 250–300 K is 16% greater than that of propene and 20% greater than that of propane. The densities inversely reflect the relative amounts of steric hindrance to packing the molecules together.

The crystal and molecular structure of the molybdenum tetracarbonyl complex of 1,4-diphenyl-2,2′,3,3′,5,5′6,6′-octamethylcyclo-1,4-diphospha-2,3,5,6-tetrasilahexane

JOSEPH C. CALABRESE, RICHARD T. OAKLEY,[1] AND ROBERT WEST
Department of Chemistry, University of Wisconsin, Madison, WI 53706, U.S.A.

Received January 25, 1979

JOSEPH C. CALABRESE, RICHARD T. OAKLEY, and ROBERT WEST. Can. J. Chem. **57**, 1909 (1979).

The crystal and molecular structure of the molybdenum tetracarbonyl complex of 1,4-diphenyl-2,2′,3,3′,5,5′,6,6′-octamethylcyclo-1,4-diphospha-2,3,5,6-tetrasilahexane, $(PhPSi_2Me_4)_2Mo(CO)_4$, has been determined by single crystal X-ray diffraction. The crystals are monoclinic, space group $P2_1/n$, with $a = 15.983(5)$, $b = 19.316(6)$, $c = 10.580(3)$ Å, $\beta = 99.99(2)°$, $V = 3217(2)$ Å^3, $Z = 4$, and $\rho_{calcd} = 1.356$ g/cm^3. The structure was solved by Patterson heavy atom methods and was refined by full-matrix least-squares procedures to a final R_1 of 3.3% and R_2 of 4.3%, for 6342 reflections with intensities greater than 2σ. The coordination of the boat-shaped $(PhPSi_2Me_4)_2$ ligand to molybdenum tetracarbonyl produces a distorted octahedral environment about the metal. The mean Si—Si (2.358(14) Å) and P—Si (2.275(19) Å) distances are not greatly altered from the values found for them in the free ligand. The structural consequences of P → Si π-bonding in the latter are therefore minimal. The relatively long P—Mo (mean length 2.592(13) Å) distances are interpreted as the result of reduced back-bonding from the metal, caused by the presence of the relatively electropositive silyl groups on phosphorus. Consistently, the equatorial Mo—C bonds, which are *trans* to the diphosphine ligand, are shorter (mean length 1.968(19) Å) than the corresponding bonds to the axial carbonyl groups (mean length 2.021(15) Å).

JOSEPH C. CALABRESE, RICHARD T. OAKLEY et ROBERT WEST. Can. J. Chem. **57**, 1909 (1979).

On a déterminé la structure cristalline et moléculaire du complexe tétracarbonylmolybdène du diphényl-1,4 octaméthyl-2,2′,3,3′,5,5′,6,6′ cyclodiphospha-1,4 tétrasila-2,3,5,6 hexane, $(PhPSi_2Me_4)_2Mo(CO)_4$, par diffraction de rayons-X de monocristaux. Les cristaux sont monocliniques, groupe d'espace $P2_1/n$, avec $a = 15.983(5)$, $b = 19.316(6)$, $c = 10.580(3)$ Å, $\beta = 99.99(2)°$, $V = 3217(2)$ Å^3, $Z = 4$ et $\rho_{calculé} = 1.356$ g/cm^3. On a résolu la structure par les méthodes de Patterson appliquées aux atomes lourds et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de R_1 de 3.3% et de R_2 de 4.3% pour 6342 réflexions avec des intensités plus grandes que 2σ. Le ligand $(PhPSi_2Me_4)_2$ qui est en forme bateau subit, par sa coordination au tétracarbonyle molybdène, une déformation autour du métal qui a un environnement octaédrique. Les distances Si—Si (2.358(14) Å) et P—Si(2.275(19) Å) moyennes ne diffèrent pas beaucoup de celles observées dans le ligand libre. Les conséquences structurales de la liaison P → Si dans ce dernier sont donc minimales. On interprète la distance P—Mo relativement longue (valeur moyenne de 2.592(13) Å) comme résultant d'une réduction de la reformation d'une liaison à partir du métal qui proviendrait de la présence de groupes silyles relativement électropositifs sur le phosphore. En conséquence, les liaisons Mo—C équatoriales qui sont *trans* par rapport au ligand diphosphine sont plus courtes (longueur moyenne de 1.968(19) Å) que les liaisons correspondantes qui sont axiales par rapport aux groupes carbonyles (longueur moyenne de 2.021(15) Å).

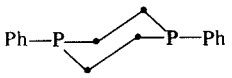
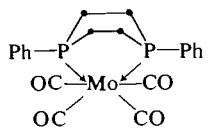
Introduction

The influence of the size (1) and electronegativity (2) of the substituents X on the coordination properties of phosphine ligands PX_3 is well known. However, the chemical and structural importance of such effects for phosphines possessing group IV substituents (X = Si≡, Ge≡, Sn≡) has not been greatly explored, and, for example, there has been only one structural report of a transition metal complex of such a compound (3). As a part of our studies on the properties of cyclic phosphasilanes we have determined the crystal and molecular structure of **II**,[2] the molybdenum tetracarbonyl complex of the



I



II

 = $SiMe_2$

cyclophosphasilane **I**. We have recently reported the preparation (5) and crystal structure (6) of the neutral ligand, and we now describe the structural changes which occur upon its coordination to a metal centre, and also the effect on the ligand–metal interaction brought about the polarity of the silicon–phosphorus bond.

Experimental

Crystals suitable for X-ray work were obtained by crystallization from warm chloroform; the one chosen for study had approximate dimensions of 0.33 × 0.35 × 0.55 mm. Crystal data (at 22°C) are:

$MoP_2Si_4O_4C_{24}H_{34}$

Monoclinic, $a = 15.983(5)$, $b = 19.316(6)$, $c = 10.580(3)$ Å, $\beta = 99.99(2)°$, $V = 3217(2)$ Å^3 (based on 15 reflections).

Data were collected on a Syntex P$\bar{1}$ diffractometer, using monochromated MoK_α radiation. Systematic absences of $0k0$ (k odd) and $h0l$ ($h + l$ odd) indicate the space group $P2_1/n$: $\pm[x, y, z]$; $\frac{1}{2} + x, \frac{1}{2} - y, \frac{1}{2} + z$; $Z = 4$; $\rho_{calcd} = 1.356$ g/cm^3; $\mu = 6.67$ cm^{-1}. Data collection (at 22°C): variable scan speed 2° to 24°/min, scan range 2°, scan method θ–2θ fixed background with background:scan time ratio 0.67, standards 2/50, 1% variation; data limits $3° < 2\theta < 50°$; total data 6342; unique data 5677; non-zero data 4581 ($I > 2\sigma(I)$); $q = 0.055$; uncorrected for absorption. The structure was solved by Patterson heavy atom methods;[3] isotropic least-squares[4] convergence at $R_1 = 6.9\%$, $R_2 = 9.2\%$;[5] anisotropic least-squares convergence $R_1 = 3.3\%$ and $R_2 = 4.3\%$; esd of an observation of unit weight, 1.14;[6] data parameter ratio 14.5. Hydrogen atoms were included as fixed atom contributers with a C—H bond length of 0.95 Å and $\beta_{iso} = 5.0$ Å^2. No attempt was made to refine the hydrogen atom parameters. The full-matrix refinement was converged to completion. The final positional parameters of the non-hydrogen atoms are given in Table 1*a*; those of the hydrogen atoms are deposited in Table 1*b*.[7] The thermal parameters of the non-hydrogen atoms are deposited in Table 2.[7] The derived bond distance and valence angle information (with esd's from the full inverse variance–covariance refinement) are given in Tables 3 and 4.

Results and Discussion

The crystal structure of the title compound consists of discrete molecules of **II**. All intermolecular contacts correspond to normal van der Waals' interactions. A general view of the molecule with the crystallographic numering scheme is shown in Fig. 1. Figure 2 gives an alternative view, and illustrates the boat conformation of the six-membered P_2Si_4 ring. The cyclic $(PhPSi_2Me_4)_2$ ligand (**I**), which exists in a chair conformation with equatorial phenyl groups when uncoordinated (6), is forced to adopt the boat conformation upon coordination to molybdenum. As a consequence, there are several angular changes. The dihedral angle between the $P_1Si_1Si_2$ and $P_2Si_3Si_4$ planes and the central $Si_1Si_2Si_3Si_4$ plane (111.4° and 108.5°, respectively) are reduced from the corresponding angles (mean value 114.8(1)°) found in the free ligand, and the endocyclic angles at phosphorus (mean value 107.3(1)°)[8] and silicon (mean value 101.5(4)°) are altered slightly in opposite senses from the values found for them (104.4(1)° and 104.9(2)°, respectively) in the uncomplexed ring.

[2]The preparation of this complex has recently been reported (4). In the present work, the compound was prepared by the displacement of norbornadiene from $C_7H_8Mo(CO)_4$ by the phosphasilane **I** in hexane (yield 84%). The product was recrystallized from benzene as pale yellow air stable prisms, dec. > 190°C. *Anal.* calcd. for $C_{24}H_{34}O_4P_2Si_4Mo$: C 43.9, H 5.2, P 9.4; found: C 44.1, H 5.2, P 9.9.

[3]All crystallographic programs used in the structural determination and least-squares refinement were written by one of us (J.C.C.). Plots were made using the ORTEP program of C. K. Johnson.

[4]The least-squares refinement was based on the minimization of $\Sigma w_i||F_o| - |F_c||^2$ with individual weights $w_i = 1/\sigma(F_o)^2$. Atomic scattering factors used for all non-hydrogen atoms are from ref. 7 and those for the hydrogen atoms are from ref. 8.

[5]$R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o| \times 100\%$. $R_2 = [\Sigma w_i||F_o| - |F_c||^2/\Sigma w_i|F_o|^2]^{1/2} \times 100\%$.

[6]The standard deviation of an observation of unit weight is defined as $[\Sigma w_i||F_o| - |F_c||^2/(m - n)]^{1/2}$, where m is the number of observations and n is the number of parameters fitted to the data set.

[7]A copy of the observed and calculated structure factor table, Table 1*b*, and Table 2 is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[8]Here and elsewhere in this report, integers quoted in parentheses refer to esd's for single-valued parameters, and indicate ranges of results for the averages of chemically equivalent parameters.

The Si—Si—C_{ax} angles (range 108.8(1)–115.9(2)°, mean 112.3°) are similar to the Si—Si—C_{eq} angles (range 111.1(1)–114.1(1)°, mean 112.5°) but the P—Si—C_{eq} angles (range 106.8(1)–107.5(1)°, mean 107.0°) differ significantly from the P—Si—C_{ax} (range 113.8(2)–117.2(1)°, mean 115.3°). The difference here is probably the result of the cross-ring repulsions of the axial methyl groups (C_5—C_8 = 3.556 Å, C_2—C_4 = 3.686 Å), which causes a mutual rotation of the Si—C_{ax} bonds away from each other, thus widening the P—Si—C_{ax} angles. Despite these changes, the C—Si—C angles (mean 108.1(8)°) are very close to those found in the free ligand (mean 108.0(2)°), and the equivalent axial and equatorial Si—C bonds (mean 1.868(25) Å) are essentially unaltered from the uncomplexed molecule (mean 1.867(3) Å). As in the free ligand, the orientation of the phenyl groups is slightly distorted, and the Si—P—C angles fall into two classes ((*i*) mean 109.5(1)° and (*ii*) mean 103.0(15)°). Nonetheless, the mean P—C (1.837(5) Å) and C—C(phenyl) (1.379(53) Å) distances and the mean C—C—C angles (120.0(26)°) are all normal.

The mean silicon–silicon distance (2.358(14) Å) is slightly longer than in the complexed molecule (2.345(3) Å) and $(SiMe_2)_6$ (2.338(6) Å) (9), the steady decrease in length along the series possibly arising from σ-hybridization changes at silicon. The mean P—Si distance (2.275(19) Å) is longer than in the uncomplexed structure (2.252(4) Å), and, even though hybridization changes would tend to accentuate the difference, the lengthening is too small to be definitely ascribed to a $p\pi$–$d\pi$ contraction in the latter. There have been several recent structural reports (3, 6, 10, 11–13) of compounds containing silicon–phos-

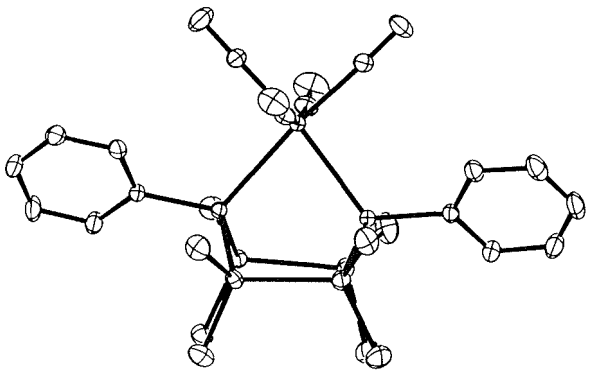

FIG. 2. An alternative view of the $(PhPSi_2Me_4)_2Mo(CO)_4$ molecule, illustrating the boat conformation of the P_2Si_4 ring. Hydrogen atoms are not shown.

gests that other factors, such as hybridization effects or non-nearest neighbour bonding, as in P_4S_3 (16), may be as important in causing bond length variations as π-donation from phosphorus to silicon.

The coordination of the $(PhPSi_2Me_4)_2$ ligand to molybdenum tetracarbonyl produces a distorted octahedral environment about the metal. The axial carbonyl groups are bent away from the perpendicular (C_{21}—Mo—C_{24} = 164.2(2)°), presumably to relieve possible steric crowding from the bulky phosphasilane ligand. Similar distortions, of varying magnitude, are observed in other diphosphine molybdenum tetracarbonyls (6, 17–21). Again as elsewhere, the axial and equatorial Mo—C bonds are of unequal length (Table 6), the shorter equatorial bonds reflecting the increased π-back-donation from the metal to the carbonyl groups *trans* to the phosphine ligand. In the case of the C—O bonds, whose lengths are less sensitive to changes in back-bonding (22), the axial and equatorial bonds are equal within experimental error.

The P—Mo bonds (mean length 2.592(15) Å)[9] are significantly longer than in other phosphine molybdenum carbonyls (2.37–2.53 Å) (6, 17–21, 23), and we believe that the lengthening, which is observed to a lesser extent in $(PhPHSi_2Me_4PPhH)Mo(CO)_4$ (3), is the result of a cumulative reduction in π-back-bonding from molybdenum to phosphorus caused by the low electronegativity of silicon and the consequent polarity of the P—Si bonds. Consistently, the carbonyl stretching frequencies of **II** are slightly but significantly lower than in related compounds (Table 6). The poorer acceptor ability of the phosphasilane ligand causes a shift of electron density from the metal into the π* levels of the carbonyl groups (2, 5).

Coordination of the $(PhPSi_2Me_4)_2$ ligand to molybdenum effectively freezes the six-membered P_2Si_4 ring into a boat conformation and, in contrast to the free ligand, whose ^1H nmr spectrum displays only averaged signals at ambient temperatures (5), the proton resonances of the axial and equatorial methyl groups are easily distinguished (Fig. 3). Both signals appear as $X_6AA'X'_6$ coupling patterns (24), and although the resolution is insufficient to allow the determination of the value of $J_{PP'}$, the appearance of the multiplets indicates that ^{31}P—^{31}P coupling in the complex **II** is considerably greater than in the ligand **I** (5).[10] As expected, electronic interactions via molybdenum are greater than through the —(Si_2Me_4)— units. The difference Δ in the ^{31}P

[9]The difference in the two Mo—P bonds (2.598(1), 2.585(1) Å) correlates well with the Mo—C_{eq} bonds *trans* to them (1.989(4), 1.978(4) Å respectively); i.e., the longer Mo—P bond is found opposite the shorter Mo—C bond, and vice versa.

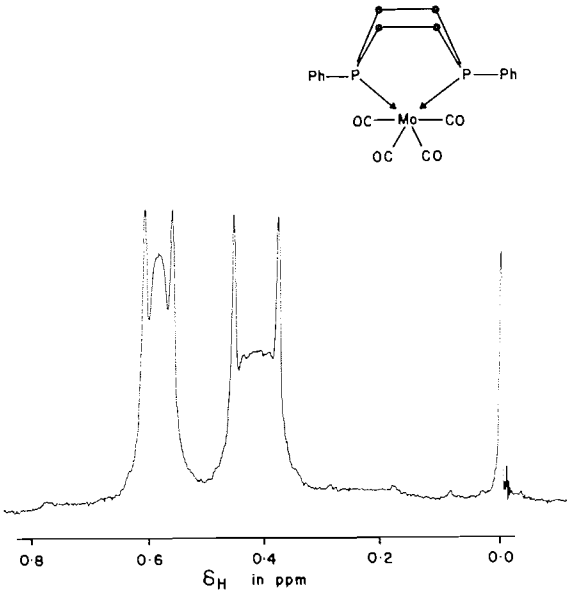

FIG. 3. The 100 MHz ^{1}H nmr spectrum $(PhPSi_2Me_4)_2Mo(CO)_4$ (phenyl region not included), illustrating the $X_6AA'X'_6$ coupling pattern of the axial and equatorial methyl groups.

chemical shifts of the free and complexed ligand[10] ($\Delta = \delta_P(\mathbf{I}) - \delta_P(\mathbf{II}) = -139.4 + 95.6 = -43.8$ ppm) is smaller than for diphos and diphos·$Mo(CO)_4$ (−67.2 ppm) (25), and is consistent with the smaller Δ values found for the more electropositive elements in the series of compounds $(Me_3E)_3PMo(CO)_5$ (E = C, Si, Ge, Sn) (26).

Excess volumes for binary liquid mixtures of butylamine with aromatic and aliphatic hydrocarbons

ABBURI KRISHNAIAH, MARIPURI SREENIVASULU, AND PULIGUNDLA R. NAIDU[1]

Department of Chemistry, College of Engineering, Sri Venkateswara University, Tirupati 517 502, India

Received December 24, 1978

ABBURI KRISHNAIAH, MARIPURI SREENIVASULU, and PULIGUNDLA R. NAIDU. Can. J. Chem. 57, 1915 (1979).

Excess volume data for binary liquid mixtures of butylamine with aromatic and aliphatic hydrocarbons were measured as a function of composition dilatometrically at 303.15 and 313.15 K. The hydrocarbons include: benzene, toluene, three isomeric xylenes, hexane, heptane, and octane. The values of V^E were found to be positive over the entire range of composition in all the eight systems at both the temperatures. The positive values were ascribed to the break-up of hydrogen bonds in the aggregates of amine by the hydrocarbons.

ABBURI KRISHNAIAH, MARIPURI SREENIVASULU et PULIGUNDLA R. NAIDU. Can. J. Chem. 57, 1915 (1979).

Faisant appel à la dilatométrie et opérant à 303.15 et à 313.15 K, on a mesuré les volumes d'excès de mélanges liquides binaires de butylamine avec des hydrocarbures aromatiques et aliphatiques. Les hydrocarbures sont: le benzène, le toluène, les trois xylènes, l'hexane, l'heptane et l'octane. On a trouvé que les valeurs V^E sont positives à toutes les compositions des huit systèmes et aux deux températures. On attribue les valuers positives au bris des liaisons hydrogène des agrégats d'amine par les hydrocarbures.

Introduction

A survey of the literature has shown that few attempts have been made to study systematically the excess thermodynamic properties of binary liquid mixtures of an alkylamine with aromatic and aliphatic hydrocarbons. Excess thermodynamic properties of these binary liquid mixtures give an insight into self-association of the amine and the structure-breaking effect of hydrocarbons. Hence excess volumes of mixtures of butylamine with aromatic and aliphatic hydrocarbons have been determined at 303.15 and 313.15 K. Aromatic hydrocarbons, benzene, toluene α, and the three isomeric xylenes, form a homologous series. Hexane, heptane, and octane constitute the homologous series of aliphatic hydrocarbons. Butylamine has been chosen as a common component as it is less volatile than the lower homologues.

Experimental

Materials

Butylamine was dried over potassium hydroxide for 3 days, then refluxed for 2 h and fractionally distilled (1). The aromatic hydrocarbons were made thiophene-free as described by Vogel (2), dried over anhydrous calcium chloride, and finally fractionally distilled over metallic sodium. The column used contained 12 theoretical plates. The aliphatic hydrocarbons were purified using the methods described by Riddick and Bunger (1). The purity of the samples was checked by comparing the measured densities with those reported in literature (3, 4). The densities were determined with a bicapillary pycnometer described by Rao (5). The data are given in Table 1.

Excess Volumes

Excess volumes were determined at 303.15 and 313.15 K using a single composition per loading type dilatometer described by Rao and Naidu (6). The mixing cell contained two bulbs of different capacities and connected through a U-tube using mercury to separate the two components. The end of one bulb was fitted with a ground glass stopper and the end of another bulb was fitted with a capillary having a detachable Teflon cap with a small orifice at the top. The composition was determined directly by weighing. Four dilatometers with different capacities were used to cover the entire mole fraction range. The dilatometers were kept in a thermostat maintained at ±0.01 K. Excess volumes were accurate to ±0.003 $cm^3\ mol^{-1}$. This accuracy offered by the dilatometer was checked by comparing the measured data for the system cyclohexane + benzene with those reported in literature (7).

TABLE 1. Densities of pure component liquids

Component	T/K	Density ρ/g cm^{-3} Experimental	Literature
Butylamine	298.15	0.73452	0.73460
Benzene	303.15	0.86835	0.86836
Toluene	303.15	0.85762	0.85766

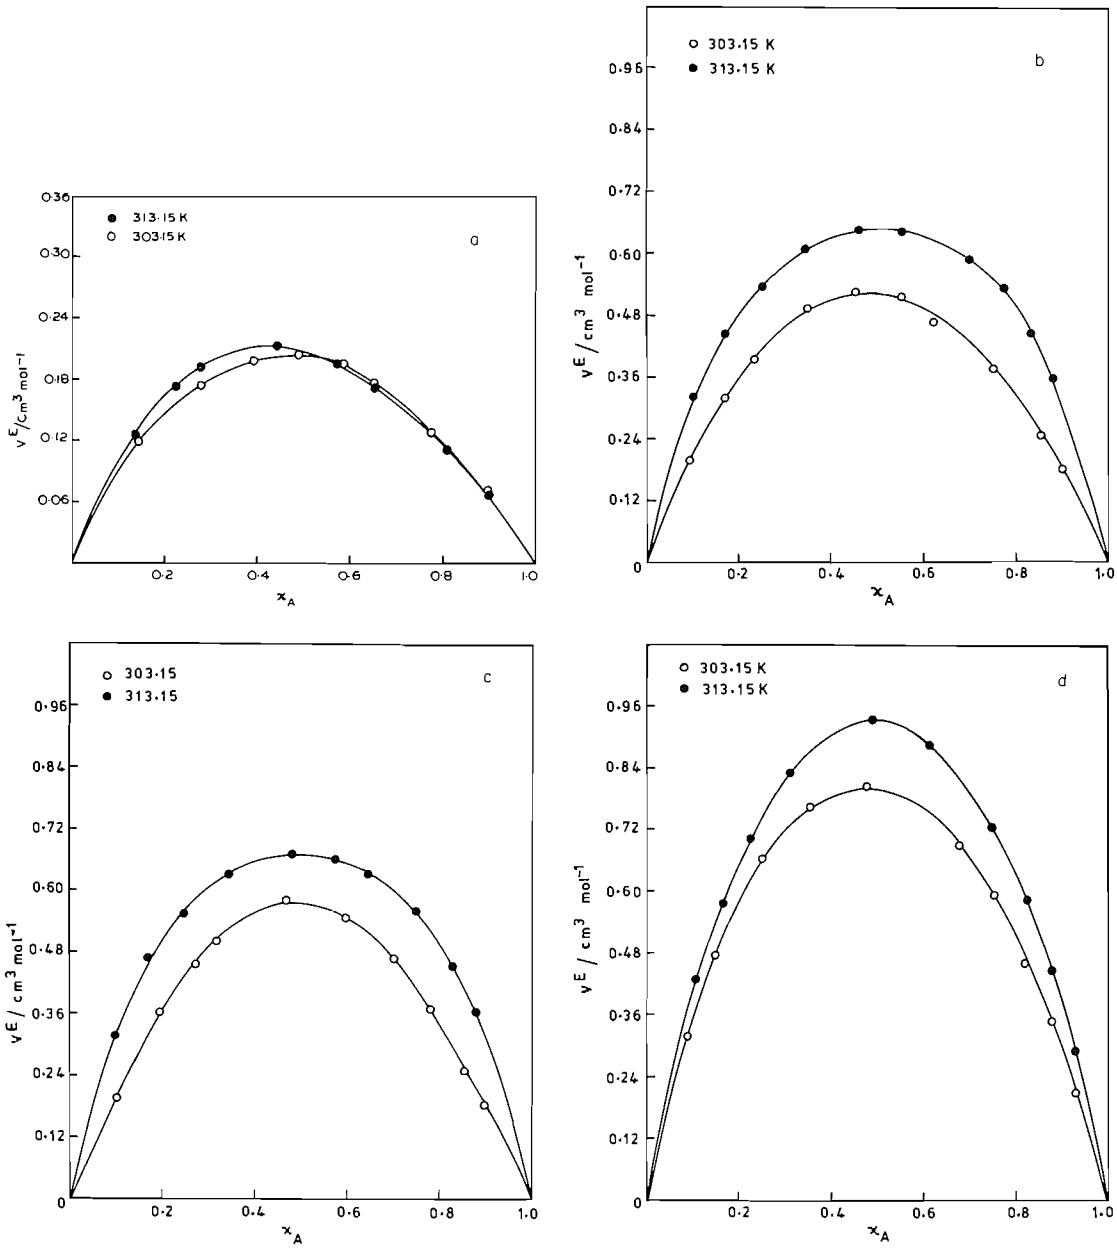

FIG. 2. The values of V^E plotted against the mole fraction x_A of butylamine for (*a*) butylamine + *p*-xylene, (*b*) butylamine + hexane, (*c*) butylamine + heptane, (*d*) butylamine + octane.

Results

Values of V^E determined for the eight systems at 303.15 and 313.15 K are graphically represented in Figs. 1 and 2. The results are fitted to the equation

$$[1] \quad V^E/\text{cm}^3\ \text{mol}^{-1} = x_A x_B[a_0 + a_1(x_A - x_B) + a_2(x_A - x_B)^2]$$

where a_0, a_1, and a_2 are adjustable parameters and x_A and x_B are the mole fractions of butylamine and hydrocarbons respectively. The parameters were evaluated by the method of least-squares. The values of the parameters along with the standard deviation $\sigma(V^E)$ are given in Table 2. Tables 3 and 4, which record the molar excess volumes of mixtures of butylamine with aromatic and aliphatic hydrocarbons at 303.15 and 313.15 K, respectively, are placed in the Depository of Unpublished Data.[2]

[2]Complete set of data may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Discussion

Values of V^E are positive over the whole range of composition in the eight mixtures. The positive values may be ascribed to break-up of hydrogen bonds in hydrogen bonded aggregates of butylamine by the aromatic and aliphatic hydrocarbons. According to Schug and Chang (8), self-association of butylamine through hydrogen bonding leads to the formation of linear trimers. The addition of hydrocarbons would, therefore, be expected to depolymerize the amine trimers. This would contribute to expansion in volume. The observed values of V^E are therefore in order.

The positive excess volumes of butylamine with benzene and toluene at 298.15 K, reported by Letcher and Bayles (9) and Letcher (10) also support the contention that the self-associated amine is depolymerized by the hydrocarbons. However, the method used by these workers offered an accuracy of 0.02 $cm^3\ mol^{-1}$. Hence the data of these workers are out of line with those presented here.

Excess volumes for mixtures of butylamine with aliphatic hydrocarbons are larger than those with aromatic hydrocarbons. This may be attributed to the presence of π-electrons in the aromatic hydrocarbons. π-Electrons in the aromatic hydrocarbons may lend themselves for the formation of weak NH---π complexes. This interaction may mitigate the expansion in volume resulting due to depolymerization.

There is no regular trend between excess volume and temperature in the mixtures of butylamine with aromatic hydrocarbons. The temperature coefficient of V^E is positive in the mixtures of amine with benzene, and the three xylenes. The coefficient is negative in mixtures of butylamine with toluene. However, the trend between V^E and temperature is regular in the mixtures of amine with aliphatic hydrocarbons. The three mixtures have a positive temperature coefficient for V^E.

Determination of solubility products of hydroxylapatite, chlorapatite, and their solid solutions

T. S. B. NARASARAJU, K. K. RAO, AND U. S. RAI

Department of Chemistry, Banaras Hindu University, Varanasi-221005, India

Received November 28, 1978

T. S. B. NARASARAJU, K. K. RAO, and U. S. RAI. Can. J. Chem. 57, 1919 (1979).

Solubility equilibria of hydroxylapatite, chlorapatite, and a series of their solid solutions were investigated at 37°C in the pH range 4.25 to 7.40 and their solubility products evaluated. Proof could be obtained for their stoichiometric dissolution.

T. S. B. NARASARAJU, K. K. RAO et U. S. RAI. Can. J. Chem. 57, 1919 (1979).

Opérant à 37°C et à des pH allant de 4.25 à 7.40, on a étudié les équilibres de solubilité de l'hydroxylapatite, de la chloroapatite et d'une série de leurs solutions solides et on a déterminé leurs produits de solubilité. On a pu obtenir une preuve concernant leur dissolution stoechiométrique.

[Traduit par le journal]

Introduction

It is well known that hydroxylapatite (OHAp), $Ca_{10}(PO_4)_6(OH)_2$, a constituent (1) of human bones and teeth, and chlorapatite (ClAp), $Ca_{10}(PO_4)_6Cl_2$, belong to an isomorphous series (2, 3) of compounds and are therefore capable of forming solid solutions. The presence of a large excess of chloride ions in the body fluids enables the formation of such solid solutions at the bone/body-fluid interface. An investigation of the dependence of the solubility product of such samples on their chloride content is of extensive biological significance from the point of view of calcification and resorption and hence the present studies were undertaken.

Experimental

While OHAp was obtained by a wet method (4) the rest of the samples were prepared by an appropriate solid state reaction (5) using OHAp and $CaCl_2$ as starting materials. The samples were characterized through chemical, X-ray, electron microscopic, infrared, and thermal analyses as reported earlier (4–6). The solubility product of each sample was determined at the biologically significant temperature of 37°C by analyses of their saturated solutions, the pH of the dissolving medium being varied in the pH range 4.25 to 7.40 using suitable buffer combinations. The experimental details for the equilibration of the samples to prepare their saturated solutions and to separate them from the likely colloidal component of the solute were reported elsewhere (7–9). From the saturated solutions so prepared calcium was determined complexometrically (10) while phosphate and chloride were estimated spectrophotometrically (11, 12), separate aliquots being taken each time.

Results and Discussion

In Table 1 are included a few representative sets of results on the determination of the solubility products of OHAp, ClAp, and nine of their solid solutions. For each sample at a given pH, from which the OH^- ion concentration was calculated and given in column 6, the experimentally determined concentrations of calcium, phosphorus, and chloride are given in columns 3 to 5. In order to scrutinize the stoichiometric dissolution of the samples, the g atom ratios, Ca/P, are reported in column 8 of the table. Adopting a method of calculation reported earlier (9), the total phosphorus, given in column 4, was subdivided into undissociated orthophosphoric acid and its dissociation products, using its three dissociation constants (13–15) and the final pH of the saturated solution given in column 2 of the table. For the sake of brevity all these subdivided values are not included in the table. However, the concentrations of PO_4^{3-} needed to calculate the ionic product, K_{ip}, of the samples are reported in column 7 while the values of the pK_{ip}'s, $(-\log K_{ip})$ and their averages are given in columns 9 and 10 respectively. Based on a series of determinations of each of these values, it could be concluded that the error limits involved did not exceed $\pm 1\%$.

The medium of dissolution adopted in the present investigations consisted of buffer (9) combinations of desired pH maintained at a molarity of 0.165 with respect to sodium nitrate in order to keep the ionic strength during dissolution virtually constant. To overcome the inaccuracy involved in the evaluation of the activity coefficients of the dissolved ionic species of these systems, La Mer (16) suggested that an aqueous solution of 0.165 *M* sodium chloride, a solvent of biological importance, may be considered as a standard solvent of reference in which all the activity coefficients may be assigned a value of unity. Since the use of sodium chloride is not permissible

*$pK_{ip} = -\log [Ca^{2+}]^{10}[PO_4^{3-}]^6[X^-]^2$ where $[X^-] = [Cl^-] + [OH^-]$.

in these systems sodium nitrate was made use of and the ionic product of the samples calculated were taken as the solubility products.

The solubilities of the samples were characterized by a marked increase with increasing hydrogen ion concentration of the medium of dissolution. It is evident that in a saturated aqueous solution of OHAp the following equilibrium is established:

[1] $Ca_{10}(PO_4)_6(OH)_2 \rightleftharpoons 10Ca^{2+} + 6PO_4^{3-} + 20H^-$

Among the products of dissolution PO_4^{3-} and OH^- are capable of participating in a few more simultaneous pH-dependent equilibria as shown below:

[2] $PO_4^{3-} + H_3O^+ \rightleftharpoons HPO_4^{2-} + H_2O$

[3] $HPO_4^{2-} + H_3O^+ \rightleftharpoons H_2PO_4^- + H_2O$

[4] $H_2PO_4^- + H_3O^+ \rightleftharpoons H_3PO_4 + H_2O$

[5] $OH^- + H_3O^+ \rightleftharpoons 2H_2O$

A shift from left to right occurs in all the above

equilibria when H_3O^+ ion concentration is increased. While all these equilibria are collectively responsible for influencing equilibrium [1], those in which PO_4^{3-} (reaction [2]) and OH^- ions (reaction [5]) participate are naturally more dominant. Analogous to the equilibria operative in the case of OHAp as mentioned above, a saturated solution of ClAp is characterized by the following equilibrium in addition to those given in reactions [2] to [4]:

[6] $Ca_{10}(PO_4)_6(Cl_2) \rightleftharpoons 10Ca^{2+} + 6PO_4^{3-} + 2Cl^-$

The above arguments are substantiated by the observed fact that the calculated proportions of PO_4^{3-} ions, given in column 7 of Table 1, decreased with an increase in the hydrogen ion concentration of the medium of dissolution. The marked pH-dependence of the solubilities of OHAp and its solid solutions with ClAp can thus be accounted for.

It could be shown (17) that the free energy of dissolution of an ionic crystal is dependent on ionic replacement since the latter brings about a change in the lattice energy. The lattice energy of ClAp being higher than that of OHAp can account for the diminution in the solubility of the former over that of the latter and also for the observed systematic reduction in the solubility of the solid solutions with an increase in the Cl^- content. In addition, the non-availability of OH^- ions as products of dissolution in the case of ClAp indicates that equilibrium [5] has no effect on its dissolution. Further, Cl^- ions produced due to dissolution of ClAp remain unaffected due to the absence of their tendency to associate with H_3O^+ ions consequent upon the high dissociation of hydrochloric acid. Such an additional consideration could be advanced to account for the low solubilities of ClAp and their solid solutions.

An explanation which can be applied exclusively to the lower solubilities of the solid solutions over that of OHAp is based on the structural considerations as was shown by Young *et al.* (18). According to them an important feature of the structure of apatite, $Ca_{10}(PO_4)_6X_2$, is the occurrence of the X^- ions in columns or linear chains, coincident with its six-fold screw (6_3) axis, where X can be, among others, F^-, Cl^-, and OH^- or a combination of them. It could be established (19, 20) through infrared spectral studies that the OH^- and Cl^- ions, constituting the lattice of a solid solution of OHAp and ClAp, are linked through hydrogen bonding. The hindrance caused to the diffusion of the OH^- ions through the X^- ion column can be a factor in reducing the solubility of the solid solutions since the X^- ion column offers itself as the most vulnerable point (21, 22) for the diffusion of the ions located in the column into the medium of dissolution.

It is evident that the pK_{ip} values and the g atom ratio, Ca/P, of the samples, reported in Table 1 provide unambiguous evidence for the stoichiometric dissolution of the samples. Arguments in favour of such a theoretically favoured stoichiometric dissolution were advanced independently by Clark (23), Moreno *et al.* (24), and Wier *et al.* (25). Based on the fundamental thermodynamic concepts (17) applicable to the dissolution of ionic crystals, it could be concluded from the present investigations that the free energy of solution of the compounds is a linear function of the Cl content.

Photochemical decomposition of selected diarylcadmium compounds in dilute benzene solutions was investigated. This reaction was found to involve initial cleavage of the aryl–cadmium bonds followed by coupling of the aryl radicals to give symmetrical biaryls in good yields. Arylation products were obtained in only 5–25% yields, in contrast with the photolysis of iodoaromatic compounds in benzene which gives arylation products in high yields. Diarylcadmium compounds derived from polynuclear aromatic compounds, e.g. di(*p*-biphenyl)-cadmium and di(α-naphthyl)cadmium gave, under the same conditions, predominantly hydrogen transfer products. In carbon tetrachloride, photolysis of diarylcadmium compounds gave chloroarenes in high yields.

A. M. OSMAN, AHMED I. KHODAIR, A. A. ABDEL-WAHAB et A. M. EL-KHAWAGA. Can. J. Chem. 57, 1923 (1979).

On a étudié la décomposition photochimique, en solutions benzéniques diluées, de composés diarylcadmium choisis. On a trouvé que cette réaction implique une rupture initiale des liaisons aryl–cadmium suivie par un couplage des radicaux aryles qui conduit aux byaryles symétriques avec de bons rendements. On a obtenu des produits d'arylation qu'avec des rendements de 5 à 25% alors que la photolyse de composés iodo aromatiques dans le benzène conduit aux produits d'arylation avec de bons rendements. Soumis aux mêmes conditions, les composés diaryl-cadmium issus de composés aromatiques polycondensés comme le di(*p*-biphényl) cadmium et le di(α-naphthyl) cadmium fournissent principalement des produits de transfert d'hydrogène. Dans le tétrachlorure de carbone, la photolyse de composés diaryl-cadmium conduit à des chloroarènes avec de bons rendements.

Introduction

Although photolytic studies on organometallic compounds received considerable attention (1), apparently photolysis of organocadmium compounds has not been investigated yet. Recent research from our laboratories (2) explored the potentialities of these compounds as useful synthetic intermediates. In extension of these studies we investigated the photolytic decomposition of selected diarylcadmium. compounds in dilute solutions.

Results and Discussion

The required cadmium reagents were prepared from the corresponding Grignard reagents and dilute solutions (2 m*M*) were photolysed in a Vycor glass cell using a Mineralight low pressure mercury arc. The solutions were irradiated for 100 h with continuous stirring and the products were identified by direct comparison with authentic samples and estimated by quantitative gas–liquid chromatography. The results are shown in Table 1.

Photolysis of diphenylcadmium in dilute benzene solution gave only biphenyl in 75% yield. No other products could be detected by glc, similar photolysis of dibenzylcadmium gave dibenzyl in 80% yield along with small amounts of diphenylmethane (5%). Di(*p*-tolyl)cadmium afforded *p*,*p*′-bitolyl in 60% yield together with *p*-methylbiphenyl in 15% yield. Photolysis of di(*p*-anisyl)cadmium behaved similarly, but no appreciable amount of the arylation product (*p*-methoxybiphenyl) could be detected.

The results presented above may be accounted for by a sequence involving initial cleavage of the aryl–cadmium bonds followed by dimerisation of the aryl radical with side reaction involving arylation as follows:

$$\mathrm{Ar{-}Cd{-}Ar} \longrightarrow 2\mathrm{Ar}^{\cdot} + \mathrm{Cd}$$

$$2\mathrm{Ar}^{\cdot} \longrightarrow \mathrm{Ar{-}Ar} \qquad \text{Major reaction}$$

$$\mathrm{Ar}^{\cdot} + \bigcirc \xrightarrow{-\mathrm{H}^{\cdot}} \mathrm{Ar{-}}\bigcirc \qquad \text{Minor reaction}$$

That the initial step involves formation of an aryl free radical is supported by trapping this radical via halogen or hydrogen abstraction. Thus photolysis of dilute solutions of the above mentioned compounds in carbon tetrachloride gave chloroarenes in high yield (cf. Exps. 7–10, Table 1). Only small amounts of the coupling products were observed. Similar photolysis in chloroform afforded predominantly

*All yields shown above are overall yields calculated on the basis of 1 mol bromoarene yielding ½ mol of coupling product or 1 mol of either arylation or abstraction products.

hydrogen abstraction products (cf. Exps. 11–16, Table 1).

It is of interest to note that no rearrangement of the initially formed radical occurred as coupling and chlorine abstraction took place at the position where the cadmium atom was originally linked to the aromatic nucleus.

Photolysis of diarylcadmium derived from polynuclear aromatic compounds behaved somewhat differently. Irradiation of di(*p*-biphenyl)cadmium in dilute benzene solutions under the usual conditions gave biphenyl in 65% yield together with *p*-terphenyl (25% yield). The coupling product *p*-tetraphenyl could not be detected by glc or tlc. The preference of hydrogen abstraction over arylation of benzene by the biphenyl radical in spite of the fact that the concentration factor could be attributed to the relative stability of the biphenyl radical which permits it to live long enough to find the hydrogen donor. Similar results were reported earlier (3). Similar photolysis of di(α-naphthyl)cadmium yielded only naphthalene and no coupling or arylation products were formed. These results complement those reported earlier by Razuvaev and Petukhov (4) on the photolysis of di(α-naphthyl)mercury who attributed the formation of naphthalene to disproportionation of the initially formed naphthyl radical. In our case, however, the fact that some of the ether inevitably remained in solution during the preparation of the organocadmium compounds may be responsible for at least some of the hydrogen transfer to the aryl radicals.

These results demonstrate the high potential of this procedure as a synthetic tool for synthesis of symmetrical biaryls.

Experimental

Physical Measurements

Distillations were done through a 2-ft simple Podbielniak-type column, and gas chromatography was done with an Aerograph (Hi-Fi) model 600 D equipped with a flame ionisation detector and an integrating recorder. Photolyses were carried out in a cell made of Vycor glass and irradiated with a Mineralight low pressure cold cathode mercury arc. Melting points were determined on a Kofler melting point apparatus and are uncorrected.

Photolysis of Diarylcadmium Compounds (General Procedure)

Diarylcadmium compounds were prepared from the corresponding Grignard reagents according to the published procedure (5). In a typical run, 0.006 g-atom of magnesium turnings were placed in a three-necked flask and a solution of 0.006 mol of the bromoarene in 50 mL dry ether was added dropwise while stirring. After the complete dissolution of magnesium, the contents of the flask were refluxed for 10 min, cooled, and 0.65 g (0.003 mol) of anhydrous cadmium chloride was added. The reaction mixture was refluxed till it gave a negative Gilman test (5). The ether was evaporated by distillation on a water bath maintained at 60°C till dryness and the produced cadmium compound was dissolved in the required solvent (benzene, carbon tetrachloride, or chloroform) and diluted to the proper concentration (2 m*M* solution).

A 100 mL of this solution was placed in the photolysis cell which was equipped with reflux condenser protected with a drying tube. This solution was irradiated, with continuous stirring, for 100 h, at the end of which the content of the cell was quantitatively transferred after filtration into a 100 mL flask. The products were then identified and estimated by gas liquid chromatography (using 8 ft × 1/8 in. SE 30 column at 100°C or 160°C). The results are presented in Table 1.

In case of photolysis of di(*p*-anisyl)cadmium in benzene, evaporation of the solvent left a solid residue which, when chromatographed using a 60 × 1 cm column packed with basic alumina, gave 0.2 g (50% yield) of *p,p'*-dianisyl from 60–80°C petroleum ether – benzene mixture (3:2), mp 170°C, lit. (6) mp 171–172°C.

Preparation of Authentic Samples

Diphenylmethane

From benzyl chloride and benzene, in the presence of amalgamated aluminium turnings (7), diphenylmethane was obtained in 50% yield, mp 25°C, lit. (7) mp 25–26°C.

Ethylbenzene

Acetophenone was converted to ethylbenzene according to the published procedure (7) in 60% yield, bp and reported bp 135–136°C.

p-*Chlorotoluene*

p-Chlorotoluene was prepared from *p*-toluidine via Sandmeyer's reaction (8) in 83% yield, bp 160°C, lit. (8) bp 158°C.

α-*Chloronaphthalene*

Starting with α-naphthylamine and with applying Sandmeyer's reaction (8), α-chloronaphthalene was collected (65% yield) at 106°C/13 mm Hg, lit. (6) bp 105°C/13 mm Hg.

Thermochemical measurement of the ligand field splitting energies for hexaaquocopper(II) and hexaamminecopper(II) ions[1]

MUHAMMAD BADRI AND JAMES W. S. JAMIESON

Department of Chemistry, Universiti Pertanian Malaysia, Serdang, Selangor, Malaysia

Received March 30, 1978[2]

MUHAMMAD BADRI and JAMES W. S. JAMIESON. Can. J. Chem. 57, 1926 (1979).

The vacuum dehydration of copper(II) sulphate pentahydrate has been shown to pass through the transitory trihydrate state before proceeding to the monohydrate composition. Based on this, the heat of solution data for the high-energy modification hydrates have been reinterpreted and the low-energy crystalline hydrates of various compositions have been prepared and their heats of solution measured. From the heat of solution data the maximum energy difference expressed in kcal/mol heptahydrate appears to be of the right order of magnitude to be regarded as the ligand field splitting energy for the hexaaquocopper(II) ion. Similar measurement for the ammine complexes of copper(II) sulphate has also been done and the maximum energy difference was found to agree well with the value of LFSE obtained by spectroscopic method.

MUHAMMAD BADRI et JAMES W. S. JAMIESON. Can. J. Chem. 57, 1926 (1979).

On a montré que la déshydratation sous vide du pentahydrate du sulfate de cuivre(II) procède par l'intermédiaire d'un état trihydraté avant d'atteindre la composition monohydraté. En ce basant sur cette observation, on a interprété les données relatives à la chaleur de solution des modifications des hydrates d'énergie élevée; on a de plus préparé des hydrates cristallins de basse énergie et de compositions diverses et on a mesuré leurs chaleurs de solution. Sur la base de ces chaleurs de solution, il semble que l'amplitude de la différence d'énergie maximale, exprimée en kcal/mol d'heptahydrate, soit telle qu'on peut la considérer comme égale à l'énergie de dissociation de champ de ligand (EDCL) pour l'ion hexaquocuivre(II). On a aussi effectué des mesures semblables pour les complexes aminés du sulfate de cuivre(II) et la différence maximale d'énergie est en bon accord avec la valeur de EDCL évaluée par une méthode spectroscopique.

[Traduit par le journal]

Introduction

In the previous publications on the thermochemical measurement of the ligand field splitting energies of the hexaaquo and hexaammine complexes of some transition metal(II) ions (1–4) the values for the complexes of copper(II) ion were not included. By spectroscopic measurement, however, the $10Dq$'s for the hexaaquocopper(II) and hexaamminecopper(II) ions have been found to be 16×10^3 cm^{-1} and 12×10^3 cm^{-1} respectively (5, 6). Later work (7–10) has shown that the values are actually lower and, furthermore, are of the same order of magnitude as has been found for similar complexes of other transition metal(II) ions of the same series, i.e. about 10×10^3 cm^{-1}.

The heat of solution data for various hydrates of copper(II) sulphate have also been published and are reproduced in Fig. 1. Frost, Moon, and Tompkins (11) found that the crystalline hydrates, which were prepared by heating the pentahydrate in an oven, have their heats of solution falling along the lines BF and FX in Fig. 1 where X, F, and B are at the pentahydrate, trihydrate, and monohydrate compositions respectively. The line FX in Fig. 1 has been extrapolated to C where C is at the heptahydrate composition. The high-energy modification hydrates, which were prepared by heating the pentahydrate *in vacuo*, have higher heats of solution compared to their corresponding low-energy hydrates. Frost *et al.* also showed that the high-energy hydrates with water contents less than that of the monohydrate have their heats of solution along the line FGH, where G and H are at the monohydrate and the anhydrous salt compositions respectively. The line CDE has been drawn parallel to the line FGH to represent the maximum possible heat of solution line for the high-energy modification hydrates originating from the heptahydrate. However, the lines FGH and CDE are not parallel to the heat of solution line BA which was obtained earlier (12, 13) for the crystalline hydrates of compositions less than that of the monohydrate. This does not concur with what has been found in other cases (1–4) even though by thermochemical method the energy difference at the monohydrate composition, BD, or at the anhydrous salt composition, AE, would give a value of an

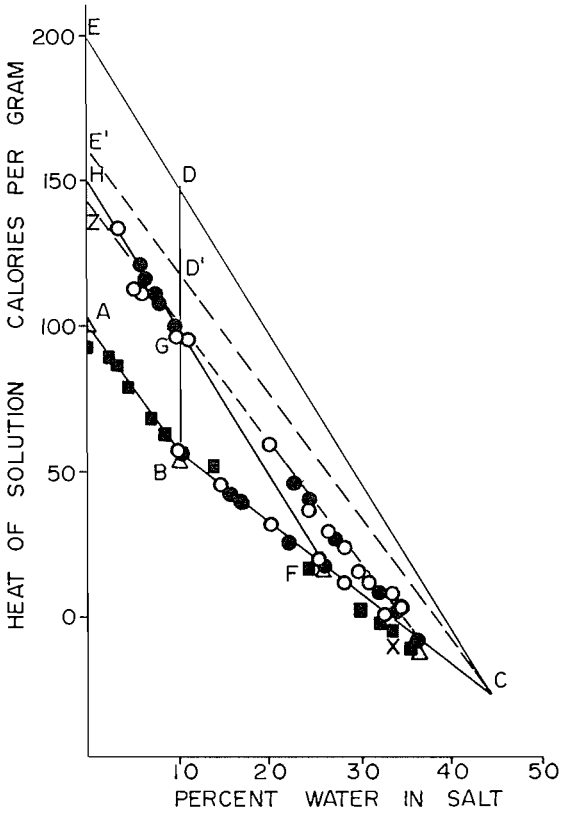

FIG. 1. Heats of solution for hydrates of copper(II) sulphate: ●, from ref. 11; ■, from ref. 13; △, from ref. 12; ○, present data.

acceptable magnitude for $10Dq$ for the complex hexaaquocopper(II) ion.

On the other hand, if all the heat of solution data for the products of vacuum dehydration of copper(II) sulphate pentahydrate were considered, a line XYZ can be drawn to pass through all the points representing them in Fig. 1, where Y and Z are at the monohydrate and the anhydrous salt compositions respectively. This line is parallel to the line BA which is in accord with all the systems that have been studied. However, if the line CD′E′ is similarly drawn to represent the heat of solution line for the high-energy modification hydrates originating from the pentahydrate, the estimation of the heat of transition from B to D′ at the monohydrate composition or from A to E′ at the anhydrous salt composition would give a value of 17 kcal/mol heptahydrate only. This value is too small to be considered as $10Dq$ for the hexaaquocopper(II) ion even compared to a low value given by Roos (28). Thus the present work is done to explain this anomaly and to help to establish the general applicability of the calorimetric technique for the measurement of the ligand field splitting energy.

Experimental

1. $CuSO_4 \cdot 5H_2O$

$CuSO_4 \cdot 5H_2O$ of Baker analysed reagent grade was used for the preparation of some lower hydrates of copper(II) sulphate. The samples, each of about 0.7 g, were ground slightly before dehydration. The methods of dehydration were similar to those described for the hydrates of other metal sulphates (1, 2).

Some small crystals of the pentahydrate were also prepared. These were obtained by adding absolute ethanol slowly to a concentrated solution of copper(II) sulphate in distilled water (14). The small crystals formed were collected and dried over a stream of air at room temperature. Thermogravimetric analysis showed that in each case the water content was in good agreement with the calculated value.

The heats of solution were measured by dissolving the samples in a calorimeter containing 1 L of distilled water.

2. $CuSO_4 \cdot 3H_2O$

$CuSO_4 \cdot 3H_2O$ was prepared by crystallizing the salt from a solution of $CuSO_4 \cdot 5H_2O$ in absolute methanol (15). The pentahydrate was added slowly, while stirring, into a beaker containing warm methanol. The solution was cooled to room temperature. When crystals of the trihydrate appeared, they were collected and dried over a stream of air. Trihydrate composition was confirmed by thermogravimetric analysis.

This salt was used to prepare other hydrates of copper(II) sulphate also. To prepare the higher hydrates, the trihydrate was rehydrated by exposing it to water vapour. To prepare the lower hydrates, the trihydrate was heated in an oven. When the lower hydrates of desired composition were obtained, the heat of solution measurements were done immediately. Samples with the monohydrate composition or less were heated in sealed glass tubes at various temperatures for various time intervals.

For the preparation of the high-energy modification hydrates, the trihydrate was dehydrated under vacuum at a pressure of 1×10^{-4} Torr or less. In each case the composition of the product obtained was determined by the loss in weight. The heat of solution was measured immediately by dissolving the salt in 1 L of distilled water.

3. $CuSO_4 \cdot 3H_2O \cdot 2D_2O$

About 1 g sample of copper(II) sulphate pentahydrate was dehydrated over concentrated H_2SO_4 to obtain the trihydrate. The sample was then exposed to $CuSO_4 \cdot 5D_2O$ (prepared by crystallizing a saturated solution of $CuSO_4$ in 99% D_2O). The completeness of rehydration was checked by measuring the gain in weight due to the absorption of D_2O.

For the ir study, the crystalline $CuSO_4 \cdot 3H_2O$ was again obtained by dehydrating $CuSO_4 \cdot 3H_2O \cdot 2D_2O$ over concentrated H_2SO_4 for a period of 3 weeks. About 0.1 g samples were used for the preparation of the high-energy modification lower hydrates under vacuum at a pressure of 1×10^{-4} Torr or less. The spectra were obtained from Nujol mulls of the samples on Beckman Acculab 3 IR Spectrophotometer.

4. Ammines of Copper(II) Sulphate

The starting material used was anhydrous copper(II) sulphate. This salt was obtained by heating $CuSO_4 \cdot 5H_2O$ (supplied by Fisher Scientific Co.) at 250°C (16) for a period of 2 days. The anhydrous salt was then reacted with anhydrous ammonia (supplied by Matheson of Canada Ltd.) in a manner previously described (17). The composition of the product

was analysed by the gain in weight as well as by gravimetric sulphate analysis. The ammonia content in the sample was found to be 34.79% which is close to the pentaammine composition. Since this salt is not stable, it was stored in a desiccator under an ammonia atmosphere.

Deammoniation of the salt was done under vacuum or in an oven at various temperatures previously determined (18–20). After partial loss of ammonia, the products were sealed in glass tubes to prevent water vapour in the air from reacting with the lower ammines. It has been pointed out (21) that the monoammine of copper(II) sulphate prepared by heating higher ammines in an oven is noncrystalline. Some lower ammines were also heated in sealed glass tubes at various temperatures and for various time intervals to ensure crystallization. The heats of solution were measured by dissolving about 0.3 g of the salt in 1 L of 0.3 *M* aqueous ammonia.

5. Calorimetry

The calorimeter used consists of a silvered Dewar flask equipped with a mechanical stirrer and a Beckmann thermometer. One litre of solvent was used in each experiment. The heat capacity of the calorimeter was determined from the change in temperature caused by a known quantity of electrical energy from a heater made of chromel A wire. Throughout the period of heating, the voltage and the current were quite steady at 4.00 ± 0.02 V and 6.00 ± 0.02 A. Time was measured with a stop watch to about 240.0 ± 0.1 s. Determination of the temperature change due to either the energy input or solution of the sample appeared to be accurate to ± 0.002°C. The average heat capacity of the calorimeter for each solvent was used in all calculations. The error in heat of solution was about ± 2.1 cal.

Results

1. $CuSO_4 \cdot 5H_2O$

The heat of solution measurements for the hydrates of copper(II) sulphate prepared by dehydrating the pentahydrate were done to reproduce the data given earlier in the literature. The values[3] have been corrected for the dilution effect by applying the experimental results obtained by Lang *et al.* (22). Some of the results are plotted in Fig. 1. The agreement with the previous data is very good except that there is no change in the slope of the line BC at the trihydrate composition.

2. $CuSO_4 \cdot 3H_2O$

The heats of solution for the hydrates of copper(II) sulphate prepared from $CuSO_4 \cdot 3H_2O$ are plotted in Fig. 2. The linear relations calculated by the method of least squares are

$$y_{BC} = 62.2 - 1.95x$$

for the low-energy hydrates, and

$$y_{FH} = 144 - 5.17x$$

for the high-energy hydrates where x is the percentage of water in that salt and y is its heat of solution. The heat of solution for the crystalline monohydrate, at B, has been estimated as 42.4 cal/g and that of the heptahydrate, at C, as -23.6 cal/g. Using the slope of the line FH as -5.17, the equation for the line CE, parallel to the lines AB and FH and passing through point C, the heptahydrate composition, on the line BC, has been calculated to be

$$y_{CE} = 205 - 5.17x$$

The heat of solution for the high-energy monohydrate, point D in Fig. 2, could then be estimated as 153 cal/g. Therefore the energy difference between points D and B is 110 cal/g monohydrate or 31.3 kcal/mol of heptahydrate. Expressed in wavenumbers, this energy is equivalent to 11.0×10^3 cm^{-1}.

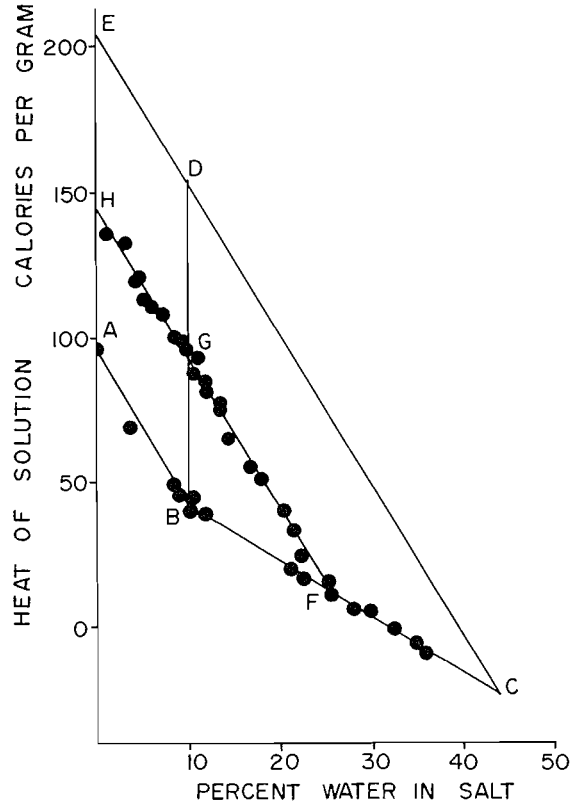

FIG. 2. Heats of solution for hydrates of copper(II) sulphate prepared from the trihydrate.

3. $CuSO_4 \cdot 3H_2O \cdot 2D_2O$

The ir spectrum from $CuSO_4 \cdot 3H_2O \cdot 2D_2O$ shows absorptions at about 3300 cm^{-1} and 2400 cm^{-1} (spectrum *A*, Fig. 3). When the salt is dehydrated over concentrated sulphuric acid, the product, $CuSO_4 \cdot 3H_2O$, shows only the absorption at 3300 cm^{-1} (spectrum *B*).

Spectra *C*, *D*, and *E* are for the salts obtained by vacuum dehydration of $CuSO_4 \cdot 3H_2O \cdot 2D_2O$. Spec-

[3]Complete set of tabular data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

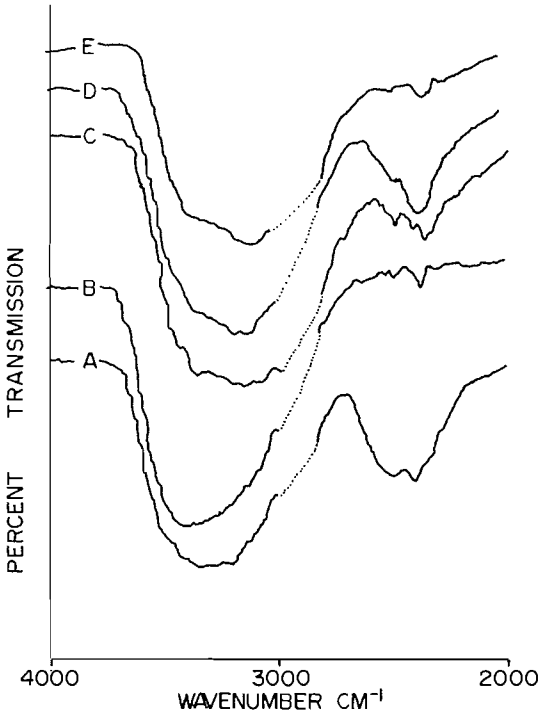

FIG. 3. Infrared spectra for hydrates of copper(II) sulphate. *A*, $CuSO_4 \cdot 3H_2O \cdot 2D_2O$; *B*, $CuSO_4 \cdot 3H_2O$; *C*, $CuSO_4 \cdot xH_2O \cdot yD_2O$ ($x + y \approx 3$); *D*, $CuSO_4 \cdot xH_2O \cdot yD_2O$ ($x + y \approx 2$); *E*, $CuSO_4 \cdot xH_2O \cdot yD_2O$ ($x + y \approx 1$).

trum *C* is that given by a hydrate of high-energy modification of composition $CuSO_4 \cdot xH_2O \cdot yD_2O$ where $x + y \approx 3$ (about the trihydrate composition). The amount of $H_2O + D_2O$ left in the sample is about 29.3%. Spectrum *C* gives both maxima at 3300 cm^{-1} and 2400 cm^{-1}. Though the intensity of the latter is comparatively less, it clearly indicates the presence of D_2O in the product. Spectrum *D* is that of $CuSO_4 \cdot xH_2O \cdot yD_2O$ with $x + y \approx 2$. The amount of $H_2O + D_2O$ left in the sample is about 18.7%. Both absorption maxima still persist and they do so even at a lower composition (spectrum *E*). Spectrum *E* is that of $CuSO_4 \cdot xH_2O \cdot yD_2O$ with $x + y \approx 1$. The amount of $H_2O + D_2O$ left in the sample is 13.4%.

4. Ammines of Copper(II) Sulphate

The heats of solution for the ammines of copper(II) sulphate are plotted as a function of percent ammonia in Fig. 4. In the figure, B, F, and C are at the monoammine, pentaammine, and heptaammine compositions respectively. The heats of solution for the low-energy ammines fall on the lines FB and BA whereas those for the high-energy modification ammines fall on the line FH. The lines AB, BC, and FH are drawn with the slopes calculated by using the method of least squares. The linear relations are

$$y_{AB} = 61.5 - 7.57x$$

$$y_{BC} = 90.6 - 3.68x$$

and

$$y_{FH} = 218 - 7.52x$$

where x is the percent ammonia in the sample and y is its solution. The heat of solution for the heptaammine of copper(II) sulphate which is probably hexaamminecopper(II) sulphate monoammine, $Cu(NH_3)_6SO_4 \cdot NH_3$, at point C, was estimated by extrapolating the line BC. It is found to be −74.5 cal/g. Using the slope of the line FH as −7.52, the line CE has been drawn to pass through the point C. This line allows the estimation of the heat of solution for the high-energy modification $CuSO_4 \cdot NH_3$ at point D as 174.7 cal/g. By using the equation for the line BC, the heat of solution for low-energy modification $CuSO_4 \cdot NH_3$ at point B is estimated to be 53.4 cal/g. Thus the heat of transition, Q_{DB}, is 121.3 cal/g monoammine which is equivalent to 11.8 × 10^3 cm^{-1} per mole heptaammine.

Discussion

The heats of solution for the crystalline hydrates of copper sulphate that are now reported in Fig. 2 give only a single straight line BC joining all the

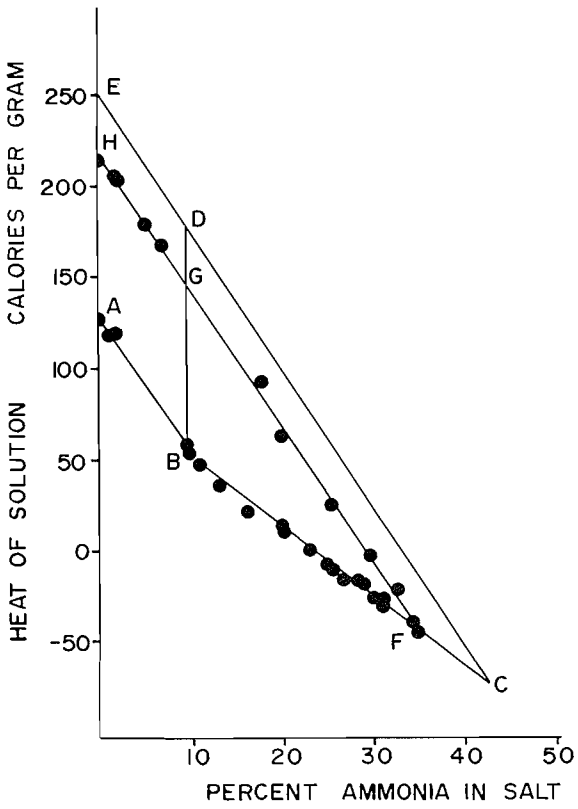

FIG. 4. Heats of solution for various ammines of $CuSO_4$.

points on the heat of solution curve. Furthermore, the gradient of the line CB in Fig. 2 is smaller than those given by Frost *et al.* (11) for the lines FB and CF in Fig. 1.

This could be explained on the assumption that the present technique for the preparation of the lower hydrates of low-energy modification yields completely crystalline products. It has been a common practice to prepare the lower hydrates by heating the pentahydrate in an oven. For example, when $CuSO_4 \cdot 5H_2O$ is heated at 101°C the trihydrate is formed (26). However, this trihydrate may contain a very small quantity of noncrystalline trihydrate (27). The quantity may be so small that the heat of solution would not give any detectable difference from that of the completely crystalline sample. Further dehydration may yield the monohydrates with a greater proportion of noncrystalline material so that the heat of solution would be considerably higher than that of the completely crystalline form.

Frost *et al.* (11) gave an equation to describe the heat of solution data for the high-energy modification hydrates of composition less than that of the monohydrate as

$$y_{FH} = 149.0 - 5.098x$$

The line FH intercepts the line BC at approximately the trihydrate composition. The equation for the line FH agrees quite well with the present results (Fig. 2) for the heats of solution for the hydrates of high-energy modification obtained by the dehydration of the crystalline trihydrate under vacuum. Therefore, it seems possible to conclude that all those hydrates that have their heats of solution described by the line FH must originally come from the trihydrate of copper(II) sulphate.

Since the line XZ in Fig. 1 intercepts the line FH at about the monohydrate composition, it seems likely that the products of vacuum dehydration of the pentahydrate which have water content higher than that of the monohydrate are really mixtures. These mixtures consist of the initial pentahydrate and high-energy modification monohydrate originating from the crystalline trihydrate. It seems that during vacuum dehydration when a molecule of $CuSO_4 \cdot 5H_2O$ loses its two molecules of ligand water, further loss of two more is enhanced. Thus that molecule will be dehydrated further to the monohydrate regardless whether other molecules adjacent to it have been dehydrated or not. If this is so, a product with an intermediate composition between the monohydrate and the pentahydrate is really a mixture of these two salts. Its heat of solution would fall on a line joining the values for the pentahydrate and the high-energy monohydrate, following a rule given by Donnan and Hope (13).

Thus it appears that the decomposition of the pentahydrate of copper(II) sulphate under vacuum to form the trihydrate would be accompanied by lattice rearrangement. The trihydrate stage is transitory (29). At the moment of its formation dehydration would proceed to the monohydrate stage with the formation of the corresponding high energy form. Garner and Tanner (30) arrived at a similar conclusion although in a less definitive way. Kohlschütter and Nitschmann (31) have studied the X-ray diffraction pattern of the products of vacuum dehydration of the pentahydrate of copper(II) sulphate and arrived at a similar conclusion.

The ir study that was done clearly shows this phenomenon. The ir spectra of free H_2O and D_2O in the gas phase show absorption maxima at about 3756 cm^{-1} and 2789 cm^{-1} respectively (23, 24) due to O—H and O—D assymetric stretchings. When the compound $CuSO_4 \cdot 3H_2O \cdot 2D_2O$ was formed from the trihydrate, it is assumed that D_2O absorbed has filled the vacant coordination positions in the $[Cu(H_2O)_2]^{2+}$ ion to form the $[Cu(H_2O)_2(D_2O)_2]^{2+}$ ion. Due to coordination, the corresponding vibrations in the salt are lowered (25). When the salt was dehydrated over concentrated H_2SO_4, it seems that all the D_2O originally present in the salt was lost, leaving the crystalline trihydrate again as the product (spectrum *B*, Fig. 3). Since the trihydrate has no D_2O, the spectrum would only show absorption at 3400 cm^{-1}. From the spectra *C*, *D*, and *E*, it is clear that under vacuum the D_2O are not completely removed even when the composition of the product is close to that of the monohydrate. This could mean one of two things: (*a*) the ligands are evolved at random, non-stepwise, regardless of the coordination positions, or (*b*) for every molecule, once D_2O is evolved, H_2O immediately follows. It is stepwise but fast in sequence to the extent that some molecules have only the anionic water left while the others still have all the ligands bonded. Since the second mechanism agrees well with the heat of solution data, it seems that it is the more likely one.

With these assumptions, it seems that the present results on the heat of solution measurements give better values than those given by earlier workers. Furthermore the value of $10Dq$ obtained by the thermochemical technique for the hexaaquocopper(II) ion as 11.0×10^3 cm^{-1} is comparable to that obtained by Pappalardo (8) as 11.2×10^3 cm^{-1} for a truely octahedral hexaaquocopper(II) ion in $CuSiF_6 \cdot 6H_2O$.

Eliott and Hathaway (10) have studied the reflectance spectra of the *d–d* transitions for the hexaamminecopper(II) halides and pentaamminecopper(II) sulphate. From their studies, they have assigned the value of $10Dq$ ranging from 10.4 ×

10^3 cm^{-1} to 10.6 × 10^3 cm^{-1} for the halides and 10 × 10^3 cm^{-1} for the sulphates. Roos (28) has calculated the energy levels for the $[Cu(NH_3)_5]^{2+}$ ion to confirm the experimental measurements of Bjerrum *et al.* (32). He assigned a value of 9.75 × 10^3 cm^{-1} to the $10Dq$ for this complex. From the present work we obtained a value of 11.8 × 10^3 cm^{-1} for the hexaamminecopper(II) ion. Even though it is slightly higher than those values quoted above it is still smaller than that originally proposed (5, 6). Compared to the value for the hexaaquocomplex it is very encouraging. Going back to the earlier paper (4) and substituting the present values in the figure showing the relative magnitudes of $10Dq$ for the complexes, the high values for that of hexaammine and hexaaquocopper(II) ions are removed. Thus the present results lend more support to the validity of the thermochemical measurement of the ligand field splitting energy.

Received October 10, 1978

GHOLAM HOSEIN HAKIMELAHI and GEORGE JUST. Can. J. Chem. **57,** 1932 (1979).

The synthesis of title compounds and some aromatic ring substituted analogues is described.

GHOLAM HOSEIN HAKIMELAHI et GEORGE JUST. Can. J. Chem. **57,** 1932 (1979).

On décrit la synthèse des composés sus-mentionnés ainsi d'analogues substitués sur le noyau aromatique.

Nocardicin A (1), the first 'monocyclic' β-lactam antibiotic described, is remarkably active against Gram-negative organisms in vivo (2) although it displays but little activity in vitro (3, 4). It differs from all hitherto described β-lactam antibiotics, 1770–1780 cm^{-1}, in having a relatively unstrained (1725 cm^{-1}) β-lactam ring, and therefore being quite stable towards nucleophilic attack. It occurred to us that the in vivo activation may well be linked to an oxidation of nocardicin A to the corresponding quinonemethine, in which the β-lactam frequency should be considerably augmented, thus leading to a chemically and therefore perhaps biologically reactive lactam.

Since the nocardicin A sidechain is relatively complex, nocardicinic acid derivatives carrying a phenylacetamide sidechain, a group known to confer antibiotic activity to classical β-lactam antibiotics, were prepared as model compounds, and the experience gathered applied to the synthesis of nocardicin A.

Because of the difficulties in preparing quinonemethines (5) it was decided to prepare, in addition to **8***N*-*f*, catechol derivatives of type **8***N*-*g*, in which an in vivo and (or) in vitro oxidation to *o*-quinones may be more easily achieved, and which may perhaps exist in part as the *p*-quinonemethine tautomer. Since several total syntheses of nocardicin have already been reported (6), it was decided to prepare 4-hydroxymethylnocardicinic acid, which would allow the synthesis of fused nocardicins. This will be described in the following paper.

Because of lack of substantial in vivo antibacterial activity of hydroxymethylnocardicin A (**17***N*), due presumably to the hydroxymethyl group, the corresponding catechol (**17***N*-*g*) was not synthesized.

As a model, methyl D,L-phenylglycinate (**3***a*) was converted to its cinnamylidine Schiff base **4***a*. Reaction with azidoacetyl chloride (7) using the methods described by Doyle *et al.* (8), gave β-lactam **5***a* as a mixture of epimers at the carboxyl bearing carbon. All the β-lactams obtained by this method were *cis*-fused (8), as could be determined by nmr (J = 5 Hz) of all derivatives in which the relevant protons did not overlap with other signals. The azide function in **5***a* was reduced with hydrogen sulfide – triethyl amine (8), and the resulting amine directly acylated with phenylacetyl chloride in pyridine to give **6***a*. This method was used throughout to convert the azide group to a phenylacetamide function and proceeded in approximately 70% overall yield. When methyl D-phenylglycinate (D-**3***a*) was transformed to **5***a*, the product was optically inactive, indicating that racemization took place as observed previously (9) in a similar reaction in which D-serine had been used as a starting material.

Next, *p*-benzyloxybenzaldehyde (**1***b*), piperonal (**1***c*), 3,4-dibenzyloxybenzaldehyde (**1***d*), and 4-carboxybenzaldehyde (**1***h*) were transformed to the corresponding cyanoamines **2***b*–*d* and **2***h* by means of $NaCN$–NH_4Cl–NH_3 in methanol, or methanol–tetrahydrofuran in the case of **1***b* and **1***d*. The cyanoamines **2** were methanolysed to the aminoester **3**, the overall yield for the transformation **1** → **3** being approximately 65% except in the case of **3***d*, in which the cyanoamine formation **1***d* → **2***d* proceeded in 5% yield only, and the methanolysis in 40%. Schiff base formation **3** → **4** proceeded in general quantitatively, and β-lactam formation **4** → **5** in approximately 70% yield. **5***b*–*e* were transformed to **6***b*–*e* as described above.

Since, at this point, it was not known whether the methyl ester group could be hydrolysed in the presence of a β-lactam group, β-lactams **6***a*, *b*, *d*, *e* were treated with 1 equiv. of sodium hydroxide in methanol as a 1% solution at room temperature.

Esters **6***a*,*b*,*d* were transformed to the corresponding acids in 60–65% yield, and were characterized by remethylation. In the case of carbomethoxyphenyl derivative **6***e*, the β-lactam function was hydrolysed more rapidly than either ester function.

Styryl-β-lactam **6***c* derived from piperonal was ozonised in methanol at −78°C, and the crude product reduced with sodium borohydride at −40°C. Although it was possible to isolate **7***c* by preparative tlc, the yield was very low, and it seemed that the methylene-dioxy bridge was attacked during ozonolysis. Moreover, the methylene bridge could not be cleaved in the presence of the β-lactams with boron trichloride – methylene chloride (10) or boron tribromide (11), so that no further work was done in this series.

Ozonolysis of the *p*-benzyloxy-β-lactam **6***b* using standard ozonolysis conditions, followed by sodium borohydride reduction at −40°C, gave the expected diols **7***b* in 20% yield only. However, when ozone and nitrogen were introduced simultaneously (12), and the reaction mixture then reduced with sodium borohydride, **7***b* was obtained in over 80% yield. Similar results were obtained in the dibenzyloxy series **7***d*. The diastereomeric mixtures **7***a*,*b*,*d* were separated into their constituents by column chromatography.

The less polar products were assigned the stereochemistry of the 'natural' nocardicin **7***N* based on the fact that the ester function absorbed in the infrared at 1740 cm^{-1} (hydrogen-bonded carbomethoxy group) and the hydroxyl function at 3300–3500 cm^{-1} (hydrogen-bonded hydroxyl), with a concomitant lowering of the chemical shift of the proton α to the carbomethoxy group to 5.8 ppm. The corresponding numbers for the more polar isomer **7***U* were 1750 cm^{-1}, 3400–3600 cm^{-1} and 5.5 ppm. Model studies indicated that hydrogen bonding of the ester and hydroxyl group resulted in the phenyl group being placed away from the β-lactam ring in the case of **7***N*, whereas in isomer **7***U*, hydrogen bonding would place the phenyl group very close to the β-lactam ring. Equilibration of two related isomers by heating either **9***U-a* or **9***N-a* (13) for a day at 80°C in pyridine gave a 30:70 ratio of **9***U-a* and **9***N-a* indicating that the hydrogen bond made **9***N-a* slightly more stable than **9***U-a*. When the hydroxy group in **9***U-a* or **9***N-a* was blocked by mesylation or acetylation, equilibration gave a 50:50 mixture of the corresponding mesylates or acetates of **9***U-a* and **9***N-a*, as established by nmr.

Catalytic hydrogenation of **7***U-b*, **7***U-d*, **7***N-b*, and **7***N-d* over Pd/C, followed by hydrolysis of the ester group with 1% aqueous sodium hydroxide, gave **8***U-f*, **8***U-g*, **8***N-f*, and **8***N-g* respectively.

In order to attach the nocardicin A sidechain to the β-lactam moiety, a mixture of diastereomeric styryl azides **5***b* were ozonised and reduced to a mixture of **10***b*, which could be separated into their constituents **10***U-b* and **10***N-b* as described for **7***U* and **7***N*.

D,L-Azido-β-lactam **10***N-b* was reduced with Pd/C in methanol, and the resulting phenolic aminoalcohol **11***N-f* obtained in nearly quantitative yield, was silylated *in situ* to give **12***N-i*. Coupling of **12***N-i* with glyoxylic acid DL-**13** using *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ) (14) in methylene chloride for 16 h, gave, after washing and chromatography on silica gel, 80% of amide **14***N* as a mixture of inseparable diastereomeric racemates. Hydrolysis with 2 equiv. of sodium hydroxide in aqueous methanol, followed by removal of the *t*-BOC group by means of trifluoroacetic acid, gave **16***N* in 56% overall yield. Oximation was carried out using $NH_2OH{\cdot}HCl$ in water at pH 7 (15). Purification by ion exchange gave **17***N* in 60% yield. The ir, nmr, and uv spectra at pH 7 and 12 of **17***N* (two racemic diastereomers) were virtually indistinguishable from those of nocardicin A, except for the presence of the CH_2OH group, which was clearly visible in the nmr spectrum. The same sequence could also be applied to the epimer **10***U-b*, giving **17***U*.

Biological Tests

Phenylacetimidonocardicinic acids **8***N-f*, **8***N-g*, **8***U-f*, and **8***U-g* and nocardicin A analog **17**-*U* were tested against 32 strains of *Ps. aeruginosa*, *K. pneumoniae*, *E. aerogenes*, *E. cloacae*, *P. mirabilis*, *P. vulgaris*, *P. morganii*, *S. aureus*, and *S. lutea* and found to be inactive at a level of 256 μg/mL.

The diastereomeric mixture of racemates **17***N* was found to be active at the level of 32 μg/mL versus *S. lutea*, as compared to nocardicin A which had a mic of 6.25 μg/mL against the same organism. However, **17***N* exhibited no in vivo activity.

Experimental

Solvents were of reagent grade unless otherwise specified. Infrared spectra were run on Unicam SP1000 and P.E. 257 spectrophotometers. Nuclear magnetic resonance spectra were run on Varian T-60A or HA-100 spectrometers. Mass spectra were taken on an AEI-MS-902 mass spectrometer using the direct sample inlet system with a 70 eV ionization energy or on a LKB-9000 mass spectrometer.

Melting points were determined on a Gallenkamp block in open capillary tubes and are uncorrected.

Merck S160 silica gel was used for column chromatography. Merck silica gel HF 254 was used for thin layer chromatography (1 mm) on glass plates (20 × 20 cm). Elemental analyses were performed by Heterocyclic Chemical Corporation or Midwest Microlab. Ltd.

Aminonitriles **2**b,c,d,h

Benzaldehydes **1** (0.02 mol) were dissolved in solvent *A*. Ammonium chloride (2.6 g, 0.05 mol) and sodium cyanide (1.25 g, 0.025 mol) were added, and the solution was saturated with ammonia at 0°C (10 min), and stirred in a pressure bottle at 25–30°C for 15 h. After evaporation, solvent *B* was added, and the product either filtered and recrystallized from solvent *C* or extracted with ethyl acetate. The nmr (DMSO-d_6) showed a 2H broad singlet at *D* ppm, exchangeable with D_2O (NH_2), a 1H singlet at δ*E* ppm (CH), aromatic proton at *F* ppm, and other appropriate signals. All compounds absorbed in the infrared at 3300–3500 cm^{-1} (NH_2) and 2200 cm^{-1} (CN). Yield *G*%.

Compound **2***b*: *A* 100 mL methanol, 30 mL THF; *B* water; *C* methanol; mp 93–95°C; *D* 2.8–3.4; *E* 4.83; *F* 6.8–7.5 (9H); 5.1 ppm (2H, s, CH_2Ph); ms *m/e*: 238 (M^+); *G* 90.

Compound **2***c*: *A* 100 mL methanol; *B* water, extracted with ethyl acetate; *D* 2.0; *E* 4.80; *F* 6.8–7.2 (3H); 6.0 ppm (2H, s, O—CH_2—O); *G* 80.

Compound **2***d*: *A* 100 mL methanol, 30 mL THF; *B* water; the precipitate consisted of methanol insoluble **2***d*, and large amounts of soluble cyanohydrin; mp 49–50°C; *D* 1.63–1.82; *E* 4.90; *F* 7.0–7.7 (13H); 5.2 ppm (4H, s, $(CH_2Ph)_2$); ms *m/e*: 344 (M^+); *G* 5.

Compound **2***h*: *A* 100 mL methanol; *B* acetic acid; filtration; water; filtration. mp >250°C (dec.); *D* 4.8 (3H); *E* 5.4; *F* 7.6–8.2 (4H); *G* 80.

Amino Acid **3**b,c,d,e

Cyanoamines **2***b,c,d,h* (0.018 mol) were dissolved in 250 mL methanol–water (95:5), and HCl gas was bubbled in at room temperature without cooling for 10 min. The solution was gently refluxed for 3 h, the solvent then evaporated and a mixture of 20 mL acetone – 60 mL ether was added. The colourless precipitate was washed with ether, and **3***b,c,e*·HCl obtained in approximately 80% yield, except for **3***d*·HCl which was obtained in 50% yield. All compounds obtained had nmr

spectra similar to those described for the cyanoamines except for additional methyl ester peaks.

Compound **3***b*·HCl: *Anal.* calcd. for $C_{16}H_{18}O_3NCl$: C 62.44, H 5.85, N 4.55; found: C 62.22, H 5.95, N 4.53.

Compound **3***d*·HCl: *Anal.* calcd. for $C_{23}H_{24}O_4NCl$: C 66.75, H 5.80, N 3.38; found: C 66.35, H 5.50, N 3.30.

All hydrochlorides were converted to the parent amine **3** according to the following procedure:

Compound **3***b*·HCl (4.6 g, 0.015 mol) was mixed with 50 mL of 10% aqueous $NaHCO_3$, and the resulting amine **3***b* extracted into 50 mL of ether. After evaporation, 3.25 g of **3***b* (80% yield) was obtained as an oil; nmr ($CDCl_3$) δ: 1.8 (s, 2H, NH_2, exchanged with D_2O); 3.5 (s, 3H, OCH_3), 4.4 (s, 1H, CH), 4.9 (s, 2H, CH_2O), 6.65–7.4 ppm (m, 9H, aromatic); ir (CH_2Cl_2): 3300–3400 (NH_2), 1740 (ester) cm^{-1}.

Schiff Base **4**a–e

All the Schiff bases were prepared in a similar manner and used without purification. The following is a representative procedure:

To a solution of **3***b* (2.71 g, 0.01 mol) in 100 mL dry CH_2Cl_2 was added cinnamaldehyde (1.32 g, 0.01 mol). The solution was brought to reflux and the CH_2Cl_2 distilled slowly with the constant addition of dry CH_2Cl_2 so as to maintain the same volume of liquid in the reaction vessel. After the water of reaction was all removed (~7 h), the solution was cooled and $MgSO_4$ was added. After 2.5 h, it was filtered and evaporated to yield 3.85 g (100%) Schiff base **4***b* as an oil; nmr ($CDCl_3$) δ: 3.8 (s, 3H, CH_3), 5.1 (s, 2H, CH_2), 5.3 (s, 1H, CH), 6.8 (m, 2H, CH=CH), 7–7.6 (m, 14H, Ph), 8.0 (m, 1H, N=CH); ir (CH_2Cl_2): 1735 (ester), 1635 (HC=N) cm^{-1}. In the case of **4***d*, the yield seemed to be somewhat lower (85%) as ascertained by nmr.

Azido-β-*lactams* **5**a–e

All β-lactams were prepared in an identical manner and obtained in approximately 80% yield. Their spectra were similar except for variations due to aromatic substituents. All their mass spectra showed $M^+ - N_2$ or, in the case of **5***a*, M^+.

The following is a representative procedure:

β-*Lactam* **5**b

To the freshly prepared Schiff base (3.85 g, 0.01 mol) in 100 mL dry CH_2Cl_2 was added at −20°C (dry ice – CCl_4) triethylamine (1.01 g, 0.01 mol). A solution of azidoacetyl chloride (1.2 g, 0.01 mol) in 30 mL dry CH_2Cl_2 was added dropwise over 10 min. The solution was stirred for 1 h and evaporated to dryness. The residue was dissolved in ether, treated with charcoal, filtered, and evaporated to give 3.7 g (80%) **5***b* as an oily mixture of diastereomers; nmr ($CDCl_3$) δ: 3.8 (d, 3H, CH_3) 4.2–4.4 (m, 1H, β-lactam) 4.7–4.9 (m, 1H, β-lactam), 5.1 (s, 2H, CH_2), 5.5–5.6 (d, 1H, CH), 6.5 (m, 2H, CH=CH), 6.8–7.6 (m, 14H, Ph). Chromatography over silica gel using CH_2Cl_2 as eluent separated one of the diastereomers, which was obtained in 30% yield as an oil; nmr ($CDCl_3$) δ: 3.75 (s, 3H, CH_3), 4.2–4.4 (m, 1H, β-lactam), 4.8 (d, 1H, J = 5 Hz, β-lactam), 5.1 (s, 2H, CH_2), 5.5 (s, 1H, CH), 6.5 (m, 2H, CH=CH), 6.8–7.5 (m, 14H, Ph); ir (CH_2Cl_2): 2100 (N_3), 1760 (β-lactam), 1740 (ester) cm^{-1}, identical to that of the diastereomeric mixture; ms *m/e*: 440 ($M^+ - N_2$).

Phenylacetamido-β-*lactams* **6**a–e

All transformations were performed in an identical manner, and the mixture of diastereomers **6** obtained in 70% yield after purification. Their spectra were similar except for variations due to aromatic substituents. All their mass spectra showed M^+, $M^+ - (Ph—CH_2CONHCH=C=O)$, $M^+ - (Ph—CH=CH—CH=CH—NHCOCH_2Ph)$, except for the dibenzyloxy derivative which showed no molecular ion but $M^+ - (Ph—CH_2CONHCH=C=O)$, $M^+ - (Ph—CH=CH—CH=CH—NHCOCH_2Ph)$.

The following is a representative procedure:

To a solution of a diastereomeric mixture of azido β-lactam **5***b* (4.68 g, 0.01 mol) in 100 mL dry CH_2Cl_2 at 0°C was added triethylamine (1.2 g, 0.012 mol). A stream of H_2S gas was bubbled in for 45 min. The solution was allowed to stand for 2 h at room temperature. Evolution of nitrogen gas was observed. A stream of nitrogen gas was bubbled in for 30 min, then was added 2.3 g (0.03 mol) pyridine, followed by dropwise addition of 1.8 g (0.012 mol) phenylacetyl chloride in 20 mL CH_2Cl_2. The solution was stirred for 2 h at 25°C, then was washed with 10% HCl solution, 10% $NaHCO_3$ solution, and brine. It was then dried over Na_2SO_4, and evaporated to give 5 g (89%) of impure amide **6***b* which was chromatographed on silica gel. Methylene chloride eluted impurities, and chloroform gave 4 g (70%) of β-lactam **6***b*, mp 100–106°C, as a mixture of diastereomers; nmr ($CDCl_3$) δ: 3.4 (s, 2H, amide CH_2), 3.6–3.8 (2s, 3H, CH_3), 4.2–4.4 (m, 1H, β-lactam), 4.8–5.1 (2s, 2H, CH_2), 5.4–5.7 (m, 2H, CH and β-lactam), 6.2–6.5 (m, 2H, CH=CH), 7–7.6 (m, 20H, Ph and NH). Two recrystallizations from absolute ethanol separated one of the diastereomers; mp 168–169°C; nmr ($CDCl_3$) δ: 3.42 (s, 2H, CH_2), 3.7 (s, 3H, CH_3), 4.2–4.4 (m, 1H, β-lactam), 5.1 (s, 2H, CH_2), 5.3–5.6 (s, 1H, C*H*COOMe and m, 1H, β-lactam, J_1 = 5 Hz and J_2 = 8 Hz), 6.2–6.6 (m, 2H, CH=CH), 6.2–7.6 (m, 20H, Ph and NH); ir (CH_2Cl_2): 3390 (NH), 1756 (β-lactam), 1740 (ester), 1680 (amide) cm^{-1}, identical to that of the mixture of diastereomers; ms *m/e*: 560 (M^+).

Compound **6***U-b* or **6***N-b*: *Anal.* calcd. for $C_{35}H_{32}O_5N_2$: C 74.98, H 5.75, N 5.00; found: C 74.63, H 5.98, N 4.88.

Compound **6***c*: *Anal.* calcd. for $C_{29}H_{26}O_6N_2$: C 69.87, H 5.22, N 5.62; found: C 69.69, H 5.27, N 5.37; mp 69–70°C (ethanol).

Compound **6***d*: *Anal.* calcd. for $C_{42}H_{38}O_6N_2$: C 75.67, H 5.70, N 4.20; found: C 75.33, H 5.79, N 3.88; mp 130–131°C (ethanol).

4-Hydroxymethyl-β-*lactams* **7**U-b, **7**U-d, **7**N-b, *and* **7**N-d

Both mixtures of diastereomeric monobenzyloxylactam **6***b* and dibenzyloxylactam **6***d* were submitted to identical reaction conditions and separation procedures, which will be described for **6***b* only.

β-Lactam **6***b* (2 g, 0.0035 mol) in a mixture of 50 mL CH_2Cl_2 and 100 mL dry methanol was saturated with nitrogen gas at −78°C (3 min). Then a mixture of O_3–N_2 gas was bubbled in until the KI starch paper showed excess ozone (30 min). The excess ozone was removed by passing a stream of N_2 for 10 min. The temperature was allowed to rise to −40°C, at which time was added $NaBH_4$ (0.2 g, 0.005 mol). The temperature of the solution was permitted to rise to 25°C over 2 h, following which 5 mL 10% HCl was added. The solution was evaporated to 50 mL, diluted with H_2O, and was extracted with ethyl acetate, washed with water, dried over Na_2SO_4, and evaporated to give crude product in quantitative yield.

A wash with a mixture of ether–hexane (1:14) removed benzyl alcohol, and a 1:1 mixture of diastereomers (1.5 g, 85%) of **7***b*, mp 50–54°C, was obtained, as evidenced by nmr.

Chromatography on silica gel and elution with $CHCl_3$ separated completely the diastereomers **7***N-b* and **7***U-b*. The less polar diastereomer **7***N-b* was obtained in 40% yield, and melted at 84–85°C after crystallization from diethyl ether; nmr ($CDCl_3$) δ: 3.4 (b, 2H, CH_2O), 3.6 (s, 2H, CH_2CO), 3.8 (s, 3H, CH_3), 4.2–4.6 (m, 1H, C*H*—CH_2OH), 5.18 (s, 2H, CH_2Ph), 5.4–5.7 (q, 1H, C*H*—NHCO, J_1 = 5 Hz and J_2 = 10 Hz, after D_2O exchange: d, J = 5 Hz), 5.8 (s, 1H, CH), 7–7.6 (m, 15H, Ph and NH); ir (CH_2Cl_2): 3380–3440 (NH and OH), 1760 (β-lactam), 1740 (ester), 1670 (amide) cm^{-1}.

Compound **7***U-b* was obtained in 40% yield and was crystallized from diethyl ether, mp 59–60°C; nmr ($CDCl_3$) δ:

2.8–3.2 (b, 2H, CH_2O), 3.5 (s, 2H, CH_2CO), 3.7 (s, 3H, CH_3), 4–4.1 (m, 1H, C*H*–CH_2OH), 5.1 (s, 2H, CH_2Ph), 5.4–5.7 (m, 1H, C*H*—NHCO, J_1 = 5 Hz and J_2 = 10 Hz, and 1H, s, CH), 6.8–7.8 (m, 15H, Ph and NH); ir (CH_2Cl_2): 3380–3440 (NH and OH), 1760 (β-lactam), 1750 (ester), 1670 (amide) cm^{-1}; ms *m/e*: 429 (M^+ − COOMe), 297 (M^+ − $HOCH_2$-CH=CHNHCOCH_2Ph), identical to that of the other diastereomer. *Anal.* calcd. for $C_{28}H_{28}O_6N_2$: C 68.84, H 5.87, N 5.73; found: C 68.62, H 6.05, N 5.47.

Compound **7***N-d* was obtained by the same purification method in 40% yield and melted at 85–87°C (Et_2O); nmr ($CDCl_3$) δ: 3–3.3 (b, 2H, CH_2O), 3.6 (s, 2H, CH_2CO), 3.8 (s, 3H, CH_3), 4.2–4.4 (m, 1H, C*H*—CH_2OH), 5.2 (s, 4H, $2CH_2Ph$), 5.3–5.6 (q, 1H, C*H*—NHCO, J_1 = 5 Hz and J_2 = 10 Hz), 5.7 (s, 1H, CH), 6.7–7.6 (m, 19H, Ph, NH). Its ir was identical to that of **7***N-b*.

Compound **7***U-d* was obtained by the same purification method in 40% yield; mp 70–72°C; nmr ($CDCl_3$) δ: 2.6–2.7 (b, 1H, OH exchanged with D_2O), 3.0–3.2 (b, 2H, CH_2O), 3.6 (s, 2H, CH_2CO), 3.7 (s, 3H, CH_3), 3.9–4.0 (m, 1H, C*H*—CH_2OH), 5.2 (s, 4H, $2CH_2Ph$), 5.4–5.72 (m, 1H, C*H*—NHCO, J_1 = 5 Hz and J_2 = 10 Hz and 1H, s, CH), 6.8–7.6 (m, 19H, Ph, NH); ir was identical to that of **7***U-b*; ms *m/e*: 594 (M^+) identical to that of the other diastereomer. *Anal.* calcd. for $C_{35}H_{34}O_7N_2$: C 70.71, H 5.72, N 4.71; found: C 70.69, H 5.70, N 4.69.

β-*Lactam* **7**U-f *and* **7**N-f

To β-lactam **7***N*-b (1.5 g, 0.003 mol) in 60 mL methanol was added 10% Pd/C (0.2 g), and the mixture was hydrogenated at room temperature and 40 psi for 1 h. (The pressure dropped to 37 psi.) The solution was then filtered and evaporated to give 1 g (83%) of **7***N-f*; mp 76–78°C (Et_2O); nmr ($CDCl_3$) δ: 3.4–3.6 (b, 2H, CH_2O), 3.7 (s, 2H, CH_2CO), 3.8 (s, 3H, CH_3), 4.2–4.6 (b, 2H, OH and C*H*—CH_2OH), 5.4–5.67 (q, 1H, C*H*—NHCOR, J_1 = 5 Hz and J_2 = 10 Hz), 5.7 (s, 1H, CH), 6.8–7.5 (m, 10H, Ph and NH), 8.3 (b, 1H, phenolic OH); ir (CH_2Cl_2): 3350 (OH and NH), 1760 (β-lactam), 1725 (ester), 1660 (amide) cm^{-1}; **7***U-f* was obtained by the same method in 80% yield; mp 68–69°C (Et_2O); nmr ($CDCl_3$) δ: 3.2 (b, 2H, CH_2O), 3.6 (s, 2H, CH_2CO), 3.79 (s, 3H, CH_3), 4.2 (b, 2H, OH and C*H*—CH_2OH), 5.4–5.7 (m, 2H, CH and C*H*NHCOR, J_1 = 5 Hz and J_2 = 10 Hz), 6.8–7.6 (m, 11H, Ph, NH and phenolic OH); ir (CH_2Cl_2): 3350 (OH and NH), 1760 (β-lactam), 1735 (ester), 1660 (amide) cm^{-1}; ms *m/e*: 339 (M^+ − COOMe), 148(M^+ − COOMe + $HOCH_2CH$=CHNH-$COCH_2Ph$) identical to that of the diastereomer **7***N-f*.

β-*Lactam* **8**U-f *and* **8**N-f

β-Lactam **7***N-f* (1 g, 0.0025 mol) was dissolved in 30 mL methanol. One percent aqueous NaOH (10 mL) was added dropwise over a period of 10 min. It was then stirred for 15 min and acidified with HCl to pH 3. The methanol was evaporated and the aqueous solution was extracted with ethyl acetate. Drying (Na_2SO_4) and evaporation gave 0.8 g (84%) **8***N-f*; mp 160–162°C, after dissolving in 5% aqueous $NaHCO_3$, and acidifying to pH 3; nmr ($CDCl_3$–DMSO-d_6) δ: 3.4–3.7 (b, 5H, CH_2O, CH_2CO, C*H*—CH_2OH), 5.2–5.4 (q, 1H, C*H*—NHCOR, J_1 = 5 Hz and J_2 = 10 Hz), 5.6 (s, 1H, CH), 6.8–7.4 (m, 11H, Ph, COOH, OH), 8.0 (b, 1H, NH). Addition of D_2O resulted in exchange of four protons and considerable sharpening of spectrum. Infrared (KBr): 3250–3350 (OH, NH, COOH), 1735 (β-lactam), 1710 (acid), 1625 (amide) cm^{-1}. Treatment of **8***N-f* with diazomethane resulted in quantitative formation of **7***N-f*. Compound **8***U-f* was obtained from **7***U-f* by the same method in 80% yield; mp 117–120°C; nmr was identical to that of the other diastereomer; ir (KBr): 3300–3400 (NH, OH, COOH), 1740–1730 (β-lactam and acid), 1660 (amide) cm^{-1}. Treatment of **8***U-f* with diazomethane gave **7***U-f* quantitatively.

β-*Lactam* **8**U-d *and* **8**N-d

Compounds **7***U-d* and **7***N-d* were hydrolysed to **8***U-d* and **8***N-d* in about 80% yield using the method described for the formation of **8***N-f*.

Compound **8***N-d*: mp 122–125°C; nmr ($CDCl_3$, DMSO-d_6, D_2O) δ: 3.3–3.7 (m, 5H, CH_2O, CH_2CO, C*H*—CH_2OD), 5.2 (s, 4H, $2CH_2O$), 5.3–5.5 (d, 1H, C*H*—NDCOR), 5.63 (s, 1H, CH), 6.8–7.4 (m, 18H, Ph); ir (KBr): 3200–3400 (NH, OH, COOH), 1750–1730 (β-lactam and acid), 1640 (amide) cm^{-1}; treatment of **8***N-d* with CH_2N_2 gave **7***N-d* quantitatively.

Compound **8***U-d*: mp 95–98°C; nmr was identical to that of the **8***N-d*; ir (KBr): 3200–3400 (NH, OH, COOH), 1750–1740 (β-lactam and acid), 1680 (amide) cm^{-1}; treatment of **8***N-d* with CH_2N_2 gave **7***U-d*.

β-*Lactams* **7**U-g, **7**N-g, **8**U-g, *and* **8**N-g

The **8***U-d* and **8***N-d* were debenzylated to **8***U-g* and **8***N-g* in 80% yield by catalytic hydrogenation as described for the preparation of **7***N-f*.

Compound **8***N-g*: mp 116–119°C (dec.); nmr (acetone-d_6, D_2O) δ: 3.5–3.8 (b, 5H, CH_2O, CH_2CO, C*H*—CH_2O), 5.3–5.5 (d, 1H, CH—ND—COR, J = 5 Hz), 5.6 (s, 1H, CH), 6.8–7.4 (m, 8H, Ph); ir (KBr): 2800–3500 (OH, COOH), 1750 (β-lactam), 1730 (acid), 1640 (amide) cm^{-1}. Treatment of **8***N-g* with CH_2N_2 gave **7***N-g* quantitatively.

Compound **7***N-g*: mp 84–87°C; nmr ($CDCl_3$–D_2O) δ: 3.4–3.8 (m, 8H, CH_2O, CH_2CO, CH_3, C*H*—CH_2O), 5.2–5.4 (d, 1H, C*H*—NDCOCH_2Ph, J = 5 Hz), 5.7 (s, 1H, CH), 6.5–7.4 (m, 8H, Ph); ir ($CHCl_3$): 3100–3500 (OH, NH), 1770 (β-lactam), 1740 (ester), 1680 (amide) cm^{-1}; ms *m/e*: 414 (M^+).

Compound **8***U-g*: mp 95–98°C; its nmr was identical to that of **8***N-g*; ir (KBr): 2800–3500 (OH, COOH), 1750–1740 (β-lactam, acid), 1670 (amide) cm^{-1}. It was treated with CH_2N_2 to give the corresponding methyl ester **7***U-g*; ms *m/e*: 414 (M^+).

Azido Alcohol **10**N-b *and* **10**U-b

β-Lactam **5***b* (4.68 g, 0.01 mol) in a mixture of 61 mL CH_2Cl_2 and 100 mL dry methanol was saturated with nitrogen gas at −78°C (3 min). Then a mixture of O_3 and N_2 gas was bubbled in until the KI starch paper showed excess ozone (60 min). The excess ozone was removed by passing a stream of N_2 for 10 min. The temperature was allowed to rise to −40°C, at which time was added $NaBH_4$ (0.38 g, 0.01 mol). The temperature of the solution was permitted to rise to 25°C over 2 h, following which 10 mL 10% aqueous HCl was added. The solution was evaporated to 50 mL, diluted with water, and extracted with ethyl acetate, washed with water, dried over Na_2SO_4, and evaporated to give crude product in quantitative yield.

A wash with a mixture of ether–hexane (1:14) removed benzyl alcohol, and an oily 1:1 mixture of diastereomers (3 g, 70%) of **10***N-b*/**10***U-b* was obtained as evidenced by nmr.

Chromatography on silica gel and elution with CH_2Cl_2 separated one of the diastereomers **10***N-b* in 30% yield as a foam; **10***U-b* was eluted with $CHCl_3$ in 30% yield as a foam.

Less polar diastereomer **10***N-b*: nmr ($CDCl_3$) δ: 3.4–3.8 (b, 4H, C*H*—C*H*$_2$O*H*), 3.7 (s, 1H, CH_3), 4.4–4.6 (d, 1H, C*H*—N_3, J = 5 Hz) 5.1 (s, 2H, CH_2), 5.78 (s, 1H, CH), 6.9–7.55 (m, 9H, Ph); ir (CH_2Cl_2): 3300–3500 (OH), 2100 (N_3), 1770 (β-lactam), 1740 (ester) cm^{-1}.

More polar diastereomer **10***U-b*: nmr ($CDCl_3$) δ: 2.2–2.4 (b, 1H, OH exchanged with D_2O), 3.2–3.4 (b, 2H, CH_2O), 3.6 (s, 3H, CH_3), 4.0–4.3 (m, 1H, C*H*—CH_2O), 4.75–4.9 (d, 1H,

CH—N_3, J = 5 Hz), 5.3 (s, 2H, CH_2), 5.5 (s, 1H, CH), 6.9–7.5 (m, 9H, Ph); ir (CH_2Cl_2): 3400–3600 (OH), 2100 (N_3), 1770 (β-lactam), 1750 (ester) cm^{-1}. Mass spectra showed M^+, $M^+ - COOMe$, $M^+ - (N_3CH{=}CH{-}CH_2OH)$, and $M^+ - (N_3{-}CH{=}C{=}O)$ identical to that of the **10***N-b*.

β-*Lactam* ***11***N-f

β-lactam **10***N-b* (3.8 g, 0.01 mol) was dissolved in 60 mL methanol. Pd/C (0.4 g) was added, and the mixture was hydrogenated at room temperature and 40 psi for 1.5 h. The solution was then filtered and evaporated to give 2.6 g (90%) β-lactam **11***N-f*, mp 110–113°C; nmr (DMSO-d_6) δ: 3.2 (b, 2H, NH_2), 3.6 (s, 3H, CH_3), 3.8-4.1 (m, 4H, CH_2O and *CH*—CH_2OH), 4.6 (m, 1H, *CH*—NH_2), 5.40 (s, 1*H*, CH), 6.6–7.4 (q, 5H, Ph and phenolic OH); ir (Nujol): 3000–3400 (OH, NH_2), 1760–1750 (β-lactam, ester).

Compound **11***U-f* was obtained by the same method in 90% yield, mp 100–103°C; nmr (DMSO-d_6) δ: 3.2 (b, 2H, NH_2), 3.6 (s, 3H, CH_3), 3.8–4.1 (m, 4H, CH_2O and *CH*—CH_2OH), 4.4–4.6 (m, 1H, *CH*—NH_2), 5.38 (s, 1H, CH), 6.6–7.4 (q, 5H, Ph and phenolic OH); ir was identical to that of **11***N-f*.

β-*Lactam* ***12***N-i

To a suspension of β-lactam **11***N-f* (2.6 g, 0.009 mol) in 50 mL dry CH_2Cl_2 containing triethylamine (1.01 g, 0.01 mol) was added dropwise within 5 min trimethyl silyl chloride (1.09 g, 0.01 mol) dissolved in 15 mL dry CH_2Cl_2. The solution was stirred for 30 min at room temperature, evaporated to dryness, and diethyl ether added. Filtration, and evaporation of the filtrate gave 3.4 g (88%) of **12***N-i* as an oil; nmr ($CDCl_3$) δ: 0.1–0.3 (d, 18H, 2(OSi(Me)$_3$)), 2.2–2.6 (b, 2H, NH_2), 3.8 (s, 3H, CH_3), 4.0–4.6 (m, 4H, *CH*—*CH*—CH_2—OSi), 5.4 (s, 1H, CH), 6.8–7.4 (q, 4H, Ph); ir (CH_2Cl_2): 3300–3400 (NH_2), 1750 (ester), 1770 (β-lactam) cm^{-1}.

Compound **12***U-i* was obtained by the same method in 85% yield. Its ir and nmr spectra were identical to those of **12***N-i*.

β-*Lactam* ***14***N

β-Lactam **12***N-i* (0.21 g, 0.49 mmol) and acid DL-**13** (0.2 g, 0.52 mmol) were dissolved in 40 mL dry CH_2Cl_2. EEDQ (0.13 g, 0.52 mmol) was added and the reaction mixture was stirred for 16 h at room temperature. The solution was washed with 10% aqueous HCl and 10% aqueous $NaHCO_3$, dried over $MgSO_4$, filtered, and evaporated to give 0.3 g (94%) crude product, which was chromatographed on silica gel using CH_2Cl_2 to remove all impurities. Elution with $CHCl_3$ gave 0.25 g (77.5%) of **14***N* as a foam; nmr ($CDCl_3$) δ: 1.4 (s, 9H, —CMe_3), 2.1–2.4 (m, 2H, CH_2), 3.7 (d, 6H, $2CH_3$), 4.0 (m, 5H, *CH*—CH_2OH and MeOOCC*H*—NHR), 4.5 (t, 2H, CH_2OPh), 5.4–5.6 (m, 1H, *CH*–NHCOR, after D_2O exchange, J = 5 Hz), 5.65 (s, 1H, CH), 6.8–7.1 (m, 9H, Ph, NH, phenolic OH), 8.2–8.4 (d, 2H, aromatic, J = 8 Hz); ir ($CHCl_3$): 3200–3450 (OH, NH), 1750–1760 (ester, β-lactam), 1715 (*t*-BOC), 1670–1680 (amide, ketone) cm^{-1}.

Compound **14***U* was obtained by the same method in 80% yield; ir was identical to that of diastereomer **14***N*; nmr was identical to that of **14***N* except for benzylic methine proton which showed at δ 5.5 ppm.

β-*Lactam* ***15***N

β-Lactam **14***N* (0.25 g, 0.38 mmol) was dissolved in 20 mL methanol. One percent NaOH (10 mL) was added dropwise over a period of 10 min. It was then stirred for 13 min and acidified with HCl to pH 3. The methanol was evaporated and the aqueous solution was extracted with ethyl acetate. Drying ($MgSO_4$) and evaporation gave 0.2 g (80%) crude product as foam, which was dissolved in 5% aqueous $NaHCO_3$ and after filtration was acidified with HCl to pH 3 to give 0.15 g (63%) **15***N*; mp 165–167°C (dec.); nmr (acetone-d_6–D_2O) δ: 1.4 (s, 9H, —CMe_3), 2.18–2.4 (m, 2H, CH_2), 3.6–3.9 (m, 3H, —CH_2—OD and DOOCC*H*—NDR), 4.2–4.5 (m, 3H, *CH*—CH_2OD and CH_2OPh), 5.4 (d, 1H, *CH*—NDCOR, J = 5 Hz), 5.6 (s, 1H, CH), 6.9–7.3 (m, 6H, Ph), 8.2–8.4 (d, 2H, aromatic, J = 8 Hz); ir (Nujol): 3100–3300 (OH, NH), 1740–1720 (β-lactam, acid, *t*-BOC), 1660 (amide, ketone).

Compound **15***U* was obtained by the same method in 67% yield; mp 158–160°C (dec.); ir and nmr were identical to those of **15***N*.

β-*Lactam* ***16***N

A solution of β-lactam **15***N* (0.2 g, 0.32 mmol) in 5 mL trifluoroacetic acid was stirred at room temperature for 2 h, then diethyl ether was added to give a white precipitate, which was filtered and washed three times with ether to give 0.15 g (90%) of **16***N*, becoming brown at 185°C; mp 226–220°C (dec); nmr (D_2O–$NaHCO_3$) δ: 2.0–2.4 (m, 2H, CH_2), 3.6–3.9 (b, 3H, CH_2OD and $^-OOCCH\overset{+}{N}D_3$), 4.0–4.2 (m, 1H, *CH*—CH_2OD), 4.3–4.5 (t, 2H, —CH_2OPh), 5.4–5.5 (d, 1H, *CH*ND—COR), 5.6 (s, 1H, CH), 6.9–7.4 (m, 6H, Ph), 8.2–8.4 (d, 2H, aromatic, J = 8 Hz); ir (Nujol): 3450 ~ 3100 and 2500 ~ 2700 (OH, NH_2, COOH), 1750–1730 (β-lactam, acid), 1660 (amide and ketone) cm^{-1}; λ_{max} ($EtOH–H_2O$): 226 (ε 18 500), 299 (15 800) nm .

Compound **16***U* was obtained by the same method in 92% yield; mp 185°C (brown), 215–218°C (dec); ir, nmr, and uv were identical to those of **16***N*.

β-*Lactam* ***17***N

β-Lactam **16***N* (0.15 g, 0.29 mmol) was suspended in 10 mL water. Hydroxylamine hydrochloride (0.1 g, 1.4 mmol) was added, then a saturated aqueous solution of $NaHCO_3$ was added dropwise until pH 7 was reached. The solution was heated at 50°C for 2 h. Then it was cooled and acidified to pH 3 with HCl (the volume of solution was about 20 mL). The solution was poured into a column containing Resin XAD4. All inorganic salts were removed by water, and the compound was eluted with methanol to give 0.1 g (62%) **17***N*; mp 184°C (brown), 217–220°C (dec.); nmr (D_2O–$NaHCO_3$) δ: 2.2–2.42 (2H, CH_2, m), 3.5–3.77 (b, 3H, *CH*—CH_2OD), 3.8–4.0 (t, 1H, DOOCC*H*ND_2, J = 6 Hz), 4.2–4.5 (t, 2H, CH_2O, J = 6 Hz), 5.3–5.5 (d, 1H, *CH*—NDCOR, J = 5 Hz), 5.6 (s, 1H, CH), 6.95–7.5 (m, 8H, Ph); ir (Nujol): 3400–3100 and 2500 ~ 2700 (OH, NH, COOH), 1740–1730 (β-lactam, acid), 1660 (amide), 1610 cm^{-1}; λ_{max} ($EtOH–H_2O$): 220 (ε 20 500), 273 (14 000) nm; λ_{max} (EtOH–0.1 *N* NaOH): 245 (ε 23 000), 286 (11 500) nm.

Compound **17***U* was obtained by the same method in 65% yield; mp 180°C (brown), 200–204°C (dec.); ir, nmr, and uv were identical to those of **17***N*.

Acknowledgements

We wish to thank the National Research Council of Canada and Lederle Laboratories for financial support, Drs. W. C. Curran, M. Sassiver, J. H. Boothe, and Ms. A. Ross for a generous gift of the nocardicin A sidechains (unpublished results) and Ms. N. Kuck for biological tests. One of us (G.H.H.) wishes to thank the Ministry of Science and Higher Education of Iran and University of Shiraz, for a scholarship.

β-Lactams. VI. The synthesis of homocycloanalogues of nocardicin A

GHOLAM HOSEIN HAKIMELAHI AND GEORGE JUST

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received October 10, 1978

GHOLAM HOSEIN HAKIMELAHI and GEORGE JUST. Can. J. Chem. **57**, 1939 (1979).

The synthesis of the title compounds is reported. It is shown that, in contrast to benzylic ketones, benzylic oximes are stable to hydrogenolysis conditions necessary for the removal of benzyl protecting groups of carboxylic acids and phenols.

GHOLAM HOSEIN HAKIMELAHI et GEORGE JUST. Can. J. Chem. **57**, 1939 (1979).

On rapporte la synthèse des composés sus-mentionnés. On a montré que, contrairement aux cétones benzyliques, les oximes benzyliques sont stables vis-à-vis les conditions d'hydrogénolyse nécessaires à l'enlèvement des groupes benzyliques utilisés pour la protection des acides carboxyliques et des phénols.

[Traduit par le journal]

We have recently described the synthesis of 4-hydroxymethylnocardicinic acid derivatives (1). In this paper, we wish to report on the cyclization of these compounds to homocyclo nocardicinic acid derivatives. Most reactions described were carried out initially on the known methyl esters of substituted phenylglycine **1***a–c*. However, β-lactam **24** could not be hydrolysed without destruction of the β-lactam ring, so that the reaction sequence was carried out on benzylesters **3***a–c*. Their reactions followed those developed for the methyl esters (1), and will be described in more detail.

Methyl glycinates **1***a–c* (1) were hydrolysed with 4% aqueous sodium hydroxide, and the amino acids **2***a–c* benzylated with thionyl chloride and benzyl alcohol (2). The resulting benzyl esters **3***a–c* were transformed to their cinnamylidene Schiff bases, **4***a–c*, and treated with azidoacetyl chloride–triethylamine in dry methylene chloride at −20°C for 1 h. An inseparable mixture of β-lactams **6***a–c* was obtained. Ozonolysis, in methylene chloride–methanol in the presence of a nitrogen stream (3), followed by sodium borohydride reduction, gave a mixture of diastereomeric alcohols **8***a–c* and **15***a–c* contaminated by some methyl ester **7***a–c* and **14***a–c*, presumably arising by transesterification. Chromatography separated isomers **8** and **15**, and their structures were assigned as described previously (1). Alcohols **8***a* and **15***a* were transformed to their respective mesylates **9***a* and **16***a*. Attempts to cyclize these mesylates in benzene containing triethylamine failed. Attempted conversion of the mesylates to their respective iodides using sodium iodide in acetone or tetra-*n*-butylammonium iodide in refluxing benzene failed, presumably because of steric hindrance (4). Successful cyclization could be achieved when alcohol **15***a* was treated with 2 equiv. of thionyl chloride and 3 equiv. of pyridine in dry benzene at 70–73°C for 7 h, in which case 70% of cyclization product **23***a* and 20% of chloro compound **11**/**18***a* were obtained. In boiling benzene, the ratio of products was reversed and 70% of the chloro compounds **11**/**18***a* were obtained, whereas at lower temperatures, little conversion took place. In the case of **15***b–c*, 80–85% of the cyclization product was obtained using the same conditions, whereas isomers **8***a–c* gave an approximately 1:1 mixture of cyclization and chloro compounds **23***a–c* and **11**/**18***a–c*. The latter compounds could be converted to the former ones in low yield by means of silver acetate refluxing in acetonitrile.

Since both diastereoisomers **8** and **15** gave one cyclization product only, we next attempted to effect cyclization without isomerisation of the benzylic proton. Alcohol **15***a* was treated with 3 equiv. of $SOCl_2$ in boiling benzene for 90 min. The resulting chlorosulfite, the structure of which was established by nmr and hydrolysis to starting alcohol **15***a*, was treated with 3 equiv. of AgOAc in boiling benzene for 2 h. Chromatographic separation gave acetate **20***a* and cyclization product **21** in 75 and 4% yield, respectively. The structure of **20***a* was deduced by comparison with **20***a*, obtained by treatment of **15***a* with boiling Ac_2O. The nmr spectrum of **21** was very similar to that of **23***a*, except for the position of the benzylic CH_2-group adjacent to the β-lactam ring, which appeared approximately 0.5 ppm downfield from the corresponding protons in **23***a*. Upon treatment of **21** with pyridine in refluxing benzene for 7 h, it was converted quantitatively to **23***a*.

The protons α to the carbobenzyloxy group and the protons of the mesylate group were clearly different in **9***a*, δ 5.6 (*CH*COOBn) and 2.85 ppm (SO_2CH_3) and **16***a*, δ 5.51 and 2.65 ppm. There was

34 R = H

equally no major problem in distinguishing acetate **13***a*, δ 5.65 (CHCOOBn) and 2.1 ppm (OAc), and **20***a*, δ 5.60 and 1.98 ppm. In chlorosulfites **12***a* and **19***a*, the benzylic methine protons appeared much closer at 5.60 and 5.59 ppm. For chloro compounds **11***a* and **18***a*, all nmr signals were identical in $CDCl_3$ and C_6D_6. In order to prove that a mixture of chloro compounds **11***a*/**18***a* was obtained during the cyclization reactions using $SOCl_2$–pyridine in benzene, **11***a* and **18***a* were treated with 3 equiv. $AgNO_3$ in boiling acetonitrile for 2 h. A 30% yield of a 1:1 mixture of products of cyclization **21** and **23***a* was obtained, as established by nmr only. The two isomers could not be separated by tlc. Epimerization using pyridine in boiling benzene converted the mixture of cyclization products to the more stable **23***a* having the 'natural' nocardicin stereochemistry. In related bicyclic nocardicin precursors, Cooper *et al.* (5) have observed a similar epimerization.

Reduction of azides **22***b*,*c* and **23***b*,*c* with H_2S–Et_3N (6), followed by acylation with phenylacetylchloride in the presence of pyridine, gave **24***b*,*c* and **25***b*,*c*. Selective hydrolysis of the methyl ester function in **24***b*,*c* failed. However, catalytic debenzylation of **25***b*,*c*, using 10% Pd/C in methanol at 40 psi, gave **26***d*,*e* in good yield. Having established that the ring system was stable to reaction conditions necessary to convert the azide function to an amide bond, and to hydrogenolysis necessary to remove the benzylic blocking groups, DL-azido-β-lactam **23***b* was converted to **27***b* by means of hydrogen sulfide – triethylamine (6). Column chromatography gave pure amine, which was coupled with DL-dibenzylglyoxylic acid **28**, using EEDQ in methylene chloride. After purification an 80% yield of **29** was obtained. Catalytic hydrogenation in methanol, using Pd/C as catalyst, resulted in complete debenzylation and reduction of the keto-function to alcohol **30**, as evidenced by nmr and uv spectra, and inability to form an oxime. We next investigated if debenzylation by catalytic hydrogenation would be achieved in the presence of an oxime. We chose as a model *p*-benzyloxybenzaldehyde oxime **33**. We found that catalytic reduction in ethanol using 10% Pd/C at 35 psi for 15–30 min removed selectively the benzyl group, and that only a mixture of **33** and **34** was isolated.

Ketone **29** was converted to *syn*-oxime **31**, using hydroxylamine hydrochloride in pyridine–ethanol. Catalytic hydrogenation in ethanol for 40 min, using 10% Pd/C as catalyst, converted oxime **31** to the deblocked oxime **32** in 81% yield. Its spectral characteristics were very similar to those of nocardicin A, except for the presence of an extra CH_2-group in the nmr.

Further reduction of **32** by the method described by Hashimoto *et al.* (7), using Pd/C in water on the sodium salt of **32**, resulted in reduction of the oxime function, as evidenced by a change in uv spectrum similar to the one described (7), and presumably gave the corresponding amine. However, no attempt was made to characterize this compound because of lack of material. It should be noted that **32** was also obtained as a mixture of two racemic diastereomers.

Because of the variability of catalyst activity, it is recommended that the reduction be carried out first on model compound **33**, and the results obtained on **33** be transposed to the nocardicin derivative. It is also imperative that the sample to be debenzylated be completely sulphur free, as judged by absence of odor.

Biological Tests

None of the nocardicin A analogs prepared showed notable activity against 32 strains of pathogenic microorganisms (1).

Experimental

For general procedures, see ref. 1.

Amino Acids **2**b,c

Amino esters **1***b,c* (0.036 mol) were stirred in 4% aqueous NaOH (40 mL) for 10 min and acidified with HCl to pH 3. The colourless precipitate was filtered, washed with water, and dried. Compounds **2***b,c* were obtained in about 90% yield; **2***b* mp 270–273°C (dec.); nmr (DMSO-d_6) δ: 5.05 (s, 1H, CH), 5.1 (s, 2H, CH_2), 7.05–7.61 (m, 9H, Ph), 11.4–11.6 (b, 3H, NH_3^+); **2***c* mp 259–261°C (dec.); its nmr spectra was similar to that of the **2***b* except for variations due to aromatic substituents.

Amino Esters **3**a–c

Amino acids **2***a–c* (0.027 mol) were suspended in benzyl alcohol (200 mL) at 0–5°C. Thionyl chloride (30 mL) was added slowly, over a period of 20 min. Then the reaction mixture was heated at 90°C while stirring for 5 h. Then it was cooled and dry diethyl ether added. The white precipitate was filtered and washed three times with ether. Compounds **3***a–c*·HCl were obtained in approximately 65% yield, except for **3***c*·HCl which was obtained in 40% yield; **3***a*, mp 235–236°C; **3***b*, 225–226°C; **3***c*, 210–212°C. All compounds obtained had nmr spectra similar to those described for the amino acids except for additional benzyl ester peaks. All hydrochlorides were converted to the parent amine **3** according to the following procedure: Compound **3***b*·HCl (6.8 g, 0.017 mol) was mixed with 50 mL of saturated aqueous $NaHCO_3$ and the resulting amine **3***b* extracted into 50 mL of ether. After evaporation 5 g of **3***b* (82% yield) was obtained as an oil; nmr ($CDCl_3$) δ: 2.0–2.1 (b, 2H, NH_2 exchanged with D_2O), 4.6 (s, 1H, CH), 5.0–5.02 (d, 4H, $2CH_2$), 6.8–7.6 (m, 14H, Ph); ir (CH_2Cl_2): 3300–3400 (NH_2), 1740 (ester) cm^{-1}.

Schiff Base **4**a–c

All the Schiff bases were prepared in a similar manner and used without purification. The following is a representative procedure: To a solution of **3***b* (5 g, 0.014 mol) in 100 mL dry CH_2Cl_2 was added cinnamaldehyde (1.9 g, 0.014 mol). The solution was brought to reflux and the CH_2Cl_2 distilled slowly with the constant addition of dry CH_2Cl_2. After ~10 h the solution was cooled and $MgSO_4$ was added. After 3 h, it was filtered and evaporated to yield 6.9 g Schiff base **4***b* as an oil; nmr ($CDCl_3$) δ: 5.15–5.27 (m, 5H, $2CH_2$ and CH), 7.0–7.6 (m, 21H, Ph and CH=CH), 8.0–8.2 (m, 1H, CH=N); ir (CH_2Cl_2): 1735 (ester), 1635 cm^{-1} (HC=N). In the case of **4***c*, the yield seemed to be somewhat lower (80%) as ascertained by nmr.

Azido-β-lactams **5**/**6**a–c

For preparation of these β-lactams, see ref. 1. Their spectra were similar to those described in the previous paper except for ester variations and variations due to aromatic substituents. All their mass spectra showed $M^+ - N_2$.

4-Hydroxymethyl-β-lactams **7**a, ***14***a, **7**b, ***14***b, **7**c, ***14***c, ***8***a, ***15***a, ***8***b, ***15***b, ***8***c, *and* ***15***c

The mixtures of diastereomeric β-lactams **5***a*, **5***b*, **5***c*, **6***a*, **6***b*, and **6***c* were submitted to identical reaction conditions and separation procedures which will be described for **6***b* only. All their mass spectra showed M^+, $M^+ - COOR$, $M^+ - (N_3CH{=}CH{-}CH_2OH)$, and $M^+ - (N_3{-}CH{=}C{=}O)$ except for **8***b*, **15***b*, **8***c*, and **15***c* which showed no molecular ion but $M^+ - (N_3CH{=}CHCH_2OH)$ and $M^+ - (N_3{-}CH{=}C{=}O)$.

β-Lactam **6***b* (5.44 g, 0.01 mol) in a mixture of 60 mL CH_2Cl_2 and 100 mL dry methanol was saturated with nitrogen gas at −78°C (3 min). Then a mixture of O_3 and N_2 gas was bubbled in until the KI starch paper showed excess ozone (60 min). The excess ozone was removed by passing a stream of N_2 for 10 min. The temperature was allowed to rise to −40°C, at which time was added $NaBH_4$ (0.38 g, 0.01 mol). The temperature of the solution was permitted to rise to 25°C over 2 h, following which 10 mL 10% aqueous HCl was added. The solution was evaporated to 50 mL, diluted with water, extracted with ethyl acetate, washed with water, dried over Na_2SO_4, and evaporated to give crude product in quantitative yield.

A wash with a mixture of ether–hexane (1:14) removed benzyl alcohol, and an oily 1:1 mixture of diastereomers (3 g, 63%) of **8**/**15***b* contaminated with approximately 5% **7**/**14***b* was obtained, as evidenced by nmr.

Chromatography on silica gel and elution with CH_2Cl_2 separated one of the diastereomers **8***b* in 30% yield as a foam. Compound **15***b* was eluted with $CHCl_3$ in 30% yield as a foam.

Less polar diastereomer **8***b*: nmr ($CDCl_3$) δ: 3.4–3.8 (b, 4H, *CH—CH*$_2$*OH*), 4.4–4.6 (d, 1H, *CH*—N_3, J = 5 Hz), 5.0–5.2 (d, 4H, $2CH_2$), 5.78 (s, 1H, CH), 6.9–7.55 (m, 14H, Ph); ir (CH_2Cl_2): 3300–3500 (OH), 2100 (N_3), 1770 (β-lactam), 1740 (ester) cm^{-1}. More polar diastereomer **15***b*: nmr ($CDCl_3$) δ: 2.2–2.4 (b, 1H, OH exchanged with D_2O), 3.2–3.4 (b, 2H, CH_2O), 4.0–4.3 (m, 1H, *CH*—CH_2O), 4.75–4.9 (d, 1H, *CH*—N_3, J = 5 Hz), 5.01–5.3 (d, 4H, $2CH_2$), 5.5 (s, 1H, CH), 6.9–7.5 (m, 14H, Ph); ir (CH_2Cl_2): 3400–3600 (OH), 2100 (N_3), 1770 (β-lactam), 1750 (ester) cm^{-1}.

Compound **8***c* was obtained by the same purification method as **8***b* in 35% yield; nmr ($CDCl_3$) δ: 3.4–3.8 (b, 4H, *CH—CH*$_2$*OH*, exchanged with D_2O), 4.3–4.5 (d, 1H, *CH*—N_3,

J = 5 Hz), 5.0–5.2 (m, 6H, $3CH_2$), 5.71 (s, 1H, CH), 6.8–7.6 (m, 18H, Ph); ir was identical to that of **8***b*.

Compound **15***c* was obtained by the same purification method as **15***b* in 35% yield; nmr ($CDCl_3$) δ: 2.2–2.4 (b, 1H, OH exchanged with D_2O), 3.1–3.25 (d, 2H, CH_2O, J = 6 Hz), 3.8–4.2 (m, 1H, C*H*—CH_2O), 4.8–4.98 (d, 1H, CH—N_3, J = 5 Hz), 5.1–5.3 (m, 6H, $3CH_2$), 5.7 (s, 1H, CH), 7.0–7.7 (m, 18H, Ph); ir was identical to that of **15***b*.

Compound **8***d* was obtained by the same purification method as **8***b* in 40% yield; nmr ($CDCl_3$) δ: 3.4–3.8 (b, 4H, C*H*—C*H*$_2$ O*H* exchanged with D_2O), 4.4–4.6 (d, 1H, CH—N_3, J = 5 Hz), 5.8 (s, 1H, CH), 7.4 (d, 10H, Ph); ir was identical to that of **8***b*.

Compound **15***a* was obtained by the same purification method as **15***b* in 40% yield; nmr ($CDCl_3$) δ: 2.2–2.4 (b, 1H, OH exchanged with D_2O), 3.2–3.37 (d, 2H, CH_2O, J = 6 Hz), 4.0–4.3 (m, 1H, C*H*—CH_2O), 4.75–4.9 (d, 1H, C*H*—N_3, J = 5 Hz), 5.5 (s, 1H, CH), 7.4 (d, 10H, Ph); ir was identical to that of **15***b*.

Compounds 7*a*, **7***b*, and **7***c* were obtained by the same purification method as **8***b* in 50% yield. Their nmr were similar to that of **8***b* except for their ester variation and variations due to aromatic substituents. Their ir spectra were identical to that of **8***b*.

Compounds **14***a*, **14***b*, and **14***c* were obtained by the same purification method as **15***b* in 40% yield. Their nmr were similar to that of the **15***b* except for their ester variation and variations due to aromatic substituents. Their ir spectra were identical to that of **15***b*.

Mesylates **9**a *and* ***16***a

To β-lactam **15***a* (0.366 g, 1 mmol) and NEt_3 (0.101 g, 1 mmol) in 50 mL dry CH_2Cl_2 was added dropwise at −20°C (dry ice – CCl_4) a solution of mesyl chloride (0.115 g, 1 mmol) in 10 mL dry CH_2Cl_2 over a period of 5 min. The solution was stirred for 30 min and evaporated to dryness. The residue was dissolved in ether, filtered, and evaporated to give 0.4 g (90%) of crude product. Chromatography on silica gel using $CHCl_3$ as eluent gave **16***a* as an oil in 80% yield, nmr ($CDCl_3$) δ: 2.65 (s, 3H, CH_3), 3.62–3.82 (t, 2H, CH_2O, J_1 = 6 Hz, J_2 = 11 Hz), 4.2–4.5 (m, 1H, C*H*—CH_2O), 4.8–4.96 (d, 1H, C*H*—N_3, J = 5 Hz), 5.2 (s, 2H, CH_2), 5.51 (s, 1H, CH), 7.38 (d, 10H, Ph); ir (CH_2Cl_2): 2100 (N_3), 1780 (β-lactam), 1750 (ester) cm^{-1}.

Compound **9***a* was obtained by the same method in 80% yield; nmr ($CDCl_3$) δ: 2.85 (s, 3H, CH_3), 3.62–3.82 (t, 2H, CH_2O, J_1 = 6 Hz, J_2 = 11 Hz), 4.25–4.5 (m, 1H, C*H*—CH_2O), 4.6–4.78 (d, 1H, *CH*—N_3, J = 5 Hz), 5.19 (s, 2H, CH_2), 5.6 (s, 1H, CH), 7.4 (d, 10H, Ph); ir was identical to that of **16***a*.

Isomerization of Mesylates **9**a *and* ***16***a

Compound **9***a* or **16***a* was refluxed with 3 equiv. pyridine in dry benzene and gave **9***a*/**16***a* (1:1) quantitatively, as determined by nmr.

Chlorosulfites ***12***a/***19***a

To a mixture of β-lactams **8***a*/**15***a* (0.183 g, 0.5 mmol) in 40 mL dry benzene was added thionyl chloride (0.36 g, 3 mmol). The solution was refluxed for 90 min and evaporated to dryness to give **12***a*/**19***a* quantitatively; nmr ($CDCl_3$) δ: 3.8 (m, 2H, CH_2O), 4.4–4.8 (m, 2H, C*H*—C*H*—N_3), 5.2 (s, 2H, CH_2), 5.59–5.60 (d, 1H, CH), 7.38 (d, 10H, Ph).

Compounds **12***a*/**19***a* were treated with water and extracted with ether to give quantitatively **8***a*/**15***a*.

Chloroesters ***10***b,c/***17***b,c *and* ***11***a–c/***18***a–c

All β-lactams were obtained in an identical manner in approximately 70% yield. Their spectra were similar except for the ester variations and variations due to aromatic substituents. All their mass spectra showed M^+.

The following is a representative procedure.

To β-lactams **8***b*/**15***b* (1 g, 0.002 mol) in 60 mL dry benzene was added pyridine (0.474 g, 0.006 mol). The solution was brought to reflux and thionylchloride (0.6 g, 0.004 mol) was added. After 2 h it was cooled and 50 mL of ether was added. The solution was washed with water, dried over $MgSO_4$, and evaporated to give 0.8 g (85%) of **11***b*/**18***b* as an oil; nmr ($CDCl_3$) δ: 3.8–4.1 (b, 3H, C*H*—*CH*$_2$Cl), 4.7 (d, 1H, C*H*N_3, J = 5 Hz), 5.13–5.23 (d, 4H, $2CH_2$), 5.6 (s, 1H, CH), 7.0–7.6 (m, 14H, Ph); ir (CH_2Cl_2): 2100 (N_3), 1760 (β-lactam), 1750 (ester) cm^{-1}; ms *m*/*e*: 490–492 (M^+). By this method about 10% **23***b* was obtained as ascertained by nmr.

β-*Lactams* ***22***a–c *and* ***23***a–c

All β-lactams were obtained in an identical manner in approximately 70–80% yield using method I and 50% yield using method II. Their spectra were similar except for the ester variations and variations due to aromatic substituents. All their mass spectra showed $M^+ - (N_3CH{=}C{=}O)$, except for **23***c* in which case no good mass spectrum was obtained.

The following is a representative procedure.

Method I

To β-lactam **15***b* (1 g, 0.002 mol) in 60 mL dry benzene was added pyridine (0.474 g, 0.006 mol). Thionylchloride (0.6 g, 0.004 mol) was added. The solution was kept at 70–73°C (bath temperature) for 7 h. Then it was cooled, diluted with 50 mL of ether, and washed with water, 5% aqueous HCl, dried over $MgSO_4$, and evaporated to give 90% of crude product. Chromatography on silica gel and elution with CH_2Cl_2 gave first 15% of **11***b*/**18***b*, as ascertained by nmr, and then 0.75 g (80%) **23***b* as an oil; nmr ($CDCl_3$) δ: 2.7–3.4 (m, 2H, CH—*CH*$_2$Ph), 4.3–4.6 (m, 1H, *CH*—CH_2Ph), 4.81–5.0 (d, 1H, *CH*N_3, J = 5 Hz), 5.1–5.3 (d, 4H, $2CH_2$), 6.8–7.5 (m, 13H, Ph); ir (CH_2Cl_2): 2100 (N_3), 1775 (β-lactam), 1750 (ester) cm^{-1}; ms *m*/*e*: 371 ($M^+ - N_3CH{=}C{=}O$).

Method II

Chloro compounds **11***b*/**18***b* (0.8 g, 0.0016 mol) and AgOAc (4 equiv.) in 60 mL dry CH_3CN were refluxed for 2 h. Then it was filtered and evaporated to dryness. The residue was dissolved in 50 mL ether and after filtration was evaporated to give 0.7 g product containing ~50% **23***b* and ~50% starting material as ascertained by nmr. These compounds have about the same polarity and could be separated with difficulty only by column chromatography using silica gel and eluted with CH_2Cl_2.

β-*Lactams* ***20***a, ***21***, ***13***a, *and* ***23***a

β-Lactam **15***a* (0.366 g, 0.001 mol) in 60 mL dry benzene containing thionylchloride (0.36 g, 0.003 mol) was refluxed for 90 min. Silver acetate (4 equiv.) was then added and refluxing continued for 2 h. Then it was filtered and evaporated to dryness. The residue was dissolved in 40 mL ether and after filtration was evaporated to give 0.3 g product containing ~80% **20***a* and ~10% **21** as ascertained by nmr; purification by column chromatography using silica gel and elution with CH_2Cl_2 gave ~4% of **21** contaminated with a trace of **20***a* as an oil, and ~75% of **20***a* contaminated with a trace of **21** as an oil.

Compound **20***a*: nmr ($CDCl_3$) δ: 1.98 (s, 3H, CH_3), 3.78 (d, 2H, CH_2O), 4.4 (m, 1H, *CH*—CH_2O), 4.8–4.91 (d, 1H, *CH*—N_3, J = 5 Hz), 5.23 (s, 2H, CH_2), 5.6 (s, 1H, CH), 7.4 (s, 10H, Ph); ir (CH_2Cl_2): 2100 (N_3), 1760 (β-lactam), 1740–1750 (ester) cm^{-1}.

Compound **21**: nmr ($CDCl_3$) δ: 3.2–3.9 (m, 2H, CH—*CH*$_2$-Ph), 4.4 (m, 1H, *CH*CH_2Ph), 4.83–4.97 (d, 1H, C*H*—N_3,

J = 5 Hz), 5.23 (s, 2H, CH_2), 5.58 (s, 1H, CH), 7.4 (s, 9H, Ph); ir (CH_2Cl_2): 2100 (N_3), 1770 (β-lactam), 1750 (ester) cm^{-1}; ms *m/e*: 348 (M^+).

Boiling **21**, which contained approximately 5% **20***a*, and 2 equiv. pyridine in benzene for 7 h gave quantitatively **23***a* and a trace of an isomeric mixture of **20***a*/**13***a* as ascertained by nmr.

β-*Lactams* ***24***b,c *and* ***25***b,c

All transformations were performed in an identical manner in approximately 75% yield. Their spectra were similar except for the ester variations and variations due to aromatic substituents. All their mass spectra showed $M^+ - (PhCH_2CONHCH{=}C{=}O)$, except for **25***c* which gave a poor mass spectrum but satisfactory microanalysis results.

The following is a representative procedure.

To a solution of β-lactam **23***c* (1.5 g, 2.4 mmol) in 60 mL dry CH_2Cl_2 at 0°C was added triethylamine (0.24 g, 2.4 mmol). A stream of H_2S gas was bubbled in for 20 min. The solution was stirred for 2 h at room temperature. Evolution of nitrogen gas was observed. A stream of nitrogen gas was bubbled in for 20 min, then 0.46 g (0.006 mol) pyridine was added, followed by dropwise addition of 0.36 g (0.0024 mol) phenyl acetyl-chloride in 15 mL CH_2Cl_2. The solution was stirred for 2 h at 0–10°C, washed with 5% aqueous HCl, 5% aqueous $NaHCO_3$, and brine. It was then dried over $MgSO_4$, and evaporated to give quantitatively impure amide **25***c*, which was chromatographed on silica gel. Methylene chloride eluted impurities, and chloroform gave 1 g (90%) of β-lactam **25***c* as a foam. Recrystallization from absolute ethanol gave 0.88 g (80%) of **25***c*; mp 140–142°C; nmr ($CDCl_3$) δ: 2.9–3.1 (m, 2H, CH—CH_2 Ph), 3.6 (s, 2H, CH_2CO), 4.2–4.41 (m, 1H, *CH*—CH_2Ph), 5.1–5.2 (d, 6H, $3CH_2$), 5.21–5.59 (q, 1H, *CH*—*NHCOCH*$_2$Ph, J_1 = 5 Hz, J_2 = 10 Hz), 5.6 (s, 1H, CH), 6.4–6.6 (d, 1H, NH), 6.9–7.6 (m, 22H, Ph); ir (CH_2Cl_2): 3350–3400 (NH), 1770 (β-lactam), 1750 (ester), 1670 (amide) cm^{-1}. *Anal.* calcd. for $C_{41}H_{36}N_2O_6$: C 75.44, H 5.56, N 4.29; found: C 75.45, H 5.56, N 4.17.

β-*Lactams* ***26***d *and* ***26***e

Both β-lactams **25***b* and **25***c* were submitted to identical hydrogenolysis procedures, and gave **26***d* and **26***e* in about 70% yield. Their spectra were similar except for variations due to aromatic substituents. Their mass spectra showed no M^+ but $M^+ - (PhCH_2CONHCH{=}C{=}O)$ while their corresponding methyl esters **24***d* and **24***e* showed M^+.

The following is a representative procedure.

To β-lactam **25***b* (1 g, 0.0018 mol), in 50 mL methanol was added 10% Pd/C (0.5 g), and the mixture was hydrogenated at room temperature and 40 psi for 1.5 h. The solution was filtered and evaporated to give 0.5 g (72%) of **26***d*; mp 147–150°C (dec.); nmr ($CDCl_3$:DMSO-d_6:D_2O), 1:1:3 drops) δ: 2.7–3.4 (m, 2H, CH—*CH*$_2$Ph), 3.61 (s, 2H, CH_2CO), 4.3 (m, 1H, *CH*—CH_2Ph), 5.3–5.38 (d, 1H, *CH*—*NDCOCH*$_2$Ph J = 5 Hz in the absence of D_2O, q, 1H, J_1 = 5 Hz and J_2 = 10 Hz), 5.45 (s, 1H, CH), 6.9–7.4 (m, 8H, Ph); ir (KBr): 3600 ~ 2700 (NH, OH, COOH), 1760 (β-lactam), 1720 (acid), 1660 (amide) cm^{-1}; ms *m/e*: 191 ($M^+ - PhCH_2CONHCH{=}C{=}O$). Treatment of **26***d* with CH_2N_2 gave **24***d* quantitatively as a foam; ms *m/e*: 380 (M^+).

β-*Lactam* ***27***b

β-Lactam **23***b* (0.5 g, 1 mmol) was dissolved in 50 mL dry CH_2Cl_2. Triethyl amine (0.12 g, 1.2 mmol) was added at 0°C. A stream of hydrogen sulfide gas was bubbled in for 15 min. The solution was stirred at room temperature for 2 h. Evolution of nitrogen gas was observed. A stream of nitrogen gas was bubbled in for 15 min. The mixture was washed with water (two times), dried, and evaporated. The oily product was purified by column chromatography using silica gel, all impurities were eluted with CH_2Cl_2 and compound **27***b* (0.4 g, 90%) was eluted with $CHCl_3$ as an oil; nmr ($CDCl_3$) δ: 1.8–2 (b, 2H, NH_2, exchangeable with D_2O), 3.1 (d, 2H, CH_2, J = 6 Hz), 4.0–4.5 (m, 2H, —*CH*—*CH*—NH_2), 5.1–5.3 (d, 4H, $2CH_2Ph$), 5.6 (s, 1H, CH), 6.83–7.6 (m, 13H, Ph); ir (CH_2Cl_2): 3300–3350 (NH_2), 1750 (ester), 1770 (β-lactam) cm^{-1}.

β-*Lactam* ***29***

β-Lactam **27***b* (0.4 g, 0.9 mmol) and acid **28** (0.491 g, 1 mmol) were dissolved in 50 mL CH_2Cl_2. EEDQ (0.247 g, 1 mmol) was added and stirred for 16 h at room temperature. The solution was washed with 5% aqueous HCl and 5% aqueous $NaHCO_3$, dried over $MgSO_4$, filtered, and evaporated to give 0.9 g (99%) of crude **29** which was chromatographed on silica gel using CH_2Cl_2 to remove impurities. Elution with $CHCl_3$ gave 0.7 g (85%) of **29** as a foam; nmr ($CDCl_3$) δ: 2.39 (m, 2H, CH_2), 3.1 (m, 2H, $PhCH_2$—CH), 3.9–4.15 (t, 2H, *CH*—CH_2 and BnOOC—*CH*—NHR, J = 6 Hz), 4.4–4.6 (t, 2H, CH_2OPh, J = 6 Hz, 5.1–5.3 (q, 8H, $4CH_2Ph$), 5.38–5.6 (q, 1H, *CH*—NHCOR, J = 5 Hz), 5.62 (s, 1H, CH), 6.8–8.4 (q, 4H, Ph, J = 8 Hz), 7.0–7.4 (m, 25H, Ph, NH); ir (CH_2Cl_2): 3400 (NH), 1770 (β-lactam), 1745 (ester), 1725 (BnOCO), 1665 (amide, ketone) cm^{-1}.

β-*Lactam* ***30***

β-Lactam **29** (0.2 g, 0.22 mmol) was dissolved in 30 mL methanol; 10% Pd/C (0.1 g) was added, and the mixture was hydrogenated at room temperature and 40 psi for 40 min. The solution was then filtered and evaporated to give 0.09 g (81%) of **30**; mp 181°C (brown), 200–205°C (dec.); nmr (D_2O–$NaHCO_3$) δ: 2.38 (m, 2H, CH_2), 3.2 (m, 2H, Ph—CH_2CH), 3.6 (m, 1H, *CH*—CH_2), 3.8 (t, 1H, $^-OOCCHND_3^+$, J = 6 Hz), 4.2 (m, 2H, CH_2OPh), 5.3 (d, 1H, CH—NDCOR, J = 5 Hz), 5.4 (s, 1H, CH), 5.5–5.8 (d, 1H, CH—OD), 6.9–7.5 (m, 7H, Ph); ir (Nujol): 3400–3100 and 2500 ~ 2700 (OH, NH, COOH), 1760 (β-lactam), 1720 (acid), 1660 (amide), 1610 cm^{-1}; λ_{max} (EtOH–H_2O): 225 (ε 18 000), 272 (2000) nm.

β-*Lactam* ***31***

β-Lactam **29** (0.2 g, 0.22 mmol) was dissolved in a mixture of 5 mL ethanol and 5 mL pyridine. Hydroxylamine hydrochloride (0.2 g, 2.8 mmol) was added. The solution was warmed at 70°C for 2 h. Then 50 mL chloroform was added and solution washed with 5% aqueous HCl. Then it was dried over Na_2SO_4, filtered, and evaporated to give 0.2 g (90%) crude **31** which was purified by column chromatography using silica gel. Elution with $CHCl_3$–EtOAc (1:1) gave 0.15 g (71%) **31** as a foam; nmr ($CDCl_3$) δ: 2.2 (b, 2H, CH_2), 3.1 (m, 2H, $PhCH_2CH$), 3.8–4.0 (b, 3H, *CH*—CH_2, *BnOOCCHNHCOR*, OH), 4.3–4.6 (m, 2H, CH_2OPh), 5.0–5.2 (q, 8H, $4CH_2Ph$), 5.3–5.5 (q, 1H, *CH*—NHR, J = 5 Hz), 5.6 (s, 1H, CH), 6.6–7.4 (m, 29H, Ph and 2NH); ir (CH_2Cl_2): 3300–3450 (OH, NH), 1775 (β-lactam), 1750–1730 (ester and BnOCO), 1680 (amide), 1520 (oxime) cm^{-1}; λ_{max}(EtOH): 273 (ε 15 000) nm.

β-*Lactam* ***32***

β-Lactam **31** (0.15 g, 0.16 mmol) was dissolved in 30 mL absolute ethanol; 10% Pd/C (0.075 g) was added, and the mixture was hydrogenated at room temperature and 35 psi for 40 min. The solution was then filtered and evaporated to give 0.07 g (81%) of **32**; mp 160°C (brown), 186–189°C (dec.); nmr (D_2O–$NaHCO_3$) δ: 2.4 (m, 2H, CH_2), 3.1 (m, 2H, $PhCH_2CH$), 3.6 (m, 1H, *CH*—CH_2), 4.0 (t, 1H, $^-OOCCHND_3^+$), 4.4 (t, 2H, CH_2OPh, J = 6 Hz), 5.3 (d, CH—NDR, J = 5 Hz), 5.5 (s, 1H, CH), 6.9–7.5 (m, 7H, Ph); ir (Nujol):

3400–3100 and 2500 ~ 2700 (OH, COOH, NH), 1755 (β-lactam), 1720 (acid), 1660 (amide), 1610 cm^{-1}; λ_{max} (EtOH–H_2O): 221 (ε 20 800), 272 (14 500) nm; λ_{max} (EtOH – 0.1 *N* NaOH): 246 (ε 23 500), 286 (12 000) nm.

β-Lactams. VII.[1] The synthesis of 3-vinyl and 3-isopropenyl 4-substituted azetidinones

ROBERT ZAMBONI[2] AND GEORGE JUST

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received November 21, 1978

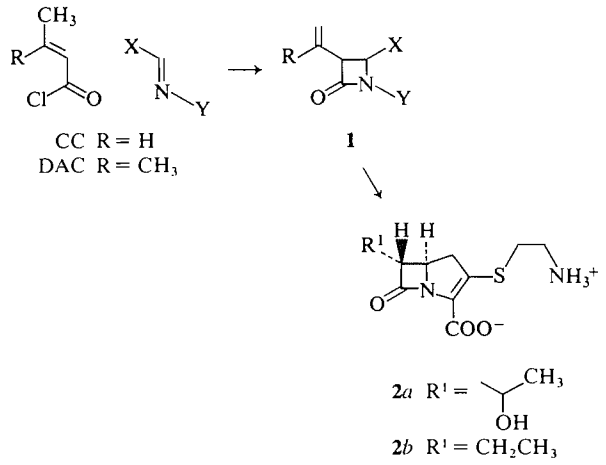
ROBERT ZAMBONI and GEORGE JUST. Can. J. Chem. **57**, 1945 (1979).

The reaction of crotonyl and dimethylacryloyl chloride with various Schiff bases is described. The resulting β-lactams derived from aliphatic amines all have a *cis* stereochemistry.

ROBERT ZAMBONI et GEORGE JUST. Can. J. Chem. **57**, 1945 (1979).

On décrit la réaction des chlorures de crotonyle et de dimethyl acrylyl avec des bases de Schiff. Ces β-lactames dérivés d'amines aliphatiques ont tous la stéréochemie *cis*.

The addition of azidoacetyl chloride to imines, as developed by Bose and used by several groups (1–4), has proven to be a powerful method for preparing β-lactam antibiotics. We wished to know if a similar methodology using crotonyl chloride (CC) or dimethylacryloyl chloride (DAC) could lead to the formation of β-lactams **1** which could be transformed to thienamycins **2***a*,*b*.



In this paper, we describe the addition of CC or DAC chloride to some Schiff bases derived from aromatic and aliphatic amines and cinnamaldehyde, furfural, or methyl glyoxylate (3).

Bose briefly reported that reaction of benzylidene aniline **3***a* and CC gave the corresponding *trans*-β-lactam **4***a* exclusively in fair yield (5), and we have confirmed this result, carrying out the reaction in methylene chloride both at room temperature and at reflux.

Much to our surprise, reaction of cinnamylidene aniline **3***b* with CC containing triethylamine in methylene chloride, conditions which were used throughout the paper, gave at room temperature a 5:1 mixture of *cis* and *trans* β-lactams **5***b* and **4***b* in approximately 30% yield. In boiling methylene chloride, this ratio was inverted, and the yield increased to 40–45%. Separation could be effected with considerable losses by flash chromatography (6). The *cis* isomer **5***b* showed a coupling constant $J_{3,4} = 6$ Hz, while *trans* isomer **4***b* showed $J_{3,4} = 2.5$ Hz. The coupling constants were typical for all the β-lactams obtained and the yields reported are based on the integration of the appropriate ^{1}Hmr signals. When furfurylidene Schiff base **3***d* was treated with either CC or DAC, an approximately 70% yield of *trans* lactams **4***d* or **4***e* was obtained. As was found out in the course of many reactions, CC or DAC could be used interchangeably with little variation in yield or stereochemistry of product obtained.

When ethyl benzylidene glycinate (**6***a*, R=Ph) was heated with DAC–triethylamine at 20°C or reflux,

		Temp. (°C)	Yield *trans* (%)	Yield *cis* (%)
a	R = Ph, R^1 = H	20–39	40	
b	R = CH=CH—Ph, R^1 = H	20	5	25
c	R = CH=CH—Ph, R^1 = H	39	35	7
d	R = furfuryl, R^1 = H	39	70	
e	R = furfuryl, R^1 = CH$_3$	39	70

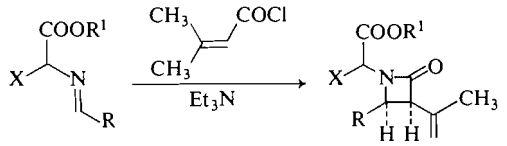
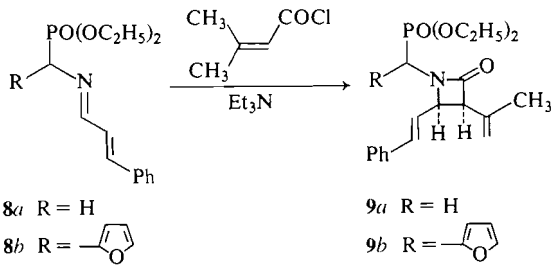
little if any β-lactam could be detected in the reaction product. However, the cinnamylidene Schiff bases of either ethyl glycinate **6***a* or serine derivative **6***b* (2) give a good yield of adduct **7***a* or **7***b* having *cis* configuration. Similarly, the furfurylidene derivative of serine **6***c* gave exclusively *cis* β-lactam **7***c*, albeit in a more modest yield.



6 **7**

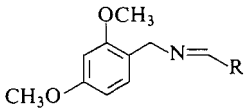
a R = CH=CHPh, X = H, R¹ = CH_2CH_3
b R = CH=CHPh, X = $CH_2OTBDMS$, R¹ = CH_3
c R = furfuryl, X = $CH_2OTBDMS$, R¹ = CH_3

Similar results were obtained with the cinnamylidene Schiff base of diethylaminomethyl phosphonate **8***a* (7) and its corresponding furyl derivative **8***b* (synthesized from furfuraldehydediazine using the procedure of Rachon and Wasielewski (8)), which both gave the corresponding *cis* β-lactams **9***a* and **9***b* in good yield. Glyoxylic ester derivative **10** (3) also afforded *cis* β-lactams **11** and **12** with CC and DAC respectively.

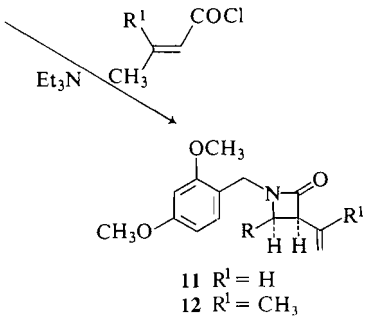


8*a* R = H
8*b* R =

9*a* R = H
9*b* R =



10 R = $COOCH_3$



11 R^1 = H
12 R^1 = CH_3

The behaviour of DMAC and CC is similar to that of azidoacetyl chloride, in that its addition to cinnamylidene and glyoxylic ester Schiff bases of aliphatic amines gave exclusively *cis* adducts. With cinnamylidine aniline one obtains mixtures. It may be recalled that with azidoacetyl chloride one obtains *cis* β-lactams with cinnamylidene Schiff bases derived from aromatic amines with pk_a's $\geq$ 2.4, while one obtains mixtures or pure *trans* β-lactams with imines derived from aromatic amines with pk_a's < 2.4 (9).

These results can be rationalized by postulating the existence of two pathways for the reaction of Schiff bases with azidoacetyl chloride, DMAC and CC. Nucleophilic imines react with these acid chlorides to give *cis* β-lactams by the mechanism proposed by Doyle *et al.* (1) and supported by Sullivan *et al.* (10). They proposed the formation of an immonium ion followed by cyclization, in which the *cis* stereochemistry is ensured by electrostatic interaction between the two 'sidechains.' With a lowering either of the nucleophilicity of the Schiff base nitrogen, or of the electrophilicity of the acid chloride, or of the acidity of the proton to be removed to effect ring closure, one could expect the rate of this reaction to slow down. A competing side reaction, perhaps involving azido ketene, may then give *trans*-lactam.

The formation of mixtures in the reaction of cinnamylidene aniline with CC can therefore be explained by the lower electrophilicity of CC versus azidoacetyl chloride, thus requiring a more nucleophilic Schiff base to give an immonium ion, and a lower acidity of the proton to be removed to effect ring closure. The effect of temperature on the *cis*–*trans* ratio in the formation of **4***a* and **5***a* probably reflects the different temperature dependence of the two reaction pathways.

Experimental

Solvents are of reagent grade unless otherwise specified. Infrared measurements were run on Unicam SP1000 and P.E. 257 spectrophotometers. Nuclear magnetic resonances were done on Varian T-60, T-60A, or Brucker FT-90 spectrophotometers. Mass spectra were taken on an AEI MS-902 or on a LKB 9000 mass spectrophotometer using the direct sample inlet system with a 70 eV ionization energy. Melting points were determined on a Gallenkamp block in open capillary tubes and were uncorrected. Merck SI60 silica gel was used for thick layer chromatography. Merck silica gel HF 254 was used for thick layer chromatography (1 mm) on glass plates (20 × 20 cm). Elemental analyses were performed by Midwest Microlab Ltd., IN.

Schiff Base **3**b, **3**d

The aldehyde (20 mmol) and aniline (1.86 g, 20 mmol), in benzene (50 mL) were refluxed for 4 h using a Dean Stark trap to remove the water formed. Evaporation of the benzene afforded the Schiff base in quantitative yield.

Schiff Base **3**b

^{1}H nmr ($CDCl_3$) δ: 7–7.6 (m, 12H, C_6H_5 + CH=CH), 8.3 ppm (t, 1H, CH=N); ir ($CDCl_3$) ν_{max}: 1630 cm^{-1} (C=N).

Schiff Base **3**d

^{1}H nmr ($CDCl_3$) δ: 6.1 (m, 1H, furan), 6.6 (m, 1H, furan),

6.8–7.2 (m, 5H, C_6H_5), 7.3 (m, 1H, furan), 7.9 ppm (s, 1H, CH=N); ir ($CDCl_3$) ν_{max}: 1630 cm^{-1} (C=N).

Schiff Base **6**a

Cinnamaldehyde (2.64 g, 20 mmol) in CH_2Cl_2 (5 mL) was added dropwise to a solution of ethyl glycinate (2.0 g, 20 mmol) in CH_2Cl_2 (40 mL) at 0°C containing $MgSO_4$ (~1–2 g). After stirring for 2 h at 0°C, the solution was filtered through Celite. Evaporation of the methylene chloride afforded Schiff base **6***a* approximately 85–90% pure by ^1H nmr; ^1H nmr (CCl_4) δ: 1.2 (t, 3H, CH_3), 4.0–4.5 (m, 4H, OCH_2CH_3, CH_2), 7.0 (d, 2H, *CH*=*CH*—Ph), 7.2–7.6 (m, 5H, C_6H_5), 7.8–8.0 ppm (m, 1H, C*H*=N).

Schiff Base **6**c

A solution of furfuraldehyde (0.96 g, 10 mmol) and amine **6***c* (2.33 g, 10 mmol) in CH_2Cl_2 (50 mL) was refluxed overnight using a Dean Stark trap filled with 4A molecular sieves. Evaporation afforded Schiff base **6***c* in approximately 90% yield by ^1H nmr; ^1H nmr (CCl_4) δ: 0.05 (s, 6H, $Si(CH_3)_2$), 0.90 (s, 9H, SiBu^t), 3.7 (s, 3H, OCH_3), 3.7–4.2 (m, 3H, $CHCH_2O$), 6.4 (s, 1H, furan), 6.8 (d, 1H, furan), 7.5 (m, 1H, furan), 8.0 ppm (s, 1H, CH=N); ir (film) ν_{max}: 2950, 1740 (ester), 1640 cm^{-1} (C=N).

β-*Lactam* **5**b

Crotonyl chloride (1.0 g, 10 mmol) in methylene chloride (20 mL) was added dropwise over 30 min to a solution of Schiff base **3***b* (2 g, 10 mmol) in methylene chloride at room temperature. After stirring for 1 more hour, the dark solution was washed with water (2 × 25 mL), dried ($MgSO_4$), and evaporated. ^1H nmr showed that the product contained approximately 25% **5***b*. Flash chromatography of the residue afforded 500 mg (15%) of pure *cis* β-lactam **5***b*; ^1H nmr (C_6D_6) δ: 4.2 (t, 1H, *CH*CH=CH_2, J = 6 Hz), 4.8 (q, 1H, *CH*CH=CHPh, $J_{3,4}$ = 6 Hz, $J_{4,5}$ = 7 Hz), 5.2–6.0 (m, 3H, —CH=CH_2), 6.2 (q, 1H, *CH*=CHPh, $J_{4,5}$ = 7 Hz, $J_{5,6}$ = 16 Hz), 6.8 (d, 1H, CH=*CH*Ph, J = 16 Hz), 7.0–7.7 ppm (m, 10H, C_6H_5); ir (film) ν_{max}: 2950, 1750 (C=O), 1600 cm^{-1} (C=C); ms *m/e*: 275 (13.70), 207 (38), 206 (100), 156 (92.9).

Preparation of Schiff Bases **8**a *and* **8**b

The aldehyde (10 mmol) was added to a solution of the amino phosphonate (10 mmol) in methylene chloride (25–30 mL) containing magnesium sulphate, at room temperature. The mixture was stirred at room temperature for 2–5 h, until the ir spectrum of the reaction mixture did not change. The solution was filtered. Evaporation of the filtrate afforded the Schiff base in 85–95% yield by ^1H nmr. All Schiff bases were used without further purification for the cycloaddition. The ^1H nmr spectrum showed a multiplet at approximately 7.8 ppm for the Schiff base proton, along with all other appropriate signals. The ir spectrum of the Schiff bases showed absorption at approximately 1650 cm^{-1} for the C=N bond.

Preparation of β-*Lactams* **4**a, **4**b, **4**d, **4**e, **7**a, **7**b, **7**c, **9**a, **9**b, ***11***, *and* ***12***

To the appropriate Schiff base (10 mmol) and triethylamine (1.0 g, 10 mmol) in methylene chloride (50 mL) at reflux under nitrogen was added dropwise over 45 minutes a solution of the acid chloride (10 mmol) in methylene chloride (25 mL). The reaction mixture was refluxed for 1 more hour and then washed with H_2O (2 × 50 mL). The methylene chloride layer was dried ($MgSO_4$) and evaporated. Recrystallization or chromatography of the residue afforded the β-lactam in the indicated yield.

β-*Lactam* **4**a

The yield was 40%, mp 100–102°C; ^1H nmr ($CHCl_3$) δ: 4.2 (bd, 1H, *CH*—CH=CH_2), 4.9 (d, 1H, *CH*—Ph, J = 2.5 Hz), 5.2–6.5 (m, 3H, CH=CH_2), 7.2–7.5 ppm (m, 10H, C_6H_5); ir ($CHCl_3$) ν_{max}: 2950, 1750 (C=O), 1600 cm^{-1} (C=C).

β-*Lactam* **4**b

The yield by ^1H nmr was ~40%, isolated yield 20%; ^1H nmr (C_6D_6) δ: 3.6 (bq, 1H, *CH*CH=CH_2), 4.3 (q, 1H, *CH*CH=CHPh, $J_{3,4}$ = 2.5 Hz, $J_{4,5}$ = 7 Hz), 5.0–6.0 (m, 3H, CH=CH_2), 6.2 (q, 1H, *CH*=CHPh, $J_{5,6}$ = 16 Hz, $J_{4,5}$ = 7 Hz), 6.6 (d, 1H, CH=*CH*Ph, J = 16 Hz), 6.8–7.4 ppm (m, 10H, C_6H_5); ir (film) ν_{max}: 2950, 1750 (C=O), 1600 cm^{-1} (C=C); ms *m/e*: 275 (12.2), 208 (21.7), 207 (57.11), 156 (100).

β-*Lactam* **4**d

The yield was 50%, mp 98–99°C; ^1H nmr ($CDCl_3$) δ: 4.05 (bq, 1H, *CH*CH=CH_2), 4.8 (d, 1H, J = 2.5 Hz, *CH*-furyl), 5.7–6.2 (m, 3H, CH=CH_2), 6.3–6.5 (m, 2H, furan), 7.0–7.5 ppm (m, 6H, C_6H_5, furan); ir (CH_2Cl_2) ν_{max}: 1750 (C=O), 1600 cm^{-1} (C=C); ms *m/e*: 239 (M^+), 120, 119.

β-*Lactam* **4**e

The yield was 30% upon recrystallization, greater than 70% by ^1H nmr, mp 84–86°C; ^1H nmr ($CDCl_3$) δ: 1.85 (s, 3H, CH_3—C=CH_2), 4.1 (bd, 1H, *CH*—C(CH_3)=CH_2), 4.9 (d, 1H, *CH*—furyl, J = 2.5 Hz), 4.9–5.1 (m, 2H, C(CH_3)=CH_2), 6.2–6.4 (m, 2H, furan), 6.8–7.4 ppm (m, 6H, C_6H_5 and furan); ir (CH_2Cl_2) ν_{max}: 1750 (C=O), 1600 cm^{-1} (C=C); ms *m/e*: 253 (M^+), 171, 134, 119.

β-*Lactam* **7**a

The yield was 50%; ^1H nmr ($CDCl_3$) δ: 1.3 (t, 3H, OCH_2CH_3), 1.7 (s, 3H, CH_2=C—CH_3), 4.2 (AB quartet, 2H, J = 18 Hz, CH_2CO_2Et), 4.0–4.4 (m, 3H, OCH_2CH_3 and $CHC(CH_3)$=CH_2), 4.5 (q, 1H, *CH*CH=CHPh, J_1 = 5 Hz, J_2 = 7 Hz), 5.1 (bd, 2H, C(CH_3)=CH_2), 6.1 (q, 1H, *CH*=CHPh, J_1 = 7 Hz, J_2 = 16 Hz), 6.7 (d, 1H, CH=*CH*Ph, J = 16 Hz), 7.2–7.5 ppm (m, 5H, C_6H_5); ir (film) ν_{max}: 3000, 1755 cm^{-1} (C=O); ms *m/e*: 299 (M^+), 282, 170, 82.

β-*Lactam* **7**b

The yield was 70%: nmr ($CDCl_3$) δ: 0.05 (d, 6H, Bu^{t}Si-(CH_3)$_2$), 0.95 (s, 9H, Bu^{t}Si(CH_3)$_2$), 1.8 (s, 3H, CHC(CH_3)=CH_2), 3.5 (s, 3H, OCH_3), 3.8–4.0 (m, 3H, CH_2O, *CH*C(CH_3)=CH_2), 4.3 (t, 1H, *CH*CH_2O), 4.4 (q, 1H, *CH*CH=CHPh, $J_{3,4}$ = 5 Hz, $J_{4,5}$ = 7 Hz), 4.8 (bd, 2H, CHC(CH_3)=CH_2), 5.8 (q, 1H, *CH*=CHPh, $J_{4,5}$ = 7 Hz, $J_{5,6}$ = 16 Hz), 6.4 (d, 1H, CH=*CH*Ph, J = 16 Hz), 6.8–7.0 ppm (m, 5H, C_6H_5); ir (film) ν_{max}: 2900, 1760 (β-lactam), 1740 cm^{-1} (ester).

β-*Lactam* **7**c

The yield was 30% by ^1H nmr, 10% upon recrystallization, mp 79–80°C; ^1H nmr ($CDCl_3$) δ: −0.1 (d, 6H, Bu^{t}Si (CH_3)$_2$), 0.80 (s, 9H, Bu^{t}Si(CH_3)$_2$), 1.3 (bs, 3H, C(CH_3)=CH_2), 3.7 (s, 3H, OCH_3), 3.8 (t, 2H, CH_2O), 4.2 (bd, 1H, *CH*C(CH_3)=CH_2), 4.4 (t, 1H, *CH*CH_2O), 4.9 (bd, 2H, C=CH_2), 5.1 (d 1H, CH—furyl, J = 2.5 Hz), 6.2 (m, 2H, furyl), 7.2 ppm (m, 1H, furyl); ir ($CHCl_3$) ν_{max}: 2900, 1760 (β-lactam), 1740 cm^{-1} (ester); ms *m/e*: 336 (M^+ − 57).

β-*Lactam* **9**a

The yield was 60%; ^1H nmr ($CDCl_3$) δ: 1.4 (d of t, 6H, OCH_2CH_3), 1.7 (s, 3H, CH_2=CCH_3), 3.4 (d of AB quartet, 2H, J_1 = 18 Hz, J_2 = 10 Hz, $CH_2PO(OEt)_2$), 4.2 (m, 5H, OCH_2CH_3, *CH*C(CH_3)=CH_2), 4.5 (d of q, 1H, *CH*CH=CHPh, J_1 = 1 Hz, J_2 = 5 Hz, J_3 = 7 Hz), 5.1 (bd, 2H, CH_2=CCH_3), 6.0 (q, 1H, J_1 = 7 Hz, J_2 = 16 Hz, *CH*=CHPh), 6.8 (d, 1H, CH=*CH*Ph, J = 16 Hz), 7.3 ppm (m, 5H, C_6H_5); ir (film) ν_{max}: 3000, 1760 (C=O), 1000 cm^{-1}; ms *m/e*: 363 (M^+), 282, 170, 82.

β-*Lactam* ***11***

The yield was 40%, mp 68–69°C; ^1H nmr (C_6D_6) δ: 3.4 (s, 6H, OCH_3), 3.5 (s, 3H, OCH_3), 3.7 (bd, 1H, *CH*CH=CH_2), 4.0 (d, 1H, J = 5 Hz, $CHCO_2CH_3$), 4.5 (2H, AB quartet, CH_2), 4.9–6.0 (m, 3H, CH=CH_2), 6.2–7.2 ppm (m, 3H,

C_6H_3); ir (KBr) ν_{max}: 2950, 1750 (C=O), 1610 cm^{-1}; ms *m/e*: 305 (M^+), 193, 151.

β-*Lactam* ***12***

The yield was 30%, mp 72–72.5°C; ^1H nmr (C_6D_6) δ: 1.6 (s, 3H, $CH_2=CCH_3$), 3.3 (s, 6H, OCH_3), 3.4 (s, 3H, OCH_3), 3.6 (bd, 1H, $CHC(CH_3)=CH_2$), 3.9 (d, 1H, J = 5 Hz, $CHCO_2CH_3$), 4.5 (AB quartet, 2H, CH_2), 5.0 (bd, 2H, $CH_2=CCH_3$), 6.0–7.0 ppm (m, 3H, C_6H_3); ir (KBr) ν_{max}: 2950, 1750 (C=O), 1610 cm^{-1}; ms *m/e*: 319 (M^+), 193, 151.

β-*Lactam* ***9***b

The yield was 60%; ^1H nmr ($CDCl_3$) δ: 1.2–1.6 (m, 6H, OCH_2CH_3), 1.6 (bs, 3H, $C(CH_3)=CH_2$), 4.0–4.8 (m, 5H, OCH_2CH_3, $CHC(CH_3)=CH_2$), 4.9 (d of q, 1H, $CHCH=$CHPh, J_1 = 2 Hz, J_2 = 5 Hz, J_3 = 7 Hz), 5.2 (bd, 2H, $CH_2=CCH_3$), 5.3 (d, $CHPO(OEt)_2$ of one diastereomer, J = 20 Hz), 5.5 (d, $CHPO(OEt)_2$ of other diastereomer, J = 20 Hz), 5.4–7.6 ppm (m, 10H, CH=CHPh, furan); ir ($CHCl_3$) ν_{max}: 1760 cm^{-1} (C=O).

The ^{13}C nmr spectra of several isomeric monosubstituted derivatives of 2-methoxytropone together with some dibromo derivatives have been obtained and analysed. Substituent parameters were defined and shown to exhibit additivity. Differences with corresponding parameters for monosubstituted benzene analogs suggest proximity interactions between the 3-substituents and the 2-OCH_3 group as well as between 7-substituents and the adjacent carbonyl group. The data indicates that the OCH_3 group is a convenient probe to investigate the orientation of mesomeric electronic charge transfer to the various carbons of the tropone seven-membered ring. Finally, it is demonstrated that ^{13}C nmr is quite useful to distinguish between the various substituted 2-methoxytropones.

J. F. BAGLI, T. BOGRI, B. PALAMETA et M. ST-JACQUES. Can. J. Chem. **57**, 1949 (1979).

On a déterminé et analysé les spectres rmn du ^{13}C de plusieurs dérivés monosubstitués isomères de la méthoxy-2 tropone de même que quelques dérivés dibromés. On a défini les paramètres des substituants et on a montré leur additivité. Les différences entre ces paramètres et ceux qui leur correspondent dans des benzènes monosubstitués suggèrent l'existence d'interactions de proximité entre les substituants en 3 et le groupe OCH_3 en 2 de même qu'entre les substituants en 7 et le groupe carbonyle voisin. Les données indiquent que le groupe OCH_3 est une sonde appropriée pour étudier l'orientation du transfert de charge électronique mésomère à divers carbones du cycle à sept chaînons de la tropone. Enfin on a démontré que la rmn du ^{13}C est très utile pour distinguer diverses méthoxy-2 tropones substituées.

[Traduit par le journal]

Tropone derivatives constitute a class of non-benzenoid aromatic substances (1) some of which are biologically active as antibacterial and antifungal agents (2). Consequently, we have been interested in the synthesis of various substituted tropones and concomitantly in establishing the value of several methods of isomer identification applicable to this family of organic compounds.

Whereas proton magnetic resonance (^1H nmr) has been used with some success in the determination of substituent position for some disubstituted derivatives of 2-methoxytropone (3), we have found that isomer identification is less straightforward for monosubstituted derivatives owing to strong coupling between the four remaining ring protons. Although shift reagents can be useful in certain cases (4), recent results (5) suggest that carbon-13 magnetic resonance (^{13}C nmr) spectroscopy should be a powerful and possibly more general technique.

Accordingly we wish to report the results of a ^{13}C nmr spectral study of several isomeric monosubstituted derivatives of 2-methoxytropone together with some dibromo derivatives. The data obtained contribute to our understanding of the complex and subtle substituent effects on the tropone skeleton in addition to further defining the scope and limitation of ^{13}C nmr spectroscopy as a characterization technique in this area of organic chemistry.

Results

Synthesis

Several methods for the preparation of isomeric mono- and dibrominated tropolones have been reported (6). We have modified the procedure described by Toda *et al.* (6*c*) to improve the yield of monobromotropolone in the resulting mixture from which the regioisomeric methyl ethers **1***a* and **1***b* were obtained. Methylation of the residual bromination mixture led to the isolation of methyl ethers **2**, **3**, and **4***b* of 5-bromotropolone, 3,7-dibromotropolone, and 5,7-dibromotropolone respectively. No unequivocal structural assignment of compound **4***b* had previously been reported (6*e*). The ^{13}C nmr analysis given herein has provided one.

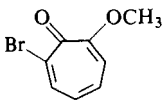
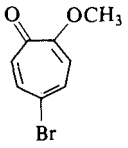
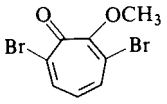
1*a*



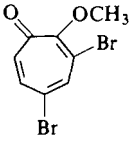
1*b*



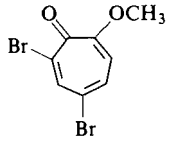
2



3



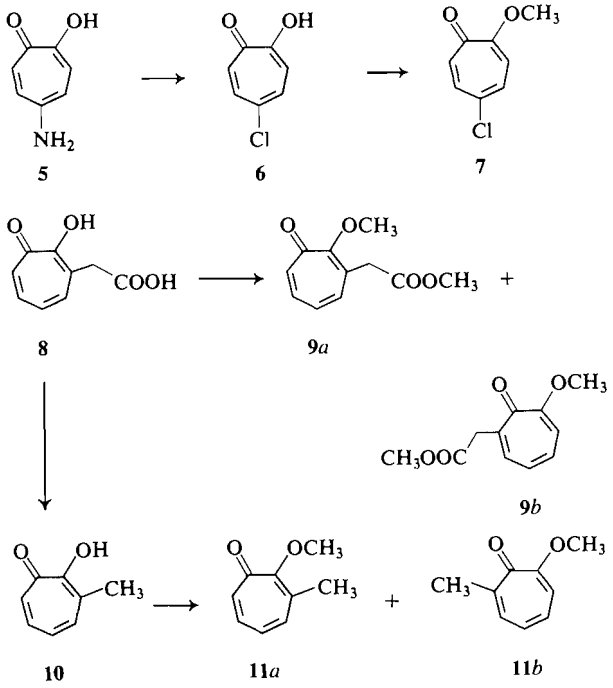
4*a*



4*b*

Compound **6**, prepared from 5-aminotropolone (**5**), was methylated with dimethyl sulfate to yield the methyl ether 7 (7, 8).

Tropolone acetic acid **8** and 3-methyltropolone[3] (**10**) (9) were each methylated to give the pairs of regioisomers **9***a*, **9***b* and **11***a*, **11***b*.



[3]The nomenclature of 3-substituted tropolone used here is for convenience. Monosubstituted tropolone derivatives exist as a mixture of undetermined proportion of 3- and 7-substituted regioisomers.

A mixture of the methoxytropolone derivatives **12** and **13** (10) was methylated and careful chromatographic separation led to the isolation of 2,3-, 2,7-, and 2,6-dimethoxytropones (**14***a*, **14***b*, and **15** respectively). The presence of a fourth compound (2,4-dimethoxytropone) was detected but it was not possible to isolate it in the pure state. Finally 2,5-dimethoxytropone (**16**) was prepared from 5-hydroxytropolone (7, 11).

^{13}C Nuclear Magnetic Resonance Spectral Assignment

The assignment of the various carbon signals for the compounds investigated in this work was achieved through a consideration of relaxation effects in the proton decoupled ^{13}C nmr spectra, signal multiplicity in the coupled spectra, ^{1}H selectively decoupled spectra, and the analysis of substituent effects on the tropone ring (12).

The ^{13}C spectral data for 2-methoxytropone recently published (5) is reported in Table 1 because these parameters will be used as reference data later on. Derivatives of this parent compound are designated by the symbol *x*-S where S is the substituent and *x* is its position on the ring.

Let us begin with the assignment of the signals for **2** (5-Br) and **7** (5-Cl) which contain a single substituent at position 5. The C-1, C-2, and C-5 lines were readily identified by their lower intensity and assigned by comparison with 2-methoxytropone. The analysis of the coupled spectrum permitted the identification of the C-3 and C-7 signals from the observed absence of splitting due to $^{3}J_{CH}$ coupling (5) and thus confirming the position of the substituent. The signal between 110 and 115 ppm was attributed to C-3 by analogy with the chemical shift of C-3 (δ 112.2) for 2-methoxytropone. The C-4 and C-6 signals of these two compounds have not been assigned unequivocally at this point; the chemical shifts given in Table 1 will be shown to be correct later from arguments involving the additivity of substituent effects.

The C-5 signal of **3** was also assigned directly from the coupled spectrum because it alone showed no splitting due to $^{3}J_{CH}$ (5).

The position of the bromine atom in the remaining two monobromo derivatives (**1***a* and **1***b*) can easily be determined from the observation (or absence) of a signal in the range 110–115 ppm attributed to protonated C-3. Consequently, the compound with a substituent on C-3 does not give a signal in that range and is labelled *a*. The C-7 substituted isomer which contains a signal between 110 and 115 ppm is labelled *b*. This labelling scheme is adopted throughout this work for other pairs of 3- and 7-substituted isomers.

TABLE 1. Carbon-13 chemical shifts of several derivatives of 2-methoxytropone in $CDCl_3$ solution[a]

Compound	C-1	C-2	C-3	C-4	C-5	C-6	C-7	C-8

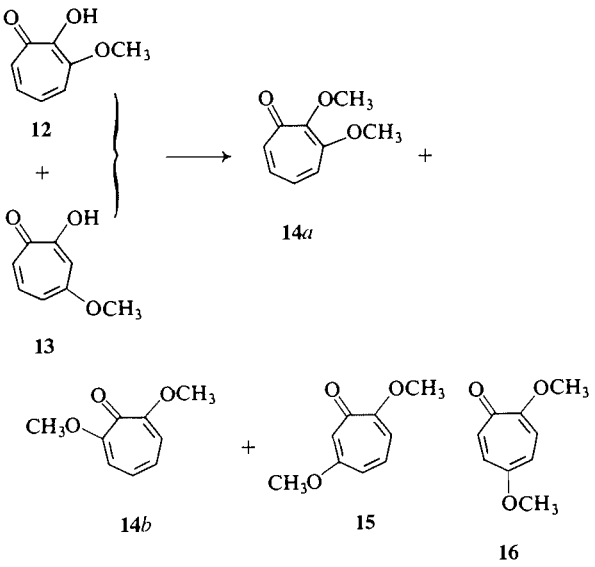
[a]The chemical shifts of the substituent carbons other than OCH_3 are not shown in this table.
[b]The chemical shifts of the parent 2-methoxytropone are listed here. The nature of the substituents for each derivative of 2-methoxytropone is shown below for clarity together with the compound identification number.
[c]Less intense lines observed in the proton decoupled spectra other than those originating from C-1 and C-2.
[d]The assignment of the two closely spaced lines could be reversed.
[e]The substituent OCH_3 groups absorbed nearby, at 52.0 and 51.8 ppm for **9***a* and **9***b* respectively.
[f]Assignment not made for each of the two methoxy groups whose chemical shifts are given in parentheses.
[g]The assignment of these two lines is assumed.



The examination of the ^{13}C nmr spectra of the two dibromo derivatives prepared revealed that of the three possible structures (**3**, **4***a*, and **4***b*), **4***a* (3,5-Br_2) was not obtained. Thus compound **3** (3,7-Br_2) was readily identified from the analysis of the coupled ^{13}C nmr spectrum while a signal at 111.5 ppm for the other isomer is compatible only with **4***b* (5,7-Br_2).

Knowing the structure of all five bromo derivatives and having assigned the signals of **2** and **3** (C-4 assumed upfield from C-6 initially) it is possible to complete the assignment for **1***a*, **1***b*, and **4***b* and confirm the assignment for **2** and **3** from a consideration of additivity of chemical shifts (*vide infra*). Thus the line assignment given in Table 1 for the bromo compound is the only one for which additivity is observed.

Of the two carbomethoxy derivatives **9***a* and **9***b*, that with a signal at 112.2 ppm is confirmed as **9***b*. Their spectral assignment is relatively straightforward and is summarized in Table 1. The spectral assignments for **11***a* and **11***b* were carried out by analogy with those of **9***a* and **9***b* because of their similar features. Here also uncertainty persists in the assignment of the C-6 and C-7 signals of **11***a* as reported in Table 1.

The different symmetry properties of **14***a* (3-OCH_3) and **14***b* (7-OCH_3) allow ready identification of these isomers and the chemical shift data characterizing **14***b* is reported in Table 1.

While the absence of a signal near 112 ppm is compatible with C-3 substitution for **14***a* the line assignment for this compound is more complex than **14***b* owing to the large shifts produced by the second methoxy group. Because **15** and **16** provide useful data on the magnitude of the substituent effect of OCH_3 on adjacent carbons, the spectral analysis of **14***a* will be deferred until later.

The identity of **16** (5-OCH_3) is clearly established from the ^{13}C nmr coupled spectrum in which the characteristic C-5 triplet (5) is absent. The three non-protonated carbon signals were readily identified from their lower intensity but the signals of C-2 and C-5 were too close for reliable assignment. The four intense lines between 105 and 140 ppm were assigned from the analysis of the coupled spectrum and ^1H selectively decoupled carbon-13 spectra (5) as described next.

The 100 MHz ^1H nmr spectrum of **16** showed two

methoxy singlets at 3.77 and 3.86 ppm, a broad A_2 singlet centered at 7.10 ppm and an AB quartet with doublet components at 6.78 and 6.39 ppm (J_{AB} = 10.8 Hz). Because H-7 is expected to be at lowest field (2, 4, 13), then the A_2 pattern must arise from both H-6 and H-7 which consequently have very similar chemical shifts. The upfield doublet component of the AB pattern is much broader owing to $^4J_{HH}$ coupling (3) with H-6; consequently it belongs to H-4 while the downfield doublet belongs to H-3. Selective irradiation of each identified ^1H frequency together with the analysis of the coupled ^{13}C nmr spectrum gave the results reported in Table 1.

Substituent shifts arising from the 5-OCH_3 group can now be determined relative to 2-methoxytropone used as reference. Thus it was calculated that the 5-OCH_3 group shifts C-4 upfield by 25.3 ppm and C-6 upfield by only 4.2 ppm.

The derivative assigned structure **15** (6-OCH_3) was identified from the observed pair of triplets for the protonated C-5 at 124.0 ppm in the coupled ^{13}C spectrum which suggested that the second methoxy group must be at either C-4 or C-6. The calculated substituent effect of −3.6 ppm for C-5 relative to 2-methoxytropone produced by the second methoxy group suggests that this group must be located on C-6 because if it had been on C-4 a much larger upfield shift (greater than 20 ppm) would have been observed for C-5 (*vide infra*).

The three weak signals from C-1, C-2, and C-6 of **15** were easily identified but a distinction between the signals of C-2 and C-6 is not made in Table 1. Of the three intense signals remaining, only the C-4 signal was identified in the coupled ^{13}C spectrum as a doublet centered at 129.9 ppm owing to the absence of $^3J_{CH}$ coupling.

The 100 MHz ^1H nmr spectrum of **15** consists of an ABC pattern with the easily recognizable H-7 signal (6.65 ppm) at the centre of the complex multiplet. Consequently, selective decoupling at the centre of the ^1H multiplet, the lower field side (+15 Hz) and the upfield side (−25 Hz) gave the complete assignment reported in Table 1.

Returning to the ^{13}C nmr spectrum of **14***a* we can easily recognize the C-1, C-2, and C-3 lines from their smaller intensity and assign the least intense of the three lines at 154.5 ppm to C-2 from arguments based on relaxation effects (13). The 3-OCH_3 group is expected to shift C-2 upfield more than C-4 although the electron donating properties of the two OCH_3 groups are modified by mutual steric interaction (*vide infra*). Thus the C-2 line is shifted upfield by 10.5 ppm, whereas either lines at 127.8 or 129.7 ppm could account for the small (4.6 or 2.5 ppm) upfield shift expected for C-4. It is therefore not possible to assign the C-4 signal on this basis. Analysis of the multiplicity in the coupled spectrum is not expected to resolve this problem and the fact that the 100 MHz ^1H nmr spectrum shows a tightly coupled multiplet for the four ring protons suggests that ^1H selective decoupling experiments will not be successful. Furthermore it is difficult to predict which of C-6 or C-7 ought to be most affected by the 3-OCH_3 and it was not possible to assign the lines at 133.2 and 140.5 ppm confidently to these carbons. The assignment given in Table 1 then appears most probable.

Discussion

A description of the chemical shift changes caused by replacing a hydrogen atom by various substituents in terms of characteristic substituent effects constitutes a useful approach to rationalize chemical shift data for many classes of compounds (14). The task of identifying the origin of the various substituent effects, whether they be the α, β, γ, and δ effects for saturated systems (15, 16) or the X, *o*, *m*, and *p* effects for benzene derivatives (17), has not been totally successful. Even though the accumulated knowledge has not provided a quantitative evaluation of the various contributions to chemical shift changes, it frequently allows one to describe the major contributing factor for a given substituent.

It is significant that the characteristic substituent effects generally are additive (14, 18) and empirical correlations based on additivity have proven to be very useful in practical applications to spectral and structural analyses. The examination of the data given in Table 1 for the bromo derivatives **1***a*, **1***b*, **2**, **3**, and **4***b* reveals that additivity exists for only one of the possible chemical shift assignment schemes. It is this combination of chemical shifts which has been retained as the correct assignment in Table 1 for these compounds. For example it can be verified that the chemical shifts of the two dibromo derivatives can be predicted from the appropriate monobromo compounds (i.e., **3** from **1***a* and **1***b*, and **4***b* from **1***b* and **2**). The exchange of any two chemical shifts for one or more compounds leads to a non-additive assignment.

Substituent Effects

It has been shown that substituent perturbation of the tropone ring electronic distribution bears some resemblance to that observed for benzene derivatives (5). Consequently, our discussion of the data from Table 1 will deal in part with a comparison of substituent effects of groups located at positions 3, 5, and 7 of 2-methoxytropone with those from suitable aromatic models.

At the outset it is useful to describe the structural

TABLE 2. Chemical shift changes produced on various ring carbons by substituents on carbon-5[a]

Substituent	C-2(δ)	C-3(γ)	C-4(β)	C-5(α)	C-6(β′)	C-7(γ′)	C-X[b]	C-*o*	C-*m*	C-*p*
Br	−0.4	−1.0	+1.6	−5.4	+3.3	−0.6	−5.5	+3.4	+1.7	−1.6
Cl	−1.0	−1.6	−2.0	+5.6	+0.9	−0.7	+6.2	+0.4	+1.3	−1.9
OCH_3	−6.0	+0.7	−25.3	+30.9	−4.2	−0.1	+31.4	−14.4	+1.0	−7.7

[a]Substituent effects are relative to 2-methoxytropone taken as reference. A + sign indicates a downfield shift.
[b]The symbols represent the following positions for monosubstituted benzene derivatives: X = substituted carbon, *o* = ortho carbon, *m* = meta carbon and *p* = para carbon. These values are taken from ref. 18.

features which characterize the three substituent positions of interest. Only position 5 is free of adjacent groups and it is here that substituent effects are expected to best reflect on the particular electronic structure of the seven-membered ring. For substituents at position 3, it will be necessary to consider the possible consequences of a steric interaction between the various substituents and the 2-methoxy group. Similarly the proximity of substituents on carbon-7 and the adjacent carbonyl group will have to be considered. Substituent effects characteristic of groups at each of the three positions will now be examined in succession.

