2-Methoxyphenol, from Aldrich Chemical Co., was prepared as 5 mol% solutions in CCl_4 and in benzene-d_6. 2-Methoxythiophenol, from Tridom Chemical Inc., was made up as a 4.6 mol% solution in CCl_4. Degassed samples containing internal tetramethylsilane (TMS) as a reference material, were sealed under vacuum into 5-mm od nmr tubes. Intermolecular proton exchange was retarded as previously described (12).

The ^{1}H nmr spectra were recorded at a probe temperature of 305 K on an HA100 spectrometer. The spectra were repeatedly calibrated in the frequency sweep mode by placing markers at ca 5 Hz intervals. Interpolation between markers yielded peak positions whose rms deviations were typically less than 0.02 Hz. The spectral dispersion amounted to 1 Hz/cm and the spectra were swept at 0.02 and/or 0.01 Hz/s.

Results and Discussion

1. Spectral Analyses

The spectra were analyzed by means of the computer program LAME (15, 16). The spectral parameters appear in Table 1. The chemical shift between H-3 and H-4 in the CCl_4 solution of 2-methoxyphenol was only 2.0 Hz. In consequence, the analysis was not as precise as desired, even under conditions in which the methyl protons were decoupled from H-3. The benzene-d_6 solution yielded a more highly dispersed spectrum and proved amenable to a precise analysis (Table 1).

The spectral quality was similar to that recently portrayed for 2-methylphenol (14). The standard deviations in the spectral parameters in Table 1 should probably be multiplied by a factor of 3 to yield a measure of accuracy.

2. Intramolecular Equilibrium in 2-Methoxyphenol

In the following discussion it is assumed that $^5J_m^{XH,H_3} \equiv {}^5J_c$ in **1** and $^5J_m^{XH,H_5} \equiv {}^5J_c$ in **2**, vanish; i.e., that an observable $^5J_m^{H,XH}$ arises only from contributions over the all-*trans* path in **1** and **2**. Furthermore, it is assumed that ^5J_t in **1** and **2** are equal. These assumptions have led to self-consistent equilibrium measurements in a large variety of phenol derivatives (9–14) and to agreement with reliable data from other methods (17, 18). That ^5J_c is not observable under the conditions in this laboratory is known for a number of phenol derivatives (10–12).

In the benzene-d_6 solution (Table 1) $^5J_m^{OH,H_5}$ is 0.42 ± 0.01 Hz and $^5J_m^{OH,H_3}$ is −0.01 ± 0.01 Hz (not significantly different from zero). It follows that only the intramolecularly hydrogen bonded *cis* conformer, **1**, is detectably populated at 305 K under these conditions. If ΔG^0 is 2.00 kcal/mol, then the *trans* conformer would be populated to the extent of 3.5%. Hence, a $^5J_m^{OH,H_3}$ of 0.015 Hz (0.42 × 0.035) should be observed in principle. However, the spectral quality is not high enough to allow such an observation. Therefore, the present result is consistent with the far infrared conclusions above.

A substantial barrier to out-of-plane rotation of the hydroxyl group follows from the unobservably small coupling over six bonds, $^6J_p^{OH,H_4}$, between the hydroxyl proton and the *para* ring proton. Appreciable out-of-plane populations of the hydroxyl rotor, allowed by a V_2 of less than about 4 kcal/mol at 305 K, would lead to a detectable σ–π coupling (12).

Turning to the CCl_4 solution, it is plain that, because of tight coupling, the errors in the spectral parameters are much larger than in the benzene-d_6 solution. Within experimental error (three times the standard deviations), the $^5J_m^{OH,H}$ values are consistent with the conformational deductions based on the data for the benzene-d_6 solution.

The relative chemical shifts in the two solutions are of interest. In general, the magnetic anisotropy of benzene molecules causes marked shifts to high field of solute proton resonances, relative to those in CCl_4 solution. However, only the CH_3 and H-3 resonances in 2-methoxyphenol display a marked upfield shift

[a]The chemical shifts, ν, are given in Hz at 100 MHz to low field of internal tetramethylsilane at 305 K.
[b]Standard deviations in the last one or two significant figures are given in parentheses.

(Table 1). This observation can be rationalized as a preferential packing of the polarizable benzene solvent molecules about electron deficient sites in the solute molecule (19, 20). If the hydroxyl proton lies near the electron rich oxygen atom of the methoxyl group, as in conformer **1**, its *low-field* shift in benzene solution can be understood. When appreciable amounts of *trans* conformers, **2**, are present, the hydroxyl and H-6 protons display large upfield shifts (up to 1 ppm) in benzene solution (13).

The conformation of the methoxy group in 2-methoxyphenol is no doubt as indicated in **1** or **2**, as corroborated by the through-space coupling of −0.3 Hz between the CH_3 and H-3 protons (21, 22).

In summary, the ^1H nmr spectral parameters for 2-methoxyphenol are consistent with a conformation, **1**, whose energy relative to **2** has been calculated from the hydroxyl torsional modes.

3. Conformational Properties of 2-Methoxythiophenol

$^5J_m^{SH,H_3}$ is larger than $^5J_m^{SH,H_5}$. The *trans* conformer, **2**, is more stable (57% abundant) than the *cis* conformer, **1**, by a free energy difference of 180 ± 120 cal/mol. The quoted error assumes an accuracy in ^5J determined by three times the standard deviation. For reasons to be given in Section 4, we prefer to write $\Delta G^0 = 0.2 \pm 0.2$ kcal/mol. This result agrees with one set of dipole moment measurements (8), whose interpretation assumes the conformers **1** and **2** (including the specified orientation of the methoxy group). The *cis* conformer in 2-methoxythiophenol is relatively more stable than in 2-nitrothiophenol (9), very likely a consequence of less favourable steric interactions in the latter compound (7).

In contrast to the analogous coupling in phenol (12) and a variety of its derivatives (10–14), the six-bond coupling, $^6J_p^{SH,H}$, in thiophenol (23) and in 2-methoxythiophenol has a finite magnitude. If, as expected from a σ–π coupling mechanism, ^6J_p has a $\sin^2\theta$ dependence (θ being the angle by which the OH or SH bonds twist out of the aromatic plane), these coupling magnitudes are consistent with the known twofold barriers to internal rotation in phenol and thiophenol. Thus, the far infrared gas phase torsions for phenol imply a V_2 of 3.6 kcal/mol (*1*). This means that at 305 K the out-of-plane populations in phenol are small and, in terms of a hindered rotor model (23), $^6J_p^{H,OH}$ should be very small in magnitude. Again, torsion data on gaseous thiophenol yield a V_2 of 0.76 kcal/mol (24). In CCl_4 solution, $^6J_p^{SH,H}$ in thiophenol is −0.33 Hz (23) and was used to derive a V_2 of 1.1 ± 0.3 kcal/mol (23). This value of V_2 depended on an assumed value for $^6J_p^{SH,H}$ ($\theta = 90°$) of −1.06 Hz. If this number is changed to −0.97 Hz, V_2 becomes 0.76 kcal/mol. Of course, a small solvent effect on the barrier is a definite possibility.

The ^1H nmr data (25) on a series of *para* substituted thiophenol derivatives strongly suggested that π electron donors cause a decrease in V_2 and that π

phenol, so t

electron acceptors entailed an increase in V_2. For example, V_2 in 4-nitrothiophenol in solution was over 2 kcal/mol and was near zero in 4-methoxythiophenol. This trend was reasonably explained by a change in conjugation of the SH group with the aromatic nucleus. Such substituent induced changes in V_2 are supported by STO-3G MO calculations (25) and are also found in analogous phenol derivatives (26).

In 2-nitrothiophenol, ${}^6J_p^{SH,H}$ is -0.03 ± 0.02 Hz, suggesting a barrier to internal rotation of greater than 3 kcal/mol (9) for the SH group.

Now, in 2-methoxythiophenol, the energy difference between conformers **1** and **2** is apparently less than 0.2 kcal/mol and therefore V_1 may well be much smaller than V_2 (see eq. [1]). In that event a hindered rotor treatment based on a twofold barrier (25, 27, 28) becomes meaningful. ${}^6J_p^{SH,H}$ is -0.14 ± 0.02 Hz. If ${}^6J(\theta = 90°)$ is -0.97 Hz, the expectation value of $\sin^2\theta$ becomes 0.14 ± 0.02, yielding a V_2 of 2.7 ± 0.6 kcal/mol. The quoted error is rather larger than implied by the error in ${}^6J_p^{SH,H}$. It is meant to indicate the approximate nature of the model.

It appears that V_1 is indeed a small fraction of V_2, so that one may write for 2-methoxythiophenol (and by analogy to eq. [1])

$$[2] \quad V(\text{kcal/mol}) = (0.2 \pm 0.2)(1 - \cos\theta)/2 + (2.7 \pm 0.6)(1 - \cos 2\theta)/2$$

Inclusion of V_n terms with $n > 2$, although correct in principle, would not be suitable here. It may be noted that a theoretical analysis of the potential function in phenol derivatives indicates that the magnitude of a V_{n+2} term amounts to between 5 and 20% of the V_n term (5).

If this treatment of the SH motion is correct, the barrier to internal rotation in both compounds is considerably higher than in the corresponding *para* derivatives. In the *para* derivatives the barrier decreases relative to the parent compounds by about 1 kcal/mol (25, 26). In the *ortho* derivatives, the V_2 component increases by about 2 kcal/mol relative to the parent compounds. We hesitate to speculate about the origin of this phenomenon.

4. The σ–π Component of ${}^5J_m^{SH,H}$

Because the SH group has significant out-of-plane populations, ${}^5J_m^{SH,H}$ will contain a small contribution from the σ–π mechanism. This contribution is proportional to $\sin^2\theta$ and should be subtracted from the observed ${}^5J_m^{SH,H}$ to yield the stereospecific ${}^5J_t$ values used above. An estimate of the σ–π contribution to ${}^5J_m^{SH,H}$ is available from its value of 0.13 Hz in 4-bromo-3-methylthiophenol (25). The barrier in this compound is only about half that in 2-methoxythiophenol, so that a much larger out-of-plane population exists in the bromo compound; for which $\langle\sin^2\theta\rangle$ is about 0.3 (25). The ratio of $\langle\sin^2\theta\rangle$ in these two compounds is 0.14/0.3, or about 0.5. Then the σ–π contribution to ${}^5J_m^{SH,H_3}$ and ${}^5J_m^{SH,H_5}$ in 2-methoxythiophenol is roughly 0.5×0.13, or 0.06 Hz. ΔG^0 becomes $-RT \ln (0.21 - 0.06)/(0.28 - 0.06)$, or 0.23 kcal/mol at 305 K. In other words, the value of 0.2 ± 0.2 kcal/mol, quoted in [2], still stands.

Tautomeric equilibria and pK_a values for 'sulfurous acid' in aqueous solution: a thermodynamic analysis

J. PETER GUTHRIE[1]

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received June 2, 1978

J. PETER GUTHRIE, Can. J. Chem. 57, 454 (1979).

The free energy of formation of dimethyl sulfite in aqueous solution can be calculated as -91.45 ± 0.79 kcal/mol; this calculation required measurement of the solubility of dimethyl sulfite. From this value and the pK_a of $SO(OH)_2$, using previously reported methods, the free energy of formation of $SO(OH)_2$ can be calculated to be -129.26 ± 0.89 kcal/mol. Comparison of this value with the value obtained from the free energy of formation of 'sulfurous acid' solutions, calculated from the free energy of formation of sulfite ion and the apparent pK_a values, permits evaluation of the free energy of covalent hydration of SO_2 as 1.6 ± 1.0 kcal/mol, in agreement with earlier qualitative spectroscopic observations. From the apparent pK_a and the anticipated pK_a values for the tautomers ($SO(OH)_2$, p$K_1 = 2.3$; $HSO_2(OH)$, p$K_1 = -2.6$) it is possible to calculate the free energy change for tautomerization of $SO(OH)_2$ to H—SO_2-(OH) as $+4.5 \pm 1.2$ kcal/mol. All equilibrium constants required for Scheme 1, describing the species present in dilute aqueous solutions of SO_2, have been calculated. In agreement with previous Raman studies the major tautomer of 'bisulfite ion' is calculated to be H—SO_3^-.

J. PETER GUTHRIE. Can. J. Chem. 57, 454 (1979).

On peut calculer que l'énergie libre de formation du sulfite de diméthyle en solution aqueuse est égale à -91.45 ± 0.79 kcal/mol; afin d'effectuer ce calcul, il faut mesurer la solubilité du sulfite de diméthyle. En utilisant les méthodes rapportées antérieurement, on peut calculer que l'énergie libre de formation du $SO(OH)_2$ est égale à -129.26 ± 0.89 kcal/mol à partir de cette valeur et du pK_a de $SO(OH)_2$. Une comparaison de cette valeur avec celle obtenue à partir de l'énergie libre de formation de solutions "d'acide sulfureux," calculées à partir de l'énergie libre de formation de l'ion sulfite et des pK_a apparents, permet d'évaluer que l'énergie libre d'hydratation covalente du SO_2 est égale à 1.6 ± 1.0 kcal/mol, en accord avec des observations spectroscopiques qualitatives. En utilisant le pK_a apparent et les valeurs de pK_a attendues pour les tautomères ($SO(OH)_2$, p$K_1 = 2.3$; $HSO_2(OH)$, p$K_1 = 2.6$), on peut calculer que l'énergie libre du changement associée à la tautomérisation du $SO(OH)_2$ en $HSO_2(OH)$ est égale à $+4.5 \pm 1.2$ kcal/mol. On a calculé toutes les constantes d'équilibre impliquées dans le schéma 1 qui décrit les espèces en présence dans des solutions aqueuses diluées de SO_2. En accord avec les études Raman antérieures, on a calculé que le tautomère principal de l'ion "bisulfite" est le HSO_3^-.

[Traduit par le journal]

Introduction

It has been recognized for some time that 'sulfurous acid' does not exist as such in aqueous solution to any large extent (ref. 1, p. 878). Infrared spectra of concentrated aqueous solutions of sulfur dioxide show only bands due to sulfur dioxide and water (2) and it has been concluded that sulfurous acid ($SO(OH)_2$) is present to the extent of less than 1 part in 30 (2). Bell has pointed out (3) that there are two peculiar features about the behavior of these solutions: first that the pK_a for what are alleged to be solutions of sulfur dioxide in water has the value expected for $SO(OH)_2$; and second that the solubility of SO_2 is much greater than would be expected by comparison with CO_2. On this basis he suggested that hydration might be much more favorable than has been considered. The present work will show that the situation is in fact more complicated than has been considered in the past and that a satisfactory analysis, explaining both the infrared spectra and the pK_a behavior, is possible. A rationalization for the solubility can also be offered.

The present work builds upon recent work from this laboratory (4–6) which has shown that the free energies of hydrolysis of esters of inorganic oxy acids (for which resonance effects are not important) can be calculated with useful precision from the pK_a of the oxy acid, using a linear free energy relationship which appears to hold over the entire accessible range of pK_a values. This permits the free energy of formation of $SO(OH)_2$ to be calculated from the known heat of formation of $SO(OCH_3)_2$. From this fact, the known free energy of formation of sulfite ion, and the observed pK_a values, the entire system can be solved.

Results and Discussion

Thermodynamic properties for the compounds discussed in this paper are found in Table 1. From data in the literature, and the solubility of dimethyl sulfite measured in this work, it was possible to determine the free energy of formation of dimethyl sulfite in aqueous solution. Then the free energy of formation of sulfurous acid, $SO(OH)_2$[2] could be calculated by methods which we have reported previously, based upon calculation of the free energy of hydrolysis of the ester. For hydrolysis reactions of type [1], provided that resonance is not important for the acid X—OH, the free energy change for the hydrolysis, corrected for symmetry and steric effects is given

[1] $$X—OR + H_2O \rightleftharpoons X—OH + HOR$$

[2] $$\Delta G'' = -4.78(\pm 0.28) + 0.336(\pm 0.024)pK_a$$

by [2] (5). This equation has been used for phosphate (5) and phosphite esters (7), and has been tested for a wide range of species X—OH; it appears to hold for oxy acids over the pK_a range from −6 to 15 with X = Cl^{VII}, S^{VI}, P^{V}, As^{III}, Si^{IV}, and C (6). In this way were calculated the free energies of formation of sulfurous acid and monomethyl sulfite in Table 1. In these calculations, it is necessary to use the pK_a value for the acid corresponding to the ester but with OH replacing OR; in the present case the acid is sulfurous acid (or its monomethyl ester). For sulfurous acid the pK_a value calculated by Kossiakoff and Harker (10) was used; these authors used a simple electrostatic model which proved quite accurate for those acids where resonance is not important in either the acid or the anion. The estimated standard deviations are based upon the differences between observed and calculated values for all the acids which they studied where the model is appropriate and the structure and pK_a of the acid are known. For monomethyl sulfite the pK_a was estimated assuming that the effect of replacing OH by OMe was the same as the average value observed for phosphate esters (5) with suitable allowance for symmetry effects (6).

From the known and unambiguous free energy of formation of sulfite ion, SO_3^{2-}, in aqueous solution and the apparent pK_a values for 'sulfurous acid' the apparent free energy of formation of 'sulfurous acid' can be calculated. This value refers to the equilibrium

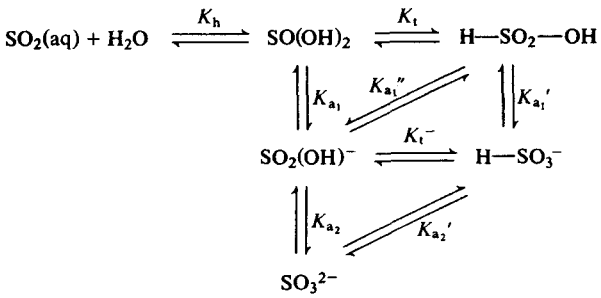
[2]In this paper 'sulfurous acid' will be used to mean the equilibrium mixture obtained when sulfur dioxide is dissolved in water, sulfurous acid will be used to refer to $SO(OH)_2$, sulfonic acid will be used to refer to $H—SO_2(OH)$; similarly the monoanions will be referred to as 'bisulfite ion,' hydrogen sulfite ion, and tetracoordinatesulfonate ion. This suggested nomenclature is analogous to that used for phosphorous acids (8).

mixture of SO_2 and $SO(OH)_2$; from the two free energies of formation, the equilibrium constant for hydration can be calculated, since it may be shown that

$$\Delta G_f^0(\text{'sulfurous acid'}) = \Delta G_f^0(SO(OH)_2) - RT \ln (1 + 1/K_h)$$

where K_h is the dimensionless equilibrium constant for hydration. This method leads to a free energy of hydration of $+1.6 \pm 1.0$ kcal/mol.

This value is in satisfactory agreement with the limit imposed by Giguere's infrared studies (2), which led to the conclusion that there was less than 1 part in 30 of sulfurous acid present. This would correspond to a free energy of hydration of $+2$. If the major species in solution is SO_2 then there is a problem explaining the pK_a which is observed, since the apparent pK_a is very close to that expected if the major species in solution were $SO(OH)_2$ but is much too acidic for a solution of SO_2 and a very minor fraction of $SO(OH)_2$. There is, however, another tautomer possible, i.e., $H—SO_2—OH$, which by analogy with the nomenclature of phosphorous compounds (8) should be called sulfonic acid. This is expected to be a strong acid and therefore could exert a marked influence on the apparent pK_a even if the equilibrium proportion is very small. The complete set of equilibria required to describe the monosulfur species present in aqueous solution is shown in Scheme 1.[3]



$$K_{a_1}^{app} = \frac{[H^+]\{[SO_2(OH)^-] + [H—SO_3]\}}{\{[SO_2] + [SO(OH)_2] + [H—SO_2—OH]\}}$$

$$K_{a_2}^{app} = \frac{[H^+][SO_3^{2-}]}{\{[SO_2(OH)^-] + [H—SO_3^-]\}}$$

SCHEME 1

From Scheme 1, the equilibrium constant K_t for tautomerization of $SO(OH)_2$ to $H—SO_2—OH$ can be expressed in terms of the other equilibrium constants as

$$[3]\quad K_t = (K_{a_1} - K_{a_1}^{app}(1 + 1/K_h))(K_{a_1}^{app} - K_{a_1}')$$

$K_{a_1}^{app}$ is of course known, being the observed apparent first pK_a of 'sulfurous acid;' pK_{a_1}, the true pK_a for $SO(OH)_2$, is not known experimentally; we will use the value calculated from an electrostatic model by Kossiakoff and Harker (10) of 2.3 ± 0.9 and also their value of 7.0 ± 0.9 for the second pK_a of $SO(OH)_2$. These values are imprecise but the results of the calculation are very insensitive to errors in them.

For sulfonic acid, the pK_a value was estimated by a Taft ρ^* correlation which was recently shown to give good predictions for sulfonic acids (6). The value so obtained is $pK_{a_1}' = 2.6 \pm 0.5$.

When these values were substituted in [3], the free energy of tautomerization was calculated as 4.36 ± 0.72 kcal/mol. All of the equilibrium constants required by Scheme 1 can now be calculated; the values are found in Table 2. These calculations simply involve calculating the one remaining equilibrium constant in a thermodynamic cycle.

Table 3 shows the concentrations of the species present in solutions of pH 1–10 for a total 'SO_2' concentration of 0.001 M. At high sulfite concentrations dimerization to 'metabisulfite' ions, $S_2O_5^{2-}$, can be important (1, p. 880; 9); this dimerization has been ignored in constructing Table 3 and is unimportant for concentrations less than 0.01 M (9).

The results of this analysis are in good agreement with earlier qualitative observations; the major monoanion is the sulfonate anion, as had been concluded from the Raman spectra of aqueous bisulfite solutions (11). There are obvious implications for the interpretation of studies of nucleophilic reactions of bisulfite ion if the reactive species (with a lone pair on sulfur) is not the major species of the monoanion but rather a minor tautomer. Fortunately the reinterpretation will not be enormous since the factor by which apparent rate constants will have to be corrected is less than 100-fold.

The contrast between the pK_a of $H—SO_3^-$, 8.6 ± 1.6, and that for $H—P(O)_2OH^-$, 28 ± 2 (7), is

very striking and shows the very large acid strengthening effect of an increase by one unit of the formal charge of the atom to which hydrogen is directly bonded. The effect amounts to 19 ± 2.6.

There remains the problem, to which Bell called attention (3), of the high solubility of sulfur dioxide in water. We suggest that the greater solubility of SO_2 in water than of CO_2 in water is due to the formal positive charge on the sulfur, leading to much stronger dipole–charge interactions of water with the central S in SO_2 than with the central C in CO_2.

Experimental

The solubility of dimethylsulfite was determined by nmr analysis of a saturated aqueous solution (pH 7 phosphate buffer, ionic strength 0.1) integrating the methyl signals relative to the solvent signal. The solubility so obtained was 1.20 ± 0.02 *M*. The vapor pressure at 25°C (14.1 Torr) was calculated from a plot of log p vs. $1/T$, using data from Beilstein (12). These values lead to a free energy of transfer from the gas phase at 1 atm to aqueous solution at 1 *M* of −2.40 kcal/mol.

Structures and properties of mixtures of branched chain compounds and lecithin: phytol, α-tocopherol (vitamin E), and phytanic acid

ROBERT J. CUSHLEY, BRUCE J. FORREST, ANNE GILLIS, AND JENIFER TRIBE

Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received August 23, 1978

ROBERT J. CUSHLEY, BRUCE J. FORREST, ANNE GILLIS, and JENIFER TRIBE. Can. J. Chem. **57**, 458 (1979).

Phospholipid bilayers containing branched chain molecules, phytol (**1**), vitamin E (**2**), and phytanic acid (**3**), have been investigated by ^{31}P nmr, esr, and differential scanning calorimetry (dsc).

A ^{31}P lanthanide induced shift study indicated varying permeabilities to Pr^{3+} in the order phytanic acid > vitamin E > phytol > egg yolk lecithin alone; the half-lives (in days) were 0.002, 0.14, 0.83, and 6.5, respectively. The activation energy for Pr^{3+} permeation through the egg yolk lecithin – phytol membrane was found to be 84.9 ± 0.8 kJ.

The following esr order parameters, S_3, were obtained using the extrinsic spin label, 5-doxylpalmitic acid, in oriented mixed multibilayers: S_3 (**1**) = 0.29, S_3 (**2**) = 0.50, and S_3 (**3**) = 0.02.

Differential scanning calorimetry revealed a lowering of the gel–liquid crystalline phase transition temperature, T_c, as the concentration of incorporated isoprenoid compound increases, with eventual disappearance of the endotherm. Specific entropy, s, calculated for dipalmitoyl lecithin + 25 mol% **3** is 126 J kg^{-1} K^{-1} compared to s = 114.2 J kg^{-1} K^{-1} for **1** and s = 85 J kg^{-1} K^{-1} for **2**.

ROBERT J. CUSHLEY, BRUCE J. FORREST, ANNE GILLIS et JENIFER TRIBE. Can. J. Chem. **57**, 458 (1979).

Faisant appel à la rmn du ^{31}P, à la rpe et à l'analyse enthalpique différentiel (aed), on a étudié des doubles couches de phospholipides contenant des molécules à chaînes ramifiées comme le phytol (**1**), la vitamine E (**2**) et l'acide phytanique (**3**).

Une étude de déplacements induits par les lanthanides des spectres rmn du ^{31}P met en relief que les diverses perméabilités au Pr^{3+} sont dans l'ordre acide phytanique > vitamine E > phytol > EYL (seul); les demi-vies respectives (en jours) sont 0.002, 0.14, 0.83 et 6.5. L'énergie d'activation pour l'imprégnation du Pr^{3+} à travers une membrane de EYL–phytol est égale à 84.9 ± 0.8 kJ.

Dans des couches multiples mixtes orientées, les paramètres d'ordre S_3, mesurés en rpe en faisant appel à l'acide doxyl-5 palmitique, un marqueur de spin intrinsèque, sont les suivants: S_3 (**1**) = 0.29, S_3 (**2**) = 0.50 et S_3 (**3**) = 0.02.

La aed met en évidence un abaissement de la température, T_c, de transition de phase gel–cristal liquide au fur et à mesure de l'augmentation de la concentration du composé isoprénique incorporé; il se produit éventuellement une disparition de l'effet endothermique. L'entropie spécifique, s, calculée pour DPL + 25% de **3** est 126 J kg^{-1} K^{-1} comparée à une s = 114.2 J kg^{-1} K^{-1} pour **1** et une s = 85 J kg^{-1} K^{-1} pour **2**.

[Traduit par le journal]

Introduction

Isoprenoid compounds assume an important role in biological systems. We have studied the effects of three of the 'phytyl' family: phytol (3,7,11,15-tetramethylhexadecyl-*trans*-2-en-1-ol, compound **1**), α-tocopherol (2,5,7,8-tetramethyl-2-(4,8,12-trimethyltridecyl)-6-chromanol, compound **2**), and phytanic acid (3,7,11,15-tetramethylhexadecanoic acid, compound **3**), on the structure and function of lecithin model membranes.

The physiology of these isoprenoids is well known. The most important of the above three is vitamin E (α-tocopherol, **2**, is the most active of the chromanols making up the vitamin). The pathogenic consequence of vitamin E deficiency is the onset of sterility and/or nutritional muscular dystrophy in rats. Less clear, and still controvertible, is the biological function of tocopherol. The most widely held view is that vitamin E functions as an antioxidant, protecting unsaturated lipids from free radical attack (1). However it has also been proposed as a specific antioxidant for protection of protein bound Se or a cofactor in mitochondrial oxidation or oxidative phosphorylation (2).

The accumulation of phytanic acid (**3**) has been found to be a factor in the progression of Refsum's disease. Patients afflicted with this disorder are not able to α-oxidize and decarboxylate phytanic or similar branched chain fatty acids, and an accumulation of branched acids results. This build-up has been cited

as a causative factor in the degeneration (demyelination) of the nervous system which eventually leads to death (3).

Furthermore, a number of observations have been made linking a common effect owing to **1–3** which suggests these compounds may play a structural role in membranes. For instance, Lucy and Dingle (4) have demonstrated that the rapid haemolysis of rabbit erythrocytes by added retinol is inhibited in vitro by α-tocopherol as well as other branched chain compounds, namely 6-*O*-acetyl-α-tocopherol, squalene, ubiquinone-30, vitamin K_1, and phytol, whereas *N,N'*-phenylenediamine and hydroquinone are completely ineffective. However, higher concentration of vitamin E and phytol were also found to cause extensive haemolysis (4). It has also been shown that cytochrome-c reductase which has been inactivated by its extraction from porcine liver is reactivated not only by vitamin E, but also by 6-*O*-acetyl-α-tocopherol, phytanic acid, and phytol (5). It appears that the effects are not due to the chromanol ring system in **2** which provides the antioxidant activity but rather that these effects are due to the branched nature of the phytyl side chain.