Substituents on Carbon-5

The data summarized in Table 2 consist of substituent effects on the chemical shifts of various ring carbons calculated for a few substituents located at position 5 of the seven-membered ring relative to the corresponding chemical shifts for 2-methoxytropone taken as reference (5).

It is useful to label the carbons on the side of the double bond as β, γ, δ, etc. and those on the side of the single bond as β′, γ′, δ′, etc. Carbon-5 is therefore labelled α in Table 2, C-4 is β, and C-6 is β′, etc.

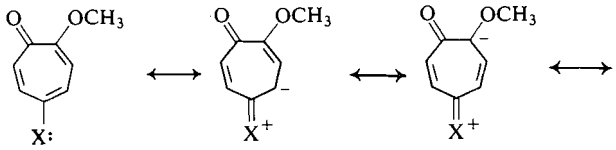
It is instructive to compare these effects with those known for the same substituents on benzene; for this purpose the C-X, C-*o*, C-*m*, and C-*p* values are also listed in Table 2. It is thus seen that C-5(α) and C-X values have very similar magnitudes whereas differences exist between either C-4(β) or C-6(β′) values and C-*o* values. For these adjacent carbon atoms, however, it is seen that similar trends are observed. In fact plots of C-4(β) and C-6(β′) values vs. C-*o* values reveal two essentially linear relationships with different slopes, the larger one belonging to C-4(β). But because only three substituents are available this observation can only be considered qualitatively. The values for C-3(γ), C-7(γ′), and C-*m* are all small as well as those for C-2(δ) and C-*p*, except for 5-OCH_3 which reveals comparable and larger shifts on these latter carbons. It is furthermore interesting to note that although the C-5(α) and C-4(β) substituent effects follow the same trend as observed for the same substituents in 1-substituted ethylenes (14), the actual values differ for each carbon atom. It may be significant to note that the substituent effect for C-2 of 1-methoxyethylene is −37.3 and therefore that the value for C-4(β) falls between this value and −14.4 observed for C-*o* (Table 2).

The relationship between ^{13}C chemical shifts and electronic structure has been reviewed recently (18) and among the various classes of compounds accounted for, aromatic compounds have received the most attention. It is now well known that the chemical shift changes observed for the ring carbon nuclei of monosubstituted benzene derivatives are primarily related to a redistribution of electron density. Furthermore, the mechanisms responsible for this redistribution are varied and dependent on the nature of the substituent, so that it has not been easy (19, 20) to assess their relative importance quantitatively for all groups. The following mechanisms need ordinarily to be considered: σ-inductive, π-inductive, mesomeric, and field effects, as well as steric interactions and bond-order changes.

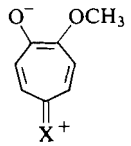
It has been amply reported that iodine and to some extent bromine exert effects not related to their electronegativity and mesomeric abilities in 1-substituted ethylene and monosubstituted aromatic compounds whereas chlorine is better behaved (17). The 'heavy halogen effect' has been used historically to single out this observation. The idea that spin–orbit interaction (21) on a heavy atom can give rise to spin polarization that may be propagated along a molecule has been used lately as a rationale. Whatever the origin of the phenomenon, it is clear that the effects of bromine and chlorine arise from different origins and that mesomeric contribution is relatively more important for the latter. On the other hand, all evidence indicates that the mesomeric contribution is dominant when an OCH_3 group is bonded to an unsaturated carbon.

In addition to the above general considerations, the alternance of single and double bond character in tropone (22, 23) imparts a distinct electronic feature which could affect the mode of transmission of substituent effects to the various ring carbon atoms. In this respect Table 2 shows that C-4(β) and C-6(β′) are indeed very differently affected by the substituents on C-5. It is seen that both OCH_3 and Cl

shift C-4(β) more than C-6(β′) whereas for Br it is the opposite. This behaviour is qualitatively in accord with a dominant contribution of mesomeric effects for Cl and OCH_3 (especially strong for the latter) which can be illustrated with the resonance forms **17** to **20**. Such a model seems to adequately account for the large upfield C-4(β) shift produced by the 5-OCH_3 group, in addition to the significant upfield shift of C-2(δ) which is comparable to that observed for *para*-carbons in aromatic compounds for which it is known that resonance plays a dominant role for this substituent.



17 **18** **19**



20

Since no resonance form with accrued negative charge on C-6 can be drawn, it is reasonable to assume that the mesomeric contribution will not be very important here in agreement with the relatively small upfield shift observed. The difference in the magnitudes of C-4(β) and C-6(β′) substituent effects for Cl are also consistent with accrued electron density on C-4 through a mesomeric contribution involving **18**.

As for the perturbations of C-4 and C-6 by the 5-Br substituent, the data in Table 2 reveal that they are of the same order of magnitude as for C-*o*. Although the C-4 (β) shift cannot be accounted for adequately by a mesomeric effect involving **18**, the fact that this carbon is less shifted downfield than C-6 suggests that some charge transfer through **18** might cancel part of the downfield shift caused by the field effect of the Br atom.

Substituents on Carbon-7

A summary of the chemical shift changes produced by several substituents located at position 7 is given in Table 3. The C-7(α) substituent effects for Br and OCH_3 are somewhat dissimilar to the corresponding C-5(α) effects in Table 2. Because significant differences between C-7(α) and C-X values also exist, some interaction between the 7-substituents and the adjacent carbonyl group is indicated.

Substituent effects published for 2-substituted tropones (5) undoubtedly provide the best indication of the importance of the above interaction and its consequence on the chemical shifts of atoms adjacent to the carbonyl group. Because in tropone both C-2 and C-7 are equivalent by symmetry, it is of interest to find out whether the C-7(α) values given in Table 3 differ significantly from the C-2(α) effects reported earlier (5). For example the values of CH_3 are +9.3 and +10.3 respectively; for OCH_3 they are +25.4 and +23.3 while for Br they are +1.2 and about −0.5.[4] Furthermore, the C-1(β′) substituent effects for CH_3 and OCH_3 in Table 3 are very similar to those reported for the corresponding 2-substituted tropones (5). In fact such a comparison is valid for all subsequent carbons whose effects are given in Table 3. Consequently, it is apparent that the suggested substituent–carbonyl proximity interaction leads to very similar chemical shift changes for both classes of compounds in agreement with expectations from the additivity of substituent effects.

It is also interesting to point out that the C-6(β) effect for OCH_3 is −22.2 and comparable to the −25.3 value for C-4(β) of Table 2.

The slight differences between the shifts produced by the CH_3 and the $CH_2CO_2CH_3$ groups in aromatic systems are best explained in terms of a π-inductive effect (19, 20) whereby the largest effect is noted for C-X whose values are +8.9 and +5.9 respectively.[5] The difference of 3.4 ppm for the C-7(α) substituent effects given in Table 3 is compatible with the above explanation.

Substituent on Carbon-3

Chemical shift changes produced by several substituents on C-3 are summarized in Table 4. Because of uncertainties in the assignment of the C-6 and C-7 signals for some of the compounds listed, these two carbons have been omitted from the table.

The proximity of the C-3 substituent and the C-2 methoxy group suggests that it is important to evaluate possible shifts resulting from the existence of a steric interaction between these two groups. Such a steric interaction has previously been suggested to explain observations for *ortho*-substituted anisoles (24).

Table 4 reveals that the C-3(α) substituent effects are much larger than the corresponding C-X effect

[4]This value for Br has been obtained by extrapolation from Fig. 2 of ref. 5 using the line characterizing the substituent effects for CH_3, Cl, and NH_2. The error is probably ±1.

[5]The C-X, C-*o*, C-*m* and C-*p* effects of the $CH_2CO_2CH_3$ group were calculated to be +5.9, +0.1, +0.9, and −1.4 ppm respectively. The actual chemical shifts are given in spectrum 40 of 'The Sadtler standard carbon-13 nmr spectra' and the substituent effects were obtained relative to benzene (δ_c = 128.6).

TABLE 3. Chemical shift changes produced by substituents on carbon-7[a]

Substituent	C-1(β′)	C-7(α)	C-6(β)	C-5(γ)	C-4(δ)
Br	−6.5	+1.2	+3.3	−2.5	+0.4
$CH_2CO_2CH_3$	−1.4	+5.9	+1.2	−1.0	−0.2
CH_3	−1.0	+9.3	−0.8	−1.2	−2.1
OCH_3	−6.4	+25.4	−22.2	−1.9	−6.7

[a]Substituent effects are relative to 2-methoxytropone taken as reference. A + sign indicates a downfield shift.

TABLE 4. Chemical shift changes produced by substituents on carbon-3[a]

Substituent	C-1(γ)	C-2(β)	C-3(α)	C-4(β′)	C-5(γ′)
Br	−0.9	−2.1	+15.7	+5.5	+0.5
$CH_2CO_2CH_3$	+1.3	−0.6	+19.8	+3.1	+1.8
CH_3	+1.0	−1.3	+24.0	+2.4	+1.4
OCH_3	+0.6	−10.5	+46.4	−4.6	+2.1

[a]Substituent effects are relative to 2-methoxytropone taken as reference. A + sign indicates a downfield shift.

for analogous benzene derivatives. It is also seen that the C-3 signals have been shifted downfield by at least 15 ppm in excess of predictions based on α-effects for C-5(α) given in Table 2. An observation of similar magnitude for 2,6-disubstituted anisoles (24) was interpreted in terms of the inhibition of resonance of the methoxy group as a consequence of steric interaction with the *ortho*-substituents. Similar reasoning applied to the 2-OCH_3 group is able to explain the greater downfield shift observed for C-3(α) in Table 4. Thus the normal upfield β-effect of 2-OCH_3 is reduced by interaction with the 3-substituents and the overall downfield shift of C-3 produced by 3-substitution is effectively larger than predicted from the 'normal' α-effect obtained from Table 2.

The β-effects determined for C-2(β) in Table 4 are significantly different from the 'normal' β-effects given in Table 2 for each of Br and OCH_3. Thus C-2 next to 3-Br is shifted more upfield than expected whereas C-2 next to OCH_3 appears less upfield than expected from the data in Table 2. The magnitude of the perturbations is much larger for 3-OCH_3 than 3-Br, however.

Assuming that the α-effect is predominantly determined by inductive effects and essentially independent of the conformation of the OCH_3 groups and furthermore that the C-2(β) shift should arise predominantly from mesomeric contributions of the 3-OCH_3 group, it then appears that a reduction in mesomeric charge transfer from the 3-OCH_3 group to C-2 could rationalize the lesser upfield shift of C-2. Thus it is suggested that the steric interaction between the 2-OCH_3 and the 3-OCH_3 groups alters the conformation of the 3-OCH_3 group relative to the C(3)—C(2) double bond from that which would exist in the absence of interaction as is the case for the 5-OCH_3 group.

The observation that C-4(β′) values for Br and OCH_3 from Table 4 are close to those for C-6(β′) from Table 2 suggests that the inhibition of resonance suggested above does not perturb C-4 significantly in agreement with very little mesomeric charge transfer across the formal single bond of the tropone ring.

The examination of Table 1 further reveals that the presence of a substituent at position 3 produces a downfield shift (2–3 ppm) of the 2-methoxy carbon. This observation is similar to the 3.9 ppm downfield shift reported for 2,6-dimethylanisole (24).

Finally it is significant to note that the difference between the C-3(α) effects of CH_3 and $CH_2CO_2CH_3$ is 4.2 ppm and of the same magnitude as that observed for C-X values; it can be accounted for by the π-inductive effect (19, 20).

Conclusions

The chemical shift changes produced by substituents located at positions 3, 5, and 7 of 2-methoxytropone given in Tables 2, 3, and 4 reveal that mesomeric effects play a very important role, especially for the methoxy group which exhibits the largest effects. The observation that such resonance is effective only for the β, γ, and δ side of each substituted carbon is particularly significant. Thus we see that the OCH_3 group is a convenient probe to investigate the orientation of mesomeric electronic charge transfer to the various carbons of the tropone seven-membered ring.

The chemical shift data for **15** (6-OCH_3) given in Table 1 yields the following substituent effects: C-6(α) = +26.9, C-7(β) = −23.1, and C-5(β′) =

−3.6. These values are very similar to those reported for 5-OCH_3 (**16**) in Table 2. Since no proximity interactions exist for **15** and **16** these substituent effects then ought to reflect the actual electronic structure of the ring and their similarity is compatible with an alternating π-electronic distribution involving single-like and double-like bonds (23). The fact that the 'normal' β-substituent effect of OCH_3 is about mid-way between those found for methylvinyl ether and anisole (i.e., −23 to −26 compared to −37.3 and −14.4 ppm respectively) might be taken as an indication of the extent of delocalization in the tropone ring.

The chemical shift changes for substituents located at positions 3 and 7 revealed proximity interactions and their consequences on chemical shifts. In addition the data has been very useful to distinguish unambiguously between pairs of regioisomers such as those identified by *a* and *b* throughout the text. The presence of a signal near 110–112 ppm indicates a protonated C-3 and hence substitution at C-7. Because several reactions of tropolone and other tropone derivatives can give similar mixtures of regioisomers, ^{13}C nmr could be an extremely valuable tool of identification.

On the other hand it is seen that, even for the relatively simple compounds investigated in this work, complete spectral assignment is often tedious. Consequently structure identification of other substituted tropones might often not be a simple task and for this purpose ^{13}C and ^{1}H nmr are shown to provide complementary information. The carbon-13 substituent effects determined in this work then provide initial basic parameters which should be useful in solving such practical problems.

Experimental

The ir spectra were taken on a Perkin Elmer diffraction grating spectrometer. Routine ^{1}H nmr spectra were recorded on a Varian A-60A spectrometer located at Ayerst Laboratories. The mass spectra were obtained on a Hitachi NMR-60 spectrometer. The melting points were determined on a Thomas Hoover apparatus and are uncorrected. Organic extracts were dried over anhydrous magnesium sulfate and all solvents were removed under vacuum. Merck silica gel 60 (70–230 mesh) was used for column chromatography.

The 100 MHz ^{1}H nmr (CW) spectra and the 22.63 MHz ^{13}C nmr (pulse FT) spectra were recorded respectively on a JEOL JNM-4H-100 and a Bruker WH-90 spectrometer located at the Université de Montréal. Heteronuclear ^{1}H–^{13}C double resonance experiments were carried out using the standard proton decoupler of the WH-90 instrument. The decoupler power was calibrated by proton off-resonance decoupling of a methanol sample (12). In the selective double resonance experiments the magnitude of irradiating field was set at about 850 Hz.

All ^{13}C nmr spectra were recorded at ambiant temperature using 10 mm tubes for solutions of the compounds in $CDCl_3$ which also acted as internal reference with δ = 76.9. The pulse duration was 6 μs (12 μs corresponds to a 90° pulse) and the number of accumulations depended on the concentration of the sample which varied with the amount available (30 to 200 mg). The coupled spectra were obtained through the gated decoupling technique (12) using the standard procedure for WH-90 spectrometers equipped with the Nicolet model 293 I/O Controller.

All spectra were recorded with 8K data points using a spectral width of 6024 Hz for ^{1}H decoupled spectra and 3012 Hz for the coupled spectra.

5-Chlorotropolone (6)

To a suspension of 5-aminotropolone (**5**) (25 g) in water (170 mL) was added hydrochloric acid (650 mL) at room temperature. The mixture was stirred and cooled to −10°C. After 15 min of stirring a solution of sodium nitrite (12.6 g) in water (36 mL) was added while maintaining the temperature at −10°C. The mixture was stirred at that temperature for 1.25 h. It was then warmed to room temperature and heated to 80°C for 2.5 h. The mixture was then cooled to room temperature, poured on to crushed ice (ca. 900 g) and the precipitate filtered to yield the crude product (20 g). The filtrate was extracted with chloroform, dried, and the solvent was removed. The residue was triturated with ether and filtered to yield 1.7 g more of solid. Total yield was 75%. The product had mp 180–182°C (lit. (7) mp 181–183°C).

2-Methoxy-5-chlorotropone (7)

5-Chlorotropolone (3.13 g, 1 equiv.) was suspended in methyl ethyl ketone (40 mL). Potassium carbonate (3.04 g, 2.2 equiv.) was added and the mixture was heated to 70°C (bath temperature) for about 10 min. Dimethyl sulfate (4.16 mL, 2.2 equiv.) was then added and the mixture kept at 80°C for 1.5 h. When the reaction was complete (indicated by tlc) the mixture was cooled and filtered. The filtrate was evaporated to dryness under vacuum, and the residue was suspended in ether and filtered to give the crude product (2.9 g). Crystallization from methanol–ether gave the pure product (2 g), mp 123–124°C (lit. (8) mp 123°C).

Bromomethoxytropones

3-Bromo- and 7-Bromo-2-methoxytropone (1a) and (1b)

Bromotropolone was methylated with dimethyl sulfate as described above to give a less polar product, mp 69–70°C (mp reported for 3-bromo-2-methoxytropone 76.5–77°C (6*d*)), and a more polar isomer, mp 87–88°C (mp reported for 7-bromo-2-methoxytropone 90–91°C (6*d*)).

3,7-Dibromo-2-methoxytropone (3)

This product was obtained from the corresponding 3,7-dibromotropolone, using the above procedure; mp 130–131°C (lit. (6*b*) mp 132–132.5°C).

5-Bromo-2-methoxytropone (2)

This compound was isolated from the methylation experiment and had mp 132–134°C (lit. (6*b*) mp 135–136°C).

5,7-Dibromo-2-methoxytropone (4b)

This compound had mp 208–210°C (lit. (6*e*) mp 207–209°C).

2-Methoxytropone-3-acetic Acetic Acid Methyl Ester (9a) and 2-Methoxytropone-7-acetic Acid Methyl Ester (9b)

These compounds were obtained from the methylation of tropolone acetic acid **8** with diazomethane. Chromatography of the mixture on silica gel yielded a more polar solid, mp 106–108°C; ir (Nujol): 1725 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 7.45 (1H, m, aromatic), 6.9 (3H, m, aromatic), 3.9 (3H, s, —OCH_3), 3.65 (5H, s, OCH_3; CH_2—CO); and a less polar oily product, ir (Nujol): 1725 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 7.02 (4H, m, aromatic), 3.90 (3H, s, OCH_3), 3.67 (5H, d, OCH_3, CH_2—CO). The solid was tentatively assigned structure **9***a* and the oil **9***b*.

*2-Methoxymethyltropones (**11**a and **11**b)*

A solution of tropolone-2-acetic acid **8** (ca. 1 g) in pyridine (5 mL) was heated to reflux for 1.5 h. The solvent was removed under vacuum to yield a residue (0.57 g) which was mixed with an ethereal solution of diazomethane and stirred for 1.5 h. The solvent was evaporated and the product was purified by chromatography on silica gel (30 g) using 30% ethyl acetate – benzene. Earlier fractions yielded an oily product (0.06 g); ^{1}H nmr ($CDCl_3$) δ: 7.1 (4H, m, aromatic), 3.92 (3H, s, OCH_3), 2.35 (3H, s, =C—CH_3). This compound was tentatively assigned structure **11***a*. Further elution gave another isomer; mp 37–39°C; ^{1}H nmr δ: 7.5 (1H, m, aromatic), 6.85 (3H, m, aromatic), 3.92 (3H, s, OCH_3), and 2.36 (3H, s, C—CH_3). The structure **11***b* followed from the above assignment. These structures were later confirmed by ^{13}C nmr.

*2,3-, 2,7-, and 2,6-Dimethoxytropone (**14**a, **14**b, **15**)*

These compounds were prepared by methylation of a mixture of isomeric methoxytropolone obtained using a described procedure (10).

Methylation using dimethyl sulfate gave a mixture of isomers that were separated by chromatography. A less polar oily isomer which showed in its ^{1}H nmr ($CDCl_3$) δ: 7.1 (4H, m, aromatic), 3.89 (3H, s, OCH_3), and 3.72 (3H, s, OCH_3), was tentatively assigned structure **14***a*. Another more polar component was obtained from chromatography; after recrystallization from methanol–ether it gave a mp 106–108.5°C. The ^{1}H nmr spectrum of this compound showed only one singlet at δ 3.78 (6H, s) indicating two equivalent OCH_3 groups and structure **14***b* was assigned to it. A third isomer was purified with difficulty by rechromatography and was obtained as an oil. A mass spectrum showed the following ions: M^+ (*m/e* 166, 100%); $M^+ - 15$ (*m/e* 151, 5%). Its ^{1}H nmr spectrum showed two singlets arising from two OCH_3 groups at δ 4.17 and 4.27. The structure was confirmed using ^{13}C nmr spectroscopy to be 2,6-dimethoxytropone (**15**).

*2,5-Dimethoxytropone (**16**)*

The title compound was prepared from 2,5-dihydroxytropone (7) as described above. The compound is reported as an oil (11). We were able to get it as a crystalline solid; mp 77–80°C; M^+ (*m/e* 166, 100%). The structure of the compound was confirmed by ^{13}C nmr.

Synthèse et réactivité des halogéno-2 sulfonyl-2 aziridines

JEAN-MARC GAILLOT, YVONNE GELAS-MIALHE ET ROGER VESSIERE

Groupe de Recherche de Chimie Organique 2, U.E.R. des Sciences Exactes et Naturelles, Université de Clermont-Ferrand, B.P. 45, 63170 Aubiere, France et Ecole Nationale Supérieure de Chimie, 71 Boulevard Côte Blatin, 63000 Clermont-Ferrand, France

Reçu le 3 janvier 1979

JEAN-MARC GAILLOT, YVONNE GELAS-MIALHE et ROGER VESSIERE. Can. J. Chem. **57,** 1958 (1979).

Les halogéno-2 phénylsulfonyl-2 aziridines sont obtenues par action du tétrahalogénure de carbone, en présence de potasse, sur les phénylsulfonyl-2 aziridines.

A partir des isopropylsulfonyl-2 aziridines, on obtient une monochloro et une dichloro-aziridine; la réaction de Ramberg–Bäcklund n'est pas observée.

Ces composés halogénés se décomposent, soit thermiquement, soit en milieu acide, pour conduire aux α-halogénoacétamides et α-phénylsulfonylacétamides *N*-substitués. Les halogéno-2 phénylsulfonyl-2 aziridines ne réagissent pas avec le cyanure de potassium ou le benzènethiolate de sodium. Elles sont réduites par le méthylate, l'éthylate et l'éthanethiolate de sodium, on obtient alors les phénylsulfonyl-2 aziridines; le rôle du solvant est précisé.

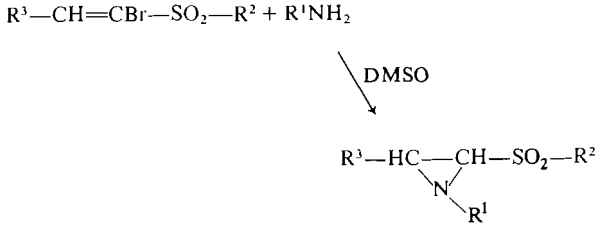
JEAN-MARC GAILLOT, YVONNE GELAS-MIALHE, and ROGER VESSIERE. Can. J. Chem. **57,** 1958 (1979).

Carbon tetrahalide reacts rapidly with 2-phenylsulfonyl aziridines in the presence of KOH, leading to 2-phenylsulfonyl 2-haloaziridines.

Starting with 2-isopropylsulfonyl aziridines, a monochloro and a dichloroaziridine are produced; the Ramberg–Bäcklund reaction is not observed.

These halo compounds decompose either thermally or in acidic medium leading to *N*-substituted α-haloacetamides and α-phenylsulfonylacetamides. 2-Phenylsulfonyl 2-haloaziridines are unreactive toward potassium cyanide or sodium thiophenoxide. Sodium methoxide, sodium ethoxide, or sodium thioethoxide reduce them to 2-phenylsulfonyl aziridines; the reaction depends upon the solvent.

Dans un précédent mémoire (1) nous avons décrit la préparation des phénylsulfonyl-2 aziridines **1**, **2** et **3** par action, dans le diméthylsulfoxyde, d'une amine primaire sur une sulfone α-bromée α,β-éthylénique. Par la suite, nous avons fait appel à ce procédé pour accéder aux alkylsulfonyl-2 aziridines **4** et **5**:



1 $R^3 = H$; $R^2 = Ph$
2 $R^3 = CH_3$; $R^2 = Ph$
3 $R^3 = Ph$; $R^2 = Ph$
4 $R^3 = H$; $R^2 = CH_3$
5 $R^3 = H$; $R^2 = CH(CH_3)_2$

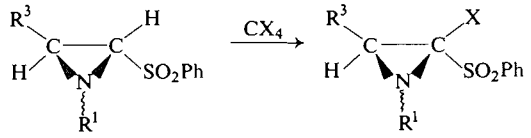
Dans le présent mémoire, nous nous proposons de décrire le comportement de cette nouvelle classe d'aziridines dans des réactions d'halogénation, au cours desquelles nous avons obtenu des halogéno-2 sulfonyl-2 aziridines, composés jusqu'alors inconnus. Certains de ces produits, généralement solides, abandonnés à température ambiante, deviennent déliquescents et présentent au bout de quelques jours un spectre de rmn considérablement perturbé. Ceci nous a conduit à étudier leur stabilité thermique et leur hydrolyse. Nous avons, par ailleurs, examiné leur comportement vis-à-vis de quelques nucléophiles.

Halogénation des sulfonyl-2 aziridines

Parmi les nombreux procédés permettant l'introduction d'un halogène en α d'une fonction sulfonyle, nous avons utilisé celui mis au point par Meyers *et al.* (2).

Les phénylsulfonyl-2 aziridines **1***b*, **1***c*, **2***b*, **2***d* et **3***a* traitées par le tétrachlorure ou le tétrabromure de carbone en présence de potasse en poudre et d'alcool *tert*-butylique, conduisent, avec de bons rendements, aux halogéno-2 phénylsulfonyl-2 aziridines **6***b*, **6***c*, **7***b*, **7***d*, **8***a*, **9***b*, **9***c*, **10***b*, **10***d* et **11***a* identifiées par leur analyse élémentaire et leur spectre de rmn (voir partie expérimentale):

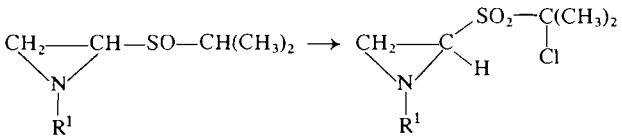
0008-4042/79/151958-09$01.00/0



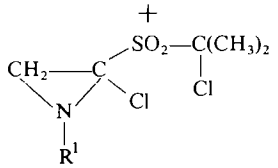
1 $R^3 = H$ — *a* $R^1 = CH_2CH_3$ — **6** $R^3 = H$; X = Cl
2 $R^3 = CH_3$ — *b* $R^1 = CH(CH_3)_2$ — **7** $R^3 = CH_3$; X = Cl
3 $R^3 = Ph$ — *c* $R^1 = C(CH_3)_3$ — **8** $R^3 = Ph$; X = Cl
d $R^1 = CH_2Ph$ — **9** $R^3 = H$; X = Br
10 $R^3 = CH_3$; X = Br
11 $R^3 = Ph$; X = Br

Ces réactions se déroulent par l'intermédiaire d'un α-sulfonylcarbanion (2). Nous avons montré dans un précédent mémoire (1) que l'α-phénylsulfonyl carbanion formé à partir des phénylsulfonyl-2 aziridines possédait très probablement une géométrie pyramidale avec une haute barrière d'inversion. En effet, traitée par l'éthylate de sodium dans l'éthanol deutérié l'aziridine **2***d* incorpore le deutérium en position 2; par ailleurs sa stéréochimie n'est pas modifiée par traitement pendant 17 h à température ambiante par une solution d'éthylate de sodium dans l'éthanol. En conséquence, les halogéno-2 phénylsulfonyl-2 aziridines **7**, **8**, **10** et **11** ont la même configuration que les dérivés **2** et **3** à partir desquels elles sont formées. Nous avons précisé par ailleurs (1) que les atomes de carbone C-2 et C-3 des composés **2** et **3** sont de configurations *R*R**. Ces mêmes atomes ont donc la configuration *R*S** chez les produits **7**, **8**, **10** et **11**.

Les isopropylsulfonyl-2 aziridines **5** possèdent en α et en α′ de la fonction sulfone deux atomes d'hydrogène mobiles. La réaction d'halogénation pourrait donc évoluer vers la formation d'un composé éthylénique du type méthylèneaziridine (réaction de Ramberg–Bäcklund) (2, 3). Du produit brut de chloration par le tétrachlorure de carbone en milieu basique de chacune des aziridines **5***b* et **5***d* nous avons isolé deux composés que nous avons identifiés aux aziridines monochlorées **12***b* et **12***d* d'une part et aux aziridines dichlorées **13***b* et **13***d* d'autre part:

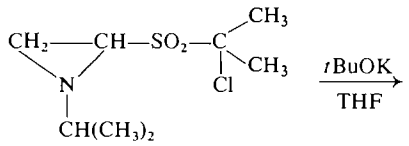


5*b* $R^1 = CH(CH_3)_2$ — **12***b* $R^1 = CH(CH_3)_2$
5*d* $R^1 = CH_2Ph$ — **12***d* $R^1 = CH_2Ph$

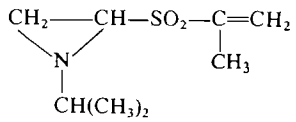


13*b* $R^1 = CH(CH_3)_2$
13*d* $R^1 = CH_2Ph$

Si l'on arrête la réaction d'halogénation de l'aziridine **5***d* avant son terme, les composés mono- et dihalogénés sont présents dans le mélange réactionnel à côté du produit de départ, le dérivé dihalogéné étant largement prépondérant (**13***d*/**12***d* = 43/7, déterminé par rmn). La dihalogénation est donc plus rapide que la monohalogénation et qu'une éventuelle élimination 1,3 ayant pour siège le composé monohalogéné. L'aziridine monohalogénée **12***b*, mise en solution dans le THF et traitée par *t*BuOK pendant 5 h à 0°C est retrouvée inchangée. Ce mélange, chauffé à reflux pendant 5 h, conduit au produit d'élimination 1,2 **14***b*:

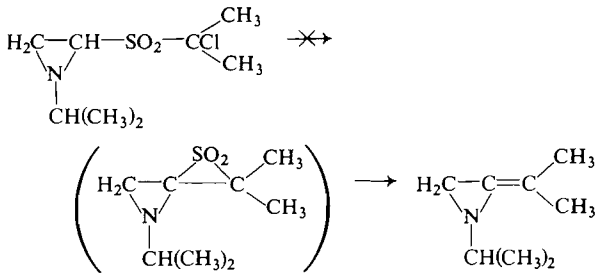


12*b*



14*b*

On n'observe pas la formation du produit éthylénique provenant d'une réaction type Ramberg–Bäcklund; ceci peut être attribué à l'importante contrainte à laquelle serait soumise l'épisulfone spirannique intermédiaire:

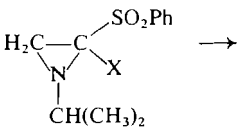


Stabilité thermique et hydrolyse des halogéno-2 sulfonyl-2 aziridines

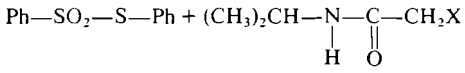
Afin de déterminer la nature des produits de décomposition spontanée des halogéno-2 sulfonyl-2 aziridines, nous avons chauffé ces composés pendant des temps variables à 60°C (température inférieure à leur température de fusion). Les durées de thermolyse et le pourcentage de transformation sont indiqués dans la partie expérimentale. On peut noter que les bromo-2 aziridines se décomposent plus facilement que les chloro-2 aziridines et que les composés possèdant un groupe méthyle en position 3 apparaissent plus stables.

Au départ des aziridines **6***b* et **9***b* on sépare, par

chromatographie sur colonne, deux produits. L'un d'eux est identifié à l'aide de ses spectres ir et de rmn et par comparaison à un échantillon authentique au *N*-isopropyl α-halogénoacétamide. Le deuxième constitue le benzènethiosulfonate de phényle:



6*b* X = Cl
9*b* X = Br



Chauffés en présence d'eau, les composés **6***b* et **9***b* se décomposent plus lentement (la réaction est totale après 6 jours de chauffage à 60°C dans le cas de **6***b*, 4 jours à 60°C pour **9***b*). Trois produits sont alors formés; le *N*-isopropyl α-halogénoacétamide, le benzènethiosulfonate de phényle et le *N*-isopropyl α-phénylsulfonylacétamide; ce dernier est identifié par ses spectres ir et de rmn et par comparaison à un échantillon authentique.

Ces résultats sont tout à fait comparables à ceux que l'on observe avec les *gem*-dihalogénoaziridines (4), les nitro-2 aziridines (5) ou les *gem*-dihalogénocyclopropanes (6). Un mécanisme analogue à ceux invoqués peut rendre compte de nos résultats (Schéma 1):

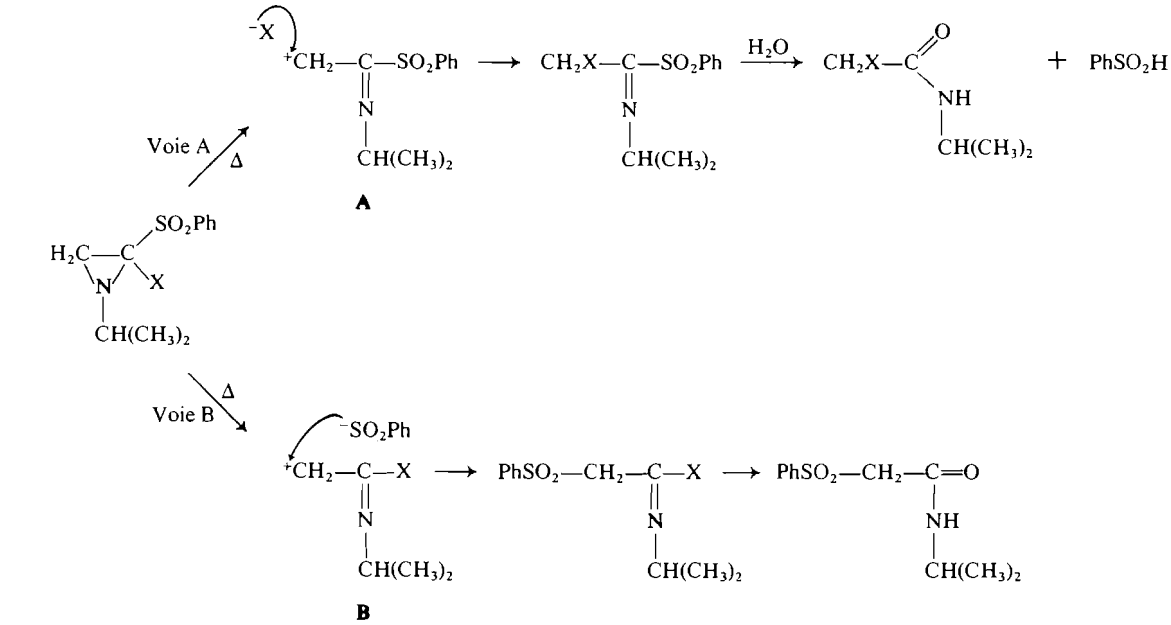


SCHÉMA 1

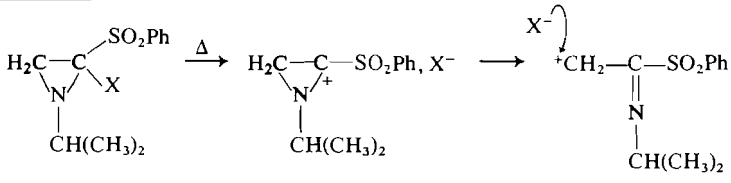
Selon la voie A (Schéma 1) l'hétérolyse de la liaison carbone–halogène et la rupture simultanée de la liaison C^3—N conduisent, par l'intermédiaire du cation A à la formation d'une sulfonylimine dont l'hydrolyse donne l'α-halogénoacétamide. Quant à l'acide sulfinique, il se décomposerait suivant [1] (7):

[1] $3PhSO_2H \rightarrow PhSO_2SPh + PhSO_3H + H_2O$

On pourrait également envisager un mécanisme non concerté faisant intervenir le cation cyclique A′; une telle voie est toutefois peu probable en raison de l'effet déstabilisant exercé par le groupe sulfonyle porté par le carbone positif (Schéma 2):



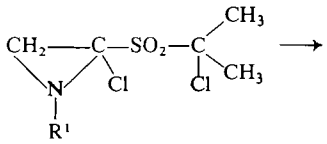
A′ A

SCHÉMA 2

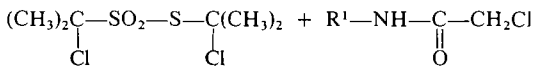
Par ailleurs, l'hétérolyse de la liaison carbone–soufre (voie B, Schéma 1) peut être compétitive avec celle de la liaison carbone–halogène. L'iminosulfone formée par l'intermédiaire du cation B est ensuite hydrolysée en *N*-isopropyl α-phénylsulfonylacétamide.

La plus grande réactivité des dérivés bromés par rapport aux dérivés chlorés est justifiée par une vitesse d'hétérolyse supérieure de la liaison C—Br par rapport à la liaison C—Cl.

Une réaction en tous points analogue est observée avec les aziridines dihalogénées **13***b* et **13***d*. En effet chacune d'elles, abandonnée quelques jours à température ambiante, est totalement décomposée en deux produits que nous avons identifiés au chloro-1 méthyl-1 éthylthiosulfonate de chloro-1 méthyl-1 éthyle et au *N*-alkyl α-chloroacétamide:



13*b* $R^1 = CH(CH_3)_2$
13*d* $R^1 = CH_2Ph$



L'hydrolyse acide en milieu homogène (HCl dans un mélange éthanol–eau) conduit à un résultat comparable; au départ de la *tert*-butyl-1 chloro-2 phénylsulfonyl-2 aziridine **6***c* on isole, à côté du benzènethiosulfonate de phényle, un composé identifié au *N-tert*-butyl α-chloroacétamide; à partir de la bromo-2 aziridine **10***b* on obtient également du benzènethiosulfonate de phényle et un mélange de deux composés que nous n'avons pas pu séparer et que nous avons identifiés au *N*-isopropyl α-chloropropionamide (55%) et au *N*-isopropyl α-bromopropionamide (45%) (pourcentage déterminé sur le spectre de rmn).

Un mécanisme identique à celui précédemment proposé permet d'interpréter ces résultats, notamment la formation d'un mélange d'amides α-bromée et α-chlorée à partir de l'aziridine bromée **10***b*. En effet, selon le Schéma 1, voie A, l'hétérolyse de la liaison carbone–halogène de l'aziridine libère le cation A qui peut alors être soumis à une attaque compétitive de la part des ions Cl^- et Br^- présents dans le milieu.

Bien que les produits obtenus dans ces réactions aient une structure analogue à ceux qui proviennent de la solvolyse de la diphényl-1,2 dichloro-3,3 aziridine (4*a*), il semble que les mécanismes de formation de ces composés soient différents. En effet, Brooks *et al.* (4*a*) ont montré dans le cas précédent que la réaction procédait, de façon prédominante, par migration intramoléculaire de chlore; la présence d'un amide α-chloré comme produit d'hydrolyse de l'aziridine bromée **10***b* prouve dans notre cas la participation des ions présents dans le milieu réactionnel.

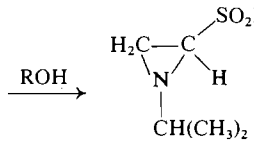
Action des nucléophiles sur les halogéno-2 arylsulfonyl-2 aziridines

Contrairement aux chlorocyclopropanes, dérivés généralement inertes vis-à-vis des agents nucléophiles, les monochloroaziridines conduisent, sous l'action de ces réactifs, aux produits de substitution normalement attendus (8). D'autre part, divers travaux (9) ont montré la très faible réactivité des α-halogénosulfones vis-à-vis des nucléophiles, lesquels provoquent quelquefois uniquement une réduction de la sulfone au niveau de l'halogène (9*c*). Compte tenu de ces résultats, il pouvait être intéressant d'étudier le comportement des halogéno-2 sulfonyl-2 aziridines vis-à-vis de divers nucléophiles.

Le benzènethiolate de sodium et le cyanure de potassium ne donnent aucune réaction avec les aziridines **6***b* et **9***b* qui sont, par contre, réduites au niveau de l'atome d'halogène, par le méthylate, l'éthylate ou l'éthanethiolate de sodium; la réaction conduit alors à l'isopropyl-1 phénylsulfonyl-2 aziridine **1***b*. L'aziridine bromée **9***b* est plus facilement réduite que l'aziridine chlorée **6***b*. On observe, par ailleurs, un accroissement de vitesse considérable lorsque la réaction est effectuée dans le diméthylsulfoxyde, par rapport aux réactions réalisées en utilisant comme solvant un alcool ou le diméthylformamide.

Les éqs [2], [3] et [4] rendent compte de nos résultats expérimentaux:

[2] 
6*b* X = Cl
9*b* X = Br
$B^- = RO^-$ ou EtS^-

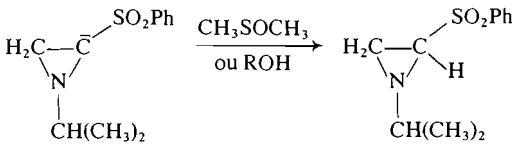


1*b*

En présence d'alcoolate ou d'éthanetiolate de sodium dans l'alcool, le nucléophile attaque directement l'halogène en créant un carbanion dont la vitesse de formation détermine la vitesse de réaction (éq. [2]). Dans le diméthylsulfoxyde, le nucléophile attaque le solvant dont la base conjuguée constitue

[3] $C_2H_5ONa + CH_3—SO—CH_3 \rightarrow C_2H_5OH + {}^-CH_2—SO—CH_3, Na^+$

[4] 



alors le véritable agent réducteur (éqs [3] et [4]), ce qui justifie l'accroissement de vitesse observé. Un mécanisme analogue a été proposé pour la réduction de *gem*-dibromocyclopropanes (10). La protonation du carbanion pourrait être réalisée, soit par le solvant, soit à l'hydrolyse. Cette deuxième hypothèse doit être écartée. En effet, l'hydrolyse par l'eau lourde du mélange réactionnel provenant de l'action de l'éthylate de sodium dans le diméthylsulfoxyde sur l'aziridine **9***b*, conduit au produit de réduction **1***b* sans incorporation de deutérium en position 2. Le composé deutérié en 2 est, par contre, obtenu lorsque la réaction est effectuée dans le diméthylsulfoxyde deutérié, après hydrolyse par H_2O, ce qui prouve l'intervention du solvant lors de la protonation du carbanion.

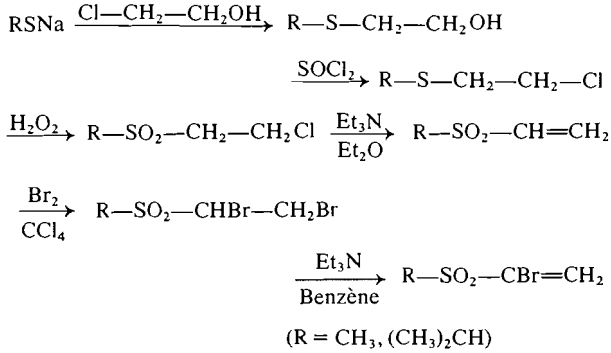
Partie expérimentale

Les spectres de résonance magnétique nucléaire ont été enregistrés à l'aide d'un appareil Varian A 60 ou Varian T 60 en utilisant le tétraméthylsilane comme référence interne; les déplacements chimiques sont exprimés en ppm et les constantes de couplage en hertz. Les spectres infrarouge ont été effectués sur un spectrophotomètre Perkin-Elmer 157. Les chromatographies sur colonne ont été réalisées sur gel de silice (7734 Merck).

*Synthèse des alkylsulfonyl-2 aziridines **4** et **5***

Préparation de la méthyl α-bromovinylsulfone et de l'isopropyl α-bromovinylsulfone

Le schéma réactionnel utilisé pour accéder à ces deux composés est le même, il est résumé ci-dessous:



(R = CH_3, $(CH_3)_2CH$)

(a) *(Hydroxy-2 éthyl)alkylsulfure*—Il est préparé selon un mode opératoire décrit (11).

(Hydroxy-2 éthyl)méthylsulfure: rdt 70%; pé 75°C/25 Torr; n_D^{20} 1.487 (lit. (14) pé 80.5–81°C/30 Torr; n_D^{30} 1.4867); ir: 3350 cm^{-1}; rmn: 3.72 (2H, t, J = 6 Hz), 3.48 (1H, s), 2.65 (2H, t, J = 6 Hz), 2.10 (3H, s).

(Hydroxy-2 éthyl)isopropylsulfure: rdt 83%; pé 88°C/25 Torr; n_D^{20} 1.466 (lit. (15) pé 82–83°C (12 Torr.); rmn: 3.70 (2H, t, J = 6 Hz), 2.6 à 2.9 (2H, m), 2.5 à 3.2 (1H, m), 2.75 (1H, s), 1.25 (6H, d).

(b) *(Chloro-2 éthyl)alkylsulfure*—Ce composé est préparé selon une méthode décrite (12).

(Chloro-2 éthyl)méthylsulfure: rdt 80%; pé 56°C/40 Torr; n_D^{20} 1.486 (lit. (14) pé 44°C/20 Torr; n_D^{20} 1.4902); rmn: 2.6 à 3.9 (4H, m), 2.18 (3H, s).

(Chloro-2 éthyl)isopropylsulfure: rdt 95%; pé 74–76°C/35 Torr; n_D^{20} 1.471 (lit. (16) pé 60–62°C/17 Torr); rmn: 3.5 à 3.8 (2H, m), 2.7 à 3.3 (3H, m), 1.28 (6H, d).

(c) *Alkylvinylsulfone*—L'alkyl(chloro-2 éthyl)sulfure est oxydé par l'eau oxygénée en milieu acétique, selon un mode opératoire connu (13). Il est utilisé brut pour la réaction suivante, également décrite (13).

Méthylvinylsulfone: rdt 60%; pé 78°C/1 Torr (lit. (13) pé 115–117°C/19 Torr); rmn: 6.1 à 7.2 (3H, m), 2.98 (3H, s).

Isopropylvinylsulfone: rdt 75%; $pé_{0.5}$ = 82°C; rmn: 6.1 à 6.7 (3H, m), 2.8 à 3.4 (1H, m), 1.82 (6H, d, J = 7 Hz). *Anal.* calc.: C 44.78, H 7.46, S 23.88; trouvée: C 44.50, H 7.42, S 24.01.

(d) *Dibromo-1,2 alkylsulfone*—Le mode opératoire utilisé a été précédemment décrit (1).

Dibromo-1,2 méthylsulfone: rdt 80%; pf = 70°C; rmn: 5.05 (1H, dd, J = 3.5 Hz, J = 8.5 Hz), 4.25 (1H, dd, J = 11.5 Hz, J = 3.5 Hz), 3.78 (1H, dd, J = 11.5 Hz, J = 8.5 Hz), 3.20 (3H, s).

Dibromo-1,2 isopropylsulfone: rdt 98%; rmn: 5.05 (1H, dd, J = 3.5 Hz, J = 10 Hz), 4.35 (1H, dd, J = 11.5 Hz, J = 3.5 Hz), 3.75 (1H, dd, J = 10 Hz, J = 11.5 Hz), 3.6 à 4.2 (1H, m), 1.42 (3H, d, J = 6.5 Hz), 1.45 (3H, d, J = 6.5 Hz).

(e) *(Bromo-1 vinyl)alkylsulfone*—Ce composé est préparé selon une méthode décrite (1).

Préparation des aziridines 4 et 5

Le mode opératoire utilisé a été précédemment décrit (1). On relève sur le spectre ir de chaque composé deux bandes, l'une à 1330 cm^{-1}, l'autre à 1150 cm^{-1}, caractéristiques de la fonction sulfone. Les rendements, constantes physiques, analyses et spectres de rmn des produits préparés sont donnés dans les Tableaux 1 et 2.

Chloration des sulfonyl-2 aziridines

Elle est réalisée selon une méthode mise au point par Meyers *et al.* (2).

On porte à reflux pendant une heure un mélange de 0.01 mol de sulfonylaziridine, 20 mL de CCl_4, 20 mL de *tert*-butanol et 11.2 g de potasse finement pulvérisée. Les solvants sont évaporés et on reprend par l'eau. Les sulfonylaziridines chlorées brutes sont filtrées ou extraites à l'éther, lavées à l'eau, séchées et recristallisées (benzène 3 – acétate d'éthyle 1). Leurs spectres ir présentent deux raies larges et intenses à 1160 et 1320 cm^{-1} caractéristiques de la fonction sulfone. Leurs rendements, points de fusion, analyses et spectres de rmn sont donnés dans les Tableaux 3 et 4.

Le produit brut de chloration de l'aziridine **5***b* d'une part, de l'aziridine **5***d* d'autre part, est purifié par chromatographie sur colonne (éther de pétrole 7 – acétate d'éthyle 3). Dans chaque cas, on isole en premier l'aziridine dichlorée, l'aziridine monochlorée est éluée ensuite.

Isopropyl-1 chloro-2 ((chloro-1 méthyl-1 éthyl)sulfonyl)-2 aziridine **13***b*: ir: 1120, 1340 cm^{-1}; rmn: 1.25 et 1.35 (6H, 2d, J = 7 Hz, $(CH_3)_2C$), 2.02 et 2.10 (6H, 2s, $(CH_3)_2C$), 1.90 (1H, s, proton du cycle), 2.95 (1H, s, proton du cycle), 2.60 (1H, m, N—CH). *Anal.* calc.: C 36.92, H 5.77, N 5.38, S 12.31; trouvée: C 37.01, H 5.72, N 5.41, S 12.27.

Benzyl-1 chloro-2 ((chloro-1 méthyl-1 éthyl)sulfonyl)-2 aziridine **13***d*: ir: 1150, 1320 cm^{-1}; rmn: 1.95 et 2 (7H, 2s, $(CH_3)_2C$ et un proton du cycle), 2.92 (1H, s, proton du cycle), 3.95 (2H, AB, J = 13.5 Hz, N—CH_2), 7.35 (5H, s, C_6H_5). *Anal.* calc.: C 46.75, H 4.87, N 4.55, S 10.39; trouvée: C 46.40, H 4.82, N 4.58, S 10.44.

Isopropyl-1 ((chloro-1 méthyl-1 éthyl)sulfonyl)-2 aziridine **12***b*: ir: 1120, 1150, 1180, 1320, 1335 cm^{-1}; rmn: 1.20 (3H, d, J = 6.5 Hz), 1.30 (3H, d, J = 6.5 Hz), 1.92 (3H, s), 2.02 (3H, s), 1.78 (1H, d, J = 6 Hz), 2.41 (1H, d, J = 2.8 Hz), 3.40 (1H, dd, J = 6 Hz et J = 2.8 Hz), 1.80 (1H, m). *Anal.* calc.: C 42.57, H 7.10, N 6.21, S 14.19; trouvée: C 42.68, H 7.08, N 6.23, S 14.30.

Benzyl-1 (chloro-1 méthyl-1 éthyl)sulfonyl-2 aziridine **12***d*: ir: 1120, 1330 cm^{-1}; rmn: 1.80 (3H, s), 1.86 (3H, s), 1.90 (1H, d, J = 6.2 Hz), 2.50 (1H, d, J = 2.8 Hz), 3.50 (1H, dd, J = 2.8 Hz, J = 6.2 Hz), 3.68 (2H, AB, J = 13 Hz), 7.4 (5H, s). *Anal.* calc.: C 52.65, H 5.85, N 5.12, S 11.70; trouvée: C 52.32, H 5.81, N 5.21, S 11.62.

Une solution de 4.4 mmol du composé **12***b* dans 50 mL de THF est agitée pendant 5 h à 0°C en présence de 13 mmol de *t*BuOK. On ajoute de l'eau, extrait à l'éther, lave le phase éthérée, sèche et évapore le solvant. Le résidu est d'après son spectre rmn constitué de la seule aziridine mise en réaction.

Un mélange de 4.4 mmol de l'aziridine **12***b*, 13 mmol de *t*BuOK et 50 mL de THF est chauffé à reflux sous agitation pendant 5 h. Après les traitements classiques, le spectre rmn de produit brut montre qu'il est constitué de 60% de l'aziridine mise en réaction et de 40% du dérivé **14***b*. Ces deux composés sont séparés par chromatographie sur colonne (éther de pétrole – acétate d'éthyle 30).

Isopropyl-1 (méthyl-1 vinyl)sulfonyl-2 aziridine **14***b*: ir: 1130, 1310, 1640 cm^{-1}; rmn: 1.15 (6H, d, J = 6 Hz), 1.75 (1H, d, J = 6 Hz), 2.20 (3H, s large), 2.45 (1H, d, J = 2 Hz), 2.80 (1H, dd, J = 2 Hz, J = 6 Hz), 5.80 (1H, s large), 6.15 (1H, s). *Anal.* calc.: C 50.79, H 7.94, N 7.41, S 16.93; trouvée: C 50.52, H 7.89, N 7.45, S 16.78.

Bromation des phénylsulfonyl-2 aziridines

Selon le mode opératoire décrit (2), on porte à reflux pendant une heure un mélange de 0.01 mol d'aziridine, 10 g de tétrabromure de carbone, 10 mL de *tert*-butanol, 15 mL de benzène et 11.2 g de potasse pulvérisée. Les solvants sont évaporés. On reprend le résidu à l'eau, extrait à l'éther, lave les extraits éthérés, sèche et évapore l'éther. Le résidu est purifié par chromatographie sur colonne. On sépare d'abord l'excès de CBr_4 (éluant: éther de pétrole) puis l'aziridine bromée (éluant: éther de pétrole 9 – acétate d'éthyle 1). Les aziridines bromées présentent en ir deux bandes larges et intenses à 1160 et 1320 cm^{-1}; leurs rendements, points de fusion, analyses et spectres de rmn sont donnés dans les Tableaux 3 et 4.

Thermolyse des halogéno-2 sulfonyl-2 aziridines

L'aziridine (0.01 mol) est portée à 60°C en tube scellé. Après un temps variable, le produit déliquescent obtenu est analysé par rmn. Les dérivés de thermolyse et le pourcentage de décomposition sont donnés dans le Tableau 5.

Le produit brut de thermolyse des composés **6***b* et **9***b* est chromatographié sur colonne. On sépare ainsi:

Le benzènethiosulfonate de phényle: eluant: éther de pétrole 9 – acétate d'éthyle 1; pf 44°C (lit. (18) pf 42–44°C); ir: 1150 et 1320 cm^{-1}; rmn: 7.2 à 7.6 (m). *Anal.* calc.: C 57.60, H 4.00, O 12.80, S 25.60; trouvée: C 57.72, H 3.94, O 12.75, S 25.56.

Le *N*-isopropyl α-halogénoacétamide: eluant: éther de pétrole 7 – acétate d'éthyle 3: *N*-isopropyl α-chloroacétamide: pf 60°C (lit. (19) pf 62–62.5°C); rmn: 1.20 (6H, d, J = 6.5 Hz), 4.0 (2H, s), 4.10 (1H, m). *N*-isopropyl α-bromoacétamide: pf 70°C (lit. (20) pf 66–67°C); ir: 3300, 1660 cm^{-1}; rmn: 1.20 (6H, d, J = 7 Hz), 3.85 (2H, s), 4.05 (1H, m).

Thermolyse avec apport d'eau

L'halogénoaziridine (0.01 mol) est portée à 60°C en tube scellé avec 0.10 mol d'eau. Après 6 jours de chauffage pour **6***b*, 4 jours pour **9***b*, on reprend au chlorure de méthylène, décante, sèche et évapore le solvant. Par chromatographie sur colonne on sépare, à côté des composés précédemment décrits, le *N*-isopropyl α-phénylsulfonylacétamide (éluant: éther de pétrole 2 – acétate d'éthyle 8): ir: 1160, 1360, 1700 cm^{-1}; rmn: 1.15 (6H, d, J = 6.5 Hz), 4.05 (1H, s), 3.7 à 4.3 (1H, m), 7.5 à 8.1 (5H, m), 6.7 (1H, pic large). *Anal.* calc.: C 54.77, H 6.22, N 5.81, O 19.92, S 13.28; trouvée: C 54.93, H 6.18, N 6.04, O 19.75, S 13.24.

Synthèse du N-*isopropyl α-phenylsulfonylacétamide*

Une solution de 1.35 g (0.01 mol) de *N*-isopropyl α-chloroacétamide dans 10 mL d'alcool est ajoutée à 1.64 g (0.01 mol) de benzènesulfinate de sodium dans 20 mL d'alcool. Le mélange est porté à reflux pendant 4 h. La solution est évaporée, reprise par le chlorure de méthylène, lavée à l'eau et séchée. Après évaporation du solvant, l'amide cristallise; pf 118°C.

Décomposition des aziridines dichlorées ***13***b *et* ***13***d

Les aziridines **13***b* et **13***d*, abandonnées quelques jours à température ambiante, se décomposent. Par chromatographie sur colonne (éther de pétrole 70 – acétate d'éthyle 30), on sépare le chloro-1 méthyl-1 éthylthiosulfonate de chloro-1 méthyl-1 éthyle et le *N*-alkyl α-chloroacétamide.

Chloro-1 méthyl-1 éthylthiosulfonate de chloro-1 méthyl-1 éthyle: rmn: 1.75 (s). *Anal.* calc.: C 28.69, H 4.78, S 25.50; trouvée: C 28.50, H 4.72, S 25.65.

N-Benzyl-α-chloroacétamide: pf 92–93°C (lit. (21) pf 93–93.6°C); ir: 1700 (C=O); rmn: 7.4 (5H, s), 4.50 (2H, s), 4.20 (2H, s).

Hydrolyse acide

On chauffe à reflux pendant 1 h 0.01 mol d'aziridine dans 34 mL d'acide chlorhydrique 2*N* en solution hydroalcoolique. On évapore l'alcool et le résidu, après extraction au chlorure de méthylène, est chromatographié sur colonne. On sépare d'abord le benzènethiosulfonate de phényle déjà décrit (éluant: éther de pétrole 9 – acétate d'éthyle 1). On obtient ensuite, à partir de l'aziridine **6***c*, le *N-tert*-butyl α-chloroacétamide (éther de pétrole 7 – acétate d'éthyle 3); pf 80°C (lit. (19) pf 82–83°C); rmn: 1.40 (10H, s, $C(CH_3)_3$ et N—H), 3.95 (2H, s large).

A partir de l'aziridine **10***b*, on obtient un mélange de 55% de *N*-isopropyl α-chloropropionamide et 45% de *N*-isopropyl α-bromopropionamide (éther de pétrole 7 – acétate d'éthyle 3); rmn: 6.50 (1H, pic large), 4.40 (1H, q, J = 7 Hz), 3.70 à 4.40 (1H, m), 1.85 (0.45H, d, J = 7 Hz), 1.70 (0.55H, d, J = 7 Hz), 1.18 (6H, d, J = 6.8 Hz).

Action des nucléophiles

A une solution de 0.01 mol d'aziridine dans 50 mL de solvant, on ajoute 0.05 mol de réactif nucléophile. Les temps et températures de réaction sont indiqués dans le Tableau 6. On ajoute 200 mL d'eau et extrait à l'éther. Après évaporation du solvant, le produit brut est analysé en rmn.

The photolysis of acetonitrile solutions of *N*-bromosuccinimide (NBS) in the presence of ethylene oxide and an excess of olefins or benzene in the $-30 \sim 20°C$ range was shown to generate the succinimidyl radical in competition with the bromine atom reactions. The succinimidyl radical preferentially attacked a π bond to give 1-succinimidyl-2-bromoalkanes, rather than abstracting alkyl hydrogens. Allylic bromination also occurred and competed with the 1,2-addition. Formation of 3-bromocyclohexene in the presence of cyclohexene at 10–20°C could be effectively reduced at lower temperatures or in the presence of a high concentration of ethylene oxide; the 1,2-addition process was favored at low temperature but surprisingly not facilitated significantly in the presence of ethylene oxide. The primary adducts from benzene readily eliminate HBr to give *N*-phenylsuccinimide. The attack of a bromine atom on a carbon–carbon double bond may become an important step in the $0 \sim -30°C$ range. The ease of the addition reaction suggests that this succinimidyl radical may have a Σ electronic configuration.

FU-LUNG LU, YOUSRY M. A. NAGUIB, MASAYUKI KITADANI et YUAN L. CHOW. Can. J. Chem. **57**, 1967 (1979).

On a montré que la photolyse de solutions de *N*-bromosuccinimide (NBS) dans l'acétonitrile en présence d'oxyde d'éthylène et d'oléfines en excès ou de benzène à des températures allant de -30 à $+20°$ donne lieu à la formation de radicaux succinimidyles en compétition avec les réactions des atomes de brome. Le radical succinimidyle attaque de préférence une liaison π pour conduire à des succinimidyl-1 bromo-2 alcanes plutôt que d'arracher les hydrogènes des groupes alkyles. La bromation allylique se produit aussi et elle est en compétition avec l'addition-1,2. On peut réduire d'une façon efficace la formation du bromo-3 cyclohexène en présence de cyclohexène à 10–20°C en abaissant la température ou en présence de concentrations élevées d'oxyde d'éthylène; la réaction d'addition-1,2 est favorisée à basse température mais elle n'est toutefois pas rendue beaucoup plus facile en présence d'oxyde d'éthylène. Les adduits primaires avec le benzène éliminent facilement du HBr et donnent lieu à la *N*-phénylsuccinimide. L'attaque d'un atome de brome sur la liaison double carbone–carbone peut devenir une étape importante à des températures de 0 à $-30°C$. La facilité avec laquelle le radical succinimidyle s'additionne suggère qu'il peut avoir une configuration électronique Σ.

[Traduit par le journal]

Introduction

Ziegler *et al* (1) have demonstrated that the decomposition of *N*-bromosuccinimide (NBS) in the presence of olefins selectively brominates allylic positions under the appropriate conditions, i.e., thermolysis and (or) photolysis of NBS in boiling carbon tetrachloride. This allylic bromination has been shown to occur by a radical chain mechanism (2–7) and has been extensively utilized in synthesis primarily because of its simplicity and good yield (2–5). The original Ziegler reaction conditions have been used for allylic bromination without much modification until recently, when it was recognized that conditions affect the NBS decomposition pathways significantly (11–14). Interest in this allylic bromination was heightened when the bromine radical chain mechanism proposed earlier by Goldfinger and co-workers (9) was confirmed in 1963 (8); a straightforward succinimidyl radical chain mechanism proposed by Bloomfield (10) was shown to be not operating *at least under Ziegler's conditions* (11).

The Goldfinger Mechanism

[1] $Br_2 \overset{\Delta \text{ or } h\nu}{\rightleftharpoons} 2Br^{\bullet}$

[2] $CH_2{=}CHCH_2{-} + Br^{\bullet} \rightleftharpoons CH_2{=}C\dot{H}CH{-} + HBr$

[3] $(CH_2CO)_2NBr + HBr \rightarrow (CH_2CO)_2NH + Br_2$

[4] $CH_2{=}C\dot{H}CH{-} + Br_2 \rightarrow CH_2{=}CHCHBr{-} + Br^{\bullet}$

[1]Some of these results have been presented at the 52nd annual meeting of the Chemical Institute of Canada at Winnipeg; June 4–7, 1978. A communication of this work submitted to the Journal of American Chemical Society in September 28, 1977 was not accepted.

[2]Revision received January 25, 1979.

The Bloomfield Mechanism

$$[5]\quad (CH_2CO)_2NBr \xrightarrow{\Delta \text{ or } h\nu} (CH_2CO)N^{\cdot} + Br^{\cdot}$$

$$[6]\quad (CH_2CO)_2N^{\cdot} + CH_2{=}CHCH_2{-} \rightarrow (CH_2CO)_2NH + CH_2{=}C\dot{H}CH{-}$$

$$[7]\quad CH_2{=}C\dot{H}CH{-} + (CH_2CO)_2NBr \rightarrow CH_2{=}CHCHBr{-} + (CH_2CO)_2N^{\cdot}$$

$$[8]\quad Br^{\cdot} + {-}CH{=}CHCH_2 \rightleftharpoons {-}CHBr\dot{C}HCH_2{-}$$

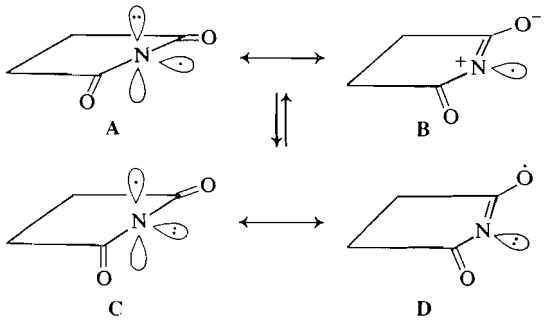
There have been numerous contributions to our knowledge of the mechanism of the NBS decomposition; these have been summarized in a review by Thaler (6). The major credit should go to Goldfinger who has suggested that NBS reacts rapidly with HBr to generate a low concentration of bromine, i.e., a concentration high enough to maintain the propagation step [4] but low enough to avoid ionic addition to olefins as an integral part of the chain processes; in other words, NBS serves as a reservoir of bromine. This proposal has been nicely substantiated recently (8*a*, 11).

In recent years, decompositions of NBS have been studied in bromination reactions of less active substrates (e.g., haloalkanes and alkanes) under a variety of conditions (e.g., uses of methylene chloride or acetonitrile as solvent to effect a homogenous reaction) much different from Ziegler's heterogeneous conditions (11–15). These studies that related to controversies over the anchimeric assistance of a neighboring bromine atom (12–15) led to the discovery that product patterns obtained in the comparative bromination of these alkanes with bromine and with NBS under homogeneous conditions are different (12, 13). This has led to the recognition of the succinimidyl radical as the possible chain carrier in the NBS decomposition (12, 13).

Although esr studies have not succeeded in identifying the succinimidyl radical directly, its presence in NBS decompositions has been indicated in the formation of β-bromopropionyl isocyanate (16) and in the esr determination of the stable nitroxide resulting from 2-nitroso-2-methyl-propane trapping (17). Oxidation of 1-phenylethanol in the decomposition of *N*-iodosuccinimide has been claimed to involve the succinimidyl radical as the chain carrier (18). It is noteworthy that the decomposition of NBS in the presence of benzyl ethers has been reported to give α-succinimidyl benzyl ethers (19); these results offer a new facet to the mechanism of NBS decomposition.

Theoretical calculations by simple molecular orbital theory carried out by Hedaya *et al.* (20) suggested that a succinimidyl radical may have Σ electronic configuration in the ground state, as in **A**, because of the electronegativity of the acyl groups attached to the nitrogen radical center; they have also predicted that a Σ radical should be more reactive and less selective. This prediction seems to be borne out by the recent works of Traynham and Lee (13) and Skell and co-workers (12) who have concluded that the succinimidyl radical is as reactive and unselective as the chlorine atom. Recent INDO calculations have shown that the ground state of the succinimidyl radical may have a Π (or Σ_0) configuration, as in **C**, and that the Σ_N configuration **A** (excited state) correlates with the electronic ground state of the acyl isocyanate radical in the β-scission (21).

Our interests in radical species at amino centers have led us to recognize the peculiar reactivities of these radicals. In particular, the aminyl (22, 23) and *N*-alkylamidyl (RCONR) (24, 25) radicals exclusively abstract allylic hydrogen atoms from olefins, while aminium radicals exclusively add to carbon–carbon double bonds (23, 26). In general, it may be expected that amine centered radicals with electron deficiency preferentially add to olefins (25). This expectation has been supported by Lessard and co-workers (27, 28) who have demonstrated that halogen substituted amidyl radicals ($XCH_2CO\dot{N}H$) add more efficiently as both the electronegativity and number of halogen atoms X increase. As the nitrogen center of the succinimidyl radical carries two electron-withdrawing acyl groups which could enter into delocalization with the lone pair electrons if it has Σ configuration as in **B**, one might expect the succinimidyl radical to have electrophilic character.



There is scattered evidence that the decomposition of NBS in the presence of olefins does give rise to addition products, although in poor yields (29–34); in some cases the adducts have been implied to arise by ionic addition pathways because of the observed orientations (32–34). However, others may have involved a direct attack of succinimidyl radical on the double bonds, particularly if substrates carry *unreactive hydrogens* (1, 29–32), e.g., $CH_2{=}CH_2$-

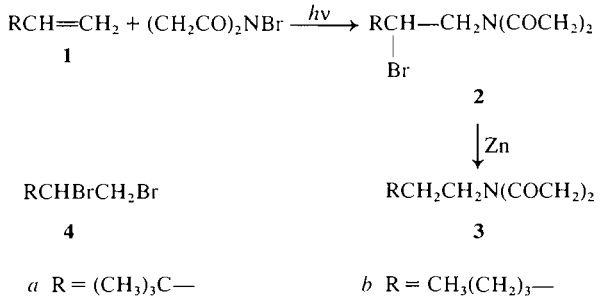
CH_2CN. These considerations have led us to reinvestigate the decomposition of NBS hoping to shed some light on the generation and reactivity of the succinimidyl radical. Recent communications by Skell and co-workers (35) on the addition of NBS to olefins and aromatic compounds when decomposed in the presence of these substrates prompts us to publish our results.

The complexity of the reaction pattern of NBS in the presence of an olefin has been discussed in detail by Thaler (6). Some of the complications arise from a reversible bromine atom addition to olefins as in reaction [8], the reversibility of reaction [2], and the instability of some allylic bromides. A general strategy of generating the succinimidyl radical would be to suppress the bromine atom chain mechanism (reactions [2]–[4]) so that NBS decomposition and propagation involving NBS as in reactions [5] and [7] can be encouraged. In practice, the $HBr–Br_2$ cycle has to be efficiently interrupted, and direct or indirect succinimidyl radical generation as in reactions [5] and [7] has to be accelerated. Our plan was to use ethylene oxide to scavenge HBr, and a high concentration of an olefin to scavenge molecular bromine (11); the latter was also the substrate in the present scheme. Epoxides have been used to scavenge HBr in bromination of ketones and aralkanes (36, 37). Acetonitrile was the choice as the solvent owing to its small tendency to donate hydrogen to electrophilic radicals and its reasonably good solubilizing power for NBS (15).

Results

In acetonitrile NBS exhibits an absorption maximum (shoulder) at 245 nm (ε 317) which tails above the 300 nm region (ε_{300} 13). This allowed us to carry out the decomposition of NBS by photolysis in a Pyrex apparatus with temperature controls. However, since there were no reliable kinetic data on reactions [1]–[8], an a priori prediction of temperature effects on the reaction pattern was not possible. Acetonitrile solution containing NBS (0.047 *M*) and ethylene oxide (0.35 *M*) reacted instantaneously at −10°C with HBr to show a pale yellow color and a weak absorption of bromine at 405 nm. A good amount of ethylene bromohydrin was also obtained from this reaction, indicating that HBr reacted rapidly with both substrates. Qualitatively, it was shown that HBr reacted with ethylene oxide with the order of decreasing efficiency in acetonitrile > methylene chloride > benzene ≈ carbon tetrachloride.

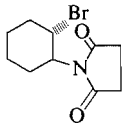
Photolysis of NBS in acetonitrile in the presence of 3,3-dimethyl-1-butene (neohexene, **1***a*) and ethylene oxide under nitrogen was carried out in a Pyrex apparatus immersed in a cooling bath. Generally the concentration of NBS was 0.016–0.02 *M* and the molar ratio of NBS, olefins, and the oxide was 1:10:8. The reaction mixture was vigorously stirred with a magnetic stirrer and its progress was monitored with potassium iodide – starch paper test and (or) iodimetry. For each experiment, a dark reaction was run simultaneously to confirm that thermal reactions occurred to only a small extent (<5%) or not at all. The photolysate was evaporated to give a crude product which, in this case, exhibited a clean nmr spectrum essentially similar to that of 1-succinimidyl-2-bromo-3,3-dimethylbutane (**2***a*, 85% yield by vpc). The gc–ms analysis of the crude product showed that it contained trace amounts of four minor products; the minor components had no succinimido moiety (no peak at *m/e* 100) and were not likely to be $BrCH_2C(CH_3)_2CH{=}CH_2$. Recrystallization of the crude product afforded **2***a* in a 65% yield which showed physical constants and analysis in agreement with an addition product. Reduction of **2***a* with zinc powder and sodium iodide gave **3***a*. The nmr spectrum of the latter exhibited, in addition to two singlets, symmetrical multiplets of type A_2B_2 at τ 8.54 and 6.48; the latter chemical shift is commonly found for a methylene attached to a succinimido group.



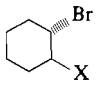
Under similar photolysis conditions, the photodecomposition of NBS in the presence of 1-hexene (**1***b*) gave a 60% yield of 1-succinimidyl-2-bromohexane (**2***b*) and a small amount of 1,2-dibromohexane (**4***b*). Reduction of **2***b* with zinc powder and sodium iodide gave *N*-hexylsuccinimide (**3***b*) synthesised from hexylamine and succinic anhydride (38). Both photoadditions indicated that the succinimido group attached itself to the less substituted carbon, and the bromine to the more substituted carbon of the double bond.

The photoaddition of NBS to cyclohexene under similar conditions gave complex product patterns (as shown by vpc analysis) which varied noticeably with a slight change of the conditions. The crude product showed an ir absorption at 2260 cm^{-1} typical of an isocyanate group and gave reproducible vpc analyses.

The photodecomposition of NBS at $-10°C$ gave the *trans*-1-bromo-2-succinimidylcyclohexane (**5**, ca. 30%) as the major product in addition to *trans*-1,2-dibromocyclohexane (**6**), *trans*-1-bromo-2(2′-bromoethoxy)cyclohexane (**7**), and 3-bromocyclohexene (**8**). By vpc analysis, several components in lesser amounts were detected, two of which were shown by gc–ms analysis and comparison with authentic mass spectra to be 2-cyclohexenol and 2-cyclohexenone. Varying amounts of succinimide were also isolated. By careful chromatography, a small amount of what appeared to be a mixture of 1- and 3-succinimidylcyclohexene was also isolated in the tail fractions; the postulate was based on the presence of succinimidyl and cyclohexene moieties in the fraction as judged from nmr, ir, and mass spectra.



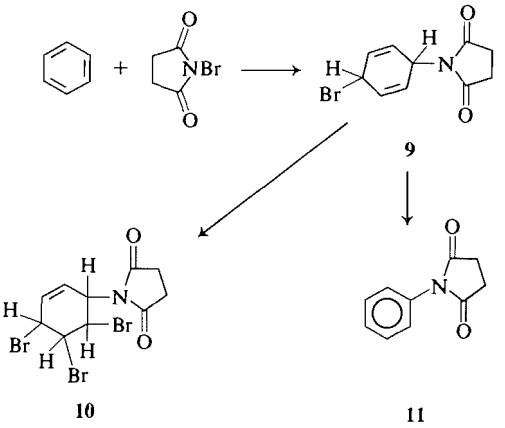
5



6 X = Br
7 X = OCH_2CH_2Br

Both **6** and **7** were prepared by the addition of bromine to cyclohexene in the presence of ethylene oxide. Adduct **5** showed ir absorptions at 1770, 1700, and 1170 cm^{-1} and a strong *m/e* peak at 100 (for $C_4H_6NO_2^+$) common to compounds containing a succinimido moiety. Zinc powder reduction of **5** gave the known *N*-cyclohexylsuccinimide independently synthesised by another route (38). The *trans* configuration in **5**, **6**, and **7** was decided by typical doublets of a triplet arising from the diaxial orientation of the 1,2-protons. A similar photolysis at $-20°C$ gave a lighter colored crude product and a better yield of adduct **5** (38%).

Photolysis of NBS in benzene in the presence of ethylene oxide was run in a similar manner at 10°C to give an isomeric mixture of **10** as the major product and a small amount of *N*-phenylsuccinimide. The isomeric mixture (40% yield) could not be separated by chromatography; these chromatographic fractions showed similar mass spectral patterns but drastically different nmr patterns, and gave good analyses for $C_{10}H_{10}Br_3NO_2$ arising from the addition of NBS and Br_2 to benzene. These fractions contained structural and stereochemical isomers of **10**. By extensive chromatography and recrystallization, small amounts of pure isomers having mp 204–207°C and mp 153–157°C were isolated; the complexity of their nmr spectra did not permit determination of structures. The structure of **11** was readily decided by direct comparison with an authentic sample prepared by the reaction of succinic anhydride and aniline. It was assumed that



9

10 **11**

both **10** and **11** were formed from the primary adducts, such as **9** or its isomer, by bromine addition and HBr elimination, respectively.

The photolysis of NBS in acetonitrile containing benzene and ethylene oxide was carried out with a 450 W Hanovia lamp through a Corex filter in the presence of neohexene (neohexene–benzene, ca. 1/15) to scavenge bromine. In this case the reaction was very rapid and a good yield of **11** (54%) was obtained. In cases where the ratio of neohexene to benzene was higher, small amounts of adduct **2***a* were also formed but the ir absorption at 2260 cm^{-1} was not present in the crude products. When a lamp with less power or a Pyrex filter was used, the time for completion of the NBS decomposition was longer and the yields of **11** were much lower. Vapor phase chromatographic analysis indicated that a considerable amount of succinimide was formed and the yields of dibromide **4***a* were at least as much as those of **11** and that no other peak, such as that of bromobenzene, was present in the spectra.

In view of the extensive formation of bromine, as witnessed by the isolation of **10**, in spite of the presence of ethylene oxide, photolysis of bromine in the presence of ethylene oxide and NBS in benzene was examined using a filter to cut off the light source below 334 nm. NBS decreased slowly owing partially to the interference from the precipitated succinimide, but no reaction of NBS and bromine was observed in the dark. From the photolysate, in addition to a nearly quantitative yield of succinimide, a large amount of a mixture of polybrominated benzene derivatives was obtained without a trace of benzene derivatives containing the succinimido moiety. Photobromination of benzene has been reported to yield hexabromocyclohexane slowly through the bromine radical addition (39, 40).

More detailed studies on the NBS decomposition in the presence of cyclohexene were carried out in order to explore the effects of changes in the con-

TABLE 1. Product patterns of NBS decompositions in the presence of cyclohexene and ethylene oxide in acetonitrile[a]

[a]Unless specified otherwise, solutions of 0.0113 mol of NBS in 240 mL of acetonitrile were photolysed with a 100 W Hanovia lamp in a Pyrex apparatus and the mole ratio of NBS:cyclohexene:ethylene oxide was 1:10:8.
[b]The % yields were based on NBS. 8 is 3-bromocyclohexene.
[c]No ethylene oxide added.
[d]Air leaked in inadvertently.
[e]The mole ratio of NBS:cyclohexene:ethylene oxide was 1:10:20.
[f]Photolysed with a 450 W Hanovia lamp in Corex filter.

ditions. For this purpose a series of photolyses in acetonitrile was carried out at various temperatures under a set of standardized conditions, e.g., apparatus, reagents, and procedures of operation and vpc analyses, as described in the Experimental. The vpc peaks of **5–8** did not change significantly (e.g., ±1%) within experimental error, but the peak of succinimide was partially superimposed on an unknown peak which increased with time; the percentage yields of succinimide were therefore less reliable (Table 1). As the temperature decreased from 20 to −30°C, the yields of adduct **5** increased and those of 3-bromocyclohexene (**8**) decreased but the yields of ionic products **6** and **7** remained substantial regardless of the conditions. Ethylene oxide had no effects on the yield of **5** but at higher concentrations it almost suppressed the formation of **8**. The presence of trace amounts of air caused erratic changes in the yields as well as photolysis times. The material balance based on the bromine was better than 90% except for a few cases which were at the 70% range. The material balance based on the succinimidyl moiety (30–80%) was better at higher concentrations of ethylene oxide and increased as the temperature was lowered. The time required for complete photolysis increased as the temperature was lowered, but particularly sharply in the range −10 to −30°C.

Photodecomposition of NBS in the presence of ethylene oxide alone in acetonitrile was shown to induce the formation of bromine, the light yellow color of which persisted even when all the NBS was decomposed. Under these conditions, ethylene bromohydrin, succinimide, and β-bromopropionamide were identified as the major products in addition to a small amount of bromoacetaldehyde and many other minor components.

Discussion

Both the failure of the dark reaction and the orientation of the NBS addition to neohexene and 1-hexene as found in **2** are straightforward indications that the succinimidyl radical has been generated in the photolysis and initiates the attack on the π-bond followed by attack of bromine atom donors as in reactions [9] and [10]. In the photolysis, radical halogenation processes probably involving allylic hydrogen abstraction also occur in competition with the 1,2-radical addition. Indeed the yields of 1,2-addition, **2** and **5**, at 0° to −10°C increase as the number of allylic hydrogens decrease as in cyclohexene < 1-hexene < neohexene; substantial amounts of 3-bromocyclohexene **8** under the comparable conditions might indicate relatively facile allylic hydrogen abstraction from cyclohexene. As shown in Table 1, the 1,2-addition product **5** increases and **8** decreases as the temperature is lowered. Such temperature effects have been observed by Touchard and Lessard (27) in the photochemical reaction of *N*-bromoacetamides with cyclohexene. The succinimidyl radical also attacks benzene efficiently under the photolysis conditions to give the 1,4-adduct **9** (or 1,2-adduct) as the primary product.

[9] $CH_2{=}CHCH_2{-} + (CH_2CO)_2N^{\cdot} \rightarrow (CH_2CO)_2NCH_2\dot{C}HCH_2{-}$

[10] $(CH_2CO)_2NCH_2\dot{C}HCH_2{-} + (CH_2CO)_2NBr(\text{or } B\dot{r}) \rightarrow (CH_2CO)_2NCH_2CHBrCH_2{-} + (CH_2CO)_2N^{\cdot}$

Judging from the excellent yield of adduct **2***a*, the abstraction of hydrogens by the succinimidyl radical from the *tertiary* butyl group does not compete to any significant extent with its addition to the π-bond of neohexene in spite of the conclusion reached by Traynham and Lee (13) and Skell and co-workers (12) that the succinimidyl radical is a voracious (and indiscriminate) hydrogen abstractor. In view of the complex product patterns observed in the detailed studies in the presence of cyclohexene, 3-bromocyclohexene **8** might be formed by both bromine and succinimidyl radical processes. While the strongly reactive succinimidyl radical (12, 13) requires only low activation energies in hydrogen abstraction or addition, the bromine atom, being a moderate (and selective) hydrogen abstractor needs a relatively higher energy (13). This implies that hydrogen abstraction by a bromine atom (reaction [2]) is retarded more than the succinimidyl radical reactions [6] and [9]) as the temperature is lowered. Therefore at −30°C succinimidyl radical reactions should be the major pathways in which addition reaction [6] occurs overwhelmingly over abstraction reaction [9]. Since the mode of the succinimidyl radical reactions is not expected to change significantly over a small temperature range, the increased yields of **8** in the −10–20°C range are most likely derived from the operation of bromine radical reaction [2]. An extrapolation of this trend (experiments 2–7) predicts that this process would probably operate more extensively at temperatures higher than 20°C; this may explain the lack of the formation of **5** in a similar experiment (in the absence of ethylene oxide) communicated by Skell and co-workers (12). However, it must be noted that at 20°C, even in the absence of ethylene oxide, a reasonable amount of adduct **5** can be formed (experiment 1) indicating that the presence of ethylene oxide is advantageous but not very effective in promoting the succinimidyl radical addition.

Epoxides have been known to scavenge HBr efficiently in the photobromination of ketones in carbon tetrachloride (36). In the present cases, ethylene oxide in polar solvents such as acetonitrile appears to scavenge HBr efficiently as shown by the formation of ethylene bromohydrin. Unfortunately, as shown in Table 1, it surprisingly exerts no effect on the yield of the 1,2-addition process but appears to retard the halogenation process only if the ethylene oxide/NBS molar ratio is of the order of 20:1. Its effects on the NBS decomposition are probably much more complex than expected as shown by the unpredictable variations of the yields of **6** and **7** as the concentrations of ethylene oxide increase (experiments 1, 2, and 10).

The uneven variation of the yields of dibromide **6** in contrast to the monotonic change of those of **7** might suggest that **6** is formed by dual pathways of ionic addition as well as bromine radical addition, while **7** is formed by the single ionic pathway. The reversibility of reaction [8] has been suggested independently by generation of β-bromocarbon radicals which preferentially undergo elimination with a small activation energy (~5 kcal/mol) (41). At −30°C, reaction [8] may not revert efficiently and constitutes the major pathway for formation of **6**. At temperatures higher than 20°C, reaction [8] reverts efficiently as demonstrated (41) and regenerates the bromine atoms for allylic bromination by Goldfinger's mechanism (9).

The persistent formation of the bromination products **6** and **7** under various conditions in spite of fairly efficient scavenging of HBr by ethylene oxide leads us to suspect there might be another pathway for bromine formation since the bromine generated by reaction [3] is expected to be a relatively minor amount under the conditions. Skell and co-workers (35) have recently suggested that reaction [11] occurs

$$[11]\quad (CH_2CO)_2NBr + Br^{\cdot} \rightarrow (CH_2CO)_2N^{\cdot} + Br_2$$

in the NBS photodecomposition in neopentane and methylene chloride, both of which are unreactive substrates. Further, they have proposed that the succinimidyl radical generated in reaction [11] is a Π-radical, different from that generated in reactions [5], [7], and [10] (a Σ radical). The formation of bromine from NBS by a radical pathway is hinted from two experiments: (*i*) photolysis of NBS in acetonitrile with ethylene oxide in the absence of an olefin to scavenge radicals efficiently and (*ii*) photolysis of bromine in the presence of NBS in benzene in which only bromination of benzene by a radical pathway can occur slowly (39, 40). Although the complexity of the reaction pattern does not allow us to pin-point the reaction for the bromine formation, reaction [11] is a straightforward possibility provided the failure of the succinimidyl radical reaction with benzene can be satisfactorily explained. However, possible mechanisms other than reaction [11] and, indeed, other pathways to account for the decomposition of NBS, cannot be excluded at this stage.

The overwhelming addition reactivity of the succinimidyl radical generated from reactions [5], [7], and [10] to olefinic and benzene π-bonds suggests that this radical is highly electrophilic and, in turn, hints that it has the Σ rather than the Π electronic configuration. It is known that a carbon radical having the unpaired electron in an sp^2 orbital is generally more electrophilic than that in

a p or sp^3 orbital (42). In analogy to this general correlation and also owing to a polar resonance contribution as in **B**, the Σ electronic configuration of the succinimidyl radical is expected to be more electrophilic than its Π electronic configuration. In view of some theoretical calculations (21) assigning the Σ configuration to a higher energy (excited) state species, it would be a challenge to identify Σ as well as Π radicals and to correlate their electronic configurations with their reactivities by quantitative means.

The addition of NBS to benzene has been observed previously (43) in a decomposition using benzene as the solvent. The comparable yields of **11** obtained under present conditions (54%) and by Skell and co-workers (45%) in the absence of ethylene oxide (35) seem to indicate, in agreement with the above conclusion, that ethylene oxide has very limited influence on the generation of the succinimidyl radical. The surprisingly good yield of tribromo adducts **10** (40%) in benzene in the presence of ethylene oxide might also be taken as an indication that bromine is formed by alternative pathways such as reaction [11]. The coupling products of the cyclohexadienyl radical, such as those obtained in homolytic additions of phenyl radicals to arenes (42), have not been isolated, probably owing to a rapid reaction of this radical with bromine donors to give **9** (or the 1,2-isomer).

It is expected that not only the *trans*-adduct **5** but also the corresponding *cis*-adduct is formed in the NBS photoaddition to cyclohexene as is generally observed in radical addition to cyclohexene (26). The probable presence of a mixture of 1- and 3-succinimidylcyclohexene suggests that these compounds might be formed by dehydrobromination of the *cis*-adduct during work-up since in this compound the C—Br bond can readily take the *axial* orientation favorable to *anti*-elimination. In conclusion, we can say that the photodecomposition of NBS in the presence of olefins and benzene containing no allylic hydrogen occurs by the succinimidyl radical addition to give straightforward addition products, but that in the presence of olefins containing readily abstractable allylic hydrogen it is complicated by various side reactions involving the bromine atom and bromine.

Experimental

Unless otherwise specified, the following conditions are used. Nuclear magnetic resonance spectra were recorded with a Varian A56/60 or XL-100 equipped with a Nicolet 1080 computer in $CDCl_3$ using TMS as the internal standard. Infrared spectra were recorded as Nujol mulls or neat liquids with a Perkin Elmer model 457 grating spectrophotometer and mass spectra with a Hitachi–Perkin-Elmer RMU-6E instrument at 80 eV. Melting points were recorded with a Fisher Johns hot stage and are uncorrected. The vpc analyses were carried out with a Varian Aerograph series 1200 with a flame ionization detector. Elemental analyses were performed by Mr. M. K. Yang, Department of Biosciences, Simon Fraser University, using a Perkin Elmer 240 microanalyser. Nitrogen was scrubbed through a Fieser solution, followed by concentrated sulfuric acid and potassium hydroxide pellets. *N*-Bromosuccinimide was recrystallized from water to give white crystals, mp 181–183°C, and was kept in a dark desiccator.

Preparations of Authentic Compounds

N-phenylsuccinimide (**11**), *N*-cyclohexylsuccinimide, and *N*-hexylsuccinimide **3***b* were prepared by the method described by Cava *et al.* (38) using succinic anhydride and the respective amines as the reactants. **11** was recrystallized from cyclohexane to give white needles; mp 154–155°C (lit. mp (43) 155.2–155.7°C); ir: 1780(w), 1710(s), 1595(w), 1500(w), 1445(m), 1395(m), 1190(s), 700(m), and 600(m) cm^{-1}; nmr τ: 2.65 (m, 5H) and 7.15 (s, 4H); ^{13}C nmr 175.9(s), 131.6(s), 128.7(d), 128.1(d), 126.1(d) and 27.9(t); ms *m/e* (%): 175(100), 120(34), 119(45), and 93(28).

N-Cyclohexylsuccinimide was sublimed to give crystals; mp 44.5–46°C (lit. (44) mp 41–42°C); ir: 1765(m), 1690(s, b), 1399(s), 1378(s), 1190(s) cm^{-1}; nmr τ: 6.03 (tt, J = 12 and 4 Hz, 1H), 7.35 (s, 4H), 7.7–8.8 (m, 10H); ^{13}C nmr: 176.6(s), 51.2(d), 28.3(t), 27.7(t), 25.5(t), 24.6(t); ms *m/e* (%): 181 (2.5, M^+), 138(10), 101(20), 100(100), and 55(28). **3***b* was distilled as an oil; ir: 1770(m), 1700(s), 1400(m), 1172(m), 1130 and 825(m) cm^{-1}; nmr τ: 6.50 (t, J = 7 Hz, 2H), 7.32 (s, 4H), ~8.7(m) and 9.11 (t, J = 5.5 Hz, 3H); ^{13}C nmr 177.0(s), 38.6(t), 31.0(t), 27.9(t), 27.4(t), 26.2(t), 22.2(t), and 13.7(q) ppm; ms *m/e* (%): 183 (54, M^+), 168(9), 140(14), 113(80), 100(100), and 84(35).

Addition of bromine to neohexene gave a colorless 1,2-dibromo-3,3-dimethylbutane (**4***b*) which darkens on storage. The distilled oil showed ir: 1380(s), 1320(m), 1260(m), 1230(m), 900(m), and 875(m) cm^{-1}; nmr τ: 5.90 (m, 2H), 6.45 (dd, J = 11 and 9.5 Hz, 1H), 8.85 (s, 9H); ms *m/e* (%): 246(0.2), 244(0.6), 242(0.3), 231(1.8), 229(3.4), 227(1.8), 165(29), 163(31), 147(9.3), 149(9.7), and 83(32).

3-Bromocyclohexene was prepared according to Ziegler *et al.*'s method (1) and was distilled at 64°C/14 Torr; ir: 3040(m), 1640(w), 1188(s), 862(s), and 732(s) cm^{-1}; nmr τ: 3.96 (m, 2H), 5.16 (m, $W_{1/2}$ = 9, 1H), 7.1–8.1 (m, 8H); ms *m/e*: 162, 160, and 81 (100%).

Photodecomposition of NBS

In the Presence of 3,3-Dimethyl-1-butene

A solution of NBS (2 g), the olefins (10 g), and ethylene oxide (2 mL) in acetonitrile (70 mL) was purged with nitrogen for a few minutes and was irradiated with a Hanovia lamp (100 W) at −10°C for 3.5 h. At intervals, small samples were withdrawn for iodimetric tests or titrations to follow the progress of the reaction. The zero hour sample kept at −10°C in the dark showed no decomposition after 4 h as shown by titration. The photolysate was evaporated to afford a white solid (2.72 g). The oil showed a nmr spectrum which was essentially that of adduct **2***a* in addition to small signals at τ 6.77, 7.74, and 9.00, and a vpc trace which contained one major and four minor peaks (2 ~ 3%). By quantitative peak matching the major peak was shown to correspond to **2***a* (85% yield); gc–ms analysis showed that the first two minor components contained no bromine atom and showed strong *m/e* at 57 and 56. The fourth peak showed a very strong peak at *m/e* 126 which was probably derived from $(CH_3)_3CCH(OCH_2CH_2Br)CH_2Br$. Recrystallization of the solid (1.56 g) from

petroleum ether gave white solid of 1-succinimido-2-bromo-3,3-dimethylbutane (**2***a*, 65%); mp 85–87°C; ir: 1700 and 1150 cm^{-1}; nmr τ: 8.85 (s, 9H), 7.25 (s, 4H), and 5.6–6.5 (m, an ABC system, 3H); ^{13}C nmr in ppm: 176.2(s), 63.9(t), 41.5(t), 34.6(s), 27.6(t), 26.9(q); ms *m/e* (%): 263(25), 261(25), 248(10), 246(10), 207(92), 205(93), 183(17), 182(100), 166(38), 149(6), 127(11), 126(90), 112(65), 100(92), 84(49), 83(78), 82(18). *Anal.* calcd. for $C_{10}H_{16}NO_2Br$: C 45.81, H 6.15, N 5.34; found: C 46.04, H 6.16, N 5.26.

Adduct **2***a* (156 mg) was stirred in 80% acetic acid (3 mL) with sodium iodide and zinc powder (900 mg) for 48 h (45). A usual work-up gave a solid (59 mg) which was recrystallized from cyclohexane to afford white crystals; mp 96–99°C; ir: 1760(w), 1695(s), 1405(s), 1355(s), 1305(w), 1235(s), and 1150(s) cm^{-1}; nmr τ: 9.08 (s, 9H), 7.32 (s, 4H), 8.54 and 6.48 (A_2B_2, multiplets, 2H each); ^{13}C nmr: 176.4(s), 40.2(t), 34.7(t), 29.1(s), 28.4(q), and 27.5(t).

In the Presence of 1-Hexene

A solution of NBS (2 g), 1-hexene (10 mL), and ethylene oxide (2 mL) in acetonitrile (70 mL) was irradiated under nitrogen for 2.5 h at 0°C until iodimetric tests were negative. A similar mixture kept in the dark at 0°C was iodimetrically titrated after 3 h to give the same amount of the titrant as the zero hour sample. The photolysate was evaporated to give a residue (2.53 g) which showed an ir absorption at 2260 cm^{-1}. This residue taken up in methylene chloride was extracted with water; the methylene chloride was dried and evaporated to give an oil (2.18 g); nmr τ: 8.5 (m, 9H), 7.25 (s, 4H), 6.2 (m, 2H), and 5.7 (m, 1H); ir: 1705, 1770, 1400, 1160, 820, and 735 cm^{-1}. Chromatography of the oil taken up in methylene chloride on silicic acid gave a forerun (128 mg) containing several minor and one major component. This oil was separated by preparative tlc to give 1,2-dibromohexane (**4***b*); ir: 2960, 2930, 2860, 1460, 1430, 1220, 1150, 965; nmr τ: 5.7–6.7 (m, 3H), 8.0 (m, 2H), 8.5 (m, 4H), 9.1 (m, 3H); ms *m/e*: 185, 187, 189, 163, and 165. The next nine fractions (1.83 g) contained 1-succinimidyl-2-bromohexane **2***b* with a trace of impurities. A portion was further chromatographed to give pure **2***b* as an oil; ir: 1775, 1702, 1400, 1160, and 819 cm^{-1}; nmr τ: 5.49 (m, 1H), 5.8–6.5 (m, 2H), 7.24 (s, 4H), 7.9–8.8 (m, 6H), and 903 (t, 3H); ^{13}C nmr ppm: 177.1(s), 51.0(d), 44.9(t), 35.4(t), 29.1(t), 27.8(t), 21.8(t), 13.4(q); ms *m/e* (%): 263 (5, M^+), 261(5), 182(74), 164(3), 162(3), 138(13), 112(47), 100(100), 99(20), 86(41), 84(68), 83(46), and 82(31).

Adduct **2***b* (156 mg), sodium iodide (150 mg), and zinc powder (900 mg) in 80% acetic acid (3 mL) were stirred for 24 h. The filtrate was evaporated and the residue was diluted with water. The aqueous phase was extracted with carbon tetrachloride. The latter phase was washed with dilute sodium thiosulfate solution and was worked up to give an oil (80 mg) of *N*-hexylsuccinimide; the ir, nmr, and mass spectra were superimposable with those of the authentic sample.

In the Presence of Cyclohexene

(*1*) A solution of NBS (2 g), cyclohexene (12 mL), and ethylene oxide (2 mL) in acetonitrile (70 mL) was kept under nitrogen at −10°C and was photolysed for 3 h until the KI–starch test showed negative. The photolysate was evaporated and the residue taken up in methylene chloride (3 ~ 4 mL) was filtered. The solid (544 mg) was identified as succinimide by ir and nmr spectroscopy and by mixture mp 121–122°C. The methylene chloride solution (containing 2.5 g of the residue) was chromatographed on a silica gel column to afford 12 fractions.

Fraction 2 (378 mg) decomposed to tar on attempted microdistillation at 10 Torr. A portion of this oil (150 mg) was subjected to preparative tlc on silicic acid using 10% CH_2Cl_2 in petroleum ether as eluent to give *trans*-1,2-dibromocyclohexane **6** (56 mg) and ether **7** (28 mg). These products showed spectra identical with those of authentic samples.

Fractions 4–7 (917 mg) showed one spot on tlc with a trace of impurity and decomposed on distillation at 120°C. A portion of this oil was subjected to preparative tlc to give an oil of *trans*-1-succinimidyl-2-bromocyclohexane (**5**); ir: 1770(m), 1700(s), 1450(m), 1176(s), 966, 820 cm^{-1}; nmr τ: 5.14 (dt, J = 11 and 4 Hz, 1H), 5.88 (dt, J = 11 and 4 Hz, 1H), 7.30 (s, 4H), 8.30(m); ^{13}C nmr ppm: 176(s), 57.1(d), 50.3(d), 37.1(t), 29.1(t), 27.5(t), 26.2(t), 24.5(t); ms *m/e* (%): 262 (47, M^+), 260(47), 180(100), 162(89), 160(89), 138(100), 110(55), 100(100), 96(60), 84(63), 82(100), and 81(100). *Anal.* calcd. for $C_{10}H_{14}NO_2Br$: C 46.17, H 5.42, N 5.40; found: C 46.35, H 5.46, N 5.31.

Fractions 8–10 (85 mg) were rechromatographed to give the adduct **5** (60 mg) and an oily fraction (15 mg). The total yield of the adduct **5** (977 mg) was 32%.

Fraction 11 (22 mg) showed one major spot and four minor spots on tlc and the following physical constants; ir: 3025, 1760(m), 1700(s), 1380(s), 1170(s) cm^{-1}; nmr τ: 4.15(m), 6.2(m), 6.8(m), 7.35(s); ms *m/e* (%): 179(100), 151(75), 150(70), 122(120), 121(100), 100(280), 81(175), and 80(290).

Adduct **5** (120 mg) was stirred with zinc powder and sodium iodide in 80% aqueous acetic acid to afford a crude product (62 mg). The oil was chromatographed to afford *N*-cyclohexylsuccinimide; the ir, nmr, and mass spectra and the vpc retention time were identical with the sample prepared by other routes (38).

(*2*) In a separate experiment, a mixture of the same composition was photolysed at −20°C for 5 h. The photolysate was worked up as before to afford a light brown oil (2.72 g) and succinimide (444 mg). The ir spectrum of the oil exhibited a weak absorption at 2260 cm^{-1}. The vpc spectrum of the oil showed the peaks matching with succinimide, 3-bromocyclohexene (**8**), *trans*-1,2-dibromocyclohexane (**6**), ether **7**, and adduct **5** in addition to four trace amount peaks. The peak of **5** was the major and others were about 1/6 to 1/7 in area of the peak of **5**. The oil was chromatographed on a silica gel column to afford adduct **5** (1.14 g, 38%). By gc–ms analysis, the first two trace amount peaks following the solvent peak were shown to possess the mass spectral patterns of 2-cyclohexenenone and 2-cyclohexenol (46).

(*3*) A solution of NBS (2 g), cyclohexene (12 mL), and ethylene oxide (4 mL) in acetonitrile (240 mL) at 0°C was purged with nitrogen and was irradiated with a Hanovia lamp (100 W). Samples were withdrawn at every hour and iodimetrically titrated. The solution was kept under a slight positive pressure of nitrogen at all times. The zero hour sample kept at 0°C in the dark for 15 h gave a titration volume the same as that at the zero hour. The same experiment was repeated at −10°C.

Photolysis of NBS in the Presence of Benzene

(1) In the Absence of Neohexene

A benzene (350 mL) solution containing NBS (1.5 g) and ethylene oxide (5 mL) was irradiated with a Hanovia lamp (200 W) in a Pyrex vessel under nitrogen at 5–10°C for 12 h until the photolysate gave a negative KI–starch test. The residue (2.2 g) obtained after evaporation of the solvent was chromatographed on a silicic acid column using methylene chloride containing 0–5% methanol as eluent. The first four fractions (455 mg) gave very similar ms and ir but different nmr patterns. The semi-solids showed major mass spectral peaks at *m/e* 338, 336, 334, 257, 256, 254, 238, 236, 234, 176, 175, 158, 156, 120, 119, 100, and 93, and major ir absorptions at about 1710(s, b), 1150, 1180, 770 cm^{-1}. Recrystallizations

of these fractions from methanol or methylene chloride gave crystalline compounds with wide melting ranges. The fifth and sixth fractions were rechromatographed to afford a similar semi-solid (81 mg) as above and a crystalline compound (120 mg) identified as *N*-phenylsuccinimide (**11**) by comparisons of ir, nmr, and mass spectra with those of the authentic sample. Elution with 5% MeOH–CH_2Cl_2 gave succinimide.

The semi-solid fractions were combined and chromatographed on an alumina column to afford many fractions, one of which (60 mg) was recrystallized from MeOH–CH_2Cl_2 to afford white crystals; mp 204–207°C; ir: 1700, 1185, 1165, and 780 cm^{-1}; nmr τ: 7.14 (s, 4H), 5.2–4.83 (m, 3H), 4.66–4.38 (m, 1H), and 4.00 (m, 2H); ms *m/e* (%): 419(0.2), 417(0.5), 415(0.5), 413(0.2), and 100(100). *Anal.* calcd. for $C_{10}H_{10}NBr_3O_2$: C 28.85, H 2.40, N 3.37; found: C 29.20, H 2.45, N 3.15.

(2) In the Presence of Neohexene

A solution of NBS (599 mg, 3.3 mmol), benzene (2.6 mL, 29 mmol), ethylene oxide (1.5 mL, 23 mmol), and neohexene (0.3 mL, 2 mmol) in acetonitrile (100 mL) was irradiated with a 450 W Hanovia lamp through a Corex filter for 20 min at 0°C under nitrogen. The solution was evaporated to afford a brown oil (769 mg), The oil (384 mg) was chromatographed on silica gel using MeOH–CH_2Cl_2 as eluent. The first fraction (53 mg) was polybrominated compounds and was not investigated further. The fractions (144 mg) collected with 0.1–0.2% MeOH–CH_2Cl_2 were mixtures containing some **11**. The fractions (191 mg) eluted with 0.5 ~ 1% MeOH were crystallized from cyclohexane to give **11**; the ir, nmr, and mass spectra were superimposable with those of the authentic compound.

In a separate experiment, a solution of benzene (10 mL), NBS (893 mg), neohexene (0.3 mL), and ethylene oxide (2 mL) in acetonitrile was irradiated in a Pyrex vessel with a 100 W Hanovia lamp at 0°C for 25 h. Half of the solution was treated with triethylamine (1 mL) for 8 h at room temperature. The solution was worked up in the usual manner to afford an oil. Analysis by the vpc peak matching method gave three peaks corresponding to dibromide **4***a* (3%), succinimide (31%), and **11** (13.6%).

The other half of the photolysate was evaporated and the residue was analysed by vpc as above to give dibromide **4***a* (4.6%), succinimide (40%), and **11** (8.6%). In both cases neither adduct **2***b* nor bromobenzene were detected.

Photolysis of Bromine in the Presence of NBS

A solution containing NBS (3.55 g), bromine (880 mg), and ethylene oxide (6 mL) in benzene (130 mL) was photolysed through a G.W.C. filter[3] (cut off at 334 nm) at about 10°C. Aliquots withdrawn at intervals were treated with a drop of cyclohexene and tested with KI–starch paper. The zero hour sample kept for 40 hours in the dark was similarly treated with cyclohexene and titrated iodimetrically to show no decomposition. It took 35 h for NBS to disappear during which white solids precipitated. The solid (1.13 g) was shown to be succinimide by an ir spectral comparison. The filtrate was evaporated to give an oil. The oil was chromatographed on silica gel to give a mixture of polybromobenzenes (1.93 g) and a small amount of succinimide. Rechromatography of the former gave five fractions that were mixtures, in various proportions, of brominated benzenes. By gc–ms analysis of each fraction, bromobenzene, dibromobenzene, tribromobenzenes, tetrabromobiphenyl, and tetrabromocyclohexadiene were identified in addition to minor amounts of other brominated benzenes. These fractions showed no ir absorption or nmr signals typical of the succinimido moiety.

Reaction of HBr with NBS and Ethylene Oxide

To a solution of NBS (167 mg) and ethylene oxide (0.35 mL, 0.007 mol) in acetonitrile (20 mL) was added an acetonitrile solution of HBr (0.01 *M*, 1.5 mL) at −10°C. The solution became pH 6–8 immediately. The uv spectrum of this pale yellow solution showed a weak absorption at 404 nm for bromine. This solution was evaporated and the residue was worked up in the usual manner to give ethylene bromohydrin as an oil; nmr τ: 7.22(s, D_2O exchangeable, 1H), 6.09(t, J = 5.2 Hz), 6.48(t, J = 5.2 Hz).

Reaction of Bromine Cyclohexene and Ethylene Oxide

To a solution of cyclohexene (14 mL) and ethylene oxide (2.3 mL) in methylene chloride (100 mL), bromine (3.2 mL) was added dropwise at 0°C. The solvents were evaporated to give an oil (14.6 g). The oil was distilled to afford a fraction at bp 112–113°C/14 Torr which showed nmr and ir spectra identical to those of **6** (46). The vpc analysis of the forerun showed no peak corresponding to 3-bromocyclohexene. The residue (1.5 g) was chromatographed on silica gel using petroleum ether as eluent to afford an oil (916 mg) which showed one peak on vpc analysis. Preparative tlc of a portion of this oil gave 1-bromo-2-(2′-bromoethoxy)cyclohexane (**7**); ir: 2930, 2860, 1445, 1190, and 1100 (s, b); nmr τ: 6.10 (t, J = 5.5 Hz, 2H), 6.60 (t, J = 5.5 Hz, 2H), 6.00 (dt, J = 8 and 3 Hz, 1H), 6.54 (dt, J = 6 and 1.5 Hz, 1H); ms *m/e* (%): 288(6), 286(11), 284(6), 165(28), 163(31), 109(41), 107(44), 97(60), and 81(100). *Anal.* calcd. for $C_8H_{14}Br_2O$: C 33.59, H 4.93; found: C 34.07, H 4.96.

Photodecomposition of NBS in the Presence of Ethylene Oxide

A solution of NBS (1.17 g) and ethylene oxide (20 mL) in acetonitrile (140 mL) was irradiated with a 450 W Hanovia lamp at 0–5°C under nitrogen. During irradiation, a yellow color developed. A sample treated with a drop of cyclohexene gave a colorless solution; potassium iodide starch test with this solution was used to follow the progress of the reaction. After 5 h, the solution remained yellowish but NBS was consumed. The zero hour sample kept in the dark showed no decomposition by iodimetry. The crude product was analysed by gc–ms to give many peaks. Most of them showed mass spectral patterns indicative of one or two bromines. Among them, the major peaks corresponding to ethylene bromohydrin, succinimide, and β-bromopropionamide and a minor peak of bromoacetaldehyde were identified by their mass spectral patterns and (or) peak matchings. The mass spectrum of β-bromopropionamide showed prominent peaks at *m/e* 153, 151, 109, 107, 72 (100%), and 44.

Photoreaction of NBS in the Presence of Cyclohexene

In a conventional Pyrex photocell, acetonitrile (240 mL), NBS (2.017 g, 0.011 mol), cyclohexene (12 mL, 9.72 g), and ethylene oxide (4 mL, 3.56 g) were placed at 0°C. The mole ratio of NBS, cyclohexene, and ethylene oxide was 1:10:8. The solution was purged with nitrogen for 5 min and brought to the desired temperature. While the solution was kept under a small positive pressure of nitrogen, it was irradiated with a 100 W medium pressure Hanovia lamp. Irradiation was continued until the photolysate responded negative to KI–starch tests.

On completion of irradiation, the photolysate (50 mL) was evaporated in a rotary evaporator. A portion of the crude oil and biphenyl were weighed into a 5 mL volumetric flask and diluted with acetonitrile to the mark. This solution was analysed with a 10% SE 30 on Chromosorb Q 100/120, 1/8 in.

[3]We are grateful to Dr. G. Pfundt, Max-Plank-Institut für Kohlenforschung, Mülheim a.d. Ruhr, who provided the filter.

× 6 ft stainless steel column with oven temperature 100–200°C (4°C/min programming, the flow rate 33 mL/min at 26 psi). Under these conditions the retention times (in brackets, in minutes) are 3-bromocyclohexene (**8**, 2.75), succinimide (3.5), *trans*-dibromocyclohexane (**6**, 5.0), ether **7** (10.5), adduct **5** (16.3), 2-cyclohexenone (2.0), 2-cyclohexenol (2.3), unknown **1** (6.3), and biphenyl (7.8). Experiments at different temperatures were repeated to ascertain the reproducibility.

For known compounds, correction factors were first established by injecting the known concentrations of biphenyl and a pure sample to be analysed. The measured areas and concentration gave the correction factors. For each sample injected, the peak areas were measured and the absolute contents of each component calculated from these correction factors. The percentage yields of each compound are summarised in Table 1.

An acetonitrile solution of 3-bromocyclohexene always gave two peaks at 0.5 and 2.5 min, even when an analytically pure compound was used. The correction factor was calculated on the second peak. The peak area corresponding to succinimide increased gradually as the time elapsed on storage of the crude product; typically, area ratios of succinimide to biphenyl changed from 0.0776 at 5 h to 0.32 at 50 h after isolation.

Pyrrolidine- and piperidine-alkanoic acid hydrochlorides. Synthesis by hydrogenation of pyrrolyl ester and pyridine-alkanoic acid hydrochlorides

SOOI-KAY TSUI AND JAMES DOUGLAS WOOD

Department of Biochemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received January 23, 1979

SOOI-KAY TSUI and JAMES DOUGLAS WOOD. Can. J. Chem. **57**, 1977 (1979).

2-Pyrrolidylacetic acid and β-(2-pyrrolidyl)propionic acid hydrochloride have been prepared by hydrogenation of ethyl 2-pyrrolylacetate and diethyl 2-pyrrolylmethylenemalonate respectively, over rhodium on alumina in HCl solution, followed by acidic hydrolysis. Similarly, 1-methylnipecotic acid, 1-methylisonipecotic acid, 2- and 3-piperidine-acetic acid, and 3-piperidine-propionic acid hydrochlorides have been prepared by hydrogenation of the corresponding pyridine-alkanoic acid hydrochlorides over platinum oxide, rhodium on alumina, or palladium on carbon in water.

SOOI-KAY TSUI et JAMES DOUGLAS WOOD. Can. J. Chem. **57**, 1977 (1979).

On a préparé les chlorhydrates des acides pyrrolidyl-2 acétique et β(pyrollidyl-2) propionique par hydrogénation respectivement du pyrrolyl-2 acétate d'éthyle et du pyrrolyl-2 méthylènemalonate de diéthyle sur du rhodium sur l'alumine en solution HCl, suivie par une hydrolyse acide. De la même manière, on a préparé les chlorhydrates des acides méthyl-1 nipécotique, méthyl-1 isonipécotique, pipéridine-2 (et -3) acétique et pipéridine-3 propionique par hydrogénation des chlorhydrates des acides pyridine alcanoïques correspondants sur de l'oxyde de platine, du rhodium sur l'alumine ou du palladium sur du charbon dans l'eau.

[Traduit par le journal]

Introduction

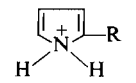
It is well established that γ-aminobutyric acid (GABA) is an important neurotransmitter in the mammalian central nervous system (1). Various structural analogues of this substance have been isolated or synthesized which affect its metabolism and function (2). Such compounds are of pharmacological interest as potential antiepileptics.

Recently, nipecotic acid **6***d* has been reported as a potent inhibitor of the uptake of GABA by slices of rat cerebral cortex (3) and we have found that 1-methylnipecotic acid **4***a* has similar effects (manuscript in preparation). As a result we became interested in the possibility of a rapid high-yield preparation of easily purifiable, water soluble, hydrochloride salts of related piperidine- and pyrroline-alkanoic acids by hydrogenation of the corresponding pyrrolyl ester and pyridine alkanoic acid hydrochlorides at medium to low pressure.

Discussion

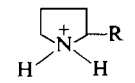
Hydrogenation was complete at 2.5 atm and at room temperature for all pyridines regardless of the catalyst used (platinum oxide, 5% rhodium on alumina, or 10% palladium on carbon); for pyrrolines, shorter times were required and less tar was found using 5% rhodium on alumina. Completeness of hydrogenation was more correctly assessed from the absence of any olefinic hydrogen in the ^{1}Hmr spectra of the products rather than from hydrogen uptake which may stop prematurely due to catalyst poisoning.

Compounds **2***a* and **2***b* were prepared by reduction of the esters **1***a* and **1***b* followed by hydrolysis, since hydrolysis of the starting pyrrolyl esters led to in-



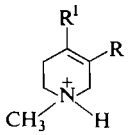
1

a R = CH_2CO_2Et
b R = $CH{=}C(CO_2Et)_2$



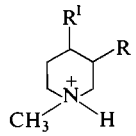
2

a R = CH_2COOH
b R = CH_2CH_2COOH



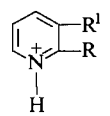
3

a R^1 = H, R = COOH
b R^1 = COOH, R = H



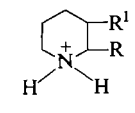
4

a R^1 = H, R = COOH
b R^1 = COOH, R = H



5

a R^1 = H, R = CH_2COOH
b R^1 = CH_2COOH, R = H
c R^1 = CH=CHCOOH, R = H
d R^1 = COOH, R = H



6

a R^1 = H, R = CH_2COOH
b R^1 = CH_2COOH, R = H
c R^1 = CH_2CH_2COOH, R = H
d R^1 = COOH, R = H

(In all cases the anion was chloride)

0008-4042/79/151977-03$01.00/0

tractable tar formation. Hydrogenation was carried out in dilute HCl (0.05 *M*), the acid added being sufficient to promote hydrogenation but not enough to cause tar formation. Solution of starting material was incomplete at the beginning of the reaction but complete at the end. This route to **2***b* is simpler than the previous 2-step procedure (4).

Compounds **4***a* and **4***b* were obtained in high yields by direct hydrogenation of **3***a* and **3***b* respectively. Compound **4***a* had previously been prepared in good yield by the hydrogenation of the corresponding 1-methylnicotinic betaine with platinum but hydrogen pressure and temperature were not specified (5). Direct hydrogenation of **5***d* over PtO_2 has provided **6***d* in high yield (6).

Piperidines **6***a* and **6***b* were obtained in high yield from **5***a* and **5***b* respectively. Compound **6***a* had previously been assumed to be unstable under these hydrogenation conditions (7). Compound **6***c* was obtained, also in high yield, from **5***c*.

Attempts to use acetic acid in place of hydrochloric acid led to longer hydrogenation times and acetate salts which were difficult to purify. The direct reduction of the hydrochloride salts of the appropriate pyridine compound avoids the need for ester hydrolysis which is frequently accompanied by decarboxylation (8). In most cases the starting hydrochloride salt is commercially available or readily obtained by hydrolysis of the corresponding ester.

Experimental

Nuclear magnetic resonance spectra were measured on a Varian T60 spectrometer in D_2O with sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) as internal standard. Infrared spectra were recorded with KBr on Perkin Elmer or Beckman infrared spectrophotometers. Melting points were determined on a Mel-Temp hot stage apparatus. Elemental analyses were conducted by Mr. R. G. Teed, Department of Chemistry and Chemical Engineering, University of Saskatchewan.

Hydrogenation of Pyrrolyl Esters with 5% Rhodium on Alumina

General Procedure

A mixture of 1.0 g of freshly prepared pyrrolyl ester in 20 mL of 0.05 *M* HCl solution was hydrogenated with 0.4 g of 5% rhodium on alumina. After a period of 20 h, the mixture was filtered. The clear solution was added to 10 mL of 37% HCl and refluxed for 4 h. The solution was then treated with charcoal and dried *in vacuo*. The residue was recrystallized from ether–ethanol. The ^{1}Hmr spectrum of the crude products after acid hydrolysis showed that the hydrogenation was complete for both the following pyrrolyl esters **1***a* (9), **1***b* (10).

2-Pyrrolidylacetic Acid Hydrochloride **2**a

The yield was 45%; mp 170–171°C; ir ν_{max}: 3170–2400, 1730, 1400, and 1180 cm^{-1}; ^{1}Hmr δ: 1.40–2.52 (m, 4H), 2.75–3.10 (m, 2H), 3.15–3.57 (m, 2H), 3.80–4.15 (s b, 1H). *Anal.* calcd. for $C_6H_{12}ClNO_2$: C 43.51, H 7.31, N 8.46; found: C 43.62, H 7.36, N 8.33.

β-*(2-Pyrrolidyl)propionic Acid Hydrochloride* **2**b

The yield was 40%; mp 115–117°C (lit. (4) mp 115–118°C); ir ν_{max}: 3100–2450, 1700, 1420, and 1200 cm^{-1}; ^{1}Hmr δ: 1.50–2.18 (m, 6H), 2.30–2.85 (m, 2H), 3.20–3.95 (m, 3H). *Anal.* calcd. for $C_7H_{14}ClNO_2$: C 46.80, H 7.85, N 7.79; found: C 46.79, H 7.88, N 7.66.

Hydrogenation of Pyridine Alkanoic Acid Hydrochloride with Different Catalysts: Platinum Oxide, Rhodium on Alumina, or Palladium on Carbon

General Procedure

A solution of 0.55 g of pyridine alkanoic acid hydrochloride in 20 mL of water was hydrogenated with 0.05 g of platinum oxide (or 0.35 g of 5% rhodium on alumina, or 10% palladium on carbon). After a period of 10 h the solution was filtered and dried in a freezer–dryer at 0.01 Torr. Except where noted, purification of product was unnecessary. The ^{1}Hmr spectra of the crude products indicated that only in the case of hydrogenation of 2-pyridineacetic acid hydrochloride **5***a* with palladium on carbon was a reduction time in excess of 10 h required, the 10-h reduction period being sufficient to complete the hydrogenation of **3***a*, **3***b* (11), **5***b*, and **5***c* to form their respective products. The compounds synthesized by these hydrogenations follow.

1-Methylnipecotic Acid Hydrochloride **4**a

The yield was 75–85%; mp 173–174°C (ether–ethanol) (lit. (5) mp 174–175°C); ir ν_{max}: 3200–2500, 1730, 1470, and 1200 cm^{-1}; ^{1}Hmr δ: 1.38–2.40 (m, 4H), 2.55–3.85 (m, 5H), 2.90 (s, 3H). *Anal.* calcd. for $C_7H_{14}ClNO_2$: C 46.80, H 7.85, N 7.79; found: C 46.80, H 8.13, N 7.77.

1-Methylisonipecotic Acid Hydrochloride **4**b

The yield was 74–86%; mp 230–232°C (ether–ethanol); ir ν_{max}: 3070–2470, 1720, 1450, 1200 cm^{-1}; ^{1}Hmr δ: 1.45–2.55 (m, 4H), 2.6–3.85 (m, 5H), 2.9 (s, 3H). *Anal.* calcd. for $C_7H_{14}ClNO_2$: C 46.80, H 7.85, N 7.79; found: C 46.46, H 7.86, N 7.54.

2-Piperidineacetic Acid Hydrochloride **6**a

The yield was 60–70%; mp 180–182°C (ether–ethanol) (lit. (12) mp 180–182°C); ir ν_{max}: 3200–2770, 1730, 1380, and 1175 cm^{-1}; ^{1}Hmr δ: 1.22–2.20 (m, 6H), 2.80–3.82 (m, 3H), 2.80 (d, 2H). *Anal.* calcd. for $C_7H_{14}ClNO_2$: C 46.80, H 7.86, N 7.79; found: C 47.16, H 7.97, N 7.51.

3-Piperidineacetic Acid Hydrochloride **6**b

The yield was 85–90%; mp 202–204°C; ir ν_{max}: 3120–2750, 1720, 1400, and 1180 cm^{-1}; ^{1}Hmr δ: 1.20–2.21 (m, 4H), 2.52–3.62 (m, 5H), 2.39 (s b, 2H). *Anal.* calcd. for $C_7H_{14}ClNO_2$: C 46.80, H 7.85, N 7.79; found: C 46.21, H 7.93, N 7.63.

β-*(3-Piperidine)propionic Acid Hydrochloride* **6**c

The yield was 86–91%; mp 224–226°C; ir ν_{max}: 3170–2730, 1730, 1395, and 1180 cm^{-1}; ^{1}Hmr δ: 1.35–2.15 (m, 7H), 2.32–2.62 (t, 2H), 2.62–3.62 (m, 4H). *Anal.* calcd. for $C_8H_{16}ClNO_2$: C 49.61, H 8.33, N 7.23; found: C 49.53, H 8.30, N 7.19.

Acidity function 'failure.' I. 2-Thiohydantoins

JOHN T. EDWARD AND SIN CHEONG WONG

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received November 6, 1978

JOHN T. EDWARD and SIN CHEONG WONG. Can. J. Chem. **57,** 1980 (1979).

The protonation of 2-thiohydantoin and of eight derivatives variously substituted at the 1-, 3-, and 5-positions with alkyl groups or a single phenyl followed h_0 (Cox–Yates $m^* \sim 1.1$); however, the protonation of 3,5-diphenyl-2-thiohydantoin followed h_T ($m^* = 1.50$), and of 5,5-diphenyl-2-thiohydantoin an acidity function intermediate between h_0 and h_T ($m^* = 1.24$). Results were analyzed also in terms of the Cox–Yates X function to obtain pK_{BH^+} values, which were compared with those obtained by alternative analyses of the data.

JOHN T. EDWARD et SIN CHEONG WONG. Can. J. Chem. **57,** 1980 (1979).

La protonation de la thio-2 hydantoine et de huit de ses dérivés, substitués en positions -1, -3 et -5 par des groupes alkyles ou un simple phényle, se fait suivant h_0 (Cox–Yates $m^* \sim 1.1$); toutefois la protonation de la diphényl-3,5 thio-2 hydantoine suit h_T ($m^* = 1.50$) alors que celle de la diphényl-5,5 thio-2 hydantoine suit une fonction d'acidité intermédiaire entre h_0 et h_T ($m^* = 1.24$). On a aussi analysé les résultats en termes de la fonction X de Cox–Yates pour obtenir des valeurs de pK_{BH^+} que l'on compare à celles obtenues par une autre analyse des données.

[Traduit par le journal]

Introduction

Forty-seven years ago Hammett and Deyrup (1) introduced the concept of the acidity function, H_0, with the expectation that it would furnish a general measure of the acidity of concentrated aqueous acid solutions, in the way that pH furnishes a general measure of the acidity of very dilute aqueous acid solutions. However, after much experimental work it became apparent that H_0 was not a unique measure of acidity, but only one of a series of acidity functions H_B, defined by

$$[1] \quad -H_B \equiv \log a_{H^+} f_B / f_{BH^+} = \log C_{BH^+}/C_B - pK_{BH^+}$$

where a = activity, C = molarity, and f = molarity activity coefficient. Each separate H_B applies to a set of closely related Brønsted bases B: H_A for amides (2), H_I for indoles (3), H_T for thiocarbonyl compounds (4), and so on. This loss of generality was characterized by Arnett (5) as 'acidity function failure.'

For a particular function H_B to be valid for the protonation of a series of bases B_1, B_2, ... , it is necessary that in all concentrations of acid

$$[2] \quad f_{B_1}/f_{B_1H^+} = f_{B_2}/f_{B_2H^+} = \ldots.$$

(the 'cancellation assumption' (6)). It is the frequent failure of the cancellation assumption to apply when bases B and C belong to different classes of compounds which leads to acidity function failure and the need for two functions H_B and H_C. It has been found, however, that the various acidity functions are approximately linear with respect to each other for concentrations of acid such that $H_0 < 0$:

$$[3] \quad H_C = mH_B$$

Hence pK_{CH^+} values are often obtained (7) in the absence of an appropriate acidity function H_C for bases C_1, C_2, ... , by the equation

$$[4] \quad \log I = -mH_B + pK_{CH^+}$$

where I ($\equiv C_{CH^+}/C_C$) is the ionization ratio. This equation yields pK_{CH^+} values not greatly different from those obtained by other treatments (8, 9), but can only be approximate: in particular, [3] must fail for more dilute solutions when all acidity functions H_B, H_C, ... are becoming equal to pH, and m is changing towards unity.

The empirical relation of Bunnett and Olsen (10, 11),

$$[5] \quad H_C + \log C_{H^+} = (1 - \phi)(H_0 + \log C_{H^+})$$

ϕ being a parameter characteristic of bases of type C, is free from this objection, applying equally to dilute and concentrated acid solutions. It leads to the additional two relations

$$[6] \quad \log \frac{f_C f_{H^+}}{f_{CH^+}} = (1 - \phi) \log \frac{f_B f_{H^+}}{f_{BH^+}}$$

$$[7] \quad \log I + H_0 = \phi(H_0 + \log C_{H^+}) + pK_{CH^+}$$

where B and BH^+ now represent the conjugate aniline–anilinium ion pairs on which the H_0 scale is

0008-4042/79/151980-06$01.00/0

now based (12). The pK_{CH^+} value of *C* may be obtained by application of [7] using H_0, and without the necessity of knowing the acidity function H_C.

On the basis of the linearity of activity coefficient terms shown in [6], Marziano, Passerini, and their co-workers (13) and more recently Cox and Yates (6) have developed alternative functions for measuring the acidity of concentrated acid solutions. Cox and Yates define their 'excess acidity' function *X* by

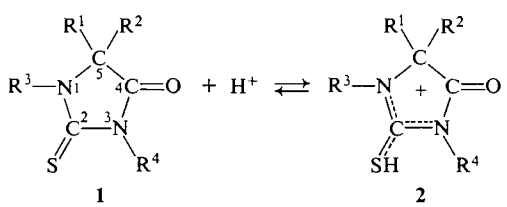
$$[8] \qquad \log \frac{f_C f_{H^+}}{f_{CH^+}} = m^* \log \frac{f_B f_{H^+}}{f_{BH^+}} \equiv m^* X$$

where B* is a hypothetical standard base. From [8] it follows that

$$[9] \qquad \log I - \log C_{H^+} = m^* X + pK_{CH^+}$$

Cox and Yates report *X* values for 0–99.5% aqueous sulfuric acid, based on ionization ratio data reported for 165 weak bases, and *X* values for 0–78% perchloric acid, based on ionization data for 76 weak bases. The *X* function has the advantage of being a single function for a given acid–water mixture covering *all* classes of bases, and hence replacing the multiplicity of functions H_0, H_0''', H_A, H_T, etc., as well as being applicable to compounds for which no acidity function has yet been developed. On the other hand, this generality has been obtained at the expense of introducing another parameter, the scaling factors m_B^*, m_C^*, ..., characteristic of the different classes of bases B, C, ... To a reasonable approximation $m^* \simeq 1 - \phi$, and hence the variation in m^* for various classes of bases, like the variation in Bunnett and Olsen's ϕ (10), can be explained very plausibly in terms of the 'solvation hypothesis' of Scorrano and his co-workers (14).

While these developments may remedy the 'acidity function failure' of the type noted by Arnett, in this series of papers we shall be concerned with a more serious type of failure: that of compounds within a single class B to follow a single acidity function H_B or, equivalently, to have constant values of ϕ or m_B^*. The problem of carbonyl compounds has already been noted by Scorrano *et al.* (14) and by us (9), and will be discussed in a future paper. In the present paper we consider the case of 2-thiohydantoins **1** which are (as we show below) protonated on



1 **2**

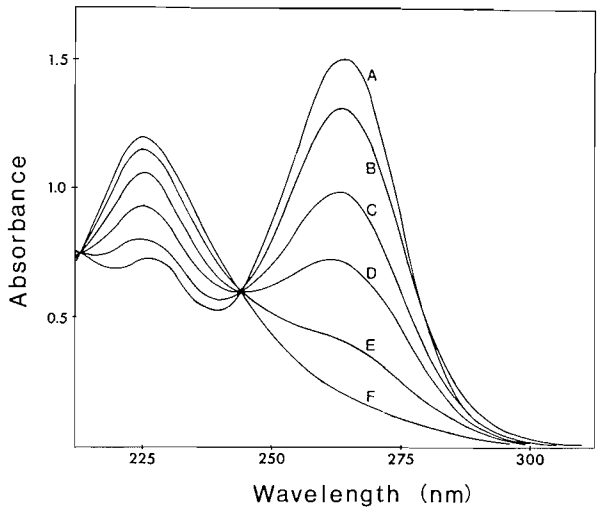


FIG. 1. Spectral curves of 5-benzyl-2-thiohydantoin in aqueous sulfuric acid: (*A*) 36.4%; (*B*) 59.7%; (*C*) 64.7%; (*D*) 67.1%; (*E*) 70.1%; (*F*) 80.5%.

sulfur to give the cation **2**. 2-Thiohydantoins are cyclic *N*-acylthioureas, and hence their protonation would be expected to follow h_T, as does the protonation of acyclic *N*-acylthioureas (15), and of the closely related 2,4-dithiohydantoins (**1**; S in place of O) (4, 16). Instead, the present (admittedly limited) data indicate the protonation of 2-thiohydantoins and of 1-acyl-2-thiohydantoins to follow h_0 (17). This requires that the cancellation assumptions ([2] or [6], [8])[1] do not apply when 2-thiohydantoins are included with other thioureas. In an attempt to understand this anomaly we have studied the activity coefficient and protonation behaviour of variously substituted 2-thiohydantoins.

Results and Discussion

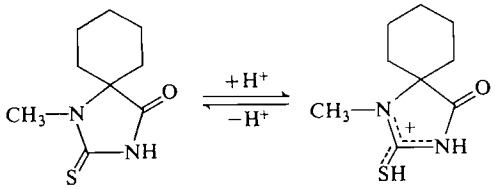
Site of Protonation

In Fig. 1 are shown the uv spectra of 5-benzyl-2-thiohydantoin in 36–80% sulfuric acid. The other 2-thiohydantoins, with the exception of the 1,3-diphenyl compound (discussed below), show similar spectral changes.

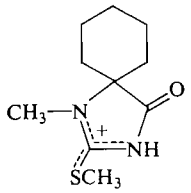
The disappearance in concentrated acid of the type II band (λ_{max} 260 nm) due to the $\pi \rightarrow \pi^*$ transition of the thioamide function suggests protonation

[1]It has been pointed out by a referee, and already pointed out by us (4), that the extrathermodynamic assumption ([2]) underlying pK_{BH^+} values obtained by the original acidity function approach is not the same as that ([6] or [8]) underlying the Bunnett–Olsen or Cox–Yates approaches, except for the special case when $\phi = 0$ or $m^* = 1$. For the same reason, the explanation of variations in ϕ in terms of differing solvation of B and BH^+ (but not H^+) by Scorrano *et al.* (14) must be regarded as a convenient simplification.

on sulfur (16), as in **3** → **4**. This is confirmed by the similarity in the spectra of 1-methyl-5,5-pentamethylene-2-thiohydantoin (**3**) in 80% acid ($\lambda\lambda_{max}$ 223, 238 nm; $\varepsilon\varepsilon_{max}$ 10 200, 7400 (shoulder)), and of 2-methylthio-1-methyl-5,5-pentamethylene-4-imidazol-4-one hydrochloride (**5**) in 10% acid ($\lambda\lambda_{max}$ 228, 245 nm; $\varepsilon\varepsilon_{max}$ 15 200, 9500). This would be expected from the similarity in structure of **4** and **5** when the



3 4



5

bathochromic effect of the S-methyl group is taken into consideration (16) and points to S-protonation. The 2-thiohydantoins accordingly resemble the acyclic acylthioureas in protonating first on sulfur rather than on oxygen (15).

The curves of Fig. 1 almost pass through an isosbestic point, so that ionization ratios[2] may be calculated by the usual procedure (1) without making corrections for medium effects (9).

The character of the spectral changes attending the protonation of 1,3-diphenyl-2-thiohydantoin is completely different (Fig. 2). Protonation results in a bathochromic, not a hypsochromic shift, and medium effects are large, like those for amides (15) and carbonyl compounds generally (9). This indicates a switchover from S-protonation to O-protonation. The pK's of S- and O-basic sites in acylthioureas are almost identical (15), and evidently flanking the S-site with two base-weakening phenyl groups (18) tilts the scales from S- to O-protonation.

Protonation Constants

The protonation constants pK_{BH^+} of the 2-thiohydantoins have been calculated from their ionization ratios by the acidity function relation [4], the Bunnett–Olsen linear free energy relation [7],

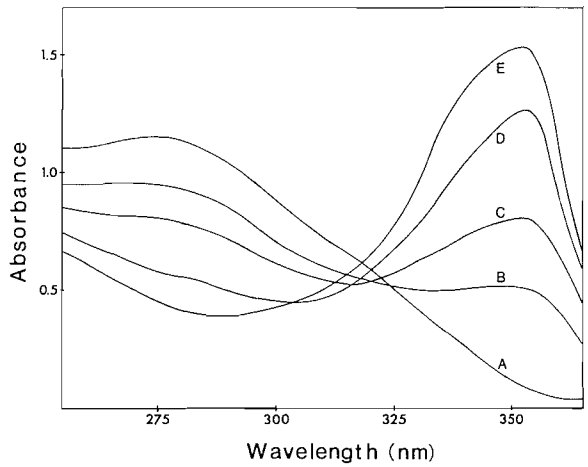


FIG. 2. Spectral curves of 1,3-diphenyl-2-thiohydantoin in sulfuric acid – water – ethanol mixture: (*A*) 56.6% acid, 10% ethanol; (*B*) 66.9% acid, 10% ethanol; (*C*) 69.2% acid, 5% ethanol; (*D*) 72.1% acid, 5% ethanol; (*E*) 76.5% acid, 5% ethanol.

and the Cox–Yates excess acidity relation [9] using H_0 (19), H_T (4), C_{H^+} (6), and X values (6) in the literature. Because of the low solubilities of the diphenyl-substituted 2-thiohydantoins in pure aqueous acid, ionization ratios of 3,5- and 5,5-diphenyl-2-thiohydantoins were determined in acid solutions containing 2% ethanol (by volume). Replacement of water by this small amount of ethanol should not significantly affect the protonation power of the acid, and the corresponding values of acidity functions or excess acidity for pure aqueous acid were used in the calculations.[3] The pK_{BH^+} values obtained from these equations are given in Table 1 along with slope parameters m (for [4] using H_0 as H_B), m' ([4] using H_T), ϕ, and m^*.[4]

It is evident that previous results (17) were not misleading: the majority of 2-thiohydantoins follow the H_0 acidity function reasonably well ($m \sim 1.0$, $\phi \sim 0$, and $m^* \sim 1.1$). Furthermore, the m, ϕ, and m^* values are (within limits) independent of the extent to which the hydrogen atoms attached to the 1- and 3-nitrogen atoms are replaced by alkyl or aryl groups. The 2-thiohydantoins differ in this respect from anilines (5) and benzamides (2), perhaps because the positive charge is so delocalized that hydration by hydrogen-bonding to acidic protons is less important. However, while the presence of a

[2]Experimental data for the thiohydantoins of Table 1 are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[3]1,3-Diphenyl-2-thiohydantoin could be dissolved only in 10% ethanol – 90% aqueous acid solutions, and its pK_{BH^+} value was not calculated.

[4]Standard deviations associated with the evaluation of pK_{BH^+} by the four procedures were calculated and are available as supplementary material. The goodness of fit was usually very slightly better with the Cox–Yates analysis, but the differences for the four procedures were not significant.

single phenyl substituent is without effect, the presence of two phenyls causes a change in behaviour: 3,5-diphenyl-2-thiohydantoin follows the h_T acidity function ($m = 1.35$, $m' = 1.03$)[5]; and 5,5-diphenyl-2-thiohydantoin follows neither h_0 nor h_T but an intermediate acidity function ($m = 1.12$, $m' = 0.86$). (The switchover to O-protonation with 1,3-diphenyl-2-thiohydantoin has been discussed above.) The pK_{BH^+} values obtained by [1] (H_0 for H_B) and by the Bunnett–Olsen relation [7] agree remarkably well, but in many cases differ considerably from the values afforded by the Cox–Yates relation [9]. This might be considered an argument against the validity of the last-named, but we think not. The accuracy of pK_{BH^+} values derived from both [1] and [7] depends on the accuracy of H_0 values, which are based on a limited number of indicators and are subject to cumulative error at higher acidities because of the overlap procedure involved, and because the parallelism of log I for different indicators in changing acid concentration is not always perfect. The excess acidity function X, on the other hand, does not depend on the parallelism of a series of indicators, but on the diverse ionization behaviour of a very large number of indicators; the only assumption is the linearity of activity coefficient terms exhibited in [6] and [8] (not the same as [2] (4)), and this seems to be well supported by the satisfactory correlations reported by Cox and Yates (6). We accordingly follow these authors in believing that the numerical values given by application of [9] are the closest approach to true thermodynamic pK_{BH^+} values available at present.[6]

The trends in pK_{BH^+} values resulting from alkyl and phenyl substitution are in very general agreement with those expected from earlier related work (16, 18, 20), but the data are not complete enough to justify a quantitative analysis such as was done by Janssen for the basicity of thioureas (18). However, the pronounced base-weakening effect of the 5-phenyl group of 3,5-diphenyl-2-thiohydantoin (**1**; $R^1 = R^4 =$ Ph; $R^2 = R^3 =$ H) (compare with 1-methyl-3-phenyl-2-thiohydantoin (**1**: $R^1 = R^2 =$ H, $R^3 =$ Me, $R^4 =$ Ph)) which is found no matter which method is used to analyze the experimental data is remarkable and is not easily explained.

Effect of Acid Concentration on f_B

The protonation behaviour of 2-thiohydantoins indicates that their activity coefficient ratios f_B/f_{BH^+} do not change with increasing acid concentration in the same way as do the activity coefficient ratios of acyclic acylthioureas and 2,4-dithiohydantoins (21, 22). We have accordingly studied the activity coefficients f_B of as many as possible of the free bases[7] in varying concentrations of acid by observing the changes in partition coefficient between chloroform and aqueous acid (22). The results are available as supplementary material,[1] and are shown graphically in Fig. 3; they include data for 5,5-pentamethylene-4-thiohydantoin (**1**; $R^1R^2 = (CH_2)_5$; $R^3 = R^4 =$ H; S and O interchanged) and 5,5-pentamethylene-2,4-dithiohydantoin (**1**; $R^1R^2 = (CH_2)_5$; $R^3 = R^4 =$ H; S in place of O), as well as for eight 2-thiohydantoins. All of the bases show similar behaviour, being first salted-out (increasing f_B) with increasing acid concentration, and then being salted-in (decreasing f_B). This is an almost universal pattern (22). The differences in f_B of 2-thiohydantoins and of 5,5-pentamethylene-2,4-dithiohydantoin are not great enough to explain why the protonation of 2-thiohydantoins follows h_0 and the protonation of the

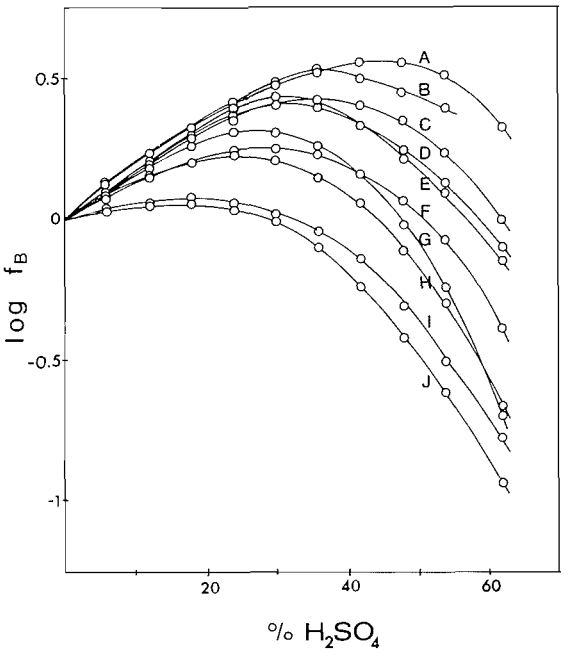

FIG. 3. Activity coefficients f_B in 0–60% sulfuric acid of 5,5-pentamethylene-2,4-dithiohydantoin (*B*), 5,5-pentamethylene-4-thiohydantoin (*G*), and the following substituted 2-thiohydantoins: 5,5-diphenyl- (*A*); 5-benzyl- (*C*); 5,5-pentamethylene- (*D*); 3,5-diphenyl: (*E*); 3,5,5-trimethyl- (*F*); 1-methyl-5,5-pentamethylene- (*H*); 1-methyl-3-phenyl- (*I*); and 1,3-dimethyl- (*J*).

[5] ϕ and m^* values are equally indicative.

[6] A referee has pointed out that "the X-function approach gives pretty good agreement with the H_T approach, which is after all based on thio compounds, even if the present compounds do not follow H_T as a class."

[7] 2-Thiohydantoin itself was insufficiently extracted by chloroform from aqueous acid for a partition coefficient to be obtained.

TABLE 1. Ionization constants of 2-thiohydantoin and of substituted 2-thiohydantoins

Substituents	Log I vs. H_0		Log I vs. H_T		Bunnett–Olsen		Cox–Yates	
	m	pK_{BH+}	m'	pK_{BH+}	ϕ	pK_{BH+}	m^*	pK_{BH+}

2,4-dithiohydantoins follows h_T. (In contrast, the protonation of amides in 0–40% sulfuric acid follows h_A and the protonation of thioamides h_T, largely because of the different responses of f_A and f_T to changing acid concentration (4).)

Accordingly, the different protonation behaviour of 2-thiohydantoins and of 2,4-dithiohydantoins must result chiefly from the differing reponse of f_{BH+} of the two classes of compounds to changing acid concentration. This can be seen in Fig. 4, which shows f_B and $f_{BH+}{}^*$ for 5,5-pentamethylene-2-thiohydantoin and 5,5-pentamethylene-2,4-dithiohydantoin, as well as for 5,5-pentamethylene-4-thiohydantoin (which protonates on the carbonyl oxygen and follows h_A (16)). The $f_{BH+}{}^*$ values (21, 22) were calculated by the equation

$$[10] \quad \log f_{BH+}{}^* = -m_B{}^* X - \log C_{H+} + \log a_{H+}{}^* + \log f_B$$

where the asterisks of $f_{BH+}{}^*$ and $a_{H+}{}^*$ indicate activity coefficients and activities *relative* to the tetraethylammonium ion (21, 22). (This equation follows from [1] and [9].) It is immediately apparent that the protonation of the 4-thiohydantoin follows h_A because the O-protonated compound (probably strongly hydrated (14)) is strongly salted-out (destabilized) as the sulfuric acid concentration goes up and the water activity goes down. This is general for protonated oxygen bases (14, 22). Both the 2-thio- and 2,4-dithiohydantoin are protonated on the sulfur at the 2-position, and protonated sulfur bases in general are weakly hydrated and hence are little salted-out as the acid concentration goes up (23). This remains true for the protonated form of 5,5-pentamethylene-2,4-dithiohydantoin, which accordingly behaves like most thiocarbonyl compounds in following h_T. The reason why the replacement of sulfur by oxygen at the 4-position should lead to a marked increase in the rate of salting-out, as the acid concentration goes up, is not readily apparent in terms of the usual hypotheses (22), and may indicate that other (e.g., counterion (24)) effects are also important. The differing behaviour of 1-acyl-2-thioureas, which follow h_T, and whose conjugate acids can assume a coiled, hydrogen-bonded conformation as in **6** (15), and 2-thiohydantoins, whose

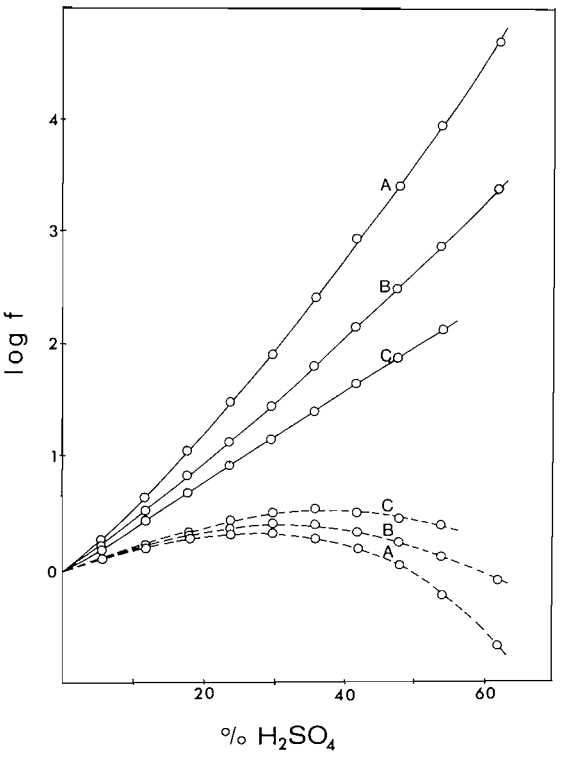

FIG. 4. Change with sulfuric acid concentration in log f_B (broken lines) and log f_{BH+} (solid lines) of (*A*) 5,5-pentamethylene-4-thiohydantoin, (*B*) 5,5-pentamethylene-2-thiohydantoin, and (*C*) 5,5-pentamethylene-2,4-dithiohydantoin.

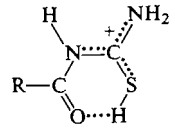

6

carbonyl groups are prevented by the ring structure from participating in such hydrogen-bonding, would seem to indicate that the interaction of the carbonyl group with some component of the acid solution is important. The desirability of further studies of thioureas containing carbonyl groups is indicated.

Experimental

Materials

The 2-thiohydantoins (20), 5,5-pentamethylene-4-thiohydantoin (25) and 5-5-pentamethylene-2,4-dithiohydantoin (25) were all prepared by the methods described in the literature and purified to constant melting points.

Sulfuric acid solutions were prepared by diluting reagent grade concentrated acid (96%) with distilled water or with distilled water and ethanol. The final acid concentrations were determined by titration.

pK_{BH^+} Measurements

Stock solutions of the 2-thiohydantoins were prepared by dissolving weighed samples in tetrahydrofuran. Aliquots of 5 μL of stock solutions were introduced by a Hamilton syringe into 5 mL volumetric flasks and diluted with sulfuric acid of appropriate concentrations. Ultraviolet spectra of the solutions were then recorded by a Unicam SP.800 spectrophotometer with a cell block thermostatted at 25.0 ± 0.1°C. Spectral curves were analyzed by conventional methods (26) at the λ_{max} of the neutral species. (Medium effects (9) were small, except for 1,3-diphenyl-2-thiohydantoin, and were neglected.) Results are given in Table 1.

Activity Coefficient Determinations

Stock solutions of the 2-thiohydantoins in chloroform (~0.025 *M*) were prepared. Aliquots (5 mL) of the solutions were shaken with 10 mL of distilled water or with 10 mL of sulfuric acid of the appropriate concentration at 25.0 ± 0.1°C. Optical densities of the aqueous and chloroform layers were then recorded by a spectrophotometer. The ratios of distribution coefficient in pure water to that of the acid solutions, corrected for protonation, gave the activity coefficients of the 2-thiohydantoins in the acid solutions (22).

Acknowledgments

The parameters characterizing the base-stacking self-association of adenosine, inosine, and guanosine 5′-monophosphate have been obtained from ^{1}H nmr dilution studies. The thermodynamic parameters for the formation of adenosine 5′-monophosphate stacks are $\Delta H^0 = -14.5$ kJ mol^{-1} and $\Delta S^0 = -42.3$ J K^{-1} mol^{-1}, with an apparent equilibrium constant of $K_c = 1.92\ M^{-1}$ at 30°C. The corresponding equilibrium constants for the self-association of inosine and guanosine 5′-monophosphate are 1.36 M^{-1} and 1.29 M^{-1}, respectively. The negative enthalpy and entropy changes cannot be explained by the concept of classical hydrophobic interactions; however, they strongly support the conclusion that dipole induced dipole forces play a major role for base-stacking in aqueous solution. The sequence of the equilibrium constants for the purine nucleoside 5′-monophosphates can be well explained by the concept of mutual polarization. The stacking geometries for adenosine and inosine 5′-monophosphate are presented as obtained from fitting the experimental shift data to refined isoshielding contours. It is concluded that the stacking pattern is not restricted to a unique geometry.

KLAUS J. NEUROHR et HENRY H. MANTSCH. Can. J. Chem. 57, 1986 (1979).

Faisant appel à des études de rmn ^{1}H à diverses dilutions on a pu déterminer les paramètres caractérisant l'auto-association par superposition des bases du monophosphate-5′ de l'adénosine, de l'inosine et de la guanosine. Les paramètres thermodynamiques pour l'empilement du monophosphate-5′ d'adénosine sont $\Delta H^0 = -14.5$ kJ mol^{-1} et $\Delta S^0 = -42.3$ J K^{-1} mol^{-1}; la constante d'équilibre apparente $K_c = 1.92\ M^{-1}$ à 30°C. Les constantes d'équilibre correspondantes pour les monophosphates-5′ d'inosine et de guanosine sont respectivement 1.46 M^{-1} et 1.29 M^{-1}. On ne peut pas expliquer les changements négatifs d'enthalpie et d'entropie à l'aide du concept d'interactions hydrophobes classiques; toutefois elles supportent fortement la conclusion que les forces dipolaires induites par des dipoles jouent un rôle important dans l'empilement des bases en solution aqueuse. L'ordre des constantes d'équilibre de monophosphates-5′ des nucléosides de bases purines peut facilement être expliqué par le concept de la polarisation mutuelle. On présente les géométries d'empilement des monophosphates-5′ d'adénosine et d'inosine telles qu'on les a obtenues en ajustant les données concernant les déplacements expérimentaux avec les contours affinés d'isoblindage. On en conclut que les empilements ne sont pas restreints à une seule géométrie.

Introduction

The association of naturally occurring nucleobases, nucleosides, and nucleotides in aqueous solution has been the subject of numerous investigations by various experimental techniques such as vapour pressure osmometry, microcalorimetry, equilibrium sedimentation, ultrasound and uv, cd, ir, and nmr spectroscopy (1–38). The field has been reviewed by Ts'o (8, 15). It is generally agreed that the self-association of these compounds is of the stacking type and that it proceeds beyond the dimer stage (2, 6, 19). It is also well established that the stacking affinity of the nucleobases, and not hydrogen bonding, represents the major contribution to the free energy sustaining the nucleic acid secondary structure (39, 40). Interactions involving base-stacking also play an important role in the selective recognition of individual nucleotides by macromolecules such as proteins and enzymes (41, 42).

Despite many studies devoted to the solution conformation of purine nucleotides and in particular to the stacking geometry of adenosine 5′-monophosphate (11, 12, 19, 33, 43–46), so far no attempts have been made to obtain thermodynamic parameters characterizing the self-association of purine mononucleotides. In the present study we describe the parameters characterizing the self-association, in aqueous solution, of the naturally occurring purine nucleotides adenosine 5′-monophosphate (5′-AMP), inosine 5′-monophosphate (5′-IMP), and guanosine 5′-monophosphate (5′-GMP). Apparent equilibrium constants, dimer shifts, and the corresponding Gibbs

energy changes are obtained from the concentration dependence of individual proton nmr shifts.

Experimental

Sample Preparation

All biochemicals were commercial products of the highest available purity. Adenosine 5′-monophosphate, inosine 5′-monophosphate, and guanosine 5′-monophosphate (sodium salts) were from Boehringer Mannheim. Nuclear magnetic resonance samples were prepared in 99.8% D_2O at pD 7.4 (meter reading), containing 10 mM phosphate buffer, 1 mM NaCl, 50 μM EDTA, and 1 mM *tert*-butanol. Individual nucleotide concentrations were accurately determined from the ultraviolet absorption, using $\varepsilon_{mM}^{260} = 15.4$ for 5′-AMP, $\varepsilon_{mM}^{249} = 12.7$ for 5′-IMP, and $\varepsilon_{mM}^{252} = 13.7$ for 5′-GMP, respectively.

Nuclear Magnetic Resonance Measurements

The ^1H nmr spectra were taken at 100 MHz with a Varian XL 100/12 spectrometer operating under a Varian 620/L data system. The digital resolution was 0.0025 ppm, the 90° pulse-time 20 μs. The temperature of the probe was regulated with the Varian temperature controller and monitored with a special thermometer in the probe. Unless specified otherwise, the probe temperature was 30°C. Typically three, but at least two, independent measurements were made for each sample. All proton chemical shifts were measured with respect to *tert*-butanol as internal reference. For the evaluation of association parameters and all other calculations a PDP 8/I computer was used.

Results and Discussion

The Self-association of Adenosine 5′-Monophosphate

As a probe for studying the concentration-dependent intermolecular association of this adenine nucleotide, we used the ^1H nmr resonances of the base protons in position 8 (A8) and 2 (A2) and that of the ribose proton in position 1′ (A1′) (see inset in Fig. 1), which are well separated from the resonances of the other strongly coupled ribose protons and have been assigned unequivocally in the literature (7, 47, 48). The resonances of these three protons undergo remarkable upfield shifts (increased shielding) with increasing 5′-AMP concentration, as displayed in Fig. 1. The differences in the magnitude of the shifts observed for individual protons is used in deriving the stacking geometry for 5′-AMP aggregates, as will be shown later. From the concentration-dependence of these ^1H chemical shifts, we have obtained the equilibrium constants characterizing this association, by applying the isodesmic model of Dimicoli and Hélène (49, 50). Figure 2 shows a typical plot, according to this model, of $(\delta\sigma/C)^{1/2}$ versus $\delta\sigma$ at 16°C, with similar plots for other temperatures ($\delta\sigma$ is the difference between the chemical shift of a particular 5′-AMP proton at concentration C and that at infinite dilution). From the slope of the linear traces in this plot, apparent microscopic equilibrium constants were obtained for the individual protons, while the x_0-intercepts yielded the corresponding dimer shifts.

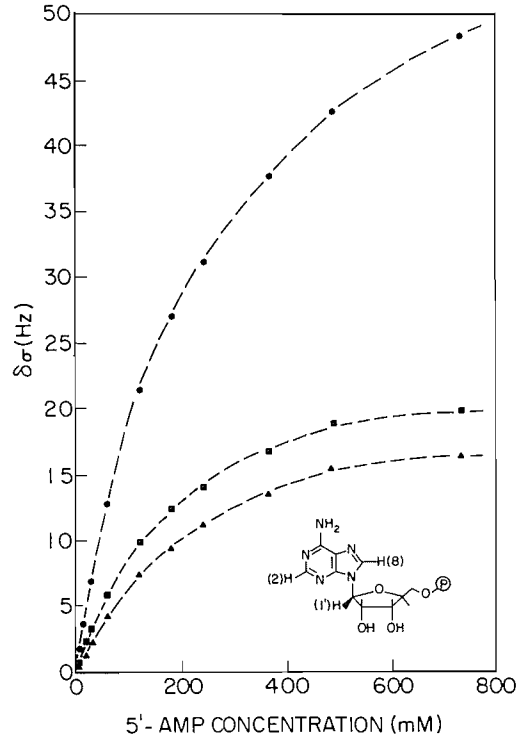

FIG. 1. ^1H nmr chemical shift differences ($\delta\sigma$) for the 5′-AMP protons A2 (●), A8 (■), and A1′ (▲) (see inset), as a function of 5′-AMP concentration, at 16°C and pH 7.4; $\delta\sigma$ is defined as $\sigma - \sigma_0$, where σ is the observed chemical shift at a given concentration, C, and σ_0 is the extrapolated chemical shift for infinite dilution.

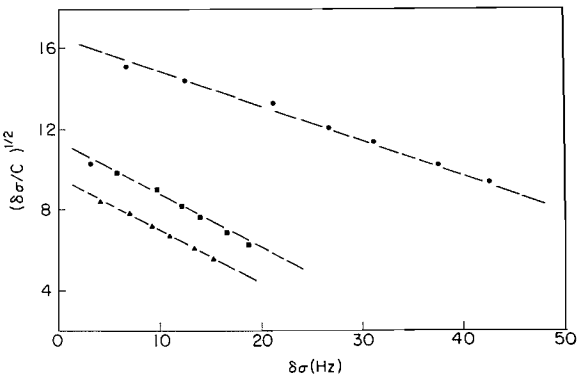

FIG. 2. Graphical evaluation of the apparent equilibrium constant for the self-association of 5′-AMP at 16°C and pH 7.4 according to the isodesmic model (49), determined from the concentration dependent chemical shift differences of the A2 (●), A8 (■), and A1′ (▲) protons.

In order to derive thermodynamic parameters,

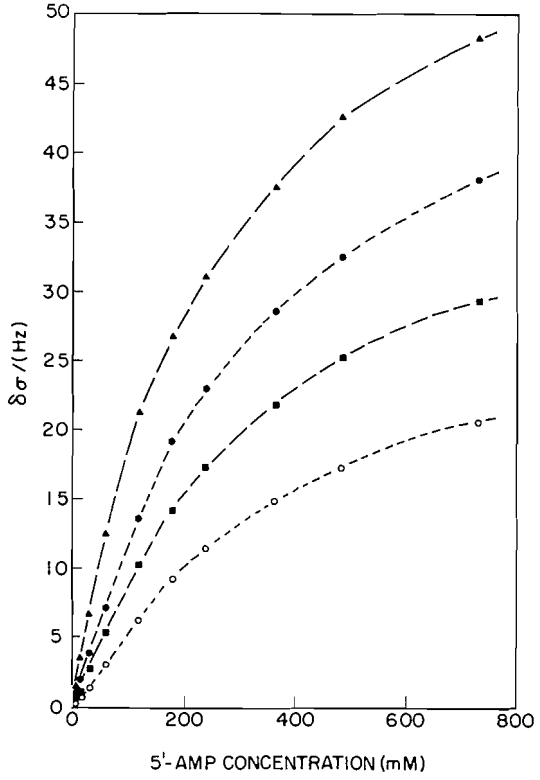

FIG. 3. Effect of temperature on the base-stacking association of 5′-AMP. Chemical shift differences are displayed for the A2 base proton as a function of 5′-AMP concentration at 16°C (▲), 30°C (●), 45°C (■), and 60°C (○).

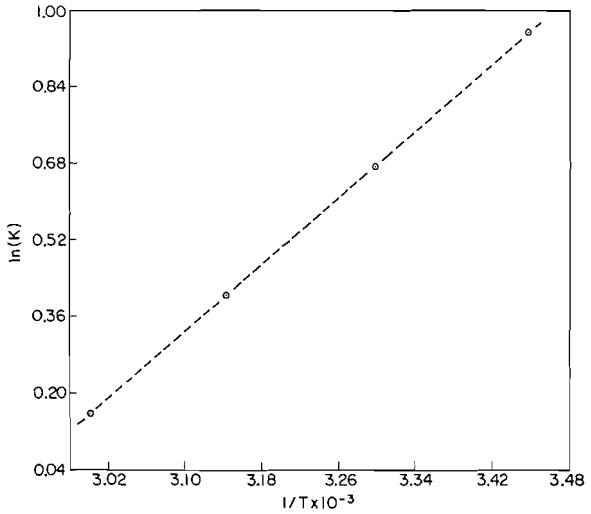

FIG. 4. van't Hoff plot representing the variation of the logarithm of the apparent equilibrium constant K_c (obtained from the A2 base proton of 5′-AMP) with reciprocal temperature.

we also investigated the concentration dependence of these ^{1}H chemical shifts at various temperatures. With increasing temperature, downfield shifts were observed, indicating a breakdown of the stacking aggregates. Displayed in Fig. 3 is the temperature effect on the chemical shift of the A2 proton of 5′-AMP. A similar temperature dependence is obtained for the A8 and A1′ protons. The corresponding equilibrium constants, dimer shifts, and Gibbs energy changes are given in Table 1. Both the equilibrium constants and standard Gibbs energy changes reported here are based on concentrations, as recommended by the ICSU Commission on Biothermodynamics (51). The magnitude of the equilibrium constant decreases with increasing temperature; the Gibbs energy changes reveal that the tendency of self-association at 16°C is about twice that at 60°C.

The thermodynamic parameters characterizing the association phenomenon have been computed from the equilibrium constants of the A2 proton obtained at different temperatures. Figure 4 shows a van't Hoff plot for this proton. From the temperature dependence of the apparent equilibrium constant K_c, we obtained an enthalpy change of −14.5 kJ mol^{-1} with an entropy change of −42.3 J K^{-1} mol^{-1} for the self-association of 5′-AMP. These

thermodynamic parameters are compared in Table 2 with literature values for other adenine derivatives which also undergo self-association via base-stacking; the sign and order of magnitude of ΔH^0 and ΔS° for 5′-AMP compares well with these data. There is an obvious decrease in the equilibrium constant in the sequence: nucleobase, nucleoside, nucleotide. Methyl substitution at the 6-amino group increases the tendency for self-association of the adenine base moiety (9, 15, 23, 24).

The Stacking Geometry of Adenosine 5′-Monophosphate Aggregates

Several studies have been devoted already to the geometry of 5′-AMP stacking aggregates (11, 12, 19, 33). This geometry was derived from experimental ^{1}H nmr shifts which were fitted to the theoretically computed isoshielding contours for the adenine base moiety (52). It is, however, not possible to derive a unique stacking geometry from only these data; thus, two different geometries have been proposed, leading to different placements of the ribosyl substituents relative to each other. While Ts'o and co-workers (4, 8, 15) and Evans and Sarma (19) have proposed a head-to-head arrangement, which places the ribosyl moieties on the same side of the stack, more recent results (11, 12, 33), based mainly on nuclear Overhauser effect studies and ^{1}H spin–lattice relaxation time measurements, favoured the head-to-tail arrangement, where the ribosyl moieties are placed on opposite sides of the stack. The older calculations of isoshielding contours were based on the ring current effect only. Recently, these calculations were refined by Giessner-Prettre and Pullman by including the anisotropy of atomic diamagnetic susceptibility (53). Inspection of the new isoshielding contours reveals that the introduction of the atomic contribution leads to an increase in shielding, which for adenine amounts to about 25%. The head-to-head and head-to-tail base-stacking patterns obtained for 5′-AMP by fitting the experimental dimer shifts from Table 1 to the new isoshielding contours are displayed in Figs. 5*a* and 5*b*, respectively. It is interesting to note that both models are in agreement with the experimental nmr shift data and it is not possible to favour one of these geometries over the other. These stacking patterns have been constructed according to the isodesmic model of Dimicoli and Hélène (49) which takes into account the magnetic anisotropy of nearest neighbours only, and assumes that these effects are additive. Shielding effects at twice the intermolecular distance are very small. The change in chemical shift of a molecule located inside an *n*-mer, relative to the free molecule, is therefore assumed to be twice that observed in the dimer. The stacking patterns in Figs. 5*a* and 5*b* show dimers; however, they also apply to *n*-mers where 5′-AMP molecules are added to both sides of the initial stack, leading to a perpetual head-to-head or head-to-tail stacking pattern. Sarma and co-workers (54–56) have determined the molecular topology of 3′,5′-, and 2′,5′-pApAp dinucleotides in aqueous solution. In the first case the two adenine bases show a preference for a head-to-head stacking while the arrangement in the latter case is neither head-to-head nor head-to-tail. It was further shown by one of us (36), that the *N*(1)-oxide analog of 5′-AMP undergoes an anomalous base-stacking in aqueous solutions where only the imidazole moieties overlap, while the pyrimidine moieties are not involved in the stacking.

The results in this study, along with the above observations, lead to the conclusion that the exact geometry of interacting adenine nucleotides can be different. Individual nucleotide molecules are in rapid motion and base-stacking is a very fast process; ultrasonic studies of the self-association of *N*(6,6)-dimethyl-

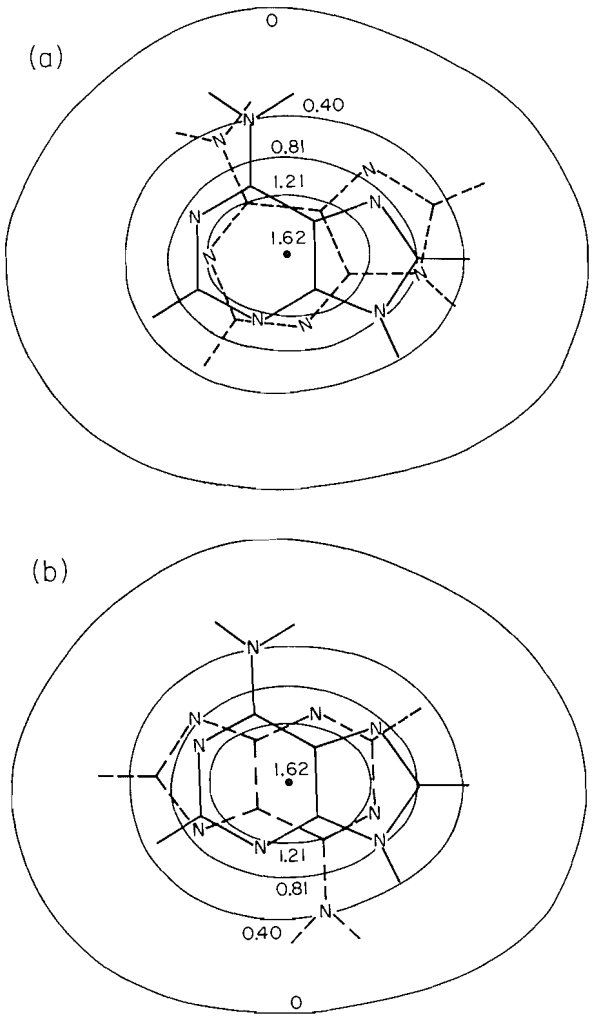

FIG. 5. Display of the head-to-head (*a*) and head-to-tail (*b*) base-stacking patterns of 5′-AMP. The ellipsoidal-shaped shielding contours represent the shielding (in ppm) experienced by the adenine base protons of the top 5′-AMP molecule (broken lines) due to the sum of the ring current effect and the anisotropy of atomic diamagnetic susceptibility of the adenine moiety of the bottom 5′-AMP molecule (solid lines). Both models have been constructed by fitting the 5′-AMP dimer shifts $\delta\sigma_{A_2}$ at 16°C from Table 1 to the recently revised isoshielding values for protons located 3.4 Å above the adenine base (53).

adenosine (38) and of similar adenine derivatives (9, 21, 27) have led to rate constants of the magnitude of 10^9 s^{-1} M^{-1}, indicating that base-stacking is a diffusion-controlled process. The dielectric properties of aqueous solutions of nucleobases and nucleosides were recently investigated by Shepherd and Schwarz (57). According to the single relaxation times found for the individual solute dispersions, an aggregation model had been suggested, where each monomer can rotate freely in the plane of stacking. From the rate constant for dissociation of *N*(6,6)-dimethyladenine (6.6×10^7 s^{-1}), the mean time for which two neighbouring bases are associated has been calculated to be 1.5×10^{-8} s (57). This value has to be compared with the dielectric relaxation time measured for *N*(6,6)-dimethyladenine at the same temperature, approximately 2×10^{-10} s (57). The comparison indicates that there is ample time for the rotation of individual molecules relative to each other within an aggregate of n monomers, before it dissociates at any of the $(n - 1)$ possible sites. Recent proton nmr data (33) yielded a reorientational correlation time for 5′-AMP of 1.1×10^{-10} s at 30°C, which again is much shorter than the mean time for which two neighbouring bases are associated.

The above studies show that the bases in the plane of stacking are very mobile and that the stacking interaction is not restricted to a unique geometry. It is thus most likely that both head-to-head and head-to-tail stacking geometries are formed when 5′-AMP molecules interact via base-stacking in aqueous solution. Also, due to the flexibility about the glycosidic bond, 5′-AMP should be able to assume any geometry, which optimizes both in-plane hydrogen bonding and out-of-plane base-stacking interactions with a given receptor macromolecule.

The Self-association and Stacking Geometry of Inosine 5′-Monophosphate

This purine nucleotide is the immediate precursor in the pathway for the biosynthesis of 5′-AMP (58). It is found in the anticodon loop of many *t*-RNAs (59); besides other unusual bases, such as the Y-base or the ψ-base, the hypoxanthine base of this nucleotide seems to play an important role in establishing the characteristic tertiary structure of *t*-RNA and is essential for its biological activity. Therefore, it becomes important to gain some information regarding the stacking capability of this base at the nucleotide level, particularly in comparison with that of the other naturally occurring purine nucleotides 5′-AMP and 5′-GMP.

We have measured the concentration dependence of the ^{1}H nmr chemical shifts of inosine 5′-monophosphate and monitored the resonances of the non-exchangeable inosine protons I2, I8, and I1′ (see Fig. 6, inset). The chemical shift differences for these protons are shown in Fig. 6 as a function of 5′-IMP concentration. All three protons show upfield shifts with increasing concentration. The shifts of the individual protons are very similar in magnitude, in contrast to 5′-AMP, where the proton in position 2 showed a much larger shift compared to those in

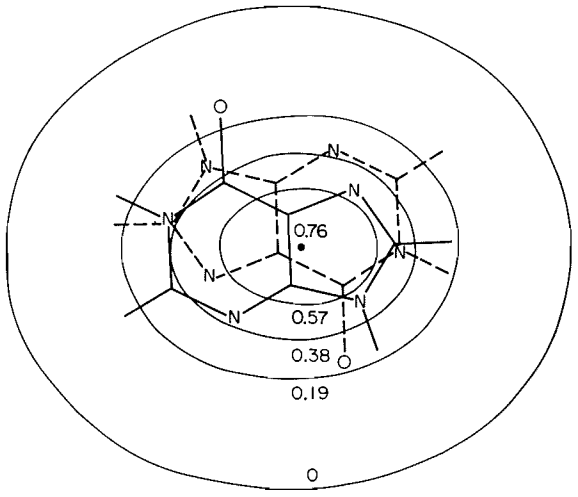

FIG. 7. Display of the head-to-tail stacking pattern of 5′-IMP. The contours show the shieldings (in ppm) experienced by the base protons of the top 5′-IMP molecule (broken lines) due to the ring current effect of the hypoxanthine base of the bottom 5′-IMP molecule (solid lines). The model was constructed from the 5′-IMP dimer shifts and the isoshielding contours calculated for a plane 3.4 Å above the hypoxanthine base (C. Giessner-Prettre. Private communication).

position 8 and 1′. We also performed an analysis of the chemical shift differences for 5′-IMP according to the isodesmic model; the corresponding microscopic equilibrium constants and dimer shifts, along with the proton averaged apparent equilibrium constant and the Gibbs energy change, are summarized in Table 3. Although K_c is smaller for 5′-IMP and ΔG^0 is about half that for 5′-AMP, this nucleotide also can engage in base-stacking interactions via its hypoxanthine base.

As in the case of 5′-AMP, the dimer shifts for the three protons investigated can be used to derive a model for the 5-IMP stacking aggregates. The theoretical isoshielding contours for the hypoxanthine base were sent to us by Dr. Giessner-Prettre prior to publication. In the calculation based on the ring current effect, the centre of shielding with a value of 0.76 ppm is located in the five-membered imidazole ring, unlike the situation with adenine where it has a considerably higher value and is localized in the six-membered pyrimidine ring. The second zone of shielding in 5′-IMP, with a value of 0.38 ppm, extends over both the five- and six-membered rings of the hypoxanthine base, while the third shielding contour covers the periphery of the two rings, where the two aromatic protons are located, and has a value of only 0.19 ppm. The shielding values for the hypoxanthine base are thus remarkably smaller than the corresponding values for the adenine base. This explains the much smaller upfield shifts observed for the 5′-IMP protons with increasing concentration, compared to the shifts for the corresponding 5′-AMP protons. Figure 7 illustrates a head-to-tail model for two stacked 5′-IMP molecules as obtained from fitting the dimer shifts in Table 3 to the isoshielding contours of Giessner-Prettre. Again, it has to be pointed out that this model represents only one of the possible stacking geometries and, as in the case of 5′-AMP, a head-to-head model would also be in agreement with the chemical shift data.

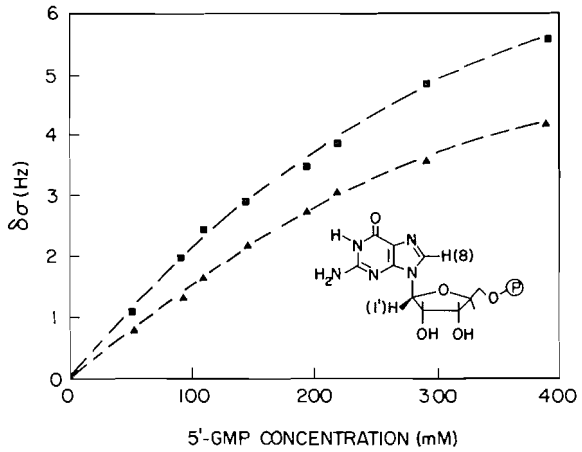

FIG. 8. ^{1}H nmr chemical shift differences for the guanosine protons G8 (■) and G1′ (▲) as a function of 5′-GMP concentration at 30°C and pH 7.4; δσ is defined as in Fig. 1.

The Self-association of Guanosine 5′-Monophosphate

Guanosine 5′-monophosphate has been shown to possess a unique ability to undergo spontaneous formation of a regular, ordered structure in aqueous solution. Guschlbauer and co-workers (60, 61) demonstrated that guanosine derivatives, in contrast to all other bases, have a strong tendency towards gel formation. The guanine base moieties first associate via hydrogen bonding to form a planar tetramer; two such tetramers then form octamers, which stack up to form highly viscous pseudopolymers. Pinnavaia *et al.* (28) investigated the 220 MHz proton nmr spectra of neutral 5′-GMP in aqueous solutions at fairly high concentrations. With increasing concentration and (or) decreasing temperature, the sharp G8 resonance broadens and two, later three, new G8 lines occur due to formation of a new regular structure in slow chemical exchange with unassociated monomers or stacked aggregates.

In order to compare the association parameters for 5′-GMP with those obtained for 5′-AMP and 5′-IMP, we also measured the concentration dependence of the ^{1}H chemical shifts of the non-exchangeable 5′-GMP protons G8 and G1′ at fairly low concentrations (up to 390 mM). As demonstrated by the concentration-dependent upfield shifts in Fig. 8, this concentration range is dominated by the formation of stacking aggregates, similar to those observed with 5′-AMP and 5′-IMP, which are in rapid chemical exchange with monomers and give time-averaged nmr spectra. The chemical shift differences were analyzed according to the isodesmic model; the apparent equilibrium constants, the Gibbs energy change, and the dimer shifts obtained from the two observable 5′-GMP protons are compared in Table 3 with the corresponding association parameters for the other two purine nucleotides. As can be seen from this table, due to the large diamagnetic ring current of the adenine base, 5′-AMP shows the highest tendency for self-association among the naturally occurring purine nucleotides. 5′-IMP and 5′-GMP have a similar, but considerably smaller tendency to form such aggregates in aqueous solutions. In the case of 5′-GMP, at concentrations above 400 mM, the self-association through base-stacking of 5′-GMP monomers is in competition with the formation of hydrogen bonded pseudopolymers (28).

Concluding Remarks

In spite of numerous publications dealing with the stacking properties of nucleobases, the nature of this interaction is still not fully understood. As base-stacking occurs only in water, the hydrophobic nature of this phenomenon has been strongly emphasized. Classical hydrophobic interactions are characterized by positive enthalpy and positive entropy changes (62). The base-stacking self-association of nucleobases, however, is accompanied by negative enthalpy and entropy changes, as has been directly obtained from calorimetric measurements of several systems (3, 5, 13), and is shown here for the 5′-AMP nucleotide. Moreover, the hydrophobic interaction is a rather unspecific phenomenon, which cannot account for the observed high specificity of the base-stacking interaction. Although the involvement of classical hydrophobic interactions in the stabilization of stacking complexes of alkylated uracils has been demonstrated (29), there is little doubt that in the case of highly polarizable purine derivatives, dipole induced dipole forces play a major role in this type of interaction (9, 22, 30). This conclusion is also supported by X-ray data (63); stacking patterns of purine bases in the crystal reveal base–base interactions with only partial overlap between neighbouring bases and with polar substituents of one base located over the ring system of an adjacent base (63). From this, the concept of mutual polarization of adjacent base moieties by partial bond moments was put forward (22). According to this concept, the stacking affinity between two adjacent bases is dependent on the degree of mutual polarization, where polarization depends both on polarizability and polarizing power.

The polarizability of an aromatic or heteroaromatic ring system, such as that of the purine bases, arises from the total electron density above and below the molecular plane. The polarizing strength is related to the bond moments of the nucleobases, due to the sp^2 nitrogen atoms and the polar keto and amino substituents. Since all nucleobases are rela-

tively polar compounds, the polarizing power is not the limiting factor and the free energy for self-association should be governed by the polarizability of the nucleobases. In Table 4 we compare the intermolecular shielding values for the purine bases which, at least to a first approximation, should parallel the polarizability of the bases, with the proton averaged equilibrium constants for the corresponding nucleotides, which should be representative for the degree of association. The data in Table 4 show that the magnitude of the intermolecular shielding values, and thus the polarizability, decreases in the order adenine, hypoxanthine, guanine. It is interesting that not only do the equilibrium constants follow these isoshielding values, but the larger difference between adenine and hypoxanthine and the smaller difference between hypoxanthine and guanine are closely paralleled in both sequences. Therefore we may conclude that the concept of mutual polarization is very useful in explaining the stacking affinities between nucleobases.

Acknowledgments

We express our thanks to Dr. I. C. P. Smith for helpful criticism and to Drs. Giessner-Prettre and Pullman for providing us with the isoshielding contours for the hypoxanthine base prior to publication. We are also grateful to the Deutsche Akademische Austauschdienst, Bonn, for a research fellowship to K.J.N.

The mass spectra of two isomeric methoxyfuranocoumarins have been investigated using electron-impact ionisation. Unambiguous distinction between the two isomers is possible through a combination of conventional mass spectra with collision-induced dissociations of the molecular ions and of selected fragment ions. The fragmentation mechanisms of these and related molecular systems were investigated in an attempt to identify the fate of each oxygen atom under electron-impact conditions. To this end, 2-pyrone, benzpyrone (coumarin), benzofuran, and some of its structural isomers were synthesised and studied via metastable spectra, collisionally activated spectra, appearance potentials, and kinetic energy release. Only partial success was achieved in this investigation, but it was possible to write a mechanistic scheme consistent with the present findings and literature data. If valid, this scheme permits identification of two of the four oxygen atoms in the methoxyfuranocoumarins.

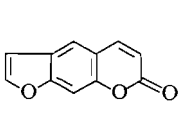
SHENG-YUH TANG, JOHN C. MCGOWAN, MARSHA SINGH, PAUL GALATSIS, BRIAN E. ELLIS, ROBERT K. BOYD et STEWART A. BROWN. Can. J. Chem. 57, 1995 (1979).

On a étudié la spectroscopie de masse de deux méthoxyfurannocoumarines isomères sous impact électronique. On peut distinguer les deux isomères sans ambiguité grâce à une combinaison de la spectroscopie de masse conventionnelle avec des dissociations induites par des collisions d'ions moléculaires et d'ions fragmentés sélectionnés. On a étudié les mécanismes de fragmentation de ces systèmes moléculaires et d'autres qui leur sont apparentés afin d'identifier le sort de chacun des atomes d'oxygène sous des conditions d'impact électronique. A cette fin, on a synthétisé la pyrone-2, la benzpyrone (coumarine), le benzofuranne et quelques-uns de ses isomères de structure et on les a étudiés grâce à des spectres métastables, à des spectres activés par collision, à leur potentiels d'apparition et par leur habilité à perdre de l'énergie cinétique. On n'a obtenu que des succès partiels au cours de cette étude; il est toutefois possible de proposer un schéma mécanistique en accord avec nos données et celles de la littérature. Si ce schéma est valable il permet l'identification de deux des quatre atomes d'oxygène des méthoxyfurannocoumarines.

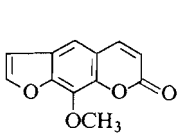
[Traduit par le journal]

Introduction

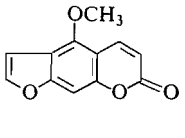
The furanocoumarins are a group of plant products of special interest for their dermal photosensitizing properties (1). Recent studies on their biogenesis (2) have outlined the route of formation of the linear furanocoumarin carbon skeleton but the source of the aromatic ring hydroxyls remains to be established. As an approach to this question we have studied the mass spectrometric fragmentation pattern of substituted furanocoumarins in hopes of identifying specific oxygen-containing fragments uniquely derived from each oxygenated portion of the furanocoumarin molecule. This information would then allow the crucial $^{18}O_2$ biogenesis experiments to be carried out.



1



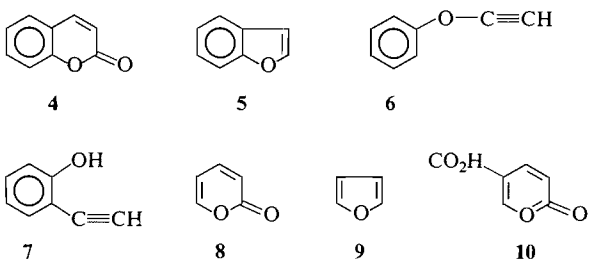
2



3

The furanocoumarins studied in the present work were psoralen (**1**), xanthotoxin (**2**), and bergapten (**3**). A comprehensive review of the mass spectrometry of these and related compounds is available (3). In addition to the mechanistic studies, it was of interest to develop a mass spectrometric technique capable of distinguishing between **2** and **3**. The conventional electron-impact (EI) mass spectra of **2** and **3** are very similar. The approach adopted in the present work

0008-4042/79/151995-09$01.00/0



has been to use the fragmentation patterns of metastable and collisionally activated ions, decomposing in the first field region of a double-focussing mass spectrometer. The diagnostic capabilities of such techniques have been well documented (4).

In addition, the identity of the oxygen atoms contained in neutral fragments expelled in various reactions was of interest from the biochemical viewpoint. The most unambiguous method of investigating this question would require synthesis of specific ^{18}O-labelled versions of **1–3**. However, these were not available, and metastable ion (MI) and collisionally activated (CA) spectra of unlabelled **1–3** were used to investigate how far the oxygen atoms in **1–3** could be identified. To this end, the EI, MI, and CA spectra of coumarin (**4**), benzofuran (**5**), phenoxyacetylene (**6**), 2-ethynylphenol (**7**), α-pyrone (**8**), and furan (**9**) were investigated.

Experimental

Apparatus

All mass spectrometric measurements were made on a VG Organic 7070F double focussing mass spectrometer, equipped with a VG 2025 data system, a collision cell in the first field-free region, and a Hall-effect probe with associated circuitry to permit linked-scans of both the B/E (daughter-ion spectra) and B^2/E (parent-ion spectra) types. Helium and nitrogen were used as collision gases, at pressures sufficient to reduce the main beam intensity to 30% of its original value. Appearance potentials were measured using an accurate 10-turn potentiometer controlling the accelerating voltage for the ionising electron beam. The peak of interest was tuned to occupy the centre two-thirds of the monitoring screen, and the integrated signal (1 s scans) fed from the integrating ion monitor to a strip-chart recorder.

Materials

The substances **1–9** were obtained as follows.

*Psoralen (**1**)*, of natural origin, was a gift of Dr. S. K. Mukerjee, Indian Agricultural Research Institute, New Delhi. It was purified by vacuum sublimation before use.

*Xanthotoxin (**2**)* was obtained from Schwarz/Mann, Orangeburg, NY.

*Bergapten (**3**)* was synthesised from isoimperatorin prepared using a published procedure (2). One gram of this isoimperatorin was dissolved in 10 mL of glacial acetic acid, with stirring at room temperature. Stirring was continued after the addition of 4 drops of concentrated sulphuric acid. Bergaptol began to separate almost immediately. After 45 min, the product (505 mg) was filtered, washed, dried, and dissolved in methylene chloride without further purification. Treatment with a substantial excess of diazomethane in ether converted the phenol to **3** in good yield.

*Coumarin (**4**)* was obtained from British Drug Houses, Ltd.

*2,3-Benzofuran (**5**)* was obtained from Aldrich Chemical Co.

*Phenoxyacetylene (**6**)* was prepared by a literature method (26, 27). The infrared spectrum (Beckman IR5A) was characterised by bands at 3310 cm^{-1} (≡C—H), 2170 cm^{-1} (C≡C), and 1240 cm^{-1} (aromatic C—O); the nmr spectrum (Varian A60 spectrometery) showed a distinctive absorption at δ = 2.32 ppm, characteristic of an acetylenic proton. The integrated nmr intensities gave a ratio very close to 5:1 for the total aromatic proton to acetylenic proton intensities, as expected.

2-Ethynylphenyl (**7**) was also prepared by a literature method (28). The infrared spectrum showed bands at 3510 cm^{-1} (aromatic O—H), 3290 cm^{-1} (≡C—H), 2140 cm^{-1} (C≡C), and 1220 cm^{-1} (aromatic C—O). The nmr spectrum had characteristic lines at δ = 2.15 ppm (≡C—H) and a broad band at δ = 5.85 ppm, typical of a phenolic proton. The integrated intensities were very close to 4:1:1, for aromatic:acetylenic:phenolic protons, as required.

2-Pyrone (**8**) was prepared by an adaptation of a literature method (29), whereby the mercury salt of coumalic acid (**10**) was heated in a stream of dry nitrogen (rather than hydrogen (29)) to give **8** in low yield. The ir spectrum showed a broad absorption in the region 1600–1750 cm^{-1}, with a distinguishable band at 1700 cm^{-1}; the latter probably corresponds to the (C=O) stretch, superimposed upon the ring vibration frequencies. Bands at 1090 and 1045 cm^{-1} correspond to C—O frequencies. The nmr spectrum was consistent with the structure of 2-pyrone but showed some evidence of impurities, also apparent from the mass spectrum.

Furan (**9**) was obtained from Aldrich Chemical Co., and was purified by fractional freezing before use.

Results and Discussion

Mass Spectrometric Distinction between Isomeric Methoxy-furanocoumarins

The EI spectra of **2** and **3** were found to be very similar, though not identical (Table 1). The most clear-cut differences lie in the lower mass range (m/e < 90), and are thus most susceptible to interference from background ions from impurities, solvent, etc. However, the $63^+/51^+$ ratio does offer a fairly clear-cut distinction between the two isomers, in the absence of such interferences.

A mass spectrometric technique which circumvents such problems involves selecting for study just one ion (typically through not necessarily the molecular ion), and generating a daughter-ion spectrum of this preselected parent ion. In the present work, the B/E linked-scan technique (5) was used to generate CA spectra of the molecular ions of **2** and **3**, and also of the corresponding M—CH_3 (m/e = 201) ions. The results obtained are summarised in Table 2; the CA spectra obtained for the molecular ions are shown in Fig. 1. Viewed simply as fingerprints, these spectra can be used to distinguish between **2** and **3**. The most clear-cut difference appears at m/e = 199 in the daughter-ion spectra of the two

molecular ions. While this peak is not very intense in the case of **2**, it is completely absent from the spectrum of **3**; repeated attempts to find this peak in the case of **3**, using various pressures of both N_2 and He as collision gases, failed completely. Other differences between the CA spectra of the isomeric molecular ions occur at m/e = 215, 188, and 174, although these are no more striking than the differences in the EI spectra (Table 1). They are, however, much less susceptible to interferences from impurities. If the $(M—CH_3)^+$ ions (m/e = 201) are used as parent ions for the CA spectra, striking differences (Table 2) are found in the relative intensities of fragment ions at mass 145. A combination of EI and CA spectra can thus unambiguously distinguish between the two isomers.

Fragmentation Mechanisms of Pyrone and Coumarin

The problem of trying to identify by mass spectrometry which oxygen atom in **1–3** is expelled in a specified fragmentation reaction involves the question of the fragmentation mechanisms responsible for the observed mass spectra. Considerable literature exists on the related systems **4**, **5**, **8**, and **9**. Most of this information has been extensively discussed previously (6) and will be briefly summarised here.

The mass spectrum (6) of 2-pyrone (**8**) is characterised by expulsion of CO followed by further fragmentations of the M—CO ion, which are closely similar to those of the molecular ion of furan (**9**). Accordingly, the $C_4H_4O^{+\cdot}$ ion (M—CO ion) from **8** has frequently been assigned a furan-like structure, even though no positive evidence exists supporting a closed-ring structure for the $C_4H_4O^{+\cdot}$ ions from either **8** or **9**. A study of the EI mass spectra of the four monodeuterio-2-pyrones (8) appears to rule out any structure for the $C_4H_4O^{+\cdot}$ ion from **8** in which the H (or D) atom, originally at the 6-position of 2-pyrone, is not unique. This experimentally observed uniqueness of the 6-position in **8** rules out a furan-like structure for the M—CO ion from **8**, even if the molecular ion of **8** does not retain the intact pyrone structure (6). A number of possible structures for this ion are consistent with these findings (6), but the objections raised (9) to exclusion of a furan-like structure, based upon earlier labelling experiments (7), appear to have been convincingly answered (6).

Studies of the shapes of metastable peaks arising from expulsion of CO from the molecular ions of substituted 2-pyrones (10) indicated no substituent effect upon the kinetic energy release in these reactions. This was considered (10) to demonstrate the existence of non-furan-like structures for the M—CO ions arising from 2-pyrones. Finally, the MI spectra of the $C_4H_4O^{+\cdot}$ ions arising from **8** and **9** have been compared (11) to demonstrate that these ions are not identical in both structure and internal energy.

In the present work, both MI and CA spectra of $C_4H_4O^{+\cdot}$ ions from **8** and **9** were obtained using the B/E linked scan technique (5); the results obtained are summarised in Table 3. Since only the $C_4H_4O^{+\cdot}$

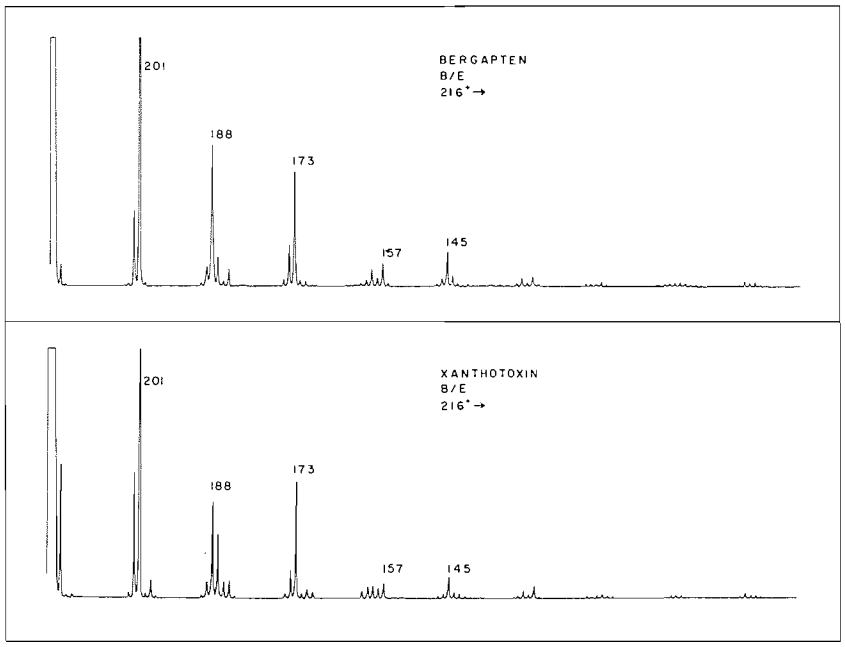

FIG. 1. Collisonally activated spectra of molecular ions of xanthotoxin (**2**) and bergapten (**3**).

ions were selected for study, the minor impurities present in our sample were of little importance. The MI spectra confirm that these ions differ in one or both of structure and internal energy, but differ somewhat from earlier results (11). In this regard, it must be emphasised that the B/E linked scan (5) picks out only those ions corresponding to the centre of a metastable peak. This accounts for the higher mass resolution of such spectra, relative to those obtained by the accelerating-voltage scans used previously (11); this could account, in part, for the larger number of peaks observed in the MI spectra. For the same reason, the intensities (peak heights) reported here are not directly comparable with the areas under the full metastable peaks (11). In addition, it is clear (12, 13) that the B/E linked-scan technique is liable to produce artifact peaks, particularly weak peaks corresponding to fragment ions arising from precursors differing by one mass unit from that actually preselected. Accordingly, the significance of some of the weaker peaks should be approached with some reserve, although the intensities of precursor ions at $m/e = 69$ and 67 are not large in the present case, and such artifacts seem unlikely to be important here. Collisionally activated (CA) spectra of ions are known (14) to be much less sensitive to internal energies of the precursor ions, so that differences observed are more likely to be ascribable to differences in structures. For purposes of such structural comparisons, it is best (14) to exclude those peaks also observed in the MI spectra, since the probabilities of the low-energy reactions responsible for such peaks will be strongly dependent upon the internal energies of the precursor ions. The most significant difference

between the two CA spectra involves the relative intensities of the peaks at $m/e = 54$ and 53 (loss of CH_2 and CH_3, respectively); the differing intensities at $m/e = 27$ and 26 also appear to be significant, and were observed consistently. These differences probably reflect different structures, or mixtures of structures, for the $C_4H_4O^{+\cdot}$ ions sampled in the CA experiments. These results alone do not, of course, permit structures to be assigned to $C_4H_4O^{+\cdot}$ ions arising from either **8** or **9**.

This question was not pursued further in this work. A thorough investigation of $C_4H_4O^{+\cdot}$ ions generated from various precursors has been undertaken (J. L. Holmes, private communication). Using information derived from CA spectra and heats of formation of ions, non-fragmenting $C_4H_4O^{+\cdot}$ ions generated by CO loss from the molecular ions of 2- and 4-pyrone were shown to have predominantly a furanoid structure, with some contribution from a vinyl ketene structure. Clearly, the structures to be assigned to $C_4H_4O^{+\cdot}$ ions depend markedly on the internal energies of the ions.

The presence of the aromatic ring fused to the pyrone ring in the compounds of interest here (**1–3**) could have a sufficiently large effect to make inapplicable these conclusions concerning the fragmentation of 2-pyrone. Accordingly, the fragmentation of coumarin (**9**) was studied in the same fashion. A vast literature exists (3) concerning the mass spectrometry of coumarins, and only the more relevant work will be mentioned here. The principal fragmentation reactions of the molecular ion of **4** involves successive expulsion of neutral CO fragments. Experiments with ^{13}C labels have shown (15, 16) that expulsion of that CO moiety which is present as the carbonyl group in the pyrone ring occurs first. This was true (15, 16) in cases where several other possibilities existed for the origins of the first CO fragment. By analogy with the case of 2-pyrone, it has been widely surmised (3) that the $C_8H_6O^{+\cdot}$ ion, formed by loss of CO from the molecular ion of **4**, has the closed-ring structure of benzofuran (**5**). This suggestion has been challenged on energetic grounds (17); it was suggested (17) that the $C_8H_6O^{+\cdot}$ ion from **4** has a structure corresponding to that of *o*-ethynylphenol (**7**).

In the present work, the three compounds **5–7** were synthesised, and their mass spectra investigated. These isomers correspond to possible stable structures arising from expulsion of the carbonyl group from **4**. The 70 eV EI mass spectra of **5–7** were very similar to one another and to that of coumarin (**4**) below $m/e = 118$. Accordingly, the MI and CA spectra of ions of $m/e = 118$, from **4–7**, were obtained, and are summarised in Table 4.

TABLE 5. Heats of formation of $C_8H_6O^{+\cdot}$ ions (kJ mol^{-1})

Precursor (H_f^0/kJ mol^{-1})[a]	AP/eV	Neutral fragment	ε/eV	$\Delta H_f^0(C_8H_6O^{+\cdot})$	References
Coumarin (**4**)	10.8	CO	1.50[b]	851	Present work

[b]ε is sum of ε_i^0 plus kinetic shift appropriate to first field-free region reaction of metastable ions.
[c]Determined (17) from width of 'metastable plateau' using single-focussing instrument.
[d]Most recent value (18) obtained using critical-slope method.

If, for the purposes of comparing ion structures, those peaks in the CA spectrum which appear also in the MI spectrum are again ignored (14), the results of Table 4 *cannot* distinguish between the $C_8H_6O^{+\cdot}$ ions arising from **4** and **5**. On the other hand, significant differences exist in the CA spectra of **6** and **7**. In the case of **6**, the strong peak at $m/e = 77$ corresponds to loss of the (O—C≡CH) group, which thus appears to remain intact in the molecular ion of **6**. The peak at $m/e = 78$ is more difficult to interpret, but is characteristic of **6** in the same way. The main distinctive features in the CA spectrum of **7** are the fragment ions of masses 105 and 101; these are weak peaks, whose significance was confirmed by several independent scans. The fragment ion of mass 101 corresponds to M—OH, which is not unexpected; however, that at mass 105 corresponds to M—CH. Since this peak is absent from all other spectra in Table 4, it must be characteristic of the ethynyl group attached directly to the benzene ring. Its origins are not known.

Thus, in contrast with the case of 2-pyrone, the CA spectra of benzofuran (**5**) molecular ion and of the M—CO ion from coumarin (**4**) are indistinguishable. As a further check upon the relationship between these ions, their heats of formation were estimated. The values obtained in the present work are compared with literature data in Table 5. Experimental heats of formation appear to be available for *none* of the neutral percursors used (**4**–**7**). Accordingly, these were estimated using group-contribution methods (22), of unknown accuracy for the compounds of interest.

The most striking discrepancy between the present work and literature data concerns the value of the kinetic energy release derived from the width of the metastable peak corresponding to loss of CO from the molecular ion of **4**. Figure 2 shows the peak shape obtained in the present work, using a high-voltage scan. At the low-energy side, a weaker peak corresponding to formation of a fragment ion of mass 118 from a parent ion of mass less than 146 can be seen. The maximum of this second peak is not clearly defined. The high-energy side is free from such interference, however, and was used to establish the peak width. Several measures of the peak width were converted to values for kinetic-energy release T, using the simple one-dimensional formula (4) (corresponding to scattering angles for the fragment ion of 0 and π only). The values obtained for T were as follows: T(horns) = 0.27 eV; T(half-height) = 0.56 eV; T(max) = 1.50 eV. The simple formula is exact for T(max).

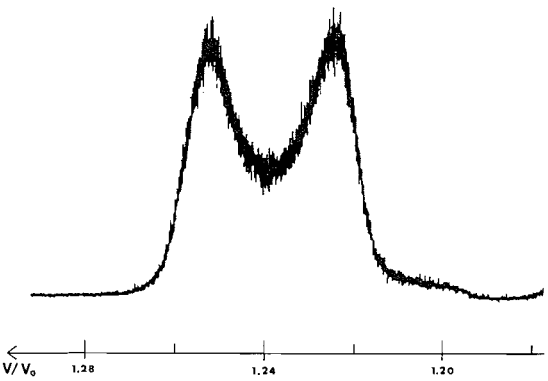

FIG. 2. Metastable peak for reaction $146^+ \rightarrow 118^+$ in coumarin (**4**), obtained by scan of accelerating voltage. Entrance and exit slits set for mass resolution of 3000, and beta slit closed until no further improvement in kinetic energy resolution obtained.

Previous measurements of this quantity yielded values of 0.26 eV (17) and 0.17 eV (10). These earlier values (19, 17) were obtained from observations of

'flat-topped' metastable peaks using single-focussing instruments; no precise information was given concerning the actual peak width parameter measured. Such a technique, involving a shorter distance travelled by the fragment ions before collection, inherently involves less *z*-axis discrimination, and thus less dishing, than does the present technique utilising the first field-free region of a double-focussing instrument (4). Thus, the present dished metastable peak (Fig. 2) could correspond to a flat-topped peak in a single-focussing instrument, with a plateau width corresponding approximately to the present separation between the horns. This is, indeed, observed, though the precise relationship depends upon details of the instrumental geometry.

In the present work the appropriate value of kinetic energy release, used to correct the appearance potential to yield ΔH_f^0 of the fragment ion, was taken to be T_{max}, corresponding to the peak width at the base. T_{max} must correspond (23) to a *lower* limit to the quantity $(\varepsilon_{MI}^{\ddagger} + \varepsilon_r^0)$, where ε_r^0 is the energy barrier for the reverse reaction and $\varepsilon_{MI}^{\ddagger}$ is the kinetic shift pertinent to the metastable ions in the instrument actually used. The correction actually desired is $(\varepsilon_{AP}^{\ddagger} + \varepsilon_r^0)$, where $\varepsilon_{AP}^{\ddagger}$ is the kinetic shift pertinent to the fragment ions formed in the ion source in the threshold region of the appearance potential measurements. In general, the longer timescale characteristic of the metastable ion experiment will tend to make $\varepsilon_{MI}^{\ddagger} < \varepsilon_{AP}^{\ddagger}$, but this trend will be at least partly compensated by the greater sensitivity available in the usual experimental procedure for measurement of appearance potentials. This procedure accounts for the discrepancy between the present and earlier values for $\Delta H_f^0(C_8H_6O^{+\cdot})$ (Table 5). This discrepancy is extremely important, since the use of T(max) as the correction gives a value for $\Delta H_f^0(C_8H_6O^{+\cdot})$, from **4** as precursor, in reasonable agreement with that from **5**, to within the experimental uncertainties. The heats of formation, thus calculated, are in agreement with the CA spectra (Table 4) in that the $C_8H_6O^{+\cdot}$ ion from coumarin (**4**) is not distinguishable from the molecular ion of benzofuran (**5**), while those arising from **6** and **7** are clearly different.

Fragmentation of Furanocoumarins

The three furanocoumarins studied here (**1**–**3**) yield intense molecular ions in their 70 eV EI spectra (Table 1). In the case of the parent compound psoralen (**1**) the only important fragmentation mechanism involves successive expulsion of 3 molecules of CO. By analogy with earlier ^{13}C labelling work on related systems (15, 16), it seems likely that the first CO moiety expelled is that originally present as the carbonyl in the pyrone ring. No further conclusion seems possible. Indeed, if formation of the M—CO ion of **1** does indeed involve closure of the furan ring, this ion would be symmetrical and no distinction between the two remaining oxygens would be possible. There is no evidence for or against ring closure in this case, though it is clear (Tables 4 and 5) that the M—CO ion from **4** is thus far indistinguishable from the molecular ion of **5**. This is in contrast with the analogous result of comparing **8** and **9**, and probably reflects a stabilising effect of the fused aromatic ring.

The two isomeric methoxy derivatives **2** and **3**, however, show at least two competing fragmentation pathways. One of these involves initial expulsion of CO (presumably that originally present as carbonyl), while the more important has as an initial step the loss of $CH_3^{\cdot}$, followed by expulsion of CO. While all three oxygen atoms are fairly readily expelled from **1** (Table 1), the situation is more complicated in the cases of **2** and **3**. Thus, loss of $(CH_3)(CO)_2$, in various permutations of three steps, occurs fairly readily with the mechanism involving initial loss of CH_3 as the main contributor. However, the ion of $m/e = 117$ (corresponding to loss of $(CH_3)(CO)_3$) is of very low intensity ($\sim 3\%$) in the EI spectra of **2** and **3**, and is completely absent from the CA spectra (Table 2). On the other hand, the ion of $m/e = 89$, which corresponds to loss of $(CH_3)(CO)_4$, is reasonably intense (Table 1). Similar trends have been noted previously (24), and can be rationalised on the basis of work (25) on the EI spectra of aromatic-methyl ethers.

Figure 3 illustrates such a speculative rationalisation for the case of xanthotoxin (**2**); a similar scheme can be written for **3**. For aromatic-methyl ethers with substituents placed in the aromatic ring such that it is possible to write quinonoid structures for the M—CH_3 ion, fission of the aromatic-ether bond is suppressed in favour of expulsion of $CH_3^{\cdot}$ (25). Otherwise, loss of CH_2O (presumably formaldehyde) is favoured. In the case of **2** and **3**, a very weak peak ($< 1\%$) at $m/e = 185$ was observed in the EI spectrum with no signal at 186. Three independent attempts to measure the accurate mass of these ions resulted in an average value of 185.024 $\pm$ 0.010. This very poor precision was due to the low intensity of the peak, but is sufficient to identify these ions as M—CH_3O rather than M—C_2H_7, from **2** and **3**. The complete absence of a peak at $m/e = 186$, corresponding to M—CH_2O, confirms that **2** and **3** follow the general pattern established previously (25) for aromatic ethers, readily rationalised in terms of structure **2***c* (Fig. 3) for the ion of $m/e = 201$. Such an ion could readily lose one or two molecules of CO, or alternatively C_2H_3 (2CO + H), etc. (Table 2).

The molecular ion of **2** has been written as in **2***a*,

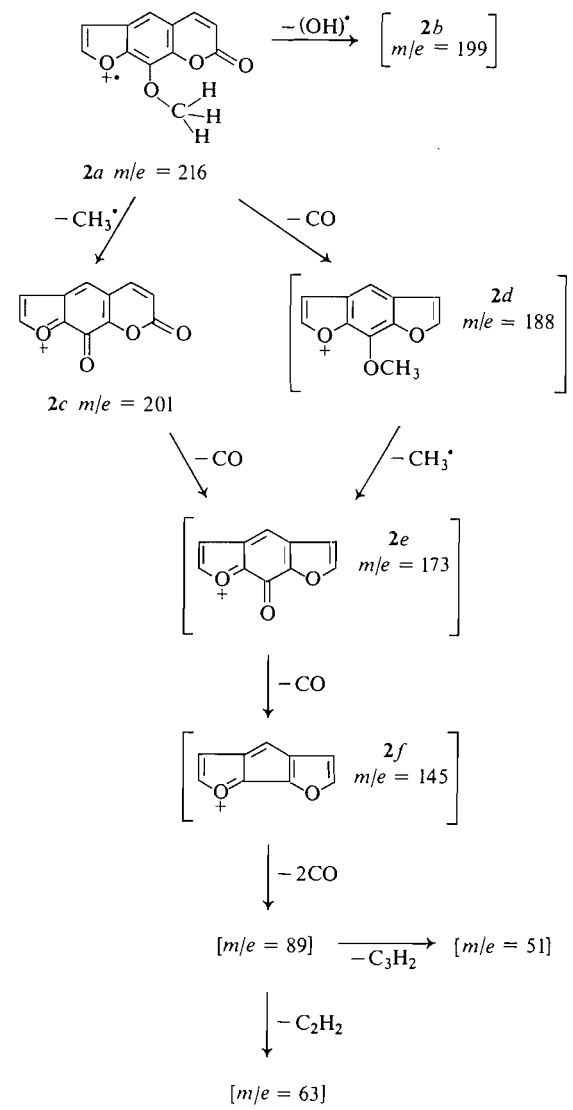

FIG. 3. Proposed rationalisation of fragmentation mechanism of xanthotoxin (**2**) under EI conditions. Ions of unknown or particularly uncertain structures are written in square brackets (see text).

with a conceivable six-membered ring intermediate leading to expulsion of HO•, (m/e = 199, Table 2). The analogous structure **3***a* could not be written in this way, thus rationalising the total absence of m/e = 199 as a daughter ion for this isomer.

Ions formed by expulsion of the carbonyl CO from the pyrone ring have been written with benzofuran-like structures **2***d* and **2***e*, i.e., with ring closure subsequent to CO loss. There is no real evidence for this assumption. The apparent identity of the $C_8H_6O^{+\bullet}$ ions from **4** and **5**, described above, does not necessarily require such closed-ring structures for either ion, but merely rules out ion structures derived from **6** and **8**.

The molecule of CO expelled from **2***e* is assumed to be the carbonyl group (i.e., that derived from the original methoxy group), again by analogy with the results of ^{13}C labelling experiments on related systems (15, 16). The resulting ion at m/e = 145 is of even more uncertain structure, and structure **2***f* written in Fig. 3 was so written merely to emphasise that this ion must have either a highly strained fused ring structure (**2***f*) or else a highly unsaturated, and thus high energy, open chain structure. The rapid expulsion of two molecules of CO from this ion is thus not unexpected, and is confirmed by the appropriate CA spectrum for the case of m/e = 145 from **2** (Table 2). It is not necessary to postulate expulsion of a single neutral fragment C_2O_2, as was done previously (16). In this regard, it is perhaps worthwhile to point out that, in the context of MI and CA spectra, the term 'simultaneous' applied to the expulsion of two molecules of CO as in the present example, means 'within the time period during which the ions are in the appropriate field-free region.'

(Ref.: Can. J. Chem. **57**, 404 (1979))
Received May 14, 1979

On p. 412, line 12 of the main paragraph of the left-hand column, should read **1–17** instead of **2–17**.

The correct caption of Fig. 7 (p. 413) should read: The $\nu_2 + \nu_6$ and $\nu_4 + \nu_6$ region of the spectrum of NH_4^+ in $(NH_4)_2SnCl_6$ (**23**) at 298 and 22 K.

On p. 423, lines 5 and 6 of the right-hand column, the chemical formulae should read $(NH_4)_3AlF_6$ and $(NH_4)_3FeF_6$.

In the first paragraph of the right-hand column on p. 413 and in the second paragraph of the left-hand column on p. 417 the discussion of NH_4SnF_3 is based, erroneously, on the assumption that the axial N—H vector points away from the Sn atom of the nearest SnF_3^- ion on the threefold axis and consequently, that the three equivalent nonaxial hydrogen bonds are to the F atoms of that SnF_3^- ion. In fact, even though the H atoms have not been located, the conclusion from the evidence presented in ref. 39 must be that the axial N—H vector points in the *opposite* direction, i.e., to the Sn atom. H–H repulsion cannot therefore be the cause of the high value of $\nu_1(a)$. This matter will be discussed more fully, together with additional ir results for NH_4SnF_3, in Part VIII of this series. The H...X and NHX* entries for **36** in Table 4 are correct.

On p. 419, right-hand column, line 20 from top, read "The displacement" instead of "This displacement".

On p. 422, the subgroup sequence on line 20 of the right-hand column should read $D_{4h}^6 \supset D_{2h}^{12} \supset C_{2h}^5$.

Thermodynamics of transfer of Ph_4C; scaled-particle theory and the Ph_4As^+/Ph_4B^- assumption for single ions

MICHAEL H. ABRAHAM AND ASADOLLAH NASEHZADEH
Chemistry Department, University of Surrey, Guildford, Surrey, England

Received November 1, 1978

MICHAEL H. ABRAHAM and ASADOLLAH NASEHZADEH. Can. J. Chem. 57, 2004 (1979).

Free energies of transfer of Ph_4C from acetonitrile to 20 other solvents have been calculated from literature data. The contribution of the cavity term to the total free energy has been obtained from scaled-particle theory and Sinanoglu – Reisse – Moura Ramos theory. It is shown that there is little connection between the cavity term and the total free energy of transfer, and that there must be, in general, a large interaction term. If the latter is important for transfer of Ph_4C, we argue that it must also be important for transfer of the ions Ph_4As^+ and Ph_4B^-. Previous suggestions that the interaction term is zero for transfer of these two ions are thus seen to be unreasonable. We also show, for six solvents, that the interaction term for Ph_4C is very large in terms of enthalpy and entropy, and that scaled-particle theory seems not to apply to transfers of Ph_4C between pure organic solvents.

The free energy, enthalpy, and entropy of transfer of $Ph_4As^+ = Ph_4B^-$ have been calculated by dividing the total transfer values into neutral and electrostatic contributions; reasonable agreement is obtained between calculated and observed values.

MICHAEL H. ABRAHAM et ASADOLLAH NASEHZADEH. Can. J. Chem. 57, 2004 (1979).

On a calculé, à partir de données de la littérature, les énergies libres de transfert du Ph_4C de l'acétonitrile à 20 autres solvants. On a déduit la contribution du terme de cavité à l'énergie libre totale à partir de la théorie des particules graduées et de la théorie de Sinanoglu – Reisse – Moura Ramos. On a montré qu'il n'existe que peu de corrélation entre le terme de cavité et l'énergie libre totale de transfert et qu'il doit exister d'une façon générale un terme d'interaction important. Si ce dernier est important pour le transfert de Ph_4C, on suggère qu'il doit aussi être important pour le transfert des ions Ph_4As^+ et PhB^-. Des suggestions antérieures à l'effet que le terme d'interaction est égal à zéro pour ces deux ions ne semblent donc pas raisonnables. On montre aussi, pour six solvants, que le terme d'interaction pour le Ph_4C est important en termes d'enthalpie et d'entropie et qu'il ne semble pas que la théorie des particules graduées puisse s'appliquer aux transferts du Ph_4C entre des solvants organiques purs.

On a calculé l'énergie libre, l'enthalpie et l'entropie de transfert de $Ph_4As^+ = Ph_4B^-$ en divisant les valeurs totales de transfert en contributions neutre et électrostatique; on a obtenu une corrélation vraisemblable entre les valeurs calculées et observées.

[Traduit par le journal]

Introduction

The free energy of transfer of a solute from one solvent to another, ΔG_t^0, is often broken down into a cavity term and an interaction term:

$$[1] \qquad \Delta G_t^0 = \Delta G_t^0(\text{cavity}) + \Delta G_t^0(\text{int})$$

The former term represents the contribution due to the work required to make a cavity in the solvents (in the scaled-particle theory, this term includes also a correction term $RT \log (V_1/V_2)$ where V_1 and V_2 are the molar volumes of the two solvents), and the latter term arises from the interaction of the solute with the solvent molecules surrounding the cavity. Treiner (1) has applied eq. [1] to test the Ph_4As^+/Ph_4B^- assumption for single-ion free energies of transfer.[1] In the method used by Treiner, an additional hypothesis was introduced, namely that $\Delta G_t^0(\text{int}) = 0$ for Ph_4As^+ and Ph_4B^-. We later advanced a number of reasons why this hypothesis could not be correct (2), but since there is always an arbitrary element in single-ion quantities we felt it would be more satisfactory to investigate the thermodynamics of transfer of a suitable nonelectrolyte. In connection with the ions Ph_4As^+ and Ph_4B^-, the tetraphenyl derivatives of the Group IV elements are obvious choices as nonelectrolytes. Since Ph_4C has been studied more extensively than the other tetraphenyl compounds, we selected this particular compound, although results for the other tetraphenyls are almost identical. Our method is simply to use literature data in order to obtain ΔG_t^0 values for Ph_4C, to calculate ΔG_t^0(cavity) by both the scaled-particle theory and the Sinanoglu – Reisse – Moura Ramos (SRMR) theory, and thus to determine via eq. [1] whether or not ΔG_t^0(int) can be taken as zero

[1]This assumption is simply that ΔG_t^0 for $Ph_4As^+ = \Delta G_t^0$ for Ph_4B^-.

[g]From data (3) for Ph_4Si, Ph_4Ge, Ph_4Sn, and Ph_4Pb.

for Ph_4C. If ΔG_t^0(int) is indeed zero (within a certain experimental error), then Treiner's hypothesis for Ph_4As^+ and Ph_4B^- must be considered reasonable. If, however, ΔG_t^0(int) is definitely not zero for Ph_4C, we can rigorously conclude that Treiner's hypothesis does not hold for Ph_4C, and hence by implication that it does not hold for the ions Ph_4As^+ and Ph_4B^-.

At the same time, we thought it useful to investigate also the corresponding hypotheses in terms of enthalpy and entropy and to consider an alternative method of calculating the thermodynamic parameters for transfer of Ph_4As^+ and Ph_4B^-.

Calculations on Ph_4C

Several workers (3–8) have determined the solubility of Ph_4C in various solvents; from these measurements the standard free energy of transfer of Ph_4C from a given reference solvent may be obtained. Quite recently, Kim (9) has redetermined many of these solubilities and has given a set of mean values of ΔG_t^0 for Ph_4C from the best data. In Table 1 are ΔG_t^0 values, mostly taken from Kim's work and converted to the mole fraction scale with acetonitrile as a reference solvent. We also give in Table 1 ΔG_t^0 values for transfer to a number of solvents not considered by Kim, so that we have a range of solvents from highly polar (water, formamide, DMSO, etc.) to quite nonpolar (carbon tetrachloride, hexane, etc.) molecules.

The ΔG_t^0(cavity) terms were calculated as before (2) using the scaled-particle theory outlined by Pierotti (10) for a solute of diameter 8.04 Å, the value suggested (11) for Ph_4C. In addition to the solute diameter, it is necessary also to estimate the values of the solvent diameters, σ. For consistency, we took, where available, values used by Treiner (1) and by ourselves (2) previously. In the case of the remaining solvents we estimated σ values from solvent heats of vaporisation, as outlined by Pierotti. Although we feel that the alternative method of estimating σ values from log K^H values of rare gases (10) is rather better, lack of data in many solvents prevented us from applying this method to all the remaining solvents;

we thought it more consistent to use just one method and so we chose only the heat of vaporisation method. The estimated solvent σ values (and hence the calculated cavity terms) are not always the same for the two methods of estimation, but our general conclusions are in no way affected by the actual method chosen. Details of the cavity term calculation by scaled-particle theory are in Table 1, together with cavity terms calculated by SRMR theory (12, 13) for a solute of molar volume 282 mL mol^{-1}. In all cases acetonitrile was chosen as the arbitrary reference solvent. It is quite clear that the ΔG_t^0(cavity) term cannot in general be equated with the overall ΔG_t^0 values for Ph_4C; the two terms differ by over 4 kcal mol^{-1} for 10 out of the 20 solvents listed. These inequalities persist, no matter which solvent is chosen as the reference solvent. We conclude that if the cavity terms are calculated by scaled-particle theory, then the interaction term in eq. [1] is generally not zero for Ph_4C in pure solvents, and we can reasonably deduce that it will not be zero for the solutes Ph_4As^+ and Ph_4B^-. As we have shown before (2), the Ph_4As^+/Ph_4B^- assumption does not itself involve any hypothesis about the interaction term other than if the cavity terms for Ph_4As^+ and Ph_4B^- are equal, then the interaction terms will also be equal in magnitude for Ph_4As^+ and Ph_4B^-. Treiner (1), however, argues that where ΔG_t^0(int) is calculated to be not zero for Ph_4As^+ or Ph_4B^-, then the Ph_4As^+/Ph_4B^- assumption is not valid. However, the large values of ΔG_t^0(int) for Ph_4C bear no relation to the Ph_4As^+/Ph_4B^- assumption, and we can argue as follows. If the scaled-particle cavity calculations are realistic, then the ΔG_t^0(int) terms can be large for Ph_4C, Ph_4As^+, and Ph_4B^-, the interaction term for Ph_4As^+ can equal that for Ph_4B^-, and the Ph_4As^+/Ph_4B^- assumption can still be valid. On the other hand, if the scaled-particle calculations are not realistic, nothing can be deduced about the Ph_4As^+/Ph_4B^- assumption, which, therefore, can still be valid. It therefore seems quite clear that the scaled-particle cavity calculations, together with the additional hypothesis that ΔG_t^0(int) is zero, cannot be used to disprove the Ph_4As^+/Ph_4B^- assumption and cannot be used to account for or to predict the total free energy of transfer of Ph_4C between pure solvents.

A few enthalpies of transfer of Ph_4C are available from the work of Cox and Parker (8), and in Table 2 are given the observed ΔH_t^0 values and the calculated ΔH_t^0(cavity) terms; the latter include also the correction terms (1, 2) $\alpha p_2 RT^2 - \alpha p_1 RT^2$. There is almost no connection between the observed transfer enthalpies and the calculated cavity terms, so that clearly the ΔH_t^0(int) term must be very large for transfers of Ph_4C between pure solvents. Again we

TABLE 2. Enthalpies and entropies of transfer from acetonitrile of the solute Ph_4C, and calculated cavity terms, at 298 K on the mole fraction scale

		ΔH_t^0(cavity)/kcal mol^{-1}

		ΔS_t^0(cavity)/cal K^{-1} mol^{-1}	
Solvent	ΔS_t^0	Scaled-particle theory	SRMR theory
Methanol	5	−12	−4
Propylene carbonate	−3[c]	73	−14
Dimethyl sulphoxide	0	6	10
Sulpholane	2	−10	−10
Dimethylformamide	1	−24	31
Acetonitrile	0	0	0

[a]All values from ref. 8.
[b]This is the term (ΔH_t^0(cavity) + $\alpha p_2 RT^2 - \alpha p_1 RT^2$), see ref. 2.
[c]These are from the original values of Cox and Parker (8) for solution of Ph_4C in propylene carbonate, $\Delta G_s^0 = 4.2$ and $\Delta H_s^0 = 7.2$ kcal mol^{-1}. Krishnan and Friedman (19) have analysed Cox and Parker's data to obtain $\Delta G_s^0 = 4.5$ and $\Delta H_s^0 = 9.8$ in propylene carbonate, but our own least-squares analysis yields values of $\Delta G_s^0 = 4.2$ and $\Delta H_s^0 = 7.8$ that are quite close to the original values.

can deduce that the interaction term must also be large for Ph_4As^+ and Ph_4B^-, when the cavity term is calculated by scaled-particle theory. It should be pointed out that the calculations and results given in Tables 1 and 2 do not by themselves indicate any failure of scaled-particle theory itself; they merely show that for Ph_4C the interaction terms ΔG_t^0(int) and ΔH_t^0(int) are in general quite large, and cannot be disregarded.

The situation is quite different in terms of entropies of transfer, because on the scaled-particle theory as used by Pierotti (10) the term ΔS_t^0(int) is indeed taken as zero. Thus if Pierotti's version of the scaled-particle theory applies to Ph_4C, the calculated cavity terms, ΔS_t^0(cavity), must equal the observed ΔS_t^0 values, at least within a reasonable error. Details of the observed (8) and calculated entropy values are in Table 2; the discrepances are so large that we are forced to conclude that the scaled-particle theory cannot be applied usefully to solutes such as Ph_4C in pure organic solvents.

We also give in Tables 1 and 2 the various cavity terms for Ph_4C calculated by the Sinanoglu – Reisse – Moura Ramos (SRMR) theory (12, 13) assuming

a solute molar volume of 282 mL mol^{-1}. For transfers between many of the solvents there are rather large discrepancies between the calculations based on SRMR theory and scaled-particle theory. For a solute such as Ph_4C there is no possibility of deciding in favour of one or other method of calculation because there is no way of independently obtaining estimates of the interaction terms. The present calculations, however, indicate that considerable caution is advisable in making deductions based on the calculation of cavity terms for large solutes in pure solvents.

Application to Ph_4As^+ and Ph_4B^-

There have been suggested a number of assumptions that may be used to obtain free energies, enthalpies, and entropies of transfer of single ions. Several workers have compared assumptions and have concluded that the Ph_4As^+/Ph_4B^- assumption, eq. [2] with P = G, yields realistic single ion free energies of transfer (6, 8, 14–17),

$$[2] \qquad \Delta P_t^0 \text{ for } Ph_4As^+ = \Delta P_t^0 \text{ for } Ph_4B^-$$

although other assumptions have sometimes been preferred (18). Indeed, it has been pointed out that there is spectroscopic and other evidence to show that in several solvents there are differences in the solvation properties of Ph_4As^+ and Ph_4B^- (19). It does seem, however, that whatever causes these solvation differences, they are not manifested in the free energy of transfer of Ph_4As^+ and Ph_4B^-. The situation is not the same for enthalpies (and hence entropies) of transfer; Krishnan and Friedman (20) have suggested on the basis of experimental data on enthalpies of transfer from methanol to propylene carbonate that solvation of Ph_4B^- is very different from that of Ph_4As^+ in methanol. In this connection, it is perhaps significant that single ion entropies of transfer obtained by the correspondence plot method (21) are usually in quite good agreement with those obtained from the Ph_4As^+/Ph_4B^- assumption, eq. [2] with P = S, for transfers involving water and aprotic solvents, yet differ in the case of transfers to or from methanol (22) and ethanol (23). Inasmuch as the differences can be ascribed to any one ion, the effects do seem to be due to the Ph_4B^- ion. Even in the transfers to or from methanol and ethanol, however, the differences between the cation and anion assignments on the two methods are only about 7 cal K^{-1} mol^{-1}, i.e. equivalent to 2 kcal mol^{-1} in free energy.

In the previous section, we have shown that for transfers of Ph_4C, and presumably of Ph_4As^+ and Ph_4B^-, the interaction term is usually quite large. Since at the present time it is not feasible to calculate the term ΔG_t^0(int) in eq. [1] for species such as Ph_4As^+ and Ph_4B^-, it follows that the total free energy of transfer, ΔG_t^0, cannot be obtained by scaled-particle theory or SRMR theory. A calculation of the thermodynamics of transfer of Ph_4As^+ and Ph_4B^- would certainly be of relevance to the Ph_4As^+/Ph_4B^- assumption, and so we have attempted such calculations using another approach.

Several workers (7, 9, 24–26) have suggested that parameters for the transfer of a charged solute can be represented by eq. [3], in which P = G, H, or S, and

$$[3] \qquad \Delta P_t^0 = \Delta P_c^0 + \Delta P_n^0$$

where ΔP_c^0 and ΔP_n^0 indicate the electrostatic and neutral contributions to the total; the neutral contribution is normally taken as the observed transfer value for a suitable nonpolar solute of the same shape and size as the charged ion. Berne and Popovych (7) first used eq. [3] to calculate ΔG_t^0 values for the ions Ph_4As^+ and Ph_4B^-. They took ΔG_n^0 as the average transfer value for Ph_4C, Ph_4Si, and Ph_4Sn and calculated ΔG_c^0 by the simple Born equation. For transfer from acetonitrile to the pure solvents methanol and ethanol, the calculated values of ΔG_t^0 for Ph_4As^+ or Ph_4B^- were too small by 1.4 and 1.8 kcal mol^{-1}, respectively. Kim (9) later used a much more elaborate procedure in which Ph_4Ge and Ph_4C were used as the neutral solutes to obtain ΔG_n^0 for Ph_4As^+ and Ph_4B^-, and in which allowance was made for ion–dipole interactions as well as for the Born charging energy. For the three pure solvents studied by Berne and Popovych, however, the results of Kim (9) were no better than those of the earlier workers, calculated ΔG_t^0 values now being too large by 1.9 and 1.5 kcal mol^{-1} for the above transfers. We therefore felt that a detailed calculation was not justified and took the solute Ph_4C as the neutral counterpart of Ph_4As^+ or Ph_4B^- and then calculated the electrostatic term by the improved theory of Abraham and Liszi (27). In Table 3 are given the calculated free energies, together with the observed values for Ph_4As^+ and Ph_4B^- (9, 22, 23, 28–30). Most of the observed values are those suggested by Kim (9); in some cases they differ slightly from those used by us before (2). Our present simple method of calculation yields results that are comparable to those obtained by Kim; for the 12 common solvents agreement with experiment averages 1.1 kcal mol^{-1} on both methods of calculation.[2]

[2]The largest disagreement between our calculated values and the observed values arises for the transfer to water. The value of ΔG_n^0 we used for this transfer is derived from the solubility of Ph_4C in water reported by Cox and Parker (5). Recent work of Kim (9) on Ph_4Ge agrees well with Cox and Parker's values, the derived ΔG_t^0 values for transfer from methanol to water

TABLE 3. Calculation of free energies of transfer from acetonitrile of Ph_4As^+ and Ph_4B^-, in kcal mol^{-1} at 298 K on the mole fraction scale

[a]Calculated by the method of Abraham and Liszi (27).
[b]From the values for Ph_4C, Table 1.
[c]From ref. 9 unless shown otherwise, assuming that ΔG_t^0 for Ph_4As^+ equals ΔG_t^0 for Ph_4B^-.
[d]These are the differences for ($Ph_4As^+ + Ph_4B^-$), found by Kim (9), divided by two.
[e]Estimated value.

Our objective, however, is not to compare our results with those of Kim, but firstly to show that both of these calculations via eq. [3] lead to very much better agreement with experimental ΔG_t^0 values than does the alternative method of calculation using only the cavity term in the scaled-particle theory (compare the results in Table 3 with those in Table 1), and secondly to calculate the corresponding enthalpy and entropy terms using eq. [3]. There are only six solvents for which the necessary ΔH_t^0 and ΔS_t^0 values are known for the neutral solute Ph_4C, Table 2, and so we have mainly restricted our calculations to these solvents. The electrostatic terms were again calculated by the method of Abraham and Liszi (27), and the results for the six solvents are given in Table 4. There is good agreement with experiment, both in the case of the enthalpy data (where there is an average deviation of 0.8 kcal mol^{-1} between calculated and observed values) and the entropy data (where the deviation is 3 cal K^{-1} mol^{-1} for the same six solvents). Since ΔS_t^0 for Ph_4C is numerically very small for transfers from acetonitrile to other aprotic solvents, we have taken this value as zero for transfers to the solvents acetone, 1,2-dichloroethane, and 1,1-dichloroethane and have thus been able to calculate also ΔS_t^0 for Ph_4As^+ or Ph_4B^- for transfer to the three additional solvents. Agreement with the observed values is again very good (Table 4).

Thus very simple calculations using eq. [3] yield free energies, enthalpies, and entropies of transfer of Ph_4As^+ or Ph_4B^- from acetonitrile to other pure organic solvents that are in substantial agreement with the experimental values obtained via the Ph_4As^+/Ph_4B^- assumption, eq. [2]. However, we wish to point out that although our calculations and those of Kim (9) indicate that the Ph_4As^+/Ph_4B^- assumption is reasonable, the calculations do not and cannot prove the assumption to be correct. For example, the calculated and observed value for ΔS_t^0 of $Ph_4As^+ = Ph_4B^-$ is 2 cal K^{-1} mol^{-1} for transfer from acetonitrile to dimethylsulphoxide, yet it is logically possible for the 'correct' division to be, say, +6 for Ph_4As^+ and −2 for Ph_4B^- and for our calculations to be wrong. A more cogent example is the entropy of transfer from acetonitrile to methanol, where there is disagreement over the cation and anion division using the Ph_4As^+/Ph_4B^- assumption or the correspondence plot method (22, 29). On the Ph_4As^+/Ph_4B^- assumption, the observed entropies of transfer are −2 for Ph_4As^+ and −2 for Ph_4B^-; the calculated values are +4 in each case, but we could argue that the Ph_4As^+/Ph_4B^- division is correct and that our calculations are in error by 6 cal K^{-1} mol^{-1}

being (in kcal mol^{-1} on the mole fraction scale) 6.1 for Ph_4C and 6.3 for Ph_4Ge. However, both these values seem very small when compared to ΔG_t^0 values for other aromatic compounds, viz. 3.4 for benzene and 5.7 for biphenyl, and we would expect the ΔG_t^0 values for the Ph_4M compounds to be not less than 10 kcal mol^{-1} for the methanol to water transfer, rather than the observed values of 6.1–6.3 kcal mol^{-1}.

TABLE 4. Calculation of enthalpies and entropies of transfer from acetonitrile of Ph_4As^+ or Ph_4B^-, at 298 K on the mole fraction scale[a]

Solvent	ΔH_e^{0b}	ΔH_n^{0c}	ΔH_t^0(calcd)	ΔH_t^0(obsd)[d]

[e]Estimated values, see text.

in each ion. Using the correspondence plot method, the observed values are +5 for Ph_4As^+ and −9 for Ph_4B^-; we could now argue that the correspondence method is correct, our calculation for Ph_4As^+ is correct, but that some additional interaction between Ph_4B^- and methanol has led to a discrepancy of 13 cal K^{-1} mol^{-1} between the observed and calculated value. Unfortunately, the present method of analysis is not refined enough to decide in favour of either the Ph_4As^+/Ph_4B^- assumption or the correspondence plot method for entropies of transfer to or from methanol.

La relation pression interne – température est discutée pour des nombreuses substances organiques et pour des sels à la température de fusion.

GIANFRANCESCO BERCHIESI, MARIA A. BERCHIESI, GIOVANNI VITALI, and VENANZIO VALENTI. Can. J. Chem. **57**, 2010 (1979).

The relation between the internal pressure and the temperature at the melting point is discussed for several organic substances and for some salts.

Introduction

Malgré les nombreux efforts, soit théoriques soit expérimentaux, dédiés jusque à maintenant à l'étude de l'énergétique de la fusion et de l'état liquide (1, 2), un remarquable interêt est adressé encore à cette problématique à cause des points obscurs. Dans cette note nous rapportons des mesures expérimentales de pression interne dans des liquides organiques et nous comparons les résultats obtenus avec ceux obtenus précédemment.

Méthodes expérimentales

La pression interne P_i d'un liquide est obtenue à l'aide des données ultrasoniques, densimétriques et calorimétriques selon les formules suivantes:

$$[1] \quad \beta_s = (u^2\rho)^{-1}$$

$$[2] \quad \beta_T = \beta_s + \alpha^2 TV/c_p$$

$$[3] \quad P_i = \alpha T/\beta_T$$

où β_s, β_T, α, T, V représentent respectivement la compressibilité adiabatique, la compressibilité isotherme, le coefficient d'expansion thermique, la température et le volume. La densité, ρ, a été obtenue par pycnométrie comme précédemment décrit (5); la thermostatation à des températures plus basses que celle ambiante a été possible au moyen d'un ultracryostat Lauda, employé comme réfrigérant d'un bain de 100 L agitée et thermorégulé; une thermostatation de ± 0.01°C était obtenue. La chaleur spécifique à pression constante c_p a été deduite de la bibliographie (6, 7). La vitesse ultrasonore, u, a été mésurée à l'aide d'un interféromètre ultrasonore IPPT (Warszawa) précédemment décrit (3, 4), en employant comme indicateur de l'impulsion le même oscilloscope de l'appareillage au lieu d'un oscilloscope externe. La precision des mésures est 1 m/s pour la vitesse et 2 bars pour la pression interne. Ce niveau de précision est suffisant pour obtenir P_i/T_f (T_f represente la température de fusion) à une précision de 0.005 cal/K mL. 1,2-Dibrométhane et 1,4-diméthylbenzène sont produits Fluka (purété > 99%).

TABLEAU 1. Valeurs des paramètres des équations expérimentales [4]–[8] et déviationsstandard pour les éqs [4], [5], [7]

Paramètre	Valeur	
	C_8H_{10}	$C_2H_4Br_2$
a (g/mL)	0.8665	2.1985
b (g/mL K)	8.45×10^{-4}	20.24×10^{-4}
c (m/s)	1364	1033
d (m/s K)	4.20	2.39

Résultats et discussion

Intéressés à la valeur de la pression interne à la température de fusion nous avons exécuté des mésures à différentes températures à partir de 1 ou 2 degrés au dessus de T_f jusqu'à une température T_{max}, indiqué dans le tableau. En général l'intervalle de température exploré est de 15 ou 20°C. Les résultats obtenus ont été exprimés sous forme d'équations derivées par la méthode des moindres carrés:

$$[4] \quad \rho = a - b(T - T_f)$$

$$[5] \quad u = c - d(T - T_f)$$

et les déviations standard ont été données dans le tableau 1, avec les paramètres empiriques de ces équations. La compressibilité β_T, la pression interne P_i, déduites à l'aide des éqs [1]–[3] et la chaleur spécifique à volume constant $c_v = c_p\beta_s/\beta_T$, ont été exprimées de la façon suivante:

$$[6] \quad \beta_T = e + f(T - T_f)$$

$$[7] \quad P_i = g - h(T - T_f)$$

$$[8] \quad c_v = i + l(T - T_f)$$

La valeur g de pression interne du liquide extrapolée à la température de fusion ($P_{i,L}$) est employée pour le calcul de P_{iL}/T_f, qui est donné en tableau 2 avec les valeurs concernant les autres substances étudiées précédemment. Il a été déjà montré (4) que le paramètre P_{iL}/T_f n'est pas un paramètre empirique, au contraire il a une signification thermodynamique précise parce qu'il représente dS/dV (où S représente l'entropie) calculé à l'extrémité de l'intervalle de fusion où le crystal est pratiquement transformé en liquide (côté liquide) selon la formule suivante:

$$[9] \quad dS/dV = P_i/T_f$$

dS/dV dans le côté crystal du processus de fusion est plus grande que dans le côté liquide parce que $P_{ic} > P_{iL}$ à T_f, comme montré (4), même si en général l'équation $P_{ic} \sim P_{iL}$ (1, 8) est acceptée comme simple approximation (P_{ic} représente la pression interne du crystal au point de fusion).

A ce moment, nous nous intéressons au paramètre P_{iL}/T_f, à cause de la difficulté d'avoir des valeurs de pression interne des solides. Ils sont donnés au tableau 2 et montrent que malgré le caractère hétérogène des composés, soit ioniques soit moléculaires à structure paraffinique ou aromatique, avec ou sans des hétéroatomes la valeur de l'entropie volumique de fusion est comprise entre 0.21 et 0.45 cal/K mL. L'équation [9] peut être écrite de la façon suivante:

$$[10] \quad \Delta S = \int_c^L dS = \int_c^L P_i/T_f \, dV$$

$$\simeq P_{iL}/T_f \int_c^L dV = (P_{iL}/T_f)V_{dis}$$

où V_{dis} n'est pas nécessairement égale au volume de fusion à cause de l'approximation de l'intégration et comme discuté précédemment (3). Les valeurs V_{dis} sont rapportées aussi au tableau 2. L'entropie de fusion peut être séparée en deux paramètres: P_{iL}/T_f, intensif et indépendant de l'extension des molécules: V_{dis} extensif et dépendant de la dimension des molécules.

Le terme P_{iL}/T_f présente une variation regulière, dans le cas des produits ioniques, avec les rayons ioniques et sauf le cas de $NaNO_3$ (pour lequel la présence d'un ion planaire produit probablement un mecanisme de fusion différent) une équation $P_{iL}/T_f = 0.42_5 - 0.080r^+r^-$ ($\sigma = 0.03$) est suffisante à rendre compte de cette variation (r^+, r^- rayons cathioniques et anioniques respectivement). Dans le cas des produits organiques la relation entre P_{iL}/T_f et la nature chimique du composé est moins évidente: ce que l'on peut remarquer est la suivante échelle de variation de P_{iL}/T_f:

Alcane, acides aliphatiques < composés aromatiques ou cycliques apolaires < composés polaires.

La présence de groupes polaires élève la valeur de P_{iL}/T_f, sauf le cas des acides aliphatiques; il faut chercher probablement la raison de cette exception dans la structure dimèrique de ces acides (9) qui "ferme" la polarité dans le dimère et qui, par conséquence, rend l'intéraction dimère–dimère semblable à celle molécule–molécule dans les alcanes. Etant donné que pour le rapport c_p/c_v, calculé au point de fusion, une échelle pareille à celle relative à P_{iL}/T_f peut être écrite (excéption: acide oléique, ethanediole) il est raisonable penser que P_{iL}/T_f (comme c_p/c_v) soit aussi affecté par l'activation de dégrés internes d'énergie. Sur cette base, probablement, il faudrait chercher l'explication de la différence de P_{iL}/T_f entre composés linéaires (alcanes et acides aliphatiques) et composés cycliques ou aromatiques.

V_{dis} (tableau 2) est dépendant de la dimension moléculaire, tandis que V_{dis}/n_t (où n_t représente le nombre total d'atomes dans la molécule) semble dépendre plutôt de la rigidité des liaisons chimiques. Dans le cas des alogénures de métaux alcalins une grossière dépendance V_{dis} contre r^+ peut être remarquée.

En outre, il est intéressant de remarquer que pour les substances examinées et dans l'intervalle de T examiné, les grandeurs P_i, V, T sont reliées par la simple équation:

$$[11] \quad P_iV = RT + A/V$$

les valeurs du paramètre A sont: 31.0 et 48.1 L^2 atm mol^{-2} pour 1,2-dibrométhane et 1,4-diméthylbenzène respectivement.

Remerciements

Nous savons gré au CNR (Rome) pour l'aide financière et à M. le Docteur Z. Kozłowski, chef du département d'acoustique physique de IPPT (Académie Polonaise des Sciences, Varsovie) pour nous avoir mis à disposition des transducteurs prévus pour les basses températures.

Primary mechanisms in the radiolysis of amines: pulse and γ-radiolysis of neutral and acidic ethylamine, *n*-propylamine and ethylenediamine

J. A. DELAIRE AND J. R. BAZOUIN

Laboratoire de Physico-Chimie des Rayonnements (Associé au CNRS), Université de Paris-Sud, Centre d'Orsay, 91405 Orsay, France

Received December 19, 1978

J. A. DELAIRE and J. R. BAZOUIN. Can. J. Chem. **57**, 2013 (1979).

The transient spectra in pure ethylamine (EA), *n*-propylamine (*n*PA), and ethylenediamine (EDA) show, besides the visible and infrared band associated with the solvated electron, e^-_s, a small ultraviolet band attributed to oxidizing radicals. Upper limits for the recombination rate constants k of e^-_s with the acidic cation are 1.5×10^{12} and 3.5×10^{12} L mol^{-1} s^{-1} in EA and *n*PA respectively, and $k = 2 \times 10^{10}$ L mol^{-1} s^{-1} in EDA. The yield of e^-_s at 3 ns ($G(e^-_s)_{3ns}$ = 1.5, 1.2, and 3.1 molecules/100 eV in EA, *n*PA, and EDA respectively) has been deduced by biphenyl scavenging. The yield of molecular hydrogen after γ-radiolysis $G_0(H_2)$ = 5.7 and 3.6 in pure *n*PA and EDA respectively. The effect of solutes, such as biphenyl, alkylammonium chloride, and allyl alcohol, on $G(H_2)$ is interpreted in terms of scavenging of e^-_s and/or H atoms. From the pulse-radiolysis determination of $G(e^-_s)$, we deduce $G_H \simeq 0$ and $G_{H_2} \simeq 2.0$ in *n*PA.

Finally, the decay of solvated electrons seems to occur only via recombination with the cation in EA and *n*PA, but in EDA there is a competition between this reaction and reaction with oxidizing radicals.

J. A. DELAIRE et J. R. BAZOUIN. Can. J. Chem. **57**, 2013 (1979).

Les spectres d'absorption transitoire dans l'ethylamine (EA), la *n*-propylamine (*n*PA) et l'éthylènediamine (EDA) pures montrent, en plus de la bande visible et infra-rouge associée à l'électron solvaté, e^-_s, une petite bande ultra-violette attribuée aux radicaux oxydants. Les constantes de vitesse de recombinaison k de l'électron solvaté avec le cation acide sont inférieures à 1.5×10^{12} et 3.5×10^{12} L mol^{-1} s^{-1} respectivement dans EA et *n*PA, et $k = 2.0 \times 10^{10}$ L mol^{-1} s^{-1} dans EDA. Les rendements de e^-_s à 3 ns ($G(e^-_s)_{3ns}$ = 1.5, 1.2 et 3.1 molecules/100 eV respectivement dans EA, *n*PA et EDA) ont été déterminés par capture par le biphényle. Le rendement d'hydrogène moléculaire après radiolyse γ $G_0(H_2)$ = 5.7 et 3.6 respectivement dans *n*PA et EDA pures. L'effet des solutés tels que le biphényle, le chlorure d'alkylammonium et l'alcool allylique sur le rendement en hydrogène est interprété en terme de capture de e^-_s et/ou des atomes H. Compte-tenu de la valeur déterminée pour $G(e^-_s)$ en radiolyse pulsée, nous déduisons $G_H \simeq 0$ et $G_{H_2} \simeq 2$ dans *n*PA. Enfin, la recombinaison des électrons solvatés semble se faire uniquement par réaction avec le cation dans EA et *n*PA, mais dans EDA, il y a compétition entre cette réaction et la capture par des radicaux oxydants.

Introduction

Amines belong to that class of solvents which have the property of dissolving alkali metals to give metastable solutions. The nature of the so-called blue solutions has been extensively studied (1). Solvated electrons (e^-_s), alkali metal cation – electron pairs (M^+,e^-_s), and anions (M^-) are present in these solutions. Pulse radiolysis has been used in the past to study absorption spectra and reactions of these species, mostly in amines (2). Yields of the solvated electron $G(e^-_s)$ have been determined in methylamine (MA) (3), ethylamine (EA) (3), and isopropylamine (*i*PA) (3) at different temperatures, but the precise mechanism of its disappearance is unknown. Attempts to determine primary yields other than that of e^-_s — essentially yields of atomic and molecular hydrogen — have been made by γ-radiolysis in MA (4) and EA (5). Furthermore, studies in ammonia (6, 7) and hydrazine (7, 8) have shown that there exists a large similarity in the primary mechanisms of the radiolysis of both solvents: the main recombining reaction of the solvated electron seems to occur with radicals and not with the counter cation. At the same time, $G(e^-_s)$ is found to be high (~3) in both solvents (7). Therefore, it seems interesting to check whether the correlation between the high G-value and the low recombination rate constant established in NH_3 (static dielectric constant ε_s = 17) and N_2H_4 (ε_s = 54) is valid for weakly polar amines as EA (ε_s = 7 (9)), *n*-propylamine (*n*PA) (ε_s = 5.5 (10)) and ethylenediamine (EDA) (ε_s = 14 (9)).

In addition to the fate of e^-_s, this paper deals with the behavior of radicals formed in the radiolysis of amines. Pulse radiolysis has been used to determine $G(e^-_s)$ and the reactivity of e^-_s with the counter

0008-4042/79/152013-09$01.00/0

cation and/or with radicals. Determination of molecular hydrogen yields after γ-radiolysis of amines with different scavengers gives information on a possible mechanism.

Experimental

The experimental set-up has been described earlier (11, 12). A 600 keV Febetron 706 accelerator with a pulse width of 3 ns was used as the electron source. Dosimetry was established from the end-of-pulse absorption of the hydrated electron taking $G_{e^-_{aq}} = 3.3$ (13) and $\varepsilon_{e^-_{aq}} = 1.3 \times 10^4$ dm^3 mol^{-1} cm^{-1} (14) at 600 nm, and corrected for the differences in density, taking $\rho(C_2H_5NH_2) = 0.68$ g cm^{-3}, $\rho(n\text{-}C_3H_7NH_2) = 0.71$ g cm^{-3}, and $\rho(NH_2C_2H_4NH_2) = 0.9$ g cm^{-3} at 20°C. As previously shown (15), the optical detection has been improved in the near infrared (ir) up to 1400 nm, the limit being due to solvent absorption. A germanium photodiode (Judson J 18) ir detector was used in the photovoltaic mode, and the photocurrent preamplified using the circuit shown in Fig. 1. Two cascade amplifiers and a line driver circuit amplify the current and match the output impedance to a 50 Ω coaxial line. The dark current was adjusted to zero using the offset on the first stage of the amplifier. The diode-preamplifier system has a rise-time (10–90%) of about 20 ns, and the gain is about 200. Signals from 50 mV to 1 V were found to be linear with the incident photon flux.

A high resolution grating monochromator (Jobin Yvon, type HRS) was used with different gratings. The bandwidth changed from 2 nm in the uv and the visible to 7.5 nm in the infrared.

The silica cell for pulse radiolysis and the purification of *n*-propylamine have been described previously (15). Ethylamine and ethylenediamine were prepared in the same way. Biphenyl (Merck, Zone refined) and acidic salts (ethylamine·HCl from Schuchardt, *n*-propylamine·HCl from Fluka, and ethylenediamine·2HCl from Merck) were used as received.

For γ-radiolysis studies, purified solvents were distilled under vacuum into Pyrex cells containing, if necessary, the needed quantities of solutes and then sealed off. The method for analysis of gases after γ-irradiation has already been described (16). The dose rate of the cobalt source was about 10^{19} eV cm^{-3} h^{-1}.

Results

1. Pure Solvents

The end-of-pulse (10 ns) spectra are shown in Fig. 2. For wavelengths greater than 1000 nm, the spectra were measured 50 ns after the beginning of the pulse and normalized to the 10 ns spectra at 1000 nm. In our detection range, only EDA exhibits a maximum

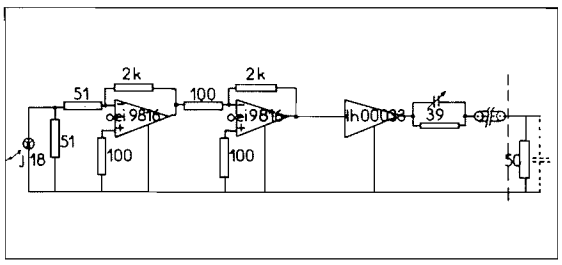

FIG. 1. Circuit diagram for the preamplifier used with germanium photodiode.

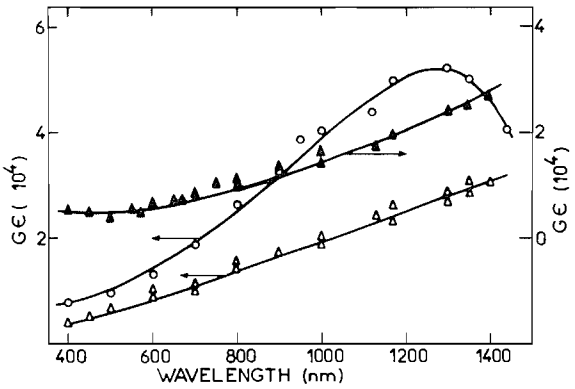

FIG. 2. End-of-pulse (10 ns) absorption spectra of solvated electron in △ ethylamine, ▲ *n*-propylamine, ○ ethylenediamine. The spectrum of *n*-propylamine has been shifted vertically for clarity.

for the ir absorption band associated with the solvated electron. This maximum is located near 1300 nm, in agreement with previous studies by pulse radiolysis (17) or dilute cesium solutions (18). For EA the maximum has been estimated to be near 1950 nm (3*b*), but λ_{max} in *n*PA is not known.

In addition to the ir and visible bands, the transient absorption spectra in each amine also exhibit a ultraviolet (uv) band which increases in intensity up to the solvent cut-off (250 nm for EA, 255 nm for *n*PA, and 290 nm for EDA). These uv bands are clearly shown in Figs. 3, 4, and 5 for EA, *n*PA, and EDA respectively.

Because the time behavior of the uv and ir absorbances are different, the former cannot be due to e^-_s. Under our experimental conditions, the decay time of e^-_s is shorter in EA and *n*PA ($\simeq 1$ μs) than in EDA ($\simeq 8$ μs) and uv absorbance decays more slowly without noticeable change in its spectrum (see curves with full circles in Figs. 3, 4, and 5). By analogy with uv absorptions in the radiolysis of ammonia (6, 12), hydrazine (8), or alcohols (19, 20), these bands are attributed to primary radicals of the radiolysis of amines. Evidence for $CH_3\dot{N}H$ radicals absorbing below 500 nm has been obtained in the pulse radiolysis of aqueous solutions of MA (21). Pulse radiolysis of pure triethylamine leads to a similar uv absorption (22).

The decay of e^-_s was found to obey second order kinetics for EA and *n*PA, as shown in Fig. 6. For EDA, the kinetics do not seem to obey any simple order, as is usually the case for e^-_s decay in pure liquids. From the slopes in Fig. 6 and the extinction coefficients of e^-_s (see section 3), upper limits for second order recombination rate constants can be given as $(1.5 \pm 0.5) \times 10^{12}$, $(3.5 \pm 1) \times 10^{12}$ L mol^{-1} s^{-1} for EA and *n*PA respectively. Each value

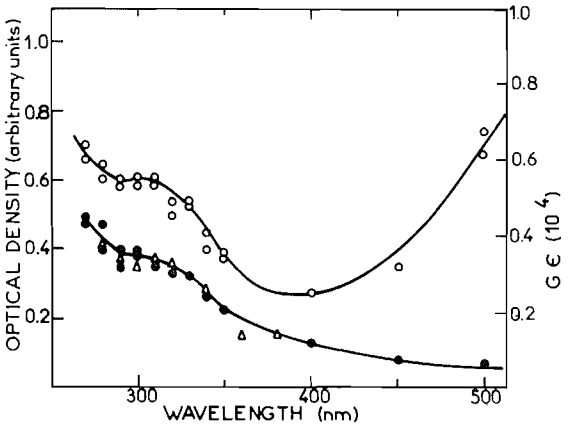

FIG. 3. Ultraviolet absorption spectra in pure ethylamine: ○ end of pulse, ● t = 400 ns; and in a solution containing ethylammonium chloride: (0.17 mol L^{-1}) △ t = 400 ns.

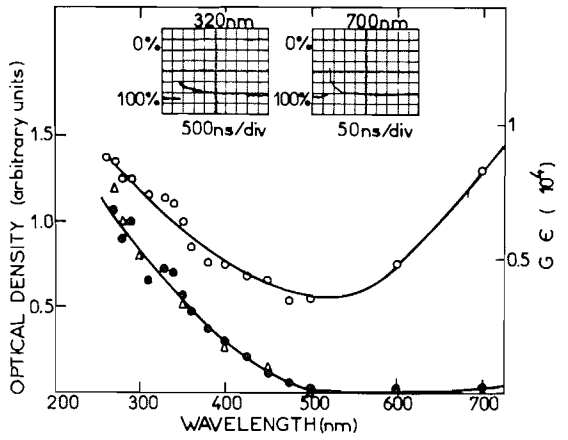

FIG. 4. Ultraviolet absorption spectra in pure n-propylamine: ○ end of pulse, ● t = 100 ns; and in a solution containing 100 ns n-propylammonium chloride (0.1 mol L^{-1}) △ t = 100 ns. Inserts: oscilloscope traces in pure n-propylamine, at 700 nm (50 ns/division) and at 320 nm (500 ns/division).

is a mean of about ten determinations, made at different wavelengths.

In the uv, the decays generally fit second order kinetics for each solvent. This is a further argument for assigning these absorbances to radicals, which are known to dimerize. Nevertheless, in order to obtain a satisfactory second order plot in the case of EDA, it is necessary to consider that the radicals dimerize to give a longer lived transient absorbing at the same wavelength (see Fig. 5). The slopes of the second order plots give the values $k/\varepsilon = 8.0 \times 10^6$, 6.7×10^6, and 3×10^6 cm s^{-1} for EA, nPA, and EDA (after correction) respectively at 300 nm.

2. Acidic Solutions

These solutions contain the 'acidic' cation RNH_3^+

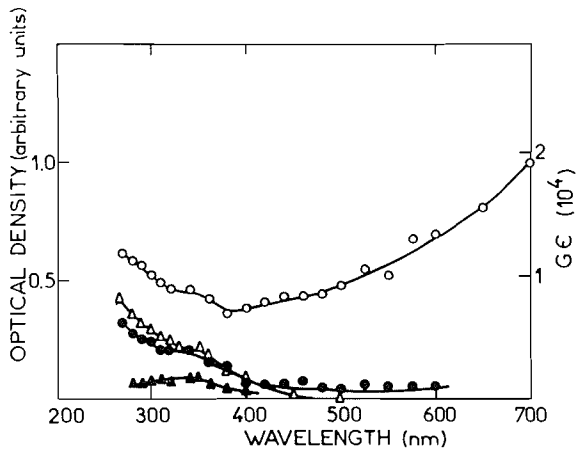

FIG. 5. Ultraviolet absorption spectra in pure ethylenediamine: ○ end of pulse, ● t = 2 μs, ▲ t = 14 μs and in a solution containing ethylenediammonium chloride (0.5 mol L^{-1}) △ t = 2 μs.

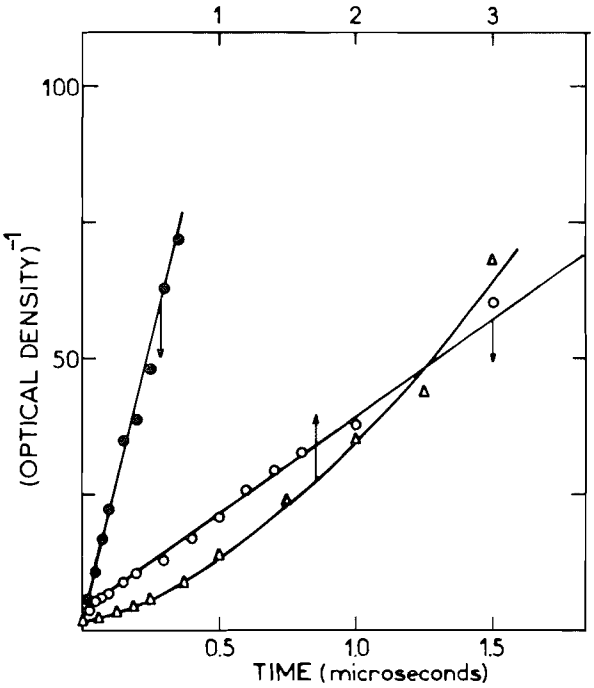

FIG. 6. Tests of second order plots for the decrease of e^-_s in pure ethylamine at 1300 nm (○), n-propylamine 900 nm (●), and ethylenediamine 800 nm (△).

of the amine RNH_2. In fact, this cation is the main cation of the radiolysis of amines (7), and a measure of its reactivity with e^-_s is useful. However, the state of association (pairs and higher associated species) of the amine hydrochlorides dissolved in their respective amines is generally unknown and a whole conductimetric study of some of these solutions is needed (10).

We shall present here the values of the rate constant k_2 for the reaction of e^-_s with the acidic salt, irrespective of its state of dissociation. Results are shown in Fig. 7, for EA and *n*PA. In both solvents, concentrations of acidic salts higher than 10^{-2} mol L^{-1} are necessary to accelerate the decay of e^-_s. At concentrations higher than 10^{-1} mol L^{-1}, experimental points deviate from linearity. From the slopes in Fig. 7 we obtain values for the second order rate constants $k_2 = 5.7 \times 10^8$ and 6.0×10^8 L mol^{-1} s^{-1} for EA and *n*PA respectively. In this concentration range (10^{-2}–10^{-1} mol L^{-1}) ions are considered to exist mainly as pairs (10) so we shall consider that both rate constants refer to the reactivity of e^-_s towards a cation paired with a chloride ion. In a previous paper (7) we considered, to a first approximation, that the rate constant between free ions had to be multiplied by a factor of ten, giving a value of $k_{e^-_s + RNH_3^+} = 7 \times 10^9$ L mol^{-1} s^{-1} for *n*PA (7). However, the decay kinetics of e^-_s in the pure solvent allow one to obtain an upper value for $k_{e^-_s + RNH_3^+}$. In fact, it will be shown in the discussion that e^-_s decays mainly by recombination with the cation in both solvents. So we may conclude from the high values measured here for the recombination rate constants in the pure solvents that the amplification factor suggested previously (7) may be as high as 10^3.

By dissolving ethylene diammonium dichloride in EDA, the monoacid $EDAH^+$ ($NH_3^+CH_2CH_2NH_2$) conjugated with the base EDA is thought to be formed, at a concentration twice that of the added salt. First order experimental rate constants are plotted in Fig. 8 versus the logarithm of the concentration of the monoacid. The main feature is the plateau value reached by the experimental rate constant for concentrations of reactant higher than 10^{-1} mol L^{-1}. Thus, it appears again that the reactivity of e^-_s towards the cation is greatly reduced when the latter is associated with the anion: a more detailed study of this reactivity in connection with conductimetric measurements gives the value of the recombination rate constant at zero ionic strength for isolated ions $k_{e^-_s + RNH_3^+} = 2 \times 10^{10}$ L mol^{-1} s^{-1} (10). This value is higher by a factor of 10^3 than that obtained in previous work using a stopped flow method (23). However, the latter results were not corrected for ionic association and ionic strength effects, which largely explains the above discrepancy.

We also investigated the influence of the acidic cation on the decay of the uv absorbance in each amine for a concentration such that e^-_s disappears in a few nanoseconds. At the end of the pulse, the spectra were found to be identical to those in pure solvents. At longer times the influence of the acidic cation differs according to the nature of the amine. As shown in Figs. 3 and 4, the decay is exactly the same as in the pure solvent for EA and *n*PA, but is slowed down in EDA. In fact, for molar concentration of $EDAH^+$ in EDA, the decay remains second order, but the rate constant is three times lower than in pure solvent.

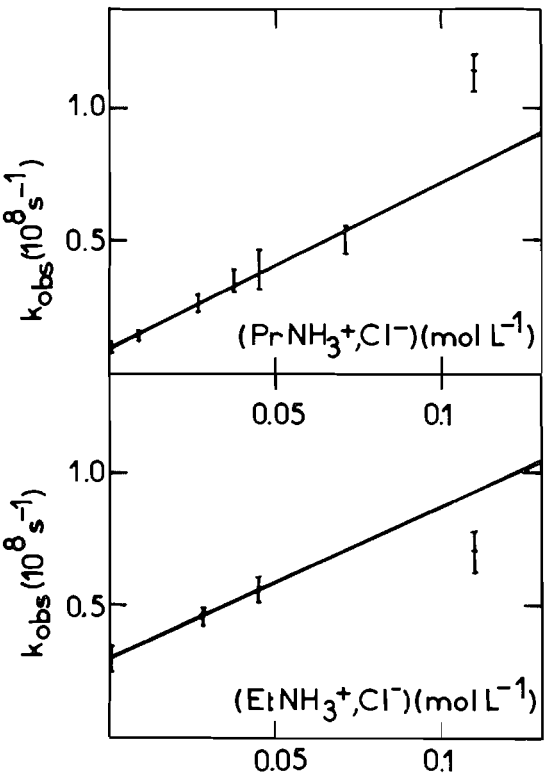

FIG. 7. Observed first order rate constant for the decay of e^-_s as a function of the amine hydrochloride concentration. Upper curve: *n*-propylamine. Lower curve: ethylamine.

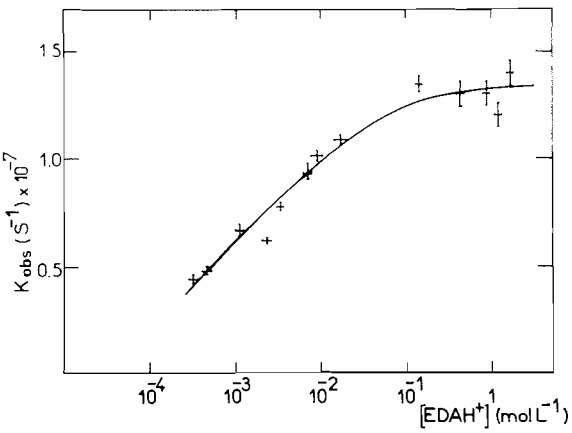

FIG. 8. Observed first order rate constant for the decay of e^-_s in ethylenediamine as a function of concentration of monoacidic ion, plotted on a logarithmic scale.

3. *Extinction Coefficient and Yield of Solvated Electron*

Yields $G(e^-_s)$ and extinction coefficients $\varepsilon_{e^-_s}$ were determined using biphenyl (Ph_2) as a scavenger. The method uses the known extinction coefficients of biphenyl anion (Ph_2^-) determined in tetrahydrofuran at 410 nm and 640 nm (24, 25) and assumes that these coefficients are independent of the solvent. Although there is no direct evidence of this hypothesis, the invariance of the Ph_2^- spectrum shape also suggests invariance of $\varepsilon_{Ph_2^-}$. Furthermore, it has been shown that the above method applied to ammonia (26) gives the same G-value (3.2) as the direct determination of the yield, knowing the deposited dose and extinction coefficient $\varepsilon_{e^-_s}$.

For concentrations of Ph_2 lower than 10^{-2} mol L^{-1}, the decrease of e^-_s absorbance was observed simultaneously with the associated increase of Ph_2^- absorbance. The absorbance of Ph_2^- was measured after a time corresponding to the end of its formation, or the end of the decay of e^-_s.

Figure 9 shows the anion yields as a function of solute concentrations, assuming $\varepsilon_{Ph_2^-} = 1.21 \times 10^4$ L mol^{-1} cm^{-1} at 640 nm (24, 25). The measured yield $G(Ph_2^-)$ depends on the scavenger concentration, a consequence of the competition between the scavenging reaction and the non-homogeneous (spur) and homogeneous (bulk) reactions of e^-_s. This solute dependence has been described according to an empirical equation originally proposed for hydrocarbons (27) and adapted to our problem (see Discussion). The calculated dependence of $G(Ph_2^-)$ on solute concentration is shown in Fig. 9 (full lines). However, the quantity of interest is $G(e^-_s)$ at a time t, $G(e^-_s)_t$. It has been shown that this quantity is exactly the inverse Laplace transform of $G(Ph_2^-)$ (28). As a first approximation, we shall consider that for a Ph_2 concentration such that the halftime of reaction is $t_{1/2} = 3$ ns (half-height duration of the triangular pulse), the yield of electrons which is scavenged is $G(e^-_s)_{3\,ns}$. This approximation is justified because the decay rate of e^-_s in the pure solvent at the end of the pulse is much slower than in the presence of the above Ph_2 concentration.

Extinction coefficients for e^-_s were also determined by comparing the optical density of e^-_s, $OD(e^-_s)$, at the end of the pulse (10 ns) with that of Ph_2^- at 640 nm, $OD(Ph_2^-)$, for a Ph_2 concentration such that the reaction half time is 10 ns. If, under such conditions, we consider that all the solvated electrons present at the end of the pulse, and only these electrons, are scavenged, eq. [1] applies:

$$[1] \quad OD(e^-_s)/OD(Ph_2^-) = \varepsilon_{e^-_s}/\varepsilon_{Ph_2^-}$$

$\varepsilon_{e^-_s}$ was also determined in another way: in the 500–700 nm region, the absorption spectra of both e^-_s and Ph_2^- have two isobestic points. These points were determined by looking for flat absorbance on oscillograms, and it was verified that they were independent of biphenyl concentration. The values obtained for $\varepsilon_{e^-_s}$ were the same as above within the limit of experimental error. The last method gives further support to the derivation of $G(e^-_s)_{3ns}$.

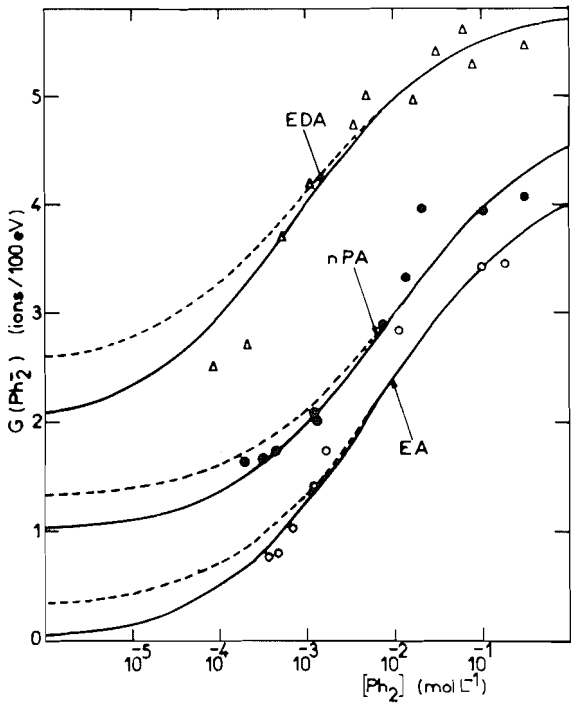

FIG. 9. Biphenyl anion yields as a function of biphenyl concentration, in ethylamine (○), *n*-propylamine (●), and ethylenediamine (△). Dashed curve: equation of ref. 27. Solid curve: eq. [4]. For sake of clarity the curves of *n*-propylamine and ethylenediamine are shifted vertically by 1 and 2 units of G respectively.

The values of $G(e^-_s)_{3ns}$ and $\varepsilon_{e^-_s}$ are given in Table 1, and compared with literature data (see Discussion).

In spite of the short lifetime of e^-_s in EA and *n*PA, it was possible to find a range of biphenyl concentrations (from 2×10^{-4} to 2×10^{-3} mol L^{-1}) from which the rate constant k_s for the reaction of e^-_s with biphenyl could be determined. Values equal to $(1.45 \pm 0.1) \times 10^{11}$, $(1.35 \pm 0.1) \times 10^{11}$, and $(1.8 \pm 0.1) \times 10^{10}$ L mol^{-1} s^{-1} were obtained in EA, *n*PA, and EDA respectively.

4. *Hydrogen Yields in the γ-Radiolysis of* n*PA and EDA*

Molecular hydrogen yields were measured for pure solvents, and for solvents containing an electron scavenger (biphenyl), electron, and H atom scaven-

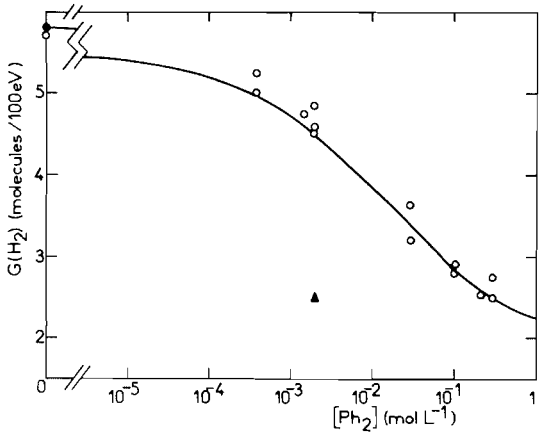

FIG. 10. Molecular hydrogen yield as a function of biphenyl concentration in pure *n*-propylamine (○) or in solutions containing propylamine hydrochloride (1 mol L^{-1}) (●) or allyl alcohol (1 mol L^{-1}) (△) solid curve: eq. [13].

gers (biphenyl + allyl alcohol) or acidic cation. The yield of hydrogen was found to be independent of dose in the range used (0.2 to 1 × 10^{19} eV mL^{-1}). In both amines, hydrogen was the main gas produced by radiolysis.

The yield of hydrogen $G_0(H_2)$ in pure *n*PA is 5.7 ± 0.3. For biphenyl concentrations higher than 10^{-1} mol L^{-1}, the yield of hydrogen drops to 2.5 ± 0.3. The same decrease is observed in a solution containing biphenyl 2 × 10^{-3} mol L^{-1} and allyl alcohol 1 mol L^{-1}. Addition of 1 *M* propylamine hydrochloride (*n*PAH$^+$Cl$^-$) has practically no effect on the yield of hydrogen ($G(H_2) = 5.8 \pm 0.3$) (see Fig. 10).

$G_0(H_2)$ in pure EDA is 3.5 ± 0.1 and rises to 4.3 ± 0.1 when the acidic salt is added at concentrations of 1.4 × 10^{-2} or 3.1 × 10^{-2} mol L^{-1}.

Discussion

1. Properties of Solvated Electrons in Amines

Table 1 summarizes some properties of e^-_s in several amines. Our values of $\varepsilon_{e^-_s}$ and those from the literature are in good agreement for EDA. Assuming that the shape of the spectrum is the same as that given in ref. 3*b* for EA, our determination of $\varepsilon_{e^-_s}$ at 1400 nm would lead to $\varepsilon_{max} = (4.5 \pm 0.5) \times 10^4$ L mol^{-1} cm^{-1}. This value is slightly higher than that given in ref. 3*b*. We interpret this discrepancy as a consequence of too high a value determined in the above reference for $G(e^-_s)$.[1]

Another physical property of interest is the mobility (μ_e) of e^-_s. Due to the instability of metal solutions in amines (1), conductance studies of such solutions have been limited to MA (30) and EDA (31). Furthermore, the limiting value of the equivalent conductance depends on the nature of the metal (30, 31). In addition there are some experiments on the conductivity of excess electrons in amines in the microsecond range (32). However, the mobilities found for these solvents of low dielectric constant may involve an associated form of the electron which may be formed in a fast process (15).

In contrast with direct methods which, due to their long response time, are unable to give mobilities of isolated solvated electrons, the calculation of mobility from the diffusion-controlled rate constant with effective scavengers is, as already suggested (33), of more general use for these solvents. Actually, the reduced Smoluchowski–Debye equation applies:

$$[2] \quad k_s = 4\pi k T \rho_s \mu_e / e$$

where k is the Boltzmann constant, T the temperature, k_s the scavenging rate constant, e the electron charge, and ρ_s the effective reaction radius. If one admits that the scavenging of e^-_s by biphenyl is diffusion controlled, use of eq. [2] with $\rho_s = 5$ Å

[1]After a 0.3 μs pulse in EA and *i*PA, as in the work by Seddon *et al.* (3*b*), the true solvated electron yield is indeed lower than the yield of escaped electrons determined from the scavenging curve, since in the pure solvent, a fraction of the latter will recombine during the pulse.

gives the mobilities listed in Table 1. In EDA, the mobility is lower by a factor of ten than in EA and *n*PA, and higher than those given in ref. 32.

2. Efficiency of e^-_s–Cation Reaction

In preceding papers (6–8) we emphasized the role of the efficiency factor for the e^-_s–cation recombination on the survival probability of e^-_s. For this purpose, diffusion-controlled rate constants are estimated from the Smoluchowski–Debye equation:

$$[3] \quad k_{diff} = 4\pi\rho_s Dx/(1 - \exp(-x))$$

where D is the mutual diffusion coefficient and x is the ratio $e^2/\varepsilon_s\rho_s kT$. As the diffusion coefficient for e^-_s, $D_{e^-_s}$, is larger than the diffusion coefficient for the cation, one can consider as a first approximation that $D \simeq D_{e^-_s} \cdot D_{e^-_s}$ is obtained from the above data on conductivity, and ρ_s is the sum of the cavity radius of e^-_s, estimated to be 2 Å, and of the crystal radius of alkylammonium ion, estimated from partial ionic molar volumes in water to be 2.7, 2.9, and 3.0 Å for EA, *n*PA, and EDA respectively (34). The diffusion-controlled rate constants k_{diff} are found to be equal to 4.7×10^{12}, 5.9×10^{12}, and 2.9×10^{11} L mol^{-1} s^{-1} in EA, *n*PA, and EDA respectively. As explained earlier, the only accurate experimental measurement of the recombination rate constant k_{exp} is for EDA: $k_{exp} = 2 \times 10^{10}$ L mol^{-1} s^{-1}. So, in this solvent, the efficiency factor f, defined as the ratio k_{exp}/k_{diff}, is only 7×10^{-2}. In EA and *n*PA, because of the arguments developed above, we think that the second order rate constants determined from analysis of the decay in the pure solvent can be used as upper limits for k_{exp}. The efficiency factors estimated with such limits are equal to 0.3 and 0.6 in EA and *n*PA respectively. So, contrary to EDA, rate constants of recombining reactions in EA and *n*PA may be almost diffusion controlled.

3. Solvated Electron, H Atom- and H_2-yields

In the three solvents, the yield of biphenyl anion formed by electron capture shows a marked dependence on biphenyl concentration (Fig. 9). In order to analyse such a dependence, we used the empirical equation proposed in the case of hydrocarbons (27), corrected to take account of homogeneous competition between the decay of free ions and their scavenging by Ph_2 (35).

$$[4] \quad G(Ph_2^-) = G(e^-_s)_f[\delta S/(1 + \delta S)] + G(e^-_s)_g[(\alpha S)^{1/2}/(1 + (\alpha S)^{1/2})]$$

where $G(e^-_s)_f$ and $G(e^-_s)_g$ represent the yields of the solvated electrons, free and geminate respectively, S is the concentration of the scavenger, α is a parameter which represents the competition between recombination of *geminate* electrons with cations or radicals in the spur and reaction towards the solute, δ is the ratio k_s/k_d where k_d is the first order rate constant for the decay of *free* electrons. This constant has been estimated from [5]

$$[5] \quad k_d = k_{e^-_s + RNH_3^+}[RNH_3^+]$$

where $[RNH_3^+]$ is the concentration of cations at the end of geminate recombination in the presence of a solute at concentration S. From the charge balance, we can write

$$[6] \quad [RNH_3^+] = 10DN_A G(e^-_s)_g \times [(\alpha S)^{1/2}/(1 + (\alpha S)^{1/2})]$$

where D is the deposited dose (eV × cm^{-3}) and N_A is Avogadro's number. The solid curves drawn in Fig. 9 represent the best fit of eq. [4] using for EA, *n*PA, and EDA, respectively: $G(e^-_s)_g = 4.0$, 3.55, and 3.3, $G(e^-_s)_f = 0.3, 0.3$, and 0.5, and $\alpha = 125$, 90, and 900. For the sake of comparison the broken curves represent values of $G(Ph_2^-)$ from the original scavenging equation (27) without corrections, using the same parameters as above. In spite of the correction expressed in eq. [4], experimental yields for concentrations of the scavenger lower than 10^{-3} mol L^{-1} are smaller than those calculated in EDA due to the decay of Ph_2^- during its formation. For this reason, the values given for $G(e^-_s)_f$ are to be considered as lowest limits.

More certain are the values of the total scavengeable yields $G_{e^-_s}$ found to be equal to 4.3, 3.85, and 3.8 for EA, *n*PA, and EDA respectively. These values are higher than those given previously for MA, EA, or *i*PA (3*b*). The discrepancy may be a consequence of the fact that, during the electron pulse (0.3 μs) used in ref. 3*b*, the biphenyl anions partly recombine.

These yields are to be compared with those deduced from molecular hydrogen yields after the γ-radiolysis of amines in the absence and presence of various scavengers. In addition to primary unscavengeable molecular hydrogen, H atoms and solvated electrons may form molecular H_2:

$$[7] \quad e^-_s + RHN_3^+ \rightarrow (RNH_3) \rightarrow H + RNH_2$$

H atoms are assumed to react with the solvent to give H_2 (36)

$$[8] \quad H + RNH_2 \rightarrow H_2 + R\dot{N}H$$

Therefore, in the pure solvent,

$$[9] \quad G_0(H_2) = G_{H_2} + G_H + \beta G_{e^-_s}$$

where G_{H_2}, G_H, and $G_{e^-_s}$ are the primary yields of H_2, H, and e^-_s, and β is the fraction of e^-_s undergoing recombination with cations (reaction [7]). When an electron scavenger such as biphenyl is added in a

high concentration, then

[10] $G(H_2)_{Ph_2} = G_{H_2} + G_H$

Similarly, in the presence of a high concentration of acidic salt, then

[11] $G(H_2)_{acid} = G_{H_2} + G_H + G_{e^-_s}$

So, if the above hypotheses are correct:

[12] $G(H_2)_{acid} - G(H_2)_{Ph_2} = G_{e^-_s}$

For EA, such a difference obtained from the literature gives $G_{e^-_s} = 2.7 \pm 0.1$ (5) which is to be compared with our limiting value of 4.3. The agreement is better for *n*PA where our results in γ-radiolysis (see Fig. 10) give $G_{e^-_s} \simeq 3.5$, to be compared with $G_{e^-_s} = 3.85$ from the Ph_2 scavenging experiments.

The decrease $\Delta G(H_2)$ of molecular hydrogen yield in the presence of biphenyl, compared to that in the presence of high concentration of acidic salt, can be expressed in the form:

[13] $\Delta G(H_2) = G(e^-_s)_f + G(e^-_s)_g \times (\alpha S)^{1/2}/[1 + (\alpha S)^{1/2}]$

By choosing the same parameters as those given above for *n*PA, one obtains the solid curve in Fig. 10. This fits the experimental data quite well, giving further support to the above values. At concentrations used, biphenyl has been considered not to scavenge H atoms that react efficiently with the solvent by reaction [8]. If H atom scavenging occurred the decrease in $G(H_2)$ would be higher and the difference in eq. [12] would give $G_{e^-_s} + G_H \simeq 3.5$. As $G_{e^-_s} = 3.85$ has been found from pulse radiolysis we deduce $G_H \simeq 0$. The same conclusion is reached when experimental data concerning allyl alcohol solutions are examined. Allyl alcohol is known as an ineffective scavenger of hydrated electrons ($k_{e^-_{aq} + CH_2=CHCH_2OH} < 10^6$ L mol^{-1} s^{-1} (37)), but as an efficient scavenger of H atoms in water such that the main scavenging reaction is

[14] $H + CH_2{=}CHCH_2OH \rightarrow C_3H_6OH$

which does not yield H_2 (37). The rate constant k_{14} is higher than 10^9 L mol^{-1} s^{-1} in water (38). Since a molar solution of allyl alcohol causes the same decrease in $G(H_2)$ as a molar solution of biphenyl, it is concluded that allyl alcohol scavenges only H atoms produced via reaction [7]. Again, the conclusion is $G_H \simeq 0$. As allyl alcohol in molar solutions competes with the solvent molecules to scavenge H atoms, we deduce that $k_8 < 5 \times 10^7$ L mol^{-1} s^{-1}.

Finally, the yield of unscavengeable molecular hydrogen G_{H_2} is deduced from the asymptotic value of $G(H_2)$ at high biphenyl concentrations (see Fig. 10): $G_{H_2} = 2.0 \pm 0.3$.

4. Main Recombination Reactions for Solvated Electrons in Amines

Mass spectrometer studies on gaseous ionic reactions in ammonia (39–41) and methylamine (42) have shown that the initial cation is rapidly replaced through ion–molecule reactions by the protonated molecule ions. Assuming that the same ion–molecule reactions occur in EA, *n*PA, and EDA, then the primary radiolysis species are as follows:

[15] $RNH_2 \rightarrow RNH_3^+, e^-_s, RNH^{\cdot}, (H^{\cdot}, R^{\cdot}, NH_2^{\cdot})$

Radicals like $RNH^{\cdot}$, $R^{\cdot}$, or $NH_2^{\cdot}$ may also be formed in small amounts by decomposition of excited molecules (43).

Because in amines the solvated electron associated with alkali cations is metastable, reactions of e^-_s with the solvent molecule or another e^-_s are relatively unimportant (7). Therefore the main reactions for the disappearance of e^-_s are [7] and [16].

[16] $e^-_s + RNH^{\cdot} \rightarrow RNH^-$

In ammonia and hydrazine, the main reaction of disappearance has been found to be reaction [16], because of the low efficiency of reaction [7] (6, 7). At the same time, $G(e^-_s)$ has been found to be high ($G(e^-_s) = 3.0$ and 3.4 in NH_3 and N_2H_4 respectively).

When acidic cation is added to both EA and *n*PA in order to accelerate the e^-_{solv}–cation recombination, the uv absorption attributed to radicals is unchanged compared with the pure solvent and there is only a slight increase in hydrogen yield ($\Delta G(H_2) = 0.1$) leading to $\beta \simeq 1$ in eq. [9]. Both features suggest that reaction [7] is the main recombination reaction in EA and *n*PA. Consequently, the measured rate constant of the decay in pure solvents has been assumed to be $k_{e^-_s + RNH_3^+}$ (see above) and has been found to be almost diffusion controlled.

The escape probability N at a given time t, $N_t = G(e^-_s)_t/G_{e^-_s}$ is 0.35 and 0.31 at 3 ns for EA and *n*PA respectively. These values are a little higher than the corresponding probability determined in dimethoxyethane ($\varepsilon_s = 5$), in which $N_{3ns} = 0.20$ if we consider that $G(e^-_s)_{3ns} = 0.8$ (7) and $G_{e^-_s} = 4.0$ by analogy with the value determined for tetrahydrofuran (44). These probabilities are low in correlation with the fact that the efficiency factor f is near unity.

The escape probability N_{3ns} equals 0.82 in EDA. This high value can be correlated, as for NH_3 and N_2H_4, with the low value of f. In fact, the mechanism for disappearance of e^-_s in EDA is intermediate between that of polar NH_3 and N_2H_4, in which $f \simeq 0$, and that of weakly polar amines, as EA and *n*PA, in which $f \simeq 1$: reaction [16] takes place in competition with reaction [7]. Indeed, by addition of acidic salts, radicals are protected and $G(H_2)_{acid}$

increases ($\Delta G(H_2) = 0.8$). Considering the initial decay rate of e^-_s and the experimental value for the rate constant of reaction [7], and supposing a radical yield equal to the solvated electron yield, we find that the rate constant of reaction [16] equals 4×10^{10} L mol^{-1} s^{-1}. This value indicates that the efficiency factor for reaction [16] is high, as is the case for NH_3 (8).

In conclusion, pulse- and γ-radiolysis studies of EA, *n*PA, and EDA give evidence for the influence of efficiency factors of the neutralization reaction and recombination with radicals on the yield of escaped solvated electrons. By solving the Smoluchowski equation with a boundary condition expressing the partially reflective character of the reaction sphere (7), we have shown that it is possible to describe qualitatively the influence of f on the escape probability. The approximation method used to solve the equation was "prescribed diffusion" (45). In order to improve the accuracy of the theoretical calculation of N_t and to introduce possible reaction with radicals, numerical solution of the Smoluchowski equation is in progress. In this way, we hope to get some idea of the mean initial thermalisation length for the solvated electron in cases where recombination with the cation is not the only recombination process.

Les deux types de polymérisation du norbornène ont été étudiés en catalyse homogène. Le palladium conduit à une polymérisation de type vinylique alors que pour le rhodium et le ruthénium nous avons ouverture de cycle. Dans le cas de la polymérisation avec le palladium, nous avons pu piéger un intermédiaire réactionnel: $PdCl_2(C_7H_{10})_4$ et étudier son comportement en polymérisation. Avec le ruthénium, nous avons étudié l'influence de deux ligands: le cyclopentadiène qui conduit à un blocage complet de la réaction et la triphénylphosphine dont l'effet varie suivant le rapport $P\phi_3$/Ru. L'utilisation de trois alcools comme solvant: EtOH, *n*-BuOH, *t*-BuOH, montre une variation de la vitesse réactionnelle en passant de EtOH à *t*-BuOH avec $RuCl_3 \cdot 3H_2O$ et aucun changement pour $RuCl_2(P\phi_3)_3$. Ceci indique que le rôle de l'alcool n'est pas limité à celui de solvant mais qu'il doit participer à la réaction elle-même, notamment au niveau de la formation de l'espèce active.

CHARLES TANIÉLIAN, ALAIN KIENNEMANN, and TEMEL OSPARPUCU. Can. J. Chem. **57**, 2022 (1979).

Both types of norbornene polymerisation with homogeneous catalysts have been studied. Palladium leads to vinyl-type polymerisation whereas rhodium and ruthenium lead to ring opening. In the case of palladium-catalysed polymerisation we have been able to trap the reactive intermediate $PdCl_2(C_7H_{10})_4$ and have studied its behaviour during polymerisation. With ruthenium we have studied the effect of two ligands: cyclopentadiene which leads to a complete blocking of the reaction and triphenylphosphine the effect of which varies according to the ratio $P\phi_3$:Ru. Use of the three alcohols, ethanol, *n*-butanol, and *tert*-butanol, as solvent shows a variation in reaction rate on charge using $RuCl_3 \cdot 3H_2O$ but no change for $RuCl_2(P\phi_3)_3$. This indicates that the role of the alcohol is not limited to that of solvent but it must participate in the reaction especially during the formation of the reactive intermediate.

[Journal translation]

Introduction

De nombreux travaux traitent de l'obtention de polymères à partir de cycloléfines et un certain nombre de mises au point ont été publiées (1–5). Certaines cycloléfines dont le norbornène ont la possibilité de se polymériser suivant deux voies: polymérisation de type vinylique ou par ouverture de cycle. Le choix du système catalytique permet de diriger la réaction vers l'une ou l'autre voie: des acides de Lewis (6), des complexes à base de palladium (7, 8), certains catalyseurs Ziegler–Natta (9–12), des peroxydes (13, 14) conduisent à une polymérisation de type vinylique, alors que la polymérisation par ouverture de cycle est obtenue si l'on utilise des catalyseurs Ziegler–Natta (10, 11, 15) des oxydes de chrome, molybdène ou tungstène réduits (16) des sels ou complexes de ruthénium, osmium, iridium en milieu alcool (17, 18) ou benzène (19) ou d'autres éléments de transition (W, Mo, Re) (20, 21). Malgré ces nombreux travaux, l'étude du mécanisme de la réaction reste d'actualité (21, 22).

Nous nous proposons, dans ce travail, d'étudier les deux types de polymérisation en catalyse homogène avec des métaux du groupe VIII: palladium (polymérisation de type vinylique), rhodium et ruthénium (ouverture de cycle). La mise en évidence d'intermédiaires réactionnels pour le palladium et l'étude d'effets de solvants et de ligands pour le ruthénium permettent une approche des schémas réactionnels de la polymérisation.

Partie expérimentale[2]

Toutes les réactions sont effectuées en utilisant l'argon comme gaz protecteur. Les spectres ir ont été obtenus sur spectromètre Beckman IR-12, solution dans CCl_4 pour les résolutions entre 4000 cm^{-1} et 400 cm^{-1} et sur Beckman IR-11, suspension dans le Nujol pour les résolutions jusqu'à 70 cm^{-1} (complexe norbornène–palladium). Les spectres de rmn ont été obtenus selon (17) sur Varian A60 et Brucker WH90 à $T = 70°C$, le monomère et les polymères étant en solution dans le benzène, à T ambiante pour le complexe norbornène–palladium.

Les alcools utilisés (puriss Fluka): MeOH, EtOH, *n*-BuOH

[1]A qui toute correspondance doit être adressée.

TABLEAU 1. Influence du catalyseur sur la polymérisation du norbornène*

Catalyseurs	Conversion norbornène (%)	Rendement en polymère (%)	Type de polymérisation
$PdCl_2(C_6H_5CN)_2$	42	40	Vinyl
$PdCl_2[P(C_6H_5)_3]_2$	20	17	Vinyl
$PdCl_2[P(Bu)_3]_2$	—	—	—
$PdCl_2(C_7H_{10})_4$	40	40	Vinyl
$RhCl_3 \cdot 3H_2O$	15	5	Ouverture de cycle *trans*
$RhCl[P(C_6H_5)_3]_2$	22	7	Ouverture de cycle *trans*
Complexe Rh–norbornène	10	7	Ouverture de cycle *trans*
$RuCl_3 \cdot 3H_2O$	71	65	Ouverture de cycle *trans*
$RuCl_2[P(C_6H_5)_3]_3$	86	80	Ouverture de cycle *trans*
$Ru_3(CO)_{12}$	43	36	Ouverture de cycle *trans*
$RuClCO[P(C_6H_5)_3]_2$	24	21	Ouverture de cycle *trans*

*T = 68°C durée: 21 h solvant EtOH. (cat Rh) = 2.67×10^{-3} mol/L; (monomère) = 2.5 mol/L. (cat Ru) = 1.5×10^{-2} mol/L; (monomère) = 1.5 mol/L. (cat Pd) = 1.1×10^{-2} mol/L; (monomère) = 2.5 mol/L.

et *t*-BuOH ont été séchés et distillés selon la méthode au phtalate (23). Le benzène (puriss Fluka) a été distillé sur potassium et le norbornène (purum Fluka) distillé et contrôlé par chromatographie phase gazeuse et rmn.

Conduite d'une réaction de cinétique: dans un ballon de 100 mL, on dissout le catalyseur $RuCl_3 \cdot 3H_3O$ (4×10^{-5} mol) dans 0.137 mol EtOH (T = 68°C). On ajoute alors 0.04 mol de norbornène dans 0.137 mol EtOH. La consommation de norbornène est mesurée par prélèvements réguliers en chromatographie phase gazeuse par la méthode de l'étalon interne (octane 2.15×10^{-6} mol). Pour chaque catalyseur la courbe de conversion présente initialement une partie linéaire correspondant à une vitesse de polymérisation constante puis une déviation par rapport à la linéarité (t = 1 h 30 min) correspondant à un début de précipitation du polymère formé. La vitesse de polymérisation décroît alors lentement et le système semble devenir progressivement inactif. Le polymère obtenu est soigneusement lavé au méthanol, séché et pesé.

Les conditions chromatographiques sont les suivantes: catharomètre (Varian 202), colonne: SE 30 10% sur Chromosorb W 80/100 mesh, (2 m, 1/8 po, 75°C) He gaz vecteur, octane étalon interne.

Préparation des catalyseurs

$PdCl_2$–norbornène: 190.5 mg de chlorure de palladium dibenzonitrile (6.8×10^{-4} mol) sont dissous dans 5 mL de méthanol ainsi que 568.4 mg de norbornène (6×10^{-3} mol) dans 25 mL de méthanol. Le mélange est refroidi à −2°C pendant 1/2 h. On note l'apparition d'un précipité jaune. Le mélange est laissé à cette température 24 h puis filtré, lavé et séché. Masse de solide obtenu 225.8 mg. Rendement 60%.

Rh–norbornène: une solution de 5.8×10^{-2} mol de norbornène et 3.2×10^{-3} mol de $RhCl_3 \cdot 3H_3O$ dans 0.45 mol d'éthanol est chauffée sous reflux pendant 2 h. Obtention d'un précipité brun-violet qui est lavé et séché. Rendement 50%.

Résultats et discussion

A. Catalyseurs au palladium

a. Activités-rendements

Des essais avec $PdCl_2$ suivant Schultz (7) ne nous ont donné qu'une faible quantité de polymères due au peu de solubilité du catalyseur dans le milieu. Par contre, des catalyseurs au palladium, solubles dans le milieu (benzène, norbornène): chlorure de palladium dibenzonitrile, chlorure de palladium triphénylphosphine et tributylphosphine ainsi 'qu'un complexe norbornène–palladium $PdCl_2(C_7H_{10})_4$ isolé et étudié en polymérisation ont donné les résultats plus significatifs (tableau 1). Ce tableau nous permet de constater:

α—Une bonne corrélation entre conversion du norbornène et rendement en polymère montrant la formation privilégiée de polymères de poids moléculaires élevés. Dans ce travail nous n'avons pas étudié les équilibres monomère–polymère ou oligomère–polymère comme dans le cas du cyclopentène et du cyclooctène (24–26).

β—Une différence d'activité marquée selon le catalyseur: l'activité décroît lorsque la basicité des ligands augmente (pK_a de $P(Bu)_3$ et $P(C_6H_5)_3$ 8.43 et 2.73 rendement en polymère 0 et 17.3%).

γ—Le complexe palladium–norbornène isolé se comporte d'une façon analogue à celle de $PdCl_2(C_6H_5CN)_2$ dont il dérive.

L'étude infrarouge et rmn des polymères obtenus indiquent une polymérisation type vinylique: en ir absence de bandes à 963 cm^{-1} et 742 cm^{-1} caractéristiques d'une ouverture de cycle, en rmn le spectre est composé de trois massifs principaux à 2.1, 1.6 et 1.1 ppm/TMS et l'assignement complet est identique à celui donné par Gaylord et coll. (13).

b. Complexe norbornène–palladium

Le complexe $PdCl_2(norbornène)_4$ préparé à partir de chlorure de palladium dibenzonitrile et norbornène en proportion 1/1 à 0–2°C dans le méthanol et dont la formule a été déterminée à partir de l'analyse élémentaire Pd, Cl, C, H présente les caractéristiques ir et rmn suivantes: en ir: bande Pd—Cl à 340 cm^{-1} et 309 cm^{-1} (27–29) et Pd—C à 480 cm^{-1}. La bande à 480 cm^{-1} suggère une liaison σ entre le palladium et le carbone. La comparaison des spectres rmn du complexe (3.4 ppm/TMS), du norbornène (5.95 ppm/TMS) et du polymère (1.47 et 1.53 ppm/TMS)

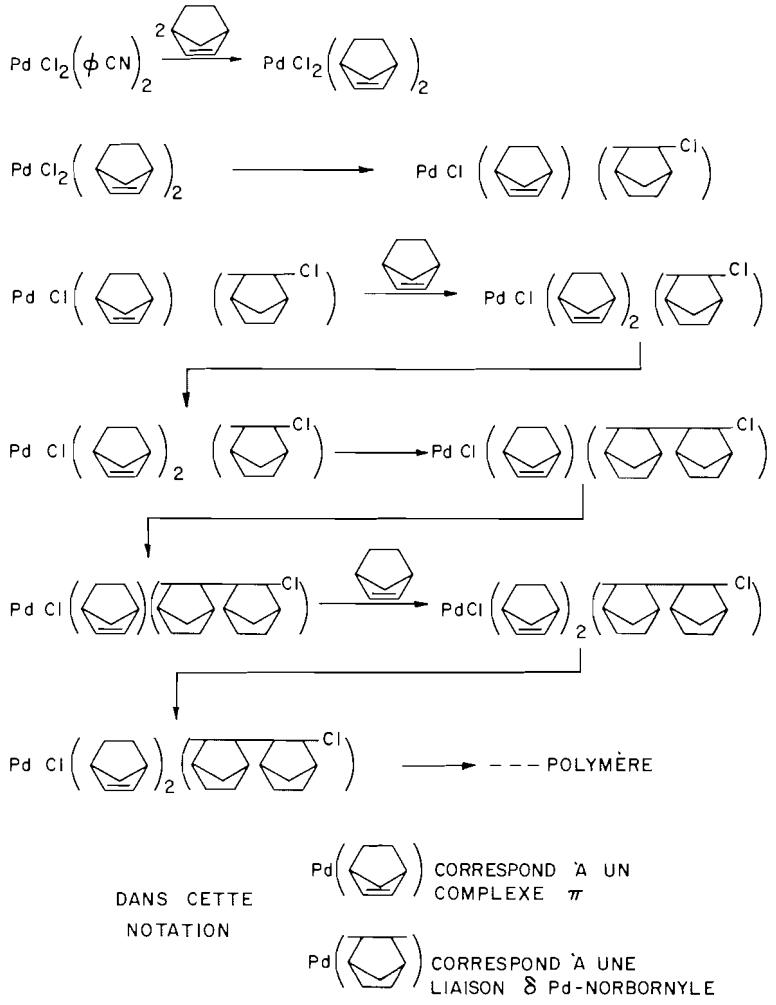

FIG. 1. Polymérisation de type vinylique avec des catalyseurs au palladium.

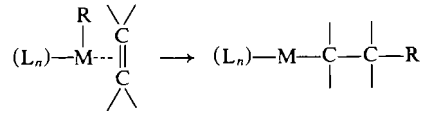
pour les protons ayant la même position que les protons oléfiniques du norbornène permet de constater une position intermédiaire des protons du complexe entre les protons oléfiniques du norbornène (liaison Π) et ceux du polymère (liaison σ), indiquant la formation d'un complexe Π entre le métal et le norbornène. Comme par ir nous avions déjà mis en évidence une liaison σ Pd—C il faut admettre que *n* motifs norbornène sont liés au métal par des liaisons Π et 4-*n* par des liaisons σ. De plus, la courbe d'intégration permet de préciser la présence d'un proton oléfinique pour dix autres protons. Dans le cas du complexe $PdCl_2$(norbornène)$_4$ ceci nécessite deux motifs monomères liés au métal par une liaison Π, et deux autres l'étant par une liaison σ. Le complexe $PdCl_2$(norbornène)$_4$ ayant donné en polymérisation le même type de polymère avec un rendement identique à celui obtenu avec $PdCl_2(C_6H_5CN)_2$ (tableau 1) ceci laisse prévoir que le complexe isolé est un intermédiaire réactionnel bien qu'il n'ait pu être isolé lors de la polymérisation avec $PdCl_2(C_6H_5CN)_2$ du fait d'une trop grande vitesse de polymérisation.

c. Schéma réactionnel

La polymérisation de type vinylique avec le palladium s'explique par la succession de deux étapes correspondant, l'une à la coordination de la double liaison oléfinique sur le métal, l'autre à une insertion:



Nos résultats ir et rmn, décrits pour le complexe $PdCl_2$(norbornène)$_4$, indiquent l'existence d'une telle liaison Π et σ entre le palladium et le norbornène. La polymérisation peut alors être schématisée de la manière suivante (fig. 1).

B. Catalyseurs au rhodium

a. Activités-rendements

Nos essais de polymérisation avec $RhCl_3 \cdot 3H_2O$, $RhCl(P\phi_3)_2$ et un complexe Rh–norbornène sont donnés dans le tableau 1.

Le tableau 1 permet les observations suivantes:

α—Nous avons polymérisation par ouverture de cycle avec formation du composé trans mais avec une conversion faible par rapport à celle obtenue dans des conditions identiques avec le ruthénium en accord avec un tableau de réactivité des métaux proposé par Dall'Asta et Motroni (2).

β—Légère augmentation en fin de réaction du taux de conversion, du rendement en polymère et de la vitesse réactionnelle en passant de $RhCl_3 \cdot 3H_2O$ à $RhCl(P\phi_3)_2$ (fig. 2). Ce phénomène, bien que moins prononcé est identique à celui observé pour les catalyseurs au ruthénium.

b. Complexe norbornène-rhodium

Le complexe signalé par Varshavsky et coll. (30): $[Rh(C_7H_9)(C_7H_{10})Cl_2]_2$ a été préparé. Il ne montre pas de variation importante du rendement ou de la vitesse de polymérisation par rapport aux autres complexes étudiés (tableau 1, fig. 2).

C. Catalyseurs au ruthénium

Nous avons repris l'observation de la réaction de polymérisation pour des complexes du ruthénium en solution alcoolique (18) en nous attachant à déterminer le rôle du solvant dans ce type de réaction pour $RuCl_3 \cdot 3H_2O$ et $RuCl_2(P\phi_3)_3$ ainsi que le rôle de ligand que peut jouer la triphénylphosphine ou l'addition d'une nouvelle oléfine tel que le cyclopentadiène.

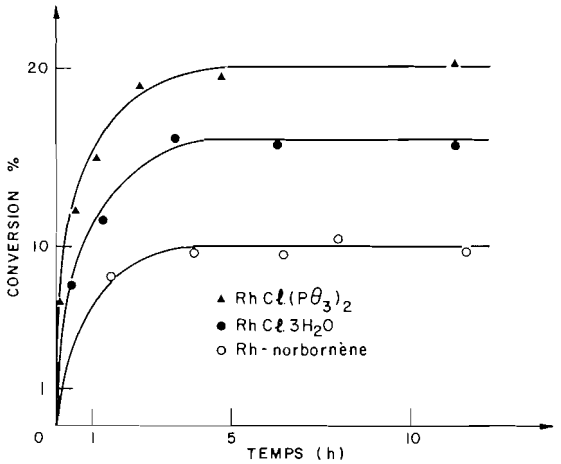


FIG. 2. Influence des catalyseurs au rhodium sur la conversion du norbornène. Solvant EtOH, $T = 68°C$; (catalyseur) $T = 2.6 \times 10^{-3}$ mol/L; (monomère) $T = 2.5$ mol/L.

a. Activités-rendements

Les résultats concernant l'activité du ruthénium en solution alcoolique sont donnés dans le tableau 1. Ce dernier permet de tirer les conclusions suivantes:

α—Polymérisation par ouverture de cycle avec formation privilégiée de polymère.

β—Les catalyseurs au ruthénium utilisés, présentent la particularité d'avoir un degré d'oxydation du métal différent: 0, 1, 2, 3. Les meilleurs résultats sont obtenus avec $Ru_{II}Cl_2(P\phi_3)_3$ alors que $Ru_ICICO(P\phi_3)_2$ donne les plus faibles rendements. Bien qu'il ne semble pas y avoir de corrélation directe entre le degré d'oxydation et le rendement de la polymérisation contrairement à ce que suggère Rinehart et Smith (31) qui proposent une réduction initiale dn métal dans son degré d'oxydation le plus bas, nos résultats ne peuvent l'exclure complètement car cette dernière peut être accompagnée éventuellement d'une variation du nombre de coordination.

b. Etude de l'effet de solvants

Alors que la polymérisation ne se fait pas en milieu dioxane ou tétrahydrofuranne, les solvants alcooliques conviennent bien et leur rôle mérite d'être précisé. Michelotti et Keaveney (17) suggèrent, dans l'étape d'initiation, une attaque nucléophile de l'éthanol sur un complexe Π-métal–oléfine. Rinehart et Smith (31) quant à eux considèrent que l'alcool est un agent réducteur nécessaire. Il faut toutefois remarquer que l'alcool, outre son rôle de solvant peut intervenir comme ligand substituant. Cette possibilité est étayée par les observations suivantes:

α—Le norbornène, en solvant hexane avec $RuCl_3 \cdot 3H_2O$ comme catalyseur ne polymérise pas. Par contre, si on ajoute de l'alcool en quantité stoechiométrique, $|EtOH|/|RuCl_3 \cdot 3H_2O| = 3$, on observe une polymérisation par ouverture de cycle avec un rendement de 48% (température 70°C, EtOH: 1.14 mmol, $RuCl_3 \cdot 3H_2O$: 0.38 mmol, norbornène: 0.05 mol, hexane: 0.15 mol).

β—Les figs 3 et 4 montrent la conversion du norbornène en fonction du temps pour différents alcools: EtOH, *n*-BuOH, *t*-BuOH avec $RuCl_3 \cdot 3H_2O$ et $RuCl_2(P\phi_3)_3$ comme catalyseurs. Les constantes de vitesse calculées sont identiques pour les trois alcools: 1.4×10^{-4} avec $RuCl_2(P\phi_3)_3$ alors qu'elles varient suivant l'alcool pour $RuCl_3 \cdot 3H_2O$ 2.1×10^{-5}, 3.2×10^{-5} et 6.1×10^{-5} pour EtOH, *n*-BuOH et *t*-BuOH respectivement.

L'influence de ligand nous apparaissant primordiale, nous l'avons alors illustrée par deux ligands particuliers: le cyclopentadiène et la triphénylphosphine.

c. Etude de l'effet de ligands

α—*Cyclopentadiène*: Quelques tentatives prélimi-

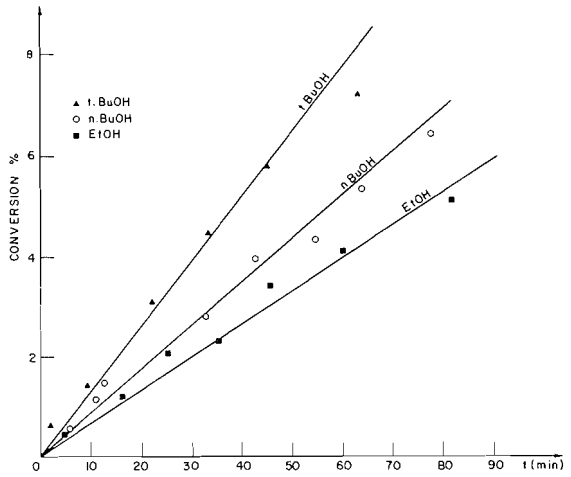

FIG. 3. Influence de l'alcool sur la vitesse de polymérisation; cat: $RuCl_3 \cdot 3H_2O$, $T = 60°C$; ($RuCl_3 \cdot 3H_2O$), $T = 3.94 \times 10^{-3}$ mol/L; (monomère) $T = 3.94$ mol/L.

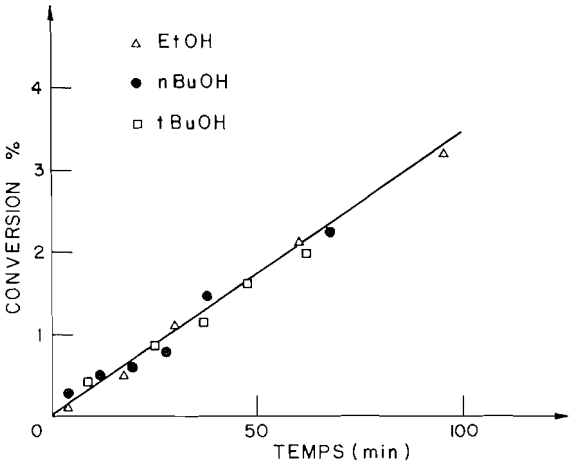

FIG. 4. Influence de l'alcool sur la vitesse de polymérisation; cat; $RuCl_2(P\phi_3)_3$, $T = 68°C$; [$RuCl_2(P\phi_3)_3$], $T = 3.95 \times 10^{-3}$ mol/L; (monomère) $T = 3.94$ mol/L.

naires nous ayant montré que l'addition de cyclopentadiène, avant mise en contact avec le norbornène, conduisait à la désactivation totale, nous avons choisi de suivre la modification de l'évolution de la réaction déjà engagée lorsqu'on ajoute le cyclopentadiène. La fig. 5 montre un blocage presque immédiat de la réaction (conversion 50%) par addition de cyclopentadiène (cyclopentadiène/Ru = 20) après 50 min de polymérisation. De même, le palier de conversion se situe à 20% par addition d'oléfine (cyclopentadiène/Ru = 1) après 20 min de réaction. Dans les deux cas, la conversion aurait dû être de 71% (tableau 1).

β—*Triphénylphosphine*. La fig. 6 montre l'évolution de la réaction par addition de triphénylphosphine. La vitesse de polymérisation varie suivant le

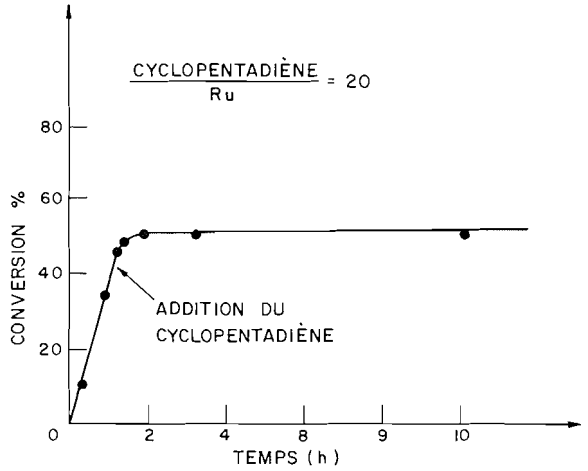

FIG. 5. Influence de l'addition de cyclopentadiène sur le blocage de la réaction; cat: $RuCl_3 \cdot 3H_2O$, $T = 68°C$, solvant EtOH; ($RuCl_3 \cdot 3H_3O$), $T = 2.5 \times 10^{-3}$ mol/L; (monomère) $T = 2.5$ mol/L; (cyclopentadiène) $T = 4.9 \times 10^{-2}$ mol/L.

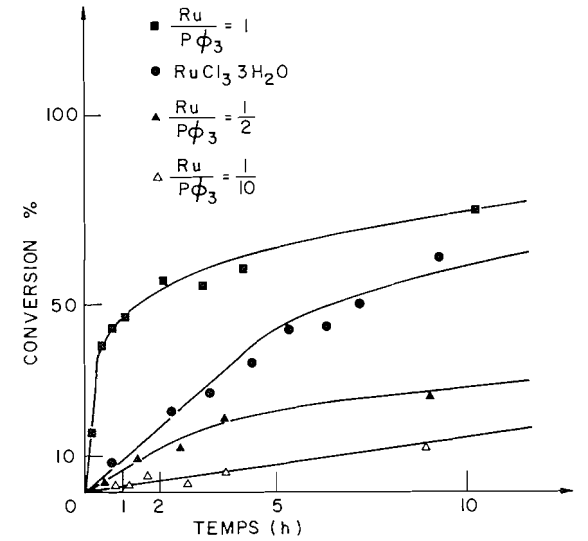

FIG. 6. Influence de la quantité de triphénylphosphine ajoutée sur la vitesse de polymérisation; cat: $RuCl_3 \cdot 3H_2O$, $T = 60°C$, solvant EtOH; ($RuCl_3 \cdot 3H_2O$), $T = 1.9 \times 10^{-3}$ mol/L; (monomère) $T = 1.9$ mol/L.

rapport $P\phi_3$/Ru (fig. 7): maximum d'activité pour le rapport 1/1 (supérieure à $RuCl_3 \cdot 3H_2O$ seul) mais blocage presque complete pour des rapports $P\phi_3$/Ru = 10 (15% de conversion du lieu de 83%).

Discussion

Dans ce travail, nous mettons en évidence l'effet particulier de deux ligands: cyclopentadiène et triphénylphosphine. Le cyclopentadiène est un ligand fort, occupant tous les sites de coordination d'une manière irréversible et empêchant toute poursuite de la réaction, ceci quelque soit le rapport diène/Ru: 1/1 ou 1/20. Ces résultats sont en accord avec ceux

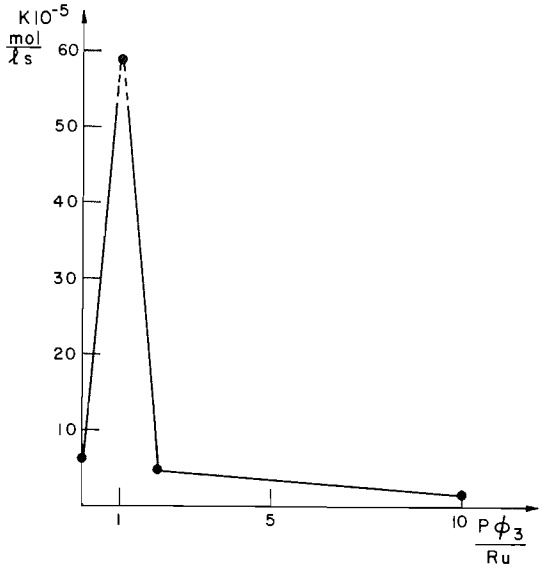

FIG. 7. Influence du rapport $P\phi_3/Ru$ sur la vitesse de polymérisation.

de Porri et coll. (19) sur l'addition d'oléfines aliphatiques. La phosphine, par contre, est un ligand moins fort mais susceptible néanmoins de provoquer la désactivation si elle est en grand excès (fig. 7).

Nous avons également montré le rôle particulier que joue la nature de l'alcool utilisé, indiquant une participation à la réaction puisqu'avec $RuCl_3 \cdot 3H_2O$, la vitesse de polymérisation dépend de l'alcool utilisé contrairement au cas de $RuCl_2(P\phi_3)_3$. L'influence de l'alcool peut s'expliquer en considérant le schéma réactionnel proposé par Laverty et coll. (21), l'alcool jouant un rôle voisin de l'eau dans le schéma proposé. Dans le cas de $RuCl_3 \cdot 3H_2O$, il peut y avoir dissociation du complexe initial $RuX_3L_3 \rightarrow RuX_3L_2 + L$ suivie d'une fixation de l'alcool pour former un nouveau complexe. Ce dernier peut évoluer de manière légèrement différente si EtOH, BuOH ou t-BuOH y sont fixés, notamment dans l'étape suivante de formation de l'hydrure métallique. L'acidité de l'hydrure ainsi formé qui conditionnerait la suite de la réaction, varierait ainsi légèrement d'un alcool à l'autre. Bien que l'eau soit présente avec $RuCl_3 \cdot 3H_2O$, la variation de la constante de vitesse indique plutôt dans notre cas une influence de l'alcool. Dans le cas de $RuCl_2(P\phi_3)_3$, le fait que la nature de l'alcool n'ait pas d'influence sur la vitesse de polymérisation, semble indiquer que l'étape lente de la réaction n'est pas l'échange de ligands mais qu'elle pourrait se situer au niveau de l'étape de métathèse.

Les résultats des effets de solvants et de ligands semblent exclure une interprétation identique pour $RuCl_2(P\phi_3)_3$ et $RuCl_3 \cdot 3H_2O$ tout au moins en ce qui concerne l'étape d'amorçage. Pour ce dernier, l'étape lente de la réaction est l'échange de ligand au niveau du catalyseur. Cette étape ne ferait pas intervenir le monomère mais uniquement le solvant et peut s'effectuer selon un mécanisme associatif ou dissociatif. Pour $RuCl_2(P\phi_3)_3$, l'étape lente de la réaction devrait se situer au niveau de la réaction de métathèse.

Temperature and concentration dependence of fluidity of mixed hydrated melts of calcium- and nickel(II)-nitrates

NURUL ISLAM AND ANWAR ALI

Department of Chemistry, Aligarh Muslim University, Aligarh 202001, India

Received January 10, 1979

NURUL ISLAM and ANWAR ALI. Can. J. Chem. 57, 2028 (1979).

The non-Arrhenius temperature dependence of fluidity, ϕ, of molten mixtures of calcium nitrate tetrahydrate and nickel(II) nitrate hexahydrate has been explained in terms of equations based upon the Vogel–Tammann–Fulcher (VTF) and the configurational entropy (CEM) models. The role of the relevant parameters in understanding the successive variations in their behaviour with concentration has been examined. The concentration dependence of fluidity has been explained satisfactorily by an isoenergetic equation. In addition to the linear dependence of the pre-exponential terms of the VTF and the Doolittle equations on the ideal glass-transition temperature, T_0, and the molar intrinsic volume, V_0, respectively, linear interdependence of the two thermodynamic parameters, T_0 on V_0, has been found. Linear dependence of the corrected activation energy, E_{cor}, on the V_0 and the T_0 values have been demonstrated in the system under investigation.

NURUL ISLAM et ANWAR ALI. Can. J. Chem. 57, 2028 (1979).

La fluidité, ϕ, de mélanges fondus du tétrahydrate du nitrate de calcium et de l'hexahydrate du nitrate de nickel(II) n'est pas reliée à la température par une fonction d'Arrhénius; ce fait est expliqué à l'aide d'équations basées sur des modèles de Vogel–Tamman–Fulcher (VTF) et d'entropie configurationnelle. On a examiné le rôle des paramètres appropriés pour comprendre les variations successives de leur comportement avec la configuration. On a expliqué d'une façon satisfaisante le fait que la fluidité varie avec la concentration en faisant appel à une équation isoénergétique. En plus de la relation linéaire des termes pré-exponentiels de VTF et des équations de Doolittle avec la température de transition vitesse idéale, T_0, et le volume molaire intrinsèque, V_0, on a aussi trouvé une relation linéaire entre les deux paramètres thermodynamiques, T_0 et V_0. On a démontré l'existence d'une relation linéaire entre l'énergie d'activation corrigée E_{cor} et les valeurs V_0 et T_0 dans le système étudiée.

[Traduit par le journal]

Introduction

In pursuance of our investigation on the concentration dependence of transport behaviour of mixtures of hydrated melts we attempt to explain such a behaviour quantitatively on the basis of constant T/T_0 $(=c)$ which has the advantage of being isoenergetic and also being independent of the T_0 values of the two constituents in a bicomponent system. The relevant reported (1) expression,

$$[1]\quad \phi = (A_{1(0)} - Q_1N)[(T_{0(0)} - Q_2N)c]^{-1/2} \times \exp\,[-k_1/(T_{0(0)} - Q_2N)(c-1)]$$

assumes the linear dependence of the pre-exponential parameter of the VTF equation, A_1, and that of the ideal glass-transition temperature, T_0, on concentration. Consequently, by combining these latter relations, an interesting linear dependence of A_1 on T_0 has also been obtained earlier (1) as

$$[2]\quad A_1 = [A_{1(0)} \mp T_{0(0)}(Q_1/Q_2)] \pm T_0(Q_1/Q_2)$$

especially in view of the role of A_1 in determining the concentration dependence of viscosities, ϕ^{-1}.

Similarly, in view of the linear concentration dependence of the pre-exponential term of the Doolittle equation and also that of the molar intrinsic volume, V_0, the following two relations obtained earlier (2) are

$$[3]\quad A_2 = [A_{2(0)} \mp V_{0(0)}(Q_3/Q_4)] \pm V_0(Q_3/Q_4)$$

and

$$[4]\quad T_0 = [T_{0(0)} \mp V_{0(0)}(Q_2/Q_4)] \pm V_0(Q_2/Q_4)$$

in which $A_{1(0)}$, $T_{0(0)}$, $A_{2(0)}$, and $V_{0(0)}$ are the corresponding values for the solvent while Q_1, Q_2, Q_3, and Q_4 are the slopes of A_1 vs. N (in mol%), T_0 vs. N, A_2 vs. N, and V_0 vs. N plots, respectively. The signs in these equations signify either increase or decrease in A_1, T_0, A_2, and V_0 with N. Equations [2] to [4] may successfully be applied to any system in which A_1, T_0, A_2, and V_0 vary linearly with concentration.

The present paper is an attempt to test the validity of the recently proposed expressions essentially describing the concentration dependence of the transport properties and to examine further the role

[a]The VTF equation is $\phi = A_1 T^{-1/2} \exp[-k_1/(T - T_0)]$.
[b]The CEM equation is $\phi = A_3 \exp[-k_3/T \ln T/T_0]$.

of these parameters in understanding the transport behaviour of molten salt systems. Molten $Ca(NO_3)_2 \cdot 3.96H_2O$–$Ni(NO_3)_2 \cdot 6.03H_2O$, being a low melting system, has been chosen for this purpose because of the ease of experimental measurements.

Experimental

Commercial calcium nitrate tetrahydrate (BDH; mp 42.7°C) was used as a solvent in the molten state while nickel(II) nitrate hexahydrate (BDH; mp 56.7°C) as a solute. Samples were prepared in a thermostated paraffin bath at about 60°C in an atmosphere of pure and dry nitrogen. Calcium nitrate tetrahydrate was found to dissolve 60.83 mol% of the solute. The prepared samples were stored in a vacuum desiccator.

Density (±0.3%) and viscosity (±0.1%) measurements were made with a dilatometer (3) of 0.01 mL division, and a Cannon–Ubbelohde type (4) viscometer, respectively, in a thermostated bath of ±0.1° thermal stability.

Results and Discussion

Calcium nitrate tetrahydrate and its mixtures with nickel(II) nitrate hexahydrate have been found to show supercooling tendency to a larger extent. However, as the concentration of the solute increases the supercooling tendency of the successive mixtures keeps decreasing. Therefore one may conclude that the crystallization kinetic constants of nickel(II) nitrate hexahydrate are comparatively more favourable to crystallization than those of calcium nitrate tetrahydrate.

The density and the viscosity of pure calcium nitrate tetrahydrate and those of its mixtures with nickel(II) nitrate hexahydrate measured as functions of temperature and concentration are listed in Tables 1 and 2.[1] The exact water of crystallization was found to be 3.96 (3, 5) and 6.03 (6) in the hydrated nitrates of calcium and nickel(II) respectively. The measured density of the solvent was found to be 0.17 and 0.39% higher when compared with those reported (3, 5) at 25°C. A difference of about 5% was noted in the viscosity at 40°C when compared with those reported by Moynihan (3).

As usual the non-linear ln η vs. $1/T$ plots were linearized by least-squares fitting the data to the VTF and the CEM equations as shown in Figs. 1 and 2.[1] Similarly, the non-linear plots of η versus reciprocal of free-volume were linearized by the Doolittle equation shown in Fig. 3.[1] The computed best fit parameters of these equations are listed in Tables 3 and 4.

The viscosity of the system under study is found to decrease quite markedly with concentration as shown in Fig. 4. Such a trend in viscosity isotherms has been found to be similar to those reported earlier (7, 8). An examination of isotherms *I*, *II*, and *III* reveals that at 10.19 and 39.83 mol%, curves *II* and *III*, in this order, show an increasing tendency for higher viscosities than expected for a smooth variation with concentration. It is apparent from Fig. 4 that as the temperature increases the isotherms tend to be linear,

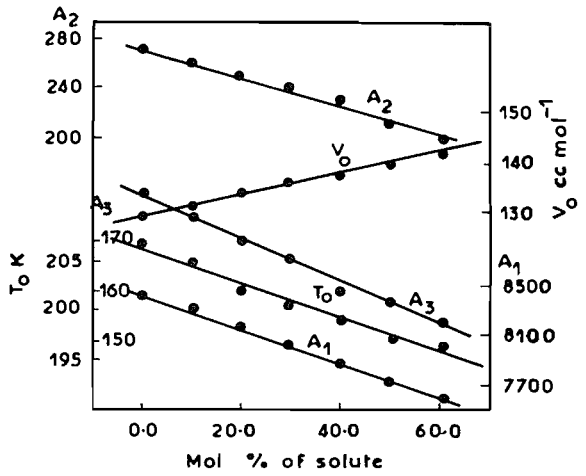

FIG. 5. Variation of A_1, A_2, A_3, T_0, and V_0 with [solute] for molten $Ca(NO_3)_2 \cdot 3.96H_2O$–$Ni(NO_3)_2 \cdot 6.03H_2O$ system.

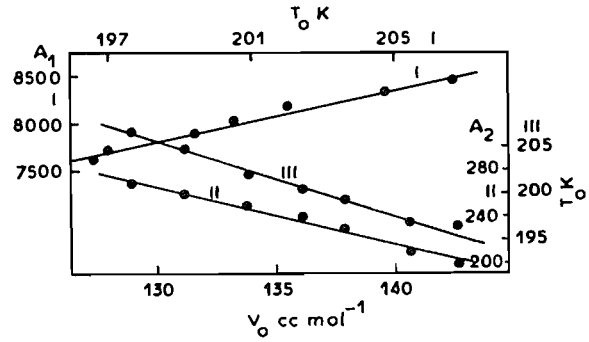

FIG. 6. Variation of (*I*) A_1 with T_0, (*II*) A_2 with V_0, and (*III*) T_0 with V_0 for molten $Ca(NO_3)_2 \cdot 3.96H_2O$–$Ni(NO_3)_2 \cdot 6.03H_2O$ system.

showing the additive nature of viscosity at higher temperatures.

The pre-exponential parameters of the VTF, the CEM, and the Doolittle equations as well as the T_0 and the V_0 values show linear dependence on [solute] as shown in Fig. 5. Thus, a decrease in the T_0 value with increase in [solute] may be due to an increase in the average molecular mass. This is in accordance with the $m^{-1/2}$ dependence relation (9). Such a decrease in T_0 with increase in $[Ni^{2+}]$ may also be due to the additive nature of T_0. The V_0 value, on the other hand, has been found to increase linearly with the [solute], unlike that found in the case of T_0. However, the pre-exponential terms follow the pattern of T_0. The V_0 has been found to be additive in nature as is the case with T_0. The linear dependences expected from [2] to [4] have actually been found in the present system (Fig. 6).

The concentration dependence of fluidities has been explained by least-squares fitting the data to [1] at several values of c corresponding to the experimental temperature, T. The best fit parameters thus obtained are listed in Table 5. The computed parameters, viz., $A_{1(0)}$, Q_1, Q_2, and $T_{0(0)}$ are close to those found from the corresponding plots (Fig. 5).

Finally, the dependence of the corrected activation energy, E_{cor}, on the thermodynamic parameters, V_0 and T_0, has been obtained as

$$[5] \quad E_{cor} = [E_{cor}' \mp V_{0(0)}(Q_5/Q_4)] \pm V_0(Q_5/Q_4)$$

and

$$[6] \quad E_{cor} = [E_{cor}' - T_{0(0)}(Q_5/Q_2)] + T_0(Q_5/Q_2)$$

by combining the linear dependences of E_{cor} vs. N

TABLE 5. Best fit parameters for eq. [1] for the fluidity of molten $Ca(NO_3)_2 \cdot 3.96H_2O$–$Ni(NO_3)_2 \cdot 6.03H_2O$ system

1.6	8443.0	13.87	671.0	206.6	0.19	0.033
1.7	8444.0	13.87	671.2	206.6	0.19	0.028

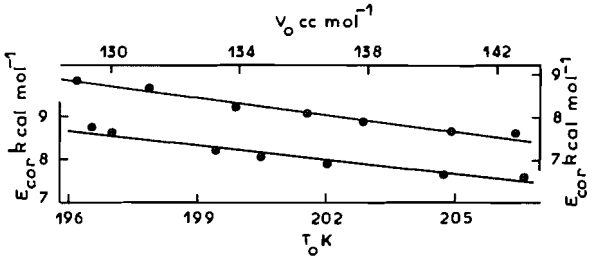

FIG. 7. Variation of E_{cor} with V_0 and T_0 for molten $Ca(NO_3)_2 \cdot 3.96H_2O$–$Ni(NO_3)_2 \cdot 6.03H_2O$ system. $E_{cor} = E_\phi + \frac{1}{2}RT$, in which E_ϕ is obtained by differentiating $\phi = A_\phi T^{-1/2} \times \exp[-k_\phi/(T - T_0)]$ of the VTF equation with respect to the reciprocal of absolute temperature. Adding $\frac{1}{2}RT$ to E_ϕ yields $E_{cor} = Rk_\phi[T/(T - T_0)]^2$.

with V_0 vs. N, and also with T_0 vs. N plots, respectively. E_{cor}' and Q_5 are the intercept and the slope, respectively, of E_{cor} vs. N plot. The expected linear behaviour has actually been found in the present system as shown in Fig. 7.[2] It is interesting to note that increase in the value of E_{cor} with T_0 is physically understandable in view of the successive increase in compactness of the system.

[2]It may be noted further that E_{cor} should also vary linearly with temperature, T, in view of the relation, $T = T_0c$. However, at constant $T/T_0 = c$, E_{cor} turns out to be a temperature independent quantity, viz., $Rk_\phi[c/(c - 1)]^2$. Consequently, this led to the transformation of the VTF equation at constant $T/T_0 = c$ to [1] for the concentration dependence of transport behaviour.

The solvent extraction of Fe(III) from acidic chloride solutions by open cell polyurethane foam sponge (OCPUFS)

J. J. OREN, K. M. GOUGH, AND H. D. GESSER

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received December 1, 1978

J. J. OREN, K. M. GOUGH, and H. D. GESSER. Can. J. Chem. **57**, 2032 (1979).

The extraction of Fe(III) by open cell polyurethane foam sponge was studied as a function of acid, chloride, and iron concentration in the aqueous phase. The results indicate a mixed extraction of $FeCl_3$ and $HFeCl_4$. The results also show a dependence of the metal distribution coefficient on [Fe(III)]aq and indicate a dissociation (in the foam) of the extracted $HFeCl_4$ species. The solid polyurethane is equated to a liquid extractant of a moderate dielectric constant.

J. J. OREN, K. M. GOUGH et H. D. GESSER. Can. J. Chem. **57**, 2032 (1979).

On a étudié l'extraction du Fe(III) par OCPUFS en fonction des concentrations d'acide, d'ion chlorure et de fer dans la phase aqueuse. Les résultats indiquent qu'il se produit une extraction mixte de $FeCl_3$ et $HFeCl_4$. Les résultats démontrent aussi qu'il existe une relation entre le coefficient de distribution du métal et [Fe(III)]aq et ceci indique qu'il se produit une dissociation (dans la mousse) d'espèces $HFeCl_4$ extraites. On considère que le polyuréthane solide ressemble à un extracteur liquide de constante diélectrique moyenne.

[Traduit par le journal]

Introduction

The use of polyurethane foams in the separation of metals from aqueous solutions was first demonstrated by Bowen (1) and the field has been reviewed by Braun and Farag (2, 3). Gesser and co-workers (4, 5) recently studied the extraction of gallium and iron from aqueous acidic chloride solutions into open cell polyurethane foam sponge (OCPUFS) and concluded that metal removal was accomplished by dissolution of the acid tetrahalide complex HMX_4 in the foam. Alternatively, the ether based polyurethane in contact with HX in solution can act as an anion exchanger in the extraction of the MX_4^- species.

The purpose of the present work was to investigate the equilibria involved in systems employing a polyurethane foam sponge as compared to systems using a liquid extractant in the removal of M^{3+} from acidic aqueous solutions. For this purpose iron(III) was chosen as the model metal due to the extensive study that has been made on its liquid extraction by various authors (6–15).

Experimental

Ether based polyurethane, oxypropylene/oxyethylene copolymer polyol, was supplied by Union Carbide. The foam was cut into cylindrical plugs of 2.15 ± 0.05 g, 4 cm diameter and 5.3 cm length. The plugs were cleaned with acetone for several hours in a Soxhlet extractor. An eccentric cam driven by a slow speed motor pushed a glass plunger up and down in a 2.2 cm stroke and at a frequency of 8 strokes per min, squeezing the plug in the test solution at the prescribed temperature. Each plug, before use, was treated three times in this manner for 30 min in 100 mL of 6 *M* HCl and finally washed free of acid with distilled water and air dried. A volume of 50–200 mL of an aqueous test solution was then equilibrated with the sponge in the same fashion for 30 min which was found to be sufficient to establish equilibrium between the two phases. A plug, when used, was cleaned before reuse by slowly flushing with 10 L of 10^{-2} *M* HCl while being squeezed repeatedly. Iron in the initial and in the equilibrium aqueous phase was analyzed by the thiocyanate method, using a Beckman DK-2A spectrophotometer with 1 or 10 cm cells (16). The Fe(III) concentration in the foam was then calculated from the difference between these two values. Proton concentration up to 10^{-1} *M* in the aqueous phase was determined by the procedure suggested by McBryde (17) and Sekine and Dyrssen (18) using a glass–calomel electrode pair and Fisher Accumet Model 520 Digital pH/Ion Meter. Equilibrium $[H^+]$ was equated to initial $[H^+]$ when the latter was > 0.1 *M* (18). The chemicals used were reagent grade.

Results and Discussion

All species in the foam are denoted by the subscript 'o' and those in the aqueous phase by the absence of a subscript. In equations, the charges on the ions are left out for simplicity.

The stability constants of iron(III) species with chloride in the aqueous phase can be represented as follows (12):

$$\mathrm{Fe} + n\mathrm{Cl} \rightleftarrows \mathrm{FeCl}_n^{3-n}$$

$$[1] \quad \beta_n = [\mathrm{FeCl}_n^{3-n}][\mathrm{Fe}]^{-1}[\mathrm{Cl}]^{-n}$$

Since the stability constants of the higher complexes, $FeCl_3$, $FeCl_4^-$, and $HFeCl_4$ are negligibly small (12, 19), the total iron(III) concentration in the aqueous phase can be expressed as follows:

$$[2] \quad [\mathrm{Fe(III)}]_{\mathrm{total}} = [\mathrm{Fe}](1 + \beta_1[\mathrm{Cl}] + \beta_2[\mathrm{Cl}]^2)$$

In the present work the extraction of HCl by the

0008-4042/79/152032-06$01.00/0

foam from an iron(III) free aqueous phase ($[Cl^-] = 4\ M$) was determined in the $10^{-1}\ M$ initial aqueous acidity range and was found to average at $5 \pm 1\%$. Parallel experiments on the extraction of LiCl ($[Li^+] = 4\ M$, $[Cl^-] = 0.1\ M$, $[SO_4] = 1.95\ M$) showed no measurable absorption of the salt by the foam from an iron(III) free aqueous phase. As will be seen, the data were found to be consistent with a mixed extraction of $FeCl_3$ and $HFeCl_4$ species and the ionization of the latter into H_o^+ and $FeCl_4^-{}_o$ in the foams. Under these circumstances the chemical equilibria involved can be presented as follows (12, 15, 20–22):

$$[3] \quad K_{ex_1} = [FeCl_3]_o[Fe]^{-1}[Cl]^{-3}$$

$$[4] \quad K_{ex_2} = [HFeCl_4]_o[Fe]^{-1}[H]^{-1}[Cl]^{-4}$$

$$[5] \quad K_d = [FeCl_4]_o[H]_o[HFeCl_4]_o^{-1} = K_{ex_2}{}^{-1}[FeCl_4]_o[H]_o[Fe]^{-1}[H^{-1}][Cl]^{-4}$$

$$[6] \quad K_{ex_3} = [HCl]_o[H]^{-1}[Cl]^{-1}$$

$$[7] \quad K_d' = [H]_o[Cl]_o[HCl]_o^{-1}$$

The electroneutrality in the organic phase can thus be written as follows:

$$[8] \quad [H]_o = [Cl]_o + [FeCl_4]_o$$

By substituting eqs. [5] through [7] into [8], we can write:

$$[9] \quad [H]_o = [[H][Cl](K_{ex_3}K_d' + K_{ex_2}K_d[Fe][Cl]^3)]^{1/2}$$

The distribution ratio of iron(III) is given by:

$$[10] \quad D = [Fe(III)]_{o,total}[Fe(III)]_{total}^{-1}$$

$$[11] \quad D = \{[FeCl_3]_o + [HFeCl_4]_o + [FeCl_4]_o\} \times \{[Fe](1 + \beta_2[Cl] + \beta_2[Cl]^2)\}^{-1}$$

By substituting eqs. [3] through [5] and [9] into eq. [11], we can write:

$$[12] \quad DY = [Cl]^3\left\{K_{ex_1} + K_{ex_2}[H][Cl] + \frac{K_dK_{ex_2}([H][Cl])^{1/2}}{(K_{ex_3}K_d' + K_{ex_2}K_d[Fe][Cl]^3)^{1/2}}\right\}$$

where $Y = (1 + \beta_1[Cl] + \beta_2[Cl]^2)$. Equation [12] can be simplified into three parts representing the major species in the foam if $K_{ex_3}K_d' \ll K_{ex_2}K_d[Fe][Cl]^3$.

$$[13] \quad DY = [Cl]^3\left\{K_{ex_1} + K_{ex_2}[H][Cl] + \frac{1}{[Cl]}\left(\frac{K_{ex_2}K_d[H]}{[Fe]}\right)^{1/2}\right\}$$

	I	II	III
Principal absorbed species	$FeCl_3$	$HFeCl_4$	$FeCl_4^-$

A summary of the expected properties of eqs. [12] and [13] is shown in Table 1.

Variation of Distribution Ratio with Metal Concentration in the Aqueous Phase

Figure 1, curves *a*, *b*, *c*, *d*, shows the plot of log *D* vs. log iron(III) concentration in the equilibrium aqueous phase at various initial and constant aqueous acid and chloride concentrations. At constant chloride and varying hydrogen ion concentrations, the break in the curve is not appreciably affected by the $[H^+]$ though the plateau value of *D* increases with increase in $[H^+]$. The break in the curve however is shifted to lower $[Fe^{3+}]$ when the $[Cl^-]$ is increased at constant $[H^+]$ (curve *d* vs. curve *b*). This is consistent with the requirements of eq. [13] and shows the overall dependence of *D* on the $[Fe][Cl^-]^3$ term in the denominator of eq. [12]. Though a discussion of the inflection point was given by Saldick (22) and was used (20, 21, 23) to reinterpret Irving and Rossotti's (24) results with $InBr_3$ only a few comparable studies (14, 15) have been reported for the iron(II) chloride – organic solvent system.

The value of *D* was virtually constant when [Fe(III)] was below $\sim 10^{-4}\ M$ but decreased steadily above this concentration with a resulting slope that varied from -0.53 (curve *a*) to about -0.9 (curve *d*) in Fig. 1. Saturation of the foam with iron would lead to a slope of -1.0. This fall-off feature (slope $-\frac{1}{2}$) of complex extraction behavior was reported for Mo(VI) (23); In(III) (24); and for Fe(III) (14, 15), in liquid–liquid extraction systems employing solvents of moderate dielectric constants and was demonstrated to be independent of the level and nature of the acid and supporting salting out electrolyte in the aqueous phase (23, 24).

A detailed study by Friedman (25) of the spectra of iron(III) in acidic chloride aqueous solutions, in diethyl ether extracts from these solutions and in

solid $KFeCl_4$ showed the existence of a $FeCl_4^-$ anion in each case. They also indicated that the proton is not chemically bound to the anion in the organic phase. Conductivity studies by Campbell *et al.* (26) of diisopropyl ether extracts of iron(III) from acidic chloride aqueous media showed that although such ether solutions conduct poorly, the conductivity is much greater than that of HCl solutions of comparable concentrations, indicating that the chloroferric acid is stronger than hydrochloric acid. Diamond and Tuck (20) and Marcus and Kertes (27) concluded that the acid strength of $HFeCl_4$ is comparable to the $HClO_4$.

The Mossbauer spectra (28) of iron in the organic phase of an extraction system of acid iron(III) halide has indicated that the neutral solvated species FeX_3 as well as the ion pair $H^+FeX_4^-$ were being extracted.

In the present work the epr spectra of the iron(III) loaded foam were studied, using a Varian Model E-3 EPR spectrometer, and were found to be identical to those obtained by Hertel and Clark (29), suggesting that $HFeCl_4$ (or the ion pair $H^+FeCl_4^-$) is dissolved in the solid foam.

The experimental slopes obtained from the data under discussion are consistent with the predicted values shown in Table 1; viz. 0 slope for ∂(log D)/∂(log [Fe]) at low concentrations of iron in solution and a slope of $-\frac{1}{2}$ at higher concentrations. At still higher concentrations of iron, the importance of the term III in eq. [12] diminishes and a slope of 0 is again expected. The foam, however, approached saturation with respect to iron before this trend could be realized. Diamond (23), however, has shown such a trend in his work on the liquid–liquid extraction of Mo(IV) from 8 *M* aqueous HCl into his (2 chloroethyl) ether. Similarly, Maddock *et al.* (15*a*), using tracer iron, have obtained the full curve under low extraction conditions, i.e. $D \simeq 10^{-2}$ to 10^{-3}.

Variation of Distribution Ratio with Hydrogen Ion Concentration in the Aqueous Phase

Figure 2, curves *a*, *b*, *c*, *d*, shows the plot of log D vs. log [H^+] concentration in the aqueous phase at constant, 4 *M*, initial chloride concentration and at a constant (1.79×10^{-3} *M* and 4.5×10^{-5} *M*) initial iron(III) concentration. The value of D was found to be practically independent of the hydrogen ion concentration when between 5×10^{-3} *M* to

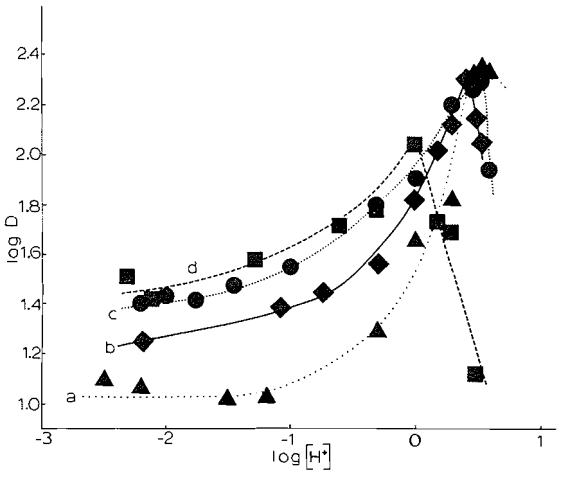

FIG. 2. log D vs. log [H] at constant [Fe] and $[Cl^-] = 4\ M$, in initial aqueous phase. (*a*) ▲, with NaCl, $1.79 \times 10^{-3}\ M$ Fe, 25 ± 1°C. (*b*) ◆, with NaCl, $4.95 \times 10^{-5}\ M$ Fe, 22 ± 3°C. (*c*) ●, with LiCl, $1.79 \times 10^{-3}\ M$ Fe, 22 ± 3°C. (*d*) ■, with LiCl, $1.79 \times 10^{-3}\ M$ Fe, 2.5 ± 1°C.

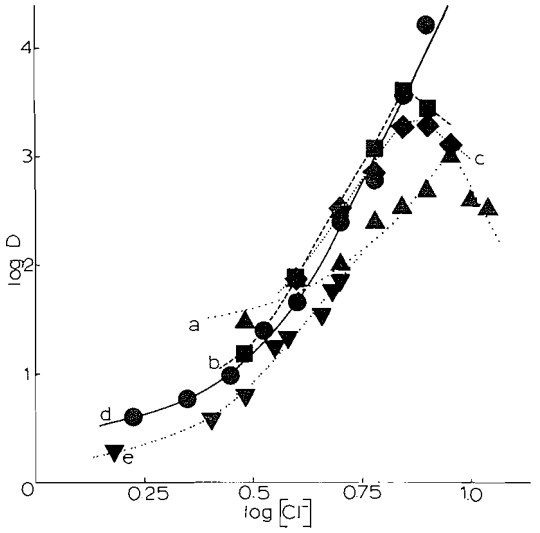

FIG. 3. log D vs. log [Cl] in initial aqueous phase at constant initial [Fe], 22 ± 3°C. Initial $[H^+]$ held constant with HCl except in (*a*). (*a*) ▲, with HCl only, $10^{-3}\ M$ Fe. (*b*) ■, with LiCl, $7.16 \times 10^{-3}\ M$ Fe, $2\ M$ H^+. (*c*) ◆, with LiCl, $7.16 \times 10^{-3}\ M$ Fe, $4\ M$ H^+. (*d*) ●, with LiCl, $10^{-3}\ M$ Fe, $10^{-2}\ M$ H^+. (*e*) ▼, with NaCl, $10^{-3}\ M$ Fe, $10^{-2}\ M$ H^+.

$\sim 10^{-1}\ M$. The distribution ratio, however, increased steadily above this concentration with a resulting slope that varied from 0.72 (curve *c*) to 1.37 (curve *a*) and averaged at 1.1 for the systems investigated at 25 ± 1°C and 22 ± 3°C, curves *a*, *b*, *c*.

Sekine *et al.* (12*a*) studied the distribution of iron(III) between hexane containing trioctylphosphine oxide and acidic chloride aqueous solutions in which $[H^+]$ was varied and $[Cl^-]$ maintained constant, 4 *M*, with NaCl and obtained the slopes of 0 and 1 by a curve fitting method of the experimental data. Similar to the present work an initial constant, $10^{-3}\ M$, [Fe(III)] was employed in these experiments.

The present work confirms most of the predicted slopes shown in Table 1, and leads to the same conclusion arrived at by these authors (12*a*), namely, that the extracted species are mainly $FeCl_3$ and $HFeCl_4$ in the low and high hydrogen ion concentration regions, respectively. Equation [13] predicts that at low concentration of Fe^{3+} and Cl^- in solution, the slope $\partial(\log D)/\partial(\log [H^+])$ should be 1/2. Reducing the concentration of Fe^{3+} from $1.8 \times 10^{-3}\ M$ to $5 \times 10^{-5}\ M$ did not change the slope for $[Cl^-] = 4\ M$. It was not possible to reduce these quantities (Fe^{3+} and Cl^-) further and still see any absorption of iron by the foam.

Variation of Distribution Ratio with Chloride Concentration in the Aqueous Phase

Figure 3, curves *b*, *c*, *d*, *e*, shows the plot of log D vs. log $[Cl^-]$, initial chloride concentration in the aqueous phase, at constant initial $[Fe^{3+}]$ and at constant and various initial $[H^+]$, but not at constant ionic strength. Curve *a* (slope varies from 2.4 to 6.5) is the plot of log D vs. log initial aqueous HCl concentration in the absence of a supporting salt electrolyte. The values of the slopes (curve *b*, 6.6; curve *c*, 5.3; curve *d*, 1.7 to 6.3; curve *e*, 1.5 to 4.4) as computed from the experimental data (Table 1) were found to be higher than those predicted by eq. [12] at the relatively high chloride concentration range. Positive deviations in the values of the slopes were also reported in the foam extraction of Ga(III) from acidic chloride aqueous solutions under similar experimental conditions and were accounted for by the change in ionic strength of the solution and the water activity and the use of concentrations instead of activities in the plots (5).

A fall in the D value was observed at a further increase in $[H^+]$ in each of the four curves in Fig. 2. A similar drop in D value was also noted when the initial [HCl] was changed in the aqueous phase in the absence of Li^+ and Na^+ salts or when the initial [HCl] was kept constant, at 2 *M* and 4 *M*, and the chloride (Li^+) concentration was varied (Fig. 3, curves *a*, *b*, *c*). However, a falloff in log D was absent when the initial $[H^+]$ was kept constant but very low, $10^{-2}\ M$, while the chloride (Li^+,Na^+) concentration was increased (Fig. 3, curves *d* and *e*).

Most recently, Shamus-ud-Zaha and Ejaz (30) recognized a similar decrease in log D when HCl concentration was increased in the absence or pres-

ence of a supporting salting out electrolyte in the extraction of Zn from acidic aqueous solution by 4-(5-nonyl) pyridine in benzene. A similar decrease in D value was also noted in the extraction of $UO_2(NO_3)_2$ into tributyl phosphate from mixed $LiNO_3$–HNO_3 solutions upon increased aqueous acidity (31). The insolubility of the organic phase in acidic chloride aqueous solutions in the above works and in the present work eliminates the possibility that the fall in the distribution ratio is due to a decrease in the aqueous HCl concentration after a volume change caused by the passage of the organic phase into the aqueous, a case that was reported by several authors (6, 10, 32). Also, since the order of hydration for the hydronium and alkali cations is $H_3O^+ \approx Li^+ > Na^+ > K^+ > Cs^+$ (33), an increase rather than a decrease in D value should result as the amount of acid replacing the salt is increased (34). In addition, since no higher chlorocomplex of iron than $FeCl_4^-$ is known (19), a decrease in the distribution ratio with increased acidity cannot be attributed to the formation of more highly charged, nonextracting, iron species. The data of the present work lend support to the suggestion put forward by Diamond (23) that an inflection in log D under these conditions could be accounted for by the extraction of HCl and its coordination with the organic phase so readily as to significantly reduce the 'free' extractant available for the metal complex.

The effect of temperature on the extraction is evident by a comparison of curve *c* (22°C) and curve *d* (2.5°C) in Fig. 2. At the lower temperature, the drop-off in the value of D occurs at a lower initial acid concentration. This premature drop in log D is believed to be due to the lowering of the water activity as the temperature decreases in the presence of a Li^+ cation (35) resulting in an increased activity of HCl in the aqueous phase.

The effect of temperature on the extraction of $FeCl_3$ into trioctylphosphine oxide in CCl_4 has been studied by Maddock and Mederiros (*15b*) who interpret their results in terms of the extraction of $FeCl_3$ as well as the anion complex $FeCl_4^-$.

It is obvious that further work on the extraction of Fe(III) from acidic chloride solution by organic solvents (ethers) and by foam under comparable conditions is required. Organic solvents allow for the analysis of H^+, Fe^{3+} and Cl^- in the organic phase, thereby making possible the determination of the composition of the extracted species. It was not possible to conduct such analysis in the polyurethane foam.

The mass spectra of trifluoroacetyl-2,5-diketopiperazines. I. *cyclo*-(-Gly-X), *cyclo*-(-Ala-X) (X = Gly, Val, Leu, Ile), and *cyclo*-(-Ala-Ala)[1]

GEORGE P. SLATER[2] AND LAWRENCE R. HOGGE

Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Sask., Canada S7N 0W9

Received November 13, 1978

GEORGE P. SLATER and LAWRENCE R. HOGGE. Can. J. Chem. 57, 2037 (1979).

The trifluoroacetyl derivatives of the 2,5-diketopiperazines *cyclo*-(-Gly-X), *cyclo*-(-Ala-X) (X = Gly, Val, Leu, Ile), and *cyclo*-(-Ala-Ala) were examined by GC–MS. The molecular ion was readily detectable only for TFA-*cyclo*-(-Gly-Gly) (*m/e* 306, 9%). For those compounds containing a valyl or leucyl/isoleucyl residue the ion of highest mass in the spectrum was formed by elimination of C_3H_6 or C_4H_8, respectively, from the molecular ion. In the TFA-*cyclo*-(-Gly-X) series this ion corresponded to the molecular ion of TFA-*cyclo*-(Gly-Gly) (*m/e* 306), and in the TFA-*cyclo*-(-Ala-X) series, to the molecular ion of TFA-*cyclo*-(-Ala-Gly) (*m/e* 320). The fragmentation patterns proposed for these compounds are based on the further degradation of these parent ions so that each compound within a series has a similar mass spectrum. However, sufficient differences were detectable in the various spectra to permit identification of the individual DKP's.

Many of the fragmentation pathways devised to explain the mass spectra were supported by high resolution data and appropriate metastable ions.

GEORGE P. SLATER et LAWRENCE R. HOGGE. Can. J. Chem. 57, 2037 (1979).

On a étudié les dérivés trifluoroacétylés des dicéto-2,5 pipérazines *cyclo*-(-Gly-X), *cyclo*-(-Ala-X) (X = Gly, Val, Leu, Ile) et *cyclo*-(-Ala-Ala) par GC-MS. Seul l'ion moléculaire du TFA-*cyclo*-(-Gly-Gly) a pu être détecté facilement (*m/e* = 306, 9%). Dans le cas des composés contenant un reste valyle ou leucyle/isoleucyle, l'ion dont la masse est la plus élevée se forme par élimination respectivement de C_3H_6 et C_4H_8 à partir de l'ion moléculaire. Dans la série TFA-*cyclo*-(-Gly-X), cet ion correspond à l'ion moléculaire de TFA-*cyclo*-(-Gly-Gly) (*m/e* = 306) et dans la série TFA-*cyclo*-(-Ala-X), à celui de l'ion moléculaire du TFA-*cyclo*-(-Ala-Gly) (*m/e* = 320). Les modèles de fragmentation proposés pour ces composés sont basés sur une dégradation ultérieure des ions parents conduisant à des spectres de masse semblables pour chaque composé. Toutefois on peut détecter suffisamment de différences dans chaque spectre pour distinguer les DCP individuelles.

Plusieurs des voies de fragmentation proposées pour expliquer les spectres de masse sont corroborées par des données à haute résolution et des ions métastables appropriées.

Introduction

2,5-Diketopiperazines (DKP's) are produced by fungi (1) and have also been identified as the bitter principles in some food products (2). These compounds also arise from thermal degradation of peptides and application of this transformation has been suggested as an aid to peptide sequencing (3–6).

DKP's can be analyzed directly by gas chromatography (7) or as the trimethylsilyl (TMS) (7) and trifluoroacetyl (TFA) derivatives (8). The TMS-derivatives of some DKP's have been examined by gas chromatography – mass spectroscopy (GC–MS) in relation to peptide sequencing (6) but little information was given about the fragmentation process.

In our experience, the TFA-DKP's are easier to prepare and less susceptible to hydrolysis than the TMS-derivatives. Consequently, a number of TFA-DKP's were examined by GC–MS and the fragmentation pathways are described in this paper.

Results and Discussion

The electron impact – mass spectra of the TFA-DKP's were obtained using a gas chromatograph coupled to a quadrupole mass spectrometer. The fragmentation pathways devised to explain the spectra indicated a number of isobaric ions of relatively high abundance. Where necessary, the TFA-DKP's were subjected to high resolution mass spectroscopy (HRMS) to determine the identity of the various isobars. In addition, several of the compounds were examined by a magnetic sector mass spectrometer to check for metastable ions.

The data from the quadrupole mass spectrometer were automatically normalized relative to the base peak by computer and ions of low relative abun-

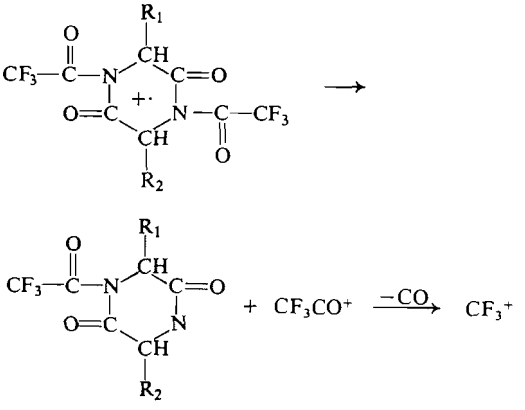
dance (<1%) were not readily apparent.[3] When examined by the magnetic sector instrument all of the TFA-DKP's gave molecular ions, those from compounds with a C_3- or C_4-side chain being the weakest, while those with only glycyl and/or alanyl residues being relatively more abundant.

The TFA-DKP's used to collect the present data were synthesized from glycine and/or amino acids of the L-series. A number of DKP's incorporating D-amino acids were also examined but could not be distinguished from their enantiomers by mass spectroscopy.

As might be expected, the ions CF_3CO^+ and CF_3^+ are present in the spectra of all the TFA-DKP's examined (Figs. 1–3), and in some cases the CF_3^+ ion (*m/e* 69) represents the base peak (Figs. 2*a*, 3). Formation of these ions directly from the TFA-DKP's can be represented as in [1] and formation from various ionic fragments in Schemes 1–5 is also possible. Data from HRMS (Tables 7 and 9), indicate that isobaric ions in Schemes 1–4 contribute little to the ion at *m/e* 69.

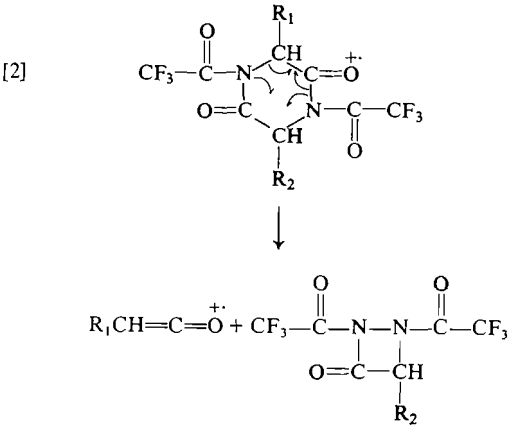
[1]



In the mass spectra of all the TFA-DKP's ions are observed corresponding to the ketene $RCH{=}C{=}\overset{+\cdot}{O}$ (R = H, CH_3). The identities of these ions have been confirmed by HRMS and one of several possible methods of formation is shown below in reaction [2].

The mass spectra of the TFA-DKP's synthesized from glycine and another amino acid (i.e. TFA-*cyclo*-(-Gly-X), (X = Val, Leu, Ile)[4]) are quite similar to each other (cf. Fig. 1 *b* and *c*) and to the spectrum of TFA *cyclo*-(-Gly-Gly) (Fig. 1*a*). In each case the ion of highest mass is observed at *m/e* 306

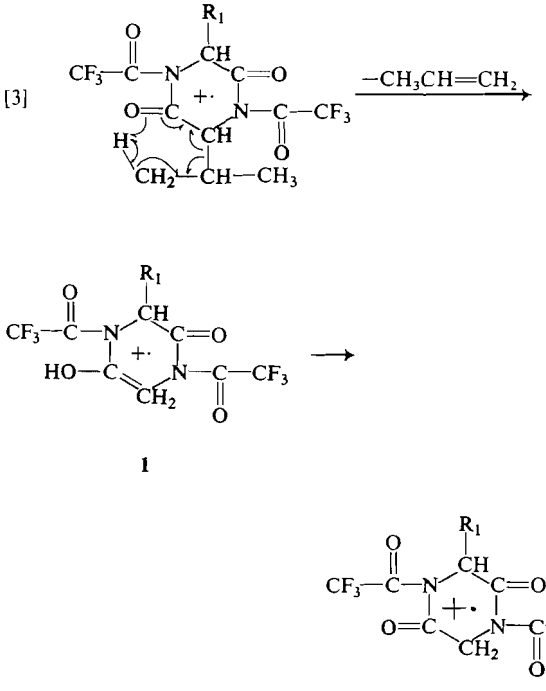
[2]



which is equivalent to the molecular ion of TFA-*cyclo*-(-Gly-Gly). This can be explained by elimination of the alkyl side chain in X as olefin [3] to give the enol (**1**, R_1 = H) of the molecular ion of TFA-*cyclo*-(Gly-Gly) which can then revert to the ketonic form and fragment as outlined in Schemes 1–5. Elimination of olefin in this manner has been observed (6, 10) in the fragmentation of underivatized DKP's incorporating valyl and/or leucyl residues. The reactions shown in [3] are supported by metastable ions in the mass spectra of TFA-*cyclo*-(-Gly-Val) (*m/e* 348 → *m/e* 306, *m** = 269.1) and TFA-*cyclo*-(-Ala-Val) (*m/e* 362 → *m/e* 320, *m** = 282.9).

As a result of the fragmentation of the molecular ion of TFA-*cyclo*-(-Gly-X) to give the ion at *m/e* 306 [3] the latter would have a lower energy than the

[3]



1

[3]The computer printout expresses relative abundances to 0.01% so that lesser values appear as zero. In compiling Tables 1–4 relative abundances less than 0.5% were reported as zero.

[4]The abbreviations used are those recommended by the IUPAC-IUB Commission on Biochemical Nomenclature (9).

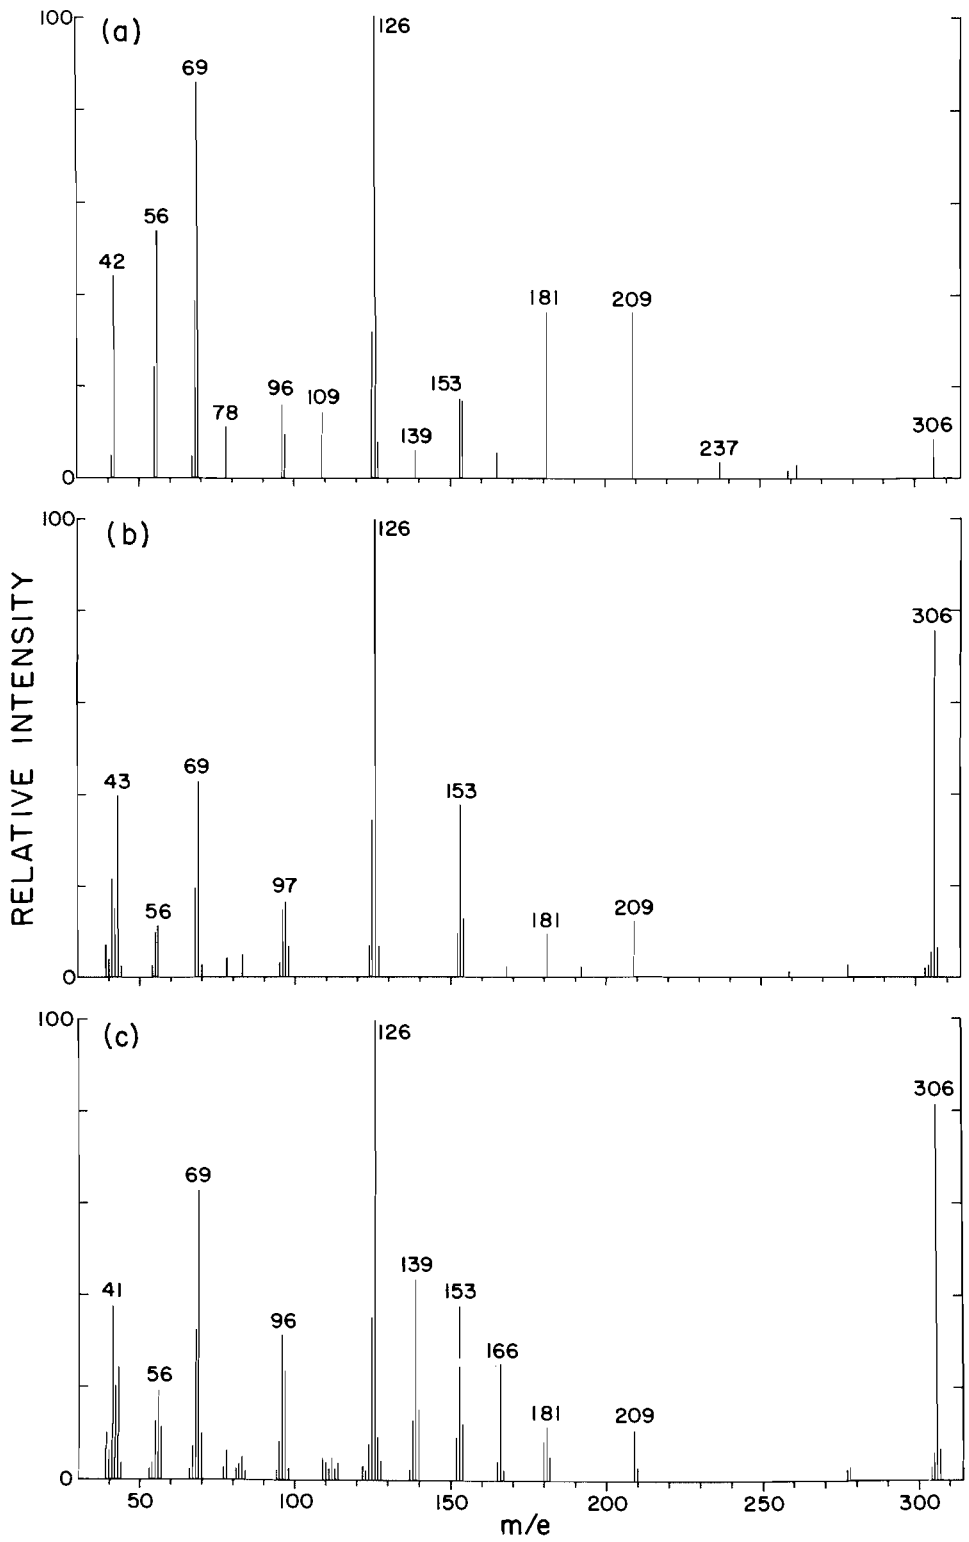


FIG. 1. Mass spectra of (*a*) TFA-*cyclo*-(-Gly-Gly), (*b*) TFA-*cyclo*-(-Gly-L-Val), (*c*) TFA-*cyclo*-(-Gly-L-Leu).

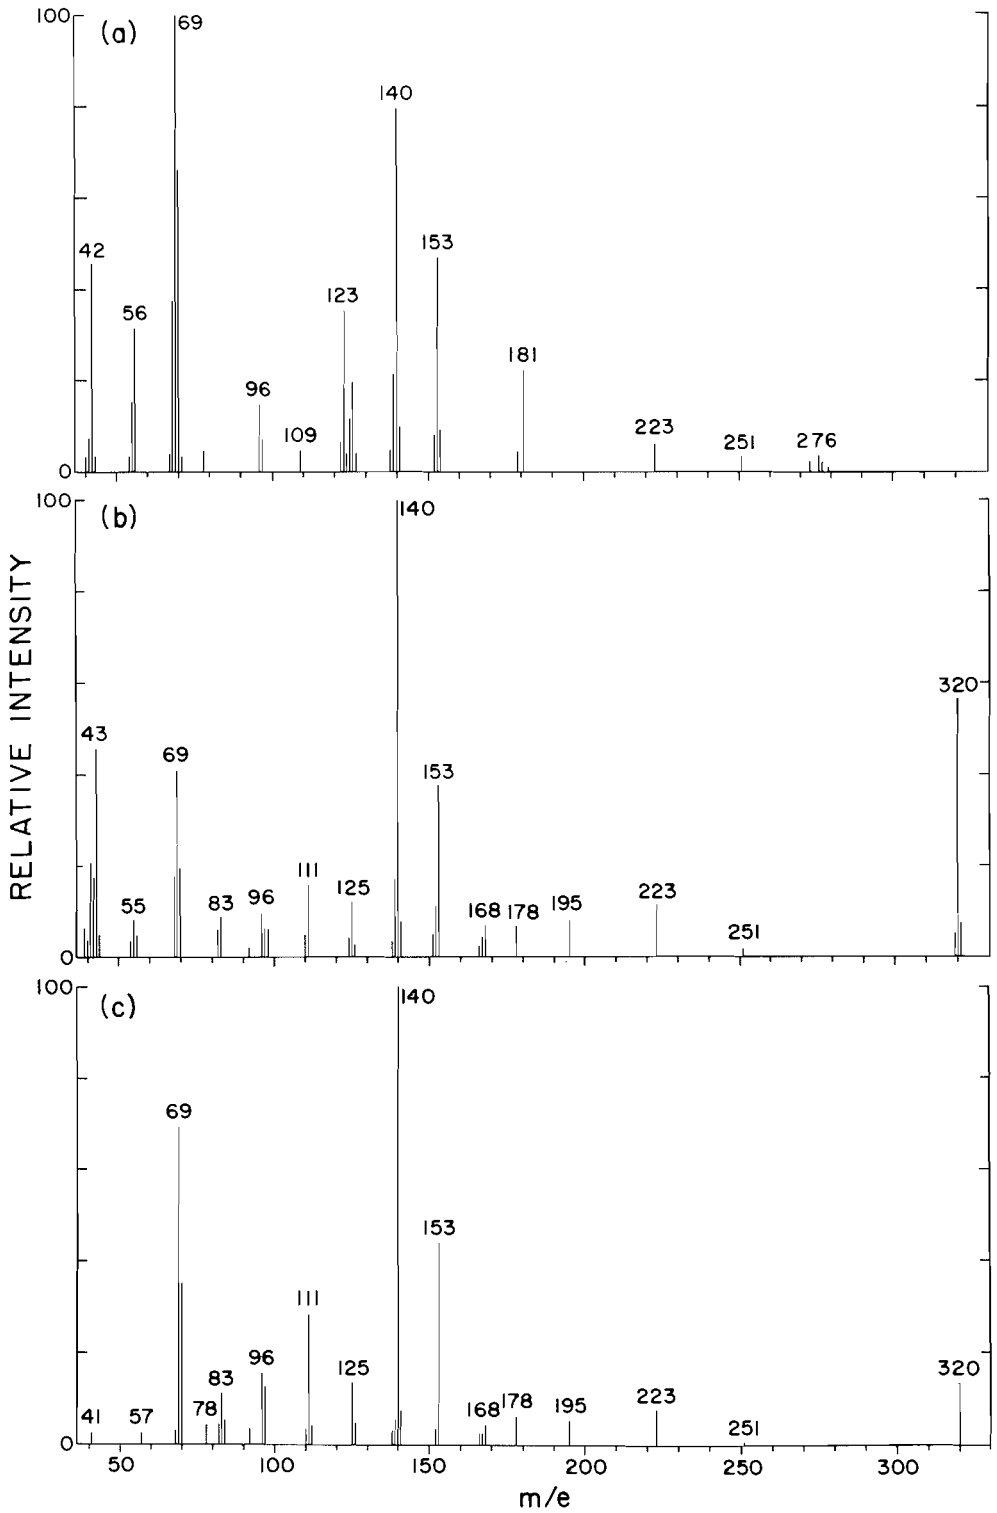

FIG. 2. Mass spectra of (*a*) TFA-*cyclo*-(-L-Ala-Gly), (*b*) TFA-*cyclo*-(-L-Ala-L-Val), (*c*) TFA-*cyclo*-(-L-Ala-L-Ile).

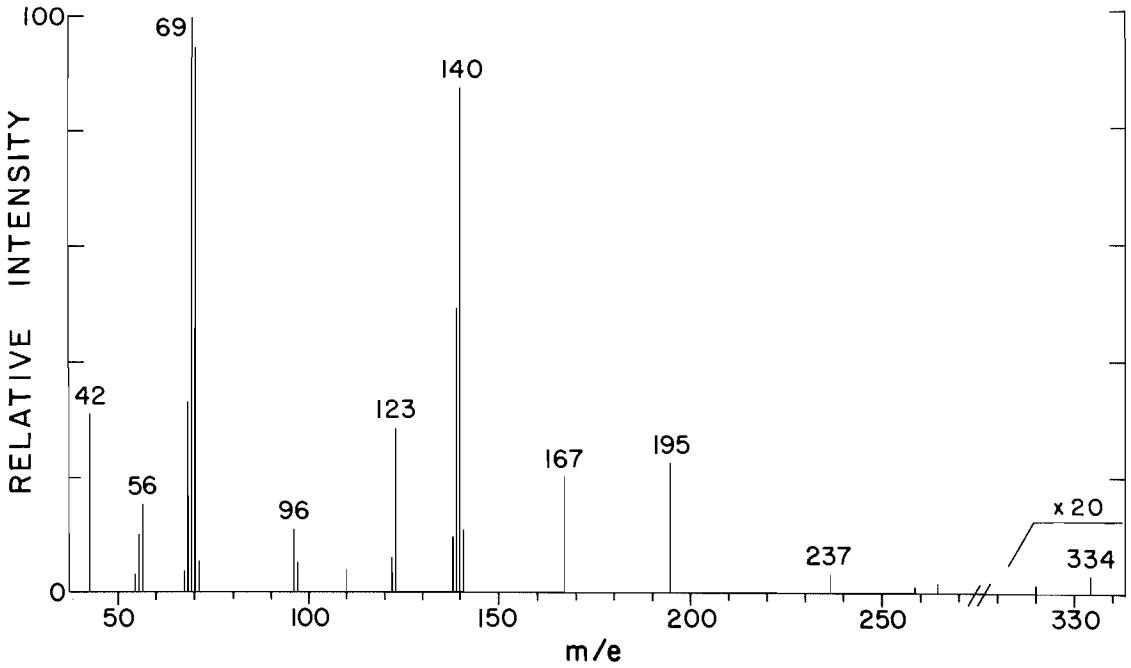

FIG. 3. Mass spectrum of TFA-*cyclo*-(-L-Ala-L-Ala).

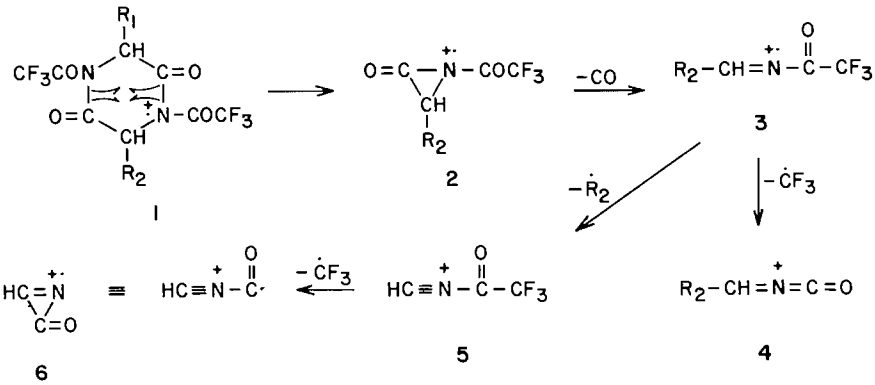
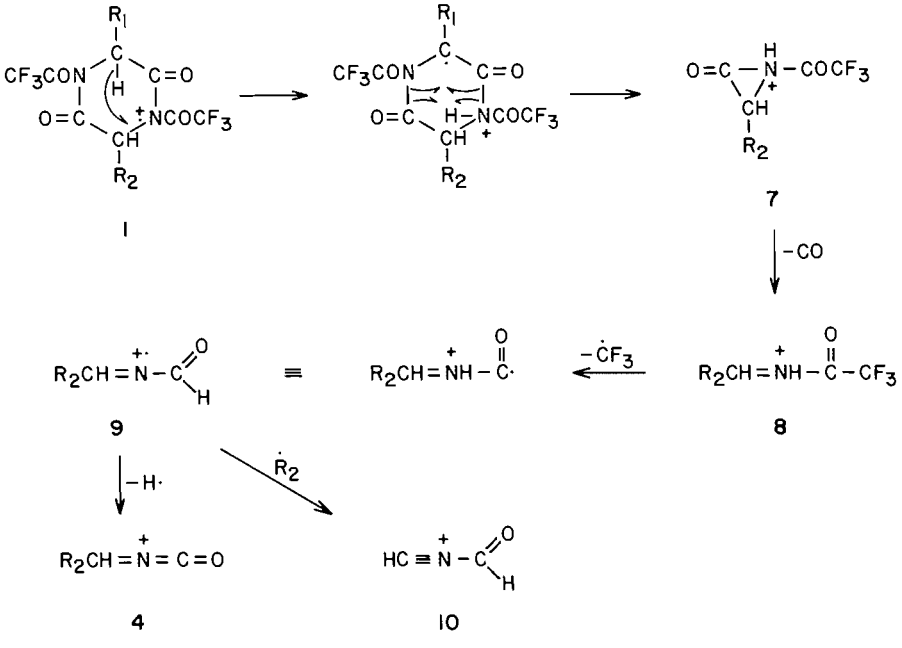
molecular ion (*m/e* 306) of TFA-*cyclo*-(-Gly-Gly). This would account for the greater relative abundance of the *m/e* 306 ion in spectra of the former compounds (Table 1). A contributing factor may be the initial formation of the *m/e* 306 ion as the enol **1** [3] for these compounds.

Mass spectral fragmentation pathways for underivatized (10, 11) and *N*-methyl-DKP's (11) have been reported but understandably these do not account for the ions observed in the spectra of the TFA-DKP's. Accordingly, a number of fragmentations are proposed (Schemes 1–5) which are based on the earlier observation (cf. [3]) that the initial step in the ionization of the TFA-DKP's bearing a C_3- or C_4-alkyl side chain is elimination of the latter as olefin. This suggestion is supported by the absence of ions incorporating a C_3H_7 or C_4H_9 group in the spectra of the TFA-DKP's containing a valyl or leucyl/isoleucyl residue. In many cases the proposed fragmentations are supported by appropriate metastable ions (Tables 6 and 8) and HRMS (Tables 7, 9, and 10).