We wish to propose, based on the following evidence garnered at the molecular level and on previous ^{13}C relaxation studies (6, 7), that the phytyl compounds **1–3** act as *membrane destabilizers* and affect the permeability of model membranes.

Experimental

Chemicals were purchased from the following sources: phytol, Nutritional Biochemical Corporation or Aldrich Chemical Co.; vitamin E (*dl*-α-tocopherol) and dipalmitoyl lecithin (99%) (DPL), Sigma Chemical Co.; disodium ethylenediaminetetraacetate (EDTA) and cholesterol, Fisher Scientific Co.; praseodymium nitrate (99.9%), Alfa Inorganics; phytanic acid (99.7%), Analabs; deuterium oxide (99.7%), Merck, Sharp and Dohme; palmitic acid, J. T. Baker Chemical Co.; methElute (methanolic trimethylanilinium hydroxide, 0.2 *M*), Aldrich Chemical Co.; 2-(10-carboxydecyl)-2-butyl-4,4-dimethyl-3-oxazolidinyloxyl (5-doxylpalmitic acid) was a generous gift of Dr. A. C. Oehlschlager, Chemistry Department, Simon Fraser University.

Egg yolk lecithin was extracted from fresh yolks by the method of Singleton *et al.* (8). Thin-layer chromatographic analysis (0.25 mm silica gel G, developed with $CHCl_3$–MeOH–H_2O 65:35:4) showed a single spot when sprayed with 50% H_2SO_4 and heated or when exposed to I_2 vapour. The fatty acid composition of egg yolk lecithin was determined by means of glpc analysis of the corresponding methyl esters using the methylating agent, methElute (methanolic trimethylanilinium hydroxide, 0.2 *M*). Approximately 1 mg of purified egg yolk lecithin was added to 0.5 mL methElute and a 1 μL aliquot injected onto a 6 ft × 4 mm Silar 10C column. Settings were as follows: column temperature, 180°C; detector temperature, 250°C; injector temperature, 250°C. Peaks were identified by comparison with known standards.

Gas–liquid partition chromatography indicates an egg yolk lecithin composition of 42.7% palmitic acid, 16.9% stearic acid, 27.7% oleic acid, 11% linoleic acid, and 1.6% palmitoleic acid.

Vesicles

Lecithin dispersions (egg yolk lecithin or DPL, 10–20% w/v) were prepared by shaking the dry phospholipid with a suitable volume of an aqueous phase (3–4 mL of H_2O in the case of dsc and 0.05 *M* Tris pH 7.22, 0.05 *M* in KCl, in the case of ^{31}P spectra). The dispersions were then sonicated under nitrogen on a Biosonic III probe type sonicator above the phospholipid gel – liquid crystalline phase transition temperature until translucence. Sonication time was approximately 10 min, except in the case of egg yolk lecithin – phytol, 1:1 mol ratio, mixed vesicles which required more prolonged sonication (20 min–2 h). The temperature was maintained at approximately 10°C in the case of egg yolk lecithin preparations and at approximately 50°C in the case of DPL preparations by means of water flowing through a jacket surrounding the sample. The vesicle preparations were then centrifuged or passed through a 0.45 μm Millipore filter to remove titanium debris or any larger liposomes and subsequently transferred under nitrogen to sample tubes. The spectra were determined immediately.

Mixed vesicle preparations were prepared in a similar manner by first codissolving the components in chloroform, followed by solvent removal, and exhaustive pumping to obtain the dry lipid mixture.

Permeability Studies

^{31}P spectra were determined on a Varian XL-100-15 nmr spectrometer in the pulse Fourier transform mode at 40.5 MHz using an external ^{19}F field-frequency lock and a 2K dataset with external H_3PO_4 (85%), as a reference.

For permeability measurements of pure egg yolk lecithin and mixed vesicle systems to Pr^{3+} initial spectra were determined and a 150 μL portion of 0.1 *M* $Pr(NO_3)_3 \cdot 5H_2O$ in the aforementioned buffer solution was then added. The use of 3 mL of vesicle preparation resulted in a Pr^{3+} concentration of 0.005 *M*. Subsequent spectra were determined at intervals and the rate of disappearance of the sharp upfield ^{31}P resonance was monitored. After the disappearance of the upfield peak, 300 μL of 0.2 *M* EDTA which complexes with Pr^{3+} was routinely added, and the spectra redetermined.

Electron Spin Resonance Spectra

Electron spin resonance spectra were determined at 23°C on a Varian E-4 epr spectrometer operating in the X band at approximately 9.5 GHz. Typical spectrometer settings were: scan range, 100–400 G; receiver gain, 5×10^2; modulation amplitude, 0.5 G; time constant, 0.3 s; scan time, 4 min; microwave power, 10–100 mW.

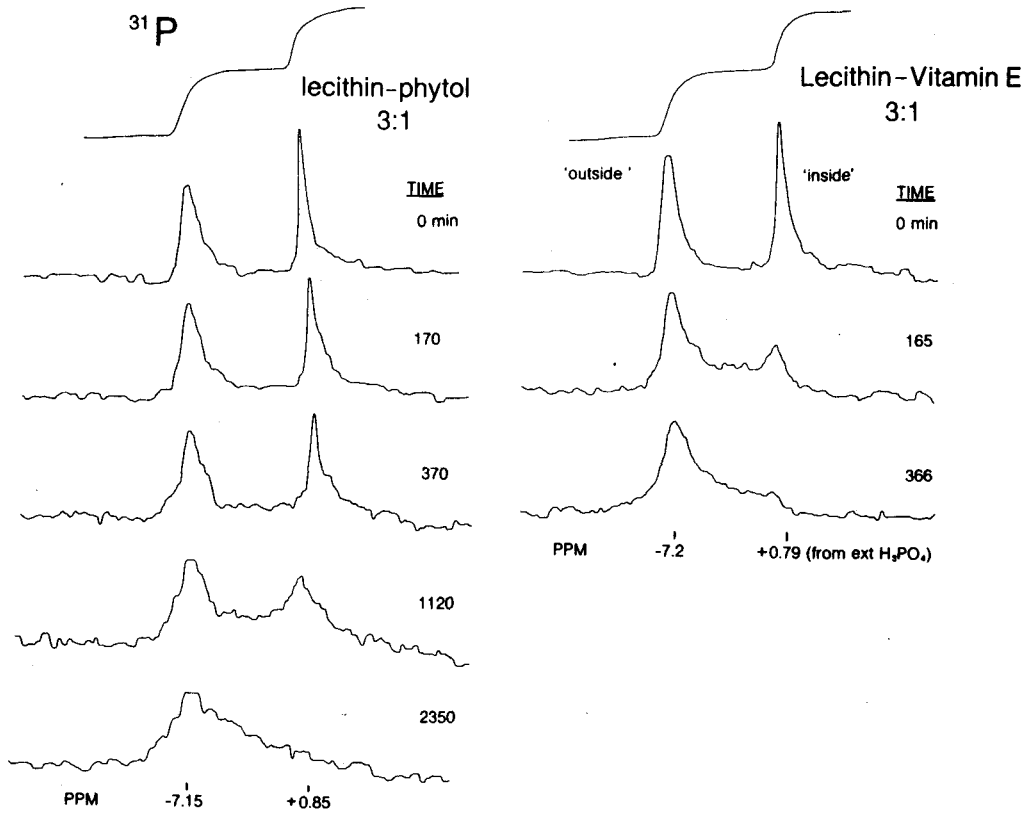

FIG. 1. ^{31}P nmr spectra of 10% w/v egg yolk lecithin vesicles containing 25 mol% phytol or 25 mol% vitamin E at the indicated times after the addition of 0.005 *M* Pr^{3+}.

Oriented lipid multilayers used in esr spectral determinations were prepared by slowly passing wet nitrogen through a quartz aqueous esr cell which contained approximately 0.10 mL of chloroform solution containing the multilayer components. This solution was prepared from stock solutions of 5×10^{-2} *M* lipid and 1×10^{-3} *M* spin label. The total lipid to spin label mol ratio was 100:1 unless otherwise specified. The lipid multilayers were then placed in the dark under vacuum for at least 3 h to remove residual chloroform and subsequently hydrated with 0.05 *M* Tris, pH 7.40. Each sample was used for at least two spectral determinations, one with the magnetic field parallel and another with the magnetic field perpendicular, to the flat cell surface.

Differential Scanning Calorimetry

Vesicle samples ($\simeq$10 wt% lecithin) were sealed in Perkin Elmer sample pans and examined on the differential scanning calorimeter (Perkin Elmer DSCI). A scan speed of 10 deg min^{-1} was used for heating and cooling runs over a temperature range of 275–350 K. Indium was used as a primary standard for power and temperature calibration. Values are accurate to ± 2 K.

Results

Lanthanide Induced Shift Studies

In a previous publication (7), preliminary results were presented which indicated that compounds **1**–**3** produced increases in the permeability of lecithin bilayers in the order **3** > **2** > **1** > lecithin alone. This work has been expanded to determine the effect of temperature and concentration on the rates.

When the lanthanide, Pr^{3+}, is added to preformed egg yolk lecithin vesicles, the phosphorus nuclei on the outside of the bilayer are shifted downfield (lis) as indicated in the top, left spectrum in Fig. 1 for egg yolk lecithin – phytol 3:1 and top, right for egg yolk lecithin – α-tocopherol 3:1. The technique used for the permeation studies is essentially that of Barsukov *et al.* (9) and Fernandez *et al.* (10) except ^{31}P nmr is substituted for ^{1}H nmr. The larger chemical shift differences of ^{31}P with added lanthanide and the simplicity of the ^{31}P spectra of phospholipid vesicles makes ^{31}P nmr more attractive for lis studies than ^{1}H nmr (11).

As Pr^{3+} crosses the bilayer phosphorus nuclei on the inside layer become shifted downfield to reside under the 'outside' resonance peak. The time lapse for the ^{31}P spectra are recorded in the rest of Fig. 1 and show the effects of Pr^{3+} on egg yolk lecithin vesicles containing both **1** and **2** (times are indicated on the spectra). The rate of disappearance of the upfield, 'inside' ^{31}P nmr signal is a zero-order process describing permeation of the bilayer by Pr^{3+}. The rate of leakage of Pr^{3+} through egg yolk lecithin

[a]800 transients; pulse width = 10 μs (56° flip angle).

bilayers for egg yolk lecithin – phytyl compound vesicles at 33°C is shown in Table 1.

An examination of these rates shows that the incorporation of 25 mol% phytol decreases the half-life for the vesicle leak from 6.5 days to 20 h, 25 mol% vitamin E from 6.5 days to 3.4 h, and 25 mol% phytanic acid by nearly 2900 times over the rate obtained for pure egg lecithin vesicles to 3.2 min.

After the disappearance of the upfield 'inside' resonance due to Pr^{3+} entering the vesicles, sufficient EDTA was routinely added to complex with accessible Pr^{3+} and spectra redetermined. Again, two peaks were resolved, the upfield peak now due to phosphorus nuclei on the outside of the bilayer which are directly exposed to the added EDTA. Such behaviour indicates two things. First, the disappearance of the upfield resonance with time after the initial addition of Pr^{3+}, cannot be due to vesicle rupture. If the destruction of vesicles were responsible for the disappearance of the upfield protected signal, the subsequent addition of EDTA should result in a single upfield peak since all Pr^{3+} should be accessible for complexation. Second, the mixed vesicles are not appreciably permeable to EDTA during the time required for the determination of a spectrum (3–10 min). Thus, the ^{31}P lis procedure indeed monitors the permeability of lecithin vesicles.

The ^{31}P nmr method lends itself best to diffusion studies which may be followed to completion during a time interval of 0–4 days. As can be seen, the observed half-life for pure egg yolk lecithin vesicles is on the order of 1 week. It was understandably not practical to conduct experiments of such duration. Therefore the observed rate for egg yolk lecithin is subject to considerably more error than for the more rapid rates in the case of the aforementioned mixed vesicle preparations. This is due to the smaller changes in peak areas in the time available. Repeated determinations of the permeability of pure egg yolk lecithin vesicles, which were run as standards for each determination, yielded rates from approximately 2×10^{-3} to 5×10^{-3} %/min. The standard deviations as computed from a least-squares treatment of the experimental data were typically on the order of 20–30% of the calculated rate. The decay rates for the mixed vesicle systems are much more easily measured over a much wider change of spectral area and are considered to be accurate to ±10%. It is clear that the incorporation of phytol, vitamin E, and phytanic acid greatly increases the permeability of egg yolk lecithin bilayers. The effects of these compounds on permeability parallels their effect on the fluidity or, more correctly, the microviscosity, of the bilayer as shown by ^{13}C T_1 relaxation times (6, 7), i.e., phytanic acid > vitamin E > phytol > lecithin alone.

Experiments were also carried out to determine the effect of temperature on the permeability of lecithin–phytol (3:1 mol ratio) mixed vesicles. The results are shown in Table 2. Raising the temperature from 11 to 52°C results in a rate increase of almost two orders of magnitude. In Fig. 2 the logarithms of the rates were plotted against the inverse of the absolute temperature (Arrhenius plot). The plot is linear, yielding an activation energy of 84.9 ± 0.8 kJ. It is interesting that the activation energy for Pr^{3+} permeation is in quite close agreement not only with that reported for Na^+ permeation through lecithin – phosphatidic acid bilayers (12) but also with that reported for the transverse diffusion (flip-flop) of spin labelled lecithin molecules across phospholipid bilayers (80.8 kJ) (13).

The rates of Pr^{3+} permeation (relative to egg yolk lecithin, 1.00) for mixed vesicles containing various amounts of α-tocopherol (2) are given in Table 3 and show a linear relationship between vitamin E concentration and log (relative rate). The table shows that even the incorporation of a small amount of vitamin E (3 mol%) results in the increase of the inward diffusion of Pr^{3+} to approximately 300% of its

TABLE 2. Permeation rates of Pr^{3+} into egg yolk lecithin vesicles containing 25 mol% phytol at various temperatures

original value. Thus, amounts of α-tocopherol, which approach the physiological ratios of α-tocopherol to phospholipid found in the human aorta (14, 15), exert a large effect on the permeability properties of the membrane.

Differential Scanning Calorimetry Measurements

Endotherms for the gel–liquid crystal phase transitions for bilayer membranes have been obtained using differential thermal analyses (dta) or differential scanning calorimetry (dsc). Figure 3 shows the dsc endotherms for phytol (**1**), α-tocopherol (**2**), and phytanic acid (**3**) incorporated into DPL at various mol percentages. As concentrations of **1**, **2**, and **3** are increased a lowering of the transition temperature, T_c, and a reduction in the heat of transition are observed. As concentrations approach 50 mol% the transition broadens out and eventually the endotherm disappears. This disappearance is no doubt due to the increased heterogeneity of the mixed DPL – phytyl compound system.

A plot of T_c vs. percentage composition for DPL–cholesterol, DPL–phytol, DPL–α-tocopherol, and DPL – phytanic acid mixtures is shown in Fig. 4. From the transition temperature lowering it is clear that phytanic acid causes the greatest destabilization of the membrane. Both phytol and α-tocopherol show similar thermal behaviour whereas **1**–**3** are all considerably lower than cholesterol.

The entropy associated with the melting of the fatty acyl chains of various DPL containing phytyl compounds can be calculated from the heat content at the transition temperature, T_c, since the Gibbs free energy for the order–disorder process is zero

$$[1] \qquad \Delta G = \Delta H - T_c \Delta S \simeq 0$$

hence $\Delta S = \Delta H/T_c$. The variation of ΔG with temperature is given by

$$[2] \qquad (\partial \Delta G/\partial T)_p = -\Delta S$$

A representative calculation of the entropy of gel – liquid crystal melt for identical mixtures (i.e., 25 mol% incorporated phytol, α-tocopherol, and phytanic acid) yields the specific entropy, s. For **1**, $s = 114.2\ \mathrm{J\ kg^{-1}\ K^{-1}}$; for **2**, $s = 85\ \mathrm{J\ kg^{-1}\ K^{-1}}$; and for **3**, $s = 126\ \mathrm{J\ kg^{-1}\ K^{-1}}$. This can be compared with the result for 25 mol% cholesterol incorporated into DPL which yields $s = 78\ \mathrm{J\ kg^{-1}\ K^{-1}}$ (specific enthalpy, $h = 24.27\ \mathrm{kJ\ kg^{-1}}$).

A significant increase in specific enthalpy is observed for the lecithin – phytanic acid – water system compared with lecithin–cholesterol–water. Lessened effects are observed for lecithin–phytol–water and lecithin – vitamin E – water mixtures show the smallest increase. As represented by the above values for s, the differences in enthalpy can be explained in terms of entropy differences. The significant difference in s values for α-tocopherol and phytol can be explained in terms of excluded volumes of **1** vs. **2** (see later).

Electron Spin Resonance

Nitroxide spin labels embedded in membranes, above T_c, undergo rapid anisotropic motion of limited amplitude. Jost *et al.* (16) used the following definition to describe the anisotropy about the molecular long axis:

$$[3] \qquad S_3 = \frac{T_{\parallel} - T_{\perp}}{T_{zz} - \frac{1}{2}(T_{xx} + T_{yy})}$$

Hubbell and McConnell (17) used a slightly modified form which takes into account the polarity of the bilayer;

$$[4] \qquad S_3 = \frac{T_{\parallel} - T_{\perp}}{T_{zz} - \frac{1}{2}(T_{xx} + T_{yy})} \frac{T_{xx} + T_{yy} + T_{zz}}{T_{\parallel} + 2T_{\perp}}$$

The order parameter, S_3, thus provides a good probe of local orientational mobility and order of lipid bilayers (18–20). In the present case relative order parameters for 5-doxylpalmitic acid in the mixed bilayers are presented, hence, the perturbing effect of the bulky nitroxide moiety is minimized. Order parameters have been determined for egg yolk lecithin multilayers containing 1% of the spin label 5-doxylpalmitic acid (2-(10-carboxydecyl)-2-butyl-4,4-dimethyl-3-oxazolidinyloxy) plus 25 mol% **1**, **2**, and **3**. 5-Doxylpalmitic acid is known to orient in egg yolk

lecithin bilayers with the long axis of the fatty acid chain normal to the surface of the bilayer. Thus, $T_{\parallel}$ is the measured hyperfine tensor when B_0 is normal to the bilayer surface; $T_{\perp}$ when B_0 is parallel to the surface plane. S_3 for 5-doxylpalmitic acid in egg yolk lecithin containing 25 mol% phytol is 0.29, S_3 for egg yolk lecithin containing 25 mol% α-tocopherol is 0.50, and S_3 for egg yolk lecithin containing 20 mol% phytanic acid is 0.02, i.e., essentially isotropic. The value of S_3 for egg yolk lecithin alone is 0.54 in keeping with literature values (21–23). Thus, vitamin E, **2**,

has a small effect on the ordering of the phospholipids in the bilayer, phytol disorders the egg yolk lecithin bilayer more while phytanic acid completely disrupts the bilayer.

Discussion

The intercalation of phytol, vitamin E, or phytanic acid was previously shown to greatly increase the fluidity of the mixed membrane, as monitored by ^{13}C T_1 relaxation times (6, 7). The fluidizing effect was found to increase in the order phytol < vitamin E < phytanic acid. For example, the incorporation of 25 mol% vitamin E increased the ^{13}C T_1 relaxation times for the lecithin fatty acid carbons by 50–100%, whereas the largest increases, which were found upon the incorporation of 25 mol% phytanic acid, were on the order of 150–200%.

The perturbations caused by the incorporation of phytol, vitamin E, and phytanic acid as monitored by the ^{13}C T_1 values have been found to correlate with permeability increases of mixed phospholipid – phytyl compound vesicles to the Pr^{3+} cation using ^{31}P nmr spectroscopy. At 33°C, the permeability of egg yolk lecithin vesicles was increased by approximately 8 times upon the incorporation of 25 mol% phytol, by approximately 48 times upon the incorporation of 25 mol% vitamin E, and by approximately 2900 times upon the incorporation of 25 mol% phytanic acid. In other words, the permeability of the two component (lecithin – phytyl compound) vesicles increases in the order phytol < vitamin E < phytanic acid. This is the same order in which the ^{13}C T_1 relaxation times increase. From the ^{13}C T_1 values of the various lecithin carbons effective correlation times, τ_{eff}, can be obtained for the motion. These τ_{eff} reflect the relative change in 'fluidity' or, more precisely, microviscosity caused by the phytyl compounds at a particular position in the bilayer.

Incorporation of a smaller amount of vitamin E which approaches physiological concentrations (3 mol%) still results in a permeability increase to 300% of the rate for pure egg yolk lecithin vesicles (Table 3).

Monolayers of phytol, α-tocopherol, and phytanic acid occupy molecular areas of 55, 60, and 61 Å^2 per molecule at 0.5 dyn/cm, respectively (24), whereas cholesterol is known to form stable monolayers of area 40 Å^2 per molecule. Thus, the area requirements for the phytyl molecules is much higher. Such large monolayer areas must be due to the branched nature of the chains, since the unbranched C18 acid, stearic acid occupies monolayer areas of the order of 24 Å^2 per molecule (24).

Above the lecithin gel–liquid crystalline transition temperature, cholesterol is known to fit into cavities created by thermal motion of the fatty acyl chains causing an 'intermediate fluid' condition (25, 26). In addition, mixed monolayers of lecithin and cholesterol do not follow the additivity rule since cholesterol occupies pockets in the membrane and causes little proportional increase in the area/molecule of mixed monolayers. Such behaviour has been correlated with a decrease in permeability above T_c (12, 27). Very recently the monolayer behaviour of vitamin E in lecithin monolayers has been studied (28). It was found that in monolayers of distearoyl- or dioleoyllecithin the additivity rule was well followed, up to 50 mol% incorporated α-tocopherol. This indicates that, unlike cholesterol, α-tocopherol is not able to fit into the cavities between adjacent lecithin molecules and displaces its full area requirement in mixed lecithin–α-tocopherol systems. Such behaviour necessarily involves an increase in lipid–lipid separation due to intercalated vitamin E.

The total interaction energy owing to London – Van der Waals dispersion forces between the long hydrocarbon tails of phospholipids is proportional to the inverse fifth power of the intermolecular distance (29). Thus, even a small lateral expansion of the lipid bilayer would result in a large decrease in the interaction energies of adjacent lipid molecules. As an example, it has been found that the presence of a single methyl group in isostearic acid reduces the interaction energy from that of stearic acid by a factor of three (29). This decrease in intermolecular attraction would be expected to become even more severe for more highly branched molecules such as phytol, vitamin E, and phytanic acid.

Decreases in intermolecular attractions and increases in phospholipid–phospholipid packing distances due to the incorporation of phytol, vitamin E, and phytanic acid are consistent with the esr results. Vitamin E (**2**), with a monolayer area of 60 Å^2 per molecule, causes the least perturbation of the three. Although **2** has nearly the same area requirements as phytanic acid (60 vs. 61 Å^2/molecule) because of its extremely hydrophobic nature it is not expected to penetrate as far into the region of the lecithin headgroup. This is reflected in the order parameter for **2**, $S_3 = 0.50$, which is essentially unchanged from S_3 for egg yolk lecithin alone (0.54). Phytol, whose hydroxyl group we have shown previously (6) to penetrate to within hydrogen bonding distance of the head group phosphate, yields a smaller order parameter for the bilayer (S_3 (**1**) = 0.29) even though the surface area requirements for phytol are smaller than those for **2** and **3**. This becomes clear when it is remembered that, although the characteristic 'plateau' of S_3 vs. hydrocarbon chain position for phospholipid bilayers is constant from C1–C10 (30), the nitroxide moiety in 5-doxylpalmitic acid probes the

local region about C1 (31). Phytanic acid causes the greatest disorder in the bilayer ($S_3 = 0.02$) since in addition to the large surface area requirement, phytanic acid penetrates furthest into the hydrophilic region, further interfering with the normal lecithin–lecithin headgroup ionic interaction, the detergent effect. Phytol (**1**) and vitamin E (**2**), on the other hand, simply decrease the attraction of one lecithin molecule for an adjacent, but now more distant, lecithin molecule by nonbonded steric interaction. The thermodynamic calculations, above, are also consistent with the fact that **2** is embedded more deeply in the bilayer than **3** and **1**.

The very high permeation rates and very low order parameter for phytanic acid indicate that interactions at the lecithin headgroup are the most important with regard to the structural integrity of the bilayer.

To confirm that the effects on the bilayer are in fact due to the branched nature of the phytyl chains, the unbranched C16 acid, palmitic acid, was studied in egg yolk lecithin bilayers. No change in the rate of Pr^{3+} permeation was observed upon the incorporation of 25 mol% of palmitic acid into egg yolk lecithin using ^{31}P lis. Over a three day period, the upfield ^{31}P signal decayed to ~90% of its original value, yielding a rate of 2.4×10^{-3} %/min, which is on the order of that obtained for egg yolk lecithin alone. Similarly, the incorporation of 25 mol% of palmitic acid into egg yolk lecithin had no effect on the 'fluidity' of the bilayer since the ^{13}C T_1 values of egg yolk lecithin varied by only an average of ±10.7% from egg yolk lecithin alone (i.e., on the error limit of the measurements). Since palmitic acid has a very small area requirement (≃24 Å^2/molecule), it is able to fit into the cavities created by thermal fluctuations of the lecithin fatty acid chains above the gel–liquid crystalline transition temperature and, because it is unbranched, causes little perturbation of the London – Van der Waals attractive forces. In contrast, incorporation of phytol, vitamin E, and phytanic acid perturb the normal phospholipid packing, resulting in increased fluidity and reorientational disorder of the bilayer and increased permeability of the bilayer to ions.

Application of the Osterberg–Sarkar–Kruck method for obtaining free ion concentrations in solutions of complex equilibria

ROGER GUEVREMONT AND DALLAS L. RABENSTEIN

Department of Chemistry, The University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received September 1, 1978

ROGER GUEVREMONT and DALLAS L. RABENSTEIN. Can. J. Chem. 57, 466 (1979).

A titration system has been developed for collecting pH titration data of sufficient accuracy for use with the method developed by Osterberg, and Sarkar and Kruck, for extracting free metal and free ligand concentrations from pH titration data. Titrant is delivered from a gravimetric buret capable of part per ten thousand precision, and a concentrated metal or ligand solution is added from a second buret to satisfy the theoretical requirement that the total metal or ligand concentration remain constant. The entire system is computer controlled. Application of the titration system and procedures for extracting free ligand and free metal concentrations from pH titration data are demonstrated with a study of the complexation chemistry of zinc with aspartic acid.

ROGER GUEVREMONT et DALLAS L. RABENSTEIN. Can. J. Chem. 57, 466 (1979).

On a mis au point un système de titrage permettant de recueillir des données de dosage de pH assez précises pour être utilisées avec la méthode développée par Osterberg, et Sarkar et Kruck, pour déduire les concentrations de métal libre et de ligand libre à partir de données de titrages de pH. Le titrant est ajouté à l'aide d'une burette gravimétrique capable d'une précision d'une partie par dix milles; on ajoute une solution concentrée de métal ou de ligand à l'aide d'une deuxième burette afin de satisfaire aux exigences théoriques voulant que la concentration totale du métal ou du ligand soit constante. Le système global est contrôlé par un ordinateur. On a démontré la validité du système de titrage et des procédés nécessaires à l'extraction des concentrations de ligand libre et de métal libre à partir de titrages de pH à l'aide d'une étude de la chimie de complexation du zinc par l'acide aspartique.

[Traduit par le journal]

Introduction

In a previous paper (1), we reported on a study of the method developed by Osterberg (2) and Sarkar and Kruck (3) for estimating the concentrations of free ligand and free metal in solutions of complex equilibria. The results of that study indicate that successful application of this method, which we call the FICS method for *F*ree *I*on *C*oncentrations in *S*olution, requires a large quantity of highly accurate data and, as pointed out by Sarkar and Kruck (3) in their original publication on this method, careful design of the experimental system so as to satisfy the theoretical requirements of the method.