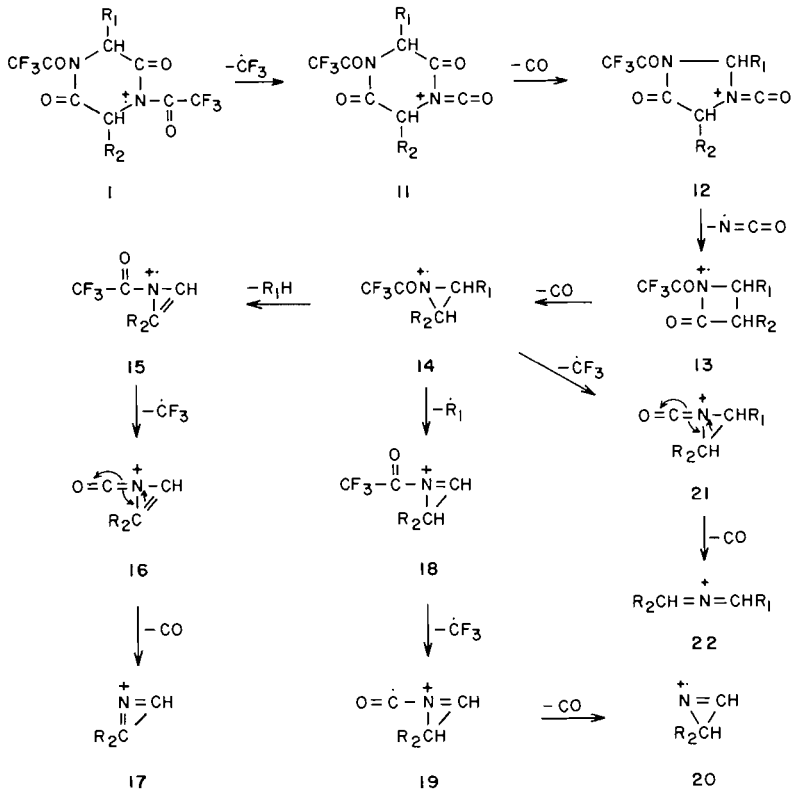
One of the abundant ions in the spectra of the TFA-*cyclo*-(-Gly-X) series (X = Gly, Val, Leu, Ile) occurs at *m/e* 153 (Fig. 1, Table 1) Since the ion of highest mass in these spectra occurs at *m/e* 306 it would appear that symmetrical cleavage of this ion gives the ion at *m/e* 153, and a fragmentation pathway based on this assumption is presented in Scheme 1. Reference to Table 1 indicates that the ions in the scheme contribute significantly to the spectra of the



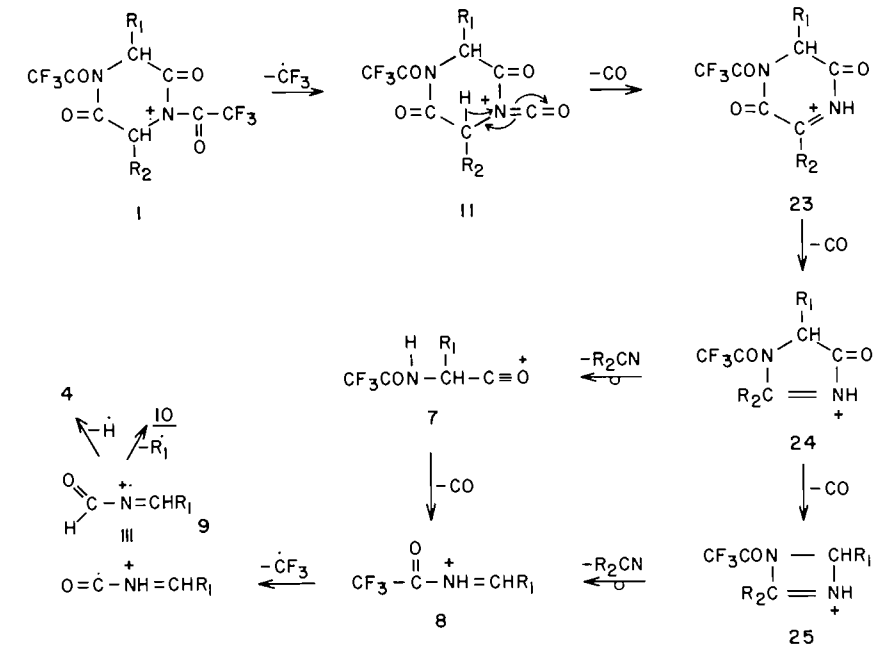
SCHEME 1



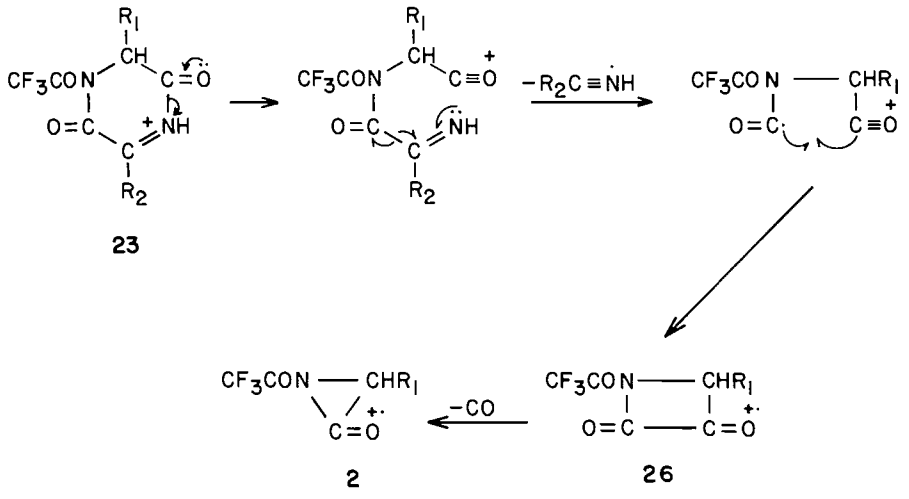
SCHEME 2



SCHEME 3



SCHEME 4



SCHEME 5

TFA-*cyclo*-(-Gly-X) compounds, and the sequence: ion **1** → ion **2** → ion **3** is supported by metastable ions (Table 6) and HRMS (Table 7). In this series, ion **4** (*m/e* 56, R_2 = H) is isomeric with ion **10** (Scheme 2) and these cannot be differentiated by HRMS.

An alternate mode of fragmentation shown in Scheme 2 involves rearrangement of a hydrogen atom prior to cleavage. The relative abundances of the ions (Table 2) indicate that this pathway also represents a major process in the fragmentation of the TFA-*cyclo*-(-Gly-X) series. Formation of the base peak as shown is supported by relevant metastable ions (Table 6). In this scheme the peak at *m/e* 57 is attributed to ion **9**, C_2H_3NO (R_2 = H) and is relatively abundant (11%, 23%) in the spectra of TFA-*cyclo*-(-Gly-Leu/Ile). The high resolution spectrum of TFA-*cyclo*-(-Gly-Ile) indicates that the C_4H_9 ion is the main component (90%) of the peak at *m/e* 57 (Table 7) so that in this case the relative abundance of ion **9** is actually 2% and is similar to that observed for TFA-*cyclo*-(-Gly-Gly/Val) (Table

2) which cannot give a C_4H_9 ion. This explanation would also account for the abundance of the ion at *m/e* 57 in the spectrum of TFA-*cyclo*-(-Gly-Leu).

The relatively prominent ion at *m/e* 209 in the spectrum of TFA-*cyclo*-(-Gly-Gly) (Fig. 1*a*) can be explained by consecutive loss of CF_3 and CO from ion **1** as shown in Scheme 3 (ion **1** → ion **11** → ion **12**). Alternatively, this loss could occur as in Scheme 4 (ion **1** → ion **11** → ion **23**), or $CF_3CO^{\cdot}$ could be eliminated from ion **1** to give ion **23** directly. Metastable ions corresponding to the latter fragmentation and to ion **11** → ion **12**/**23** were observed (Table 6). Further degradation of ion **12** (Scheme 3) gives a number of ions of relatively high abundance (Table 3), viz. ion **14** (*m/e* 139), ion **16** (*m/e* 68), ion **19** (*m/e* 69), ion **20** (*m/e* 41), and ion **22** (*m/e* 42). However, ion **19** is isobaric with CF_3^+ and ion **22** with $CH_2{=}C{=}\overset{+\cdot}{O}$ and high resolution data (Table 7) show that ions **19** and **22** are minor components but that ions **14** and **16** are single species. The ion at *m/e*

41 is of appreciable abundance in the spectra of the valyl-, leucyl-, and isoleucyl-DKP's (Table 3) and for these compounds the ion is mainly due to $C_3H_5^+$ (Table 7).

Scheme 4 shows an alternate fragmentation of ion **11** leading to ions **4**, **7–10** by way of the apparently abundant ions **24** (*m/e* 181) and **25** (*m/e* 153). The latter is isobaric with ion **2** (Scheme 1) and contributes little to the peak at *m/e* 153 (Table 7) whereas ion **24** is isobaric with ion **26** (Scheme 5) and these are present in the ratio 1:3 (Table 7).

Fragmentation of ion **23** as shown in Scheme 5 leads to ion **26** which is the major component of the peak at *m/e* 181 (Table 7) and a metastable ion corresponding to this transition was observed (Table 6). Elimination of CO from ion **26** would provide an alternate pathway to ion **2** (and the remaining ions of Scheme 1); however the corresponding metastable ion was not detected.

The structure of ion **26** is such that alternate fragmentation (loss of ketene and $\cdot CF_3$ or loss of $\cdot CF_3$ and 2CO are possible. In the TFA-*cyclo*-(-Ala-X) series these would lead to isobaric ions of relatively high abundance; however these were eliminated on the basis of HRMS.

Ion **1** (*m/e* 306, $R_1 = R_2 = H$), the starting point for the fragmentations of the TFA-*cyclo*-(-Gly-X) series outlined in Schemes 1–5, is symmetrical so that only one set of ions is possible. For the TFA-*cyclo*-(-Ala-X) compounds (X = Gly, Val, Leu, Ile), however, ion **1** (*m/e* 320, $R_1 = CH_3$; $R_2 = H$; or vice versa) is not symmetrical and two sets of homologous ions are possible depending on the location of the positive charge. Tables 1–5 have been compiled to reflect this possibility and show the occurrence of fragmentation to give ions derived from both the alanyl and glycyl portions of ion **1**. In several instances the ions retaining the methyl group are in greater abundance than their lower homologues which are derived from the glycyl portion of the DKP. Where this occurs (e.g. ions **3**, **4**, **8**; Tables 1

and 2) the methyl group is conjugated with the charge site and the ions may be stabilized relative to the lower homologues by hyperconjugation [4]. In

[4] 
3

other cases (e.g. ions **2**, **7**) the methyl group is not conjugated with the charge site and the relative abundances of the homologous ions are of the same order of magnitude (Tables 1 and 2), except for TFA-*cyclo*-(-Ala-Gly) which may behave differently since its molecular ion has not undergone olefin elimination as have the other DKP's in this group.

The fragmentations suggested in Schemes 1–5 account for the majority of ions in the spectra of the TFA-*cyclo*-(-Ala-X) compounds (Fig. 2). Several of these pathways are supported by the occurrence of relevant metastable ions (Table 8) and the identities of prominent fragments have been confirmed by HRMS (Table 9).

A number of isobaric ions are also indicated for the TFA-*cyclo*-(-Ala-X) series (cf. Tables 1–5) and the more prominent of these were examined by HRMS (Table 9). One of the more interesting groups of isobaric ions occurs at *m/e* 55. This ion was expected to be a mixture of ion **6** (C_2HNO) and ion **20** (C_3H_5N). However, one of the abundant ions was found to correspond to C_3H_3O which could arise by loss of a hydrogen radical from the ketene $CH_3—CH=C=\overset{+\cdot}{O}$. A comparable ion ($C_2HO$, *m/e* 41) was not observed in the TFA-*cyclo*-(-Gly-X) series (Table 7) but was detected at *m/e* 83 ($C_3H_7—CH=C=\overset{+\cdot}{O}$ – [H·]) and *m/e* 97 ($C_4H_9—CH=C=\overset{+\cdot}{O}$ – [H·]) in the spectra of TFA-DKP's synthesized from valine, leucine, and isoleucine (Part II, following paper).

The mass spectra of TFA-*cyclo*-(-Gly-X) (Fig. 1) contain an ion at *m/e* 42 due to ketene [2] and ion **22** (Table 7). By analogy the spectra of TFA-*cyclo*-(-Ala-X) would be expected to show the homologues of these ions and this was confirmed by HRMS (Table 9). However, these spectra also contain an ion at *m/e* 42 which comprises two ions of formula C_2H_2O and C_2H_4N (Table 9) previously found in the spectra of TFA-*cyclo*-(-Gly-X) (Table 7). The C_2H_2O ion results from formation of ketene from the X-position of the DKP [2]. The ion C_2H_4N cannot be accounted for as in the TFA-*cyclo*-(-Gly-X) series, i.e. ion **22**, $R_1CH=\overset{+}{N}=CHR_2$ ($R_1 = R_2 = H$), since in the TFA-*cyclo*-(-Ala-X) DKP's either R_1 or R_2 is a methyl group. Formation of an ion of formula C_2H_4N may result from a process such as the following [5].

[5] 
4

The metastable ion corresponding to this fragmentation (*m/e* 70 → *m/e* 42) would be expected at *m/e* 25.2. A metastable ion at this position observed in the spectra of TFA-*cyclo*-(-Ala-X) could also be due to ion **3** (*m/e* 125) → ion **4** (*m/e* 56). However, the same metastable ion occurs in the spectrum of TFA-*cyclo*-(-Ala-Ala) for which the transition ion **3** (*m/e* 125) → ion **4** (*m/e* 56) does not occur (Table 1).

An ion at *m/e* 42 is also quite prominent in the spectrum of TFA-*cyclo*-(-Ala-Ala) (Fig. 3) and was found to contain the same ions as observed in the spectrum of the TFA-*cyclo*-(-Ala-Gly) although the ratio of the C_2H_4N ion to the C_2H_2O ion was much greater (Table 10). The first ion can be accounted for as before [5] but there is no immediate explanation for the second ion.

The mass spectrum of TFA-*cyclo*-(-Ala-Ala) (Fig. 3) is similar to the spectrum of TFA-*cyclo*-(-Ala-Gly)

TABLE 8. Metastable ions in mass spectra of TFA-*cyclo*-(-Ala-X) (X = Gly, Val, Leu, Ile)

Fragmentation	Metastable ion	
	m/e calculated	*m/e* observed
Ion **2** (*m/e* 153) → ion **3** (*m/e* 125)	102.1	102.3
Ion **3** (*m/e* 125) → ion **4** (*m/e* 56)	25.1	25.2
Ion **1** (*m/e* 320) → ion **7** (*m/e* 168)	88.2	88.2
Ion **7** (*m/e* 168) → ion **8** (*m/e* 140)	116.7	116.5
Ion **10** (*m/e* 181) → ion **2** (*m/e* 153)	129.3	129.5
Ion **12** (*m/e* 84) → ion **4** (*m/e* 56)	37.3	37.2
Ion **15** (*m/e* 251) → ion **16** (*m/e* 223)	198.1	198.4
Ion **4** (*m/e* 70) → C_2H_4N (*m/e* 42) [5]	25.2	25.2

(Fig. 2*a*) except that ions due to the glycine portion of the latter are absent (e.g. *m/e* 125, 126, 153, 154). Metastable ions corresponding to ion **2** → ion **3** → ion **4** were observed and the identities of several ions were established by HRMS (Table 10).

In Scheme 3 ion **14** → ion **15** is shown as occurring by elimination of R_1H. For TFA-*cyclo*-(-Ala-Ala) $R_1 = R_2 = CH_3$ so that elimination of C_2H_6 is possible and the sequence: ion **14** → ion **15** → ion **16** → ion **17** gives ions at *m/e* 137, 68, 40. The ion at *m/e* 68 is relatively abundant (30%) and was found by HRMS (Table 10) to be identical to the *m/e* 68 ion observed in the spectra of the other TFA-DKP's.

The fragmentations outlined in Schemes 1–5 and eqs. [1–3] account for the majority of significant ions in the spectra of the TFA-DKP's. However, one ion (10–30% relative abundance) which is present in the spectrum of each compound and is not indicated by the above schemes occurs at *m/e* 96 (Figs. 1–3). The formula C_2HF_3N ($HC{\equiv}N{-}CF_3$) for this ion was established by HRMS. Formation of the ion could result by rearrangement of ion **3** (Scheme 1) and successive elimination of R_2 and CO [6], or by re-

[6] $R_2CH{=}\overset{+\cdot}{N}{-}\overset{O}{\overset{\|}{C}}{-}CF_3 \longrightarrow R_2CH{=}\overset{+}{N}{-}\overset{CF_3}{\overset{|}{C}}{=}O \xrightarrow{-R_2}$

m/e 125, R_2 = H
m/e 139, R_2 = CH_3

$$HC{=}\overset{+}{N}{<}\begin{matrix}CF_3\\|\\C{=}O\end{matrix} \xrightarrow{-CO} HC{\equiv}\overset{+}{N}{-}CF_3$$

m/e 96

arrangement of the CF_3 group in ion **5** (Scheme 1) followed by elimination of CO. The elimination of CO first rather than R_2 from ion **3** would give an ion at *m/e* 97 (R_2 = H) for the TFA-*cyclo*-(-Gly-X) series and at *m/e* 111 (R_2 = CH_3) for the TFA-*cyclo*-(-Ala-X) compounds. The ion at *m/e* 97 would be isobaric with CF_3CO^+ which was the only ion

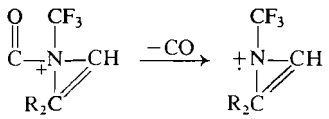
indicated by HRMS (Table 7). The ion at *m/e* 111 was also eliminated on the basis of high resolution data.

In addition to the ions described so far, several spectra contain ions which are unique to a TFA-DKP containing a particular amino acid residue. These ions and possible fragmentations leading to their formation are listed below. In each case the identity of the ion was confirmed by HRMS.

m/e *43*. This ion is present in the spectra of TFA-*cyclo*-(-Gly-Val/Leu) (40%, 20% relative abundance) and TFA-*cyclo*-(-Ala-Val/Leu) (40%, 17%), but is barely detectable in the normalized spectra of the other TFA-DKP's examined. The ion could be due to $C_3H_7^+$ from the valyl or leucyl portion of the DKP together with a contribution from ^{13}C-ketene. High resolution data (Table 7) show that the ion is in fact due to $C_3H_7^+$ and $C_2H_3O^+$ in the ratio 3:1. The latter ion may be due to protonated ketene $CH_2{=}C{=}\overset{+}{O}H$, which would require rearrangement of a hydrogen atom prior to cleavage as in [2]. The greater abundance of the *m/e* 43 ion in the spectra of the valyl compounds helps to distinguish them from the leucyl-DKP's.

m/e *109(123)*. In the spectrum of TFA-*cyclo*-(-Gly-Gly) the ion at *m/e* 109 is present in 16% relative abundance (Fig. 1*a*). The formula $C_3H_2F_3N$ was indicated by HRMS and an ion of this composition could be formed from ion 14, Scheme 3, as shown below in [7].

[7] 
14 (*m/e* 139, $R_1 = R_2 = H$)
(*m/e* 153, $R_1 = H$; $R_2 = CH_3$; or vice versa)
(*m/e* 167, $R_1 = R_2 = CH_3$)



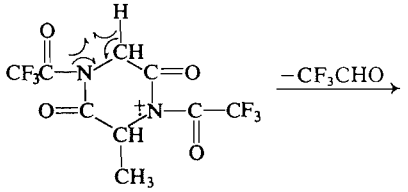
m/e 109 ($R_2 = H$)
m/e 123 ($R_2 = CH_3$)

This mechanism also accounts for the ion at *m/e* 123 in the spectra of TFA-*cyclo*-(-Ala-Gly/Ala) (Figs. 2*a*

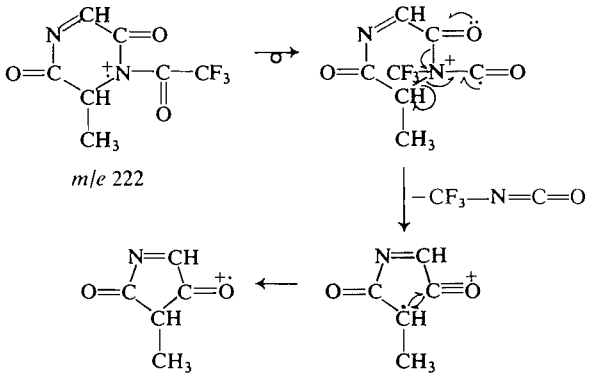
and 3) but does not explain why these ions are not as prominent in other relevant spectra.

m/e *111*. The spectra of TFA-*cyclo*-(-Ala-Val/Leu/Ile) contain the ion at *m/e* 111 (16%, 12%, 29%) which is absent in the spectra of the remaining TFA-DKP's. This suggests that the ion is due in part to retention of the alanyl portion of the DKP. High resolution data indicated the formula $C_5H_5NO_2$ and an ion of this composition could arise as follows in [8].

[8]



1, *m/e* 320

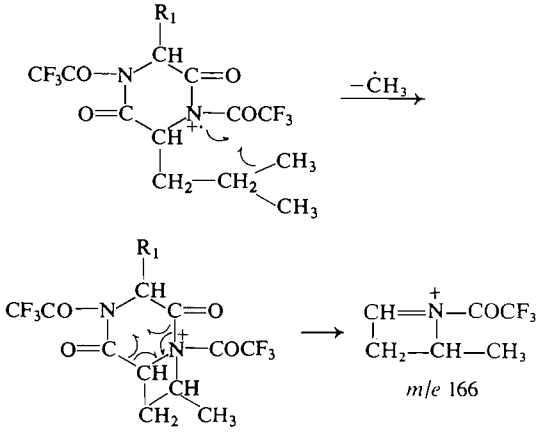


The occurrence of the ion at *m/e* 111 only in the spectra of the alanyl-DKP's containing ion **1** (*m/e* 320) in relatively high abundance lends some support to the proposed fragmentation. In the TFA-*cyclo*-(-Gly-X) series, a similar fragmentation would require formation of a primary radical centre and lead to an ion at *m/e* 97 isobaric with CF_3CO^+, but only the latter was observed (Table 7).

m/e *166*. This ion is abundant (25%, 23%) only in the spectra of TFA-*cyclo*-(-Gly-Leu) and TFA-*cyclo*-(-Ala-Leu) and suggests that the leucyl residue is involved. The formula of this ion $C_6H_7F_3NO$, established by HRMS, has insufficient hydrogen to accommodate the C_4H_9 leucyl side chain. However, if the CF_3CON group is present, the residue C_4H_7 can be accounted for as in eq. [9]. For the isoleucyl-DKP's this fragmentation would require elimination of a primary methyl group which may be energetically less favourable.

One of the objectives of the present study was to determine if the various DKP's could be identified

[9]



unequivocally by the mass spectra of their TFA-derivatives. On the basis of the fragmentations in Schemes 1–5 and eq. [3] it is possible to assign a DKP to the TFA-*cyclo*-(-Gly-X) or TFA-*cyclo*-(-Ala-X) series (X = Gly, Val, Leu, Ile). TFA-*cyclo*-(-Ala-Ala) can be distinguished from members of the latter series by the absence of ions in its mass spectrum (e.g. *m/e* 125, 126, 153) derived from the glycyl residue (formed by elimination of olefin [3]). Further distinction between compounds within a group is possible using the ions listed above, e.g. the ion at *m/e* 43 is observed only in the spectra of the valyl- and leucyl-DKP's while the ion at *m/e* 166 is found only in spectra of the latter. There are no such special ions in the spectra of TFA-*cyclo*-(-Gly-Gly/Ile) to permit distinguishing between these two compounds. However, the spectrum of TFA-*cyclo*-(-Gly-Ile) contains relatively abundant ions at *m/e* 57 (53%) due to $C_4H_9^+$ (Table 7) and *m/e* 41 (43%) due to $C_3H_5^+$ (Table 7). Although ions at *m/e* 57, 41 are predicted for TFA-*cyclo*-(-Gly-Gly) in Scheme 2 (ion 9) and Scheme 3 (ion 20), respectively, these are barely detectable (Fig. 1*a*). Distinguishing between TFA-*cyclo*-(-Ala-Gly) and TFA-*cyclo*-(-Ala-Ile) is also unpredictable as the spectrum of the latter does not show prominent ions at *m/e* 57, 41 (Fig. 2*c*). Identifying the members of the two pairs of compounds, TFA-*cyclo*-(-Gly-Gly/Ile) and TFA-*cyclo*-(Ala-Ala/Ile), on the basis of mass spectrometry is not unequivocal; however, the GC retention times are sufficiently different to permit a distinction to be made.

The composition of a number of ions in the spectra of the TFA-DKP's have been confirmed by HRMS (Tables 7, 9, and 10). However, this does not indicate the source of the atoms comprising these ions or establish the fragmentations leading to them. Appropriate isotopic labelling can indicate the method of formation of ionic fragments and this will be the subject of a future paper.

Experimental

The mass spectral data in Tables 1–5 were obtained using a Finnigan 3300 GC–MS and 6000 Data System. A glass column, 152 cm (5 ft) long, 6 mm OD, 2 mm ID, packed with 3% OV-1 on Chromosorb W, HP, 80/100 mesh, was used for chromatography of the TFA-DKP's. Helium at 20 cm^3/min was used as carrier gas and the column was programmed from 80 to 250°C at 8°C/min.

High resolution mass spectra were obtained using a MS-902 spectrometer (Associated Electrical Industries) or a CEC 21-110B spectrometer (Du Pont). Metastable ions were determined using a MS-12 instrument (Associated Electrical Industries).

The diketopiperazines were synthesized by hydrogenolysis of appropriate benzyloxycarbonyl dipeptide methyl esters (12). Conversion to the trifluoroacetyl derivatives was achieved by heating (80°C) the DKP's in Reacti-Vials (Pierce Chemical Co.) containing trifluoroacetic anhydride for 10–20 min.

Acknowledgements

High resolution mass spectra were supplied by Dr. D. Durden, Psychiatric Research Division, University Hospital, Saskatoon, and by Dr. D. Jamieson, Atlantic Regional Laboratory, NRCC, Halifax. The metastable ions were recorded by Mr. D. Bain, Chemistry Department, University of Saskatchewan, Saskatoon.

The mass spectra of trifluoroacetyl-2,5-diketopiperazines. II. *cyclo*-(-Val-Val/Leu/Ile), *cyclo*-(-Leu-Leu/Ile), and *cyclo*-(-Ile-Ile)[1]

GEORGE P. SLATER[2] AND LAWRENCE R. HOGGE

Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Sask., Canada S7N 0W9

Received November 13, 1978

GEORGE P. SLATER and LAWRENCE R. HOGGE. Can. J. Chem. **57**, 2052 (1979).

The trifluoroacetyl derivatives of the 2,5-diketopiperazines *cyclo*-(-Val-Val/Leu/Ile), *cyclo*-(-Leu-Leu/Ile), and *cyclo*-(-Ile-Ile) were examined by GC–MS. The fragmentation of these compounds generally follows the same pathways as previously observed for the TFA-*cyclo*-(-Gly-X) series (X = Gly, Val, Leu, Ile). However, the spectra can be interpreted on the basis that the molecular ion fragments prior to, or after, one of the alkyl groups is eliminated as olefin. Some ion fragments indicate that both alkyl groups are eliminated but this does not appear to occur directly from the molecular ion. Support for fragmentation of the molecular ion by the suggested route is indicated by a number of isobaric ions although corresponding metastable ions were not observed.

The spectra enable the compounds in the series TFA-*cyclo*-(-Val-X) (X = Val, Leu, Ile) to be readily identified but this is not the case for TFA-*cyclo*-(-Leu-Leu/Ile) and TFA-*cyclo*-(-Ile-Ile). However, all of these compounds can be distinguished from TFA-*cyclo*-(-Gly-X) and TFA-*cyclo*-(-Ala-X) (X = Gly, Val, Leu, Ile).

GEORGE P. SLATER et LAWRENCE R. HOGGE. Can. J. Chem. **57**, 2052 (1979).

On a étudié les dérivés trifluoroacétylés des dicéto-2,5 pipérazines *cyclo*-(Val-Val/Leu/Ile), *cyclo*-(Leu-Leu/Ile) et *cyclo*-(Ile-Ile) par GC–MS. Les fragmentations de ces composés suivent généralement les mêmes voies que celles observées pour la série TFA-*cyclo*-(-Gly-X) (X = Gly, Val, Leu, Ile). Toutefois on peut interpréter les spectres en faisant l'hypothèse que la fragmentation de l'ion moléculaire se produit avant ou après que l'un des groupes alkyles ait été éliminé sous forme d'oléfine. D'après quelques ions de fragmentation, il semble que les deux groupes alkyles sont éliminés mais il n'apparait pas que ces éliminations se fassent directement à partir de l'ion moléculaire. Les données suggérant le type de fragmentation proposé découlent du nombre d'ions isobares même si l'on n'a pas observé la présence d'ions métastables.

Les spectres permettent d'identifier facilement les composés de la série TFA-*cyclo*-(-Val-X) (X = Val, Leu, Ile) mais tel n'est pas le cas pour les composés TFA-*cyclo*-(-Leu-Leu/Ile) et TFA-*cyclo*-(-Ile-Ile). Toutefois on peut distinguer tous les composés des séries TFA-*cyclo*-(-Gly-X) et TFA-*cyclo*-(-Ala-X) (X = Gly, Val, Leu, Ile).

[Traduit par le journal]

Introduction

In Part I of this series (2) the mass spectra of the trifluoroacetyl derivatives of *cyclo*-(-Gly-X), *cyclo*-(-Ala-X) (X = Gly, Val, Leu, Ile)[3], and *cyclo*-(-Ala-Ala) were described. A number of fragmentation pathways and supporting evidence were presented to account for the mass spectral patterns observed. In general, the spectra could be explained by a series of fragmentations common to all the trifluoroacetyl-2,5-diketopiperazines (TFA-DKP's) examined. Several differences between the various spectra were also noted and these could be used to help characterize the individual DKP's.

The first series of TFA-DKP's examined (2) contained several compounds bearing a C_3-alkyl(valyl) or C_4-alkyl group (leucyl/isoleucyl). The present study is concerned with DKP's synthesized from valine, leucine, and isoleucine only. Thus we have a series of trifluoroacetyl-dialkyl-2,5-diketopiperazines (TFA-DA-DKP's) each of which contains two C_3- or two C_4-alkyl groups, or one of each. This report describes the mass spectra of the TFA-DA-DKP's and indicates apparent differences in the fragmentation of the molecular ions of these compounds and the molecular ions of the TFA-DKP's previously examined (2).

Results and Discussion

The mass spectra of the TFA-DA-DKP's were obtained by gas chromatography – mass spectroscopy (GC–MS) using a quadrupole mass spectrometer, as previously described (2). In addition a number of ions were subjected to high resolution mass spectroscopy (HRMS) and some of the compounds were examined with a magnetic sector instrument to check for metastable ions.

As before (2) the molecular ions of these com-

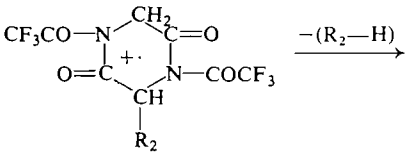
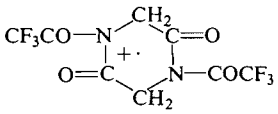
0008-4042/79/152052-06$01.00/0

pounds do not appear in the normalized mass spectra (Figs. 1 and 2) produced by the computer. However, these ions are easily seen on the oscillograph trace of maximum sensitivity from the magnetic sector instrument. Several of the remaining ions in the spectra of the TFA-DA-DKP's (Figs. 1 and 2) have the same *m/e* values as ions in the spectra of TFA-*cyclo*-(-Gly-Gly) (2), viz. *m/e* 69, 70, 96, 97, 125, 126, 139, 153, 154, although the relative abundances differ. Examination of these ions by HRMS[4] indicates that the corresponding ions in both sets of spectra are identical, except that several of the above ions for the TFA-DA-DKP's contain isobaric ions which are not possible for TFA-*cyclo*-(-Gly-Gly). The ions at *m/e* 125, 126, 139, 153, 154 in the spectra of the TFA-DA-DKP's imply that these compounds fragment as previously suggested (2) for the TFA-*cyclo*-(-Gly-X) compounds (i.e. both alkyl groups are eliminated as olefin from the molecular ion [1]

[1] 



1, *m/e* 348 ($R_2 = C_3H_7$)
m/e 362 ($R_2 = C_4H_9$)



2, *m/e* 306

to give the ions at *m/e* 306 (**2**) corresponding to the molecular ion of TFA-*cyclo*-(-Gly-Gly)). However, the spectra of the valyl-DKP's and the leucyl/isoleucyl-DKP's in the present series contain ions at *m/e* 168 (Fig. 1) and *m/e* 182 (Figs. 1 *b* and *c*, 2) which were found[4] to be the higher homologues of the ion at *m/e* 126 (i.e. ion 8, $R_2CH{=}\overset{+}{N}H{-}COCF_3$; *m/e* 126, $R_2 = H$; *m/e* 168, $R_2 = C_3H_7$; *m/e* 182, $R_2 = C_4H_9$). Since all three ions are present in the spectra of TFA-*cyclo*-(-Val-Leu/Ile) it would appear that the molecular ion fragments to give a mixture of the two higher homologues (*m/e* 168, 182) which could eliminate olefin to produce the ion at *m/e* 126. However, in the spectra of the valyl-DKP's (Fig. 1) and the leucyl/isoleucyl-DKP's (Fig. 2) ions at *m/e* 348, 362 (**1**, [1]) correspond to the loss of C_3H_6 and/or C_4H_8 as previously observed for the TFA-*cyclo*-(-Gly-X) compounds. Fragmentation of ion **1** by pathways proposed for the latter compounds (2) would also account for the ions typical of TFA-*cyclo*-(-Gly-Gly) and the homologous ions at *m/e* 168, 182. Unfortunately, no metastable ions corresponding to these fragmentations of the molecular ion were detected although a metastable ion was observed for *m/e* 153 → *m/e* 125 (*m** 102.1).

To further complicate the issue, the ions at *m/e* 139, 70 have the same formulae ($C_4H_4F_3NO$, C_3H_4NO, respectively) as the corresponding ions in the spectrum of TFA-*cyclo*-(-Gly-Gly), i.e. ions 14, 21 in ref. 2. For these ions to occur their precursor(s) must eliminate both alkyl groups and this could happen by elimination of olefin from ion **1** [1] to give ion **2** (*m/e* 306) which corresponds to the molecular ion of TFA-*cyclo*-(-Gly-Gly). The absence[5] of the ion at *m/e* 306 and low abundances of precursors of ion 14 in which both alkyl groups are absent (viz. ion 11, *m/e* 327; ion 12, *m/e* 204; ion 13, *m/e* 167, cf. Table 3, ref. 2) appear to exclude this possibility. An alternative explanation would require elimination of olefin from ion 14, *m/e* 181 ($R_2 = C_3H_7$) or *m/e* 195 ($R_2 = C_4H_9$). In the absence of relevant metastable ions the present data do not indicate which of the pathways is preferred, however a metastable ion (*m** 35.3) corresponding to elimination [2] of $\cdot CF_3$

[2] 
14, *m/e* 181 ($R_2 = C_3H_7$; $R_1 = H$) → **21**, *m/e* 112
m/e 195 ($R_2 = C_4H_9$; $R_1 = H$) → *m/e* 126
m/e 139 ($R_1 = R_2 = H$) → *m/e* 70

from the ion at *m/e* 139 was observed. The presence of one of the higher homologues of ion 21 (viz. *m/e* 126) as an isobar of ion 8 was confirmed by HRMS.[4]

Of the remaining ions in the spectra of the TFA-DA-DKP's which have *m/e* values identical to those in the spectra of the TFA-*cyclo*-(-Gly-X) compounds (2) only the ions at *m/e* 69, 166 (latter for leucyl-

[4]A complete set of these data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[5]The ion at *m/e* 306 is too small to be seen in the normalized mass spectra produced by computer but is readily apparent in the oscillograph trace for the magnetic sector instrument.

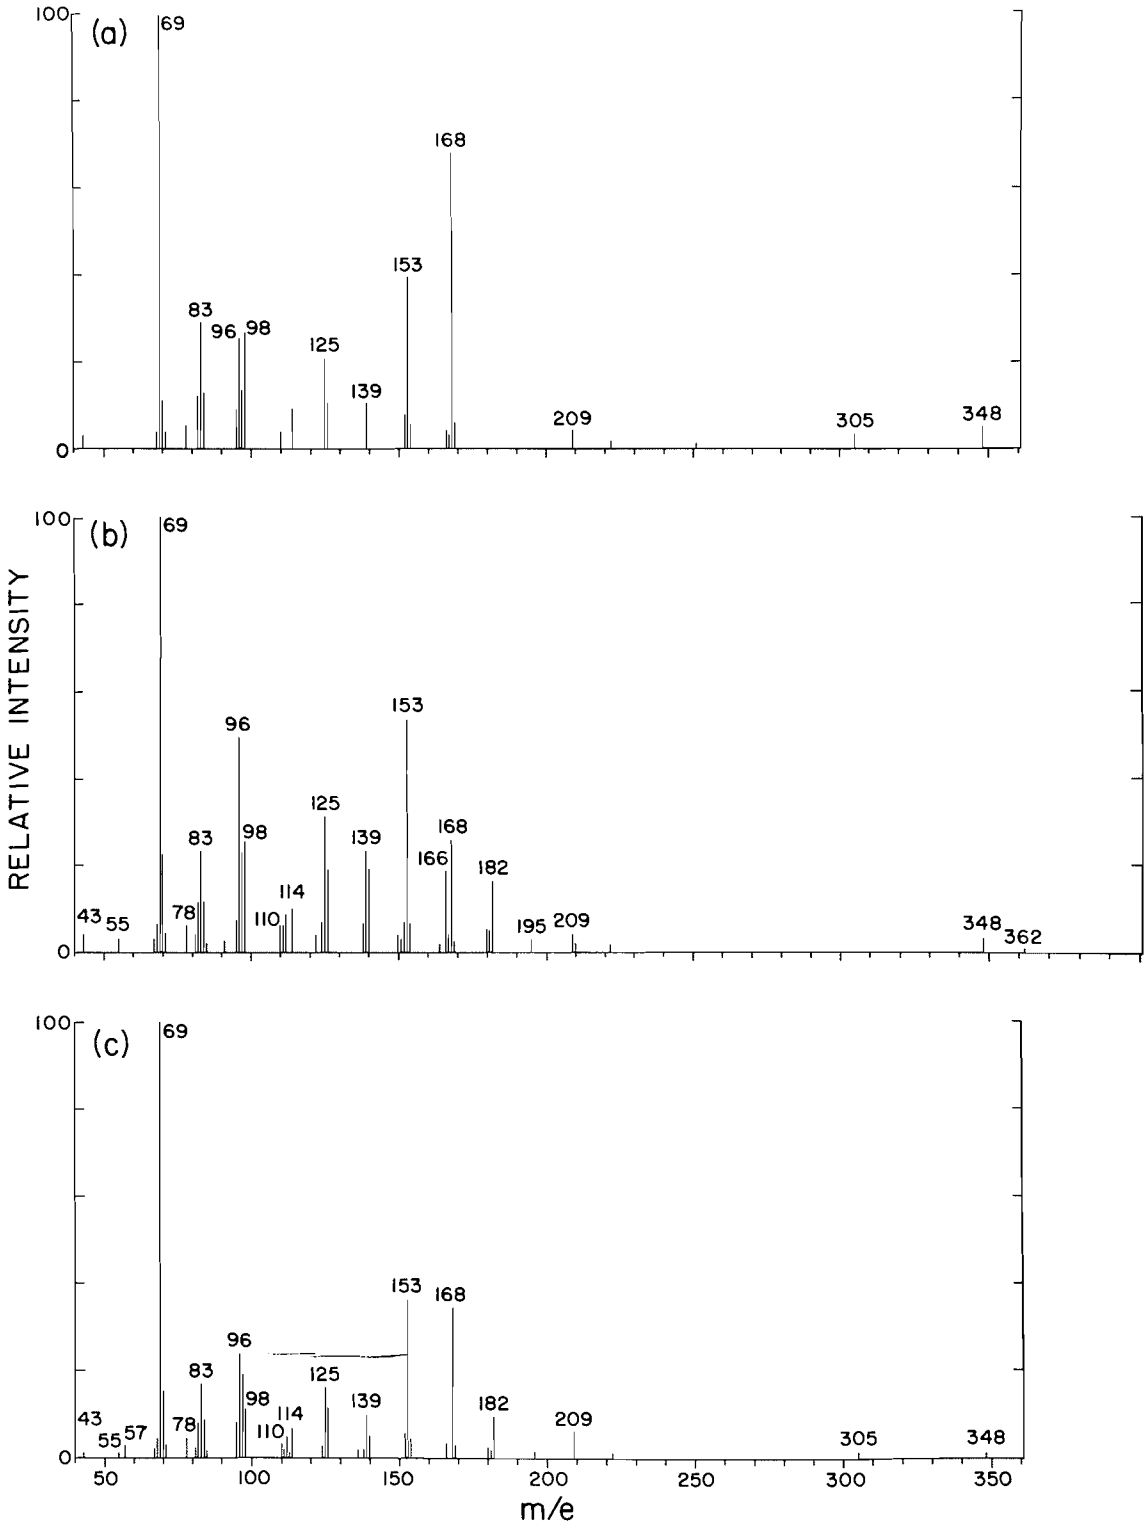


FIG. 1. Mass spectra of (*a*) TFA-*cyclo*-(-Val-Val), (*b*) TFA-*cyclo*-(-Val-Leu), (*c*) TFA-*cyclo*-(-Val-Ile).

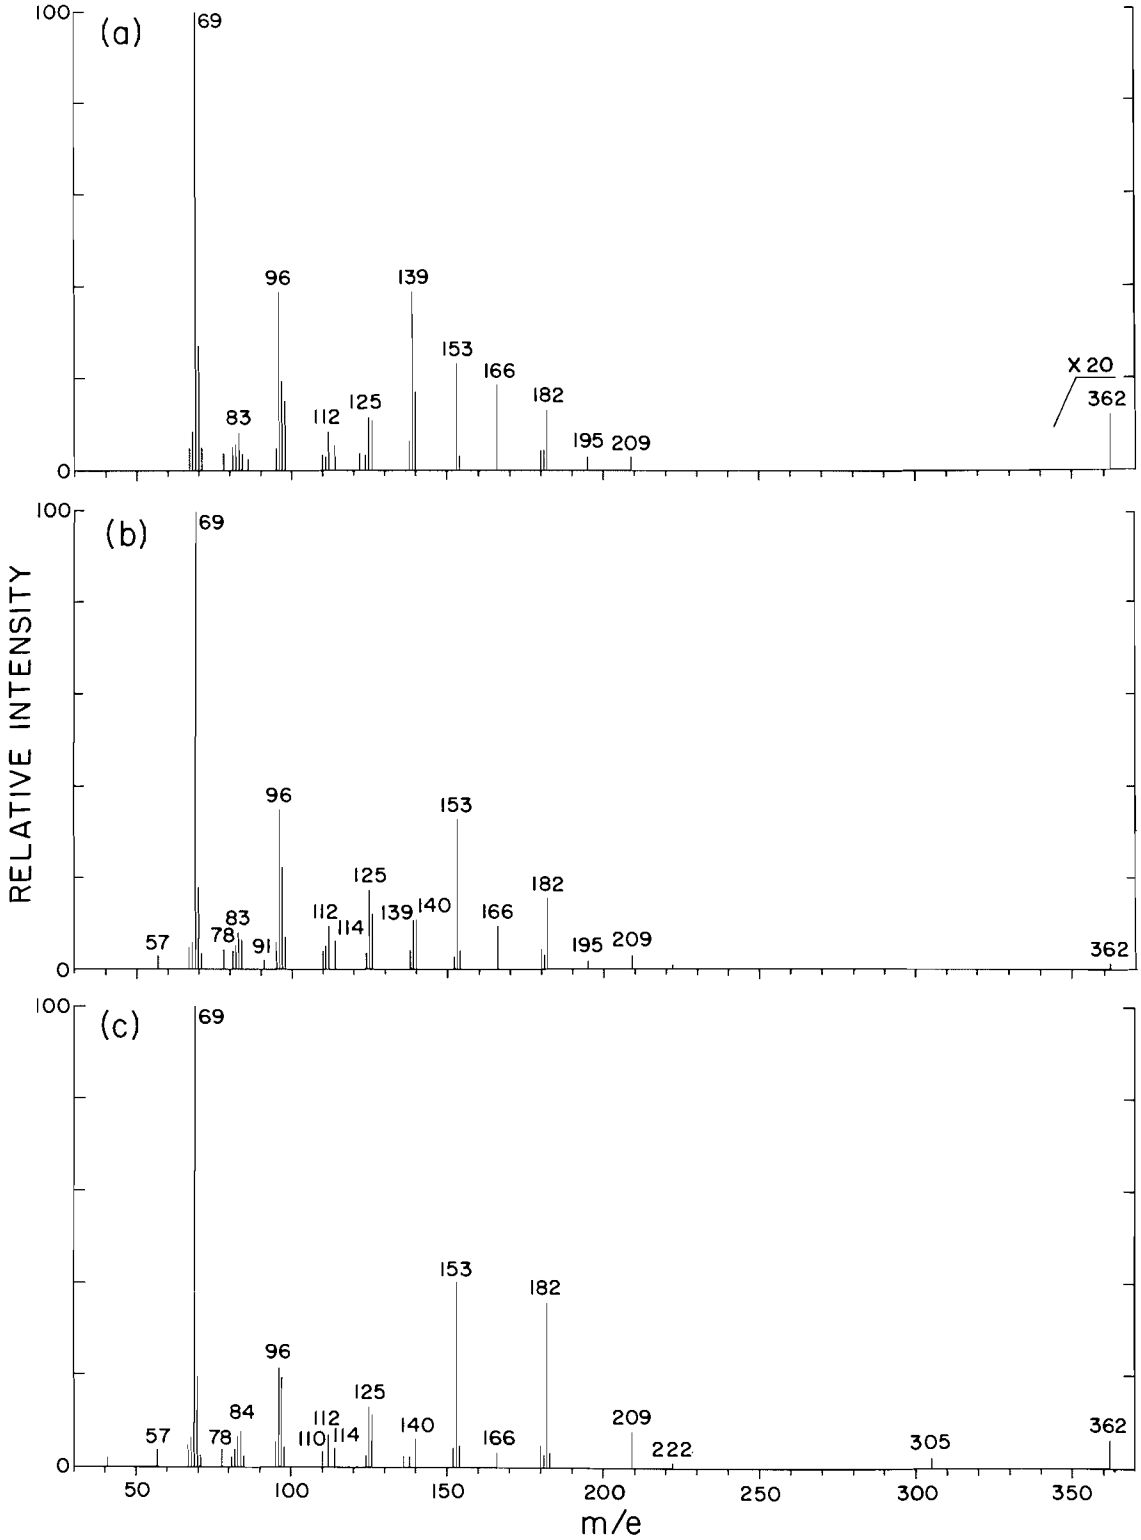

FIG. 2. Mass spectra of (*a*) TFA-*cyclo*-(-Leu-Leu), (*b*) TFA-*cyclo*-(-Leu-Ile), (*c*) TFA-*cyclo*-(-Ile-Ile).

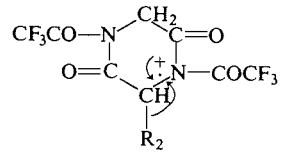
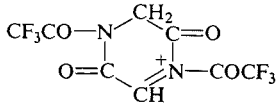
DKP's) were the same for both groups.[4] The ion at *m/e* 96 in the spectra of the leucyl/isoleucyl-DKP's contained three isobars, C_2HF_3N (previously detected, ref. 2), C_4H_9—C_2HN (a homologue of ion 17, ref. 2) and C_6H_8O (C_4H_9—$CH{=}C{=}\overset{+\cdot}{O}$ – $[H_2]$) in the ratio 8:1:8.[4] For TFA-*cyclo*-Val-Val only C_2HF_3N is possible and was the only ion seen. The ion at *m/e* 97 also comprises three isobars for the leucyl/isoleucyl-DKP's, viz. CF_3CO, C_4H_9—C_2H_2N (homologue of ion 20, ref. 2), and C_6H_9O (2:1:3)[4]. The last ion corresponds to loss of H· from the ketene ion C_4H_9—$CH{=}C{=}\overset{+\cdot}{O}$ and the lower homologue at *m/e* 83 (C_3H_7—$CH{=}C{=}\overset{+\cdot}{O}$ – [H·]) was also observed in the spectra of the valyl-DKP's.[4] The ion at *m/e* 83 contained two other isobars, viz. C_3H_7–C_2H_2N (homologue of ion 20, ref. 2) and an ion of formula C_3HNO_2 (possibly $O{=}C{=}CH{-}\overset{+\cdot}{N}{=}C{=}O$ derived from ion **3** [3]).

[3]



1, *m/e* 348 ($R_2 = C_3H_7$)
m/e 362 ($R_2 = C_4H_9$)



3, *m/e* 305

In the spectra of TFA-*cyclo*-(Val-Val/Ile) (Fig. 1 *a* and *c*) a relatively small ion occurs at *m/e* 305 (cf. footnote 5) which could arise from ion **1** by expulsion of the second alkyl group as a radical [3] and the corresponding metastable ion (*m/e* 267.1) was obtained in the spectrum of TFA-*cyclo*-(-Val-Ile). A metastable ion corresponding to the loss of this radical in the spectrum of underivatized *cyclo*-(-Val-Ile) has been reported previously (3). Several fragmentations of ion **3** involving loss of $\cdot CF_3$, CO, ketene, etc. are possible but none lead to relatively abundant ions.

The spectra of the TFA-DA-DKP's also contain ketene ions, $RCH{=}C{=}\overset{+\cdot}{O}$, at *m/e* 84 (R = C_3H_7) and *m/e* 98 (R = C_4H_9), but none at *m/e* 42 (R = H). The ketene ion, *m/e* 42, was relatively abundant (11–42%) in the spectra of TFA-*cyclo*-(-Gly-X) (X = Gly, Val, Leu, Ile) (2) and its absence in the spectra of the TFA-DA-DKP's (Figs. 1 and 2) suggests that formation of ketene ions in the spectra of the latter compounds occurs preferentially from the molecular ion or from the portion of ion **1** [1] retaining the alkyl group. This is contrary to the results for the TFA-DKP's (2) where ketene ions retaining the valyl- or leucyl/isoleucyl-side chains were not observed.

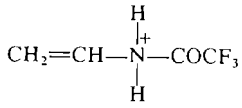
The ketene ions at *m/e* 84, 98 are isobaric with ions predicted for the TFA-DA-DKP's by Schemes 1 and 3 in the previous paper (2). In the case of TFA-*cyclo*-(-Val-Val) the ion at *m/e* 98 should be due solely to C_3H_7—$CH{=}\overset{+}{N}{=}C{=}O$ (corresponding to ion 4) and this was confirmed by HRMS.[4] For TFA-*cyclo*-(-Val-Leu/Ile) two other isobars are possible, viz. C_4H_9—$CH{=}\overset{+}{N}{=}CH_2$ (ion 22) and the ketene C_4H_9—$CH{=}C{=}\overset{+\cdot}{O}$. All three isobars were found in the high resolution spectrum of TFA-*cyclo*-(-Val-Leu) and is consistent with fragmentation of this compound by way of ion **1** [1] and then Schemes 1–5, or directly by Schemes 1–5. In the case of TFA-*cyclo*-(-Leu-Leu/Ile) and TFA-*cyclo*-(-Ile-Ile) only C_4H_9—$CH{=}\overset{+}{N}{=}CH_2$ and the ketene are possible but only the latter was detected.[4] The high resolution spectrum of TFA-*cyclo*-(-Val-Val) indicated that the ion at *m/e* 84 was due to ketene (C_3H_7—$CH{=}C{=}\overset{+\cdot}{O}$) only.

Identifying the three valyl-DKP's on the basis of the spectra in Fig. 1 is relatively straightforward since the valyl residue gives rise to the characteristic ion at *m/e* 168 and the leucyl/isoleucyl residue to the homologue at *m/e* 182. The ion at *m/e* 166 then allows the leucyl-DKP to be identified. On the other hand, the spectra in Fig. 2 are so similar that it is not possible to identify the individual compounds on this basis. Even the ion at *m/e* 166 occurs in the spectrum of TFA-*cyclo*-(-Ile-Ile) although the relative abundance (3%) is less than that in the spectra of the other two compounds (19%, 10%). The only distinguishing feature appears to be that the ion at *m/e* 139 is quite prominent (39% relative abundance) in the spectrum of TFA-*cyclo*-(-Leu-Leu), much less abundant in the spectra of TFA-*cyclo*-(-Leu-Ile) (11%) and TFA-*cyclo*-(-Ile-Ile) (2%). No reason for the variation in intensity of this ion is apparent since HRMS[4] indicates a single ion of formula $C_4H_4F_3NO$ (ion 14, both alkyl groups removed [2]).

The spectra of TFA-*cyclo*-(-Val-Leu) (Fig. 1*b*) and TFA-*cyclo*-(-Leu-Leu/Ile) (Fig. 2 *a* and *b*) contain an ion at *m/e* 140 which is relatively abundant (18%, 17%, 11%) compared to the other spectra (2–6%). The formula $C_4H_5F_3NO$ was indicated by HRMS[4] and an ion of this composition could be formed from the ion at *m/e* 182 by elimination of propylene [4].

For the isoleucyl-DKP's the analogous fragmentation would result in the loss of ethylene to give an

[4] 
m/e 182



m/e 140

ion at *m/e* 154. This relatively weak ion was in the spectra of all these compounds (Figs. 1 and 2) but was not examined by HRMS. Loss of propylene from leucyl residues in peptides and of ethylene from isoleucyl residues has been noted previously (4), but only the above loss of propylene [4] appears to occur in the fragmentation of the TFA-DA-DKP's.

Comparison of the spectra of the TFA-DA-DKP's (Figs. 1 and 2) with those previously obtained (2) indicates a number of differences. These enable the two groups of compounds to be distinguished but also suggests that the molecular ions of the compounds in the two groups behave differently. When only one alkyl group is present in a TFA-DKP it appears that the molecular ion eliminates the alkyl group as olefin prior to fragmentation since ions containing an alkyl group were not observed in the spectra of these compounds (2). In contrast, when the TFA-DKP's contain two alkyl groups, the spectra (Figs. 1 and 2) indicate the following possibilities: (*1*) the molecular ion fragments (as shown in Schemes 1–5, ref. 2) to give a mixture of ions retaining one or other of the alkyl groups.[4] Some of these ions then partially eliminate the alkyl group as olefin to give fragments identical to those in the spectra of the TFA-glycyl-DKP's (2); (*2*) the molecular ion eliminates one alkyl group to give ion **1** [1] which can then fragment as in (*1*) to give a mixture of ions with and without an alkyl group. Again, some of these ions would have to eliminate olefin to give ions at *m/e* 139, 70, for example; (*3*) concurrent with (*1*) and/or (*2*), ion **1** may eliminate the remaining alkyl group as olefin [1] prior to fragmentation by Schemes 1–5.

The data obtained from the present work do not establish unequivocally all of the proposed fragmentations. In some cases additional information would be available by examination of isotopically labelled compounds and this will be considered in a future communication.

Experimental

The trifluoroacetyl-2,5-diketopiperazines and their mass spectra were obtained as previously described (2).

Received February 8, 1979

KEITH C. LEE and FRIEDHELM AUBKE. Can. J. Chem. 57, 2058 (1979).

The synthesis of a number of compounds containing the hexakis(fluorosulfato)palladate(IV) anion and the cations Cs^+, Ba^{2+}, NO^+, and ClO_2^+ is reported. All compounds are diamagnetic. Also reported is the synthesis of $Pd[M(SO_3F)_6]$, where M = Pt(IV) and Sn(IV). Here, palladium(II) is found in a regular octahedral environment. Both compounds are paramagnetic, consistent with a $^3A_{2g}$ ground state. Curie–Weiss law behavior is found and ligand field parameters for the Pd(II) derivatives are reported.

Vibrational spectra are reported for all new fluorosulfato complexes.

KEITH C. LEE et FRIEDHELM AUBKE. Can. J. Chem. 57, 2058 (1979).

On rapporte la synthèse d'un certain nombre de composés contenant l'anion hexakis(fluorosulfato)palladate(IV) et les cations Cs^+, Ba^{2+}, NO^+ et ClO_2^+. Tous les composés sont diamagnétiques. On rapporte aussi la synthèse du $Pd[M(SO_3F)_6]$ où M = Pt(IV) et Sn(IV). On a trouvé dans ce cas que le palladium(II) est dans un environnement octaédrique régulier. Les deux composés sont paramagnétiques ce qui est en accord avec un état fondamental $^3A_{2g}$. On a trouvé un comportement qui suit la loi de Curie–Weiss et on rapporte les paramètres de champ de ligand pour les dérivés Pd(II).

On rapporte les spectres vibrationnels de tous les nouveaux complexes fluorosulfato.

[Traduit par le journal]

Introduction

We have recently (1) reported on the syntheses and structural characterization of two binary fluorosulfates of palladium, $Pd(SO_3F)_2$ and '$Pd(SO_3F)_3$'. In contrast to most palladium(II) compounds (2), the fluorosulfates are paramagnetic and for $Pd(SO_3F)_2$ a regular octahedral environment for Pd^{II} is suggested.

In analogy to PdF_3 (3–5), the compound '$Pd(SO_3F)_3$' is best formulated as $Pd^{II}[Pd^{IV}(SO_3F)_6]$, again with Pd^{II} in a regular octahedral environment

In the present study, our work on palladium fluorosulfates is extended in two general directions: (*a*) the synthesis and characterization of Pd^{II} derivatives of the type $Pd^{II}[M^{IV}(SO_3F)_6]$ with M = Pt or Sn; and (*b*) the preparation of complexes containing the $[Pd(SO_3F)_6]^{2-}$ anion, as well as the attempted synthesis of $Pd(SO_3F)_4$.

Magnetic and spectroscopic studies on both sets of compounds are undertaken in support of our earlier structural conclusion.

Experimental

Chemicals

Palladium and platinum powder (both −60 mesh and of 99.95% purity) were obtained from Ventron Corp., and tin (−20 mesh, 99.97% pure) was supplied by BDH. Technical grade fluorosulfuric acid (Allied Chemicals) was doubly distilled at atmospheric pressure as described previously (6). Nitrosylchloride (Matheson) was purified by trap-to-trap distillation and stored over $CaSO_4$ before use. Bis(fluorosulfuryl)peroxide (7), $S_2O_6F_2$, and chlorylfluorosulfate (8), ClO_2SO_3F, were synthesized according to published method. The previously reported fluorosulfates: $Sn(SO_3F)_4$ (9), $Pt(SO_3F)_4$ (10), and '$Pd(SO_3F)_3$' (1) were obtained by an alternative, more convenient method: the oxidation of the metal by $S_2O_6F_2$ in HSO_3F at about +100°C. $Pd(SO_3F)_2$ was obtained by the thermal decomposition of $Pd[Pd(SO_3F)_6]$ at 130°C (1). All other chemicals used in this study were obtained from commercial sources.

Instrumentation

Raman spectra were obtained with either a Cary 81 or a Spex Ramalog 5 spectrophotometer fitted with either a He–Ne (635.5 nm) or an argon ion (514.5 nm) laser respectively. Raman spectra at liquid N_2 temperature were recorded only on the Spex Ramalog 5. The samples were contained in Pyrex melting point tubes. An evacuable two part Pyrex cell, fitted with quartz windows at a 90° angle and a brass sample holder directly cooled with liquid N_2, was employed for the Raman spectra at 80 K.

Infrared spectra were recorded on a Perkin-Elmer 457 spectrophotometer. AgCl, AgBr, and BaF_2 (Harshaw Chemicals) were used as window materials. Spectra were obtained from thin solid films, since the compounds were found to react with the commonly used mulling agents.

Electronic spectra were obtained on powdered samples using a Bausch and Lomb Spectronic 600 spectrophotometer (diffuse reflectance) and on samples mulled in $C_8F_{17}SO_2F$ (perfluoro-octyl sulfuryl-fluoride) using a Cary 14 spectrophotometer. Magnetic susceptibilities were measured using the Gouy apparatus described earlier (12). The coil current of the magnet was regulated to give a field of approximately 4500 G. The temperature of the sample was controlled by the rate of

[2]To whom all correspondence should be addressed.

0008-4042/79/152058-07$01.00/0

evaporation of N_2 around the chamber. Calibration was achieved using $HgCo(SCN)_4$ (13). Diamagnetic corrections were made using published Pascals constants (2). For SO_3F^-, a suggested (14) correction of 40×10^{-6} cgs units was used.

All reactions were performed in Pyrex reaction vials of about 40 mL contents fitted with Kontes Teflon stem valves. Volatile materials were handled using vacuum line techniques. Solids were handled in a Vacuum Atmospheres Corp. 'Dri Lab' Model No. HE-43-2 filled with purified dry nitrogen and equipped with a 'Dri-Train' Model No. HE-93-B circulating unit. Filtrations of moisture sensitive materials were carried out in an apparatus described by Shriver (11).

Synthetic Reactions

(a) $Cs_2[Pd(SO_3F)_6]$

A Pyrex reaction vial was charged with 0.104 g (0.977 mmol) of palladium and 0.329 g (1.954 mmol) of CsCl, and approximately 9 g of HSO_3F was added by vacuum distillation. After removal of the HCl *in vacuo*, ~13 g of $S_2O_6F_2$ was distilled onto the mixture *in vacuo*. Reaction occurred at room temperature and the solution turned deep red. The reaction mixture was heated to +120°C for 3 days. After this time all metal powder had been consumed. Removal of all volatiles *in vacuo* with the reaction vial at room temperature yielded a dark red crystalline solid which analysed as $Cs_2[Pd(SO_3F)_6]$. In this reaction, 0.927 g (0.960 mmol) were obtained. $Ba[Pd(SO_3F)_6]$ was prepared in an identical fashion. $BaCl_2 \cdot 2H_2O$ was dried in an oven for 24 h at 150°C. The reaction temperature was 90°C, and the reaction time was 1 week.

(b) $Pd^{II}[Pt^{IV}(SO_3F)_6]$

To a mixture of 0.319 g (1.05 mmol) of $Pd(SO_3F)_2$ and 0.666 g (1.13 mmol) of $Pt(SO_3F)_4$, approximately 5 mL of HSO_3F were added by distillation *in vacuo*. After heating the mixture for 3 days at 80°C, a homogeneous green precipitate had formed. The mixture was filtered and washed with HSO_3F repeatedly. The material was dried by heating to 80°C *in vacuo*.

$Pd^{II}[Sn^{IV}(SO_3F)_6]$ was prepared in an analogous fashion. Reaction time was 1 week and the reaction temperature was +70°C.

(c) $(ClO_2)_2[Pd(SO_3F)_6]$

0.129 g (1.21 mmol) of palladium were allowed to react with a mixture of approximately 0.5 mL of ClO_2SO_3F and 5 mL of $S_2O_6F_2$. After maintaining a reaction temperature of 70°C for 3 days, dark red crystals were formed. Removal of all volatiles yielded 1.013 g (1.21 mmol) of a crystalline material of the composition $(ClO_2)_2[Pd(SO_3F)_6]$.

(d) $(NO)_2[Pd(SO_3F)_6]$

By reaction of 0.110 g (1.03 mmol) palladium with approximately 3 mL of ClNO for 12 h at room temperature, 0.31 g (1.03 mmol) of $(NO)_2PdCl_4$ was formed. This intermediate was allowed to react with a mixture of about 3 mL of HSO_3F and 3 mL of $S_2O_6F_2$ for 1 h at 80°C. Removal of all volatile materials while heating the sample to 70°C yielded a bright red solid analysed as $(NO)_2[Pd(SO_3F)_6]$.

Analysis

Microanalyses on all new compounds were performed by Microanalytical Laboratories, formerly A. Bernhardt, Elbach, West Germany. The nitrogen content of $(NO)_2[Pd(SO_3F)_6]$ was determined by Mr. P. Borda of this department. $Cs_2[Pd(SO_3F)_6]$, dark red hygroscopic crystals, diamagnetic, soluble in HSO_3F, thermally stable up to 200°C. *Anal.* calcd.: Cs 27.50, Pd 11.01, F 11.79; found: Cs 27.25, Pd 10.85, F 11.67. $Ba[Pd(SO_3F)_6]$, orange-red, hygroscopic powder, very sparingly soluble in HSO_3F, thermally stable to approximately 200°C. *Anal.* calcd.: Ba 16.39, Pd 12.70, S 22.95, F 13.60; found: Ba 16.24, Pd 12.64, S 22.89, F 13.82. $(NO)_2[Pd(SO_3F)_6]$, bright red hygroscopic crystals, soluble in HSO_3F, melts with decomposition at about 200°C. *Anal.* calcd.: N 3.68, Pd 13.99, S 25.29, F 14.99; found: N 3.44, Pd 13.81, S 25.11, F 15.17. $(ClO_2)_2[Pd(SO_3F)_6]$, deep red, hygroscopic crystals, soluble in HSO_3F, stable up to ~200°C. *Anal.* calcd.: Cl 8.48, Pd 12.73, F 13.64; found: Cl 8.60, Pd 12.82, F 13.68. $Pd[Pt(SO_3F)_6]$, green powder, hygroscopic, insoluble in HSO_3F at room temperature, thermally stable to about 200°C. *Anal.* calcd.: Pd 11.88, Pt 21.80, F 12.72; found: Pd 11.62, Pt 21.74, F 12.88. $Pd[Sn(SO_3F)_6]$, light blue hygroscopic powder, insoluble in HSO_3F at room temperature, decomposes at around 250°C into a light purple solid. *Anal.* calcd.: Pd 12.98, Sn 14.48, S 23.47, F 13.91; found: Pd 13.06, Sn 14.61, S 23.31, F 13.72.

Results and Discussion

Synthesis

The principal oxidizing and fluorosulfonating agent used in the synthesis of the new hexakis(fluorosulfato)palladates(IV) is a concentrated solution of bis(fluorosulfuryl)peroxide, $S_2O_6F_2$, in fluorosulfuric acid, HSO_3F. This solution combines the excellent oxidizing ability of $S_2O_6F_2$ and the solvating property of HSO_3F rather well and may be effectively used in the syntheses of binary transition metal fluorosulfates, or fluorosulfato complexes (15, 16).

The formation of $Cs_2[Pd(SO_3F)_6]$ via:

$$[1]\quad 2CsSO_3F + Pd + 2S_2O_6F_2 \xrightarrow[3\ \text{days}]{+120^\circ C} Cs_2[Pd(SO_3F)_6]$$

with $CsSO_3F$ formed *in situ* from CsCl and HSO_3F, employs the oxidation of palladium metal to the +4 oxidation state, while the synthesis of $(NO)_2[Pd(SO_3F)_6]$ illustrates the oxidation of palladium from +2 to +4 with the replacement of chloride by fluorosulfate groups:

$$[2]\quad (NO)_2[PdCl_4] + 3S_2O_6F_2 \xrightarrow[1\ \text{h}]{+80^\circ C} (NO)_2[Pd(SO_3F)_6] + 2Cl_2$$

The starting material $(NO)_2[PdCl_4]$ is easily obtained by oxidation of palladium with a large excess of ClNO. The oxidation is followed by weight and the presence of $(NO)_2[PdCl_4]$ is suggested by 2 ir bands at 2150 (νNO) and 332 cm^{-1} ($\nu PdCl_4$). The preceding examples and the syntheses of $Ba[Pd(SO_3F)_6]$ and $(ClO_2)_2[Pd(SO_3F)_6]$ by similar methods suggest that $Pd(SO_3F)_4$ may be obtainable as well and, indeed, solutions containing Pd(IV) in $HSO_3F/S_2O_6F_2$ are obtained by two main routes:

(*a*) The oxidation of palladium yields deep red-brown solutions. The uv spectrum is identical to the one produced by solutions of $(NO)_2[Pd(SO_3F)_6]$ with λ_{max} at 320 nm and an approximate molar absorption coefficient of $1.3 \times 10^4\ M^{-1}\ cm^{-1}$.

(*b*) $Pd[Pd(SO_3F)_6]$ (1) is insoluble in HSO_3F; however, addition of $S_2O_6F_2$ to the suspension produces a dark red-brown solution, but even at elevated reaction temperatures and long reaction times a residue of $Pd[Pd(SO_3F)_6]$ still remains.

Attempts to isolate $Pd(SO_3F)_4$ from solutions after filtration were unsuccessful. Removal of all volatiles *in vacuo* with the solution at room temperature resulted in the gradual precipitation of $Pd[Pd(SO_3F)_6]$. It appears that $Pd(SO_3F)_4$ may not be thermally stable enough to allow its isolation. When the oxidation of palladium in $HSO_3F/S_2O_6F_2$ at temperatures ranging from 25 to 120°C is allowed to go to completion, removal of all volatiles *in vacuo* yields quantitatively pure $Pd[Pd(SO_3F)_6]$ This one step procedure offers a distinct advantage over the originally (1) published method.

In contrast to these findings, the synthetic usefulness of the $HSO_3F/S_2O_6F_2$ mixtures is illustrated by the facile preparation of both $Pt(SO_3F)_4$ and $Sn(SO_3F)_4$ via:

$$[3]\quad M + 2S_2O_6F_2 \xrightarrow[HSO_3F]{} M(SO_3F)_4$$

M = Pt or Sn, where short reaction times, the absence of reaction intermediates, and the use of highly pure metals present additional advantages over the originally reported synthetic routes to both compounds (9, 10).

The subsequent syntheses of the palladium(II) derivatives of $Pd[Sn(SO_3F)_6]$ and $Pd[Pt(SO_3F)_6]$ proceed reasonably fast at +70 to +80°C according to:

$$[4]\quad Pd(SO_3F)_2 + M(SO_3F)_4 \xrightarrow[HSO_3F]{} Pd[M(SO_3F)_6]$$

M = Pt or Sn.

Exactly stoichiometric amounts of both reactants are required to ensure complete reaction.

Compounds containing both the $[Sn(SO_3F)_6]^{2-}$ and the $[Pt(SO_3F)_6]^{2-}$ ions have been reported previously (15, 17, 18) and characterization based on vibrational spectra should be facilitated by these precedents.

The synthesis of $(ClO_2)_2[Pd(SO_3F)_6]$ departs from the general scheme. The presence of a large excess of ClO_2SO_3F, and undercooled liquid at room temperature, makes the addition of HSO_3F unnecessary and the oxidation of palladium by bis(fluorosulfuryl)peroxide proceeds to completion within 3 days.

The hexakis(fluorosulfato)palladates reported here have both heterocations, such as NO^+ and ClO_2^+, or uni- or divalent metal cations, such as Cs^+ and Ba^{2+}, as counter ions. They all are thermally stable up to about 200°C.

Vibrational Spectra

Both infrared and Raman spectra of the fluorosulfato complexes discussed here are not readily obtained for a number of reasons. The oxidizing ability of the hexakis(fluorosulfato)palladates(IV) precludes the use of mulling agents and limits the choice of suitable window materials to BaF_2 with a transmission range to about 800 cm^{-1}. The dark colour of these compounds also interferes with the recording of Raman spectra. When using the 514.5 nm line of the Ar ion laser, well resolved Raman spectra are only obtained when the sample is cooled to ~80 K. At this temperature the colour becomes lighter and higher laser power may be used without risking local thermal decomposition of the sample. Alternatively, Raman spectra at room temperature are obtained for $(NO)_2[Pd(SO_3F)_6]$ and $(ClO_2)_2[Pd(SO_3F)_6]$ on the Cary 81 instrument equipped with a He–Ne laser; however, caused by both low scatter efficiency and low laser power (< 20 mW at the sample), the resolution is rather poor. It can be inferred from the room temperature spectra that the frequency shifts to lower wave numbers for the low temperature spectra are rather small (about 3 to 5 cm^{-1}).

Strong fluorescence of the sample prevented the recording of Raman spectra for $Pd[Sn(SO_3F)_6]$; however, for this compound and for $Pd[Pt(SO_3F)_6]$, infrared spectra down to 450 cm^{-1} are obtainable on solid films pressed between AgCl plates.

A tracing of the Raman spectrum of $Pd[Pt(SO_3F)_6]$ is shown in Fig. 1. The observed vibrational bands together with estimated intensities for all six new compounds and for $Pd[Pd(SO_3F)_6]$ (1) are listed in Table 1. Since generally good agreement between ir and Raman spectra in regard to band position is observed, the Raman shifts are tabulated, because they extend down to about 100 cm^{-1}.

The spectra obtained are typical for monodentate fluorosulfate groups in anionic complexes and agreement with direct precedents, the spectra for $K_2[Sn(SO_3F)_6]$ (17), $Ag[Sn(SO_3F)_6]$ (15), and $Ag[Pt(SO_3F)_6]$ (15), is very good. The Raman spectra for the hexakis(fluorosulfato)palladates(IV) are very similar as well and a common, tentative assignment

is attempted. In all cases band proliferation, particularly in the SO_3F stretching range, is observed, presumably caused by extensive vibrational coupling and solid state splitting. Interesting intensity differences between ir and Raman spectra point to vibrational coupling resulting in in-phase and out-of-phase vibrations within the anion. For the $[Pd(SO_3F)_6]^{2-}$ derivatives, strong Raman bands at $\sim$1240 (νSO_2 sym) and $\sim$1020 cm^{-1} (νS–O*P*d) have weaker side bands at $\sim$1210 and $\sim$980 cm^{-1} respectively, with the intensities reversed in the infrared spectra.

Bands at $\sim$1170 to 1190 and $\sim$1040 to 1050 cm^{-1} are observed for the three Pd^{II} compounds as well as for the previously reported Ag^{II} complexes, $Ag[Pt(SO_3F)_6]$ and $Ag[Sn(SO_3F)_6]$ (15). Absorptions in this region are generally associated with bidentate bridging fluorosulfate groups (19), and their occurrence here and in the Ag^{II} complexes may be attributed to the polarizing abilities of the two divalent cations and the resulting coordination via oxygen. Hence ionic formulations as $M^{II}[M^{IV}(SO_3F)_6]$, where $M^{II} = Pd^{II}$ and Ag^{II} and $M^{IV} = Pt^{IV}$ and Sn^{IV}, may be somewhat misleading.

Strong Raman bands at $\sim$620 to 640, 440 to 460, and 270 to 280 cm^{-1} are observed for all anionic complexes, with variations in band positions seemingly dependent on the central atoms. These bands, occasionally split into doublets, may be due to M—O vibrations, presumably mixed with SO_3F deformation modes. A similar interpretation has been advanced recently for the $[Au(SO_3F)_4]^-$ ion (16). Strong metal–oxygen bonds are suggested by the vibrational coupling of SO stretching modes discussed earlier.

Absorption bands due to the heterocation NO^+ at 2330 cm^{-1} and for ClO_2^+ at 1293 and 1050 cm^{-1} are consistent with precedents (19, 20); however, the ClO_2 bending mode, usually found at $\sim$520 cm^{-1} (20) is not observed. The NO stretch is found in the ir spectrum only. The band is raised by $\sim$30 cm^{-1} to 2330 cm^{-1} when compared to 2300 for $NOSO_3F$ (21).

In summary, the apparent spectral similarities indicate strong structural similarities. Formulation of '$Pd(SO_3F)_3$' as $Pd[Pd(SO_3F)_6]$ is consistent with the observed vibrational spectrum, when allowance is made for additional coordination of the SO_3F group to Pd^{II}.

Electronic Spectra

Of primary interests are absorption bands due to *d–d* transitions for palladium(II). Previous work (1) had presented evidence for a regular octahedral environment for Pd(II) in $Pd(SO_3F)_2$, implying a tridentate fluorosulfate group, and a ${}^3A_{2g}$ ground state.

The spectra obtained for $Pd[Pt(SO_3F)_6]$ and $Pd[Sn(SO_3F)_6]$, together with values for $Pd(SO_3F)_2$, are listed in Table 2. Of the three expected *d–d* transitions, the two low energy bands ν_1 and ν_2 are obtained from the mull spectra. Diffuse reflectance spectra also yield ν_2 and for $Pd[Sn(SO_3F)_6]$ also a broad band assigned as ν_3. In the platinum compound, ν_3 is not observed because a strong band, presumably due to a charge transfer transition, originates in the ultraviolet and extends well into the visible region.

The good agreement in band positions for all three Pd(II) compounds suggests (*a*) a similar octahedral environment for palladium and (*b*) a ${}^3A_{2g}$ ground state in all instances. The obtained $10Dq$ values are also listed in Table 2 as well as the ligand field parameter B, obtained from the measured ν_2/ν_1 ratio, using Tanabe–Sugano diagrams as suggested by Lever (22). The third band, ν_3, is calculated by using Tanabe–Sugano diagrams as well.

It appears that in the series $Pd(SO_3F)_2$, $Pd[Pt-$

$(SO_3F)_6]$, $Pd[Sn(SO_3F)_6]$, the ligand field splitting ($10Dq$) gradually decreases while interelectronic repulsion (B) increases, with the observed B values approaching the free ion value B^0 of 830 cm^{-1} (23). Differences in both $10Dq$ and B may reflect the different coordination of the SO_3F group to Pd(II), tridentate in $Pd(SO_3F)_2$ and presumably monodentate in the two fluorosulfato complexes. In addition, greater free ion character in $Pd[Sn(SO_3F)_6]$ than in $Pd[Pt(SO_3F)_6]$ suggests either structural differences, not apparent from the vibrational spectra, or more likely, a greater ability of Sn(IV) to attract SO_3F groups thus reducing their abilities to produce a ligand field around Pd(II) and to delocalize electron density from it.

Finally, the solution of $(NO)_2[Pd(SO_3F)_6]$ in HSO_3F has been mentioned before. The high intensity of the band at 320 nm is suggestive of a charge transfer spectrum. The observed band extends well into the visible region and seems to obscure any bands due to d–d transitions.

Magnetic Measurements

As expected, the new hexakis(fluorosulfato)palladate(IV) complexes are all diamagnetic, consistent with a d^6 electron configuration and a regular octahedral environment.

The two new Pd(II) derivatives are found to be paramagnetic and, in agreement with expectations for an ion with a $^3A_{2g}$ ground state, the Curie–Weiss law is followed in the range of our measurements (~306 to 80 K). The magnetic susceptibilities and the magnetic moments are listed in Table 3. A $1/\chi$ vs. T plot for all Pd(II) fluorosulfate derivatives is shown in Fig. 2. The two new palladium(II) hexakis(fluorosulfato)metallates have identical Weiss constants of -10 ± 2 K and consequently μ_{eff} for both compounds decreases with temperature. In contrast both $Pd(SO_3F)_2$ and $Pd[Pd(SO_3F)_6]$ have small but positive θ values of $+13 \pm 4$ and $+10 \pm 2$ K respectively. A similar situation is encountered for

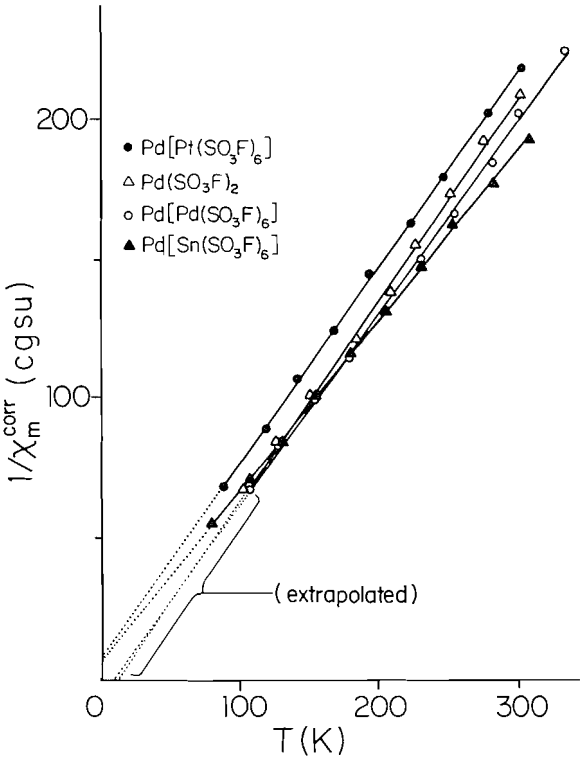

FIG. 2. The temperature dependence of the corrected molar susceptibilities for Pd^{II} fluorosulfate derivatives.

Ag(II) fluorosulfate derivatives where $Ag(SO_3F)_2$ has a positive Weiss constant of +20 K and both $Ag[Sn(SO_3F)_6]$ and $Ag[Pt(SO_3F)_6]$ have small negative Weiss constants. In addition, if the Curie–Weiss law is used in the form: $\chi_M^{corr} = C/(T - \theta)$, negative values for θ are also found for palladium(II) complexes of the type $Pd[MF_6]$ where M = Pt, Pd, Sn, or Ge (4).

Since the Weiss constants are rather small, corrected magnetic moments are calculated for all Pd(II) fluorosulfate compounds by using the relationship: $\mu = 2.828[\chi_M^{corr}(T - \theta)]^{1/2}$, and as seen in Table 3,

TABLE 4. Magnetic properties of some Pd(II) compounds at room temperature

	$\chi_M^{corr} \times 10^3$ (cgsu)	$\mu_{eff,corr}$ (BM)	Temperature dependence (θ = Weiss constant)	Reference
PdF_2	1.28	1.74	Antiferromagnetic coupling	4, 24
$Pd[PdF_6]$	3.31	2.88	$\theta = -28$ K	4, 24
$Pd[SnF_6]$	3.37	2.98	$\theta = -28$ K	4, 24
$Pd[PtF_6]$	3.10	2.72	$\theta = -1$ K	4, 24
$Pd[GeF_6]$	3.34	2.82	$\theta = -31$ K	4, 24
$Pd(SO_3F)_2$	4.77	3.30	$\theta = 13 \pm 4$ K	1
$Pd[Pd(SO_3F)_6]$	4.93	3.37	$\theta = 10 \pm 2$ K	1
$Pd[Sn(SO_3F)_6]$	5.26	3.60	$\theta = -10 \pm 3$ K	This work
$Pd[Pt(SO_3F)_6]$	4.61	3.37	$\theta = -10 \pm 2$ K	This work

the magnetic moments are now independent of temperature in the range of our measurements.

The same corrections are applied for $Pd(SO_3F)_2$ and $Pd[Pd(SO_3F)_6]$. The resulting values and a summary of the magnetic properties for a number of paramagnetic palladium(II) compounds are listed in Table 4.

In contrast to the fluorides, all palladium(II) fluorosulfates are magnetically dilute and the obtained magnetic moments are all substantially higher than the 'spin only' value of 2.83 BM. The corrected magnetic moments increase in the order $Pd(SO_3F)_2 < Pd[Pt(SO_3F)_6] \sim Pd[Pd(SO_3F)_6] < Pd[Sn(SO_3F)_6]$, suggesting an increase in free ion character. The results are consistent with previously discussed trends in Dq and B for $Pd(SO_3F)_2$, $Pd[Pt(SO_3F)_6]$, and $Pd[Sn(SO_3F)_6]$. The complex fluoride derivatives of the type $Pd^{II}[MF_6]$ show a similar trend. The highest magnetic moment, again after correcting for Curie–Weiss law behavior (4, 24), is observed for $Pd[SnF_6]$. However, all magnetic moments for the fluoro complexes fall below 3.00 BM. It seems that orbital contributions to the magnetic susceptibility are more effectively quenched than in the fluorosulfate compounds. Unfortunately, no electronic spectra were reported for the fluoro compounds.

The magnetic moment at room temperature for $Pd[Sn(SO_3F)_6]$ is 3.61 BM. Even though this value is the highest yet observed for Pd^{2+}, values to about 4.0 BM have been reported for divalent Ni^{2+} compounds (2), with Ni^{2+} in an octahedral environment.

Conclusions

Even though $Pd(SO_3F)_4$ could not be obtained, a number of diamagnetic compounds containing the $[Pd(SO_3F)_6]^{2-}$ are obtained and characterized by their vibrational spectra. More extensive spectroscopic and magnetic information on rather unusual octahedral Pd^{2+} complexes are also obtained.

Kinetics and mechanism of oxidation of tris-(1,10-phenanthroline)iron(II) by chlorine and bromine and of the reduction of tris-(1,10-phenanthroline)iron(III) by iodide ions

JIDE IGE, J. FOLORUNSO OJO,[1] AND OLUSEGUN OLUBUYIDE

Department of Chemistry, University of Ife, Ile-Ife, Nigeria

Received November 30, 1978

JIDE IGE, J. FOLORUNSO OJO, and OLUSEGUN OLUBUYIDE. Can. J. Chem. 57, 2065 (1979).

The rates of the oxidation of tris-(1,10-phenanthroline)iron(II) by chlorine and bromine, and of the reduction of tris-(1,10-phenanthroline)iron(III) by iodide ions have been measured at ionic strength $I = 1.0$ mol dm^{-3} ($LiClO_4$). All the reactions obey second-order rate law:

$$\text{Rate} = k_{obsd}\,[\text{oxidant}][\text{reductant}]$$

The activation parameters for the reactions are: $Fe(Phen)_3^{2+}/Br_2$: $\Delta H^{\ddagger} = (64.2 \pm 3.2)$ kJ mol^{-1}, $\Delta S^{\ddagger} = -(24.9 \pm 1.5)$ J mol^{-1} K^{-1}. $Fe(Phen)_3^{3+}/I^-$: $\Delta H^{\ddagger} = (39.8 \pm 2.1)$ kJ mol^{-1}, $\Delta S^{\ddagger} = -(19.7 \pm 0.8)$ J mol^{-1} K^{-1}.

The reactions of tris-(1,10-phenanthroline)iron(II) with chlorine and bromine are unaffected by chloride, bromide, and acid. The proposed mechanism for these reactions involves a series of one-electron changes, with the species X_2^- (X = Cl, Br) as reaction intermediates, since good linear free energy correlations for the primary step, resulting in the formation of X_2^-, are obtained. The reduction of tris-(1,10-phenanthroline)iron(III) by iodide ions is catalysed by bromide and chloride ions, whereas the reduction of aquoiron(III) by iodide ions is known to be inhibited by bromide and chloride ions. A mechanistic interpretation of this observation is suggested.

JIDE IGE, J. FOLORUNSO OJO et OLUSEGUN OLUBUYIDE. Can. J. Chem. 57, 2065 (1979).

On a mesuré les vitesses d'oxydation du tris-(phénanthroline-1,10)fer(II) par le chlore et le brome et la réduction du tris-(phénanthroline-1,10)fer(III) par les ions iodures à une force ionique $I = 1.0$ mol dm^{-3} ($LiClO_4$). Toutes les réactions obéissent à une équation de vitesse du deuxième ordre:

$$\text{Vitesse} = k_{obsd}\,[\text{oxydant}][\text{réducteur}]$$

Les paramètres d'activations des réactions sont: $Fe(Phen)_3^{2+}/Br_2$: $\Delta H^{\ddagger} = (64.2 \pm 3.2)$ kJ mol^{-1}, $\Delta S^{\ddagger} = -(24.9 \pm 1.5)$ J mol^{-1} K^{-1}. $Fe(Phen)_3^{3+}/I^-$: $\Delta H^{\ddagger} = (39.8 \pm 2.1)$ kJ mol^{-1}, $\Delta S^{\ddagger} = -(19.7 \pm 0.8)$ J mol^{-1} K^{-1}.

Les réactions du tris-(phénanthroline-1,10)fer(II) avec le brome et le chlore ne sont pas affectées par les ions chlorures et bromures ou par les acides. Le mécanisme proposé pour ces réactions implique une série de changements d'un électron dans laquelle les espèces X_2^- (X = Cl, Br) sont des intermédiaires; ces conclusions reposent sur le fait que l'on obtient de bonnes corrélations linéaires d'énergie libre pour la première étape au cours de laquelle il y a formation de X_2^-. La réduction du tris-(phénanthroline-1,10)fer(III) par les ions iodures est catalysée par les ions chlorure et bromure alors que l'on sait que la réduction de l'aquofer(III) est inhibée par les ions bromure et chlorure. On suggère une interprétation mécanistique de cette observation.

Introduction

A study of the oxidation reactions of the halogens, X_2 (X = Cl, Br, I) is interesting because these provide an example of chemically related members of the same group in the periodic table. Their physicochemical behaviour shows the similarities and general gradation in properties often observed from top to bottom within a group (1). They oxidise the metal ions (2–16) at rates which follow the general sequence $k_{Cl_2} > k_{Br_2} > k_{I_2}$ in accordance with their oxidation potentials (17). Also, they are overall two-electron oxidants, and hence their study could provide a means of distinguishing between the two-electron-transfer scheme:

$$[1]\quad \text{Fe(II)} + X_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{Fe(IV)} + 2X^-$$

$$[2]\quad \text{Fe(IV)} + \text{Fe(II)} \xrightarrow{k_2} 2\text{Fe(III)}$$

and the series of one-electron changes:

$$[3]\quad \text{Fe(II)} + X_2 \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} \text{Fe(III)} + X_2^-$$

$$[4]\quad \text{Fe(II)} + X_2^- \xrightarrow{k_4} \text{Fe(III)} + 2X^-$$

Shakhashiri and Gordon (18) had studied the oxidation of tris-(1,10-phenanthroline)iron(II) by chlorine

[1]To whom all correspondence should be addressed.

0008-4042/79/152065-06$01.00/0

in chloride and nitrate media, with the iron complex in the sulphate form.

The oxidation potential of the couple (19) $Fe(Phen)_3^{2+}/Fe(Phen)_3^{3+}$ (−1.06 V), and those of the halogen (17) systems $X_2/2X^-$ (−1.36 V (Cl_2), −1.06 V (Br_2), and −0.62 V (I_2)) suggest that the reaction represented by eq. [5]

$$[5] \quad 2Fe(Phen)_3^{2+} + X_2 \rightarrow 2Fe(Phen)_3^{3+} + 2X^-$$

is thermodynamically feasible for Cl_2 but less so for Br_2 and I_2.

The reduction of aquoiron(III) by iodide ions (20, 21) had been shown to be inhibited by added bromide and chloride ions. This has been explained in terms of the formation of FeX^{2+} (X = I, Br, Cl) from the complexation of ferric ions with the halide ions, with FeX^{2+} being less reactive than aquoiron(III). In the unlikely event that tris-(1,10-phenanthroline)iron(III) could complex with the halide ions, the effects of bromide and chloride ions on the $Fe(Phen)_3^{3+}/I^-$ system should be of mechanistic interest.

We report here a study of the oxidation of tris-(1,10-phenanthroline)iron(II) by chlorine and bromine and of the reduction of tris-(1,10-phenanthroline)iron(III) by iodide ions in perchlorate medium, bearing in mind the points raised above.

Experimental

Materials

The complexes $Fe(Phen)_3^{2+}$ and $Fe(Phen)_3^{3+}$ were prepared as the perchlorate salts (22, 23) and characterised for purity (24) by their uv–visible spectra. Solutions of $Fe(Phen)_3^{3+}$ in 5 mol dm^{-3} $HClO_4$ were freshly prepared each day and kept in ice before use. Aqueous solutions of chlorine and bromine were prepared and their concentrations determined as recorded in the literature (25). Sodium iodide, sodium bromide, and lithium chloride which were the sources of the anions were Analar grade reagents. Lithium perchlorate, used to maintain the ionic strength at 1.0 mol dm^{-3}, was prepared from Analar lithium carbonate and perchloric acid, and recrystallised thrice, by the usual method (26).

Kinetics

The oxidation of tris-(1,10-phenanthroline)iron(II) by chlorine and bromine was monitored on a Pye Unicam SP 500 spectrophotometer by following the decreasing absorbance (24) of the tris-(1,10-phenanthroline)iron(II) at λ = 510 nm ($\varepsilon = 1.09 \times 10^4$ dm^3 mol^{-1} cm^{-1}). The halogen concentration was always in large excess (≥ tenfold). The fast reduction of tris-(1,10-phenanthroline)iron(III) by iodide ions was monitored on a Durrum-Gibson stopped-flow spectrophotometer at λ = 510 nm, where the tris-(1,10-phenanthroline)iron(II) product has maximum absorption. The iodide concentration was always in large excess. Pseudo first-order behaviour was observed to more than 80% reaction in all cases. The cell compartments were well thermostatted (±1°C) by circulating water from a water-bath regulated to the desired temperature.

Results

The Oxidation of Tris-(1,10-phenanthroline)iron(II) by Chlorine and Bromine

The linearity of the pseudo first-order rate plots for these reactions and the non-dependence of the second-order rate constants on the concentrations of the oxidants (Table 1) suggest that the reactions represented by eq. [5] (X = Cl, Br) obey the rate law:

$$[6] \quad (-1/2)d[Fe(Phen)_3^{2+}]/dt = k_5[Fe(Phen)_3^{2+}][X_2]$$

The rate constants for the reactions of tris-(1,10-phenanthroline)iron(II) with chlorine and bromine are not affected by added chloride and bromide, respectively, and acid (Table 1).

Our results for the oxidation of tris-(1,10-phenanthroline)iron(II) by chlorine agree with those of Shakhashiri and Gordon (18), indicating that sulphate and nitrate ions do not affect the reactions. The reductant self-exchange rate constants (k_{11}), one-electron redox rate constants (k_{12}), and the standard free energy changes (ΔG_{12}^0) for the reduction of chlorine and bromine by some metal ions, including tris-(1,10-phenanthroline)iron(II) are presented in Table 2. The one-electron reduction of a halogen by a metal centre is represented by eq. [7]

$$[7] \quad M_{red} + X_2 \xrightarrow{k_{12}} M_{ox} + X_2^-$$

and the corresponding self-exchange reactions are represented by eqs. [8] and [9].

[8] $$M_{red} + M_{ox}{}^* \underset{}{\overset{k_{11}}{\rightleftharpoons}} M_{red}{}^* + M_{ox}$$

[9] $$X_2 + {}^*X_2{}^- \underset{}{\overset{k_{22}}{\rightleftharpoons}} X_2{}^- + {}^*X_2$$

Marcus (27) suggested that reactions represented by eqs. [7]–[9] occur by outer-sphere mechanism, if the relationship among the free energies of activation is of the form:

[10] $$\Delta G_{12}{}^{\neq} = 0.5\Delta G_{11}{}^{\neq} + 0.5\Delta G_{22}{}^{\neq} + 0.5\Delta G_{12}{}^0 - 0.5RT \ln f$$

where

[11] $$\ln f = \frac{(-\Delta G_{12}{}^0/RT)^2}{4 \ln \frac{k_{11}k_{22}}{Z^2}}$$

and $Z = 10^{11}$ dm^3 mol^{-1} s^{-1}. Equation [10] implies that if $\Delta G_{12}{}^{\neq} - 0.5(\Delta G_{11}{}^{\neq} - RT \ln f)$ is plotted against $\Delta G_{12}{}^0$, a linear fit should result, with slope 0.5 and intercept $0.5\Delta G_{22}{}^{\neq}$. The free energies of activation were calculated (28) from the familiar eq. [12] where $\bar{K}$ = Boltzmann's constant, h =

[12] $$\Delta G^{\neq} = RT \ln(\bar{K}T/h) - RT \ln k$$

Planck's constant, and T is the absolute temperature. Figures 1 and 2 show the free energy plots obtained, using the data in Table 2. Woodruff and Margerum (29) had obtained k_{22} (eq. [9]) for X = Br and I from the intercepts of such plots by an iterative procedure, using EDTA complexes of iron(II) and cobalt(II) as reductants. The slopes and k_{22} which we obtained from Figs. 1 and 2 are 0.43 ± 0.12, 0.7 dm^3 mol^{-1} s^{-1} (X = Cl) and 0.30 ± 0.10, 84.7 dm^3 mol^{-1} s^{-1} (X = Br), respectively. The

[a]Average of k_6 for [H^+] = 0.10–1.00 mol dm^{-3}.
[b]Average of k_6 for the iodide concentration given in the table.
[c][H^+] = 0.10 mol dm^{-3}.
[d]All average rate constants are subject to standard error of ≤5%.

$$\Delta H^{\ddagger} = (64.2 \pm 3.2)\ \text{kJ mol}^{-1}$$

$$\Delta S^{\ddagger} = -(24.9 \pm 1.5)\ \text{J mol}^{-1}\ \text{K}^{-1}$$

The Reduction of Tris-(1,10-phenanthroline)iron(III) by Iodide Ions

The data obtained for the reaction (Table 3) fit the rate law:

$$[13] \quad -\mathrm{d}[Fe(Phen)_3^{3+}]/\mathrm{d}t = k_6[Fe(Phen)_3^{3+}][I^-]$$

and the stoichiometry of the reaction was confirmed to be of the form:

$$[14] \quad Fe(Phen)_3^{3+} + I^- \xrightarrow{k_6} Fe(Phen)_3^{2+} + \tfrac{1}{2}I_2$$

The reaction is not affected by added acid, but it is catalysed by added chloride and bromide ions (Table 3), with bromide ions having greater catalysing effect. The observed second-order rate constants (k_{obsd}) vary with the concentrations of the added anion [X^-] according to eq. [15]. Figure 3 shows such

$$[15] \quad k_{obsd} = k_0 + k_x[X^-]$$

variation for X = Br. The values of k_0 and k_x obtained from such variation are:

$$k_0 = 0.85 \times 10^5\ \text{dm}^3\ \text{mol}^{-1}\ \text{s}^{-1}$$

$$k_{Br} = 4.7 \times 10^5\ \text{dm}^6\ \text{mol}^{-2}\ \text{s}^{-1}$$

$$k_0 = 0.68 \times 10^5\ \text{dm}^3\ \text{mol}^{-1}\ \text{s}^{-1}$$

$$k_{Cl} = 1.7 \times 10^5\ \text{dm}^6\ \text{mol}^{-2}\ \text{s}^{-1}$$

The values of the anion-independent rate constants (k_0) agree very well for the two anions (Cl^- and Br^-), and with that (k_6, eq. [13]) obtained in the absence of added anion (Table 3).

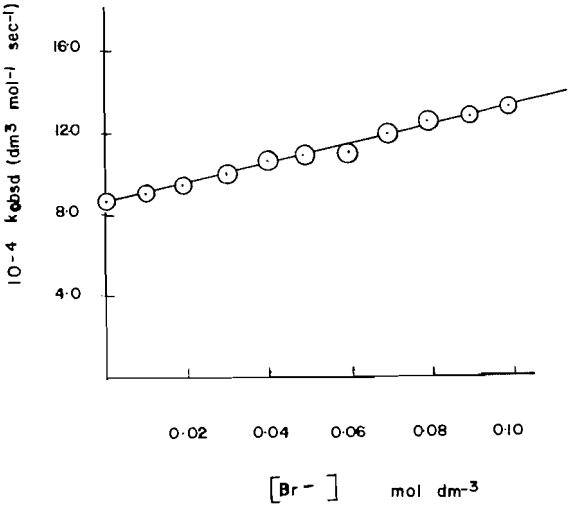

FIG. 3. Effect of added bromide ions on the rate constants for $Fe(Phen)_3^{3+} + I^-$ reaction.

The temperature variation of the rate constant k_6 was investigated, and the activation parameters obtained were

$$\Delta H^{\ddagger} = (39.8 \pm 2.1)\ \text{kJ mol}^{-1}$$

$$\Delta S^{\ddagger} = -(19.7 \pm 0.8)\ \text{J mol}^{-1}\ \text{K}^{-1}$$

Discussion

Application of the steady-state approximation to the concentrations of the transient species (Fe(IV) and X_2^-) involved in the two reaction schemes, eqs. [1] and [2] and eqs. [3] and [4], gives identical second-order rate laws under the likely conditions that $k_{-1} \ll k_2$ and $k_{-3} \ll k_4$. The second-order rate law [6] obtained in this study does not therefore distinguish between these two possibilities. The good linear-free energy correlations obtained (Figs. 1 and 2) suggest that the reactions of chlorine and bromine with tris-(1,10-phenanthroline)iron(II) probably occur by the series of one-electron changes [3] and [4]. The reactions of the other metal ions (5, 8, 10) with the halogens had been shown to occur by these series of one-electron changes. The slopes of the linear-free energy plots are lower than the theoretical value of 0.5, probably as a result of the failure of some of the assumptions of the Marcus theory which has been used to calculate the kinetic parameters from various sources as has been pointed out by various workers (5, 29, 30) and Marcus (31) has suggested some reasons why the slopes of such plots could be less than 0.5 also. Assignment of outer-sphere or inner-sphere mechanism to the reactions cannot be made with certainty on the basis of the linear-free energy correlations obtained, since some inner-sphere redox reactions (32–34) have also shown this Marcus type (26) dependence of reaction rates on ΔG_{12}^{0}. Our main support for suggesting outer-sphere mechanism for the reactions is the substitution — inertness of $Fe(Phen)_3^{2+}$ (35). The formation of $FeCl^{2+}$ as an initial product in the aquoiron(II)–chlorine reaction (25) has been used to support inner-sphere mechanism for this reaction. A similar inner-sphere complex between $Fe(Phen)_3^{2+}$ and X_2 is unlikely, since $Fe(Phen)_3^{2+}$ is inert to substitution.

Inhibition by added ions [X^-] accompanies the oxidation of most metal ions (5, 8–11, 16, 28) as a result of the formation of trihalide ions according to the equilibrium:

[16] $X_2 + X^- \rightleftharpoons X_3^-$

with X_3^- being less reactive than X_2. Our data suggest that Cl_3^- and Br_3^- do not constitute significant reactive species in the oxidation of $Fe(Phen)_3^{2+}$ by chlorine and bromine, since inhibition is not observed.

The form of the rate law for the reduction of tris-(1,10-phenanthroline)iron(III) by iodide ions (eq. [13]) suggests a bimolecular interaction between the reactants. Complicated rate laws have been obtained in the reduction of aquoiron(III) (21, 22) and ferricyanide ions (36, 37) by iodide ions; and inhibition by added chloride and bromide ions (21, 22) observed for the reduction of aquoiron(III). These results have been attributed to inner-sphere complex formation between the oxidant and the added halide ion in the primary step, with FeX^{2+} being less reactive than aquoiron(III). Ford-Smith and Rawsthorne (38) obtained simple second-order rate law in the reduction of octacyanomolybdate(V) by iodide ions and therefore ruled out inner-sphere complexation between the oxidant and the reductant. More recently, Ferranti (39) studied the $Mo(CN)_8^{3-}/I^-$ reaction, but his results are not too different from those of Ford-Smith and Rawsthorne. Inner-sphere coordination of tris-(1,10-phenanthroline)iron(III) to halide ions is also unlikely, since a simple second-order rate law, as observed by Ford-Smith and Rawsthorne (38), is obtained here, and catalysis by chloride and bromide ions rather than inhibition is observed. The added anions could associate with atomic iodine while it is in the process of being formed and since the added anion [X^-] stabilises I, it lowers the energy barrier for the reaction. This implies that in addition to the primary second-order path [17]

[17] $Fe(Phen)_3^{3+} + I^- \rightarrow Fe(Phen)_3^{2+} + I$

there is also the path [18]

[18] $Fe(Phen)_3^{3+} + I^- + X^- \rightarrow Fe(Phen)_3^{2+} + IX^-$

Similar paths have been observed by Wilmarth and Haim (46) in the oxidations of halides and pseudohalides.

Carbon-13 nuclear magnetic resonance spectroscopy of phorbol

M. NEEMAN AND O. D. SIMMONS

Roswell Park Memorial Institute, Buffalo, NY 14263, U.S.A.

Received December 7, 1978

M. NEEMAN and O. D. SIMMONS. Can. J. Chem. 57, 2071 (1979).

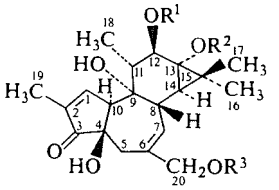
The ^{13}C nmr spectrum of the diterpene phorbol has been recorded and the signals of all carbons assigned.

M. NEEMAN et O. D. SIMMONS. Can. J. Chem. 57, 2071 (1979).

On a enregistré le spectre rmn du ^{13}C du diterpène phorbol et on a attribué les signaux de tous les carbones.

[Traduit par le journal]

Phorbol **1**, a pentahydroxy-ketone diterpene from *Croton tiglium* L., and its diesters (for example **2** and **3**) are of continuing interest in oncology: the parent diterpene **1** has leukemogenic action, as well as systemic promoting action in liver, lung, and mammary carcinogenesis in certain rodent strains (1–4). 12,13-Diesters of phorbol (natural products such as **2**, or partially synthetic products such as **3**) have been widely studied as tumor promoters in mouse skin initiation–promotion carcinogenesis (5–9). The phorbol triester **6** is devoid of biological activity.



1 $R^1 = R^2 = R^3 = H$
2 $R^1 = CH_3(CH_2)_{12}CO—$, $R^2 = CH_3CO—$, $R^3 = H$
3 $R^1 = R^2 = CH_3(CH_2)_8CO—$, $R^3 = H$
4 $R^1 = CH_3(CH_2)_{12}CO—$, $R^2 = R^3 = H$
5 $R^1 = R^2 = CH_3CO—$, $R^3 = H$
6 $R^1 = R^2 = R^3 = CH_3CO—$
7 $R^1 = R^3 = H$, $R^2 = CH_3CO—$

The determination of the structure and stereochemistry of phorbol and its derivatives utilized ^1H nuclear magnetic resonance (^{1}Hmr) data as evidence for earlier proposed structures (10–12), which were erroneous, and of a later structure **1** (13, 14) which was supported by X-ray crystallographic data for the structure and relative stereochemistry (15, 16), and the absolute configuration (16) of phorbol derivatives.

The present paper reports the ^{13}C nuclear magnetic resonance (^{13}Cmr) spectrum of phorbol. The spectrum was recorded (*a*) without spin decoupling, (*b*) with wide-band noise ^1H decoupling, and (*c*)–(*h*) with selected single frequency ^1H decoupling at 6 frequencies. These frequencies were selected over ranges of 500–600 Hz straddling the decoupling frequency Δν of each protium. The ^{13}C–^1H coupling constants J_0 from (*a*), and residual couplings J_r from (*c*)–(*h*) were utilized to calculate $J_r(J_0^2 - J_r^2)^{1/2}$ for the single frequencies, and Pachler plots were fitted, from which the values of protium decoupling frequency Δν were obtained (17). A ^{1}Hmr spectrum of phorbol was recorded, and the ^1H signals observed were assigned utilizing the ^{1}Hmr analysis of Hecker *et al.* (18). Comparison of the Δν values in the ^{13}Cmr spectrum of phorbol with the chemical shifts of signals in its ^{1}Hmr spectrum made possible the assignment of the ^{13}Cmr signals shown in Table 1, in good accord with the observed J_0 coupling constants and ^{13}Cmr chemical shifts.

The singlets at 212.3 ppm and at 141.3 ppm were assigned, by analogy with the model compound 2-methyl-2-cyclopentenone (19), to carbonyl C-3

TABLE 1. The ^{13}Cmr and ^{1}Hmr spectra of phorbol **1**[a]

and vinyl C-2, respectively. The singlet in the vinyl region at 134.9 ppm was assigned to C-6, and the singlets at 80.0 and 75.3 ppm tentatively to the angular hydroxyl-bearing carbons C-4 and C-9, the more deshielded C-4 being α to conjugate carbonyl C-3. The C-17 methyl group, the axial (13*c*) 11β-H and *pseudo*axial 8β-H in the half chair-ring C (the latter is a 'flagpole' in ring B which has the distorted boat conformation), and the 'flagpole' angular β-OH on C-4 undergo nonbonded interactions, in contrast to the angular 10α-H which does not interact with the remote α-equatorial (13*c*) C-18 methyl group. Carbon C-8 (which is deshielded by one β-OH substituent, and sterically compressed) is 18.8 ppm upfield from C-10 (deshielded by two β-OH substituents). Assignments of the cyclopropyl methyls C-16 and C-17 were made on the basis of the 6.3 ppm difference in shifts between them, which is attributed to steric compression of C-17.

The effects of acylation of 12β-OH or 13α-OH can be compared with those reported for the model compounds *trans*-4-*tert*-butylcyclohexanol and its acetate: acylation effected a downfield shift of the carbinol carbon and an upfield shift of the contiguous carbons (20). The observed shifts given in Table 2 were in the expected directions for C-11, C-12, and C-13 in the mono-acylated phorbol esters **4** and **7**; small upfield shifts were observed for C-14 in **4** as well as **7**. The shifts in the diacetate **5** and in the triacetate **6** were not completely additive in comparison to those in the mono-esters **4** and **7**; the additivity was highest for C-11 and C-13 (Table 2).

Experimental

Phorbol **1** and phorbol 12,13,20-triacetate **6** were purchased from Consolidated Midland Corporation, Brewster, NY, U.S.A., and phorbol 12-myristate **4**, phorbol 12,13-diacetate **5**, and phorbol 13-acetate **7** from Dr. Peter Borchert, Eden Prairie, MI, U.S.A.

The ^{13}Cmr spectra were recorded on a Varian XL-100 nmr spectrometer at 25.2 MHz, and ^{1}Hmr spectra at 100.1 MHz. The undecoupled ^{13}Cmr spectrum of phorbol **1** was run with acquisition time 0.666 s, flip angle 45°, and pulse delay 0.5 s, under conditions of gated decoupling.

ALEXANDER J. FINLAYSON, SAMUEL L. MACKENZIE, and JOHN W. FINLEY. Can. J. Chem. **57**, 2073 (1979).

The reaction of alanine-3-sulfinic acid with 2-mercaptoethanol (2-ME) was examined at pH 1.5 and pH 4.0 at 110°C. The sulfinic acid is readily reduced at pH 1.5 to cysteine, 2-L-amino-7-hydroxy-4,5-dithiaheptanoic acid, cystine, and three other ninhydrin positive substances. The reduction is much slower at pH 4.0; the major reaction product is the 2-ME/cysteine mixed disulfide. The results show that 2-ME at acid pH does not give quantitative reduction of alanine-3-sulfinic acid to cysteine.

ALEXANDER J. FINLAYSON, SAMUEL L. MACKENZIE et JOHN W. FINLEY. Can. J. Chem. **57**, 2073 (1979).

Opérant à 110°C et à des pH de 1.5 et de 4.0, on a étudié la réaction de l'acide alanine sulfinique-3 avec le mercapto-2 éthanol. A un pH de 1.5, l'acide sulfinique est facilement réduit en cystéine, en acide L-amino-2 hydroxy-7 dithia-4,5 heptanoïque, en cystéine et en trois autres substances qui donnent une réaction positive avec la ninhydrine. La réduction est beaucoup plus lente à un pH de 4.0 et le produit principal est le sulfure mixte de M2E/cystéine. Les résultats démontrent qu'à pH acide, le mercapto-2 éthanol ne conduit pas à une réduction quantitative de l'acide alanine sulfinique-3 en cystéine.

Introduction

The oxidations of both protein sulfhydryl and disulfide groups have been shown to be among the contributing factors leading to a wide variety of effects such as enzyme inactivation and reduced protein digestibility. Complete exclusion of oxygen in many reactions involving proteins is not always practical and often small excesses of reducing agents, such as thiols, may be added to protect the sulfur from oxidation.

The reactions between the disulfide reducing agents dithiothreitol (DTT) and 2-mercaptoethanol (2-ME) and cystine have been studied in detail (1, 2) but their reactions with partially oxidized cystine or cysteine derivatives (i.e., alanine-3-sulfinic acid) have not received as much attention. The mechanism for the reduction of a disulfide is generally accepted to be a series of sulfhydryl–disulfide interchange equilibria although the structures of the reactants would influence both the reaction route and the stabilities of the intermediates (2). No doubt, the relative ease of formation of the reducing agent disulfide has an influence on the course of the reaction but since the thiol is nearly always present in excess, its effect on the equilibria is difficult to estimate. The following is one of the accepted mechanisms for disulfide reduction:

$$\left.\begin{matrix} R\text{—}SH + CyS\text{—}SCy \\ R\text{—}S^- + H^+ \end{matrix}\right] \rightleftharpoons RS\text{—}SCy + CyS^-$$

$$RS\text{—}SCy + RS^- \rightleftharpoons CyS^- + RS\text{—}SR$$

$$2CyS^- + 2H^+ \rightleftharpoons 2CySH$$

Because it is possible to have oxidation of the protein disulfide proceed beyond the disulfide stage, it is important to study the reactions of these partially oxidized cystine derivatives with reagents such as DTT and 2-ME. Since 2-ME is widely used in protein chemistry as an anti-oxidant and because the sulfinate state is relatively easily produced by oxidation (3), we have studied the reaction of 2-ME with alanine-3-sulfinic acid at pH 1.5 and 4.0 in an attempt to determine the course of the reduction.

Materials and Methods

Alanine-3-sulfinic acid (Sigma) (1.0 mol) was reduced by 2-ME (Eastman) (1.0 mol to 50 mol excess) at 110°C in a sealed tube for 18 h. A typical experiment was as follows: alanine-3-sulfinic acid (0.013 mmol) in 6 mL 0.05 *M* hydrochloric acid (pH 1.5) containing 0.13 mmol 2-ME was heated at 110°C for 18 h. A series of experiments were also made at pH 4.0, 110°C for 18 h. After reaction, the mixture was evaporated to dryness *in vacuo* at 40°C and stored in a desiccator. A series of reductions at various times from 1 through 18 h at pH 1.5 were made. The reactions of 2-ME at pH 1.5 and 110°C

[1]NRCC No. 17466.

0008-4042/79/152073-05$01.00/0

were also examined to estimate the conditions of formation of the 2-ME disulfide.

The mixed disulfide, 2-L-amino-7-hydroxy-4,5-dithiaheptanoic acid (**1**) was prepared by a modification of the procedure of Abe *et al.* (4). Crystallization of the amino acid (**1**) could not be induced because of the presence of 2-ME side reaction products (i.e., 2-ME disulfide). However, a reasonably pure sample was recovered after chromatography of the reaction mixture on Whatman 3 mm paper using *n*-butanol : ethanol : water (40:11:19) as the solvent. Cystine has an R_f 0.15 while the mixed disulfide had an R_f 0.2. The synthetic **1** had a retention time of 68–69 min on the amino acid analyzer and was distinct from cysteine (62 min) and cystine (90 min). The solid but not crystalline amino acid had a sulfur content of 32.5%; calcd. S content for $C_5H_{11}NO_3S_2$, 32.4%. The mixed disulfide was reduced by 2-ME in 0.05 *M* hydrochloric acid as described above.

Aliquots of all experiments were analyzed by both ion exchange amino acid analysis (Beckman model 120C) and gas–liquid chromatography (gc) (Hewlett-Packard model 7611). Samples for gc were converted to their *N*(*O*)-heptafluorobutyryl (HFB) isobutyl derivatives in the case of amino acids and to their *N*(*O*,*S*)-HFB derivatives for the 2-ME reaction products (5). The column packing and operating temperatures of the gc have been previously described (5). Mass spectra were obtained using a Finnigan model 3300 gas chromatograph – mass spectrometer operated in both the electron impact (ei) mode and the chemical ionization (ci) mode. In the latter mode, methane was used as the carrier gas. All data manipulations were performed using an INCOS data system.

Results and Discussion

The reduction of alanine-3-sulfinic acid at both pH 1.5 and 4.0 produced six ninhydrin positive substances (Fig. 1), three of which appear to represent one of the reduction routes. They are cysteine, the mixed disulfide, 2-L-amino-7-hydroxy-4,5-dithiaheptanoic acid (**1**), and cystine. A number of ninhydrin negative compounds were also produced; two of them are 2,2′-dihydroxydiethyl disulfide and a 'polymer' derived from 2-ME (Fig. 2).

Synthetic **1** was prepared by the method of Abe *et al.* (4); it and the material isolated from the reduction were indistinguishable on both ion exchange and gas–liquid chromatography. The ci mass spectra of **1** from both sources were the same; the major fragmentation peaks are given in Table 1. The molecular weight of the acylated ester of **1** was identified by the ions $M + 1$ (*m/e* 646), $M + 29$ (*m/e* 674), and $M + 41$ (*m/e* 646). The series of ions $M - C_4H_7$ (*m/e* 590), $M - OC_4H_9$ (*m/e* 572), and $M - OCOC_4H_9$ (*m/e* 544) are characteristic of isobutyl esters of a carboxylic acid (6). The mixed disulfide (**1**) was eluted 7 min after cysteine (Fig. 1) on the amino acid analyzer using the protein hydrolyzate buffer system. It was eluted at 27 min on the SE-30 gc column (10 ft × 2 mm id) as its HFB isobutyl derivative (Fig. 2). The recovery of the mixed disulfide corresponds with the results of other work (2) where it has been suggested as an intermediate in the reduction of cystine by 2-ME. The yield of **1** increases until the molar ratio of sulfinic acid:2-ME is about 1:10 but then it declines as the 2-ME concentration increases (Fig. 3).

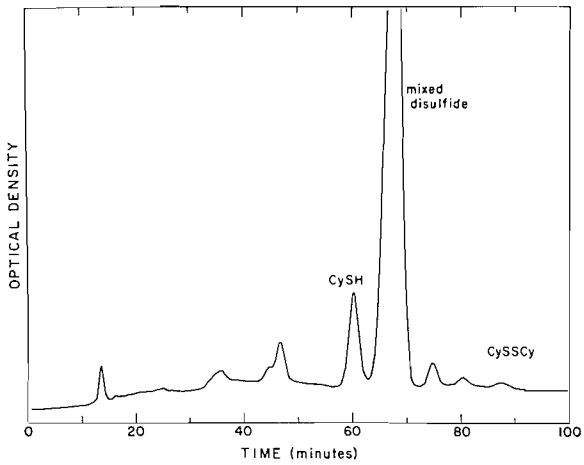

FIG. 1. Reproduction of the amino acid analyzer trace of the reaction products from the reduction of alanine-3-sulfinic acid by 2-mercaptoethanol (1 mol amino acid:20 mol 2-ME) at pH 1.5. The elution times are: cysteine (CySH), 59–61 min; the 2-ME/cysteine mixed disulfide, 68–69 min; cystine (CySSCy) 88–90 min.

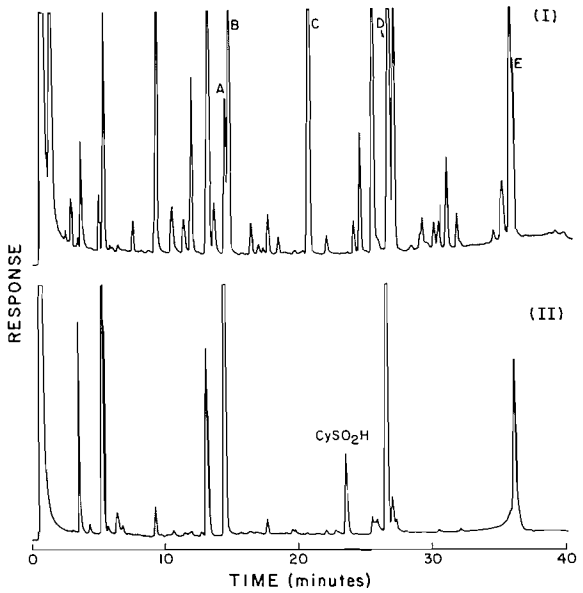

FIG. 2. Chromatographs of *N*(*O*,*S*)-heptafluorobutyryl isobutyl esters of reaction products of alanine-3-sulfinic acid ($CySO_2H$) and 2-mercaptoethanol (2-ME). (I) Reaction mixture of 0.013 mmol $CySO_2H$ and 0.065 mmol 2-ME in 1 *M* HCl at 110°C for 18 h. (II) Reaction mixture of 0.013 mmol $CySO_2H$ and 0.065 mmol 2-ME in water (pH 4.0) at 110°C for 18 h. Peak A denotes the dimer of 2-ME and corresponds to the major peak in II; peak B is cysteine (not present in II); peak C is $(HO—CH_2CH_2—S—CH_2)_2$; peak D is 2-L-amino-7-hydroxy-4,5-dithiaheptanoic acid (present in II); and peak E is cystine.

An analogous reaction between cystine and dithiothreitol (DTT) is considered to involve the mixed

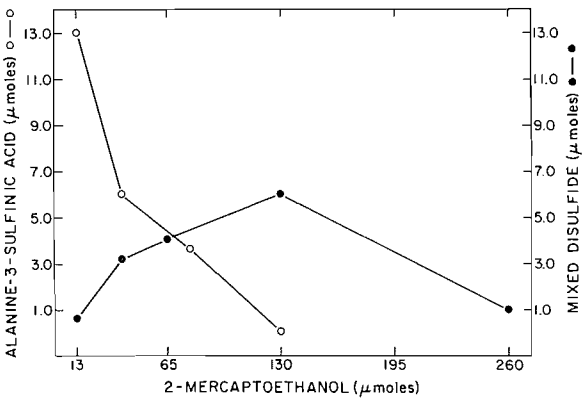

FIG. 3. Yields of the mixed disulfide, 2-L-amino-7-hydroxy-4,5-dithiaheptanoic acid (closed circles), produced from the reduction of alanine-3-sulfinic acid by 2-mercaptoethanol (pH 1.5). Recoveries of unreacted alanine-3-sulfinic acid are shown by the open circles.

disulfide intermediate (**2**) which subsequently reacts with another mole of DTT to yield cysteine.

The release of cysteine from **2** is 10^3–10^4 times faster than it is from the 2-ME/cysteine disulfide and furthermore the rate of reaction between a thiol and the mixed disulfide (DTT/Ellman's reagent) (2) is 10–10^2 times faster than the reaction between a thiol and the 2-ME/Ellman's reagent disulfide. Thus, the recovery of **1** in most of the experiments here is not unusual. It appears then that an excess of 2-ME is required to react with **1** completely although large excesses would certainly enhance the rates of its side reactions (7).

The disulfide, 2,2′-dihydroxydiethyl disulfide is one of the major reaction products (Fig. 2). Its ei mass spectrum (diacylated derivative) is given in Table 2. The molecular ion *m/e* 546 was identified by ei ionization and confirmed by ci. The ions *m/e* 333 ($M - C_3F_7COO$), *m/e* 273 (*M*/2), *m/e* 241 ($C_3F_7COOCH_2CH_2$), *m/e* 169 (C_3F_7), and *m/e* 91 ($CH_2—S—S—CH_2$) were consistent with the structure of the 2,2′-dihydroxydiethyl disulfide. Although a sulfur atom may be hard to distinguish from two oxygen atoms, it is difficult to imagine how such oxygenated derivatives could be products of this reaction. Other compounds from 2-ME are produced in amounts which are related to the acid concentration. The mass spectral data indicate a possible structure for peak C (Fig. 2(I)) is

$$HO—CH_2CH_2—S—(CH_2CH_2—S)_n—CH_2CH_2OH$$

where n = 10–20 accommodates the observed sulfur content. The recovery of this material with about 50% S appears to eliminate the possibility that the 'polymer' is a disulfide. Its production was favored by HCl concentrations of 0.1 *M* and higher. At pH 4, the reaction produced only the dimer of 2-ME (Fig. 2(II)).

Alanine-3-sulfinic acid is readily reduced by 2-ME at acid pH; under the conditions studied here, cysteic acid is not reduced. The sulfinic acid is reduced much more slowly at pH 4.0 than it is at pH 1.5 (Figs. 4, 5) and excess reducing agent is required; 3- to 4-fold excesses do not give complete reduction of the sulfinic acid. For instance, it has completely reacted in 4 h at pH 1.5 but at pH 4.0 about 10% of the sulfinic acid remains after 18 h (Fig. 5). In spite of the slow reaction, the mixed disulfide (**1**) appears to be the initial, stable ninhydrin positive substance produced until the 2-ME concentration in the reaction mixture is about 10 times that of the amino acid. Since at least 10 mol of 2-ME at pH 1.5 are required to react com-

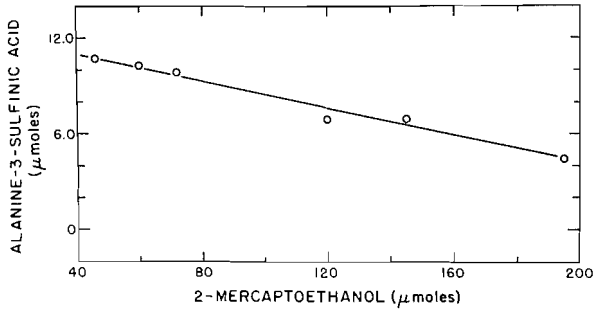

FIG. 5. Amounts of alanine-3-sulfinic acid after reaction with 2-mercaptoethanol for 18 h at 110°C (pH 4.0).

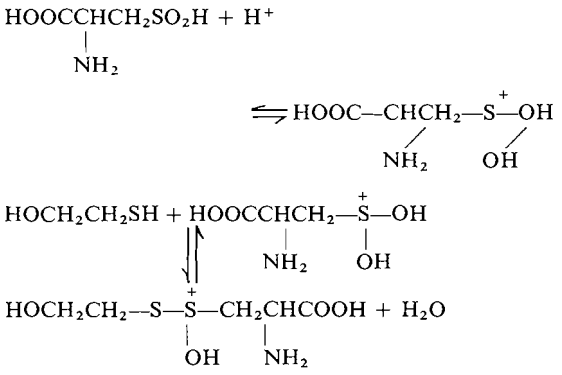
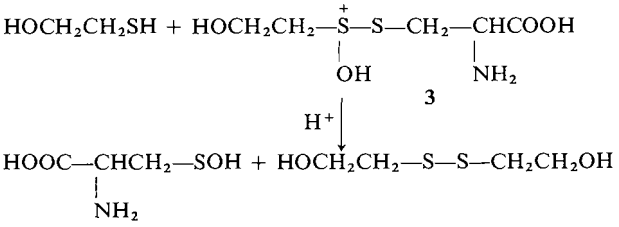
pletely with alanine-3-sulfinic acid, it is obvious the side reactions of 2-ME contribute to the requirement for excess reducing agent. Although the yield of cysteine does not exceed 35% even with a 50-fold excess of 2-ME, a 20-fold excess gives a 30% yield. The yield of cysteine is higher (60%) when alanine-3-sulfinic acid is reduced by DTT in a 1:20 mol ratio; this result agrees with the observation (2) that the cysteine/DDT mixed disulfide is more susceptible to reduction than **1**. Cystine is produced at intermediate concentrations (approximately 20-fold) of 2-ME at pH 4.0 but its recovery is very low at the higher concentrations of reducing agent.

There are three other ninhydrin positive compounds produced in small amounts during the reduction but not all of them have been positively identified. It is not clear where they fit into the reaction scheme. The results we have obtained from the quantitation of **1**, cysteine, and cystine suggest the following as a possible reaction sequence: the initial step is probably the protonation of the sulfinate group analogous to that proposed for the thiosulfinate group (8).

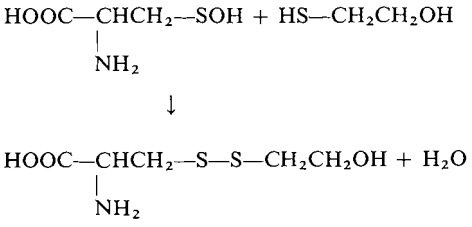


3

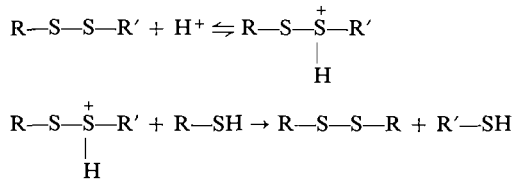
Subsequent displacement of the hydroxyl on the sulfur by 2-ME yields the hydroxydisulfide (**3**) which then reacts with a second molecule of 2-ME giving 2,2′-dihydroxydiethyl disulfide and the sulfenic acid, R—SOH.



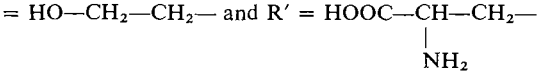
The sulfenic acid, which is apparently too unstable to isolate (9), is then reduced to the mixed disulfide (**1**) by displacement of the hydroxyl on the sulfenic acid by 2-ME.



In excess 2-ME, the mixed disulfide is reduced to cysteine although the cysteine yields do not exceed 35% (Fig. 4). The sequence



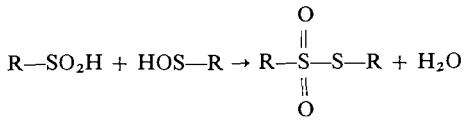
where



has been suggested (10) to account for disulfide interchange in acid solutions. Presumably, a sulfur atom in the mixed disulfide could be protonated and thus convert a poor leaving group (RS′—) into a better one (10). Subsequent nucleophilic attack by RSH produces the 2-ME disulfide (R—S—S—R) and cysteine (R′—SH). The low yields of cysteine, even when large excesses of thiol are present, may be explained by the stability of the mixed disulfide (**1**) or may result from increases in the rates of side reactions of 2-ME when it is present in high concentrations (2–3 m*M*). For instance, a 3 m*M* solution of 2-ME in 0.5 *M* HCl at 110°C for 18 h gave an 85% yield of the 'polymer'.

The reaction sequence outlined above agrees with the finding that **1** is the initial, stable reaction product and that cysteine and cystine are subsequently derived from it. Because 2-ME itself forms 2,2′-dihydroxydiethyl disulfide under all the conditions examined here, its complete role in the reaction sequences is difficult to assess. High concentrations of it may well inhibit interchange (11) and thus reduce the yields of cysteine but no doubt they also enhance the rates of the other reactions which 2-ME undergoes.

The reduction of alanine-3-sulfinic acid has been postulated to pass through a sulfinic acid intermediate. It has been shown that aryl sulfinic acids and sulfenic acids condense in the following manner (8):



It is not clear if this route occurs in the present case since the cystine dioxide ($CySO_2SCy$) dismutates under acid conditions to alanine-3-sulfinic acid and cystine. The reaction could represent the source of cystine, however.

Some experiments on the reduction by 2-ME of both native and partially oxidized hen's egg white lysozyme showed, after acid hydrolysis, that an amino acid was produced which had chromatographic characteristics the same as **1**. Thus, reductive hydrolysis of a protein using 2-ME at an acid pH would produce some mixed disulfide (**1**); in fact, exposure of the protein to 2-ME at room temperature results in the slow formation of **1**.

To conclude, the results show very clearly that, because of the stability of the cysteine/2-ME mixed disulfide, the reduction at acid pH of alanine-3-sulfinic acid by 2-ME does not give quantitative recoveries of cysteine and that the ratios of the products obtained are pH dependent. Further, the slow release of cysteine from the mixed disulfide is one of the limiting factors in the use of 2-ME for the reduction of either protein cystine residues or their partly oxidized derivatives.

Ion association and charge-transfer excitation between *N*-heterocyclic cations and cyanoiron complexes

HENRIQUE E. TOMA
Instituto de Química, Universidade de São Paulo, Caixa Postal 20780, São Paulo, Brasil

Received December 13, 1978

HENRIQUE E. TOMA. Can. J. Chem. 57, 2079 (1979).

N-Heterocyclic cations form with substituted pentacyanoferrates a series of outer-sphere complexes of general formula $Fe(CN)_5L//N$-Het, suitable for systematic studies in aqueous solution. The equilibrium constants for the association of dipositive cations (e.g. *N,N'*-dimethyl-4,4-bipyridyl, or paraquat ion) and monopositive cations (e.g. *N*-methylpyrazinium) with the hexacyanoferrate(II) anion are typically in the range of 30–40 M^{-1} and 10–13 M^{-1}. The optical charge-transfer energies depend on the nature of the *N*-heterocyclic acceptor, and on the binding properties of the ligand L as they modify the ionization potentials of the $Fe(CN)_5L^{n-}$ complexes. A linear correlation between the optical charge-transfer energies and ΔE^0 was found, with a slope $(\Delta E_{op}/\Delta G^0)$ of 1.03 ± 0.03. The results were interpreted on the light of Hush's theory for intervalence transitions, with the aid of the equation $E_{op} = 2(\Delta G_{11}^* + \Delta G_{22}^*) + \Delta G_{12}^0$, which correlates the optical energy (E_{op}) for electron-transfer with the intrinsic barriers $(\Delta G_{11}^* + \Delta G_{22}^*)$ of the donor and acceptor ions, and the free energy change (ΔG_{12}^0) for the process.

HENRIQUE E. TOMA. Can. J. Chem. 57, 2079 (1979).

Les cations *N*-hétérocycliques forment avec des pentacyanoferrates substitués une série de complexes de couche externe de formule générale $Fe(CN)_5L//N$-Het, qui sont appropriés pour des études systématiques en solutions aqueuses. Les constantes d'équilibre pour l'association de cations doublement positifs (comme *N,N'*-diméthylbipyridyl-4,4' ou l'ion paraquat) et de cations monopositifs (comme le *N*-méthylpyrazinium) avec l'anion hexacyanoferrate(II) s'échelonnent entre 30–40 M^{-1} et 10–13 M^{-1}. Les énergies de transfert de charge optique dépendent de la nature de l'accepteur *N*-hétérocyclique et des propriétés de liaison du ligand L puisqu'elles modifient les potentiels d'ionisation des complexes $Fe(CN)_5L^{n-}$. On a trouvé une corrélation linéaire entre les énergies de transfert de charge optique et ΔE^0 avec une pente $(\Delta E_{op}/\Delta G^0)$ de 1.03 ± 0.03. On interprète les résultats à la lumière de la théorie de Hush relative aux transitions d'intervalle à l'aide de l'équation $E_{op} = 2(\Delta G_{11}^* + \Delta G_{22}^*) + \Delta G_{12}^0$ qui établit une relation entre l'énergie optique (E_{op}) pour le transfert électronique et les barrières intrinsèques $(\Delta G_{11}^* + \Delta G_{22}^*)$ des ions donneurs et accepteurs et le changement d'énergie libre (ΔG_{12}^0) du processus.

[Traduit par le journal]

Introduction

Aromatic, *N*-heterocyclic cations are of great interest in electron-transfer processes. Due to their high electron affinities, they can act as quenchers of the luminescence of many excited molecules in solution (1, 2), also being able to inhibit the electron-transfer in the cytochrome chain of mitochondria and the electron-transfer chain of chloroplasts.

In the presence of donor species, e.g. iodide (3, 4), MX_4^{2-} ions (5) (M = Cu, Mn, Fe, Co, Zn, Cd, Hg, Pb, Pd, Ag, and Sn; X = Cl, Br, and I) and dianionic dithiolene complexes (6), the aromatic *N*-heterocyclic cations exhibit characteristic charge-transfer bands in the visible and ultraviolet regions, indicative of the occurrence of donor–acceptor interactions.

Generally, the energy of the charge-transfer bands does not depend solely on the nature of the donor and acceptor species, but also, on the properties of

0008-4042/79/162079-06$01.00/0

the solvents. A very useful parameter of solvents (7) has been introduced by Kosower (8) based on the strong solvatochromism exhibited by 1-alkylpyridinium iodides, particularly 1-ethyl-4-methoxycarbonylpyridinium iodide.

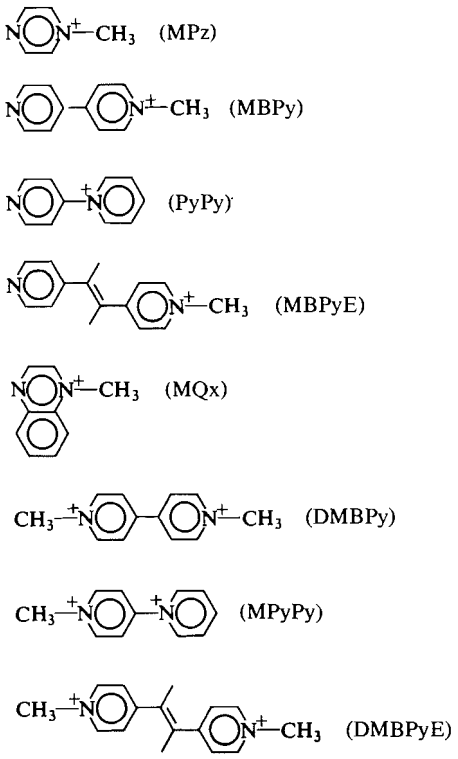
Despite the importance of charge-transfer association in aqueous solution the number of systematic studies reported up to the present in the literature is relatively small. It is well known that many pyridine and pyrazine cations can coordinate with π-donor ions such as $Ru(NH_3)_5^{2+}$ and $Fe(CN)_5^{3-}$, forming stable, internal charge-transfer complexes (9, 10). However, the outer-sphere association of the *N*-heterocyclic cations with such donor ions in aqueous solution has never been investigated.

In this paper, a study on the association of a series of substituted cyanoiron complexes and *N*-heterocyclic cations is reported, showing the trends and correlation which exist between the optical electron-transfer energies and the electrochemical properties of the donor and acceptor ions.

Experimental

Compounds

The pentacyanoferrate(II) compounds were prepared from sodium amminepentacyanoferrate(II) trihydrate, as previously described (2, 10–12). The aromatic *N*-heterocyclic cations below were obtained as iodide salts according to the following procedures:



N-Methylpyrazinium Iodide (MPzI) and N-*Methylquinoxalinium Iodide (MQxI)*

Pyrazine (10 g) (Aldrich, gold label) or quinoxaline (Aldrich) was dissolved in 50 mL of methyl iodide and the resulting solution was kept in the dark at room temperature for one week. The hygroscopic yellow (MPzI) or brown (MQxI) crystals formed were recrystallized from ethanol at 60°C and stored under vacuum. *Anal.* calcd. for $C_5N_2H_7I$ (MPzI): C 27.0, N 12.6, H 3.18; found: C 27.1, N 12.8, H 3.22. *Anal.* calcd. for $C_9N_2H_9I$ (MQxI): C 39.7, N 10.9, H 3.33; found: C 40.2, N 10.3, H 3.28.

N-*Methyl-4,4′-bipyridyl Iodide (MBPyI) and* N-*Methyl-1,2-bis(4-pyridyl)ethylene Iodide (MBPyEI)*

4,4′-Bipyridyl (2 g) (Aldrich) or 1,2-bis(4-pyridyl)ethylene (Aldrich) was dissolved in 50 mL of benzene, filtered, and then mixed with 2 mL of methyl iodide. After 3 days in the dark, the yellow solids formed were separated by filtration and recrystallized from ethanol (60°C). *Anal.* calcd. for $C_{11}N_2H_{11}I$ (MBPyI): C 44.3, N 9.39, H 3.72; found: C 44.7, N 9.41, H 3.69. *Anal.* calcd. for $C_{13}N_2H_{13}I$ (MBPyEI): C 48.2, N 8.63, H 4.04; found: C 47.5, N 8.71, H 4.06.

N,N′-*Dimethyl-4,4′-bipyridyl Iodide (DMBPyI$_2$) and* N,N′-*1,2-bis(4-pyridyl)ethylene Iodide (DMBPyEI$_2$)*

4,4′-Bipyridyl (2 g) or 1,2-bis(4-pyridyl)ethylene was dissolved in 50 mL of benzene in the presence of 5 mL of ethanol, and mixed with 20 mL of methyl iodide. The solution was stirred in the dark for one week at room temperature. The red-orange solid formed was separated by filtration and washed with ethanol. The presence of monomethylated products can be easily tested by dissolving a very small amount of the solid in an aqueous solution of the $Na_3Fe(CN)_5NH_3$ complex. A red or violet color indicates the formation of $Fe(CN)_5$(MBPy) or $Fe(CN)_5$(MBPyE) complexes, respectively. When the test was positive, the solid was stirred in a methanolic methyl iodide solution for three days and then filtered and washed with ethanol. The bimethylated cations, in contrast to the monomethylated ones, do not coordinate with the pentacyanoferrate(II) ion. *Anal.* calcd. for $C_{14}N_2H_{16}I_2$ (DMBPyEI$_2$): C 36.1, N 6.00, H 3.46; found: C 36.4, N 6.55, H 3.33. *Anal.* calcd. for $C_{12}N_2H_{14}I_2$ (DMBPyI$_2$): C 32.7, N 6.36, H 3.20; found: C 32.3, N 6.64, H 3.31.

4-Pyridylpyridinium Iodide (PyPyI) and N-*Methyl-4-pyridylpyridinium Iodide (MPyPyI$_2$)*

Pyridylpyridinium hydrochloride (4.5 g) (Aldrich) was dissolved in 100 mL of methanol and then carefully neutralized with 0.85 g of solid lithium hydroxide. The yellowish solution was mixed with 100 mL of ethanol containing 6 g of sodium iodide and then filtered. To this solution, 100 mL of ethyl ether was added in order to precipitate the pyridylpyridinium salt. The solid was dissolved in 200 mL of ethanol at 60°C, and filtered through a sintered glass filter. After one day in the freezer, bright yellow crystals of PyPyI were obtained. The ethanolic solution containing an appreciable amount of dissolved pyridylpyridinium iodide was treated with 20 mL of methyl iodide. After a week in the dark, the orange-brown crystals of the MPyPyI$_2$ salt were separated from the solution and washed with pure ethanol. The product gave a negative test with the pentacyanoferrate(II) ion. *Anal.* calcd. for $C_{10}N_2H_9I$ (PyPyI): C 42.3, N 9.86, H 3.19; found: C 42.1, N 9.28, H 2.90. *Anal.* calcd. for $C_{11}N_2H_{12}I_2$ (MPyPyI$_2$): C 31.0, N 6.57, H 2.83; found: C 31.7, N 6.57, H 2.75.

Spectra

Ultraviolet–visible range spectra were measured on a Cary 14 spectrophotometer at room temperature. Most scans

were made using 10.0 mm quartz cells and solutions containing equimolar amounts of the $Fe(CN)_5L^{n-}$ complexes and of the *N*-heterocyclic ions (usually 10^{-2} *M*). A corresponding solution of the *N*-heterocyclic ion was used as a blank to correct for the absorption of the reactant at the proximity of the ultraviolet region.

Equilibrium Constants

The determination of the association constants of the outer-sphere complexes was made spectrophotometrically, using the 0–0.1 expanded absorbance scale of the Cary 14 spectrophotometer. Potassium nitrate was used to adjust the ionic strength of the 10^{-3} *M* solutions of the donor and acceptor ions. All the manipulations and measurements were carried out in the dark. Solutions of ferrocyanide should be previously stabilized with traces of sodium cyanide; otherwise, the small amounts of $Fe(CN)_5H_2O^{3-}$ which result from the thermal and photochemical dissociation of $Fe(CN)_6^{4-}$ react readily with the monomethylated ions such as MPz and MQx, masking the absorption of the charge-transfer complexes in solution. Such a precaution is not necessary for the dimethylated ions; however, in any case an excess of the CN^- ion should be avoided since this ion was observed to react with most of the *N*-heterocyclic cations. For the $Fe(CN)_5L^{n-}$ complexes, an excess of L was maintained in solution to prevent the dissociation of the coordinated ligand.

The equilibrium constants at 25°C and 0.100 *M* KNO_3 were computed by an iterative procedure, using a Hewlett-Packard, Model 97, calculator. Details concerning the method used to calculate the equilibrium constants are presented in the text.

Results and Discussion

In order to observe the formation of outer-sphere complexes in aqueous solution, a high concentration of the donor and acceptor ions is usually required, since most of the complexes are relatively unstable in ionizing solvents. Moreover, in many cases, the charge-transfer bands of these kind of complexes fall in the ultraviolet region, where they are frequently masked by the absorptions of the donor and acceptor ions. All these difficulties probably explain the small number of systematic studies on charge-transfer interactions in outer-sphere complexes in aqueous solution, reported up to the present in the literature.

By using the highly charged $Fe(CN)_6^{4-}$ ion as a donor, it was possible to detect the occurrence of typical charge-transfer interactions with *N*-heterocyclic cations in aqueous solution. Since $Fe(CN)_6^{4-}$ is very inert to substitution and most of the *N*-heterocyclic cations investigated here cannot coordinate to metal ions, an outer-sphere association process can be postulated, as indicated below.

$$Fe(CN)_6^{4-} + N\text{-Het}^+ \rightleftharpoons Fe(CN)_6^{4-}//N\text{-Het}^+$$

In all the cases, a new, broad band was observed in the visible region, as shown in Fig. 1. The absorption band, not observed in the spectra of the donor and acceptor ions separately, was assigned to the electron-transfer transition, $d(t_{2g}^6)\cdot p(\pi^0)^* \rightarrow d(t_{2g}^5)\cdot p(\pi^1)^*$,

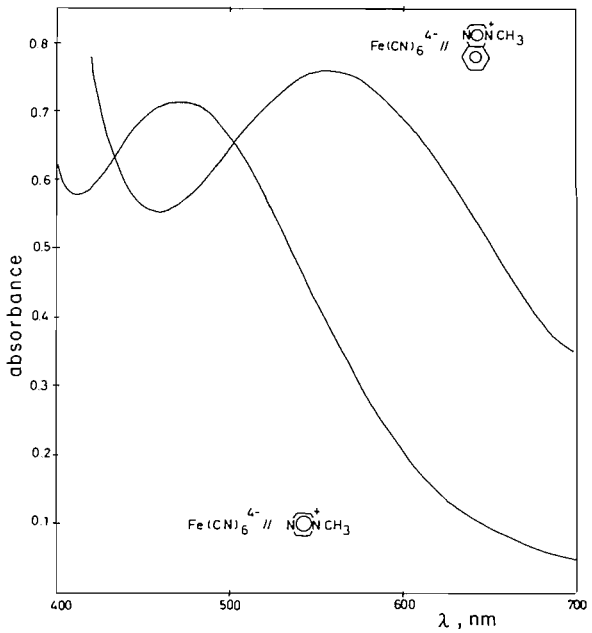


FIG. 1. Absorption spectra of 0.020 *M* solutions of $Fe(CN)_6^{4-}$ and MQx, or MPz ions.

from the occupied metal d_{xz}, d_{yz}, and d_{xy} orbitals to the lowest unoccupied π^* orbitals of the aromatic *N*-heterocyclic cations.

The charge-transfer nature of the $Fe(CN)_6^{4-}//N\text{-Het}^+$ complexes was corroborated by the spectra of acetonitrile solutions of the iodide salts of the *N*-heterocyclic cations, which also exhibited the characteristic charge-transfer bands, although shifted to higher energies. A comparison of the CT energies of the hexacyanoferrate(II) and iodide complexes of the various *N*-heterocyclic cations can be seen in Table 1.

The trends in the energies of the optical electron-transfer can be rationalized according to the simplified equation (13, 14)

$$[1] \quad E_{op} = I_D - E_A + C$$

where I_D is the ionization potential of the donor, E_A is the electron affinity of the acceptor, and C is a coulombic term. For a given donor, D, as the electron affinity of the acceptor A increases, the optical electron-transfer energy is expected to decrease proportionally. Therefore, based on Table 1, the following order of electron affinity can be postulated, MQx > DMBPyE ~ DMBPy > MPyPy > MPz > MBPyE > MBPy ~ PyPy, with the *N*-methylquinoxalinium cation (MQx) as the best electron acceptor of the series.

It is interesting to note that some of the organic

acceptors can form stable complexes, by coordinating with the $Fe(CN)_5^{3-}$ ion. Such complexes display very strong charge-transfer bands in the visible, in contrast with the medium-weak intensity observed for most of the outer-sphere complexes. The inner-sphere complexes have been previously investigated by Toma and Malin (10) and are collected in Table 1 for comparison purposes. Although the trends in the electron acceptor properties are practically the same in the three series of complexes (Table 1), it seems that the charge-transfer energies vary more rapidly for the inner-sphere complexes, as compared with the outer-sphere analogs. This may be due to the strong interaction between the metal and the *N*-heterocyclic cation in the inner-sphere complexes, in contrast to the weak interactions in the outer-sphere complexes.

The association constants of the $Fe^{II}(CN)_6//N\text{-Het}^+$ charge-transfer complexes were evaluated from spectrophotometric measurements of equimolar solutions of the donor and acceptor ions (1.0–7.0 × 10^{-3} *M*) using the equation

$$[2]\quad \kappa = \frac{[Fe^{II}(CN)_6^{4-}//N\text{-Het}^+]}{[Fe^{II}(CN)_6^{4-}][N\text{-Het}^+]} = \frac{\varepsilon \cdot A}{\{\varepsilon[Fe(CN)_6^{4-}]_T - A\}\{\varepsilon[N\text{-Het}^+]_T - A\}}$$

where *A* is absorbance, and the subscript T refers to the total concentration of the species. Since the extinction coefficient, ε, for the charge-transfer complex is not known, an iterative procedure was employed in order to obtain the best value of this parameter which minimizes the standard deviation over κ.

For dipositive cations such as DMBPy, association constants of 30–40 M^{-1} were obtained, as compared with 10–13 M^{-1} for monopositive cations such as MPz and MQx. The optimized extinction coefficients were typically 150–200 M^{-1} cm^{-1}, varying slightly with the acceptor properties of the *N*-heterocyclic cation. The association constants agree reasonably well with those predicted for outer-sphere complexes, using the Eigen–Fuoss equation (15) with the crystallographic distance for ferrocyanide (16) (4.4 Å) and approximate radii, previously measured (e.g. DMBPy (17), 6.0 Å; MPz (18), 2.10 Å; MQx (18), 3.12 Å) for some of the *N*-heterocyclic cations.

In order to test for the influence of the donor ion on the charge-transfer energies, the DMBPy ion was used as acceptor (19) in the presence of a series of $Fe(CN)_5L^{n-}$ complexes, where L = CO, dimethylsulfoxide (DMSO), triphenylphosphine, CN^-, pyridine, and imidazole. Some typical charge-transfer spectra obtained for these outer-sphere complexes can be seen in Fig. 2.

The charge-transfer energies of the $Fe(CN)_5L^{n-}//$DMBPy complexes follow approximately the trends of the spectrochemical series for L, in the sequence: 18 000 (imidazole); 18 800 (pyridine); 19 700 (triphenylphosphine); 22 200 (S-bound dimethylsulfoxide); and 25 000 cm^{-1} (CO). The result agrees with the expected behavior from eq. [1], since the stabilization of the metal d_π orbitals through back-bonding interactions with the unsaturated ligands should increase the ionization potentials of the donor ion.

The electronic excitation in the $Fe(CN)_5L^{n-}//N\text{-Het}^+$ complexes can be regarded as an optical

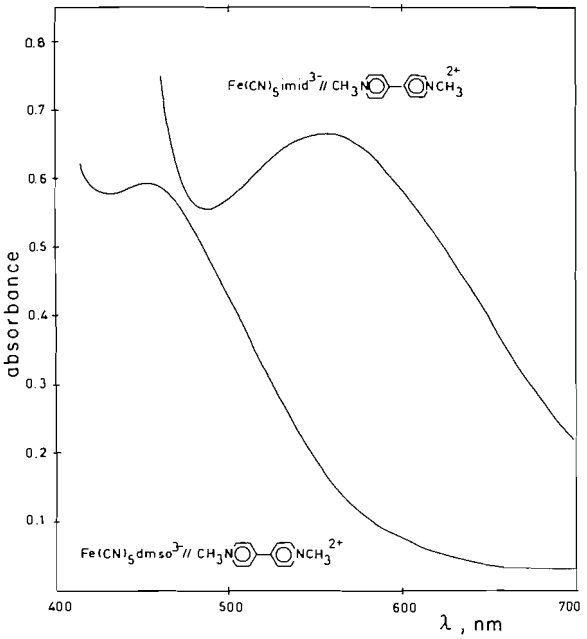

FIG. 2. Absorption spectra of 0.020 *M* solutions of the DMBPy and $Fe(CN)_5(imidazole)^{3-}$ or $Fe(CN)_5(dmso)^{3-}$ ions.

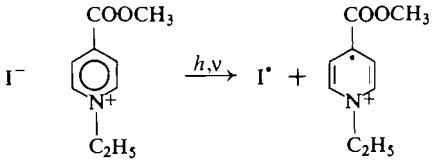
electron-transfer process,

$$Fe^{II}(CN)_5L//N\text{-Het}^+ \xrightarrow{h\nu} Fe^{III}(CN)_5L//N\text{-Het}$$

as in the so-called 'mixed-valence complexes'. Indeed, evidence for radicals has been reported (20), for example, in the photoexcitation of the 4-carbomethoxy-1-ethylpyridinium iodide charge-transfer complex,



It would be interesting now to compare the optical excitation in those complexes with the thermal electron-transfer process. It is well known that both the $Fe(CN)_5L^{n-}$ complexes and the *N*-heterocyclic species can participate in electron-transfer reactions, acting as reducing and oxidizing agents, respectively. Electron-transfer (1, 2) with excited molecules, e.g. $*Ru(bipy)_3^{2+}$, has proved to be very effective with most of the *N*-heterocyclic cations, proceeding with diffusion controlled rates for DMBPy (1), DMBPyE (1), and MPz (2) cases,

$$*Ru(bipy)_3^{2+} + N\text{-Het}^+ \rightarrow Ru(bipy)_3^{3+} + N\text{-Het}^{\bullet}$$

For a general case of outer-sphere electron-transfer reaction, the following steps have been postulated (21):

$$Ox_1 + Red_2 \rightleftharpoons Ox_1//Red_2$$

$$Ox_1//Red_2 \rightleftharpoons Red_1//Ox_2$$

$$Red_1//Ox_2 \rightleftharpoons Red_1 + Ox_2$$

The activation energies for electron-transfer within the outer-sphere complex, $Ox_1//Red_2$, can be expressed according to the Marcus (22) and Hush (23) equation,

$$[3] \quad \Delta G_{12}^* = (\Delta G_{11}^* + \Delta G_{22}^*)/2 + \Delta G_{12}^0/2$$

provided that $(\Delta G_{12}^0)^2 \ll 8(\Delta G_{11}^* + \Delta G_{22}^*)$. Here, ΔG_{12}^* refers to the activation barrier for electron-transfer from Ox_1 to Red_2, and ΔG_{11}^* and ΔG_{22}^* are the intrinsic barriers associated with the self-exchange reactions, respectively. The ΔG_{12}^0 term expresses the free energy change for the net reaction, and is proportional to the difference of the electrochemical potentials, ΔE_{12}^0, of the reactants.

For an optical electron-transfer process, as shown in Fig. 3, the excitation energy deduced from the harmonic potentials (24) can be expressed by

$$[4] \quad E_{op} = 2(\Delta G_{11}^* + \Delta G_{22}^*) + \Delta G_{12}^0$$

For a symmetrical system, based on eqs. [4] and [3], the energy of the optical Franck–Condon transition is predicted to be four times the activation energy for the thermal electron-transfer. For a non-symmetrical system, as is the case of the complexes reported here, the relationship between E_{op} and E_{th}, the optical and thermal energies, respectively, becomes

$$[5] \quad E_{op} = 4E_{th} - \Delta G_{12}^0$$

Based on eq. [4] one can also expect that the energies of optical electron-transfer in a series of complexes with similar intrinsic barriers should increase linearly with ΔG_{12}^0, with a unit slope. This

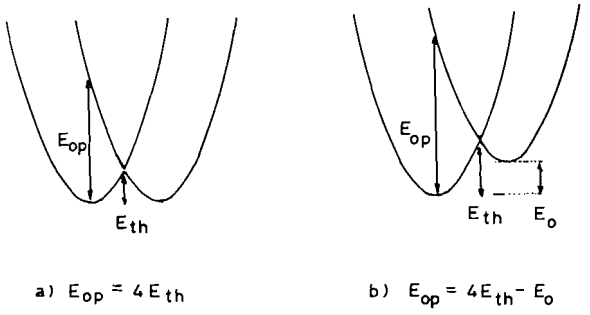


FIG. 3. Reaction coordinate diagrams for electron-transfer: (*a*) $\Delta G^0 = 0$; (*b*) $\Delta G^0 > 0$.

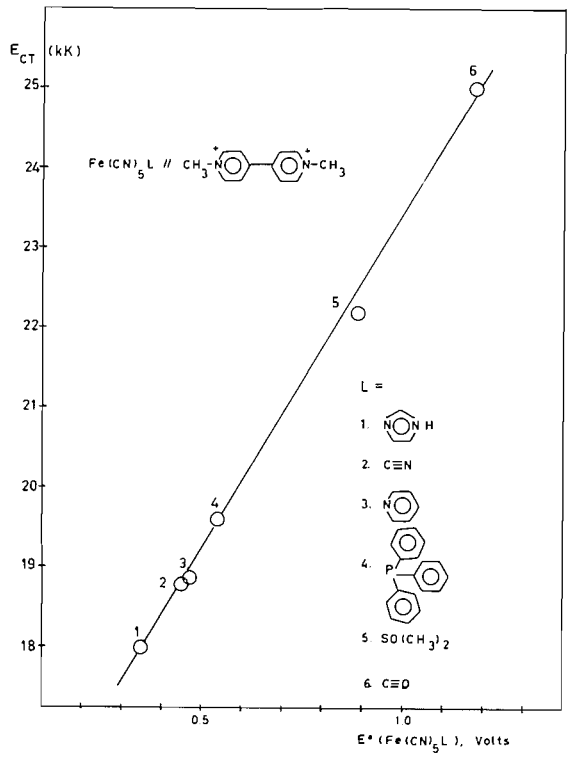

FIG. 4. Correlation of charge-transfer energies with the ΔE^0 values (ref. 2) of the $Fe(CN)_5L$ complexes.

expectation differs from the case of thermal electron-transfer (21), where the theoretical slope of the linear relationship between $\Delta G_{12}{}^*$ and $\Delta G_{12}{}^0$ equals 1/2.

In order to test for the validity of Hush's theory in the outer-sphere complexes reported here, one can estimate the free energy changes from the electrochemical potentials of the free, donor, and acceptor ions, with the assumption that they are not influenced in a significant extent, by the association process. As shown in Fig. 4, a good linear correlation between E_{op} and $\Delta G_{12}{}^0$ (proportional to the E^0 values for the $Fe(CN)_5L$ complexes) results for the several DMBPy//$Fe(CN)_5L$ complexes, with a calculated slope of 1.03 ± 0.03.

A linear correlation between E_{op} and E^0 has also been reported (6) for a series of outer-sphere complexes between pyridinium cations and dianionic, dithiolene complexes, as well as for a series of pyridinium iodides (4). The observed slopes ($\Delta E_{op}/\Delta G_{12}{}^0$) were respectively 1.24 and 1.25 for those series of complexes. A similar behavior has been observed recently for a number of $Ru(NH_3)_6{}^{3+}$//$Fe(CN)_5L^{3-}$ complexes (25, 26).

It is remarkable that the agreement with the theory seems quite reasonable, despite the obvious criticism which arises from the use of harmonic potentials to describe the optical and thermal electron-transfer barriers.

Stannic tetrachloride catalysed glycosylation of 8-ethoxycarbonyloctanol by cellobiose, lactose, and maltose octaacetates; synthesis of α- and β-glycosidic linkages[1]

JOSEPH BANOUB[2] AND DAVID R. BUNDLE

Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received December 21, 1978

JOSEPH BANOUB and DAVID R. BUNDLE. Can. J. Chem. 57, 2085 (1979).

The 1,2-*trans*-octaacetates of cellobiose, lactose, and maltose were converted to β-glycosides of 8-ethoxycarbonyloctanol in good yield by a single step reaction. A 1,2-acetoxonium ion generated by stannic tetrachloride in dichloromethane at −10°C leads initially to β-glycosides via 1,2-orthoacetate intermediates. *In situ* anomerisation of the β-maltoside occurred during reaction (4 h) at room temperature and provided a preparative route to this α-glycoside of the disaccharide. The β-lactose and cellobiose glycosides were also anomerised to the respective α-glycosides. The three β- and three α-disaccharide glycosides of the disaccharides have been functionalised for conversion to artificial carbohydrate antigens.

JOSEPH BANOUB et DAVID R. BUNDLE. Can. J. Chem. 57, 2085 (1979).

Les octaacetates *trans*-1,2 du cellobiose, lactose et maltose ont été convertis en glycosides-β du ethoxycarbonyl-8-octanol dans de bon rendements par une reaction en une seule étape.

A −10°C un ion acetoxonium-1,2 est generé par le tétrachlorure d'étain dans le dichloromethane pour conduire initiallement aux glycosides-β via les orthoesters-1,2 comme intérmediaire. L'anomerisation *in situ* du maltoside-β a lieu durant la reaction (4 h) à temperature ambiante et produit ainsi une nouvelle route pour preparer ce glycoside-α du disaccharide.

Les glycosides-β du lactose et cellobiose ont été anomerisés en glycosides-α correspondant.

Les trois disaccharides glycosides-β et les trois disaccharides glycosides-α ont été fonctionalisé afin d'être convertis en antigens artificiels de carbohydrate.

Introduction

The antibody specific for an artificial lactose antigen agglutinates cells of *Neisseria gonorrhaeae* (1), due to the presence of a terminal galactopyranose residue in the cell wall lipopolysaccharide (LPS) (2). In order to investigate further the nature of this cross reaction, related disaccharide antigens have been synthesised, either for subsequent modification at the terminal glycosyl residue prior to conversion to an artificial antigen or for immediate use as antigens, following covalent attachment to protein (3).

A previous preparation of the lactose hapten gave a poor yield of the glycoside **5** (1) but this has been improved by use of silver trifluoromethanesulphonate (triflate) promoted Koenigs–Knorr reactions starting from acetylated glycosyl bromides (4). It has been known for some time that methyl β-D-glucopyranoside may be prepared from penta-*O*-acetyl-β-D-glucopyranose under Lewis acid catalysis (5), and the procedure has been modified recently to provide 1,2-*trans*-linked disaccharides (6, 7). During the preparation of β-glycosides of 8-ethoxycarbonyloctanol by reaction with cellobiose, lactose, and maltose octaacetates in dichloromethane containing 1 mol of stannic tetrachloride, it was observed that extended reaction times and higher temperatures can lead to α-glycosides of disaccharides (Scheme 1).

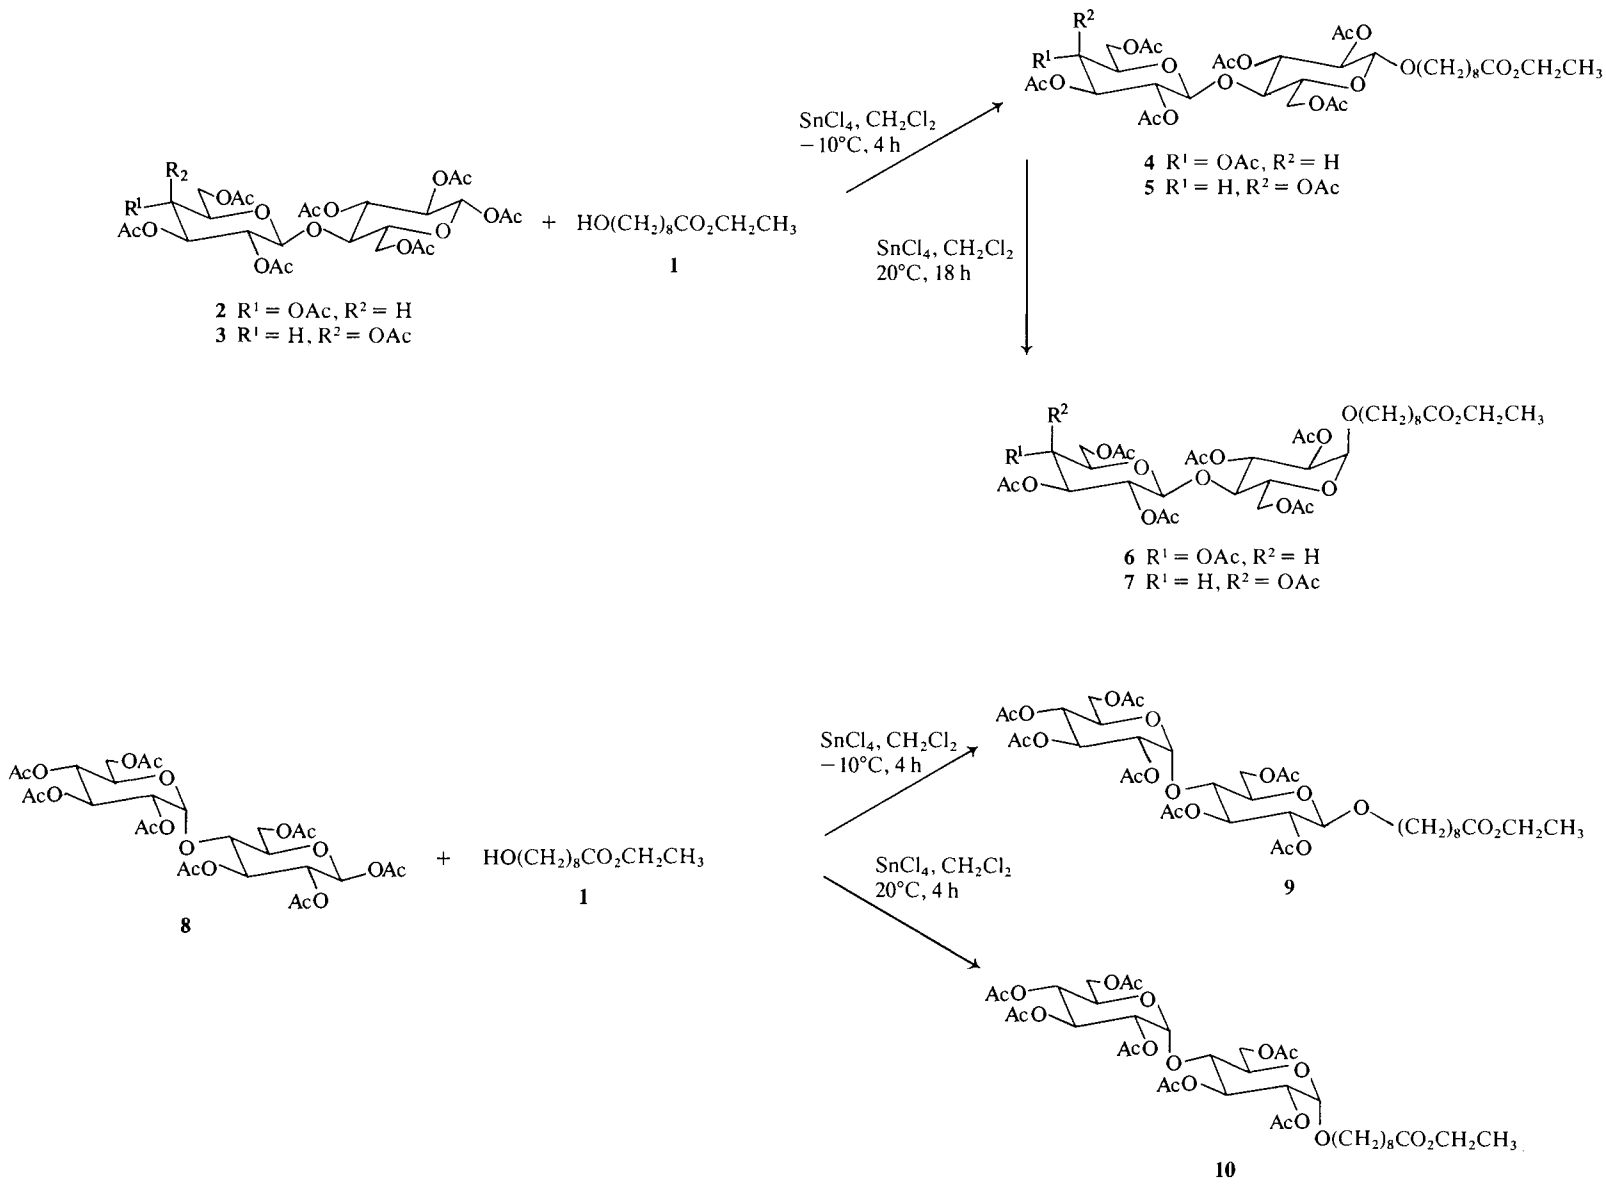
Results and Discussion

The octaacetates of cellobiose, lactose, and maltose are readily prepared in crystalline form as the β-anomers by standard procedures (8, 9) using sodium acetate and acetic anhydride. When a 1,2-*trans*-sugar per-*O*-acetate is dissolved in dichloromethane containing a molar equivalent of stannic tetrachloride 1,2-acetoxonium ion formation results (10) as is the case with other Lewis acids such as antimony pentachloride (11). Addition of alcohol at −10°C under anhydrous conditions gives *trans*-linked glycosides in excellent yield (6, 7). Under these conditions, −10°C for 4 h, cellobiose **2**, lactose **3**, and maltose **8** octaacetates gave 61–68% yields of the heptaacetyl-β-glycosides of the disaccharides **4**, **5**, and **9** (Scheme 1). Acetylated 8-ethoxycarbonyloctanol, disaccharide hexaacetates, and small amounts of hexaacetyl-disaccharide glycosides are formed as side products in this reaction. This latter product exhibited similar properties to the 2-hydroxy glycoside isolated from Koenigs–Knorr reactions (4). Indeed, if the crude product from the above reaction is de-*O*-acetylated and the 8-methoxycarbonyloctyl-β-glycosides **11**, **12**, and **15** extracted from aqueous solution by chloroform–ethanol (3:2),

[1]NRCC No. 17338.

[2]MDS Health Group Limited, Rexdale, Ontario.

0008-4042/79/162085-06$01.00/0



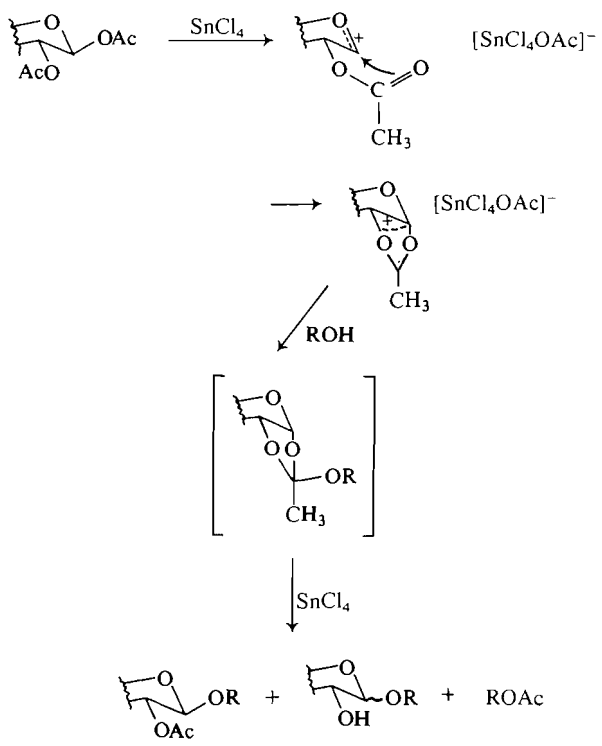
SCHEME 1

the yield of these glycosides is increased by 10–15% over that obtained by de-*O*-acetylation of the purified heptaacetyl glycosides **4**, **5**, and **9**. The increased yield is attributed to the presence in the reaction mixture of significant amounts of 2-hydroxy β-linked glycosides.

Extension of reaction times in conjunction with higher temperatures (20°C) leads to increasing proportions of α-glycosides due to anomerisation. Also observed is a small amount of chloroacetyldisaccharide (7), the yield of which increases if addition of alcohol to the reaction vessel is delayed. Although reaction of maltose octaacetate **8** with 8-ethoxycarbonyloctanol gave optimum yields of the α-glycoside **10** after only 4 h at 20°C, the related glycosides of cellobiose (**6**) and lactose (**7**) were obtained in optimum yields only after work-up and retreatment of the β-glycosides **4** and **5** with stannic tetrachloride in dichloromethane.

Examination of the side-products of this reaction, acetylated aglycon and glycosides lacking a 2-*O*-acetate, supports the conclusion that this reaction proceeds to β-linked glycosides via 1,2-orthoacetate intermediates. The reasoning which leads to this conclusion is similar to that invoked in the accompanying paper (4) which postulates 1,2-orthoacetate intermediates for Koenigs–Knorr reactions. However, in this case it is well documented that suitably oriented polyacetates in the presence of Lewis acid will give 1,2-acetoxonium ions (11). Hanessian and Banoub prepared 1,2-orthoesters via such species, under conditions similar to those used in this work (10). Reaction of cyclic oxocarbonium ions of the type represented in Scheme 2 can lead directly to 1,2-*trans*-glycosides but in the light of the side products of the reaction, probably do so via a 1,2-(8-ethoxycarbonyloctyl orthoacetate) intermediate, which we have demonstrated (4) to rearrange by stannic tetrachloride catalysis. The product distribution seen in this Lewis acid catalysed isomerisation of orthoester is identical to that observed during glycoside synthesis from 1,2-*trans*-octaacetates **2**, **3**, and **8**, ethoxycarbonyloctanol (**1**), and stannic tetrachloride.

The acetylated β- and α-glycosides **4**–**9** were de-*O*-acetylated to provide the corresponding 8-methoxycarbonyloctylglycosides **11**–**16**. Proton nmr (Table 3) in deuterium oxide solution confirmed the anomeric configuration of these glycosides. Conversion to the 8-hydrazinocarbonyloctyl glycosides was performed in ethanol solution with excess hydrazine hydrate. The hydrazides **17**–**22** were analytically pure and gave ^{13}C nmr data in agreement with the assigned structures. The hydrazides are the immediate precursors to artificial antigens and have been coupled



SCHEME 2

to BSA to provide artificial antigens according to a previously published procedure (3, 12).

In addition to the synthesis of the six disaccharide haptens described here, the β-glycoside haptens of

glucose and galactose have been synthesized in approximately 75% yield from the respective penta-*O*-acetyl-β-D-hexopyranoses. Not only is the Lewis acid catalysed glycosylation reaction more rapid than Koenigs–Knorr reactions (1, 4) but the yields of the 8-ethoxycarbonyloctyl glycosides are higher.

Experimental

The general experimental conditions and methods used were as described in the preceding paper (4). Merck silica gel G60 (70–230 mesh) and redistilled solvents were used for column chromatography. Identical but more rapid separations were achieved with a Waters high pressure liquid chromatograph Prep. 500. Proton chemical shifts are expressed relative to 1% tetramethylsilane (TMS) in deuteriochloroform and relative to sodium 3-trimethylsilylpropionate-2,2,3,3-d_4 for deuterium oxide solutions. Carbon-13 shifts are expressed relative to internal TMS in deuteriochloroform and to external TMS for deuterium oxide solutions. Assignments of ^{13}C resonances are based on literature values for monosaccharides and disaccharides (13, 14).

*General Procedure for Preparation of 8-Ethoxycarbonyloctyl 1,2-*trans*-Glycosides*

Stannic tetrachloride (0.98 mL, 9 mmol) was added to a solution of the 1,2-*trans*-disaccharide octaacetate (8, 9) (6.04 g, 9 mmol) in dry dichloromethane (90 mL). After 10 min at room temperature the solution was cooled to −10°C and a white precipitate resulted. A solution of 8-ethoxycarbonyloctanol (3) (2.02 g, 10 mmol) in 10 mL of dichloromethane was added to the reaction mixture and that was then kept at −10°C for 4 h. The reaction mixture was poured into a saturated solution of sodium bicarbonate (60 mL), which was then extracted with chloroform (2 × 100 mL), and the organic phase was washed with water. After solvent removal 10 g of crude syrup was obtained. Column chromatography on silica gel with the solvent ethyl acetate – Skellysolve B 1:1 yielded the pure glycoside **4**, **5**, or **9**. The yields and physical constants for these compounds are reported in Table 1.

Acetylated 8-ethoxycarbonyloctanol was isolated from the reaction mixture together with other side products, which were glycosidic components with tlc mobilities slower than the glycosides **4**, **5**, or **9**. Disaccharide hexaacetates containing no aglycon were also observed. The identification of all three side products was similar to that reported in the accompanying paper (4). Proton spectra for compounds **4**, **5**, and **9** are not reported since this data is not instructive for analytical purposes with the exception that the ratio of polymethylene (—$(CH_2)_6$—, CH_3CH_2) and methyl protons integrate relative to acetate and ring protons in the correct proportion. ^{13}C nmr (Table 2) is much more useful for the identification of the anomeric configuration of the glycosidic linkages.

*8-Ethoxycarbonyloctyl 2,3,6-Tri-*O*-acetyl-4-*O*-(tetra-*O*-acetyl-α-D-glucopyranosyl)-α-D-glucopyranoside (**10**)*

β-Maltose octaacetate (**8**) (17.1 g, 25.5 mmol) was dissolved in dry dichloromethane and stannic tetrachloride (3.5 mL, 25.5 mmol) was added. Immediately after this, 8-ethoxycarbonyloctanol (**1**) (5.1 g, 25 mmol) was added in dichloromethane (10 mL). After 4 h at room temperature the reaction mixture was worked up as described earlier. After purification on silica gel the α-maltose glycoside **10** was obtained as a syrup (12.2 g, 59%). The analytical data and

*Chemical shifts are expressed relative to internal sodium 3-trimethylsilylpropionate-2,2,3,3-d_4.

^{13}C nmr parameters are recorded in Tables 1 and 2 respectively.

Preparation of 8-Ethoxycarbonyloctyl-α-lactoside 6 and Cellobioside 7

The purified 1,2-*trans*-glycosides **4** or **5** (0.82 g, 1 mmol) were dissolved in dry dichloromethane and stannic tetrachloride (0.12 mL, 1 mmol) was added. After 18 h at room temperature the reaction mixture was worked up in the usual manner. The crude syrup was purified on silica gel to yield **6** or **7** (Tables 1 and 2).

Preparation of 8-Methoxycarbonyloctyl β- and α-Glycosides (11–16)

The acetylated glycosides (**4–10**) (1.6 g, 2 mmol) in 10 mL of dry methanol were transesterified by addition of freshly prepared 0.1 *M* sodium methoxide (0.5 mL). After 18 h the solution was neutralized with Rexyn H^+ resin, filtered, and concentrated to a syrup that could be recrystallised from ethanol (Table 1). Confirmation of the expected structures was obtained by ^{13}C nmr and ^1H nmr which gave the anomeric configuration of glycosidic linkages from the chemical shift and $J_{1,2}$ coupling constants data (Table 3). Physical constants and analytical data are recorded in Table 1.

Preparation of 8-Hydrazinocarbonyloctyl β- and α-Glycosides (17–22)

The de-*O*-acetylated disaccharide glycoside (**11–16**) (518 mg) was suspended in ethanol (4 mL), a solution of 85% hydrazine hydrate (0.5 mL) was added, and the reaction was left at room temperature for 18 h. In some cases the hydrazide crystallised from the reaction mixture and in other cases solvent removal and co-distillation of hydrazine with toluene was necessary prior to crystallisation from ethanol. The physical and analytical data for these compounds are reported in Table 1. Carbon-13 nmr data (Table 2) confirmed the assigned structures.

1,2-Orthoacetate intermediates in silver trifluoromethanesulphonate promoted Koenigs–Knorr synthesis of disaccharide glycosides[1]

JOSEPH BANOUB[2] AND DAVID R. BUNDLE

Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received December 21, 1978

JOSEPH BANOUB and DAVID R. BUNDLE. Can. J. Chem. 57, 2091 (1979).

The three disaccharides lactose, cellobiose, and maltose in the form of their acetylated glycosyl bromides have been reacted with 8-ethoxycarbonyloctanol to provide the 1,2-*trans*-glycosides. Conventional Koenigs–Knorr and Helferich conditions provided these glycosides in poor yield but silver trifluoromethanesulphonate, *N,N*-tetramethylurea gave the disaccharide glycosides in 50–60% yield. Use of 2,4,6-trimethylpyridine as proton acceptor provided the corresponding 1,2-orthoacetates in 60–70% yield. These 1,2-orthoesters were rearranged by stannic tetrachloride to the 1,2-*trans*-glycosides. The isolation of acetylated 8-ethoxycarbonyloctanol from Lewis acid catalysed isomerisation of 1,2-orthoesters and from Koenigs–Knorr reactions in which *N,N*-tetramethylurea was the proton acceptor is discussed in terms of a reaction mechanism proceeding from glycosyl halide to glycosidic products via a 1,2-orthoester intermediate. This proposal is supported by ^{1}H nmr evidence for the presence of 1,2-orthoacetate in Koenigs–Knorr reaction mixtures, and by 1,2-orthoacetate isomerisation to glycoside by the conjugate acid of *N,N*-tetramethylurea.

JOSEPH BANOUB et DAVID R. BUNDLE. Can. J. Chem. 57, 2091 (1979).

Les trois disaccharides, lactose, cellobiose et maltose sous forme de bromure de glycosyles peracetylés ont été traités avec le ethoxycarbonyl-8-octanol pour produire les glycosides *trans*-1,2.

Les réactions conventionelles type Koenigs–Knorr et conditions d'Helferich ont produit ces glycosides, dans des pauvres rendements, mais la glycosidation en présence du trifluoromethanesulphonate d'argent et la tetramethyluree-*N,N* conduit aux disaccharides glycosides dans des rendements de 50–60%. L'utilisation de la trimethylpyridine-2,4,6 comme accepteur de proton conduit aux orthoesters-1,2 correspondants dans des rendements de 60–70%. Ces orthoesters-1,2 sont rearrangés par le tétrachlorure d'étain pour former les glycosides *trans*-1,2.

L'isolation de l'acetate du ethoxycarbonyl-8-octanol obtenu à partir de l'isomerisation catalysée par l'acide de Lewis des orthoesters-1,2 et des reactions de Koenigs–Knorr dans lequelles la tetramethylurée-*N,N* est l'accepteur de proton, est discuté en terme de mechanisme de reactions procedant à partir des halogenures de glycosyles pour former les glycosides *trans*-1,2 via les orthoesters-1,2 comme intermediaires. Ceci est verifié par le mise en evidence par rmn de ^{1}H de orthoesters-1,2 dans les mélanges obtenus par les réactions de Koenigs–Knorr et par l'isomérisation de orthoacetates-1,2 en glycosides par l'acide conjugée de la tetramethylurée-*N,N*.

Introduction

Disaccharide glycosides were required in order to investigate serological cross reactions between pathogenic bacteria and antibody prepared against artificial carbohydrate antigens (1, 2). Previous attempts to prepare the 1,2-*trans*-linked glycoside of lactose and the alcohol, 8-ethoxycarbonyloctanol (the alcohol used to prepare artificial antigens, via covalent attachment to proteins (3, 4)) by standard Koenigs–Knorr or Helfrich conditions resulted in very poor yields (2). Following its initial use by Kronzer and Schuerch (5) it has been demonstrated independently in two laboratories (6,7) that silver trifluoromethanesulphonate (triflate), in conjunction with an appropriate proton acceptor, is an excellent promotor of glycosylation reactions between alcohols and glycosyl halides. Consequently it was decided to prepare the disaccharide glycosides in question by this method. In the course of this work it was found that 1,2-orthoacetates are formed exclusively when the acceptor is 2,4,6-trimethylpyridine (collidine), whereas 1,2-*trans*-glycosides are the major product if the proton acceptor is *N,N*-tetramethylurea. ^{1}H nmr and chemical evidence and a consideration of the products of the latter reaction suggest that 1,2-orthoacetates are intermediates in Koenigs–Knorr reactions of acetylated glycosyl halides.

Results

Glycosylation of 8-ethoxycarbonyloctanol in dichloromethane with either acetobromolactose (**2**) or acetobromocellobiose (**1**) (8,9) was accomplished in 60–65% yield by silver triflate, *N,N*-tetramethyl-

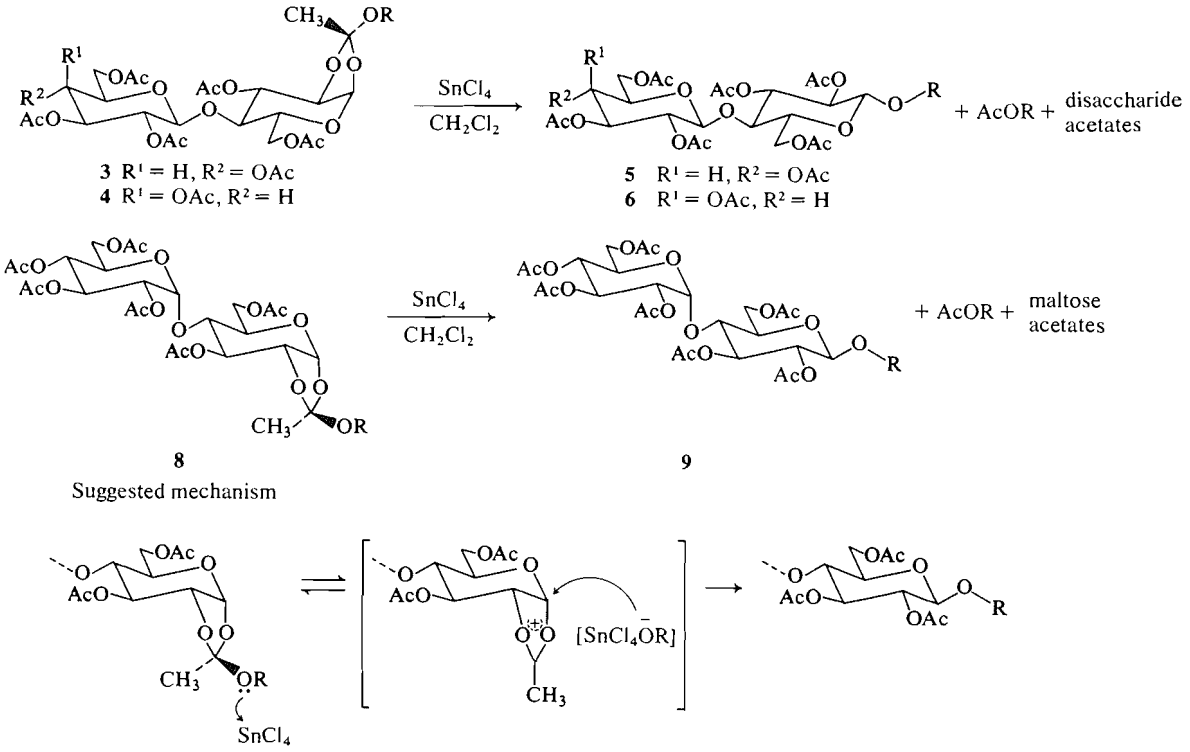
Reaction condition *A*: silver trifluoromethanesulphonate, collidine in CH_2Cl_2
Reaction condition *B*: silver trifluoromethanesulphonate, *N*,*N*-tetramethylurea in CH_2Cl_2

SCHEME 1. Synthesis of cellobiose, lactose, and maltose 1,2-orthoacetates and 8-ethoxycarbonyloctyl glycosides.

urea promoted Koenigs–Knorr reaction (6). Acetobromomaltose (**7**) (8, 9) reacted with 8-ethoxycarbonyloctanol under these conditions to provide glycoside (**9**) in 58% yield. However, when the bromo sugars **1**, **2**, and **7** were reacted with 8-ethoxycarbonyloctanol in the presence of molar quantities of silver triflate and collidine, 60–80% yields of the corresponding 1,2-orthoacetates (**3**, **4**, and **8**) resulted (Scheme 1). Under these latter conditions, which do not use the solvent quantities of hindered pyridines used in standard literature (10, 11) methods of orthoester synthesis, the only side products were unreacted alcohol and a reducing disaccharide heptaacetate. Reaction with silver triflate and *N*,*N*-tetramethylurea (rather than collidine) produced acetylated 8-ethoxycarbonyloctanol, glycoside hexaacetate(s), and reducing disaccharide hexaacetate in addition to the glycoside heptaacetates **5**, **6**, and **9**. The glycoside hexaacetate(s) exhibited tlc mobilities slightly lower than the heptaacetyl glycosides **5**, **6**, and **9**, and integration of ^1H nmr spectra indicated the presence of six acetate groups. The disaccharide hexaacetate contained no aglycon and from ^1H nmr spectra clearly contained no acetate at C-1. Although the product(s) have been assigned the 3,6,2′3′4′6′-hexa-*O*-acetylglycosyl-glucose structure(s) the ^{13}C nmr evidence for this must be considered tentative. Related products were obtained from the glycosylation reactions conducted with acetobromocellobiose (**2**) and acetobromolactose (**1**).

Similar products to those mentioned above were observed when the 1,2-orthoacetates **3**, **4**, and **8** were isomerised by acid. This isomerisation was also performed with stannic tetrachloride (12), which unlike the more general conditions (13) performed at elevated temperatures with Lewis acid or proton catalysis, proceeds at low temperature without additional quantities of alcohol (14) (Scheme 2). Stannic tetrachloride isomerisation of 1,2-orthoacetates **3**, **4**, and **8** to the glycosides **5**, **6**, and **9** gave acetylated



SCHEME 2. Lewis acid catalysed rearrangement of α-D-disaccharide 1,2-orthoacetate to 8-ethoxycarbonyloctyl-β-D-glycosides.

8-ethoxycarbonyloctanol, glycoside hexaacetates, and reducing disaccharide hexaacetates. This product distribution is also reported for the single-step synthesis of the 1,2-*trans*-glycosides **5**, **6**, and **9** from the corresponding 1,2-*trans*-disaccharide octaacetates (15), a process known to occur via a 1,2-acetoxonium intermediate (16).

The presence in Koenigs–Knorr reaction mixtures of acetylated aglycon is consistent with 1,2-orthoacetate intermediates during such reactions and therefore attempts were made to isomerise orthoacetates under these conditions. Glycosylations conducted with silver triflate were observed both in this and other work (17) to give a precipitate of silver halide at temperatures between −40 and −30°C. Since the net result of halide abstraction and attack of alcohol on an acetoxonium ion is formation of the conjugate acid of either *N*,*N*-tetramethylurea or collidine, it was of interest to examine the effect of these acids on 1,2-orthoacetates at low temperatures. A crystalline orthoacetate available from other work (17), 3,4-di-*O*-benzyl-β-L-rhamnose 1,2-(methyl orthoacetate) was particularly suitable for study by ^{1}H nmr, since isomerisation to glycoside would provide new signals uncomplicated by other acetate or ethoxy signals. This would not have been the case for orthoacetates **3**, **4**, or **8**. Isomerisation with *N*,*N*-tetramethylurea – triflic acid (2:1) did not occur at −70°C and only very slowly at −30°C. At −10°C a molar or 0.1 molar equivalent of this acid–base mixture gave a near quantitative yield of methyl 2-*O*-acetyl-3,4-di-*O*-benzyl-α-L-rhamnopyranoside from the 1,2-orthoacetate in 3 h. At 20°C the same isomerisation was complete after 5 min. No isomerisation of 1,2-orthoacetates was observed after several hours when a molar equivalent of triflic acid – collidine 1.02:1.0 was added to the rhamnose 1,2-orthoacetate or the cellobiose 1,2-orthoacetate (3).

When a Koenigs–Knorr reaction between tri-*O*-acetyl rhamnopyranosyl bromide and 8-ethoxycarbonyloctanol in the presence of silver triflate and *N*,*N*-tetramethylurea was quenched at −20°C, it was possible to observe by ^{1}H nmr of the crude mixture the presence of glycoside and 1,2-orthoacetate in approximately equimolar proportions. The complex ^{1}H nmr spectrum was simplified to that of 8-ethoxycarbonyloctyl-tri-*O*-acetyl-α-L-rhamnoside by addition of a catalytic amount of *N*,*N*-tetramethylurea – triflic acid to the contents of the nmr tube. A similar result was obtained when the 1,2-*cis*-glycosyl halide, tetra-*O*-acetyl-α-D-glucopyranosyl bromide was reacted in the same manner.

SCHEME 3. Possible mechanism for 1,2-orthoacetate intermediates leading to glycosidic products in Koenigs–Knorr reactions.

Discussion

We have demonstrated that whereas silver triflate, *N*,*N*-tetramethylurea promotes reaction between acetobromo sugars and an alcohol to yield 1,2-*trans*-glycosides (route *B*, Scheme 1), silver triflate, collidine yields the isomeric 1,2-orthoacetates (route *A*, Scheme 1). Furthermore, the conjugate acid of the proton acceptor, which results when alcohol reacts with intermediates formed from acetobromo sugars, is capable in the case of *N*,*N*-tetramethylurea, but not collidine, of catalysing the rearrangement of 1,2-orthoacetate to 1,2-*trans*-glycoside.