In this paper, we describe a titration system designed for the purpose of collecting potentiometric data suitable for the FICS method. The system has been designed to minimize those potential sources of error identified in previous publications (1, 3, 4). The heart of the system is a gravimetric buret (5), which is capable of part per ten thousand precision. To compensate for changes in metal or ligand concentration due to dilution by titrant, which can lead to large errors in the FICS method, a concentrated metal or ligand solution is added from a second buret. The entire system is computer controlled because of the large amount of data required. The titration system and the procedures described previously (1) for extracting formation constants from pH titration data by the FICS method are then tested with a study of the complexation chemistry of zinc with aspartic acid.

The FICS Method

The FICS method is based on the general relations (2, 3)

$$[1] \quad p[L] = p[L]_0 - \int_{pH_0}^{pH} \left(\frac{dC_H}{dC_L}\right)_{C_M,pH} dpH$$

$$[2] \quad p[M] = p[M]_0 - \int_{pH_0}^{pH} \left(\frac{dC_H}{dC_M}\right)_{C_L,pH} dpH$$

where C_H is the total concentration of titratable protons, C_L and C_M are the total analytical concentrations of ligand and metal, respectively, and [L] and [M] are their free concentrations. $p[L]_0$ is the negative logarithm of the concentration of free L at some initial pH_0. If possible, a pH_0 is usually chosen at which no complex is formed so that $[L]_0$ and $[M]_0$ are equal to (or can be calculated from) C_L and C_M. The integral of $(dC_H/dC_L)_{C_M,pH}$ or $(dC_H/dC_M)_{C_L,pH}$ is evaluated from pH_0 to the pH at which p[L] or p[M] are to be evaluated. This requires that $(dC_H/dC_L)_{C_M,pH}$ and $(dC_H/dC_M)_{C_L,pH}$ be determined experimentally

as a function of pH over the pH range pH_0 to the given pH. One way to accomplish this for $(dC_H/dC_L)_{C_M,pH}$ is to perform a series of titrations where C_L is varied while the concentrations of all other components are kept constant, and then to compare the C_H values from the series of C_L values at each pH (3). The rate of change in C_H with C_L at a given pH is equal to $(dC_H/dC_L)_{C_M,pH}$. Similarly, a series of titrations on solutions of varying C_M will serve to provide $(dC_H/dC_M)_{C_L,pH}$.

As stated by Sarkar and Kruck (3) and confirmed in our previous study (1), C_M and C_L must indeed remain constant to obtain correct values for $(dC_H/dC_L)_{C_M,pH}$ and $(dC_H/dC_M)_{C_L,pH}$, respectively, by this titration procedure. If C_M is allowed to decrease as titrant is added in the titrations designed for the evaluation of $(dC_H/dC_L)_{C_M,pH}$, serious error of a systematic nature results in p[L] (1). The error is cumulative, and increases in magnitude as the difference between pH_0 and pH increases. Similarly, variations in C_L cause errors in p[M]. We also found that random errors in C_H of a magnitude greater than 2 parts per thousand of the initial C_H significantly increased the errors in the final estimates of [L] and [M] (1).

Experimental

Apparatus

A schematic diagram of the computer controlled potentiometric titration system designed to collect data specifically for the FICS method is shown in Fig. 1. The titrant is delivered to the sample cell from an optically-coupled gravimetric buret capable of parts per ten thousand precision (5). The weight sensing component is a Sartorius 3015 electronic top loading balance with a sensitivity of 1 mg. The sample pH is monitored with a Corning glass electrode and a reference (Ag/AgCl, Na_2SO_4(satd)) electrode pair. The electrode potential is measured with a sensitivity of 0.1 mV with a Fisher Accumet 520 digital pH meter. The binary coded decimal (BCD) outputs of the pH meter and electronic balance are fed to a simple multiplexer circuit. Because output from the balance consists of six BCD digits, these are divided into two channels of the multiplexer. The data are collected from the multiplexer by a PDP11/10 minicomputer. The computer was equipped with a Laboratory Peripheral System (LPS) which included 16 bit digital input, 16 bit digital output, and programmable clock options. The data were stored on cassette tape or on floppy disc. To compensate for dilution by titrant, a concentrated ligand or metal solution was added to the sample solution from an auxiliary delivery system (Mettler DV11 piston buret).

The program controlling the automatic collection of potentiometric data was written in FORTRAN IV. The main functions of this program are to control the delivery of titrant from the gravimetric buret and from the Mettler DV11 piston buret, to collect BCD data from the pH meter and electronic balance, to supply the appropriate delay intervals and time the above operations, and to store the data for further manipulations. In addition the program performs several logical operations. These include deciding if electrode equilibrium has been reached, estimation of the quantity of titrant to be added before the next data point, and calculation of the quantity of concentrated ligand or metal solution to be added from the auxiliary delivery unit in order to compensate for dilution.[1]

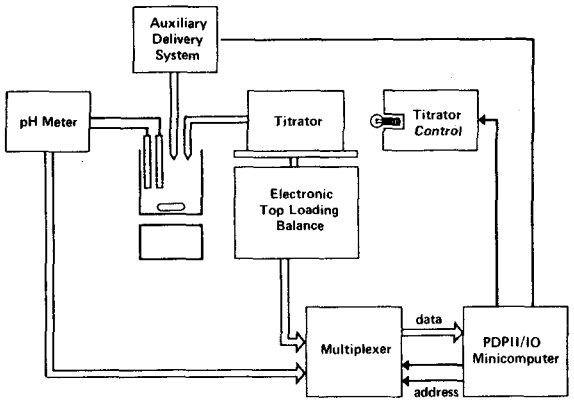

FIG. 1. Schematic diagram of the automatic titration system.

The most important logical processes are those involving electrode equilibrium and the delivery of titrant. The electrode potential is sampled over an interval of, for example, 6 s and the average, standard deviation (sd), and drift in those sampled values are calculated. Typically 5 values are taken over this time interval. Optimum values of allowable SD and drift are chosen to arrive at a working compromise between the selection of a reliable electrode potential and avoiding unnecessary repetition of sampling the electrode potential. The quantity of titrant to be added for the next data point is estimated on the basis of the effect of the previous addition on the electrode potential. If the electrode potential changes by less than some minimum value, perhaps 5 mV, then the previous addition is doubled. Within other appropriate limits the increment is increased or decreased by factors of two to five. The limits are chosen on the basis of the number of data points desired.

Procedure

The measured electrode potentials were converted to p_aH on the basis of standardization with NBS reference solutions of phthalate (pH 4.008), phosphate (pH 7.413), and carbonate (pH 10.012) (6). The role of the pH measurement in the FICS method (1) makes it unnecessary to convert hydrogen ion activity to hydrogen ion concentration.

All solutions were prepared or standardized on the basis of weight. Carbonate-free NaOH titrant was standardized by gravimetric titration of primary standard KHP. A standard zinc solution was prepared by dissolution of Zn metal in a small volume of HNO_3. The excess acid was neutralized with NaOH before dilution. $NaClO_4$ was added to bring the ionic strength to 0.3 mol/kg. Aspartic acid was recrystallized from cold ethanolic solution, washed thoroughly with ethanol, and dried in air. A stock solution prepared from the recrystallized aspartic acid and $NaClO_4$ (0.3 mol/kg) was standardized by gravimetric titration with NaOH. All of the sample solutions were prepared by combination of a weighed portion of a 0.3 mol/kg $NaClO_4$ stock diluent solution, a weighed portion of the zinc solution, and a weighed portion of the aspartic acid solution to bring the total to 200.00 ± 0.01 g. These solutions were titrated gravimetrically with NaOH at 25.0 ± 0.1°C and

[1]More details about the computer program can be obtained from the authors.

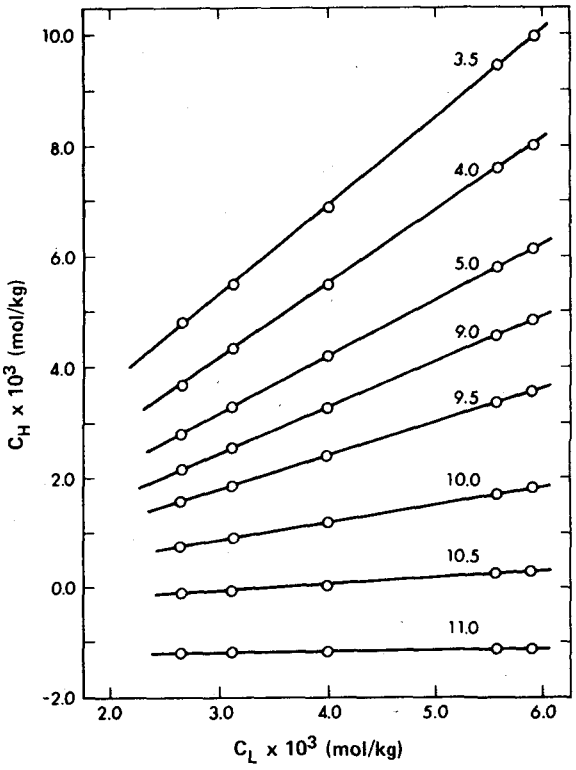

FIG. 2. C_H vs. C_L at selected pH values for aspartic acid.

under a CO_2-free nitrogen or argon atmosphere. The series of titrations in which each component was varied was carried out in the order C_3, C_2, C_4, C_1, and C_5 where $C_1 < C_2 < C_3 < C_4 < C_5$.

Results

The Protonation Constants of Aspartic Acid

A series of solutions of varying aspartic acid concentration (2.643×10^{-3} to 5.908×10^{-3} mol/kg) was titrated from pH 3.5 to pH 11.0. The concentration of titratable protons (C_H) was calculated, and the change in C_H with change in the total concentration of aspartic acid is shown in Fig. 2. The slopes of the lines are the experimental values of the term $(dC_H/dC_L)_{pH}$ of eq. [1]. The values of these derivatives are shown as a function of pH in Fig. 3. The overall formation constants of the protonated forms of aspartic acid were calculated from these data by the iterative procedure described previously (1). First, the concentration of completely deprotonated ligand, [L], was estimated to be equal to the total aspartic acid concentration at pH 11.0. The concentration of completely deprotonated ligand was then calculated as a function of pH with this estimated $p[L]_0$ and the data for (dC_H/dC_L) shown in Fig. 3. The overall formation constants of the protonated forms of aspartic acid were calculated from these values for [L] and the mass balance (C_L) for the aspartic acid,

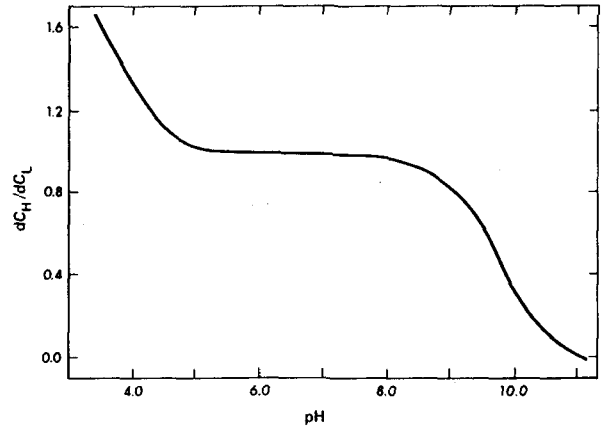

FIG. 3. (dC_H/dC_L) as a function of pH for aspartic acid.

and finally the value of [L] at pH 11 was calculated using these constants. As expected, the initial estimate that [L] equalled C_L was slightly incorrect and the calculated value of [L] was therefore taken as a next best estimate of $p[L]_0$ at pH 11.0. The above series of calculations was repeated to get a new estimate of $p[L]_0$ at pH 11.0. After three such iterations there was no change in the value of $p[L]_0$. The final values of the protonation constants are shown in Table 1. A summary of literature values (7–14) is also included in Table 1.

The Formation of Complexes Between Zinc and Aspartic Acid

Two series of titrations of mixtures of zinc and aspartic acid were carried out, the first designed to study the general nature of the changes in C_H with changes in the total aspartic acid concentration at a fixed zinc concentration, and the second designed to provide [L] and [M] data with which to calculate formation constants.

The first set of titrations was carried out at a constant zinc concentration of 9.370×10^{-4} mol/kg and total aspartic acid concentration varying from 1.1×10^{-3} to 5.6×10^{-3} mol/kg. The zinc concentration was maintained at a constant value by adding the appropriate amounts of a concentrated zinc solution after each addition of titrant. Plots of C_H as a function of the total aspartic acid concentration showed some curvature below a ligand-to-metal ratio of 2 to 1. Though the curvature was not severe, our previous studies (1) indicate that the most reliable results are obtained if the C_H vs. C_L plots are linear. To obtain linear C_H vs. C_L plots in the second set of titrations, ligand-to-metal ratios greater than 3 to 1 were used.

Ten titrations were performed, five at a constant zinc concentration of 9.370×10^{-4} mol/kg, and five at a constant aspartic acid concentration of $5.308 \times$

10^{-3} mol/kg. The change in C_H with change in C_L at constant C_M is shown in Fig. 4 and the change in C_H with change in C_M at constant C_L is shown in Fig. 5. The slopes, $(dC_H/dC_L)_{C_M,pH}$ and $(dC_H/dC_M)_{C_L,pH}$, are plotted as a function of pH in Fig. 6. Data are shown in Figs. 4–6 for selected pH values; (dC_H/dC_L) and (dC_H/dC_M) were actually evaluated at 0.1 pH unit intervals. The curve for (dC_H/dC_L) is similar to, but not identical with, that shown in Fig. 3 for aspartic acid in the absence of zinc. The curve for (dC_H/dC_M) indicates that complexation begins in the pH range 4.0 to 5.0 where (dC_H/dC_M) first deviates significantly from zero.

The concentrations of free aspartic acid in the completely deprotonated form, [L], and free zinc, [M], were calculated using the (dC_H/dC_L) and (dC_H/dC_M) data and eqs. 1 and 2. It was assumed as a first approximation that [M] at pH 4.0 equalled C_M, and [L] was calculated from C_L and the protonation constants measured above. Using these as initial estimates for [L] and [M] over the pH range 5 to 8, formation constants were calculated by the procedure described previously (1). Since there is some complexation at pH 5.0, the iterative procedure was used to obtain final values for $p[L]_0$ and $p[M]_0$. The free ligand and free metal data were used as described previously (1) to determine the stoichiometries of the complexes. Over the pH range 5 to 8, the complexes ZnL and ZnL_2^{2-} account for nearly all the complexed zinc and aspartic acid, and the best estimates for $\log \beta_{ZnL}$ and $\log \beta_{ZnL_2}$ were 5.66 and 10.14, respectively. With a somewhat wider pH range, from 4.0 to 9.0, there appear to be complexes with the stoichiometries $HZnL^+$ and ZnL_3^{4-} forming at the extremes of the pH range. $\log \beta_{HZnL}$ and $\log \beta_{ZnL_3}$ were estimated to be 10.8 and 12.9, respectively. Other workers have reported the species $HZnL^+$ and $ZnL_2(OH)_2^{4-}$ (10).

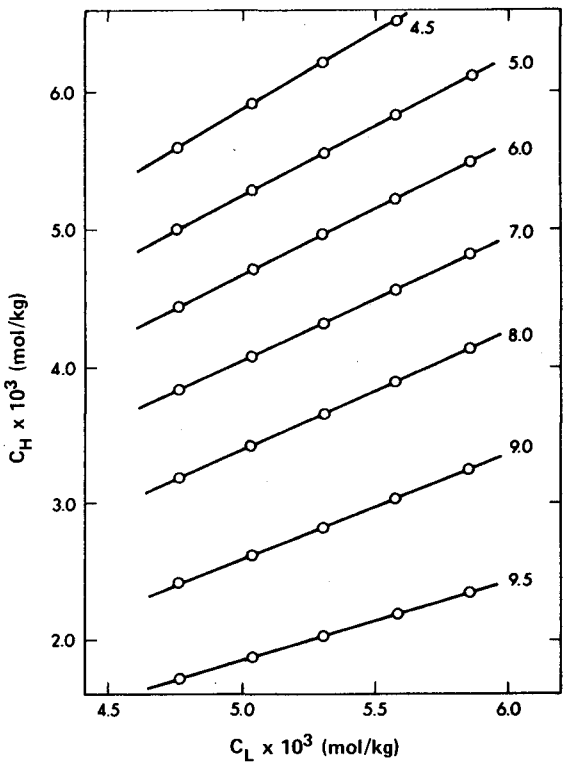

FIG. 4. C_H as a function of the total concentration of aspartic acid (C_L) for the zinc – aspartic acid system. The total zinc concentration was 9.370×10^{-4} mol/kg.

Discussion

A study of the complexation chemistry of zinc with aspartic acid was chosen to test the titration apparatus and the procedures described previously (1) for extracting free ion concentrations from titration data by the FICS method. A relatively simple system was chosen to avoid difficulty in assigning a model to the complexation equilibria. The fol-

lowing discussion will deal first with details of the application of the FICS method, and then the results of the zinc – aspartic acid experiments.

Our earlier studies (1) based on simulated titration data revealed that the FICS method will provide accurate values of [L] and [M] only if the data are highly reliable and, as pointed out by Sarkar and Kruck (3), only if the theoretical requirements of the method are met. The experiments with the zinc – aspartic acid system have revealed several other difficulties which can be encountered in an application of the FICS method. The accuracy of the derivative terms, (dC_H/dC_L) and (dC_H/dC_M), is dependent on the accuracy of C_H, C_L, and C_M, and the changes in C_H, C_L, and C_M. The most severe problems are associated with obtaining data of sufficient accuracy below pH 4 and above pH 10. At these pH extremes, the pH is changing relatively slowly as titrant is added. The result is that the error in C_H due to an error of a fixed magnitude in pH, for example ± 0.1 mV which corresponds to ± 0.002 pH units, is larger than when the pH is changing more rapidly. However, it is necessary to start the titration at a low pH where the ligand is protonated and the metal ion free so that $p[L]_0$ and $p[M]_0$ can be estimated. In the study of the zinc – aspartic acid system, a pH of 5.0 was used for pH_0 even though some complex has formed at this pH. The correct values of $p[L]_0$ and $p[M]_0$ were then obtained by an iterative procedure (1). This is a workable solution to the problems associated with using a very low pH_0, unless a model cannot be found for the complexation at pH_0 or if a large portion of the metal and ligand is complexed at this pH.

The FICS method for extracting [L] and [M] as a function of pH from titration data has a considerable advantage over other calculation methods in that it provides free ligand and free metal concentrations without a priori assumptions about a model for complexation (3). Since the values of [L] and [M] obtained from the raw data do not reflect the effect of application of some arbitrary hypothetical model, a model may be systematically derived from the data. The method also has considerable advantage with respect to the role of the pH measurement (1). The calibration must be accurate and reproducible from titration to titration, but, as illustrated in this work, a conversion from hydrogen ion activity to hydrogen ion concentration is unnecessary if the C_M and C_L

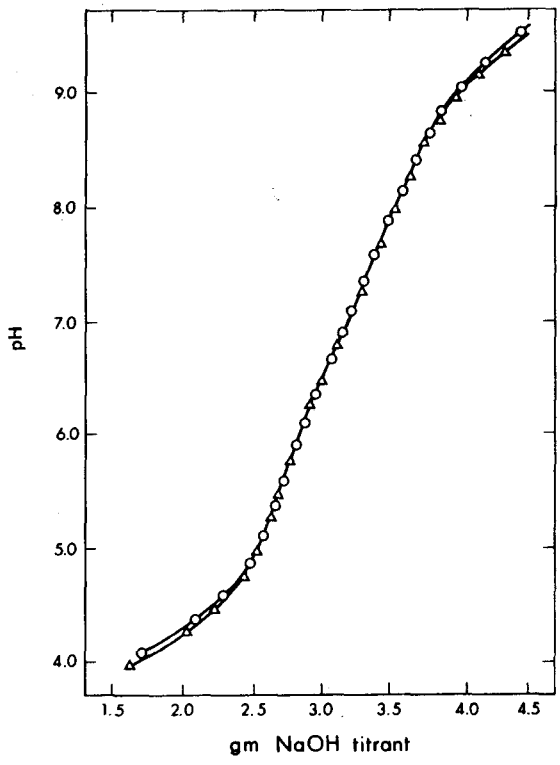

FIG. 7. Experimental (○) and simulated (△) titration curves for a solution containing 9.370×10^{-4} mol/kg of zinc and 5.308×10^{-3} mol/kg of aspartic acid. The titrant contained 0.3925 mol NaOH/kg titrant.

mass balances are used for extracting the formation constants. However, if the C_H mass balance is also used, the pH readings must be converted to hydrogen ion concentrations.

The comparison of data predicted by the model and the formation constants with the experimental data is the final important step in an application of the FICS method. The experimental titration curve for the zinc – aspartic acid system and that predicted from the formation constants obtained in this work for ZnL and ZnL_2^{2-} are shown in Fig. 7. The agreement is good over the pH region from which data were used for the evaluation of the formation constants. As discussed above, other complexes begin to form outside of the pH region 5 to 8.

The agreement between the acid dissociation constants and formation constants obtained in this work with those from other studies (Table 1) indicates that the FICS method can provide reliable equilibrium constants. It must be emphasized, however, that to obtain reliable results by the FICS method requires highly accurate data and careful design of the experiment to meet the theoretical requirements of the method (1, 3).

Received September 1, 1978

R. L. CLAIR and T. B. MCMAHON. Can. J. Chem. **57**, 473 (1979).

Reactions of trifluoromethoxide ion, CF_3O^-, with carboxylic acids have been examined. Facile fluoride transfer is observed to occur to the acids and a subsequent fluoride transfer equilibrium established in mixtures of carboxylic acids. From the equilibrium constant obtained for fluoride transfer acetic acid and propionic acid are found to have near identical fluoride binding energies. Further reaction between the acid solvated fluoride ions and the carboxylic acids is observed to occur resulting in HF displacement and formation of bicarboxylate anions. In mixtures of acetic and propionic acids acetate and propionate anion transfer equilibria are again established. An analysis of the energetics for these processes reveals that propionic acid binds the carboxylate anions more strongly than acetic acid by 0.1 to 0.2 kcal/mol.

R. L. CLAIR et T. B. MCMAHON. Can. J. Chem. **57**, 473 (1979).

On a étudié les réactions de l'ion trifluorométhylate, CF_3O^-, avec les acides carboxyliques. On a observé qu'un transfert facile de fluor vers les acides peut se produire et qu'il s'établit un équilibre de transfert de fluor subséquent dans des mélanges d'acides carboxyliques. En se basant sur des constantes d'équilibre obtenues pour les transferts de fluor, on a trouvé que les énergies de liaison des fluorures aux acides acétique et proprionique sont pratiquement identiques. On a observé que des réactions ultérieures se produisent entre les ions fluorés solvatés en milieu acide et les acides carboxyliques; il en résulte une élimination de HF et la formation d'anions bicarboxylates. Dans des mélanges d'acides acétique et proprionique, il se produit de nouveau des équilibres de transfert des anions acétate et proprionate. Une analyse des énergies impliquée pour ces processus révèle que l'acide proprionique lie les anions carboxylates plus fortement que l'acide acétique par environ 0.1 à 0.2 kcal/mol.

Introduction

During the last decade the development of various techniques for the study of gas phase ion–molecule reactions has led to a detailed and quantitative understanding of the intrinsic stabilities of ionic species and the fundamental nature of electronic substituent effects (for excellent review of gas phase ion thermochemistry, see ref. 1). In many cases relative orderings of ionic stabilities are found to be in sharp contrast to those inferred from comparable solution data indicating that for ionic reactions in solution the solvent plays an important, if not dominant, role in determining relative reactivity and stability. In order to bridge the gap between gas phase and solution data Kebarle and co-workers have used a pulsed electron beam high pressure mass spectrometer to study the energetics of individual solvation steps for a wide variety of positive and negative ions (2–4). Such studies involve measurement of equilibria between ions $A^{\pm}$ in the presence of a typical solvent molecule, S, in the gas phase and the solvated species $AS^{\pm}$, eq. [1].

$$[1] \qquad A^{\pm} + S \underset{\leftarrow}{\overset{[M]}{\rightleftharpoons}} AS^{\pm}$$

In a number of cases solvation of ions by several molecules has been characterized by observation of the successive clustering equilibria given by eq. [2] (5–7).

$$[2] \qquad A^{\pm}(S)^{n-1} + S \underset{\leftarrow}{\overset{[M]}{\rightleftharpoons}} A^{\pm}(S)^{n}$$

0008-4042/79/050473-05$01.00/0

From the relative magnitudes of the enthalpy changes associated with individual solvation steps the relative total solvation energies may be inferred (5) and from these a correlation between gas phase and solution stabilities of ions deduced.

The study of equilibria involving solvated or cluster ions such as [1] or [2] is usually inaccessible to ion cyclotron resonance (ICR) experiments since thermalizing collisions with some bath gas M must occur within a time short compared to the lifetime of the initially formed cluster. This cluster ion will be produced with an amount of excess energy equal to the solvent binding energy and this energy must be dissipated by collision with the bath gas in order that the species be observable and in order that true thermodynamic equilibrium be established. This condition necessitates the use of pressures beyond those usually available to the ICR trapped-ion technique[1] and thus makes observation of termolecular clustering equilibria untenable.

In spite of the difficulties associated with observation of normal clustering equilibria by ICR *relative* solvation equilibrium processes may be readily obtained by use of appropriate bimolecular reactions leading to production of solvated ions. In the presence of two or more appropriate solvents cluster ions thus formed may undergo 'solvent switching' reactions and a bimolecular solvent transfer equilibrium thus established. This then allows the determination of accurate *relative* single molecule solvation energies. If an accurate absolute value for some individual single molecule solvation energy is known then all additional solvation energetics may be referenced to this species and an accurate scale of absolute solvation energies may therefore be established.

One such appropriate bimolecular reaction leading to the production of solvated species is fluoride transfer. As part of our continuing program of investigation of ion–molecule reactions of fluorinated organic and inorganic molecules it was found that the trifluoromethoxide ion, CF_3O^-, generated by dissociative electron attachment to trifluoromethylhypofluorite, CF_3OF, acts as an efficient fluoride donor in the gas phase to both protic and Lewis acids, eq. [3] (9).

$$[3] \qquad CF_3O^- + A \rightarrow AF^- + CF_2O$$

If two acidic species are present which have comparable fluoride affinities a fluoride transfer equilibrium may be established, eq. [4],

$$[4] \qquad AF^- + B \rightleftharpoons BF^- + A$$

and from the measured equilibrium constant accurate relative free energies of fluoride attachment obtained.

The equilibrium technique also offers the advantage of allowing study of systems where the fluoride affinity of the acidic molecule is very large. In the high pressure mass spectrometric experiment clustering equilibria cannot normally be studied where the free energy of binding is greater than about 35 kcal/mol since this would necessitate conditions of temperature and pressure beyond the normal range of the apparatus. Unfortunately most fluoride attachment free energies for even moderately acidic molecules lie above this upper limit (3, 9).

In addition to straightforward fluoride transfer processes protic acids, HX, of greater gas phase acidity than HF will initiate HF displacement reactions, eq. [5], where HF is preferentially replaced by HX as the more favorable solvent for a general anion, Y^- (10).

$$[5] \qquad YHF^- + HX \rightarrow YHX^- + HF$$

Further, if both HX and HY are present and have similar gas phase acidities another series of solvent exchange equilibria will be established, eq. [6].

$$[6a] \qquad XHX^- + HY \rightleftharpoons XHY^- + HX$$

$$[6b] \qquad XHY^- + HY \rightleftharpoons YHY^- + HX$$

In the present publication we wish to report equilibrium measurements for fluoride transfer between pairs of carboxylic acids and the subsequent displacement of HF to produce both symmetrical and mixed bicarboxylate ions. From equilibria involving these bicarboxylate ions relative solvation energies of carboxylate ions by carboxylic acids are obtained.

Experimental

All experiments were conducted at ambient temperature (25°C) using an ICR spectrometer of basic Varian V-5900 design but which had been extensively modified to permit trapped-ion experiments according to the method of McMahon and Beauchamp (11). Details of the design and operation of the trapped-ion ICR technique and conventional ICR single and double resonance experiments have been described in detail elsewhere (12, 13).

Trifluoromethylhypofluorite was obtained from PCR Inc. Acetic acid and propionic acid were analytical grade reagents obtained from Aldrich. All materials were used without further purification other than simple freeze–pump–thaw cycles to remove volatile impurities.

CF_3OF is an extremely toxic material that reacts vigorously with many organic and inorganic compounds (14). It is extremely moisture- and light-sensitive and it was found most desirous to use it in darkened, passivated vessels. Fresh samples were prepared for use daily.