It is generally accepted (18) that glycosyl halides possessing a participating group at C-2 react under Koenigs–Knorr conditions to yield initially a 1,2-acyloxonium intermediate. The essential elements of these processes have been succinctly summarised by Lemieux (19) and are abbreviated in Scheme 3. The glycosyl halide under the driving force of ring oxygen participation forms an oxocarbonium–halide ion-pair **11**. Participation from an acetate at C-2 leads to an acetoxonium ion **12**. The mechanistic interpretation of the steps leading from **12** or **11** to 1,2-orthoester or glycosidic products are numerous (18, 20, and references cited therein), as are the empirical modifications used to achieve the transformation of

glycosyl halide (**10**) to glycoside (**14**). The results presented in this paper illustrate important aspects of these mechanisms and are interpreted on the basis of a 1,2-orthoester intermediate.

Attack of alcohol on the ambidentate cation **12** may occur at either the dioxolenium carbon atom, leading to 1,2-orthoacetates, or at the anomeric centre, leading to 1,2-*trans*-glycosides. Since the nature of the proton acceptors, *N*,*N*-tetramethylurea or collidine, seems unlikely to influence the site of attack when present directly in only molar ratios, the different products which result in each case are attributed to the ability of protonated *N*,*N*-tetramethylurea to isomerise the initially formed 1,2-orthoacetate. Under kinetic control (−30°C) 1,2-orthoacetates were observed, and isolated, and shown to isomerise when exposed to catalytic amounts of protonated *N*,*N*-tetramethylurea. Protonated collidine was demonstrated to be incapable of catalysing the same isomerisation even when present in molar proportion. The observation of acetylated alcohol (8-ethoxycarbonyloctanol), a frequently observed side product of Koenigs–Knorr reactions (2, 21, 22), is most convincingly explained via a 1,2-orthoacetate intermediate (cf. ref. 18).

We propose, therefore, that acetylated glycosyl halides react under Koenigs–Knorr conditions via 1,2-orthoacetate intermediates, which isomerise under proton or Lewis acid (e.g., in the case of mercuric cyanide promoted glycosylations) catalysis to yield the thermodynamic product, 1,2-*trans*-glycosides. A schematic representation of this argument is presented (Scheme 3) which is based on recent mechanistic proposals of Garegg and Kvanström (14, 23) for proton catalysed 1,2-orthoester isomerisation. In brief, the essentials of the three pathways *a*, *b*, and *c* are as follows. Protonation via pathway *a* leads by way of an acetoxium ion **12** to glycoside **14**. Pathway *b* may result after *intra*molecular rearrangement of **15** in α-glycosides, or alternatively via **17** with loss of acetylated alcohol and either α- or β-glycoside (**19**) formation. The glycosyl cation (**18**) which results from pathway *c* ultimately yields a similar product, the 2-hydroxy α- or β-glycoside (**19**). In the absence of sufficient alcohol, **18** may presumably react to give products during work-up such as the disaccharide hexaacetates observed in these studies (these products appear to be related to products obtained from 1,2-orthoesters in acidic methanol (24)). In polar solvents or at higher temperature (20°C), the direct reaction of **11** or **12** to glycoside cannot be excluded. However, when the Koenigs–Knorr reaction is performed at low temperature (−20–0°C) in weakly polar solvents, the products of kinetic control, 1,2-orthoesters, are formed initially and subsequently isomerise or 'break down' to 1,2-*trans*-glycosides and side products.

The empirical modifications of the Koenigs–Knorr reaction are many and varied (see refs. 18, 20) and several factors affect the stereochemical outcome of the reaction. Consequently an all embracing mechanism which satisfactorily explains all aspects of these reactions is still lacking. However, it has been suggested (25) in the more recent literature that 1,2-orthoester intermediates enjoy at least transient existence in such reactions, and the results reported here support this prediction. Irrespective of mechanistic aspects, silver triflate – *N*,*N*-tetramethylurea provides an excellent route to 1,2-*trans*-linked glycosides especially for alcohols which have been shown to be unreactive in the more conventional Koenigs–Knorr or Helfrich conditions. The use of silver triflate – collidine gives excellent yields of the 1,2-orthoacetates of disaccharides, which are sometimes difficult to prepare by more conventional routes (10, 11).

Experimental

Thin-layer chromatography was performed with Merck precoated silica gel 60 F-254 plates, and the detection of compounds was achieved by quenching of uv fluorescence and by charring after spraying with 5% sulphuric acid in ethanol. Silica gel G60 (70–230 mesh) and redistilled solvents were used for column chromatography. The loading on all columns was 1:50 unless otherwise indicated. Skellysolve B refers to hexane supplied by Getty Refining and Marketing Company, Tulsa, OK. Solvents were purified and dried according to standard procedures (26). Processed solutions were dried over anhydrous sodium sulphate and solvent was removed at bath temperatures 40°C or lower unless otherwise stated. Melting points were determined on a Fisher-Johns apparatus and are uncorrected. Optical rotations were measured at 589 nm in a 1 dm cell at room temperature (20–23°C). Carbon-13 and ^{1}H nmr spectra were recorded at 20 and 79.9 MHz respectively in the pulsed Fourier transform mode on a Varian CFT-20 spectrometer. Proton chemical shifts are expressed relative to 1% tetramethylsilane (TMS) in deuteriochloroform. Carbon-13 shifts are expressed relative to internal TMS in deuteriochloroform.

*3,6-Di-*O*-acetyl-4-*O*-(tetra-*O*-acetyl-*β*-*D*-glucopyranosyl)-*α*-*D*-glucopyranose 1,2-(8-Ethoxycarbonyloctyl Orthoacetate) (3)*

A solution of 8-ethoxycarbonyloctanol (1.61 g, 8 mmol) in 15 mL of dry dichloromethane containing silver triflate (2.57 g, 10 mmol) and collidine (1.21 g, 10 mmol) was cooled to −40°C. Hepta-*O*-acetyl α-D-cellobiosyl bromide (**1**) (6.4 g, 9.15 mmol) (8) in 30 mL of dichloromethane was added dropwise with stirring. After 30 min at −40°C the reaction temperature was allowed to reach 20°C and the reaction was left for 3 h at room temperature. The reaction mixture was filtered through charcoal and Celite and the filtrate was washed with 3% hydrochloric acid, saturated sodium bicarbonate, and water. After evaporation, 7.4 g of crude syrup was obtained and purified by chromatography on silica gel with the solvent mixture, ethyl acetate – Skellysolve B 1:1. Pure orthoester **3** (5.8 g, 78%) crystallised from ether – Skellysolve B, mp 85–86°C, $[\alpha]_D$ +10.3 (*c* 1.1, $CHCl_3$); ^{1}H nmr ($CDCl_3$) δ: 1.15–1.45 (m, 15H, $-(CH_2)_6-$, CH_3-CH_2), 1.69 (s, 3H, CH_3-C

endo), 1.85–2.13 (m, 18H, CH_3CO—), 2.25 (t, 2H, CH_2CO), 3.64 (t, 2H, CH_2O). 5.59 (d, $J_{1,2}$ = 5.5 Hz, 1H, H-1), 3.3–5.5 (remaining protons). *Anal.* calcd. for $C_{37}H_{56}O_{20}$: C 54.14, H 6.88; found: C 54.01, H 6.90.

*3,6-Di-*O*-acetyl-4-*O*-(tetra-*O*-acetyl-*β*-*D*-galactopyranosyl)-*α*-*D*-glucopyranose 1,2-(8-Ethoxycarbonyloctyl Orthoacetate) (**4**)*

The procedure was similar to that described for **3** except that alcohol (5.05 g, 25 mmol) in 30 mL of dichloromethane containing silver triflate (8.48 g, 32 mmol) and collidine (3.98 mL, 30 mmol) was reacted with hepta-*O*-acetyl-α-D-lactosyl bromide (**2**) (22.7 g, 32 mmol) (9). After chromatography (Skellysolve B – ethyl acetate 1:1), orthoester **4** (12.2 g, 62%) was obtained as a homogeneous syrup, $[\alpha]_D$ = −2.4 (*c* 3.7, $CHCl_3$); R_f 0.62, that contained C—CH_3 *endo* and *exo* isomers in the ratio 11:3; ^{1}H nmr ($CDCl_3$) δ : 1.12–1.42 (m, 15H, —$(CH_2)_6$, CH_3–CH_2), 1.52, 1.69 (S, 3H, *endo* and *exo* CH_3—C), 1.96 (s, 3H, CH_3CO), 2.03 (s, 3H, CH_3CO), 2.09 (s, 6H, CH_3CO), 2.12 (s, 3H, CH_3CO), 2.14 (s, 3H, CH_3CO), 2.25 (t, 2H, CH_2CO), 5.62 (d, $J_{1,2}$ = 5.1 Hz, 1H, H-1), 3.30–5.50 (remaining protons).

Pure **4** (1.2 g) was de-*O*-acetylated in dry methanol (5 mL) containing a catalytic amount of sodium methoxide. After 18 h amorphous crystals (650 mg) were collected; mp 168–170°C (recryst.), $[\alpha]_D$ +14.3 (*c* 3.6, methanol). *Anal.* calcd. for $C_{24}H_{42}O_{14}.H_2O$: C 50.34, H 7.75; found: C 50.65, H 7.79.

*3,6-Di-*O*-acetyl-4-*O*-(tetra-*O*-acetyl-*α*-*D*-glucopyranosyl)-*α*-*D*-glucopyranose 1,2-(8-Ethoxycarbonyloctyl Orthoacetate) (**8**)*

Hepta-*O*-acetyl-α-D-maltosyl bromide **7** (8.8 g, 12.7 mmol) (8) was added to a solution of 8-ethoxycarbonyloctanol (2.02 g, 10 mmol) containing silver triflate (3.34 g, 13 mmol) and collidine (2.5 mL, 12 mmol) under the conditions described for the preparation of orthoester **3**. After chromatography of the crude syrup (9 g) the orthoester **9** (4.9 g) was obtained as a syrup which resisted crystallisation and which by ^{1}H nmr appeared to be a mixture of isomers CH_3—C *endo*:*exo* 9:4, $[\alpha]_D$ +6.8 (*c* 7.5, $CHCl_3$); ^{1}H nmr ($CDCl_3$) δ: 1.12–1.45 (m, 15H, —$(CH_2)_6$—, CH_3CH_2), 1.58, 1.72 (s, 3H, *exo* and *endo* CH_3—C), 1.99–2.15 (m, 18H, CH_3CO), 2.27 (t, 2H, CH_2CO), 5.65 (d, $J_{1,2}$ = 5.0 Hz, 1H, H-1), 3.40–5.60 (remaining protons).

Lewis Acid Rearrangement of 1,2-Orthoacetates **3**, **4**, *and* **9** *to 1,2-*trans*-Glycosides*

General Procedure

Lewis acid, stannic tetrachloride (0.01 mL, 0.1 mmol) was added to a cooled solution of 1,2-orthoacetate (1 mmol) in dry dichloromethane 10 mL. The reaction temperature was maintained at −10°C for 30 min and the mixture was then poured into 10 mL of saturated sodium bicarbonate solution. Extraction with 20 mL of dichloromethane followed by washing of the organic phase provided crude glycosides **5**, **6**, or **9** after the usual work-up. Chromatography on silica gel with the solvent ethyl acetate – Skellysolve B 1:1 yielded pure glycosides and the acetate of 8-ethoxycarbonyloctanol (Table 1). The ^{1}H nmr data for glycosides **5**, **6**, and **9** were exactly as reported later in this section. Acetylated 8-ethoxycarbonyloctanol gave the expected nmr spectrum; ^{1}H nmr ($CDCl_3$) δ: 1.23 (t, 3H, OCH_2CH_3), 0.9–1.60 (b m, 12H, —$(CH_2)_6$—), 2.03 (s, 3H, CH_3CO), 2.26 (t, 2H, CH_2CO), 4.49 (t, 2H, OCH_2), 4.59 (q, 2H, OCH_2CH_3).

Formation of 8-Ethoxycarbonyloctyl Glycosides Using Silver Triflate and N,N*-Tetramethylurea*

*8-Ethoxycarbonyloctyl 2,3,6-Tri-*O*-acetyl-4-*O*-(tetra-*O*-acetyl-*β*-*D*-glucopyranosyl)-*β*-*D*-glucopyranoside (**5**)*

A solution of 8-ethoxycarbonyloctanol (1.01 g, 5 mmol) and *N,N*-tetramethylurea (0.6 mL, 5 mmol) in 10 mL of dry dichloromethane containing silver triflate (1.03 g, 4 mmol) was cooled to −40°C. Hepta-*O*-acetyl-α-D-cellobiosyl, bromide (**1**) (2.8 g, 4 mmol) (8) in dry dichloromethane (20 mL) was added dropwise over 15 min. After 30 min at −40°C the cooling bath was allowed to warm to 20°C and the mixture was left for a further 3 h. The suspension was filtered through a pad of Celite and charcoal and the solids were washed with dichloromethane (50 mL). The filtrate was extracted with saturated sodium bicarbonate and water. After concentration of the dried solution the crude syrup was purified by column chromatography and crystallised from ether, yield 2.23 g, 68%; mp. 91–92°C, $[\alpha]_D$ −15 (*c* 1.0, $CHCl_3$); ^{1}H nmr ($CDCl_3$) δ: 1.1–1.7 (m, 15H, —$(CH_2)_6$—, CH_3CH_2), 2.11 (m, 21H, CH_3CO), 2.24 (t, 2H, CH_2CO), 3.35–5.55 (remaining 18 protons). *Anal.* calcd. for $C_{37}H_{56}O_{20}$: C 54.14, H 6.88; found: C 53.96, H 6.92. Elution of the column after the glycoside was obtained yielded components with ^{1}H and ^{13}C nmr consistent with disaccharide hexaacetates.

*8-Ethoxycarbonyloctyl 2,3,6-Tri-*O*-acetyl-4-*O*-(tetra-*O*-acetyl-*β*-*D*-galactopyranosyl)-*β*-*D*-glucopyranoside (**6**)*

The reaction was carried out on a 4 mmol scale as described for glycoside **5** using hepta-*O*-acetyl-α-D-lactosyl bromide (**2**) (9). Column chromatography gave **6** as a pure syrup (2.03 g), 62%; $[\alpha]_D$ −11.2 (*c* 2.0, $CHCl_3$); ^{1}H nmr ($CDCl_3$) δ: 1.10–1.80 (m, 15H, —$(CH_2)_6$—, CH_3CH_2), 1.93, 2.02, 2.05, 2.07 (s, 21H, CH_3CO), 2.26 (t, 2H, CH_2CO), 3.25–5.55 (remaining 18 protons).

In addition, acetylated 8-ethoxycarbonyloctanol was isolated in 20% yield together with a lactose hexaacetate whose ^{13}C nmr gave C-1(α) 90.0, C-1(β) 95.1, and C-1′(β) 101.0, which is consistent with a reducing disaccharide hexaacetate lacking an acetate at C-2.

*8-Ethoxycarbonyloctyl 2,3,6-Tri-*O*-acetyl-4-*O*-(tetra-*O*-acetyl-*α*-*D*-glucopyranosyl)-*β*-*D*-glucopyranoside (**9**)*

The bromide **7** (4 mmol) (8) was reacted with 8-ethoxycarbonyloctanol in the manner described for glycoside **5**. The glycoside **9** (1.93 g) crystallised from ether and Skellysolve B, mp 63–64°C, $[\alpha]_D$ 39.1 (*c* 1.0, $CHCl_3$); ^{1}H nmr ($CDCl_3$) δ: 1.10–1.80 (m, 15H, —$(CH_2)_6$—, CH_3CH_2), 1.97, 2.00, 2.02, 2.06, 2.10 (s, 21H, CH_3CO), 2.25 (t, 2H, CH_2CO), 3.25–5.55 (remaining 18 protons). *Anal.* calcd. for $C_{37}H_{56}O_{20}$: C 54.14, H 6.88; found: C 53.96, H 6.92.

In addition, a compound with the properties of a hexaacetate was isolated by continued elution after **9** had been eluted from the silica column. The ^{13}C nmr showed no aglycon signals and anomeric signals C-1′(α) 95.5, C-1(β) 94.8, and C-1(α) 89.8 ppm. The intensity of these signals were respec-

tively 8:5:3; ^{1}H nmr gave acetate signals and ring protons only in the ratio 18:16.

Observation of 1,2-Orthoester Intermediates by ^{1}H Nuclear Magnetic Resonance

8-Ethoxycarbonyloctanol (600 mg, 3 mmol) was dissolved in dry dichloromethane (7 mL) containing silver triflate (770 mg, 3 mmol) and *N,N*-tetramethylurea (0.72 mL, 6 mmol). The mixture was cooled to −40°C and 3 mL of a dichloromethane solution containing 2,3,4-tri-*O*-acetyl-α-L-rhamnopyranosyl bromide (1.02 g, 2.89 mmol) (16) was added dropwise over 15 min. The reaction was maintained between −20 and −30°C for 3 h and a mixture of water (1 mL) and triethylamine (1 mL) were added to quench the reaction. The reaction was poured into dichloromethane (10 mL), filtered through a pad of Celite, and then washed with sodium bicarbonate and water. After drying the syrup under high vacuum the ^{1}H nmr was recorded; ^{1}H nmr ($CDCl_3$) δ: 1.08–1.50 (m, $-(CH_2)_6-$, CH_3CH_2, H-6) 1.64 (s, *endo* CH_3C), 1.90 (s, CH_3CO) 1.97 (b s, CH_3CO), 2.03 (b s, CH_3CO).

To the nmr tube containing the crude syrup, one drop of a solution containing *N,N*-tetramethylurea – triflic acid 2:1 (the solution was 1 *M* with respect to acid) was added and the ^{1}H nmr was rerun. The orthoester C—CH_3 peak δ 1.64 was no longer evident and the multiplet complex due to acetate signals had simplified to 3 singlets. The chemical shifts of these signals were identical to those obtained with an authentic sample of 8-ethoxycarbonyloctyl 2,3,4-tri-*O*-acetyl-α-L-rhamnopyranoside (27); ^{1}H nmr ($CDCl_3$) δ: 1.08–1.80 (m, $-(CH_2)_6-$, CH_3CH_2, H-6) 1.94 (s, CH_3CO), 2.00 (s, CH_3CO), 2.10 (s, CH_3CO), 2.25 (t, CH_2CO), 3.30–5.50 (remaining protons).

Reaction of 1,2-Orthoesters with N,N-Tetramethylurea/ Collidine–Triflic Acid

The orthoacetate, 3,4-di-*O*-benzyl-β-L-rhamnose-1,2-(methyl orthoacetate) (1 mmol) in dichloromethane (5 mL) was reacted with 1 mL of *N,N*-tetramethylurea – triflic acid 2:1 (the solution made up in dichloromethane was 1 *M* with respect to triflic acid) at room temperature. After 5 min tlc (Skellysolve B – ethyl acetate 3:1) showed complete reaction to the corresponding glycoside. The reaction was repeated on a small scale in a nmr tube using deuteriochloroform as solvent. The glycoside, methyl 2-*O*-acetyl-3,4-di-*O*-benzyl-α-L-rhamnopyranoside, had ^{1}H nmr ($CDCl_3$) δ: 1.38 (d, $J_{5,6}$ = 6.0 Hz, 3H, H-6), 2.17 (s, 3H, CH_3CO), 3.37 (s, 3H, OCH_3), 3.88 (d d, $J_{2,3}$ = 4 Hz, $J_{3,4}$ = 10 Hz, 1H, H-3), 5.32 (d d, $J_{1,2}$ = 2 Hz, $J_{2,3}$ = 4 Hz, 1H, H-2), 7.34 (b s, 10H, ϕCH_2), 3.35–5.00 (remaining protons). Isomerisation of 1,2-orthoacetate to glycoside was essentially quantitative.

The experiment described above was repeated with 0.1 mmol of *N,N*-tetramethylurea triflic acid with similar results. When this was repeated at −10°C the reaction took 3 h to reach completion. At −70 and −30°C no detectable rearrangement had occurred after 4 h. In these instances reactions were quenched with excess triethylamine.

The rhamnose orthoacetate (1 mmol) was reacted with 1 mmol of collidine – triflic acid 1:1 (1 *M* in dichloromethane) for 4 h at room temperature. After this period tlc showed only starting material, which was confirmed by a similar experiment performed in a nmr tube. The nmr parameters for the 3,4-di-*O*-benzyl-β-L-rhamnose-1,2-(methyl orthoacetate) were ^{1}H nmr ($CDCl_3$) δ: 1.31 (d, $J_{5,6}$ = 5.8 Hz, 3H, H-6), 1.73 (s, 3H, CH_3CO), 3.29 (s, 3H, OCH_3), 3.27–3.79 (m, 3H, H-3, H-4, H-5), 4.40 (d d $J_{2,3}$ = 3.7 Hz, $J_{1,2}$ = 2.4 Hz, 1H, H-2), 4.58–5.02 (m, 4H, ϕCH_2), 5.28 (d, $J_{1,2}$ = 2.4 Hz, 1H, H-1), 7.34 (b s, 10H, ϕCH_2).

The cellobiose 1,2-orthoacetate was treated with *N,N*-tetramethylurea – triflic acid 2:1 and also collidine – triflic acid 1:1.02 in the manner described for the rhamnose orthoacetate. With collidine – triflic acid the two C—CH_3 (*exo* and *endo*) signals at δ 1.61 and δ 1.69 remained unchanged after 4 h. *N,N*-Tetramethylurea – triflic acid caused these signals to disappear after 5 min at room temperature. In addition the H-1 doublet δ $J_{1,2}$ = 5 Hz also disappeared indicating reaction of the orthoester.

The oxidation potentials of *cis*- and *trans*-1,2-diphenylcyclopropane and *cis*- and *trans*-2,3-diphenyloxirane[1]

D. R. ARNOLD[2] AND P. C. WONG

Photochemistry Unit, Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received January 19, 1979

D. R. ARNOLD and P. C. WONG. Can. J. Chem. 57, 2098 (1979).

The oxidation potentials of *cis*- and *trans*-1,2-diphenylcyclopropane (**1**) and *cis*- and *trans*-2,3-diphenyloxirane (**2**) have been determined by cyclic voltammetry, spectroscopically (using an empirical correlation of the long wavelength transition of the charge-transfer complexes with tetracyanoethylene) and by using an empirical correlation based upon the gas phase ionization potentials measured by photoelectron spectroscopy. The values obtained by these three very different techniques agree to within ± 0.15 V. The results are interpreted in terms of the initial formation of the phenyl radical cation with the three-membered ring intact. The higher oxidation potentials of *cis*- and *trans*-**2**, relative to those of *cis*- and *trans*-**1**, are attributed to inductive electron withdrawal from the phenyl group by the oxygen of the oxirane ring. The relevance of these results to the photosensitized (electron transfer) behaviour of these compounds is discussed.

D. R. ARNOLD et P. C. WONG. Can. J. Chem. 57, 2098 (1979).

Faisant appel à de la voltamètrie cyclique, on a déterminé les potentiels d'oxydation des diphényl-1,2 cyclopropanes-*cis* et -*trans* (**1**) et des diphényls-2,3 oxiranne-*cis* et -*trans* (**2**) en utilisant une corrélation empirique de la transition à la grande longueur d'onde des complexes de transfert de charge avec le tétracyanoéthylène et en utilisant une corrélation empirique basée sur les potentiels d'ionisation en phase gazeuse tels que mesurés par spectroscopie photoélectronique. Les valeurs obtenues par ces trois techniques très différentes ne diffèrent que par ± 0.15 V. On interprète les résultats en termes de la formation initiale d'un radical cation phényle avec le cycle à trois chaînons intact. On attribue le fait que les potentiels d'oxydation des produits **2**-*cis* et *trans* sont plus élevés que ceux des produits **1**-*cis* et *trans* à une électro-attraction par l'oxygène du cycle oxiranne qui retire des électrons du phényle. On discute de la relation entre ces résultats et leur comportement photosensibilisé (transfert d'électron).

[Traduit par le journal]

Introduction

We have recently reported the photosensitized (electron transfer) *cis–trans* isomerization of 1,2-diphenylcyclopropane (**1**) (*1a*) and 2,3-diphenyloxirane (**2**) (2). The key step in the mechanism we proposed for these reactions involves electron transfer from the phenyl ring of the cyclopropane or oxirane to the sensitizer singlet excited state. Ring-opened intermediates resulting from cleavage of the cyclopropane or oxirane radical cation, followed by back electron transfer, and subsequent reclosure of the ring allow for the isomerization. We were particularly surprised by the observation that both 1-cyanonaphthalene (**3**) and 1,4-dicyanonaphthalene (**4**) were effective sensitizers for the cyclopropane isomerization; however, while the oxirane isomerization could be sensitized by **4**, **3** was ineffective. Photophysical studies confirmed the involvement of the sensitizer singlet and gave a further indication of the sensitizer–quencher specificity. The fluorescence of **4** was quenched by both *trans*-**1** and *trans*-**2**, while the fluorescence of **3**, which was quenched by *trans*-**1**, was not measurably quenched by *trans*-**2**. The measured fluorescence quenching rate constants are summarized in Table 1.

To account for these results we proposed that the electron transfer step, involving **2** and the excited state of **3**, was uniquely inefficient in this series. We supported this explanation with an estimate of the free-energy (ΔG) for the electron transfer process which was based upon the Weller equation (Table 1); electron transfer from **2** to the singlet excited state of **3** is not favorable. Application of the Weller equation required measurement of the oxidation potentials ($E_{1/2}^{ox}$) of **1** and **2**. These we obtained by cyclic voltammetry. However, analysis of the cyclic voltammagrams clearly indicated that the anodic electron transfer processes were irreversible, and therefore the measured oxidation potentials do not have thermodynamic significance.

TABLE 1. Measured fluorescence quenching rate constants and calculated free energy for the electron transfer processes between the singlet excited states of 1-cyanonaphthalene (**3**) and 1,4-dicyanonaphthalene (**4**) and *trans*-1,2-diphenylcyclopropane (*trans*-**1**) and *trans*-2,3-diphenyloxirane (*trans*-**2**)

Fluorescer	Quencher	k_q (s^{-1} M^{-1})	ΔG (kcal mol^{-1})[a]
3	*trans*-**1**	1.38×10^{10}	−9.3
	trans-**2**	$<3\times10^{7}$[b]	+6.4
4	*trans*-**1**	1.50×10^{10}	−21.5
	trans-**2**	1.16×10^{10}[b]	−6.8

[a]Using the Weller equation $\Delta G = 23.06[E(D/D^+)_V - E(A/A^-)_V - e_0^2/\varepsilon\alpha] - \Delta^1E_{0,0}$ (kcal mol^{-1}), ref. 3. The redox potentials employed are: $E_{1/2}{}^{ox}$ for *trans*-**1** (1.2 V), *trans*-**2** (1.8 V) and $E_{1/2}{}^{red}$ for **3** (−2.33 V) (ref. 4*a*) and **4** (−1.67 V) (ref. 4*a*) vs. $Ag/AgNO_3$ in acetonitrile. The Coulombic attraction term is −1.3 kcal mol^{-1} while the singlet energy of the acceptors are **3** (89.4 kcal mol^{-1}) (ref. 4*a*) and **4** (86.4 kcal mol^{-1}) (ref. 4*a*).
[b]Ref. 2.

Unfortunately, it is not unusual for the interesting electron transfer processes to be irreversible at the electrode; nevertheless, potentials based upon such data have been used and in fact seem to give meaningful correlations (1, 2, 4).

In view of the growing importance of the Weller equation, and similar semi-empirical treatments for the correlation of photophysical and photochemical behaviour which involves electron transfer processes, it is becoming increasingly desirable to have some convenient method for obtaining meaningful oxidation potentials.

We report here the comparison of the oxidation potentials of **1** (*cis*- and *trans*-) and **2** (*cis*- and *trans*-) determined by three very different techniques; (*1*) cyclic voltammetry, where the electron transfer processes are not reversible; (*2*) spectroscopically, using an empirical correlation of the long wavelength transitions of the charge-transfer complexes with tetracyanoethylene (TCNE); and (*3*) using an empirical correlation based upon the gas phase ionization potentials measured by photoelectron spectroscopy. We found acceptable (±0.15 V) agreement between the oxidation potentials of these four compounds using these three methods which, therefore, gives us confidence that the data are meaningful. There are advantages and disadvantages for each of these techniques.

Cyclic voltammetry provides the best in accuracy among these methods; however, complication does arise when the oxidation process is irreversible. Charge-transfer complex measurement provides the simplest method in obtaining reversible oxidation potentials, but the accuracy is hampered by uncertainty in determining the maximum of a broad structureless absorption band and sometimes further complicated in cases of overlapping bands. There has been a dramatic improvement in instrumentation for photoelectron spectroscopy over the past decade; however, on our instrument it is still difficult to get good resolution for large non-volatile molecules. Furthermore, the estimate of oxidation potential is very sensitive to relatively small error in determining the peak position.

Results and Discussion

The cyclic voltammagrams of all four compounds, **1** (*cis* and *trans*) and **2** (*cis* and *trans*), measured in acetonitrile solution using a platinum working electrode and a $Ag/AgNO_3$ (0.1 *M*) reference electrode, were typical of irreversible oxidative electron transfer. No reduction wave was observed upon scanning the voltage from 0 to −2.2 V which is the practical limit of this solvent–electrolyte system. The oxidation potentials ($E_1/_2{}^{ox}$) were estimated as 0.03 V less than the peak position of the voltammagrams using a 100 mV/s sweep rate. These results are summarized in Table 2.

Pysch and Yang have shown that a linear relationship exists between the absorption energy of the charge-transfer complex (ΔE_{CT}) and the oxidation potential ($E_1/_2{}^{ox}$) for a series of aromatic electron donors with 2,4,7-trinitrofluorenone-9 as the electron acceptor (6*a*). They established the empirical relationship

$$E_1/_2{}^{ox} = \Delta E_{CT} + \Delta E_{solv} + \text{constant}$$

where the difference in the solvation term (ΔE_{solv}) is assumed to be constant with a given electron acceptor (6). The absorption energy of the charge-transfer complex (ΔE_{CT}) is taken as the maximum of the long wavelength charge-transfer transition.

The charge-transfer transition of the complex between **2** with trinitrofluorenone would be partially obscured by the long wavelength absorption tail of the acceptor; so tetracyanoethylene was chosen as the acceptor in this study. Solutions (methylene chloride) of all four compounds and the strong electron acceptor tetracyanoethylene were visibly coloured due to the charge-transfer transitions. The visible spectra of these solutions had, in the case of both *cis*- and *trans*-**1**, two obvious, broad, structureless maxima. These overlapping bands were resolved by using a Gaussian–Lorentzian curve fitting computer program. Only one long wavelength maximum was observed in the visible spectra of solutions of both *cis*- and *trans*-**2** under these conditions. The positions of the maximum of these transitions are listed in Table 2. Solutions (methylene chloride) of **1** and **2** with dichloromaleic anhydride (another common acceptor) had absorption at long wavelength due to the charge-transfer complexes, but no distance maximum could be observed. The

[b]Values obtained from uv-visible spectra of the donors (55 m*M*) plus DCMA (18 m*M*) in methylene chloride.

approximate onset of the long wavelength absorptions and the positions (calculated) of the charge-transfer maxima are listed in Table 3.

Fortunately, there has been a sufficient number of maxima for the charge-transfer transitions of various donors complexed with TCNE reported in the literature. We summarize these data, along with the reliable oxidation potentials of the donors, in Table 4. The plot of these data, shown in Fig. 1, has the expected linear relationship represented by [1].

$$[1] \quad E_{1/2}{}^{ox} = 0.095\Delta E_{CT}\,(\text{kK}) - 0.455\ \text{V}$$

From [1] and the observed maximum of the long wavelength transition of the charge-transfer complex between *cis*- and *trans*-**1** and *cis*- and *trans*-**2** with TCNE, estimates of the oxidation potentials were obtained. These are listed in Table 2.

The results from the photoelectron spectra (Fig. 2) of *cis*- and *trans*-**1** and *cis*- and *trans*-**2** are summarized in Table 5. The first (i.e., lowest energy) distinct peak is sharp for all four compounds. This transition can be assigned to the lowest vertical ionization potential (IP) associated with removal of a π-electron of a phenyl ring. Several additional bands are observed below ca. 11 eV which can be attributed to ionization of lower-lying π-electrons. Near 11 eV there is a steep onset of a broad, structured plateau which represents unresolved ionizations from closely spaced σ (and perhaps π) orbitals.

The oxiranes show an additional feature, a doublet peak near 10.4 eV, which we attribute to ionization from the lone pair electrons on oxygen. The comparable transitions are observed near 10.57 eV in the photoelectron spectra of the parent

[d]Solvent was chloroform.

molecule, ethylene oxide (*7a*), and a doublet at ca. 10.5 eV for the phenyloxirane (*7b*).

The expression which relates gas phase ionization potential with the oxidation potential in solution is given in [2] (*6b*). This can be simplified to [3] (6) if all the terms on the right, except the ionization potential, are either relatively small or constant.

$$[2]\quad E_{1/2}^{ox} = \alpha IP + \Delta E_{solv} - \beta EA - \frac{T\Delta S}{F} - \frac{RT}{F} \times \ln \frac{F_0^+ D_R}{F_R D_0^+} + \text{constant}$$

$$[3]\quad E_{1/2}^{ox} = aIP + b$$

The reported values for the constants a and b in [3] vary to some extent depending on the choice of compounds included. The most extensive study has been reported by Miller and co-workers (9) where $a = 0.89$ and $b = -6.04$. When these values are used, along with the first vertical ionization potentials of *cis*- and *trans*-**1** and *cis*- and *trans*-**2**, in [3], the oxidation potentials listed in Table 2 were obtained.

The agreement between the oxidation potentials of *cis*- and *trans*-**1** and *cis*- and *trans*-**2**, obtained by the three techniques (Table 2) is remarkably good considering the experimental limitations and the empirical treatment of the data. We have very little basis for choosing the best values and therefore accept the data from the cyclic voltammetric study.

The larger oxidation potential of *cis*- and *trans*-**2**, relative to *cis*- and *trans*-**1**, can be explained in terms of inductive withdrawal of electrons from the phenyl rings by the more electronegative oxygen of the oxirane ring, relative to the methylene group of the cyclopropane.

It seems likely that, in both cases **1** and **2**, the initially formed radical cations have the ring-closed structure which, from the observed chemical behaviour, must subsequently open to the 1,3-radical cation (1, 2). If the ring cleavage processes were concurrent with oxidation, we would have expected that the greater stability of the α-oxycarbonium ion would have been reflected in a lower oxidation potential for the oxiranes relative to the cyclopropanes.

The oxidation potentials of the *cis*-isomers are (assuming one exceptional determination) slightly (<ca. 0.2 V) greater than those of the *trans*-isomers. This is additional evidence against direct formation of an identical ring-opened radical cation from both configurations, since it is firmly established that the *trans*-isomers are thermodynamically more stable than the *cis*-isomers (11). This is consistent with the results of a photoionization and ion cyclotron resonance study of the parent system ethylene oxide,

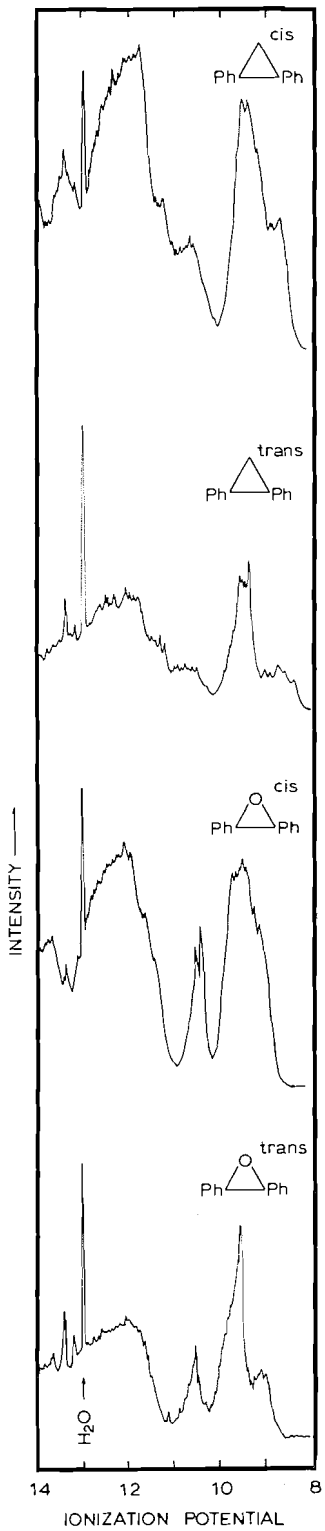

FIG. 2. The photoelectron spectra of *cis*- and *trans*-1,2-diphenylcyclopropane (**1**) and *cis*- and *trans*-2,3-diphenyloxirane (**2**).

TABLE 5. Photoelectron peaks

where the parent radical ion is formed by removal of an electron which, in this case, is largely localized on the oxygen atom (12).

Conclusions

The similarity in the oxidation potentials of **1** (*cis* and *trans*) and **2** (*cis* and *trans*) determined by these three different techniques gives us confidence that the values determined by cyclic voltammetry are useful, even though the anodic electron transfer process is irreversible. We must, however, caution against the use of this type of data generally, and we emphasize the utility of analysis of the CT transition and photoelectron spectroscopy as alternative techniques.

We now have additional confidence in the proposed explanation that the inefficiency of the isomerization of *cis*- and *trans*-**2** with **3** as a photosensitizer is the result of the unfavourable electron transfer process.

Experimental

Methylene chloride (Fischer spectroscopic grade) was dried with anhydrous calcium chloride, distilled from phosphorous pentoxide, and stored over a 4A molecular sieve. Acetonitrile (Aldrich Gold Label) was refluxed over calcium hydride under a dry nitrogen atmosphere and distilled. The stilbene oxides were prepared by oxidation of the corresponding stilbene with *m*-chloroperbenzoic acid in chloroform at room temperature (13). The *trans*-isomer was purified by recrystallization, first from methyl alcohol and then twice from cyclohexane. The *cis*-isomer was purified by two recrystallizations from hexanes and was then passed through a column of neutral alumina (Fischer) eluting with cyclohexane and was finally recrystallized once more from hexanes. The isomers were pure as observed by uv and vapour phase chromatography (vpc) (10% SE 30 on on Chromosorb W 60/80, 5 ft at 180°C). The 1,2-diphenylcyclopropanes were prepared following the method described in the literature (14). They were purified by chromatography on a column of silica gel eluting with hexanes and were then separated by preparative vpc (10% DEGS on Chromosorb W 60/80, 6 ft at 180°C). For uv studies, a final purification was performed by passing each isomer through a column of neutral alumina eluting with cyclohexane. Dichloromaleic anhydride was twice vacuum sublimed, recrystallized from methylene chloride, and stored under vacuum. Tetracyanoethylene was recrystallized twice from chlorobenzene and was then twice vacuum sublimed before use.

Spectrophotometric measurements were carried out on a Cary 118 spectrophotometer. All spectra were taken immediately after the solutions were prepared. No reaction between any of the donor–acceptor pairs in methylene chloride was observed (monitoring with vpc and thin layer chromatography). The concentration of dichloromaleic anhydride was 18 m*M* and tetracyanoethylene was 12 m*M*. The concentration of the donors was between 55 and 120 m*M*.

The electrolytic oxidation potential measurements were carried out using a three electrode cyclic voltammetric cell with a Princeton Applied Research Electrochemistry System model 170. The working electrode was a platinum wire. The reference electrode was $Ag/AgNO_3$ (0.1 *M*) with 0.1 *M* tetraethylammonium perchlorate, as the supporting electrolyte, in acetonitrile solution.

Photoelectron spectra were obtained on a McPherson ESCA 36 photoelectron spectrometer. The samples were introduced as vapour at room temperature and 10^{-6} Torr. The He(I) radiation of a He(II) lamp was employed.

On a synthétisé les méthyl-2 méthylamino-6 heptène-2 ols-1 *trans*-(*E*) (**6**) et *cis*-(*Z*) (**13**), deux métabolites *in vivo* de l'agent antispasmodique isometheptène (**2**) triméthyl-*N*,1,5 hexenylamine-4 (±). Dans la première synthèse de l'isomère *trans*, on oxyde le dérivé *N*-trifluoroacétyle de **2** par le bioxyde de sélénium dans l'éthanol afin d'obtenir le méthyl-2 *N*-méthyltrifluoro acétamido-6 heptène-2 al-1 *trans* (**4**). On transforme l'aldéhyde **4** en **6** par une réaction avec le borohydrure de sodium dans l'éthanol. Dans la deuxième synthèse, on hydrolyse sans isomération les éthylènecétals des méthyl-2 oxo-6 heptène-2 ol-1 *trans* (**8**) et *cis* (**11**) en hydroxycétones **9** et **12**. La réduction aminante de **9** et **12** conduit aux métabolites désirés **6** et **13**.
[Traduit par le journal]

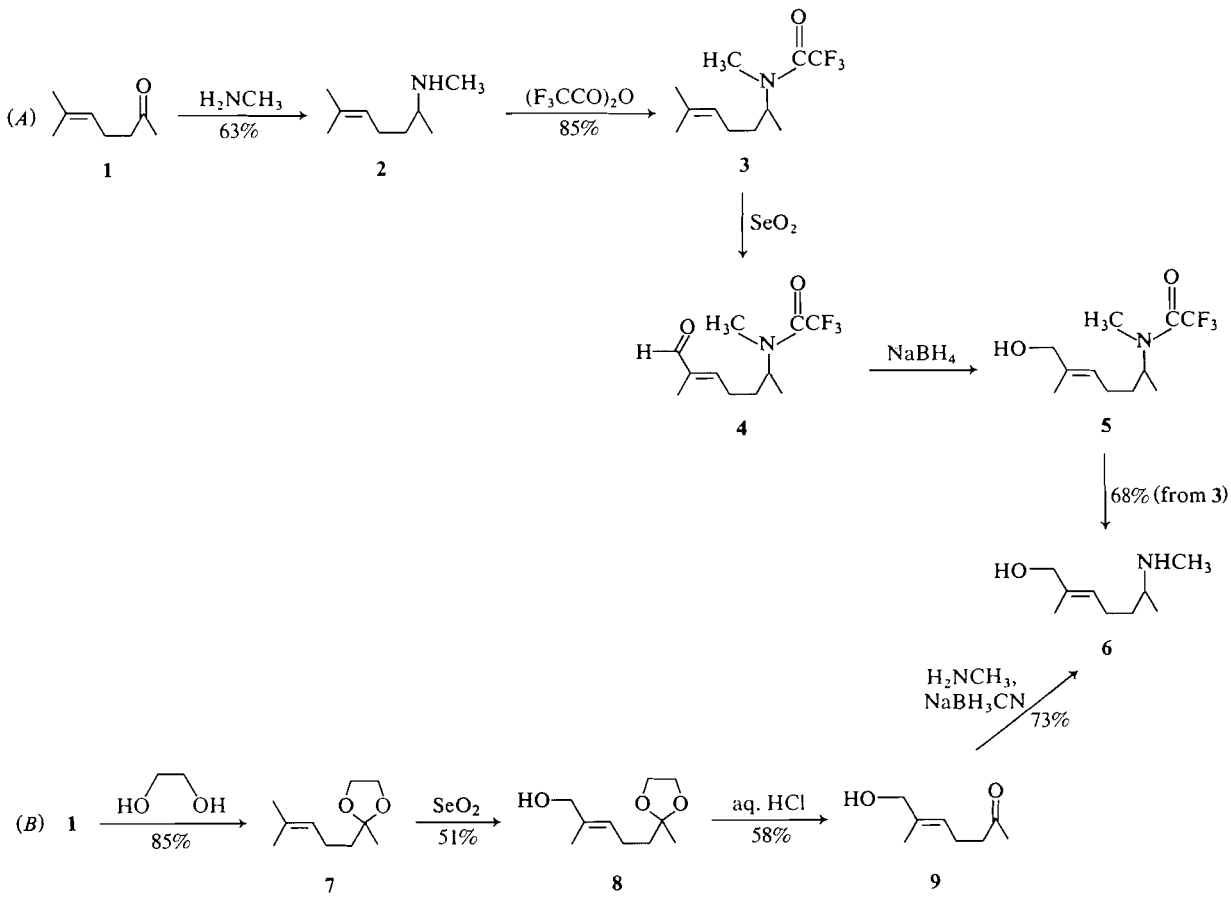
Isometheptene (**2**), an *N*-methylamine possessing the isobutenyl group, is a drug used in medicine as an antispasmodic agent. After oral administration to male rats, **2** was recently shown (1) to undergo allylic monohydroxylation at each of the methyl carbon atoms of the isobutenyl group. One urinary metabolite was identified as *trans*-2-methyl-6-methylamino-2-hepten-1-ol (**6**); the other was tentatively concluded to be *cis*-2-methyl-6-methylamino-2-hepten-1-ol (**13**). These isomers were detected in rat urinary extracts in an approximate ratio of 80% (*trans*) to 20% (*cis*). An authentic sample of the *trans* isomer (**6**) could not be synthesized for direct comparison with the major rat metabolite of isometheptene. The *N*-acetyl derivative of **6** was synthesized, however, and was identical (by gas chromatography (gc) and mass spectrometry) to the *N*-acetylated metabolite, but numerous attempts to hydrolyze this derivative were unsuccessful. Since it was desirable to compare the properties of metabolites **6** and **13** with those of the parent compound **2**, further attempts were made to prepare these isomers. Synthetic approaches to **6** and **13** are the subject of this paper.

Two routes to the *trans* isomer were explored according to Scheme 1. Both routes utilized selenium dioxide as a key reagent because of its known ability to oxidize isobutenyl groups at one of the methyl carbon atoms with *trans* selectivity (1–4).

In method *A*, the starting material, 6-methyl-5-hepten-2-one (**1**) was converted to **2** using the conditions of Borch (5). The trifluoroacetyl derivative (**3**) was formed in high yield by reacting **2** with trifluoroacetic anhydride in the presence of methylene chloride and pyridine. It was established initially that the *N*-trifluoroacetyl group in **3** could be removed in methanolic ammonia at room temperature and concluded that if **3** could be oxidized at the allylic position, the *N*-protecting group of the expected product **5** could be cleaved under similar mild conditions. This contrasts with the *N*-acetyl derivative of **6** which was stable to *N*-deacetylation even under the influence of boiling barium hydroxide (1).

By reacting **3** with selenium dioxide in refluxing ethanol, the desired trifluoroacetyl aldehyde **4** was obtained as the major product (gc and mass spectral evidence). Crude **4** was reduced with sodium borohydride in ethanol for 1.5 h and, when the reaction mixture was examined by gc, two main components were observed. Both were identified by gc and mass spectrometry; the compound with the longer reten-

0008-4042/79/162103-05$01.00/0



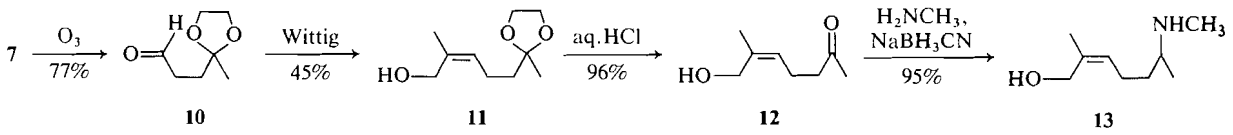
SCHEME 1

tion time was the trifluoroacetyl alcohol, **5**, whereas the more volatile compound was the desired *trans*-2-methyl-6-methylamino-2-hepten-1-ol, **6**. When the reduction reaction was continued for 4–5 h, the quantity of **6** increased at the expense of **5**. Thus, under these conditions, not only was the aldehyde functionality of **4** reduced but also the trifluoroacetyl group of **5** was removed in a gradual and complete manner. The desired product, **6**, was isolated in 68% yield (from **3**).

Molecular ions in the mass spectra of the trifluoroacetyl intermediates were either very weak (**3** and **4**) or absent (**5**). However, the appearance of prominent fragment ions, occurring at *m/e* 154, 110, and 42, were informative and aided in establishing the structures. These three ions have previously been observed in the mass spectra of related trifluoroacetyl compounds (6).

In the synthesis of **6** by method *B*, 6-methyl-5-hepten-2-one ethylene ketal, **7**, was converted to the *trans* olefinic alcohol **8** by reaction with selenium dioxide and then sodium borohydride as outlined previously (3). Deketalization of **8** in an acidified solution of tetrahydrofuran gave hydroxyketone **9** in a moderate yield. The introduction of the methylamino group of **6** was accomplished in 73% yield by the Borch procedure (5), which involved reacting **9** with methylamine and sodium cyanoborohydride in methanol solution.

Although higher yields were generally obtained by method *A*, method *B* was also quite efficient (Scheme 1). Conversion of **3** to **6** did not require purification of **4** and isolation of **5**, thus simplifying the method *A* sequence. Conventional purification methods gave pure compounds (viz. **2**, **3**, **7**, **8**, and **9**) but the final product from both routes was more difficult to purify. Attempts at purification of **6** by salt formation (tartrate, mucate, maleate, or hydrochloride) were unsuccessful because hydroscopic semi-solids or viscous oils formed. The free base was eventually purified by column chromatography on silica gel, followed by fractional distillation. Pure samples of **6** from method *A* and method *B* had identical nmr spectra. The *trans* stereochemistry of **6** was established by *N*-acetylation of **6** with acetic anhydride in methanol. It was found that the *N*-acetyl derivatives



10 11 12 13

SCHEME 2

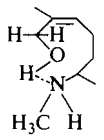
were identical with the *N*-acetyl derivative of **6** that had been previously characterized (1).

Scheme 2 outlines the synthesis of the *cis* isomer (**13**). Ketal alcohol **11** was obtained from 4-oxo-1-pentanal ethylene ketal (**10**) by a modification of the Wittig reaction that provides *cis* stereoselectivity (7, 8) as previously described (3). Ketal alcohol **11** was converted to aminoalcohol **13** via the hydroxyketone **12** by the same procedures as outlined for the *trans* isomer. The *N*-acetyl derivative of **13** had the same properties as the minor component in the acetylated rat urinary extracts (1).

A verification of *cis* stereochemistry for **13**, and of *trans* stereochemistry for **6**, came from their ^{13}C nmr spectra. Of particular interest were the ^{13}C chemical shifts for the carbon atom bearing the hydroxyl group (C-1). For **13**, C-1 resonated at 61.5 ppm whereas **6** showed a signal for C-1 at 68.2 ppm. These differences in chemical shifts have permitted the assignment of *cis* or *trans* stereochemistry to geometrical isomers of this particular type (1, 2).

The ^1H nmr spectra of the isomers were also informative. When **13** was examined in deuterochloroform solution, the methylene protons at C-1 showed an AB quartet centered at 4.1 ppm. This unexpected nonequivalence contrasted to the appearance of the methylene protons at C-1 in **6**, which resonated as a two-proton singlet near 4 ppm.

Examination of molecular models suggested a plausible explanation for the nonequivalence of the methylene protons at C-1 in the *cis* isomer. As shown by **14**, only the *cis* isomer was capable of adopting an internal hydrogen bonded conformation. The hydrogen bonded conformer **14** imposes a different environment on the C-1 protons because of restricted rotation about the C-1 to oxygen bond. This case is somewhat analogous to the nmr nonequivalence of methylene protons adjacent to the oxygen atom of certain hindered ethers (9).



14

The intramolecular hydrogen bonding argument was supported on running the ^1H nmr spectra of **6** and **13** in deuterated dimethylsulfoxide. In this polar solvent, the C-1 methylene protons in both isomers resonated as singlets at 3.8 and 3.9 ppm, respectively.

It is relevant to note that *cis* and *trans* hydroxylation of the isobutenyl group of **2** was species dependent. Although rats gave predominantly **6**, the *cis* isomer **13** was the only isomeric alcohol that was detected in human urine (10). In the case of pentazocine, an analgesic with the isobutenyl group, *cis* hydroxylation was also found to occur in vivo in man (11, 12).

Experimental

Melting points and boiling points are uncorrected. Infrared spectra were taken as liquid films on a Unicam SP 1000 spectrophotometer and on a Perkin Elmer model 137 Infracord instrument. ^1H nmr spectra were recorded at ambient temperature on a Varian EM-360A spectrometer and ^{13}C nmr spectra were measured with a Bruker WP-60 instrument with tetramethylsilane as the internal standard (δ 0). Gas–liquid chromatography was performed on Hewlett-Packard models 5710A and 5838A instruments. The glass column, 1.2 m long and 4 mm id, was packed with 5% OV-101 on acid washed – DMCS treated Chromosorb 750 and the flow rate (nitrogen) was 60 mL/min. Combined gc–ms was performed as described before (1) except for compounds **9** and **12**, whose spectra were recorded (at 70 eV) on a DuPont 21-491 instrument. Elemental analyses were obtained from Galbraith Laboratories, Knoxville, TN, and by Dr. C. Daessle, Montreal, P.Q. Trifluoroacetic anhydride, sodium cyanoborohydride, and 6-methyl-5-hepten-2-one were purchased from the Aldrich Chemical Co. SilicAR cc-7 (200–325 mesh) was obtained from Mallinckrodt Chemical Works, St. Louis, MO.

Isometheptene (2)

This compound was prepared from **1** and isolated as a maleate salt by a known (1) method (45% yield of maleate, mp 109–110°C) or by the method of Borch (5). The latter procedure, using **1** (42.75 g, 0.34 mol), methylamine hydrochloride (30.38 g, 0.45 mol), potassium hydroxide (7.07 g, 0.126 mol), and sodium cyanoborohydride (9.55 g, 0.152 mol) in methanol (350 mL), gave, after adding maleic acid to an ether solution of the crude free base, 54.7 g (63% yield) of **2** maleate, mp 107–108°C. The pure free base was obtained as an oil (gc retention time at 130°C was 1.0 min) by ether extraction of a basified aqueous solution of the maleate salt. The bp of **2** was 43°C at 0.3 Torr.

N-*Trifluoroacetyl*-N-*1,5-trimethyl-4-hexenylamine (3)*

A solution of **2** (18.0 g, 0.128 mol) in dry methylene chloride (400 mL) containing pyridine (20 mL) was cooled to 5°C. Trifluoroacetic anhydride (40 mL) in methylene chloride (100 mL) was added dropwise during 30 min. The mixture was stirred at room temperature (ca. 20°C) for 3 h. After evaporation of the solvent, methanol was added (200 mL). The mixture was stirred and then concentrated on the rotary evaporator. Water (150 mL) was added and the pH was adjusted to 4.5 with 0.1 *N* hydrochloric acid. The aqueous layer was extracted with ether. Evaporation of the dried ($MgSO_4$) organic extract

gave 25.6 g (85%) of **3** as a colorless oil. An analytically pure sample was obtained by distillation: bp 82°C (1.5 Torr); gc retention time (130°C) was 3.1 min; ir: 1695 cm^{-1} (C=O); ms *m/e* (% relative abundance) [identity]: 237 (0.5) [$M^{\ddagger}$], 222 (7) [$M - CH_3$]$^+$, 168(23), 167(11), 154(26) [$CH_3CH{=}\overset{+}{N}(CH_3)COCF_3$], 140(13), 110(90) [$CF_3C{\equiv}\overset{+}{N}(CH_3)$] and [$M - CH_3NHCOCF_3$]‡, 95(100), 85(15), 69(31) [CF_3]$^+$, 67(21), 42(15) [$CH{\equiv}\overset{+}{N}(CH_3)$]. *Anal.* calcd. for $C_{11}H_{18}F_3NO$: C 55.68, H 7.64, N 5.90; found: C 55.89, H 7.64, N 5.65.

The trifluoroacetyl group of **3** was removed (**2** was recovered) by stirring **3** in methanol saturated with ammonia gas for 4 days in a parafilm-sealed flask.

trans-*2-Methyl-6-methylamino-2-hepten-1-ol* (**6**, *Method* A)

To a stirred solution of **3** (23.7 g, 0.1 mol) in 95% ethanol (1000 mL) was added selenium dioxide (26.82 g, 0.24 mol) and the reaction mixture was heated under reflux for 16 h. After leaving overnight at room temperature, the mixture was filtered and the orange filtrate was evaporated to near dryness. The resulting brown oil was dissolved in ether and washed with aqueous sodium bicarbonate solution. The aqueous layer was extracted with ether and the combined organic extracts were dried ($MgSO_4$). A brown, viscous oil (24.85 g) was obtained on evaporation. Gas chromatography at 130°C showed one main peak (gc retention time 10.75 min) which was identified as **4** by ms: *m/e* (% relative abundance) [identity]: 251(0.2) [$M^{\ddagger}$], 236(3) [$M - CH_3$]$^+$, 182(5), 154(100) [$CH_3CH{=}\overset{+}{N}(CH_3)COCF_3$], 124(38) [$M - CH_3NHCOCF_3$]‡, 110(46) [$CF_3{\equiv}\overset{+}{N}CH_3$], 109(15), 95(10), 69(9) [CF_3]$^+$, 42(23) [$CH{\equiv}\overset{+}{N}(CH_3)$].

Aldehyde **4** (12.4 g) was dissolved in 95% ethanol (200 mL) and added dropwise with stirring to a 5°C solution of sodium borohydride (6.2 g) in 95% ethanol (600 mL). The solution was stirred and an aliquot was removed after 1.5 h (see below). After allowing the reaction mixture to approach room temperature during 4.5 h, the ethanol was removed on the rotary evaporator and the resulting yellow semi-solid was dissolved in water (250 mL). The pH was adjusted to 12 with sodium hydroxide. After extracting exhaustively with ether and drying ($MgSO_4$), 5.35 g (68%) of **6** were obtained. This yellow oil was identical with **6** isolated in method *B*.

The aliquot from above was examined by gc and two components were detected in nearly equal amounts. The component with a retention time of 3.2 min (oven temperature 130°C) was identified by ms as **6**. The other component with a retention time of 11.6 min was identified as trifluoroacetyl alcohol **5** by ms: *m/e* (% relative abundance) [identity]: 235(2) [$M - H_2O$]‡, 154(100) [$CH_3CH{=}\overset{+}{N}(CH_3)COCF_3$], 110(50) [$CF_3C{\equiv}\overset{+}{N}CH_3$], 108(32), 93(18), 69(9) [CF_3]$^+$, 42(21) [$CH{\equiv}\overset{+}{N}(CH_3)$].

trans-*2-Methyl-6-oxo-2-hepten-1-ol* (**9**)

Using conditions similar to those of Zoretic and Chiang (13), **8** (14.81 g) was deketalized at room temperature in the presence of tetrahydrofuran (180 mL) and 5.0 *N* hydrochloric acid (60 mL). The mixture was stirred for 11 h, and neutralized to pH 7 with solid sodium bicarbonate. The solvent was removed on the rotary evaporator and the residue was stirred with a saturated solution of sodium chloride. After extracting with ether, drying ($MgSO_4$), and evaporating the solvent, the crude product was distilled under vacuum. There was obtained 6.58 g (58.2%) of **9** as a pale yellow liquid. An analytically pure sample was obtained by column chromatography (silicAR cc-7) eluting with hexane, hexane–ether, and hexane–ethyl acetate mixtures: bp 82°C (0.1 Torr); gc retention time (120°C) was 3.5 min; ir: 3470 (OH) and 1720 cm^{-1} (C=O); ^{1}Hmr ($CDCl_3$) δ: 5.40 (ragged t, 1H, C=C*H*), 4.02 (s, 2H, CH_2OH), 2.17 (s, 3H, CH_3), 2.75–1.30 (m, 5H, CH_2CH_2 and CH_2OH, the latter exchanged with D_2O), 1.68 (s, 3H, C=CCH_3); ms *m/e* (% relative abundance) [identity]: 142(0.1) [$M^{\ddagger}$], 124(24) [$M - H_2O$]‡, 84(24) [$CH_2{=}CHCH_2\overset{+}{C}OCH_3$]‡, 82(14), 81(15), 43(100) [$CH_3C{\equiv}\overset{+}{O}$]. *Anal.* calcd. for $C_8H_{14}O_2$: C 67.57, H 9.92; found: C 67.86, H 10.05.

trans-*2-Methyl-6-methylamino-2-hepten-1-ol* (**6**, *Method* B)

To a solution of methylamine hydrochloride (3.38 g, 0.05 mol) and potassium hydroxide (0.785 g, 0.014 mol) in methanol (100 mL) was added hydroxyketone **9** (5.69 g, 0.04 mol) and the resulting suspension was stirred at room temperature for 30 min. Sodium cyanoborohydride (1.07 g, 0.017 mol) in methanol (30 mL) was added dropwise during 30 min and the reaction mixture was stirred at room temperature for 19 h. Potassium hydroxide (3.0 g) was added and stirring was continued until the pellets dissolved. The suspension was filtered and the KCl cake was washed well with methanol. After evaporating the filtrate under reduced pressure, the resulting oil was stirred with a saturated solution of sodium chloride (75 mL). The mixture was extracted with ether, washed with water, and the organic extract dried ($MgSO_4$). Evaporation of the ether gave 4.6 g (73.1%) of **6**. This oil was further purified by column chromatography on silicAR cc-7. Eluting with hexane–ethyl acetate mixtures and with ethyl acetate removed some brown impurities. Further elution with ethyl acetate – methanol mixtures and finally with methanol gave **6** as a nearly colorless oil. This sample was further purified by distillation: bp 86–88°C (0.2 Torr); gc retention time (130°C) was 3.2 min; ir: 3340 cm^{-1} (OH, NH); ^{1}Hmr ($CDCl_3$) δ: 5.43 (ragged t, 1H, C=C*H*), 4.00 (s, 2H, CH_2OH), 2.40 (s, 3H, NCH_3), 1.70 (s, 3H, C=CCH_3), 2.90–1.20 (m, 5H, CH_2CH_2, $CHCH_3$), 1.07 (d, 3H, J = 6 Hz, $CHCH_3$); ^{13}Cmr ($CDCl_3$) δ: 68.2 ppm (CH_2OH); ms identical to metabolite A in ref. 1. *Anal.* calcd. for $C_9H_{19}NO$: C 68.74, H 12.18, N 8.91; found: C 68.58, H 12.38, N 8.95.

cis-*2-Methyl-6-oxo-2-hepten-1-ol* (**12**)

This alcohol was prepared from **11** (7.0 g) by the same procedure that gave **9** from **8** except that the time of reaction was 4 h. After drying and concentrating the organic extracts, there was obtained 5.13 g (96%) of **12** as a slightly impure yellow oil. An analytically pure sample was obtained by column chromatography on silicAR cc-7, eluting with hexane, hexane–ether, and hexane – ethyl acetate: gc retention time (120°C) was 3.0 min; ir: 3500 (OH) and 1720 cm^{-1} (C=O); ^{1}Hmr ($CDCl_3$) δ: 5.20 (ragged t, 1H, C=C*H*), 4.13 (s, 2H, CH_2OH), 2.13 (s, 3H, CH_3), 2.75–1.30 (m, 5H, CH_2CH_2 and CH_2OH, the latter exchanged with D_2O), 1.79 (s, 3H, C=CCH_3); ms *m/e* (% relative abundance) [identity]: 142(0.2) [$M^{\ddagger}$], 124(22) [$M - H_2O$]‡, 84(24) [$CH_2{=}CHCH_2\overset{+}{C}OCH_3$]‡, 82(15), 81(15), 43(100) [$CH_3C{=}\overset{+}{O}$]. *Anal.* calcd. for $C_8H_{14}O_2$: C 67.57, H 9.92; found: C 67.86, H 10.12.

cis-*2-Methyl-6-methylamino-2-hepten-1-ol* (**13**)

This compound was prepared from **12** (4.98 g, 0.035 mol) by the same procedure used to prepare **6** from **9**. The product, as a brown oil (5.25 g, 95% yield), was purified by silicAR cc-7 chromatography (as described for **6**) and then distilled: bp 85–89°C (0.3 Torr); gc retention time (130°C) was 3.1 min; ir: 3330 cm^{-1} (OH, NH); ^{1}Hmr ($CDCl_3$) δ: 5.25 (ragged t, 1H, C=C*H*), 4.23 and 3.90 (two doublets of an AB quartet, J = 12 Hz, 2H, CH_2OH), 2.33 (s, 3H, NCH_3), 1.80 (s, 3H, C=CCH_3), 3.10–1.20 (m, 5H, CH_2CH_2, $CHCH_3$), 1.03 (d, J = 6 Hz, 3H, $CHCH_3$); ^{13}Cmr ($CDCl_3$) δ: 61.5 ppm

(CH_2OH); ms was the same as obtained for **6**. *Anal.* calcd. for $C_9H_{19}NO$: C 68.74, H 12.18, N 8.91; found: C 68.42, H 11.93, N 8.79.

Acknowledgments

We thank the Medical Research Council of Canada for partial financial assistance. One of us (W.G.T.) thanks Dr. W. O. Haufe, Research Branch, Agriculture Canada, for support in completing this work. We also thank Dr. T. Nakashima, University of Alberta, for useful discussions on the ^1H nmr data and for recording the ^{13}C nmr spectra.

Resonant ejection of ion species from the quadrupole ion store (QUISTOR) is shown to reveal the coupling of reactant ions with product ions in ion/molecule reactions studied with the QUISTOR – quadrupole mass filter combination. The technique involves the use of selective ejection of a chosen ionic precursor and the simultaneous observation of the perturbations in the concentration of product ions. The technique is demonstrated in studies of the ion chemistry and reaction kinetics of two known chemical systems.

MARY ALISON ARMITAGE, JOHN EDWARD FULFORD, DUONG-NHU-HOA, RICHARD JAMES HUGHES et RAYMOND EVANS MARCH. Can. J. Chem. **57**, 2108 (1979).

On a montré que l'éjection résonante d'espèces ioniques par un réservoir d'ions quadrupolaires (QUISTOR) révèle le couplage d'ions réactifs avec des ions produits dans des réactions ion/molécule étudiées à l'aide de la combinaison QUISTOR-filtre de masse quadrupolaire. La technique implique l'utilisation d'une éjection sélective d'un précurseur ionique choisi et l'observation simultanée des perturbations dans la concentration des ions produits. On a démontré la technique dans des études de la chimie ionique et de la cinétique réactionnelle de deux systèmes chimiques connus.

[Traduit par le journal]

Introduction

Much of the available information on ion/molecule reactions has been compiled with non-specific techniques such as high pressure mass spectrometry (1) and the flowing afterglow (2). In complex systems these methods involve the simultaneous reactions of many ion species, analysis of all the products, and interpolation of reaction mechanisms. The same is also true of the first studies with the QUISTOR–quadrupole combination (3–6). Recent interests have been concerned with techniques which permit the selection of one reactant ion and elimination of much of the speculation that was once necessary. Thus tandem mass spectrometers such as the selected ion flow tube (7) are receiving much attention. A recent communication from this laboratory (8) described a selective ion reactor, wherein the QUISTOR–quadrupole combination was operated in a tandem mass spectrometric mode.

Ion cyclotron resonance mass spectrometry has been used widely for the study of ion/molecule reactions. The ion cyclotron double resonance (ICDR) technique can be used to probe specific ion/molecule mechanisms by exciting precursor ions with radiation, and observing perturbations in the product ion distribution (9, 10). In our current investigations of ion motion in the QUISTOR a technique similar to ICDR has been developed and is described as QUISTOR Resonance Ejection (QRE). In both techniques, ions may be selectively excited and ultimately ejected from the ion trap by resonant power absorption. As the resonant excitation is mass dependent, the technique may be applied in a fashion similar to that of ICDR except for the mass analysis which, in the case of the QUISTOR, is carried out with a quadrupole mass filter rather than a marginal oscillator. In this paper we present a demonstration of the use of QRE as a means of elucidating ion/molecule mechanisms and kinetics.

Theory

As has been discussed elsewhere (11, 12), the equations of motion for ions in a three dimensional quadrupole field take the general form of the Mathieu equation

$$[1] \quad d^2u/d\xi^2 + (a_u - 2q_u \cos 2\xi)u = 0$$

where

$$[2] \quad u = r \text{ or } z$$

$$[3] \quad q_z = -2q_r = -4\,eV/mr_0^2\Omega^2$$

$$[4] \quad a_z = -2a_r = -8eU/mr_0^2\Omega^2$$

$$[5] \quad \xi = \Omega t/2$$

U is the dc voltage, V is the o-p RF voltage, m/e is

0008-4042/79/162108-06$01.00/0

the mass-to-charge ratio, r_0 is the radius of the ring electrode, and Ω is the radial frequency of the RF voltage. From the general solution of the Mathieu equation of motion

$$[6] \quad u = \alpha' e^{i\beta\xi} \sum_{n=-\infty}^{\infty} C_{2n} e^{2in\xi} + \alpha'' e^{-i\beta\xi} \sum_{n=-\infty}^{\infty} C_{2n} e^{-2in\xi}$$

The β value is related to the frequency of the ion trajectory and more specifically to the dominant secular frequency, ω_u:

$$[7] \quad \omega_u = \beta_u \Omega/2$$

The oscillation frequency is mass dependent, i.e.

$$[8] \quad \omega_u = \beta_u \Omega/2 = (a_u + q_u^2/2)^{1/2}\Omega/2$$

and in the z direction with $a_z = 0$ (with no dc component)

$$[9] \quad \omega_z = (q_z^2/2)^{1/2}\Omega/2 = \sqrt{2}eV/mr_0^2\Omega$$

The imposition of a low level sinusoidal potential of frequency ω_z will cause the ion oscillating at this frequency to absorb energy and in the limit to be lost from the trapping field. This property permits the selective resonant ejection of a given ion species without disturbance of the other ions being stored under low pressure conditions. The resonant ejection technique can be used as a specific probe for ion/molecule interactions at higher sample pressure. Resonant perturbation of a precursor ion will be transmitted through chemical interactions and change the relative abundance of product ions.

Experimental

The basic apparatus has been described in detail elsewhere (5). In the 2-propanol study, a constant pressure of 5.5×10^{-5} Torr was maintained, while in the argon/carbon dioxide study a 7:1 mixture of argon:carbon dioxide was used at a total pressure of 1×10^{-4} Torr. Pressures were measured using an MKS Baratron gauge. Neutral gas temperatures were estimated to be approximately 320 K. In the 2-propanol study, ion densities within the QUISTOR were estimated from the space charge induced perturbation of the secular frequency, ω_z, from the theoretical value (11). The average ion density after 1 ms of storage was 3.1×10^6 cm^{-3}. The storage times used in this study ranged from 200 μs to 10 ms though the present practical limitation is 100 ms. The resonance oscillator was connected to the repeller endcap (upper end cap electrode in Fig. 1) for application of the resonant signal in the z-direction.

The resonant frequency was applied for continuous ejection of a particular ion mass and in this manner the ion/molecule mechanisms of 2-propanol were probed. The Wavetek Model 134 sweep generator has the capability to provide a burst of a resonant frequency and this technique was used for a kinetic study of the argon:carbon dioxide system. The pulse train is shown in Fig. 2. The Wavetek generator triggered the creation pulse generator which triggered the scan delay generator (Brookdeal Ortec 9425A). The trigger pulse from the scan delay generator triggered simultaneously the ejection pulse generator and the sample-and-hold circuit (Brookdeal Ortec Linear Gate 9415). The argon and carbon dioxide were used as obtained from Matheson of Canada Ltd. The 2-propanol was obtained from Fisher Scientific and degassed by freeze–pump–thaw cycles before use. The spectra were not corrected for the mass discrimination due to the QUISTOR or quadruple mass filter.

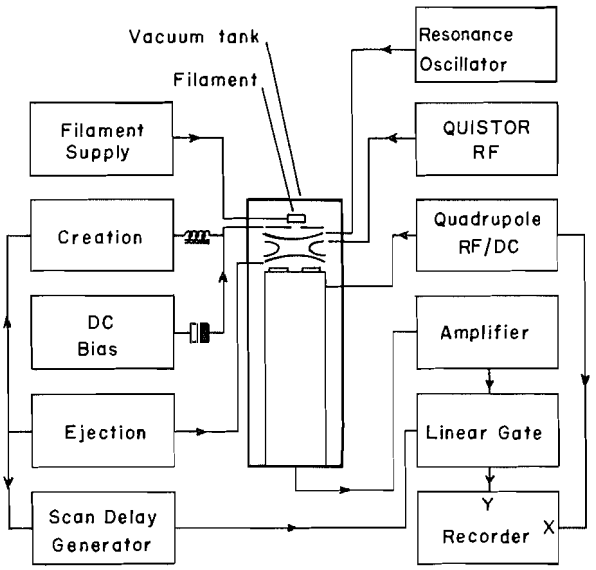

FIG. 1. Schematic diagram of apparatus.

Results and Discussion

The ion chemistry of 2-propanol has been studied by Beauchamp *et al.* (13, 14) using the ion cyclotron double resonance technique (ICDR).

As the 2-propanol system is well documented and falls within the convenient mass range of the quad-

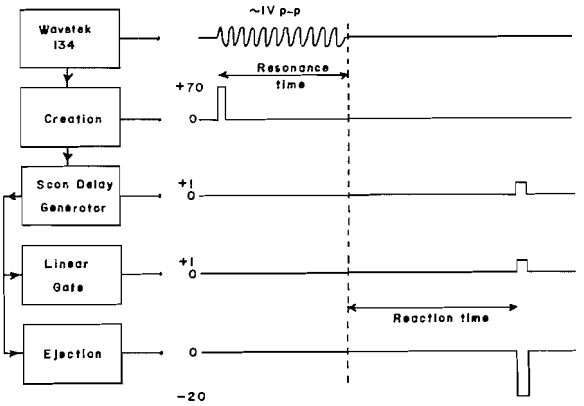

FIG. 2. Pulse train for pulsed resonant ejection.

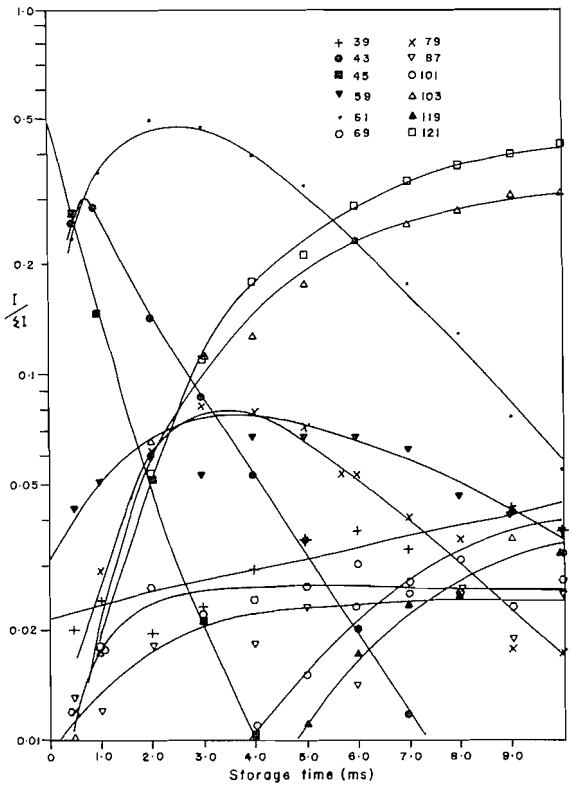

FIG. 3. Variation in the logarithm of normalized ion abundances in 2-propanol; 0–10 ms, 300 Vo-p at 1.6 MHz, 5.5 × 10^{-5} Torr.

rupole mass filter, 2-propanol was chosen as the subject for investigation in the QUISTOR using the resonant ion ejection technique (QRE). The ion profiles of 2-propanol are shown in Fig. 3 and a comparison of observations by ICR and the QUISTOR is shown in Table 1. A comparison of the precursor to product ion dependencies indicated by ICDR and QRE is shown in Table 2. An example of the spectra obtained with and without resonant ion ejection by QRE is shown in Fig. 4. Upon resonant ejection of *m/e* 61, reduction of the ion signal intensities of *m/e* 79, 101, 103, 119, and 121 are readily observed. The data obtained by ICDR and QRE are remarkably similar except for two points: (*i*) *m/e* 39 was observed as a minor component (~4%) in the QRE study but was not reported as a persistent ion in the ICDR studies. (*ii*) *m/e* 59 and its associated product ions were not reported in the ICDR studies. The ICDR work was carried out with ionizing beams of 70 eV and 13.5 eV electrons whereas the QRE study used nominally 70 eV electrons.

The *m/e* 39 ion may originate from a slightly endothermic pathway which becomes available as a result of the small fraction of ions which may be stored with energies in excess of thermal (15). Simi-

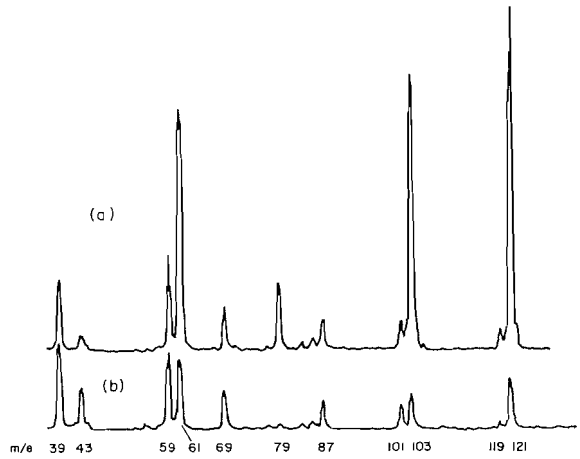

FIG. 4. Spectra of 2-propanol (*a*) without and (*b*) with resonant ejection of *m/e* 61 (ω_z = 86 kHz), RF-254 Vo-p at 1.6 MHz; 4 ms storage time.

larly the observation in the QUISTOR of *m/e* 59 may be explained by dehydrogenation of excited *m/e* 61 according to eq. [10].

$$[10]\quad \left[(CH_3)_2\overset{H}{\underset{|}{C}}-\overset{+}{O}\begin{matrix}H\\H\end{matrix}\right]^* \longrightarrow (CH_3)_2C{=}\overset{+}{O}H + H_2$$

m/e 61 *m/e* 59

ΔH = 12 kcal/mol

The *m/e* 59 ion profile goes through a maximum simultaneously with the *m/e* 61 ion profile; the *m/e* 61 ion being formed from *m/e* 43 (13), *m/e* 45 (a reaction which is exothermic by 11 kcal/mol (14)) and by proton transfer between *m/e* 59 (protonated acetone) and 2-propanol: the proton affinities of acetone and 2-propanol being equal (16).

$$[11]\quad \underset{m/e\ 59}{(CH_3)_2C{=}\overset{+}{O}H} + (CH_3)_2CHOH \rightarrow \underset{m/e\ 61}{(CH_3)_2C\overset{+}{H}OH_2} + (CH_3)_2C{=}O$$

The regeneration of *m/e* 61 through the intermediacy of *m/e* 59 may account for the coupling of both *m/e* 59 and *m/e* 61 with *m/e* 101 and *m/e* 119.

According to the QRE experiments the protonated acetone, *m/e* 59, is coupled to *m/e* 79, 103, and 121. This may be rationalized in the following manner: *m/e* 61, which is coupled with *m/e* 59 through eq. [11], reacts with 2-propanol to form the di-solvated proton, *m/e* 121.

$$[12]\quad \underset{m/e\ 61}{(CH_3)_2C\overset{+}{H}OH_2} + (CH_3)_2CHOH \rightarrow \left[(CH_3)_2CHO\cdots\overset{+}{H}\cdots OCH(CH_3)_2\right]^*$$

or to lose water and yield *m/e* 101:

[16] $$\left[(CH_3)_2C{=}O\cdots\overset{+}{H}\cdots\overset{H}{\underset{\vert}{O}}CH(CH_3)_2\right]^* \rightarrow \underset{m/e\ 101}{(CH_3)_2C{=}\overset{+}{O}{-}CH(CH_3)_2} + H_2O$$

Studies with low energy electrons were not undertaken with the QUISTOR.

A second application of resonant ejection is the simplification of kinetic studies by the isolation of single reactant ion species. For example, the resonant ejection technique was applied to a 7:1 argon and carbon dioxide mixture for the determination of individual rate constants:

[17] $Ar^+ + CO_2 \rightarrow Ar + CO_2^+$

[18] $Ar^{2+} + CO_2 \rightarrow Ar^+ + CO_2^+$

[19] $Ar^{2+} + Ar \rightarrow 2Ar^+$

Although partial charge transfer reactions of doubly charged ions with neutrals have been investigated intensively in beam experiments (17), relatively few data are available for partial charge transfer reactions, such as reactions [18] and [19], in the thermal energy region. Resonant ejection of Ar^{2+}, formed by electron bombardment, enabled the clear measurement of k_{17} in the absence of contributions to the Ar^+ concentration by reactions [18] and [19]. Pulsed resonant ejection was used to remove Ar^+ during the study of reactions [18] and [19] which enhanced the sensitivity for measurements of the relatively low Ar^{2+} and CO_2^+ signals.

The contribution of reaction [19] to the decay of Ar^{2+} in reaction [18] was calculated from the value obtained for k_{19} and found to be 3%; this is negligible in comparison to the overall uncertainty in k_{18}. The values of rate constants obtained are listed in Table 3 together with values determined by other techniques. The values are in broad agreement except k_{19} which was larger under the conditions of this study in comparison with the flow-drift tube measurement of Howorka (23). Further examination of k_{19} revealed a pressure dependence, implying that more reactive higher electronic states of Ar^{2+} may not be quenched at 1×10^{-4} Torr. This observation is presently under examination and will be reported in a subsequent paper. An extension of the pulsed resonant ejection technique to several ion species in a chemical system could be used for selective storage of a single ion species, thus permitting observation of the reactions of the remaining ion species. This technique would require the superposition of several resonant frequencies and has been demonstrated elsewhere (11).

A present limitation of the pulsed resonant ejection technique is the duration of the irradiation pulse. The pulse must be of sufficient duration to

eject completely a specific ion species yet at a power which will not perturb the storage conditions for the remaining ions of interest (11). The optimum irradiating power level, applied to an end-cap electrode, varied from 150 mV to 850 mV peak-to-peak depending on the ion intensity. The minimum separation of the end-cap electrodes was 1.414 cm. The irradiating power was applied in tone bursts of up to 1 ms duration; the duration could not be excessively long in comparison to the half-life of the ion/molecule reaction under study. Details of the application of QRE to other systems are given in ref. 11.

Regiospecific preparation of 10-allyl-1-ketoquinolizidine and an unexpected disproportionation during its Wolff–Kischner reduction

JOHN M. MCINTOSH

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received March 16, 1979

JOHN M. MCINTOSH. Can. J. Chem. 57, 2114 (1979).

Regiospecific formation of 10-allyl-1-ketoquinolizidine (**7**) is achieved in high yield by a [2.3] sigmatropic rearrangement of *N*-allyl-1-ketoquinolizidinium bromide (**6**). Wolff–Kischner reduction of **7** affords 10-allylquinolizidine (**8**) contaminated by the 10-propyl and 10-ethynyl analogs in amounts which depend on the reaction conditions. The carbon-13 spectrum of **8** indicates a *trans*-fused ring system with an axial substituent at C-10.

JOHN M. MCINTOSH. Can. J. Chem. 57, 2114 (1979).

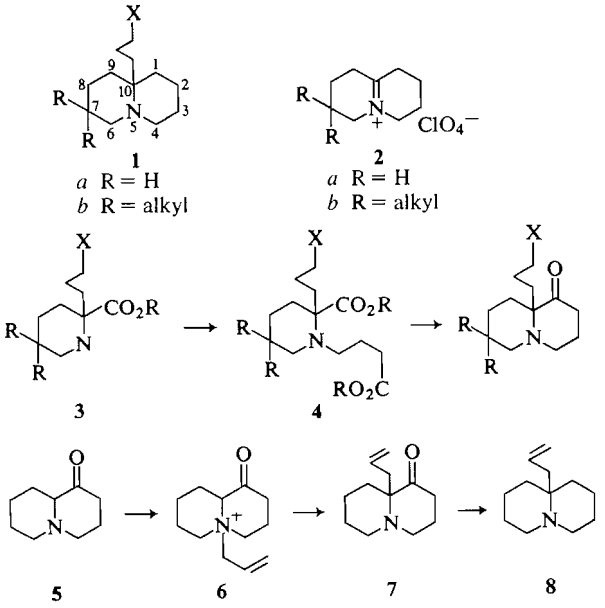
On a effectué, avec un excellent rendement, la formation régiospécifique de l'allyl-10 céto-1 quinolizidine (**7**) en faisant appel à une transposition sigmatropique du bromure du *N*-allyl céto-1 quinolizidinium (**6**). La réduction selon Wolff–Kischner de **7** conduit à l'allyl-10 quinolizidine (**8**) contaminé par les analogues propyl-10 et éthynyl-10 dont les quantités dépendent des conditions de la réaction. Selon le spectre rmn du ^{13}C de **8** le système cyclique est lié par une jonction *trans* et porte un substituant axial en C-10.

[Traduit par le journal]

In connection with an ongoing research program[1] we required a synthesis of some 10-substituted quinolizidines which contained functionality in the 10-substituent and geminal substitution in one of the heterocyclic rings (e.g., **1***b*). Several examples of **1***a* have been prepared from 5,10-dehydroquinolizidinium perchlorate (**2***a*) (1) or its cyanide adduct and Grignard reagents (2), a reaction pioneered by Leonard and co-workers. However, the syntheses available for **2** at the time we initiated our work were not attractive in terms of yield or applicability to **2***b*. Even less attractive was a route involving cyclization of **4**, since preparation of its precursor **3** appeared complicated and cyclization would be expected to be inhibited by the quaternary centre adjacent to nitrogen. The direct alkylation of **5** (3) at C-10 also appeared to present problems in terms of regiospecificity, but **5** is an attractive starting material since geminally substituted derivatives should be readily prepared.

In this connection, it occurred to us that quaternization of **5** with an allylic halide would provide a product (**6**) in which the hydrogen at C-10 would be greatly labilized and a facile [2.3] sigmatropic rearrangement would be expected (4). Deoxygenation of **7** would provide **8**, which would be capable of functionalization at the double bond by standard methods.

In the event, **5** reacted with allyl bromide quantitatively to give **6** as an extremely hygroscopic solid. Treatment of **6** with potassium *tert*-butoxide in THF/DMSO at −30°C gave a very rapid reaction leading to **7** in 75–80% yield.



1 *a* R = H, *b* R = alkyl; **2** *a* R = H, *b* R = alkyl; **3**; **4**; **5**; **6**; **7**; **8**

The carbonyl group was now ready for removal. It has been shown that **5** can be reduced using the Wolff–Kischner method, but that acidic conditions (Clemmensen) lead to rearranged products (5). We have been unable to satisfactorily reduce **7** to **8** using a variety of conditions. These failures are *not* due to steric hindrance at the carbonyl group, as a variety of addition reactions at C-1 can be performed successfully. Thus, reduction of **7** using sodium borohydride led to **9***a* as a single diastereomer, and the ethylene ketal (**9***b*), hydrazone **9***c*, and tosylhydrazone **9***d* are all formed in nearly quantitative yield under

0008-4042/79/162114-04$01.00/0

standard conditions. However, attempted preparation of the thioketal **9***e* as a prelude to reductive desulfurization (6) led only to addition at the olefinic double bond.

When the formation of the mesylate of alcohol **9***a* was attempted, only decomposition products could be isolated. This facile decomposition may be initiated by participation of the nitrogen atom in an intramolecular displacement (e.g., **10**) followed by further reactions.

When hydrazone **9***c* was treated with potassium *tert*-butoxide in refluxing xylene, conditions recommended for other α-aminoketones (7), no deoxygenated material was formed. Application of the usual Wolff–Kischner (WK) conditions led to a mixture of products, depending on the reaction conditions. When decomposition of the hydrazone was carried out in refluxing triethylene glycol without distilling out the volatile fraction, two peaks in a ratio of 1 :1 appeared in the gas chromatogram. The proton nmr of the crude mixture was as expected for **8**, except that the integration in the vinyl region was only 0.6 of the expected value and some high field absorption (δ 0.9–1) was evident. No trace of **12** could be detected. Hydrogenation of the WK product led to the uptake of 1.02 equiv. of hydrogen and the formation of a *single* product, identical in all respects with the shorter retention time material formed in the WK reduction. The spectral data and picrate melting point identified this material as 10-propylquinolizidine (**11**) (2). Using refluxing ethylene glycol as the WK solvent and distilling the volatile fraction as it was formed nearly eliminated the formation of **11**, and gave **8** in 52% yield. When **8** was heated with potassium hydroxide in refluxing triethylene glycol, **11** was again formed.

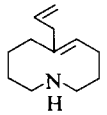
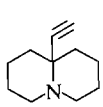
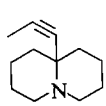
11



12



13*a*



13*b*

In each case where **11** was formed, the longer retention time peak still showed a deficiency in the integration of the vinyl proton region. Whereas the electron-impact mass spectrum of the crude WK reaction mixture showed no molecular ion, field-ionization mass spectrometry (FIMS) showed three strong peaks at m/z = 181, 179, and 177. The first two correspond to the molecular ions of **8** and **11**. The peak at m/z = 177, the formation of **11** from **8**, the reduced vinyl integration, and the formation of *only* **11** when the crude WK product was hydrogenated can only be rationalized by the presence of **13***a* and (or) **13***b* as an inseparable mixture with **8**. Base-catalyzed disproportionation of **8** to **11** and **13** apparently occurs when the temperature exceeds 200°C. Considerable decomposition accompanies the disproportionation as is evidenced by the rapid darkening of the reaction mixture. The absorptions for the acetylenic proton in **13***a* or the methyl group in **13***b* would be obscured by other absorptions in the molecules. It is interesting to note that the same disproportionation apparently occurs when the tosylhydrazone **9***d* is reduced with sodium cyanoborohydride (8) in 1 :1 DMF/sulfolane at 120°C.

Further investigations designed to improve the yield of **8** were abandoned when it was found that the hydroboration–oxidation of **8** led to a mixture of alcohols plus other products. Thus, the goal of preparing **1***a* (X = OH) was frustrated. We hope to report shortly on more successful approaches to this system.

Finally, it is interesting to note that the C-13 spectra of **8** and **11** show only eight lines with chemical shifts which strongly suggest that the C-10 substituent is axially disposed in a *trans*-fused ring system. Extensive investigations on variously methylated quinolizidines (9, 10) have shown a strong preference for *trans*-fused rings, but to our knowledge, this is the first data on the 10-substituted series with a substituent larger than methyl.

Experimental

Proton magnetic resonance spectra were run on a JEOL C60HL spectrometer and C-13 spectra were run on a Bruker CXP 100 spectrometer at 22.64 MHz, using a flip angle of 40°. Spectra are reported in ppm downfield from internal Me_4Si. Gas chromatographic analyses were performed on a Hewlett-Packard model 5750 instrument utilizing a 10 ft × 0.25 in. column packed with 20% SE-30 on Chromosorb W (column A) or a 10 ft × 0.375 in. column packed with 15% Carbowax 20M on Chromosorb W (column B). Mass spectra were run on a Varian MAT CH-5 DF instrument equipped with a field-ionization source. Elemental analyses were performed by Galbraith Laboratories or Canadian Microanalytical Service (Vancouver).

N-Ally-1-ketoquinolizidinium Bromide (6)

1-Ketoquinolizidine (**5**) was prepared from methyl pipecolate by *N*-alkylation with ethyl 4-bromobutyrate in DMF containing excess potassium carbonate at 80°C (62%), followed by cyclization and decarboxylation according to the method

of Leonard (3) (79%). To a solution of 14.0 g (0.09 mol) of **5** in 100 mL of dry acetonitrile was added 14 g (0.115 mol) of allyl bromide. The solution was stirred at ambient temperature for 36 h, the solvent evaporated, and the residue triturated with acetone. Filtration in a dry-box gave 25 g (100%) of a pale brown solid which could be purified by treatment with charcoal in boiling acetonitrile and reprecipitation with acetone to give white crystals, mp 107–110°C (dec.). The material is extremely hygroscopic and normally was not purified before rearrangement. *Anal.* calcd. for $C_{12}H_{20}NOBr$: C 52.56, H 7.35; found: C 52.49, H 7.24.

1-Keto-10-allylquinolizidine (7)

Compound **6** (3 g, 0.011 mol) was dissolved in 20 mL of dry DMSO and 20 mL of dry THF was added. The solution was cooled to −30°C and 1.4 g (1.14 equiv.) of potassium *tert*-butoxide was added all at once. The cooling bath was removed and the mixture stirred under nitrogen at ambient temperature for 1 h. The mixture was diluted with 50 mL of pentane, washed with water (2 × 50 mL), saturated brine (2 × 50 mL), dried over magnesium sulfate, and evaporated to give 1.7 g (80%) of a pale yellow oil. Gas chromatographic analysis (column A, 155°C) indicated a purity of greater than 95% Distillation gave a colorless liquid, bp. 80–83°C (0.4 Torr), which crystallized in the freezer. Compound **7** is a low melting solid which rapidly turns brown on contact with air or chloroform; ir($CHCl_3$): 1710, 1640, 920 cm^{-1}; ^1H nmr (C_6D_6) δ: 5.85–4.71 (bm, 3H), 3.05–1.06 (bm, 16H); ^{13}C nmr (C_6D_6) δ: 208.3, 133.6, 117.2, 67.5, 49.6, 47.8, 37.0, 30.5, 29.2, 25.9, 24.9, 20.3.

The picrate crystallized from ethanol as yellow plates, mp 168–170°C. *Anal.* calcd. for $C_{18}H_{22}N_4O_8$: C 51.18, H 5.25, N 13.26; found: C 51.34, H 5.14, N 13.12.

1-Hydroxy-10-allylquinolizidine (9a)

One gram (5 mmol) of **7** was dissolved in 10 mL of 2-propanol and added dropwise to a mixture of 0.1 g of sodium borohydride (2 equiv.) in 3 mL of 2-propanol and 3 drops of 3 *N* sodium hydroxide. The mixture was stirred at ambient temperature for 3.5 h and then excess hydride was decomposed with 10% HCl. The solution was made basic with 3 *N* hydroxide diluted to 40 mL with water and extracted with ether (3 × 50 mL). The combined ether extracts were washed with water and saturated brine and dried over sodium sulfate. Evaporation of the solvent gave 0.89 g (88%) of white crystals, mp. 74–75°C. This material did not discolor when dissolved in chloroform; ir($CHCl_3$): 3580, 1630, 1110, 1050, 1025, 970, 920 cm^{-1}; ^1H nmr (C_6D_6) δ: 6.52–5.80 (m, 1H), 5.22–4.80 (m, 2H), 3.68–3.05 (m, 1H), 2.50–1.10 (m, 17H); ^{13}C nmr (C_6D_6) δ: 138.2, 115.4, 77.4, 59.5, 49.2, 48.5, 32.8, 29.9, 27.2, 26.3, 24.1, 20.3. *Anal.* calcd. for $C_{12}H_{21}NO$: C 73.80, H 10.84, N 7.17; found: C 73.64, H 10.81, N 6.99.

The sharp melting point and the presence of only 12 signals in the ^{13}C nmr spectrum indicate the presence of only one diastereomer to which we assign the structure ***9a***.

Ethylene Ketal of 7 (9b)

Ketone **7** (0.316 g, 1.6 mmol) was dissolved in 5 mL of ethylene glycol, and 0.4 g triethyl orthoformate and 0.55 g (1.1 equiv.) of tosic acid were added. The flask was flushed with nitrogen and heated at 100°C for 2 h. The cooled solution was diluted with a mixture of 50 mL of water and 10 mL 12 *N* sodium hydroxide and extracted with ether (3 × 25 mL). The ether was washed with water and brine and dried over magnesium sulfate. Evaporation gave 0.34 g (91%) of a pale yellow liquid which gc analysis (column A, 240°C) showed to be 96% pure. Samples for analysis and spectra were collected from glc; ir($CHCl_3$): 1640, 1140, 955, 910 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.20–5.50 (m, 1H), 5.03–4.65 (m, 2H), 3.80 (s, 4H), 2.75–1.30 (m, 16H). *Anal.* calcd. for $C_{14}H_{23}NO_2$: C 70.85, H 9.77, N 5.90; found: C 70.55, H 9.76, N 5.71.

Attempted hydroboration–oxidation of ***9b*** using either borane or 9-BBN led to mixtures of products.

Hydrazone of Ketone 7 (9c)

Ketone **7** (0.9 g, 4.7 mmol) dissolved in 4 mL ethylene glycol and 4 mL of 85% hydrazine hydrate was added. The system was purged with nitrogen and heated at 120–130°C for 4 h. The hot solution was poured into 50 mL of water and extracted with ether (3 × 25 mL). The combined ether extracts were dried over sodium sulfate and evaporated to give 0.6 g (62%) of a pale yellow solid, mp 72–74°C; ir($CHCl_3$): 3600–2400, 1640 cm^{-1}.

Attempted Wolff–Kischner reaction of this material using potassium *tert*-butoxide in either hot xylene (7) or DMSO at 50°C (11) failed.

Tosylhydrazone of Ketone 7 (9d)

Ketone **7** (0.425 g, 2.2 mmol) was dissolved in 10 mL of methanol and 0.61 g (1.5 equiv.) of toluenesulfonylhydrazine was added followed by 0.5 g tosic acid. The mixture was sitrred at ambient temperature overnight, evaporated, diluted with 40 mL of water, and made basic with 3 *N* sodium hydroxide. The solution was extracted with chloroform (3 × 25 mL) and the combined organic layers washed with water and dried over sodium sulfate. The filtered solution was evaporated and the residue triturated with ether. The precipitate was filtered and washed with ether to give 0.48 g (60%) of white crystals, mp 122–125°C. Recrystallization from ethanol–water gave a material whose infrared and proton nmr spectra were identical to the above material, but whose melting point was 74–75°C. The analysis and solution spectra of the crude and the recrystallized materials were identical, indicating that two different crystal modifications were being obtained. ir($CHCl_3$): 3250, 1645, 1610, 1170, 1110, 930 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 8.00–7.12 (AB q, 4H), 5.05–4.40 (m, 3H), 2.70–2.26 (m, 7H), 2.00–1.25 (m, 13H). *Anal.* calcd. for $C_{19}H_{27}N_3O_2S$: C 63.13, H 7.53, N 11.62; found: C 62.78, H 7.98, N 11.17.

Reduction of this material using sodium cyanoborohydride in 1 :1 DMF–sulfolane at 120°C (8) gave the same result as the direct Wolff–Kischner reduction described below.

Wolff-Kischner Reduction of Ketone 7

Method A

Ketone **7** (0.795 g, 4.1 mmol) was dissolved in 10 mL triethylene glycol and 5.5 mL hydrazine hydrate was added. The solution was stirred at 120°C for 8 h, cooled, 0.87 g (3 equiv.) of potassium hydroxide was added, and the solution was refluxed for 24 h. The cooled solution was diluted with 50 mL of water and extracted with pentane (3 × 75 mL). The combined organic phases were washed with water, dried over sodium sulfate, and evaporated to give 0.36 g of pale yellow liquid. Gas chromatographic analysis (column B, 145°C) showed two compounds in a 1 :1 ratio. The shorter retention time material was identical to **11** (*vide infra*). The longer retention time material gave the same spectral data as that reported below under method *B* except that the absorptions between δ 6.05 and 4.80 accounted for only two protons. The FIMS of the crude reaction mixture showed strong peaks at m/z = 181, 179, 177, 138, and 137.

Method B

Carrying out the reaction in refluxing ethylene glycol and allowing the volatiles to distill out led to the isolation of a pale yellow liquid which showed the same two peaks in the gas chromatogram, but now in the ratio of ca. 1 :20. The major

product was isolated by glc collection; ir(CCl_4): 2930, 1450, 1300, 1120, 1110, 1000, 910 cm^{-1}; ^1H nmr (C_6D_6) δ: 6.05–5.32 (m, 1H), 5.20–4.80 (m, 2H), 2.75–2.00 (m, 4H), 1.90–0.93 (m, 14H); ^{13}C nmr (C_6D_6) δ: 135.9, 116.5, 55.5, 49.6, 36.1, 26.6, 25.9, 20.5. *Anal.* calcd. for $C_{12}H_{21}N$: C 80.38, H 11.81, N 7.81; found: C 79.88, H 11.52, N 7.43. Refluxing the product of method *B* with potassium hydroxide in triethylene glycol led to the formation of a mixture, identical to that obtained from method *A*.

Hydroboration–oxidation of the product from method *B* afforded a mixture of compounds whose nmr spectrum showed absorptions *inter alia* at δ 3.45 (t) and 3.62 (*m*) suggesting the presence of primary and secondary alcohols.

*10-Propylquinolizidine (**11**)*

The crude reaction mixture from method *A* (0.4 g, 2.23 mmol as $C_{12}H_{21}N$) was dissolved in 5 mL glacial acetic acid and added to a suspension of prereduced platinum oxide in 5 mL of the same solvent. After 30 min, 55.4 mL (99.5%) of hydrogen had been absorbed and the absorption ceased. The solution was filtered and the product **11** (0.395 g, 97%) was isolated as a clear oil. The picrate crystallized from ethanol, mp 177–179°C (lit (2) mp 185–186°C). The ^{13}C spectrum ((C_6D_6) δ: 55.0, 49.4, 36.1, 26.6, 23.7, 20.7, 17.5, 15.3) supports a *trans*-fused quinolizidine bearing an axial 10-substituent. The infrared spectrum, glc retention times, and picrate melting points (separate and mixed) of this material, and the shorter retention time material isolated from method *A* of the Wolff–Kischner reduction indicated the identity of the two substances.

A ^{13}C nmr study of metal ion binding to pyridoxine

J. STEPHEN HARTMAN[1] AND ERIC C. KELUSKY

Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received October 10, 1978

J. STEPHEN HARTMAN and ERIC C. KELUSKY. Can. J. Chem. **57**, 2118 (1979).

^{13}C nmr confirms that coordination of metal ions by pyridoxine is through the C-3 and C-4′ oxygens in aqueous solution. Nitrogen appears to become more effective as a donor site in water–dimethylsulfoxide mixtures, while with increasing proportions of DMSO some cations are coordinated by DMSO rather than by pyridoxine. Changes in ^{13}C spin–lattice relaxation times on metal ion coordination are more informative about metal binding sites than changes in ^{13}C chemical shift. Some analogous results are reported for pyridoxamine.

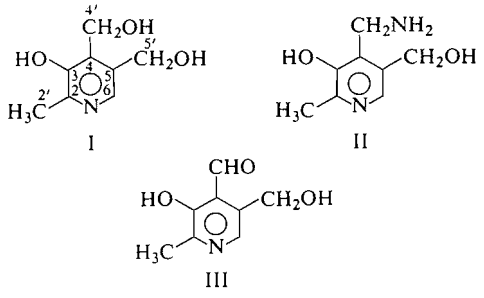
J. STEPHEN HARTMAN et ERIC C. KELUSKY. Can. J. Chem. **57**, 2118 (1979).

La rmn du ^{13}C confirme qu'en milieu aqueux la coordination des ions métalliques par la pyridoxine se fait par les oxygènes en C-3 et en C-4′. Il semble que l'azote devient un site donneur plus efficace dans des mélanges eau–diméthylsulfoxyde; si on augmente les proportions de DMSO, quelques cations sont coordonnés par le DMSO plutôt que par la pyridoxine. Les changements dans les temps de relaxation ^{13}C spin–réseau lors de la coordination d'un ion métallique fournissent plus d'informations concernant les sites de complexation métallique que les changements dans les déplacements chimiques ^{13}C. On a obtenu des résultats analogues avec la pyridoxamine,

[Traduit par le journal]

Introduction

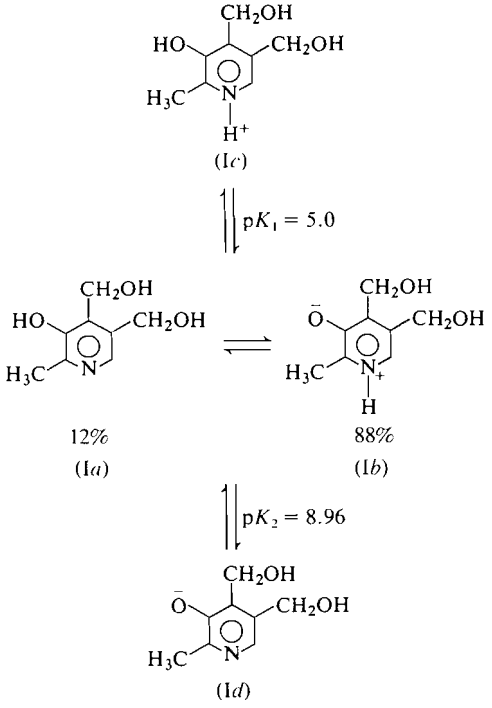
Pyridoxine (I) and pyridoxamine (II) are members of the vitamin B6 family of compounds. Enzymic reactions utilizing vitamin B6 can be mimiced by systems containing pyridoxamine or pyridoxal (III),



I II III

an amino acid, and a metal ion. Schiff base formation is involved, and the metal ion possibly acts as a template in its formation (1). Thus vitamin B6 – metal complexes have been extensively studied as models of enzymatic behaviour (1). Chaturvedi has reported that in aqueous solution pyridoxine forms 1:1 and 1:2 metal–ligand complexes with Cd^{2+} and Pb^{2+} (2). Similar coordination was found with Cu^{2+} and Ni^{2+}, and because of the similarity of stability constants with 2-picoline, it was proposed that coordination occurred through the ring nitrogen (3). Pyridoxamine's interactions with metals in solution have been studied by a number of workers (4–6) and recently the first crystal structure of a metal complex with pyridoxamine has been determined (7).

^{13}C chemical shifts of the vitamin B6 family of compounds have been reported (8–11). These show pronounced pH-dependence because of protonation and deprotonation reactions (12, 13). For pyridoxine these are:



At neutral pH the zwitterionic form I*b* predominates over the non-dipolar form I*a* (12). Similar effects are found in II and III.

[a]0.50 *M* in pyridoxine and in metal salt. Positive values indicate shifts (ppm) to lower applied field.
[b]pH 6.2 for sodium salts, 6.7 for all others.
[c]Reference 17 gives similar values for a 0.050 *M* solution, pH 6.8.
[d]Chemical shifts (pH 6.7) agree closely with those of ref. 17.

There have also been ^{13}C nmr studies of Schiff base formation involving pyridoxal 5′-phosphate and amino acids (14–16). Gallais and co-workers have reported the effects of $CdCl_2$ on ^{13}C chemical shifts of pyridoxine (17); a 1:1 interaction was indicated. However it is known that the presence of salts can cause serious environmental effects on ^{13}C chemical shifts, quite apart from complex formation (18).

With the development of pulse and Fourier transform nmr techniques that have made the measurement of ^{13}C spin–lattice relaxation times (T_1's) a routine, if time-consuming, procedure (19, 20) it has become possible to use T_1 measurements to probe sites of metal ion binding to various molecules, including some which act as ligands for metal ions in biologically important systems (21–23). We report here our initial ^{13}C nmr studies of metal ion – pyridoxine interactions, utilizing changes in chemical shift and in spin–lattice relaxation times in the presence of metal ions.

Results and Discussion

A. Effect of Added Salts on ^{13}C Chemical Shifts

Table 1 summarizes changes in ^{13}C chemical shifts of pyridoxine in H_2O and in DMSO-d_6 on addition of various salts. We note that:

(*i*) The sodium salts have only very small effects; that of sodium iodide is greater than that of the chloride or acetate, especially on the side-chain carbons. However the effects become more pronounced when an excess of the sodium salt is present. Neglect of this, together with the use of sodium chloride to maintain constant ionic strength, has yielded incorrect binding sites in a number of studies of tetracycline, as discussed by Everett and co-workers (24).

(*ii*) The divalent metal halides give much larger shifts than the sodium salts, the most pronounced being at C-3 and C-4, consistent with metal ion chelation at the C-3 and C-4′ oxygens. However, substantial shifts occur at various other carbons as well. The C-4′ shifts are not as great as expected from chelation at C-4′ oxygen, and a steric compression shift might partially counteract the expected low-field shift.

(*iii*) Excess metal halide also has pronounced effects on chemical shifts, as illustrated in Fig. 1 for CdI_2. The break in the curve at 1:1 proportions does indicate a 1:1 complex, consistent with the report of Gallais and co-workers for the pyridoxine–$CdCl_2$ system (17). However, the continuing change in chemical shift past 1:1 proportions must be attributed to the effects of non-complexed CdI_2.

(*iv*) At low pH (2.75), zinc, cadmium, and mercury(II) chlorides have little effect on ^{13}C chemical shifts ($\lesssim$0.2 ppm for most carbons), consistent with the inability of these cations to compete with the proton for donor sites when I*c* is the predominant species.

(*v*) Metal ion-induced shifts in DMSO-d_6 are

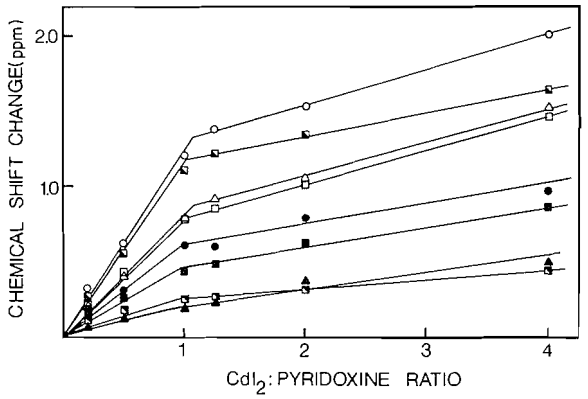

FIG. 1. Plot of ^{13}C chemical shift changes (in ppm) against the CdI_2: pyridoxine ratio. (C-4, ○; C-3, ◪; C-2′, △; C-4′, □; C-2, ●; C-5′, ■; C-6, ▲; C-5, ◪.)

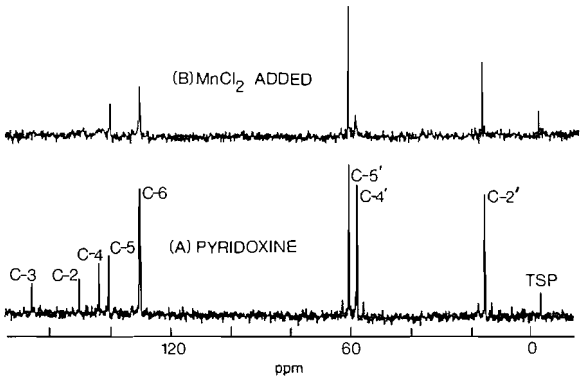

FIG. 2. ^{13}C nmr spectra of (*A*) pyridoxine (0.50 *M*) in D_2O and (*B*) pyridoxine with $MnCl_2$ (1.0×10^{-3} *M*) added.

larger than for the corresponding species in water, and the carbons which are most affected (C-2, C-2′, C-6) are different. This is suggestive of coordination through nitrogen; however, the C-3, C-4′, and C-5′ are also strongly affected. In fact all carbons except C-4 and C-5, which are remote from the periphery and from a possible donor site, are significantly shifted. It is interesting that the effects are greater for $ZnCl_2$ than for $CdCl_2$ or $HgCl_2$. Results discussed below indicate that DMSO displaces pyridoxine from the coordination sphere of some metal ions.

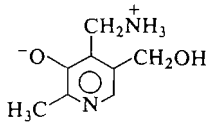
Thus ^{13}C chemical shift changes on adding metal salts can indicate coordination sites but not confirm them. It should be kept in mind that metal ion-induced shifts are small changes superimposed on parameters that are already subject to medium effects such as solvent (Table 1) and pH (17).

B. Effects of Added Mn^{2+}

Figure 2 shows the effect of 0.0010 *M* $MnCl_2$ on the ^{13}C spectrum of pyridoxine in D_2O. The line broadening effect of paramagnetic Mn^{2+} is a result of the shortening of the spin–spin relaxation time T_2, which varies inversely with the line width. If the dipolar relaxation mechanism predominates, T_2 varies directly with the sixth power of the metal to carbon distance (25), and hence line broadening is most pronounced for the carbon atoms nearest to the metal binding sites. The disappearance of the C-2, C-3, C-4, and C-4′ resonances indicates extreme broadening and hence binding of Mn^{2+} to the C-3 and C-4′ oxygens. However, in many cases of line broadening due to Mn^{2+} the dipolar relaxation term is not predominant; scalar coupling can predominate (23, 26). The effects of scalar coupling need not be localized at the donor site but can extend around an aromatic ring. The greater broadening of C-6 compared to C-5 and C-2′ could be due either to scalar coupling or to a small fraction of bonding to the nitrogen. This study does indicate that the principal binding sites are the C-3 and C-4′ oxygens.

A similar study in DMSO-d_6 showed no broadening of pyridoxine resonances, indicating preferential binding of Mn^{2+} to DMSO. This is consistent with the known strong bonding of DMSO to cations of the first transition series (27).

Preliminary studies of pyridoxamine with $MnCl_2$ in D_2O and in DMSO-d_6 gave similar results. Pyridoxamine, in spite of its greater complexing ability compared with pyridoxine (28), is unable to compete with DMSO for Mn^{2+}. In aqueous solution selective broadening removed the C-3 and C-4 peaks, *but not the C-4′ peak*, from the spectrum. This last result is intriguing and merits further investigation. It is known that Cu^{2+} can form a chelate complex with the C-3 oxygen and the C-4′ nitrogen of pyridoxamine (7), and there seems little reason why Mn^{2+} should not do the same. Espersen and Martin (29) have proposed that at high ligand-to-metal-ion ratios the metal ion might be passed from ligand to ligand before proton transfer reactions can occur. Since pyridoxamine is predominantly in the zwitterionic form II*a* (12), with no lone pairs on the C-4′ nitrogen,



II*a*

insufficient time for proton transfer could account for the lack of broadening of the C-4′ peak. If so, this would illustrate the suggestion (29) that at high ligand-to-metal-ion ratios the predominant complex may not be the same as that existing at more nearly stoichiometric ratios.

C. Spin–Lattice Relaxation Times (T_1's)

^{13}C T_1 values for pyridoxine and pyridoxamine are given in Table 2. These are shorter than typical

TABLE 2. ^{13}C T_1 values (s) at 32°C

a. Protonated carbons

Solute (0.50 *M*)	Solvent	Mol% of DMSO	^{13}C T_1 C-6	C-2′	C-4′	C-5′
Pyridoxine	D_2O(p*D* 5.5)[a]	0	0.78±0.07	2.82±0.12	0.89±0.08	1.16±0.05
Pyridoxine	D_2O/DMSO	13.3	0.39±0.04	1.49±0.11	0.52±0.05	0.46±0.05
Pyridoxine	D_2O/DMSO	26.5	0.34±0.03	1.24±0.12	0.38±0.04	0.39±0.03
Pyridoxine	D_2O/DMSO	33.7	0.38±0.03	1.30±0.15	0.38±0.04	0.41±0.04

Pyridoxine	DMSO	100	0.68±0.05	2.04±0.25	0.73±0.05	0.75±0.06
Pyridoxamine	D_2O(p*D* 6.1)	—	1.37±0.10	3.50±0.25	0.80±0.06	1.25±0.09

b. Non-protonated carbons

Solute (0.50 *M*)	Solvent	^{13}C T_1 C-2	C-3	C-4	C-5
Pyridoxine	D_2O(p*D* 5.5)	6.6±0.7	7.1±1.0	7.60±0.9	13.9±1.2
Pyridoxine + $CuCl_2$ (1×10^{-6} *M*)	D_2O(p*D* 5.5)	5.1±0.6[b]	4.2±1.0[b]	7.1 ±1.3	11.2±1.3

[a]p*D* = pH + 0.41.
[b]Determined by manual plotting.

T_1's for organic liquids (19, 20) since strong solvent–solute hydrogen bonding slows the rotation of solute molecules (19). T_1's of pyridoxine are similar in D_2O and in DMSO solutions, indicating a similar extent of solvent–solute interaction in each solvent. Interestingly, pyridoxine T_1's are much shorter in D_2O/DMSO solvent mixtures. This is in accord with the proposal that water–DMSO association is greater than water–water association, due to a combination of hydrogen bonding and dipolar attraction (30). Such strong association would further restrict the tumbling of solute molecules.

Table 2 includes T_1's for non-protonated carbons in aqueous pyridoxine, with and without added Cu^{2+}. On adding Cu^{2+} there is a pronounced decrease in T_1 for C-3, indicating proximity to a donor site. However the errors are large. Time and instrument stability factors led us to concentrate on protonated carbons for which T_1 data can be accumulated relatively rapidly.

The effect of a paramagnetic metal ion on the relaxation process is given by the relationship

$$[1] \quad 1/T_{1P} = 1/T_{1(obs)} - 1/T_{1,0}$$

where $T_{1(obs)}$ and $T_{1,0}$ are the relaxation times in the presence and absence of the paramagnetic metal, respectively, and T_{1P} is the relaxation time due specifically to the paramagnetic species. T_{1P}, unlike T_{2P}, is dominated by the dipolar relaxation mechanism (23, 29), with only rare exceptions (31). Hence, if a number of simplifying assumptions are made (23), T_{1P}^{-1} can be shown (23, 32) to exhibit reciprocal sixth-power dependence on the metal-to-carbon distance, so that relative T_{1P}^{-1} values can be used to determine metal coordination sites.

In practice the assumptions made, such as isotropic tumbling of molecules, will not be fully valid. In particular, delocalization of unpaired electron density onto ligand carbons is possible. This can be an important perturbing factor even when the extent of such delocalization is very small, because of the reciprocal sixth-power dependence of the dipolar relaxation mechanism (23, 29). In spite of these limitations, Espersen and Martin (29) consider selective T_1 measurements to be useful in estimating metal–carbon and metal–proton distances, and to be certainly far better than the widely used selective line broadening (T_2) method. Led and Grant (31) warn that extreme caution is warranted in drawing *quantitative* conclusions from limited T_1 information.

Table 3 gives T_{1P}^{-1} values for pyridoxine/$CuCl_2$, pyridoxamine/$CuCl_2$, and pyridoxine/$MnCl_2$ solutions. In aqueous solutions, by far the largest T_{1P}^{-1} (corresponding to the greatest metal ion effect in shortening T_1) is found for C-4′, in accord with chelation involving the C-3 oxygen and the C-4′ substituent. The pronounced decrease of pyridoxine/$CuCl_2$ T_{1P}^{-1} values at the higher temperature is indicative of the desired fast exchange conditions (25). The similarity of the effects of Mn^{2+} and Cu^{2+}, when the Mn^{2+} concentration is lower by a factor of five to correct for its five unpaired electrons, indicates a similar mode of interaction of both metal ions with pyridoxine.

TABLE 3. T_{1P}^{-1} values (s^{-1})

Solute (0.50 *M*)	Solvent	Mol% DMSO	T_{1P}^{-1} (s^{-1}) C-6	C-2′	C-4′	C-5′
	A. For addition of 5.0×10^{-6} *M* $CuCl_2$; 32°C

	C. For addition of 1.0×10^{-6} *M* $MnCl_2$; 32°C					
Pyridoxine	D_2O(p*D* 5.5)	0.0	0.0±0.2	0.1±0.1	0.7±0.2	0.0±0.1

Assuming chelation from the C-3 oxygen and the C-4′ substituent in aqueous solution, T_{1P}^{-1} values for the other protonated carbons should be less than 0.1 s^{-1}, based on the geometry of related species (7, 33). Since some T_{1P}^{-1} values for these carbons are somewhat greater than 0.1 s^{-1}, there appears to be either some breakdown of the inverse sixth power dependence, or some interaction of Cu^{2+} with the ring nitrogen or C-5′ oxygen. We can apparently exclude our choice of $T_{1,0}$ value (eq. [1]) as the source of error. $T_{1,0}$ values are only slightly affected by the addition of diamagnetic ions (Mg^{2+} or Zn^{2+}, 5×10^{-6} *M*) to simulate any effects of Cu^{2+} in addition to its paramagnetism. The largest effect of the diamagnetic ions was on C-2′ (T_1 = 2.4 s rather than 2.8 s), and this change had only a small effect on T_{1P}^{-1}.

As noted above, some deviation from the inverse sixth power dependence on distance is to be expected (29, 31), and does not affect our qualitative conclusion of chelation from the C-3 and C-4′ substituents in aqueous solution.

^1H T_{1P}^{-1} values were obtained for the C-H protons of pyridoxine and pyridoxamine in aqueous solution. The C-4′ protons were the most affected by Cu^{2+}, further supporting the C-4′ substituent being a donor to Cu^{2+}. However, there were quite large effects on the other protons as well.

Striking effects occur in the pyridoxine/Cu^{2+} system when the solvent is changed from D_2O to DMSO. In an intermediate solvent mixture T_{1P}^{-1} of C-6 becomes large, but T_{1P}^{-1}'s for both C-6 and C-4′ decrease to small values in a DMSO-rich solution (Table 3). This suggests that the ring nitrogen becomes an important donor site in D_2O/DMSO mixed solvent, but that Cu^{2+} is tied up by DMSO coordination at higher DMSO concentrations.

Donation from ring nitrogen in water–DMSO mixtures is reasonable since neutral pyridoxine, primarily in the zwitterionic form I*b* in aqueous solution, should undergo a shift of the equilibrium to the uncharged form as the dielectric constant of the solvent decreases. Such an effect has indeed been reported in water–dioxane mixtures (12). Large changes in acid–base equilibria are frequently found on transfer from water to dipolar aprotic solvents (34). I*a*, unlike I*b*, has a lone pair on nitrogen, so the nitrogen is much more accessible to metal ions.

Coordination of Cu^{2+} by DMSO in preference to pyridoxine in DMSO-rich solvent mixtures is consistent with our line broadening results with Mn^{2+}, and with the known (27) strong complexing ability of DMSO toward ions of the first transition series; $[Cu(DMSO)_6]^{2+}$, $[Cu(DMSO)_3Cl]^+$, and $[Cu(DMSO)_2Cl_2]$ apparently predominate.

Conclusions

Our evidence is consistent with metal ion coordination through the C-3 and C-4′ oxygens of pyridoxine in aqueous solution, but with a shift to nitrogen coordination on addition of DMSO, and eventual displacement of pyridoxine from the coordination sphere of some metal ions by DMSO. The indications of a shift to coordination by ring nitrogen in D_2O/DMSO solvent mixtures are of particular interest in that this lower dielectric constant medium may mimic enzyme sites more closely than aqueous solutions can.

Experimental

Pyridoxine hydrochloride and pyridoxamine dihydrochloride (Sigma Chemical Co.) were used without further purification for chemical shift measurements in H_2O. For all T_1 measurements and for chemical shifts in DMSO-d_6, pyridoxine was prepared by neutralization of an aqueous solution of the hydrochloride with sodium hydroxide, evaporation to dryness, and separation of pyridoxine from sodium chloride by solution in ethanol. Pyridoxamine monohydrochloride was prepared from the dihydrochloride by a similar procedure. Solutions were made up in deionized distilled water (H_2O or D_2O), or

DMSO or DMSO-d_6, and oxygen was removed by bubbling nitrogen through the solutions for several minutes. Glassware was soaked in EDTA solution prior to use to remove traces of paramagnetic metal ions. Following the addition of metal salts, pH was adjusted to within 0.05 pH units, using a conventional pH meter and glass electrode. For D_2O solutions a correction must be made to the meter reading (35):

$$pD = pH + 0.41$$

pD was adjusted using NaOD or DCl solutions.

Metal salts were reagent grade. Fisher certified reagents were used except for $CuCl_2$ (British Drug Houses), $CdCl_2$ (Research Organic/Inorganic Chemicals), and CdI_2 (AnalaR). All nmr spectra were obtained on a Bruker WP-60 Fourier transform nmr spectrometer. ^{13}C spectra were obtained at 15.08 MHz and 32°C using 10 mm sample tubes. A 3759 Hz sweep width was used, with a 1.09 s acquisition time for an 8K FID. Proton noise decoupling (5 W) was applied. For chemical shift measurements a 30° pulse was used, with the Phase Alternating Pulse Sequence. Between 3000 and 16 000 pulses were accumulated. The FID's were transformed with 0.5 Hz of line broadening. In the H_2O samples used for chemical shift measurements, a concentric 5 mm tube of D_2O containing 5% TSP ($(CH_3)_3SiCD_2CD_2CO_2Na$) was used as the deuterium lock signal; the TSP provided the ^{13}C reference (−1.49 ppm from TMS; values in Table 1 have been converted to ppm to low field of TMS). Internal tetramethylsilane was used as the reference in DMSO-d_6 solutions.

^{13}C T_1 measurements were made using the inversion recovery technique (36, 37) and the Nicolet T_1 Program/II (developed by J. W. Cooper, Nicolet Instrument Corporation). In the pulse sequence $\{180°-\tau-90°-D_2\}_n$ the delay time D_2 was set at 5 times the largest T_1 value and at least eight different τ values between 0.001 and D_2 seconds were used. The 90° pulse varied between 8.8 and 9.2 μs and was checked frequently. Proton noise decoupling (5 W) was applied. Between 100 and 200 scans were accumulated at each τ value. The FID's were transformed with 2.0 Hz of line broadening. All samples were filled to a volume of 2.0 mL.

^1H T_1 measurements were obtained in a similar fashion to the ^{13}C measurements, but at 60 MHz and 29°C using 5 mm tubes, a 500 Hz sweep width, and accumulation of 4 scans. The 90° pulse was 3.8 μs. Spectra were transformed with 0.10 Hz of line broadening.

An efficient synthesis (stereo- and regiospecific) of compound **I** (Scheme 1) from *o*-cresol is described.

THOMAS Y. R. TSAI, KRISHNAN P. NAMBIAR, DIKRAN KRIKORIAN, MAURIZIO BOTTA, RINALDO MARINI-BETTOLO et KAREL WIESNER. Can. J. Chem. 57, 2124 (1979).

On décrit une synthèse efficace (stéréo- et régiospécifique) du composé I (schéma 1) à partir du *o*-crésol.

[Traduit par le journal]

Introduction

We have described recently a direct fully stereo- and regiospecific synthesis of 13-desoxydelphonine **VII** (1).

The approach which we have used is illustrated in Scheme 1 and it represents the most recent very simple and efficient generation of our systematic studies in this field (2). The starting material **I** was constructed by a fully stereo- and regiospecific process from vanillin (3).

We now wish to disclose the preferred route to the same aromatic intermediate **I** from *o*-cresol.

Discussion

The cresol **1** was simply converted to the indanone **3** via the β-chloropropionyl ester **2** by the procedure of Wagatsuma (4).[1] Methylation of **3** with dimethyl sulfate and potassium carbonate in acetone yielded the methoxy derivative **4**, which was transformed into the enol ether **5**. This last operation was carried out in two steps. The indanone **4** was first converted into the corresponding dimethylacetal in methanol and trimethyl orthoformate in the presence of the acidic ion exchanger Rexyn 101. Pyrolytic elimination of methanol from the dimethylacetal in refluxing *o*-xylene completed the preparation of the enol ether **5**.

Compound **5** was now carboxylated in tetrahydrofuran at −70°C with *n*-butyl lithium and carbon dioxide gas; hydrolysis of the enol ether group on work-up gave the crystalline keto acid **6**. The keto group of **6** was reduced with sodium borohydride and the product **7** was heated under reflux with phosphoric acid in dioxane. The elimination of the hydroxyl was followed by a shift of the double bond and the resulting indene acid was esterified with methanolic hydrogen chloride to the ester **8***a* (Scheme 2).

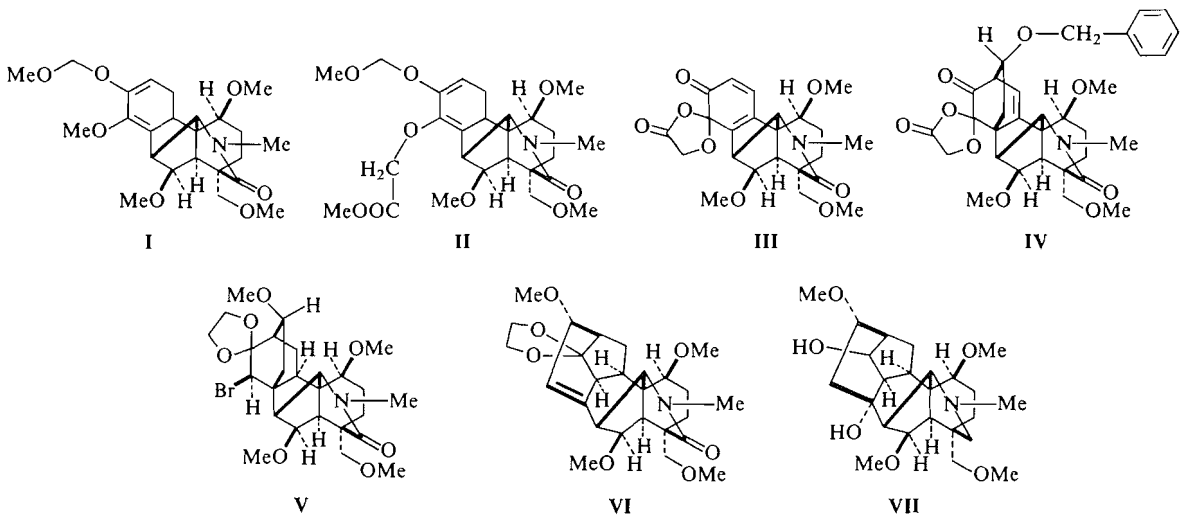
Compound **8***a* is in a thermal equilibrium with the *o*-quinonoid tautomer **8***b* and as a consequence it adds maleic anhydride quantitatively and yields the adduct **9**. Finally, decarboxylation of this last product by the method of Trost (5) gave the tricyclic olefin **10** in a yield of 85%.

The tricyclic compound **10** was next converted to the acetylaziridine **11** by treatment with trimethyl silyl azide followed by acetic acid and acetic anhydride. The aziridine was not isolated, but it was rearranged *in situ* by several days heating under nitrogen to 85°C. The product of the stereo- and regiospecific aziridine rearrangement **12** was purified by crystallization and it was obtained in a yield of 70%. The mechanism of the rearrangement is portrayed by the arrows in formula **11**. Its complete regiospecificity is due to the aromatic methoxyl, which increases the migratory aptitude of the bond in the *ortho* position and to the ester carbonyl, which makes the competing rearrangement more difficult. This last process is initiated by the opening of the other aziridine carbon–nitrogen bond and it requires the transient development of a positive charge on the carbon α to the carbonyl group—a situation well known to be energetically unfavourable.

In all of our previous work (2) we have used benzenesulfonyl aziridines rather than acetylaziri-

[1]The entire synthesis is in principle similar to our previous work in this field. Consequently to conserve space the Discussion has been abbreviated and the reader is referred to the Experimental for procedures and the characterization of the products.

0008-4042/79/162124-11$01.00/0



SCHEME 1

dines at a similar stage of the synthesis. This led to some complications and additional steps, but we were unable to prepare efficiently the required acetylaziridines prior to the development of the present trimethyl silyl azide (6) process.

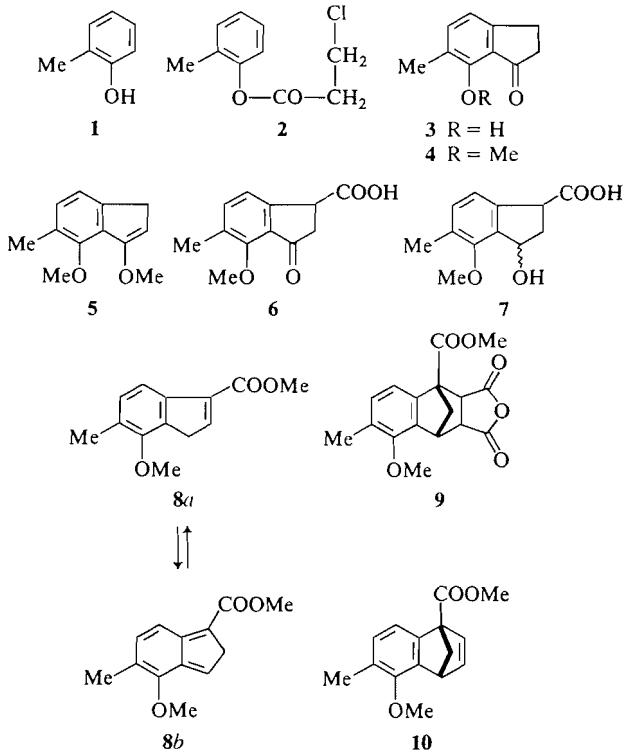
The rearrangement product **12** was oxidized in aqueous acetic acid with ceric ammonium nitrate (7) at room temperature and the aldehyde **13** was obtained in a yield of 75% after crystallization. Methanolysis of **13** in the presence of potassium carbonate yielded the alcohol **14** which was benzylated in dichloromethane with benzyl chloride and potassium carbonate to the benzyl ether **15**.

Finally, the aldehyde group in **15** was degraded with *m*-chloroperbenzoic acid in dichloromethane and the resulting unstable formate ester **16** was immediately methanolyzed in the presence of potassium carbonate to the crystalline phenol **17**. The overall yield of the two steps was 96%.

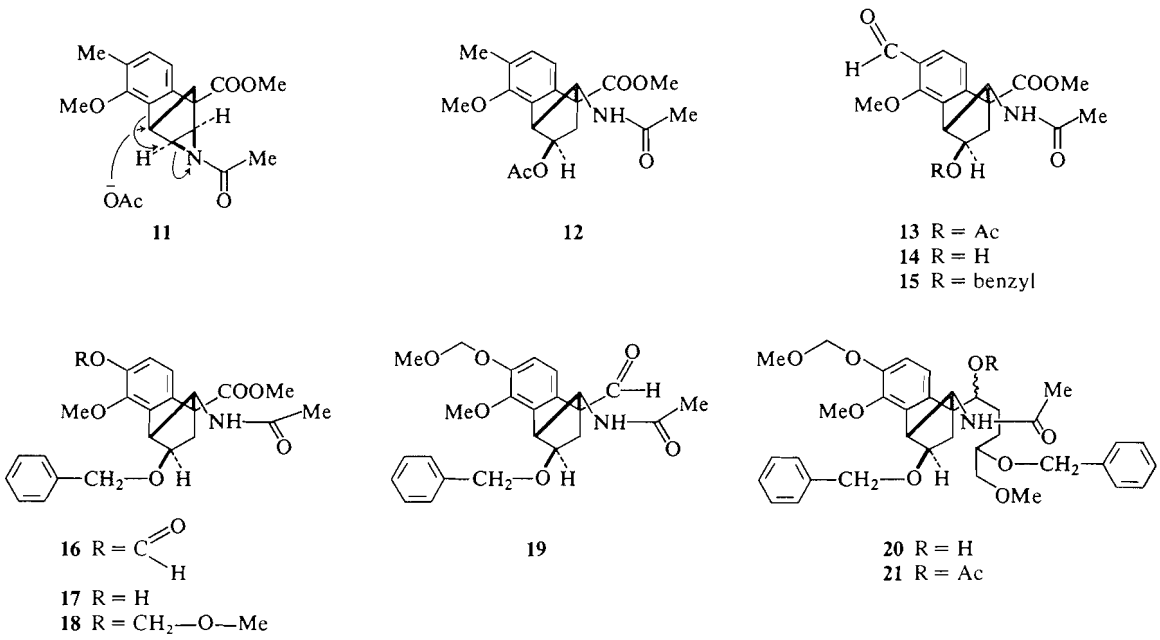
The high yield of these operations shows clearly that in suitable situations an aromatic methyl group may be used with advantage as a 'stand-in' for a phenol. The purpose of using this device in the present situation is simple. It would have been impossible to conduct the rearrangement of compound **11** in a regiospecific manner in the presence of an electron-releasing substituent in place of the aromatic methyl (cf. ref. 8).

The phenolic group of compound **17** was finally blocked by alkylation with chloromethyl-methyl ether and the product **18** was obtained in a yield of 93%.

It still required the transformation of the carbomethoxyl to an aldehyde group, which was accomplished by reduction with lithium borohydride, followed by reoxidation of the resulting primary alcohol with dimethyl sulfoxide and dicyclohexylcarbodiimide. The overall yield of these transformations was 86% and the synthon **19** was ready for the annelation of the substituted ring A (Scheme 3).



SCHEME 2



SCHEME 3

The aldehyde **19** was treated with an excess of 3-benzyloxy-4-methoxy-*n*-butyl magnesium bromide (9) and the mixture of the epimeric alcohols **20** was obtained in a yield of 87%. For purposes of characterization and analysis, the subsequent epimeric mixtures were separated by preparative thin layer chromatography (see Experimental). In the main preparative run, however, the epimers were not separated since they finally yielded one single intermediate, the keto lactam **32**.

The alcohols **20** were now quantitatively acetylated to the acetates **21** and this material was hydrogenolyzed over palladium on charcoal to the diols **22**. Oxidation of the two secondary alcoholic groups in this last product with the pyridine – chromium trioxide complex in dichloromethane yielded 85% of the epimeric diketones **23**.

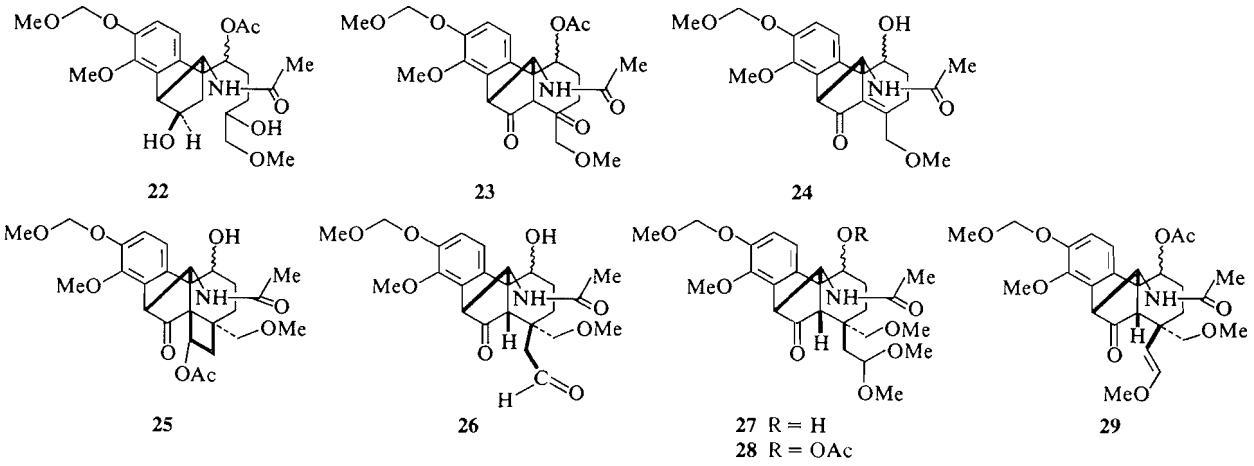
The stage was now set for the closure of ring A. This was accomplished by boiling the diketone **23** under nitrogen with a saturated solution of potassium carbonate in absolute methanol and the α,β-unsaturated ketone **24** was isolated in a yield of 90%.

Photoaddition of vinyl acetate to the conjugated system of compound **24** under our standard conditions is a stereospecific process and the epimers **25** were obtained in a yield of 95% (Scheme 4). While the regiospecificity of the photoaddition is unusual, the stereospecificity is predictable by our addition rule (10) and similar to the observed behaviour of related systems.

Saponification of the acetoxy group by mild treatment with base was accompanied by a retro aldol cleavage and the homo-aldehyde **26** was obtained in a yield of 97%. The configuration of the two newly created chiral centers in compound **26** was deduced (as in similar cases, cf. ref. 1) from the proton magnetic resonance (^{1}Hmr) spectrum of this material. The singlet of the primary methoxyl in the ^{1}Hmr spectrum of compound **26** was shifted upfield to $\tau = 7.27$ as a result of the shielding by the aromatic ring. The only configuration in which the primary methoxyl can find itself in the shielding zone of the aromatic ring is the one portrayed in the formula. It is thus clear that the configuration of the quaternary carbon has been set up correctly, but the configuration of the A/B ring junction was dictated by the greater stability of the cisoid system.

It is now necessary to remove the extra carbon of the homo-aldehyde prior to the closure of the nitrogen ring. Compound **26** was converted into the dimethylacetal **27**, acetylated to **28**, and heated under reflux with dry *o*-xylene and pyridine. Elimination of methanol from the acetal group yielded 92% of the acetylated enol ether **29**. Oxidation of compound **29** with permanganate–periodate followed by esterification with diazomethane gave finally the ester **30** in a yield of 81%. The ^{1}Hmr spectrum of compound **30** (primary methoxyl singlet $\tau = 7.44$) showed clearly that no change has occurred in the A/B *cis* stereochemistry during the various operations to which the material was subjected.

The system **30** is clearly unable to close a lactam



SCHEME 4

ring since the carbomethoxy group can sterically not reach the nitrogen. However, reflux of compound **30** with dilute methanolic sodium methoxide led, as expected, to the formation of the secondary lactam **31** with a simultaneous epimerization of the ring junction in a yield of 85%. The ^{1}Hmr spectrum of compound **31** showed the subject of the primary methoxyl at lower field (τ = 6.63) in agreement with the inverted configuration of the A/B ring junction. Finally, oxidation of the epimeric hydroxylactams **31** with the chromium trioxide – pyridine complex in dichloromethane completed the stereospecific synthesis of the beautifully crystalline diketolactam **32** (mp 178–179°C) in a yield of 90%.

The transformation of the α,β-unsaturated ketone **24** to the keto lactam **31** was carried out in an overall yield of 60%. Nevertheless, we have been attempting for a long time without success to discover a shorter alternative route. Thus, for example, the photoaddition of an acetylenic derivative to compound **24** followed by a direct oxidative cleavage of the resulting cyclobutene was tried in many variations.

Another possibility is the construction of the nitrogen ring by attachment of a suitable side-chain to the nitrogen followed by base-catalysed internal β-addition. The schemes which we developed in this direction offered little advantage over our present process with regard to the number of steps needed and none of them could match our present yields. Nevertheless, we believe that the conversion of the α,β-unsaturated ketone **24** to the keto lactam **31** must be capable of some simplification and of a consequent small improvement in the overall yield.

The diketolactam **32** was next reduced with tri-*tert*-butoxy aluminum hydride and the diol **33** was obtained stereospecifically in a yield of 86% after crystallization. Methylation of this material in dry dioxane with sodium hydride and methyl iodide at reflux temperature gave finally the polymethoxylated *N*-methyl lactam **34**.

Compound **34** was identical in all respects with the same material obtained from vanillin (3) and used as intermediate in our recent synthetic work (1). The correctness of its structure and the configuration of all of its substituents was corroborated, not only by the identity of the final product of the synthesis **VII** with the naturally derived material, but also by an X-ray structural analysis performed recently by Przybylska and Ahmed on the advanced nordenudatine intermediate **VIII** (1) (Fig. 1; Schemes 5, 6).

SCHEME 5

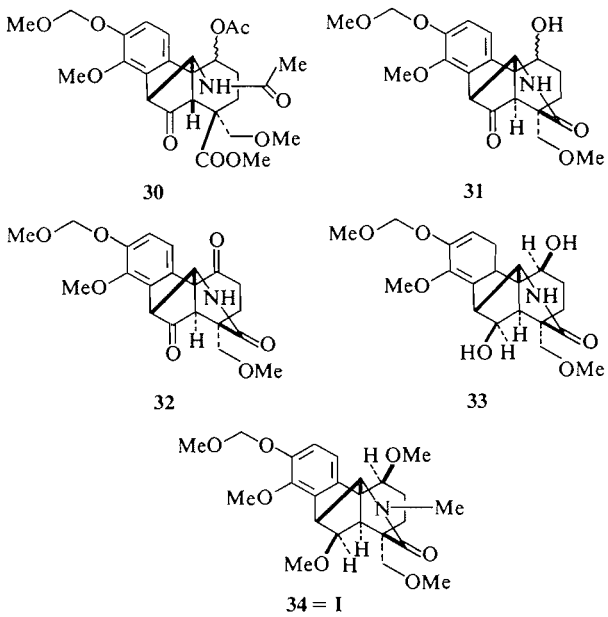
Experimental

Preparation of the Ester 2

A solution of *o*-cresol (103 mL) and 3-chloropropionyl chloride (114.5 mL) in benzene (200 mL) was stirred at room temperature until the evolution of hydrogen chloride ceased. The mixture was heated slowly and finally refluxed for 1 h. The reaction mixture was cooled and the unreacted *o*-cresol was extracted several times with 200 mL of 5% aqueous NaOH. The organic layer was dried over anhydrous magnesium sulfate and distilled to give 157.7 g (79%) of the ester (**2**), bp 104–105°C/2 Torr; *m/e*: 198; ir (CCl_4): 1740 (C=O) cm^{-1}; nmr ($CDCl_3$) τ: 2.9 (m, 4H, aromatic protons), 6.18 (t, 2H, J = 3 Hz, —CH_2—Cl), 7.02 (t, J = 3 Hz, 2H, —OCO—CH_2), 7.85 (s, 3H, aromatic —CH_3).

Preparation of the Ketone 3

Ester **2** (165 g) and $AlCl_3$ (560 g) were mixed with stirring



SCHEME 6

and the mixture was heated carefully to 90–100°C for 1 h. After this time the mixture was gradually warmed to 160°C over a period of 2 h and this temperature was maintained for one additional hour. Finally, it was heated to 180°C for 1 h. The cooled reaction mixture was decomposed by cautious addition of ice followed by 200 mL of concentrated HCl. Steam distillation of the decomposed reaction mixture gave 27.4 g (22.6%) of the 6-methyl-7-hydroxy-indan-1-one (**3**) crystallized from petroleum ether to a mp 80–83°C; *m/e*: 162; ir ($CHCl_3$): 3370 (—OH), 1720 (C=O) cm^{-1}; nmr (CCl_4) τ: 7.8 (s, 3H, aromatic —CH_3), 3.3 (AB_q, 2H, J = 7 Hz, $\Delta\nu$ = 15 Hz, aromatic protons), 0.2 (s, 1H, OH). *Anal.* calcd. for $C_{10}H_{10}O_2$: C 74.41, H 6.59; found: C 74.05, H 6.22.

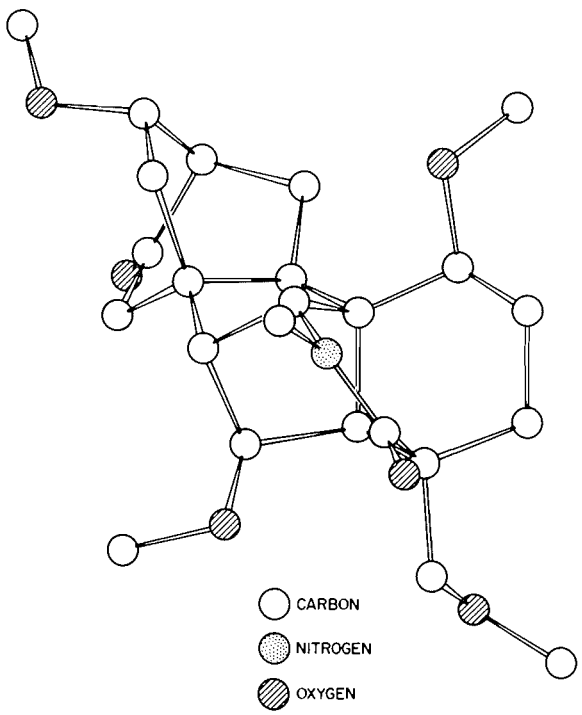


FIG. 1. X-ray structure of Compound **VIII**.

Preparation of Indanone 4

A mixture of 6-methyl-7-hydroxy indan-1-one (**3**) (20 g, 0.17 mol), acetone (508 mL), anhydrous K_2CO_3 (25.8 g, 0.20 mol), and dimethyl sulfate (17.1 mL, 0.18 mol) was refluxed under nitrogen overnight. After cooling, the inorganic salts were removed by filtration, the solvent was evaporated *in vacuo*, and the residue was dissolved in $CHCl_3$. The solution was washed with 2 *N* aqueous hydrochloric acid, water, brine, dried over anhydrous $MgSO_4$, and evaporated to dryness. The crude product was purified by column chromatography on silica gel (30% Et_2O in hexane) affording after crystallization from petroleum ether 27.9 g of indanone (**4**) (94%), mp 54–56°C; *m/e*: 176; ir (CCl_4): 1720 (C=O) cm^{-1}; nmr ($CDCl_3$) τ: 7.8 (s, 3H, aromatic —CH_3), 6.2 (s, 3H, aromatic —OCH_3), 2.8 (AB_q, 2H, J = 7 Hz, aromatic protons). *Anal.* calcd. for $C_{11}H_{12}O_2$: C 74.97, H 6.86; found: C 75.05, H 6.92.

Preparation of the Keto Acid 6

A solution of the indanone (**4**) (50 g) in benzene (200 mL) and absolute methanol (100 mL) was mixed with trimethyl orthoformate (100 mL) and Rexyn 101 (H) (5 g) and the mixture was stirred at room temperature. When the reaction was completed (nmr) the Rexyn was filtered off and the filtrate was basified with triethylamine and evaporated *in vacuo* to give a mixture of the enol ether (**5**) and the corresponding dimethoxyacetal. The mixture was then refluxed for 1 h in dry *o*-xylene (400 mL). The solvent was distilled off and the residue (**5**) was used immediately for the subsequent step.

A solution of the crude enol ether **5** in absolutely anhydrous tetrahydrofuran (1200 mL) was cooled to −70°C (acetone – dry ice) and *n*-butyllithium (225 mL of 2.1 *N* in hexane) was added dropwise with stirring under nitrogen. After the addition was completed, the stirring was continued for 5 h, after which time dry carbon dioxide gas was passed through the solution at a moderate rate overnight. After warming to room temperature, the solution was acidified with 6 *N* aqueous hydrochloric acid.

The aqueous phase was extracted with $CHCl_3$. The combined organic extracts were washed with aqueous solution of $NaHCO_3$, the aqueous extracts were acidified with hydrochloric acid, and the product was taken up in chloroform. The chloroform solution was dried over Na_2SO_4 and evaporated to dryness. The crude residue was crystallized from CCl_4 to give 14.9 g of the pure keto acid **6**, mp 145–146°C; *m/e*: 220; ir ($CHCl_3$): 3300–2800 (—COOH), 1720 (C=O, —COOH) cm^{-1}; nmr (CCl_4) τ: 7.8 (s, 3H, aromatic —CH_3), 6.1 (s, 3H, aromatic —OCH_3), 2.7 (s, 2H, aromatic protons), −0.9 (s, 1H, —COOH). *Anal.* calcd. for $C_{12}H_{12}O_4$: C 65.44, H 5.49; found: C 65.34, H 5.39.

Preparation of the Secondary Alcohol 7

Sodium borohydride (31 g) was added in small portions to a stirred and cooled solution of the keto acid **6** (90 g) in ethyl alcohol (2000 mL). The mixture was stirred at room temperature for 2 h, acidified with 5% aqueous HCl, and the ethanol was evaporated on a rotary evaporator. The residue was taken up in ethyl ether and washed with brine. The ether extracts were dried over anhydrous Na_2SO_4 and evaporated to afford the crude secondary alcohol **7**. The product was purified by recrystallization from ethanol and gave 90 g (98%) of the pure compound, mp 145–146°C; *m/e*: 222; ir ($CHCl_3$): 3550

(—OH), 3200–2800 (—COOH), 1710 (—CO—OH) cm^{-1}; nmr ($CDCl_3$) τ: 7.8 (s, 3H, aromatic —CH_3), 6.1 (s, 3H, aromatic —OCH_3), 4.5 (m, 2H), 2.9 (AB_q, J = 7 Hz, aromatic protons). *Anal.* calcd. for $C_{12}H_{14}O_4$: C 64.85, H 6.35; found: C 64.67, H 6.33.

Preparation of the Indene Ester ***8***a

The alcohol **7** (90 g) was refluxed in dioxane (2000 mL) in presence of 85% *p*-phosphoric acid (200 mL) for 5 h. After cooling to room temperature, the solution was poured into ice – sodium chloride. The mixture was extracted with chloroform and the extract was washed with brine and dried over sodium sulfate. Removal of the solvent gave the indene acid as yellow crystalline compound, 81.4 g (98%); *m/e*: 205; ir ($CHCl_3$): 1600 (olefin), 1690 (—COOH) cm^{-1}; nmr ($CDCl_3$) τ: 7.8 (s, 3H, aromatic —CH_3), 6.4 (d, 2H, J = 2 Hz, —CH_2—), 6.2 (s, 3H, aromatic —OCH_3), 2.8 (AB_q, 2H, J_{AB} = 7 Hz), 2.3 (d, 1H, J = 2 Hz, vinylic H). *Anal.* calcd. for $C_{12}H_{12}O_3$: C 70.57, H 5.92; found: C 70.31, H 5.92.

Saturated methanolic hydrogen chloride (50 mL) was added to a solution of the indene acid (90 g) in dry methanol (2000 mL), and the solution was refluxed overnight. Evaporation of the solvent gave a dark residue which was chromatographed on silica gel with 15% ether in petroleum ether. Recrystallization from petroleum ether afforded the white crystalline indene ester ***8a***, 91 g (95%), mp 57.5–58°C; *m/e*: 218; ir ($CHCl_3$): 1725 (—$COOCH_3$) cm^{-1}; nmr ($CDCl_3$) τ: 7.73 (s, 3H, aromatic —CH_3), 6.5 (d, 2H, J = 2 Hz, benzylic H), 6.2 (s, 6H, aromatic —OCH_3, —$CO{\cdot}OCH_3$), 2.43 (d, 1H, J = 7 Hz, aromatic H), 2.88 (d, 1H, J = 7 Hz, aromatic H), 2.8 (t, 1H, J = 2 Hz, vinylic H). *Anal.* calcd. for $C_{13}H_{14}O_3$: C 71.54, H 6.47; found: C 71.37, H 6.39.

The Adduct ***9***

A solution of the indene ester ***8a*** (26.1 g), maleic anhydride (23.6 g), and hydroquinone (100 mg) in dry *o*-xylene (50 mL) was heated under nitrogen to 185°C (oil bath temperature) for 5 h. After cooling, the excess maleic anhydride and *o*-xylene were removed *in vacuo* at 75°C (bath temperature). The resulting paste was scratched in ether and the crude adduct **9** (33.8 g, 89.3%) crystallized. The crystals and the mother liquors were used in the next reaction without further purification. An analytical sample of the adduct, mp 135–136.5°C, was prepared by crystallization from acetone–ether; *m/e*: 316; ir ($CHCl_3$): 1865, 1785 (anhydride), 1735 (—$COOCH_3$) cm^{-1}; nmr ($CDCl_3$) τ: 7.8 (aromatic —CH_3), 7.78 (d, 2H, J = 3 Hz, apex H), 6.2 (s, 3H, —$COOCH_3$), 6.16 (s, 3H, aromatic —OCH_3), 5.88 (m, 2H, H next to anhydride), 3.05 (s, 2H, aromatic H). *Anal.* calcd. for $C_{17}H_{16}O_6$: C 64.55, H 5.10; found: C 64.52, H 5.11.

Benzobicycloheptene ***10***

A mixture of the adduct **9** (20 g) and bistriphenylphosphine nickel dicarbonyl (81 g) in anhydrous diglyme (990 mL) was heated in a nitrogen atmosphere to vigorous reflux (bath temperature 200°C) for 6 h. After cooling to room temperature, the reaction mixture was filtered through Celite to remove the black nickel precipitate and the solvent was distilled off under reduced pressure. The residue was taken up in ether and filtered. After evaporation of the ether filtrate the residue was subjected to chromatography on silica gel. Elution with 7% ether in *n*-hexane yielded the oily olefin **10** (13.12 g, 85%) homogeneous in tlc; *m/e*: 244; ir ($CHCl_3$): 1735 (—$COOCH_3$) cm^{-1}; nmr ($CDCl_3$) τ: 7.83 (s, 3H, aromatic —CH_3), 7.52 (d, 2H, J = 2 Hz, apex proton), 6.22 (s, 3H, —$COOCH_3$), 6.17 (s, 3H, aromatic —OCH_3), 5.8 (m, 1H, bridgehead H), 3.22 (m, 4H, aromatic H, vinylic H).

Aziridine Rearrangement Product ***12***

The tricyclic olefin **10** (20 g) was dissolved in trimethyl silyl azide (174 mL) and the solution was heated in a nitrogen atmosphere to 85°C for 2 days. The reaction mixture was cooled to room temperature and the excess trimethyl silyl azide was distilled off under reduced pressure. The last traces of trimethyl silyl azide were removed by connecting to a high vacuum pump for 15 min. The residue was dissolved in dry benzene (122 mL) and then cooled in a cold water bath while a mixture of acetic acid (61 mL) and acetic anhydride (61 mL) was added dropwise. After the nitrogen evolution had subsided, the mixture was heated in a nitrogen atmosphere to 85°C for 2 days. The solvent was removed on a rotary evaporator and the last traces were removed by heating to 40°C on the vacuum pump for half an hour. The residue was taken up in chloroform and washed with 5% sodium bicarbonate and saturated sodium chloride. After drying over anhydrous $MgSO_4$ and evaporation of the solvent, 30.5 g crude product was obtained. Column chromatography on silica gel, eluting with 10% ether in chloroform, and recrystallization from ether–petroleum ether yielded the pure crystalline rearrangement product **12** (21 g, 70%), mp 128–130°C. *m/e*: 361; ir ($CHCl_3$): 3450 (N—H), 1735 (—$COOCH_3$ + —O—CO—CH_3), 1685 (—CONH—) cm^{-1}; nmr ($CDCl_3$) τ: 7.98 (s, 3H, —$OCOCH_3$), 7.87 (s, 3H, —$NHCOCH_3$), 7.77 (s, 3H, aromatic —CH_3), 6.19 (s, 3H, —$COOCH_3$), 6.09 (s, 4H, aromatic —OCH_3 and bridgehead H), 5.5 (d, 1H, J = 8 Hz, apex H), 5.08 (m, 1H, $CHCOCH_3$), 3.44 (d, 1H, J = 8 Hz, NH), 3.04 (AB, 2H, J = 8 Hz, $\Delta\nu$ = 9 Hz, aromatic H). *Anal.* calcd. for $C_{19}H_{23}O_6N$: C 63.13, H 6.42, N 3.88; found: C 62.88, H 6.48, N 3.86.

Aromatic Aldehyde ***13***

To a stirred solution of the aziridine rearrangement product **12** (29 g) in 60% aqueous acetic acid (390 mL), a solution of ceric ammonium nitrate (175.36 g) was added dropwise, at room temperature. The mixture was stirred for 4 h at room temperature, extracted several times with ethyl acetate, and the extract was washed several times with aqueous sodium bicarbonate and saturated sodium chloride. After drying over anhydrous $MgSO_4$ and evaporation of the solvent, the crude product was purified by recrystallization from chloroform–ether. The mother liquors were subjected to column chromatography on silica gel, eluting with 10% ether in chloroform. The aromatic aldehyde **13** was obtained (23 g, 75%) as white crystals, mp 162–164°C; *m/e*: 375; ir ($CHCl_3$): 3480 (N—H), 1740 (—OCO—), 1690 (—NHCO, —CHCO) cm^{-1}; nmr ($CDCl_3$) τ: 8.18 (s, 3H, —$OCOCH_3$), 8.06 (s, 3H, NH—CO—CH_3), 6.32 (s, 3H, —$COOCH_3$), 6.08 (s, 3H, aromatic —OCH_3), 5.5 (d, 1H, J = 3 Hz, apex H), 3.44 (d, 1H, J = 8 Hz, NHCO), 3.04 (AB, 2H, J = 8 Hz, aromatic H), −0.2 (aromatic —COH). *Anal.* calcd. for $C_{19}H_{21}O_7N$: C 60.79, H 5.64, N 3.73; found: C 60.61, H 5.52, N 3.44.

Alcohol ***14***

A standard solution of potassium carbonate in methanol was prepared by adding a few drops of 5% aqueous potassium carbonate to methanol until the pH was approximately 9.5–10.0. The aromatic aldehyde **13** (10 g) was dissolved in the standard solution (250 mL) and was stirred at room temperature for 1 h. The reaction mixture was carefully neutralized by the addition of 5% aqueous hydrochloric acid, and the methanol was removed on the rotary evaporator. The residue was taken up in aqueous saturated sodium chloride and extracted 4 times with chloroform. The chloroform extracts were dried over anhydrous magnesium sulfate and evaporated. The product was purified by recrystallization from ether–chloroform and the mother liquors were subjected to

column chromatography on silica gel, eluting with 25% ether in chloroform. The aromatic aldehyde **14** (8.05 g, 93%) was obtained as white crystals melting at 174–175°C; *m/e*: 333; ir ($CHCl_3$): 3615 (OH), 3440 (NHCO), 1740 (—$COOCH_3$), 1690 (—C=OH, $NHCOCH_3$) cm^{-1}; nmr ($CDCl_3$) τ: 8.2 (s, 3H, $NHCOCH_3$), 6.3 (s, 3H, —$COOCH_3$), 6.1 (s, 3H, aromatic —OCH_3), 2.7 (AB_q, 2H, J = 10 Hz, aromatic H), −0.3 (s, 1H, aromatic —C=OH). *Anal.* calcd. for $C_{17}H_{19}O_6N$: C 61.25, H 5.75, N 4.20; found: C 61.27, H 5.57, N 3.91.

Benzyl Ether ***15***

To a solution of the secondary alcohol **14** (10 g) in dry dichloromethane (250 mL), potassium carbonate (20.72 g), benzyl bromide (20.54 g), and crown ether (18-crown-6) (0.015 g) were added. The resulting suspension was refluxed in a nitrogen atmosphere for 2 days. After cooling to room temperature, the carbonate was filtered off and washed with dichloromethane. The solvent was removed *in vacuo* to give an oil which was subjected to column chromatography on silica gel eluting with 10% ether in dichloromethane. Recrystallization from ether afforded the white crystalline compound **15** (10.15 g, 80%), mp 107–109°C; *m/e*: 423; ir ($CHCl_3$): 3420 (NHCO), 1745 ($COOCH_3$), 1680 ($NHCOCH_3$, —C=OH) cm^{-1}; nmr ($CDCl_3$) τ: 8.2 (s, 3H, $NHCOCH_3$), 6.3 (s, 3H, —$COOCH_3$), 6.1 (s, 3H, aromatic —OCH_3), 5.5 (s, 2H, benzylic H), 2.7 (s, 5H, aromatic H of the benzyl), 2.7 (AB_q, 2H, J = 10 Hz, aromatic H), −0.3 (aromatic —C=OH). *Anal.* calcd. for $C_{24}H_{25}O_6N$: C 68.07, H 5.95, N 3.31; found: C 67.87, H 5.87, N 3.07.

Benzyl Phenol ***17***

The aldehyde **15** (10 g) was dissolved in dichloromethane (300 mL) and 85% *m*-chloroperbenzoic acid (5.15 g) was added in portions. The solution was refluxed for 6 h and the progress of the reaction was followed by nmr. After cooling, the solution was washed with aqueous sodium bicarbonate, sodium bisulfite, and saturated sodium chloride and dried over anhydrous $MgSO_4$. Removal of the solvent gave the unstable formate **16** (10 g) which was used in the next reaction without further purification; ir ($CHCl_3$): 3455 (N—H), 1760 (—OCOH), 1735 (—$COOCH_3$), 1675 ($NHCOCH_3$) cm^{-1}; nmr ($CDCl_3$) τ: 8.15 (s, 3H, $NHCOCH_3$), 6.3 (s, 6H, —$COOCH_3$ + aromatic —OCH_3), 5.43 (s, 2H, benzylic H), 3.18 (d, 2H, J = 2 Hz, aromatic H), 2.8 (s, 5H, aromatic H of the benzyl group), 1.9 (s, 1H, —OC=OH).

The formate **16** (10 g) was dissolved in methanol (200 mL) and the pH of the solution was adjusted to 9–10 with 1 *N* aqueous potassium carbonate. The reaction mixture was stirred for 30 min at room temperature. The solution was neutralized with 5% aqueous hydrochloric acid and the methanol was removed on a rotary evaporator. The residue was taken up with ether, washed with saturated sodium chloride, and dried over anhydrous $MgSO_4$. The solvent was removed *in vacuo* to give white crystalline material. Recrystallization from chloroform yielded 9.32 g compound **17** (96%, after two steps), mp 197–199°C; *m/e*: 411; ir ($CHCl_3$): 3600 (—OH), 3450 (NHCO), 1730 ($COOCH_3$), 1690 ($NHCOCH_3$) cm^{-1}; nmr (DMSO, $CDCl_3$) τ: 8.10 (s, 3H, —$NHCOCH_3$), 6.22 (s, 3H, —$COOCH_3$), 6.19 (s, 3H, aromatic —OCH_3), 5.38 (s, 2H, benzylic H), 3.2 (d, 2H, J = 2 Hz, aromatic H), 2.6 (s, 5H, aromatic H of benzyl groups). *Anal.* calcd. for $C_{23}H_{25}O_6N$: C 67.14, H 6.12, N 3.40; found: C 66.96, H 6.07, H 3.34.

Protected Phenol ***18***

A mixture of phenol **17** (10 g), THF/CH_2Cl_2 (1:1) (300 mL), K_2CO_3 (16.4 g), and crown ether (18-crown-6) (0.015 g) was stirred for 30 min at room temperature. Chloromethyl-methyl ether (3.9 g) was added dropwise and the resulting solution was stirred for 10 h at room temperature. The solid was filtered off and the solution was washed with saturated aqueous sodium chloride and dried over anhydrous magnesium sulfate. The solvent was removed *in vacuo* and the oily residue was chromatographed on silica gel eluting with 15% ether in chloroform. Recrystallization from ethyl ether gave 10.3 g (93%) of the protected phenol **18**, mp 95–96°C; *m/e*: 455; ir ($CHCl_3$): 3430 (NHCO), 1730 ($COOCH_3$), 1690 (—$NHCOCH_3$) cm^{-1}; nmr ($CDCl_3$) τ: 8.10 (s, 3H, —$NHCOCH_3$), 6.5 (s, 3H, H_3C—O—CH_2—O—), 6.20 (s, 3H, —$OCOCH_3$), 6.15 (s, 3H, aromatic —OCH_3), 5.38 (s, 2H, benzylic H), 4.8 (s, 2H, H_3C—O—CH_2—O—), 3.0 (s, 2H, aromatic H), 2.6 (s, 5H, aromatic H of benzyl group). *Anal.* calcd. for $C_{25}H_{29}O_7N$: C 65.92, H 6.42, N 3.08; found: C 65.80, H 6.25, N 2.84.

Preparation of Aldehyde ***19***

The protected phenol **18** (4.55 g) was dissolved in absolutely dry THF (80 mL) and lithium borohydride (0.22 g) was added in portions in a nitrogen atmosphere. After stirring for 2 h, the reaction mixture was cooled in an ice bath while water was added to destroy the excess hydride. The resulting solution was evaporated and the residue was extracted several times with chloroform. After washing with saturated aqueous sodium chloride and drying over anhydrous $MgSO_4$, the solvent was removed *in vacuo*. Column chromatography on silica gel, eluting with 20% ether in chloroform, and recrystallization from chloroform–ether yielded the white crystalline primary alcohol (3.84 g, 90%), mp 103–104°C; *m/e*: 427; ir ($CHCl_3$): 3400 (NHCO + OH), 1625 ($NHCOCH_3$) cm^{-1}; nmr ($CDCl_3$) τ: 8.40 (d, 2H, J = 5 Hz, protons β to the benzyloxy), 8.03 (s, 3H, $NHCOCH_3$), 6.5 (s, 3H, CH_3—O—CH_2—O—), 6.1 (s, 3H, aromatic —OCH_3), 5.4 (s, 2H, benzylic H), 4.8 (s, 2H, CH_3—O—CH_2—O—), 3.08 (s, 2H, aromatic H), 2.5 (s, 5H, aromatic H of benzyl). *Anal.* calcd. for $C_{24}H_{29}O_6N$: C 67.42, H 6.83, N 3.28; found: C 67.41, H 6.79, N 3.22.

To a solution of the primary alcohol (35 g) in dry benzene (440 mL), dimethyl sulfoxide (133 mL), dicyclohexyl carbodiimide (47.92 g), pyridine (6.6 mL), and trifluoroacetic acid (3.3 mL) were added in sequence and the mixture was stirred at room temperature for 24 h. The reaction mixture was diluted with ether and filtered. The filtrate was washed with water and aqueous saturated NaCl, dried over anhydrous $MgSO_4$, and evaporated. Chromatography on silica gel and elution with chloroform containing 20% ether and 2% methanol gave the pure aldehyde **19** (33.8 g, 97%) as an amorphous solid, homogeneous in tlc; *m/e*: 425; ir ($CHCl_3$): 3410 (N—H), 2840, 2730 (—C=OH), 1718 (—C=OH), 1675 (NHCO) cm^{-1}; nmr ($CDCl_3$) τ: −0.07 (s, 1H, —C=OH), 2.65 (s, 5H, aromatic H of benzyl), 3.12 (AB_q, J = 8 Hz, Δν = 7.55 Hz, 2H, aromatic H), 4.83 (s, 2H, —O—CH_2—O), 5.37 (s, 2H, benzylic H), 6.12 (s, 3H, aromatic —OCH_3), 6.50 (s, 2H, —O—CH_2—O—CH_3), 8.12 (s, 3H, NHCO—CH_3).

Preparation of the Alcohol ***20***

A small portion (4 mL) of a solution of 3-benzyloxy-4-methoxy-*n*-butyl bromide (9) (89.7 g, sixfold excess) in anhydrous THF (100 mL) was added to a stirred mixture of magnesium turnings (7.8 g) and a crystal of iodine in anhydrous THF (75 mL) under nitrogen at 85°C (oil bath temperature). When the colour of iodine had disappeared, the remaining solution of the bromide was added dropwise with stirring at the same temperature. After the addition was completed, the mixture was stirred for another 2 h. The Grignard reagent was then cooled to 30–35°C and a solution of the aldehyde **19** (23 g) in dry THF (800 mL) was added dropwise with stirring. After the addition was completed, the mixture

was stirred at the same temperature for another hour. The reaction mixture was then cooled in an ice–water bath and the excess Grignard reagent was destroyed by slow addition of saturated aqueous ammonium chloride. The aqueous phase was extracted with ether and the extracts were dried over anhydrous $MgSO_4$ and evaporated. The crude product was chromatographed on silica gel and elution with hexane containing 30% acetone and 2% methanol gave two epimers of **20** in the ratio 11:1 and a yield of 87%.

The Major α-Epimer

Mass spectra *m/e*: 619; ir ($CHCl_3$): 3550–3350 (—OH + N—H), 1655 (NHCO) cm^{-1}; nmr ($CDCl_3$) τ: 2.63 (m, 10H, aromatic H of benzyl), 3.03 (AB_q, J = 8 Hz, Δν = 8.94 Hz, aromatic H), 4.87 (s, 2H, O—CH_2—O), 5.33 (AB_q, J = 12 Hz, Δν = 7.21 Hz, 2H, benzylic H), 5.41 (s, 2H, benzylic H), 6.14 (s, 3H, aromatic —OCH_3), 6.51 (s, 3H, —O—CH_2—O—CH_3), 6.62 (s, 3H, —OCH_3), 8.09 (s, 3H, NHCOCH_3).

The Minor β-Epimer

The mass spectra of both epimers were identical, *m/e*: 619; ir ($CHCl_3$): 3550–3350 (OH + N—H), 1655 (NHCO) cm^{-1}; nmr ($CDCl_3$) τ: 2.61 (m, 1H, aromatic H of benzyl), 3.07 (s, 2H, aromatic H), 4.83 (s, 2H, O—CH_2—O), 5.35 (AB_q, J = 12 Hz, Δν = 7.12 Hz, 2H, benzylic H), 5.38 (s, 2H, benzylic H), 6.14 (s, 3H, aromatic —OCH_3), 6.50 (s, 3H, O—CH_2—O—CH_3), 6.61 (s, 3H, —OCH_3), 8.18 (s, 3H, NH—CO—CH_3).

Preparation of the Acetate ***21***

A solution of the alcohol **20** (35 g) in dry pyridine (70 mL), acetic anhydride (45 mL), and 4-dimethylamino pyridine (0.4 g) were mixed and the mixture was heated to 50–60°C for 24 h. Excess acetic anhydride and pyridine were removed under reduced pressure, and the residue was diluted with ether (300 mL) and washed successively with water, 5% aqueous citric acid, water, saturated $NaHCO_3$, and saturated NaCl. The ether solution was dried over anhydrous $MgSO_4$ and evaporated. Crystallization of the crude product from CH_2Cl_2–hexane gave the pure acetate **21** (35.6 g, 95.3%).

α-Epimer

The melting point was 111–112°C; *m/e*: 661; ir ($CHCl_3$): 3400 (N—H), 1735 (—O—CO—CH_3), 1670 (NH—CO—CH_3) cm^{-1}; nmr ($CDCl_3$) τ: 4.55 (t, J = 6 Hz, 1H, CH—NH—CO), 7.94 (s, 3H, O—CO—CH_3), 8.10 (s, 3H, NH—CO—CH_3). *Anal.* calcd. for $C_{38}H_{47}O_9N$: C 68.98, H 7.18, N 2.11; found: C 68.98, H 7.15, N 2.06.

β-*Epimer*

Oil. The mass spectra of both epimers were identical, *m/e*: 403; ir ($CHCl_3$): 3600 (OH), 3410 (N—H), 1750 (5-membered C=O), 1665 (NHCO) cm^{-1}; nmr ($CDCl_3$) τ: 3.03 (AB$_q$, J = 8 Hz, Δν = 6 Hz, 2H, aromatic H), 4.83 (s, 2H, O—CH$_2$—O), 6.12 (s, 3H, aromatic —OCH$_3$), 6.50 (s, 3H, —O—CH$_2$—O—C*H*$_3$), 6.63 (s, 3H, —CH$_2$—OC*H*$_3$).

Preparation of Diketo Lactam **32**

A solution of compound **31** (α-epimer) (0.5 g) in dry dichloromethane (10 mL) was added at room temperature to a solution of the chromium trioxide – pyridine complex (1.93 g) in dry dichloromethane (50 mL) with stirring. Stirring was continued at room temperature for 30 min, after which time the mixture was diluted with ether (50 mL) and the solid residue was filtered off. The filtrate was washed successively with saturated aqueous sodium bicarbonate, water, 5% citric acid, and water, dried over anhydrous $MgSO_4$, and evaporated *in vacuo*. The crude product was crystallized from dichloromethane–ether to give fine colourless needles of the diketo lactam **32** (0.446 g, 89%), mp 178–179°C; *m/e*: 401; ir ($CHCl_3$): 3400 (N—H), 1755 (5-membered CO), 1712 (6-membered CO), 1670 (NHCO) cm^{-1}; nmr ($CDCl_3$) τ: 2.45 (d, J = 4 Hz, 1H, N—H), 2.83 (AB$_q$, J = 8 Hz, Δν = 10.24 Hz, 2H, aromatic H), 4.80 (s, 2H, O—CH$_2$—O), 6.12 (s, 3H, aromatic —OCH$_3$), 6.49 (s, 3H, —O—CH$_2$—O—C*H*$_3$), 6.60 (s, 3H, —CH$_2$—O—C*H*$_3$). *Anal.* calcd. for $C_{21}H_{23}O_7N$: C 62.83, H 5.78, N 3.49; found: C 62.89, H 5.74, N 3.23.

Reduction of the Diketo Lactam **23** *to Diol* **33**

Lithium tri-*tert*-butoxy aluminum hydride (2.54 g) was added to a solution of the diketo lactam **32** (0.48 g) in dry tetrahydrofuran (50 mL) under nitrogen and the mixture was heated in an oil bath to 50–55°C for 8 days. The reaction mixture was then cooled and excess reagent was destroyed by dropwise addition of water. The mixture was filtered through Celite and the residue was washed with 10% methanol–chloroform. The filtrate was diluted with chloroform (100 mL) and washed with 5% aqueous citric acid and then with saturated NaCl. The organic layer was dried over anhydrous $MgSO_4$ and evaporated *in vacuo*. The crude product was crystallized from methanol–ether to give the pure diol **33** (0.415 g, 85.7%), mp 190–191°C. The β-hydroxy keto lactam **31** on similar reduction gave the same diol **33**; *m/e*: 405; ir ($CHCl_3$): 3600–3200 (—OH + N—H), 1665 (NH·CO) cm^{-1}; nmr ($CDCl_3$) τ: 3.12 (AB$_q$, J = 8 Hz, Δν = 6 Hz, 2H, aromatic H), 4.85 (s, 2H, O—CH$_2$—O), 5.53 (m, 1H, ring A C*H*OH), 5.58 (t, J = 4 Hz, 1H, ring B C*H*OH), 6.10 (s, 3H, aromatic —OCH$_3$), 6.50 (s, 3H, —O—CH$_2$—O—C*H*$_3$), 6.67 (s, 3H, —CH$_2$—O—C*H*$_3$). *Anal.* calcd. for $C_{21}H_{27}O_7N$: C 62.21, H 6.71, N 3.45; found: C 61.97, H 6.62, N 3.27.

Methylation of Diol ***33***

A solution of diol **33** (415 mg) in dry dioxane (24 mL) was refluxed with sodium hydride (490 mg, 57% oil suspension) under nitrogen for 2 h. The mixture was then cooled, excess methyl iodide (3 mL) was added, and reflux was continued for another 2 h. After cooling, the mixture was filtered through Celite and the residue was washed with dioxane. The solvent was then evaporated under reduced pressure and the crude product was chromatographed on silica gel. Elution with 5% methanol in chloroform gave the pure *N*-methyl lactam **34** (343.5 mg, 75%). A sample after recrystallization from dichloromethane–hexane melted at 163–165°C; *m/e*: 447; ir ($CHCl_3$): 1635 cm^{-1} (⟩NCO); nmr ($CDCl_3$) τ: 3.14 (AB_q, J = 8 Hz, $\Delta\nu$ = 15 Hz, 2H, aromatic H), 4.82 (s, 2H, O—CH_2—O), 6.06 (s, 3H, aromatic —OCH_3), 6.47 (s, 3H, —O—CH_2—O—CH_3), 6.57 (s, 6H, 2 secondary —OCH_3), 6.67 (s, 3H, —CH_2—OCH_3), 7.03 (s, 3H, —N—CH_3). *Anal.* calcd. for $C_{24}H_{33}O_7N$: C 64.41, H 7.43, N 3.13; found: C 64.05, H 7.65, N 2.93.

Conformational preferences of the *syn*-pyridinecarboxaldehyde oximes

WERNER DANCHURA, RODERICK E. WASYLISHEN, JAMES DELIKATNY, AND MOIRA R. GRAHAM

Department of Chemistry, University of Winnipeg, Winnipeg, Man., Canada R3B 2E9

Received March 9, 1979

WERNER DANCHURA, RODERICK E. WASYLISHEN, JAMES DELIKATNY, and MOIRA R. GRAHAM. Can. J. Chem. 57, 2135 (1979).

The results of an ^1H and ^{13}C nmr study of the three *syn*-pyridine aldoximes are reported. Observed $^6J(H_\alpha,H_{para})$ values in the 2- and 3-pyridine aldoximes indicate that the oxime group is twisted approximately 20° out of the pyridine ring plane. Stereospecific $^5J(H_\alpha,H_{meta})$ values measured for acetone solutions of 2-pyridine aldoxime indicate that the ratio of the NCCN *trans* conformation to the NCCN *cis* conformation is 0.86 ± 0.14. The results of similar measurements on 3-pyridine aldoxime give 0.60 ± 0.10 for the ratio of the C_2CCN *trans* and C_2CCN *cis* conformations. *Ab initio* molecular orbital calculations are in good qualitative agreement with experiment. Carbon-13 chemical shifts of the oximes are compared with those previously measured for the parent aldehydes.

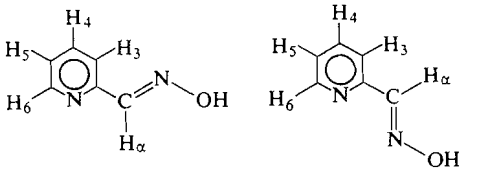
WERNER DANCHURA, RODERICK E. WASYLISHEN, JAMES DELIKATNY et MOIRA R. GRAHAM. Can. J. Chem. 57, 2135 (1979).

On rapporte les résultats d'études rmn ^1H et ^{13}C effectuées sur trois aldoximes *syn* de la pyridine. Les valeurs observées pour $^6J(H_\alpha,H_{para})$ des pyridines aldoximes-2 (et -3) indiquent que le groupe oxime est décalé d'approximativement 20° par rapport au plan du cycle de la pyridine. Les valeurs de $^5J(H_\alpha,H_{meta})$ stéréospécifiques mesurées pour des solutions de pyridinealdoxime-2 dans l'acétone indiquent que le rapport des conformations HCCN *trans*:*cis* est de 0.86 ± 0.14. Les résultats de mesures semblables avec le pyridinealdoxime-3 conduisent à un rapport des conformations *trans* et *cis* des C_2CCN de 0.60 ± 10. Des calculs *ab initio* d'orbitales moléculaires sont en bon accord qualitatif avec les expériences. On compare les déplacements chimiques ^{13}C des oximes à ceux mesurés antérieurement pour leurs aldéhydes.

[Traduit par le journal]

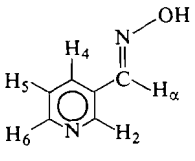
Introduction

In recent years several techniques have been used to study the conformation of the CHO group in pyridine aldehydes (1–7). In contrast little attention has been given to the conformation of the oxime moiety in pyridine aldoximes. Here we wish to report the results of an nmr study of the three *syn*-pyridine aldoximes.[1] The principal objective of this study was to estimate the relative stabilities of **1***a* (NCCN *trans*) and **1***b* (NCCN *cis*) and of **2***a* (C_2CCN *trans*) and **2***b* (C_2CCN *cis*) in solution. Experimental results are compared with those obtained using *ab initio* molecular orbital theory with the minimal STO-3G basis set (7–9). The experimental technique used here is based on the stereospecific long-range spin–spin coupling constants over five bonds between the oxime proton, H_α, and the pyridine ring protons (2, 10, 11).

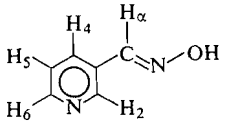


1*a*

1*b*



2*a*



2*b*

As well, the conformational preferences derived for the oximes are compared with those obtained for the pyridine aldehydes. Finally, the influence of the oxime and carbonyl moieties on the ^{13}C nmr chemical shifts of the pyridine ring are compared. The ^{13}C chemical shifts of the pyridine ring carbons are shown to be relatively insensitive to the conformation of the oxime moiety.

Experimental

The pyridine aldoximes were obtained from ICN : K & K Laboratories Inc. The observed melting points of the 2-, 3-, and 4-pyridine aldoximes were 110–112°C, 149–151.5°C, and 130–132°C respectively. The samples used for the proton nmr studies were prepared as degassed solutions in acetone-d_6. The 4-pyridine aldoxime was prepared as a 5 mol% solution whereas the 2- and 3-pyridine aldoximes were prepared as saturated (< 5 mol%) solutions. The samples used for the ^{13}C nmr studies were 1 *M* solutions in DMSO-d_6.

Proton nmr spectra were obtained at 30 ± 2°C using a

[1] In the IUPAC system all *syn*-aldoximes become *E*-aldoximes and all *anti*-aldoximes become *Z*-aldoximes.

Varian CFT-20 spectrometer operating at 79.54 MHz. Acquisition times of 20.0 s or longer were used to obtain the data reported here. The free induction decay was not weighted. Typically ^1H line widths were less than 0.18 Hz. Proton chemical shifts were measured with respect to the ^1H signal of the residual protons in the solvent. This resonance was found to be 163.08 ± 0.05 Hz down field from internal TMS.

Proton-decoupled ^{13}C nmr spectra were also obtained on the Varian CFT-20 spectrometer at 32 ± 2°C. Chemical shifts were measured with respect to the solvent DMSO-d_6 and converted to the TMS scale by adding 39.56 ppm (12).

The geometry used for all molecular orbital calculations carried out in this study was obtained as follows. The coordinates for the pyridine ring were taken from a microwave study of pyridine (13*a*). The C_α—H_α and O—H bond lengths were 1.08 and 0.96 Å, respectively (14); C_{ring}—C_α (1.469 Å), C_α=N (1.275 Å), and N—O (1.390 Å) were taken from an X-ray diffraction study of *syn*-4-pyridine aldoxime (**3**) (15). In each case the $C_{ring}C_{ring}C_\alpha$ bond angle was taken to be the same as the corresponding CCH bond angles in pyridine (13*a*). The bond angle NOH was taken as 102.77° (13*b*). All other bond angles were taken from the X-ray diffraction study (15): $C_{ring}C_\alpha N$ (120.0°), $C_{ring}C_\alpha H_\alpha$ (122.0°), $H_\alpha C_\alpha N$ (118.0°), and $C_\alpha NO$ (111.1°).

Spin–spin coupling constants were calculated using semi-empirical molecular orbital calculations at the CNDO/2-FPT and INDO-FPT levels of approximation (16, 17). The reliability of these techniques for the calculation of spin–spin coupling constants has recently been reviewed (17*b*).

Results and Discussion

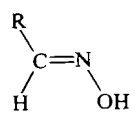
Spectral Analyses

Proton nmr spectra were analyzed using the computer program LAME (18). Results are presented in Table 1. The rms deviations between observed and calculated transition frequencies lie between 0.014 and 0.033 Hz for the various samples. For the 3- and 4-pyridine aldoximes the standard deviations of all spectral parameters are less than 0.01 Hz. For the 2-pyridine aldoxime the largest standard deviation was 0.04 Hz (for $^3J(H_4,H_5)$ and $^4J(H_3,H_5)$).

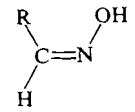
The coupling constants among the pyridine ring protons are all within 0.25 Hz of those previously observed in the corresponding pyridine aldehydes (2).

Assignment of Isomers

Often it is possible to prepare two different oximes from a given aldehyde, the so-called *syn*- and *anti*-aldoximes (19, 20). Because it is difficult to predict



syn



anti

a priori which form will be most stable, a number of techniques have been devised to distinguish between these two isomers (see for example refs. 19–30).

Although both the *syn*- and *anti*-4-pyridine aldoximes are known (15), only one isomer of the 2- and 3-pyridine aldoximes appears to be known (27). On the basis of observed $^2J(^{15}N,H)$ values, Crepaux and Lehn (27) have shown that these latter two compounds exist as the *syn* isomers.

TABLE 2. Calculated spin–spin coupling constants (in Hz)

	1*a*		1*b*

$^5J(H_\alpha,H_5)$	0.80	1.47	0.06	0.27	1.04
$^6J(H_\alpha,H_6)$	−0.01	−0.40	0.04	−0.30	−1.00

	3	
	CNDO/2	INDO
$^5J(H_\alpha,H_2)$	0.06	0.24
$^4J(H_\alpha,H_3)$	0.32	−0.29
$^4J(H_\alpha,H_5)$	0.09	−0.83
$^5J(H_\alpha,H_6)$	0.84	1.52

It is of interest to point out that the ^{1}H chemical shift differences between the O*H* and C*H*$_\alpha$ resonances for 10% DMSO-d_6 solutions of 2-, 3-, and 4-pyridine aldoximes are 3.57, 3.39, and 3.66 ppm respectively, making it difficult to apply the criterion proposed by Kleinspehn *et al.* (21) for distinguishing between *syn*- and *anti*-isomers.

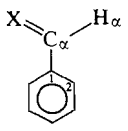
Conformations About The Ring Carbon – Imino Carbon Bond

^{6}J(H_α,H_p) as a Measure of the Planarity of 1 and 2

Previous studies on substituted benzenes indicate that the six-bond coupling between a side chain proton and the proton *para* to the substituent is given by an equation of the form

[1] $^6J(H_\alpha,H_p) = {}^6J_0 + {}^6J_1 \sin^2\theta$

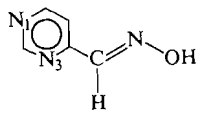
Here $^6J_1 \gg {}^6J_0$ and θ is the $H_\alpha C_\alpha C_1 C_2$ dihedral angle.



θ = 0°

For the pyridine aldehydes (X = O), $^6J(H_\alpha,H_p) <$ 0.05 Hz and hence $^6J_0 \simeq 0.0$ and $\theta \simeq 0°$. Reliable experimental values of $^6J_1$ are not available. However, on the basis of INDO-MO-FPT calculations (Table 2) we estimate $^6J_1 = -1.05 \pm 0.3$ Hz. This value of $^6J_1$ is similar to the value estimated in toluene (31) and used in a study of 2,6-dichlorobenzaldoxime (32). Thus using [1] with $^6J_0 = 0.0$ and taking $^6J_1 = -1.05 \pm 0.3$ Hz, the observed values of −0.18 Hz and −0.16 Hz in **1** and **2** suggest that the oxime group is twisted out of the pyridine ring plane by 24 ± 6° and 23 ± 6°.

X-ray diffraction data on *syn*-4-pyridine aldoxime (**3**) and *syn*-4-pyrimidine aldoxime (**4**) indicate that



4

the oxime group is twisted out of the ring plane by 13.7° and 5° respectively (15, 33). Early X-ray data on *syn*-4-chlorobenzaldoxime indicated that the oxime moiety lay 19° out of plane (34).

On the basis of the X-ray data above it appears that the nmr estimates of θ are upper limits.

*^{5}J(H_α,H_m) as a Measure of the Relative Populations of 1*a *and 1*b *and of 2*a *and 2*b

In *syn*-4-pyridine aldoxime (**3**) the observed value of $^5J(H_\alpha,H_{2,6})$, 0.36 Hz, is an average of $^5J(H_\alpha,H_2)$ and $^5J(H_\alpha,H_6)$. Previous experimental studies on various aromatic aldehydes (2, 10, 11) indicate that for the conformation of *syn*-4-pyridine aldoxime shown below, $^5J(H_\alpha,H_2)$, must be small (<0.1 Hz), while $^5J(H_\alpha,H_6)$ is approximately 0.7 Hz. This

TABLE 3. Some *ab initio* MO results for the *syn*-pyridine aldoximes

Compound	Conformation	Total energies (au)	Relative energies (kcal/mol)	Dipole moments (D)
1	NCCN *trans*	−409.159664	0.00	2.04
	NCCN *cis*	−409.155882	2.37	1.94
	NCCN 90°	−409.149164	6.59	2.10
2	C(2)CCN *trans*	−409.159442	0.00	2.02
	C(2)CCN *cis*	−409.158820	0.390	1.96
	C(2)CCN 90°	−409.149754	6.08	1.99

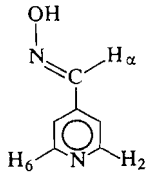
	CCCN 90°	−409.149516	5.93	1.96

hypothesis is also supported by the CNDO/2-MO-FPT results given in Table 2.

For *syn*-2-pyridine aldoxime, **1**, $^5J(H_\alpha,H_4) = 0.62 \pm 0.02$ Hz while $^5J(H_\alpha,H_6) \leq 0.15$ Hz. Assuming that $^5J_1(H_\alpha,H_4)_{obs} = X_{1a}{}^5J(H_\alpha,H_4)_{1a} + X_{1b}{}^5J(H_\alpha,H_4)_{1b}$ and that $^5J(H_\alpha,H_4)_{1a}$ is 0.72 Hz, or (2 × 0.36) Hz, and that $^5J(H_\alpha,H_4)_{1b}$ is zero, X_{1a}, the fractional population of the *trans* conformation, is 0.62/0.72 = 0.86 ± 0.14. The CNDO/2-MO-FPT calculations support our assumption that for **1***a* $^5J(H_\alpha,H_4)$ will be similar to $^5J(H_\alpha,H_2)$ in **3**.



3

For *syn*-3-pyridine aldoxime, **2**, $^5J(H_\alpha,H_5)$ is 0.43 ± 0.02 Hz and using the same procedure as above the fractional population of **2***a* is 0.60 ± 0.10. The CNDO/2-MO-FPT calculations predict almost identical values for $^5J(H_\alpha,H_5)$ in **2***a* and $^5J(H_\alpha,H_6)$ in **3**.

STO-3G ab initio *Molecular Orbital Calculations*

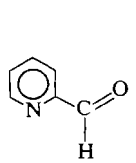
The above estimates for the fractional populations of the *trans* conformations, X_{1a} and X_{2a} for **1** and **2** may be compared with the results of *ab initio* MO calculations presented in Table 3. The calculations predict **1***a* to be 2.38 kcal/mol more stable than **1***b*, hence at 30°C, $X_{1a} = 0.98$. **2***a* is predicted to be only 390 cal/mol more stable than **2***b*, hence at 30°C, $X_{2a} = 0.66$. The relative populations of **1***a* and **1***b* and of **2***a* and **2***b* calculated using the STO-3G basis set are in good qualitative agreement with the values estimated for solutions of **1** and **2** in acetone.

The *ab initio* calculations predict the conformation in which the oxime group is perpendicular to the pyridine ring-plane to be about 6 kcal/mol higher in energy than the completely planar conformations. These values are similar to those calculated (7) and observed (4, 5) for the pyridine aldehydes.

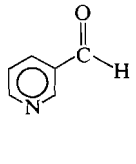
Finally, it is of interest to note that the calculated dipole moments of the pyridine aldoximes are insensitive to the conformation of the oxime group. Consequently, the relative populations of **1***a* and **1***b* and of **2***a* and **2***b* should be relatively insensitive to solvent polarity (2).

Comparison with Related Molecules

It is of interest to compare the results obtained here for the *syn*-pyridine aldoximes with those obtained for the parent aldehydes. In the case of 2-pyridine aldehyde, microwave (3) and nmr data (2, 4, 5) and *ab initio* MO calculations (7) are in agreement that the fractional population of the NCCO *trans* conformation, X_t, is 0.9 ± 0.1.



NCCO *trans*



C_2CCO *trans*

For the 3-pyridine aldehyde there is general agreement that the C_2CCO *trans* conformation is slightly favored over the C_2CCO *cis* conformation (X_t = 0.7 ± 0.1). The values obtained for X_t are somewhat dependent on the solvent polarity and temperature (2, 4, 5)

In contrast to the oximes, the aldehydes appear to be planar (2, 3).

Finally it is of interest to mention that in the solid state *syn*-4-pyrimidine aldoxime (**4**) exists entirely in the N_3C_4CN *trans* conformation (33).

Carbon-13 Chemical Shifts

Carbon-13 chemical shifts of the *syn*-pyridine aldoximes are given in Table 4. The influence of the *syn*-CHNOH group on ^{13}C chemical shifts of the pyridine ring is displayed in Table 5. For comparison the analogous literature values for the CHO groups are included in parentheses (35–37). In general the CHNOH group influences the pyridine ring carbon shifts less than does the CHO group. This is particularly true for the carbon *para* to the substitutent; in the 2- and 3-substituted oximes the *para*-substituent effect is 0.1 and 0.0 ppm, respectively, while

TABLE 4. Observed carbon-13 chemical shifts (ppm) of the *syn*-pyridine aldoximes

	1	2	3
C_α	149.0	145.8	146.7
C_2	152.2	147.9	150.2
C_3	119.8	129.1	120.7
C_4	136.8	133.1	140.4
C_5	124.0	123.9	120.7
C_6	149.5	150.1	150.2

TABLE 5. Effect of *syn*-CHNOH and CHO substitution on pyridine ring ^{13}C chemical shifts[a,b] (in ppm)

Substituent at:	C_2	C_3	C_4
C_2	*2.1* (3.2)	−2.2 (1.1)	0.1 (1.4)
C_3	−4.1 (−2.1)	*5.2* (8.4)	−3.2 (−1.1)
C_4	1.0 (1.9)	−2.7 (0.6)	*4.6* (6.1)
C_5	0.1 (4.4)	0.0 (1.1)	−3.2 (−1.1)
C_6	−0.6 (0.4)	0.0 (5.1)	0.1 (1.4)

[a]Values in parentheses are for CHO substitution.
[b]Positive values indicate a downfield shift relative to the value in pyridine.

in the corresponding aldehydes the values are 4.4 and 5.5 ppm. This is also the case when one compares the influence of the CHO and CHNOH moieties on the benzene ring; here the oxime group shifts C_{para} 1.7 ppm downfield while the CHO group induces a 6.0 ppm downfield shift (37, 38).[2]

One might expect the carbon β to the oxime group to be most sensitive to the conformation of the CHNOH moiety (i.e., C_3 in **1**, C_2 and C_4 in **2**, C_3 and C_5 in **3**). In the case of **1**, where the NCCN *trans* conformation is highly favored, the substituent effect on C_3 is −4.1 ppm, not very different from the value of −3.2 ppm observed for C_3 and C_5 in **3**. On the basis of these data it appears that the chemical shifts of the pyridine ring are relatively insensitive to the conformation of the CHNOH group.

A nuclear magnetic resonance study of pyridinium and *p*-anisidinium carboxylate salts

JOAN A. GOWLAND AND ROBERT A. MCCLELLAND

Department of Chemistry, University of Toronto, Scarborough College, West Hill, Ont., Canada M1C 1A4

Received November 21, 1978

JOAN A. GOWLAND and ROBERT A. MCCLELLAND. Can. J. Chem. 57, 2140 (1979).

The proton nmr chemical shifts for *p*-anisidinium chloride, chloroacetate, dichloroacetate, and trichloroacetate and pyridinium dichloroacetate, trichloroacetate, and trifluoroacetate salts in seven solvents are reported. These shifts are used to estimate the extent of proton transfer between the amine base and carboxylic acid. In non-polar solvents the *p*-anisidinium ion lies intermediate in acidity between monochloroacetic acid and trichloroacetic acid. The pyridinium system is similar; there is also some evidence here for the presence of charge transfer complexes.

JOAN A. GOWLAND et ROBERT A. MCCLELLAND. Can. J. Chem. 57, 2140 (1979).

On rapporte les déplacements chimiques en rmn ^1H pour les chlorure, chloroacétate, dichloroacétate et trichloroacétate de *p*-anisidinium et pour les dichloroacétate, trichloroacétate et trifluoroacétate de pyridinium dans sept solvants. On utilise ces déplacements pour évaluer le taux de transfert protonique entre l'amine basique et l'acide carboxylique. Dans des solvants non polaires, l'acidité de l'ion *p*-anisidinium se situe entre celle des acides monochloro- et trichloro-acétiques. Le système pyridinium est semblable; il existe aussi ici quelques indications relatives à la présence de complexes de transfert de charge.

[Traduit par le journal]

With the recent availabilities of acidities and basicities in the gas phase, it has become increasingly important to evaluate the effects of solvation on acid–base equilibria in solution, since the gas phase measurements underline the importance of this factor in determining the position of equilibria. To date the majority of solution studies have focussed on polar or protic solvents, with few detailed investigations in weakly polar aprotic solvents. In this paper, we report an nmr study of the interaction of two amine bases, *p*-anisidine and pyridine, with chloro-, dichloro-, and trichloroacetic acids in a series of solvents ranging in polarity from water to chloroform. These two bases were chosen since they have similar aqueous solution dissociation constants. The carboxylic acids were chosen since their aqueous pK_a values are such that proton transfer to the two amines is essentially complete in water. Proton nmr was chosen as the tool for the investigation; this technique has been well established to serve as a measure of the electron density of the aromatic system, and as such should serve as a probe for the type of interaction between the aromatic amino base and the added acid (1–8).

Experimental

Chloroacetic acid and trichloroacetic acid were recrystallized from chloroform. *p*-Anisidine was recrystallized from petroleum ether (80–100°C). Dichloroacetic acid was distilled at reduced pressure. Chloroform and pyridine were purified according to standard procedures. Other solvents were Fisher AnalaR or spectral grade, or Merck, Sharp and Dohme deuterated solvents (D_2O, DMSO-d_6, $CDCl_3$, acetone-d_6). Melting points were taken on a Fischer-Johns melting point apparatus and are uncorrected. Infrared spectra were obtained on a Perkin Elmer 237-B Grating IR spectrophotometer. Ultraviolet spectra were obtained on a Unicam SP 800 spectrometer. Analyses were done by A. Gygli, Toronto. Nuclear magnetic resonances were obtained on a Varian T60 nmr spectrometer. Approximately 10% w/w solutions of the salts were used. Chemical shifts are given relative to TMS.

The salts were prepared as follows:

p-*Anisidinium Chloroacetate*

Approximately equimolar amounts of chloroacetic acid and *p*-anisidine were combined in chloroform to give a white precipitate. This was recrystallized from acetone and chloroform to give fluffy white needles, mp 128–119°C. *Anal.* calcd. for $C_9H_{12}ClNO_3$: C 49.61, H 5.57, N 6.29, Cl 16.45; found: C 49.76, H 5.51, N 6.43, Cl 16.29.

p-*Anisidinium Dichloroacetate*

Approximately equimolar amounts of dichloroacetic acid and *p*-anisidine were combined in chloroform. The solution was heated briefly and then cooled to give a white precipitate. This product was recrystallized from acetone and chloroform to give a white powder, mp 133–134°C. *Anal.* calcd. for $C_9H_{11}Cl_2NO_3$: C 42.84, H 4.24, N 5.44, Cl 27.94; found: C 42.68, H 4.36, N 5.55, Cl 28.12.

p-*Anisidinium Trichloroacetate*

Approximately equimolar amounts of trichloroacetic acid and *p*-anisidine were combined in a small amount of chloroform. The solution was heated for two hours and then cooled and scratched to give a white precipitate. The product was recrystallized from chloroform to give white needle-shaped crystals, mp 94–95°C. *Anal.* calcd. for $C_9H_{10}Cl_3NO_3$: C 37.68, H 3.52, N 4.78, Cl 37.09; found: C 37.57, H 3.49, N 4.88, Cl 37.11.

p-*Anisidinium Chloride*

Concentrated hydrochloric acid was added to a solution of *p*-anisidine in benzene to give a white precipitate. This was

[a]Where two numbers are given the first refers to protons *ortho* to the methoxy group.

TABLE 2. Chemical shifts for pyridinium ring protons in various solvents (ppm from TMS)

Solvent	Pyridine	Pyridinium dichloroacetate	Pyridinium trichloroacetate	Pyridinium trifluoroacetate
$CDCl_3$	8.63,[a] 7.65, 7.27	8.81, 8.11, 7.80	8.95, 8.33, 7.88	8.89, 8.33, 7.88
Tetrahydrofuran	8.63, 7.65, 7.25	8.58, 7.77, 7.35	8.75, 8.06, 7.62	8.77, 8.15, 7.68
Acetone-d_6	8.58, 7.77, 7.33	8.69, 8.10, 7.65	8.98, 8.47, 7.98	8.98, 8.52, 8.05
Acetonitrile	8.44, 7.57, 7.17	8.70, 8.16, 7.72	8.78, 8.35, 7.88	8.78, 8.35, 7.87
Methanol	8.59, 7.80, 7.42	8.72, 8.28, 7.82	8.83, 8.53, 8.02	8.85, 8.55, 8.05
DMSO-d_6	8.62, 7.75, 7.38	8.61, 7.85, 7.47	8.53, 7.76, 7.38	8.87, 8.41, 7.92
D_2O	8.43, 7.72, 7.35	8.71, 8.53, 8.00	8.73, 8.56, 8.05	8.71, 8.53, 8.03

[a]First number corresponds to H_α, second $-H_\gamma$, third H_β.

recrystallized from ethyl acetate and methanol (cf. ref. 1), mp becomes glossy >186°C. *Anal.* calcd. for $C_7H_{10}ClNO$: C 52.61, H 6.21, N 8.76, Cl 22.2; found: C 52.87, H 6.46, N 8.76, Cl 22.11.

Pyridinium Dichloroacetate

Approximately equimolar amounts of dichloroacetic acid and pyridine were combined in chloroform to give a waxy yellow solid which was very hygroscopic. Recrystallization from anhydrous ether gave colourless needle-shaped crystals, mp 52–54°C (ref. 9 only reports obtaining a hygroscopic salt). Only dry crystals were used for spectral work, but the extremely hygroscopic nature of the salt did not permit satisfactory analysis.

Pyridinium Trichloroacetate

Approximately equimolar amounts of trichloroacetic acid and pyridine were combined in a small amount of chloroform to give shiny white plate-like crystals which were recrystallized from benzene, mp 106–107°C (lit. (10) mp 100–102°C). *Anal.* calcd. for $C_7H_6Cl_3NO_2$: C 34.64, H 2.47, N 5.77, Cl 43.91; found: C 34.44, H 2.43, N 5.71, Cl 43.86.

Pyridinium Trifluoroacetate

Trifluoroacetic acid and pyridine were combined in a small amount of chloroform to give a white precipitate. This was recrystallized from chloroform and ether to give small needle-like crystals, mp 79–81°C (lit. (11) mp 82–83°C).

Results and Discussion

The approach that was employed to prepare the nmr solutions was to synthesize and purify salts of the acid and base, and dissolve these in the solvent in question. With one exception, elemental analysis of the solid salts so prepared corresponds to a 1:1 mixture of acid and base, and their KBr infrared spectra show carboxylate and ammonium bands, and no carboxylic acid band. These are then normal 1:1 salts of an acid and a base. The one exception is the solid which precipitates from concentrated solutions of chloroacetic acid and pyridine; this material appears to be a product of nucleophilic substitution.

In Tables 1 and 2 ring proton chemical shifts for the salts, as well as for the parent bases, are given in ppm relative to TMS. In a small number of cases spectra were obtained without preforming a solid salt, simply with a 1:1 molar solution of acid and base. Spectra of these solutions are identical to those obtained with the salts. The chemical shifts given in the tables are the weighted mean of the set of peaks corresponding to each proton. This is an approximation, since the pyridine spectrum is of the type AA'BB'C, while that of *p*-anisidine is of the type AA'BB'. However, relative shifts at 60 MHz are fairly large, and the shifts of Tables 1 and 2 are probably accurate to ±0.05 ppm. As has been shown previously (6), where a comparison is possible with shifts arrived at by exact analysis, numbers arrived at by this approximate analysis show good agreement.

p-Anisidinium Salts

As anticipated the nmr results obtained in D_2O are consistent with essentially complete proton transfer from acid to base, forming solvent separated ion pairs. This is seen by the fact that all salts have the same ring proton shifts, and is not surprising since

TABLE 3. Percent proton transfer[a] of *p*-anisidinium salts

Solvent	*p*-Anisidinium chloroacetate	*p*-Anisidinium dichloroacetate	*p*-Anisidinium trichloroacetate
DMSO-d_6	0	13	16
Acetonitrile	13	33	38
Tetrahydrofuran	6	20	90[b]
Methanol	12	40	92
Acetone-d_6	16	45	89
$CDCl_3$	30	90	100[b]
D_2O	100	100	100

[a]Numbers are accurate to ± 5–10%.
[b]The chemical shifts for *p*-anisidinium chloride were estimated as 7.4, 7.0.

even with chloroacetic acid the difference in pK_a between the acid and the *p*-anisidinium ion is greater than three. The KBr ir spectra of the solid salts also show full proton transfer.

In the other solvents the general conclusion which emerges is that proton transfer is not as complete. In Table 3 are presented rough estimates of the percent proton transfer, with the solvents arranged in order of increasing ionizing ability. The numbers were arrived at by taking the chemical shift of *p*-anisidine alone for that of a system with no proton transfer, and the chemical shift of *p*-anisidinium chloride for that of a system with full proton transfer. Although no claim can be made that these numbers are very precise (we estimate their accuracy to be at best ±10), several trends emerge.

In acetonitrile and DMSO the acid–base equilibrium is shifted to favor un-ionized species, i.e., there is very little proton transfer. This can be attributed to the very poor solvating capabilities of these two solvents for carboxylate anions (12). In the other four solvents, the trichloroacetate salt is mainly ionized, the chloroacetate salt is mainly un-ionized, and the dichloroacetate takes an intermediate position. Evidence was obtained that the nmr shifts do reflect the position of equilibrium, in that addition of excess acid to a solution of a partially ionized salt causes a downfield chemical shift in the ring protons, i.e., towards that of the ionized form. The general conclusion that emerges is that in these four solvents there is a considerable shift in the *relative* acidities of the *p*-anisidinium ion and the carboxylic acids, such that the former is now somewhere intermediate in acidity between monochloroacetic acid and trichloroacetic acid. This amounts to a change of approximately three log units in the ΔpK_a values, and, what is also somewhat surprising, this change is similar in the four solvents, chloroform, tetrahydrofuran, acetone, and methanol. We can also point out that ir studies have reached a similar conclusion as to the effect of solvent on the ΔpK_a of protonated amines and carboxylic acids (13, 14), indicating that there is consistency between the ir and nmr analyses.

One additional comment should be made regarding this system. It is probably reasonably valid to say that in these non-polar solvents the anilinium carboxylate salt exists in relatively tight ion pairs, so that the counter-ion can have an influence on the exact nmr shift of the *p*-anisidinium group (1). This obviously limits the accuracy of any pK_a value measured using nmr chemical shifts (as in Table 3). For example the difference in *p*-anisidinium chloride and *p*-anisidinium trichloroacetate in acetone can be taken as indicative of less than complete proton transfer for the carboxylate, or more likely can be taken as indicative of different degrees of association within the ion pair.

Pyridinium Salts

In general it can be concluded that the behavior of the pyridinium salts is fairly similar to that of the *p*-anisidinium salts. Both sets are fully ionized in D_2O while in the other solvents significant shifts in acid–base equilibria occur. Pyridine appears to be a weaker base in acetonitrile, as could be expected. The aqueous pK_a values of ions of this type are strongly influenced by hydrogen bonding (15) between N—H and solvent water molecules, but this type of solvation will be far less important in acetonitrile. The *p*-anisidinium ion, which can form three such hydrogen bonds, is stabilized more in water by this type of interaction than the pyridinium ion, where there is only one available hydrogen. The *p*-anisidinium equilibrium therefore suffers more, relatively speaking, on proceeding to the acetonitrile solvent.

A further feature of the pyridinium system which can be commented on is the chemical shift of the α protons, which were found to be very concentration dependent. Typically the H_α chemical shift moved to lower field as the salt concentration increased. The shift, for example, of H_α for pyridinium trichloroacetate varied from 8.70 (5% solution) to 9.21 (saturated solution). In addition to their concentration dependency, the downfield position of these chemical shifts is somewhat unusual. Examination of the litera-

ture reveals that in general H_α of the pyridinium salt appears at 8.8 ± 0.1 (3, 4). The only exceptions to this behavior of which we are aware are the shifts for the α protons of 1,4-diethylpyridinium chloride and iodide, which in $CDCl_3$ appear at 9.81 ppm and 9.45 ppm respectively (7).

We propose that these downfield chemical shifts arise when the pyridinium ion is forming charge-transfer complexes. This is of course a well established feature of pyridinium ions, especially in non-polar solvents (16), but has not been discussed for pyridinium carboxylate salts. In general the presence of a charge transfer interaction is seen in the uv spectrum of a salt by the appearance of additional bands not found in the spectrum of either the cation or anion (16). Neither the pyridinium ion nor the chloroacetate ions show uv absorbance above 300 nm. However absorbance can be seen in this region for the pyridinium chloroacetate salts, particularly with the trichloroacetate (Fig. 1). This long wavelength absorption is consistent with the presence of some charge transfer interaction.

Intuitively one might then expect small upfield nmr shifts for pyridinium protons in a charge transfer complex, since the ion, acting as an acceptor, would have a gain in electron density. However, the following is consistent with downfield shifts for the α protons. Theoretical calculations (17) show that pyridinium chloride in its charge transfer form has the chloride sitting preferentially over C-2 and C-6 of the pyridinium ring. These calculations also suggest that the chlorine–carbon distance in this form is less than the van der Waals radius. Moreover, although there is a net transfer of charge to the pyridinium ring, the charges on C-2 and C-6 become more positive, thus enhancing the electrostatic interaction with the chloride ion (17). Such an interaction would lead to a downfield shift for the α protons while the β and γ protons would remain the same or move somewhat upfield, as we in fact observe. Further evidence for this type of interaction comes from the halide order observed in the 1,4-diethylpyridinium salts (7), where the H_α downfield shifts occur in the order $Cl^- > I^-$. This is opposite to the expected order for charge transfer formation (18, 19). However, the nmr shifts would be a combination of the charge transfer effect and an electrostatic interaction and for the latter, Cl^- would be expected to show the largest effect. (One of the referees suggested that charge transfer complex formation might result in line broadening, due to the production of spin density in the aromatic ring. We find no significant line broadening in our spectra, but this could be obscured because of the complexity of the spectra.)

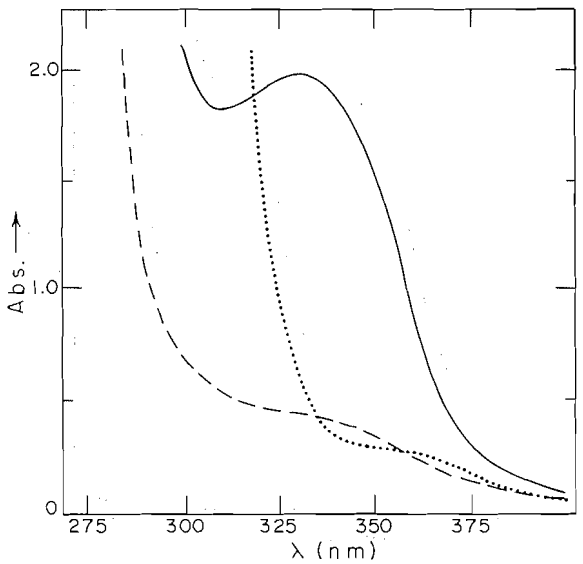

FIG. 1. Ultraviolet spectra of pyridinium solutions in chloroform: (--) saturated pyridinium trichloroacetate salt solution: (—) 0.4 *N* trichloroacetic acid + 0.24 *N* pyridine; (· ·) filtrate of an 0.8 *N* chloroacetic acid + 4 *N* pyridine solution.

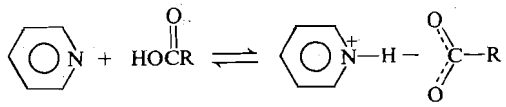
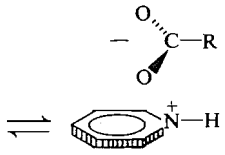
For the pyridinium salts in this study the following equilibria can be proposed in non-polar or weakly polar solvents.



I, ion pairs



II, charge transfer complexes

Structures I and II differ in the position of the carboxylate group, which is sitting on top of the ring in II, over N, C-2 and C-6. This leads to a similar rearrangement of charge to that observed with the pyridinium halides, and, we propose, accounts for the downfield nmr shifts of H_α and the presence of charge transfer bands in the uv spectra.

Chemoselectivity in the synthesis of thiocyanates and isothiocyanates: the reaction of alkenes with benzeneselenenyl thiocyanate in methylene chloride

DENNIS G. GARRATT,[1] M. DOMINIC RYAN, AND MARK UJJAINWALLA

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received February 7, 1979

DENNIS G. GARRATT, M. DOMINIC RYAN, and MARK UJJAINWALLA. Can. J. Chem. **57**, 2145 (1979).

The reactions of benzeneselenenyl thiocyanate with some simple alkylsubstituted acyclic and cyclic alkenes have been investigated, and the relative distribution of isomeric adducts determined. The relative distribution of β-thiocyanatoalkyl phenyl selenide to β-isothiocyanatoalkyl phenyl selenide is found to be dependent upon the degree of substitution of the initial alkene. Thus mono- and disubstituted alkenes favour formation of the thiocyanato species, whereas tri- and tetrasubstituted alkenes yield isothiocyanato adducts almost exclusively. Stereospecific *anti* addition was established in all cases except that of tricyclo[4.2.2.0^{2,5}]deca-3,9-diene-7,8-dicarboxylic anhydride which gives a 33:67 mixture of *cis* and *trans* adducts.

DENNIS G. GARRATT, M. DOMINIC RYAN et MARK UJJAINWALLA. Can. J. Chem. **57**, 2145 (1979).

On a étudié les réactions du thiocyanate de benzènesélénényle avec quelques alcènes linéaires et cycliques substitués par des groupes alkyles simples et on a déterminé la distribution relative des adduits isomères. On a trouvé que la distribution relative du sélénure de β-thiocyanatoalkyle et de phényle par rapport au sélénure de β-isothiocyanatoalkyle et de phényle dépend du degré de substitution de l'alcène de départ. Les alcènes mono- et disubstituées favorisent la formation d'espèces thiocyanato alors que les alcènes tri- et tétra-substitués conduisent presqu'exclusivement aux adduits isothiocyanato. On a établi que l'addition est stéréospécifiquement *anti* dans tous les cas excepté celui de l'anhydride de l'acide tricyclo[4.2.2.0^{2,5}] décadiène-3,9 dicarboxylique-7,8 qui conduit à un mélange 33:67 des adduits *cis* et *trans*.

[Traduit par le journal]

The isolation of an areneselenenyl thiocyanate was first reported by Foss in 1947 (1) from the reaction of 2-nitrobenzeneselenenyl bromide with potassium thiocyanate in ethyl acetate–methanol solution (eq. [1]). There have been few studies of this class of compounds, with the exception of a brief investigation by Rheinboldt and Perrier on nucleophilic substitution at selenenyl selenium (2).

[1] 
We wish to present the results of an experimental investigation of the addition of benzeneselenenyl thiocyanate to a series of simple alkylsubstituted olefins. In previous papers we have discussed the reactions of the analogous areneselenenyl chlorides with unsaturated substrates of various types and structure, both from the point of view of kinetics and the stereochemical and regiochemical nature of these reactions (3). It was anticipated that areneselenenyl thiocyanates would behave like the analogous chlorides and thus allow one by virtue of the ambident character of the pseudohalide anion, SCN, to draw further mechanistic conclusions with respect to the importance of ion-pairs during these reactions and the subsequent isomerizations of the adducts. Furthermore, it was felt that the use of areneselenenyl thiocyanates might open up a new series of potentially useful synthetic reagents for the introduction, both stereo- and regiospecifically, of sulphur and nitrogen moieties based on the chemistry of alkyl thiocyanates and isothiocyanates. Related studies utilizing iodine thiocyanate have recently been published by Woodgate and co-workers (4).

Benzeneselenenyl thiocyanate, C_6H_5SeSCN, was prepared *in situ* by a modification of the method of Foss from benzeneselenenyl chloride and sodium thiocyanate in methylene chloride as solvent. The presence of a strong sharp peak at 4.65 μm in the infrared spectrum, characteristic of a thiocyanate group, and the absence of an intense, broad band in the 4.67–5.03 μm region indicative of an isothiocyanate group, clearly indicates the reagent to be C_6H_5SeSCN rather than C_6H_5SeNCS. The sodium chloride is removed by filtration and the resultant clear yellow-orange solution used directly for the additions. These solutions should be used within a few hours of preparation. On prolonged standing a

deep orange crystalline solid precipitates out of solution. This material is also obtainable directly via evaporation of the solvent and appears to be a form of benzeneselenenyl thiocyanate in a higher state of aggregation. Although this alternate form of the reagent will react with alkenes, we have limited ourselves in this report to a study of the chemistry of the first formed species.

Results and Discussion

Reactions of benzeneselenenyl thiocyanate, **1**, in methylene chloride at ambient temperature with simple alkenes give adducts of the type shown in [2].

[2] $C_6H_5SeSCN + \diagup C{=}C \diagdown \longrightarrow$

1

$C_6H_5Se{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}SCN$ + $C_6H_5Se{-}\overset{|}{\underset{|}{C}}{-}\overset{|}{\underset{|}{C}}{-}NCS$

A **B**

The relative distribution of β-thiocyanates, **A**, to β-isothiocyanates, **B**, is found to be dependent on the degree of substitution of the initial alkene. For example, the reaction of **1** with ethylene gives under conditions of kinetic control 2-thiocyanatoethyl phenyl selenide **2**, whereas with 2,3-dimethyl-2-butene, one isolates the isothiocyanate adduct **3**.

[3] $C_6H_5SeSCN + H_2C{=}CH_2 \rightarrow C_6H_5SeCH_2CH_2SCN$

2

[4] $C_6H_5SeSCN + (CH_3)_2C{=}C(CH_3)_2 \longrightarrow$

$C_6H_5Se{-}\overset{CH_3}{\underset{CH_3}{C}}{-}\overset{CH_3}{\underset{CH_3}{C}}{-}NCS$

3

When carried out with freshly prepared solutions of **1** these reactions are essentially quantitative: glc yields ≥98%, isolated yields at least 90%, unless otherwise stated. Structural assignments are based on infrared and nmr spectroscopy. Thus the thiocyanato adducts exhibit a sharp absorption between 4.6 and 4.7 μm which is medium to strong in intensity depending upon the surrounding atoms. In contrast the isothiocyanato adducts absorb very strongly, exhibiting a broad band between 4.5 and 5.3 μm with a number of shoulders appearing on either side of the main absorption.

In the assignment of regiochemistry of these and similar species by ^1H nmr it has been observed that protons α to the isothiocyanato group are deshielded relative to those of either the thiocyanato or phenylseleno moieties. In general protons α to the thiocyanato group are *only slightly* deshielded relative to those α to the phenylseleno group. For example, compound **2** exhibits a single sharp resonance at δ 3.16 integrating as four protons (60 MHz, chloroform-*d* solvent). At 100 MHz some fine splitting indicative of a tightly coupled AA'BB' spin system is observed.

In a manner similar to the above, carbon-13 atoms directly bonded to the aforementioned groups are shielded in the order —NCS < —SCN < $—SeC_6H_5$, and therefore allow confirmation of the assignments initially based on ir and ^1H nmr.

The ^1H nmr parameters of the adducts obtained during this investigation are reported in Tables 1, 3, and 4. In every case it was possible to find at least one non-overlapping signal from which the initial (kinetically controlled) isomer distribution could be calculated. The ^{13}C nmr parameters are given in Table 2 and the experimental section. It should be noted that an immediate *in situ* determination of the adduct isomer ratio was necessary because of the observed tendency of many of the adducts to isomerize.

Two types of isomerization are observed. In general, the fastest form of isomerization is the regiospecific conversion of thiocyanate to isothiocyanate and its converse (eq. [5]). Somewhat slower is the

[5] $C_6H_5Se{-}\overset{R'''\ R''}{\underset{R\ \ R'}{C{-}C}}{-}SCN \rightleftharpoons C_6H_5Se{-}\overset{R'''\ R''}{\underset{R\ \ R'}{C{-}C}}{-}NCS$

stereospecific isomerization of regioisomers (eq. [6]). It is not clear in all cases from our data to what degree these secondary isomerizations retain chemical functionality (i.e. RSCN → R'SCN vs. R'NCS).

Exceptions to the above, qualitative observations, have been observed and therefore indicate a note of caution must be applied towards all assignments. For example, the reaction of **1** with propene yields two thiocyanato adducts in the ratio 60:40. It is observed that the subsequent isomerization, **4** ⇌ **5**, which favours formation of the Markownikoff ad-

[6] $C_6H_5Se{-}\overset{R'''\ R''}{\underset{R\ \ R'}{C{-}C}}{-}SCN \rightleftharpoons NCS{-}\overset{R\ R'}{\underset{R'''\ R''}{C{-}C}}{-}SeC_6H_5$

+ $SCN{-}\overset{R\ R'}{\underset{R'''\ R''}{C{-}C}}{-}SeC_6H_5$

duct, **4**, proceeds much faster than the corresponding isomerization(s) to isothiocyanato adducts, in contrast to the normal results for more highly substituted systems.

$C_6H_5SeCH_2CH(SCN)CH_3$ **4** $\qquad$ $NCSCH_2CH(SeC_6H_5)CH_3$ **5**

In the tables we use the designation Markownikoff, M, and *anti*-Markownikoff, *a*M, to distinguish between isomeric adducts. Since such nomenclature is confusing for adducts derived from 1,2-disubstituted or tetrasubstituted ethylenes, we have adopted the convention that when both olefinic carbon atoms contain an identical number of alkyl groups, the Markownikoff isomer is defined as that one in which the pseudohalide is bonded to the carbon whose sum of Taft's inductive substituent constants, $\Sigma\sigma^*$, is the more negative. This method of nomenclature has been previously reported (5).

Reactions with Acyclic Terminal Alkenes

Simple alkenes upon reaction with **1** give only thiocyanato adducts under conditions of kinetic control. For example, 4-methyl-1-pentene yields an 80:20 mixture of *anti*-Markownikoff to Markowni-

koff thiocyanato adducts while 3-methyl-1-butene gives the *anti*-Markownikoff species exclusively. These ratios are very similar to those previously reported for the analogous additions of C_6H_5SeCl and C_6H_5SeBr (6). Only in the case of 3,3-dimethyl-1-butene is an anomaly observed in that a 40:60 mixture of thiocyanato to isothiocyanato *anti*-Markownikoff adducts is isolable. These data are indicative of the importance of steric factors towards directing the approach of the SCN anion to the initially formed intermediate at the least hindered primary site, although the importance of nonrepulsive electronic effects cannot be totally ruled out.

1,1-Disubstituted ethylenes, such as methylpropene and 2-methyl-1-butene, give mixtures of all four possible adducts (eq. [7]) with the Markownikoff thiocyanate predominating under conditions of kinetic control. The presence of the *anti*-Markownikoff species was surprising since C_6H_5SeCl had been found to yield the Markownikoff adducts exclusively under equivalent conditions (3*f*, 7). If steric hindrance towards approach of the nucleophile, SCN, to the intermediate were to be important in the product-determining step one would have anticipated the regioselectivity to favour the formation of the *anti*-Markownikoff species as in arenesulphenylation (8).

While a very fast isomerization of the form *anti*-Markownikoff ⇄ Markownikoff might be hypothesized to explain the apparent anomaly between monosubstituted and 1,1-disubstituted ethylenes, it is readily ruled out by the observation that the thermodynamic product distributions often favour the *anti*-Markownikoff adducts in yields greater than those observed under kinetic control.

Reactions with Acyclic Non-terminal Alkenes

The ^1H nmr data (Tables 1, 3, and 4) are consistent with products formed by stereospecific *anti* addition. Symmetrical *E,Z* isomeric alkenes such as the 2-butenes, 3-hexenes, and 2,5-dimethyl-3-hexenes each give only one adduct which differs in its ^1H and ^{13}C nmr spectra in the expected manner. Infrared analysis further indicates that the thiocyanato adducts are the products of kinetic control. It should be noted, however, that the subsequent isomerization to isothiocyanate is quite rapid, usually reaching completion within a few hours at 25°C.

In the case of unsymmetrically 1,2-disubstituted

ethylenes, such as the 2-pentenes, it is possible to observe the formation of the two possible regioisomers in essentially equal amounts (see Table 5). In contrast, the reaction of **1** with the isomeric 4-methyl-2-pentenes and 4,4-dimethyl-2-pentenes is regiospecific or highly regioselective in the *anti*-Markownikoff sense as shown in [8].

Once again steric hindrance to approach by SCN on the intermediate appears important; the greater steric bulk of the isopropyl and *tert*-butyl groups ensuring regiospecificity or high regioselectivity in the *anti*-Markownikoff sense. These data also differ from those observed for the addition of C_6H_5SeCl to the same series of alkenes where the regioselectivity is much less.

Also of note is the observation that *E*-4,4-dimethyl-2-pentene reacts about 400 times slower than the *Z* isomer in contrast to the normal factor of 10 or less, therefore suggesting a steric barrier to the addition (7). Further comment on this matter must, however, await more quantitative rate studies.

With trisubstituted ethylenes, **1** reacts regiospecifically in the Markownikoff sense, electronic factors apparently overriding steric hindrance to approach

*M = Markownikoff; *a*M = *anti*-Markownikoff.

as was observed for the 1,1-disubstituted ethylenes. Furthermore it is observed that the isomer distributions strongly favour the isothiocyanato adduct over the corresponding thiocyanate. In comparison it may be noted that areneselenenyl chlorides show an equivalent regiospecificity, whereas arenesulphenyl chlorides add regioselectively in the opposite, i.e. *anti*-Markownikoff, sense (5, 8).

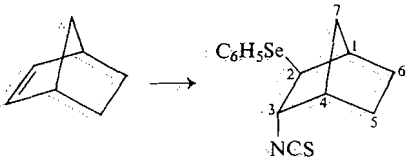
The reaction of **1** with the isomeric 3-methyl-2-pentenes and 3,4-dimethyl-2-pentenes is stereospecific, presumably *anti* in accord with the stereospecificity observed for simple 1,2-disubstituted ethylenes.

The reaction of **1** with the tetrasubstituted ethylenes (Table 5) is of particular interest since the analogous chloro adducts from the reaction of C_6H_5SeCl proved to be highly unstable under equivalent reaction conditions (3*f*, 7). The isothiocyanates isolated from these reactions are quite stable at room temperature with a shelf life of many months.

Reactions with Cyclic Olefinic Compounds

Bicyclo[2.2.1]hept-2-ene (norbornene) reacts with **1** to yield exclusively the *trans* adduct: *exo*-2-phenylseleno-*endo*-3-isothiocyanatobicyclo[2.2.1]heptane. At 80 MHz the ^1H nmr spectrum has an apparent triplet of a doublet at δ 3.60 ppm and a doublet of doublets at δ 2.78 ppm, each multiplet integrating as one proton. Associating the downfield "dt" with the proton geminal to the isothiocyanato moiety and the "dd" with the proton geminal to the phenylseleno group allows one to make the aforementioned assignment using the observed $^1H...^1H$ coupling constants: $J_{2,3} = 4.9$ Hz, $J_{3,4} = 3.6$ Hz, $J_{2,7-anti} = 2.5$ Hz, and $J_{3,5-exo} = 0.6$ Hz.

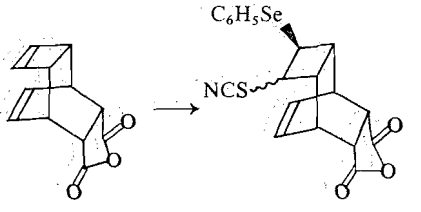
[9]



The presence of a very strong broad absorption at 4.75 μm in the infrared confirms the assignment. Attempts to isolate the corresponding thiocyanate or independently synthesize it from the analogous chloride, bromide, or tosylate via attack with sodium thiocyanate in the presence of 18-crown-6, with or without prior ionization using silver hexafluorophosphate, were unsuccessful. Only the isothiocyanate was isolable or observable.

In contrast to the above, the reaction of **1** with tricyclo[4.2.2.0^{2,5}]deca-3,9-diene-7,8-dicarboxylic anhydride is *nonstereospecific*, yielding both *cis* and *trans* thiocyanato adducts in the ratio 33:67 from attack upon the cyclobutene double bond (for related reactions see ref. 9). No evidence for the analogous isothiocyanato species or products of transannular addition was observed. This reaction requires a further comment with respect to the length of time required to reach completion. The aforementioned reactions of **1** with simple alkenes in methylene chloride at 25°C require in general no more than a few minutes. The reaction of **1** with the tricyclic diene above, however, requires approximately 5 h. The value while perhaps slow is much faster than the analogous reaction time of 10 days for C_6H_5SeCl.[2] It should also be noted that C_6H_5SeCl normally reacts much faster than **1** under equivalent conditions. A similar observation has been previously reported for the related sulphenyl derivatives (10). The reason for these anomalous reaction times is not immediately obvious, but suggests a significant change in mechanism for one of the reactants or different transition state geometries in general.

[10]



Conclusions

In summary, benzeneselenenyl thiocyanate shows chemical behaviour similar to that of the corresponding halides but with a few marked differences in the regioselectivity as noted in the discussion.

In regard to our initial aim of investigating the potential synthetic utility of this reagent towards the introduction of sulphur and nitrogen synthons, the chemoselectivity, i.e. the distribution of thiocyanato to isothiocyanato adducts under conditions of kinetic control, bears some comment. The relative distribution of these adducts is found to be highly dependent upon the substitution pattern of the substrate olefin. In general, there exists a trend towards a greater reactivity of the nitrogen atom of SCN with increasing electrophilic character of the reaction site on the intermediate. As the electrophilic character of this site increases, the reactivity of the more basic nitrogen atom increases relative to that of the more polarizable sulphur atom. This reagent would therefore appear to hold some promise for selective transformations where synthons of this type are required.

With respect to our alternative aim it is unfortunate that until such time as we or others are able to obtain a more quantitative picture of the rate-determining step, little can be said authoritatively about the effect of types of ion-pairs, etc. on the reaction coordinate.

Experimental

General

Melting points were determined on a Fisher-Johns apparatus and are uncorrected. The ir spectra were recorded as CH_2Cl_2 solutions in matched NaCl cavity cells (0.1071 mm) on a Unicam 1100 spectrophotometer. Only the principal, sharply defined peaks are reported. The ^1H nmr spectra were run on Varian T60, HA100, and (or) HFT 80 spectrometers. The spectra were measured from approximately 30–40% (w/v) solutions in chloroform-*d* with TMS as an internal standard. The ^{13}C nmr spectra were run on a Varian FT 80 spectrometer in 10 mm od amberized tubes as chloroform-*d* solutions. All resonances are referenced to internal TMS. All analytical and preparative tlc separations were performed on Analtech or Macherey-Nagel precoated plates (silica gel GF). Visualization of the spots was accomplished by uv (254 nm) and phosphomolybdic acid/EtOH. Suitable elemental analyses were obtained for all new compounds.

Benzeneselenenyl chloride was a commercial product (Aldrich); recrystallized from CCl_4, mp 64.5°C. Olefins were in general available commercially from Chemical Samples, Inc. Norbornene (Aldrich) was used without further purification.

endo-*Tricyclo[4.2.2.0^{2,5}]deca-3,9-diene-7,8-dicarboxylic Anhydride*

This compound was prepared by the cycloaddition of maleic anhydride with 1,3,5,7-cyclooctatraene (Aldrich) in chlorobenzene under reflux, and crystallized from chlorobenzene; ^1H nmr identical to that reported by Huisgen and co-workers (11).

Benzeneselenenyl Thiocyanate

To 0.192 g (1 mmol) of C_6H_5SeCl in 25 mL of anhydrous CH_2Cl_2 was added 0.082 g (1 mmol) of anhydrous NaSCN. The reaction mixture was stirred for $\simeq$ 1 h until the intense red coloration of the selenenyl chloride had disappeared leaving a bright yellow solution. Filtration followed by evaporation gave an orange oil–platelets from pentane mp > 300°C. This species was normally used without isolation; ^1H nmr ($CDCl_3$) δ:7.82 m (2H), 7.47 m (3H); uv (CH_2Cl_2) λ_{max} (ε):236 (6300), 257 (5600), 352 (445) nm; ir (μ):3.26 w, 3.42 w, 4.65 s, 5.74 m, 6.79 s ~ m, 6.95 s ~ m, 7.30 w, 7.53 w, 7.69 w, 7.90 w, 9.40 w, 9.52 w, 9.80 m, 10.0 w, 14.6 s, 14.9 w, 15.6 m ~ s.

General Procedure for the Reaction of Benzeneselenenyl Thiocyanate with Alkenes

To 0.214 g (1 mmol) of C_6H_5SeSCN in 25 mL of CH_2Cl_2 was added 1 mmol of the respective alkene dissolved previously in 15 mL CH_2Cl_2. The reaction mixture is stirred until the bright yellow coloration of the reagent disappears (formation of RSCN) or is replaced by an intense orange coloration (characteristic of RNCS) usually with a precipitation of the adduct. General reaction times are 2–10 min although exceptions have been noted (see Discussion). Immediate evaporation of the solvent yields colorless to pale yellow oils (RSCN) or deep orange oils (RNCS).

Experimental Data Not Given in Tables

Bicyclo[2.2.1]hept-2-ene gave with **1** after 1.8 h a bright orange oil; ^1H nmr ($CDCl_3$)δ: 3.59 dt (1H), 2.79 dd (1H), 2.53 m (1H), 2.38 m (1H), 1.73 m (2H), 1.56 m (2H), 1.43 m (2H); ir (μ, CH_2Cl_2): 4.75 very broad, intense.

Ethylene gave with **1** a colorless to pale yellow oil; ^1H nmr (60 MHz, $CDCl_3$)δ: singlet, 3.21 ppm (4H) relative to aromatic; tlc silica (80:20 *n*-C_7H_{16}/EtOAc); R_f 0.20–0.34 RSCN, 0.41–0.45 RNCS (sample left a minimum of 5 days from initial formation); ir (μ, CCl_4): 4.67 very sharp RSCN.

Propene gave with **1** a colorless oil shown to be a 60:40 mixture of the M and *a*M adducts, RSCN. M: ^{13}C nmr δ: 34.5 t, 45.0 d, 20.8 q, 110.3 s SCN; ^1H nmr δ: 1.58 d (3H) J = 6.0, 3.0–4.2 ABC spin system; ir (μ, CH_2Cl_2): 4.61 vs sharp. *a*M: ^{13}C nmr δ: 36.7 t, 41.7 d, 19.5 q, 111.9 s SCN; ^1H nmr δ: 1.61 d (3H) J = 6.3, 3.0–4.2 ABC spin system; ir (μ, CH_2Cl_2): 4.59 vs sharp.

3-Methyl-1-butene gave with **1** a single adduct. *a*M, RSCN: ^{13}C nmr δ: 21.7 q, 18.4 q, 30.0 d, 53.6 d, 38.9 t, 134.9 d, 129.5 d, 128.3 d, 129.3 s, 112.0 s SCN; ^1H nmr δ: 0.98 d (3H) J = 6.0, 1.15 d (3H), J = 6.0, 2.2 m (1H), 3.47 m ABC spin system (3H); ir (μ, CCl_4): 4.58 vs sharp. A second species was found upon isomerization (after 2 weeks): M, RSCN: ^{13}C nmr δ: 58.4 d, 31.2 d, 31.0 t, 20.4 q, 17.2 q, 133.4 d, 129.3 d, 127.7 d, 134.6 s; ^1H nmr δ: 0.95 d (3H) J = 6.0, 1.05 d (3H), J = 6.0, 2.1 m (1H), 2.8 m, 3.7 m ABC spin system (3H); ir (μ, CCl_4): 4.73 vs broad.

4-Methyl-1-pentene gave with **1** an 80:20 mixture of the *a*M, RSCN, and M, RSCN adducts as a pale yellow oil. *a*M, RSCN: ^{13}C nmr δ: 22.9 q, 21.3 q, 25.8 d, 34.2 t, 41.9 d, 135.6 d, 129.4 d, 128.6 d, 113.2 SCN; ir (μ, CCl_4): 4.59 vs sharp. M, RSCN: ^{13}C nmr δ: 43.0 t, 49.2 d, 34.0 t, 25.7 d, 22.8 a, 21.2 q, 133.5 d, 129.3 d, 128.9 d; ir (μ, CCl_4): 4.59 vs sharp.

Methylpropene gave with **1** a mixture of all four possible adducts in the ratio 66:11:19:4 for M, RSCN: *a*M, RSCN: M, RNCS: *a*M, RNCS. ^1H nmr: M, RSCN: δ: 1.62 s (6H), 3.42 s (2H); *a*M, RSCN: δ: 1.56 s (6H), 3.32 s (2H); M, RNCS: δ: 1.52 s (6H), 3.20 s (2H); *a*M, RNCS: δ: 1.46 S (6H), 3.53 s (2H). The above ratio changed to 14:0:74:12 after 3 weeks.

2-Methyl-1-butene gave with **1** a mixture of three adducts in the ratio 41:8:51 for M, RSCN: *a*M, RNCS: M, RNCS. M,

RSCN: ^{13}C nmr δ: 40.3 t, 60.8 s, 32.8 t, 25.8 q, 134.7 d, 129.2 d, 127.7 d, 8.9 q, 111.2 s SCN; ^{1}H nmr δ: 1.45 s (3H), 3.17 s (2H), 1.9 m (2H), 0.95 t (3H). M, RNCS: ^{13}C nmr δ: 40.2 t, 65.2 s, 34.2 t, 26.1 q, 8.6 q, 138.3 s NCS, 133.4 d, 129.1 d, 127.5 d; ^{1}H nmr δ: 1.53 s (3H), 3.37 s (2H), 2.1 q (2H), 0.95 t (3H). *a*M, RNCS: ^{1}H nmr δ: 1.33 s (3H), 3.48 s (2H), 2.2 q (2H), 0.95 t (3H).

Crystal structures of medium ring compounds. Part III. The crystal and molecular structure of *trans-anti-trans*-4,5:9,10-biscyclohexano-1,3,6,8-tetraoxecane

ARIS TERZIS[1] AND T. BRUCE GRINDLEY[2]

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received January 23, 1979

ARIS TERZIS and T. BRUCE GRINDLEY. Can. J. Chem. 57, 2154 (1979).

The crystal structure of *trans-anti-trans*-4,5:9,10-biscyclohexano-1,3,6,8-tetraoxecane (**3**) has been determined by X-ray diffraction. The crystals are monoclinic, $a = 11.919(3)$, $b = 17.330(7)$, $c = 7.019(2)$ Å, $\beta = 98.91(1)°$, $P2_1/c$, with $Z = 4$. The structure was solved by application of the tangent formula and refined by large block least squares to a final R value of 0.060 ($R_w = 0.058$).

The ten-membered ring is present in the crystal in a twist-chair-boat-chair conformation — one which has been calculated to be relatively unstable for cyclodecane. Possible reasons why **3** adopts this conformation are discussed.

ARIS TERZIS et T. BRUCE GRINDLEY. Can. J. Chem. 57, 2154 (1979).

On a déterminé la structure cristalline du biscyclohexano-4,5:9,10 tétraoxécanne-1,3,6,8 *trans-anti-trans* (**3**), par diffraction de rayons-X. Les cristaux sont monocliniques, $a = 11.919(3)$, $b = 17.330(7)$, $c = 7.019(2)$ Å, $\beta = 98.91(1)°$, $P2_1/c$, avec $Z = 4$. On a résolu la structure par l'application de la formule tangente et on l'a raffinée par la méthode des moindres carrés (blocs diagonaux) jusqu'à une valeur finale de R de 0.060 ($R_w = 0.058$).

La conformation, dans le cristal, du cycle à dix chaînons est croisée-chaise-bateau-chaise qui d'après les calculs, serait assez instable dans le cas du cyclodécane. On discute des raisons pour lesquelles **3** adopterait cette conformation.

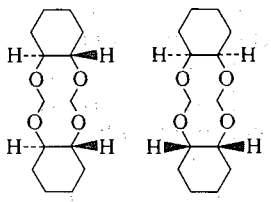
Introduction

Compounds containing seven-membered and medium rings are in one of the few classes of compounds in which non-bonded interactions are very important in the determination of molecular geometry. There has been considerable interest in these systems (1–5), particularly in those molecules which contain ten-membered rings. Virtually all cyclodecane derivatives studied in the solid state contain the ring in one conformation, the boat-chair-boat[3] (BCB) (1), and most force-field calculations performed on cyclodecane (2–4) suggest that this conformation is the most stable, although two of the earlier force fields gave a different result (3). All calculations indicate that there are a number of conformations which are within about 20 kJ/mol of the BCB and there is some experimental evidence in support of this conclusion. For instance, an electron diffraction spectrum (4) of cyclodecane at 130° was analysed as arising from contributions from the BCB (49%), the twist-boat-chair (TBC, 25%), the twist-boat-chair-chair (TBCC, 8%), and the boat-chair-chair (BCC, 8%) conformations. In addition, the substitution pattern of 1,1,5,5-tetramethylcyclodecane is such that the BCB conformation is of high energy and a crystal of this compound contained both the TBC and TBCC conformations (5).



1 **2**

We have shown (6, 7) that two substituted stereoisomeric 1,3,6,8-tetraoxecanes (**1**, **2**) both adopt one BCB conformation in the solid state although the conformational situation for both compounds in solution was more complicated. The BCB conformation observed was considerably narrower than those of cyclodecane derivatives because of relief of some of the transannular non-bonded interactions present in the latter compounds. Surprisingly, another group[4] has observed that *trans*-2,7-diphenyl-2,7-dithieno-1,3,6,8-tetraoxa-2,7-diphosphecane, which has the same arrangement of oxygen atoms as the above molecules and which could accommodate all the substituents on phosphorous in low

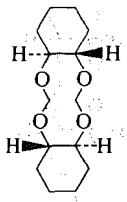
0008-4042/79/162154-05$01.00/0

energy positions, adopts a twist-chair-chair-chair (TCCC) conformation. We report here the crystal structure of *trans-anti-trans*-4,5:9,10-biscyclohexano-1,3,6,8-tetraoxecane (**3**). In this compound, the stereochemistry of ring fusion makes all BCB conformations unstable. Thus, a study of **3** gives information about the other conformations which are energetically accessible for 1,3,6,8-tetraoxecanes. Accurate structural data for molecules such as **3**, in which nonbonded interactions involving oxygen are important in determining conformation, will be of use for the development of force fields which are parameterized for oxygen.



3

Experimental

trans-anti-trans-4,5:9,10-Biscyclohexano-1,3,6,8-tetraoxecane (**3**) was prepared according to the procedure of Brimacombe *et al.* (9). Physical constants of the sample agreed with those recorded in the literature (9). Crystals suitable for study were obtained by recrystallization from ethanol. Crystal data are as follows.

$C_{14}H_{24}O_4$ fw = 256.34

Monoclinic, a = 11.919(3), b = 17.330(7), c = 7.019(2) Å, β = 98.91(1)°, V = 1432.35 Å^3, Z = 4, ρ_c = 1.188 g cm^{-3}, ρ_o = 1.20 g cm^{-3} (18°C $CuK_{\alpha 1}$, λ = 1.54051 Å, μ = 6.16 cm^{-1}). $F(000)$ = 560e.

Preliminary X-ray photographs showed the following systematic absences: $h0l$, $l = 2n + 1$; $0k0$, $k = 2n + 1$. The space group is thus $P2_1/c$. A crystal (0.06 × 0.15 × 0.45 mm) was mounted with the c axis nearly parallel to the ϕ axis of a Picker FACS-1 automated diffractometer with a graphite monochromator. The cell dimensions were refined from 12 general reflections with 2θ between 70–76°. Because the exposed crystal sublimed in the X-ray beam, it was sealed in a capillary tube. Data were collected by the θ–2θ scan technique from 0.95° below the calculated 2θ position for $CuK_{\alpha 1}$ to 0.95° above the calculated position for $CuK_{\alpha 2}$ at 1° min^{-1}. Stationary background counts were taken for 20 s at either end of the scan range. During the course of the data collection, three standard reflections were measured every 58 reflections. Their intensities decreased steadily throughout the data collection by 7%, but could be adjusted to a standard scale by a least-squares fit (σ = 0.035) to a first order decay; from the counting statistics the ratio of esd to reflection for these standards was 0.040. A total of 1919 independent reflections were measured, of which 744 had $I > 3\sigma(I)$. The data were reduced to $|F_o|$ by the routine procedure. Lorentz and polarization but not absorption or extinction corrections were applied. The scattering factors for neutral atoms were taken from Ref. 10; they were corrected for the real part of the anomalous dispersion. Reflections with $|E| > 1.2$ were used to solve the structure by an application of the tangent formula which examined $4096 = 2^{12}$ sets of starting phases and successively eliminated all but the most likely. This program is part of an X-ray system written by Sheldrick (11). The positions of all but the hydrogen atoms were found on the E-map with lowest Karle R factor (12).

The structure was refined by large block least squares ($\Sigma(\Delta|F|)^2$ = min) initially with isotropic temperature factors using only reflections with $I > 3\sigma(I)$. When the conventional R was 0.14, the positions of the hydrogen atoms were calculated from the geometry of the molecule. The subsequent refinement with anisotropic temperature factors on the nonhydrogen atoms converged with R = 0.060 and R_w = 0.058. The least-squares weights were calculated from $w = (\sigma^2|F_o| + 0.000173|F_o|^2)^{-1}$ where σ is the weight for each reflection derived from the diffractometer counting statistics.

Results and Discussion

Atomic positions for **3** are given in Table 1. Tables of observed and calculated structure factor amplitudes, of temperature factors, and of bond angles involving hydrogen were put on deposit.[5] Numbering, bond lengths, torsional angles, and short intramolecular distances of interest are shown in Fig. 1. Table 2 lists the bond angles and Table 3 lists the torsional angles not shown in Fig. 1. Figure 2 is an ORTEP (13) diagram of the crystal structure. This structure determination confirmed the *anti* configuration previously assigned (14) to the relative orientations of the cyclohexane rings on the basis of the ^{1}H nmr spectrum.

The ten-membered ring in **3** adopted a twist-chair-boat-chair (TCBC) conformation which has, within experimental error, the D_2 symmetry expected for such a conformation. Two force-field calculations have been performed on the TCBC conformation of cyclodecane (*2a*, 4). The agreement between the torsional angles found for these two calculations is poor (Table 4). Furthermore the two sets of calculations gave quite different energies (37.5 (4) and 17.0 kJ/mol (*2a*)) relative to the BCB conformation of cyclodecane. However, both results suggest that the TCBC is not an important contributor to the conformational mixture present in cyclodecane.

Several features of the present molecule are particularly favourable for the TCBC conformation. The replacement of methylene groups by oxygens in a cyclodecane ring markedly lowers the transannular non-bonded interactions, since, in the cyclodecane analogue of **3**, the inner hydrogen on a methylene group where O(1) is located would have severe nonbonded interactions with an inner hydrogen on a methylene group in the position of O(4) and to a

lesser extent with H(10) and H(6) (the O(1)—H(10) and O(1)—H(6) distances in **3** are 2.84 and 2.55 Å respectively). The near D_2 symmetry of **3** requires similar interactions between hydrogens on positions occupied by O(2), O(3), C(9), and C(1). In **3**, the comparable interactions are at distances which are larger than the sum of the van der Waals radii. Moreover, in the TCBC conformation, the two dialkoxymethane fragments can nearly adopt the $+sc$, $+sc$ orientations calculated to be most stable for dimethoxymethane (15, 16), and shown to be present in the gas phase (17) and in crystal structures of carbohydrates (15). The average of the torsional angles in R—O—C—O—R fragments in **3** (80.3°) is somewhat larger than the calculated (60°) (15) to be most stable for dimethoxyethane but the increase in energy required to assume these angles is probably not large (15). However the energy surface has not been mapped in detail. A third factor arises because there are four torsional angles of ~120° in the TCBC conformation which cause eclipsing interactions which considerably destabilize this conformation in the case of cyclodecane itself. Since the comparable torsional angles in **3** are in C—C—O—C fragments, the TCBC conformation for **3** should be considerably stabilized in comparison.

The difference between the O—C bond lengths in O—C—O and O—C—C segments is larger in **3** (0.014 Å) then calculated or observed (15) in the other molecules having R—O—C—O—R segments in a $+sc$, $+sc$ conformation (15). Since the back-donation from oxygen non-bonding *p* orbitals to electronically depleted carbon *p* orbitals which causes this difference in bond lengths (18) is maximized at 90° torsional angles, a structure like **3** with torsional angles closer to 90° than 60° would be expected to show this increase in bond length variation. The ten-membered ring in 1,3,5,7,9-pentaoxecane (**4**) also adopts a TCBC conformation (19) and in it only one R—O—C—O—R group can adopt the $+sc$, $+sc$ conformation. The torsional angles observed were smaller (see Table 4) and, as a result, the short O—C bond lengths were longer (1.411 and 1.408 Å).

It is interesting to note that **3** adopts the TCBC conformation in the solid state, rather than one of the other ten-membered ring conformations which have been calculated (*2a*) to be considerably more stable for the case of cyclodecane. Because of the position, the *anti* relationship and the *trans* fusion of the two cyclohexane rings fused to the tetraoxecane ring, any energetically viable conformation of the tetraoxecane ring must contain two torsional angles which have the same sign and have magnitudes of ~55–80°. Furthermore, these angles must be associated with bonds which are separated by four intervening bonds. Two of the conformations of cyclodecane more stable than the TCBC conformation, namely, the TBC and BCC conformations, fulfil this requirement. The TBC conformation as calculated by Ermer (*2a*) is about 13 kJ/mol more stable than the TCBC. If compound **3** adopted this conformation, it would have ring fusion angles of 60.4° and would have favourable torsional angles in the R—O—C—O—R fragments of +53.5° and +68.4°. Models suggest that a TBC conformation of **3** would be somewhat disfavoured by non-bonded interactions between the hydrogens on one O—CH_2—O group and methylene groups on the two cyclohexane rings. The BCC conformation is

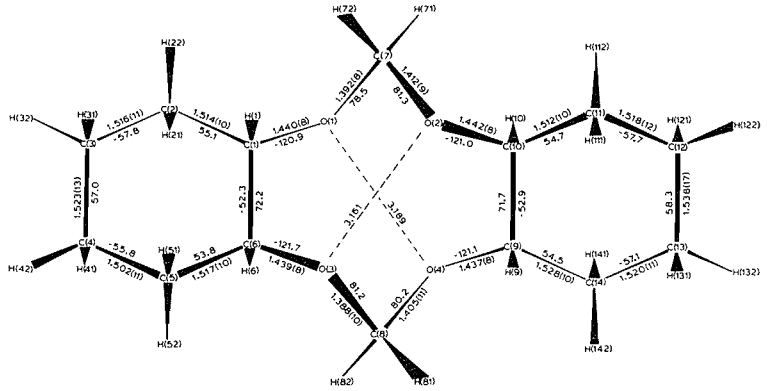

FIG. 1. Numbering and structural parameters from *trans-anti-trans*-4,5:9,10-biscyclohexano-1,3,6,8-tetraoxecane. Bond lengths (Å) with their errors in parentheses (10^3 Å) are shown on the outside of the molecule, torsional angles (deg) between carbon and oxygen atoms are shown on the interior. Intramolecular distances (Å) are indicated by a dashed line. The C(1)—C(6) and C(9)—C(10) bond distances were 1.524(10) and 1.525(10) Å respectively.

C(4)—C(5)—C(6)	113.2(7)	C(13)—C(14)—C(9)	111.4(7)
C(5)—C(6)—C(1)	111.5(6)	C(14)—C(9)—C(10)	112.3(6)

calculated to be 8.5 kJ/mol more stable for cyclodecane (2*a*). A BCC conformation of **3** would have favourable fusion angles for the cyclohexane rings (average 60.6°) but would have the unfavourable *sc*, *ap* conformation in its R—O—C—O—R fragments. In comparison the TCBC conformation of cyclodecane has been calculated to have torsional angles of 88.1° (2*a*) or 116° (4) at the position where the cyclohexane rings are fused in **3**; the observed average values were 71.9°. The value observed is somewhat larger than in *trans*-disubstituted cyclohexane derivatives but distorting a cyclohexane ring in this manner is known to be energetically cheap (20). The effect on the interaction between the heteroatoms of slightly opening this torsional angle is probably not unfavourable; for instance, the energy minimum for 1,2-difluoroethane has been calculated to lie at a dihedral angle of 72.7° (21).

[d]From ref. 2*a*.

The crystal packing is shown in Fig. 3. Very few non-bonded intermolecular interactions at distances significantly shorter than the sum of the van der Waals radii were observed. One H(51)···H(51) distance was 2.264 Å and there were four other interactions at distances slightly less (<1.5%) than the sum of the van der Waals radii. The density of the crystal (1.188 g cm^{-3} calculated) is considerably less than for the two tetraoxecanes (**1**, **2**) previously examined (1.296 and 1.255 g cm^{-3} respectively) (6, 7), both of which adopted BCB conformations. The more efficient packing of the BCB conformation may have an additional factor favouring it in the solid state.

A particularly interesting feature of **3** is that the oxygen atoms in it are ideally oriented for interaction with cations of appropriate size (see ref. 8 for a discussion of the geometric requirements for complex formation). An investigation of the complex-forming ability of **3** is in progress.

Stabilities of complexes $(N_2)_nH^+$, $(CO)_nH^+$, and $(O_2)_nH^+$ for $n = 1$ to 7 based on gas phase ion-equilibria measurements

K. HIRAOKA,[1] P. P. S. SALUJA, AND P. KEBARLE

Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received March 8, 1979

K. HIRAOKA, P. P. S. SALUJA, and P. KEBARLE. Can. J. Chem. 57, 2159 (1979).

The equilibria $B_{n-1}H^+ + B = B_nH^+$ for B = N_2, CO, and O_2 were measured with a pulsed electron beam high ion source pressure mass spectrometer. Equilibria up to $n = 7$ could be observed. van't Hoff plots of the equilibrium constants lead to $\Delta G_{n-1,n}^0$, $\Delta H_{n-1,n}^0$, and $\Delta S_{n-1,n}^0$. While the proton affinities increase in the order $O_2 < N_2 < CO$, the stabilities of the B_2H^+ towards dissociation to $BH^+ + B$ increase in the reverse order, i.e. $CO < N_2 < O_2$. The stabilities towards dissociation of B for B_nH^+ where $n > 2$ are much lower for all three compounds; however for N_2 and CO the stability decreases only very slowly from $n = 3$ to $n = 6$, then there is a large fall off for $n = 7$. The $(O_2)_nH^+$ clusters show large decrease of stabilities as n increases. The B_nH^+ (for $n > 3$) of CO are more stable than those of N_2 or O_2. The above experimental results can be partially explained with the help of results from molecular orbital STO-3G calculations for B, BH^+, and B_2H^+ and general considerations. BH^+ and B_2H^+ for CO and N_2 are found to be linear while those for O_2 are bent. The most stable O_2H^+ is a triplet, while $(O_2)_2H^+$ is a quintuplet.

K. HIRAOKA, P. P. S. SALUJA et P. KEBARLE. Can. J. Chem. 57, 2159 (1979).

On a mesuré l'équilibre $B_{n-1}H^+ + B = B_nH^+$ où B = N_2, CO et O_2 en faisant appel à un spectromètre de masse à pression à source ionique intense avec un faisceau électronique pulsé. On a pu observé l'équilibre jusqu'à $n = 7$. Des courbes de van't Hoff des constantes d'équilibre conduisent à $\Delta G_{n-1,n}^0$, $\Delta H_{n-1,n}^0$ et $\Delta S_{n-1,n}^0$. Alors que les affinités protoniques augmentent dans l'ordre $O_2 < N_2 < CO$, les stabilités de B_2H^+ vis-à-vis la dissociation en $BH^+ + B$ augmente dans l'ordre inverse soit $CO < N_2 < O_2$. Les stabilités vis-à-vis la dissociation de B pour B_nH^+ où $n > 2$ sont beaucoup plus faibles pour les trois composés; toutefois dans le cas de N_2 et de CO, la stabilité ne diminue que très lentement de $n = 3$ à $n = 6$ avant de subir une diminution importante à $n = 7$. Pour les agrégats de $(O_2)_nH^+$, il se produit une diminution rapide des stabilités avec une augmentation de n. Les B_nH^+ (où $n > 3$) de CO sont plus stables que ceux de N_2 ou O_2. Les résultats expérimentaux mentionnés peuvent être expliqués partiellement à l'aide de résultats de calculs d'orbitales moléculaires STO-3G pour B, BH^+ et B_2H^+ et de considérations générales. On a trouvé que BH^+ et B_2H^+ pour CO et N_2 sont linéaires alors que ceux de O_2 sont recourbés. L'état le plus stable pour O_2H^+ est un triplet alors que pour $(O_2)_2H^+$ il s'agit d'un quintuplet.

[Traduit par le journal]

Introduction

The stabilities of gas phase complexes between the proton and a variety of bases B have been examined in previous publications from this and other laboratories (1). The present work deals with proton held complexes: $(B)_nH^+$ of the three diatomic bases: N_2, CO, and O_2. The previously studied bases involved various classes. One group consisted of strong bases containing protic hydrogens which formed strongly hydrogen bonded clusters on protonation. A prime example of this group is the protonated water clusters (2, 3) $H_{2n+1}O_n^+$. Strong bases with blocked hydrogen bonding positions, i.e. dimethyl ether, were another group. In this case, the proton associated strongly with only two of the bases (3). The bonding involving the very weak σ donor bases H_2 and CH_4 was also examined (4). Compared with the above compounds $(N_2)_nH^+$, $(CO)_nH^+$, and $(O_2)_nH^+$ form again a separate class. N_2, CO, and O_2 are weak bases essentially devoid of dipole moment. The formation of large clusters is therefore not expected. On the other hand, since the molecules are small and linear more than two molecules may arrange themselves in close proximity to the proton. If the clusters formed are held largely by physical forces, the absence of dipoles and the similar magnitude of the polarizabilities of N_2, CO, and O_2 should lead to very similar complex stabilities. On the other hand, the operation of specific chemical forces will lead to distinct stability differences.

Carbon monoxide and O_2 are also two important ligands in transition metal ion complexes. The bonding of these molecules to the proton might

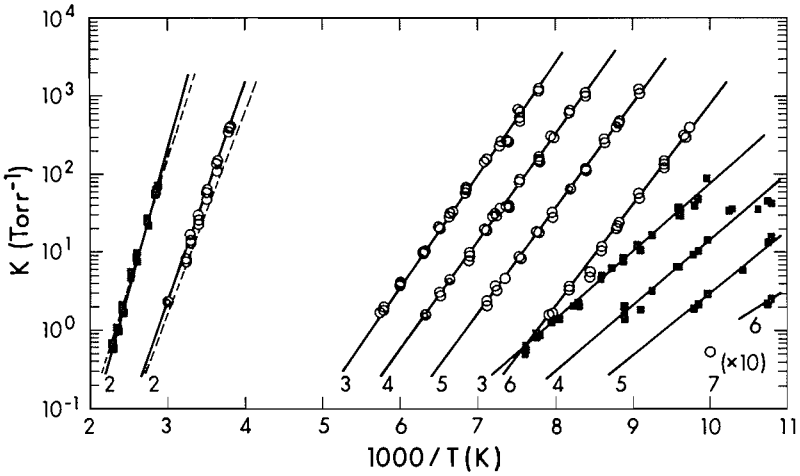

FIG. 1. van't Hoff plots for reactions: $(B)_{n-1}H^+ + B = (B)_nH^+$. ■ B = N_2, ○ B = CO. Numbers below plots give value of n. --- earlier results by Meot-Ner and Field (5). Note stabilities reversal: $D(HN_2^+—N_2) > D(HCO^+—CO)$ but $D(H(N_2)_n^+—N_2) < D(H(CO)_n—CO)$ for $n > 1$. Results also directly indicate large stability changes between $(B)_2H^+$ and $(B)_3H^+$ and $(B)_6H^+$ and $(B)_7H^+$. Latter stability difference based on single point determination of $K_{6,7}(CO)$, see point at lower right of figure.

prove interesting to compare with bonding in the transition metal ion complexes.

Experimental

The measurements of the ion equilibria were made with the pulsed electron beam high pressure ion source mass spectrometer which has been described previously (2).

The ions B_nH^+ where B = CO, N_2, or O_2 were obtained by adding 3–300 mTorr of the gas B to some 4 Torr of hydrogen (carrier) gas. The ions in pure hydrogen are $H_3^+(H_2)_n$ as has been shown by previous studies (4). In the presence of B, which are stronger bases than H_2, the switching reactions shown below occur.

$$(H_2)_nH^+ + B = BH^+ + nH_2$$

These are followed by further clustering of B.

$$B + B_{n-1}H^+ = B_nH^+ \qquad [n-1, n]$$

In some cases the mixed clusters $B_x(H_2)_yH^+$ could also be observed in equilibrium with the B_nH^+ clusters.

The equilibrium constants $K_{n-1,n}$ were found to be essentially independent of the pressure of B for a pressure change by a factor of about 10.

The reaction $HCO^+ + CO + M = (CO_2)_2H^+ + M$ was found to be unusually slow. This equilibrium could be measured only in the presence of relatively large CO partial pressures ($p_{CO} > 0.1$ Torr). This precluded the measurement of the equilibrium constant at lower temperatures since with the relatively large CO pressure, the equilibrium ratio $[(CO)_2H^+]/[HCO^+]$ became too large rapidly at low temperatures. Therefore the temperature range over which this particular equilibrium could be measured was narrower than usual.

In all the above measurements special precautions had to be taken in order to keep the reagent gases and reaction system dry. Even small traces of water interfere with the measurements, since water, being a much stronger base than B, displaces B by the reaction shown below:

$$B_nH^+ + H_2O = (H_2O)B_{n-x}H^+ + xB$$

The traces of water were removed from the H_2 carrier gas by passing it through a trap maintained at 77 K containing molecular sieve 5 Å. The mixed H_2 + reagent gas (N_2, O_2, or CO) at a total pressure of ~4 Torr was then passed through a spiral glass trap maintained at 77 K.

Results and Discussion

(a) Experimental Results

The results for the experimentally measured equilibrium constants for the reactions [1] and [2]

[1] $(CO)_{n-1}H^+ + CO = (CO)_nH^+$

[2] $(N_2)_{n-1}H^+ + N_2 = (N_2)_nH^+$

are summarized in the van't Hoff plots shown in Fig. 1. Also shown in Fig. 1 are the van't Hoff plots obtained earlier by Meot-Ner and Field (5) for reactions [1] and [2] involving [1,2] equilibria. As can be seen from the figure, Field's results are in quite good agreement with the present work.

The spacings between the lines of the van't Hoff plots in Fig. 1 reveal directly the changes of the relative stabilities of the complexes. There is a big gap between the [1,2] and [2,3] equilibria for both $(CO)_nH^+$ and $(N_2)_nH^+$. This shows that the B_2H^+ complexes are very much more stable (towards loss of one ligand) than the B_3H^+ and higher n complexes. These data also reveal that the interactions are not dominated by physical forces, i.e. polarizabilities. For example the greater stability of $(N_2)_2H^+$ would not have been expected on the basis of the polarizabilities of N_2 and CO which are $\alpha_{N_2} = 1.76$ and $\alpha_{CO} = 1.95$ Å^3 (6), i.e. $\alpha_{CO} > \alpha_{N_2}$. Furthermore since N_2 and CO are isoelectronic and of similar size the rather dramatic reversal of relative stabilities ob-

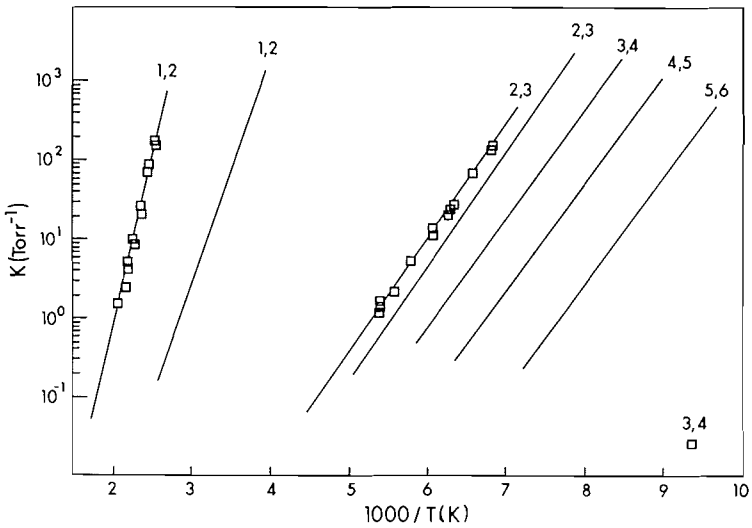

FIG. 2. van't Hoff plots for reactions: $(O_2)_{n-1}H^+ + O_2 = (O_2)_nH^+$. Numbers above plots give $[n-1, n]$. $K_{3,4}$ could be measured at only one temperature. Lines without data points are for equilibria $(CO)_{n-1}H^+ + CO = (CO)_nH^+$, which were displayed in Fig. 1 and are given here for comparison. Note that stability changes for the O_2 system show a very different pattern from those for CO.

served for B_nH^+, $n > 2$ (see Fig. 1), could not have been predicted on the basis of simple considerations.

It is also interesting to note in Fig. 1 that the $(CO)_nH^+$ stabilities decrease very gradually between [2,3], [3,4], [4,5], and [5,6] but then there is a large gap between [5,6] and [6,7]. This means that the $(CO)_7H^+$ is much less stable than $(CO)_6H^+$. We were unable to detect the $(N_2)_7H^+$ ion even at very low temperatures. This means that the $(N_2)_7H^+$ is very much less stable than $(N_2)_6H^+$, i.e. a stability gap occurs also for the $(N_2)_nH^+$ series between $n = 6$ and $n = 7$.

The results for the $(O_2)_nH^+$ equilibria are shown in Fig. 2 together with the $(CO)_nH^+$ equilibria which are included for comparison. It is immediately evident that the $(O_2)_nH^+$ clusters show rather different stability changes when compared to $(CO)_nH^+$ and $(N_2)_nH^+$. The bonding in $(O_2)_2H^+$ is somewhat stronger than that in $(N_2)_2H^+$ and considerably stronger than that in $(CO)_2H^+$. The gap between the [1,2] and [2,3] equilibria is quite large for O_2 and there is an even larger gap between [2,3] and [3,4]. No such gap occurred for the $(CO)_nH^+$ and $(N_2)_nH^+$ equilibria, which showed only small stability decreases from $n = 3$ to $n = 6$.

The $\Delta G_{n-1,n}^0$, $\Delta H_{n-1,n}^0$, and $\Delta S_{n-1,n}^0$ obtained from the van't Hoff plots in Figs. 1 and 2 are summarized in Table 1. The $\Delta H_{n-1,n}^0$ changes with n for the three systems are shown in Fig. 3. These results reflect what was already deduced from the direct examination of the van't Hoff plots.

For CO and N_2 the $\Delta H_{n-1,n}^0$ are found to be almost constant between [3,4] and [5,6], i.e. the stability decreases in that range are indicated to be almost entirely due to entropy decreases. Since the van't Hoff plots were obtained over a rather narrow temperature range, and the presence of some small systematic error cannot be excluded, it may be that the $\Delta H_{n-1,n}$ decreases in this range are actually somewhat larger than the present measurements indicate.

Included in Table 1 are also some results involving equilibria in mixed clusters between H_2 with O_2 or N_2. The corresponding van't Hoff plots are shown in Fig. 4. Results for clusters involving H_2 and HCO^+ were published earlier (7).

(b) Stabilities of $(N_2)_nH^+$, $(CO)_nH^+$, and $(O_2)_nH^+$

In considering the stabilities of the protonated clusters of N_2, CO, and O_2 it is useful first to examine the protonated monomers N_2H^+, OCH^+, and O_2H^+. The proton affinities PA(O_2) = 101, PA(N_2) = 113.7, and PA(CO) = 139.0 kcal/mol have been determined by Bohme and co-workers (8) from measurements of proton transfer equilibria. *Ab initio* theoretical calculations for OCH^+ and N_2H^+ are available in the literature (9, 10). The more extensive and recent calculations of Forsén and Roos (10) lead to PA(N_2) = 118 and PA(CO) = 137 kcal/mol in relatively good agreement with the experimental values given above. The calculated SCF energies for the protonated and unprotonated species were near the Hartree Fock limit; however no corrections for electron correlation were made (10).

[a]At 298 K.
[b]From measured equilibrium constant at one temperature, from which $\Delta G^0 = -RT \ln K$ was evaluated. ΔH^0 was then obtained by assuming that $\Delta S^0 = -20$ eu which is an average value for these reactions as evidenced by measured ΔS^0 for the other reactions given in the table.

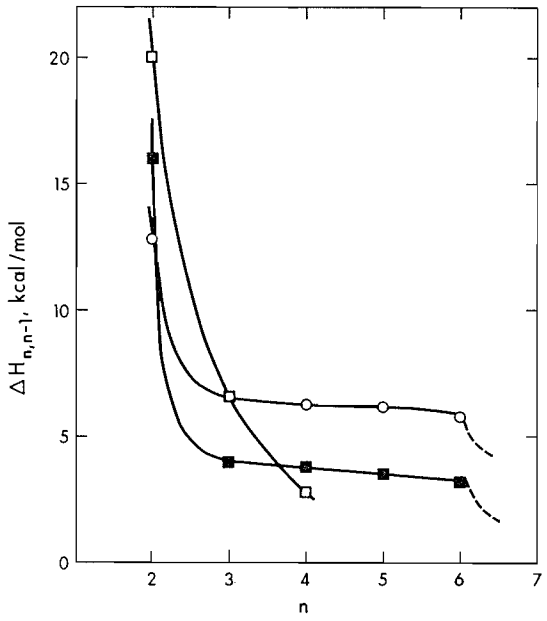

FIG. 3. $\Delta H_{n,n-1} = -\Delta H_{n-1,n}$ values obtained from van't Hoff plots displayed in Figs. 1 and 2. □, $(O_2)_nH^+$; ■, $(N_2)_nH^+$; ○, $(CO)_nH^+$. Note that the B_2H^+ species is of high stability for all three bases. CO and N_2 then build clusters up to B_6H^+ with small ΔH fall offs while $(O_2)_nH^+$ behaves differently showing a large ΔH decrease with every step.

Therefore the relatively good agreement with experiment indicates the near complete cancellation of the correlation error in the protonated and unprotonated species. No theoretical calculations for O_2H^+ and any of the higher protonated clusters of N_2, CO, and O_2 seem to be available in the literature. In order to obtain some theoretical information, we made STO-3G calculations (11) for: N_2, N_2H^+, $(N_2)_2H^+$, O_2, O_2H^+, $(O_2)_2H^+$, CO, COH^+, $(CO)_2H^+$. The proton affinities obtained from the differences of the total energies of the bare and protonated molecule are given in Table 2. The stabilization energies of the dimers obtained from the ΔE(STO-3G) for the reactions $B_2H^+ = BH^+ + B$ are also given in Table 2. The lowest energy structures predicted by STO-3G are shown in Fig. 5. The STO-3G predicted proton affinities and the stabilization energies of the dimers are much larger than the experimental values. Considering Forsén and Roos' (10) calculations, which were in fair agreement with the experimental proton affinities, it is obvious that the minimal basis sets used in STO-3G are at fault. An additional problem occurs for O_2H^+ and $(O_2)_2H^+$. Since the ground state of O_2 is a triplet, if O_2 retains its triplet character O_2H^+ could be a triplet and $(O_2)_2H^+$ a quintuplet. These are in fact the ground states predicted by the STO-3G calculations using open shell unrestricted Hartree Fock. The singlets for these molecules are predicted to be 44 and 95 kcal/mol of higher energy. The STO-3G calculated energy difference between triplet and singlet O_2 is 52 kcal/mol while the spectroscopic value for this separation ($^3\Sigma_g$ to $^1\Delta_g$) is only 22.6 kcal/mol (12). The exaggerated calculated difference is probably largely due to neglect of electron correlation since electron correlation will have a larger stabilizing effect on the singlet state. Differences in cancellation of the correlation error in

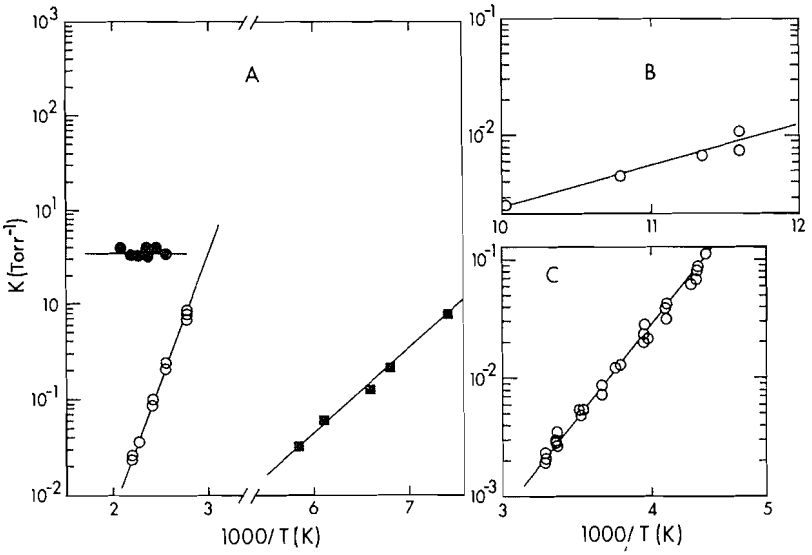

FIG. 4. (*A*) van't Hoff plots for equilibria: $H_3^+ + O_2 = O_2H^+ + H_2$, ●; $O_2H^+ + H_2 = O_2H_2H^+$, ○; $(O_2)_2H^+ + H_2 = (O_2)_2(H_2)H^+$, ■. (*B*) $(N_2)(H_2)H^+ + H_2 = N_2(H_2)_2H^+$. (*C*) $N_2H^+ + H_2 = N_2(H_2)H^+$.

$(CO)_2H^+$	−207.0	O_2H(bent, 1)[c]	−117.0
$D(OCH^+—CO)$	31.4[d]	$(O_2)_2H^+$(bent, 5)[c]	−199.2
		$(O_2)_2H^+$(bent, 1)[c]	−104.1
		$D(O_2H^+—O_2, 5)$[c]	37.8[d]

[a]ΔE corresponds to energy relative to $E(B) = 0$ where B = N_2, CO, and O_2 (triplet) respectively. For geometries of structures see Fig. 5.
[b]$\Delta E(BH^+) = -PA(B)$.
[c]Number inside parentheses corresponds to multiplicity due to electron spin. Because of differences in cancellation of electron correlation, energies for singlet states are probably ~30 kcal/mol lower than shown in table.
[d]STO-3G predicted bond dissociation energies $D(BH^+ — B) = \Delta E(BH^+) - \Delta E(B_2H^+)$.

the singlets N_2 and N_2H^+ and triplets O_2 and O_2H^+ are probably responsible for the STO-3G predicted proton affinity order $PA(O_2) > PA(N_2)$ which is the reverse of the experimentally observed one.

Evidently the STO-3G closed shell and particularly the open shell calculations are of too low an accuracy to provide relative proton affinities and binding energies. Nevertheless some qualitative information of value is obtained. The COH^+ and N_2H^+ ions are predicted to be linear. This is in agreement with the results of more accurate calculations (9, 10). The bond distances obtained are also very similar to those from the literature (9, 10). The predicted linear geometries and distances in $(CO)_2H^+$ and $(N_2)_2H^+$ are probably also reliable. Of special interest is the predicted bent geometry for O_2H^+ and $(O_2)_2H^+$ (see Fig. 5). The STO-3G calculations for closed shell, singlet, O_2H^+, and $H(O_2)_2^+$ predicted the same bent geometries as those for the multiplets (Fig. 5).

An examination of the electronic changes on formation of the protonated species is of some interest. The approach of the positive field of the proton leads to significant lowering of the energies of all the (formerly diatomic) molecular orbitals. For example in N_2 there is a fairly uniform decrease of about 0.4 au for all orbitals including the core 1*s* orbitals when the proton is brought to its equilibrium position. The spatial changes of the orbitals in N_2 and CO are of three types: hardly any spatial change in the core 1*s* orbitals, polarization of the π orbitals, and polarization and modification through overlap with the 1*s* orbital of the H atom in the 2*s*, 2*p*, σ orbitals. The linearity of the OCH^+ and N_2H^+ species is a consequence of the overlap of the 1*s* of H only with the σ type orbitals. The difference of the proton affinities of the isoelectronic N_2 and CO may be attributed to the electronegativity differences between the N and C atoms. In CO, the orbital with the highest energy is the 5σ which is located on the C atom. It is this orbital which overlaps strongly with the 1*s* of H and experiences the largest energy lowering. In N_2, because of the higher electronegativity of N, the σ orbital that interacts with the 1*s* of H is of lower energy and a weaker interaction and energy lowering occurs on protonation. The proton affinity of CO for protonation on the O atom was calculated by Forsén and Roos (10) to be 19 kcal/mol lower than that for protonation on the carbon atom. This result is also qualitatively in line with electronegativity differences between C and O.

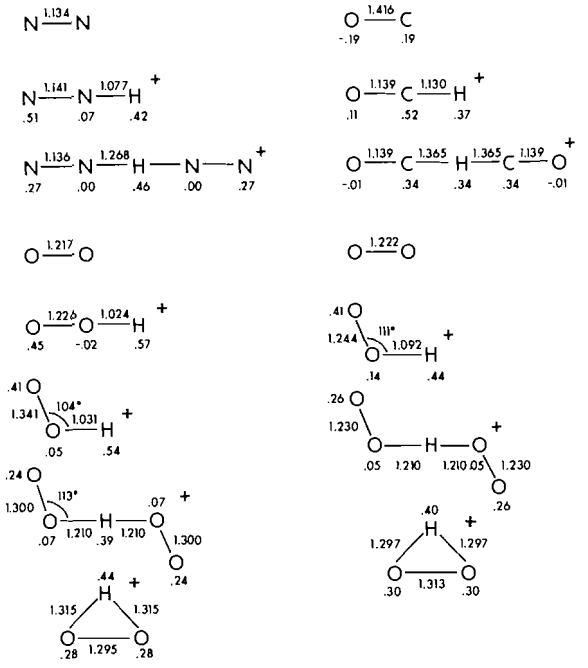

FIG. 5. Structures obtained from STO-3G calculations. Distances in Å. Numbers below atoms correspond to net atomic charges based on Mulliken population analysis. All species except the diatomic molecules are singly charged positive ions. The oxygen containing species involve triplet O_2 on the left side of figure and singlet O_2 on right side of figure. For corresponding energies see Table 2. Most stable oxygen species are bent O_2H^+ (triplet) and bent (*trans*) $(O_2)_2H^+$ (quintuplet).

On the basis of electronegativities a low proton affinity may be expected for O_2. For O_2 the σ type orbitals with which N_2 and CO interacted with the 1*s* of H are of low energy; also they are shielded from the proton by the presence of the unpaired electrons in the antibonding π^* orbital. Therefore quite a different binding occurs. A reorganization somewhat similar to sp^2 hybridization occurs which leads to the bent O_2H^+ molecule. It is interesting to note that the O protonated COH^+ was found (10) to be linear. Thus the sp^2 mixing is found only when the antibonding π^* orbital of the diatomic is occupied.

The changes occurring on formation of the dimers might be thought of as a repetition of the protonation but on a much smaller scale. This view is justified by the geometries for the dimers (Fig. 5). The linear OCH^+ and N_2H^+ are succeeded by linear dimers and the dimer $(O_2)_2H^+$ has a geometry which is like a repetition of the first bond in O_2H^+. As expected the distances between H and the neighbouring atom(s) are considerably larger in the dimers. The optimum geometry for all the three dimers was for H being in the middle between the two neighbouring atoms. A double potential well for motion of H between the two neighbouring atoms was observed only for larger distances between the bases; however these geometries had higher energies.

While the geometries of the dimers were presaged by the geometries of the protonated bases, the experimental binding energies of the dimers do not follow the order of the binding energies of the proton to the bases, i.e. the proton affinities. The STO-3G calculations reproduce the experimental results $D(OC—H^+) > D(N_2—H^+)$ and the reversal $D(OCH^+—CO) < D(N_2H^+—N_2)$ but examination of the orbital energies and changes does not lead to an understanding of the reasons for the reversal of the order in the dimers, since the orbital changes from BH^+ to B_2H^+ are quite numerous. A possible explanation may be contained in the net atomic charges based on the Mulliken population analysis (Fig. 5). While the Mulliken population analysis is strongly basis set dependent and quantitatively unreliable, it may be qualitatively useful. In N_2H^+ and O_2H^+, where two identical atoms are present, electron donation and polarization lead to the development of an appreciable positive charge on the atom which is not directly bonding to the proton, while the directly bonding atom remains almost uncharged. Because of the electronegativity difference between O and C in CO, the situation in OCH^+ is quite different. There is only little electron donation from the O atom and therefore an appreciable positive charge on the C atom. For the same reason we can expect an appreciable positive charge on the C atoms also in the $OCHCO^+$ dimer. Such a distribution is indeed predicted by the calculations (Fig. 5). The repulsion between the partially positive carbons in $OCHCO^+$ is probably responsible for the weak bonding in this dimer. Significantly, the bonding in OCH^+—CO is the one that experiences the greatest lowering relative to the H^+—B bonding in the monomers.

It is interesting to note that in B_2H^+ the bond distances and the charges on the N_2, O_2, and CO change relative to those in BH^+ by moving closer to those present in the unprotonated molecules B (Fig. 5). This is to be expected, of course. Further addition of ligands will promote this return to 'normalcy'. In addition to this change, also the distances to the proton will increase. The observed bonding in the higher clusters $(B)_nH^+$, $n > 2$, may be partially understood on these grounds. CO with the highest polarizability ($\alpha_{CO} = 1.95$, $\alpha_{O_2} = 1.6$, $\alpha_{N_2} = 1.76$ Å^3) (6) may be expected to gradually lead to the strongest bonding. The non-linearity in O_2H^+ and

$(O_2)_2H^+$ may be expected to repeat in the further growth of oxygen clusters. The observed rapid fall off in bonding with increase of n for oxygen is probably due to steric reasons, i.e. rapidly increasing repulsions between the O_2 molecules because of crowding caused by the nonlinear geometry.

The fall off of stability after the $(CO)_6H^+$ and $(N_2)_6H^+$ suggests that these species have octahedral geometry. An interesting question is whether the proton is evenly shared by the six ligands or whether the structure is unsymmetric and one CO interacts strongly with the proton and is solvated by 5 other CO molecules. If this is the case, then of further interest is the height of the six-fold potential barrier for motion of the proton from one CO to the other.

It is interesting to note that a much greater stability of CO as a ligand relative to O_2 and N_2 in the higher clusters parallels the much greater binding power of CO as ligand in transition metal complexes. It is also worthy to note that the bent geometry of O_2H^+ occurs also in some complexes of O_2 with transition metal ions, including the important O_2 complex with porphyrin in myo and hemoglobin (13, 14).

Some transition metal ion complexes with O_2 are π complexes in which the ion interacts equally with the two oxygen atoms such that an isosceles triangle structure results. The O—O distance in such complexes is longer than that in the O_2 molecule and the O_2 is more often in the singlet state (Class I compounds in ref. 14). The STO-3G predicted energies of the singlet and triplet isosceles complexes of O_2 with H^+ are appreciably higher than that of the bent triplet structure. (See Fig. 5 and Table 2.) The triplet isosceles O_2H^+ is some 54 kcal/mol higher than the singlet. Even though the STO-3G calculations exaggerate the stability of the triplets by some 30 kcal/mol, this still means that probably the more stable isosceles O_2H^+ is a triplet. As already mentioned, the STO-3G calculations of the BH^+ and B_2H^+ species are of low accuracy. We believe that the species O_2H^+, $(O_2)_2H^+$, and some of the other protonated bases and dimers are of sufficient interest and therefore merit more accurate calculations by theoretical chemists.

(c) Reactions Involving H_2 as a Base

The last five reactions shown in Table 1 involve H_2. These processes are due to the use of H_2 as carrier gas in the experiments made for the measurements of the B_nH^+ equilibria. Since these reactions are of interest, a brief discussion will be given here.

The proton transfer equilibrium [3], could be measured between the temperatures 120 to 210°C. At lower temperatures clustering interfered, while at higher temperatures the ion signal became weak, because of more rapid diffusion of the ions to the wall and reactions with impurities desorbed from the walls of the apparatus. The van't Hoff plot (Fig. 4) of the available equilibrium constants indicates a zero slope, i.e. $\Delta H_3^0 \approx 0$ although the data are rather scattered. The average equilibrium constant is $K_3 = 3.4 \pm 1$. Assuming $\Delta H_3^0 = 0$, this means that $K_3 \approx 3.4 \pm 1$ also at 25°C. This result is in agreement with the value of 2.3 ± 0.9 by Fehsenfeld *et al.* (15) but in only fair agreement with the value of 0.95 due to Fenelly *et al.* (8). The result $\Delta H_3 \approx 0$ is in agreement with the observation of Fehsenfeld *et al.* (15) that K_3 remained unchanged as the kinetic energy of the participating ions was increased. Assuming $\Delta H_3 = 0$ one obtains $\Delta S_3^0 = 2.4$ eu. Since O_2H^+ is bent and H_3^+ probably has a D_{3h} symmetry (16) a ΔS^0 evaluation, based on rotational symmetry number changes only, gives: $\Delta S_3^0 \approx R \times \ln 6 = 3.5$ eu which is close to the experimental result.

Reactions [4]–[7] represent clustering of H_2 onto O_2H^+ and N_2H^+.

[3] $H_3^+ + O_2 = H_2 + O_2H^+$

[4] $O_2H^+ + H_2 = (O_2)(H_2)H^+$

[5] $(O_2)_2H^+ + H_2 = (O_2)_2(H_2)H^+$

[6] $N_2H^+ + H_2 = (N_2)(H_2)H^+$

[7] $(N_2)(H_2)H^+ + H_2 = (N_2)(H_2)_2H^+$

The ΔH^0 and ΔG^0 results in Table 1 show that H_2 addition leads to clusters of lower stability than the addition of O_2 or N_2. Results for $(H_2)_nH^+$ were reported earlier from this laboratory (4). Weakly held three centre bond structures in which the H—H bond interacts with the partially positive hydrogen in BH^+ were proposed (4) on the basis of theoretical work (16) and the experimental results. In the present reactions [4]–[7] the structures involved are probably of a similar nature.

Excited state properties of nitrobenzene derivatives

GIUSEPPE BUEMI, SALVATORE MILLEFIORI, FELICE ZUCCARELLO, AND ARCANGELO MILLEFIORI

Istituto Dipartimentale di Chimica e Chimica Industriale, Università di Catania, Viale A, Doria 8, 95125 Catania, Italy

Received August 17, 1978[1]

GIUSEPPE BUEMI, SALVATORE MILLEFIORI, FELICE ZUCCARELLO, and ARCANGELO MILLEFIORI. Can. J. Chem. 57, 2167 (1979).

Gas-phase and solution spectra of methoxy nitroanilines are reported. MIM and PPP configuration analyses were used to calculate the properties associated with the electronic transitions. The excited state dipole moments associated with the first intense electronic transition were evaluated by the solvent shift method. The spectra of the title compounds are tentatively correlated with those of the corresponding disubstituted benzene derivatives. The effect of the methoxy group on the absorption features of the isomeric nitroanilines is briefly discussed.

GIUSEPPE BUEMI, SALVATORE MILLEFIORI, FELICE ZUCCARELLO et ARCANGELO MILLEFIORI. Can. J. Chem. 57, 2167 (1979).

On rapporte les spectres en solution et en phase gazeuse de méthoxynitroanilines. On a utilisé des analyses configurationnelles MIM et PPP pour calculer les propriétés associées aux transitions électroniques. On a évalué les moments dipolaires de l'état excité associé avec la première transition électronique intense à l'aide de la méthode des déplacements induits par les solvants.

On a établi une corrélation préliminaire entre les spectres des composés mentionnés dans le titre et ceux des dérivés benzéniques disubstitués correspondants. On discute brièvement de l'effet du groupe méthoxy sur les caractéristiques d'absorption des nitroanilines isomères.

[Traduit par le journal]

Introduction

In previous papers (1–3) theoretical (MIM and PPP) and experimental (solvent shift) methods were applied to study the electronic structure of some nitrobenzene derivatives. Extension of this work to some methoxy nitroanilines is here reported with the purpose of correlating the absorption features of methoxy nitroanilines with those of the corresponding disubstituted compounds and to evaluate the effects induced by a third substituent of intermediate donating power (the methoxy group) on the electronic structure of the isomeric nitroanilines. We discuss the nature of the electronic transitions of the studied compounds in terms of locally excited (Λ) and charge transfer configurations. Solvent dependence of the electronic transitions, which is useful for evaluating charge redistribution on excitation and the nature of excited states together with frequency assignment, is obtained by comparing solution spectra with gas-phase spectra.

Experimental

The compounds investigated were commercial products purified by chromatography and crystallization. Gas-phase and solution absorption spectra were obtained as previously described (1). The spectra of methoxy nitroanilines (Fig. 1) resemble the gas-phase spectra of the corresponding nitroanilines (1); the absorption bands in the vapour of the corresponding nitroanisoles are shown in Fig. 2. In every case the gas-phase spectrum appears displaced towards shorter wavelength, thus indicating that all the apparent electronic transitions are of $\pi^* \leftarrow \pi$ type.

Excited-state dipole moments associated with the various electronic transitions can be determined by means of the equation (2)

$$\Delta\nu = \nu_{gas} - \nu_{CE} = \frac{\mu_e^2 - \mu_g^2}{hca^3}\Delta\Phi(D)$$

where CE refers to the solvent cyclohexane, D is the dielectric constant of the solvent, $\Phi(D) = (D - 1)/(D + 2)$ and a is the radius of the cavity, which was evaluated from the molecular volume as previously described (4); a mean value of 3.47 Å was obtained for the three compounds. In the vapour D was taken as unity, $\Phi(D)_{CE} = 0.2543$. Dipole moment changes are reported in Table 1, together with those evaluated by means of Suppan's equation (5)

$$-\Delta\nu = \frac{(\mu_e - \mu_g)\mu_g}{hca^3}\Delta f(D)$$

with $f(D) = 2(D - 1)/(2D + 1)$, in order to compare the present $\Delta\mu$ values with those of the corresponding isomeric nitroanilines obtained by the same method (2, 5). The relation ν versus $f(D)$ is shown in Fig. 3. Both equations give parallel results.

Calculations

Calculations were performed at MIM and PPP levels. The parametrization for MIM calculations on nitroaromatics was previously described in detail (3). It is retained here in order to compare electronic

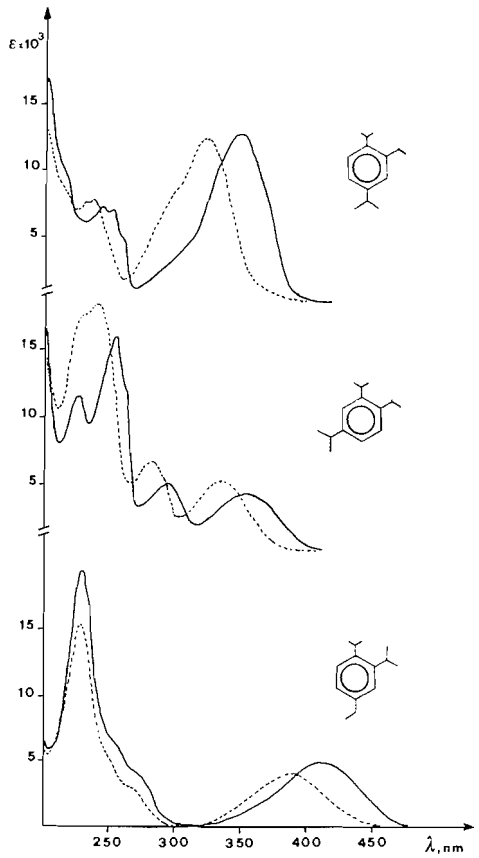

FIG. 1. Gas-phase (---) and solution (cyclohexane) (—) spectra of methoxy nitroanilines. From the top: 2-methoxy-4-nitroaniline, 2-methoxy-5-nitroaniline, 4-methoxy-2-nitroaniline.

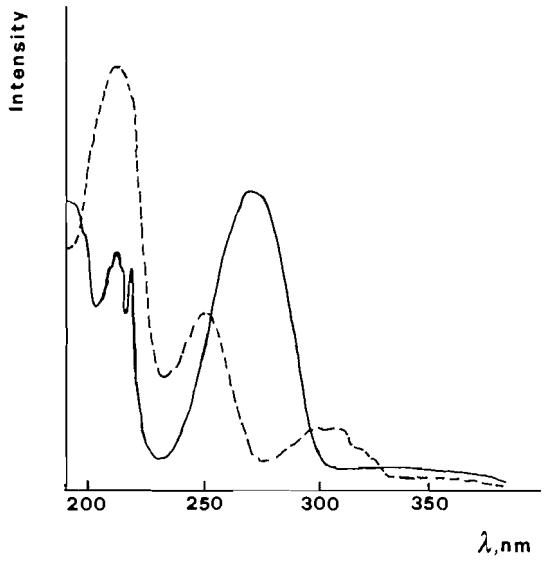

FIG. 2. Gas-phase spectra of *meta*-nitroanisole (---) and *para*-nitroanisole (—).

states of methoxy nitroanilines with those of the corresponding disubstituted benzene derivatives. The MIM calculations have previously applied in the study of nitroaromatics (1, 6, 7). The effect of electron affinity (EA) of the nitro group on the calculated electronic transitions was tested: variation of $EA(NO_2)$ from -0.4 eV to -0.7 eV does not appreciably change the calculated spectroscopic features; a maximum variation of 0.2 eV is observed in the energy of electronic transitions which are charge-transfer in nature, and meaningless variations are observed in the energy of locally excited states.

The PPP calculations were carried out as suggested by Roos and Skancke (8). They optimized integral parameters in order to reproduce ionization potentials and electronic transitions on numerous specimen molecules including nitrobenzene. In particular they introduced in the semiempirical parameter $W\mu$ a dependence on the type of nearest neighbouring atoms. For consistency reasons the geometry of the nitrobenzene framework used by Roos and Skancke was adopted in PPP calculations. The PPP results were interpreted in terms of locally excited and charge-transfer states by means of a configuration analysis (9). The results of the calculations are reported in Table 2.

Results and Discussion

The effect of the methoxy group on the absorption characteristics of nitroanilines can be evaluated by comparing gas-phase spectra and theoretical results on the methoxy nitroanilines with the corresponding experimental (1, 3) and theoretical figures in the isomeric nitroanilines and nitroanisoles. The assignment of the electronic transitions in the *p*-nitroaniline reported in ref. 3 differs from that recently reported by Khalil *et al.* (10), based on CNDO/S-CI calculations. The disagreement is mainly due to the fact that we did not observe in the vapour spectrum of the *p*-nitroaniline a distinct band at 277 nm in hydrocarbon solutions, so that this band was not considered in our calculations.

2-Methoxy-4-nitroaniline

The first low-energy intense absorption band occurs at 3.87 eV; the corresponding band in the *p*-nitroaniline lies at 4.24 eV. This bathochromic shift, as well as the band intensity, is correctly predicted by the calculations. As found in the *p*-nitroaniline, the associated electronic transition is essentially CT (benzene → acceptor) in nature with an appreciable contribution of charge-transfer from the donor (NH_2) to the acceptor (NO_2) group.

However, the CT character is somewhat smaller than in *p*-nitroaniline. These results are in agreement

TABLE 1. Solvent shifts and dipole moment changes, $\mu_e - \mu_g$, in methoxy nitroanilines

Compound	ν_{gas} (cm^{-1})	ν_{CE} (cm^{-1})	μ_g[a] (D)	$\Delta\mu$ (D)
2-Methoxy-4-nitroaniline	31 213	28 955	6.9	4.4, 7.2[b]
p-Nitroaniline				10.1[b,c,d]

with the solvent-shift data and with the relative $\Delta\mu$ values. The second band appears as a shoulder of the first band on the high-energy side at ~4.20 eV. The second transition is calculated at 4.27–4.16 eV (MIM–PPP) and is predicted as less intense than the first transition; it is a benzene locally excited Λ_1 in nature with little contribution of CT_2^A and CT_D^3 states. The composition and intensity of this transition is similar to that found for the first computed transition in *p*-nitroaniline and *p*-nitroanisole (3). The band at 4.20 eV probably includes the first observed band at ~4.08 eV in the *p*-nitroanisole and the first transition at 4.38–4.23 eV in the *p*-nitroaniline. The high energy spectrum shows crowded bands, which are not easily correlated with the corresponding bands in the disubstituted compounds.

2-Methoxy-5-nitroaniline

The first band of 2-methoxy-5-nitroaniline, found at 3.77 eV, corresponds in position and composition to the first band of the *m*-nitroaniline at 3.80 eV, very little bathochromically shifted. The band intensity is higher than in *m*-nitroaniline and this is correctly predicted by the calculations. The corresponding electronic transition is computed at 4.12–3.83 eV (MIM–PPP). The MIM calculations attribute to this band an essentially Λ (benzene) character, while PPP calculations state it to be a mixture of Λ and CT states. A similar result was found for the first electronic transition in *m*-nitroaniline (3). CNDO/S-CI calculations on *m*-nitroaniline (10) indicate a considerable CT nature of this transition. The solvent-shift and $\Delta\mu$ values point to a CT character of the band. The second band shows a maximum at 4.48 eV and a shoulder (not evident in the solution spectrum) at ~4.40 eV. This band could originate from the superposition of the band at 4.57 eV in the *p*-nitroanisole and the band at ~4.96 eV in the *m*-nitroaniline. In this spectral region one transition is computed at 4.45–4.40 eV (MIM–PPP) which is CT_1^A in nature as in the corresponding disubstituted compounds. The two computed transitions at ~5.10 eV and 5.50 eV have a CT_2^A and prevailing Λ (benzene)

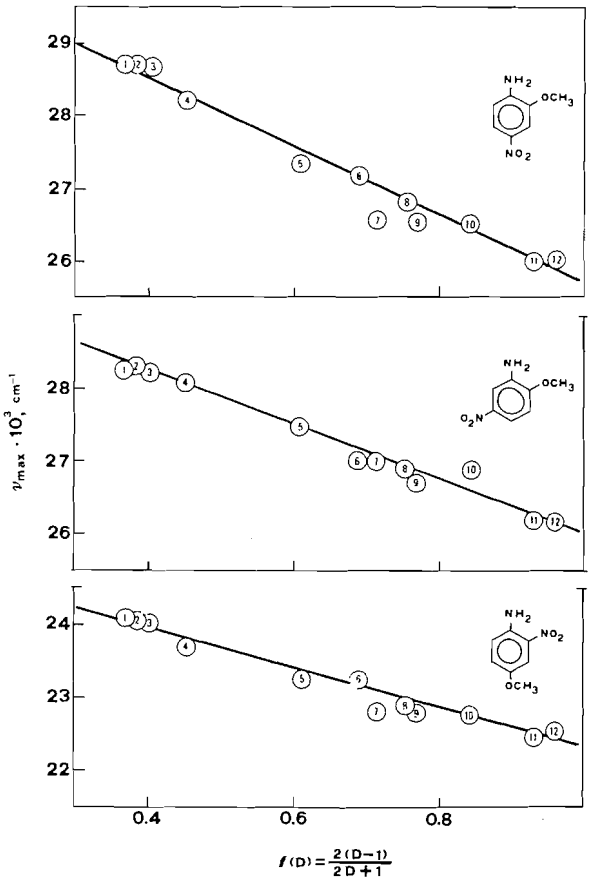

FIG. 3. Solvent shift in methoxy nitroanilines. Solvents: (1) *n*-hexane; (2) isooctane; (3) cyclohexane; (4) carbon tetrachloride; (5) trichloroethylene; (6) ether; (7) chloroform; (8) chlorobenzene; (9) ethylacetate; (10) methylene chloride; (11) methylethylketone; (12) acetonitrile.

character respectively; accordingly the first band at 5.23 eV shows a noticeable solvent shift, while the second band at 5.51 eV is much less solvent dependent. These two bands can be correlated with the CT band at 5.63 eV in *m*-nitroaniline and with the Λ (benzene) band at 5.82 eV in *p*-nitroanisole.

[a]The first value refers to cyclohexane solution, the second to vapour phase (sh = shoulder).
[b]Values in parentheses are log ε.
[c]Λ = locally excited state; T = charge transfer state (A = NO_2, D = NH_2). (The numbers in parentheses refer to MIM and PPP calculations respectively; PPP figures come from a configuration analysis.)

4-Methoxy-2-nitroaniline

The first computed transition in the 4-methoxy-2-nitroaniline lies at 3.84–3.26 eV (MIM–PPP); it has a CT character with a fair contribution of the Λ_1 (benzene) state. This composition corresponds to that of the first transition in the *o*-nitroaniline computed at 3.87 eV (6). Accordingly the first band at 3.18 eV corresponds to the band at 3.49 eV in the *o*-nitroaniline bathochromically shifted. The solvent shift of this band, 1500 cm^{-1}, is the smallest among those observed in the methoxy nitroanilines, in agreement with the computed composition of the first transition in these compounds.

The second computed transition lies at 4.62–4.41 eV (MIM–PPP) and is a mixture of CT and Λ (benzene) states. The second band is found as a shoulder at ~4.59 eV. The third transition, again a mixture of CT and Λ (benzene) states, is computed to lie at 5.08–5.15 eV (MIM–PPP); it is predicted to be more intense than the previous transition. The third band is found also as a shoulder at ~4.96 eV. The latter two bands correspond to the band at 4.77 eV in *o*-nitroaniline and to the band at 4.92 eV in the *m*-nitroaniline respectively. This correlation is supported by the relative band intensity and composition; however, their relative positions are uncertain. The fourth computed transition at 5.31 eV results from a mixture of Λ (benzene) and CT states and is predicted to be intense (f = 0.45–0.27) (MIM–PPP). This transition can be associated with the intense band (f = 0.40) at 5.46 eV, and correlated to the Ψ_4 in *o*-nitroaniline and *m*-nitroanisole, which show comparable intensity and composition.

Conclusions

The spectra of the studied methoxy nitroanilines can be correlated with the spectra of the corresponding disubstituted compounds by using as a criterion of comparison the nature, energy, and intensity of the electronic transition of the associated experimental band, and the solvent shift of the band. The main effect (inductive) of the methoxy group on the absorption features of the isomeric nitroanilines is related to the lowering of the energy of CT configurations of the nitro group. In particular, as refers to the first absorption band of methoxy nitroanilines, we may summarize the effect of the OCH_3 group as follows.

(*i*) The first band in the spectrum is bathochromically shifted by about 30 nm with respect to the corresponding nitroanilines, with the exception of 2-methoxy-5-nitroaniline where a very small shift is observed. In this compound the enhancement in the band intensity with respect to the *m*-nitroaniline is remarkable.

(*ii*) The $\nu_{gas} - \nu_{CE}$ shift is generally smaller than in the corresponding nitroanilines, suggesting a smaller polarizability of the first excited state in methoxy nitroanilines than in nitroanilines; accordingly the calculated $\Delta\mu$ values in the methoxy nitroanilines are smaller than in the corresponding nitroanilines (Table 1). Moreover, the relative order

of $\Delta\mu$ is the same as in the nitroanilines, where $\Delta\mu$(*p*-nitroaniline) > $\Delta\mu$(*m*-nitroaniline) > $\Delta\mu$(*o*-nitroaniline) (5).

(*iii*) The contributions of CT configurations to the first electronic transition are smaller in methoxy nitroanilines than in the corresponding nitroanilines, in agreement with the above solvent shift results.

By comparing experimental and theoretical results it appears that MIM and PPP calculations correctly predict the observed band shift on passing from the isomeric nitroanilines to the corresponding methoxy nitroanilines; they also correctly predict the relative order of the lowest transition energy in these compounds.

An esr study of the dediazoniation of 2,4,6-tri-*tert*-butylaniline with butyl nitrite in methylene chloride indicated the formation of the 2,4,6-tri-*tert*-butylphenyl radical which was spin trapped by the butyl nitrite. The persistent 2,4,6-tri-*tert*-butylphenoxy radical was also formed. Product studies from reactions catalyzed by pivalic acid indicate a novel rearrangement of an *ortho-tert*-butyl group under dediazoniation conditions forming such products as: 3-(3,5-di-*tert*-butylphenyl)-2-methylpropene (**4**), 1-(3,5-di-*tert*-butylphenyl)-2-methylpropene (**5**), 3-(3,5-di-*tert*-butylphenyl)-2-methyl-2-propanol (**6**), 3-(3,5-di-*tert*-butylphenyl)-2-butoxy-2-methylpropane (**7**), 3-(3,5-di-*tert*-butylphenyl)-2-methyl-2-trimethylacetoxypropane (**8**), 2,4,6-tri-*tert*-butylphenyl trimethylacetate (**9**), and 2,4,6-tri-*tert*-butyl-1,4-quinol (**10**). The major products (**4**–**7**) are accounted for by a free radical pathway by rearrangement of the 2,4,6-tri-*tert*-butylphenyl radical. The minor products (esters **8** and **9**) probably form by competing ionic reactions. *N*-Nitroso-2,4,6-tri-*tert*-butylacetanilide decomposes (at least in part) by a radical pathway leading to the rearranged radical $(CH_3)_2\dot{C}CH_2$—Ar which was spin trapped by the nitroso group of the substrate. Spin trapping experiments during the dediazoniation of 2,5-di-*tert*-butylaniline similarly gave evidence for the formation of aryl radicals.

L. Ross C. Barclay, Alexander G. Briggs, William E. Briggs, Julian M. Dust et Jean A. Gray. Can. J. Chem. 57, 2172 (1979).

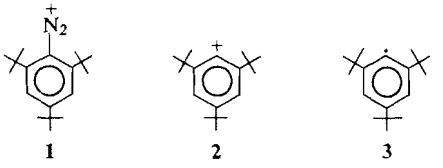
Une étude rpe de la dédiazotation de la tri-*tert*-butyl-2,4,6 aniline avec le nitrite de butyle en solution dans le chlorure de méthyle indique qu'il y a formation du radical tri-*tert*-butyl-2,4,6 phényle dont le spin est piégé par le nitrile de butyle. Il y a aussi formation du radical tri-*tert*-butyl-2,4,6 phénoxyle. Une étude des produits formés lors de réactions catalysées par l'acide pivalique indique qu'il se produit, dans les conditions de dédiazotation, une nouvelle transposition d'un groupe ortho *tert*-butyle conduisant à la formation des produits suivants: (di-*tert*-butyl-3,5 phényl)-3 méthyl-2 propène (**4**), (di-*tert*-butyl-3,5 phényl)-1 méthyl-2 propène (**5**), (di-*tert*-butyl-3,5 phényl)-3 méthyl-2 propanol-2 (**6**), (di-*tert*-butyl-3,5 phényl)-3 butoxy-2 méthyl-2 propane (**7**), (di-*tert*-butyl-3,5 phényl)-3 méthyl-2 triméthylacétoxy-2 propane (**8**), triméthylacétate de tri-*tert*-butylphényle-2,4,6 (**9**) et tri-*tert*-butyl-2,4,6 quinol-1,4 (**10**). On peut expliquer la formation des produits principaux (**4**–**7**) à l'aide du chemin réactionnel radicalaire impliquant une transposition du radical tri-*tert*-butyl-2,4,6 phényle. Les produits mineurs (esters **8** et **9**) se forment probablement par des réactions ioniques en compétition. Le *N*-nitroso tri-*tert*-butyl-2,4,6 acétanilide se décompose (au moins en partie) par un mécanisme radicalaire conduisant au radical transposé $(CH_3)_2\dot{C}CH_2$—Ar dont le spin est piégé par un groupe nitroso du substrat. Des expériences de piégeage de spin au cours de la dédiazotation de la di-*tert*-butyl-2,5 aniline fournissent des données relatives à la formation de radicaux aryles.

[Traduit par le journal]

Introduction

The aromatic dediazoniation reaction is receiving considerable attention by a number of investigators (1–7). In particular the role of reactive aryl intermediates, aryl cations, aryl radicals, and arynes, is frequently discussed. *Ortho-tert*-butyl-aryldiazonium salts, including the 2,4,6-tri-*tert*-butyldiazonium ion (**1**) (8), are known to be very unstable and this has been attributed to rapid formation of an aryl cation due to steric acceleration (7). There is substantial kinetic evidence for the formation of the aryl cation from benzenediazonium salts (1, 3) and this cation has been the subject of theoretical (9) and some recent experimental (esr) (10) study. On the other hand, aryl dediazoniations are capable of proceeding by either homolytic or heterolytic pathways (6, 7) and small changes in conditions, such as the addition of pyridine (11) or the presence of oxygen (12) appear to cause a changeover in mechanism. We have independently observed the 2,4,6-tri-*tert*-butylphenyl radical (**3**) directly in solution and followed its rearrangement (13). The known properties of this radical should aid in the discrimination between radical and ionic pathways for the reaction of **1**. In addition, formation of an aryne (via **2**) is blocked unless there is extrusion of a *tert*-butyl cation which would be de-

0008-4042/79/162172-08$01.00/0



1 2 3

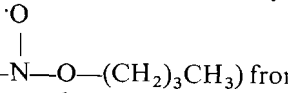
tected by product analysis. Such dealkylations may account for anomalies previously reported in the aqueous acid diazotizations of 2,4,6-tri-*tert*-butylaniline (14). We are investigating the unusual reactivity in dediazoniation of **1** and, with the above features in mind, have undertaken an exploratory study on the esr and product studies from **1**. Some comparative studies are also reported for the 2,5-di-*tert*-butylaryl system.

Results

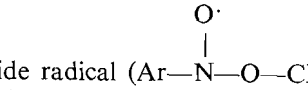
Dediazoniation of 2,4,6-Tri-tert-*butylphenyldiazo Compounds*

(a) Electron Spin Resonance Studies

Treatment of 2,4,6-tri-*tert*-butylaniline with butyl nitrite and pivalic acid in methylene chloride (aprotic diazotization (15)) in the probe of the esr spectrometer at −40°C generated two sets of esr signals in 30–40 min (see Fig. 1). These became more intense as the temperature was raised through 0°C and the solution quickly became blue in color. The central part of the spectrum consisted of a very persistent 1:2:1 triplet of multiplets ($a^{H}(2H) \simeq 1.6$ G). This proved to be the well-known 2,4,6-tri-*tert*-butylphenoxy radical. The center triplet could be enhanced by injecting a sample of the latter prepared independently by lead dioxide oxidation of the phenol and observing the increase in the superimposed signals. The second radical *appeared* to be a 1:1:1 triplet (the centre portion only partially observed at higher gain due to the more intense signal of the above phenoxy radical) of 1:2:1 triplets ($a_N = 23.86$, $a_{H(2H)} = 2.80$, and $a_{H(2H\ meta)} = 0.75$ G, and $g = 2.00521$). This second radical is assigned to *n*-butoxy-2,4,6-tri-*tert*-butylphenylnitroxide



(Ar—N—O—$(CH_2)_3CH_3$) from its close relationship to the analogous ethoxy-2,4,6-tri-*tert*-butylphenylnitroxide radical



(Ar—N—O—CH_2CH_3, $a_N = 23.98$, $a_{H(2H)} = 2.52$, $a_{H(2H\ meta)} = 0.78$ G, and $g = 2.00528$) generated by spin trapping of ethoxy by photolysis of diethylperoxide in the presence of 2,4,6-tri-*tert*-butylnitrosobenzene. While this work was in progress, the pentoxyphenylnitroxide radical was reported (16) from the reaction of aniline with pentyl nitrite. This radical showed a nitrogen splitting (15.75 G) similar to other simple alkoxyphenylnitroxides (17). The interesting variation in the nitrogen splitting of our substituted alkoxyarylnitroxides ($a_N = 23.86$–23.98 G) contrasted with the $a_N = 15.75$ G for the phenyl case is attributed to the steric hindrance provided by two *ortho-tert*-butyl groups in our hindered nitroxides which force a non-coplanar conformation of the radical so that the a_N approaches the values found for alkylalkoxy nitroxides (17). This effect has been observed before in related aryl nitroxide radicals (18, 19).

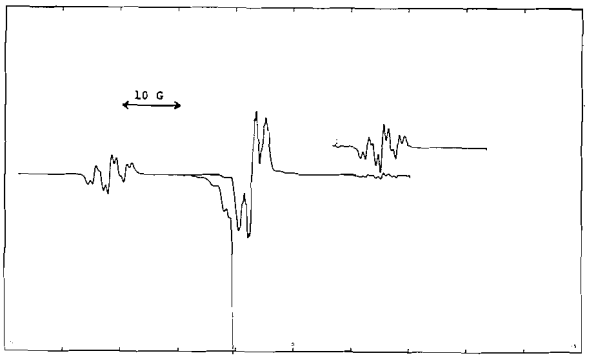


FIG. 1. Electron spin resonance spectrum from diazotization of 2,4,6-tri-*tert*-butylaniline with butyl nitrite and pivalic acid in methylene chloride at 0°C.

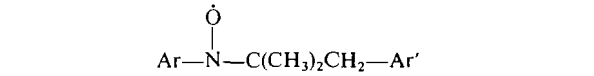
It was of interest to study the formation of these free radical species in the *absence* of pivalic acid when the overall reaction proceeded more slowly according to product studies (see (b) below). Under this condition, it was possible to readily observe the consecutive formation of the radicals, as illustrated in Fig. 2*a–d*. The first species observed was the tri-*tert*-butylphenoxy radical (Fig. 2*a*), followed by butoxy-2,4,6-tri-*tert*-butylphenylnitroxide (Fig. 2*b*, when the tri-*tert*-butylphenoxy radical was now hardly observable), then the tri-*tert*-butylphenoxy radical became more prominent as usual (Fig. 2*c*). Finally, on extended reaction time, it was still possible to observe the above two radicals plus a third very persistent species (Fig. 2*d*). This third radical has not been definitely characterized. Assuming that the central portion lies under the prominent tri-*tert*-butylphenoxy, it is estimated that there is a 1:1:1 triplet of 1:2:1 triplets where $a_N = 15.6$ G, $a_{H(2H,meta)} = 1.4$ G, and $g = 2.0058$. This suggests an aromatic nitroxide radical, possibly of the type



Ar—N—$C(CH_3)_2CH_2$—Ar′

(Ar = 2,4,6-tri-*tert*-butylphenyl, Ar′ = 3,5-di-*tert*-butylphenyl)

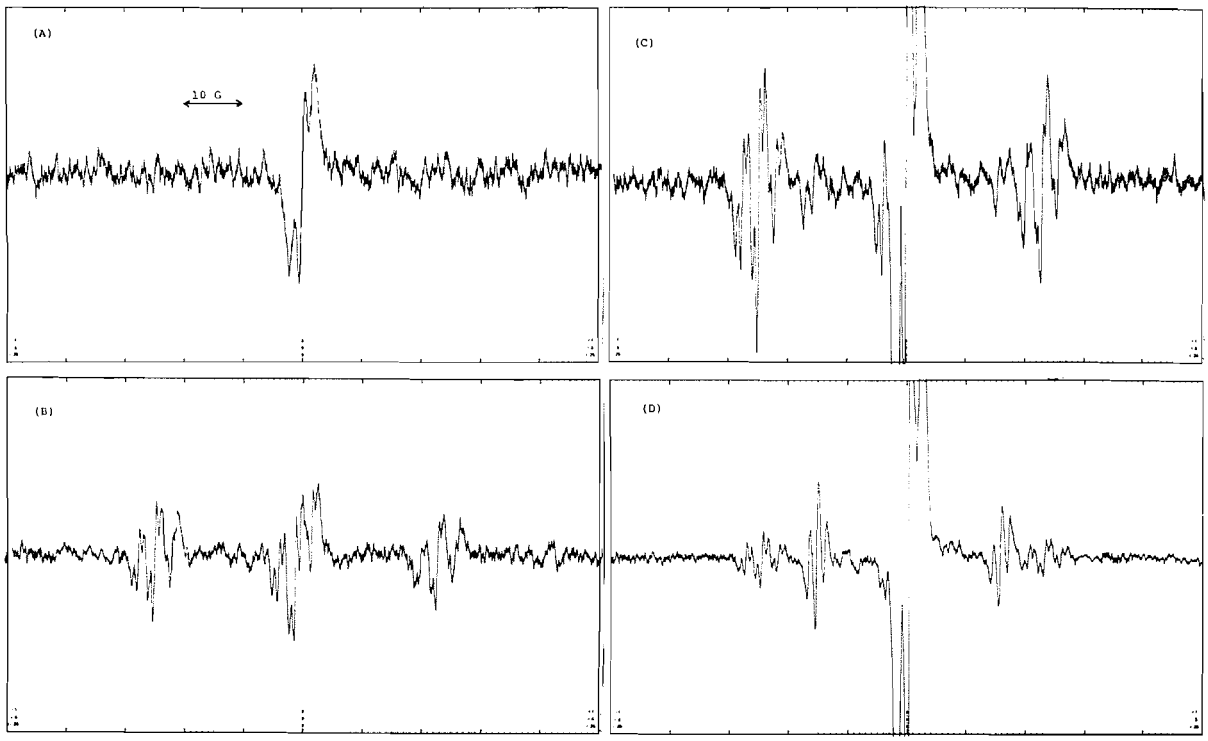


FIG. 2. Electron spin resonance spectra from diazotization of 2,4,6-tri-*tert*-butylaniline with butyl nitrite in methylene chloride at −10°C: (*a*) after 2½ h, appearance of 2,4,6-tri-*tert*-butylphenoxy (**12**); (*b*) after 3½ h, illustrating the butoxy-2,4,6-tri-*tert*-butylphenylnitroxide radical (**11**); (*c*) after 4½ h, showing the mixture of radicals **11** and **12**; (*d*) extended reaction time, showing the appearance of a third radical (triplets) between **11** and **12**.

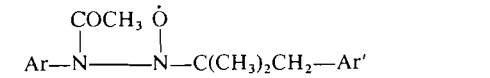
Decomposition of *N*-nitroso-2,4,6-tri-*tert*-butylacetanilide[1] in methylene chloride in the esr spectrometer at room temperature or above (20–40°C) gave an esr spectrum consisting of a simple 1:1:1 triplet of 1:1:1 triplets without further additional fine structure (a_{N_α} = 13.84 and a_{N_β} = 3.26 G and g = 2.00616). The couplings and g value observed are indicative of a hydrazoxy radical (21) and the lack of additional coupling to hydrogen is suggestive of a radical of the type



(Ar = 2,4,6-tri-*tert*-butylphenyl, Ar′ = 3,5-di-*tert*-butylphenyl)

formed by spin trapping by the starting nitroso compound of a radical generated in the system (see Discussion). There was no evidence for the tri-*tert*-butylphenoxy radical in this reaction.

(b) Product Studies

Butyl nitrite diazotization of 2,4,6-tri-*tert*-butylaniline, under similar conditions as the esr studies, yielded a complex mixture containing the hydrocarbons 3-(3,5-di-*tert*-butylphenyl)-2-methylpropene (**4**), 1-(3,5-di-*tert*-butylphenyl)-2-methylpropene (**5**), the alcohol 3-(3,5-di-*tert*-butylphenyl)-2-methyl-2-propanol (**6**), the ether 3-(3,5-di-*tert*-butylphenyl)-2-butoxy-2-methylpropane (**7**), the esters 3-(3,5-di-*tert*-butylphenyl)-2-methyl-2-trimethylacetoxypropane (**8**) and 2,4,6-tri-*tert*-butylphenyl trimethylacetate (**9**), and the 2,4,6-tri-*tert*-butyl-1,4-quinol (**10**) (see Table 1).

The hydrocarbons **4** and **5** were identified by their nmr spectra (see Experimental), by the ready acid-catalyzed isomerization of **4** to **5**, and by the oxidation of **5** to the known 3,5-di-*tert*-butylbenzoic acid. The alcohol **6** gave the expected spectroscopic data and it readily underwent dehydration to yield **5**. The ether **7** gave a complex ^{1}Hmr spectrum due to the overlap of the *n*-butyl resonances with those of the other alkyl hydrogens. The structure was determined from its ^{13}C n.m.r. spectrum and the fact that it underwent partial decomposition under glc conditions to yield some **4**, **5**, and *n*-butyl alcohol. The ester **8** was identified from its spectroscopic properties and it also underwent some decomposition on the glc to yield

[1]Such compounds were reported (20) to be too unstable to isolate in pure form. However, we were able to purify this compound by tlc suitable for analytical and spectroscopic data. Product analyses from this decomposition will be reported separately.

TABLE 1. Products from diazotization of 2,4,6-tri-*tert*-butylaniline

Compound	% yields			
	Run 1 (Air)[a]	Run 2 (Air)[b]	Run 3 (N_2)[c]	Run 4 (O_2)[c]
Hydrocarbon **4**	24.3[d]	19.0	22.4	26.6
Hydrocarbon **5**	—	7.4	6.1	7.3
Alcohol **6**	29.2	36.1	32.7	35.6

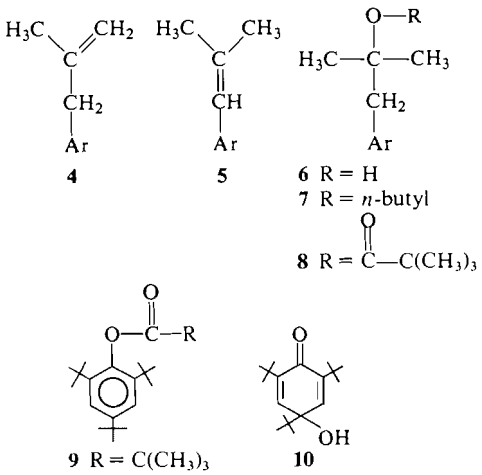
Ester **8**	7.5	8.5	7.8	8.9
Ester **9**	1.6	2.6	—	—
Quinol **10**	2.9	—	2.6	3.4
Totals	87.1	98.2	90.8	98.5

[a]Products were separated by column chromatography on alumina and further purified by tlc.
[b]Relative percentages, determined by glc.
[c]Products were separated by tlc and the percentages of 4 and 5 estimated by nmr.
[d]This value is for 4 and 5.

the hydrocarbons **4** and **5**. The ester **9** gave the expected spectroscopic data and unlike **8** was stable under various glc conditions. A minor product, the quinol **10**, was identified as 2,4,6-tri-*tert*-butyl-4-hydroxy-2,5-cyclohexadien-1-one by its nmr spectrum and by comparison with properties given in the literature. The various compounds **4**–**10** were formed when the reaction was carried out in air, or in a nitrogen or oxygen atmosphere. Furthermore, the percent yields of the various compounds identified remained approximately the same under these conditions (see Table 1). The reaction was also observed directly in the nmr probe whereby the formation of the major components (**4**–**7**) could be observed qualitatively. A comparative small scale (nmr) run was also carried out with triethylsilane added. The latter has been used in methylene chloride as a trap for carbonium ions (22, 23). The same major components were observed (nmr) to form with and without added triethylsilane and the product analyses



(glc) were also similar. In the absence of pivalic acid, the conversion to these products at temperatures below 0°C was extremely slow and estimated (nmr) to be less than 50% after 6 days. After an additional 2 days at room temperature, this reaction was 82% complete (based on recovered amine). This reaction mixture also contained the hydrocarbons **4** and **5**, the alcohol **6**, the ether **7**, and traces of the quinol **10**.

*Aprotic Diazotization of 2,5-Di-*tert*-butylaniline*

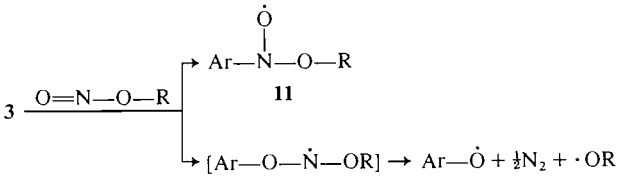
The aprotic diazotization of 2,5-di-*tert*-butylaniline leads to arynoid adducts in the presence of furan (15) and it has been proposed (7, 15) that this is a case of rapid formation of an *ortho-tert*-butylaryl carbonium ion through steric acceleration of dediazoniation. We reinvestigated this reaction to determine if aryl radicals could be trapped. Using 2,5-di-*tert*-butylnitrosobenzene as a trap at room temperature, this reaction did indeed produce a very persistent esr signal consisting of a triplet (1:1:1) of multiplets assigned to the Ar_2N—Ȯ radical (24) (Ar = 2,5-di-*tert*-butylphenyl) (a_N = 11.0 and $a_H \simeq$ 0.5–1 G and g = 2.00579). With tetraphenylcyclopentadienone (tetracyclone) as a trap in this reaction, we observed a very persistent radical (stable for days at room temperature) consisting of a complex 16-line pattern (g = 2.00302) almost superimposable on the radical formed in a similar way by addition of a phenyl radical to position 2 of tetracyclone (g = 2.0032) (2).

Discussion

The following conclusions are derived from these dediazoniations studied to date.

1. The aprotic diazotizations of the aromatic amines, aniline, 2,5-di-*tert*-butylaniline, and 2,4,6-tri-*tert*-butylaniline, with butyl nitrite gave evidence for aryl radicals in solution. With the first two amines, the aryl radicals were trapped with tetracyclone. The 2,5-di-*tert*-butylaryl radical was also spin trapped with 2,5-di-*tert*-butylnitrosobenzene.

In the case of 2,4,6-tri-*tert*-butylaniline, the derived aryl radical (**3**) was trapped by the butyl nitrite used to form the *n*-butoxy-2,4,6-tri-*tert*-butylphenylnitroxide radical (**11**). The formation of the 2,4,6-tri-*tert*-butylphenoxy radical (**12**) in carefully degassed solutions, at the same time or preceding the formation of **11**, can be accounted for by some spin trapping of **3** at the oxygen of butyl nitrite (Scheme 1). Steric effects are known to cause spin trapping at oxygen of a nitroso group, for example, in the case of 2,4,6-tri-*tert*-butylnitrosobenzene (25). Alternatively **12** could form by hydrogen atom transfer from the corresponding phenol. The latter could form from the combination of the aryl radical (**3**) with hydroxy radical (Scheme 2, (*v*)).



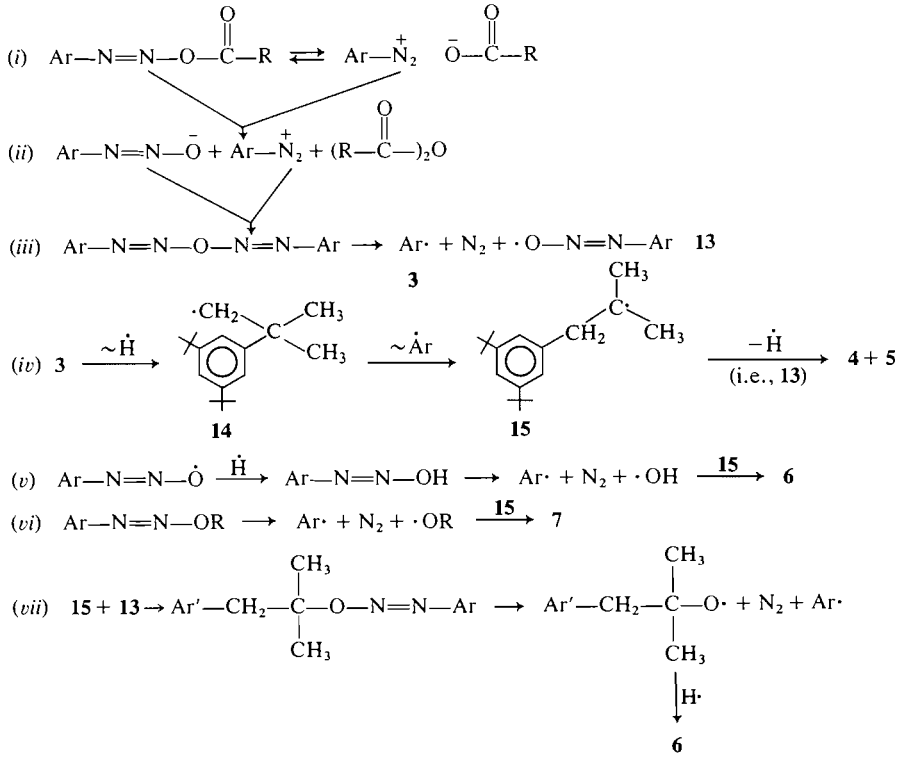
SCHEME 1

2. Decomposition of *N*-nitroso-2,4-6-tri-*tert*-butylacetanilide gave a radical apparently formed by spin trapping of the rearranged radical $Ar'—CH_2—\dot{C}(CH_3)_2$ (**15**, Scheme 2) by the nitroso group of the substrate.

3. The unusual hydrocarbon products **4** and **5** from the butyl nitrite diazotization of 2,4,6-tri-*tert*-butylaniline can be accounted for by a free radical pathway as outlined in Scheme 2. Steps (*i*)–(*iii*) follow the generally accepted (7, 26) Rüchardt mechanism (27) for the formation of aryl radicals by homolytic decomposition of an unstable diazoanhydride intermediate. Although the rather elusive aryl diazotate radical (i.e., **13** in Scheme 2) reported by Cadogan (28) was questioned on the basis of nuclear polarization studies (29), more recent evidence (30) points to its important role in the generation of aryl radicals and related radical reactions. The rearrangements in step (*iv*) (**3** → **14** → **15**) are consistent with the observed behavior of the aryl radical **3** generated independently (13).

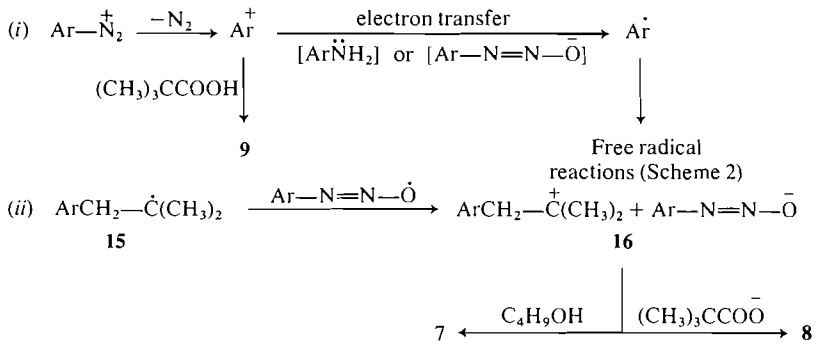
4. There are several possibilities for the formation of the oxygenated products. For example, the major oxygen-containing products, the alcohol **6** and the ether **7**, could be formed by free radical combinations of **15** with hydroxy radical and butoxy radical as shown in steps (*v*) and (*vi*). Other speculations include the oxygenation of **15** by **13** (step *vii*) (and analogously of **3** by **13** leading to the stable radical **12**). Furthermore, the trapped radical **11** could be a source of alkoxy radicals via the reported (16) decomposition route $Ar—\overset{\dot{O}}{\underset{|}{N}}—O—R \rightarrow Ar—NO + \cdot OR$. The quinol **10**, a minor product, probably results from hydroxylation of **12** at the *para* position (31) (step (*viii*)), although we cannot rule out oxygenation of **12** by **13** followed by hydrogen abstraction or even air oxidation of **12** during work-up (32).

5. The esters **8** and **9** most probably form in com-



Ar = 2,4,6-tri-*tert*-butylphenyl, Ar′ = 3,5-di-*tert*-butylphenyl

SCHEME 2



SCHEME 3

peting polar side reactions. The ester **8** is *not* a result of secondary reactions. We found that neither the hydrocarbons (**4** and **5**) nor the alcohol **6** react with pivalic acid or pivalic anhydride under these conditions to give this ester. Thus the formation of **8** and **9** is a strong indication of a competing carbonium ion type reaction. We further speculate that such aryl cationic and free radical reactions may be directly related by electron transfer processes (i.e., step (*i*), Scheme 3). The other oxygen-containing products, such as the alcohol **6** and ether **7**, could also result from ionic reactions on the cation **16** in contrast to the free radical steps (*v*) and (*vi*) suggested in Scheme 3. The cation **16** could result from electron transfer to the aryl diazotate radical (step (*ii*), Scheme 3). A somewhat similar electron transfer from a carbon radical to phenyl diazotate has recently been postulated (30).

6. There was no evidence for the formation of products from a substituted benzyne by the elimination of an *ortho-tert*-butyl from the 2,4,6-tri-*tert*-butylphenyl cation (**2**).

Experimental

The procedures for spectroscopic and chromatographic analyses given earlier (33) were followed unless otherwise stated herein.

Materials

2,4,6-Tri-*tert*-butylaniline was prepared by reduction of the nitro compound with sodium amalgam (34). 2,5-Di-*tert*-butylaniline was best prepared by the catalytic hydrogenation procedure (34). These amines were purified by column chromatography on acidic alumina by elution with petroleum ether–benzene mixtures. The butyl nitrite, pivalic acid, and solvents used were all freshly distilled. The tetracyclone used was commercial material (Eastman). 2,5-Di-*tert*-butylnitroso- and 2,4,6-tri-*tert*-butylnitrosobenzene were described earlier (33). *N*-Nitroso-2,4,6-tri-*tert*-butylacetanilide, prepared by nitrosation of the anilide (mp 273°C) with nitrosyl chloride, was purified by preparative tlc using chloroform solvent, the solvent removed under reduced pressure and the product analyzed without further purification or drying. It melted at 121°C, showed ir (CCl_4) bands at 1750 (C=O) and 1375 (—N=O) cm^{-1}, and nmr bands at δ: 1.12 (s, 18H, 2 × $(CH_3)_3C$—), 1.30 (s, 9H, $(CH_3)_3C$—), 2.80 (s, 3H, CH_3CO), and 7.40 (s, 2H, aryl). *Anal.* calcd. for $C_{20}H_{32}N_2O_2$: C 72.24, H 9.70, N 8.43; found: C 71.63, H 9.75, N 8.56.

Electron Spin Resonance Studies

Electron spin resonance spectra were measured on a Varian E-3 spectrometer or where noted[2] on a Varian E-104A spectrometer. The diazotizations of the amines were carried out in an esr reactor tube equipped with a glass capillary inlet and outlet for purging with dry oxygen-free nitrogen and a third side arm for injecting reactants through a septum. In a typical run, a solution of the amine (0.11 mmol) and pivalic acid (0.14 mmol) in 0.5 mL of methylene chloride was thoroughly purged with nitrogen. The tube was cooled to −40°C in the esr probe, then butyl nitrite (0.11 mmol) in an equal volume of methylene chloride was injected through the septum while the reaction solution was mixed with the inlet nitrogen. The temperature was slowly raised to 0°C while spectra were determined. The same procedure was used in runs without pivalic acid and typical spectra are illustrated in Figs. 1 and 2. Such spectra were also obtained[2] during the diazotization of 2,4,6-tri-*tert*-butylaniline when the solutions were carefully degassed under high vacuum by alternately freezing and thawing. Experiments with radical traps (2,5-di-*tert*-butylnitrosobenzene or tetracyclone) were carried out by mixing equimolar amounts of the amine and the trap before the addition of butyl nitrite as above. The ethoxy-2,4,6-tri-*tert*-butylphenylnitroxide radical was generated by ultraviolet irradiation of a solution of diethylperoxide and 2,4,6-tri-*tert*-butylnitrosobenzene in pentane at −40°C in the esr spectrometer.[2] The *g* values were measured relative to that of tetracene in sulfuric acid, $g = 2.002604$ (35).

Product Analysis

The preparative scale reaction on 2,4,6-tri-*tert*-butylaniline was carried out by adding a solution of the amine (10.6 g, 0.0406 mol) and pivalic acid (5.30 g, 0.0473 mol) in 100 mL of methylene chloride over a 1 h period to a stirred solution of butylnitrite (5.90 g, 0.0573 mol) in 100 mL of methylene chloride kept at 0°C. The solution was kept cold overnight, then allowed to warm to room temperature. The reaction mixture was extracted with aqueous sodium hydroxide, water, dried over sodium sulfate, and the solvent distilled under reduced pressure. The residual oil (11.9 g) was chromatographed on a neutral alumina column by elution with petroleum ether followed by petroleum ether – ethyl ether. The first fraction contained the hydrocarbons **4** and **5**. Fraction 2 contained a mixture of the hydrocarbons with the ether **7** (mainly), fraction 3 contained the ether **7**, fraction 4 the ether mixed with the ester

[2]These studies were made in the laboratory of Dr. K. U. Ingold, Division of Chemistry, National Research Council of Canada, Ottawa, Ont.

8, fraction 5 was a mixture of the esters **8** and **9**, and fraction 6 contained the alcohol **6** mixed with the quinol **10**. The various compounds in the above chromatograph fractions 2–6 were further separated and purified by preparative tlc on silica gel that had been acid treated with 0.1 *m* HCl, with benzene eluent. The compounds eluted on tlc in the order hydrocarbons (**4** and **5**), ether (**7**), esters (**9** then **8**), quinol (**10**), and alcohol (**6**). The percentages of the various compounds are given in Table 1 (run 1).

Gas–liquid chromatographic analysis (8 ft × 1/4 in. column, 20% Carbowax on Chromosorb W at 175°C and helium at 30 cm^3/min) of the products from another run gave the results summarized in Table 1 (run 2). Gas–liquid chromatographic analysis of the purified (tlc) ether **7** showed that it undergoes partial decomposition into hydrocarbons **4** and **5** and *n*-butyl alcohol under these conditions. Similarly the ester **8** yielded some **4** and **5** under these conditions.

Product analyses from smaller scale runs (4 mmol) were carried out by preparative tlc directly after removal of solvent (Table 1, runs 3 and 4). On this scale we failed to detect the ester **9**. Details on the individual products are given below.

*3-(3,5-Di-*tert*-butylphenyl)-2-methylpropene (**4**) and 1-(3,5-Di-*tert*-butylphenyl)-2-methylpropene (**5**)*

The less stable nonconjugated hydrocarbon **4** predominated in the hydrocarbon fraction. Hydrocarbon **4** showed nmr bands at δ: 1.35 (s, 18H, 2 × $(CH_3)_3C$), 1.72 (t, $J \simeq 1$ Hz, 3H, $H_3C-\underset{|}{C}=C$), 3.40 (s, broad, 2H, benzylic—CH_2—), 4.89 (multiplet, 2H, C=CH_2), 7.23 (d, $J \simeq 2$ Hz, 2H, aryl H's 2 and 6), and 7.45 (t, $J \simeq 2$ Hz, 1H, aryl H 4). A sample of this hydrocarbon mixture (270 mg) (mainly **4**) was converted into **5** by refluxing for 30 min in benzene containing 22 mg of *p*-toluenesulfonic acid. Nuclear magnetic resonance analysis of the product showed that it was almost entirely the conjugated alkene **5**. The nmr spectrum of **5** showed bands at δ: 1.35 (s, 18H, 2 × $(CH_3)_3C$), 1.91 (d, $J \simeq 1$ Hz, 6H, $(CH_3)_2C=$), 6.49 (m, 1H, Ar—$\underset{|}{C}=\underset{\diagdown}{\overset{\diagup}{C}}$), 7.29 (d, $J \simeq 2$ Hz, 2H, aryl H's 2 and 6), and 7.46 (t, $J \simeq 2$ Hz, 1H, aryl H 4).

A sample of **5** (1.9 mmol) in 80% pyridine–water was oxidized overnight at room temperature by a mixture of potassium permanganate (37 mg) and periodic acid (4.7 g). One millilitre of this solution was distilled into a solution of 2,4-dinitrophenylhydrazine reagent. The precipitate was collected and chromatographed on neutral alumina by elution with benzene to yield yellow crystals, mp 126°C alone or mixed with authentic acetone 2,4-dinitrophenylhydrazone. The solution from the oxidation was evaporated to dryness, the residue extracted with ethyl ether, which in turn was extracted with aqueous sodium hydroxide. Acidification gave a colorless solid which after sublimation melted at 164°C. This proved to be 3,5-di-*tert*-butylbenzoic acid by mixture melting point and identical infrared spectra with an authentic sample of acid (mp 163–164°C) (36).

*1-(3,5-Di-*tert*-butylphenyl)-2-propanol (**6**)*

The alcohol **6**, purified by sublimation *in vacuo*, gave a mp of 83.5–84°C. It showed a strong band in the infrared at 3400 (—OH) cm^{-1} and nmr bands at δ: 1.15 (s, 6H, $(CH_3)_2\underset{|}{C}-O$), 1.30 (s, 18H, 2 × $(CH_3)_3C$—), 1.43 (s, exchanges with D_2O, 1H, OH), 2.67 (s, 2H, Ar—CH_2—), 6.94 (d, $J \simeq 2$ Hz, 2H, aryl H's 2 and 6), and 7.18 (t, $J \simeq 2$ Hz, 1H, aryl H 4). *Anal.* calcd. for $C_{18}H_{30}O$: C 82.38, H 11.52, Mol. Wt. 262; found: C 82.98, H 11.52, Mol. Wt. (mass spectrum *m/e* 262 M^+).

TABLE 2. The ^{13}Cmr spectrum of ether **7**[a]

Carbon	Chemical shift (decoupled)	Multiplicity (undecoupled)[b]
C-1 × 2	151.3	s
C-2	139.1	s
C-3 × 2	126.4	d
C-4	121.1	d
C-5	76.4	s
C-6	62.6	d
C-7	49.3	t
C-8 × 2	36.2	s
C-9	34.4	—[c]
C-10 × 6	33.5	q
C-11 × 2	26.8	q
C-12	21.0	t
C-13	15.5	q

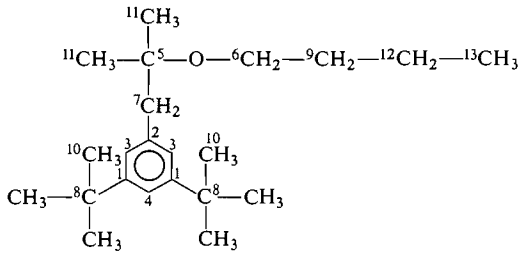
[a] *Anal.* calcd. for $C_{22}H_{38}O$: C 83.02, H 11.95, Mol. Wt. 318; found: C 82.86, H 11.70, Mol. Wt. (mass spectrum *m/e* 318 M^+).
[b] Abbreviations: s, singlet; d, doublet; t, triplet; q, quartet.
[c] C-9 multiplet obscured under C's at 10.

The alcohol **6** (1.0 mmol) in 6 mL of benzene containing 26 mg of *p*-toluenesulfonic acid was heated under reflux for 2 h in an apparatus fitted with a (Stark) water trap. The solution was washed with aqueous sodium hydroxide, water, and dried over sodium sulfate. Evaporation of the benzene left a product which proved to be better than 96% of the alkene **5** according to glc and nmr analyses.

*1-(3,5-Di-*tert*-butylphenyl)-2-butoxy-2-methylpropane (**7**)*

The ether was isolated as a colorless oil. It gave a strong ir band at 1090 (C—O—C) cm^{-1} and nmr bands at δ: 1.36 (s, 18H, 2 × $(CH_3)_3\underset{|}{C}$—), 1.14 (s, 6H, $(CH_3)_2\underset{|}{C}-O$—), 0.84–1.64 (overlapping above bands) (complex multiplets, 7H, CH_3CH_2-CH_2—), 2.79 (s, 2H, Ar—CH_2—), 3.48 (t, 2H, —CH_2—O—), 7.24 (d, $J \simeq 2$ Hz, 2H, aryl H's 2 and 6), and 7.46 (t, $J \simeq 2$ Hz, 1H, aryl H 4).

The ^{13}Cmr spectrum of **7** measured in $CDCl_3$ on a Varian CFT-20 spectrometer gave a 13-line spectrum. The results are given in Table 2 in order of decreasing chemical shifts and assignments according to the arbitrary numbering of carbons given below:



7

*3-(3,5-Di-*tert*-butylphenyl)-2-methyl-2-trimethylacetoxypropane (**8**)*

Sublimed **8** gave a mp of 43–46°C. The nmr spectrum had bands at δ: 1.15 (s, 9H, $(CH_3)_3COO$—), 1.37 (s, 18H, 2 × $(CH_3)_3\underset{|}{C}$—), 1.49 (s, 6H, $(CH_3)_2\underset{|}{C}-O$), 1.73 (s, 2H, Ar—$CH_2$—), 7.23 (d, $J \simeq 2$ Hz, 2H, aryl H's 2 and 6), and

7.49 (t, $J \simeq 2$ Hz, 1H, aryl H 4). A strong band in the ir spectrum appeared at 1735 (ester C=O) cm^{-1}. *Anal.* calcd. for $C_{23}H_{38}O_2$: C 79.71, H 11.05, O 9.23, Mol. Wt. 346; found: C 79.70, H 10.99, O 9.31, Mol. Wt. (mass spectrum *m/e* 346 M^+).

2,4,6-Tri-tert-*butylphenyl Trimethylacetate (**9**)*

Sublimed **9** gave a mp of 108–109°C. The nmr spectrum showed four singlets, δ: 1.38 (9H, *para*-$(CH_3)_3C$—), 1.40 (18H, 2-*ortho*-$(CH_3)_3C$—), 1.49 (9H, $(CH_3)_3C$—C(=O)—O), and 7.64 (2H, aryl H's). A strong band appeared in the ir spectrum at 1755 (ester C=O) cm^{-1}. *Anal.* calcd. for $C_{23}H_{38}O_2$: C 79.71, H 11.05, O 9.23, Mol. Wt. 346; found: C 79.77, H 11.00, O 9.30, Mol. Wt. (mass spectrum *m/e* 346 M^+).

2,4,6-Tri-tert-*butyl-1,4-quinol (**10**)*

Sublimed **10** melted at 132°C. The nmr spectrum had bands at δ: 1.00 (s, 9H, $(CH_3)_3C$—), 1.26 (s, 18H, 2 × $(CH_3)_3C$—), 2.05 (s, exchanges with D_2O, 1H, —OH), and 6.55 (s, 2H, H's at 3 and 5). The ir spectrum was in agreement with that given for **10** (mp 126–127°C) (37). There was not sufficient **10** for an elemental analysis.

The reaction of benzeneselenenyl thiocyanate with *E*- and *Z*-1-phenylpropene: evidence for anomalous stereospecific *syn* addition

DENNIS G. GARRATT

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received February 23, 1979

DENNIS G. GARRATT. Can. J. Chem. 57, 2180 (1979).

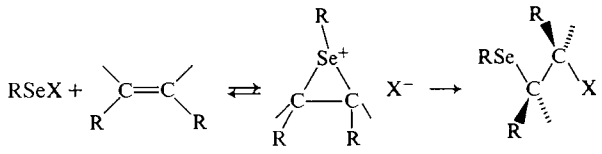
The reaction of benzeneselenenyl thiocyanate with *E*- and *Z*-1-phenylpropene has been shown to give products under conditions of kinetic control of *net* stereospecific *syn* addition in the Markownikoff orientation. Furthermore, the reactions were highly specific in that a thiocyanato adduct was formed exclusively from the *Z*-isomer, whereas an isothiocyanato adduct was formed exclusively from the *E*-isomer.

DENNIS G. GARRATT. Can. J. Chem. 57, 2180 (1979).

On a montré que la réaction du thiocyanate de benzènesélénényle avec les phényl-1 propènes *E* et *Z* conduit, dans des conditions de contrôle cinétique, à des produits impliquant une addition stéréospécifique *nette* qui est *syn* dans une orientation Markownikoff. De plus, les réactions sont très spécifiques; en effet il se forme exclusivement un adduit thiocyanate à partir de l'isomère *Z* alors qu'il se forme uniquement un adduit isothiocyanate à partir de l'isomère *E*.

[Traduit par le journal]

The chemistry of organylselenenic acid derivatives, such as areneselenenyl halides and acetates, has been the subject of numerous studies during the last few years. Electrophilic additions of these species to carbon–carbon double and triple bonds have attracted considerable interest (for general reviews see refs. 1*a–c*; 2). Few mechanistic studies have, however, been reported in the literature. In general these additions have been observed to occur in a stereospecific *anti* manner. This observation has been explained by means of a mechanism involving a seleniranium ion intermediate (3). Recently it has been reported that an open cationic species may exist prior to the product determining step in addition to vinyl ethers such as 3,4-dihydro-2*H*-pyran (4). The intermediacy of a bridged species was, however, evident from an analysis of kinetic data, suggesting therefore that a seleniranium ion-like species precedes any cation of the open structure.



1

In the preceding paper of this series we have extended our studies to areneselenenyl thiocyanates and shown that additions to simple alkyl-substituted alkenes occur in the analogous *anti* stereospecific manner (5). The regiochemistry of these additions and nature of attack by the ambident anion, SCN, is determined by the degree and type of substitution of alkyl groups about the double bond.

Since the stability of an ion such as **1** is determined to some extent by the nature of the counter ion, it was of interest to us to determine to what degree the ion would be stabilized or destabilized by substitution of the thiocyanate ion for a chloride or bromide ion. The 1-phenylpropenes were chosen for this study because the incipient benzylic carbonium ion would be of greater stability than the possible carbonium ions derivable from alkyl-substituted alkenes.

We wish to present studies which have a direct bearing upon the above and which indicate the presence of an alternative mechanistic pathway.

Results

The reaction of a freshly prepared solution of benzeneselenenyl thiocyanate **2** in methylene chloride, with *Z*-1-phenylpropene at 25°C gives, under conditions of kinetic control, a single product **3**. After standing for a few hours the formation of a second product **4** was observed via both ir and ^{1}H nmr. It was further observed that after a period of approximately 5 days two additional products **5** and **6** were also formed, but in relatively low overall yield ($[\mathbf{5} + \mathbf{6}] \leq 8\%$).

The addition of **2** to *E*-1-phenylpropene similarly gives a single product under conditions of kinetic control. This compound was determined to be identical to **5**, above, in all respects. There was no initial observable tendency for **5** to isomerize. After a period of approximately 1 week a small amount of a second

0008-4042/79/162180-05$01.00/0

product identified as **4** was also observed ([**5**]:[**4**] = 95:5). Further isomerization was observed over the next 6 weeks, which gave a mixture of **3–6** with **5** and **6** predominating ([**5**]:[**6**] = 64:36; [**5** + **6**]:[**3** + **4**] = 92:8).

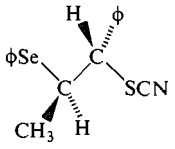
Characterization of compounds **3–6** was initially accomplished by means of infrared and nmr spectroscopy. The infrared spectra of compounds **3** and **6** show strong sharp peaks at 4.63 and 4.60 mμ, respectively, indicative of a thiocyanate group, while compounds **4** and **5** show intense broad bands at 4.84 and 4.75 mμ, indicative of an isothiocyanate group (6).

The Markownikoff orientation of the adducts was established by means of mass spectroscopy. The mass spectra of **3–4** show α-cleavage fragmentation to yield $[C_6H_5SeCHCH_3]^{+\cdot}$ ions (eq. [1]), *m/e* = 185, and $[C_6H_5CHSCN]^{+\cdot}$ ions *m/e* = 148, in accord with the regiochemical specificity shown below.

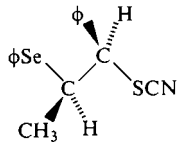
[1] $$\left[C_6H_5\underset{X}{C}H\underset{SeC_6H_5}{C}HCH_3\right]^{+\cdot} \rightarrow [C_6H_5SeCHCH_3]^{+\cdot} + [C_6H_5CHX]^{\cdot}$$

X = SCN, NCS $\qquad [C_6H_5CHX]^{+\cdot} + [C_6H_5SeCHCH_3]^{\cdot}$

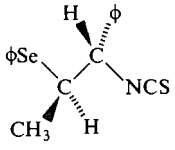
Assignment of stereochemistry was arrived at by two spectroscopic means and an independent synthesis. First of all, it is known that in the proton nmr spectra of a series of racemic *erythro* and *threo* isomers of 1,2-disubstituted 1-arylpropanes, the β-methyl protons of the *threo* isomer always appear at higher field than those of the corresponding *erythro* isomer (7). Secondly, it has been observed that the vicinal proton–proton coupling constant in *erythro* diastereomers is larger than the corresponding coupling in the *threo* isomer (8). Thus it is apparent from an examination of Table 1, if one compares the thiocyanate adducts **3** and **6** or the isothiocyanate adducts **4** and **5**, that compounds **5** and **6** are the *threo* isomers, while **3** and **4** are the *erythro* isomers.



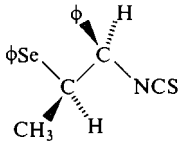
3



6



4



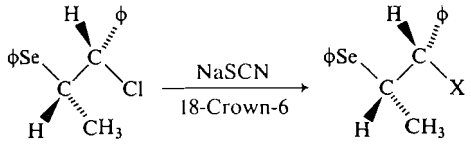
5

These results are very surprising, since they are indicative of a rather anomalous stereospecific *syn* addition under conditions of kinetic control. Furthermore, the stereospecificity of subsequent isomerizations was lost.

In view of the apparent anomalous stereochemistry of the reaction, an independent synthesis of the adducts was carried out. Benzeneselenenyl chloride is known to add across the double bond of *Z*- and *E*-1-phenylpropene in a stereospecific *anti* manner to yield *threo*- and *erythro*-1-chloro-1-phenylpropyl-2 phenyl selenide, **7** and **8**, respectively under conditions of kinetic control (9).

Treatment of the *threo* isomer **7** with 5 equiv. of NaSCN and a catalytic amount of 18-crown-6 in methylene chloride solution gives **5** and **6** stereospecifically in the ratio of 3:7 after approximately 12 h (eq. [2]). Similarly, treatment of the *erythro*

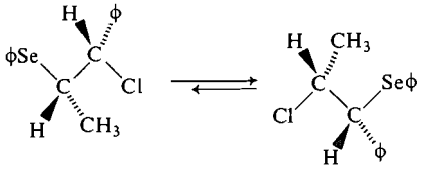
[2]



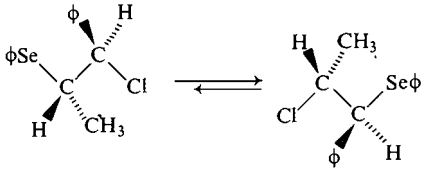
7

isomer **8** yields a 5:3 mixture of **3** and **4**, respectively. In addition to the adducts mentioned above, we isolated smaller amounts (≤20%) of the isomeric chlorides **9** and **10** from the known isomerizations of **7** to **9** and **8** to **10** (eq. [3]).

[3]



7 **9**



8 **10**

Somewhat surprisingly, we did not isolate or observe under our reaction conditions the formation of the corresponding thiocyanato or isothiocyanato anti-Markownikoff adducts.

We believe that **5** and **6** and **3** and **4** were formed here with retention of configuration at carbon. Control experiments using NaCl instead of NaSCN

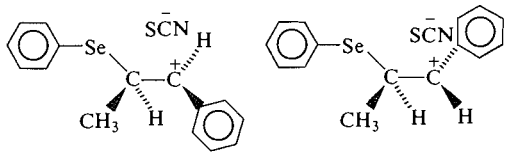
showed no loss of configuration in the presence or absence of 18-crown-6. It seems improbable that retention at carbon would occur in the case of chloride but not for thiocyanate or isothiocyanate. However, as one additional test of this ascertainment we have generated the respective *Z*- and *E*-seleniranium ions (*3a*) by treating, independently, samples of **7** and **8** with a molar equivalent of $AgPF_6$ in anhydrous methylene chloride at 12°C. Filtration of the precipitated AgCl followed by the addition of a molar equivalent of NaSCN to the seleniranium hexafluorophosphates gives the anticipated thiocyanato and isothiocyanato adducts with the latter species predominant in both cases.

Our initial synthesis using simple displacement from the chloro species is therefore in accord with neighbouring group participation of the phenylseleno group during carbon–chlorine bond breaking. Support for anchimeric assistance of this type is found in the stereospecific isomerizations: **7** ⇆ **9**; **8** ⇆ **10**. Furthermore, McManus and Lam have recently shown that the solvolysis of 2-chloroethyl phenyl selenide is an anchimerically assisted reaction in methanol and aqueous ethanol (12).

In summary we believe that these experiments serve to confirm our hypothesis of stereospecific *syn* addition.

Discussion

From the results presented in this paper, it is clear that the addition of benzeneselenenyl thiocyanate to *E*- and *Z*-1-phenylpropene is stereospecifically *syn* within the limits of our ^1H nmr analysis. This result is incompatible with the normal interpretation of a seleniranium ion intermediate. It is difficult to reach any firm mechanistic conclusions in this case because of the absence of kinetic data; particularly the kinetic order of the reaction. However, in analogy with the known second order kinetics of areneselenenyl chlorides to these and related alkenes (*9b*, 10), plus the stereospecificity (*anti*) of benzeneselenenyl thiocyanate additions to alkyl-substituted alkenes, one might also predict an Ad_E2 process to be operating here. In this case a classical open carbonium ion is probably formed, paired with a thiocyanate ion, collapse of the intimate ion-pair occurring with overall *syn* addition. Since different products are obtained from the isomeric alkenes it is concluded that these intimate ion pairs, **11** and **12**, do not equilibrate



11 **12**

prior to the product forming step. If such a scenario correctly explains these observations one must accept the rationale that the stability of the ionic intermediates is dependant upon the nature of the counter ion. This implies that a seleniranium ion is stable, be its' ring-carbon substituents alkyl or aryl, when the counter ion is, for example, chloride or hexafluorophosphate. A change in stability is, however, observed when the counter ion is thiocyanate. In this case we postulate the existence of a seleniranium ion intermediate only when alkyl ring-carbon substituents are present.

The stereospecific synthesis of compounds **3–6** from seleniranium ions originally coupled to chloride or hexafluorophosphate ions is compatible with the above. When the counter ions exchange, presumably via an ion-pair mechanism, the seleniranium ion will, using the rationale given above, open to a classical carbonium ion. *Anti* attack is still anticipated since the thiocyanate ion would be expected to fill the void in the solvation shell left by the departing counter ion. Our only assumption is that collapse to product must occur faster than reorientation of the thiocyanate ion to the *syn* side which should be retarded in any case because of the bulk of the attached phenylseleno group, as seems reasonable.

Alternatively, an Ad_E3 mechanism might be involved, in accord with the observed third order kinetics, second order in PhSeCl, for benzeneselenenyl chloride additions to both alkenes and alkynes, found in certain solvents such as ethyl acetate (9*b*, 11). A third possibility is the *syn* collapse of an episelenurane species. Unfortunately, until such time as the kinetics may be unambiguously established, our data do not warrant further mechanistic speculation.

Perhaps the most interesting aspect of these experiments is the observation of chemospecific formation of the thiocyanato adduct from the *Z*-isomer and the isothiocyanato adduct from the *E*-isomer. One possible explanation of this observation is based on the theory of hard and soft acids and bases. In general one expects the harder and more basic nitrogen atom of the nucleophile to attack at the more electrophilic site of the resonance stabilized benzylic carbon derived from the *E*-isomer, whereas the softer, more polarizable sulphur atom would prefer to attack the less stabilized benzylic carbonium ion derived from the *Z*-alkene. The reason for the different electrophilicities of the two benzylic carbons is the degree of stabilization one obtains from the phenyl ring. In the *E*-alkene the phenyl ring may easily obtain coplanarity. In the *Z*-alkene coplanarity is essentially impossible because of repulsive interactions with the adjacent methyl group.

Experimental

General

Infrared spectra were recorded on either a Perkin–Elmer 337 or Unicam SP 1100 spectrometer. Proton magnetic resonance samples were run in amberized 5 mm od sample tubes, as chloroform-*d* solutions using Varian T-60 and HA 100 spectrometers. Microanalyses were carried out by Scandinavian Microanalytical Labs, Herlev, Denmark.

Chemicals

Z- and *E*-1-phenylpropene were purchased from Chemical Samples Co. and used without further purification. Methylene chloride was purified as previously reported (9*a*). Benzeneselenenyl chloride was purchased from Aldrich Chemical Co. and recrystallized from petroleum ether 80–90 prior to use. 18-Crown-6 was purchased from Aldrich Chemical Co.

Benzeneselenenyl Thiocyanate, **2**

This compound was prepared as previously described (5).

*1-(*RS*),2-(*SR*)-1-Thiocyanato-1-phenylpropyl-2 Phenyl Selenide*, **3**

To 0.214 g (0.001 mol) of **2** in 25 mL of anhydrous methylene chloride was added 0.118 g (0.001 mol) of *Z*-1-phenylpropene. The reaction mixture was stirred for approximately 3 min until no further color change (yellow to colorless) was observed. Evaporation of the solvent gave a pale yellow oil in 90% yield. Chromatography on silica gel showed no evidence for alternate species under a variety of solvent conditions; ir ($CHCl_3$, mμ): 4.63 vs. sharp *RSCN*; ^{13}C nmr ($CDCl_3$): 52.7 d, 49.8 d, 19.8 q, 130.9 s, 135.8 d, 129.4 d, 128.3 d, 128.7 s, 129.9 d, 129.1 d, 128.9 d, 112.5 s SCN. *Anal.* calcd. for $C_{16}H_{15}SeSN$: C 57.83, H 4.55, S 9.65, N 4.21; found: C 57.80, H 4.48, S 9.69, N 5.08.

*1-(*RS*), 2-(*SR*)-1-Isothiocyanato-1-phenylpropyl-2 Phenyl Selenide*, **4**

From the isomerization of **3** in CH_2Cl_2 or $CHCl_3$ separation was carried out on silica gel eluted with CH_2Cl_2; ir ($CHCl_3$, mμ): 4.84 vs. broad *RNCS*; ^{13}C nmr ($CDCl_3$): 59.7 d, 42.2 d, 19.1 q, 129.9 s, 135.5 d, 129.2 d, 126.9 d, 129.4 d, 128.6 d, 128.4 s, 128.1 d, 137.7 s NCS. *Anal.* calcd. for $C_{26}H_{15}NSSe$: C 57.83, H 4.55, S 9.65, N 4.21; found: C 57.96, H 4.67, S 9.33, N 4.06.

*1-(*RS*), 2-(*RS*)-1-Isothiocyanato-1-phenylpropyl-2 Phenyl Selenide*, **5**

This compound was prepared as for **3** above, but substituting *E*-1-phenylpropene; ir ($CHCl_3$, mμ): 4.75 vs. broad *RNCS*; ^{13}C nmr ($CDCl_3$): 65.2 d, 45.5 d, 15.5 q, 130.9 s, 135.5 d, 129.9 d, 128.2 d, 134.7 d, 129.4 d, 128.4 s, 128.7 d, 137.0 s NCS. *Anal.* calcd. for $C_{16}H_{15}NSSe$: C 57.83, H 4.55, S 9.65, N 4.21; found: C 57.81, H 4.55, S 9.32, N 4.35.

*1-(*RS*), 2-(*RS*)-1-Thiocyanato-1-phenylpropyl-2 Phenyl Selenide*, **6**

This compound was prepared from the isomerization of **5** in CH_2Cl_2; separation was carried out on silica gel eluted with CH_2Cl_2; ir ($CHCl_3$, mμ): 4.60 vs. sharp *RSCN*. *Anal.* calcd. for $C_{16}H_{15}NSSe$: C 57.83, H 4.55, S 9.65, N 4.21; found: C 57.69, H 4.49, S 9.73, N 4.30.

Independent Synthesis and Control Experiments

(i) Synthesis and Reactivity of **7**

To a solution of *Z*-1-phenylpropene (3.42 mmol) in 20 mL of anhydrous methylene chloride was added 3.31 mmol of C_6H_5SeCl, previously dissolved in 5 mL CH_2Cl_2. Upon completion of the reaction this solution was divided into 5 equal parts. In the first case, nothing was done. In the second case was added 5 molar equiv. of NaCl. The third was as above, but with the addition of a catalytic amount of 18-crown-6. The fourth and fifth were as the third and fourth, respectively, but with substitution of NaSCN for NaCl. After 12 h, 1 mL aliquots were worked up (filtration, evaporation of solvent). In samples 1–3 only compounds **7** and **9** were isolated or observed. Samples 4 and 5 gave mixtures of **5**, **6**, **7**, and **9**, although the total amount of **5** + **6** was normally $\leq 5\%$ in experiment 4.

(ii) Synthesis and Reactivity of **8**

A series of experiments were carried out as above with the substitution of *E*-1-phenylpropene for the *Z*-isomer. The work up of subsequent aliquots over a period of 2 weeks showed a gradual isomerization (loss of configurational integrity) between species **3**–**6**. In no case was there observed isomerization between the chlorides except for the known **7** ⇄ **9**; **8** ⇄ **10**.

Synthesis and Reactivity of Z- *and* E-*2-Phenyl-3-methylseleniranium Hexafluorophosphates*

To 0.192 g (1.0 mmol) of benzeneselenenyl chloride in 30 mL CH_2Cl_2 was added 0.118 g of *Z*-1-phenylpropene previously dissolved in 20 mL CH_2Cl_2. To the above was added 0.253 g of $AgPF_6$ (Alfa-Ventron) under nitrogen, followed by filtration under nitrogen to remove the AgCl. The immediate quenching of the filtrate with 0.082 g of NaSCN, previously dried for 24 h, gives the respective adducts in yields of 90% or greater (3*a*).

Received February 16, 1979

DENIS GEORGE KAY, RICHARD FRANCIS LANGLER, and JUNE ELLEN TRENHOLM. Can. J. Chem. 57, 2185 (1979).

The pathway for the aqueous chlorinolysis of a series of β-sulfonyl-sulfides is elucidated and the S_N2 cleavage step examined. Steric effects in the cleavage of the α-polychloro-oxochlorosulfonium chloride intermediates are held to be responsible for the suppression of the established nucleophilic competition between water molecules and chloride ions with the result that all cleavage products arise from nucleophilic attack by chloride ions. This report details the second known example of successful S_N2 displacement on a carbon atom α to a sulfonyl group.

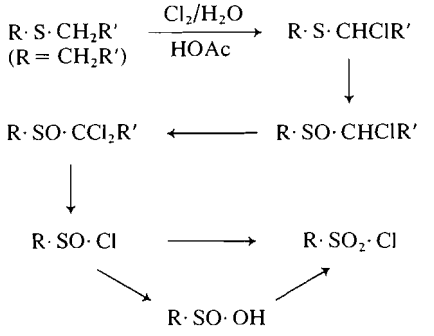
DENIS GEORGE KAY, RICHARD FRANCIS LANGLER et JUNE ELLEN TRENHOLM. Can. J. Chem. 57, 2185 (1979).

On a étudié les chemins réactionnels impliqués lors de la scission d'une série de β-sulfonyl-sulfures sous l'influence du chlore et on a examiné l'étape de clivage S_N2. On croit que des effets stériques dans le clivage d'intermédiaires chlorure d'α-polychloro-oxo-chlorosulfonium sont responsables de la suppression de la compétition nucléophile bien établie entre les molécules d'eau et les ions chlorures qui donne lieu au fait que tous les produits de clivages proviennent d'une attaque nucléophile par les ions chlorures. Dans ce travail, on donne les détails du deuxième exemple d'une substitution S_N2 réussie sur un atome de carbone en α d'un groupe sulfonyle.

[Traduit par le journal]

Introduction

As a part of our program to study the chlorination of sulfur compounds (1–10), we have recently published details which support a generalized pathway for the conversion of dialkyl sulfides into sulfonyl chlorides (5). The generalized pathway was called the sulfohaloform reaction (*vide* Scheme 1).



SCHEME 1. The sulfohaloform reaction

The intermediate α-polychloro-oxochlorosulfonium chloride salts were shown (5) to undergo three competing processes, viz. (*i*) cleavage by nucleophilic attack of water molecules on the chlorine-bearing carbon α to the sulfonium sulfur atom, (*ii*) cleavage by nucleophilic attack on the same carbon atom by chloride ions, and (*iii*) Pummerer rearrangement to furnish another α-polychlorosulfoxide. These competing processes are presented for trichloromethyl methyl sulfoxide in Scheme 2.

TABLE 1.* Relative percentages of oxochlorosulfonium chloride cleavage by competing nucleophiles

Sulfoxide precursors	Nucleophile (%)	
	H_2O	Cl^-
$ClCH_2SOCH_3$	0	0
$Cl_2CHSOCH_3$	100	0
Cl_3CSOCH_3	86	14
Cl_3CSOCH_2Cl	71	29
$ClCH_2SOCH_2Cl$	0	0
$Cl_2CHSOCH_2Cl$	84	16
Cl_3CSOCH_2Cl	71	29

*Data calculated from previously published results (5).

Flow charts were detailed (5) defining the balance between the competing processes when the di- and trichlorodimethyl sulfoxides were converted into methane and chloromethane sulfonyl chlorides. Table 1 presents the relative percentages of the cleavage products from the oxochlorosulfonium chloride salts[2] (derived from the sulfoxides listed) induced by nucleophilic attack of water molecules and chloride ions.

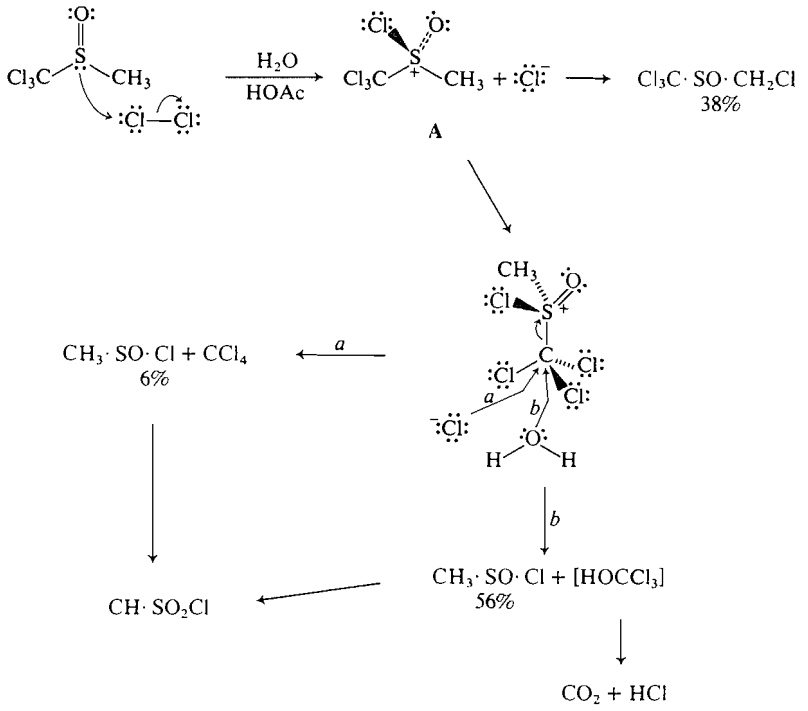
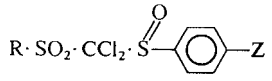


SCHEME 2

From the data in Table 1, we have tentatively inferred that increasing incorporation of bulky chlorine atoms in the oxochlorosulfonium chloride intermediates hinders nucleophilic attack by water molecules substantially more than nucleophilic attack by chloride ions. In order to test this point experimentally, we have undertaken the preparation of systems which would (*i*) provide even more crowded α-polychloro-oxochlorosulfonium chloride intermediates and (*ii*) structurally preclude complicating Pummerer rearrangements. We have chosen to meet these objectives with substrates of the type shown below:



For some time, it was believed that leaving groups attached to a sulfonyl-bearing carbon atom could not be displaced (11–19). The lack of reactivity for these systems was ascribed to "the repulsion of the nucleophilic species by the negative field of the sulfonyl oxygen atoms" (17). An examination of models led to the conclusion that a mesyl group[3] would have "only a small steric effect, unless it is assumed that the partial negative charge on the oxygen atoms would greatly extend their effective radius" (15).

Later, the surprising report of Robson *et al.* (20) documented, without comment, the successful displacement of the chlorine atom of chloromethyl methyl sulfone by mercaptide anions. This reaction was subsequently exploited for synthetic purposes (8, 21) and formed the basis for a more extensive investigation of nucleophilic displacements involving chlorinated sulfones and mercaptide anions (3). Furthermore, an examination of space-filling models convinced us that a mesyl group is very similar in volume to a tertiary butyl group and that the analogy of the mesylmethyl group with the neopentyl group, first suggested and discarded by Bordwell (15), is a very good one. It appeared, at least tentatively, that the assumption of nucleophilic repulsion by sulfonyl oxygen atoms might be unnecessary to account for the known chemistry. In this connection, it is interesting to note that di-*tert*-butyl-methanesulfinyl chloride could not be converted to the corresponding sulfonyl chloride, even under forcing conditions (22). Such an observation might well be a consequence of the crowding necessary to introduce a bulky chlorosulfonyl group into an already crowded molecule.

Results and Discussion

Our previous study (5) established two modes of behaviour for chlorosulfonium chloride salts generated in aqueous media, i.e., (*i*) dialkyl chlorosulfonium chloride salts are very resistant to hydrolysis

[3]Mesyl is an abbreviation of methylsulfonyl.

TABLE 2. Chlorinolysis of 0.1 g $CH_3SO_2CH_2SPh$ (**1***a*)

Volume of Cl_2/H_2O* (mL)	$CH_3SO_2CH_2SPh$ (%)	$CH_3SO_2CH_2SOPh$ (%)	$CH_3SO_2CHClSOPh$ (%)	$CH_3SO_2CCl_2SOPh$ (%)
1.5	90	10	0	0
3	80	15	2	3
6	47	21.2	14.3	17.5
9	21	31	21	26

*H_2O was saturated with Cl_2 at ambient temperature.

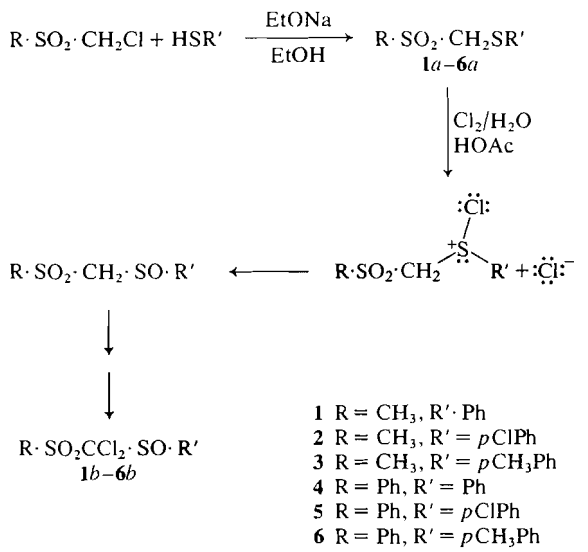
and react essentially exclusively by Pummerer rearrangement (1*b*) and (*ii*) α-chlorodialkyl chlorosulfonium chloride salts undergo quantitative hydrolysis with essentially no Pummerer rearrangement as shown in Scheme 1.

A priori, either reaction could be advanced as the first step in the pathway for the aqueous chlorinolyses of the sulfone-sulfides **1***a*–**6***a*, since (*i*) the sulfonyl methyl groups are substantially more electron withdrawing than a chloromethyl group[4] and therefore should enhance the electrophilicity of the sulfonium sulfur atom, thus facilitating hydrolysis of the chlorosulfonium chloride salts derived from **1***a*–**6***a*, and (*ii*) the sulfonyl methyl groups greatly enhance the acidity of the protons adjacent to the sulfonium sulfur atom and consequently might be expected to enhance the rate of the elimination step by which the sulfenium ion (Pummerer intermediate (1*b*)) forms.

The results of a series of controlled chlorinolyses of **1***a* are presented in Table 2. These results establish that the first formed chlorosulfonium chloride salt undergoes hydrolysis preferentially and that further products arise through the intermediacy of the unchlorinated sulfone-sulfoxide. Larger amounts of chlorine furnished the corresponding α,α-dichlorosulfoxide **1***b*. Scheme 3 presents the synthesis and pathway for the reactions which provided the dichlorosulfone-sulfoxides **1***b*–**6***b*. The structure of **1***b* was confirmed by converting a sample into the corresponding dichlorodisulfone (**1***d*). The disulfone **1***d* was shown to be identical to a sample prepared by oxidation of the dichlorosulfone-sulfide **1***c*.

Exhaustive chlorinolysis of the dichlorosulfone-sulfoxides **1***b*–**6***b* furnished an equimolar mixture of the appropriate trichloromethyl sulfone and sulfonyl chloride shown in Table 3. Nucleophilic attack by water molecules at the carbon atom of the dichloromethylene group in the intermediate oxochlorosulfonium chloride would result in the formation of an intermediate hydroxydichloromethyl sulfone. Such a compound would be expected to eliminate

[4]Pauling electronegativities: X_p ($ClCH_2$) = 2.47, X_p ($CH_3SO_2CH_2$) = 2.85, and X_p ($PhSO_2CH_2$) = 2.75 (1*b*, 23).



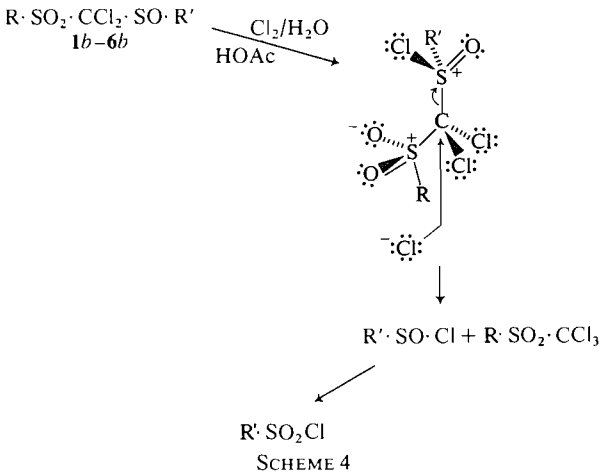
SCHEME 3

HCl, hydrolyze, decarboxylate, and react with molecular chlorine to furnish the appropriate sulfonyl chloride, e.g., this sequence in the case of **1***b* would result in the formation of methanesulfonyl chloride. In no case was there any detectable sulfone-derived sulfonyl chloride present in the product mixture. Consequently the only nucleophiles to attack at the central carbon atom in the oxochlorosulfonium chlorides derived from **1***b*–**6***b* were chloride ions. Scheme 4 presents a rationale for the formation of the observed products.