Mixtures of acetic and propionic acids were prepared manometrically and ranged in ratios from 5:1 acetic:propionic acid to 2:1 propionic:acetic acid. Experiments were carried out over a pressure range of 10^{-6} Torr to 10^{-5} Torr and a range of trapping times up to 1 s. Where possible rate constants of equilibrium reactions were determined using the time-delayed

[1]At the pressures necessary to observe termolecular clustering reactions in trapped-ion ICR experiments ion loss effects become significant, see ref. 8.

ion ejection technique (15). Equilibrium constant values reported are an average of six separate experimental determinations.

Results

The variation of relative abundances for a 1:4:5 mixture of CF_3OF:$C_2H_5CO_2H$:CH_3CO_2H at a total pressure of 5×10^{-6} Torr is shown in Fig. 1. The reaction sequence initiated by the CF_3O^- ion confirmed by double resonance experiments is summarized by eqs. [7] to [15].

[7] $CF_3O^- + CH_3CO_2H \rightarrow CH_3CO_2HF^- + CF_2O$

[8] $CF_3O^- + C_2H_5CO_2H \rightarrow C_2H_5CO_2HF^- + CF_2O$

[9] $CH_3CO_2HF^- + C_2H_5CO_2H \rightleftharpoons C_2H_5CO_2HF^- + CH_3CO_2H$

[10] $CH_3CO_2HF^- + CH_3CO_2H \rightarrow (CH_3CO_2)_2H^- + HF$

[11] $CH_3CO_2HF^- + C_2H_5CO_2H \rightarrow (CH_3CO_2)(C_2H_5CO_2)H^- + HF$

[12] $C_2H_5CO_2HF^- + CH_3CO_2H \rightarrow (CH_3CO_2)(C_2H_5CO_2)H^- + HF$

[13] $C_2H_5CO_2HF^- + C_2H_5CO_2H \rightarrow (C_2H_5CO_2)_2H^- + HF$

[14] $(CH_3CO_2)_2H^- + C_2H_5CO_2H \rightleftharpoons (CH_3CO_2)(C_2H_5CO_2)H^- + CH_3CO_2H$

[15] $(CH_3CO_2)(C_2H_5CO_2)H^- + C_2H_5CO_2H \rightleftharpoons (C_2H_5CO_2)_2H^- + CH_3CO_2H$

In addition to the reactions of CF_3O^- a reaction sequence arising from F^- is also observed given by eqs. [16] to [18].

[16] $F^- + CH_3CO_2H \rightarrow CH_3CO_2^- + HF$

[17] $F^- + C_2H_5CO_2H \rightarrow C_2H_5CO_2^- + HF$

[18] $CH_3CO_2^- + C_2H_5CO_2H \rightleftharpoons C_2H_5CO_2^- + CH_3CO_2H$

The carboxylate ions are found to be unreactive toward either CF_3OF or the carboxylic acids permitting the proton transfer equilibrium, eq. [18], to be established. The known value of the equilibrium constant for eq. [18] of 7.6 (16) was reproducible, providing a confirmation of the ratio of pressures of the two carboxylic acids.

Equilibrium constants obtained from steady state ionic abundances and the known ratio of carboxylic acids for eqs. [9], [14], and [15] are summarized in Table 1. Also included are thermodynamic data derived from these equilibrium constants. Entropy changes have been estimated on the basis of symmetry changes in the equilibrium reactions.

Some care was taken to insure that true thermodynamic equilibrium rather than a steady state had been reached for the reactions studied. Within limits of normal experimental error all equilibrium constants were found to be in good agreement for the range of concentration ratios, pressures, and reaction

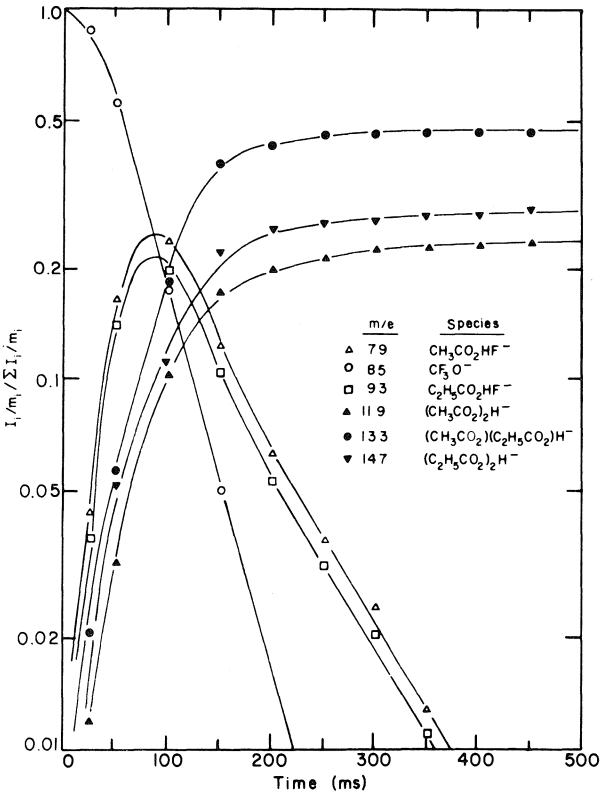

FIG. 1. Variation of relative ionic abundances with reaction time in a 1:4:5 mixture of CF_3OF:$C_2H_5CO_2H$:CH_3CO_2H at a total pressure of 5×10^{-6} Torr.

times studied. Cluster ions produced via exothermic bimolecular reactions become thermalized by a variety of processes analogous to those operative for proton transfer equilibria in low pressure ICR experiments. These are symmetric thermoneutral anion exchange reactions resulting in no observable reaction but diminishing any excess internal energy in the ionic species by a factor of one-half (17) and simple non-reactive collisional deactivation. In addition, although no quantitative data are available, radiative cooling may occur within the time scale of the trapped-ion ICR experiment.

For the fluoride exchange equilibrium, [9], the equilibrium constant was also determined from the ratio of forward and reverse rate constants obtained from time delayed ion ejection experiments (15). Within experimental error these rate constants are determined to be identical as $7.0 \pm 0.7 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}. The overall loss of *m/e* 79 and 93 via HF displacement proceeds with an average rate constant of $7.0 \pm 0.7 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1}. According to the analysis of Davidson *et al.* (18) this permits fluoride transfer equilibrium to be established and observed since the fluoride exchange is ten times faster than HF displacement.

TABLE 1. Equilibrium constant and thermodynamic data for anion exchange equilibria

	Reaction	K	ΔG^0 (kcal/mol)	ΔS^0 (eu)	ΔH^0 (kcal/mol)
[9]	$CH_3CO_2HF^- + C_2H_5CO_2H \rightleftharpoons C_2H_5CO_2HF^- + CH_3CO_2H$	1.0 ±0.1	0.0±0.05	0	0.0±0.05
[14]	$(CH_3CO_2)_2H^- + C_2H_5CO_2H \rightleftharpoons (CH_3CO_2)(C_2H_5CO_2)H^- + CH_3CO_2H$	2.5 ±0.2	−0.5±0.1	1.4	−0.1±0.1
[15]	$(CH_3CO_2)(C_2H_5CO_2)H^- + C_2H_5CO_2H \rightleftharpoons (C_2H_5CO_2)_2H^- + CH_3CO_2H$	0.75±0.1	0.2±0.1	−1.4	−0.2±0.1

Due to the kinetic complexity of the sequence of carboxylate exchange equilibria all of the rate constants for the two equilibria [14] and [15] cannot be extracted from the time delayed ejection technique. However, both k_{14} and k_{-15} may be obtained and are found to be $2.4 \pm 0.2 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} and $1.3 \pm 0.1 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}, respectively. Using the A.D.O. theory (19) the collision rate constants for the bicarboxylate ions are estimated to be 1.4×10^{-9} cm^3 molecule^{-1} s^{-1}. Thus each ion will undergo between five and fifteen non-reactive collisions for every reactive carboxylate exchange reaction which occurs. During the time scale for the experiment for the pressures employed over 100 collisions will have occurred and given this ratio of non-reactive to reactive collisions thermalization of the ions is insured. Combining the measured values of K_{14} and K_{15} with the rate constants k_{14} and k_{-15} allows the determination of the remaining rate constants of the equilibria as $k_{-14} = 9.8 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1} and $k_{15} = 9.7 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1}.

Discussion

Previous experimental correlations (3) and recent *ab initio* calculations (20, 21) support the very small differences in observed anion binding energies of acetic and propionic acids. Yamdagni and Kebarle (3) have proposed a relationship, eq. [19], between anion binding energies and gas phase acidities of a number of protic solvents.

$$[19] \quad D(BH{-}X^-) = aD(H^+{-}X^-) - bD(H^+{-}B^-)$$

Based on values of $D(F^-{-}HCl)$ and $D(F^-{-}H_2O)$ of 50 and 23 kcal/mol, respectively, the constants a and b of eq. [19] for fluoride binding may be determined to be 0.56 and 0.47. Using gas phase acidity values of 348.5 and 347.3 kcal/mol for acetic and propionic acids fluoride binding energies of 42.6 and 43.7 kcal/mol, respectively, are calculated. Given the rather approximate nature of the relationship the difference in fluoride binding energies may be regarded as in excellent agreement with our experimental results. Applying eq. [19] to acetate and propionate ion binding energies leads to the values summarized in Table 2. Also included are the predicted binding energies of these anions to HF.

TABLE 2. Calculated bond dissociation energies $D(X^-{-}AH)$ in kcal/mol*

	D for AH =		
X^-	HF	CH_3CO_2H	$C_2H_5CO_2H$
F^-	—	42.6	43.1
$CH_3CO_2^-$	19.3	30.0	30.5
$C_2H_5CO_2^-$	18.6	29.3	29.9

*Calculated from eq. [19], by the empirical method outlined in ref. 3.

Ab initio calculations of fluoride binding energies to formic and acetic acids (20, 21) of 59.7 and 59.5 kcal/mol, respectively, also support the experimentally observed small difference in fluoride affinities of carboxylic acids. The magnitude of binding energies calculated is greater than that predicted experimentally from eq. [19]. This is known to be a common occurrence for Gaussian 70 calculations of fluoride affinities (22, 23).

The *ab initio* geometry optimization for fluoride – carboxylic acid adducts yields a structure with linear O...H...F$^-$ bonds and a coplanar arrangement of all heavy atoms (23). An examination of O—H and H—F bond distances in these adducts reveals a long O—H distance and a short H—F distance indicating that these species may be more correctly regarded as carboxylate ions solvated by HF rather than fluoride solvated by carboxylic acids. This is consistent with intuitive expectation based on the greater gas phase acidity of carboxylic acids than HF. Viewed in this manner eqs. [10] to [13] are readily seen to be solvent displacement reactions where the weakly acidic solvent HF is replaced by carboxylic acid solvents of greater acidity. From the data of Table 2, the HF displacement reactions are seen to each be roughly 11 kcal/mol exothermic.

Ab initio calculations have also been carried out for the energetics and structure of the biformate ion which may be regarded as a model for the bicarboxylate ions (24). These studies yield a planar *trans* configuration of C_{2v} symmetry with a linear O···H···O bond and a binding energy $D(HCO_2^-{-}HCO_2H)$ of 29 kcal/mol. This is in excellent agreement with the

values for other bicarboxylate ions obtained from empirical correlations given in Table 2. These values show transfer of acetate from acetic to propionic acid, eq. [14], to be 0.5 kcal/mol exothermic and transfer of propionate from acetic to propionic acid, eq. [15] to be 0.6 kcal/mol exothermic. The difference in exothermicity of 0.1 kcal/mol is again in excellent agreement with our experimentally determined difference.

Conclusions

The results presented above demonstrate that the ICR trapped ion technique may be extremely useful in the study of bimolecular solvent exchange equilibria and in the generation of accurate relative single molecule solvation energies. The experimental data have been shown to be in good agreement with *ab initio* calculations and empirical correlations from other solvation studies. In addition replacement of HF by carboxylic acids in fluoride – carboxylic acid adducts has been shown to be exothermic and to proceed facilely. Further studies of solvation energetics involving solvents of markedly weaker gas phase acidity are currently in progress.

Structural changes at hydrophobic/hydrophilic interfaces induced by thermal changes and isotopic composition of the water

FRED Y. FUJIWARA[1] AND LEONARD W. REEVES[2]

Chemistry Department, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received August 24, 1978

FRED Y. FUJIWARA and LEONARD W. REEVES. Can. J. Chem. **57**, 478 (1979).

A lyomesophase prepared from decylammorium tetrafluoroborate, ammonium tetrafluoroborate, and water, which orients in a magnetic field perpendicular to the directors (type II), has been investigated with respect to the isotopic composition, H_2O/D_2O of the aqueous compartment at constant overall chemical composition. An effect of the isotopic composition of the water has been discovered, which influences the packing of the water and tetrafluoroborate ions at the interface. An interface structure transition occurs at ~14 mol% D_2O in H_2O. The ammonium ions, which do not form part of the first bound layer at the interface, are affected to a much smaller degree and the sudden changes in the direction of variation of nmr parameters are not observed for this ion. The interface structure at > 14 mol% D_2O evidently does include more remote participation of NH_4^+ ions.

Recent low angle X-ray diffraction studies, available to us, indicate that the mesophases which orient in magnetic fields have two levels of structure, the packing of amphiphiles in discrete anisotropic micelles and the super-packing of the micelles themselves. These studies now enable us to reinterpret other similar thermally induced structural changes in the interface, from results previously encountered, in the decylammonium chloride system. It is possible to have changes in the packing of water, amphiphiles, and ions at the interface without changes in the superstructure. Such changes in interface packing might well go undetected in a measurement of bulk properties but are revealed by measurement of nmr parameters for the oriented mesophase of different species involved in the interface structure. The isotope effect on structural packing at the interface is absent in two other mesophases investigated.

FRED Y. FUJIWARA et LEONARD W. REEVES. Can. J. Chem. **57**, 478 (1979).

On a étudié une lyomésophase préparée à partir de tétrafluoroborate de décylammonium, de tétrafluoroborate d'ammonium et d'eau qui oriente dans un champ magnétique perpendiculaire aux directeurs (type II); ces études ont porté sur la composition isotopique, H_2O/D_2O du compartiment aqueux à des compositions chimiques globales qui étaient constantes. On a découvert un effet de composition isotopique de l'eau qui influence l'arrangement de l'eau et des ions tétrafluoroborates à l'interface. Il se produit une transition de structure d'interface à ~14 mol% de D_2O dans H_2O. Les ions ammonium qui ne font pas partie de la première couche liée à l'interface, sont moins affectés et il ne se produit pas de changement soudain dans la direction de la variation des paramètres rmn de cet ion. La structure interfaciale à > 14 mol% de D_2O contient évidemment plus de participation à distance des ions NH_4^+.

Des études récentes de diffraction de rayons-X à petits angles qui nous étaient disponibles indiquent que les mésophases qui orientent dans les champs magnétiques ont deux niveaux de structure: l'arrangement des amphiphiles dans des micelles anisotropes définies et des super-arrangements des micelles elles-mêmes. Ces études nous permettent maintenant de réinterpréter d'autres changements de structures semblables induits d'une façon thermique dans l'interface à partir de résultats obtenues antérieurement dans le système de chlorure de décylammonium. Il est possible d'obtenir des changements dans l'arrangement de l'eau des amphiphiles et des ions à l'interface sans changement dans la super-structure. De tels changements à l'interface pourraient passer inapercus lors de mesures de propriétés globales; on les décèle toutefois par des mesures de paramètres de rmn de la mésophase orientée de différentes espèces impliquées dans la structure de l'interface. Il n'y a pas d'effet isotopique sur l'arrangement de structure à l'interface dans les deux autres mésophases étudiées.

[Traduit par le journal]

We have recently been able to show that some effects of ions and water at a hydrophobic/hydrophilic interface can be detected and interpreted by the study of nmr spectra of oriented lyomesophases (1, 2). It is clear, for instance, that the hydration of carboxylate head groups is the principal reason for the higher ordering of water molecules in the interface for those systems in which this head group is mixed in different proportions with pyridinium and trimethylammonium (1). These last head groups are

[1]Present address: Instituto de Quimica, Universidade Estadual de Campinas, UNICAMP, Campinas, S.P., Brasil.

[2]To whom all correspondence should be addressed.

0008-4042/79/050478-05$01.00/0

not strongly hydrated and systems in which the interface is rich in these groups are characterised by a low degree of order for the water molecule O—D axis as measured from the partially averaged deuterium nuclear quadrupole splittings (1, 2). By preparing mesophases that are oriented by the magnetic field but with variations in the chemical nature of the amphiphiles which compose the basic bilayer structure, the subtle study of interface water becomes accessible.

It is now possible to ascert from these previous investigations by us (1, 2) and by others (3) that the order parameter measured by nmr studies is a very sensitive tool for studying the interface region from the aqueous side. Water and ions which reside remotely from the interface have low degrees of order, while ions or molecules at the interface near the highly ordered head groups have higher order parameters. The relationship between head group order and that of H_2O and Cl^- ions was discovered by Fujiwara and Reeves some time ago (4) in a decylammonium chloride mesophase system. The experimental work now accumulated indicates that, on the nmr time scale, rapid exchange between remote and low ordered water and ions and the more ordered interface water and ions occurs. The linear concentration average is the observable in the measured order parameter. Sodium ion in the mixed detergent mesophase systems dodecanoate/decyltrimethylammonium has three available specific sites, including strong association with the carboxylate, association between a shared carboxylate/trimethylammonium, and sodium remote from the interface. The bromide counter ion on the other hand achieves appreciable order only at interfaces rich in the $—N(CH_3)^+$ head group. The differential ordering of different ions at chemically varied interfaces is clearly observable (1, 4).

Since hydrogen bonding to polar and ionic head groups by water molecules is evidently a strong intermolecular force contributing to interface ordering of water molecules, we have searched for an isotope effect at the interface between H_2O and D_2O molecules, there being a difference in hydrogen bond strengths for these species. Such an observation, as reported here, has important bearing on this same type of interface in biological systems.

Experimental

The mesophase studied, in which evidence for isotope effects has been found, is similar to one reported earlier by us in a study of the distortion of the BF_4^- ion in unaxial media (5). Preparation and purification of the required compounds have been previously described (5). Mesophases of type II (6, 7), which orient with directors perpendicular to the applied field, were prepared from decylammonium tetrafluoroborate, ammonium tetrafluoroborate, deuteriated and normal water. The water used in the preparation of the mesophase was varied in deuterium content from 0 to 100%. The composition of mesophases was not varied in the mol% of detergent, electrolyte, and water. Table 1 gives these compositions. The water was always acidified to 0.1 *N* HCl in order to inhibit exchange of deuterium and/or protons between the ammonium ions and water. Proton, ^{19}F, ^{11}B, and ^2D nmr signals were detected using a Varian HR60 or a Varian HA 100 spectrometer. The frequency of the carrier was 7.95 MHz for deuterium, 15.1 MHz for ^{11}B, 94.1 MHz for fluorine, and 100 MHz for protons. The spectra of ^{11}B and deuterium were calibrated by the audio side band technique (8). The random error on peak position assignment was as indicated in the table of splittings observed.

As the H_2O/D_2O content of the aqueous compartment of the mesophase was varied; four nmr parameters were measured. The quadrupole splitting was investigated for the deuterium in the water signal and for the ^{11}B in the tetrafluoroborate ion. In the latter case the signal is a triplet from $I = 3/2$ and the measured splitting was between adjacent peaks. The magnitude of the scalar spin–spin coupling and dipole–dipole coupling between ^{11}B and ^{19}F, $|D_{BF} + J_{BF}|$, was measured between adjacent peaks in the ^{19}F spectrum. The ^{1}Hmr spectrum of NH_4^+, NDH_3^+, $ND_2H_2^+$, and ND_3H^+ were examined to determine the magnitude of the scalar plus dipolar coupling between ^{14}N and protons ($|J_{NN} + D_{NH}|$).

In a search for other interface isotope effects a decylammonium chloride mesophase (9) as well as a mesophase based on sodium decylsulphate, decanol, water, and sodium sulphate (10) were examined. The results were negative in both cases indicating that such detectable effects as will be described here are a special and not a general case.

Results

The investigation of the four nmr parameters listed in the Experimental section were necessarily, under the conditions available, measured on different days. Some small temperature differences were recorded for the different nuclei.

In the case of the deuterium doublet splittings from the water, the measurements were deliberately made at temperatures in separate series which were 3° apart to exaggerate any effect of temperature variation. Other than a small change in the absolute

*Mol% of D_2O in H_2O used to prepare the mesophase is given in the first column. The deuterium quadrupole splitting '$V_Q(D_2O)$' for water is given for 26.9°C and 29.9°C. The fourth and fifth columns list the quadrupole splitting of boron-11 and coupling $|D_{BF} + J_{BF}|$ for the BF_4^- ion. The last two columns list the deuterium quadrupole couplings for the ammonium ion and also the value $|D_{NH} + J_{NH}|$.

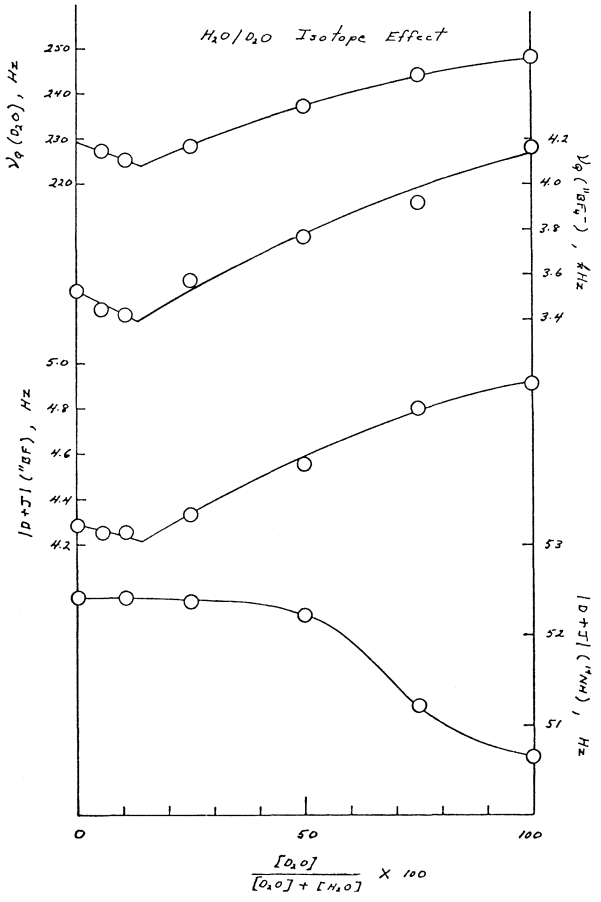

FIG. 1. Variations of the measured nmr parameters in mesophases of constant molar composition but varied fraction of deuterium content in the water compartment. The top curve shows the variation of the deuterium quadrupole splitting of the water against the left hand scale. The next curve down is the ^{11}B quadrupole splitting for the BF_4^- ion plotted against a scale on the right in kHz. The value of $|D_{BF} + J_{BF}|$ in Hz is the third curve from the top, against the scale in Hz at the left. The bottom curve was obtained from values of the proton ^{14}N coupling $|D_{NH} + J_{NH}|$ for the ammonium ion.

values of the quadrupole splittings measured, there was no change in the variation of nmr parameters with composition H_2O/D_2O of the water compartment, which variations clearly indicate an isotope effect at the interface. The sensitivity for detection of deuterium resonance in the ammonium ion was insufficient to measure the quadrupole splitting below 74% deuterium content in the water.

In Table 2 are listed the nmr parameters measured with the quoted error limits being the maximum obtained for random error over a typical set of repeated measurements. The results for all parameters measured are plotted in Fig. 1, selecting the deuterium quadrupole splittings for water at 29.9°C for display in the graph.

Discussion

The interface head groups in the system under study are cationic and the counter ions BF_4^- are of such a concentration that from the aqueous side a neutralising layer can be considered to be essentially complete at the interface. The ammonium ions, being positively charged, are not expected to be so closely bound at the interface sites. The number of water molecules per $-NH_3^+$ head group was 11.26 while the corresponding ratio for BF_4^- ions is 1.19 and for NH_4^+ ions 0.19. The effect of charge on an ion in determining its location at the charged interface or removed from it is an electrostatic consequence well known previously, but also illustrated in recent nmr measurements of parameter order by Lee *et al.* (1, 11).

The fact that the water and counter ion derive their order from the head group contact has been shown by Fujiwara and Reeves (4). In the case of similar mesophases of type II (6) formed using decylammonium chloride, ammonium chloride, with varied water content, the deuterium doublet splitting of the D_2O and the ^{35}Cl residual quadrupole coupling

vary linearly to a high degree of experimental precision with the deuterium quadrupole splitting measured for the $—ND_3^+$ head group of the decylammonium ion. Unlike the simple proportionality among the deuterium quadrupole splittings of the chain segments (4), there is a residual head group coupling constant of 500 Hz for the $—ND_3^+$ group when the water and ^{35}Cl splitting have become zero for the extrapolated state of very high water content (4). This intercept of residual order in the head group is the only difference in behaviour detected between hydrocarbon segments connected by chemical bonds to the head group and water or counter ions which are subject to the weaker hydrogen bonding, ion–dipole, and coulombic attraction at the interface.

The mesophases that have been the subject of study in this and our previous work (1, 2, 4, 6, 7, 9) have the significant property that they orient in an applied magnetic field normally used for nmr studies. It is now clear from recent low angle X-ray diffraction work that these lyotropic liquid crystals are not the classic superstructures reported for the middle (hexagonal) or neat (lamellar) mesophases (12, 13). Recent unpublished X-ray diffraction work[3] has shown that in the original type II mesophase reported by Lawson and Flautt (15) there are no repeated distances but the single diffraction spots are characteristic of two size factors in the colloid range. A distance of 38 Å is indicative of the bilayer thickness of an anisotropic micelle, while a diffuse diffraction has been associated with a water layer which has thicknesses distributed between 90 and 130 Å. The micelle sizes are evidently of finite dimensions and their shape and packing leads to the anisotropic properties of the uniaxial fluid. It is logical to associate at least one case of the type II (6) mesophase with disc-like micelles which orient with the plane of the disc in the magnetic field, and thus the director of the mesophase perpendicular to it. One case of the type I mesophase (6) can probably be associated with finite cylinders, which orient with their axes along the magnetic field, co-linear with the director of the mesophase. This is contrary to the speculations made before the X-ray work became available (4). In both type I and type II mesophases the extended hydrocarbon chains in the bilayer of the anisotropic micelles contrive to orient perpendicular to the magnetic field, that is, in the direction for minimum diamagnetic susceptibility. This is a rational driving force for the macroscopic orientation process in the magnetic field (16).

This recent understanding is a precursor to the consideration of isotope effects at the interface and it also serves to interpret more fully Fig. 4 of the work of Fujiwara and Reeves (4). A subtle change in slope of the dependence of $—CD_2$-segment quadrupole splittings with temperature is accompanied by an abrupt change in the deuterium quadrupole splitting of the D_2O in the same mesophase at the same temperature (32 ± 2°C). The dependence of the D_2O splitting on temperature changes slope from positive below 32°C to negative above 32°C. The fact that an anisotropic micelle could undergo an internal re-arrangement of amphiphile ion packing without affecting the superstructure packing of the micelles leaves us in principle with the possibility of a change in the structure of the interface without a phase change being strongly reflected in the superstructure or bulk liquid crystal properties. The liquid crystal depends for its anisotropic properties on the superstructure packing of micelles. The change in slope of the linear dependence of quadrupole splitting of deuterium in D_2O from positive below 32°C to negative above indicates a change in sign of the order parameter for the —O—D bonds. This must arise from a change in the hydration arrangement at the interface at which location the D_2O gains its order. This prior example of a subtle change in packing at the interface leads us to interpret the present results in a like manner.

The mesophase, used in this study, prepared from decylammonium tetrafluoroborate has some unusual features (4, 5). The ammonium ion ND_4^+ in a decylammonium chloride mesophase manifests a deuterium quadrupole splitting in the low range of ~7 Hz while in the mesophase containing tetrafluoroborate, the deuterium quadrupole splittings are found between 50 and 102 Hz (4, 5), being for the present mesophase ~85 Hz. This indicates that although the ND_4^+ ion is not in contact with the head $—NH_3^+$ groups, it is more distorted from tetrahedral shape in the tetrafluoroborate-containing mesophase (5). A reasonable conclusion would be that there is some association of the ammonium ions in the more remote part of a necessarily compact electrical double layer. It would be reasonable to assume that each $—NH_3^+$ head group is associated with about two water molecules in a strong hydrogen bonded association, while the BF_4^- ion must also enter into the interface structure. Using the fraction of the total water estimated at the interface and assuming non-interface water has zero degree of order a quadrupole coupling at the interface of ~1400 Hz can be computed assuming rapid exchange using the observed quadrupole couplings for water (Table 2). This is somewhat low, but the geometry of the interface association may involve

[3]L. Queiroz de Amaral, C. Pimentel, and M. Tavares. Private communication.

—OD axes being constrained to align near the magic angle of $\cos^{-1}(1/3)$ to the interface normal. The quadrupole coupling of —CD-groups adjacent to the ND_3^+ are indicative of the order parameter for rather rigid axes oriented in the plane of the interface (4) but with the freedom to take all orientations in this plane in very short time intervals.

The feature of the figure is the similarity in the position of a change in sign of the slope of the dependence of an nmr parameter on H_2O/D_2O content, close to 14% D_2O in the aqueous compartment, for the water and tetrafluoroborate ions. These parameters would be expected to have no dependence on isotropic content of the water or to have a very small but smooth variation without sudden changes or reversals in slope. These discontinuities can be interpreted as a change in the interface structure provoked by a change in the average hydrogen bond strengths and furthermore one which affects the arrangements of the water and the tetrafluoroborate ions. The ammonium ion has no direct involvement in this change in interface packing, but does show a small but smooth change in the parameter $|D_{NH} + J_{NH}|$. The value of J_{NH}, the scalar coupling between nitrogen-14 and protons, has been repeatedly measured in our previous work and is known to be $+52.24 \pm 0.05$ Hz. For mesophases which are rich in H_2O the figure shows that almost no distortion of the ammonium ion occurs. At high D_2O contents the value of D_{NH} is appreciable, reaching -1.59 ± 0.1 Hz at 100% D_2O in the aqueous compartment. The figure shows that the appearance of a dipole–dipole coupling between ^{14}N and protons in the ammonium ion is a smooth function of the D_2O content of the water and, furthermore, appreciable distortion of the ammonium ion occurs only after the subtle structural change at the interface, which involves the BF_4^- ions and water directly, has occurred. This is suggestive that although the NH_4^+ ion is not a species directly involved in the interface structure, it does play a secondary role in the Gouy or second hydration layer and thus is affected somewhat by a rather profound structural change associated with the BF_4^- and interface water arrangements. It would be premature at this stage of understanding of molecular and ionic packing at interfaces to venture specific models.

The bulk anisotropic properties of these liquid crystals, for example, diamagnetic anisotropy, are smaller than for thermotropic liquid crystals (14) and it is probable that with direct measurements of bulk physical properties parallel and perpendicular to the director, the changes in structural packing at the interface without changes in the superstructure packing of the large anisotropic micelles would pass undetected. This emphasizes the special and sensitive applicability of the nmr studies, which are appropriate for local microscopic studies of interface packing. These local structural changes must in their turn be of considerable importance in the chemical reactivity of ions, molecules, and amphiphiles at such interfaces. Such studies are being pursued.

New heteropolymetallic complexes of platinum(II) with palladium(II)-, gold(I)-, cadmium(II)-, or mercury(II)-chloride

FLAVIO BONATI[1] AND HOWARD C. CLARK

Guelph–Waterloo Centre for Graduate Work in Chemistry, Guelph Campus, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received August 10, 1978

FLAVIO BONATI and HOWARD C. CLARK. Can. J. Chem. **57**, 483 (1979).

The platinum(II) complex *trans*-$PtCl(PEt_3)_2(CH{=}NC_6H_4\text{-}p\text{-}CH_3)$ gives 1:1 complexes with $CdCl_2$, $HgCl_2$, and AuCl and a 1:2 *trans*-adduct with $PdCl_2$, thus showing its character as a monodentate, *N*-ligand.

FLAVIO BONATI et HOWARD C. CLARK. Can. J. Chem. **57**, 483 (1979).

Le complexe de platine(II), *trans*-$PtCl(PEt_3)_2(CH{=}NC_6H_4\text{-}p\text{-}CH_3)$, donne des complexes 1:1 avec du $CdCl_2$, du $HgCl_2$, du AuCl et un adduit 1:2 *trans* avec $PdCl_2$; ces résultats démontrent son caractère de ligand azoté monodentate.

[Traduit par le journal]

Introduction

The problem of synthesizing mixed-metal chain oligomers with two or more different metals in specific ligand sites has been successfully tackled by the use of a metal-containing molecule in which the coordinatively saturated central atom is kinetically inert and where at least one basic function is available to serve as a donor group. Such a molecule, in reaction with a suitable acceptor, may then give a heteropolymetallic complex. Examples of this approach can be found in the adducts formed between various salts and $(ligand)_2Pt[C(OR){=}NR']_2$, or $(ligand)_2Pt(1\text{-pyrazolyl})_2$ complexes (1, 2) or the $[Cl(R_3P)Pt\{P(=O)(OMe)_2\}_2]^-$ anions (3); in the adducts, the platinum-containing compounds act as chelating ligands. Other metal complexes have been used as monodentate, or bidentate but not chelating ligands, e.g. $(Ph_3P)Au[C(OR){=}NR']$ (4), *trans*-$(Et_3P)_2PtH(CN)$ (5), or $Hg[C(OR){=}NR']_2$ (4), respectively.

A new family of such ligands has recently (6) been prepared by the insertion of isocyanide into platinum–hydrogen bonds to give compounds of the type *trans*-$PtCl(PEt_3)_2[CH{=}NAr]$ (Ar = substituted phenyl), L, and after further reaction (7) *trans*-$Pt(PEt_3)_2[C(OMe){=}NAr][CH{=}NAr]$, **1**, These compounds are potentially monodentate and bidentate *N*-ligands, respectively. In particular, L is known (6) from both chemical reactivity and nmr spectroscopic data to be weakly basic and hence, in view of its availability, stability, and solution behavior (6, 7), its characteristics as a ligand have now been investigated.

[1]On leave of absence from the University of Camerino, Italy. Author to whom correspondence should be addressed at Istituto di Chimica Generale, via Venezian 21, 20133 Milano, Italy.

Experimental

The starting material, *trans*-$Cl(PEt_3)_2PtCH{=}NC_6H_4\text{-}p\text{-}Me$, L, was prepared from *p*-tolyl isocyanide and [*trans*-$HPt(PEt_3)_2CNC_7H_7]Cl$, according to the literature (6, 7). Evaporation was always carried out under reduced pressure (water aspirator) unless otherwise stated. Infrared spectra were recorded on a Beckman-IR-5A (NaCl region) or Perkin-Elmer 457 (low frequency region) spectrometer. Nuclear magnetic resonance spectra were recorded on a Bruker instrument operating at 24.88 or 60 MHz for ^{31}P or ^1H, respectively. Analyses were carried out by MHW, Phoenix, Arizona.

*$L{\cdot}HgCl_2$, **2***

An ether solution (10 mL) of mercury(II) chloride (87.8 mg; 0.32 mmol) was added dropwise to a stirred solution of L (122.5 mg; 0.21 mmol) in the same solvent (15 mL). A white crystalline precipitate separated out, which was filtered 2 h later and washed with ether to afford compound **2** (161 mg; 89% on platinum); it was purified by dissolving in methylene chloride (2.5 mL) and precipitating with ether (20 mL) to give the analytical sample (56.8 mg) which, upon heating, softened at 114°C and melted at 116°C with subsequent decomposition. The compound is soluble in $CHCl_3$, CH_2Cl_2, and acetone, although the chloroform solution becomes turbid upon standing.

*$L{\cdot}CdCl_2$, **3***

Compound L (161.4 mg; 0.278 mmol) was dissolved in methanol (10 mL) and $CdCl_2{\cdot}2.5H_2O$ (170.1 mg; 0.245 mmol) added. The suspension was stirred for 4 days and then evaporated to dryness. The residue was extracted with dichloromethane (10 mL) and the extract concentrated to 1 mL; addition of diethyl ether (4–5 mL) gave a white crystalline precipitate, **3** (111 mg; 52% on platinum).

*L·AuCl, **4***

To a solution of L (202.9 mg; 0.347 mmol) in dichloromethane (1.7 mL) solid (dimethylsulphide)chlorogold (**1**) (105 mg; 0.357 mmol) was added. The solution became brownish-yellow and some insoluble, finely divided material was removed by filtration. After addition of more methylene chloride (0.5 mL), ether was added (2 mL) and the clear solution was concentrated to half volume; more ether was added to give a total volume of 5 mL and the analytical sample (174 mg; 60% on platinum) separated as a snow-white crystalline precipitate, which was washed with ether. The compound is light sensitive and may become bluish-gray during filtration.

[b]Mercury.
[c]Chlorine.
[d]The analytical sample was bluish-gray owing to the action of light.

*L_2·$PdCl_2$, **5***

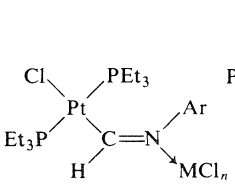
A dichloromethane solution (1 mL) of L (162.5 mg; 0.278 mmol) was mixed with a solution of bis(acetonitrile)-dichloropalladium(II) (36 mg; 0.14 mmol) in the same solvent (6 mL). The solution was then concentrated to 1 mL, ether (6 mL) added, and the yellow, crystalline compound, **5** (114 mg; 61%), was filtered.

Miscellaneous Experiments

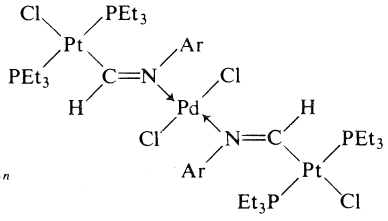
Only a dark, oily residue was left after solvent removal from an ether solution of L and $[(CO)_2RhCl]_2$. After evaporation of the reaction mixtures of L with zinc(II) chloride in ether, or with hydrated tin(II) chloride in methanol, compounds were obtained which cannot be adducts, because of the presence in the ir spectrum of the ν(NH) and δ(NH) bonds associated with the protonated form of L. A black precipitate was obtained on treatment of L with silver nitrate in methanol.

Results and Discussion

The reaction of L with suitable Lewis acids such as mercury(II) or cadmium(II) chloride, or the displacement by L of a volatile or labile ligand such as dimethylsulfide or acetonitrile from Me_2SAuCl or $(MeNC)_2PdCl_2$, gave readily the adducts **2**–**5** (Table 1).



2, M = Hg, *n* = 2
3, M = Cd, *n* = 2
4, M = Au, *n* = 2



5

These adducts are white or yellow (**5**) crystalline solids which decompose on heating between 110 and 190°C, on exposure to laboratory light (**4**), or slowly in solutions in chlorinated solvents (**2** and **3**). As a consequence, a molecular weight determination could be carried out only on **5** which was found to be monomeric in chloroform solution. Similar measurements for the mercury and cadmium derivatives, **2** and **3**, gave ratios of 1.27 and 1.44, respectively, between the experimental and calculated molecular weights, in agreement with the partial formation of chlorine-bridged structures involving tetrahedrally coordinated M(II) species.

In the 5000–625 cm^{-1} region, the infrared spectra of the adducts **2**–**5** resemble that of the free ligand L. The most meaningful difference is the shift to lower frequency of ν(C=N) consequent upon the participation of the nitrogen atom in dative bonding. This shift is of the order 15–80 cm^{-1} (see Table 2) and is accompanied by a simplification of the band which in L is broad and flanked by a broad shoulder, perhaps connected with the presence of the *syn* and *anti* isomers, whose existence in solution can be established by nmr spectroscopy. In the far infrared region, bands due to both Pt—Cl and M—Cl (M = Cd, Hg, Pd, or Au) stretching frequencies are expected in the 300 cm^{-1} region. Two such bands are observed in all cases except for the cadmium derivative **3**, where only one broad band is observed. In the absence of additional data, it is not possible to make definite assignments to ν(Pt—Cl) and ν(M—Cl).

Both the ^1H and ^{31}P nmr spectra show the expected resonances. In particular, those due to the formylic hydrogen (Pt—C—*H*) are found at fields (−0.68 to −2.06τ) which are very low in comparison with that for L (−0.6τ). The assignment is supported by the presence of satellites due to coupling to ^{195}Pt and to two magnetically equivalent phosphorus nuclei with ^2J(PtCH) and ^3J(PPtCH) comparable, but different, to those in the starting ligand L. It should be noted that, both for the formylic and the aryl hydrogens, each of the two sets of signals corresponds to one of the two isomers (*syn* and *anti*) of L, a fact that shows how easily such protons are influenced by even a modest change of environment. Thus, substantial changes in position are observed for the resonances of the C_6H_4 protons of the adducts

[a]The spectra were run in $CDCl_3$ at ca. 27°C using Me_4Si as internal reference or 85% phosphoric acid as external standard. Integration supports the assignments given in the table; s = singlet, c = complex, pq = pseudoquartet.
[b]Two isomers (*syn* and *anti* to the double bond) were found (6, 7).
[c]In the proton nmr the *anti*/*syn* ratio was found to be 2:1 (6, 7).
[d]The coupling was not observed probably owing to the broadness of the signal.
[e]In the ^{31}P nmr the intensity ratio of the signals due to the *anti* and to the *syn* form was found to be ca. 2:1.

2–**5**, while the *p*-methyl protons on the periphery of the molecules are scarcely affected. The phosphine–ethyl resonances are complex and spread over a wide range.

The ^{31}P spectrum (Table 3) of L shows two singlets, the more intense (ca. ×2) being assigned to the *anti* form in agreement with the results (5) of the proton nmr spectrum. Each singlet is flanked by satellites with ^1J(PtP) ~ 2.8 kHz. The adducts **2**–**5** give simple ^{31}P spectra, each showing only one singlet with satellites having ^1J(PtP) between 2.4 and 2.6 kHz. The two phosphorus nuclei are therefore magnetically equivalent, both in each isomer of the L and in the adducts **2**–**5**, in agreement with the requirements of a square planar arrangement about platinum and of a Pt—C=N plane perpendicular to it. In the case of the trinuclear compound **5**, the results are in agreement with a symmetric arrangement of the two platinum-containing ligands, L, around the palladium atom, an arrangement which also will minimize steric crowding around the innermost coordination centre. Hence, the ligand L coordinates only in one of the two possible forms in which it is capable of existing. It is highly likely that it coordinates in the *anti* form, since in this arrangement the metal atoms and their ligands will be kept on opposite sides of the C=N bond. Moreover, we previously found (4) by nmr studies that only this *anti* form interacts with lanthanide shift reagents. In any event, our results demonstrate the ability of the

compound L to act as an *N*-ligand which affords both binuclear and trinuclear complexes.

Polarizable acid–acid and acid–water hydrogen bonds with H_3PO_2, H_3PO_3, H_3PO_4, and H_3AsO_4[1]

MARTIN LEUCHS AND GEORG ZUNDEL

Physikalisch-Chemisches Institut der Universität München, Theresienstraße 41, D-8000 München 2, West Germany

Received July 24, 1978

MARTIN LEUCHS and GEORG ZUNDEL. Can. J. Chem. **57**, 487 (1979).

Hypophosphorous, phosphorous, phosphoric, and arsenic acids, pure and their aqueous solutions were studied by ir spectroscopy. Strong continuous absorptions observed with the pure liquid acids and with solutions containing less than one water molecule per acid molecule demonstrate that acid–acid hydrogen bonds in these systems are easily polarizable. The discussion of the PO and AsO bands as well as the discussion of the structure of the continuum demonstrates, however, that the degree of asymmetry of the energy surfaces in these hydrogen bonds is relatively large. It is shown that extended networks of such bonds exist. Due to the polarizability of these bonds, the proton motion in these bonds is strongly correlated. With addition of water, easily polarizable acid–water hydrogen bonds (I) $AH\cdots OH_2 \rightleftharpoons A^-\cdots H^+\text{-}OH_2$ (II) are formed. The energy surfaces in these hydrogen bonds are similar to those in the acid–acid hydrogen bonds. With further addition of water, proton boundary structure II receives noticeable weight, i.e., the degree of asymmetry of the energy surfaces in these bonds decreases due to addition of water molecules. The degree of symmetry of the energy surfaces in the acid–water hydrogen bonds increases in the series arsenic, phosphoric, phosphorous, and hypophosphorous acid.

MARTIN LEUCHS et GEORG ZUNDEL. Can. J. Chem. **57**, 487 (1979).

Faisant appel à la spectroscopie ir, on a étudié les acides hypophosphoreux, phosphoreux, phosphorique et arsenique à l'état pur et en solutions aqueuses. Les absorptions continues intense observées dans les cas des acides liquides à l'état pur et dans des solutions contenant moins d'une molécule d'eau par molécule d'acide démontrent que les liaisons hydrogène acide–acide dans ces systèmes sont facilement polarisables. Une discussion des bandes PO et AsO de même qu'une discussion de la structure du continuum démontre toutefois que le degré d'asymétrie des surfaces d'énergie dans ces liaisons hydrogène est relativement large. On a montré qu'il existe un réseau étendu de telles liaisons. Due à la polarisabilité de ces liaisons, une forte corrélation existe avec le mouvement des protons dans ces liaisons. Par addition d'eau, il y a formation de liaisons hydrogènes eau–acide facilement polarisables, (I) $AH\cdots OH_2 \rightleftharpoons A^-\cdots H^+OH_2$ (II). Les surfaces d'énergie de ces liaisons hydrogènes sont semblables à celles des liaisons hydrogènes acide–acide. Par addition subséquente d'eau, le poids statistique de la structure limite (II) du proton augmente, c'est à dire que le degré d'asymétrie des surfaces d'énergie de ces liaisons diminue à cause de l'addition de molécules d'eau. Le degré de symétrie des surfaces d'énergie des liaisons hydrogènes acide–eau augmente dans la série des acides arsenique, phosphorique, phosphoreux et hypophosphoreux.

[Traduit par le journal]

Introduction

Hydrogen bonds with double minimum energy surface or with an energy surface having a very broad flat well are easily polarizable (1–3). All these energy surfaces are time-dependent. The absorption of a quantum proceeds, however, so rapidly that with strong hydrogen bonds, as considered in the following, it does not change considerably during the absorption process. These easily polarizable hydrogen bonds are indicated by continuous absorptions in the infrared spectra (4, 5). Easily polarizable are hydrogen bonds of the type

$$B^+H \cdots B \rightleftharpoons B \cdots H^+B$$

i.e., bonds with which the acceptor and the donor are the same. A large number of bonds of this type is summarized in Table 1 of ref. 5. Recently, it was shown that not only hydrogen bonds with symmetrical structure are easily polarizable but also bonds of type (6–10)

$$B_1H \cdots B_2 \rightleftharpoons B_1^- \cdots H^+B_2 \qquad B_1 \neq B_2$$

In the case of acids with $pK_a < 1$, easily polarizable acid–water hydrogen bonds

$$AH \cdots OH_2 \rightleftharpoons A^- \cdots H^+OH_2$$

are observed if these acids can be studied at very high concentrations (water:acid ratio, $n < 1$) (11–13).

Results and Discussion

In this paper, the following acids are studied with which the proton is not so easily removed from the

[1]Dedicated to Professor G.-M. Schwab on the occasion of his 80th birthday.

0008-4042/79/050487-07$01.00/0

anion: hypophosphorous acid H_2POOH, pK_a 1.1 (14); phosphorous acid $HPO(OH)_2$, pK_a of the first dissociation step 1.8 (14); phosphoric acid $PO(OH)_3$, pK_a of the first dissociation step 2.2 (14) (hydrogen bonding in aqueous solutions at pH values in the range of the second and the third dissociation step has been studied in ref. 15). For arsenic acid, $AsO(OH)_3$, the pK_a of the first dissociation step is 2.5 (14).

Figure 1 shows selected spectra of aqueous solutions of these acids at various concentrations. For comparison, spectra of aqueous solutions of primary sodium salts are given in the regions in which these groupings show characteristic vibrations. The most important bands and their assignment taken from refs. 15–17 are summarized in Table 1.

Degree of Dissociation

Hypophosphorous Acid (Fig. 1 a *and* b*)*

In the spectrum of the 5.7 *M* solution (*n*, number of water molecules per acid molecule = 7.3) $\nu_s PO_2$ of $H_2PO_2^-$ groupings is observed as a weak band. A quantitative estimation shows that the degree of dissociation is less than 0.25 in the 0.5 *M* solution.

Phosphorous Acid (Fig. 1 c *and* d*)*

In the spectrum of the 4.5 *M* solution ($n = 9.7$) $\nu_s PO_2$ of $(PO_2OH)^-$ groupings is found as a very weak shoulder which becomes stronger with increasing dilution. A quantitative estimation shows that the degree of dissociation at 0.5 *M*, however, is less than 0.15.

Phosphoric Acid (Fig. 1 e *and* f*)*

With dilution, in the spectrum of the 2.5 *M* solution ($n = 19.4$) the band of $\nu_s PO_2$ at 1065 cm^{-1} arises as a weak shoulder indicating $(PO_2(OH)_2)^-$ groupings, i.e., removal of the first protons from the phosphoric acid molecules. The degree of dissociation in the 0.5 *M* solution is also less than 0.15.

*Arsenic Acid (Fig. 1*g*)*

No bands of dissociated groupings can be found even in the 0.8 *M* ($n = 57$) solution.

Polarizable Hydrogen Bonds and Liquid Structure

In all spectra in this study, strong continuous absorption is found. The absorbance of these continua is plotted in Fig. 2 as a function of the mole fraction of water x_{H_2O} and as a function of *n*.

Pure Acids

Figure 2 shows that the continua do not vanish when the last water molecule is removed. Arsenic acid could not be studied pure. No decrease of the absorbance, however, is found with this acid in the region $n = 1$ to $n = 0.5$.

These continua demonstrate that in the water-free acids easily polarizable hydrogen bonds are present.

$$POH \cdots OP \rightleftharpoons PO^- \cdots H^+OP$$

or

$$AsOH \cdots OAs \rightleftharpoons AsO^- \cdots H^+OAs$$

I II

In the preceding section, however, it was shown that all protons are present at the anions. Thus the weight of proton boundary structure II in these bonds is very low.

From theory it is known (18) that with increasing degree of asymmetry of the double minimum energy surfaces the residence time in the higher well decreases much stronger than the fluctuation frequency of the proton. Even when the residence time of the proton in the higher well is very short, the polarizability is smaller but still appreciable. This theoretical result was confirmed by results with carboxylic acid – N-base systems. It was shown with these studies (see Fig. 2 of ref. 6) that when the proton is largely located at the N-base the absorbance of the continuum is weaker but can still be observed. These continua, however, no longer extend to the low wave number region. In the case of the acids studied in this paper in the region below 1400 cm^{-1}, the very intense νPO, νAsO, and δOH vibrations are observed. Therefore, the decrease of intensity of the continuum toward smaller wave numbers cannot be observed.

The absorbance of the continuum in the large wave number region shows three maxima, one very

intense in the region 3000–2500 cm^{-1}, a less intense one in the region 2400–2200 cm^{-1} (the band at 2410 cm^{-1} with hypophosphorous acid and the band at 2410 cm^{-1} with phosphorous acid are caused by νPH vibrations), and finally a very broad maximum around 1600 cm^{-1}. This band-like structure is similar to the bands which are observed with asymmetrical acid–acid hydrogen bonds. Analogously, as with Hadži's ABC bands (19), with these acids, the broad band in the region 3000–2500 cm^{-1} is ascribed to νOH, and the band in the region 2400–2200 cm^{-1} to the 2δOH vibration which is intensified by Fermi resonance. With the acids studied in this paper, this band-like structure is most pronounced with arsenic acid. The above discussion of the dissociation behaviour shows that the proton is more strongly bound to the anion in the case of arsenic acid than in the case of the phosphorous-containing acids. Hence the energy surfaces in the acid–water hydrogen bond should be more asymmetrical with arsenic acid than with phosphoric acid. This is in good agreement with the result that the band-like structure is more pronounced with arsenic than with phosphoric acid.

All these results and considerations taken together show that the energy surfaces in these acid–acid hydrogen bonds are relatively asymmetrical but not so asymmetrical as to cause sharp bands instead of a continuum. Thus the polarizability of these bonds is much smaller than that of symmetrical hydrogen bonds with double minima, but much larger than the polarizability of asymmetrical hydrogen bonds.

Finally, it is important to consider the reasons why, in this pK_a region, hydrogen bonds between the acid molecules become so symmetrical that they are easily polarizable. The degree of asymmetry of the acid–acid bonds should decrease if the proton is less easily removed from the anions and if the hydrogen bond acceptor strength of the acceptor sites at the acid molecules increases. Hence, with increasing pK_a of the acids, a pK_a region should occur in which the

acid–acid hydrogen bonds are less asymmetrical. The prevailing results show that this is the case with the acids studied in this paper.

Liquid Structure of these Acids

Hypophosphorous Acid (Fig. 1a)

At 3570 cm^{-1}, a weak shoulder is found. This shoulder is caused by non-hydrogen bonded OH groups. The number of POH groups which cannot find an acceptor is very small. Thus extended chains of acid molecules are present

$$\begin{matrix} H & & H & & H \\ OPOH & \cdots & OPOH & \cdots & OPOH \cdots \\ H & & H & & H \end{matrix}$$

Because of the polarizability of these hydrogen bonds, the proton motion in these hydrogen bonds is strongly correlated (20).

Phosphorous Acid (Fig. 1c)

No band or shoulder of non-hydrogen bonded POH groups is found in the spectrum of the pure acid. Thus all POH groups are bound to PO groups of neighbouring acid molecules. Each PO group is an acceptor for two POH groups. Thus, an extended network of hydrogen bonds is present, because of the polarizability of these hydrogen bonds, the proton motion in these bonds is strongly correlated (20).

Phosphoric Acid (Fig. 1e)

In contrast to both other acids, a broad band occurs at the high wave number slope of the continuum. This band demonstrates that a large number of less strongly bound POH groups is present in the network of easily polarizable bonds between the phosphoric acid molecules. This occurs with phosphoric acid since the number of hydrogen bond donor groups is larger than the number of hydrogen bond acceptor sites.

Thus with all these water-free acids, chains or extended networks of easily polarizable bonds are present. Because of the polarizability of the hydrogen bonds, the proton motion in these bonds is strongly correlated (20).

Number of Water Molecules per Acid Molecule Less than One

When one water molecule per acid molecule is added the continua remain largely unchanged. This is true with regard to the structure of the continua as well as to its intensity. With H_3PO_4 and H_3PO_3, a small intensity increase is observed even though the molarity of the acid decreases.

These results show that the energy surfaces in the acid–water hydrogen bonds are very similar to those in the acid–acid hydrogen bonds. Although

$$POH \cdots OH_2 \rightleftharpoons PO^- \cdots H^+OH_2$$

or

$$AsOH \cdots OH_2 \rightleftharpoons AsO^- \cdots H^+OH_2$$

$$\text{I} \qquad\qquad \text{II}$$

are still easily polarizable, the weight of proton boundary structure II is so small that no anion bands are found in the spectra.

No scissor vibration band of the water molecules in this grouping is observed. Thus, this vibration couples with transitions of the proton of the easily polarizable hydrogen bond and merges in the continuum due to this coupling.

With hypophosphorous acid, the stretching vibration of the water molecules in these groupings is found as a broad band with maximum at 3370 cm^{-1}. Thus, the OH groups of these water molecules are bound via hydrogen bonds to acceptor sites of PO groups, and are in this way integrated in the network of hydrogen bonds of the liquid structure. With phosphorous acid, an intense shoulder is found at about 3600 cm^{-1}. This band is caused by the stretching vibration of non-hydrogen bonded OH groups of water molecules. Thus with this acid, a relatively large number of OH groups of water molecules is not, or only weakly, bound to their environment. With phosphoric acid, this number of non-hydrogen bonded OH groups of water molecules is even greater, as indicated by a very intense shoulder at about 3600 cm^{-1} (Fig. 1*a*). This series of increasing non-hydrogen bonded OH groups reflects the trend of the ratio of donor groups and acceptor sites with these acids.

Number of Water Molecules per Acid Molecule Greater Than One

With increasing n, the absorbance of the continuum decreases with all these acids since the concentration of easily polarizable acid–water hydrogen bonds decreases due to dilution.