TABLE 3. Yields* of sulfones and sulfonyl chlorides from exhaustive aqueous chlorinolyses of **1***b*–**6***b*

Substrate	Products: RSO_2Cl (% yield)	Products: $R'SO_2CCl_3$ (% yield)
1*b*	R = Ph (80)	R' = CH_3 (78)
2*b*	R = *p*Cl—Ph (80)	R' = CH_3 (80)
3*b*	R = *p*CH_3Ph (75)	R' = CH_3 (83)
4*b*	R = Ph (86)	R' = Ph (90)
5*b*	R = *p*ClPh (72)	R' = Ph (78)
6*b*	R = *p*CH_3Ph (83)	R' = Ph (81)

*For mechanism see Scheme 4.



SCHEME 4

We have previously observed (5) a difference in the overall rate of reaction for the aqueous chlorinolysis of chloromethyl phenyl sulfide (product: benzenesulfonyl chloride; relative rate: 1) and the aqueous chlorinolysis of chloromethyl methyl sulfide (product: methanesulfonyl chloride, relative rate: 6.5). The slower reaction for the phenyl sulfide was attributed to an electron-donating effect from the phenyl group which would reduce the electrophilicity of the sulfonium sulfur atom in the oxochlorosulfonium chloride intermediate. However, a comparison of the overall rate of the chlorinolysis of the mesyl dichlorosulfoxide **1***b*, and the rate of chlorinolysis of phenyl trichloromethyl sulfoxide (5) indicates that **1***b* reacts some 22.3 times slower. This difference cannot be attributed to an electronic effect originating with the phenyl group. One might then examine the possible role of the mesyl group in terms of the effect of sulfonyl oxygen atoms on approaching nucleophiles, as outlined earlier. Clearly, if the sulfonyl oxygen atoms offer a 'negative field' they would repel incoming chloride ions much more than incoming water molecules. Since cleavage by nucleophilic attack at the central carbon atom occurs exclusively by the agency of chloride ions we conclude that the effect of the mesyl group is not a special electronic effect but rather a more familiar steric effect.

In order to determine the relative sizes of chloride ions and water molecules, we have made accurate scaled drawings of each species. The somewhat remarkable conclusion was that there is essentially no difference in the cross-sectional area of a chloride ion and a water molecule. The most likely reason for the superior nucleophilicity of chloride ions lies with the greater polarizability of these nucleophiles. An interesting alternative or additional consideration arises from an overview of S_N2 displacements of leaving groups α to sulfonyl groups.

The successful displacement of the sulfinyl chloride group by chloride ions represents the second known case of an S_N2 displacement α to a sulfonyl group. Both nucleophiles, viz. chloride ions and mercaptide ions, which have been effective in accomplishing these displacements involve third-row nucleophiles. An intriguing possibility is that of a complexing interaction between these nucleophiles and the adjacent sulfonyl sulfur atom. We have recently proposed such an interaction in order to rationalize a novel thiolester hydrolysis (1*a*).

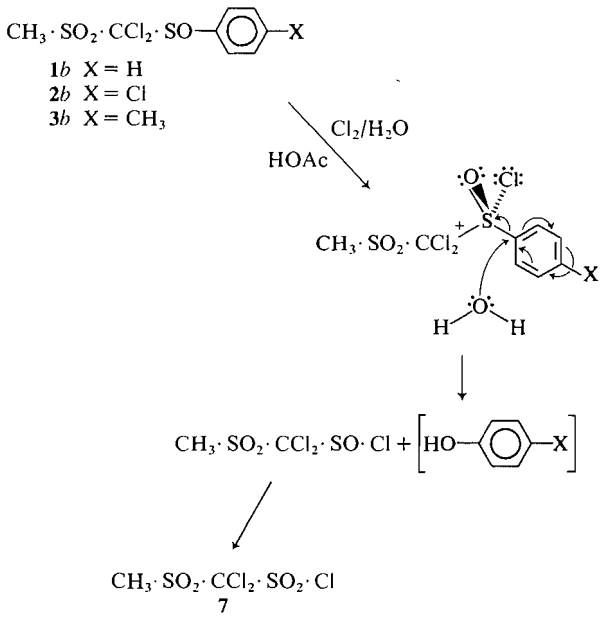
The chlorinolyses of the sulfone-sulfoxides **1***b*–**3***b* resulted in the formation of a minor product (ca. 5%) which gave rise to a singlet in the nmr of the crude at δ 3.50. Thin layer chromatography, visualized with NaI–acetone (7), showed the presence of a compound at R_f 0.50. These properties are in accord with the presence of $CH_3SO_2CCl_2SO_2Cl$ (7) which we have characterized previously (8). Furthermore, column chromatography furnished dichloromethyl methyl sulfone which was absent in the crude reaction mixture.

Dichloromethyl methyl sulfone is the known hydrolysis product obtained from $CH_3SO_2CCl_2$-SO_2Cl (3, 8). Chromatography has been shown to furnish substantial hydrolysis of a close structural relative of 7 (7).

It appears that the severe crowding in the oxochlorosulfonium chloride salts derived from **1***b*–**3***b* has succeeded in diverting some nucleophilic attack to the phenyl ring. Attack at the less crowded centre would presumably be carried out by water molecules. A rationale for this process is presented in Scheme 5. The preceding account details the first evidence that nucleophilic attack can be diverted from the chlorine-bearing carbon atom in the cleavage of α-polychloro-oxochlorosulfonium chlorides.

A consequence of the results reported in this paper is that methylsulfonyl groups have potential application in the design of molecules intended for the study of steric effects on chemical reactions. A feature worth noting is the great facility with which they may be introduced into substrates, a feature which they do not share with the ubiquitous tertiary butyl group. A potentially useful property of these groups is their destablization of nearby carbocationic centres (24) which would permit studies of S_N2 cleavages without facilitating S_N1 processes.

In conclusion, a study of sulfonyl substituted α-polychlorosulfoxide chlorinations has shown that the corresponding oxochlorosulfonium chlorides undergo cleavage in which steric factors favor nucleophilic attack by chloride ions and disfavor nucleophilic attack by water molecules. The results obtained are inconsistent with the view that the adjacent sulfonyl groups offer a 'negative field'



SCHEME 5

which repels nucleophiles. Finally, the substantial crowding achieved in the transition state has shifted a small amount of the nucleophilic attack to the less crowded carbon attached to the sulfonium sulfur atom.

Experimental

General

The ir spectra were recorded on a Perkin Elmer 237B grating spectrophotometer. The nmr spectra were obtained on a Varian T-60 instrument using TMS as the internal standard. The mass spectra were recorded on a Dupont-CEC model 21-104 mass spectrometer. The samples were directly introduced using an all glass probe and the spectra run at 30 eV with a source temperature of 150°C. Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected.

Preparation of Sulfone-sulfides ***1***a–***6***a

Sodium metal (1 equiv.) was dissolved in absolute ethanol (100 mL) and the appropriate mercaptan (1 equiv.) added. Chloromethyl phenyl sulfone (25) or chloromethyl methyl sulfone (26) (10 g) was added and the reaction mixture refluxed for 24 h. Water (100 mL) was added and the resultant mixture was washed with chloroform (3 × 100 mL aliquots). The organic layers were combined, dried ($MgSO_4$), filtered, concentrated, and the residue recrystallized from 95% ethanol.

$CH_3SO_2CH_2SPh$ **1***a* (9.413 g, mp 47–49°C); ir ($CHCl_3$): 1320 and 1145 cm^{-1}; nmr ($CDCl_3$) δ: 7.36 (5H, m), 4.23 (2H, s), and 2.93 (3H, s); ms *m/e*: 202 (M^+, 4.7%), 123 (86%), and 45 (100%).

p-$ClPhSCH_2SO_2CH_3$ **2***a* (15.88 g, mp 105–106°C); ir ($CHCl_3$): 1320 and 1145 cm^{-1}; nmr ($CDCl_3$) δ: 7.43 (4H, pseudo-quartet), 4.17 (2H, s), and 2.97 (3H, s); ms *m/e*: 238 (1.8%), 236 (M^+, 5.7%), 159 (33.3%), 157 (100%), and 45 (80%).

p-$CH_3PhSCH_2SO_2CH_3$ **3***a* (14.67 g, mp 63.5–65°C); ir ($CHCl_3$): 1320 and 1140 cm^{-1}; nmr ($CDCl_3$) δ: 7.37 (4H, pseudo-quartet), 4.20 (2H, s), 2.90 (3H, s), and 2.33 (3H, s); ms *m/e*: 216 (M^+, 10.3%), 137 (100%), and 45 (41.5%).

$PhSO_2CH_2SPh$ **4***a* (11.00 g, mp 56–58°C); ir ($CHCl_3$): 1320 and 1140 cm^{-1}; nmr ($CDCl_3$) δ: 7.66 (10H, m) and 4.40 (2H, s); ms *m/e*: 264 (M^+, 7.3%), 123 (100%), and 45 (30%).

p-$ClPhSCH_2SO_2Ph$ **5***a* (11.88 g, mp 67–69°C); ir ($CHCl_3$): 1320 and 1145 cm^{-1}; nmr ($CDCl_3$) δ: 7.57 (9H, m) and 4.30 (2H, s); ms *m/e*: 300 (2.2%), 298 (M^+, 6.6%), 159 (33.3%), 157 (100%), and 45 (40%).

p-$CH_3PhSCH_2SO_2Ph$ **6***a* (11.10 g, mp 83–85°C); ir ($CHCl_3$): 1320 and 1145 cm^{-1}; nmr ($CDCl_3$) δ: 7.40 (9H, m), 4.30 (2H, s), and 2.26 (3H, s); ms *m/e*: 141 (58%), 91 (33%), and 77 (100%).

Preparation of $CH_3SO_2CCl_2SPh$ (***1***c)

The sulfone-sulfide **1***a* (1.000 g) was dissolved in carbon tetrachloride (20 mL) and Cl_2 (ca. 200 mL/min) was bubbled into the solution for 20 min. The solvent was evaporated and the residue recrystallized from 95% ethanol affording **1***c* (1.176 g, mp 53–54°C); ir ($CHCl_3$): 1320 and 1145 cm^{-1}; nmr ($CDCl_3$) δ: 7.66 (5H, m) and 3.50 (3H, s); ms *m/e*: 195 (14%), 193 (69%), 191 (100%), 109 (34%), and 77 (44%).

Preparation of $CH_3SO_2CCl_2SO_2Ph$ (***1***d)

The dichlorosulfone-sulfide **1***c* (0.5002 g) was oxidized with chromium trioxide in glacial acetic acid in standard fashion (3). The crude dichlorodisulfone was recrystallized from 95% ethanol (0.276 g, mp 102–105°C); ir: 1355 and 1152 cm^{-1}; nmr ($CDCl_3$) δ: 7.90 (5H, m) and 3.53 (3H, s); ms *m/e*: 141 (73%), 125 (41%), and 77 (100%).

*Preparation of Dichlorosulfone-sulfoxides (****1***b–***6***b)

The desired sulfone-sulfide (**1***a*–**6***a*) (5.00 g) was added to a solution of glacial acetic acid (25 mL) and water (5 mL). Cl_2 (ca. 200 mL/min) was bubbled into the reaction mixture for 0.5 h. During the chlorination the product precipitates from solution. Upon completion of the chlorination water (50 mL) and methylene chloride (100 mL) were added. The layers were separated and the organic layer washed with 2.5% w/v NaOH (2 × 50 mL aliquots), dried ($MgSO_4$), filtered, and the solvent evaporated. The residue was recrystallized from 95% ethanol affording the following compounds.

$CH_3SO_2CCl_2SO·Ph$ **1***b* (5.284 g, mp 149–151°C); ir ($CHCl_3$): 1345, 1150, and 1080 cm^{-1}; nmr ($CDCl_3$) δ: 7.77 (5H, m) and 3.46 (3H, s); ms *m/e*: 290 (0.1%), 288 (0.6%), 286 (M^+, 1%), 125 (100%), 109 (39%), and 77 (43%). *Anal.* calcd. for $C_8H_8Cl_2O_3S_2$: C 33.45, H 2.80; found: C 33.07, H 2.91.

p-$ClPhS(O)CCl_2SO_2CH_3$ **2***b* (5.353 g, mp 84–86°C); ir ($CHCl_3$): 1340, 1145, and 1080 cm^{-1}; nmr ($CDCl_3$) δ: 7.73 (4H, pseudo-quartet) and 3.50 (3H, s); ms *m/e*: 229 (2.2%), 227 (5.7%), 225 (5.7%), 161 (33.3%), and 159 (100%). *Anal.* calcd. for $C_8H_7Cl_3O_3S_2$: C 29.87, H 2.19; found: C 29.95, H 2.15.

p-$CH_3PhS(O)CCl_2SO_2CH_3$ **3***b* (5.150 g, mp 145–147°C); ir ($CHCl_3$): 1345, 1150, and 1085 cm^{-1}; nmr ($CDCl_3$) δ: 7.73 (4H, pseudo-quartet), 3.50 (3H, s), and 2.53 (3H, s); ms *m/e*: 139 (100%), 91 (27.5%), and 45 (12.5%). *Anal.* calcd. for $C_9H_{10}Cl_2O_3S_2$: C 35.88, H 3.34; found: C 35.83, H 3.14.

$PhSO_2CCl_2·SO·Ph$ **4***b* (4.894 g, mp 134–136°C); ir ($CHCl_3$): 1350, 1150, and 1090 cm^{-1}; nmr ($CDCl_3$) δ: 7.80 (m); ms *m/e*: 141 (36%), 125 (64%), 109 (48.6%), and 77 (100%). *Anal.* calcd. for $C_{13}H_{10}Cl_2O_3S_2$: C 44.70, H 2.88; found: C 44.82, H 2.57.

p-$ClPhS(O)CCl_2SO_2Ph$ **5***b* (3.870 g, mp 115–117°C); ir ($CHCl_3$): 1350, 1150, and 1095 cm^{-1}; nmr ($CDCl_3$) δ: 7.83 (m); ms *m/e*: 161 (33.3%), 159 (100%), 141 (43.6%), and 77 (65.9%). *Anal.* calcd. for $C_{13}H_9Cl_3O_3S_2$: C 40.69, H 2.36; found: C 40.47, H 2.42.

p-$CH_3PhS(O)CCl_2SO_2Ph$ **6***b* (4.563 g, mp 140–141°C); ir ($CHCl_3$): 1350, 1150, and 1095 cm^{-1}; nmr ($CDCl_3$) δ: 7.70

(9H, m) and 2.46 (3H, s); ms *m/e*: 139 (100%), 91 (16.6%), and 77 (26.8%). *Anal.* calcd. for $C_{14}H_{12}Cl_2O_3S_2$: C 46.28, H 3.32; found: C 46.01 and H 3.49.

Preparation of $Ph{\cdot}SO{\cdot}CH_2SO_2CH_3$ *1*e

The sulfone-sulfide **1***a* (1.002 g) was dissolved in a solution of 30% H_2O_2 (0.568 g) in dioxane (25 mL). The reaction mixture was refluxed for 0.75 h. The solvent was evaporated and the residue recrystallized from 95% ethanol, (0.815 g, mp 88–90°C); ir ($CHCl_3$): 1320, 1140, and 1045 cm^{-1}; nmr ($CDCl_3$) δ: 7.60 (5H, s), 4.20 (1H, d, J = 3 Hz), 4.13 (1H, d, J = 3 Hz) (26), and 3.23 (3H, s); ms *m/e*: 218 ($M^{\ddagger}$, 10.9%), 125 (100%), 109 (23.1%), and 77 (32.9%). *Anal.* calcd. for $C_8H_{10}O_3S_2$: C 44.01, H 4.61; found: C 43.89, H 4.21.

Controlled Aqueous Chlorinolysis of *1*a

A series of chlorinolyses of **1***a* were conducted and the results are tabulated in Table 2. Details below are provided for the run from which products were isolated.

The sulfone-sulfide **1***a* (0.100 g) was dissolved in glacial acetic acid (75 mL) and distilled water (9 mL). Water (9 mL) which had been saturated with Cl_2 at ambient temperature was added and the reaction mixture stirred at room temperature for 0.5 h. Water (150 mL) was added and the reaction mixture washed with chloroform (300 mL). The organic layer was washed with 2.5% w/v NaOH (3 × 100 mL aliquots), dried, and concentrated. The residue showed four spots on analytical tlc (chloroform development). The nmr of the crude indicated the presence of **1***a* (21%), the corresponding sulfone sulfoxide (**1***e*) (31%), $CH_3SO_2CHClS(=O)Ph$ (21%), and **1***b* (26%). The mixture was run on preparative tlc, developed with $CHCl_3$–Et_2O (1:1). The band at R_f 0.27 was scraped and washed with $CHCl_3$ (60 mL) affording **1***e* which was identical with authentic material by nmr, ir, and tlc. The band at R_f 0.57 was handled in the same way and furnished a mixture of **1***a* and another compound. The identity of **1***a* was confirmed by tlc and addition of authentic material which caused the expected change in the appropriate signals in the nmr of the mixture. Subtraction of the signals due to **1***a* from the nmr of the mixture left the spectrum δ: 7.50 (5H, m), 5.17 (1H, s), and 3.23 (3H, s). On this basis the second compound in the mixture was assigned the monochlorosulfone-sulfoxide structure shown above. The band at R_f 0.81 was processed as described above, and afforded **1***b* which was identical with authentic material by nmr, ir, and tlc.

Oxidation of *1*b

The dichlorosulfone-sulfoxide **1***b* (0.500 g) was oxidized to the dichlorodisulfone **1***d* in the same way described for the oxidation of **1***c*. After recrystallization, the disulfone (0.350 g) was shown to be identical to authentic disulfone by ir, nmr, mp, and mixture mp.

Exhaustive Chlorination of *1*b–*6*b

Exhaustive chlorinations of the dichlorosulfone-sulfoxides **1***b*–**6***b* were carried out as illustrated by the details provided below for the reaction on **2***b*. Results for these systems appear in Table 3.

The sulfone-sulfoxide **2***b* (0.500 g) was dissolved in glacial acetic acid (75 mL) and water (18 mL) added. Cl_2 (ca. 200 mL/min) was bubbled into the reaction mixture for 8 h. Water (150 mL) was added and the resultant mixture washed with methylene chloride (3 × 100 mL aliquots). The combined organic layers were washed with 2.5% w/v NaOH (3 × 100 mL aliquots). The organic layer was dried and concentrated.

The residue was chromatographed on silica gel (50 g) employing carbon tetrachloride elution (50 mL aliquots). Fractions 4–9 were combined and concentrated affording *p*-chlorobenzenesulfonyl chloride (0.262 g) which was identical to authentic material by ir, nmr, ms, and tlc. Fractions 40–60 were combined and concentrated furnishing trichloromethyl methyl sulfone (0.245 g) which was identical to authentic material (27). Fraction 95 contained dichloromethyl methyl sulfone (0.015 g) which was identical to authentic material by ir, nmr, and mp (27).

Received February 26, 1979

FRANK E. HRUSKA, JAMES G. DALTON, and MIECZYSLAW REMIN. Can. J. Chem. 57, 2191 (1979).

A high resolution proton magnetic resonance spectrum for 2,2′-anhydro-O^2-β-D-arabinosyluracil in aqueous solution at 80°C is presented. The spectrum provides evidence for the presence of long-range four-bond ($^4J_{1'3'}$, $^4J_{1'4'}$, $^4J_{2'4'}$) and five-bond ($^5J_{1'5'}$, $^5J_{1'5''}$, $^5J_{2'5'}$, $^5J_{2'5''}$) coupling interactions involving the furanose hydrogens. The ^5J data represent the first reported evidence for the presence of coupling interactions involving the anomeric proton and exocyclic $C_{5'}$ protons in a furanose system. The relative signs of the ^4J and ^5J couplings were determined by double resonance methods. The ^4J and ^5J interactions are discussed using crystallographic data and the theory of long-range couplings.

FRANK E. HRUSKA, JAMES G. DALTON et MIECZYSLAW REMIN. Can. J. Chem. 57, 2191 (1979).

On rapporte les spectres de résonance magnétique à haute résolution de l'anhydro-2,2′ O^2-β-D-arabinosyluracile en solution aqueuse à 80°C. Le spectre fournit des preuves de la présence d'interactions de couplage à longue distance à travers quatre liaisons ($^4J_{1'3'}$, $^4J_{1'4'}$, $^4J_{2'4'}$) et cinq liaisons ($^5J_{1'5'}$, $^5J_{1'5''}$, $^5J_{2'5'}$, $^5J_{2'5''}$) impliquant les hydrogènes du furannose. Les données de ^5J représentent les premières preuves rapportées concernant l'existence d'interactions de couplage impliquant un proton anomère et les protons $C_{5'}$ exocycliques dans un système furannose. On a déterminé les signes relatifs des couplages ^4J et ^5J par des méthodes de double résonance. On discute des interactions ^4J et ^5J en faisant appel à des données cristallographiques et à la théorie des couplages à longue distance.

Introduction

The appearance of long-range spin–spin coupling interactions involving the hydrogens of a furanose system has been of interest since Hall and coworkers (1) noted that such systems can exhibit an extensive array of ^4J and ^5J H—H couplings which undoubtedly contributed to spectral broadening beyond the 'natural' linewidths. In early 100 MHz studies of the anhydronucleoside, 2,2′-anhydro-O^2-β-D-arabinosyluracil[2] (aU) (Fig. 1), evidence for the presence of the four-bond couplings $^4J_{1'3'}$, $^4J_{1'4'}$, and $^4J_{2'4'}$ was reported for aU in D_2O solution (2–4). Analogous coupling interactions are also apparent in the spectra of several purine nucleosides in liquid ND_3 (5). In more recent 100 and 250 MHz studies on aU in aqueous and DMSO solution (6, 7) long-range coupling interactions were not observed and in fact the presence of these interactions was questioned (6).

In this work we discuss ^{1}H nmr evidence for the appearance of the five-bond ($^5J_{1'5'}$, $^5J_{1'5''}$, $^5J_{2'5'}$, $^5J_{2'5''}$) coupling interactions as well as the four-bond ($^4J_{1'3'}$, $^4J_{1'4'}$, $^4J_{2'4'}$) interactions involving the furanose hydrogens in aU. The five-bond couplings are particularly interesting since they are, to the best of our knowledge, the first reported examples

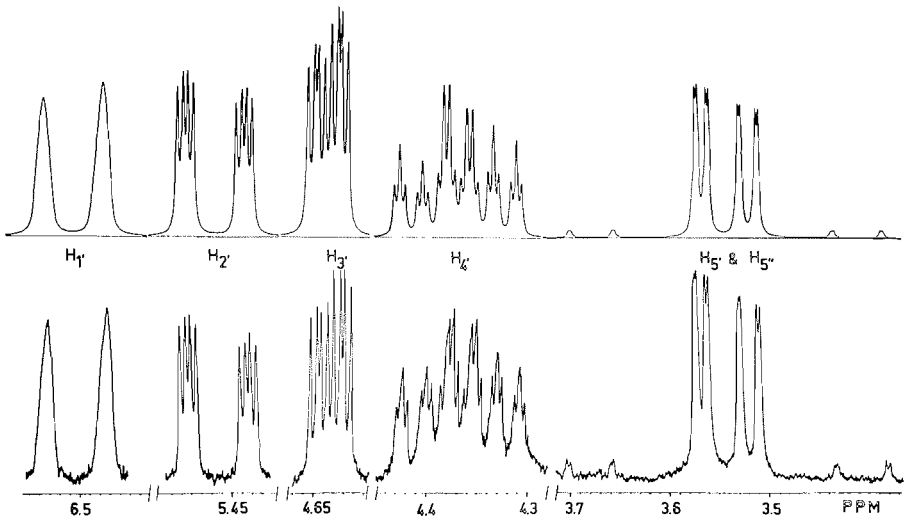

FIG. 2. (*a*) Single scan, continuous wave 100 MHz spectrum of the ribose protons of aU (0.2 *M* in D_2O, pD = 7.0, 80°C). (*b*) Computer simulated spectrum.

of coupling interactions of the anomeric $H_{1'}$ and $H_{2'}$ protons with the exocyclic hydroxymethyl protons in a furanoside. Analogous five-bond coupling between the anomeric hydrogen and the exocyclic methylene hydrogens in pyranoside systems has been suggested by Lemieux *et al.* (8).

Experimental

Samples of aU were obtained from Dr. K. K. Ogilvie and from Terra Marine Bioresearch, California, and used without further purification. The quality of the spectra obtained indicates the absence of significant amounts of paramagnetic impurities (see Fig. 2). DSS was used as an internal nmr reference. Samples were thrice freeze-dried and finally dissolved in 100% D_2O (final concentration ca. 0.2 *M*). The pD of the solution was adjusted to 7.0 ± 0.1 with DCl and NaOD. Spectra were obtained on Bruker WH-90DS and Varian HA-100 spectrometers. The calibration of spectra and double resonance experiments were carried out by standard methods. Spectral analyses were carried out using LAME (9). Computer-stimulated spectra were generated as a test of the chemical shift (δ) and coupling constant (*J*) data. Since our discussion will be restricted to the *J* data, only these are given in Table 1; the δ data have been presented elsewhere (10). Decomposition of aU, presumably by hydrolysis to arabinouridine, was observed at 80°C, but caused no difficulties since the spectra could be accumulated quickly at the concentrations used.

Results and Discussion

Spectra

The 100 MHz spectrum (80°C) of the sugar protons of aU is shown in Fig. 2 accompanied by a computer-generated spectrum. The spectrum is quite unlike nucleoside spectra reported in the literature (those for anhydronucleosides included (6, 7)), showing clearly an extensive array of small splittings which can be attributed to long-range (^4J,^5J) H—H coupling constants. For example, the complex $H_{4'}$ band (4.36 ppm) with 20 discernible lines is completely accounted for by the three vicinal couplings ($^3J_{3'4'}$, $^3J_{4'5'}$, $^3J_{4'5''}$) and a pair of four-bond interactions, $J_{1'4'}$(−0.52 Hz) and $J_{2'4'}$(+0.55 Hz). The sign of $^4J_{2'4'}$ was determined by selective irradiation of the $H_{3'}$ band, while the $H_{2'}$ resonances were being observed. In Fig. 3 are illustrated the results of weak irradiation experiments which demonstrate that $^4J_{1'4'}$ is negative, i.e., of opposite sign to $^4J_{2'4'}$. A series of weak irradiating fields was applied at 0.10 Hz intervals to one, or the other, of the broad $H_{1'}$ bands at 6.53 and 6.47 ppm while the $H_{2'}$ quartets were recorded. As the perturbing field was stepped through the bands towards *high field*, the point of maximum perturbation in the $H_{2'}$

TABLE 1. Proton coupling constants (Hz)[a] for 0.2 *M* 2,2′-anhydro-O^2-β-D-arabinosyluracil in D_2O (pD = 7.0)

J[b]	5°C	30°C	80°C
$^3J_{56}$	7.4	7.4	7.4
$^3J_{1'2'}$	6.0	5.9	5.8
$^3J_{2'3'}$	0.7	0.8	1.0
$^3J_{3'4'}$	1.8	1.9	2.3
$^3J_{4'5'}$	2.9	3.3	4.2
$^3J_{4'5''}$	4.7	4.9	5.1
$^2J_{5'5''}$	(−13.9)[c]	−13.5	−12.6
$^4J_{1'3'}$	−0.81	−0.75	−0.64
$^4J_{1'4'}$	−0.32	−0.36	−0.42
$^4J_{2'4'}$	0.54	0.54	0.55

$^5J_{1'5''}$	[d]	[d]	0.33
$^5J_{2'5'}$	[d]	[d]	0.05–0.1
$^5J_{2'5''}$	[d]	[d]	0.05–0.1

[a]Estimated error < 0.1 Hz.
[b]Signs were determined at 80°C only.
[c]Not observable since $H_{5'}$ and $H_{5''}$ are isochronous at 5°C. Obtained by extrapolation of 30 and 80°C values.
[d]Not observable.

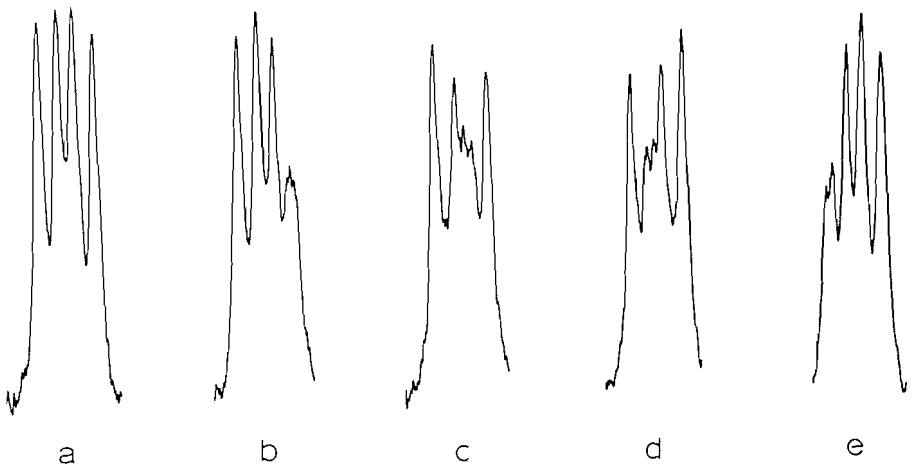

FIG. 3. Low-field $H_{2'}$ quartet (5.04 ppm): (*a*) unperturbed by second irradiating field; (*b–e*) with weak irradiation of the low-field $H_{1'}$ band (6.54 ppm) at 653.68, 653.25, 652.99, and 652.60 Hz respectively. As the perturbing field is stepped towards *high* field, the point of maximum perturbation in the $H_{2'}$ quartet progresses towards *low* field. This pattern of changes indicates that $J_{1'4'}$ and $J_{2'4'}$ have opposite signs, i.e., $J_{1'4'}$ is negative.

quartets progressed uniformly towards *low* field. For example, Fig. 3*a* shows the *unperturbed* low-field $H_{2'}$ quartet at 5.04 ppm while Figs. 3*b*–3*e* show the influence of perturbing fields at 653.68, 653.25, 652.99, 652.60 Hz, respectively. With these careful experiments the progression of the perturbation towards low field is unmistakable. It is a simple matter to show with energy level diagrams that this sequence of changes in the $H_{2'}$ quartets is consistent with opposite signs for $J_{1'4'}$ and $J_{2'4'}$, i.e., $J_{1'4'}$ is negative.

The most interesting of the long-range couplings can be observed in the 5′,5″ spectral band at 80°C (Fig. 2). The four intense lines, as well as the satellite lines, show an additional splitting of about 0.3 Hz. In contrast at 5 and 30°C only two broad bands, with no fine structure, are found in the 5′ region indicating that the 5′,5″ protons are nearly isochronous. The increase in temperature has, therefore, increased the $H_{5'}$,$H_{5''}$ relative shift, and this coupled with the improved resolution at 80°C leads to the appearance of the fine structure.

Strong irradiation of the $H_{1'}$ bands leads to a collapse of the fine splittings in the 5′,5″ region, demonstrating that they are due to $^5J_{1'5'}$ and $^5J_{1'5''}$ interactions. On the other hand, when $H_{2'}$ is irradiated with a strong decoupling field, the linewidths in the 5′,5″ band are noticeably reduced and the fine splittings due to $^5J_{1'5'}$,$^5J_{1'5''}$ interactions become more apparent (Fig. 4). This narrowing provides evidence for the presence of ^5J couplings between $H_{2'}$ and *both* the $H_{5'}$ and $H_{5''}$ protons.

A series of careful selective spin-decoupling and spin-tickling experiments, analogous to those used

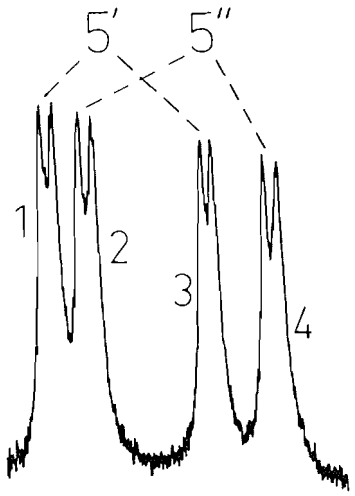

FIG. 4. The strong central resonances of the 5′,5″ band of aU with $H_{2'}$ decoupled (80°C, single scan, 100 MHz).

to determine the signs of $^4J_{2'4'}$ and $^4J_{1'4'}$ (above and Fig. 3), allowed us to determine the signs of the ^5J interactions involving $H_{5'}$, and $H_{5''}$ (all positive). Further details of these experiments are available from the authors upon request.

Double resonance experiments demonstrated that the eight-line $H_{3'}$ band (4.63 ppm) could be attributed to $^3J_{2'3'}$ and $^3J_{3'4'}$ couplings (both positive) and the four-bond interaction $^4J_{1'3'}$ (0.64 Hz and negative). The linewidths in this region are about 0.2 Hz, indicating that ^4J interactions of $H_{3'}$ with $H_{5'}$ and $H_{5''}$ must be less than 0.1 Hz.

Also note (Fig. 2) that the $H_{1'}$ band widths can be reproduced by our spectral simulation which

incorporated the ^4J and ^5J interactions involving $H_{1'}$. Thus, long-range couplings account for the $H_{1'}$ broadening in aU, and undoubtedly contribute to the $H_{1'}$ linewidths for nucleosides in general.

^{3}J *Coupling Constants*

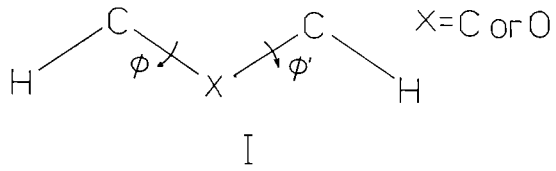
The vicinal couplings $^3J_{1'2'}$, $^3J_{2'3'}$, and $^3J_{3'4'}$ for aU have been discussed elsewhere (2–4, 6, 7, 11) and presented as evidence that the geometry of the furanose ring in solution is similar to that found in the crystal state, i.e., 4′-*endo* (12, 13). Particularly informative are the diminutive *trans* couplings $^3J_{2'3'}$ and $^3J_{3'4'}$ which exhibit, in the 5–80°C interval, ranges of 0.7–1.0 Hz and 1.8–2.3 Hz, respectively, consistent with dihedral angles near 90°. In the crystal two molecules (labelled A and B) are found in the unit cell of aU (12, 13); the observed dihedral angles for $H_{2'}$—$C_{2'}$—$C_{3'}$—$H_{3'}$ and $H_{3'}$—$C_{3'}$—$C_{4'}$—$H_{4'}$ lie in the range 86–96°.

In the crystal state aU assumes the *gauche–trans* conformation about the $C_{4'}$—$C_{5'}$ bond. In solution at 80°C, however, interconversion occurs between the three staggered conformers, with approximately equal populations of each (3, 10).

Not shown in our spectrum is the pair of doublets due to the H_5 and H_6 protons of the base ($^3J_{56}$ = 7.4 Hz). The linewidths in these bands are 0.3 Hz (H_5) and 0.4 Hz (H_6). Hence, long-range interaction $^5J_{1'5}$ and $^5J_{1'6}$ cannot be larger than about 0.1–0.2 Hz. The low value of $^5J_{1'5}$ is consistent with the presence of the *high-syn* conformation about the *N*-glycosyl linkage (12, 13).

^{4}J *Coupling Constants*

^4J H—H couplings in the saturated fragments (I)



I

are known to depend on the ϕ and ϕ' torsion angles, reaching a maximum (positive) value for the all-*trans* ($\phi = \phi' = 180°$) situation (14, 15). Relevant to our discussion of the $^4J_{1'3'}$, $^4J_{2'4'}$, and $^4J_{1'4'}$ are the fragments $H_{1'}$—$C_{1'}$—$C_{2'}$—$C_{3'}$—$H_{3'}$ (114°, 146°)[3], $H_{2'}$—$C_{2'}$—$C_{3'}$—$C_{4'}$—$H_{4'}$ (148°, 146°), and $H_{1'}$—$C_{1'}$—O—$C_{4'}$—$H_{4'}$ (143°, 146°), respectively. Barfield *et al.* (14) have reported the ϕ,ϕ' dependencies of ^4J in propanic fragments (X = C). Using their plots and assuming the crystallographic angles we estimate $^4J_{2'4'}$ = 0.5–1.0 Hz and $^4J_{1'3'} \simeq 0$ Hz. In the former case, agreement with the experimental value (+0.55 Hz) is reasonable, whereas in the latter case the observed coupling (−0.64 Hz) is somewhat smaller than predicted. However, the predicted stereochemical trend (i.e., $J_{2'4'}$ is more positive than $J_{1'3'}$) agrees with the experimental data.

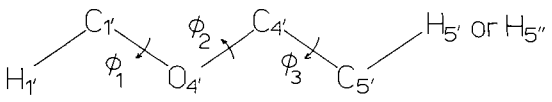
Though the stereochemistry (ϕ,ϕ') of the four-bond fragments of $^4J_{2'4'}$ and $^4J_{1'4'}$ is virtually identical (see above), these couplings differ markedly (+0.55 Hz and −0.42 Hz, respectively). This difference is probably due to the change in the central atom in the fragments. Barfield and co-workers (14) have studied the effect on ^4J of the change X = C to X = O in fragment I, but unfortunately data for only two conformations were reported: $^4J(cis) = {}^4J(120°, 120°)$ and $^4J(trans) = {}^4J(120°, 240°)$. Their calculations predicted that this substitution should lead to more negative values of $^4J(cis)$ and more positive values of $^4J(trans)$, the changes being 0.5–0.6 Hz in an absolute sense. If we can assume that the $^4J_{2'4'}$ and $^4J_{1'4'}$ fragments, with $\phi \simeq \phi' \approx 145°$, are more *cis*-like than *trans*, then we state that calculations of Barfield *et al.* (14) are in reasonable agreement with the observed trend.

^{5}J *Coupling Constants*

The appearance of the $^5J_{1'5'}$ and $^5J_{1'5''}$ splittings in the 80°C spectrum may be a consequence of several factors, one of which must be the high resolution achievable in water solution at this temperature. Also important must be the fact that, except for $H_{5'}$ and $H_{5''}$, the furanose protons form a loosely coupled spin system, the ratio of relative shift to mutual coupling constant being no less than 11.6 (at 100 MHz) for any pair of protons. Of the many nucleosides examined, aU provides the most loosely coupled system. This means that broadening of the $H_{5'}$,$H_{5''}$ resonances due to virtual coupling to $H_{2'}$ and $H_{3'}$ is minimal.

Another reason, perhaps, why we observe $^5J_{1'5'(5'')}$ interactions in aU, while similar interactions have not been reported in normal nucleosides, i.e., those without the anhydro linkage, could lie in the unique geometry of its sugar *rings*. In aU the ring assumes a 4′-*endo* pucker (12, 13), whereas in solution the furanose ring of normal nucleosides pseudorotates between 2′-*endo* and 3′-*endo* conformations (16, 17). Each of the exocyclic protons in a nucleoside is connected to the anomeric proton by a *single* five-bond path (II) which may be considered a butanic fragment (14, 15) with a single oxygen substitution. Alternate six-bond paths through $C_{2'}$ and $C_{3'}$ also connect these nuclei, but these longer paths should

[3]The angles listed in parentheses will refer respectively to ϕ and ϕ'. For example, in the $H_{1'}$—$C_{1'}$—$C_{2'}$—$C_{3'}$—$H_{3'}$ fragment they refer to the torsion angle about $C_{1'}$—$C_{2'}$ (ϕ) and $C_{2'}$—$C_{3'}$ (ϕ') (see Barfield *et al.* (14)). The values are taken from ref. 13.



II

be less important than II. In the 4′-*endo* conformation of crystalline aU (12, 13), the dihedral angles ϕ_1 and ϕ_2 are 143 and 96°, respectively. From the Altona–Sundaralingam analysis of nucleoside crystallographic data (16), we estimate that ϕ_1 is approximately 50 and 25° smaller in the 2′-*endo* and 3′-*endo* conformations, respectively. Thus, ϕ_1(2′-*endo*) $\approx$ 95° and ϕ_1(3′-*endo*) $\approx$ 120°. On the other hand ϕ_2 should be larger in the 2′- and 3′-*endo* conformations, i.e., ϕ_2(2′-*endo*) $\approx$ 120° and ϕ_2(3′-*endo*) $\approx$ 145°.

Theoretical calculations, reviewed by Barfield and Chakrabarti (15), indicate that if the indirect mechanism of ^5J coupling predominates in a butanic fragment, then this coupling should be independent of ϕ_2 but should display a Karplus-like dependence on ϕ_1 (as well as ϕ_3, see below). Now, if this theory can be applied to nucleosides, then from the ϕ_1 values we can predict for $^5J_{1'5'(5'')}$ the following trend: ^5J(4′-*endo*) > ^5J(3′-*endo*) > ^5J(2′-*endo*).

The ^5J interactions in fragment II should depend also on ϕ_3 (which can be 180 or 60° depending on whether the $C_{4'}$—$C_{5'}$ bond is oriented *gauche–gauche*, *gauche–trans*, or *trans–gauche*). However, in solution interconversion occurs between the three staggered conformations, making difficult the evaluation of the influence of this conformational feature on the ^5J couplings.

The electrochemical synthesis of some heteronuclear metal carbonyls

JACOB J. HABEEB, DENNIS G. TUCK, AND SAMUEL ZHANDIRE
Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received January 22, 1979

JACOB J. HABEEB, DENNIS G. TUCK, and SAMUEL ZHANDIRE. Can. J. Chem. **57**, 2196 (1979).

The electrochemical oxidation of zinc, cadmium, or indium in the presence of $Co_2(CO)_8$ or $Mn_2(CO)_{10}$ in an organic solvent gives rise to the appropriate heteronuclear metal carbonyl $M[M'(CO)_n]_m$ (M = Zn, Cd, In; M′ = Co, Mn; n = 4, 5; m = 2, 3). The advantages of this method are discussed, as is the mechanism of the processes which lead to the reaction products.

JACOB J. HABEEB, DENNIS G. TUCK et SAMUEL ZHANDIRE. Can. J. Chem. **57**, 2196 (1979).

L'oxydation électrochimique du zinc, du cadmium et de l'indium en présence de $Co_2(CO)_8$ ou de $Mn_2(CO)_{10}$ dans un solvant organique conduit au métal carbonyle hétéronucléaire approprié $M[M'(CO)_n]_m$ (M = Zn, Cd, In; M′ = Co, Mn; n = 4, 5; m = 2, 3). On discute des avantages de cette méthode de même que du mécanisme du processus qui conduit aux produits de la réaction.

[Traduit par le journal]

Introduction

The synthesis of heteronuclear metal – metal bonded carbonyls of the general formula $M[M'(CO)_n]_m$ and of the adducts $M[M'(CO)_n]_m \cdot L$ has been a subject of some interest in recent years. One of the reasons for this concern is that such compounds involve the bonding of a transition metal M′ to a main group element (M = Sn, Pb; Ga, In, Tl; Zn, Cd, Hg). The first reported preparation (1) involved the reaction of Zn or Cd with $Co_2(CO)_8$ at high temperatures under high pressures of carbon monoxide. Similar methods, but under milder conditions (refluxing diglyme, 120°C, 10 h), have more recently yielded $M[Mn(CO)_5]_2$ (M = Zn, Cd) (2), and milder conditions again suffice for $M[Co(CO)_4]_4$ (M = Sn, Pb) (3). A different approach, first used in this field by Carey and Noltes (4), involves alkane elimination between a metal alkyl R_2M (M = Zn, Cd) and manganese pentacarbonyl hydride, and similar methods have been employed in the preparation of $M[Re(CO)_5]_2$ (M = Zn, Cd) (5). Another source of the transition metal carbonyl moiety is the carbonylate anion, which reacts with $Hg(CN)_2$ to produce $Hg[Re(CO)_5]_2$ (5), or with RHgOH to give $Hg[Mn(CO)_5]_2$ (6).

We now report electrochemical methods by which zinc, cadmium, or indium can be oxidised in the presence of $Mn_2(CO)_{10}$ or $Co_2(CO)_8$ in non-aqueous media to give the appropriate $M[M'(CO)_n]_m$ species. The compound may be recovered directly, but it is equally convenient to isolate the adduct with some neutral bidentate donor such as 2,2′-bipyridine by adding the latter to the electrochemical cell.

Experimental

Materials

The general experimental set-up was identical to that used previously (7). Cadmium (m4N+) and zinc (m4N5) were used in the form of rods (10 cm long and 1 cm diameter), with the lower part hammered flat to increase the surface area. Tin metal was used in the form of a sheet (5 cm × 5 cm × 0.127 mm) supported by a platinum wire lead, as was the indium electrode, made from indium shot hammered into a thin sheet (2 cm × 2 cm). All metals were supplied by Alfa Inorganics. Platinum wire (10 cm long and 1 mm diameter) was used as the cathode in all experiments.

Methanol (analytical grade) was dried over Linde molecular sieves, and benzene, diethyl ether, and petroleum ether (36–55°C bp) over sodium. Dicobalt octacarbonyl and dimanganese decacarbonyl were used without further purification. 2,2′-Bipyridine (bipy) was used as supplied; *N,N,N′,N′*-tetramethylethylendiamine (TMED) was dried over KOH and then distilled under nitrogen.

Electrochemical Procedures

The electrochemical procedures are very similar to those described earlier (7). The metal to be oxidised formed the anode of a simple cell containing a solution of the metal carbonyl in an organic solvent mixture; this solution also contained any neutral bidentate donor. The details of the solution compositions used are shown in Table 1. The applied voltage was 20–50 V, as dictated by the solution conditions, given that a current of 20–50 mA produced a reasonable rate of reaction without overheating the solution (see Table 1). A Coutant 50/50 power supply provided the applied voltage. Tetraethylammonium perchlorate (ca. 10–15 mg) was generally added to enhance the conductivity of the solution, although in those cases in which more methanol than benzene was present, a sufficient current flowed without any ammonium salt being added.

Infrared and nmr spectra were recorded with Beckman IR-12 and Varian EM-360 spectrometers respectively. Mass spectra were obtained on a Varian CH-5 spectrometer operating in the field desorption mode. Metal analysis was by atomic absorption spectrophotometry.

Isolation of Products

We describe the electrochemical preparation of two compounds to illustrate the general method used.

$Cd[Co(CO)_4]_2$

A solution of 0.4 g $Co_2(CO)_8$ in 50 cm^3 methanol was electrolysed for 6 h at a current maintained at approximately 40 mA; the initial voltage of 8 V was adjusted occasionally as (presumably) surface contamination of the electrodes occurred. During this period, the brown solution became pale yellow, and some pink material deposited on the cathode. The mixture was filtered under dry nitrogen, and the resulting filtrate evaporated to dryness *in vacuo* to yield pale yellow crystals. This crude product was sublimed at 80°C *in vacuo* yielding 0.35 g of product, a 65% yield on the basis of 0.2 g of Cd dissolved from the previously weighed anode.

$Cd[Co(CO)_4]_2$·TMED

A mixture of 20 mg Et_4NClO_4, 30 cm^3 of methanol, 30 cm^3 of benzene, 0.3 g of TMED, and 0.6 g of $Co_2(CO)_8$ was electrolysed for 13 h at a current of 25 mA (initial voltage 10 V). The voltage was raised as appropriate to maintain this current. At the end of electrolysis, 0.25 g of cadmium was found to have been dissolved from the anode. The mixture of products was filtered, and a (dried) pink residue (0.3 g) was found to contain 52.1% cobalt; insolubility of this product made characterization impossible. The orange-yellow filtrate was reduced in volume *in vacuo* at ambient temperature to give yellow crystals which were filtered off and dried *in vacuo* for 3 h. The total yield of the yellow product was 1.0 g (74%, based on Cd dissolved).

A list of the compounds prepared and the analytical results are given in Table 2. Field desorption mass spectrometry, which has many advantages in inorganic and organometallic chemistry, was also used to identify the products of the electrochemical reactions. In three cases, namely $Cd[Co(CO)_4]_2$, $Cd[Mn(CO)_5]_2$·bipy, and $In[Co(CO)_4]_3$, a molecular ion was observed, and in all other cases ions such as $M[M'(CO)_n]_2^+$, or $LM[M'(CO)_n]^+$ provided clear identification of the reaction products. Further evidence is provided by the infrared spectra in the ν(CO) region (Table 3). The frequencies are in good agreement with the literature values, except in the case of $Zn[Mn(CO)_5]_2$·bipy. For this compound, Mays and Hsieh (8) found only three of the seven predicted absorptions, whereas the spectra of our compounds did in fact show all seven bands for both Zn and $Cd[Mn(CO)_5]$·bipy. The presence of the bidentate ligands bipy and TMED was confirmed in each case by infrared and nmr spectroscopy.

Results and Discussion

The synthetic methods described represent simple and direct routes to these interesting heteronuclear metal carbonyl complexes. The electrochemical

synthesis requires simple apparatus, readily available starting materials, and mild conditions (room temperature and pressure). Under the conditions which we have used, the rate of dissolution of the metal typically corresponds to the production of gram quantities of product in a few hours, and it seems likely that larger cells and electrodes, and improved cell design, would allow a substantial increase in the rate of production if required. These factors emphasize the advantages of the method over many of those in the literature (see Introduction), both in the use of ambient conditions, and in the avoidance of the synthesis of intermediates such as carbonyl hydrides, carbonylate anions, or metal alkyls.

Reaction Mechanism

It has been pointed out elsewhere (7, 9) that the current efficiency (E_F) of electrochemical reactions may give an important clue as to the mechanism of the reaction at the anode. We have accordingly measured the mass of anodic metal dissolving at constant current in a number of systems, with the results shown in Table 4.

Any discussion of the interpretation of these E_F values must start with the known polarographic behaviour of $Mn_2(CO)_{10}$ and $Co_2(CO)_8$. Dessy and his co-workers (10, 11) have shown that both compounds undergo 2-electron cathodic reduction to yield two $Mn(CO)_5^-$ and $Co(CO)_4^-$ anions respectively. We assume that these species are the significant current carriers, and that product formation involves reactions during, or subsequent to, the discharge of these anions to radicals at the anode surface. The E_F values for the oxidation of a given metal with either $Mn_2(CO)_{10}$ or $Co_2(CO)_8$ are generally the same, so that we assume that the same mechanism pertains for both anions unless otherwise noted.

Perhaps the simplest system is that involving indium. For $In_{(+)}/Mn_2(CO)_{10}$, the E_F of 1.0 implies that the primary processes at the anode are

[1] $Mn(CO)_5^- \rightarrow Mn(CO)_5 + e^-$

[2] $Mn(CO)_5 + In_{(+)} \rightarrow InMn(CO)_5$

TABLE 4. Current efficiencies (E_F) in the electrochemical preparation of heteronuclear metal carbonyls

System	E_F (mol F^{-1})[a]
$Zn/Co_2(CO)_8/bipy$	0.49
$Zn/Mn_2(CO)_{10}/bipy$	0.49
$Cd/Mn_2(CO)_{10}/bipy$	0.52
$Sn/Mn_2(CO)_{10}/bipy$	0.47
$In/Mn_2(CO)_{10}$	1.01
$In/Co_2(CO)_8$	0.89

[a]At constant currents of approximately 25 mA.

The product is an indium(I) complex, and it is well established (12) that the reaction of indium(I) halides with $Mn_2(CO)_{10}$ yields an indium(III) product by oxidative insertion (13), and the reaction

[3] $In(I)Mn(CO_5) + Mn_2(CO)_{10} \rightarrow In[Mn(CO)_5]_3$

clearly parallels such a process. Reactions [1]–[3] then lead to $E_F = 1.0$ for the production of $In[Mn(CO)_5]_3$ and its adducts. For $In/Co_2(CO)_8$, E_F is significantly below unity (0.89) and we suggest that this reflects a less efficient oxidative insertion process

[4] $InCo(CO)_4 + Co_2(CO)_8 \rightarrow In[Co(CO)_4]_3$

than in the manganese system. In fact products containing indium and cobalt in ratios significantly below 1:3 were obtained on occasions. A yellow insoluble solid containing 40% indium was presumably $InCo(CO)_4$ (calcd. In 40.1%), but the yield was small (~15 mg), and not reproducible. Further work on this topic is planned.

The case of $Sn/Mn_2(CO)_{10}$ is equally interesting. Here the dissolution of Sn in a solution of $Mn_2(CO)_{10}$ in methanol gave $E_F = 0.5$, implying the formation of $Sn[Mn(CO)_5]_2$ by the overall reaction

[5] $Sn_{(+)} + 2Mn(CO)_5^- \rightarrow Sn[Mn(CO)_5]_2$

although we should note immediately that considerable uncertainties exist as to the details of this process (cf. the discussion of zinc and cadmium systems below). We were not able to isolate

$Sn[Mn(CO)_5]_4$ or its adducts from the electrochemical cell. Despite the known (13) reactivity of tin(II) halides towards $Mn_2(CO)_{10}$, it appears that the insertion reaction between $Sn[Mn(CO)_5]_2$ and $Mn_2(CO)_{10}$ does not occur, although a number of uncharacterized products of indeterminate stoichiometry containing Sn, Mn, and CO were in fact isolated. Attempts to find better media for the electrochemical reaction (e.g. acetonitrile, glyme) were unsuccessful.

For zinc and cadmium, the E_F values of 0.5 are readily explicable in terms of the overall reaction stoichiometry

[6] $2Mn(CO)_5^- + Zn_{(+)} \rightarrow Zn[Mn(CO)_5]_2 + 2e^-$

[7] $Zn[Mn(CO)_5]_2 + bipy \rightarrow Zn[Mn(CO)_5]_2 \cdot bipy$

Unfortunately, as in the case of tin, neither the measurement of E_F nor reactions [6] and [7] cast any light on the number or nature of the steps involved in the transformation of $Mn(CO)_5^-$ anions into $—Mn(CO)_5$ ligands. Dessy and his co-workers (10) observed the formation of $Hg[Mn(CO)_5]_2$ when $Mn_2(CO)_{10}$ was reduced at a mercury cathode, and proposed the formation of the radical $Mn(CO)_5^\cdot$ as an intermediate. If this species is generated at the (say) cadmium anode (cf. reaction [1]), an analogy with work on halogens (14) or organic halides (7) leads to the reaction sequence

[8] $Cd + X \rightarrow CdX$

[9] $CdX + X_2 \rightarrow CdX_2 + X$

($X = Mn(CO)_5$), but the regeneration of $Mn(CO)_5$ to perpetuate reactions [8] + [9] would then give current efficiencies in excess of those observed (cf. ref. 14).

A number of possible explanations can be advanced for the E_F values of 0.5. In the first, it is postulated that the reaction sequence involves the discharge of a second $(Mn(CO)_5^-$ anion at a $CdMn(CO)_5$ site before the latter can react with dissolved $Mn(CO)_{10}$. A second approach assumes that the radicals regenerated by reaction [9] at or near the anode migrate and react with $Mn(CO)_5$ anions

[10] $Mn(CO)_5 + Mn(CO)_5^- \rightarrow Mn_2(CO)_{10} + e$

in which case the sum of reactions [1] + [8] + [9] + [10] gives $E_F = 0.5$, but only if reaction [10] accounts for the consumption of each $Mn(CO)_5$ radical formed in [9]. Finally, two $CdMn(CO)_5$ units may dimerise near the electrode surface to give $(CO)_5MnCdCdMn(CO)_5$, which on disproportionation would yield the product plus cadmium metal.

In view of the quantitative uncertainties in these arguments, a detailed comparison of the merits of various schemes does not appear worthwhile at the present time. These problems apart, the main features of the reaction scheme, and the advantages of the electrochemical technique, seem clearly established.

Pyrolysis of trifluoroacetaldehyde, initiated by di-tertiary-butyl peroxide decomposition

LEON F. LOUCKS, MICHAEL T. H. LIU, AND DAVID G. HOOPER
Department of Chemistry, University of Prince Edward Island, Charlottetown, P.E.I., Canada C1A 4P3

Received November 10, 1978

LEON F. LOUCKS, MICHAEL T. H. LIU, and DAVID G. HOOPER. Can. J. Chem. 57, 2201 (1979).

The thermal decomposition of 95:5 mixtures of trifluoroacetaldehyde (TFA) and di-*tert*-butyl peroxide (DTBP) has been studied at 100 Torr over the temperature range of 390 to 440 K. The major decomposition products included CO, CF_3H, CH_3COCH_3, and CH_4 while C_2F_6, $CF_3CHOHCH_3$, CF_3CH_3, CF_3COCH_3, C_2H_6, $(CF_3)_2CHOH$, and H_2 were also found. In addition to the usual reactions for TFA thermal decomposition, reactions of methyl radicals with TFA to form isopropoxyl radicals were found. The alcohol products result from H atom abstraction reactions of the isopropoxyl radicals while CF_3COCH_3 is a decomposition product. Arrhenius parameters for several reactions were determined: for DTBP decomposition, $\log k = 15.82 - 37.73/2.303RT$; for H abstraction from TFA by CH_3, $\log k = 8.30 - 7.37/2.303RT$; for H abstraction from TFA by CF_3, $\log k = 8.98 - 8.61/2.303RT$.[1] Consideration has also been given to several rate constant ratios for the formation and decomposition of isopropoxyl radicals.

A study of the reaction order for the formation of CF_3H, C_2F_6, and CH_4 showed that the orders were 3/2, 1, and 1 respectively for these three products. A reaction mechanism involving 14 individual steps is proposed to explain the reaction products and the observed orders of reaction.

LEON F. LOUCKS, MICHAEL T. H. LIU et DAVID G. HOOPER. Can. J. Chem. 57, 2201 (1979).

Opérant à 100 Torr et à des températures allant de 390 à 440 K, on a étudié la décomposition thermique de mélanges 95:5 de trifluoroacétaldéhyde (TFA) et de peroxyde de di-*tert*-butyle (DTBP). Les produits principaux de la décomposition comprennent CO, CF_3H, CH_3COCH_3, et CH_4 alors que l'on retrouve aussi C_2F_6, $CF_3CHOHCH_3$, CF_3CH_3, CF_3COCH_3, C_2H_6, $(CF_3)_2CHOH$ et H_2. En plus des réactions habituelles pour la décomposition thermique du TFA, on a aussi observé des réactions de radicaux méthyles avec le TFA conduisant à la formation de radicaux isopropoxyles. Les produits hydroxylés proviennent des réactions d'enlèvement d'atomes de H à partir des radicaux isopropoxyles alors que la CF_3COCH_3 est un produit de décomposition. On a déterminé les paramètres d'Arrhénius pour plusieurs réactions: pour la décomposition du (PDTB), $\log K = 15.82 - 37.73/2.303RT$; pour l'enlèvement d'un H du TFA par un CH_3, $\log K = 8.30 - 7.37/2.303RT$; pour l'enlèvement d'un H du TFA par le CF_3, $\log K = 8.98 - 8.61/2.30RT$.[1] On a aussi accordé une certaine considération à plusieurs rapports de constantes de vitesse pour la formation et la décomposition de radicaux isopropoxyles.

Une étude de l'ordre de réaction pour la formation de CF_3H, C_2F_6 et CH_4 a montré que les ordres sont respectivement 3/2, 1 et 1 pour ces trois produits. On propose un mécanisme réactionnel impliquant 14 étapes individuelles pour expliquer la nature des produits réactionnels et les ordres de réaction observés.

[Traduit par le journal]

Introduction

The thermal decomposition of trifluoroacetaldehyde (TFA) has been investigated in detail in several previous studies (1–3) at temperatures near 770 K. The results support a chain mechanism initiated by a first-order process believed to be the cleavage of the C—C bond and terminated by a second-order recombination of CF_3 radicals. In earlier work on the pyrolysis of acetaldehyde (4, 5) at 770 K the

[1]In this paper all energies are in kcal and R is taken to be 0.00199 kcal mol^{-1} K^{-1}.

0008-4042/79/172201-10$01.00/0

formation of acetone as a product was observed and its formation was attributed to the decomposition of isopropoxyl radicals generated by the addition of methyl radicals to acetaldehyde (4). In the pyrolysis of trifluoroacetaldehyde no hexafluoroacetone was observed although the same general mechanism could prevail. The present study was undertaken to determine the differences between the two pyrolyses and to determine whether or not the isopropoxyl radicals and their decomposition products are involved in the trifluoroacetaldehyde system.

Quite a number of previous studies have examined the decomposition of isopropoxyl radicals. Isopropoxyl radicals generated from isopropyl nitrite in the presence of nitric oxide were studied by Ferguson and Phillips (6), Cox, Livermore, and Phillips (7), and Batt and Milne (8). Also, in a nitric oxide system, Yee Quee and Thynne (9) studied the decomposition of isopropoxyl radicals generated from the thermal decomposition of di-isopropyl peroxide. In these systems the acetone formation has been explained by reactions other than the isopropoxyl radical decomposition; the major product for the radical decomposition was observed to be acetaldehyde and a methyl radical. The activation energy for the latter decomposition was reported to be 11.5 to 17.3 kcal mol^{-1} in the various studies (8). In the study by Batt and Milne, acetone formation by disproportionation of isopropoxyl radicals with NO was ruled out and although acetone was observed in amounts about equal to that of acetaldehyde, isopropoxyl radical was discounted as the acetone source because no inhibition by nitric acid oxide was observed. Systems involving no nitric oxide have also been used to generate isopropoxyl radicals. Wijnen (10) studied the gas-phase photolysis of isopropyl propionate and attributed acetaldehyde formation to the decomposition of isopropoxyl radicals by C—C bond scission; although acetone was also observed as a product, its source in this study was believed to be other than the C—H bond scission of the isopropoxyl radical. Yee Quee and Thynne (11) used di-isopropyl peroxide decomposition to generate isopropoxyl radicals. They reported acetaldehyde as the major decomposition product of the radical but also found small amounts of acetone; they estimated the activation energy for this latter decomposition to be about 20 kcal mol^{-1}. Most recently, Hiatt and Rahimi (12) have reported on the decomposition of di-isopropyl peroxide in solution; a reaction mechanism, in part quite different from that proposed by Yee Quee and Thynne for the gas phase, has been invoked to explain their products and product distributions.

To maximize the participation of isopropoxyl radicals in the TFA pyrolysis, the long-chain decomposition of TFA needs to be minimized and this is accomplished at lower temperatures. The appropriate temperature conditions to provide reasonable stability to the isopropoxyl radicals and fairly short-chain decomposition of TFA were obtained with the use of di-*tert*-butyl peroxide as a chain initiating agent. The same general design of experiment was used previously by Morris and Thynne (13) but their emphasis on minor product analysis was much less extensive than in the present work.

Experimental

Trifluoroacetaldehyde (TFA) was prepared by decomposing the ethyl hemiacetal obtained from K & K Laboratories Inc. with concentrated H_2SO_4 (14). The TFA was purified by trap-to-trap distillation from 150 K to 77 K, the initial fraction being discarded. Infrared (ir) and gas chromatography (gc) analyses confirmed the identity and the purity of TFA (99.9%). Di-*tert*-butyl peroxide (DTBP) was obtained from K & K Laboratories and used after degassing. The gc analysis showed no significant impurities in the DTBP.

TFA and DTBP were mixed in a 2 L bulb and stored at 77 K. The reactant was transferred to a 2 L mixing vessel prior to each experiment and mixed with a magnetic stirring device for 45 min. Experiments were conducted in a conventional glass vacuum system with greased stopcocks. The reaction vessel was a 419.6 mL quartz cylinder enclosed in an electrically heated steel cylinder encased in an asbestos board box, packed with glass wool. The temperature of the reaction vessel was controlled to ± 0.3 K by a Thermo Electric Model 400 temperature controller. All experiments were conducted with a reactant mixture containing 5% DTBP and 95% TFA. The reaction vessel was conditioned with about 30 Torr of reactant for 5 min prior to each experiment. Experiments were started by expanding the appropriate amounts of reactant into the reaction vessel and were terminated by freezing the condensable contents of the vessel into two spiral traps at 77 K.

The products were divided into three fractions. Products not condensable in a charcoal trap at 77 K were collected by a Toepler pump and measured in a gas burette. The fraction collected in the charcoal trap was then analyzed by gc on a 2 m molecular sieve column. This fraction contained CO and CH_4. The remaining products were distilled from 150 K to 77 K with pumping for 3 h. The volatile fraction was then analyzed on a 2 m Porapack Q column; this fraction contained CF_3H, C_2F_6, CF_3CH_3, $C_2F_2H_2$, C_2H_6, and the residual TFA. The products which remained nonvolatile at 150 K were analyzed on a 30 cm Porapack Q column; this fraction contained CF_3COCH_3, CH_3COCH_3, $CF_3CHOHCH_3$, and $(CF_3)_2CHOH$. All columns were kept at room temperature and a hot filament detector unit was used.

The compounds used for identification of product peaks were obtained from the following companies: CF_3H, CO, CH_4, C_2F_6, C_2H_6, and CF_3COCF_3 from Matheson; CF_3CH_3 from K & K Laboratories; $CF_3CHOHCH_3$, $CF_3CHOHCF_3$ from Matheson, Coleman and Bell; and CF_3COCH_3 from Aldrich Chemicals.

Results

The decomposition of trifluoroacetaldehyde initiated by the thermal decomposition of di-*tert*-butyl peroxide has been investigated over the temperature

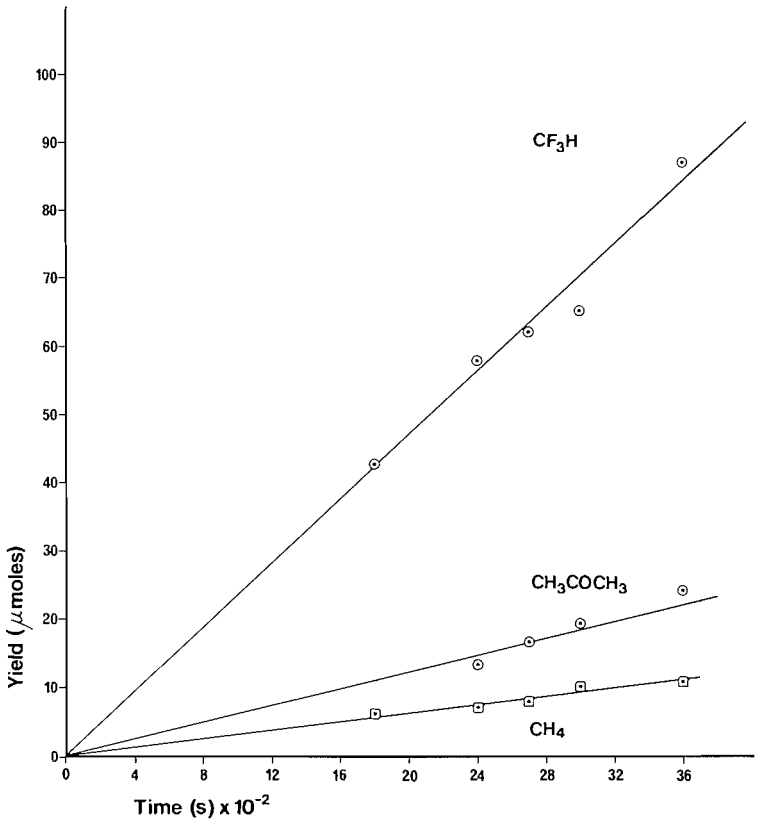

FIG. 1. Major products of the thermal decomposition at 402.2 K. Pressure = 100 Torr (5% DTBP and 95% TFA).

range of 390–440 K at a pressure of 100 Torr. The products observed, in decreasing order of magnitude, were: CO, CF_3H, CH_3COCH_3, CH_4, C_2F_6, $CF_3CHOHCH_3$, CF_3CH_3, CF_3COCH_3, C_2H_6, and H_2. Significant amounts of $(CF_3)_2CHOH$ were detected at the lower temperatures. It was expected that CF_4, $C_2F_2H_2$, and HF might have been observed products but a search for these materials did not reveal their presence. One minor product in the most volatile fraction is known to be none of the above, but remains unidentified.

Typical plots of product yield as a function of time are shown in Figs. 1 and 2. The initial rates given in Table 1 were obtained by extrapolating rates to zero time. For Table 1, all rates were normalized to the rate of formation of acetone set equal to unity; however, as the absolute rate of formation of acetone is given, the absolute rates of formation of all other products can be recalculated.

As part of the overall study, the effect of pressure on the rates of formation of CF_3H and C_2F_6 was investigated in detail at 402.2 K (129°C) over the pressure range of 45 to 271 Torr. The order plots resulting from this study are shown in Fig. 3. It was found that the orders of reaction were 1.49 ± 0.07 and 1.00 ± 0.03 for CF_3H and C_2F_6 respectively.

Discussion

To explain the observed decomposition products and the effects of pressure and temperature on the distribution of products the following mechanism is suggested:

[1] $DTBP \rightarrow 2CH_3 + 2CH_3COCH_3$

[2] $CH_3 + CF_3CHO \rightarrow CH_4 + CF_3CO$

[3] $CH_3 + CF_3CHO \rightarrow CH_3{-}\underset{\displaystyle CF_3}{\overset{\displaystyle O}{\overset{|}{\underset{|}{C}}}}{-}H$

[4] $CH_3{-}\underset{\displaystyle CF_3}{\overset{\displaystyle O}{\overset{|}{\underset{|}{C}}}}{-}H + CF_3CHO \rightarrow CH_3{-}\underset{\displaystyle CF_3}{\overset{\displaystyle OH}{\overset{|}{\underset{|}{C}}}}{-}H + CF_3CO$ (z)

[5] $CH_3{-}\underset{\displaystyle CF_3}{\overset{\displaystyle O}{\overset{|}{\underset{|}{C}}}}{-}H \rightarrow CH_3COCF_3 + H$

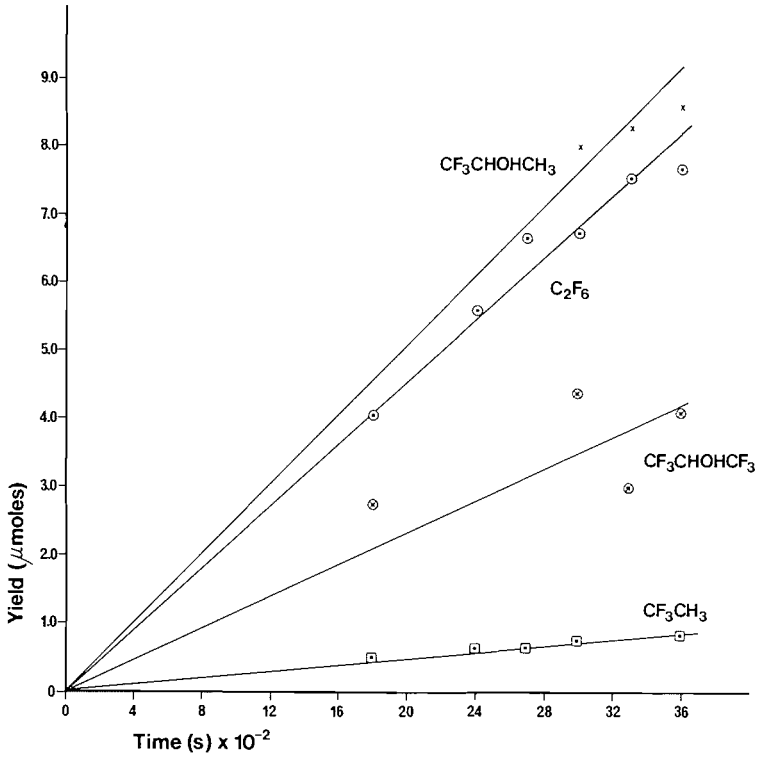

FIG. 2. Minor products of the thermal decomposition at 402.2 K. Pressure = 100 Torr (5% DTBP and 95% TFA).

[6] $CF_3CO \rightarrow CF_3 + CO$

[7] $CF_3 + CF_3CHO \rightarrow CF_3H + CF_3CO$

[8] $CF_3 + CF_3CHO \rightarrow CF_3\text{—}\underset{\displaystyle CF_3}{\overset{\displaystyle O}{\overset{|}{C}}}\text{—}H$

[9] $CF_3\text{—}\underset{\displaystyle CF_3}{\overset{\displaystyle O}{\overset{|}{C}}}\text{—}H + CF_3CHO \rightarrow CF_3\text{—}\underset{\displaystyle CF_3}{\overset{\displaystyle OH}{\overset{|}{C}}}\text{—}H + CF_3CO$

[10] $CF_3 + CF_3 \rightarrow C_2F_6$

[11a] $CF_3 + CH_3 \rightarrow CF_3CH_3^* \xrightarrow{M} CF_3CH_3$

[11b] $CF_3CH_3^* \rightarrow CH_2{=}CF_2 + HF$

[12] $CH_3 + CH_3 \rightarrow C_2H_6$

[13] $H + CF_3CHO \rightarrow H_2 + CF_3CO$

With this mechanism the chain reaction decomposition of TFA is initiated by the methyl radicals arising from the DTBP decomposition; this chain initiation reaction [2] leads to the CH_4 production. The chain carrier reactions are reaction [6], the decomposition of the CF_3CO radical and reaction [7], the abstraction of the aldehyde hydrogen by the CF_3 radical. The chain termination reactions include the various CF_3 and CH_3 combination and disproportionation reactions of reactions [10] to [12]. The reaction products CH_3COCH_3, CH_4, CF_3H, CO, C_2F_6, CF_3CH_3, and C_2H_6 could all be accounted for by a reaction scheme involving only the reactions discussed thus far. However, the fluorinated acetone, fluorinated alcohols, and hydrogen are not explained by a simple mechanism. We believe that these products arise from isopropoxyl radicals formed by the addition of methyl radicals to the reactant molecules. As there are both CH_3 and CF_3 radicals in our system, both an F_3-isopropoxyl and an F_6-isopropoxyl radical can be formed as shown by reactions [3] and [8] respectively. At the temperatures of this study, the isopropoxyl radicals are sufficiently stable to exhibit an abstraction reaction; thus a portion of the isopropoxyl radicals yield F_3-isopropyl alcohol and F_6-isopropyl alcohol as a result of the abstraction of the aldehyde hydrogen from the reactant molecules (reactions [4] and [9], respectively). The decomposition of the isopropoxyl radicals is expected to be facile and one pathway can give acetone and hydrogen atoms. In the present system the F_3-acetone resulting from the F_3-isopropoxyl radical decomposition by reaction [5] was observed but the F_6-acetone was not observed. The fact that the F_6-alcohol was observed in substantially smaller quantities than the F_3-alcohol while the F_3-acetone yield was much smaller than

the F_3-alcohol suggests that the yield of F_6-acetone would be expected to be very small and perhaps it was beyond the limit of collection and detection in our experiments. The hydrogen atoms produced along with the F_3-acetone would be expected to yield H_2 through abstraction by reaction [13]; H_2 was confirmed to be a product. The fact that the $R_{11a}/R_{10}^{1/2}R_{12}^{1/2}$ value observed in this work was only 0.78 suggests that $C_2F_2H_2$ and HF should have been formed in this system. Although a search for these products was conducted, we were unable to detect them and we conclude that they are not significant products. Nevertheless we are including reaction [11*b*] in our scheme, since it is known to occur in related systems (15), where the above ratio was found to be 2.0 at similar pressures.

DTBP Decomposition

The thermal decomposition of DTBP has been thoroughly studied by previous workers and the results of the various studies have been summarized by Shaw and Pritchard (16). An internal check on the consistency of the present work is provided in the measurement of the Arrhenius parameters for DTBP decomposition. The overall rate constant, k_1, for this decomposition can be derived from the rate of formation of acetone. The experimental values for k_1 are shown in Table 2. The Arrhenius plot of Fig. 4 displays the data and the equation of the Arrhenius plot is given by:

$$\log k_1\,(s^{-1}) = 15.82 \pm 0.79 - (37.73 \pm 1.49)/2.303RT$$

where $R = 0.00199$ kcal mol^{-1} K^{-1} and the error limits are standard error estimates. The Arrhenius parameters are in excellent agreement with the values recommended by Shaw and Pritchard (16).

Abstraction Reactions by Methyl Radicals

Under our present experimental conditions, abstraction reactions ([2], [4], [7], [9]) and addition reactions ([3], [8]) are more important than the radical combination reactions ([10], [11*a*], and [12]). The product distribution given in Table 1 shows that the abstraction reaction products CF_3H and CH_4 are more abundant than the predominant radical combination product, C_2F_6; the abstraction reactions become relatively less favored at higher temperatures. With experimental values for the rates of formation of CH_4 and C_2H_6 and upon accepting the literature value for $k_{12} = 10^{10.34}$ L mol^{-1} s^{-1} (17, 18), the rate constant k_2 can be evaluated from:

$$k_2 = R_{CH_4}k_{12}^{1/2}/(R_{C_2H_6})^{1/2}[CF_3CHO]$$

The results shown in Table 2 for k_2 yield the Arrhenius plot shown in Fig. 4; the equation for this

TABLE 1. Relative rates of product formation (acetone rate = 1.0)

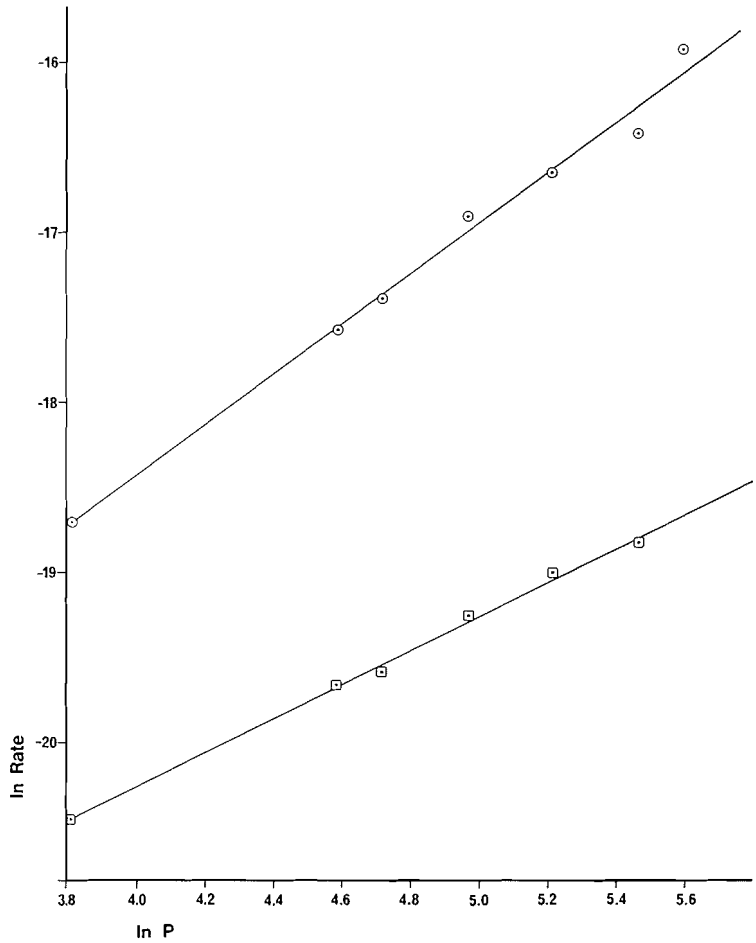

FIG. 3. Order plots for CF_3H formation (indicated by ○) and for C_2F_6 formation (indicated by □) at 402.2 K.

TABLE 2. Rate constant values at four temperatures for reactions [1], [2], and [7], DTBP decomposition, H abstraction by CH_3, and H abstraction by CF_3, respectively

T (K)	k_1 (s^{-1})	k_2 ($L\ mol^{-1}\ s^{-1}$)	k_7 ($L\ mol^{-1}\ s^{-1}$)
390.7	5.55×10^{-6}	1.65×10^{4}	1.48×10^{4}
402.2	1.73×10^{-5}	1.93×10^{4}	1.99×10^{4}
420.7	1.84×10^{-4}	2.95×10^{4}	3.20×10^{4}
440.7	1.24×10^{-3}	4.70×10^{4}	5.22×10^{4}

Arrhenius plot is:

$$\log k_2\ (L\ mol^{-1}\ s^{-1}) = 8.30 \pm 0.41 - \frac{7.37 + 0.77}{2.303RT}$$

The values of activation energy and A-factor compare moderately well with the values 8.7 kcal mol^{-1} and $10^{9.10}$ L mol^{-1} s^{-1} reported by Morris and Thynne (13).

Values of k_7 may be determined by an analogous manner from the rates of formation of CF_3H and C_2F_6 and with Ayscough's value of $k_{10} = 10^{10.36}$ L mol^{-1} s^{-1} (18, 19). The values of k_7 calculated from:

$$k_7 = R_{CF_3H}{k_{10}}^{1/2}/[CF_3CHO](R_{C_2F_6})^{1/2}$$

are shown in Table 2 and the Arrhenius plot is shown in Fig. 4. The equation of the Arrhenius plot is given by:

$$\log k_7\ (L\ mol^{-1}\ s^{-1}) = 8.98 \pm 0.07 - \frac{8.61 \pm 0.14}{2.303RT}$$

The activation energy and A-factor are in good agreement with the values of 8.8, 7.2, 8.2, and 8.44 kcal mol^{-1} and $10^{8.95}$, $10^{8.05}$, $10^{8.65}$, and $10^{8.66}$ L mol^{-1} s^{-1} reported previously by Morris and Thynne (20), Pearce and Whytock (21), Dodd and Smith (18, 22), and the present authors (3), respectively.

It is interesting to note from the data of Table 2 how closely the absolute values of k_2 and k_7 compare with one another in the temperature range of this

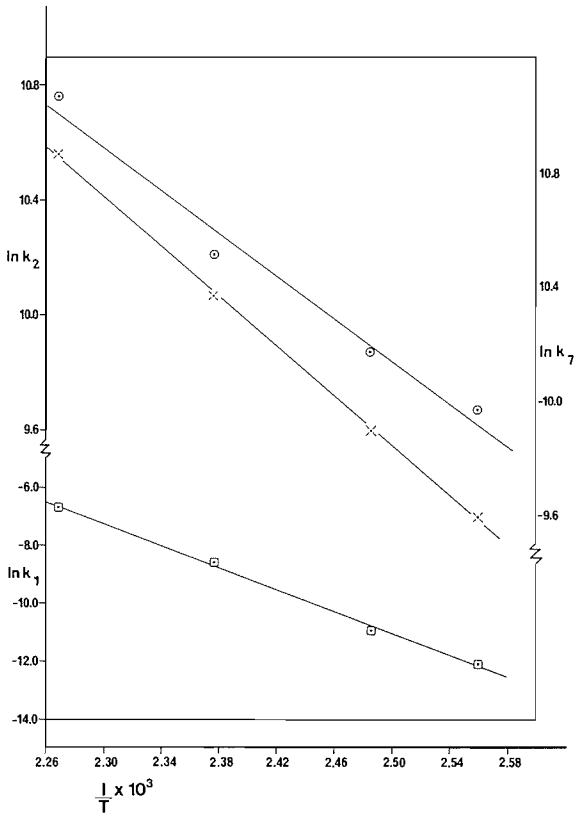

FIG. 4. Arrhenius plots for k_1 (□), k_2 (×), and k_7 (○).

study. Although the abstraction rate constant for CF_3 is usually greater than that for CH_3 (see pp. 279–280 of ref. 18), the present data tend to show that the substrate CF_3CHO may be less anomalous than previous data seemed to indicate. At the same time it should be noted that all values of k_7 would have to be reduced by a factor of $10^{0.32}$ if Hiatt and Benson's value (15) of k_{12} were accepted instead of Ayscough's value.

Methyl Radical Addition to TFA

As seen from the reaction mechanism, the F_3-isopropoxyl radical generated from the addition of CH_3 to TFA leads to the products F_3-isopropanol and F_3-acetone by reactions [4] and [5] respectively. Since these two reaction paths represent the only consumption of the F_3-isopropoxyl radicals the sum of the rates of reactions [4] and [5] must equal the rate of reaction [3] which produces the F_3-isopropoxyl radical. It follows that

$$\frac{k_3}{k_2} = \frac{R_{\text{F}_3\text{-alcohol}} + R_{\text{F}_3\text{-acetone}}}{R_{\text{CH}_4}}$$

An Arrhenius plot for this rate constant ratio is shown in Fig. 5; the data at the three lower temperatures were believed to be more reliable and only these data were used. The activation energy difference $E_2 - E_3$ was evaluated to be 3.4 ± 1.2 kcal mol^{-1}. With $E_2 = 7.37 \pm 0.77$ kcal mol^{-1} from the earlier result of this paper, it follows that E_3, the activation energy for the addition of CH_3 to TFA, is 4.0 ± 2.0 kcal mol^{-1}. This rather low activation energy allows the F_3-isopropoxyl radical to play a major part in the reaction mechanism and results in the experimental observation of significant amounts of F_3-acetone and F_3-alcohol.

The addition of CF_3 to TFA by reaction [8] yields the F_6-isopropoxyl radical. Although its decomposition was expected to yield hexafluoroacetone, none of this product was observed. Thus the rate of formation of the F_6-alcohol may be taken as the rate of formation of the F_6-isopropoxyl radical. From the kinetic expressions it follows that:

$$k_8/k_7 = R_{\text{F}_6\text{-alcohol}}/R_{\text{CF}_3\text{H}}$$

The Arrhenius plot for this rate constant ratio is displayed in Fig. 5; on this occasion data at only the three lower temperatures are available as the F_6-alcohol could not be measured at the highest temperature. The activation energy difference $E_8 - E_7$ was evaluated to be 4.2 ± 1.8 kcal mol^{-1}. With the value of $E_7 = 8.61 \pm 0.14$ kcal mol^{-1} assigned earlier in this paper, it follows that the activation energy for the addition of CF_3 radicals to TFA is 12.8 ± 2.0 kcal mol^{-1}. Notice that whereas the activation energy for addition of CH_3 to TFA was less than the activation energy for the H atom abstraction, in the case of CF_3, the activation energy for addition to TFA is greater than that of the H atom abstraction. The rather low abundance of F_6-isopropoxyl radical reaction products relative to that of F_3-isopropoxyl radical reaction products is the observed experimental consequence of these differences in activation energies.

It is evident from Fig. 5 that a considerable uncertainty exists in the evaluation of these rate constant ratios and this uncertainty is reflected in the standard error estimates in the Arrhenius parameters. While the absolute values for the activation energies show considerable uncertainty, it seems clear that $E_3 < E_2$ while $E_8 > E_7$.

Isopropoxyl Radical Decomposition

The F_3-isopropoxyl radical appears to react only through reactions [4] and [5]. The relative importance of the decomposition pathway relative to the H atom abstraction can be examined from values of the k_5/k_4 ratio evaluated from the rearrangement of rate expressions to the form:

$$k_5/k_4 = R_{\text{F}_3\text{-acetone}}[\text{CF}_3\text{CHO}]/R_{\text{F}_3\text{-alcohol}}$$

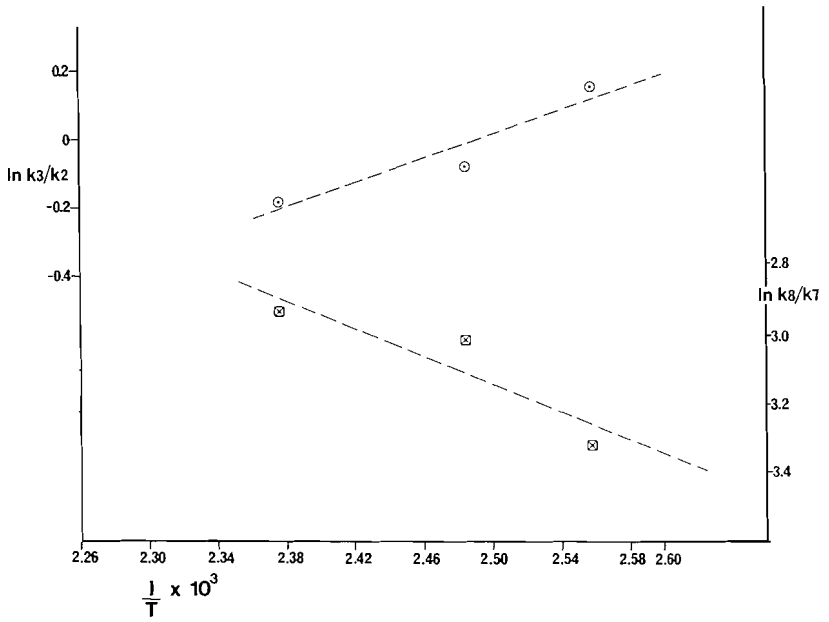

FIG. 5. Arrhenius plots for k_3/k_2 (○) and k_8/k_7 (⊠).

Owing to a significant uncertainty in the F_3-acetone rates, the ratio determined for k_5/k_4 was not entirely reliable. Nevertheless it appeared that the values at higher temperature were greater than those at the lower temperature and hence E_5 for the radical decomposition appears to be greater than E_4 for the abstraction reaction. Although no quantitative evaluation of E_5 is provided here, it should be recalled that Yee Quee and Thynne (11) have suggested an activation energy of 20 kcal mol^{-1} for the decomposition of the unfluorinated analogue to acetone and H atom.

For the decomposition of the F_6-isopropoxyl radical, no F_6-acetone was observed while small but significant amounts of the F_6-alcohol were observed at the lower temperatures. The failure to observe the F_6-acetone while observing the F_6-alcohol suggests that the activation energy for the decomposition of the F_6-isopropoxyl radical according to reaction [14],

$$[14]\quad CF_3{-}\overset{\displaystyle O}{\overset{\|}{C}}{-}H \rightarrow CF_3COCF_3 + H$$

is substantially greater than the activation energy for H atom abstraction from TFA.

As no F_6-acetone is formed, it follows that the only source of H atoms in our system would be from reaction [5]. The H atoms so produced would yield H_2 by reaction [13] and hence the yield of H_2 would be expected to be exactly equal to the yield of F_3-acetone. Such is not the experimental observation as the F_3-acetone is found in amounts several times greater than that of H_2. The excess F_3-acetone may arise from the reactions:

$$[15]\quad CH_3{-}\overset{\displaystyle O}{\overset{\|}{C}}{-}H + R \rightarrow CF_3COCH_3 + RH$$

where $R = CF_3$ or CH_3. The occurrence of these reactions could not be confirmed unequivocally in our system as CF_3H and CH_4 arise in large quantities from other reactions.

Most readers will have noticed our omission of isopropoxyl radical decomposition pathways involving C—C bond scission to give acetaldehydes and methyl radicals. In our experiments this type of reaction occurring as the reverse of reactions [3] and [8] could not be detected as the reaction product would be one of our reactants. We do not dispute the occurrence of the reverse of reactions [3] and [8] and indeed we do expect that they are occurring. There is, however, one C—C bond scission reaction which we expected to see. The decomposition of the F_3-isopropoxyl radical could occur not only by the reverse of reaction [3] but also by a C—C bond scission that would give CF_3 and CH_3CHO. A search for acetaldehyde in the products provided no evidence of that product. However, due to the fact

that the acetaldehyde gc peak occurred at an unfavorable position on the tail of the reactant peak we feel that there is some possibility that the failure to observe acetaldehyde was an analysis problem. Nevertheless, our current evidence indicates no acetaldehyde product and this influences us to believe that the C—C bond scission of isopropoxyl radicals relative to C—H bond scission may not be as strongly favored as earlier work has suggested.

Order of Reaction

As supporting evidence for the reaction mechanism, the order of reaction was experimentally determined at 402.2 K for some of the readily measured products. The orders of formation of CF_3H and C_2F_6 were of special significance to the reaction mechanism.

A steady-state treatment for the reaction mechanism is simplified by the following assumptions which are supported by the experimental observations: (*a*) that production of CF_3CO by reaction [13] is minor; (*b*) that the rates of reactions [8] and [9] are equal, as no other product from the F_6-isopropoxyl radical was observed; (*c*) that reactions [11*a*] and [11*b*] are minor termination steps compared to reaction [10] and may be neglected (at the higher temperatures this is not entirely valid but holds well at the temperature of the order study); (*d*) that CH_3 radical consumption occurs predominantly by reactions [2] and [3] rather than by reactions [11*a*], [11*b*], and [12]; and (*e*) that the rate of reaction [4] is essentially the same as the rate of reaction [3] since $R_5 \ll R_4$.

This simplified steady-state treatment gives the following expressions for the concentrations of CH_3 and CF_3:

$$[16] \quad [CH_3] = \frac{2k_1[DTBP]}{(k_2 + k_3)[CF_3CHO]} = \frac{2k_1}{19(k_2 + k_3)}$$

$$[17] \quad [CF_3] = \left(\frac{k_2 + k_3}{2k_{10}}\right)^{1/2} \times [CF_3CHO]^{1/2}[CH_3]^{1/2} = \left(\frac{k_1}{19k_{10}}\right)^{1/2} [CF_3CHO]^{1/2}$$

In turn these quantities can be used in the rate expressions for the rates of formation of CF_3H, C_2F_6, and CH_4 and one finds that the orders of reaction with respect to CF_3CHO should be 1.5 for CF_3H formation, 1.0 for C_2F_6 formation, and 1.0 for CH_4 formation. The order plots of Fig. 3, already referred to, confirm these orders in the cases of CF_3H and C_2F_6 where experimental orders of 1.49 ± 0.07 and 1.00 ± 0.03, respectively, were observed. A less extensive study involving only four points gave an order of 0.92 ± 0.03 for CH_4, a value rather close to the 1.0 required by the reaction mechanism. Thus the proposed reaction mechanism is consistent with the observed orders of reaction for these individual products.

Additional support for the validity of eqs. [16] and [17] comes from the calculations of the steady-state concentrations of CF_3 and CH_3. Values of k_1 and k_2 were taken from Table 2 while values for k_3/k_2 were obtained from an interpolation of Fig. 5. At 402.2 K the CH_3 concentration was calculated from eq. [16] to be 4.7×10^{-11} mol L^{-1}, a value which is in excellent agreement with a calculation from the observed rate and the rate expression $R_{C_2H_6} = k_{13}[CH_3]^2$. For CF_3 the concentration calculated from eq. [17] was 3.7×10^{-10} mol L^{-1}; again this value showed good agreement with a value calculated from the C_2F_6 rate and rate expression. At 440.7 K the same calculations gave values of 1.6×10^{-9} and 2.5×10^{-9} mol L^{-1} for the concentrations of CH_3 and CF_3 respectively in good agreement with the values calculated from the rate expressions. It should be noted that whereas the $[CF_3]/[CH_3]$ ratio is about 8 at 402.2 K, the temperature at which the order study was conducted, this ratio is reduced to a value of 2 at 440.7 K. All of the above calculations were conducted for a pressure of 100 Torr.

Received November 27, 1978

RAM K. NIGAM, PREM P. SINGH, and KRISHAN C. SINGH. Can. J. Chem. **57**, 2211 (1979).

Heats of mixing, H^E, of aniline + benzene at 298.15 and 308.15 K have been measured over the entire composition range. The results have been analysed in terms of Barker's and ideal associated model theory of non-electrolyte solutions. It has been observed that the ideal associated model approach which assumes the presence of AB, AB_2, A_2B_2, and B molecular species well describes (within ±120 J/mol at the worst) the general behaviour of H^E with x_B (mole fraction of aniline) over the whole composition range for aniline + benzene mixtures. The equilibrium constants for the various association reactions along with the enthalpy of formation of various molecular species have also been calculated.

RAM K. NIGAM, PREM P. SINGH et KRISHAN C. SINGH. Can. J. Chem. **57**, 2211 (1979).

On a mesuré les chaleurs de mélange, H^E, de l'aniline + benzène à 298.15 et à 308.15 K à toutes les compositions. On a analysé les résultats en termes de la théorie de Barker et du modèle associé idéal des solutions non électrolytiques. On a observé que l'approche du modèle associé idéal qui fait l'hypothèse de la présence d'espèces moléculaires AB, AB_2, A_2B_2 et B décrit bien (à ±120 J/mol) le comportement de H^E avec x_B (fraction molaire de l'aniline) à toutes les compositions de mélanges de l'aniline + benzène. On a calculé les constantes d'équilibre des diverses réactions d'association ainsi que l'enthalpie de formation des divers espèces moléculaires.

[Traduit par le journal]

Introduction

Recent trends in the thermodynamics of associated mixtures have been limited to the evaluation of equilibrium constants for 1 : 1 and 1 : 2 molecular complexes only (1, 2). However, Tucker and Christian (3) have made notable contributions by identifying the various associated species in pure alkanols. Aniline molecules are known to be associated (4–7) through hydrogen bonding in the pure state and recent ir spectroscopic studies (8) have indicated that while one of the hydrogens of the $-NH_2$ group of aniline forms a strong hydrogen bond, the second hydrogen in the NH_2 group interacts weakly with the π-electrons of adjacent aniline molecules. It would, therefore, be interesting to study the nature of aniline in its binary mixtures with benzene. The present work describes interactions in aniline + benzene mixtures.

Experimental

Analytical grade aniline and benzene were purified as suggested by Vogel (9) and the purity of the final samples was checked by density determination at 298.15 ± 0.01 K which agreed to within ±0.00005 g/mL with the corresponding literature values (10, 11).

Heats of mixing measurements were made in an adiabatic calorimeter (12) which has been described previously. The time was recorded by an electronic timer (type TO1 SR No. 010, Systronic, Ahemdabad, India) which could read to ±0.0001 s. The temperature fluctuations of the thermostatic bath were found to be within ±0.01 K. The uncertainty in H^E values is about 0.3%.

[1]To whom all correspondence should be addressed.

Results

The heats of mixing at 298.15 and 308.15 K have been fitted by the equation:

$$[1]\quad H^E/x_Ax_B = h_0 + h_1(x_B - x_A) + h_2(x_B - x_A)^2$$

where x_B and x_A are the mole fractions of aniline and benzene respectively. The parameters (h_0, h_1, and h_2) were evaluated by the method of least squares and are recorded together with the standard deviations of molar heats of mixing $\sigma(H^E)$ in Table 1.

Discussion

Deshpande and Pandya (13) have determined H^E for the aniline (B) + benzene (A) system at 298.15 K. Our results are in excellent agreement with those reported by these workers for $0 \leq x_B \leq 0.25$ and $x_B \geq 0.75$. However, in the intermediate range, our results differ from theirs by as much as +80 J mol^{-1} at $x_B = 0.42$. Heats of mixing for aniline + benzene are endothermic throughout the entire concentration range. H^E data at 308.15 K when combined with G^E data (14) at 308.15 K yielded positive TS^E values for all aniline mole fractions. The curve of TS^E against x_B is unsymmetrical about x_B (Fig. 1).

At the simplest qualitative level, the observed H^E data for this mixture may be accounted for if it is

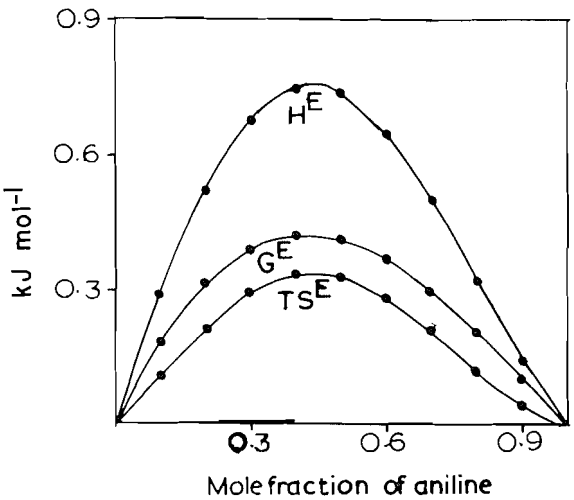

FIG. 1. Properties of the aniline + benzene system at 308.15 K.

assumed that: (*i*) aniline is self-associated and there is a decrease in self-association when it is mixed with benzene, (*ii*) there are weak interactions between aniline and benzene. Consequently, the orientational freedom of unlike molecules would increase due to factor (*i*) so that TS^E should be positive. On the other hand, since the measured H^E is due to the cumulative effects of factors (*i*) and (*ii*), the positive H^E for this mixture may be accounted for if it is assumed that the heat effects due to factor (*i*) outweigh those due to factor (*ii*).

The state of liquid aniline has been a subject of speculation; while some authors favoured self-association in liquid aniline through hydrogen bonding (4–8), Bellamy and Williams (15) suggest that there is no self-association in it. Furthermore, aniline has a permanent dipole moment and its interactions with such simple compounds as benzene should be characterized by dipole-induced dipole interaction. Consequently, it was thought worthwhile to analyse our H^E data for aniline + benzene mixtures in terms of Barker's theory (16) by taking into account the abovementioned views about the nature of aniline.

It was assumed that aniline (B) + benzene (A) have the following geometrical parameters: lattice $Z = 4$, aniline molecule = B, $r_B = 2$, $Q_H^B = 1$, $Q_N^B = 1$, $Q_R^B = 4$, benzene molecule = A, $r_A = 2$, $Q_{R'}^A = 6$ (since molar volumes of aniline + benzene at 298.15 K are nearly the same, it was taken $r_A = r_B = 2$). Three different models were assumed.

Model α

This model assumed that there is no self-association in aniline and that its interaction with benzene is characterized by specific (R...R′) interactions of strength U_2 between the aromatic ring of aniline (R) and the aromatic ring of benzene (R′) and non-specific interactions of strength U_1 for all the remaining contacts. This model was based on the observations of Bellamy and Williams (15) that there is no self-association in aniline.

Model β

This model assumed (*i*) specific (N...H) interactions of strength U_3 between the nitrogen and hydrogen of aniline and (*ii*) an interaction (R...R′) of strength U_2 between the aromatic ring (R) of aniline with the

TABLE 2. Comparison of H^E values calculated according to Barker's theory with the corresponding H^E experimental values at $x_B = 0.3$, 0.5, and 0.7 at 298.15 and 308.15 K for aniline (B) + benzene (A) mixtures

Temperature (K)	H^E (J/mol)	Mole fraction of aniline (x_{B_2})			Interaction energies (J/mol)			
		0.3	0.5	0.7	U_1	U_2	U_3	U_4
298.15	Experimental	743.44	816.23	573.66	—	—	—	—
	From Model α	547.39	742.19	789.42	491.0	−49.08	—	—
	From Model β	618.92	773.64	810.00	491.90	−49.08	−1005.03	—
	From Model γ	660.48	862.83	893.50	491.90	—	−1005.03	−49.08
308.15	Experimental	678.02	738.04	449.54	—	—	—	—
	Model γ	563.60	738.83	762.92	416.35	—	−672.13	−12.78

aromatic ring (R′) of benzene. These interactions correspond to a model that takes into account the self-association of aniline and also dipole-induced dipole interactions (14) between aniline and benzene.

Model γ

Visualized (*i*) specific (N...H) interactions of strength U_3 between aniline–aniline molecules and (*ii*) specific (H...R′) interactions of strength U_4 between the hydrogen of the $—NH_2$ group and aromatic ring (R′) of hydrocarbon. This model is based on the ir spectroscopic studies (8) of aniline by Wolff and Mathias (8).

For the sake of simplicity, non-specific interactions of all the remaining contact sites in these three modes were considered to have the same strength U_1. Excess energy of mixing at constant volume (U_V^E) at x_B = 0.3, 0.5, and 0.7 were then calculated for these three models. Conversion of U_V^E to H^E was performed utilizing the relationship:

$$[2] \qquad U_V^E = H^E - TV^E\alpha_m/(K_T)_m$$

where α_m, $(K_T)_m$, and V^E are the expansivity, isothermal compressibility, and excess volume of the mixture. As $V^E \approx 0$, therefore, $U_V^E \approx H^E$. It is evident from Table 2 that Model α and Model β do not represent adequately the H_{expt}^E values. Model γ provides good agreement at $x_B = 0.3$ and 0.5, but it is poor for $x_B > 0.5$. The probable reason for this failure of Model γ for $x_B > 0.5$ is its simplicity, which does not account for the presence of associated complexes of general formula A_mB_x and B_l.

H_{expt}^E and H_{calc}^E for the three models given above for $x_B = 0.3$, 0.5, and 0.7 at 298.15 and 308.15 K are given in Table 2 along with their interaction energies U_i (i = 1, 2, 3, 4, ...).

The H^E data for this mixture were then analysed in terms of the ideal associated model (17, 18). It is assumed that in a binary solution of aniline + benzene mutual equilibrium of the species A_kB_k, A_mB_x, and B_l occurs. Hereinafter aniline and benzene are designated respectively as B_n and A, the notation B_n indicating that aniline is self-associated. Here:

$$l = 1, 2, 3, ..., l$$
$$m = 1, 2, 3, ..., m$$
$$x = 1, 2, 3, ..., x$$
$$k = 1, 2, 3, ..., k$$
$$n = 1, 2, 3, ..., n$$

The mutual equilibrium is represented by the equation:

$$[3] \qquad A + B_n \rightleftharpoons A_kB_k + A_mB_x + B_l$$

Equilibrium constants for the various association reactions represented by eq. [3] are:

$$[4] \qquad K_{k,k/n} = a_{A_kB_k}/a_A{}^k a_{B_n}{}^{k/n}$$

$$[5] \qquad K_{m,x/n} = a_{A_mB_x}/a_A{}^m a_{B_n}{}^{x/n}$$

and

$$[6] \qquad K_{l/n} = a_{B_l}/a_{B_n}{}^{l/n}$$

where 'a' denotes activities. If the activity coefficients of the various species represented in eq. [3] are assumed to be unity (17), the material balance equation for the system can be written as

$$[7] \quad a_A + a_{B_n} + \sum_k K_{k,k/n} a_A{}^k a_{B_n}{}^{k/n} + \sum_m K_{m,x/n} a_A{}^m a_{B_n}{}^{x/n} + \sum_l K_{l/n} a_{B_n}{}^{l/n} = 1$$

Consider the two simple cases:

Case (*i*)

$$l = m = k = 1; \quad n = 2; \quad x = 2$$

Case (*ii*)

$$l = m = 1; \quad x = n = 2; \quad k = 1, 2$$

The material balance equations for the two cases are then:

$$[8] \quad a_A + a_{B_2} + K_{1,0.5} a_A a_{B_2}{}^{1/2} + K_{1,1} a_A a_{B_2} + K_{0.5} a_{B_2}{}^{1/2} = 1$$

and

$$[9]\quad a_A + a_{B_2} + K_{1,0.5}a_A a_{B_2}^{1/2} + K_{1,1}a_A a_{B_2} + K_{2,1}a_A^2 a_{B_2} + K_{0.5}a_{B_2}^{1/2} = 1$$

Algebraic manipulation of eqs. [8] and [9] yields

$$[10]\quad K_{1,0.5}a_A + K_{1,1}a_A a_{B_2}^{1/2} + K_{0.5} = (1 - a_A - a_{B_2})/a_{B_2}^{1/2}$$

and

$$[11]\quad K_{1,0.5}a_A + K_{1,1}a_A a_{B_2}^{1/2} + K_{2,1}a_A^2 a_{B_2}^{1/2} + K_{0.5} = (1 - a_A - a_{B_2})/a_{B_2}^{1/2}$$

respectively.

Since the observed thermodynamic properties of this mixture would be the cumulative sum of the effects due to (*i*) dispersion forces and (*ii*) equilibria represented by eq. [3], evaluation of the various K's in the eqs. [10] and [11] would require that the observed activities of the components of these binary mixtures be corrected (19–21) for dispersion contributions by expressing

$$a_A = \gamma_A x_A/\gamma_A^*$$

$$a_{B_2} = \gamma_{B_2} x_{B_2}/\gamma_{B_2}^*$$

where γ_A^* and $\gamma_{B_2}^*$ are the activity coefficients of a reference mixture. As cyclohexane is inert and has nearly the same molar volume as that of benzene, cyclohexane (A*) + aniline (B_2*) was taken as the reference system (22) for the present analysis. A series of values were then assumed for the various K's in eqs. [10] and [11] and the process was repeated until a set of K values was obtained which yielded

$$(1 - a_A - a_{B_2})/a_{B_2}^{1/2} = D$$

values that corresponded very closely to those obtained from the experimental a_A and a_{B_2} values. It was observed that eq. [10] with a set of values:

$$K_{1,0.5} = 0.754$$

$$K_{1,1} = 0.076$$

$$K_{0.5} = 0.05$$

and eq. [11] with a set of values:

$$K_{1,0.5} = 0.75$$

$$K_{1,1} = 0.08$$

$$K_{0.5} = 0.08$$

$$K_{2,1} = 0.05$$

yields D values which reproduce well with those obtained from experimental data with this equation. The criterion of effectiveness was the variance of the fit $\sigma^2 D$ defined by

$$[12]\quad \sigma^2 D = \sum_q (D_{calc} - D_{expt})^2/(q - p)$$

where q is the number of points used in the fit and p is the number of adjustable parameters.

Since $\sigma^2 D_{10} = 0.010$ and $\sigma^2 D_{11} = 0.011$ are nearly the same, the analysis of the activity coefficients data described above suggests that these mixtures may be assumed to have either AB, AB_2, and B or AB, AB_2, A_2B_2, and B molecular species in solution.

The experimental H^E data for this mixture were next examined in terms of models that involved consideration of the *First Case* (AB, AB_2, and B) and the *Second Case* (AB, AB_2, A_2B_2, and B) and H^E was expressed as:

$$[13]\quad H^E = (n_{AB}\Delta H_{AB} + n_{AB_2}\Delta H_{AB_2} + n_B\Delta H_B)/(N_A + N_{B_2})$$

$$[14]\quad H^E = (n_{AB}\Delta H_{AB} + n_{AB_2}\Delta H_{AB_2} + n_{A_2B_2}\Delta H_{A_2B_2} + n_B\Delta H_B)/(N_A + N_{B_2})$$

where n_{AB}, n_{AB_2}, $n_{A_2B_2}$, and n_B are the amounts of species AB, AB_2, A_2B_2, and B which are present at equilibrium in solution. N_A and N_{B_2} are the stoichiometric amounts of A and B_2. If the equilibrium mole fractions of A, B_2, AB, AB_2, and B are represented by Z_A, Z_{B_2}, Z_{AB}, Z_{AB_2}, and Z_B then for an ideal associated mixture A + B_2, containing AB, AB_2, and B molecular species, one can write:

$$[15]\quad Z_A + Z_{B_2} + Z_{AB} + Z_{AB_2} + Z_B = 1$$

where

$$Z_{AB} = K_{1,0.5}Z_A Z_{B_2}^{1/2}$$

$$Z_{AB_2} = K_{1,1}Z_A Z_{B_2}$$

$$Z_B = K_{0.5}Z_{B_2}^{1/2}$$

The experimental H^E values were again corrected for dispersion contributions by subtracting from H_{expt}^E the H^E values (21) for the cyclohexane + aniline system at 308.15 K.

Consequently, in eqs. [13] and [14]

$$[15a]\quad H^E = H_{expt}^E - H^E\,(\text{cyclohexane} + \text{aniline})$$

Algebraic manipulation of eqs. [13] and [14] and the material balance equations

$$[16]\quad N_A = n_A + n_{AB} + n_{AB_2}$$

$$[17]\quad N_{B_2} = n_{B_2} + \tfrac{1}{2}n_{AB} + \tfrac{1}{2}n_B + n_{AB_2}$$

TABLE 3. Equilibrium constants K and the enthalpy of formation ΔH for the various molecular species in benzene (A) + aniline (B) mixtures

Property	Value				Reaction
	AB	A_2B_2	AB_2	B	
K	0.754	—	0.076	0.05	$A + B_2 \rightarrow AB + AB_2 + B$
ΔH (kJ/mol)	−3.2	—	−0.50	+2.0	
K	0.75	0.05	0.08	0.08	$A + B_2 \rightarrow AB + A_2B_2 + AB_2 + B$
ΔH (kJ/mol)	−4.5	−1.5	−0.5	+2.1	

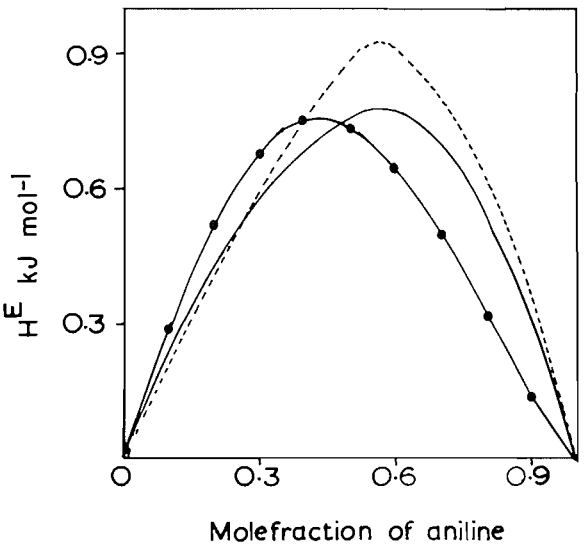

FIG. 2. H^E values of the aniline + benzene system at 308.15 K: ●, experimental; ---, first case; —, second case.

leads to

$$[18] \quad JH^E = K_{1,0.5}Z_A\Delta H_{AB} + K_{1,1}Z_A\Delta H_{AB_2} + K_{0.5}Z_{B_2}{}^{1/2}\Delta H_B$$

where

$$J = (Z_{B_2}{}^{1/2} + 0.5K_{0.5} + 0.5K_{1,0.5}Z_A + K_{1,1}Z_AZ_{B_2}{}^{1/2})/x_{B_2}$$

Further combination of [15]–[17] yields

$$[19] \quad x_{B_2} = \frac{Z_{B_2} + 0.5K_{1,2}Z_{B_2}{}^{1/2} + 0.5K_{1,0.5}Z_AZ_{B_2}{}^{1/2}}{Z_A + Z_{B_2} + 0.5K_{1,1}Z_{B_2}{}^{1/2} + 1.5K_{1,0.5}Z_AZ_{B_2}{}^{1/2}}$$

where

$$Z_A = \frac{1 + Z_{B_2} - K_{0.5}Z_{B_2}{}^{1/2}}{1 + K_{1,0.5}Z_{B_2}{}^{1/2} + K_{1,1}Z_{B_2}}$$

using the various K values described above for a solution containing AB, AB_2, and B molecular species, values of x_{B_2} were calculated from eq. [19] for several values of Z_{B_2}. A number of values was then assigned to ΔH_{AB}, ΔH_{AB_2}, and ΔH_B until they reproduced H^E values (from eqs. [15*a*] and [18]) which compared well with the experimental data. The various ΔH values are presented in Table 3 and calculated H^E values are compared with $H_{expt}{}^E$ values in Fig. 2. It is evident, from Fig. 2, that the predicted H^E values are good for the range $0 \leq x_{B_2} \leq 0.5$. However, for $x_{B_2} > 0.5$ the theoretical H^E values were found to exceed the corresponding $H_{expt}{}^E$ by as much as 140 J/mol.

A similar procedure was applied to the case when the mixture contained AB, AB_2, A_2B_2, and B molecular species. The final expressions are:

$$[20] \quad J'H^E = (K_{1,0.5}Z_A\Delta H_{AB} + K_{1,1}Z_AZ_{B_2}{}^{1/2}\Delta H_{AB_2} + K_{2,1}Z_A{}^2\Delta H_{A_2B_2} + K_{0.5}\Delta H_B)$$

where

$$J' = (Z_{B_2}{}^{1/2} + 0.5K_{0.5} + 0.5K_{1,0.5}Z_A + K_{1,1}Z_AZ_{B_2}{}^{1/2} + K_{2,1}Z_A{}^2)/x_{B_2}$$

and

$$[21] \quad x_{B_2} = \frac{Z_{B_2} + 0.5K_{0.5}Z_{B_2}{}^{1/2} + 0.5K_{1,0.5}Z_AZ_{B_2}{}^{1/2} + K_{1,1}Z_AZ_{B_2} + K_{2,1}Z_A{}^2Z_{B_2}}{Z_A + Z_{B_2} + 0.5K_{0.5}Z_{B_2}{}^{1/2} + 1.5K_{1,0.5}Z_AZ_{B_2}{}^{1/2} + 2K_{1,1}Z_AZ_{B_2} + 3K_{2,1}Z_A{}^2Z_{B_2}}$$

and

$$[22] \quad Z_{B_2} = \frac{-(K_{1,0.5}Z_A + K_{0.5}) \pm \sqrt{(K_{1,0.5}Z_A + K_{0.5})^2 - 4(Z_A - 1)(K_{1,1}Z_A + K_{2,1}Z_A{}^2 + 1)}}{2(K_{1,1}Z_A + K_{2,1}Z_A{}^2 + 1)}$$

where

$$Z_{AB} = K_{1,0.5} Z_A Z_{B_2}^{1/2}$$

$$Z_{AB_2} = K_{1,1} Z_A Z_{B_2}$$

$$Z_{A_2B_2} = K_{2,1} Z_A^2 Z_{B_2}$$

$$Z_B = K_{0.5} Z_{B_2}^{1/2}$$

For different values of Z_A, H^E values were again calculated as already explained. The theoretical H^E curve reproduces reasonably well the corresponding experimental results as is evident from Fig. 2. The various ΔH values are given in Table 3.

The analysis of H^E and activity coefficients data for benzene + aniline mixtures thus suggests that this mixture is characterized by the presence of AB, AB_2, A_2B_2, and B molecular species in the solution.

Structural studies of steric effects in phosphine complexes. Part VII.[1] Synthesis, crystal and molecular structure of the chloroperchloratotri(*o*-tolyl)phosphinemercury(II) dimer

ELMER C. ALYEA, SHELTON DIAS, GEORGE FERGUSON, AND MASOOD KHAN

Guelph–Waterloo Centre for Graduate Work in Chemistry, Guelph Campus, Department of Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received February 23, 1979

ELMER C. ALYEA, SHELTON DIAS, GEORGE FERGUSON, and MASOOD KHAN. Can. J. Chem. 57, 2217 (1979).

The synthesis and crystal and molecular structure of the chloroperchloratotri(*o*-tolyl)phosphinemercury(II) dimer are reported. The compound $[HgP(o\text{-tolyl})_3ClClO_4]_2$ belongs to the orthorhombic space group *Pbca* (D_{2h}^{15}, No. 61) with $a = 12.218(2)$, $b = 13.814(2)$, $c = 26.074(3)$ Å, and $Z = 4$. The structure was refined to a final R of 0.046 for 2584 reflections measured by diffractometer. The crystal structure consists of discrete centrosymmetric dimeric molecules of $[HgP(o\text{-tolyl})_3ClClO_4]_2$ separated by normal van der Waals distances. The unique mercury atom forms two strong bonds (Hg—P 2.395(3), Hg—Cl(1) 2.332(4) Å) which deviate from linearity (P—Hg—Cl 164.1(1)°) and two weak bonds (Hg—O(1) 2.73(2) to the perchlorato group, Hg—Cl(1*) 3.109(4) Å linking the mercury atoms about centers of symmetry). The four-fold coordination geometry about each mercury can be described as trigonal bipyramidal with the phosphorus and Cl(1) axial, and one equatorial site unoccupied. Intramolecular interactions are discussed with the assistance of cone angle calculations and a ligand profile for $P(o\text{-tolyl})_3$ ($\theta = 198°$). Vibrational and ^{31}P nmr spectra data are also presented for $[HgP(o\text{-tolyl})_3ClClO_4]_2$.

ELMER C. ALYEA, SHELTON DIAS, GEORGE FERGUSON et MASOOD KHAN. Can. J. Chem. 57, 2217 (1979).

On rapporte la synthèse et la détermination de la structure cristalline du dimère du chloroperchloratotri(*o*-tolyl)phosphine mercure(II). Le composé $[HgP(o\text{-tolyl})_3ClClO_4]_2$ appartient au groupe d'espace orthorhombique *Pbca* (D_{2h}^{15}, No. 61) avec $a = 12.218(2)$, $b = 13.814(2)$, $c = 26.074(3)$ Å et $Z = 4$. On a raffiné la structure jusqu'à une valeur finale de R de 0.046 pour 2584 réflexions mesurées à l'aide d'un diffractomètre. La structure cristalline est formée de molécules dimères individuelles centro-symétriques de $[HgP(o\text{-tolyl})_3ClClO_4]_2$ séparées les unes des autres par des distances de van der Waals normales. L'atome de mercure unique forme deux liaisons fortes (Hg—P 2.395(3), Hg—Cl(1) 2.332(4) Å) qui ne sont pas linéaires (P—Hg—Cl 164.1(1)° et deux liaisons faibles (Hg—O(1) 2.73(2) avec le groupe perchlorato, Hg—Cl(1*) 3.109(4) Å reliant les atomes de mercure autour des centres de symétrie). On peut décrire la géométrie de coordination quaternaire autour de chaque mercure comme étant trigonale bipyramidale avec le phosphore et le chlore (1) axiaux et un site équatorial inoccupé. On discute des interactions intramoléculaires à l'aide de calculs d'angle conique et un profil de ligand pour le $P(o\text{-tolyl})_3$ ($\theta = 198°$). On présente aussi des données de spectres vibrationnels et rmn ^{31}P pour $[HgP(o\text{-tolyl})_3ClClO_4]_2$.

[Traduit par le journal]

Introduction

Steric effects of phosphorus ligands have been described (1) in terms of cone angles, θ, and estimates of θ from space filling molecular models (1) have been complemented by X-ray analysis (2, 3) of metal complexes of several bulky phosphine ligands.[2] We have also developed the concept of a "ligand profile" (2) which not only yields precise maximum cone angle data based on the X-ray structural results, but also provides quantitative information about the gaps between moieties in a ligand. The steric environments of $P(o\text{-tolyl})_3$ in $[HgP(o\text{-tolyl})_3(OAc)_2]_2$ (4), $Pt[P(o\text{-tolyl})_3]_2I_2$ (5), and $Ir[P(o\text{-tolyl})_3]_2ClCO$ (5, 6) have been previously described. In an attempt to prepare $Hg[P(o\text{-tolyl})_3]_2(ClO_4)_2$ for comparison with $Hg(PCy_3)_2(ClO_4)_2$ (2, 7) we isolated a compound shown by this X-ray analysis to be $[HgP(o\text{-tolyl})_3ClClO_4]_2$. Cone angle data from the single crystal structural determination and spectroscopic results are presented in this paper.

Experimental

Spectroscopic and other physical measurements were performed as previously described (8).

[1]For Part VI, see ref. 3.

[2]Bulky phosphine ligands which have been studied in our laboratories include tri(cyclohexyl)phosphine (PCy_3), tris(*tert*-butyl)phosphine (PBu_3^t), tri(*o*-tolyl)phosphine ($P(o\text{-tolyl})_3$), and trimesitylphosphine ($P(mesityl)_3$).

Preparation of the Chloroperchloratotri(o-tolyl)phosphinemercury(II) Dimer, $[HgP(o\text{-tolyl})_3ClClO_4]_2$

A solution of mercury(II) chloride (2.72 g, 10.0 mmol) in absolute ethanol (50 mL) was added to a solution of silver perchlorate (4.15 g, 20.0 mmol) in the same solvent (50 mL). The precipitated pale-yellow solid was filtered off and the filtrate diluted to 100 mL in the same solvent. A 20 mL aliquot of this solution was then added to a hot solution of $P(o\text{-tolyl})_3$ (1.30 g, 4.0 mmol) in absolute ethanol (100 mL). The white solid which precipitated was isolated by filtration and washed successively with ethanol and ether. Crystallization from ethanol afforded a white crystalline solid suitable for X-ray analysis; mp 202–204°C (dec). *Anal.* calcd. for $[HgP(o\text{-tolyl})_3ClClO_4]_2$: C 39.42, H 3.31; found: C 39.62, H 3.32.

X-ray Crystallographic Analysis

Weissenberg and precession photographs provided approximate unit cell dimensions; accurate lattice parameters were obtained by a least-squares treatment of the diffractometer setting angles for 12 reflections for which θ_{hkl} (Mo-K_α) was between 10 and 20°. Crystal data (at 21°C) are

$C_{42}H_{42}Cl_4Hg_2O_8P_2$ fw = 1279.7

Orthorhombic, $a = 12.218(2)$, $b = 13.814(2)$, $c = 26.074(3)$, $V = 4400.8$ Å^3, $Z = 4$, $D_c = 1.93$ g cm^{-3}, $F(000) = 2464$, μ(Mo-K_α) = 70.4 cm^{-1}. Absent reflections $hk0$, $h \neq 2n$, $h0l$, $l \neq 2n$ and $0kl$, $k \neq 2n$ determine space group $Pbca$ (D_{2h}^{15}, No. 61) uniquely and require the molecule to be centrosymmetric.

The intensity data for a unique octant within the limits $2 < \theta < 25°$ were collected on a computer-controlled Y290 Hilger and Watts four-circle diffractometer using graphite monochromated Mo-K_α radiation as described previously (9). The crystal turned black during irradiation and the intensities of three standard reflections, monitored every 100 reflections, decreased by 20% during data collection; this was allowed for by appropriate scaling. Data were corrected for Lorentz and polarization factors and a numerical absorption correction was applied. Maximum and minimum values of transmission coefficients are 0.472 and 0.432 respectively. Of the 4075 measured reflections, 2584 reflections with $I > 2\sigma(I)$ were used in the final refinement of the structure parameters.

The structure was solved by Patterson and Fourier methods.[3] The fractional coordinates for the unique mercury atom were obtained from a sharpened three-dimensional Patterson map. A Fourier synthesis phased with the mercury atom contributions revealed the entire structure. Full-matrix least-squares refinement with anisotropic thermal parameters resulted in $R = \Sigma||F_o| - |F_c||/\Sigma(F_o)$ being lowered to 0.055. A difference synthesis at this stage revealed all hydrogen atoms.

In subsequent refinement cycles the hydrogen atoms were constrained to have idealized geometry with C—H 0.95 Å and separate isotropic thermal parameters were refined for phenyl and methyl hydrogens. In three more rounds of calculation, refinement converged with $R = 0.046$ and $R^1 = [\Sigma w\Delta^2/\Sigma wF_o^2]^{1/2} = 0.044$. The weights used were derived from the counting statistics via the expression $w = K/((\sigma^2F_o + gF_o^2)$ where the final values of K and g are 1.885 and 0.0003 respectively. The scattering factors for hydrogen atoms were obtained from ref. 10 and for the non-hydrogen atoms from ref. 11. Anomalous dispersion corrections were applied (12) for Hg, P, and Cl atoms. In the final cycle of refinement the shifts were less than 0.3 esd and a final difference synthesis was featureless.

[3]Calculations were performed on the University of Guelph IBM 370/155 computer using the program system SHELX written by G. M. Sheldrick, University Chemical Laboratory, Cambridge CB2 1EW, England.

Discussion

Earlier work (8, 13) demonstrated that tri(*o*-tolyl)phosphine forms only 1:1 complexes with mercury(II) halides, thiocyanate, and acetate. In attempts to prepare a 1:2 complex by the reaction of commercially available mercury(II) perchlorate with two or more molar equivalents of tri(*o*-tolyl)-phosphine no products with satisfactory elemental analyses were obtained. Consequently, the presently reported attempt to generate anhydrous mercury(II) perchlorate was carried out, leading to the isolation of a crystalline solid following the reaction with

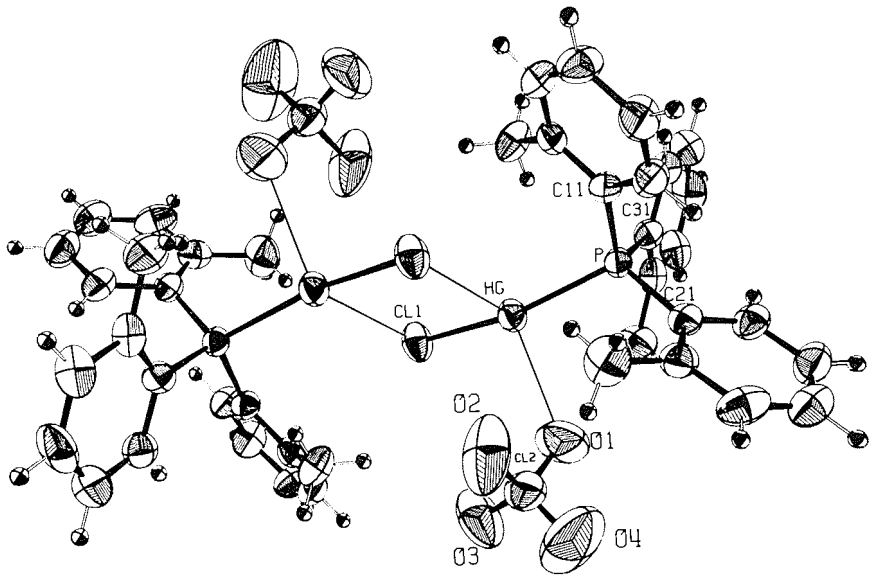

FIG. 1. View of the centrosymmetric $[HgP(o\text{-tolyl})_3ClClO_4]_2$ structure showing our numbering scheme.

tri(*o*-tolyl)phosphine. The stoichiometry of the product was established by the X-ray single crystal determination; subsequent characterization by other physical methods was consistent with the proved structure. $[HgP(o\text{-tolyl})_3ClClO_4]_2$ is a non-electrolyte in dichloroethane (Λ 8.6 ohm^{-1} cm^2 mol^{-1}, 10^{-3} mol dm^{-3}) but becomes a conductor in nitromethane (Λ 133 ohm^{-1} cm^2 mol^{-1}, 10^{-3} mol dm^{-3}). The ^{31}P nmr spectrum for a DMSO-d_6 solution at ambient temperature showed a broad peak at δ 18.0 ppm (downfield from 85% H_3PO_4 as reference) with no satellites due to coupling with mercury -199. The coordination chemical shift of 50.4 ppm is, as expected, comparable to the values found for $HgP(o\text{-tolyl})_3Cl_2$ and $HgP(o\text{-tolyl})_3(OAc)_2$ (14). The low solubility of the complex in non-coordinating solvents did not allow us to obtain meaningful ^{31}P nmr spectral data at lower temperatures or to determine the molecular weight in solution. The infrared spectrum of $[HgP(o\text{-tolyl})_3Cl(ClO_4)]_2$ shows the following bands in the perchlorate region not observed in the spectrum of the free ligand $P(o\text{-tolyl})_3$: 1110 (vs br), 1070 (vs), 1045 (vs), 925 (sh), 917 (m), 686 (w), 666 (w), and 622 (s) cm^{-1}. In the ionic, T_d ClO_4^- ion, the infrared active modes appear at 1119 (s br) cm^{-1} (ν_3) and 625 (m) cm^{-1} (ν_4) (15). Thus the splitting of the ν_3 and ν_4 bands, together with the appearance of ν_1, of ClO_4^- at 917 cm^{-1}, indicates the presence of coordinated perchlorate groups. A weak peak at 190 cm^{-1} observed in the far ir and Raman spectra can tentatively be assigned to the bridging Hg—Cl stretching mode (13). Comparison of the Raman spectrum with those observed previously (8, 13) for similar mercury–phosphine complexes also makes possible the assignment of a medium peak at 158 cm^{-1} to ν(Hg–P).

The crystal structure (Fig. 2) contains discrete centrosymmetric dimeric molecules of $[HgP(o\text{-tolyl})_3ClClO_4]_2$ separated by normal van der Waals distances. The unique mercury atom (Fig. 1) forms two strong bonds (Hg—P 2.395(3), Hg—Cl(1) 2.332(4) Å) which deviate from linearity (P—Hg—Cl 164.1(1)°) because of intramolecular overcrowding (see below). The perchlorate group is weakly bound to mercury (Hg—O(1) 2.73(2) Å) and pairs of $(HgP(o\text{-tolyl})_3ClClO_4)$ moieties are linked about centres of symmetry by weak Hg—Cl(1*) bonds (3.109(4) Å). The four-fold coordination geometry so produced at the mercury can be described as trigonal bipyramidal with the phosphorus and Cl(1) axial, and one equatorial site unoccupied.

The non-linearity of the P—Hg—Cl(1) angle comes about to reduce intramolecular interaction between (*a*) the wedge-like perchlorate group and *o*-tolyl methyl groups (O(2)···H(273) 2.60 Å, O(3)···H(173*) 2.78 Å) and (*b*) atom Cl(1) and *o*-tolyl methyl C(17*) (Cl(1)···H(173*) 3.11 Å). As a consequence of these interactions, C(17) is bent 0.109 Å (Table 2) and the phosphorus atom -0.193 Å, from the C(11)—C(16) plane. Atom C(27) is displaced 0.055 Å and phosphorus 0.104 Å from the C(21)—C(26) plane; the third *o*-tolyl ring (C(31)—C(36)), which is not affected by intramolecular overcrowding, has the methyl group and phosphorus atom coplanar with the ring. The mercury coordination is thus very similar to that found in two of the

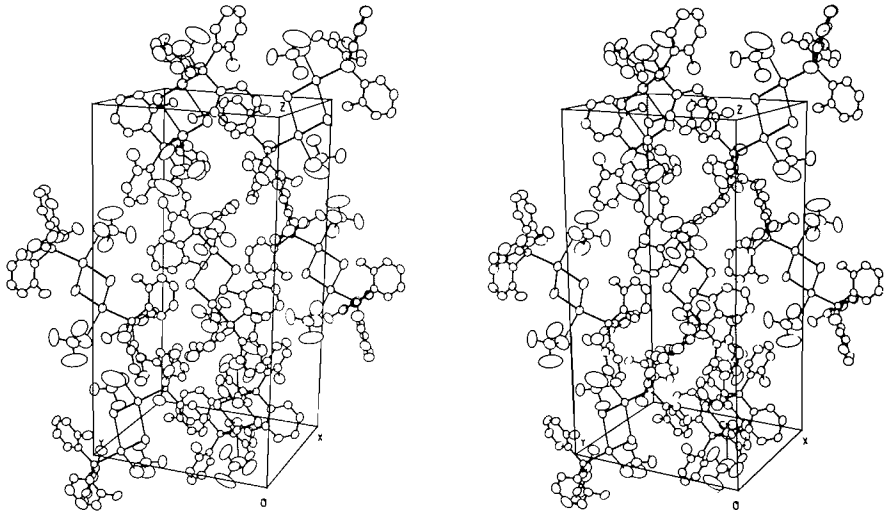

FIG. 2. Stereoview of the crystal structure of $[HgP(o\text{-tolyl})_3ClClO_4]_2$. In this diagram the cell shown runs from $(-\frac{1}{2}, -\frac{1}{2}, -\frac{1}{2})$ to $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$; the points labelled '*O*', '*X*', '*Y*', and '*Z*' have crystal coordinates $(-\frac{1}{2}, -\frac{1}{2}, -\frac{1}{2})$, $(\frac{1}{2}, -\frac{1}{2}, -\frac{1}{2})$, $(-\frac{1}{2}, \frac{1}{2}, -\frac{1}{2})$, and $(-\frac{1}{2}, -\frac{1}{2}, \frac{1}{2})$ respectively.

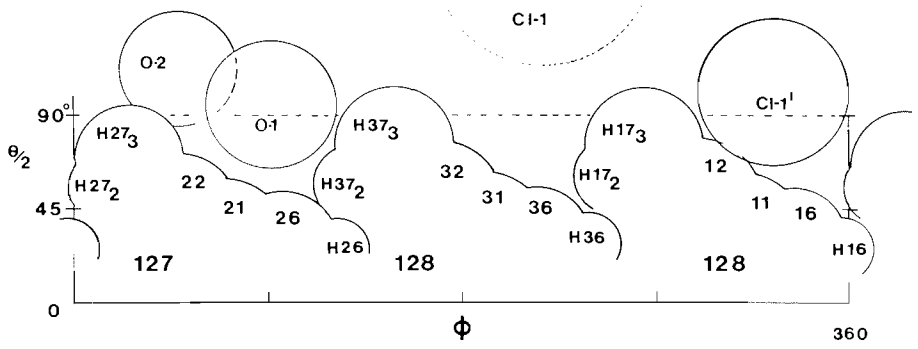

FIG. 3. Ligand profile for $P(o\text{-tolyl})_3$ in $(HgP(o\text{-tolyl})_3ClClO_4]_2$. The ordinate is the maximum semi-cone angle θ/2, the abscissa is the angle φ through which a cone generating vector Hg → X is rotated about the Hg—P bond. For full details see ref. 2. Also included in the profile diagram are the outlines of the encroaching chlorine and perchlorato oxygen atoms. The labels and numbers under the profile curves are the appropriate atom numbers, and values of the Hg—P—C—C(H) torsion angles.

four molecules comprising the asymmetric unit of chloro(diethyl phosphonato)mercury(II) (Cl—Hg—$PO(OC_2H_5)_2$) (16) with dimensions Hg—Cl 2.31–2.38; Hg—P 2.31–2.40; and P—Hg—Cl 173°. Other examples of strong digonal axial phosphorus coordination at mercury with weaker equatorial bonding are found in $Hg(PCy_3)_2(ClO_4)_2$ (7) and $Hg(PCy_3)_2(OAc)_2$ (7).

The $P(o\text{-tolyl})_3$ geometry is unexceptional with mean dimensions Hg—P—C(1) 110.1°, C—P—C 108.8°, and P—C 1.81 Å in agreement with those previously reported in $[HgP(o\text{-tolyl})_3(OAc)_2]_2$ (4), $Pt[P(o\text{-tolyl})_3]_2I_2$ (5), and $Ir[P(o\text{-tolyl})_3]_2ClCO$ (6). The perchlorate ion has the expected tetrahedral geometry with Cl—O 1.36–1.42 Å and O—Cl—O 107–114°. Apart from the weak bond Hg—O(1), the next shortest Hg···O distance (Hg···O(2) 3.13 Å) is just greater than the sum of the van der Waals radii (2.90 Å).

The ligand profile of the *o*-tolyl rings in $[HgP(o\text{-tolyl})_3ClClO_4]_2$ is shown in Fig. 3 (for details of the ligand profile calculations see ref. 2). The *o*-tolyl rings adopt a regular propeller conformation with Hg—P—C—C(H) torsion angles 127, 128, and 128°. The maximum semi-cone angles, θ/2, are 93.6, 101.4, and 102.2° giving a maximum cone angle of 198°, close to the value (194°) predicted by Tolman (1). The ligand profile also shows clearly the gaps between the *o*-tolyl rings whose conformations place steric limitations on the coordination geometry at the mercury atom. With the more strongly bonding acetato anion, the *o*-tolyl phosphine conformation

changes to a non-propeller one, e.g. in $[HgP(o\text{-tolyl})_3(OAc)_2]_2$ (4), with $\theta = 191°$. The flexibility and cog-like nature of the $P(o\text{-tolyl})_3$ ligands is amply demonstrated in the synthesis of *bis* $P(o\text{-tolyl})_3$ metal complexes with bulky anions, e.g. $Pt(P(o\text{-tolyl})_3)_2I_2$ (5), $Ir(P(o\text{-tolyl})_3)_2ClCO$ (6). Ligand profile calculations show that the $P(o\text{-tolyl})_3$ ligand in these complexes adopts a very irregular non-propeller conformation to accommodate ligand intermeshing, with a concomitant decrease in cone angle to 183° (2, 5).

J. S. TSE, T. K. SHAM, and G. M. BANCROFT. Can. J. Chem. **57**, 2223 (1979).

Extended ligand–ligand repulsion calculations have been applied to a number of six coordinate organotin complexes of the type $RR'Sn(bidentate)_2$ (R, R′ = Me, Ph, Cl). Qualitatively, the calculations readily predict the decrease in the R—Sn—R′ angle with decrease in bite size of the bidentate ligand. The steric calculations are generally successful in predicting both the *cis–trans* preference of the R groups and the bond angles about the Sn atom. For the Me_2Sn complexes, electronic effects (as expressed by Bent's rule) sometimes have to be used in conjunction with the steric calculations to rationalize the observed stereochemistry.

J. S. TSE, T. K. SHAM et G. M. BANCROFT. Can. J. Chem. **57**, 2223 (1979).

On a appliqué des calculs étendus de répulsion ligand–ligand à un certain nombre de complexes organostanneux hexacoordonnés du type $RR'Sn(bidentate)_2$ (R,R′ = Me, Ph, Cl). Qualitativement, les calculs permettent facilement de prédire une diminution dans la grosseur du ligand bidentate. Les calculs stériques permettent généralement de prédire avec succès la préférence *cis–trans* des groupes R et les angles de liaison autour de l'atome de Sn. Dans le cas des complexes du Me_2Sn, on doit quelquefois faire appel à des effets électroniques (exprimés sous la forme de la règle de Bent) de concert avec des calculs stériques pour rationaliser la stéréochimie observée.

Introduction

Recent X-ray structures and ^{119}Sn Mössbauer studies of six coordinate dimethyl and diphenyl tin compounds have shown that the C—Sn—C bond angle varies from close to 90° to 180° (1–4). Nearly all six coordinate dimethyl compounds have the *trans* or distorted *trans* structure, whereas most of the diphenyl analogues have the *cis* structure. The C—Sn—C angle in the dimethyl compounds varies widely, for example from 110° to 136° to 160° to 180° in $Me_2Sn(oxin)_2$, $Me_2Sn(S_2CNMe_2)_2$, $Me_2Sn(Salen)$, and $Me_2Sn(acac)_2$ respectively.

Simple theoretical models based on ligand–ligand repulsion have been proposed to account semiquantitatively for the variation in the C—Sn—C bond angles and the *cis–trans* preference in some organotin compounds (5–7). For example, Kepert (6, 7) has shown that the C—Sn—C angle in $Me_2Sn(bidentate)_2$ compounds decreases from 180° in steric response to a decrease in bite size of the chelating ligand.

In this paper, we incorporate Zahrobsky's concept (5) of steric cone angle into Kepert's ligand–ligand repulsion model, and calculate equilibrium geometries for a number of six coordinate diorganotin compounds. Our calculated angles are usually in good agreement with the observed structural values, although the *cis–trans* preference is sometimes not predicted solely on steric grounds.

Theory

The ligand–ligand repulsion model assumes that the repulsion between donor atoms within a molecule is the predominate factor in determining the equilibrium geometry of that molecule. In Kepert's model (6, 7), donor atoms are assumed to lie on a sphere of unit radius with the metal atom at the centre (i.e. all central atom – donor atom bond distances are equal). However, in reality, bond lengths are seldom equal. In order to apply Kepert's model to obtain bond angles, the concept of steric angle (5) is incorporated into Kepert's model. Thus, in the present model, we suggest that the repulsion between two donor atoms i and j is inversely proportional to their separation r_{ij} and directly proportional to their steric angles θ_i and θ_j subtended at the centre (n_L is the number of ligands):

$$[1] \quad U_{tot} = \frac{1}{2}\sum_{\substack{i}}^{n_L}\sum_{\substack{j \\ i \neq j}}^{n_L} \theta_i\theta_j r_{ij}^{-n} \qquad (n = 1, 2, \ldots)$$

The equilibrium geometry can be calculated by minimizing the total repulsion energy with respect to the donor atom positions.

$$[2] \quad U_{min} = \frac{\delta U_{tot}}{\delta r_{ij}} = \sum_{i=1}^{n_L} \theta_i\theta_j \frac{\delta}{\delta r_{ij}}(r_{ij})^{-n}$$

The steric angles are calculated as by Zahrobsky (5)

TABLE 1. Van der Waals radii and the range of steric angles used in this work (5)

Element	Van der Waals radius (Å)	Steric angle (deg)†
C	2.00 (methyl)	133–144
	3.40 (phenyl)*	153
N	1.50	83–88
O	1.40	81–83
Cl	1.80	97–100
S	1.85	76–96

*The Van der Waals radius of the phenyl group is taken as the sum of the distance from the centre of the phenyl ring to a carbon atom and the Van der Waals radius of H attached to that carbon.

†The exact steric angle used in the calculation depends of course on the observed Sn—X bond length in the individual compound.

from the known covalent bond lengths and the Van der Waals radii of the ligand atoms. The radii used in calculating the steric angles (mostly taken from Zahrobsky (5)) are given in Table 1. The bond lengths are taken from the literature crystal structures. The minimization of the potential function was carried out using the quasi-Newton Algorithm. All computations were performed using the University of Western Ontario CDC Cyber 73 computer.

The most appropriate value of n in the repulsion energy expression (eq. [1]) cannot be known exactly. As noted previously (7) and again verified through our calculations, variation of n from 1 to 12 does not change our calculated bond angles significantly. Therefore $n = 1$ is used in this paper (as in the previous work (6, 7)), owing to the simplification of the calculations.

For the *trans*-$R_2Sn(bidentate)_2$ compounds, the treatment used is similar to that given by Kepert (6) and the Sn—D (D = O, S, etc.) distances are taken to be equal. For the *cis*-$R_2Sn(bidentate)_2$ compounds, the treatment is more complex. The only symmetry element in such a *cis* compound is a twofold axis, and there are four variables.

We have also done calculations on a number of diorganotin molecules having only unidentate ligands. As suggested by Zahrobsky (5), the minimization problem is simplified by approximating the three dimensional problem into three two dimensional ones. The number of variables is then reduced from nine in the three dimensional case to three variables per plane.

Results and Discussion

(a) The cis–trans *Preference*

Our calculations on diorganotin compounds such as $Me_2SnCl_2(pyO)_2$ (8), $Me_2SnCl_2(DMSO)_2$ (9), and $Ph_2SnCl_2(DMSO)_2$ (10) containing only unidentate ligands confirm Zahrobsky's previous observations (5). Contrary to the *trans*-R_2Sn structure observed

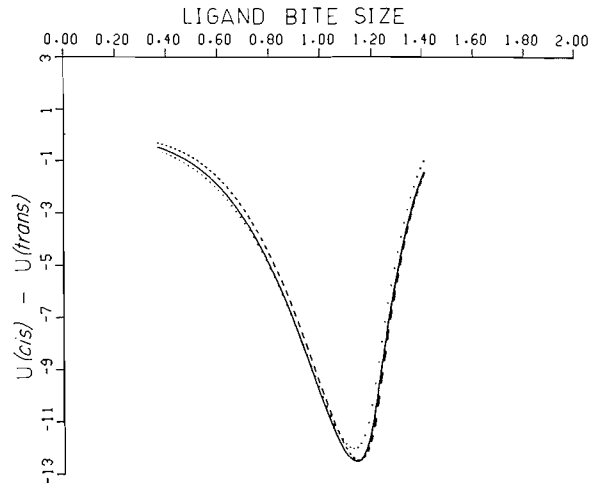

FIG. 1. Stabilization of *cis*-RR′Sn(O—O′)$_2$ relative to *trans*-RR′Sn(O—O′)$_2$ as a function of the ligand normalized bite size; dotted line, R = R′ = Me; full line, R = Me, R′ = Ph; broken line, R = R′ = Ph. The $U_{cis} - U_{trans}$ energy unit is arbitrary. The problem is discussed in ref. 7.

(8–10), the repulsion model predicts the *cis* structure. Electronic effects, as expressed by Bent's rule (11), may outweigh the steric requirements: to maximize Sn 5*s* density in the Sn—C bonds, the strong σ donor R groups prefer the *trans* geometry where they overlap with Sn *sp* hybrids.

For the RR′Sn(bidentate)$_2$ compounds, the repulsion model again sometimes fails to predict the correct stereochemistry (e.g., when R and R′ are *both* Me) at least partially for the electronic reason given above. Plots of $U_{cis} - U_{trans}$ vs. the ligand bite b (7) (Fig. 1) for such compounds show that, except at very large bites, the *cis* structure is always favoured sterically, whereas the Me_2Sn complexes in Table 2 give the *trans* structure. The three plots for Me_2Sn, MePhSn, and Ph_2Sn compounds (Fig. 1) show that there is little change in $U_{cis} - U_{trans}$ with change in steric angle of R. At small bite sizes (e.g. oxin, b = 1.19), $U_{cis} - U_{trans}$ is close to a minimum, and the predicted *cis*-$Me_2Sn(oxin)_2$ structure is observed (12) (Table 3).

In the above discussion we invoked Bent's rule to explain the *trans* preference of the Me_2Sn moiety. To investigate this preference further, we have undertaken Extended-Hückel calculations (13) on different geometries of $Me_2Sn(acac)_2$ and $Cl_2Sn(acac)_2$. The Extended-Hückel method has been evaluated thoroughly and shown to be capable of predicting reasonable geometries for many organometallic compounds (14). We have assumed a 'D_{3d}' symmetry for the R_2SnL_2 complex. We can then vary the R—Sn—R bond angle from 90° to 180° (i.e. *cis* to *trans*) by rotating one plane of the molecule about the 'C_3'

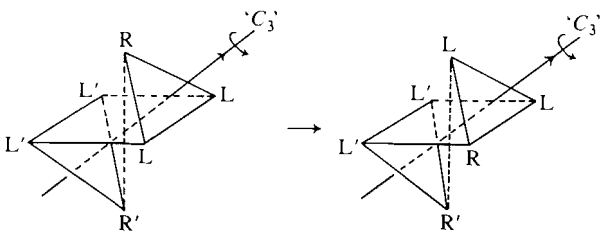
axis. The parameters used in the calculation are described in the Appendix and Table 4. Figure 2 shows the results of the Extended-Hückel calculation on $Me_2Sn(acac)_2$ and $Cl_2Sn(acac)_2$. The conclusion we obtained from the molecular orbital calculation is puzzling. The calculation predicts the *cis* conformation for both $Me_2Sn(acac)_2$ and $Cl_2Sn(acac)_2$. This is contradicted by the observed *trans*-$Me_2Sn(acac)_2$ and *cis*-$Cl_2Sn(acac)_2$ structures. The calculation also predicts a local minimum at R—Sn—R bond angle of ca. 140°. We think this local minimum is fortuitous. The potential surface of the conformation of a molecule is a function of many variables. Without full optimization of all variables in each geometry, the total valence energy may not be a reliable parameter in predicting the geometry of a molecule. It is also interesting to note that the local minimum occurred when the planes of the molecule are in eclipsed conformation. However, the calculation does show that the main minimum occurs at an R—Sn—R angle of ca. 110°. This bond angle is very close to the 'normal' sp^3 hybridized tetrahedral angle at the tin atom. This observation is in agreement with our argument that the tin atom in a number of R_2SnL_2 complexes is probably sp^3 hybridized having a tetrahedral arrangement of ligands around the metal center (*vide infra*). The differences in Sn—D distances in *trans* compounds (Table 5) may well be a factor in the retention of the *trans* structure. An increase in C—Sn—C angle increases the steric repulsion between the donor ligands and the methyl groups. In order to relieve this repulsion force, one end of the donor bidentate ligand is pushed further away from the Sn atom. Our steric calculations reveal that this distorted *trans* structure is indeed more stable than the undistorted *cis* structure.



In the *cis* compounds, there is less reason sterically for the Sn—D distances to become different. Also on electronic grounds, the Sn atoms in *cis*-Cl_2Sn and *cis*-Ph_2Sn compounds will be more electronegative than in *trans*-Me_2Sn, and invite better overlap with the bidentate donors. The Sn–donor distances (Table 5) support this argument. Thus, the average Sn—O bond lengths in *trans*-$Me_2Sn(ONR'COMe)_2$ is 2.25 Å, compared to the average of the four Sn—O bond lengths in *cis*-$Cl_2Sn(ONHCOMe)_2$ of 2.09 Å.

It is interesting to note that the energy difference between *cis* and *trans* structures must indeed be very small for large ligand bite size, since *cis*-$Me_2Sn(acac)_2$ has been observed in solution (15), whereas *trans*-$Me_2Sn(acac)_2$ forms in the solid state. Also,

FIG. 2. Variation of total valence molecular orbital energy as a function of ∠R—Sn—R in $R_2Sn(acac)_2$ compounds: (*a*) R = methyl, (*b*) R = chloro.

cis-MePhSn compounds form, in contrast to their *trans*-Me_2Sn analogues (16). Thus, *cis*-MePhSn-$(acac)_2$ is obtained rather than *trans*-$Me_2Sn(acac)_2$.

(b) Bond Angles

Within either the *cis* or *trans* structures, the steric model is very successful in predicting the C—Sn—C angle and other bond angles in $RR'Sn(bidentate)_2$ compounds. The predicted variation of C—Sn—C angle with ligand bite size for the *trans*-Me_2Sn, MePhSn, and Ph_2Sn compounds is shown in Fig. 3 (taking all Sn—D distances equal). Qualitatively, as the ligand bite angle increases from 60.5° (*b* = 1)

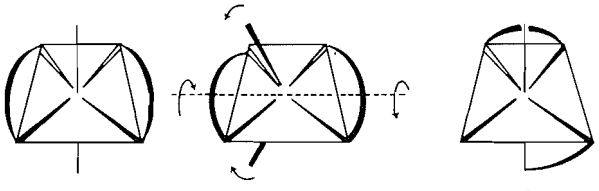
to 72.5° (b = 1.18), the C—Sn—C angles increase from 126° to 180°, and remain at 180° as the ligand bite size increases. The angle between the bisector of the C—Sn—C angle and the line joining the central atom and a ligand donor atom decreases from 82° (b = 1.0) to 54° (b = 1.18). These observations are consistent with those reported by Kepert (6, 7). As the ligand bite size decreases, the R–ligand repulsion increases. The molecule then tends to distort to a skew-trapezoidal bipyramid structure. This distortion is physically equivalent to a compression of the C—Sn—C angle followed by a twist of the bidentate ligands. The intermediate of such a rotation is the skew-trapazoidal bipyramid structure II. If the ligand bite size decreases further, the *cis*-structure is formed.



trans II *cis*

On steric grounds alone, for $b < 1.05$, the predicted C—Sn—C angle in *trans* compounds increases in the order $Me_2Sn < MePhSn < Ph_2Sn$; whereas for $b > 1.05$, the C—Sn—C angle increases in the opposite direction (Fig. 3). For *cis* structures, the predicted C—Sn—C angle increases in the order $Me_2Sn < MePhSn < Ph_2Sn$ (Table 3, $Me_2Sn(oxin)_2$, 99.0°; $MePhSn(oxin)_2$, 100.6°, $Ph_2Sn(oxin)_2$, 102.4°). However, at least partially because of Bent's rule, the observed C—Sn—C angle in *cis*-Me_2Sn compounds will tend to increase more than in the other two cases (e.g. $Me_2Sn(oxin)_2$, 110.7°, see below). Figure 3 also indicates that ligand bite size normally plays a much more important role than steric angle of the R groups in determining the C—Sn—C angle in *trans*-RSnR′ compounds (7).

More quantitatively, we have calculated bond angles for the few *trans*-$R_2Sn(bidentate)_2$ compounds known (Table 2). Except for $Me_2Sn(NO_3)_2$, the calculated C—Sn—C angles are in very good agreement with those observed, indicating the considerable power of our simple method for rationalizing and in-

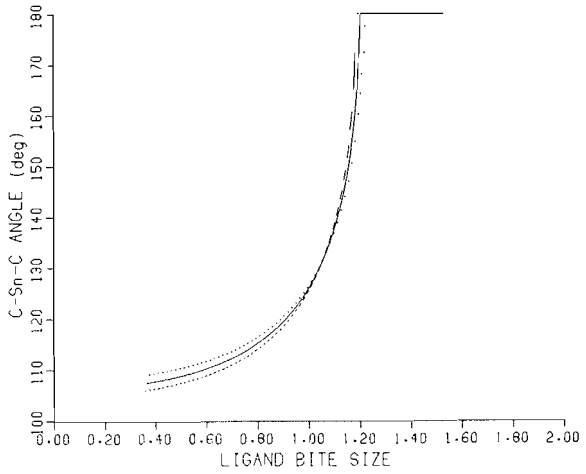


FIG. 3. Variation of C—Sn—C angle (deg) as a function of the ligand normalized bite size; dotted line, R = R′ = Ph; full line, R = Me, R′ = Ph; broken line, R = R′ = Me.

deed predicting bond angles in compounds of this type.

As suggested by Fig. 1, the *cis* configuration is more stable than *trans* on steric grounds, and indeed the *cis* configuration is formed except when R and R′ = Me. Five crystal structures have been determined (12, 17–20) (Table 3) and the experimental bond angles are compared with those observed. Other compounds such as $Ph_2Sn(oxin)_2$, MePhSn-$(oxin)_2$, $MeClSn(acac)_2$, and $PhClSn(acac)_2$ have *cis* structures from Mössbauer and other evidence (16). Predicted bond angles for the two oxin compounds are included in Table 3. In contrast to the *trans* compounds, our calculations for the *cis*-species show that the R—Sn—R (R, R′ = Me, Ph, Cl) angle is not very sensitive to the variation in ligand bite size. Thus the calculated angle is always in the 90°–105° range. Neglecting R, R′ = Me for electronic reasons, the predicted R—Sn—R′ angle for a given ligand bite on steric grounds alone increases in the order Cl—Sn—Cl < Me—Sn—Cl < Ph—Sn—Cl < Me—Sn—Ph < Ph—Sn—Ph.[3] Mössbauer parameters for Ph_2Sn and MePhSn compounds have been previously rationalized using this order (16).

Quantitatively, the agreement between predicted and observed angles is rather good except for Me_2Sn-$(oxin)_2$. For this compound, the observed C—Sn—C angle is 12° higher than that calculated. To maximize the *s* character in the Sn—Me bonds, the C—Sn—C angle increases to approach the tetrahedral value. The C—Sn—C angle in $Me_2Sn(ONHCOMe)_2$ (20) (109.1°) also approaches the tetrahedral value. In these *cis*-Me_2Sn compounds, the Sn atom is probably sp^3 hybridized as proposed by Schlemper (12) and our Extended-Hückel calculations, so that the *s* character is once again maximized in the Sn—Me bonds. The two other Sn hybrid orbitals form two 'three centre' bonds with the chelating ligands. This sp^3 hybridization also gains support from the $^2J_{CH_3-Sn^{119}}$ coupling constants. Thus ^2J is 71.2 Hz for *cis*-$Me_2Sn(oxin)_2$ — almost identical to that for four coordinate compounds such as Me_2SnCl_2 (16).

[3]It is also possible to argue that for a specific orientation of the phenyl group, the steric angle of the phenyl group and chloro group will be smaller than the methyl group, hence the angle will be smaller. We think this explanation is not satisfactory as we have shown that the C—Sn—C angle is not very sensitive to the steric angles in *cis* compounds, and also this cannot explain the apparent constancy of 109.5° for dimethyl compounds.

Conclusions

For RR′Sn(bidentate)$_2$ compounds (R, R′ = Me, Ph, Cl), the ligand–ligand repulsion model is generally successful in predicting both the steric preference of the R groups and the bond angles about the Sn atom. Kepert's work (7) and recent calculations on transition metal complexes (22, 23) also suggest that far more attention should be paid to steric effects when considering the stereochemistry of inorganic and organometallic compounds.

Appendix

The calculations were performed using the Extended-Hückel method (13). The geometry of $Me_2Sn(acac)_2$ was taken from its crystal structure (25). For simplicity, the methyl groups on the acetylacetonate ligand were replaced by hydrogen atoms. The Sn—Cl bond distance in $Cl_2Sn(acac)_2$ was taken from ref. 18. Parameters used for the calculation are tabulated in Table 4. All geometrical deformations were examined by extended Hückel calculations without charge iteration. The off diagonal matrix elements were calculated using the Wolfsberg and Helmholz approximation (21):

$$H_{ij} = 0.5KS_{ij}(H_{ii} + H_{jj})$$

with K fixed at 1.75.

The synthesis of oligoribonucleotides. III.[1] The use of silyl protecting groups in nucleoside and nucleotide chemistry. VIII

Received December 22, 1978

KELVIN K. OGILVIE, ARIA L. SCHIFMAN, and CHRISTOPHER L. PENNEY, Can. J. Chem. **57**, 2230 (1979).

The synthesis of all isomeric mono- and disilyl derivatives of cytidine, guanosine, and their *N*-benzoyl analogues using the *tert*-butyldimethylsilyl protecting group is described. These compounds and those containing a 5′-monomethoxytrityl group have been condensed via the phosphodichloridite procedure to produce nucleotides rapidly and in good yields. The synthesis of 2′–5′-linked nucleotides is described. A cautionary note is introduced in regard to the preparation of 5′-monomethoxytritylguanosine and a novel methanolysis of certain *N*-benzoylcytidines is mentioned.

KELVIN K. OGILVIE, ARIA L. SCHIFMAN et CHRISTOPHER L. PENNEY, Can. J. Chem. **57**, 2230 (1979).

On décrit une synthèse de tous les dérivés isomères mono- et disylés de la cytidine, de la guanosine et de leurs analogues *N*-benzoylés qui fait appel au groupe protecteur *tert*-butyldiméthylsilyle. On a condensé ces composés et ceux portant un groupe monométhoxytrityl-5′ grâce à la méthode du phosphodichloridite pour obtenir rapidement et avec de bons rendements des nucléotides. On décrit la synthèse de nucléotides reliés par les positions 2′ et 5′. On signale les précautions à prendre lors de la préparation de la monométhoxytrityl-5′ guanosine et on mentionne une nouvelle méthanolyse de cartaines *N*-benzoylcytidines.

[Traduit par le journal]

Introduction

We have recently described the use of alkylsilyl groups, particularly *tert*-butyldimethylsilyl (TBDMS), for protection of hydroxyl groups of deoxynucleosides (1–3), deoxynucleotides (4), ribonucleosides (5, 6), and ribonucleotides (6). The latter work has led to the development of a rapid synthesis of oligoribonucleotides. The previous paper in this series (6) described in detail the synthesis of oligonucleotides of uridine and adenosine using TBDMS and the chlorophosphite triester procedure (7). In this manuscript we wish to describe the extension of these procedures to cytidine and guanosine and their *N*-benzoyl derivatives.

Preparation of Silylated Nucleosides

Two solvent systems have been employed for the silylation of nucleosides (Scheme 1). The DMF–imidazole system usually leads to faster rates of reaction while pyridine as solvent provides higher yields of desired products. These results are summarized in Table 1. Good yields of the desired 2′-protected nucleosides are obtained in all cases. For example the 2′,5′-disilylcytidine (**3***a*) is obtained in 60% yield after a 48 h reaction in pyridine, or in 50% yield after a 2 h reaction in DMF–imidazole (DMF–Im). Similar yields are obtained for 2′,5′-disilyl-N^4-benzoylcytidine (**3***b*; 62% (pyridine), 52% (DMF–Im)). Selective silylation at the 2′-position of 5′-methoxytritylcytidine (**6***a*) and 5′-methoxytrityl-N^4-benzoylcytidine (**6***b*) also proceeds well, particularly in pyridine where yields of **7***a* and **7***b* were 63 and 64% respectively.

With guanosine yields of 2′,5′-protected derivatives are generally lower than for cytidine. For example 2′,5′-disilylguanosine (**3***c*) is obtained in 41% yield while the *N*-benzoyl derivative **3***d* is obtained in 39% yield. Yields for the corresponding 5′-methoxytrityl derivatives are also in the 30–40% range. However, such yields of protected guanosines are quite remarkable especially considering the few steps involved.

The conditions described in Table 1 lead to a minimum of silylation at the bases of cytidine and guanosine. Using larger excesses of silylating agent can lead to silylation at the base particularly in the case of guanosine. We have also noted that the TBDMSCl deteriorates with time and repeated exposure to air such that higher ratios of reagent to nucleoside must be used to obtain the results of Table 1 as the reagent ages.

The position of silylation is easily determined from the ^{13}C spectra. Silylation at a sugar hydroxyl leads to a downfield shift of the sugar carbon to which it is attached. This is true for all of the silylated

*Pyridine-d_5; data collected by F. Hruska and W. G. Niemczura of the University of Manitoba. Similar results have been obtained by Dr. W. Pfleiderer (personal communication).

Additional proof of structure for the *N*-benzoylated compounds (series *b* and *d*) was their direct debenzoylation to the expected (series *a* and *c*) compounds which were prepared directly from the nucleosides as described. Elemental analyses were consistent with the assigned structures.

Compounds **10–12** which have the 5′-position unprotected can be obtained by acetic acid treatment (Scheme 2) of the 5′-silyl nucleosides **3–5** or from the 5′-methoxytrityl compounds **7–9**. In general higher yields are obtained on removal of the methoxytrityl groups (>80% using 80% HOAc at 80–90°C for 20 min) than from removal of a 5′-TBDMS group (50–60% yields). The advantage of using the fully silylated compounds is that they are so readily obtained. The properties of compounds **10–12** are described in Table 2.

We would like to point out a cautionary note in connection with the synthesis of 5′-methoxytritylguanosine (**6***c*). In our attempts to repeat the original Khorana procedure (8) we always obtained very low yields (0–10%). As a result we changed the procedure slightly by using triethylamine as base instead of pyridine. Under these conditions we consistently isolated 43–48% yields of a compound X whose tlc properties were virtually identical to those of authentic 5′-methoxytritylguanosine, **6***c*, prepared by debenzoylation of 5′-methoxytrityl-N^2-benzoylguanosine (**6***d*). However, compound X had a uv spectrum that was definitely different from authentic **6***c* (see Experimental). Further compound X and **6***c* were cleanly separable by high pressure liquid chromatography (hplc). Furthermore, on monosilylation compound X was converted in 80% yield to a new compound (**14**, Scheme 3) which possesses a 5′-TBDMS group since on detritylation it is converted initially to 5′-TBDMS guanosine (**2***c*). These results are in marked contrast to those of authentic **6***c* which is

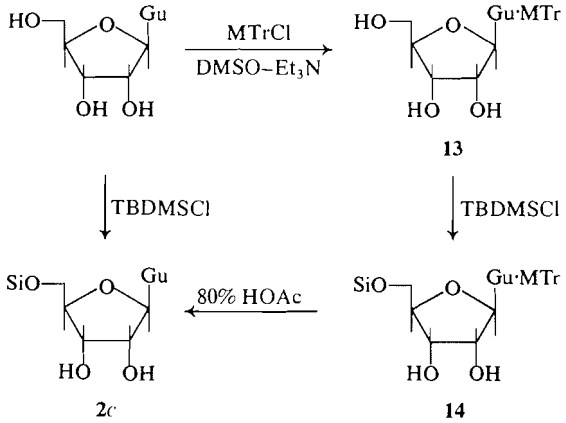
converted on silylation to a mixture of 2′- and 3′-silyl derivatives, **7***c* and **8***c* (Table 1). These compounds are identical to those obtained by debenzoylation of **7***d* and **8***d*. As a result of these experiments it is obvious that compound X possesses a methoxytrityl group on the guanine ring, most likely at N^2 (compound **13**). The remarkably similar (tlc) chromatographic properties of **13** and **6***c* as well as those of **14** and **7***c* make it necessary to use extreme caution when preparing these compounds. The uv spectrum is critical (8) to interpretation and hplc in determining purity.



SCHEME 3

Isomerization

As previously reported (6), compounds possessing a silyl group on the 2′- or 3′-position do not isomerize under conditions used for phosphorylation and are stable in most solvents. However, in alcohol solvents isomerization does occur and at rates that are dependent both on the particular nucleoside derivative and on the alcohol employed. For example 2′,5′-disilylcytidine (**3***a*) is converted to a mixture of **3***a* (82%) and the 3′,5′-disilyl isomer (**4***a*, 18%) after 24 h at 30°C in methanol (ratio of **3***a*:**4***a* is 2:1 after 7 days). Compound **8***a* isomerizes most rapidly of all the cytidine derivatives and is converted to a mixture of **8***a* (57%) and **7***a* (42%) after 24 h under the above conditions. However, in ethanol at 30°C only 6%

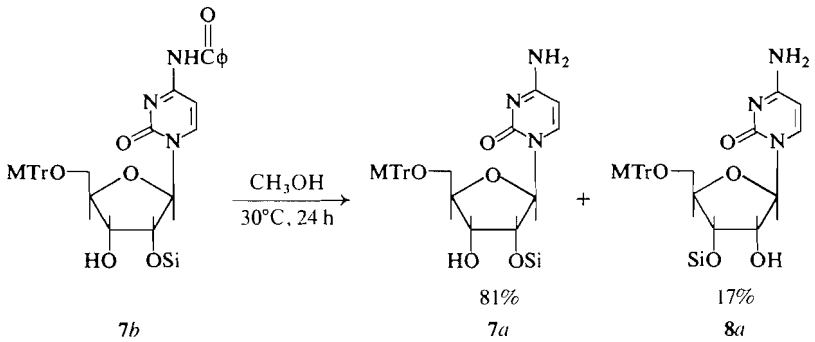
of **8***a* is isomerized to **7***a*. Guanosine derivatives tend to isomerize at rates similar to those for the cytidine derivatives. A complete study of all the silylated ribonucleosides has been done and will be reported separately (9).

Methanolysis of N-*Benzoylcytidines*

The silylated *N*-benzoylcytidines give rise to a remarkably interesting result in methanol. The 5′-methoxytrityl-2′-TBDMS-N^4-benzoylcytidine **7***b* in methanol (30°C) leads to a mixture of the debenzoy-



7*b* 7*a* 8*a*

SCHEME 4

lated compound **7***a* (81%) and the isomerized debenzoylated compound **8***a* (17%) after 24 h (Scheme 4). Compound **8***b*, however, is 93% unaffected (neither debenzoylation nor isomerization) after 24 h under the same conditions (0.8% **7***a*, 1.5% **8***a*, 4.6% **7***b*). Both 2′,5′- and 3′,5′-disilyl-N^4-benzoylcytidines (**3***b* and **4***b*) undergo nearly complete debenzoylation after 24 h. Furthermore 5′-TBDMS-N^4-benzoylcytidine is 49% debenzoylated after 24 h. The 2′-TBDMS-C^{Bz} (**10***b*) is 64% debenzoylated after 24 h while the 3′-isomer **11***b* is only 6% debenzoylated and this occurs in the form of **10***a* (3%) and **11***a* (3%) which may result from prior isomerization of **11***b* to **10***b* which may then debenzoylate and isomerize to the observed products. In all cases methyl benzoate is observed and it is obvious that a silyl group on the 2′- or 5′-position is essential. Similar results are obtained with adenosine but not with guanosine. The solvolysis is not observed in ethanol. This very interesting observation is being studied in detail and will be fully discussed (9).

Synthesis of Nucleotides

The silylated derivatives of cytidine and guanosine are easily condensed to form ribonucleotides using the Letsinger phosphorodichloridite procedure (7). This procedure does not require *N*-protection even with cytidine and guanosine. The general procedure is outlined in Scheme 5 and yields for a variety of condensations are recorded in Table 3. These reactions were carried out as described previously (6) at −78°C with total reaction times of about $2\frac{3}{4}$ h. Yields of 3′-5′-linked nucleotides are between 50 and 90%. The reactions described in this report were all worked up using conventional silica gel thick layer chromatography (tlc). The *N*-protected nucleotides of cytidine and guanosine have greater mobilities in less polar solvents than the unbenzoylated analogues. Thus for the synthesis of long chains using tlc separations, the *N*-protected derivatives offer a practical advantage. This feature is not nearly so important if hplc is used to separate products and for such separations the ability to avoid *N*-protection will offer a major advantage.

The general procedure was used (Scheme 6) to prepare the fully protected trinucleotide MTr-$G^{Bz\ Si}_{p}$(TCE)$C^{Bz\ Si}_{p}$(TCE)$C^{Bz\ Si}_{Si}$(**19***a*) and the fully protected tetranucleotide MTr-$G^{Bz\ Si}_{p}$(TCE)$G^{Bz\ Si}_{p}$(TCE)-$C^{Bz\ Si}_{p}$(TCE)$C^{Bz\ Si}_{Si}$(TCE) (**20**). Yields at the tri- and tetranucleotide stages were 56 and 66% respectively. All of the nucleotides described in this report were deprotected as described below to the free nucleotides. The 3′-5′-linked nucleotides were completely degraded by snake venom and spleen phosphodiesterases. Cytidine-containing nucleotides are also completely degradable by pancreatic ribonuclease.

SCHEME 5

In order to compare the properties of the 3′-5′-nucleotides with those of the 2′-5′-analogues, some of the latter were prepared. The required starting materials (**4** and **8**) are always obtained as by-products in the preparation of the normally preferred 2′-5′-diprotected nucleosides (**3** and **7**). The fully protected 2′–5′-linked nucleotides of CC (**21**) and GU (**22**) were synthesized by the general procedure. Their chromatographic properties are slightly different from their 3′–5′-linked isomers (Table 5). On

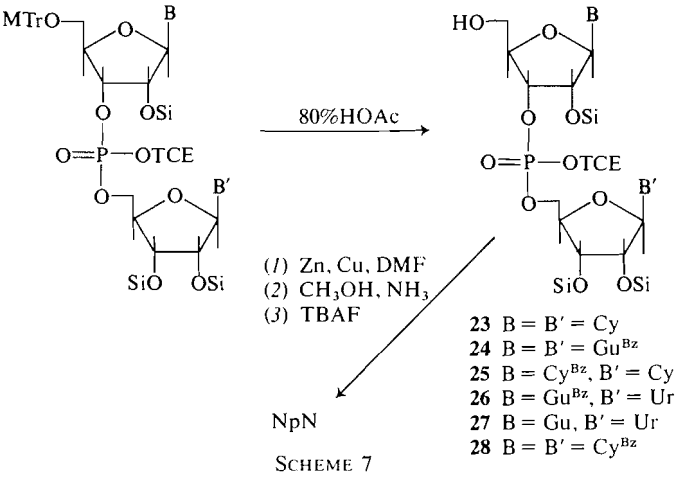
Deprotection of Protected Nucleotides

For compounds such as **13** which do not contain *N*-protecting groups, acetic acid treatment followed by tetrabutylammonium fluoride (TBAF) gives an 85–90% conversion to the free nucleotide (CpC). Fluoride ion removes both the silyl and trichloroethyl groups in one 30 min step. It also causes ~10% cleavage of the internucleotide linkage as has been noted by others (10). This is a serious limitation in the direct deprotection of longer chains. However, fluoride ion does not cause either degradation or isomerization of phosphodiesters. Consequently all that is necessary is to remove the trichloroethyl group before treatment with TBAF to remove the silyl groups. The whole procedure can be illustrated (Scheme 1) by the deprotection of compound **14***a*



SCHEME 7

($SiC^{Bz\,Si}_{p}(TCE)C^{Bz\,Si}_{Si}$). The trichloroethyl group is removed in 3–20 h using Zn–Cu couple (11) in DMF at 50°C. The time varies from experiment to experiment and may be due to inefficient stirring or variations in quality of the Zn–Cu couple. The progress of the reaction is easily followed by tlc. The resulting diester ($SiC^{Bz\,Si}_{p}(OH)C^{Bz\,Si}_{Si}$) can be isolated on tlc (chloroform–ethanol 9:1) or treated directly with methanolic ammonia to remove the benzoyl groups. We find that for small amounts (< 15 mg) it is best to continue to the end of the ammonia treatment and then isolate the nucleotide (in this case, $SiC^{Si}_{p}C^{Si}_{Si}$) on paper chromatography. Regardless of the manner of isolation we have been consistently obtaining deprotection with *no* other nucleosidic or nucleotidic products arising. Finally the silyl groups are removed in a 30 min treatment with TBAF (6). This step is quantitative with absolutely no chain degradation. However, we find that if isolation after the zinc treatment at either of the two stages mentioned above is omitted then desilylation is incomplete. Apparently the presence of metal ions interferes at this step.

Conclusions

This manuscript, along with the previous article in the series (6), describes the first complete set of protecting groups common to all four normal ribonucleosides. The alkylsilyl groups can be seen to provide a remarkably facile protection of the hydroxyl groups in nucleosides. The silylated nucleosides both with and without *N*-protection are easily coupled to form ribonucleotides using the phosphodichloridite procedure. We are currently using the procedure described in this and the previous article in an attempt to synthesize the sequence of a transfer RNA.

Experimental

General Methods

All general procedures and techniques including chromatography, uv, nmr, mass spectrometry, elemental analyses, melting points, enzyme assays, silylating conditions, phosphorylation procedures and general reagents are as previously described (6) with the following exceptions.

Thin layer chromatographic data (R_f values) are recorded from Brinkman Polygram SIL G/UV 254 analytical sheets. High pressure liquid chromatography experiments were performed using a Spectrophysics SP8000 microprocessor based hplc unit. All results described in this report are based on a Lichrosorb 10 μm RP-8 column (4.6 mm × 25 cm) and the purity of all nucleoside derivatives as well as nucleotides up to and including tetranucleotides can be verified on this column.

Reagents and Chemicals

N^2-Benzoylguanosine (mp 228–231°C dec.) (12, 13), 5′-methoxytrityl-N^2-benzoylguanosine (mp 156–162°C) (14), N^4-benzoylcytidine (mp 218–220°C) (14, 15), 5′-methoxytrityl-N^4-benzoylcytidine (mp 120–125°C) (14), and 5′-methoxytritylcytidine (mp 150–152°C dec.) (8) were all prepared according to literature procedure.

*5′-Methoxytritylguanosine (**6**c)*

Compound **6***d* was treated with an excess of the hydrazine hydrate reagent for 1 h as described by Letsinger (16). On standing the reaction mixture separated into two phases. The top phase was collected and evaporated. The residue was washed with ethanol to leave pure 5′-methoxytritylguanosine (λ_{max}(EtOH)): 236, 250 (sh), and 270 (sh) nm). This compound had identical properties to those reported by Khorana (8). The compound was pure according to the chromatographic techniques used and had a retention time of 164 s (k' 2.6) on hplc (MeOH–H_2O (7:3), 20°C, 2.0 mL/min at 1770 psi).

*N^2-Methoxytritylguanosine (**13**)*

To guanosine (2.83 g, 10 mmol) in DMSO (15 mL) was added triethylamine (4 mL) followed by methoxytrityl chloride (3.3 g, 11 mmol). The mixture was stirred at room temperature for 3 h and poured into 300 mL of 15% NaCl in H_2O. After stirring for a few minutes the residue was collected by filtration (sintered glass) and the gum was washed with ether (300 mL). The residue was then dissolved in methanol (50 mL), the solution was filtered from some insoluble material, and the clear solution was evaporated at reduced pressure. After repeated evaporation of hexane the gum was dried under vacuum, and this usually resulted in a light brown solid. If not, the residue was dissolved in the minimum amount of methanol, and ether was added to induce precipitation. Usually a light brown solid was formed on evaporation of the solvents at re-

duced pressure. The solid obtained at this point was identified as *N*-methoxytritylguanosine, **13**, 2.67 g, 48%, mp dec. < 205°C. This compound was usually 97% pure at this stage as determined by hplc (retention time 225 s, k' 3.6 under same conditions as **7***c* above). Compound **13** showed λ_{max}(EtOH) 231, 261, and 276 nm with λ_{min}(EtOH) 246 and 272 nm.

Compound **13** was treated with TBMSCl under the standard conditions and a compound **14** (mp 140–144°C, R_f(EtOAc) 0.24, R_f($CHCl_3$–EtOH (9:1)) 0.61) was obtained in 80% yield. On treatment with 80% HOAc at room temperature the methoxytrityl group was removed from **14** faster than the TBDMS group such that 5′-TBDMS-guanosine (**2***c*) was produced. On standing in acetic acid for 20 h only guanosine was present.

Silylation of Nucleosides

These procedures were identical to those previously described. The products were isolated from thick layer chromatography and the solvents used to develop the plates are listed in Table 4.

Synthesis of Nucleotides

The procedures used were identical to those previously reported (6). Products were isolated by thick layer chromatography as described. For cytidine we observed very little formation of the 3′–3′-linked by-products (< 5%) and none of the 5′–5′-linked products. This contrasts with the uridine case previously reported (6). For guanosine the amount of 3′–3′-linked products was between 10 and 20% and 5′–5′-linked by-products were also found in 20–30% yields. These products usually have very different chromatographic properties than those of the desired products and are easily separated on chromatography. Properties of isolated products are listed in Table 5. The dinucleotides containing a methoxytrityl group

were detritylated and the properties of these compounds are also listed in Table 5.

Deprotection of Nucleotides

Fully silylated (or detritylated) nucleotides were treated with Zn–Cu couple in DMF for 3–20 h. Fully silylated compounds were often isolated after this step by tlc chromatography in chloroform–ethanol (9:1). The product at this stage was treated with methanolic ammonia for 48 h as described in the literature (11). If chromatography had not been performed after the Zn–Cu treatment, then the product was chromatographed on Whatman 3MM paper in solvent *A* to remove residual metal ions. The product was then treated with TBAF in THF for 30 min. The products were then passed through a Dowex 50W-X8 (Na^+ form) ion exchange column and applied to Whatman 3MM sheets developed in solvent *A* or *F*. Only single, desired products were obtained from these reactions. The chromatographic and electrophoretic properties of free nucleotides are summarized in Table 6. For dinucleotides reference standards are available from Sigma Chemical Co. Nucleotides were subjected to enzymatic degradation using standard procedures (6) and all 3′–5′-linked nucleotides were completely degraded.

Received March 5, 1979

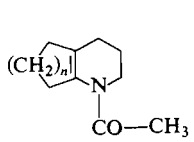
ROBERT R. FRASER, JEAN-LOUIS A. ROUSTAN, and JASWANT R. MAHAJAN. Can. J. Chem. 57, 2239 (1979).

The barriers to rotation about the N—CO bonds in a series of *N*-vinyl amides have been determined by a study of their proton spectra at variable temperatures. A complete LACN 3 analysis of compound **1** gave the parameters used in a complete line shape (CLS) analysis to obtain $\Delta G^{\ddagger}$. A new approximate method was shown to give a value for ΔG that agreed within 0.1 kcal/mol of that obtained by CLS. The approximate method was employed to determine $\Delta G^{\ddagger}$ for other members of the series. The barrier in the *N*-vinyl amide **1** was found to be 2.5 kcal/mol higher than that in its saturated analog. Variations within the series of *N*-vinyl amides amounted to only 1.2 kcal/mol. A steric effect is proposed for the increase in barrier height. The new approximation formula was tested for the general case of unequal singlet coalescence and found to give k's accurate to within 4% for $\Delta\nu > 10$ and to within 10% at lower values of $\Delta\nu$.

ROBERT R. FRASER, JEAN-LOUIS A. ROUSTAN et JASWANT R. MAHAJAN. Can. J. Chem. **57,** 2239 (1979).

On a déterminé les barrières à la rotation autour des liaisons N—CO dans une série de *N*-vinylamides à l'aide d'une étude de leurs spectres protoniques à températures variables. Une analyse LACN 3 complète du composé **1** conduit à des paramètres utilisés dans une analyse complète de la forme des raies (CLS) afin d'en déduire le $\Delta G^{\ddagger}$. On montre qu'une nouvelle méthode approximative conduit à une valeur de ΔG qui est en accord, à 0.1 kcal/mol près, à celle obtenue par CLS. On a employé la méthode approximative pour déterminer le $\Delta G^{\ddagger}$ des autres membres de la série. On a trouvé que la barrière dans le *N*-vinylamide **1** est 2.5 kcal/mol plus élevée que celle de son analogue saturé. Les variations à l'intérieur de la série des *N*-vinylamides ne sont que de 1.2 kcal/mol. On propose un effet stérique pour expliquer l'augmentation dans la hauteur de la barrière. On a vérifié la nouvelle formule approximative dans le cas général de la coalescence en un singulet inégal et on a trouvé qu'elle fournit des valeurs de k qui sont précises à 4% pour un $\Delta\nu >$ et à 10% pour des valeurs de $\Delta\nu$ plus faibles.
[Traduit par le journal]

Measurement of barriers to rotation about the N—CO bond in a wide variety of amides has been achieved through study of their temperature dependent ^{1}H nmr spectra (1–3). Yet the rotational barriers in simple *N*-vinyl amides (acyl enamines) have been reported for only two compounds, *N*-vinyl formamide and *N*-vinyl acetamide (4). In that paper the spectral analysis employed the peak separation method whose inaccuracy has been recognized for some time (5, 6). As a result, the activation parameters reported (E_a and A) for the two amides cannot be considered as accurate and any conclusions based thereon are unreliable. More recently, Grindley *et al.* reported the barrier for the sulfur containing heterocyclic enamide, 4-benzoyl-1-thia-4-azacyclohex-2-ene, to be 14.4 kcal/mol (7). In this paper we wish to describe the determination of barriers to rotation for a series of *N*-acetyl enamines (**1–5**) in order to provide an indication of the effect of the double bond on the rotational barrier. In analysis of the spectra of **1** the accuracy in $\Delta G^{\ddagger}$ at the coalescence temperature using the complete line shape (CLS) method was shown to be comparable to that calculated using a new two-site equation. For the spectra of **2–5** $\Delta G^{\ddagger}$ was obtained by this two-site equation. In addition the use of this approximate



1 $n = 1$
2 $n = 2$
3 $n = 3$
4 $n = 4$
5 $n = 8$

SCHEME 1

equation as applied to the coalescence of two unequally populated singlets was shown to offer an improvement over previous approximate treatments.

The enamines investigated herein were synthesized by a method described earlier by one of us (8). The ^{1}H spectrum of **1** ($n = 1$) at 0°C exhibited two separate multiplets for the protons at C-2 representing the two diasteroisomers present due to slow rotation about the N—CO bond (see **1A** and **1B** in Scheme 1).[1] Each multiplet represents the AA′ portion of an AA′MM′YY′ system, one which is too large to permit a variable temperature analysis by the CLS method.[2]

We have therefore decided to treat the AA′ absorptions as part of an AA′MM′ system perturbed by first-order coupling with the methyl group (10) and the YY′ nuclei (11). For the CLS analysis these effects are incorporated into the value of T_2^{eff} chosen to best reproduce the observed spectrum at −46°C. The validity of this approximation can be assessed at this temperature where there is no broadening by kinetic exchange. We have conducted exact calculations of the system as an AA′MM′YY′ using LACN3 with the further inclusion of variable first-order long range coupling to the methyl group as well as varied values for T_2. In no case was any better agreement obtained than by incorporating all long range couplings into T_2^{eff}. Figure 1 shows the agreement obtained between the AA′ portion of the calculated spectrum and that measured at −46°C. The parameters employed are given in Table 1. For CLS calculations of the spectra in the region of coalescence, the same parameters were used with the additional inclusion of a small temperature dependence of the chemical shifts AA′ and of the equilibrium constant between conformers, both estimated by extrapolation from measurements between −20 and −46°C as well as by comparison with CLS analysis of spectra at +10°C. The spectra in the region of coalescence are shown in Fig. 2. If we define T_c as the temperature at which only two inflection points remain (*vide infra*), the CLS curve indicates a value for k at T_c of between 38 and 44 s^{-1}. This translates to a barrier to rotation of 14.9_5 kcal/mol.

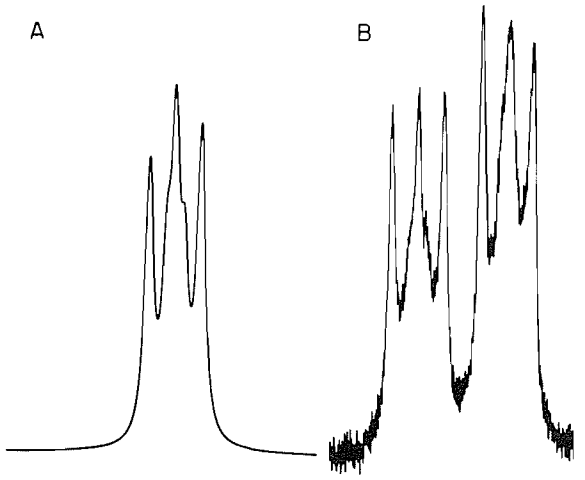

FIG. 1. (A) The absorption due to the C-2 methylene protons of conformer A of **1**, as calculated by LACN 3 using the parameters listed in Table 1, using a line broadening of 2 Hz as determined experimentally and including a first-order perturbation of 0.2 Hz due to long range coupling with the methyl group. (B) The spectrum of the C-2 methylene protons of both conformers of **1** measured at −46°C.

TABLE 1. Parameters used for the LACN 3 calculations in Fig. 1 and, in parentheses where different, for the DNMR 3 calculations in Fig. 2

	Conformer A	Conformer B
$J_{AA'} = J_{MM'}$ (Hz)	−14	−14
$J_{A'M'} = J_{AM}$	3.5	3.13
$J_{AM'} = J_{A'M}$	7.25	6.88
$\delta_A = \delta_{A'}$ (ppm)	3.70 (3.71)[a]	3.52
$\delta_M = \delta_{M'}$	1.84	1.99
ρ	0.46 (0.44)	0.54 (0.56)

[a]Values in parentheses refer to parameters at T_c; others represent values at −46°C.

Accuracy of CLS

While a rigorous error analysis would not be possible due to the number of assumptions made and the variables present, our experience in matching the calculated with the experimental curve indicates the derived k to be little influenced by our choice of T_2^{eff}, in that a 30% change in T_2^{eff} (0.15–0.12) causes no visible change in the curve for a given value of k_A. However, a 2 deg uncertainty in T_c leads to a 0.1 kcal/mol change in $\Delta G^{\ddagger}$ so that k_A would have to change by 15% to produce the same variation in $\Delta G^{\ddagger}$. The very good agreement between the calculated and the experimental spectra around T_c

[1]The major isomer is assigned the *Z* configuration on the basis of the known deshielding effect on the N—CH_2 by an acetyl methyl (13) as observed in the ^{13}C spectrum of 2 at 0°C and correlated with **1–5** by the proton shifts for the N—CH_2 protons.

[2]Our copy of the CLS program (9) has been written to handle up to four spins and each calculated spectrum requires 10 min on our IBM 360/65 computer. Thus, expansion of the program to include six spins in a calculation was deemed too demanding in computer time to be undertaken.