As discussed in the section concerning the degree of dissociation, with increasing n, protons are removed from the anions. Before the protons transfer in the network of hydrogen bonds between water molecules, i.e., before $H_5O_2^+$ is formed, the weight of proton boundary structure II of the acid–water

$$POH \cdots OH_2 \rightleftharpoons PO^- \cdots H^+OH_2$$

$$\text{I} \qquad\qquad \text{II}$$

hydrogen bonds increases. As discussed with other systems (6, 8, 21–23) an increase of the weight of the polar proton boundary structure is caused by polar environments. Hence with these acid solutions, the additional water molecules cause the weight increase of proton boundary structure II. As shown by the

bands of the anions, removal of protons from the anions, i.e., a noticeable weight of proton boundary structure II, is observed, with hypophosphoric acid for $n = 7.3$ (Fig. 1*b*), with phosphorous acid for $n = 9.7$ (Fig. 1*d*), and with phosphorous acid for $n = 19.4$ (Fig. 1*f*). With arsenic acid, even in the 0.8 *M* solution, i.e., for $n = 57$, no removal of protons from the anions is found, within the limit of experimental error.

Conclusions

With the acids studied, the acid–acid hydrogen bonds

$$POH \cdots OP \rightleftharpoons PO^- \cdots H^+OP$$

or

$$AsOH \cdots OAs \rightleftharpoons AsO^- \cdots H^+OAs$$

I II

which are formed in water-free and highly concentrated solutions, cause very intense continuous absorbance, indicating polarizability of these hydrogen bonds. The weight of proton boundary structure II, however, is so small that no anion bands are found. Furthermore, the structure of the continuum indicates that the degree of asymmetry of the energy surfaces is relatively large. The energy surfaces in these bonds are, however, sufficiently symmetrical that these hydrogen bonds are still easily polarizable. The fact that the energy surfaces in these structurally asymmetrical hydrogen bonds become sufficiently symmetrical to be easily polarizable is explained as follows: with increasing pK_a, the protons are more strongly bound to the anions, and the hydrogen bond acceptor strength of the acceptor sites at the acid molecules becomes stronger. Both changes together cause a decrease of the degree of asymmetry of the acid–acid hydrogen bonds.

With hypophosphorous acid, extended chains of acid molecules, and with phosphorous, phosphoric acid, and arsenic acid, a network of hydrogen bonded acid molecules is present. The proton motion in these hydrogen bonds is correlated because of the polarizability of the hydrogen bonds. The number of less strongly bound OH groups increases from hypophosphorous to phosphoric acid, since the ratio of hydrogen bond donor groups to acceptor sites decreases in this series of molecules.

When one water molecule per acid molecule is added, easily polarizable acid–water hydrogen bonds

$$POH \cdots OH_2 \rightleftharpoons PO \cdots H^+OH_2$$

or

$$AsOH \cdots OH_2 \rightleftharpoons AsO \cdots H^+OH_2$$

I II

are formed. The energy surfaces of these bonds are very similar to those of the acid–acid hydrogen bonds. The OH groups of these water molecules are bound via moderately strong hydrogen bonds to acceptor sites at PO or AsO groups of acid molecules. The number of only weakly or non-hydrogen bonded OH groups increases, in the series from hypophosphorous to phosphoric acid, i.e., with increasing ratio of hydrogen bond donor groups to acceptor sites on the acid molecules.

With increasing number of water molecules per acid molecule, proton boundary structure II gains noticeable weight, and protons transfer in the network of hydrogen bonds formed between water molecules, i.e., they are present in $H_5O_2^+$ groupings. This removal of protons is indicated by anion bands, which become apparent in the spectra, for hypophosphorous acid at $n = 7.3$, for phosphorous acid at $n = 9.9$, and for phosphoric acid at $n = 19.4$. With arsenic acid no anion bands are found, even in the 0.8 *M* solution, i.e. at $n = 57$.

Materials and Methods

All phosphor acids, analytical grade, were purchased from Merck, Darmstadt, Germany. H_3PO_3 and H_3PO_2 were dried under vacuum and $P_2O_5 \cdot H_3AsO_4$ was prepared by mixing 3 mol As_2O_5 with 5 mol H_2O.

The ir spectra were recorded at 293 ± 1 K using a Perkin-Elmer double-beam spectrophotometer, model 325. The air in the spectrophotometer was dried and made CO_2-free by treatment with silica gel and sodium asbestos. The cells used had silicon windows and a wedge-shaped layer (mean thickness 9.5 μm) in order to avoid an interference pattern superimposed on the spectra. To take the wedge-shape into account, the absorbance was corrected as described in ref. 6. The absorbance of the continuum was determined as previously described (24) referring to the same background absorbance at 4700 cm^{-1}. Degree of dissociation was estimated comparing the spectra with bands of the respective anions in sodium salt solutions.

σ complexes as biophysical and biochemical probes. Part III.[1] Competitive demethylation and σ-complex formation in reaction of 4,6-dinitro-7-methoxybenzofuroxan with nucleophiles

ERWIN BUNCEL,[2] NOEMI CHUAQUI-OFFERMANNS, ROBERT Y. MOIR, AND ALBERT R. NORRIS[2]

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received July 11, 1978

ERWIN BUNCEL, NOEMI CHUAQUI-OFFERMANNS, ROBERT Y. MOIR, and ALBERT R. NORRIS. Can. J. Chem. **57**, 494 (1979).

4,6-Dinitro-7-methoxybenzofuroxan (**4**) reacts with MeONa–MeOH or with Et_2NH competitively by σ-complex formation and demethylation, by nucleophilic reaction at the aromatic and aliphatic carbon centers, respectively. Carbonate ion in $CHCl_3$ in the presence of 18-crown-6 polyether also results in rapid demethylation. The facile leaving group ability in these S_N2 displacements is consistent with the large acidity constant of 4,6-dinitro-7-hydroxybenzofuroxan (pK_a ca. -3.7), i.e., 4 pK units stronger than picric acid. Some unusual features exhibited in the nmr spectral characteristics of the σ-complexes are accounted for in terms of stereoelectronic effects.

ERWIN BUNCEL, NOEMI CHUAQUI-OFFERMANNS, ROBERT Y. MOIR et ALBERT R. NORRIS. Can. J. Chem. **57**, 494 (1979).

Le dinitro-4,6 méthoxy-7 benzofuroxanne (**4**) réagit avec le MeONa–MeOH ou avec le Et_2NH, en compétition avec la formation d'un composé σ et une diméthylation; les deux types de réactions proviennent respectivement de réactions nucléophiles au niveau des carbones aromatiques et aliphatiques. L'ion carbonate dans le $CHCl_3$ en présence de polyéther-6 couronne-18 conduit aussi à une diméthylation rapide. La facilité avec laquelle ces substitutions S_N2 se produisent est en accord avec la constante d'acidité élevée ($pK_a \approx -3.7$) du dinitro-4,6 hydroxy-7 benzofuroxanne qui est environ 4 unités de pK plus élevée que celle de l'acide picrique. On peut expliquer quelques caractéristiques inattendues des spectres rmn des complexes σ en termes d'effets stéréoélectroniques.

[Traduit par le journal]

In relation to our studies of σ complexes as biophysical and biochemical probes (1), we have been investigating σ-complex (2) formation in the nitro benzofuroxan and benzofurazan series, as this type of interaction has been implicated in explanation of the antileukemic activity of these compounds (3). We found (1*a*) that 7-methoxy-4-nitrobenzofuroxan (**1**) reacts with methoxide ion in dimethyl sulfoxide – methanol solution to yield the 5-methoxy adduct (**2**) in a kinetically preferred process and the 7-methoxy adduct (**3**) in a thermodynamically preferred process, Scheme 1; no other reactions were detected. Extension of the work to the 4,6-dinitro-7-methoxybenzofuroxan analog (**4**) has revealed a different type of behaviour which is the subject of the present report.

Results and Discussion

Reaction of 4 with Nucleophiles

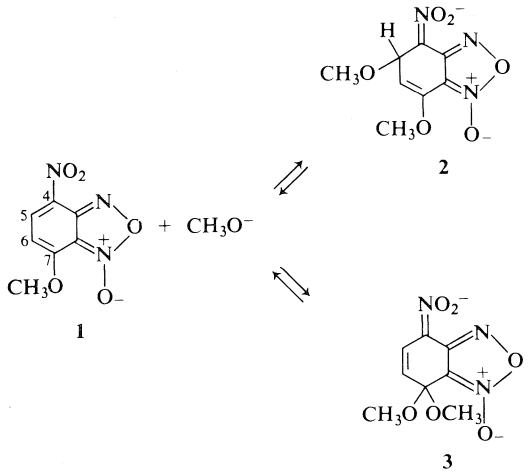
The course of the reaction of **4** with methoxide ion was studied by nmr and uv–visible spectroscopy. When a solution of **4** in CD_3OD was treated with CD_3ONa–CD_3OD (final concentrations, [**4**] = 0.11 *M*, $[CD_3O^-]$ = 0.07 *M*), the solution color changed from pale yellow to orange. The nmr spectrum taken 5 min after mixing exhibited the H-5 signal at δ 8.80 characteristic of **4** and a signal at δ 9.03 which was assigned to H-5 of the σ-complex **5**.[3] In addition, a signal at δ 3.30 was present and could be assigned to CH_3OD resulting from methoxyl exchange between solvent and substrate. This exchange apparently also occurs via the σ-complex **5**. As the reaction progressed further the signals at δ 8.80 and 9.03 due to **4** and **5** decreased while a signal at δ 9.18 correspondingly increased in intensity. The latter could be assigned to H-5 of the anion of 4,6-dinitro-7-hydroxybenzofuroxan, i.e. **6**, by comparison with an authentic sample in this medium. After 12 h at ambient temperature only **6** could be detected. The above observations can be explained by the reaction scheme given in Scheme 2, i.e., a rapid reversible formation of σ-complex **5** occurring concurrently with a slower

[1]For Part II see ref. 1*b*.

[2]Authors to whom correspondence should be addressed.

[3]The conventional techniques used in this work allowed only the thermodynamically stable product **5** to be observed and it is presumed that a kinetically preferred σ adduct would be detected using fast reaction techniques, as has been found in related systems (4).

0008-4042/79/050494-06$01.00/0



SCHEME 1

demethylation to yield **6**. Complete structural assignment for **5** was obtained by reacting **4** with CD_3O^- in CD_3OD–CD_3CN (6:94 v/v) which allowed the observation of H-5 as well as the methoxy signal of **5** occurring at δ 3.10, shifted from δ 4.23 in the substrate. The uv–visible spectral characteristics of **4**, **5**, and **6** are given in Table 1.

We sought to corroborate our results by investigating the reactivity of **4** with another common nucleophile, namely diethylamine. The reaction, in $CDCl_3$ solvent, was found by nmr to proceed as outlined in Scheme 2, i.e., initial rapid formation of a σ complex (H-5, δ 8.87) followed by slower formation of the demethylated product **6**. In contrast, reaction of **4** with triethylamine in $CDCl_3$ led to the rapid formation of **6**, with no indication of the formation of **5**, which is in agreement with the general finding that tertiary amines and nitroaromatic compounds do not normally give rise to stable σ complexes (2).

In view of the above results on demethylation it

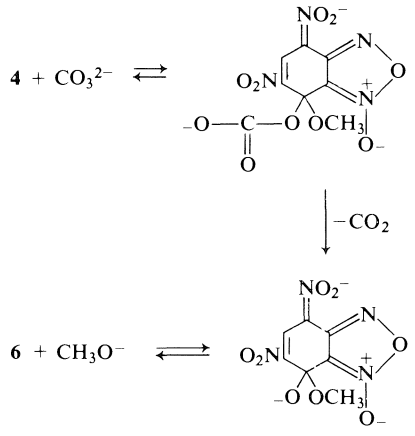
appeared of interest to examine a weaker nucleophile and carbonate ion was chosen for this purpose using the nonpolar solvent chloroform in presence of 18-crown-6 ether to render solubilization. Immediate reaction was found to occur on mixing the reagents and the initially recorded nmr spectrum showed that complete conversion to **6** had occurred. A possible mechanism for this reaction would invoke attack by carbonate ion at the aromatic carbon to form a metastable σ-complex intermediate which would lose successively CO_2 and CH_3O^- to yield **6** as shown in [1]:



[1]

Although we cannot exclude this possibility on the basis of present evidence, we do not know of a precedent for CO_3^{2-} acting as an effective nucleophile at aromatic carbon (5). Demethylation by nucleophilic displacement at the methyl carbon would describe the observations fully and is in agreement also with the other results reported herein.

There are several cases recorded in the literature for competitive demethylation and σ-complex formation in attack by methoxide ion, notably 3,5-dinitro-

[a]Values of chemical shifts, in Hz, as obtained on a spectrometer operating at 60 MHz (see Experimental).

2-methoxypyridine (6) and 2,4-dinitroanisole (7). The latter was found to react with piperidine also by S_NAr attack at the ring carbon competitively with S_N2 displacement at the methyl carbon (8), which bears some analogy to the present observations with diethylamine. It is interesting that 2,4,6-trinitroanisole reacts with methoxide ion under corresponding conditions only by σ-complex formation. There is however no report of demethylation by carbonate in these or related nitroaromatic systems.

Stereoelectronic Effects in σ-complex Formation

An unusual feature of the nmr spectral characteristics of the σ-complex **5** is the downfield shift, by 14 Hz, of the H-5 resonance with respect to this signal in the reactant **4** (Table 2). Upfield shifts accompanying σ-complex formation have been uniformly observed hitherto (2) and have been explained on the basis of the increased charge density in the anionic σ complexes. For example, in the conversion of 1,3,5-trinitrobenzene (TNB) **12** to its methoxy adduct **13**, an upfield shift of 46 Hz is observed in the signal for H_α. The corresponding upfield shift in the conversion of 2,4,6-trinitroanisole **10** to the 1,1-dimethoxy σ-complex **11** is only 24 Hz and examination of Table 2 shows that the value has been lowered (with respect to that from **12** and **13**) in two ways. In the first place, H_α in the reactant **10** has been shielded (with respect to H_α in **12**) by the introduction of methoxyl, an effect conventionally attributed to the conjugative electron release of methoxyl having a small effect at a *meta* position. In the second place, H_α in the complex **11** is deshielded (with respect to H_α in **13**) by the introduction of the second methoxyl, an effect explicable by the inductive effect of the second tetrahedrally-bound methoxyl.

In the benzofuroxan series, σ-complex formation is expected to lead to a relatively smaller upfield shift in H_α as a result of the greater electron withdrawing capacity of the annelated furoxan ring relative to a nitro group (*vide infra*), which leaves a smaller net negative charge to be accommodated on the benzene ring in the σ complex. This effect is seen on comparing ΔH_α in the conversion **8** → **9** (27 Hz) with the analogous conversion **12** → **13** (46 Hz).

Another factor must however be operating to account for the reversed shift in H_α in the conversion **4** → **5**. Examination of the data in Table 2 shows that the reversed shift in **4** → **5** is due both to relative deshielding of H_α in the product **5** and to relative shielding of the same hydrogen in the reactant **4**. The deshielding of H_α in **5** (36 Hz with respect to **13**) is somewhat larger than the sum (29 Hz) expected for the combined effects of introduction of a second

methoxyl (15 Hz from **13** → **11**) and of replacement of nitro by the furoxan ring (14 Hz from **13** → **9**). It is proposed that the additional factor is steric compression between the methoxyl group and the *peri* *N*-oxide function in **4** and the relief of this interaction in formation of **5**. The magnitude of the effect of steric compression in **4** is manifested in the 19 Hz upfield shift between **8** and **4**, whereas the corresponding shift on going from **12** to **10** is only 7 Hz.

An approximate summation of the electronic and steric effects can be performed by means of the data in Table 2 and the above considerations regarding H_α shielding. The electronic effect of the furoxan ring in σ-complex formation can be taken from the differences of the H_α shifts in the pairs **12**,**13** and **8**,**9** which yields $\Delta\Delta H_\alpha = 46 - 27 = 19$ Hz. The steric decompression effect is taken from the pairs **8**,**4** and **12**,**10**, giving $\Delta\Delta H_\alpha = 19 - 7 = 12$ Hz. The sum of two $\Delta\Delta H_\alpha$ terms, 31 Hz, then represents the estimated overall downfield shift of the H-5 resonance in formation of **5**, relative to formation of **11**, from their respective precursors. The observed effect on the H_α shift (Table 2), i.e., 24 + 14 = 38 Hz, is of the same order of magnitude.

The deshielding of H_α as a result of the steric compression factor can be explained as arising from the magnetic anisotropy of the nearer oxygen in the nitro group situated above H_α in the figures (9). This effect will be larger the more nearly coplanar the nitro group is with its attached ring and the closer that the group is made to approach H_α. In both **10** and **4**, the adjacent methoxyl will have some effect in forcing the *ortho* nitro group out of coplanarity but the effect will be larger in **4** because of the presence of the *N*-oxide function in the fused furoxan structure. Thus in **4** it is to be expected that the nitro group will be tipped away from H_α, with a consequent decrease in its deshielding effect larger than that in **12**, **10**, or **8**. However the tetrahedrally disposed pair of methoxyls in **11** and **5** will tend both to return the nitro group to a more nearly coplanar position, and to press it backwards against H_α. As before, this effect should be greater in **5** than in the less rigid **11**, with a consequent increase in the relative deshielding of H_α in the former. Slight changes in geometrical alignments usually have large effects at the short distances present in the H_α–NO_2 systems, so that the local anisotropy effects would be expected to dominate any further secondary electronic effects that might be postulated for this group of compounds.

Acidity of 4,6-Dinitro-7-hydroxybenzofuroxan

The remarkably facile demethylation process undergone by **4** shows that this nucleophilic displacement is associated with an unusually good leaving group. Since leaving group ability is related to the pK_a of the conjugate acid, it was of interest to determine the acidity constant for the equilibrium in [2].

[2] 
6 **7**

We have therefore studied the protonation of **6** in media of increasing acidity taking advantage of the different spectral characteristics of **6** and **7** in the uv–visible region. The resulting spectral changes are shown in Fig. 1 for sulfuric acid solutions of increasing concentrations. It is seen that the absorptions associated with the anionic species **6** (λ_{max} 438, 311 nm) decrease with acidity while the absorptions associated with the protonated species **7** (λ_{max} 358, 275 nm) correspondingly increase. Reasonably well defined isosbestic points occur at 372 and 328 nm. From the absorbance changes as a function of acid concentration one can estimate that 50% protonation occurs in a medium of ~45% H_2SO_4.

Since molarity (or % H_2SO_4) does not give a valid measure of the effective acidity of media in the moderately concentrated range, an operationally defined acidity function is used for this purpose. The acidity function appropriate to a protonation equilibrium of the charge type $A^- + H^+ \rightleftarrows AH$ is H_-, as given by (10) $H_- = -\log a_{H^+}(f_{A^-}/f_{AH})$. However it is now recognized that the protonation behaviour of anions of different structural types will not be subject to the same acidity function since the activity coefficient ratio will be structure dependent. Unfortunately literature data on H_- functions are available for only few structural types and over limited acidity ranges. An H_- acidity scale has been established (11) for the protonation of cyano substituted carbanions, eq. [3], covering the range up to 80% H_2SO_4. A more

[3] 
8 **9**

suitable acidity function for the process at hand would be given by the protonation of picrate anion or of the nitronate anion derived from the TNB–phenoxide σ complex (12) but these are limited to a lower acid concentration range corresponding to the smaller acidity constants of the conjugate acids (picric acid, $pK_a = 0.2$; nitronic acid, $pK_a = -1.2$). The anions **8**, are, however, charge delocalized

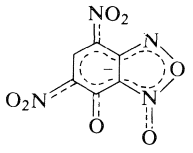
[b]Absorbance values of solutions with stoichiometric concentration of **4** = 4.24×10^{-5} *M* and cell path length of 1.00 cm.
[c]$I = [A^-]/[AH] = (A - A_{AH})/(A - A_{A^-})$ calculated at 438 nm using $A_{A^-} = 0.880$ and $A_{AH} = 0.290$.

species with negative charge essentially distributed on electronegative atoms and in this sense there is analogy with species **6**. Additionally, the degree of adherence to a given acidity function can be ascertained from the slope of the log I vs. H_- plot where I is the ionization ratio, i.e. $I = [A^-]/[AH]$. For a 'Hammett indicator' the slope should be unity.

The ionization ratios have been evaluated from the measured absorbance at each acid concentration. Thus $I = (A - A_{AH})/(A_{A^-} - A)$ where A is the measured absorbance whereas A_{AH} and A_{A^-} are the absorbance values due to the protonated and anionic species respectively at the given wavelength. The calculations were performed for absorbance values at 438 nm (λ_{max} for A^-) since this absorption undergoes the largest changes with acidity. The results for one set of determinations are given in Table 3. The plot of log I vs. H_- (11) while approximately linear showed appreciable deviation in the dilute acid range, suggesting that a differential medium effect is operating on the anionic species. Two such plots were constructed from two separate sets of determinations, yielding slope values of 0.75 and 0.80. The H_- values corresponding to log $I = 0$ were −3.7 and −3.8, respectively. A value for the pK_a could also be obtained by plotting A_{438} vs. H_- which yielded well defined sigmoid plots with H_- values at the inflexion point given by −3.8 and −3.6 for the two sets of experiments. In summary, a pK_a value of −3.7 is indicated by these results though it is apparent that the protonation behaviour is rather poorly represented by the given H_- function (11) of necessity employed.[4] Though the exact pK_a value may thus be somewhat in doubt, this does not affect appreciably our main conclusion.

The pK_a value of −3.7 for **7** when compared with the value 0.2 for picric acid shows that **7** is the stronger acid by ~4 pK_a units.[5] It follows from this result that the annelated furoxan ring has a powerful electron withdrawing capacity and that the anion **6** should be correctly written as



with negative charge delocalized over both rings. This conclusion is also in agreement with the results of quantitative studies on nucleophilic addition to benzofuroxan systems by Terrier and co-workers (13).

[4]It is recognized that the pK_a thus derived is not the thermodynamic pK_a and a more exact description of the experimental results should quote the H_- value (−3.7) at half-protonation.

[5]We note that the difference in the acidities of picric acid and **7** may not solely be ascribed to the difference in electron withdrawing power of the nitro and the furoxan moieties since picric acid is associated with an aromatic ring system whereas in **7** we have a diene type structure.

Concluding Remarks

In conclusion, it has been shown in this work that **4** is a methylating agent of unusually high reactivity (cf. ref. 14 for reactivity in alkylation by $ROSO_2Cl$ and $ROSO_2OAr$). As a corollary, **6** should be an exceedingly good leaving group and this is borne out by the observed pK_a value of -3.7 for the conjugate acid **7**. Also, the bifunctional reactivity of **4** in demethylation and σ-complex formation offers the possibility of evaluating selectivity in reactions of nucleophiles at aliphatic and aromatic carbon centers. Finally, the bifunctional reactivity of **4** could have implication in biological systems noting that the processes of methylation and σ-complex formation have both, separately, been considered of biological importance. The hypothesis that the observed antileukemic activity of nitrobenzofuroxan derivatives is the result of σ-complex formation by intracellular amino and thiol functions was discussed by us previously (1*b*) in light of the transformations undergone by the initially formed σ complex in the interaction of methoxide ion with 4-nitrobenzofuroxan.

Experimental

Materials

The purification of dimethyl sulfoxide and preparation of sodium methoxide solution have been described previously (1). Diethylamine was purified by conversion to the *p*-toluenesulfonamide which was recrystallized from dry ligroin (15*a*). Hydrolysis with aqueous HCl followed by treatment with NaOH and distillation three times under nitrogen yielded the purified diethylamine. Triethylamine was purified by treatment with acetic anhydride followed by distillation (15*b*).

4,6-Dinitro-7-methoxybenzofuroxan (4)

The preparation of **4** was effected by the nitration of **1**. To a solution of 1.2 g (5 mmol) of **1** (1*b*) in 25 mL 96% H_2SO_4 was added over 1 h 3 mL of nitrating mixture consisting of concentrated H_2SO_4 and fuming HNO_3 (3:1) while keeping the temperature at 0–5°C. Addition of the mixture to crushed ice gave a precipitate which was filtered, dried, and recrystallized from CCl_4 to give pale yellow crystals of product in 30% yield, mp 110°C; *m/e* 256. *Anal.* calcd. for $C_7H_4N_4O_7$: C 32.82, H 1.57, N 21.87; found: C 32.86, H 1.57, N 20.89.

4,6-Dinitro-7-hydroxybenzofuroxan (7)

This compound was obtained as the main product in the nitration of **1**, demethylation of **4** apparently occurring under the reaction conditions. The acidic aqueous solution obtained following the nitration and addition to ice was extracted with ether and the extracts were dried and evaporated to dryness. Recrystallization from benzene yielded orange crystals, mp 119°C; *m/e* 242. *Anal.* calcd. for $C_6H_2N_4O_5$: C 29.76, H 0.83, N 23.14; found: C 29.78, H 0.86, N 22.18.

The product obtained as above had identical physical properties to the product of demethylation obtained in the reaction of **4** with CH_3ONa–CH_3OH, CO_3^{2-}–18-crown-6–$CDCl_3$, or Et_2NH–$CDCl_3$.

Reaction of 4 with Nucleophiles

The course of the reactions was followed on a Bruker 60 MHz HFX-60 instrument using both the normal and the FT modes of operation. Tetramethylsilane was used as an internal standard. The species formed were also characterized by uv–visible absorption spectroscopy (Table 1).

pK_a Determination

Sulfuric acid solutions were prepared by dilution of Fisher reagent grade concentrated H_2SO_4 and standardized by titration with base. A stock solution of **7** was prepared in methanol and aliquots added to the H_2SO_4 solutions, the resulting solutions containing 0.2% CH_3OH by volume. The spectral measurements were performed using a Unicam SP800B and a Beckman 25 spectrophotometer.

JOAQUIM JOSE MOURA RAMOS, JACQUES REISSE, and M. H. ABRAHAM. Can. J. Chem. **57**, 500 (1979).

A new treatment of the solvent effect on the solvolysis of *tert*-butyl chloride is proposed. This treatment is based on activation free energy measurements and on transfer free energy measurements of the reactant (R) on the one hand and of a model (M) of the activated complex (AC) on the other hand. Solute–solvent interaction free energies for the reactant, the activated complex and the model compound are estimated. This estimation involves the calculation of the free energy of cavity formation of these various solutes (R, AC, and M) in all the solvents. These cavity terms, which are a function of the cohesive properties of the solvent and of the surface of the cavity do not reflect the electronic structure of the solute whereas the interaction free energy term does. The method we propose can be described as a new 'experimental' approach for the study of the charge separation in an activated complex.

JOAQUIM JOSE MOURA RAMOS, JACQUES REISSE et M. H. ABRAHAM. Can. J. Chem. **57**, 500 (1979).

Un nouveau traitement de l'effet de solvant sur la vitesse de solvolyse du chlorure de tertiobutyle est proposé. La démarche suivie est basée sur des mesures d'énergie libre d'activation et aussi sur des mesures d'énergie libre de transfert pour le réactif d'une part, pour une molécule modèle du complexe activé d'autre part. Les termes d'énergies libres associées à l'interaction solvant–soluté sont estimés et ceci tant pour le réactif (R) que pour le complexe activé (AC) ou pour le dérivé modèle (M). Ces estimations nécessitent le calcul préalable de l'énergie libre associée à la formation de cavités dans les solvants et ceci pour les trois types de solutés étudiés (R, AC et M). Ces termes de cavité qui sont fonction des propriétés de cohésion du solvant et de la surface de la cavité ne reflètent pas la structure électronique du soluté alors que les termes d'interactions, eux, reflètent cette structure. La méthode que nous proposons peut être décrite comme une nouvelle approche "expérimentale" pour l'étude de la séparation de charge dans un complexe activé.

In the solvolysis of *tert*-butyl chloride, the reactant (R) is only slightly polar, whereas the activated complex (AC) is highly polar. There is therefore a large solvent effect on the rate of solvolysis of this compound (1) and Winstein and Grunwald (2) used the log k values to define a solvent scale (the Y scale). An interpretation of the solvent effect on the solvolysis[4] rate was given by one of us in 1972 (3, 4). This work was based on the determination of free energies of transfer of the reactant, the activated complex, and a model compound (M) that was chosen because of its similarity to the activated complex. The ion pair $Me_4N^+Cl^-$ was selected as the model because it is highly polar and is about the same size as the activated complex. From plots of free energy of transfer of AC against free energy of transfer of M, it was concluded that the charge separation in the activated complex is less in apolar solvents than in polar solvents (3).

We propose, in the present paper, a new method of treatment for the effect of solvents on the rate of solvolysis of *tert*-butyl chloride. The method has been discussed in detail by two of us in the case of enthalpies of transfer (5, 6) and the formal treatment is the same for free energies of transfer. In this method, the free energy of transfer of a solute (X) is considered as the sum of two contributions: (*i*) the free energy required to create a cavity in the solvent and (*ii*) the free energy term associated with the solute–solvent interactions. Since it is the latter term

[1]For Part III, see ref. 6.

[2]Author to whom all correspondence should be addressed.

[3]Revision received May 31, 1978.

[4]For *tert*-butyl chloride the term solvolysis is normally restricted to the reaction in hydroxylic solvents, leading mainly to *tert*-butyl alcohol and ethers together with some isobutene. In aprotic solvents, the product is only isobutene. For convenience, we use in this paper the term solvolysis to cover both of these types of reaction.

0008-4042/79/050500-03$01.00/0

only that is important in the deduction of the nature of the solute, we hope that by separating out this term for the solvolysis reaction, a better understanding of the nature of the activated complex will be obtained than was possible by the previous method used.

The free energy change associated with the transfer of a solute (X) from the gas phase (g) to a solvent (s) can be described as in [1], where $|\bar{G}_{cav}|_s$ is the free energy needed to create a cavity in the solvent and $|\bar{G}_{int}|_s$ is the free energy term corresponding to the solvent–solute interactions (7).

$$[1] \qquad |\bar{G}_t|_s^g = |\bar{G}_{cav}|_s + |\bar{G}_{int}|_s$$

$|\bar{G}_{cav}|_s$ is a function of the cohesive properties of the solvent (8) and is also a function of the surface of X if the surface tension is used to characterise the cohesion of s (7, 9). For reasons well discussed (10), the free energy of reorganisation of solvent molecules around the solute can be considered as negligible and thus no other terms are needed in [1]. The calculation of $|\bar{G}_{cav}|_s$ (cal mol^{-1}) is carried out through [2],

$$[2] \qquad |\bar{G}_{cav}|_s = 9.761 \times K(r) \times V_x^{2/3} \times \sigma_s$$

with

$$K(r) = 1 + (V_s/V_x)^{2/3}(K_s - 1)$$

where σ_s is the surface tension of s (dyn cm^{-1}), V_x and V_s are the molar volumes of X and s (cm^3 mol^{-1}), and K_s is a numerical factor characteristic of each solvent and introduced to take into account the microscopic dimensions of the cavity (9, 11). K_s can be derived from the solvent free energy of vaporization at 25°C. The derivation is similar but not identical to the one which has been used to calculate the corrective coefficient in the case of $\bar{H}_{cav}$ (6). In the particular case of $\bar{G}_{cav}$, the estimation of K_s also requires the knowledge of the gain of translational entropy which follows the transition liquid → gas. The details concerning the method we use to calculate K_s and the theoretical basis of [2] will be discussed elsewhere.[5]

We calculated the cavity term $|\bar{G}_{cav}|_s$ for R, M, and AC and then took methanol as the reference solvent to obtain the relative cavity terms $|\bar{G}_{cav}|_s^{s_1}$. Combination with the transfer free energies given in ref. 3 then enables the relative interaction terms, $|\bar{G}_{int}|_s^{s_1}$, to be obtained. Since the charge separation in a given solute will be reflected in $|\bar{G}_{int}|_s^{s_1}$ but not in $|\bar{G}_{cav}|_s^{s_1}$, it seems clear that the calculated $|\bar{G}_{int}|_s^{s_1}$ terms will provide a more sensitive probe for charge separation than the overall $|\bar{G}_t|_s^{s_1}$ terms used previously (3).

[5]J. J. Moura Ramos and J. Reisse. To be published.

TABLE 1. Relative interaction free energies at 25°C ($\S_1$ = CH_3OH)

Solvents	$\delta\|\bar{G}_{int}\|_s^{\S_1}$ (kcal mol^{-1})[a,b] AC	M	R
1 CH_3OH	0.0	0.0	0.0
2 Pentane	17.9	24.6	2.3
3 Ether	11.1	18.0	2.0
4 Benzene	8.2	14.0	0.0
5 C_6H_5Cl	6.5	11.7	−0.6
6 Acetone	5.7	7.9	0.5
7 CH_3CN	2.6	3.9	−1.0
8 1-Butanol	2.3	3.4	0.7
9 1-Propanol	1.3	1.9	−0.4
10 Ethanol	1.3	1.7	−0.1
11 CH_3NO_2	1.0	1.4	−2.0
12 Water	−11.7	−12.5	−5.2

[a]The signs are such that a positive value corresponds to a system less stable (on a free energy scale) in this solvent than in CH_3OH.

[b]The estimated errors of $\delta[\bar{G}_{int}]_s^{\S_1}$ for AC and M are of the order of ±1 kcal mol^{-1}, probably lower for R. The accuracy of the values obtained for C_6H_5Cl and CH_3NO_2 may be lower owing to the greater difficulty in estimating the entropy associated with the cavity formation in these solvents (because of lack of internal pressure values for these solvents).

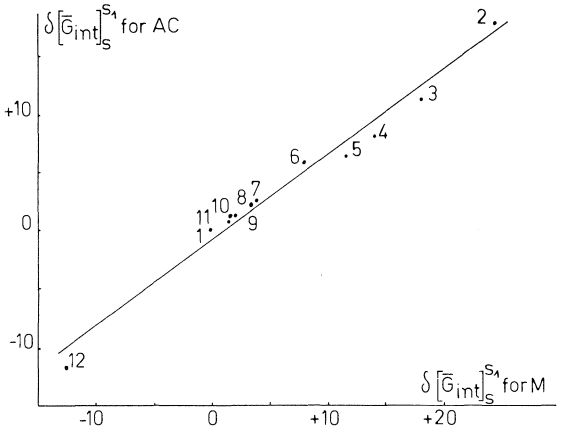

FIG. 1. The linear correlation between differential solvent–solute interaction enthalpy of AC and M ($\delta[\bar{G}_{int}]_s^{\S_1}$ in kcal mol^{-1}; numbers refer to Table 1).

In Table 1 are given the relative interaction free energies for R, M, and AC, and these interaction energies are compared directly for AC and M in Fig. 1. An excellent linear correlation exists between the $|\bar{G}_{int}|_s^{s_1}$ terms for AC and M over all the solvents studied (correlation coefficient: 0.99). The value of the slope (0.73) confirms again the highly polar nature (3) of the activated complex. The fact that the same straight line, Fig. 1, is obtained over all the solvents studied suggest that charge separation in the transition state must remain approximately constant.

Interestingly, this phenomenon does not seem to be unusual because in the Menschutkin reaction (3, 4) plots of the free energy of activation against various solvent parameters also yield straight lines over a wide range of solvents, so that, again the charge separation in the transition state seems to remain constant with change in the solvent.

The present method yields results that are quantitatively somewhat different from the previous results (3) although qualitatively similar. Futhermore, the present results are in excellent agreement with results of calculations, using the reaction field theory, that suggest in aprotic solvents the charge separation in the activated complex is 0.67 units (12).

^{1}H nmr spectroscopy has been used to demonstrate hydrogen–deuterium exchange in solutions of $NaBH_4/NaB^2H_4$ in diglyme and KBH_4/KB^2H_4 in 18-crown-6 ether/chloroform. Earlier observations of such exchange with $LiBH_4/LiB^2H_4$ in an ethereal solvent were confirmed. Spectra were simplified by broadband decoupling of deuterium, facilitating quantitative measurement of the degree of exchange.

IAN A. OXTON, A. GAVIN MCINNES et JOHN A. WALTER. Can. J. Chem. **57**, 503 (1979).

On a fait appel à la rmn du ^{1}H pour mettre en évidence l'échange hydrogène–deutérium dans des solutions de $NaBH_4/NaB^2H_4$ dans le diglyme et de KBH_4/KB^2H_4 dans un mélange de couronne-18 éther-6/chloroforme. On a pu confirmer des résultats antérieurs relatifs à de tels échanges dans $LiBH_4/LiB^2H_4$ dans l'éther. On a simplifié les spectres par découplage de deutérium; ce procédé a rendu plus facile la détermination quantitative du degré d'échange.

[Traduit par le journal]

Introduction

Hydrogen–deuterium exchange in tetrahydroborate salts has been accomplished previously by rather inconvenient means (1, 2), usually involving hydrogen–deuterium gas mixtures at high temperatures and/or pressures. Recently it has been shown that this exchange could be performed readily with lithium tetrahydroborate merely by dissolving mixtures of $LiBH_4$ and LiB^2H_4 in an ethereal solvent (3, 4). This type of exchange would appear to provide an attractive way to incorporate low concentrations of the $BH_3{}^2H$ ion into tetrahydroborate salts for their study by the isotopic dilution technique (cf. refs. 5 and 6 for other tetrahedral species). We found that the exchange process could be extended to sodium tetrahydroborate in diglyme solution and potassium tetrahydroborate in 18-crown-6 ether/chloroform solution. Smith *et al.* (4) had previously reported that sodium tetrahydroborate did not exchange in diglyme. The isotopically-exchanged tetrahydroborate species were monitored by ^{1}H nmr spectroscopy, with ^{2}H-decoupling to facilitate the observation of peaks separated by deuterium isotope-induced differences in chemical shift and boron–hydrogen spin–spin coupling constant.

Experimental

Preparation of Samples

(*i*) Lithium tetrahydroborate. Approximately 20 mg each of $LiBH_4$ and LiB^2H_4 (both from ICN Pharmaceuticals Inc., Plainview, NY) were dissolved in ca. 1.0 mL tetrahydrofuran-$^2H_8$ containing 1/6 hexafluorobenzene by volume (for nmr lock) at room temperature.

(*ii*) Sodium tetrahydroborate. Approximately equal amounts (ca. 50 mg each) of $NaBH_4$ (BDH Chemicals, Montreal, P.Q.) and NaB^2H_4 (Merck, Sharp and Dohme Ltd., Montreal, P.Q.) were dissolved at room temperature in ca. 2.0 mL diglyme-$^2H_{14}$ (bis(2-methoxyethyl) ether-$^2H_{14}$), to which was added a small amount of hexafluorobenzene (ca. 1/6 of the solution volume).

(*iii*) Potassium tetrahydroborate. 18-Crown-6 ether (640 mg) (Aldrich Chemical Co., Milwaukee, WI) was warmed until just molten (ca. 40°C), then roughly equal amounts (ca. 61 mg) of KBH_4 (Anachemia Chemicals Ltd., Montreal, P.Q.) and KB^2H_4 (Merck, Sharp and Dohme Ltd., Montreal, P.Q.) were dissolved in it.

No special precautions to dry samples or solvents were taken and spectra were recorded after the usual small amount of hydrogen had been evolved.

Nuclear Magnetic Resonance Measurements

All ^{1}H nmr spectra were recorded with a Varian XL-100/15 Fourier-transform spectrometer equipped with a Varian 620L computer. Conditions were: frequency 100.06 MHz, spectral bandwidth 1000 Hz, acquisition time 8.0 s (16 000 data points), flip angle 90° (23 μs pulse length), delay between pulses 15 s, unweighted free induction decay used for Fourier transformation, broadband decoupling of ^{2}H at 15.36 MHz by 0 to 180° phase modulation (at 40 Hz) of decoupling field ($\gamma H_2/2\pi$ ca. 310 Hz), ^{19}F internal lock to C_6F_6, reference to internal $(CH_3)_4Si$, temperature ca. 30°C, 5 mm diameter sample tubes, sample compositions as above.

Results and Discussion

(*i*) $LiBH_4/LiB^2H_4$ in tetrahydrofuran-$^2H_8/C_6F_6$. The ^{1}H nmr results were consistent with those previously reported (3, 4), although chemical shifts

[1]NRCC No. 17117.

0008-4042/79/050503-03$01.00/0

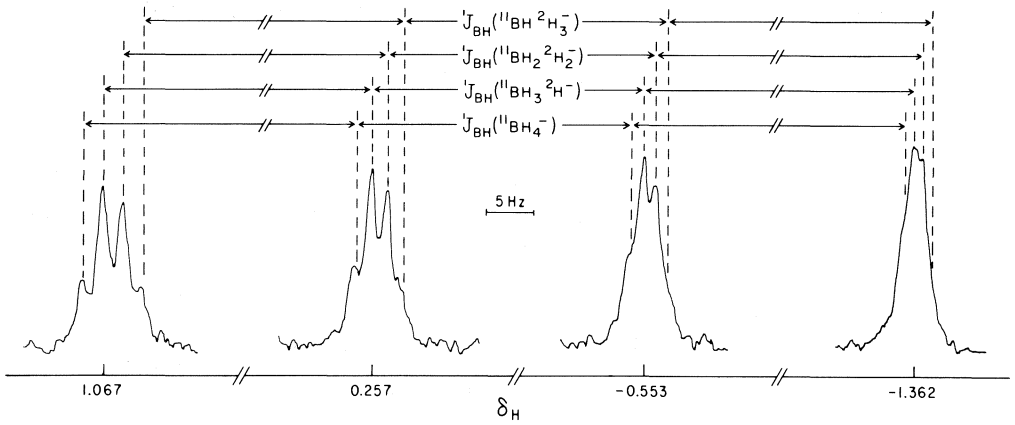

FIG. 1. ^1H nmr spectrum, ^2H-decoupled, of $K^{11}BH_4/K^{11}B^2H_4$ after complete $^1H \rightleftarrows {}^2H$ equilibration ($p = 0.62 \pm 0.02$). Individual components of the quartet due to ^{11}B–H coupling are shown on an expanded scale, with the distances between them truncated.

differed due to C_6F_6 in the solvent. The spectra were considerably simplified by decoupling ^2H. Hydrogens bonded to ^{11}B gave a quartet of quartets, very similar to that shown in Fig. 1 for $K^{11}BH_4/K^{11}B^2H_4$, due to ^{11}B–H spin–spin coupling and isotope effects on both the ^1H chemical shift and $^1J_{^{11}B-H}$ (4) for the species $^{11}BH_4^-$, $^{11}BH_3{}^2H^-$, $^{11}BH_2{}^2H_2^-$, $^{11}BH^2H_3^-$ (Table 1). Similar splittings of individual components of the septet due to ^{10}B–H spin–spin coupling were not resolved.

The ratios of intensities, e.g. $I(^{11}BH_4^-)$: $I(^{11}BH_3{}^2H^-)$ for each pair of peaks within the two well-resolved quartets at lowest field (as in Fig. 1) were in accord with the relation

$$I(^{11}BH_4^-):I(^{11}BH_3{}^2H^-):I(^{11}BH_2{}^2H_2^-):$$
$$I(^{11}BH^2H_3^-) = p^4:4p^3(1-p):6p^2(1-p)^2:4p(1-p)^3$$

where $p = 0.53 \pm 0.03$ is the probability of ^1H; $1 - p$ the probability of ^2H. This random distribution, which did not change with time or upon further heating, indicates a complete $^1H \rightleftarrows {}^2H$ exchange equilibration at (or below) probe temperature (30°C). Thus the degree of equilibration is readily monitored quantitatively using deuterium-decoupled ^1H spectra. Intensities should be unaffected, within error, by nuclear Overhauser enhancements due to irradiation of ^2H. The maximum theoretical enhancement is small ($\gamma(^2H)/2\gamma(^1H) = 0.077$) and would not be attained because of strongly competing dipolar spin–lattice relaxation via ^1H and/or ^{11}B. Saturation effects, due to differences in spin–lattice relaxation time in the tetrahydroborate species, were avoided by using a long delay time between radiofrequency pulses.

(*ii*) $NaBH_4/NaB^2H_4$ in diglyme-$^2H_{14}/C_6F_6$. The ^1H nmr spectrum was very similar to that of $LiBH_4/LiB^2H_4$ (Table 1) and, apart from chemical shift changes due to C_6F_6 in the solvent, agreed with previous results (4). In this case the peak intensities (see *i* above) showed only a slight degree of exchange after approximately 1 h at room temperature. It was necessary to warm the tetrahydroborate solution to ca. 60°C to attain exchange equilibration, indicated by peak intensities in agreement with the relation above (with $p = 0.64 \pm 0.02$) and unchanged after further heating at 75°C. This may explain why Smith *et al.* (4) observed $NaBH_4/NaB^2H_4$ exchange in a preliminary experiment, but were unable to reproduce this result.

(*iii*) KBH_4/KB^2H_4 in 18-crown-6 ether and chloroform-$^2H/C_6F_6$. The crown ether was chosen to test the premise that potassium tetrahydroborate would exchange, provided an ethereal solvent could be found. This salt is insoluble in simpler ethers but dissolves readily in molten 18-crown-6 ether, which is known to complex preferentially to K^+ (7). The resulting complex was heated at 175°C for 2 h and cooled to 20°C before being dissolved in 1.2 mL chloroform-^2H/0.1 mL C_6F_6. Nuclear magnetic resonance examination of this solution at 30°C showed no evidence of exchange, so it was heated at its boiling point (62°C) and periodically monitored by nmr, until $^1H \rightleftarrows {}^2H$ exchange equilibrium was attained (ca. 50 min). The peak intensities (see Fig. 1) were unchanged by further heating, the average value of p from four spectra being 0.62 ± 0.02.

‡Different solvents used for each compound; see text.

It is interesting to note the increasing difficulty of exchange on going from the lithium to the sodium and potassium salts, and the absence of exchange in the latter unless the crown ether complex is dissolved. The fact that each salt achieved a $^1H \rightleftarrows {}^2H$ exchange equilibrium corresponding to a constant p for all tetrahydroborate species, demonstrates that the free energies of the species in solution are indistinguishable. As regards the original intent of this study, to achieve isotopic exchange in the higher alkali tetrahydroborates, the most promising procedure would appear to be to secure isotopic equilibration in sodium tetrahydroborate, followed by metathetical reaction with a suitable salt of the desired cation in aqueous or alcoholic solution (8).

The kinetics and equilibrium of the hydration of phthalaldehyde[1]

ROBERT S. MCDONALD AND EARL V. MARTIN
Department of Chemistry, Mount Saint Vincent University, Halifax, N.S., Canada B3M 2J6

Received August 1, 1978

ROBERT S. MCDONALD and EARL V. MARTIN. Can. J. Chem. **57**, 506 (1979).

The equilibrium position and the kinetics of the extensive hydration of the title compound **1** have been investigated by spectroscopic (uv and nmr) techniques. The hydrate exists exclusively as the geometrically isomeric 1,3-phthalandiols and the hydration equilibrium constant is 7.7 ± 0.5 at 25°C. From the temperature dependence of the equilibrium position, values of the enthalpy and entropy of hydration were calculated. The reaction is general acid – general base catalyzed; the Brønsted α and β coefficients are both near 0.5. Catalysis by Zn(II) is observed. The mechanism of the reaction (which probably proceeds via rate-determining formation of the normal *gem*-diol followed by rapid cyclization) is discussed.

An analysis of the thermodynamic data for the hydration of a variety of carbonyl compounds reveals that the degree of hydration is normally determined by both enthalpy and entropy contributions to the free energy. However, the extensive hydration of **1** is determined solely by the enthalpy term. No hydration could be detected for benzaldehyde or the other isomeric dialdehydes.

ROBERT S. MCDONALD et EARL V. MARTIN. Can. J. Chem. **57**, 506 (1979).

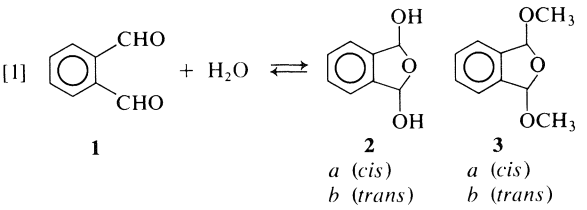
Faisant appel à des techniques spectroscopiques (uv et rmn), on a étudié la position de l'équilibre et la cinétique de l'hydratation du composé **1**. L'hydrate existe uniquement sous la forme des isomères géométriques du phtalanediol-1,3; la constante d'équilibre pour l'hydratation est égale à 7.7 ± 0.5 à 25°C. En se basant sur la variation de la position de l'équilibre avec la température, on a pu calculer les valeurs des enthalpie et entropie d'hydratation. La réaction subit une catalyse générale par les acides et par les bases; les valeurs des deux coefficients α et β de Brønsted sont près de 0.5. On a observé une catalyse par le Zn(II). On discute du mécanisme de la réaction qui procède probablement par la formation du *gem*-diol, comme étape déterminant la vitesse, suivie par une cyclisation rapide.

Une analyse des données thermodynamiques associées à l'hydratation d'un certain nombre de composés carbonylés révèle que le degré d'hydratation est généralement déterminé par des contributions à la fois de l'enthalpie et de l'entropie à l'énergie libre. Toutefois l'hydratation poussée de **1** résulte uniquement du terme enthalpique. On ne peut pas détecter d'hydratation dans le cas du benzaldéhyde ou d'autres dialdéhydes isomères.

[Traduit par le journal]

Reactions of phthalaldehyde (**1**) often involve chemical modification of both of the aldehyde groups. Thus, base-catalyzed condensations with active methylene compounds lead to 2-substituted-1-indanones (1) and reaction with amines yields a variety of compounds, most of which contain phthalimidine rings (2). Treatment with acidic methanol produces the cyclic bis-acetal, 1,3-dimethoxyphthalan (**3**) as one of the products (3).

During a recent study of the behavior of **1** in aqueous base, we observed anomalously low extinction coefficients (ε) in the 200–330 nm region of the uv spectrum. Other workers (4) have also observed this but interpreted these low ε values in terms of steric and electronic effects. However, these results, coupled with the recently reported proton nmr spectrum in D_2O (2) (which we had also observed independently), point towards extensive hydration of **1** in aqueous solutions [1] and, further, that the hydrate exists exclusively as the cyclic 1,3-phthalandiol **2**.



Seekles (5) reported the isolation of a compound proposed to be the monohydrate from concentrated aqueous solutions of **1**, although no structural information was given. Evaporation of aqueous solutions of **1** to dryness leads only to recovered starting material (2).

The position of equilibrium and the kinetics of the reversible hydration of carbonyl compounds have been studied extensively[2] but most of this work has

[1]Presented, in part, at the annual conference of the Chemical Institute of Canada, Winnipeg, Man., June, 1978.

[2]For an excellent review of much of the earlier work see ref. 6.

0008-4042/79/050506-11$01.00/0

been limited to aliphatic compounds since only these are normally significantly hydrated. Aromatic carbonyl compounds without strongly electron-withdrawing substituents are not significantly hydrated. Thus, although benzaldehyde itself has been estimated to have a hydration equilibrium constant (K_{H_2O}) of 1×10^{-2} (7, 8), values for the nitrobenzaldehydes are in the range 0.08–0.20 (7, 9, 10) whereas that for 4-pyridine carboxaldehyde is 1.5 (11).

Since **1** provides us with an example of an extensively hydrated aromatic aldehyde, we investigated in more detail the equilibrium position and the kinetics of the hydration reaction [1]. In the light of the unique cyclic structure of the hydrate, we were particularly interested in the thermodynamics of the equilibrium and the susceptibility of the reaction to catalysis by acids, bases, and a divalent metal ion. Hydration of aliphatic carbonyl compounds is known to be general acid and general base catalyzed (6). The uv and nmr spectra of benzaldehyde and the isomeric dialdehydes were recorded for comparison purposes.

Experimental

General

Melting points were taken on a Gallenkamp apparatus and are uncorrected. An Orion 601A pH meter equipped with a combination electrode was used to measure all pH values. The meter was standardized using Fisher certified buffer solutions at pH 1.00, 4.00, 7.00, and 10.00. Ultraviolet spectra were recorded on a Beckman model 24 spectrophotometer or on a Beckman DB-G instrument coupled to an Omniscribe recorder (Houston Instruments). Routine nuclear magnetic resonance spectra were taken on a Varian EM 360A 60MHz spectrometer. Those recorded at temperatures above ambient were taken on a Varian HA 100 instrument. Peak positions were measured in ppm (δ) relative to tetramethylsilane (TMS) as internal reference in $CDCl_3$ and relative to sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) in the aqueous solutions.

Materials

Benzaldehyde (Aldrich) was freshly distilled under vacuum (bp 43°C/2.5 Torr) immediately before use and stored under nitrogen until stock solutions were prepared. Isophthalaldehyde and terephthalaldehyde (Aldrich) were used as obtained. Phthalaldehyde (Aldrich) was twice recrystallized from ether – petroleum ether (30–50°C), the first time using decolorizing charcoal, to yield pale yellow needles, mp 56.5 58°C (lit. (12) mp 56–56.5°C, (13) mp 55.5–56°C).

Distilled water was used in the preparation of all solutions. Compounds used in the preparation of all buffer solutions were all reagent grade and used without further purification. Stock solutions of 1.0 and 0.10 *N* hydrochloric acid and sodium hydroxide were prepared by diluting the appropriate Fisher concentrate with freshly boiled, then cooled, distilled water.

The D_2O (Stohler Isotopes) was 99.8% enriched. 1,4-Dioxane (Fisher) used in the preparation of all stock solutions was purified before use by passage through a column of Super Grade I W-200 aluminum oxide (ICN Pharmaceuticals).

Kinetics

The rate of the hydration reaction [1] was measured by monitoring the decrease in intensity of the uv absorption bands which occurred when a few microlitres of a stock solution of **1** in dioxane were injected into water or buffered aqueous solution. The half-life for the disappearance of **1** in water was about 2 min. Identical (within experimental error) observed rate constants were obtained by monitoring the reaction at each of three λ_{max} values of **1** in water (i.e., at 222, 263 and 300 nm).

Buffer solutions were maintained at an ionic strength (μ) of 1.0 with KCl unless otherwise noted. All kinetic measurements were carried out at 28.0 ± 0.5°C in the cell compartment of the Beckman DB-G spectrophotometer described above. One-centimetre quartz cells with Teflon stoppers were used throughout.

Typically the kinetic run was initiated by injecting 5–25 μL of a 0.03 *M* stock solution of **1** in dioxane into 3.0 mL of buffer solution in a cuvette which had been preequilibrated in the cell compartment. After rapidly mixing the cell contents, the absorbance of the solution at the preselected wavelength was traced out on the recorder. The reaction was monitored over at least 4 half-lives and an 'infinity' absorbance was taken after at least 10 half-lives. Pseudo-first-order rate constants (k_{obs}) were then obtained from the slopes of the semi-logarithmic plots of ($A - A_\infty$) vs. time in the usual way. The kinetic plots were linear up to at least 80% reaction. Quoted rate constants are the average of at least duplicate determinations; agreement between replicate runs was normally within 5%. The pH of the kinetic solution was taken immediately after the run. Using this technique we were able to measure reliably the rates of reactions having half-lives as short as 4 s.

Varying the initial substrate concentration over the range $0.5–2.5 \times 10^{-4}$ *M* had no effect on the k_{obs} value. Similarly, the presence of up to 1% dioxane, introduced by injecting the substrate as a stock solution in dioxane, had no observable effect on the rate.

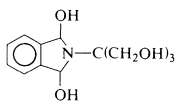
Runs were monitored at 263 nm in the carboxylate buffers and at 222 nm in the other buffer solutions. A steady A_∞ was obtained in all solutions except those in which tris(hydroxymethyl)aminomethane was a component of the buffer. In these cases, the absorbance continued to decrease very slowly even after 10 half-lives of the very rapid hydration reaction. This is presumably due to Schiff's base formation between the residual dialdehyde and the primary amine.[3] Choosing an A_∞ after 10 half-lives of the initial hydration reaction gave linear kinetic plots up to at least 2 half-lives for this reaction.

Results and Discussion

Hydration Equilibrium

As pointed out in the Experimental, fairly rapid decreases in intensity of the uv absorption bands of **1** were observed when a few microlitres of a stock

[3]We thank a referee for making the alternative suggestion that this absorbance decrease may be due to the formation of compound **7**. Compounds of this type have been detected (2) when **1** reacts with primary amines in ether and would be expected to absorb only weakly at these wavelengths.