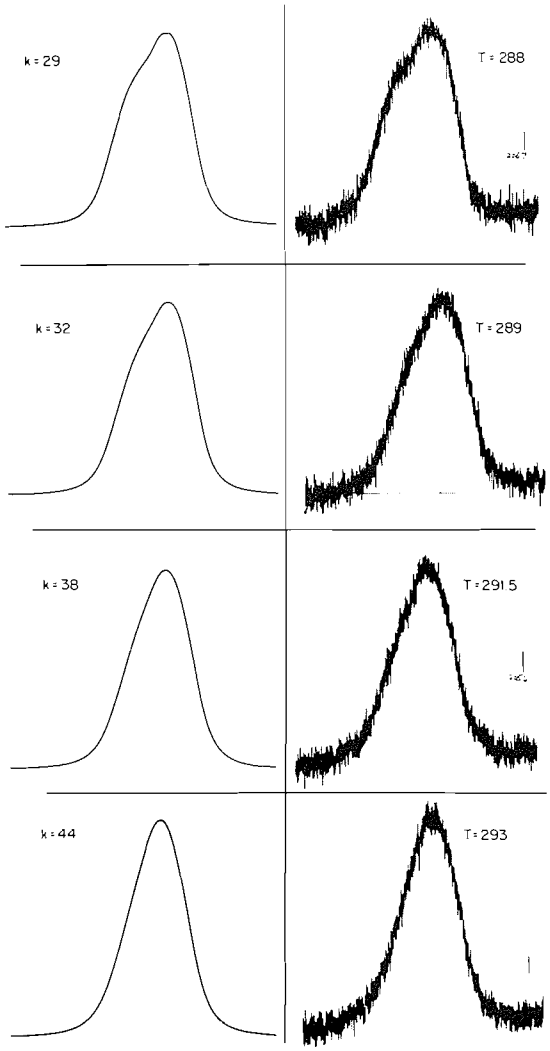

FIG. 2. The proton absorption for the C-2 methylene group of conformer A of **1** as calculated from DNMR 3, using a line broadening of 2.7 Hz for k = 29, 32, 38, and 44 Hz (left side curves) and measured at 288, 289, 291.5, and 293°C (right side curves).

suggest that the error in k_A (due to our choice of T_2^{eff} and our spin system approximation) is less than this amount. This leads to an upper error in $\Delta G^{\ddagger}$ of 1% (i.e., $\Delta G^{\ddagger}$ for **1**A → **1**B = $14.9_5 \pm 0.15$ kcal/mol as estimated using the formula for the linearized relative statistical error (12).

Approximate Methods for Determining k

The complete line shape method of analysis has been a powerful tool for the study of exchange phenomena. In many cases, a careful study of spectral changes over a wide range of temperatures can yield accurate estimates of k throughout the range. Nevertheless, that the accuracy in the measurement of $\Delta G^{\ddagger}$ far exceeds that for $\Delta H^{\ddagger}$ is widely documented (12).

It is because of this limitation in accuracy that approximate methods have been utilized to obtain values for rate constants which are often as reliable as those obtained by the CLS method. The simplest of these, the Gutowsky–Holm eq. [*a*] provides an accurate value for the rate constant k for an exchange between two equally populated sites (each giving rise to singlet absorption) at the coalescence temperature, T_c. Application of this equation to the coalescence of two singlets of unequal intensity has been shown to provide a useful alternate to CLS by Raban and co-workers (14). We wish to examine use of the Gutowsky–Holm equation in a more rigorous way and to assess its applicability to both simple and complex systems undergoing exchange.

In the case of the exchange of an uncoupled proton between two unequally populated sites A and B having $K = \rho_B/\rho_A = 2$, where ρ_B and ρ_A represent the fractional populations of the two sites, Raban (13) found that the larger rate constant $k_{A\to B}$ when calculated from [*a*] is within 20% of the true value (obtained from CLS). The definition proposed for T_c was that temperature at which $\partial^2 G/\partial V^2 = \partial G/\partial V = 0$ (14). Thus, below T_c the spectrum appeared as two maxima separated by a valley (Fig. 4, k = 70) which disappeared at T_c (Fig. 4, k = 98). It can be seen that at this T_c one of the interior inflection points has a tangent of slope zero.

In this treatment the value obtained for the larger of the two rate constants is independent of the value for K. In the present study we have chosen a different definition for T_c, with the result that the values for k_A and k_B will be dependent upon K. In the spectra showing coalescence of equally populated singlets the spectrum below T_c is represented by a curve with four inflection points (Fig. 3) and above T_c one sees a single maximum to a curve containing only two inflection points. At the point of coalescence, which we define as the temperature at which the valley disappears, there are only two inflection points (see Fig. 3). It is this characteristic of T_c which we wish to maintain in defining T_c in the case of unequally populated sites. Specifically one searches for the spectrum possessing the longest "flat spot" (where $\partial G/\partial V$ is constant) as illustrated by the curve for k_A = 145 in Fig. 4.

We have tested the validity of the new approximate formulae [*a*]–[*c*] for the coalescence of two singlets and $K = \rho_B/\rho_A = 2$.

[*a*] $k = (\pi/\sqrt{2})\Delta\nu$

[*b*] $k_A = 2k\rho_B$

[*c*] $k_B = 2k\rho_A$

where k_A represents the process A → B.

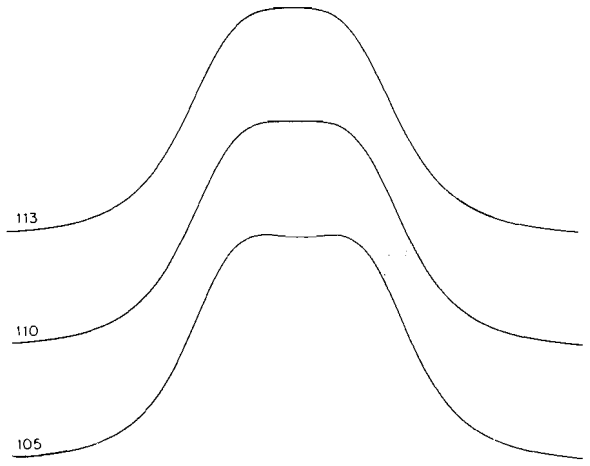

FIG. 3. The curves computed by DNMR 3 to represent a rate of exchange between two equally populated sites which is above, equal to, or below that defined as representing the coalescence temperature.

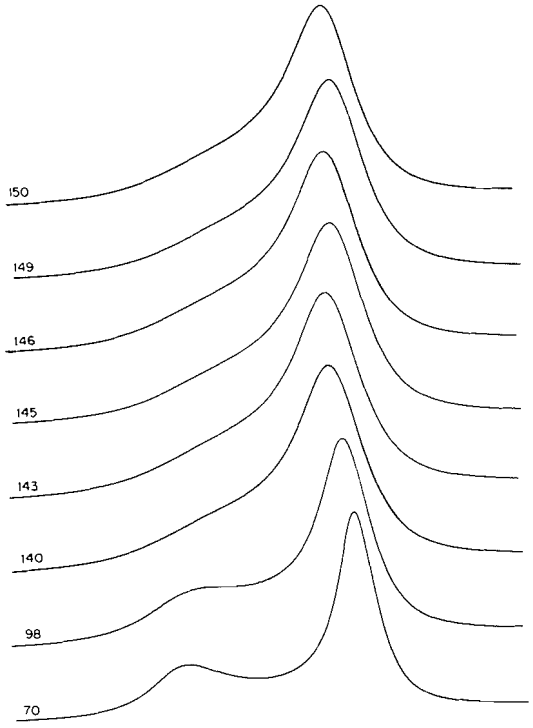

FIG. 4. The curves computed by DNMR 3 to illustrate coalescence of two unequally populated singlets ($K = 2$). The rates chosen represent the following situations: $k = 70$, below coalescence; $k = 98$ represents coalescence as defined by Raban; $k = 140$, 143, rates approaching our definition of coalescence; $k = 145$, 146, 149, rates which could represent the rate at the coalescence temperature; $k = 150$ clearly represents a rate above the coalescence.

Table 2 compares the values for k_A calculated from [*a*] and [*b*] with those obtained by CLS. Examination of the curves computed by DNMR 3 for a range of k's at each value of $\Delta\nu$ revealed surprisingly little uncertainty in the assignment of a curve as that representing T_c. Comparing this curve with a number of those representing rates greater and smaller leaves no doubt as to the choice of k at T_c within the accuracy quoted in Table 2. The curves calculated by CLS for $\Delta\nu = 50$ and a range of k^{CLS} values are illustrated in Fig. 4.

It is thus evident that the two-site approximate equation [*b*] gives an accuracy of better than 5% in k when $\Delta\nu$ is greater than 10. This level of accuracy exceeds that reported by Raban *et al.* and is comparable to that obtained by the more laborious graphical procedure of Shanan-Atidi and Bar-Eli (15*a*).[3] Since it leads to an uncertainty in $\Delta G^{\ddagger}$ of less than that due to an uncertainty in temperature cf ± 2°C (± 0.10 kcal/mol), it is as accurate a method as the CLS for measuring $\Delta G^{\ddagger}$ at T_c.

Application of the Approximate Method to the Exchange Process of ***1***

We next examined the possibility that the approximate two-site equation for unequally populated singlets could be applied with adequate accuracy to the coalescence of the two multiplets representing the AA′ absorptions of the enamide **1**. Equations [*a*] and [*b*] give a value of 47 s^{-1} for k_A from which $\Delta G^{\ddagger}$ is calculated to be 14.8_5 kcal/mol (at 292°C). These values are in good agreement with those obtained by CLS, k (41 s^{-1}) and $\Delta G^{\ddagger}$ (14.9_5 kcal/mol), and thereby justify use of the approximate method to determine k for the closely related acyl enamines **2**–**5**. The rate constants obtained in this way and their associated $\Delta G^{\ddagger}$'s are given in Table 3. Based on a maximum uncertainty in k of 35% and in T_c of 2 deg, the linearized relative statistical error (12) in $\Delta G^{\ddagger}$ is 0.25 kcal/mol.

It can be seen that all the measured barriers fall within the range 13.6 to 14.9 kcal/mol. This activation energy for rotation is lower than that reported for most amides (1). However, an appropriately selected model of similar structure is required to allow the assessment of the effect of a vinyl group on $\Delta G^{\ddagger}$. For this purpose we have prepared *N*-acetyl-*trans*-decahydroquinoline, **6**, (16), and measured its barrier to rotation about the amide bond. This was accomplished by determining the temperature of coalescence of the two equatorial proton absorptions at C-2 to be at -10°C, which by use of our approximate eq. [*c*] with [*a*] gives a $\Delta G^{\ddagger}$ minor → major

[3]For another solution method see ref. 15*b*.

TABLE 2. Comparison of k_A with k^{CLS}

Δν (Hz)	k_A (s^{-1})	k^{CLS} (s^{-1})	Precision[a] (%)
50	149	145–150	3
40	119	115–120	4
30	89	86–90	4
20	59	57–60	4
10	29.8	28.5–30	5
5	14.9	14–15	6
4	11.9	10.8–12	10
3	8.9	8–9	11

[a]The precision is calculated from the range of uncertainty in k^{CLS} as estimated from the average of the independent assessments of two of us.

TABLE 3. Barriers to N—C=O rotation in **1–6**

Compound	T_c	Δν (at T_c)	p_B	k_A	$\Delta G_{A\rightarrow B}$ (±0.25)
1	292	19	0.56	47	14.8_5
			0.56	41	14.9_5 (by CLS)
2	269	16	0.67	47	13.6
3	284	15	0.60	40	14.5
4	270	15	0.56	37	13.8
5	279	9	0.55	22	14.1
6	263	106	0.60	282	12.4

of 12.4 and a $\Delta G^{\ddagger}$ major → minor of 12.6 kcal/mol. Thus, the effect of the double bond in a cyclic vinyl amide is to raise the barrier, whereas previously it was claimed that such barriers would be lower in any vinyl amide (4). One would predict that the resonance interaction of the lone pair on nitrogen with the double bond would lower the barrier to rotation as is clearly the case in *N*-acetyl pyrrole (17) where the barrier is lowered 6 kcal/mol by transition state stabilization. Although the resonance effect may be present and contributing to a lowering of the barrier in **1–5**, it is obvious that in compounds **1–5** other effects must dominate over the resonance effect of the double bond. The observed barrier can be accounted for by steric effects which would be destabilizing and most important in the *ground state* of the saturated amide. Previous studies indicate strong repulsive interaction between the oxygen (or carbon) of the *N*-acetyl group and an equatorial *alpha* substituent, i.e., the proximate methylene group (e.g.; C-8 in **6**). For example, two independent methods of analysis of the ^1H spectral behaviour of *N*-acetyl-2-methylpiperidine assign an exclusive axial orientation to the methyl group (18, 19). Since this conformation possesses 1.9 kcal/mol of strain (19) an equatorial methyl must encounter at least 3.3 kcal/mol of strain when *syn* to either the carbon or oxygen of the acetyl group. In **6**, the *trans* ring junction places the C-8 carbon in just such an equatorial orientation. The fact that the proton spectrum of **6** shows a 4:6 ratio of conformers (with respect to N—CO bond) indicates comparable high strain in either conformer.

With similar and only slightly less strong steric interactions being present in the amides **1–5** it is reasonable that a variation in steric interactions in this series of acetyl enamines could give rise to the observed 1.1 kcal/mol range of barriers. A lack of precise knowledge of the favoured conformations[4] in this series precludes a more accurate interpretation of the barrier data.

It is interesting to note that the raw coalescence data, as opposed to the E_a's used by the authors (4), in the previous paper on acyl enamines reinforces our above interpretation. If one calculates the $\Delta G^{\ddagger}$ for rotation from the measured coalescence temperatures of *N*-vinyl-*N*-methyl formamide and *N*-vinyl-*N*-methyl acetamide, the values obtained are within 1 kcal/mol of the barriers for the corresponding dimethyl amides. The comparative data appears in Table 4. In these simpler amides less severe steric interactions are present and the similarity in $\Delta G^{\ddagger}$ values for amides and enamides indicates the unimportance of a resonance effect of the vinyl substituent.

In summary, we have established that use of the simple two-site formula can be applied to the determination of rates of interconversion of conformations of unequal population whose signals are singlets and also to one case of two multiplets representing the AA′ portions of two AA′MM′ systems. This has allowed determination of the barriers to rotation for a series of acetylenamines all of which were found to be greater than in a model lacking the double bond. The lower barrier in the saturated amide is thought to result from steric destabilization of its ground state.

Experimental

All proton spectra were recorded on a Varian HA-100 spectrometer. Solutions of concentration 0.2 *M* in deuterochloroform were used throughout. The probe temperature was determined before and after the measurement of each spectrum using a thermocouple placed inside a sample tube containing deuterochloroform. This method is thought to provide the temperature to an accuracy of better than ±1°C.[5] Spectra near the coalescence temperature were recorded at sweep widths of 250 Hz using a sweep rate of 0.25 Hz/s. Care was taken to avoid saturation. Coupling constants and chemical shifts have been measured using 250 Hz sweep widths and are accurate to 0.2 Hz.

The ^{13}C spectra of 2 were measured on a 0.2 *M* solution in

[4]The values for J_{cis} (3.5 Hz) and J_{trans} (7 Hz) in **1** are consistent with a normal half-chair conformation for **1**, but do not preclude the presence of up to 30% of one or more boat conformations.

[5]A liberal allowance of ±2°C for the uncertainty in temperature was used in calculating the statistical errors in $\Delta G^{\ddagger}$.

TABLE 4. Barriers to rotation (ΔG^*) calculated from $k = 2.22\Delta\nu$ at T_c

Amide	Solvent	T_c (°C)	$\Delta\nu$ (Hz)	$\Delta G_{T_c}{}^*$ (kcal/mol)	Ref.
$HCON(CH_3)_2$	Neat	386	8.1	20.9	[a]
$HCON(CH_3)CH{=}CH_2$	Neat	372	5.7	20.1	4
$CH_3CON(CH_3)_2$	CCl_4			17.3	10
$CH_3CON(CH_3)CH{=}CH_2$	Neat	309	5.2	16.7	4

[a]Reference 1 lists numerous papers in which the barrier has been measured. The barrier of 20.9 kcal/mol appears to be the most carefully determined one (20).

deuterochloroform using a Varian FT-80 spectrometer. Calculations using the LACN 3 and DNMR 3 programs were carried out on an IBM 360/65. The enamides used in this study were prepared by methods reported in an earlier paper (8).

Effects of organic cosolvents on enzyme stereospecificity.[1] The enantiomeric specificity of α-chymotrypsin is reduced by high organic solvent concentrations

J. Bryan Jones and Mladen M. Mehes

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received February 27, 1979

J. Bryan Jones and Mladen M. Mehes. Can. J. Chem. **57**, 2245 (1979).

The influence of a range of protic and aprotic solvents of varying polarities on the enantiomeric specificity of α-chymotrypsin has been examined using methyl (2*S*)- and (2*R*)-2-acetamido-2-phenylacetate (**1**) as representative L- and D-substrates. The rates of hydrolysis were determined in solutions containing up to 30% organic solvent. The addition of organic solvent reduced the overall rates of hydrolysis of (2*S*)- and (2*R*)-**1** in each case, with those of the L-enantiomer (2*S*)-**1** being affected more than those of the D-stereoisomer (2*R*)-**1**. However, the enzyme overwhelmingly retains its normal L-enantiomeric preference under all conditions surveyed. It is concluded that α-chymotrypsin, and possibly other strongly stereospecific enzymes, can be used with confidence for asymmetric synthesis or resolution purposes in aqueous solutions to which moderate (up to 40%) proportions of organic cosolvents have been added to increase solubility of hydrophobic organic substrates.

J. Bryan Jones et Mladen M. Mehes. Can. J. Chem. **57**, 2245 (1979).

Faisant appel aux acétamido-2 phényl-2 acétates de méthyle-(2*S*) et -(2*R*) (**1**) comme substrats L et D représentatifs, on a étudié l'influence de divers solvants protiques et aprotiques de polarités variables sur la spécificité énantiomérique de l'α-chymotrypsine. On a déterminé les vitesses d'hydrolyse dans des solutions contenant jusqu'à 30% de solvant organique. L'addition de solvants organiques réduit les vitesses globales d'hydrolyse de chacun des isomères (2*S*) et (2*R*) de **1**; l'énantiomère L, **1**-(2*S*), est plus affecté que l'énantiomère D, **1**-(2*R*). Toutefois l'enzyme retient pratiquement toute sa préférence normale pour l'énantiomère L dans toutes les conditions étudiées. On en conclut que l'α-chymotrypsine, et possiblement d'autres enzymes fortement stéréospécifiques, peuvent être utilisés avec confiance pour des synthèses asymétriques ou pour effectuer des résolutions dans des milieux aqueus auxquels on a ajouté des proportions modérées (jusqu'à 40%) de cosolvants organiques dans le but d'augmenter la solubilité de substrats organiques hydrophobes.

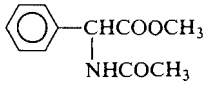
[Traduit par le journal]

The potential of enzymes as practical catalysts for asymmetric synthesis is becoming increasingly recognized. Their advantages derive mainly from the often unique stereospecificity with which they effect their catalyses. A knowledge of all the factors influencing enzymic stereospecificity is therefore of critical synthetic importance.

Up till now, most systematic stereospecificity studies have been carried out in largely aqueous solutions. However, a majority of the substrates of interest to organic chemists are likely to be hydrophobic, requiring the addition of significant proportions of organic cosolvents in order to achieve solubility in the aqueous media preferred for enzyme-catalyzed reactions.

Despite the fact that the effects of organic solvents on various aspects of enzyme catalysis have been quite extensively studied (2–5), virtually no attention has been devoted to their influence on the stereospecificity of enzymes. Accordingly, in view of its obvious importance with respect to asymmetric synthetical applications of enzymes, we have initiated a general study of this topic.

In this paper we report on the effects of some representative protic and aprotic solvents on the enantiomeric specificity of the well documented enzyme α-chymotrypsin. The results obtained show that α-chymotrypsin's capacity to discriminate between the enantiomers of methyl 2-acetamido-2-phenylacetate (**1**) is reduced when the proportion of



1

each solvent surveyed is increased. However, the effect is not large enough to prevent the enzyme from being used to effect practical-scale resolutions of racemic substrates in solutions containing significant proportions of any of the organic solvents examined.

Results

The enantiomers of methyl 2-acetamido-2-phenylacetate (**1**) were obtained via α-chymotrypsin-cata-

[1]Enzymes in organic synthesis. 15. For Part 14, see ref. 1.

lyzed hydrolysis of the racemate. The *R*-ester (2*R*)-**1** was recovered unchanged from the hydrolysis mixture. The 2*S*-acid isolated was reesterified to give the other enantiomer required, (2*S*)-**1**. This method was found to be much superior to one involving resolution of the racemic acid by recrystallizations of its (+)- and (−)-α-phenethylamine salts.

The kinetics of α-chymotrypsin-catalyzed hydrolysis for each enantiomer were determined at two concentrations of each of the cosolvents dimethylsufoxide, acetonitrile, dimethylformamide, methanol, acetone, isopropanol, and dioxan. The lower concentration was set at 5% for each cosolvent since this conferred sufficient substrate solubility to ensure homogeneous solutions for each kinetic run. The higher concentration used varied for each cosolvent. For all except dimethylsulfoxide, the cosolvent level employed was the maximum for which kinetically significant hydrolysis rates could still be observed. The values determined for the Michaelis constants, K_m, which reflect binding efficiency, and of the overall rate constants, k_{cat}, are recorded in Table 1.

Discussion

Our initial concern over the effects of added organic solvents on enzyme stereospecificity was prompted by the observation that up to 100-fold differences in the specificity constants (k_{cat}/K_m) were manifest for the chymotrypsin-catalyzed hydrolyses of the L- and D-enantiomers of **1** and their homologues in 41.7% aqueous dimethylsulfoxide (6). More disturbing from the asymmetric synthesis viewpoint was the discovery that the enzyme lost all specificity in 100% dimethylsulfoxide (7). With addition of organic solvents being unavoidable in any widespread application of enzymes in organic synthesis, it was clear that more information on this aspect was

required, particularly for the most commonly used water-miscible organic solvents.

α-Chymotrypsin was selected as the enzyme for this initial study since its specificity is well documented and readily rationalized (3*a*) and considerable data are already available on the influence of organic solvents on various aspects of the catalytic process (3, 5, 7, 8–16). The protic and aprotic solvents selected have been used before with α-chymotrypsin (3*a*). They encompass a broad range of polarities, having dielectric constants ranging from 2.2–48. They are also representative of the water-miscible solvents most likely to be employed by organic chemists for increasing the aqueous solubility of any hydrophobic substrate.

The choice of the *S*(L)- and *R*(D)-enantiomers of **1** as the substrates was based on the observation that, although chymotrypsin retained its normal L-enantiomeric specificity preference towards **1**, both enantiomers were kinetically reasonable substrates (6). It was therefore felt that changes in enantiomeric specificity could be readily detected. Also, with potential applications possibilities always in mind, the fact that the acyl group of (2*R*)-**1** is present in ampicillin and amoxycillin did not escape attention.

The kinetics of each enantiomer were determined in aqueous solutions containing 5% of organic cosolvent as a common lower limit and from 15–30% of cosolvent as the upper limit. In each case, the higher limits used (see Table 1) represent the practical maximum for the pH-stat assay procedure employed. The upper cosolvent proportions for dimethylsulfoxide and acetone were restricted by the sluggishness of the electrode response in the partly organic medium. For acetonitrile, dimethylformamide, methanol, 2-propanol, and dioxan, aggregation or precipitation of the enzyme at the higher cosolvent levels became the controlling factor. Furthermore, as the levels of organic solvents are raised, the corresponding reductions in the effective concentration of water contribute towards progressive lowerings of the overall rates of hydrolysis.

A measure of the degree of enantiomeric preference of the enzyme at each solvent concentration is provided by the stereospecificity ratio.[2] As Table 1 shows, the *S*:*R*-stereospecificity ratio is diminished at the higher cosolvent concentration for each of the solvents examined.[3] However, with the exception of dioxan, the reductions in *S*(L):*R*(D) stereospecificity are modest, being in the range 1.6–5.8-fold only. The overall rates of catalysis, as reflected by the specificity constants, of the more efficiently hydrolyzed (2*S*)-**1** enantiomer are affected to a much greater degree then those of the more slowly transformed (2*R*)-**1** stereoisomer under the same conditions. Nevertheless, the enzyme retains an overwhelming L-stereochemical preference throughout, with hydrolysis of the *S*- being favoured over *R*-enantiomer by a large factor under all conditions. With the possible exception of 20% dioxan, α-chymotrypsin could clearly be used with confidence to effect complete resolutions on preparative-scale reactions under each of the aqueous organic solutions listed. The order of decreasing influence of solvent on stereospecificity in the current study is: dimethylsulfoxide < methanol < acetonitrile < 2-propanol < dimethylformamide < acetone < dioxan. This may be used as a guide in selecting the most appropriate solvent for any future resolution experiments.

The introduction of organic solvents to α-chymotryptic-catalyzed hydrolyses of various substrates has generally been found to increase K_m's profoundly while leaving k_{cat}'s relatively unchanged (3*a*, 6, 8, 10*a*, 11). A similar trend is seen for the kinetic constants of (2*S*)-**1**, with K_m generally larger at the higher cosolvent concentration, and k_{cat} much less affected. For (2*R*)-**1**, however, the picture is much more random and no clear patterns of K_m and k_{cat} variations are evident. K_m for (2*R*)-**1** is even reduced at times. This indication of tighter binding is presumably the consequence of increased non-productive binding (3, 8).

The overall influences of the individual cosolvents are complex and the current data do not permit the various contributing factors to be identified. Some of the reasons which have been invoked previously to account for solvent effects, such as nucleophilic participation in the catalytic process by methanol and isopropanol (8–11), and competitive inhibition by acetonitrile, methanol, acetone, and dioxan (8, 10*a*, 12), are undoubtedly important. General solvent effects, including cosolvent-induced dielectric, pK_a, and conformational changes, and denaturation may also be influential (3, 5–8, 10, 13–15, 16*a*). The current data do not show any clear correlation between the stereospecificity ratio and the dielectric constant of the solvent (10*a*, 16*b*).

It is evident that, even with a substrate such as **1** which does not provide an optimum fit at the active site (3*a*), the stereospecificity of α-chymotrypsin is only marginally affected by the presence of 15–25% of several diverse organic solvents. However, from the evidence obtained previously at very high dimethyl-

[2]The stereospecificity ratio is the ratio of the specificity constants, k_{cat}/K_m, for the *S*(L)- and *R*(D)-enantiomers under the same assay conditions.

[3]The 25% dimethylsulfoxide results are the only exception. However, even in this case, the rates of hydrolysis of both enantiomers are much reduced compared with those in 5% dimethylsulfoxide.

sulfoxide concentrations (7), retention of stereospecificity cannot be guaranteed at excessive cosolvent levels even for an enzyme like chymotrypsin,[4] which has such strong enantiomeric preferences. Fortunately, in practice this is unlikely to pose a serious problem for preparative work since loss of catalytic activity will accompany, or even precede, the disappearance of stereospecificity.

On the basis of this quantitative study, and the qualitative data which exist for other enzymes (*3a*), we conclude that in aqueous solutions containing moderate amounts ($\leq$40–50%) of many organic cosolvents, α-chymotrypsin, and probably most other highly specific enzymes, will maintain sufficient stereospecificity to enable them to be used with confidence in asymmetric synthesis applications.

Experimental

All solvents used were reagent grade. They were further purified and redistilled prior to use. α-Chymotrypsin (EC 3.4.-21.1, 3 × crystallized) was purchased from Worthington.

*Preparation of Methyl (2R)- and (2S)-Acetamido-2-phenylacetate (**1**)*

The procedure of Pattabiraman and Lawson (6) was followed. The racemic ester (±)-**1**, mp 76.5–77°C after recrystallization from diisopropyl ether[5] (lit. (6) mp 75.5–76.5°C), was resolved on a 9 g scale using α-chymotrypsin to give (2*R*)-**1** (2.1 g), mp 116–117°C after recrystallization from diisopropyl ether, $[\alpha]_D^{25}$ −176.2° (*c* 0.95, EtOH), (lit. (6) mp 112–113°C, $[\alpha]_D^{25}$ −175.8° (*c* 0.95, EtOH)) and, after esterification of the (2*S*)-acid (3.0 g), the methylester (2*S*)-**1** (0.8 g), mp 117–117.5°C after recrystallization from diisopropyl ether, $[\alpha]_D^{25}$ +178.4° (*c* 1.05, EtOH), (lit. (6) mp 110–112°C, $[\alpha]_D^{25}$ +180.5° (*c* 1.05, EtOH)).

Kinetic Studies

The kinetic studies were carried out at 25°C under nitrogen using Radiometer pH-stat-controlled addition of 10^{-1} to 2.5×10^{-3} *M* aqueous sodium hydroxide to maintain the apparent pH at 8. Stock solutions of the enzyme (in 10^{-3} *M* HCl) and of the (2*R*)- and (2*S*)-**1** substrates (freshly prepared in the appropriate solvent and CO_2-free water) were made up and appropriate aliquots taken to enable 7–10 runs to be performed under steady-state conditions within the substrate concentration range 0.1 to $\leq 5\,K_m$ (depending on solubility factors) and with enzyme concentrations of 3–40 × 10^{-6} *M*. A reaction volume of 10 mL of constant ionic strength (0.1 *M* KCl) was employed throughout. Corrections for spontaneous hydrolysis of (2*R*)- and (2*S*)-**1**, and for enzyme autohydrolysis at high enzyme concentrations, were made when necessary. The enzyme concentration was determined spectrophotometrically (17). The data were analyzed by the Lineweaver–Burk method and were subjected to least-squares regression analysis. The K_m and k_{cat} values obtained at the various solvent concentrations are recorded in Table 1.

[4]However, α-chymotrypsin's substrate binding site seems to be preserved even in 100% dimethylsulfoxide (7).

[5]Caution: explosive peroxides form in air. Only fresh diisopropyl ether, which had been stored over ferrous sulfate crystals for several hours, was used. Mother liquors were discarded immediately. No attempts should be made to recover extra material from them.

Intramolecular alkylation of α,β-unsaturated ketones: a total synthesis of (±)-isolongifolene and an approach to the synthesis of zizaane-type sesquiterpenoids

EDWARD PIERS AND MICHAEL ZBOZNY

Department of Chemistry, University of British Columbia, 2075 Wesbrook Mall, Vancouver, B.C., Canada V6T 1W5

Received February 26, 1979

EDWARD PIERS and MICHAEL ZBOZNY. Can. J. Chem. 57, 2249 (1979).

A total synthesis of (±)-isolongifolene **6**, a C_{15} hydrocarbon derived from the acid-catalyzed rearrangement of the sesquiterpenoid longifolene, is described. The known carbomethoxyoctalone **10** was transformed via a 10-step sequence into the unsaturated keto tosylate **9**. The key step of the overall synthesis involved the efficient intramolecular γ alkylation of **9** to produce the tricyclic α,β-unsaturated ketone **5**. The latter compound was converted into the enone **33**, which had previously served as a precursor for the synthesis of (±)-isolongifolene **6**.

EDWARD PIERS et MICHAEL ZBOZNY. Can. J. Chem. 57, 2249 (1979).

On décrit une synthèse totale du (±) isolongifolène **6**, un hydrocarbure en C_{15} qui provient d'une transposition acido-catalysée du sesquiterpène longifolène. Dix étapes sont nécessaires pour transformer la carbométhoxyoctalone connue **10** en tosylate cétonique non saturé **9**. L'étape clé dans la synthèse globale implique l'alkylation intramoléculaire en γ efficace de **9** conduisant à la cétone α,β-non saturée tricyclique **5**. On transforme ce dernier composé en énone **33** qui a servi antérieurement comme précurseur pour la synthèse du (±) isolongifolène **6**.
[Traduit par le journal]

The intramolecular alkylation of α,β-unsaturated ketones has not been employed extensively in organic synthesis. Presumably, one of the main reasons for this lack of use is related to the fact that an alkylation of this type can, in theory, take place at one or more of three different sites: the α′ position, the α position, and the γ position (cf. **1**). Indeed, a perusal of the chemical literature shows that all three modes of cyclization have been observed, the specific site of alkylation depending mainly on the structure of the substrate.[1]

In connection with work related to the synthesis of natural products, we were intrigued by the possibility of forming specifically functionalized tricyclic ring systems by means of intramolecular alkylation of α,β-unsaturated ketones at the γ position. With the exception of those reactions which resulted in the closure of three-membered rings,[2] this type of process apparently has not been employed previously in the area of natural product synthesis.[3] More explicitly, we were interested in the possibility of effecting intramolecular alkylation of the keto tosylate **2**. It is clear that although two different enolate anions (**3** and **4**) could be formed from compound **2**, the only alkylative cyclization reaction possible would involve ring closure of **4** at the γ position to afford **5**. The alternative modes of ring closure involving **3** (α′ alkylation) and **4** (α alkylation) would be precluded by severe strain (bridgehead double bonds) in the (projected) products. On the other hand, successful internal γ alkylation of **4** would produce the intermediate **5**, which would appear to have the potential of serving as an excellent precursor for the synthesis of (±)-isolongifolene (**6**).[4] In addition, it seemed reasonable to propose that **5** could also serve as a convenient precursor for the keto ester **7**. The latter compound had been employed previously by MacSweeney and Ramage (4) as an intermediate in their synthesis of the racemic modification of the sesquiterpenoid zizanoic acid (**8**), which in turn had been transformed into other members of the zizaane class of natural products (4).

In this paper we report (*a*) the preparation of the keto tosylate **9**, (*b*) the efficient intramolecular alkylation of **9** to afford the intermediate **5**, and (*c*) the conversion of **5** into the tricyclic α,β-unsaturated ketone **33**. Since the latter compound had been converted previously into (±)-isolongifolene (**6**) (6), the acquisition of this material completed, in a formal sense, the total synthesis of the sesquiterpene.

[1]For a summary, including specific examples and references, and for a study of the effect of experimental conditions and substrate structure on the site of alkylation, see ref. 1.

[2]For some examples, see ref. 2.

[3]It should be noted that the intramolecular alkylation of substituted phenolic compounds at the *para* position, a type of reaction which is formally analogous to the alkylative cyclization of an α,β-unsaturated ketone at the γ position, has found use in the synthesis of diterpenoids (3).

[4]Isolongifolene is obtained from the acid-catalyzed rearrangement of the well-known sesquiterpenoid longifolene. For the structural elucidation of isolongifolene, see ref. 5. For a previous synthesis of this compound, see ref. 6.

Synthesis and Intramolecular Alkylation of the Keto Tosylate 9 (see Scheme 1)

Alkylation (potassium *tert*-butoxide, *tert*-butyl alcohol) of the known (7) carbomethoxyoctalone **10** with methyl iodide afforded the dimethylated compound **11**, which, when allowed to react with methylenetriphenylphosphorane in dimethylsulfoxide at room temperature, gave the diene **12** (66% from **10**). The latter compound was subjected to hydroboration with disiamylborane in tetrahydrofuran (8) and the intermediate organoborane was oxidized with alkaline hydrogen peroxide. Spectral analysis of the product obtained from this reaction indicated that it consisted of a mixture of the epimeric compounds **13** and **14**. Analysis of this material by gas–liquid chromatography (glc) also indicated the presence of two components, in a ratio of approximately 1:1. However, when a pure sample of each component was obtained by means of preparative glc and subjected to spectral analysis, it became clear that only one of them produced spectra consistent with those expected from a hydroxy ester. This substance was assigned the *trans* structure **14**. Spectral analysis of the second component, a crystalline compound with mp 79–80°C, showed that it was the lactone **15**. It was thus evident that lactonization of the *cis* hydroxy ester **13** had occurred on the glc column.

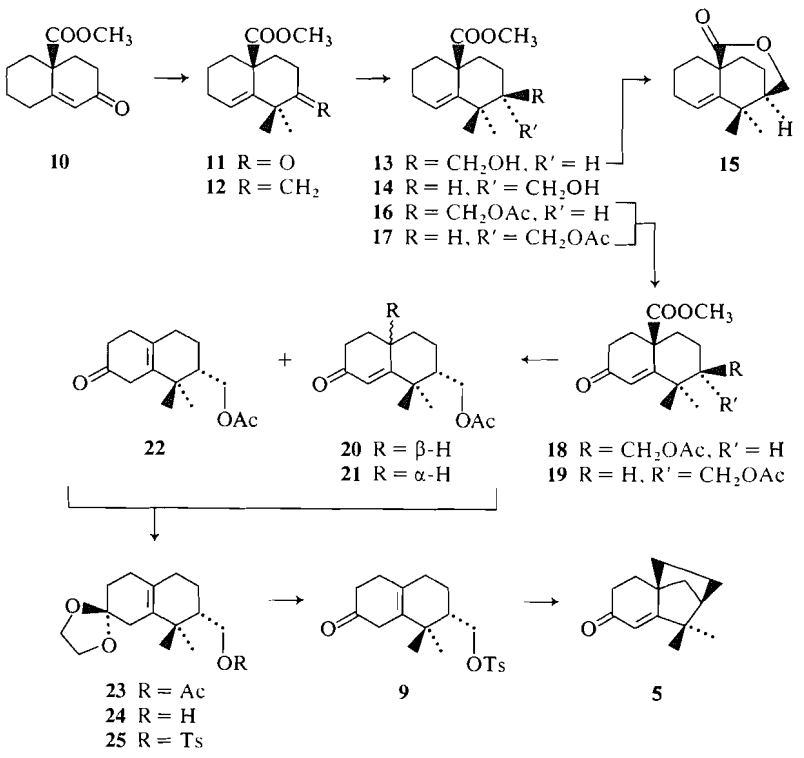
Treatment of the mixture of hydroxy esters **13** and **14** with acetic anhydride in pyridine produced a mixture of the corresponding diesters **16** and **17**. Allylic oxidation of this material with chromium trioxide – dipyridine complex in dichloromethane (9) proved to be quite sluggish and, therefore, alternative methods to effect this transformation were investigated. Eventually, it was found that the procedure of Finucane and Thomson (10) produced excellent results. Thus, when a solution of compounds **16** and **17** in dioxane was treated with *N*-bromosuccinimide, calcium carbonate, and water, and the resultant mixture was irradiated with visible light, a mixture of the octalones **18** and **19** was obtained in 96% yield.

It is pertinent at this point to comment briefly regarding the stereochemistry of compounds **16–19**, inclusive. Although this point was not crucial in the overall synthetic sequence, it was nevertheless of interest to determine whether or not the stereochemistry of these substances could be assigned. As it turned out, the various configurations could be designated readily on the basis of ^{1}H nmr spectra.

The *trans* hydroxy ester **14** (*vide supra*) showed two 3-proton singlets at δ 1.00 and 1.07, readily assignable to the two tertiary methyl groups. On the other hand, the mixture of **14** and the *cis* epimer **13** exhibited, in addition to the signals at δ 1.00 and 1.07, two singlets at δ 0.82 and 1.22, obviously due to the geminal methyl groups of the *cis* compound **13**. It was thus clear that the chemical shift difference between the two methyl groups of the *cis* compound **13** ($\Delta\delta = 0.40$) was much larger than the corresponding difference in the *trans* isomer **14** ($\Delta\delta = 0.07$). Furthermore, the methyl signals of the latter compound appeared between those of the former substance. This pattern was also present in the diesters **16** and **17** and in the epimeric octalones **18** and **19**.[5] Thus, the diester which exhibited the tertiary methyl signals at δ 0.99 and 1.06 was assigned the *trans* stereochemistry (cf. **17**)[6] while the acetate which showed the comparable singlets at δ 0.80 and 1.19 could be assigned the *cis* configura-

[5]Pure samples of each of the compounds **16–19**, inclusive, were obtained by means of preparative glc.

[6]Mild base hydrolysis of **17** gave a hydroxy ester identical with the *trans* compound **14**, obtained from the hydroboration of **12**.



SCHEME I

tion (cf. **16**). In similar fashion, the two octalones **18** and **19** exhibited singlets due to the geminal methyl groups at δ 0.90 and 1.27 and at δ 1.12 and 1.18, respectively.

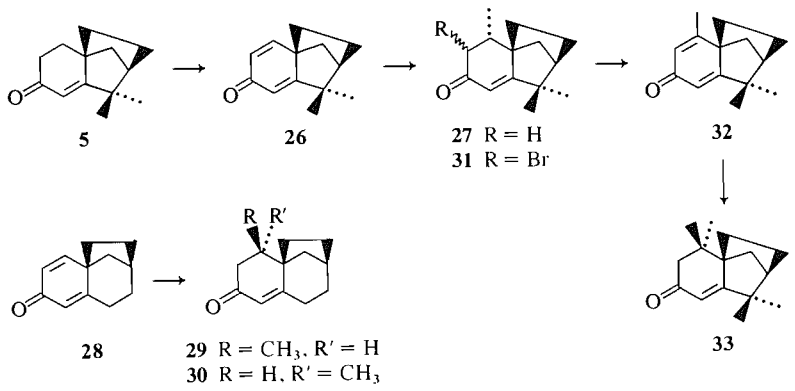
Decarbomethoxylation of the mixture of octalones **18** and **19** was achieved smoothly by treatment of this material with anhydrous lithium bromide in hot (140–150°C) hexamethylphosphoramide[7] for 4 h. During this time it was necessary to bubble nitrogen through the mixture in order to remove the methyl bromide as it was formed. If this was not done, the enolate anion produced from the decarboxylation step was partially methylated, thus complicating the purification of the final product and lowering the yield of desired material. Appropriate analysis (spectra, glc) of the distilled product of the reaction indicated that it was a mixture of three compounds, presumably the epimeric octalones **20** and **21**, along with the β,γ-unsaturated ketone **22**. Without further purification, this mixture was subjected to standard ketalization conditions (ethylene glycol, *p*-toluenesulfonic acid, benzene), thus affording in 73% overall yield from the octalones **18** and **19** the crystalline ketal acetate **23**, mp 101–102°C. Reduction of this material with lithium aluminum hydride in tetrahydrofuran, followed by tosylation (*p*-toluenesulfonyl chloride in pyridine, room temperature) of the resultant ketal alcohol **24**, produced the ketal tosylate **25**, mp 100–101°C (84% from **23**). Mild hydrolysis (aqueous sulfuric acid in acetone) of **25** gave the β,γ-unsaturated keto tosylate **9** in nearly quantitative yield, thus setting the stage for the key (proposed) intramolecular alkylation reaction.

The alkylative cyclization of compound **9** proved to be a remarkably facile process. Thus, brief treatment of this material with potassium *tert*-butoxide in hexamethylphosphoramide at room temperature afforded, after recrystallization of the distilled product, the tricyclic ketone **5** (mp 63–64°C) in 61% yield. The fact that this product possessed an α,β-unsaturated ketone functionality was shown by its ir (1670, 1640 cm^{-1}) and uv (238 nm, ε = 13 000) spectra. Furthermore, the ^1H nmr spectrum (one-proton singlet at δ 5.70, vinyl proton; six-proton singlet at δ 1.13, tertiary methyl groups) of this material was in full accord with structure **5**.

Conversion of the Tricyclic Endone 5 into the α, β-Unsaturated Ketone 33

The transformation of the tricyclic α,β-unsaturated ketone **5** into enone **33** was accomplished via a straightforward sequence of reactions as outlined in Scheme 2. When **5** was allowed to

[7]This method for ester cleavage is similar to that recorded earlier by McMurry and Wong (11).



SCHEME 2

react with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) (12) in refluxing dioxane containing acetic acid, the crystalline cross-conjugated dienone **26** was obtained in 60% yield. Conjugate addition of lithium dimethylcuprate (13) to this material was highly site-selective[8] and stereoselective, producing a single enone **27** in 81% yield. The stereochemistry of the newly introduced methyl group was assigned on the basis of steric approach control. The tentative nature of this conclusion should be emphasized, since Marshall and Brady (14) had shown that addition of lithium dimethylcuprate to the structurally similar dienone **28** afforded a mixture of the epimeric enones **29** and **30**, in ratios of 3:1 (reaction done in ether) and 3:2 (reaction done in dioxane–ether), respectively. Nevertheless, molecular models appeared to indicate that the β two-carbon bridge in **26** would offer appreciably greater steric hindrance to approach of the cuprate reagent than the α one-carbon bridge. On the other hand, models indicated that a similar steric preference for approach of the cuprate reagent to the dienone system in **28** was lacking.

Attempted conversion of the enone **27** into the corresponding dienone **32** by treatment of the former compound with DDQ (12) produced very low yields of the desired product. On the other hand, bromination of **27** with pyridinium hydrobromide perbromide in tetrahydrofuran – acetic acid, followed by dehydrobromination (lithium bromide, lithium carbonate, dimethylformamide, reflux) (15) of the resultant crude bromo ketone **31**, afforded the dienone **32** in 40% yield. Addition of lithium dimethylcuprate (13) to this material gave, in mediocre yield, the racemic tetramethyl tricyclic enone **33**. The melting point of this compound, as well as the spectral data (particularly the ^{1}H nmr spectrum) agreed very well with those reported in the literature (5, 6). Since compound **33** had already been converted into (±)-isolongifolene (**6**) (6), the acquisition of the former material formally completed the total synthesis of the sesquiterpene.

The overall conversion of **27** into **33** via the route described above was quite inefficient and it appears highly likely that a more efficient route could be devised. However, lack of sufficient material at this stage of the work precluded the possibility of examining alternatives. Furthermore, investigations into the possibility of converting the tricyclic enone **5** into the keto ester **7** (a precursor for the synthesis of zizaane-type sesquiterpenoids) will also have to await the acquisition of further quantities of **5**.

[8]The chemical literature contains ample precedent for the site-selective addition of cuprate reagents to cross-conjugated dienones possessing structures similar to **26** (see ref. 13).

Experimental

General

Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected. Infrared spectra were recorded on a Perkin-Elmer model 710 spectrophotometer. Proton magnetic resonance spectra were measured using Varian Associates spectrometers, models T-60 and (or) HA-100 or XL-100. Signal positions are given in δ units, with tetramethylsilane as the internal standard; the multiplicity, integrated peak areas, and proton assignments are indicated in parentheses. High resolution mass spectrometric measurements were recorded on an A.E.I. model MS-50 mass spectrometer. Gas–liquid chromatographic analyses were carried out with a Hewlett-Packard model 5832A gas chromatograph, while preparative gas–liquid chromatography was accomplished with an Aerograph Autoprep, model 700. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver, B.C.

Preparation of the Keto Ester ***11***

To a warm (35°C), stirred solution of potassium *tert*-butoxide (37 g) in 600 mL of *tert*-butyl alcohol under an atmosphere of nitrogen was added, over a period of 15 min, 34 g (0.16 mol) of the octalone **10** (7). After the resulting solution had been cooled with an ice bath, freshly distilled methyl iodide (140 g, 1 mol) was added and the mixture was heated under reflux for 90 min. Most of the solvent was removed under reduced pressure and the milky residue was

diluted with water, neutralized by addition of dilute hydrochloric acid, and thoroughly extracted with ether. The combined extract was washed successively with water, aqueous sodium thiosulfate, and brine, and then dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 118–122°C/0.4 Torr) of the residual oil afforded 31 g (80%) of the keto ester **11**; ir (film): 1730, 1710 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.26 (s, 6H, tertiary methyls), 3.66 (s, 3H, —$COOCH_3$), 5.85 (t, 1H, vinyl proton, J = 4 Hz). *Exact mass* calcd. for $C_{14}H_{20}O_3$: 236.1412; found: 236.1408.

Preparation of the Diene ***12***

To a solution of sodium methylsulfinylmethide (20 g, 0.2 mol) in dry dimethyl sulfoxide (250 mL), under an atmosphere of nitrogen, was added a solution of methyltriphenylphosphonium bromide (75 g, 0.21 mol) in 350 mL of dimethyl sulfoxide. After the mixture had been stirred for 15 min, a solution of the keto ester **11** (10 g, 0.042 mol) in 200 mL of dimethyl sulfoxide was added dropwise. The reaction mixture was stirred for 1 h, diluted with 600 mL of water, and then thoroughly extracted with ether – petroleum ether. The combined extract was washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 120–125°C/0.4 Torr) of the residual oil, gave 8.0 g (83%) of the pure diene **12**; ir (film) 1735, 1640, 890 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.10 (s, 3H, tertiary methyl), 1.24 (s, 3H, tertiary methyl), 3.60 (s, 3H, —$COOCH_3$), 4.58–4.70 (m, 2H, =CH_2), 5.78 (t, 1H, vinyl proton, J = 4 Hz). *Anal.* calcd. for $C_{15}H_{22}O_2$: C 76.88, H 9.46; found: C 76.97, H 9.60.

Hydroboration of the Diene ***12***

To a cold (0°C), stirred solution of disiamylborane (2.0 g, 13 mmol) in 40 mL of dry tetrahydrofuran, under an atmosphere of nitrogen, was added a tetrahydrofuran solution (40 mL) of the diene **12** (2.1 g, 9 mmol). The solution was allowed to warm to room temperature and was stirred at this temperature for 2 h. The solution was cooled and treated (dropwise) successively with 12 mL of 3 *N* sodium hydroxide and 12 mL of 30% hydrogen peroxide. The resulting mixture was stirred at room temperature for 1.5 h and then most of the solvent was removed under reduced pressure. The residue was diluted with water and extracted with ether. The combined extract was washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent followed by distillation (air-bath temperature 130–140°C/0.3 Torr) of the residual oil afforded 1.9 g (84%) of a clear, colorless oil. The ir and ^1H nmr spectra of this material indicated that it was a mixture of the two diastereomeric alcohols **13** and **14**. The gas–liquid chromatogram of this material showed the presence of two components, in a ratio of about 1:1. A sample of each component was collected by preparative glc. The first compound was the hydroxy ester **14**; ir (film): 3450, 1725 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.00 (s, 3H, tertiary methyl), 1.07 (s, 3H, tertiary methyl), 3.36–3.84 (m, 2H, AB part of ABX system, —CH_2OH), 3.66 (s, 3H, —$COOCH_3$), 5.73 (t, 1H, vinyl proton, J = 4 Hz). *Anal.* calcd. for $C_{15}H_{24}O_3$: C 71.39, H 9.59; found: C 71.20, H 9.76.

The second component isolated by preparative glc was the lactone **15**; mp 79–80°C; ir ($CHCl_3$): 1720 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.22 (s, 6H, tertiary methyls), 4.04–4.64 (m, 2H, AB part of ABX system, —CH_2O—), 5.80 (t, 1H, vinyl proton, J = 4 Hz). *Anal.* calcd. for $C_{14}H_{20}O_2$: C 76.33, H 9.15; found: C 75.90, H 9.30.

Preparation of the Acetates ***16*** *and* ***17***

A mixture of 10 g (0.04 mol) of the alcohols **13** and **14**, 20 mL of acetic anhydride, and 40 mL of pyridine was heated on a steam bath for 2 min, and the resulting solution was allowed to stand at room temperature for 18 h. The solution was poured into water and the resulting mixture was extracted with ether. The combined ether extract was washed successively with 1 *N* hydrochloric acid, water, aqueous sodium bicarbonate, and brine, and then dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 125–130°C/0.5 Torr) of the residual oil, afforded 11.0 g (94%) of a mixture of the acetates **16** and **17**. An analytical sample of each of these compounds was obtained by preparative glc. The *trans* acetate **17** exhibited ir (film): 1730 cm^{-1} (broad); ^1H nmr ($CDCl_3$) δ: 0.99 (s, 3H, tertiary methyl), 1.06 (s, 3H, tertiary methyl), 2.01 (s, 3H, —$OCOCH_3$), 3.63 (s, 3H, —$COOCH_3$), 3.82–4.24 (m, 2H, AB part of ABX system, —CH_2OAc), 5.69 (t, 1H, vinyl proton, J = 4 Hz). *Anal.* calcd. for $C_{17}H_{26}O_4$: C 69.36, H 8.90; found: C 69.10, H 9.10.

The *cis* acetate **16** exhibited ir (film): 1730 cm^{-1} (broad); ^1H nmr ($CDCl_3$) δ: 0.80 (s, 3H, tertiary methyl), 1.19 (s, 3H, tertiary methyl), 2.04 (s, 3H, —$OCOCH_3$), 3.67 (s, 3H, —$COOCH_3$), 3.72–4.20 (m, 2H, AB part of ABX system, —CH_2OAc), 5.87 (t, 1H, vinyl proton, J = 4 Hz). *Anal.* calcd. for $C_{17}H_{26}O_4$: C 69.36, H 8.90; found: C 69.31, H 8.78.

Preparation of the Octalones ***18*** *and* ***19***

To a stirred solution of the mixture of acetates **16** and **17** (4.1 g, 13.9 mmol) in 250 mL of dioxan was added 7.4 g (41.7 mmol) of *N*-bromosuccinimide, 2.8 g (27.8 mmol) of calcium carbonate, and 22 mL of water. The reaction mixture was allowed to stir at room temperature for 20 h while being irradiated with visible light. After the mixture had been filtered through Celite, the filtrate was extracted with ether. The combined ether extract was washed successively with water, aqueous sodium thiosulfate, and brine, and then dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 165–170°C/0.25 Torr) of the residual oil, afforded 4.1 g (96%) of a mixture of the two substituted octalones **18** and **19**. An analytical sample of each compound was obtained by preparative glc. The *trans* compound **19** exhibited mp 62–64°C; ir ($CHCl_3$): 1740, 1680, 1610 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.12 (s, 3H, tertiary methyl), 1.18 (s, 3H, tertiary methyl), 2.02 (s, 3H, —$OCOCH_3$), 3.71 (s, 3H, —$COOCH_3$), 3.80–4.30 (m, 2H, AB part of ABX system, —CH_2OAc), 6.14 (s, 1H, vinyl proton). *Anal.* calcd. for $C_{17}H_{24}O_5$: C 66.21, H 7.84; found: C 65.96, H 8.00.

The *cis* compound **18** exhibited ir (film): 1730 (broad), 1675, 1610 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.90 (s, 3H, tertiary methyl), 1.27 (s, 3H, tertiary methyl), 2.04 (s, 3H, —$OCOCH_3$), 3.70 (s, 3H, —$COOCH_3$), 3.80–4.38 (m, 2H, AB part of ABX system, —CH_2OAc), 6.23 (s, 1H, vinyl proton). *Anal.* calcd for $C_{17}H_{24}O_5$: C 66.21, H 7.84; found: C 66.49, H 7.80.

Preparation of the Ketal Acetate ***23***

To a stirred solution of the mixture of octalones **18** and **19** (5.0 g, 16.2 mmol) in 250 mL of hexamethylphosphoramide was added 18.0 g (0.21 mol) of anhydrous lithium bromide and the resulting mixture was heated to 140–150°C and kept at this temperature for 4 h. During this time, nitrogen was bubbled through the mixture in order to remove the methyl bromide as it was formed. The cooled mixture was diluted with water and then thoroughly extracted with petroleum ether. The combined extract was washed with water and brine and then dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 140–150°C/0.35 Torr) of the residual material gave 3.4 g (84%) of decarbomethoxylated material. The latter, which

was shown by glc analysis to be a mixture of three compounds (presumably **20**, **21**, and **22**), was not purified further.

To a solution of the above mixture in benzene (125 mL) was added ethylene glycol (1.3 g, 21 mmol) and a catalytic amount of *p*-toluenesulfonic acid. The solution was refluxed under a Dean-Stark apparatus for 20 h, cooled, washed successively with aqueous sodium bicarbonate and water, and then dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 150–160°C/0.3 Torr) of the residual oil, afforded 3.5 g (73% from the octalones **18** and **19**) of the ketal acetate **23**. This material crystallized on standing. Recrystallization of a small amount of this compound from ether – petroleum ether gave an analytical sample; mp 101–102°C; ir ($CHCl_3$): 1730 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.87 (s, 3H, tertiary methyl), 1.03 (s, 3H, tertiary methyl), 2.01 (s, 3H, $—OCOCH_3$), 3.74–4.32 (m, 2H, AB part of ABX system, $—CH_2OAc$), 3.95 (s, 4H, ketal protons). *Anal.* calcd. for $C_{17}H_{26}O_4$: C 69.36, H 8.90; found: C 69.19, H 8.83.

Preparation of the Ketal Alcohol ***24***

To a stirred solution of lithium aluminum hydride (1.6 g, 42.1 mmol) in 250 mL of dry tetrahydrofuran was added, dropwise, a solution of 5.0 g (17.0 mmol) of the ketal acetate **23** in 50 mL of dry tetrahydrofuran. The solution was heated under reflux for 1.5 h. The solution was cooled and the excess hydride was destroyed by careful addition of sodium sulfate decahydrate. The resulting mixture was filtered through Celite and the filtrate was evaporated under reduced pressure. The residual material was diluted with ether and the resulting solution was washed with water and brine and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 150–155°C/0.2 Torr) of the residual material, gave 4.0 g (93%) of the ketal alcohol **24**; ir (film): 3400 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.83 (s, 3H, tertiary methyl), 1.03 (s, 3H, tertiary methyl), 3.26–3.96 (m, 2H, AB part of ABX system, $—CH_2OH$), 3.92 (s, 4H, ketal protons). *Exact mass.* calcd. for $C_{15}H_{24}O_3$ 252.1725; found: 252.1697.

Preparation of the Ketal Tosylate ***25***

To a solution of the ketal alcohol **24** (4.0 g, 15.8 mmol) in 50 mL of dry pyridine was added 4.5 g (23.7 mmol) of freshly recrystallized *p*-toluenesulfonyl chloride. The solution was stirred at room temperature for 12 h and then poured into 200 mL of ice-water. After the resulting mixture had been stirred for 15 min, it was thoroughly extracted with ether. The combined ether extract was washed successively with ice-cold 1 *N* hydrochloric acid, water, and brine, and then dried over anhydrous magnesium sulfate. Removal of the solvent gave a yellow oil which crystallized on standing. Recrystallization of this material from petroleum ether – acetone gave 5.8 g (90%) of the ketal tosylate **25** as white needles; mp 100–101°C; ir($CHCl_3$): 1600, 1360, 1180 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.82 (s, 3H, tertiary methyl), 0.99 (s, 3H, tertiary methyl), 2.46 (s, 3H, aromatic methyl), 3.66–4.32 (m, 2H, AB part of ABX system, $—CH_2OTs$), 3.96 (s, 4H, ketal protons), 7.38, 7.82 (d, d, 2H each, aromatic protons, J = 8.5 Hz). *Anal.* calcd. for $C_{22}H_{30}O_5S$: C 65.01, H 7.44, S 7.88; found: C 65.18, H 7.40, S 7.97.

Preparation of the Keto Tosylate ***9***

To a stirred solution of the ketal tosylate **25** (6.4 g, 15.7 mmol) in a mixture of 125 mL of acetone and 30 mL of water was added, dropwise, 2 mL of sulfuric acid. The solution was warmed to 50°C and stirred at this temperature for 45 min. The cooled solution was poured into ice-cold saturated aqueous sodium bicarbonate and the resulting mixture was extracted with ether. The combined ether extract was washed with water and brine and dried over anhydrous magnesium sulfate. Removal of the solvent yielded 5.6 g (98%) of the keto tosylate **9** as a pale yellow oil which was not purified further; ir (film): 1718, 1360, 1170 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.73 (s, 3H, tertiary methyl), 0.93 (s, 3H, tertiary methyl), 2.37 (s, 3H, aromatic methyl), 3.52–4.26 (m, 2H, AB part of ABX system, $—CH_2OTs$), 7.32, 7.73 (d, d, 2H each, aromatic protons, J = 9 Hz).

Preparation of the Tricyclic α,β-*Unsaturated Ketone* ***5***

To a stirred solution of potassium *tert*-butoxide (1.2 g, 15.8 mmol) in 50 mL of dry hexamethylphosphoramide, under an atmosphere of nitrogen, was added, dropwise, a solution of 2.3 g (6.35 mmol) of the crude keto tosylate **9** in 50 mL of dry hexamethylphosphoramide. After the addition was complete, the reaction mixture was allowed to stir for an additional 10 min and was then poured into ice-cold dilute hydrochloric acid. The resulting mixture was extracted thoroughly with petroleum ether. The combined extract was washed several times with water and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 95–110°C/0.2 Torr) gave a colorless oil which crystallized on standing. Recrystallization of this material from ether – petroleum ether afforded 733 mg (61%) of the tricyclic ketone **5**; mp 63–64°C; uv (MeOH): λ_{max} 238 nm (ε = 13 000); ir ($CHCl_3$): 1670, 1640 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.13 (s, 6H, tertiary methyls), 5.70 (s, 1H, vinyl proton). *Exact mass* calcd. for $C_{13}H_{18}O$: 190.1361; found: 190.1357.

Preparation of the Dienone ***26***

To a stirred solution of the enone **5** (500 mg, 2.63 mmol) in 70 mL of dioxan was added 3 mL of glacial acetic acid and 890 mg (3.94 mmol) of 2,3-dichloro-5,6-dicyanobenzoquinone. After the resulting mixture had been heated under reflux (nitrogen atmosphere) for 17 h, it was cooled and filtered through a bed of Celite. Most of the solvent was removed (reduced pressure) from the filtrate and the residual material was taken up in ether. The ether solution was washed successively with water, aqueous sodium bicarbonate, and brine, and then dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 95–110°C/0.3 Torr) of the residual oil afforded 296 mg (60%) of the cross-conjugated dienone **26** as a colorless oil which crystallized on standing. Recrystallization of a small amount of this material from petroleum ether gave an analytical sample; mp 72–73°C; uv (MeOH): λ_{max} 246 nm (ε = 14 700); ir ($CHCl_3$): 1660, 1630, 1600 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.07 (s, 3H, tertiary methyl), 1.13 (s, 3H, tertiary methyl), 6.00 (d, 1H, vinyl proton, J = 1.5 Hz), 6.24 (d of d, 1H, vinyl proton, J = 9.5, 1.5 Hz), 7.00 (d, 1H, vinyl proton, J = 9.5 Hz). *Anal.* calcd. for $C_{13}H_{16}O$: C 82.94, H 8.57; found: C 82.65, H 8.50.

Preparation of the Tricyclic α,β-*Unsaturated Ketone* ***27***

To a cold (0°C), stirred solution of lithium dimethylcuprate (4.5 mmol) in 20 mL of dry ether, under an atmosphere of nitrogen, was added, over a period of 10 min, a solution of the dienone **26** (425 mg, 2.26 mmol) in 15 mL of dry ether. After the solution had been stirred at 0°C for an additional period of 1 h, it was treated with saturated aqueous ammonium chloride and the resultant mixture was stirred for 20 min and then diluted with water and extracted with ether. The combined ether extract was washed with water and brine and then dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 105–110°C/0.35 Torr) of the residual oil afforded 375 mg (81%) of the enone **27** as a colorless oil which crystallized on standing. This material exhibited mp 63–64°C; ir ($CHCl_3$): 1655,

1640 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.02 (d, 3H, secondary methyl, J = 7 Hz), 1.10 (s, 3H, tertiary methyl), 1.14 (s, 3H, tertiary methyl), 5.71 (s, 1H, vinyl proton). *Anal.* calcd. for $C_{14}H_{20}O$: C 82.30, H 9.87; found: C 81.98, H 10.00.

Preparation of the Dienone 32

To a warm (45°C), stirred solution of the enone **27** (325 mg, 1.59 mmol) in 50 mL of dry tetrahydrofuran and 2 mL of glacial acetic acid, under an atmosphere of nitrogen, was added 530 mg (1.73 mmol) of pyridinium hydrobromide perbromide. After the reaction mixture had been allowed to stir for 1 h, it was cooled and neutralized with sodium bicarbonate. The resulting mixture was extracted thoroughly with ether. The combined extract was washed with water and brine and dried over anhydrous magnesium sulfate. Removal of the solvent gave a crude product which was dissolved in 50 mL of *N,N*-dimethylformamide. To the resulting solution was added 490 mg of lithium bromide and 420 mg of lithium carbonate and the stirred mixture was heated under reflux (nitrogen atmosphere) for 3 h. The reaction mixture was cooled, diluted with water, and extracted with petroleum ether. The combined extract was washed with water and brine and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 125–130°C/0.2 Torr) gave 240 mg of a yellow oil, which was purified further by column chromatography on silica gel. Elution of the column with petroleum ether containing increasing amounts of ether afforded 67 mg of starting material **27** and 100 mg (40%, based on unrecovered starting material) of the pure dienone **32**; ir (film): 1665, 1635 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.12 (s, 3H, tertiary methyl), 1.20 (s, 3H, tertiary methyl), 2.02 (d, 3H, vinyl methyl, J = 1.5 Hz), 6.01 (d, 1H, vinyl proton, J = 1.5 Hz), 6.14 (overlapped pair of q, 1H, vinyl proton, J = 1.5 Hz). *Exact mass* calcd. for $C_{14}H_{18}O$: 202.1357; found: 202.1321.

Preparation of the Tricyclic α,β-Unsaturated Ketone 33

To a cold (0°C), stirred solution of lithium dimethylcuprate (0.59 mmol) in 5 mL of dry ether, under an atmosphere of nitrogen, was added, dropwise, a solution of the dienone **32** (30 mg, 0.148 mmol) in 2 mL of ether. After the reaction mixture had been stirred for 5 h at room temperature, it was treated with saturated aqueous ammonium chloride. The resultant mixture was stirred for 20 min, diluted with water, and thoroughly extracted with ether. The combined extract was washed with water and brine and dried over anhydrous magnesium sulfate. Removal of the solvent gave an oil which was subjected to column chromatography on silica gel. Elution of the column with petroleum ether containing increasing amounts of ether gave 14 mg (47%) of starting material **32** and 7 mg (44%, based on unrecovered starting material) of the crystalline enone **33**; mp 53–54°C (lit. (6) mp 54–55.5°C) ir ($CHCl_3$): 1675, 1640 cm^{-1}; ^1H nmr (CCl_4) δ: 1.00, 1.05, 1.10, 1.15 (4 singlets, 3H each, tertiary methyls), 5.66 (s, 1H, vinyl proton). *Exact mass* calcd. for $C_{15}H_{22}O$: 218.1670; found: 218.1692.

The ultraviolet photoelectron spectra of C_6F_5X compounds, X = (F, Cl, Br, I, H, CH_3)

BARRY C. TRUDELL AND S. JAMES W. PRICE[1]

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received February 15, 1979

BARRY C. TRUDELL and S. JAMES W. PRICE. Can. J. Chem. 57, 2256 (1979).

This work provides a study of the $1a_{2u}\pi$, $2e_{2g}\sigma$, and $1e_{1g}\pi$ levels of a series of C_6F_5X compounds (X = F, Cl, Br, I, H, CH_3) using ultraviolet photoelectron spectroscopy or more simply PES. The three levels are assigned from the PES spectra using the perfluoro effect. A correlation between the energies of these levels and the energies predicted by CNDO/2 and INDO is presented.

BARRY C. TRUDELL et S. JAMES W. PRICE. Can. J. Chem. 57, 2256 (1979).

Dans ce travail, on rapporte une étude des niveaux $1a_{2u}\pi$, $2e_{2g}\sigma$ et $1e_{1g}\pi$ d'une série de composés C_6F_5X (X = F, Cl, Br, I, H, CH_3) basée sur la spectroscopie photoélectronique ultraviolette ou plus simplement la spectroscopie EP. En se basant sur l'effet perfluoro on peut attribuer les trois niveaux des spectres PE. On présente une corrélation entre les énergies de ces niveaux et les énergies prédites par des calculs CNDO/2 et INDO.

[Traduit par le journal]

Introduction

In two previous works (1, 2) the X-ray photoelectron spectra of the core levels of some C_6F_5X compounds were studied. This is a report furthering the ESCA investigation of six of these molecules. The study utilizes the technique of ultraviolet photoelectron spectroscopy, or more simply PES, to obtain information about the valence levels in C_6F_6, C_6F_5Cl, C_6F_5Br, C_6F_5I, C_6F_5H, and $C_6F_5CH_3$ in the gaseous phase. The ultraviolet spectra of benzene and substituted benzenes have been the topic of study for many workers (3–8). A PES study on the abovementioned perfluoroaromatic compounds has been reported by Turner and co-workers (8), but these spectra were not calibrated with an internal standard and the theoretical discussion is limited.

In the present work, semi-empirical molecular orbital calculations are used as an aid in the interpretation of the spectra obtained.

Experimental

All of the molecules of which ultraviolet photoelectron spectra were taken, i.e. C_6F_5X (X = F, Cl, Br, I, H, CH_3), were obtained from the Imperial Smelting Corporation. They were purified by distillation with only the middle fraction being used in the experimental work.

The spectra were taken from a MacPherson Esca 36 spectrometer employing HeI type radiation at 21.21 eV and gaseous samples. The combined pressure of the sample and internal standard (argon) was always 7×10^{-5} Torr. The argon $3p^3/2$ level (15.81 eV) (9) was used as a calibration. The ionization potentials (binding energies) reported are for the highest peak positions (most number of points) for the particular band, i.e. the vertical ionization potential.

Eigenvalues were calculated using the CNDO and INDO approximations from QCPE No. 290, GEOMO.[2]

Results and Discussion

The spectra for each of the molecules are shown in Fig. 1. The bands in the 14 to 21 eV region represent σ bonding in the ring system, as well as 'π' levels in the fluorine species which are always incorporated to some extent into the σ bonding of the ring system and are of little interest here. The primary consideration in the interpretation of the spectra is the assignment of the levels up to and including the $1a_{2u}\pi$. The assignment of these bands was done using the concept of the perfluoro effect (5, 10, 11). This effect states that on perfluoronation of a particular species, e.g. C_6H_5X to C_6F_5X, the σ molecular orbitals become stabilized by 2 to 3 eV, the π orbitals from about 0 to 1 eV, and the non-bonding orbitals around 1 eV. The assignments of the corresponding C_6H_5X compounds have been well established by various authors (3–8). Figure 2 shows the assignments for the C_6H_5X compounds, as well as their corresponding C_6F_5X partner. Knowing the correct assignments for the C_6H_5X compounds allows for the prediction of the levels in a similar series of C_6F_5X molecules, using the established effect of perfluoronation.

The compounds C_6H_6 and C_6F_5H will be used to demonstrate the procedure for the administration of the perfluoro effect on the assignment of the $1a_{2u}\pi$, $2e_{2g}\sigma$, and $1e_{1g}\pi$ levels. The first three levels

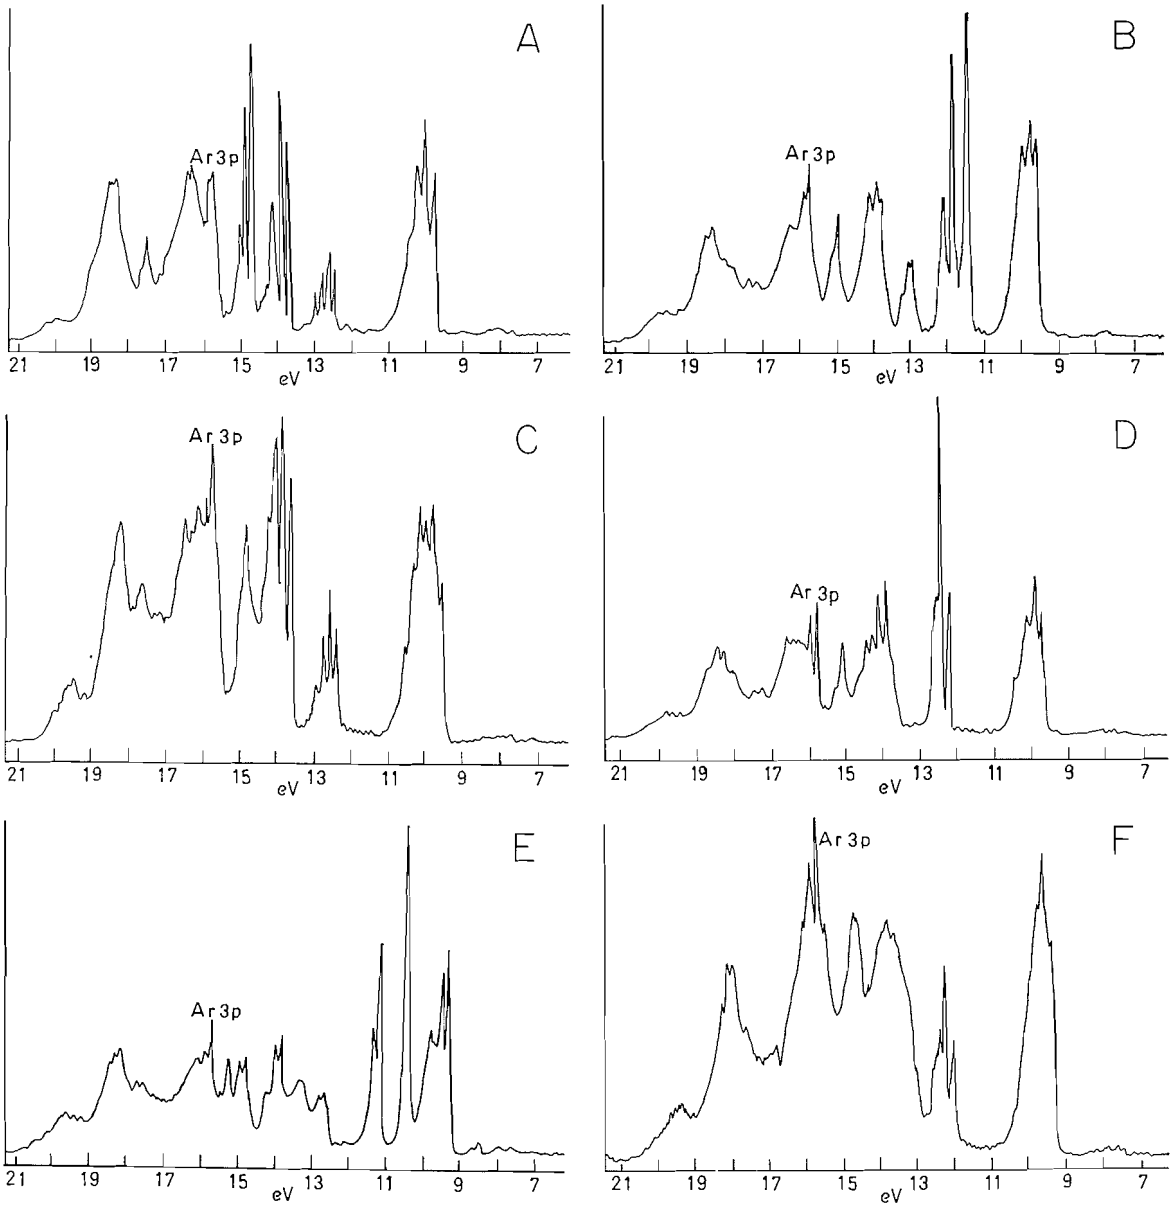

FIG. 1. The photoelectron spectra of (*A*) C_6F_6, (*B*) C_6F_5Br, (*C*) C_6F_5H, (*D*) C_6F_5Cl, (*E*) C_6F_5I, (*F*) $C_6F_5CH_3$.

in C_6H_6 are the $1e_{1g}\pi$ at 9.3 eV, the $2e_{2g}\sigma$ at 11.6 eV, and finally the $1a_{2u}\pi$ band with a binding energy of 12.3 eV. The first three bands in the C_6F_5H spectra have ionization potentials of 9.90, 12.74, and 13.94 eV respectively. A comparison made of the first band in each spectra produces a shift of 0.60 eV which is typical for a π band. Therefore, the first band in C_6F_5H is assigned to the $1e_{1g}\pi$ orbital. The second band in the C_6H_6 spectra appears at 11.6 eV and is labelled $2e_{2g}\sigma$. The perfluoro effect suggests a shift from the σ level of 2 to 3 eV. In the C_6F_5H spectra, there is a band at 13.94 eV which gives a shift of 2.3 eV. This band is then labelled $2e_{2g}\sigma$. The one remaining band in each of the molecules is then matched as the $1a_{2u}\pi$ level and gives a shift of approximately 0.4 eV, which is reasonable for a π band.

Various lone pair or non-bonding levels which lie within the three levels of interest here have also been assigned where applicable. (Diagrams of the assign-

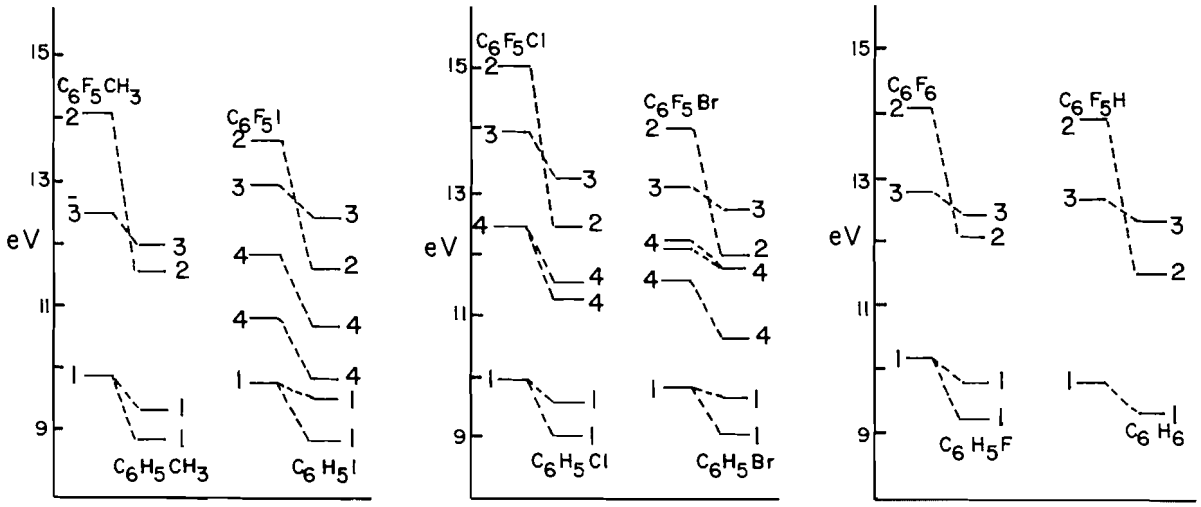

FIG. 2. Correlation of the energy levels using the perfluoro effect. (*1*) $1e_{1g}\pi$, (*2*) $2e_{2g}\sigma$, (*3*) $1a_{2u}\pi$, (*4*) lone pair.

ments for all of the compounds are shown in Fig. 2.)

Since the assignments have been made, some comparisons may be made. First of all, as in the XPS work, all of the binding energies of the various levels in the perfluorinated compounds are higher than in the unfluorinated species. Also, in all cases, the splitting of the $1e_{1g}\pi$ level is smaller or non-existent in the perfluorosystems. It is interesting to compare the ionization potential of the $1e_{1g}\pi$ level in this series of molecules. If the value of ionization potential for the $1e_{1g}\pi$ level in C_6F_5H is taken as a reference level, i.e. the hydrogen substituent has not altered the ionization potential of the $1e_{1g}\pi$ level, it is found that the other binding energies for the same level in the other compounds fall on either side of the reference level, depending on the strength of the inductive and mesomeric effects of the substituent. The first four, C_6F_5X (X = F, Cl, Br, I), follow a decreasing trend due to electronegativity. However, the Br and I substituting species have binding energies less than that of C_6F_5H, indicating that the mesomeric effect is predominant in these cases. The CH_3 group donates charge, both inductively and mesomerically, but very weakly and accordingly has a slightly lower ionization potential than C_6F_5H.

Although the assignments for the $1a_{2u}\pi$, $2e_{2g}\sigma$, and $1e_{1g}\pi$ levels have been made via the perfluoro effect, it was decided to try and correlate the experimental binding energies with the calculated eigenvalues, using CNDO/2 and INDO approximations and Koopmans' (12) theorem. A comparison between the experimental and theoretical values is shown in Table 1. Although the INDO results predict slightly better (lower) energies, both the CNDO/2 and INDO fail to take into account re-

TABLE 1. The CNDO/2, INDO, and experimental values for the ionization potentials of the $1a_{2u}\pi$, $2e_{2g}\sigma$, and $1e_{1g}\pi$ levels in C_6F_5X (X = F, Cl, Br, I, H, CH_3)

[a]CNDO/2 eigenvalues predicted for C_6F_5Br could not be assigned to specific levels.
[b]INDO calculations for Br and I were not possible.

organization and correlation effects and, mainly for these reasons, all of the eigenvalues are about 4 to 5 eV too high. Another difficulty in these molecular orbital calculations noted by other authors (13–16) is that in most cases the σ and π levels are not predicted in their correct order. In order to correct this, a 20% reduction in the eigenvalues for the π levels only seems to solve the problem. After the compensation, ordering in agreement with that

The hydrolysis of coumarin diethyl acetal and the lactonization of coumarinic acid ethyl ester. The partitioning of tetrahedral intermediates generated from independent sources

R. A. McClelland, R. Somani, and A. J. Kresge

Department of Chemistry, University of Toronto, Scarborough College, West Hill, Ont., Canada M1C 1A4

Received February 19, 1979

R. A. McClelland, R. Somani, and A. J. Kresge. Can. J. Chem. 57, 2260 (1979).

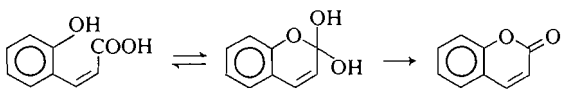
The hydrolysis of coumarin diethyl acetal to coumarin proceeds via two detectable intermediates. A short-lived transient is observed in strongly acidic solutions (pH < 2.5); this is the oxocarbonium ion intermediate of the hydrolysis. That this cation can be detected suggests unusual stability, a fact which can be explained in terms of its pyrilium ion nature. A long-lived intermediate is also observed; kinetic and spectral evidence suggest that this is coumarinic acid ethyl ester. The lactonization of this ester shows a change in rate-determining step as the pH is varied. A corresponding change in products is found in the acetal hydrolysis, the coumarinic acid ester being the major product at high pH, with coumarin the major product at low pH. Both observations can be explained in terms of different modes of partitioning of cationic and neutral tetrahedral intermediates. Analysis in quantitative terms shows that the same tetrahedral intermediate is generated in the two different cases.

R. A. McClelland, R. Somani et A. J. Kresge. Can. J. Chem. 57, 2260 (1979).

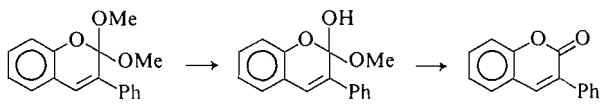
L'hydrolyse du diéthylacétal de la coumarine en coumarine se produit via deux intermédiaires que l'on a pu détecter. En solutions fortement acides (pH < 2.5) on observe une espèce provisoire de courte existence; il s'agit de l'ion oxocarbonium intermédiaire dans l'hydrolyse. Le fait que ce cation peut être détecté suggère qu'il est d'une stabilité exceptionnelle qui serait due à sa nature liée à l'ion pyrilium. On observe aussi un intermédiaire de vie plus longue; les données cinétique et spectrale suggèrent qu'il s'agit de l'ester éthylique de l'acide de coumarinique. Si l'on fait varier le pH, il se produit un changement dans l'étape qui détermine la vitesse de lactonisation de cet ester. On note un changement correspondant dans la nature des produits d'hydrolyse de l'acétal; l'ester de l'acide coumarinique est le produit majoritaire à pH élevé alors que la coumarine prédomine à des pH plus faibles. On peut expliquer les deux observations en termes de modes différents de bris des intermédiaires tétraédriques cationique et neutre. Une analyse en termes quantitatifs démontre que le même intermédiaire tétraédrique est généré dans les deux cas différents.

[Traduit par le journal]

The lactonization of coumarinic acids has now seen considerable kinetic investigation. This is in part due to the fact that certain substituted coumarinic acids lactonize with a remarkably enhanced rate (1). This reaction also shows an interesting change in rate-determining step, attributed to the different modes of partitioning of the various protonic forms of the tetrahedral intermediate (2–4).



Our interest in this system was prompted by an earlier report (5) that the hydrolysis of 3-phenylcoumarin dimethyl acetal[1] to 3-phenylcoumarin proceeds via an observable intermediate, this intermediate being assigned a hemiacetal[1] structure. This is the tetrahedral intermediate of the lactonization of a



coumarinic acid ester, and bears a close resemblance to the tetrahedral intermediates of the lactonization of the coumarinic acids themselves. Molecules containing the functional group $R'C(OR)_2OH$ have in general been implicated as intermediates in a number of important reactions: ester hydrolysis and alcoholysis, lactonization, ortho ester hydrolysis. However, such a grouping is found in stable species only under special circumstances (6–9), and there are few reports, other than that of the coumarin study (5), of their observation as transient intermediates (10–15). With our involvement in this latter area (11–15), we felt a reinvestigation of the coumarin system was in order, and we report here the results of our study.

Experimental

2-Ethoxy-5,6-benzopyrilium Fluoroborate

Coumarin (0.01 mol) and triethyloxonium fluoroborate

[1]Coumarin acetals are in fact ortho esters. Similarly the hemiacetals are also hemiortho esters or hydrogen ortho esters.

0008-4042/79/172260-08$01.00/0

(0.01 mol) were dissolved in dry methylene chloride (30 mL) and stirred overnight. Dry ether (50 mL) was added, and the resultant white solid filtered in a glove box with exclusion of moisture. The salt was washed with dry ether and the remaining solvent removed in a vacuum desiccator. The salt had mp 90–92°C; nmr (100% H_2SO_4, ext. $(Me)_4Si$) δ: 8.43 (d, 1H, J = 9 Hz), 7.5 (broad s, 4H), 6.87 (d, 1H, J = 9 Hz), 4.77 (q, 2H, J = 7 Hz), 1.33 (t, 3H, J = 7 Hz).

Coumarin Diethyl Acetal

The above salt was dissolved in a minimum amount of dry methylene chloride and added to a stirred solution of sodium ethoxide (excess) in ethanol at 0°C. After 1 h of additional stirring, most of the solvent was removed on a rotary evaporator. Ether and water were added, the ether was dried (K_2CO_3), and distilled. Coumarin diethyl acetal had bp 104°C (0.5 Torr); nmr ($CDCl_3$, $(Me)_4Si$) δ: 6.9–7.2 (m, 4H), 6.75 (d, 1H, J = 10 Hz), 5.72 (d, 1H, J = 10 Hz), 3.67 (q, 4H, J = 7 Hz), 1.18 (t, 6H, J = 7 Hz). *Anal.* calcd. for $C_{13}H_{16}O_3$: C 70.89, H 7.32; found: C 71.12, H 7.37.

Kinetics

(a) Coumarin Diethyl Acetal to Coumarin (pH > 6)

The absorbance increase at λ = 281 nm was monitored. First-order kinetic plots were excellently linear over several half-lives. Rate constants were evaluated as the slopes of plots of ln $(A_\infty - A)$ versus time.

(b) Pyrilium Ion Formation and Decomposition

Coumarin diethyl acetal dissolved in 0.001 M NaOH was mixed in a Durrum–Gibson stopped-flow apparatus with excess HCl, and the oscilloscope trace corresponding to the change in absorbance at λ = 325 nm recorded. This wavelength corresponds to a maximum absorbance of the 2-ethoxy-5,6-benzopyrilium ion. In strongly acidic solutions there is a rapid increase in absorbance at this wavelength, followed by a slower decrease. Rate constants representing the formation of the ion were obtained from the increase in absorbance using the Guggenheim approach over the first three to four half-lives of the reaction. Rate constants for the decay of the ion were obtained from the absorbance decrease from a plot of ln $(A - A_\infty)$ versus time. The initial absorbance readings used in constructing this plot were obtained only after a time corresponding to six to eight half-lives for the formation reaction. Rate constants were obtained only in acids where the formation process is at least 10 times as fast as the decomposition process.

(c) Coumarinic Acid Ethyl Ester to Coumarin

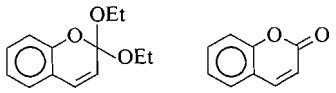
Coumarin diethyl acetal was dissolved in 0.0005 M HCl. After waiting 25 s this solution was mixed with an equal volume of an aqueous HCl solution or an aqueous buffer. The absorbance decrease at 240 nm was monitored; rate constants were obtained as the slopes of plots of ln $(A - A_\infty)$ versus time.

Partitioning of Hemiacetal in Acetal Hydrolysis

A stock solution of coumarin diethyl acetal (0.22 mol L^{-1}) in dry acetonitrile was prepared, and used throughout. A sample of this solution (10 μL) was added to aqueous HCl or aqueous buffer in a 10 mL volumetric flask. After waiting a time corresponding to six half-lives of $k_1[H^+]$ (see Results and Discussion) the absorbance reading at 240 nm was recorded. A second absorbance reading was obtained in several cases by allowing this solution to stand until any coumarinic acid ester was converted to coumarin. This reading was the same, within experimental error, in each case.

Results and Discussion

In solutions with pH > 6 coumarin diethyl acetal **1** is cleanly converted to coumarin **2** with no detectable build-up of any intermediate. This reaction is first order; observed first-order rate constants follow the equation (see also Fig. 1)



1 **2**

$$k_{obsd}(pH > 6) = k_{H^+}{}^1[H^+] + k_0{}^1 + k_{HA}{}^1[HA]$$

with $k_{H^+}{}^1 = 6.63 \times 10^3\ M^{-1}\ s^{-1}$ and $k_0{}^1 = 1.6 \times 10^{-4}\ s^{-1}$ (25°C, μ = 1.0). The term in HA represents general acid catalysis, which is weak (phosphate buffer) but detectable.

In solutions more acidic than pH 6, there can be detected two intermediates in the overall hydrolysis of coumarin diethyl acetal to coumarin, a short-lived species to which we assign the pyrilium ion structure **3**, and a long-lived species to which we assign the structure of the coumarinic acid ester **4**. The hemiacetal **5** is not observed, although it must be formed during the course of the reaction. In the following

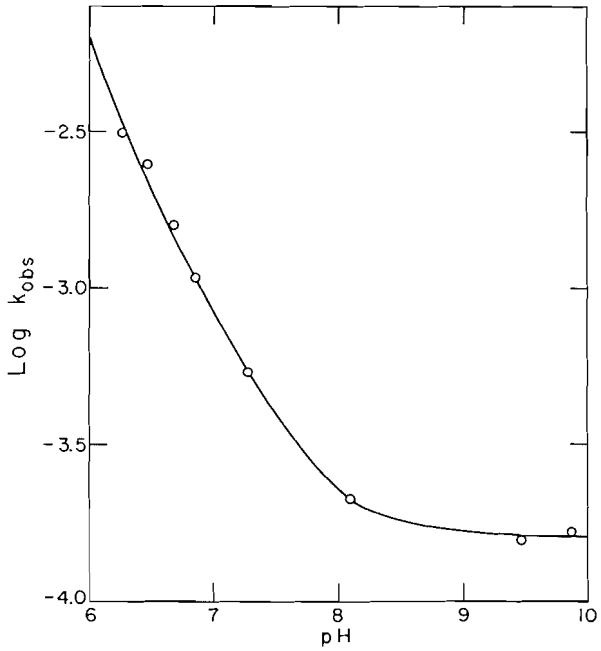


FIG. 1. First-order rate constants for the conversion of coumarin diethyl acetal to coumarin (25°C, μ = 1.0). The points are experimental, and have been obtained after extrapolation to zero buffer concentration. The curve is calculated from $k_{obsd} = 6.63 \times 10^3[H^+] + 1.6 \times 10^{-4}$.

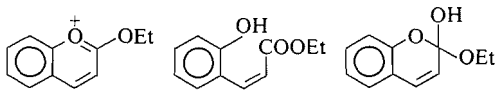
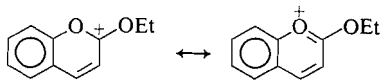


3 4 5

discussion we will present our evidence that structures **3** and **4** do represent the two intermediates. The formation of the ester **4** is particularly significant. The hemiacetal **5** can break down in two directions, forming ester **4** by ring opening or forming coumarin **2** by loss of the ethoxy group. As we will describe, this partitioning is pH dependent, and we have been able to place a quantitative measure on the partitioning, based on the ratio of **4**/**2**. The ester **4**, once formed, lactonizes to coumarin. This process is very rapid at pH > 6, but is relatively slow in more acidic solutions, and we have constructed the rate–pH profile. This lactonization, like that of the coumarinic acids (2–4), shows a change in rate-determining step, attributable to a change in the partitioning of the hemiacetal **5** which must be an intermediate. With an appropriate kinetic analysis, we have again obtained a quantitative measure of the partitioning. This means that there are available two independent measures of the partitioning of the same intermediate.

Pyrilium Ion Intermediate

When coumarin diethyl acetal dissolved in dilute NaOH is mixed with HCl solutions in a stopped-flow spectrophotometer, a short-lived transient is observed. The uv spectrum of this species was constructed in 0.5 *M* HCl (Fig. 2), where its rate of formation is much greater than its rate of decay. We propose that this transient is the ion **3**, the oxocar-



3

bonium ion intermediate of the acetal hydrolysis. This cation can be obtained in stable form as its fluoroborate salt by the alkylation of coumarin with triethyloxonium fluoroborate. The salt is relatively stable in 60% H_2SO_4 (half-life ca. 4 h). The uv spectrum in this acid is given in Fig. 2 and obviously bears a close resemblance to the spectrum of the transient species.

First-order rate constants for the formation of the pyrilium ion from coumarin diethyl acetal and its subsequent decomposition were measured, and are given in Table 1. The ion forms in a reaction which is first order in hydronium ion. The value of the second-order rate constant ($k_{H^+} = k_{obsd}/[H^+]$) is the same, within experimental error, as the rate constant $k_{H^+}{}^1$ obtained in the conversion of coumarin diethyl acetal to coumarin at high pH. The implication of this observation is that in the latter reaction the rate-limiting step in the overall conversion to coumarin is the formation of the pyrilium ion, all subsequent reaction steps being rapid. The pyrilium ion decays in a reaction which is independent of acidity. In simple terms, the pH-independent rate constant represents the hydration of the oxocarbonium ion, forming the hemiacetal.[2]

Perhaps the most significant aspect of our observation of the pyrilium ion intermediate is the very fact that it is observed. The life-times in general of the oxocarbonium ion intermediates of acetal and ortho ester hydrolysis have now been established to be short (16, 17) with the ion having a sufficient life-time to be seen only in cases where there is present some other structural feature which imparts unusual stability to the cation (18). There is such a stabilizing feature here, inasmuch as the present oxocarbonium ion is in fact an aromatic pyrilium ion. Herschfield and Schmir (3) have also suggested that cations of this type are unusually stable. The above authors propose that the extra stability provides the driving force for the cationic tetrahedral intermediate to break down to coumarin (protonated coumarin) rather than ring open.

Coumarinic Acid Ethyl Ester Intermediate

There is also observed a second longer-lived intermediate, whose structure we propose to be the ester **4**. This intermediate is most clearly observed, for reasons which will become apparent later, in dilute acids (pH 3–5). In Fig. 2 we display a uv spectrum obtained 20 s after dissolving coumarin diethyl acetal in 0.0005 *M* HCl. In this acid, the acetal has a half-life of about 3 s (based on $k_{H^+}{}^1$) and the pyrilium ion is also rapidly hydrated. The spectrum recorded, however, is not that of coumarin, although there is a slow spectral change (half-life 720 s in 0.0005 *M* HCl) resulting eventually in a spectrum identical to that of coumarin. Candidates for this second intermediate are the hemiacetal **5** and the ester **4**. The uv spectrum of the hemiacetal should be fairly similar to that of coumarin diethyl acetal, since the only structural difference involves the replacement of an ethoxy group by a hydroxy group. The spectrum observed, however, shows none of the characteristics of the acetal spectrum, and in fact bears a much closer resemblance to the spectrum of coumarin itself. The

[2]Neither of the observed products of this reaction are the hemiacetal itself. This means that the reaction being observed represents (at least) two stages, hydration to form hemiacetal, followed by the decomposition of this species. The interpretation that the rate of decay of pyrilium ion is equal to the hydration rate is valid only if the hydration stage is rate-limiting, that is, if the hemiacetal goes on to products rather than returns to ion.

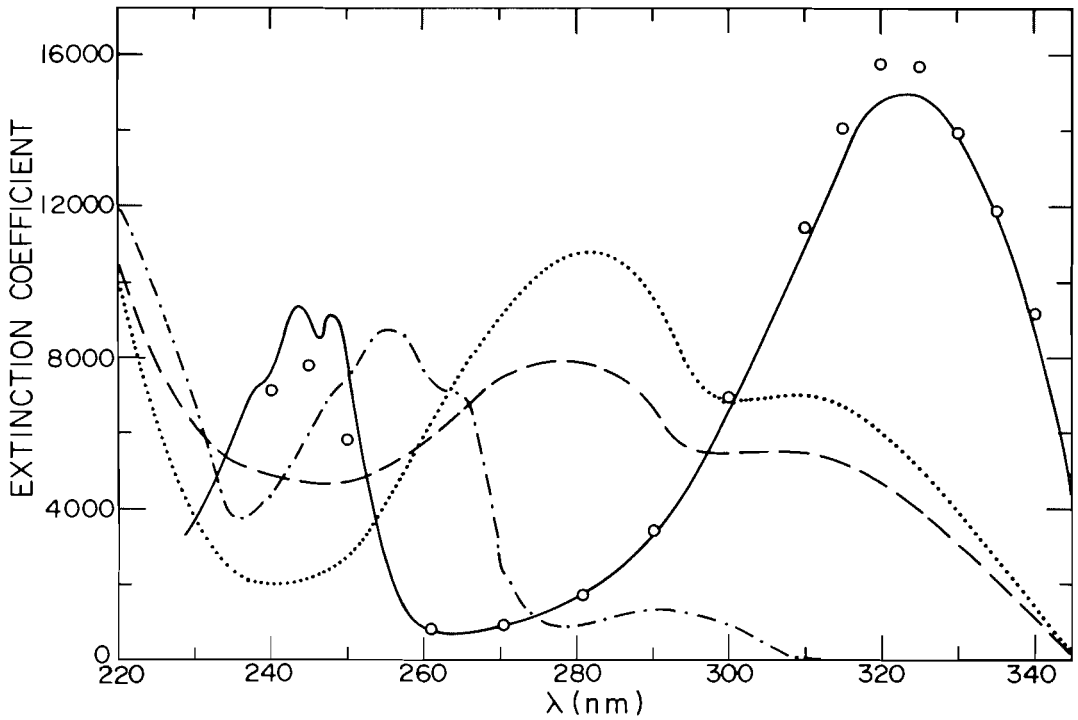


FIG. 2. Ultraviolet spectra. (---) Coumarin diethyl acetal, 0.001 *M* NaOH. (—) 6-Ethoxy-2,3-benzopyrilium borofluorate, 60% H_2SO_4. (○) Short-lived transient, based on absorbance readings obtained on the stopped-flow apparatus 5 ms after mixing coumarin diethyl acetal in 0.001 *M* NaOH with 1 *M* HCl. coumarinic acid ester, on the other hand, has the same basic chromophoric system as coumarin, and its uv spectrum should be similar.

As will become apparent, the intermediate spectrum discussed above represents a mixture (of the ester and coumarin), and thus our spectral argument for the identity of the intermediate might be open to question. A second, and perhaps more convincing, argument is based on a consideration of the kinetics of the conversion of the second intermediate to coumarin, a process which according to our proposal represents the lactonization of coumarinic acid ethyl ester. Our kinetic approach was to dissolve coumarin diethyl acetal in 0.0005 *M* HCl in order to generate the second intermediate. After waiting 20–30 s this solution was mixed with various acids or buffers, and rate constants obtained for the conversion to coumarin. The rate–pH profile is depicted in Fig. 3, where it also compared with the profile obtained by Herschfield and Schmir (3) for the lactonization of coumarinic acid. Although the actual numbers themselves are different, there is obviously a close similarity in these two profiles. In particular both include a break at pH 2–3 where a change in rate-determining step occurs (3). It is doubtful that hemiacetal decomposition would follow such a rate–pH profile (13–15), and obviously far more consistent if what we are following is the lactonization reaction.

We feel that in the previous study involving 3-phenylcoumarin diethyl acetal (5), the intermediate that was observed was also the coumarinic acid ester, and not the hemiacetal. Unfortunately the presence, and identity, of the intermediate in that study was based only on the fact that the hydrolysis of the acetal to 3-phenylcoumarin does not exhibit clean isobestic points. No detailed uv spectral analysis was presented. Rate constants, however, were reported for

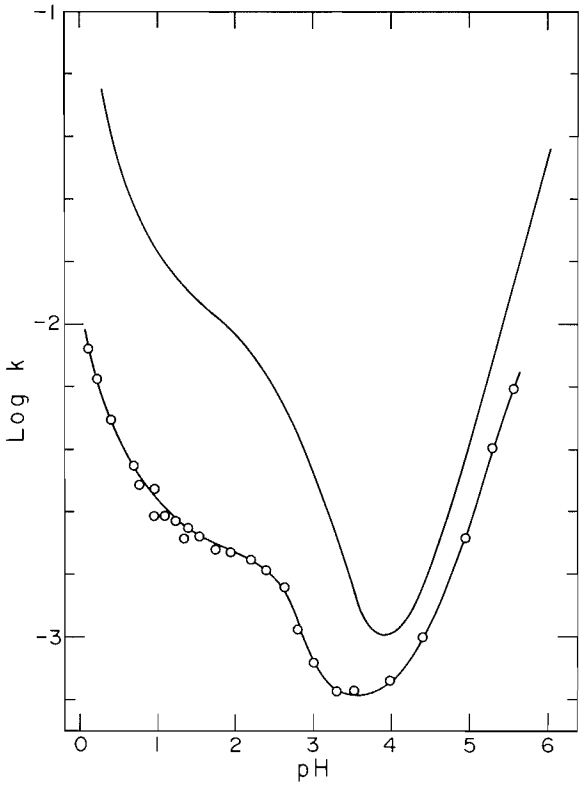

FIG. 3. First-order rate constants for the conversion of coumarinic acid ethyl ester to coumarin (25°C, μ = 1.0). The points are experimental, while the curve is based on the equation presented in the text (3). The upper curve represents first-order rate constants for the conversion of coumarinic acid to coumarin (3), in terms of the neutral substrate.

the conversion of the intermediate to 3-phenylcoumarin (5), and these are of the same order of magnitude as the rate constants that we obtain for the conversion of our second intermediate to coumarin.

Hemiacetal Partitioning – Lactonization

Herschfield and Schmir (3) propose that the break in the rate–pH profile for the lactonization of a coumarinic acid is caused by a change in rate-determing step. Scheme 1 shows the mechanism suggested by these workers, with the addition of a further route to the tetrahedral intermediate from the acetal. This scheme does not account for the base-catalyzed lactonization observed above pH 4. This mechanism for lactonization produces the steady-state rate equation

$$k_{obsd} = \frac{k_1([H^+]P^+ + K'P^0)([H^+] + K'(1 - P^0)/(1 + P^+))}{[H^+] + K'}$$

where $P^+(= k_3/(k_2 + k_3))$ and $P^0(= k_3'/k_2' + k_3'))$ are the partitioning ratios for the cationic and neutral tetrahedral intermediate respectively, and $K' = K_1(k_2' + k_3')/(k_2 + k_3)$. This equation contains four unknown constants. Values of these constants which best fit our experimental data are given in Table 2 along with the values for the lactonization of coumarinic acid (3). There is a close similarity in the two sets of data, consistent with our suggestion that the two processes are very similar. The one constant which differs significantly is k_1, which is 10 times smaller for the ester than for the acid. This refers to the acid-catalyzed nucleophilic addition of the phenol hydroxyl to the carbonyl. The difference in rate constant is probably just a reflection of the different susceptibilities of the acid and ester to nucleophilic attack. As another example, acid-catalyzed oxygen exchange of acetic acid (20) proceeds about an order of magnitude more rapidly than the acid-catalyzed hydrolysis of ethyl acetate (21).

The change in rate-determining step is most clearly seen in considering the partitioning ratios. In strongly acidic solution the cationic tetrahedral intermediate is the species which undergoes decomposition, and this breaks down preferentially to coumarin ($P^+ \approx 1$). The formation of the tetrahedral intermediate is therefore rate-determining in the lactonization. At higher pH, the neutral tetrahedral intermediate is involved, and this breaks down preferentially to coumarinic acid or its ester ($P^0 \approx 0$). The rate-determining step in the lactonization is therefore the breakdown of the tetrahedral intermediate to coumarin.

Hemiacetal Partitioning – Acetal Hydrolysis

This behaviour has important consequences when the initially formed products in the hydrolysis of the acetal are considered. There is little doubt that this hydrolysis proceeds with initial loss of one of the ethoxy groups, generating the intermediate pyrilium ion. This must then be followed by hydration of the ion to produce a hemiacetal, a species which is in fact the tetrahedral intermediate of the lactonization. With a change in rate-determining step in the lactonization, there should be a corresponding change in products in the acetal hydrolysis. This is indeed the case. In less acidic solutions, such as 0.0005 *M* HCl, the uv spectrum at the intermediate stage is significantly different from that of coumarin. This can be attributed to a significant amount of the ester intermediate being formed. In 0.1–1.0 *M* HCl, a spectrum very close to that of coumarin appears immediately. Since the ester is not converted to coumarin during the time required to record this spectrum, we can only conclude that there is little ester being formed in acid, that is, the hemiacetal breaks down preferentially to coumarin. (We verify here incidentally another suggestion of Herschfield and Schmir (3). The symmetry properties of the rate equation for the lactonization are such that it is not possible to assign the nature of the rate-limiting step at high pH and low pH on the basis of the kinetics alone; a second mathematical solution exists which equally satisfies the kinetic data, but which predicts the opposite modes of partitioning. The above authors assigned the nature of the rate-determining steps on the basis of analogy. Our results offer concrete proof that the assignment is correct.)

The partitioning of the intermediate of the acetal hydrolysis can be put on a more quantitative basis. To do this we have added acetal to a series of solutions of differing pH, and measured at 240 nm the apparent extinction coefficient (absorbance/concentration) after a time corresponding to six half-lives of the first reaction stage (based on $k_{H^+}[H^+]$). In solutions with pH < 4 this means that the measurement is being taken before a significant amount of ester can lactonize to coumarin, so that we are observing the actual partitioning of the intermediate. As is seen in Fig. 4 the experimental data trace out a sigmoidal titration curve; the curve drawn in the figure is based on the standard equation for such a curve, and represents the best fit of this equation to our data. This curve has limiting values of ε_{app} of 2020 and 5360 in acid and base respectively, with an inflection point at pH = 2.75.

In terms of Scheme 1, the following equation is produced:

$$\varepsilon_{app} = \frac{((1 - P^+)\varepsilon_E + P^+\varepsilon_C)[H^+] + ((1 - P^0)\varepsilon_E + P^0\varepsilon_C)K'}{[H^+] + K'}$$

where P^+, P^0, and K' are the same as defined previously, and ε_E and ε_C are the extinction coefficients at 240 nm of ester and coumarin respectively. This equation does take the form of a sigmoidal titration curve, with an inflection point at pH = pK'. It can immediately be noted that there is excellent agreement of the value of pK' obtained from the titration curve (2.75) and the pK' obtained in the kinetic analysis of the lactonization (2.79). The equation also predicts a limiting ε_{app} in acid of $(1 - P^+)\varepsilon_E + P^+\varepsilon_C$. The observed value is in fact very close to the extinction coefficient of coumarin itself, a value which can be accurately obtained using the same solutions used to determine ε_{app}, simply by allowing these solutions to stand until any ester is converted to coumarin (see the points △ in Fig. 4). The titration curve therefore predicts $P^+ \approx 1$, in agreement again with the more precisely determined kinetic value of $P^+ = 0.994$. The limiting value of ε_{app} at high pH is given by $(1 - P^0)\varepsilon_E + P^0\varepsilon_C$. Unfortunately we were unable to obtain a value of ε_E, since all attempts to prepare pure samples of this ester failed. This means that a value of P^0 cannot be calculated from the titration curve. The kinetic value is 0.045, so that the limiting ε_{app} in base must be close to ε_E.

Partitioning of Tetrahedral Intermediates Generated from Different Sources

However, simply on the basis of the agreement in the independently obtained pK' values we can con-

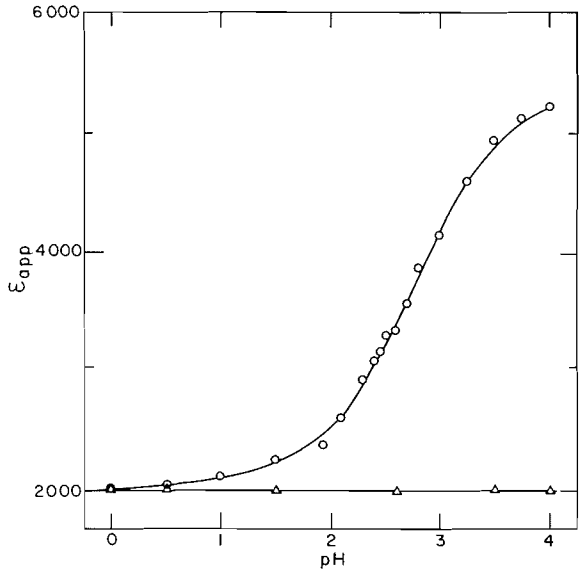

FIG. 4. Apparent extinction coefficient (240 nm) based on intermediate absorbance on dissolving coumarin diethyl acetal in aqueous solution (25°C, μ = 1.0). The points (○) are experimental; the curve is calculated (see text). The points (△) were obtained after a time corresponding to the complete conversion of any coumarinic acid ethyl ester to coumarin.

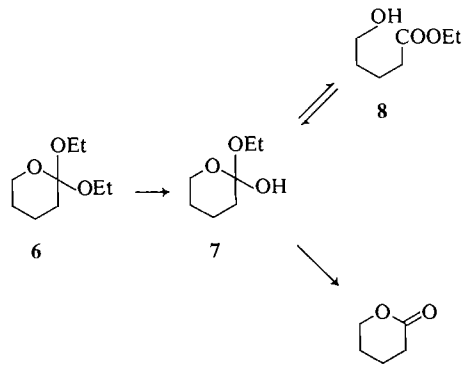
clude that the mode of partitioning of the tetrahedral intermediate is the same, regardless of whether the intermediate is generated in the lactonization of coumarinic acid ethyl ester or in the hydrolysis of coumarin diethyl acetal. Although this may seem a trivial point, there are cases where independently generated tetrahedral intermediates have been suggested to have different modes of breakdown. In a system closely related to that of this study, Deslongchamps *et al.* (22) have suggested that there may be a difference in the lone-pair orientation in tetrahedral intermediates generated in the hydrolysis of ortho esters (such as **6**) and in the lactonization of related hydroxy esters (such as **8**).



The intermediate in question (**7**) is very similar to that involved in our study. Our results suggest that its partitioning should be independent of its origin. Deslongchamps *et al.* based their conclusions principally on the basis of their observations that ortho esters such as **6** produce hydroxy esters as the initial products and not lactones.[3] Although this result is consistent with lone-pair orientation, an alternate explanation is simply that the tetrahedral intermediates **7** have a preference for ring opening. This latter suggestion leads to the prediction that the rate-determining step in the lactonization of the hydroxy ester is the breakdown of the tetrahedral intermediate to lactone. To our knowledge this has not been established for these simple lactonizations.

A case where more substantial evidence exists for a difference in modes of partitioning involves tetrahedral intermediates generated in imidate hydrolysis reactions and related ester ammonolysis reactions (23). These intermediates, although identical as to structure, are generated in different protonic forms, and it is proposed that they break down before protonic equilibrium is achieved. This is entirely reasonable since the life-times of these intermediates are exceedingly short (23). The tetrahedral intermediates of our study are probably also generated initially with the proton on different oxygens; our results suggest that they must have a sufficient life-time to equilibrate before breakdown. This is also entirely reasonable. We have established in several cases now (11–15) that hydrogen ortho ester life-times are relatively long, certainly long enough for acid–base equilibria to be established.

Double layer structure at the mercury/dimethylformamide interface

W. RONALD FAWCETT, BRIAN M. IKEDA, AND JAMES B. SELLAN

Guelph–Waterloo Centre for Graduate Work in Chemistry, Guelph Campus, Department of Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received November 24, 1978

W. RONALD FAWCETT, BRIAN M. IKEDA, and JAMES B. SELLAN. Can. J. Chem. 57, 2268 (1979).

The differential capacity of the mercury/solution interface has been measured for various tetraalkylammonium and alkali metal perchlorates in dimethylformamide (DMF) at 25°C, and for tetraethylammonium perchlorate (TEAP) in DMF at −15°C, 0°C, and 40°C. On the basis of established analyses, it is shown that ionic specific adsorption at mercury from TEAP solutions in DMF is negligible. The properties of the inner layer are analyzed in detail on the basis of a statistical mechanical model in which the solvent molecules represented as hard polarizable spheres can occupy three orientations: with their dipole vectors towards the surface, away from the surface, and parallel to the surface. It is shown that this model provides a reasonable description of the electrostatic properties of the inner layer at the Hg/DMF interface.

W. RONALD FAWCETT, BRIAN M. IKEDA et JAMES B. SELLAN. Can. J. Chem. 57, 2268 (1979).

On a mesuré la capacité de l'interface mercure/solution des divers perchlorates de tétraalkylammonium et de métaux alcalins dans le diméthylformamide (DMF) à 25°C et de perchlorate de tétraéthylammonium (PTEA) dans le DMF à −15, 0 et 40°C. En se basant sur des analyses établies, on montre que l'adsorption spécifique ionique au niveau du mercure à partir de solutions de PTEA dans le DMF est négligeable. On a analysé en détail les propriétés de la couche intérieure en se basant sur un modèle mécanique statistique dans lequel les molécules de solvant représentées comme des sphères polarisables dures, peuvent occuper trois orientations; leurs vecteurs dipolaires peuvent être orientés vers la surface, à l'opposé de la surface et parallèle à la surface. On montre que ce modèle fournit une description des propriétés électrostatiques de la couche intérieure à l'interface Hg/DMF.

[Traduit par le journal]

Introduction

The thermodynamic properties of the mercury/dimethylformamide (DMF) interface were first examined by Minc *et al.* (1) who showed that the differential capacity – potential curves were rather featureless in comparison with those observed for many other solvents (2). In particular, the capacity hump which occurs at negative potentials for the protic amide solvents, and which is often attributed to solvent reorientation (3), is not found with DMF. Bezugly and Korshikov (4) studied the dependence of interfacial tension – potential curves on the nature of the ions in common 1–1 electrolytes; in the case of $LiClO_4$ solutions in DMF, the interfacial tension at the potential of zero charge (pzc) increased with increase in salt concentration, indicating that the relative ionic surface excesses decrease in the same direction. This behaviour is opposite to that observed for most salts at the mercury/solution interface. Damaskin and co-workers studied the adsorption of various inorganic ions (5, 6) and organic molecules (7, 8) from DMF solutions and compared the results with those obtained for water and other solvents. In addition, the adsorption of DMF at Hg from aqueous electrolyte solutions has been investigated by Bezugly and Korshikov (4) and by Payne (9). In the latter study, it was concluded that the DMF molecule is predominantly adsorbed at the pzc on Hg with its dipole vector parallel to the metal/solution interface. Under these circumstances, a capacity curve without a hump is expected in the pure solvent when ionic adsorption is absent (10).

Except for the electrocapillary curve for 0.1 *M* tetraethylammonium (TEA^+) iodide reported by Bezugly and Korshikov (4), the properties of the double layer for solutions of tetraalkylammonium salts (TAA^+) in DMF have not been investigated. These systems are of special interest in the area of organic electrochemistry since the Hg electrode may be polarized to very negative potentials, thereby permitting a study of the reduction of organic molecules to stable anion radicals and dianions (11). The purpose of the present study was to obtain double layer data for these electrolytes and to determine the extent of ionic adsorption especially at negative potentials. Inner layer capacity – potential curves obtained in the absence of specific adsorption in the temperature range −15 to 40°C are analyzed on the basis of a three state model for aprotic solvent structure at charged interfaces (10).

0008-4042/79/172268-10$01.00/0

Experimental

Differential capacity against potential data were obtained with an ac bridge operating at 1000 Hz as described previously (12). The cell, which was surrounded by a jacket through which a constant temperature fluid was circulated, consisted of two compartments, a working compartment and a reference electrode compartment, connected by fritted glass. The dropping mercury electrode was constructed from a fine capillary drawn from Pyrex tubing. The end of the capillary was bent through 180° so that the mercury emerged in an upwards vertical direction (Fig. 1) with a flow rate of ~ 0.1 mg s^{-1}. This unconventional design was chosen to avoid problems due to solution creep which are more troublesome in non-aqueous media. The electrode was stable over a long period of time and permitted data to be obtained with the reproducibility achieved with a normal dropping mercury electrode in aqueous systems. The area of the glass over which the emerging drop was formed was $\sim 2 \times 10^{-5}$ cm^2; this area was subtracted from the total area of the drop at balance (~ 0.01 cm^2) to obtain the area in contact with the solution. The bridge was normally balanced at 5 s after the beginning of drop growth except at far negative potentials where shorter periods were used because of the reduced natural life time of the drop. The counter electrode was a cylinder of Pt (~ 3 cm^2 area) which surrounded the dropping mercury electrode. The reference electrode (Ag/0.05 *M* $AgNO_3$, 0.1 *M* TEAP in DMF//) was placed in the reference electrode compartment which contained the same solution as the working compartment; the liquid–liquid junction was established in a fritted glass disc. The silver nitrate solution in this electrode was replaced daily because of the instability of Ag^+ in DMF to photoreduction. TAA^+ perchlorates (TEAP, tetrapropylammium perchlorate (TPAP) and tetra-*n*-butylammonium perchlorate (TBAP) were recrystallized several times from triply distilled water and dried *in vacuo* over P_2O_5 at 50°C. The alkali metal perchlorates were purified by the same procedure, the drying operation being carried out at 140°C. Spectroquality DMF (Matheson, Coleman and Bell) was dried with calcium hydride and stored over 4A molecular sieves. It was distilled at reduced pressure (1–2 mm Hg) under a nitrogen atmosphere before use. The experiments were carried out in a controlled atmosphere chamber (Vacuum Atmospheres) containing a nitrogen atmosphere which was continuously purged of oxygen and water. The temperature of the cell was maintained at temperatures in the range -15 to 40°C to ± 0.1°C by passing constant temperature methanol through the jacket surrounding the working and reference electrode compartments; the ambient temperature of the chamber was maintained close to that of the cell. The working solutions were degassed with purified nitrogen saturated with DMF prior to the experiment. Other details of the experiment are described elsewhere (12).

Results

Differential capacity – potential data were obtained for TEAP solutions in DMF in the concentration range 0.01 to 0.2 *M*. These data were numerically integrated as described previously to obtain values of electrode charge density σ for integral increments in σ. Typical capacity data plotted against σ are shown in Fig. 2. A diffuse layer minimum is apparent at the pzc indicating that specific adsorption is not important in this potential region. A shallow capacity

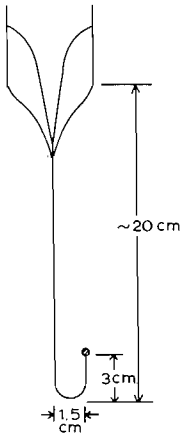

FIG. 1. Sketch of the rate determining portion of the thin walled capillary designed to prevent solution creep at the mercury/glass/solution interface. The shaded sphere at the end of the capillary represents an emerging Hg drop.

minimum is observed for large negative charge densities (-0.17 C m^{-2}) and a steep maximum at large positive charge densities (0.19 C m^{-2}). The capacity curves are similar to those observed for the Hg/acetonitrile (AN) interface (13) with the exception that data are reported at more positive charge densities in DMF. The absence of ionic specific adsorption in the vicinity of the pzc may be demonstrated on the basis of plots of the reciprocal of the experimental capacity $1/C$ against the reciprocal of the diffuse layer capacity $1/C_d$ as estimated by the Gouy–Chapman model for constant σ and varying electrolyte concentration (14). The fact that the slope of these plots is unity in the range $-0.04 \leq \sigma \leq +0.04$ C m^{-2} (Fig. 3) indicates that the inner layer capacity C_i is independent of electrolyte concentration for constant σ, and, therefore, that ionic specific adsorption is negligible. Since experimental activity coefficient data are not available for TEAP in DMF, the presence of specific adsorption at higher charge densities could not be tested by the method of Esin and Markov plots. However, under these conditions where $C_d \gg C_i$, the experimental capacity curves are almost independent of electrolyte concentration (Fig. 2), indicating that specific adsorption is not important. Thus, it is concluded that specific adsorption at the Hg/DMF interface may be neglected over the experimentally accessible potential range when the electrolyte is TEAP. The differential and integral capacities of the inner layer for this system are tabulated in Table 1.

It is interesting to examine the applicability of the Gouy–Chapman–Stern model to this system at the pzc on the basis of the test described earlier (15).

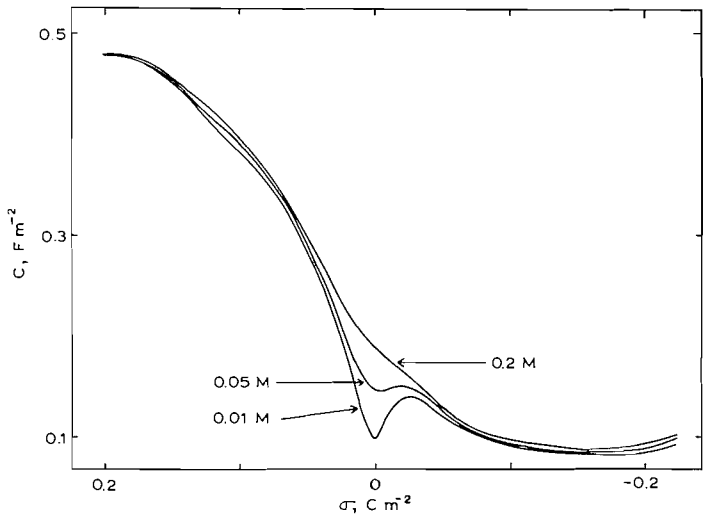

FIG. 2. Plots of differential capacity against electrode charge density for the mercury/dimethylformamide solution interface with various concentrations of tetraethylammonium perchlorate (TEAP) at 25°C. The concentration of TEAP is indicated for each curve.

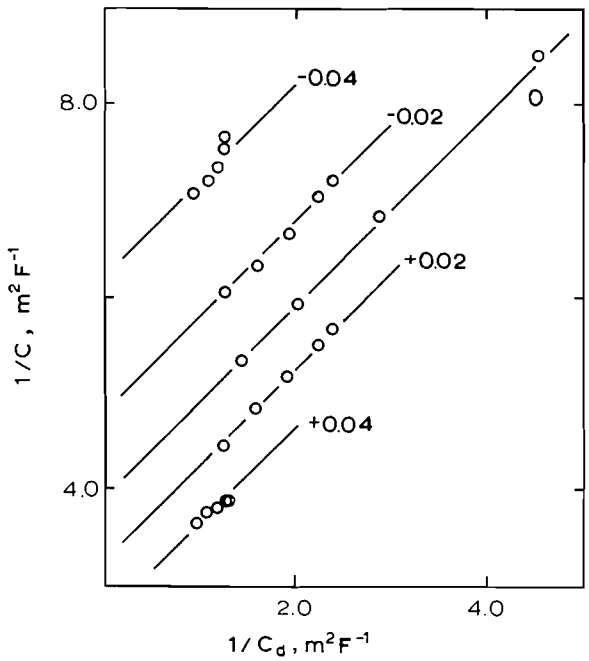

FIG. 3. Reciprocal of the differential capacity at constant electrode charge density plotted against the reciprocal of the diffuse layer capacity estimated by Gouy–Chapman theory for various concentrations of TEAP in DMF at 25°C. The integers adjacent to each curve indicate the value of the electrode charge density in C m^{-2}.

Accordingly,

$$[1] \quad 1/C_0 = 1/C_{i0} + 1/(f\theta\sqrt{c})$$

where C_0 is the capacity at pzc; C_{i0}, the corresponding inner layer capacity; c, the electrolyte concentration; $\theta^2 = 2RT\varepsilon\varepsilon_0$; and $f = F/RT$, ε being the dielectric constant of the solvent and ε_0 the permittivity of free space. A plot of $1/C$ against $1/\sqrt{c}$ for the TEAP data gave an excellent straight line (r = 0.999) with slope equal to 20.15 $m^{1/2}$ F^{-1} mol^{-1}. The corresponding value of the dielectric constant (37.0) agrees very well with published values for DMF (16). This result suggests that the Gouy–Chapman–Stern model provides a very good description of the Hg/DMF interface when TEAP is the electrolyte. Although one expects some lowering of the dielectric constant of the solvent especially in concentrated solutions (17), this effect is apparently not significant for TEAP in the concentration range considered. It should also be noted that the above analysis can be used to detect incomplete electrolyte

*K_i is defined by the equation $1/K_i = (\phi^m - \phi_0{}^m - \phi^d)/\sigma$ where ϕ^m is the electrode potential measured with respect to a given reference electrode, $\phi_0{}^m$, the corresponding value at the pzc, and ϕ^d, the potential drop across the diffuse layer estimated by the Gouy–Chapman equation.

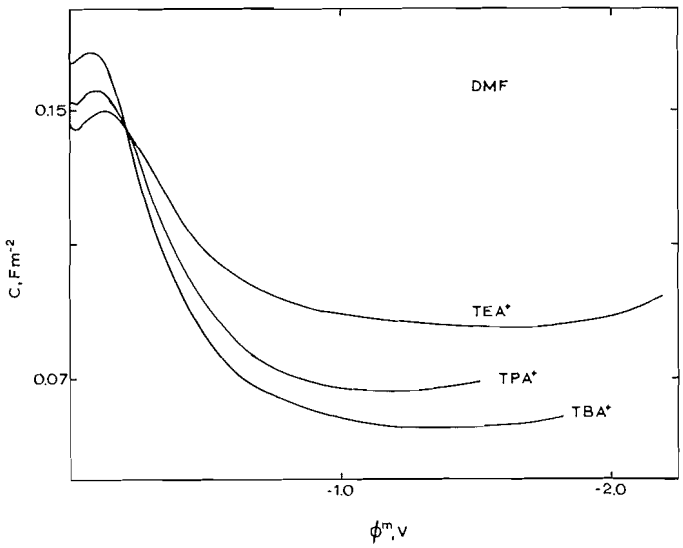

FIG. 4. Differential capacity of the Hg/solution interface plotted against electrode potential measured with respect to the potential of zero charge for various 0.05 *M* tetraalkylammonium perchlorate solutions in DMF. The cations involved are tetraethylammonium (TEA^+), tetrapropylammonium (TPA^+), and tetrabutylammonium (TBA^+) as indicated.

dissociation in non-aqueous solutions. Thus, Dzhaparidze and co-workers (18, 19) observed that the slopes of plots of $1/C$ against $1/\sqrt{c}$ were considerably higher than predicted by eq. [1] for $LiClO_4$ and KF solutions in ethylene glycol. In the present case, the above result indicates that TEAP is completely dissociated in DMF.

The effect of the size of the TAA^+ cation on the experimental differential capacity at negative potentials is illustrated in Fig. 4. As the size of the cation increases in the series $TEA^+ < TPA^+ < TBA^+$, the capacity decreases. This can be chiefly attributed to a corresponding increase in the thickness of the inner layer. However, as was observed earlier for the corresponding systems in AN (13), the ordering of capacities in the vicinity of the pzc is reversed. This suggests that the cation has an influence on the dielectric properties of the inner layer when the charge density on the electrode is low. One obvious way in which cation size effects dielectric properties is by changing the average number of solvent molecules per unit area in the inner layer, and, thus, the mean dielectric constant. As the field of the electrode increases, its influence on solvent dipole orientation predominates and the dielectric properties of the first solvent monolayer become the most important factor determining inner layer capacity.

The influence of alkali metal cations on capacity – potential curves in DMF is illustrated in Fig. 5. At sufficiently negative potentials, the capacity rises sharply in a potential region which becomes more negative as solvation of the cation increases, that is, in the order $Cs^+ < K^+ < Na^+ < Li^+$. This observation can be attributed to cation specific adsorption which is most pronounced in the case of Cs^+ (5). It is interesting to note that at less negative potentials where cation adsorption is not significant, the ordering of capacities is reversed, that is, $C(Li^+) > C(Na^+) > C(K^+)$. Although this effect is small, it is similar to the cation effects observed for formamide (20), *N*-methylformamide (15), *N*-methylacetamide (21), and dimethylsulphoxide (22). This ordering can be attributed to a dependence of both the dielectric properties and the thickness of the inner layer on the nature of the cation at the outer Helmholtz plane (oHp) (15).

The dependence of the interfacial capacity for the Hg/0.05 *M* TEAP system on temperature is illustrated in Fig. 6. It is interesting that the capacity is almost independent of temperature at far negative potentials. At far positive potentials, the capacity decreases with increase in temperature in the vicinity of the maximum. The present results may be compared with those obtained earlier for the Hg/H_2O (23, 24) and Hg/methanol interfaces (2). In the case of the aqueous system, the interfacial capacity varies markedly with temperature for positive charge densities on Hg and very little at negative charge densities. For the methanol interface where the capacity curve contains one minimum with no other extrema, very little variation in capacity with temperature is observed. On the basis of recent models (10, 25), the shape of capacity curves for non-aqueous systems in the absence of specific adsorption can be attributed to variation in dielectric properties of a solvent monolayer adjacent to the electrode with

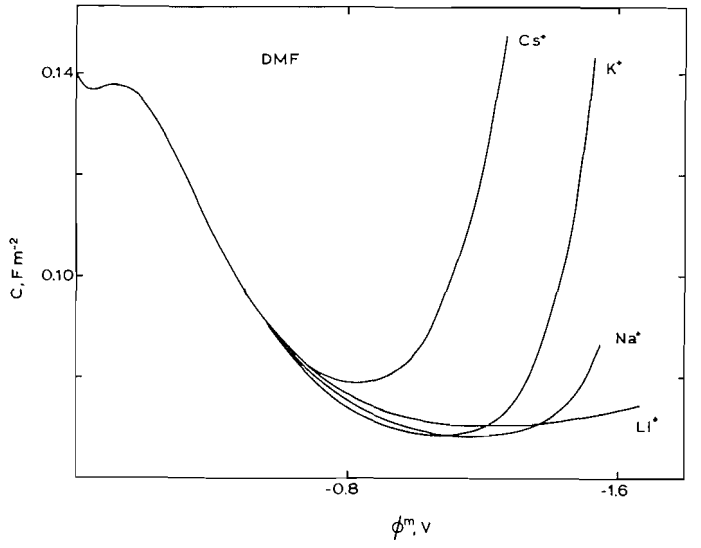

FIG. 5. Differential capacity of the Hg/solution interface plotted against electrode potential measured with respect to the potential of zero charge for various 0.05 *M* alkali metal perchlorate solutions in DMF. The nature of the cation is indicated adjacent to each curve.

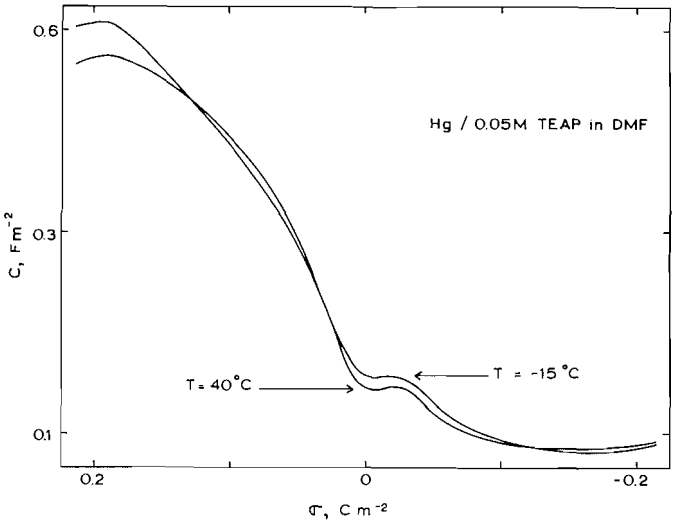

FIG. 6. Differential capacity of the Hg/0.05 *M* TEAP solution in DMF plotted against electrode charge density at −15°C and 40°C as indicated.

electrode charge density. The small variation in capacity with temperature is examined on the basis of these models below.

Discussion

Since the inner layer capacity curve for the Hg/DMF interface possesses two extrema, it does not fit clearly into the three categories discussed by Parsons (25). In previous investigations of this system (1, 3, 5), the maximum observed here at far positive potentials was not reported. Accordingly, DMF was classified together with solvents such as AN and acetone as a solvent with a featureless capacity curve characterized by a broad minimum. However, Borkowska (26) recently reported that a capacity maximum is also observed for the Hg/acetone interface when the electrolyte is chosen so that the electrode can be polarized to sufficiently positive potentials. According to the three state model proposed recently (10), the dielectric properties of these solvents at a polarizable interface can be accounted for if it is assumed that the solvent is predominantly adsorbed on the electrode with its dipole vector parallel to the surface. The other two states considered in the model

are solvent molecules adsorbed with the positive end of the dipole towards the metal ('up' orientation) and with the negative end towards the metal ('down' orientation) (10). If the electrode can be polarized over a sufficiently wide potential range, one would predict according to the three state model an inner layer capacity curve with three extrema, a central minimum and two maxima at far positive and negative potentials. The central minimum corresponds to the electrostatic condition at which the surface concentration of 'up' dipoles is equal to that of 'down' dipoles. As the electrode charge density is made more positive, the concentrations of 'parallel' and 'up' dipoles decrease and that of 'down' dipoles increases. The positive maximum then corresponds to the electrostatic condition at which the surface concentration of 'down' dipoles equals that of 'parallel' dipoles. The opposite situation holds at the negative maximum with the surface concentrations of 'up' and 'parallel' dipoles equal. On the basis of this model, the negative maximum is not observed at the Hg/DMF interface because reduction of the cation from the electrolyte limits the polarizable range of the electrode in the negative direction. An alternative explanation of the capacity curve might involve attributing the maximum observed at positive potentials to reorientation of 'up' dipoles which are strongly adsorbed at the pzc; the small increase in capacity at negative potentials could then be associated with electrostriction of solvent dipoles in the large negative electrode field (27). However, under these circumstances one would expect a large positive surface potential due to oriented dipoles at the pzc. In fact, the experimental evidence from studies of the adsorption of DMF at Hg from DMF–water solutions is that the solvent dipoles are predominantly adsorbed with their dipole vectors parallel to the surface (9). Thus, the first interpretation of the capacity offered above on the basis of the three state model is consistent with all experimental evidence obtained to date.

The equations defining the surface concentrations of 'up', 'down', and 'parallel' dipoles in a monolayer at the electrode/solution interface are (10)

$$[2] \quad N^{\uparrow} + N^{\downarrow} + N^{0} = N_{T}$$

$$[3] \quad kT \ln (N^{\uparrow}/N^{\downarrow}) = U_{r}^{\downarrow} - U_{r}^{\uparrow} - 2p(E + X)$$

and

$$[4] \quad kT \ln (N^{\downarrow}/N^{0}) = U_{r}^{0} - U_{r}^{\downarrow} + p(E + X)$$

$N^{\uparrow}$, $N^{\downarrow}$, and N^{0} are the number densities of solvent dipoles in the 'up', 'down', and 'parallel' orientations, respectively; $U_{r}^{\uparrow}$, $U_{r}^{\downarrow}$, and U_{r}^{0} are the corresponding residual energies which account for non-electrostatic contributions to interactions between the metal and solvent dipoles in each of the three states; E is the field due to the charge on the electrode, X, the mean field in the same direction at an average dipole site due to surrounding dipoles, p, the permanent dipole moment of the solvent molecule, and N_{T}, the total number of solvent molecules per unit area on the basis of hexagonal close packing of solvent molecules represented as hard spheres. On the basis of methods worked out by Levine *et al.* (28), it was shown that the dipole reaction field X is given by

$$[5] \quad X = c_{e}(pr - \alpha E)/Ad^{3}$$

where $r = (N^{\uparrow} - N^{\downarrow})/N_{T}$ and $A = 1 + c_{e}\alpha/d^{3}$; c_{e} is an effective coordination number for a dipole in the hexagonal array between the conducting electrode and the diffuse layer, α, the average molecular polarizability and d, the molecular diameter. Equations [2]–[4] form a set of non-linear equations in $N^{\uparrow}$, $N^{\downarrow}$, and N^{0} which may be solved iteratively. The total potential drop across the monolayer is

$$[6] \quad \Delta\phi = 4\pi\sigma d + (4\pi N_{T} d^{3} X/c_{e})$$

where σ is the charge density on the electrode. The differential capacity of the monolayer is then given by

$$[7] \quad \frac{1}{C_{i}} = \left(\frac{\partial \Delta\phi}{\partial \sigma}\right) = 4\pi d + \frac{4\pi N_{T} d^{3}}{c_{e}} \left(\frac{\partial X}{\partial \sigma}\right)$$

In order to determine $(\partial X/\partial\sigma)$, one must calculate the derivatives $(\partial N^{\uparrow}/\partial\sigma)$, $(\partial N^{\downarrow}/\partial\sigma)$, and $(\partial N^{0}/\partial\sigma)$; these are estimated on the basis of three equations derived from eqs. [2]–[4] by differentiation with respect to σ (10).

In order to determine whether eqs. [6] and [7] describe the electrostatic properties of the inner layer at the Hg/DMF interface one must determine values for the residual energies. As shown previously (10), these parameters may be estimated from the electrostatic properties of the interface at the extrema. In the present case, at the capacity minimum, $N^{\uparrow} = N^{\downarrow}$, and therefore from eqs. [3] and [5]

$$[8] \quad U_{r}^{\downarrow} - U_{r}^{\uparrow} = 2pE_{m}/A$$

where $E_{m} = 4\pi\sigma_{m}$, E_{m} and σ_{m} being the electrode field and charge density, respectively, at the minimum. At the maximum $N^{\downarrow} = N^{0}$ and assuming that $N^{\uparrow}$ is negligible, $N^{\downarrow}/N_{T} = N^{0}/N_{T} = 0.5$. From eqs. [4] and [5],

$$[9] \quad U_{r}^{\downarrow} - U_{r}^{0} = pE_{r}/A - 0.5c_{e}p^{2}/Ad^{3}$$

where E_{r} is the electrode field at the maximum. The values of the dipole moment and polarizability reported for DMF in the literature are 3.86 D (29) and

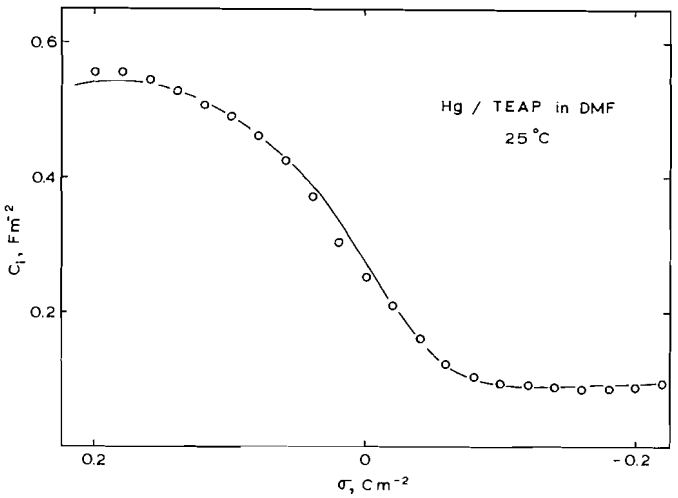

FIG. 7. Plot of the inner layer differential capacity C_i for the Hg/DMF interface with TEAP as electrolyte against electrode charge density at 25°C. The solid curve was calculated from the three state model as described in the text with $d = 0.340$ nm, $p = 3.86$ D, $\alpha = 7.81 \times 10^{-3}$ nm^3, $c_e = 14.84$, $U_r^{\downarrow} - U_r^{\uparrow} = -75.41$ kJ mol^{-1}, and $U_r^0 - U_r^{\downarrow} = 0.77$ kJ mol^{-1}.

7.81×10^{-24} cm^3 (30, 31), respectively. Thus, having chosen the parameters d and c_e, one can estimate the residual energy differences defined in eqs. [8] and [9].

Given the molecular parameters for the solvent (d, p, and α), effective coordination number c_e, and the residual energy differences $U_r^{\downarrow} - U_r^{\uparrow}$ and $U_r^{\downarrow} - U_r^0$, the dependence of $\Delta\phi$ and C_i on σ was determined as outlined previously (10). The calculated values of $\Delta\phi - \Delta\phi_0$, where $\Delta\phi_0$ is the potential drop across the dipole layer at the pzc, were compared with the rational potential drop across the inner layer ϕ^{md} (Table 1) determined experimentally; at the same time, the experimental and calculated values of C_i were compared. The criterion for the best values of the adjusted parameters d and c_e was a minimum in the standard deviations between experimental and calculated values of both C_i and $\Delta\phi - \Delta\phi_0$. The results of applying the three state model for the inner layer differential capacity data are shown in Fig. 7. From the values of the electrode charge density at the minimum (-0.17 C m^{-2}) and maximum (0.19 C m^{-2}), and using the best values of d (0.340 nm) and c_e (14.84), $U_r^{\downarrow} - U_r^{\uparrow} = -75.4$ kJ mol^{-1} and $U_r^{\downarrow} - U_r^0 = -0.77$ kJ mol^{-1}. It is apparent that an excellent fit to the experimental data can be made on the basis of the above model. It should be emphasized that only two parameters, namely d and c_e, were adjusted to achieve this fit. It was noted that very small variations in the effective coordination number c_e had a very large effect on the quality of the fit. Levine *et al.* (28) have shown the c_e should equal 15.2 for a monolayer of hexagonally close-packed spherical dipoles with all dipole vectors normal to the surface, and situated between a conducting electrode and electrolyte solution. The present result that the best fit was obtained with a lower value of c_e may be a reflection of the conclusion that a large fraction of the surface is covered by solvent dipoles in a 'parallel' orientation.

Calculated and experimental values of the integral capacity of the inner layer K_i which is defined by the equation

$$[10] \quad 1/K_i = (\Delta\phi - \Delta\phi_0)/\sigma$$

are shown in Fig. 8. Although the fit is quite good at negative charge densities, the calculated capacity is higher than the experimental values at positive charge densities. In comparing Figs. 7 and 8, it should be kept in mind that small discrepancies between calculated and experimental values of C_i are added in the integration process involved in calculating $\Delta\phi$ and thus K_i from C_i. Thus, the small differences between the experimental and calculated curves in Fig. 7 are much more apparent in Fig. 8.

On the basis of the above parameters one may estimate the fraction of the surface covered by each of the three species. Over most of the polarizable range, the majority of the Hg surface is covered by DMF molecules in a 'parallel' orientation, the concentration of 'up' dipoles being negligible (Fig. 9). As the electrode charge density becomes more positive, the fraction of solvent dipoles in the 'down' orientation, that is, with the oxygen atom towards the surface, increases at the expense of the 'parallel' orientation. On the basis of the Courtauld model and assuming that the dipole vector is approximately parallel to a

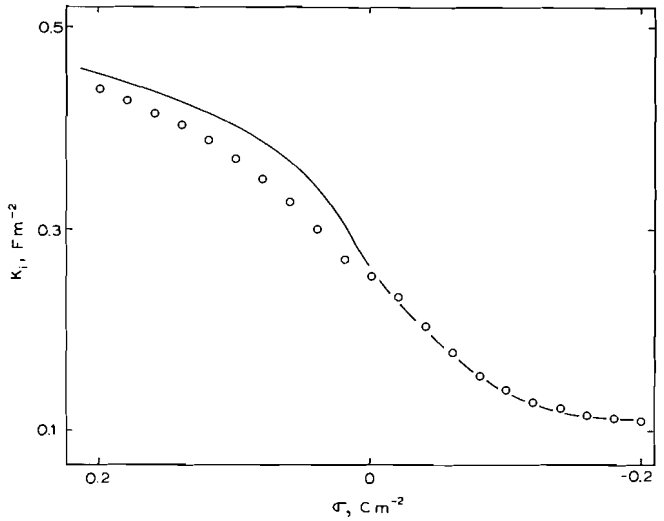

FIG. 8. Plot of the inner layer integral capacity K_i for the Hg/DMF interface with TEAP as electrolyte against electrode charge density at 25°C. The solid curve was calculated from the three state model as described in the text using the parameters given in the caption to Fig. 7.

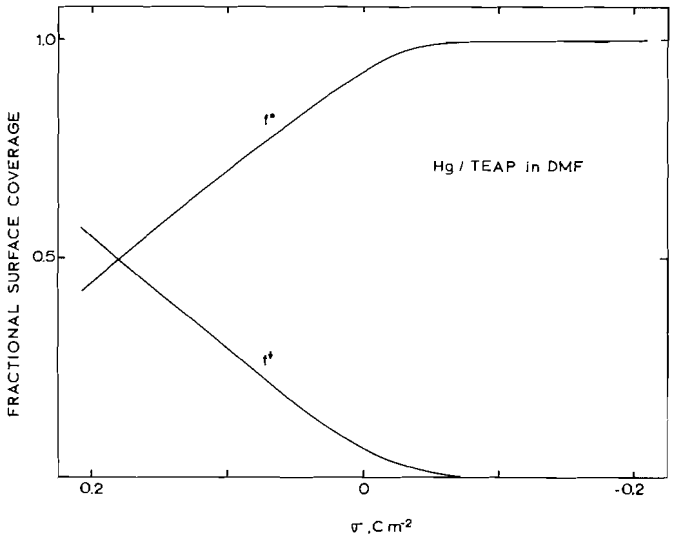

FIG. 9. Plot of the fractions of molecules in the down ($f^\downarrow$) and parallel (f^o) orientations against electrode charge density for a DMF monolayer at Hg. The parameters assumed in estimating these fractions are given in the caption to Fig. 7.

line drawn through the oxygen and nitrogen atoms in the DMF molecule (Fig. 10), the 'parallel' orientation corresponds to a solvent molecule positioned with its methyl groups on the surface. A similar conclusion was reached by Payne on the basis of a comparison of the potential shift of the pzc of aqueous solutions of DMF, *N*-methylformamide, and formamide with change in amide concentration (9). The value of the surface potential (−0.293 V) reflects the small net concentration of negatively oriented dipoles at the pzc. The distortional contribution to the effective inner layer dielectric constant ε_∞ estimated on the basis of the equation (10)

$$[11] \quad 1/\varepsilon_\infty = 1 - 4\pi\alpha N_T/Ad$$

is 3.71. In assessing these results one should keep in mind the fact that the isotropic polarizability has been used in the above calculations. Since the polarizability depends to some extent on molecular orientation (31) and electrode field (32), the effective polarizability is expected to vary somewhat with electrode charge density.

It is interesting to examine the predictions of the three state model regarding the temperature depen-

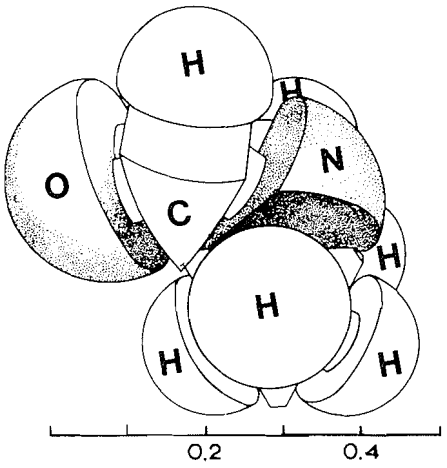

FIG. 10. Sketch of a dimethylformamide molecule on the basis of its Courtauld model. The scale defines the position of the surface in a 'parallel' orientation corresponding to the dipole vector parallel to the surface.

dence of $\Delta\phi$ and C_i. On the basis of eqs. [5] and [6],

$$[12]\quad \left(\frac{\partial\Delta\phi}{\partial\beta}\right)_\sigma = \frac{4\pi N_T d^3}{c_c}\left(\frac{\partial X}{\partial\beta}\right)_\sigma = \frac{4\pi N_T p}{A}\left(\frac{\partial r}{\partial\beta}\right)_\sigma$$

where $\beta = 1/kT$, and

$$[13]\quad \frac{\partial(1/C_i)}{\partial\beta} = \frac{4\pi N_T p}{A}\left(\frac{\partial^2 r}{\partial\beta\partial\sigma}\right)$$

From eqs. [2]–[4], it may be shown (10) that

$$[14]\quad r = (1 - a_1 e^{2y})/R$$

where $R = 1 + a_1 e^{2y} + a_2 e^{y}$, $a_1 = \exp[\beta(U_r^{\uparrow} - U_r^{\downarrow})]$, $a_2 = \exp[\beta(U_r^{\uparrow} - U_r^{0})]$, and $y = p\beta(E + X)$. Differentiating eq. [14] with respect to β at constant σ, one obtains

$$[15]\quad \left(\frac{\partial r}{\partial\beta}\right)_\sigma = \frac{-a_1 e^{2y}\Delta U_1}{R} - \frac{2a_1 e^{2y}}{R} \times \left[p(E + X) + \frac{c_c p^2\beta}{Ad^3}\left(\frac{\partial r}{\partial\beta}\right)_\sigma\right] - \frac{(1 - a_1 e^{2y})}{R^2}\left\{a_1 e^{2y}\Delta U_1 + a_2 e^{y}\Delta U_2 + (2a_1 e^{2y} + a_2 e^{y}) \times \left[p(E + X) + \frac{c_c p^2\beta}{Ad^3}\left(\frac{\partial r}{\partial\beta}\right)_\sigma\right]\right\}$$

where $\Delta U_1 = U_r^{\uparrow} - U_r^{\downarrow}$ and $\Delta U_2 = U_r^{\uparrow} - U_r^{0}$. Rearranging and setting $f^{\uparrow} = N^{\uparrow}/N_T = 1/R$, $f^{\downarrow} = N^{\downarrow}/N_T = a_1 e^{2y}/R$ and $f^{0} = N^{0}/N_T = a_2 e^{y}/R$, it is easily shown that

$$[16]\quad \left[\frac{1 + 2c_c p^2\beta f^{\downarrow}}{Ad^3} + r(2f^{\downarrow} + f^{0})\frac{c_c p^2}{Ad^3}\right]\left(\frac{\partial r}{\partial\beta}\right)_\sigma = -f^{\downarrow}\Delta U_1 - 2f^{\downarrow}p(E + X) - r[f^{\downarrow}\Delta U_1 + f^{0}\Delta U_2 + (2f^{\downarrow} + f^{0})p(E + X)]$$

At the minimum, $f^{\uparrow} = f^{\downarrow}$, $r = 0$, and therefore, on the basis of eq. [3], $\Delta U_1 = -2p(E + X)$. From eq. [16], it is apparent that $\partial r/\partial\beta = 0$ and thus $\partial(\Delta\phi)/\partial\beta = 0$ at the minimum. Similarly, for the present system, $f^{\downarrow} = f^{0} = 0.5$ at the maximum, and from eq. [4], $U_r^{0} - U_r^{\downarrow} = \Delta U_1 - \Delta U_2 = -p(E + X)$; on substituting these values into eq. [16], it is found that $\partial r/\partial\beta$ and $\partial(\Delta\phi)/\partial\beta$ are zero at the maximum. Thus, according to the three state model, the potential difference $(\Delta\phi)_m - (\Delta\phi)_r = (\phi^{md})_m - (\phi^{md})_r$ is independent of temperature where $(\Delta\phi)_m$ and $(\phi^{md})_m$ are the potential drops across the dipole layer according to the model, and as estimated from experiment on the basis of the rational potential, respectively, at the minimum, and $(\Delta\phi)_r$ and $(\phi^{md})_r$, the corresponding values at the maximum. From the experiments, $(\phi^{md})_m - (\phi^{md})_r = -1.923 \pm 0.006$ V, in the temperature range -15 to 40°C, that is, it is independent of temperature within experimental error. The above results suggest an effective way of defining an absolute potential scale for unassociated solvents at a polarizable electrode. If the principle extremum on the capacity curve observed with an electrolyte whose ions are not adsorbed occurs at the same charge density independent of temperature, one may assume that the absolute potential drop across the inner layer is also temperature independent and on this basis defines an absolute potential scale according to which the variation in surface potential with temperature is automatically accounted for.

On differentiating eq. [16] with respect to σ, one may derive an expression for the temperature dependence of the inner layer capacity C_i (eq. [13]). It can then be shown that the inner layer capacity does depend on temperature at the two extrema, although the temperature coefficient at the minimum is negligible in the present case. Comparison of calculated and experimental values of dC_i/dT (Fig. 11) reveals that the model gives the correct sign of the temperature dependence of the capacity at the maximum, but the coefficient calculated on the basis of the parameters given above is approximately twice that observed experimentally. In addition, the positive values of dC_i/dT observed for values of σ in the range $0.02 < \sigma < 0.14$ C m^{-2} are not predicted by the model. However, considering the fact that the variation in C_i with temperature is not large with

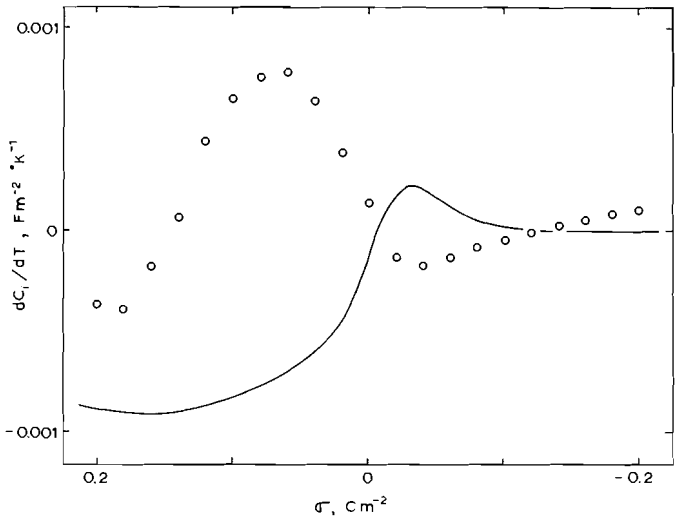

FIG. 11. The temperature derivative of the inner layer differential capacity dC_i/dT plotted against electrode charge density for data obtained at the Hg/DMF interface with TEAP as electrolyte in the temperature range −15 to 40°C. The solid curve was calculated from the three state model on the basis of the parameters given in the caption to Fig. 7.

respect to experimental error, one should not place great emphasis on the quantitative aspects of the above comparison. The present results may be compared with those obtained for the Hg/methanol interface where a small temperature coefficient was also observed (2).

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received March 15, 1979

JOHN E. DRAKE, BORIS M. GLAVINĆEVSKI, and KRYSTYNA GORZELSKA. Can. J. Chem. **57**, 2278 (1979).

He(I) and He(II) pe spectra of the series Me_2GeX_2 (X = H, F, Cl) are reported. Assignments are based on comparisons with the spectra of related Me_3GeX and $MeGeX_3$ series as well as semi-empirical CNDO/2 calculations.

JOHN E. DRAKE, BORIS M. GLAVINĆEVSKI et KRYSTYNA GORZELSKA. Can. J. Chem. **57**, 2278 (1979).

On rapporte les spectres pe de He(I) et He(II) dans une série de Me_2GeX_2 (X = H, F, Cl). On base les attributions sur des comparaisons avec des spectres de séries apparentées Me_3GeX et $MeGeX_3$ ainsi que sur des calculs semi-empiriques CNDO/2.

[Traduit par le journal]

Introduction

We recently reported (1, 2) the uv photoelectron spectra of the series of compounds Me_3GeX and $MeGeX_3$, where X = H, F, and Cl. This supplemented several earlier reports of the spectra of the germanium halides, germane, methylgermane, tetramethylgermane (3–9), and most recently, chlorotrimethylgermane (10). We complete the series by reporting the He(I) and He(II) spectra of the dimethylgermane derivatives, Me_2GeH_2, Me_2GeF_2, and Me_2GeCl_2. The spectra are relatively complicated because in C_{2v} local symmetry there are no degenerate orbitals. Thus, in addition to CNDO/2 calculations as an aid to assignment, particular use is made of correlation diagrams with the assignments for the $MeGeX_3$ and Me_3GeX series (1, 2).

Experimental

The spectra were recorded on a McPherson ESCA-36 photoelectron spectrometer, using both He(II) and He(I) excitation. The peaks were calibrated against the argon lines at 15.76 and 15.94 eV.

The CNDO/2 calculations utilized the program GEOM-FORTRAN IV (i.e. GEOMO, QCPE 290 (written in Fortran)) developed by Rinaldi (11). A non-standard basis, not including *d*-orbitals, was used for germanium and chlorine. The parameters that differ from those provided in the manual are the core integrals Cl(*s*)(19.235), Cl(*p*)(9.38) and Ge(*s*)(12.715), Ge(*p*)(6.845) (12) and the Slater exponents Cl(*s*)(2.3561) and Cl(*p*)(2.0387) (13). The coordinates of the atoms were calculated using bond lengths previously reported in the literature (14–17). All tetrahedral angles were assumed.

As in our earlier studies (1, 2), trial runs which included exact angles gave only small changes to eigenvalues and eigenvectors. This was also true of runs that utilized the optimisation routine so that this was also not used, resulting in considerable savings in computer time.

Materials

Dimethylgermane and difluorodimethylgermane were prepared by well-established methods (18, 19). Dichlorodimethylgermane was supplied by Laramie Chem. Co., WY. The samples were purified by vacuum fractionation and their purity was confirmed by ^1H nmr and vibrational spectroscopy (19–21).

Results and Discussion

The experimental vertical ionisation energies and the values of the orbitals calculated by the CNDO/2 method are recorded in Table 1, along with the designated symmetry and principal contributions to the molecular orbitals.

A comparison of the spectrum of Me_2GeH_2 (Fig. 1) with those of Me_3GeH (1) and $MeGeH_3$ (2) indicates similar features which, along with the CNDO/2 calculations, allows for a reasonable assignment. The calculations place the $3b_2$, $3b_1$, and $4a_1$ orbitals close together and three peaks can be clearly seen in the feature centred at 11.09 eV. In $MeGeH_3$, the $3a_1$ orbital (mainly Ge(*p*)—C(*p*)) was assigned to the lower energy peak because it was clearly sharper and less intense than the 2*e* (mainly Ge(*p*)—H(*s*)). Similarly, in Me_3GeH the broader, more intense band was assigned to 4*e* (now mainly Ge—C) which was the less stable orbital. Thus, in contrast to the CNDO predictions, the orbitals mainly involving Ge—H bonding are slightly more stable than those involving Ge—C bonding. The order of the orbitals in Me_2GeH_2 is assigned on the same basis in terms of the AO participation and the correlation diagram (Fig. 2) as $3b_1 < 4a_1 < 3b_2$. This order is identical to that proposed for Me_2SiH_2 (22). The transformation of the 2*e* orbital is from one that has predominantly H—Ge but some Ge—C character in $MeGeH_3$, to one of predominantly Ge—C character in Me_3GeH via the $3b_2$ and $3b_1$ orbitals. The former can be described as a Ge—H

bonding orbital while the latter is best described as a Ge—C bonding orbital. In general, the energy of the Ge(p)—C bonding orbitals remains essentially constant in all three molecules which is consistent with the very similar Ge—C bond lengths that have been reported (14, 15). Also, there is an indication that the Ge—H bonding is not changing significantly along the series trihydride to monohydride which correlates with reported bond lengths of Ge—H in $MeGeH_3$ (1.529 Å) (15) and Me_3GeH (1.532 Å) (14). The predominantly CH_3-group bonding orbitals around 14 eV are relatively broad features in Me_2GeH_2 as was also observed for $MeGeH_3$ and Me_3GeH. There are, however, four fairly sharp peaks within the envelope which are assigned to the $1a_2$, $2b_1$, $3a_1$ and $2b_2$ orbitals in accord with the CNDO/2 predictions. The correlation diagram (Fig. 2) illustrates the similar energies in all three hydrides of these orbitals involving the methyl groups. Finally, the $2a_1$ orbital has the characteristic feature noted for the presence of the s-orbital of germanium (1, 2, 23), namely, the marked increase in its peak height in the He(II) spectrum relative to a virtually insignificant peak in the He(I) spectrum. Thus, its assignment at 17.0 eV is confirmed.

The He(I) and He(II) spectra of Me_2GeF_2 (Fig. 1) are assigned as shown in Table 1. The number of orbitals in Me_2GeF_2 increases as compared with Me_2GeH_2 because of the presence of the p orbitals of fluorine that are available for bonding. The $4b_1$ and $4b_2$ orbitals of Me_2GeF_2 are the central orbitals in the transition of the $5e$ orbital in $MeGeF_3$, which mainly involves fluorine and germanium orbitals, into the $5e$ orbital of Me_3GeF, where it essentially involves Ge—C bonding (Fig. 3). The $4b_1$ can be described as a Ge—C orbital and the $4b_2$ as a lone-pair orbital. This could account for the considerable splitting in their energies in contrast with the hydrides. The three remaining fluorine "lone-pair orbitals", the "methyl bonding orbitals", and the "Ge(p)—F(p) bonding orbitals", all fall relatively close together to form a large envelope, and the orbitals, with the exception of $2a_2$, have considerably mixed character. The lone-pair orbitals, $3b_2$ and $5a_1$, which include contributions from CH_3 bonding orbitals, are around the 14 eV region (Table 1). In the trifluoride, the corresponding orbitals are distinctly more stabilized while in the monofluoride, those that transform mainly as the lone-pairs are slightly destabilized. The $1a_2$ orbital in Me_2GeF_2, as well as the orbitals with which it is correlated in the series $MeGeF_3$, Me_2GeF_2, and Me_3GeF, are all found in the range of 15.5–14.2 eV. The gradual destabilization across the series correlated well with

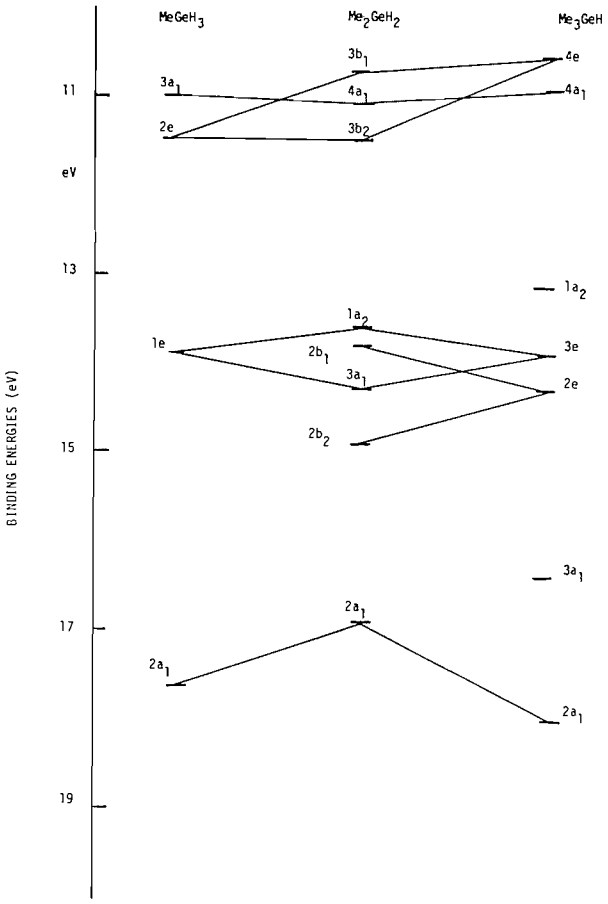

FIG. 2. Correlation of the binding energies across the series $MeGeH_3$, Me_2GeH_2, and Me_3GeH.

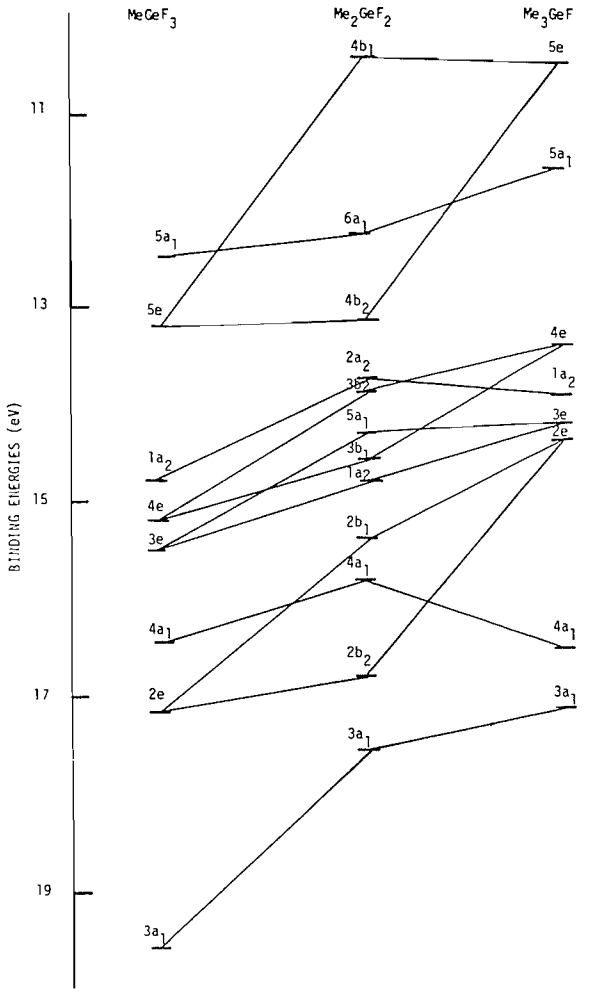

FIG. 3. Correlation of the binding energies across the series $MeGeF_3$, Me_2GeF_2, and Me_3GeF.

the successive substitution of methyl groups for fluorine. Thus, the predominantly fluorine lone-pair $3e$ orbital in $MeGeF_3$ at 15.5 eV, splits into the $5a_1$ (14.56 eV) and $1a_2$ (14.80) eV orbitals in Me_2GeF_2, both of which have increased CH_3 character. Further destabilization occurs when the $1a_2$ and $5a_1$ orbitals are correlated to the predominantly $CH_3(3e)$ orbital in Me_3GeF (14.2 eV). As in the case of the $4b_1$ and $4b_2$ orbitals, there is considerable splitting in energy between the $2b_1$ and $2b_2$ orbitals. The $4a_1$ orbital which according to the CNDO/2 calculations is the most stable of those involving mainly methyl groups, is assigned to the 13–15 eV region. The correlation diagram (Fig. 3) suggests that the assignment of the $4a_1$ orbital, which caused us some difficulties in Me_3GeF, should be in the region of 14.9–16.5 eV, rather than at 17.5, as we tentatively suggested in our earlier paper (1). The $3a_1$ orbital is assigned on the basis of the marked increase in its relative intensity in the He(II) spectrum which is expected from the CNDO/2 predictions of considerable contributions from the *s*-orbital of germanium. It is less stable than the most stable orbital assigned in $MeGeF_3$, but slightly stabilized relative to the corresponding orbital in Me_3GeF. There is a correlation between destabilization and increase in Ge—F bond length across the series ($MeGeF_3$, 1.714 Å; Me_2GeF_2, 1.739 Å; and Me_3GeF, 1.742 Å) (16).

The He(I) and He(II) spectra of Me_2GeCl_2 (Fig. 1) are assigned as indicated in Table 1. As in the fluorides there is a steady destabilization in the highest a_1 orbital along the $MeGeCl_3$, Me_2GeCl_2, and Me_3GeCl series (Fig. 4). The CNDO/2 calculations predict that there should be less energy difference between the $4b_1$ and $4b_2$ orbitals in Me_2GeCl_2 compared with Me_2GeF_2 and this is indeed the case. As with the fluoride, the b_2 orbital is closer in energy to the $5e$ orbital in $MeGeCl_3$ and the b_1 orbital is closer in energy to the $3e$ orbital in Me_3GeCl. There

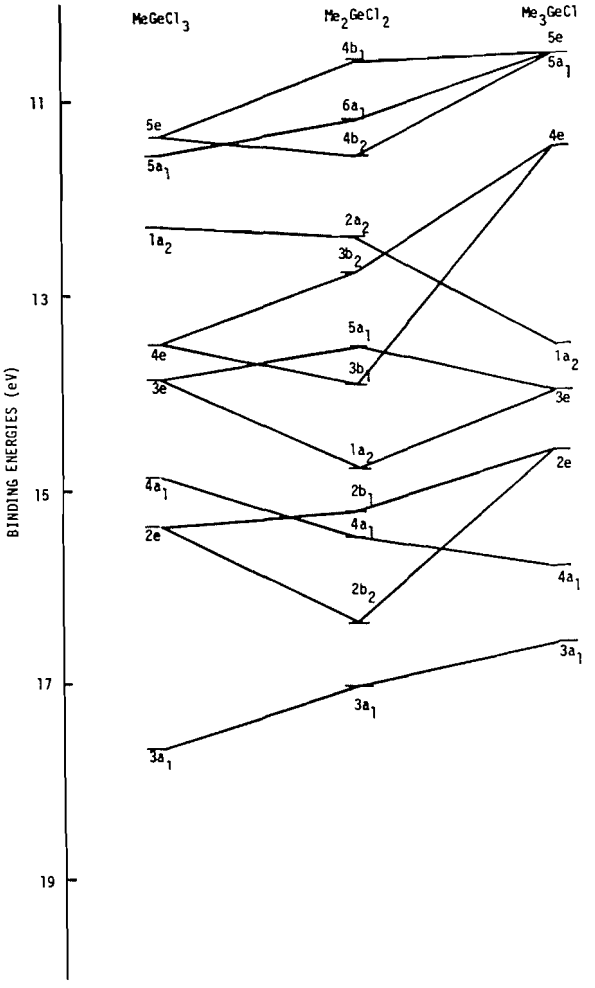

FIG. 4. Correlation of the binding energies across the series $MeGeCl_3$, Me_2GeCl_2, and Me_3GeCl.

is little change in the energy of the a_2 orbitals between $MeGeCl_3$ and Me_2GeCl_2 as both represent a lone-pair of chlorine (12.30 eV and 12.40 eV respectively). However, in Me_3GeCl the orbital is more stabilized as it now consists mainly of methyl group bonding (13.90 eV). The principal lone-pair chlorine orbitals, $2a_2$, $3b_2$, and $5a_1$ in Me_2GeCl_2 are clearly less energetically stable than those in the fluorides. The $2b_1$ and $2b_2$ orbitals show a noticeable degree of splitting. The latter orbital is apparently considerably stabilized because of contributions from the *s*-orbital of chlorine. This increasing participation of the *s*-orbitals also accounts for the fact that across the chloride series for the $4a_1$–$4a_1$–$4a_1$ sequence there is stabilization. The trend in the most stable valence orbitals involving the *s*-orbitals of germanium reverts to the sequence which shows increasing destabilization as chlorine is substituted by methyl groups. This essentially linear decrease in the energy of related orbitals was also noted for the series $MeSiCl_3$–Me_2SiCl_2–Me_3SiCl and also interpreted as indicating that the inductive effects of the Me and Cl groups predominate and that *d*-orbital participation need not be invoked (24). The lack of important involvement by *d*-orbitals was also indicated in work on silicon hydride derivatives (22, 25).

The first IP remains remarkably constant for all three molecules, Me_2GeX_2, X = H, F, Cl, suggesting that the Ge—C bonding characteristic predominates in all three cases despite the contributions from the F and Cl *p*-orbitals. The overlap integral matrices suggest that these *p*-orbitals of F and Cl are slightly anti-bonding and this factor apparently just overrides the general inductive stabilizing effect that might have been expected along the series Me_2Ge–(H_2)–(Cl_2)–(F_2). It is also interesting to note that the first IP in Me_2SiH_2 (11.2 eV) (22) is close to that in Me_2SiCl_2 (10.99 eV) (24) and both values are only slightly greater than those in the germanium analogues. Thus a change in the central atom from germanium to silicon causes only slight changes in the general features of the photoelectron spectra.

The plot of $-$CNDO/2 vs. experimental ionisation energies gives a slope of -1.40 and an intercept of 0.31 which compare very favourably with values reported for similar series (26) and for those we previously reported for Me_3GeX (1) and $MeGeX_3$ (2). In none of the calculations did we consider *d*-orbital participation by germanium. As with our earlier studies, we noted ill-defined features in the region above 20 eV which could correspond to the 2*s*-orbitals of carbon. In the spectra of Me_2GeCl_2 there were further peaks that probably indicate the 3*s*-orbitals of chlorine.

Crystals of $[Re(CO)_3(P(Me_2pz)_2C_6H_5)Br]$ (where Me_2pz is 3,5-dimethylpyrazolyl) are monoclinic, space group $P2_1/c$, with $a = 8.964(4)$, $b = 14.441(10)$, $c = 18.156(8)$ Å, $\beta = 111.32(4)°$, and $Z = 4$. Crystals of $W(CO)_3(P(Me_2pz)_2(C_6H_5))$ are monoclinic, space group $P2_1/c$, with $a = 12.479(7)$, $b = 10.207(4)$, $c = 16.118(7)$ Å, $\beta = 98.77(2)°$, and $Z = 4$. In both structures there is irregular octahedral geometry about the metal atom with the carbonyl groups in a *fac* arrangement. The phenylbis(3,5-dimethylpyrazolyl)phosphine ligand, $[P(Me_2pz)_2(C_6H_5)]$, is coordinated to the tungsten atom through the two 2N nitrogen atoms of the pyrazolyl rings and to two carbon atoms of the phenyl ring so that the ligand is essentially tridentate. In the rhenium complex this ligand is bidentate with coordination via the 2N nitrogen atoms with a bromine atom occupying the sixth site.

R. E. COBBLEDICK, L. R. J. DOWDELL, F. W. B. EINSTEIN, J. K. HOYANO et L. K. PETERSON. Can. J. Chem. **57**, 2285 (1979).

Les cristaux de $[Re(CO)_3(P(Me_2pz)_2C_6H_5)Br]$ (où Me_2pz = diméthyl-3,5 pyrazolyle) sont monocliniques, groupe d'espace $P2_1/c$ avec $a = 8.964(4)$, $b = 14.441(10)$, $c = 18.156(8)$ Å, $\beta = 111.32(4)°$ et $Z = 4$. Les cristaux de $W(CO)_3(P(Me_2pz)_2(C_6H_5))$ sont monocliniques, groupe d'espace $P2_1/c$ avec $a = 12.479(7)$, $b = 10.207(4)$, $c = 16.118(7)$ Å, $\beta = 98.77(2)°$ et $Z = 4$. Dans les deux structures, la géométrie autour de l'atome de métal est octaédrique régulière et les groupes carbonyles sont dans un arrangement *fac*. Le ligand phénylbis(diméthyl-3,5 pyrazolyl)phosphine, $[P(Me_2pz)_2C_6H_5]$ est coordonné à l'atome de tungstène par les deux atomes d'azotes 2N des noyaux pyrazolyles et à deux atomes de carbone des noyaux phényles d'une façon telle que le ligand est essentiellement tridentate. Dans le complexe de rhénium, ce ligand est bidentate avec une coordination par l'intermédiaire des atomes d'azotes 2N avec un atome de brome occupant le sixième site.

[Traduit par le journal]

Introduction

The syntheses of a number of complexes of the set of ligands $\phi_x(R_2pz)_{3-x}$ ($x = 0$–2; R_2pz = pyrazolyl or 3,5-dimethylpyrazolyl, ϕ = phenyl) have been reported, together with structural assignments based on mass, infrared, ^1H, and ^{31}P nmr spectroscopic data (1). The modes of coordination of the pyrazolylphosphines are illustrated in structures **1**–**12**. The four-membered PNNM metallocycle in **1** was confirmed by an X-ray diffraction study (2). The PNNM metallocycles in the Mo(0) and W(0) derivatives (**3** and **4**) are more susceptible to ring opening reactions than in the Mn(I) and Re(I) analogues (**1** and **2**). Thus, the phosphorus bonded derivatives $[(\phi_2P(R_2pz))_2M(CO)_4]$ (M = Mo, W) are readily obtained, contrasting with the failure to obtain corresponding bis-phosphine analogues of Mn(I) and Re(I). In the remaining complexes **5**–**7**, the phosphorus atom does not appear to coordinate to the

metal centre; reduced basicity of the phosphorus atom has been attributed to the electron-withdrawing effects of the attached pyrazolyl rings. The *facial* structures **5** and **6** seem to be preferred over *meridial* structures containing *trans* CO groups. Compounds **7** and **8** give rise to tricarbonyl species $[\phi P(R_2pz)_2M(CO)_3]$, obtainable in two isomeric forms (red and yellow). These isomers give identical mass spectra, but show distinct infrared, ^1H, and ^{31}P nmr spectra. This work describes the structure determination of the red form of $[\phi P(Me_2pz)_2W(CO)_3]$ and of compound **6**. The X-ray diffraction study of $[\phi P(Me_2pz)_2W(CO)_3]$ (red) shows that a portion of the phenyl ring occupies one of the coordination sites of the six coordinate tungsten centre in a rather unusual fashion.

Tris-chelate structures analogous to **9–12** have been postulated for various pyrazolylborate complexes, including $[RB(R_2pz)_3Mn(CO)_3]$, $[B(R_2pz)_4Mn(CO)_3]$, and $[HB(Me_2pz)_3M(CO)_3]^-$ (M = Mo, W) (3). Based on ir data (ν_{CO} region), the ligands $P(Me_2pz)_3$ and $HB(Me_2pz)_3$ coordinate in essentially the same way to Mo(0) and W(0) in comparable tricarbonyl complexes. While the given tris-chelate structures for **9** and **10** are consistent with nmr and ir data, an alternative bis-chelate structure, containing covalently bound halogen and rapidly exchanging pyrazolyl groups, cannot as yet be ruled out.

The structural studies reported here were undertaken in order to corroborate proposed structures, and to help clarify the uncertainties described above.

Experimental

Structure Determination of $[Re(CO)_3(P(Me_2pz)_2C_6H_5)Br]$

A colourless crystal in the form of a rectangular prism of approximate dimensions 0.09 × 0.25 × 0.33 mm was used in the X-ray analysis. The space group was determined from the absent reflections on photographs taken with Cu Kα radiation. Unit cell parameters were obtained by least-squares refinement from the setting angles of 12 reflections centred on a Picker FACS-I automatic diffractometer using Mo Kα radiation.

Crystal data are shown below:

$C_{19}H_{19}N_4O_3PBrRe$ fw = 648.50
Monoclinic, $a = 8.964(4)$, $b = 14.441(10)$, $c = 18.156(8)$ Å, $\beta = 111.32(4)°$, $V = 2189.4$ Å^3, $Z = 4$, $\rho_c = 1.967$, $\rho_m = 1.94$ g cm^{-3} (by flotation), μ(Mo Kα) = 79.1 cm^{-1}, $T = 22°C$. Absent reflections: $h0l$, $l = 2n + 1$ and $0k0$, $k = 2n + 1$ uniquely define the space group $P2_1/c$.

Details concerning the collection of intensity data are shown in Table 1. Lorentz and polarization corrections were applied to the intensities but no absorption correction was made. The extreme error in F resulting from this is estimated to be ±18%.

The rhenium atom position was determined from a Patterson map and the remaining non-hydrogen atom positions were obtained from subsequent Fourier and electron density difference maps. Full-matrix least-squares refinement using anisotropic thermal parameters for the rhenium, bromine, and phosphorus atoms and isotropic ones for the remaining atoms gave a factor $R = 0.085$ (where $R = \sum ||F_o| - |F_c|| / \sum |F_o|$). An electron density difference map indicated regions of excess (1.4–2.2 e Å^{-3}) and deficient electron density ($\simeq -3.3$ e Å^{-3}) in the neighbourhood of the rhenium atom compared with $\simeq 6$ e Å^{-3} for a typical carbon atom. The map did not reveal the positions of the hydrogen atoms and these were omitted from the structure. There was no evidence of anisotropic motion of the lighter atoms and consequently the refinement was terminated at this stage. Unit weights were used through-

out. Anomalous dispersion corrections were applied to the rhenium, bromine, and phosphorus atoms. Atomic scattering factors for rhenium were taken from ref. 4 and those of ref. 5 were used for the rest of the atoms. Crystallographic computer programs used in the analysis have been cited elsewhere (6).

Final positional parameters for both compounds are listed in Table 2 and the thermal parameters in Table 3. A listing of calculated structure factors and observed structure amplitudes has been deposited in the Depository of Unpublished Data.[2]

Structure Determination of $[W(CO)_3(P(Me_2pz)_2C_6H_5)]$

Unless otherwise stated in the text or Table 1 the experimental details are the same as for the rhenium compound. Crystals of the complex were obtained as red platelets elongated along the *b* axis. A plate-shaped crystal of dimensions 0.20 × 0.45 × 0.15 mm was used for the data collection. The crystal was mounted with the *b* axis offset from the ϕ axis of the diffractometer. No correction for absorption was applied to the data and, in extreme cases, the error in *F* could be ±7%.

Crystal data are shown below:

$C_{19}H_{19}N_4O_3PW$ fw = 566.23

Monoclinic, $a = 12.479(7)$, $b = 10.207(4)$, $c = 16.118(7)$ Å, $\beta = 98.77(2)°$, $V = 2029.0$ Å^3, $Z = 4$, $\rho_c = 1.853$, $\rho_m = 1.83$ g cm^{-3} (by flotation), Mo Kα radiation ($\lambda = 0.70926$ Å), μ(Mo Kα) = 61.2 cm^{-1}, $T = 23°$C. Absent reflections: $h0l$, $l = 2n + 1$ and $0k0$, $k = 2n + 1$ uniquely define the space group $P2_1/c$.

The coordinates of the tungsten atom were determined from the Patterson map and those of the remaining non-hydrogen atoms were determined from subsequent Fourier and difference maps. Anisotropic thermal parameters were introduced for those atoms indicating anisotropy on the difference maps. The coordinates of the 19 hydrogen atoms eventually were revealed by a difference map. These hydrogen atoms were included in the structure factor calculations but not allowed

[2]The listing is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

to refine. The final R was 0.067 for the observed reflections. At this stage the only significant peaks (2.2–3.3 e Å^{-3}) were close to the tungsten atom. The maximum parameter shift was 0.15σ. Initially unit weights were used but in the later stages of refinement a weighting scheme was used with weights, $w = 1/\sigma^2(F)$. Anomalous dispersion factors were used for the tungsten atom and these and the atomic scattering factors were taken from ref. 7, except for the hydrogen atoms which were taken from ref. 8.

Results and Discussion

Perspective views of the rhenium and tungsten complex molecules are shown respectively in Figs. 1 and 2. Bond lengths and angles (excepting those involving hydrogen atoms) are listed in Tables 4 and 5. In both structures there is an irregular octahedral configuration around the central metal atom and in each case the three carbonyl groups have a *fac* arrangement. The phenylbis(3,5-dimethylpyrazolyl)-phosphine ligands coordinate via the two 2N nitrogen atoms of the pyrazolyl rings in both structures and the nitrogen atoms are *trans* to carbonyl groups. In the rhenium complex the sixth site is occupied by a bromine atom while in the tungsten complex the site is occupied by two carbon atoms of the phenyl group of the $P(Me_2pz)_2(C_6H_5)$ ligand. Both mole-

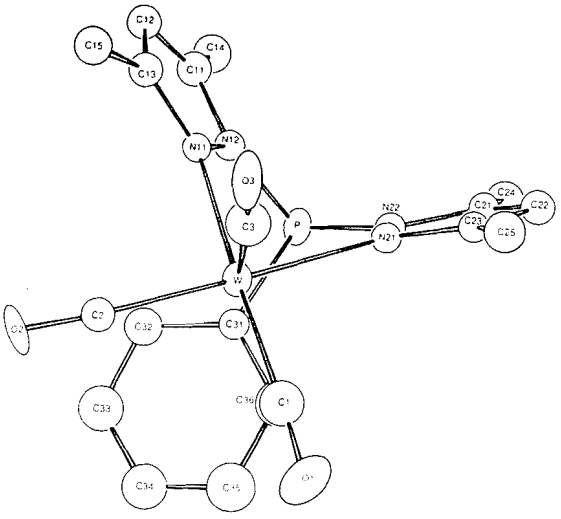

FIG. 2. Perspective view of $[W(CO)_3(P(Me_2pz)_2C_6H_5)]$.

cules have approximate non-crystallographic mirror symmetry about a plane containing atoms P, C3, O3 and the metal. The Re—Br distance is 2.623(7) Å and correction for the bromine riding motion on the metal atom gives 2.639 Å. The distance is intermediate in the range 2.469–2.769 Å reported for Re—Br distances (15). In both compounds there is little deviation from linearity of the carbonyl groups. As a result of the large errors, comparison of bond lengths and angles is of limited value. The carbon atom C3 in the tungsten complex behaved poorly in the least-squares refinement and the W—C3 bond length of 1.67(3) Å appears to be unreasonable. We attribute this to poor positioning of C3 (the C3—O3 distance is consequently long at 1.31(3) Å), despite various attempts to correct this

TABLE 4. Bond lengths (Å). Estimated standard deviations are given in parentheses

by placing it at a reasonable calculated starting position. Taking the W---O distances (2.97–3.10(5) Å) all three CO groups appear to be identical. The Re—N distances are 2.15(4), 2.21(4) Å while the W—N distances are 2.26(2) and 2.27(2) Å. In both structures the metal atom, the four nitrogen atoms, and the phosphorus atom form a six-membered ring with a boat configuration. In the rhenium compound the boat arrangement places the phenyl ring close to the carbonyl group *trans* to the bromine (C3---C31 = 3.04(7) Å). This interaction between the phenyl ring and the carbonyl group appears to displace the boat ring towards the bromine atom; the two N—Re—Br angles are 85(1)° and the two N—Re—C3 angles are 96(2)°. In the tungsten compound the boat ring is displaced in the opposite direction in such a way that C31 and C36 of the phenyl ring occupy the site occupied by the carbonyl group in the rhenium complex. The two N—W—C3 angles of 97(1) and 96(1)° indicate the displacement (cf. the comparable

N—Re—Br angles of 85(1)°). Another way of comparing the tilt of the boat ring is by examining the displacement of the ring atoms from the plane defined by the metal and the two carbonyl groups C2—O2 and C1—O1. Calculations for these and other relevant planes are shown in Table 6.

The W—C31 distance of 2.58(2) Å and the W—C36 distance of 2.82(2) Å, although longer than usual W—C contacts (e.g. 2.246 Å in bis-(η-cyclopentadienyl)bis-(3,5-dimethylbenzyl)tungsten (9)), are sufficiently short to suggest a weak interaction. In this way the tungsten atom could achieve an 18-electron configuration but, since the distances are long, the possibility of a 16-electron system certainly cannot be ruled out. All other W---C contacts with the phenyl ring are greater than 3.20 Å. The shorter contact involves the P-bonded carbon and the weaker interaction occurs with an *ortho* carbon. The assumed hydrogen atom on the *ortho* carbon atom does not point at the tungsten atom so the interaction is not similar to that observed in (diethyldi-1-pyrazolylborato)(trihapto-2-phenylallyl)-(dicarbonyl)molybdenum where the α carbon atom of an ethyl group is directed toward the molybdenum atom (10), giving it an effective 18-electron

configuration. In the analogous (diphenyldipyrazolylborato)(2-methylallyl) (dicarbonyl)molybdenum where it might have been expected that the 18-electron configuration would be achieved by interaction with an *ortho* C—H bond of a phenyl group (11) no such interaction occurs and the metal atom remains with a 16-electron configuration. Cotton proposes that the apparent reason for this is that the attainment of a satisfactory conformation of the four rings about the boron atom (the two pyrazole rings are fixed in coordination to the molybdenum) is inconsistent with the orientation of one of the phenyl groups to give such an interaction.

Two platinum structures in which two adjacent carbon atoms of a substituted benzene ring are bonded to a metal are known (12, 13). The Pt—C distances lie in the range 2.05(2)–2.15(2) Å. In both these structures the C—C bond distances are alternately short and long (i.e. double and single bonds) with the exception of the double bond coordinated to the metal atom which has been appreciably lengthened. In the present structure, the estimated standard deviations are too large to establish the significance of differences in bonds of this type but the distances appear typical. The interaction does not appear to be of this type and is more similar to that occurring in the structure of tris(triphenylphosphine)rhodium(I) perchlorate (14) in which the Rh atom is 2.48(2) Å from the P-bonded carbon atom, 2.62(2) Å from the *ortho* carbon atom, and 2.56 Å from the assumed *ortho* hydrogen atom and in the structure of bis(2-methyl-2-phenylpropyl)-manganese(II) (16) where the Mn—C distances are ca. 2.7 Å with the *ortho* hydrogen atom close to the manganese atom.

An intriguing and unique system has been observed during the otherwise routine study of the cobalt(III) complex of *trans*-1,2-cyclohexanedinitrilotetraacetic acid (CyDTA). Using classical spectrophotometric methods to determine the stoichiometry and the stability of a complex, significant deviations from the predicted 1:1 complex were observed in a system buffered at pH = 4.6. It is postulated that in addition to the usual 1:1 complex, the propensity of the reactants to form complexes and the strong oxidizing conditions used in this investigation result in the formation of a second, higher order complex between Co(III) and CyDTA. When the concentration of CyDTA exceeds that of Co(III), the metal:ligand ratio for this complex is 1:2. A structure is proposed, and approximate stability constants of both complexes are discussed.

RITA K. HESSLEY, SHOBA WAYKOLE et ROBERT L. SUBLETT. Can. J. Chem. 57, 2292 (1979).

On a observé un système unique et curieux au cours d'une étude par ailleurs routinière des complexes du cobalt(III) avec l'acide cyclohexanedinitrilo-1,2 tétraacétique (CyDTA). Faisant appel à des méthodes spectrophotométriques pour déterminer la stoechiométrie et la stabilité du complexe et opérant dans un système tamponné à pH 4.6, on a observé des déviations importantes par rapport au complexe 1:1 prédit. On fait l'hypothèse qu'en plus du complexe 1:1 habituel, la propension des réactifs à former des complexes et les conditions très oxydantes utilisées au cours de cette étude conduisent à la formation d'un second complexe d'un ordre plus élevé entre le Co(III) et le CyDTA. Lorsque la concentration du CyDTA est supérieure à celle du Co(III), le rapport métal/ligand pour ce complexe est de 1:2. On propose une structure et on discute des constantes de stabilité approximative des deux complexes.