7

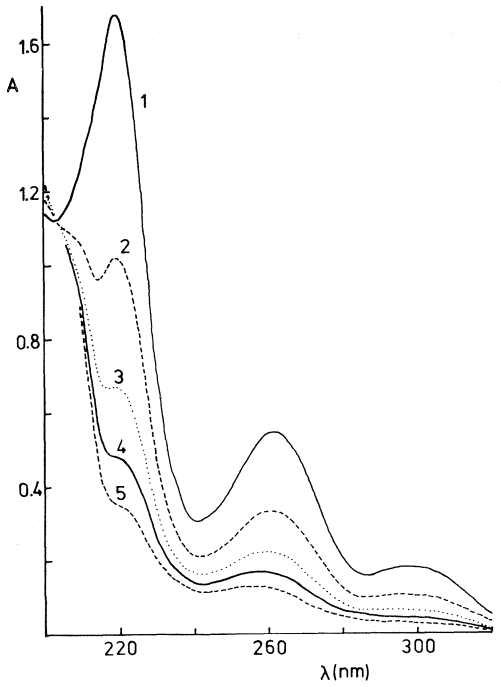


FIG. 1. Repetitive scans of the uv spectrum of **1** (1.0×10^{-4} *M*) in water, $\mu = 0$, 25°C. Scans (from 360 nm) were: *1*, 30 s; *2*, 170 s; *3*, 320 s; *4*, 500 s; *5*, 1100 s (times after mixing). The last scan represents the final spectrum in water.

solution of substrate were injected into water. The results of a series of repetitive scans are shown in Fig. 1. Extinction coefficients calculated from the residual (final) absorbances and those determined at the three λ_{max} values extrapolated back to the mixing time (initial) from kinetic runs are reported in Table 1. Also included in Table 1 are the spectral data for **1** in dioxane and methanol and that for benzaldehyde and the other isomeric dialdehydes in these three solvents.

It now seems clear that the very low absorbances of **1** in aqueous solution, rather than being due to steric inhibition of resonance (4), are indicative of extensive hydration. Correcting the final absorbance values at 263 and 300 nm for the small absorbance due to hydrate at these wavelengths,[4] we can calculate that there remains 10.5 ± 1% free dialdehyde at equilibrium in aqueous solution at 25°C. This compares remarkably well with results from nmr (below) which gives more direct and accurate information on the equilibrium position.

The 'initial' spectrum of **1** in water is similar to that in dioxane. For the other aromatic aldehydes, a change in solvent from dioxane to water causes only a small shift in λ_{max} and less than a 10% change in ε. However, owing to the uncertainty of comparing ε values in different solvents, we can only conclude that no spectral changes associated with appreciable (greater than 10%) hydration is occurring for any of these compounds. Spectra recorded immediately after mixing and after 30 min were superimposable.

The spectra in methanol were all recorded at least 30 min after mixing (corresponding to 'final' spectra). Absorptions associated with the carbonyl group have ε values significantly lower in methanol than those in dioxane or water. This is interpreted in terms of hemiacetal formation; the lowering of intensity of the $\pi \rightarrow \pi^*$ and the $n \rightarrow \pi^*$ bands of benzaldehyde by 10% is completely consistent with the equilibrium constant for hemiacetal formation in methanol of 0.09 (14). This value is expected to increase for benzaldehydes with electron-withdrawing substituents and the spectra for the *meta* and *para* dialdehydes in methanol are certainly in accord with more extensive hemiacetal formation. The spectrum of **1** in methanol shows even weaker absorptions than it does in water; nmr results indicate directly that less than 5% exists as the free dialdehyde and that the predominant products are the geometrical isomers of 3-methoxyphthalan-1-ol.

We have taken the residual absorbance (A_∞) at 222 or 263 nm of the aqueous solutions of **1** from the kinetic runs as a measure of the amount of free dialdehyde remaining in the solution. We find no significant or systematic shifts in the position of equilibrium with changes in ionic strength from 0 to 1, in HCl solution up to 0.01 *M*, or in the presence of any of the buffers (except Tris; see Experimental for an explanation) up to a concentration of 1.0 *M* and over the pH range 2.3–10.5 even where the rates were too rapid to be followed by our conventional techniques. In solutions of pH greater than 10.5, systematic absorbance decreases at 260 and 300 nm were observed up to 1.0 *M* NaOH. We interpret this behavior in terms of ionization of the hydrate [2] and have been able to assign a pK_a of 11.6 ± 0.2 to **2** at an ionic strength of 1.0 at 25°C. Further work is underway on the chemistry of **1** and **2** in more

[2] 
2

strongly basic solutions where we can also observe the much slower intramolecular Cannizzaro reaction leading to the *o*-hydroxymethylbenzoate ion.

Information on the structure of the hydrate comes

[4]The hydrate of structure **2** is assumed to have ε values in aqueous solution similar to those for *o*-xylene (i.e., $\varepsilon_{265} \approx 200$, $\varepsilon_{300} \approx 0$).

TABLE 1. Ultraviolet absorption data for benzaldehyde and the isomeric dialdehydes

Compound	Solvent[a]	λ_{max}[b] (nm) (ε)

[a]D = 1,4-dioxane, M = methanol, W = water.
[b]Errors are estimated to be ± 1 nm in λ_{max} and ± 5% in ε. The symbol sh denotes a shoulder.
[c]The initial (i) ε values for **1** in water were obtained from absorbance values in kinetic runs extrapolated back to the mixing time.
[d]The final (f) ε values were obtained from the spectrum after at least 10 half-lives of the hydration reaction.

from nmr spectral results. The spectrum of a saturated solution of **1** in D_2O is shown in Fig. 2. Clearly only residual peaks due to free dialdehyde are present (multiplet centred at δ 7.90, aromatic; δ 10.33, singlet, C*H*O). However, three new singlets have appeared at δ 6.27, 6.61, and 7.49 integrating in the ratio 1:1:4. These new signals are reasonably interpreted (2) in terms of extensive hydration where the hydrate exists exclusively as the geometrically isomeric 1,3-phthalandiols **2**. The spectrum cannot be interpreted in terms of 'normal' hydration at one or both of the aldehyde groups or a mixture of these forms with unreacted **1**. Furthermore such hydration would not be expected to occur to any significant extent from results of the other isomeric dialdehydes. As expected the aromatic protons of **2** resonate to higher field than those of **1** and are observed to be coincident at δ 7.49 for the *cis* and *trans* isomers. By analogy to assignments of the methine proton signals for the corresponding dimethyl acetals **3** (15), the δ 6.27 signal is assigned to the *cis* isomer and the δ 6.61 signal to the *trans* form. Multiple integrations over the two methine proton signals reveal a *cis* to *trans* ratio of 1.02 ± 0.06 (average of seven determinations).

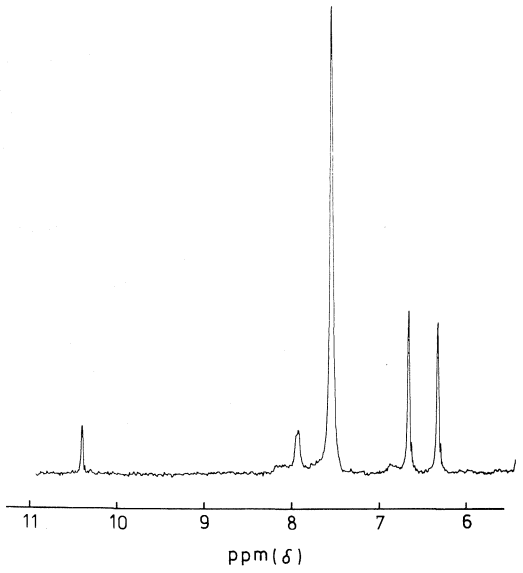

FIG. 2. The proton nmr spectrum of a saturated solution of **1** in D_2O at 25.5°C (relative to DSS at δ = 0.00).

The ratio of the integrals over the combined hydrate methine signals to that for the free dialdehyde at δ 10.33 reveal a hydrate to aldehyde ratio of 88.5:11.5 (±0.6%; average of seven determinations) at 25.5°C (EM 360A probe temperature). This corresponds to a hydration equilibrium constant in D_2O (K_{D_2O})[5] of 7.6 ± 0.5. These results agree well with those obtained from residual absorptions in the uv spectrum. Spectra recorded in D_2O solution in the presence of 0.01 *M* HCl or 0.001 *M* NaOH yielded the same value for K_{D_2O}. Spectra recorded in H_2O lead to a K_{H_2O} value of 7.6.

The methine proton signals of the hydrate at δ 6.27 and 6.61 appear as sharp singlets ($\nu_{1/2}$ = 1.2 Hz) in all of these solutions where the sulfonate salt, DSS, was used as internal reference. However, these peaks were very significantly broadened ($\nu_{1/2} \sim 8$ Hz) when the weakly basic internal reference, sodium 3-trimethylsilylpropionate-2,2,3,3-d_4 (TSP), was used. The position of equilibrium, however, remained unchanged. On warming the solution, the peaks broadened further, coalesced to a single very broad peak (at 40°C, $\nu_{1/2} \sim 16$ Hz) and finally to a fairly sharp resonance (at 70°C, $\nu_{1/2} \sim$ 4 Hz). Similar observations are made in NaOH solutions at concentrations above 0.01 *M* at room

[5]K_{D_2O} = [hydrate]/[aldehyde].

temperature. In 0.10 *M* NaOH, for example, a single fairly sharp resonance is observed at δ 6.49 due to these methine protons. We interpret this behavior in terms of the interconversion of the *cis* and *trans* hydrates (presumably via the free dialdehyde) which is slow on the nmr time scale in dilute HCl or NaOH. The equilibration is, however, catalyzed by either the high concentration (~10%) of the weakly basic carboxylate salt or by increasing concentration of NaOH and is more rapid at higher temperatures. The results in NaOH solution must be regarded with suspicion, however, since we know hydrate ionization [2] is significant under these conditions (see uv results above).

The position of the hydration equilibrium of **1** was investigated as a function of temperature in D_2O solution from the ratios of multiple integrations of the hydrate methine and free aldehyde signals. The K_{D_2O} values obtained over the temperature range 25.5–70°C are collected in Table 2. A plot of $\log_{10} K_{D_2O}$ vs. $1/T$ (Fig. 3) is reasonably linear and a short extrapolation yields a K_{D_2O} value of 7.7 ± 0.5 at 25.0°C (corresponding to a ΔG_{hyd} of −1.20 ± 0.04 kcal/mol). From the slope can be calculated $\Delta H_{hyd} = -8.90 \pm 0.34$ kcal/mol which leads to a value for $\Delta S_{hyd} = -25.8 \pm 1.1$ cal K^{-1} mol^{-1}.

The very limited solubility of the *meta* and *para* dialdehydes in D_2O precluded detection of any hydration for these compounds by nmr. However, spectra of concentrated solutions in 50 v/v% CH_3CN–D_2O revealed less than 2% hydrate could be present for either of these compounds under these conditions. Although solubility is considerably enhanced, hydration will be depressed in the mixed solvent. However, combined with the uv results, we conclude that an upper limit for K_{D_2O} for either of these compounds can be set at 0.05. This is in complete accord with the limited literature data (7–10) for the hydration of ring-substituted benzaldehydes. However, on the basis of polarographic measurements, Bover and Zuman (16) have concluded that although the *meta* isomer does not hydrate to any significant extent, *both* the *ortho* and the *para* isomers are significantly hydrated. This conclusion for the *para* isomer must be in error. Other reports of extensive hydration for *m*-chlorobenzaldehyde (17) and *o*-nitrobenzaldehyde (18), on the basis of polarographic measurements, have also required correction (9).

TABLE 2. Equilibrium constants for phthalaldehyde hydration in D_2O[a]

T (°C)	K_{D_2O} (n)[b]
25.5	7.66±0.44(7)
28	6.21±0.29(5)
40	3.99±0.16(4)
50	2.25±0.22(3)
55	1.99±0.07(4)
70	1.06±0.04(4)

[a]Determinations at 25.5°C were made on the EM 360A instrument. Those at 28°C and higher were made on the HA 100 instrument.
[b]K_{D_2O} = [hydrate]/[aldehyde]. The errors quoted are standard deviations of multiple integration ratios. n = number of separate determinations.

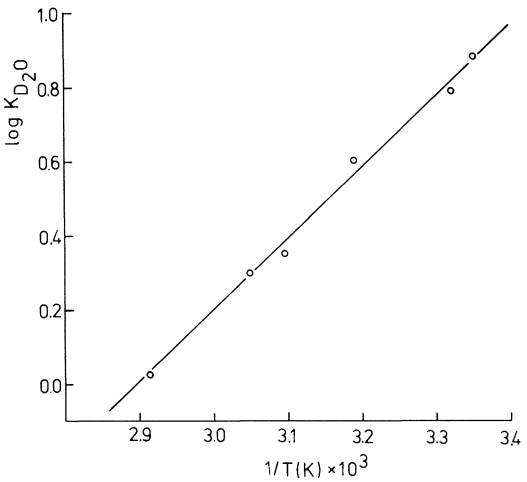

FIG. 3. A plot of $\log_{10} K_{D_2O}$ for **1** vs. the reciprocal of the absolute temperature.

Hydration Kinetics

Some preliminary kinetic results carried out in unbuffered H_2O solution at ionic strength 0.0 and 1.0 (with KCl) and in D_2O solution are collected in Table 3. The H_2O results include runs carried out with several different batches of distilled water, at each of the three λ_{max} values of **1**, and with several different substrate concentrations over the range 0.5–2.5 × 10^{-4} *M*. The k_{obs} value is independent of these effects and, further, is unaffected by a change in ionic strength from 0 to 1. However, the rate in D_2O is 30% lower than that in H_2O.

Kinetic runs were then carried out in aqueous (H_2O) solutions of dilute HCl and in a series of buffers over the pH range 2.6–7.8. The k_{obs} values

TABLE 3. Preliminary kinetic results for the hydration of **1** in unbuffered aqueous solutions at 28.0°C

Conditions	pH[a]	k_{obs} × 10^3 (s^{-1}) (n)[b]
H_2O (μ = 0.0)	6.7	6.3±0.2 (7)
H_2O (μ = 1.0)	6.6	6.2±0.1 (2)
D_2O (μ = 0.0)	7.3	4.5±0.1 (3)

[a]The pH values are only approximate in these unbuffered solutions. The value in D_2O is a pD value where pD = meter reading + 0.4.
[b]The k_{obs} values quoted are mean ± standard deviation. n = number of runs.

[a] *n* = number of runs.
[b] The errors quoted are standard deviations.

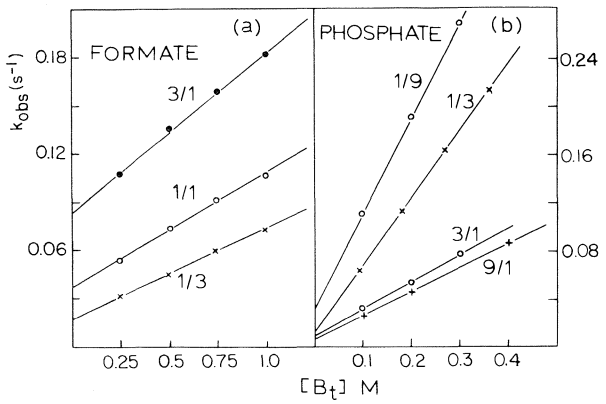

FIG. 4. Buffer plots for the hydration of **1** in aqueous solution, μ = 1.0, 28.0°C. The buffer ratios ([HA]/[A⁻]) are noted.

were found to be linear functions of the total buffer concentration, [B_t], for each buffer and buffer ratio employed [3]. At least duplicate runs were carried

$$[3] \qquad k_{obs} = k_0 + k_{B_t}[B_t]$$

out at each buffer concentration and normally three to four buffer concentrations were studied. The buffer plots for formate and phosphate (Fig. 4) are representative. The least-squares-calculated values of the intercepts of the buffer catalysis plots at zero buffer concentration, k_0, and the second-order buffer-catalyzed rate constants, k_{B_t}, are collected in Table 4.

The pH–rate profile (Fig. 5) illustrates the sensitivity of the k_0 values to pH. The k_0 values follow [4] where either the second or third terms can be

$$[4] \qquad k_0 = k_{H_2O} + k_H[H^+] + k_{OH}[OH^-]$$

neglected over certain ranges of pH. Thus, a plot of k_0 vs. [H^+] (calculated from the pH) for the data in Table 4 at pH values less than 4.6 (Fig. 6*a*), where the third term in [4] can be neglected, gave a linear correlation from which values of $k_H = 70.4 \pm 2.5\ M^{-1}\ s^{-1}$ and $k_{H_2O} = 0.010 \pm 0.003\ s^{-1}$ can be calculated from the slope and intercept, respectively. Similarly, a plot of k_0 vs. [OH^-] at pH values greater than 5.9 (Fig. 6*b*), where the second term in [4] can be neglected, also give a linear correlation from which values of $k_{OH} = (7.9 \pm 0.4) \times 10^4\ M^{-1}s^{-1}$ and

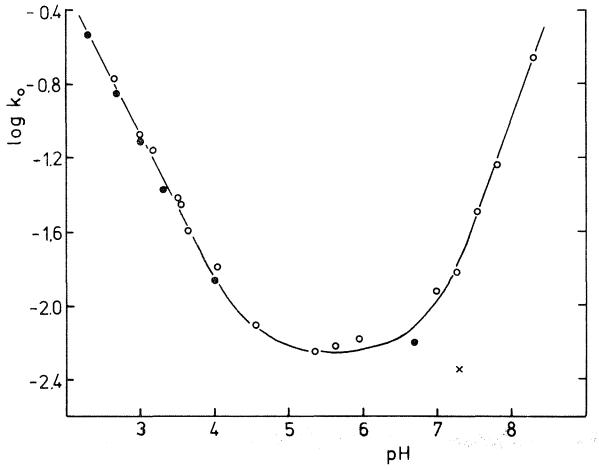

FIG. 5. The pH–rate profile for the hydration of **1** in aqueous solution at 28.0°C (●, HCl solutions and H_2O; ○, intercepts of buffer plots; ×, D_2O, pH = pD).

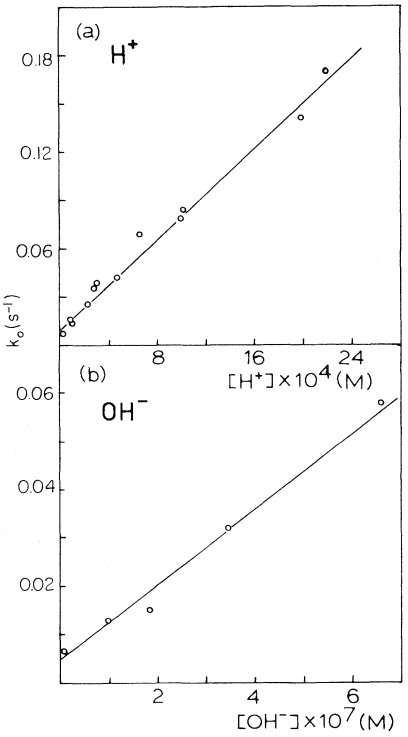

FIG. 6. Plots of k_0 vs. (*a*) [H^+] (at pH values less than 4.6), (*b*) [OH^-] (at pH values greater than 5.9) for the hydration of **1** at 28.0°C (μ = 1.0).

$k_{H_2O} = 0.005 \pm 0.001\ s^{-1}$ could be evaluated. The k_{H_2O} values from the intercepts of these plots are rather unreliable. We chose instead to correct the k_0 values obtained from the intercepts of the buffer plots in the plateau region (pH 4.5–6) for the contributions from the second and third terms in [4] which can now be calculated. This lead to a value for $k_{H_2O} = (5.6 \pm 0.4) \times 10^{-3} s^{-1}$. The solid curve in Fig. 5 follows [4] where k_H, k_{OH}, and k_{H_2O} have the values derived above. The minimum value of k_0 occurs at pH 5.5 where the last two terms in [4] contribute roughly 10% to its value.

The buffer-catalyzed rate constants, k_{B_t}, contain, in general, significant contributions from both the acidic and basic forms of the buffer. If k_{HA} and k_B are the second-order rate constants for catalysis by the acidic and basic forms of the buffer, respectively, then k_{B_t} is given by [5], where f_B is the fraction of the buffer in the basic form. Values of k_{HA} and k_B are

$$[5] \qquad k_{B_t} = k_{HA} + (k_B - k_{HA})f_B$$

then obtained from the intercepts at $f_B = 0$ and 1, respectively, of the plots of k_{B_t} vs. f_B (Fig. 7). The plots for the carboxylate buffers are reasonably linear and the extrapolations are straightforward. Only two buffer ratios (9:1 and 3:1) were employed

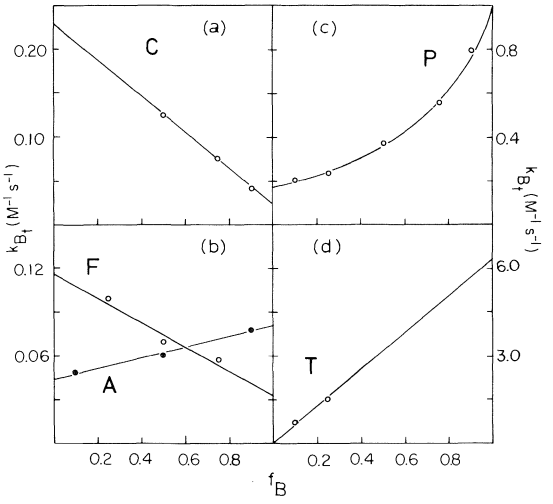

FIG. 7. Plots of the buffer-catalyzed rate constants vs. the fraction of base in the buffer. The buffer species are (*a*) chloroacetate; (*b*) formate (○), acetate (●); (*c*) phosphate; (*d*) Tris.

for Tris since lower ratios gave rates which were beyond the scope of our instrumentation. However, making the reasonable assumption that k_{HA} for Tris is zero,[6] a value for $k_B = 6.2 \pm 0.4\ M^{-1} s^{-1}$ can be calculated. The plot for the five phosphate buffers shows definite curvature. We have observed no systematic changes of pH with dilution which could account for such an effect. Curved plots of this type have been observed previously (19) but the interpretation (a change in rate-determining step with pH) has been questioned (20). We are not prepared to offer an explanation for this 'negative cooperativity' at this time and have simply made the rather short nonlinear extrapolations to $f_B = 0$ and 1 to obtain values for k_{HA} and k_B.

The acid–base catalysis data are collected in Table 5. Included are the values for k_H and k_{OH} and the value for k_{H_2O} which has been converted to a second-order rate constant and is included both as a potential general acid and a general base. The Brønsted plots for acid–base catalysis are illustrated in Fig. 8. The general acids H^+ and the carboxylic acids define a line of slope $\alpha = 0.52 \pm 0.03$. The point for water lies 3 powers of 10 above this line but it does fall nicely on the plot defined by the general bases. The point for $H_2PO_4^-$ lies above the line defined by the other buffer acids by 1.8 powers of 10. Such enhanced catalytic activity is commonly observed for phosphate (21, 22) since it can serve as a bifunctional acid–base catalyst in some proton transfer reac-

[6]This assumption would appear to be reasonable since, if k_{HA} for Tris falls on the Brønsted plot for the other acids, a value of $3 \times 10^{-4}\ M^{-1} s^{-1}$ can be calculated. Such weak catalysis would not be detectable.

TABLE 5. Rate constants for general acid – base catalysis of the hydration of **1** at 28.0°C

Catalyst (HA/B)	pK_{HA}[a]	k_{HA}[b] ($M^{-1}s^{-1}$)	k_B[b] ($M^{-1}s^{-1}$)
(*1*) H^+/H_2O	−1.74	70.4±2.5	(1.01±0.06)×10^{-4}
(*2*) $ClCH_2CO_2H/ClCH_2CO_2^-$	2.66	0.230±0.006	0.022±0.003
(*3*) HCO_2H/HCO_2^-	3.52	0.118±0.010	0.033±0.010
(*4*) $CH_3CO_2H/CH_3CO_2^-$	4.56	0.044±0.003	0.081±0.003
(*5*) $H_2PO_4^-/HPO_4^{2-}$	6.50	0.18±0.03	0.99±0.08
(*6*) Tris H^+/Tris	8.32	[c]	6.2±0.4
(*7*) H_2O/OH^-	15.74	(1.01±0.06)×10^{-4}	(7.9±0.4)×10^4

[a]For the buffer species (entries *2–6*), the pK_{HA} is taken to be the pH at half neutralization at μ = 1.0; pK_{H^+} = −log [H_2O]; pK_{H_2O} = pK_w + log [H_2O].
[b]The errors quoted are standard deviations.
[c]Assumed to be zero (see text).

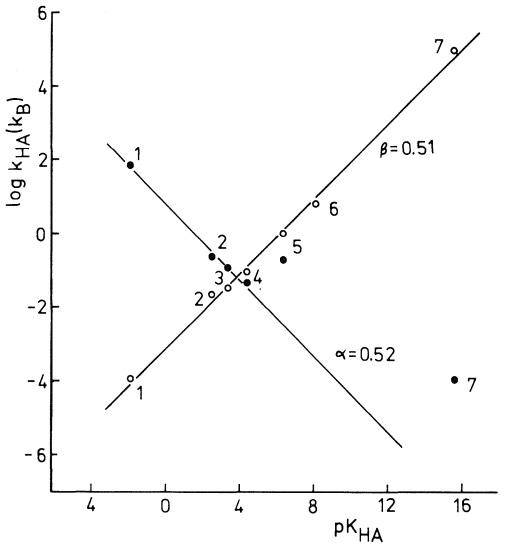

FIG. 8. Brønsted plots for general species catalysis of the hydration of **1** at 28.0°C (the numbers refer to the species in Table 5).

tions.[7] The points for $H_2PO_4^-$ and H_2O were omitted from the general acid correlation. Our series of buffer acids is limited by the dominance of the H^+- catalyzed pathway at pH values less than 2.5 and by the increasing importance of catalysis by the basic component of the buffer for acids having a pK_{HA} greater than 5.5.

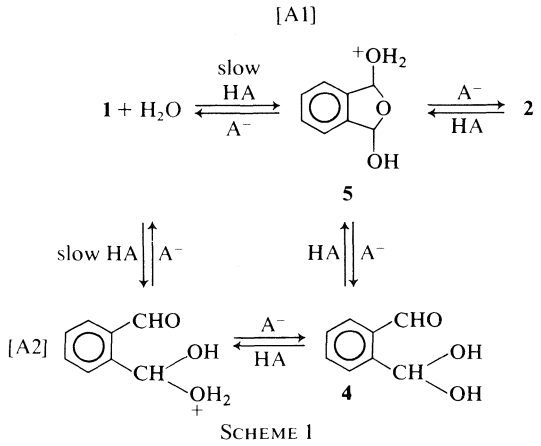
The Brønsted plot for the general bases, however, is noteworthy. All species studied, representing a catalytic range of nearly 10^9 and several different base and charge types, fall on a single straight line with remarkably good correlation (β = 0.51 ± 0.01, correlation coefficient = 0.998). Water appears to be functioning as a general base in the spontaneous process. Hydroxide also falls on this line and there appears to be no need to invoke a nucleophilic pathway for this species. The statistically corrected plots (of $\log_{10} k_{HA}/p$ and $\log_{10} k_B/q$ vs. $\log_{10} qK_{HA}/p$) show no improvement in the correlations nor any significant changes in the slopes (α' = 0.50 ± 0.03; β' = 0.51 ± 0.02).

These rate constants refer to the overall rate of approach to equilibrium and thus are the sum of the hydration (k_{hyd}) and dehydration (k_{dehyd}) rate constants. However, since K_{H_2O} (= k_{hyd}/k_{dehyd}) is independent of pH, buffer type, and concentration over the range in which kinetic data were obtained, then k_{hyd} and k_{dehyd} must be proportional to one another and have α and β coefficients identical to those above.

Bell and co-workers (21, 23, 24) have reported Brønsted coefficients similar to those above for the hydration of several aliphatic aldehydes and ketones and for the dehydration of the hydrates. However, it is difficult to determine the sensitivity of the α and β values to the structure and reactivity of the carbonyl compound since some of Bell's earlier work was carried out at temperatures significantly different from 25°C and in mixed aqueous–organic solvents. Nevertheless, the observation of general species catalysis is indicative of proton transfer between substrate and catalyst occurring in the rate-determining step.

The mechanism of carbonyl hydration has been discussed in detail elsewhere (6, 25, 26). An analysis of the magnitude of the α values observed for the acid-catalyzed addition of a variety of nucleophiles to carbonyl compounds has lead Jencks (25, pp. 197–198) to conclude that the catalysis is true general acid catalysis in the forward direction (hydration) and that the reverse reaction (dehydration) is subject to specific acid – general base catalysis (kinetically indistinguishable from general acid). Possible pathways for the acid-catalyzed hydration equilibrium of **1** are outlined in Scheme 1. Mechanism [A1] involves general acid catalyzed water attack concerted with cyclization in the (slow) first step followed by rapid deprotonation of **5**. Alternatively, a stepwise pathway

[7]In fact, Bell and Evans (21) observed the k_{HA} values for chloroacetic acid and $H_2PO_4^-$ were identical although they differ by 4 units in pK_{HA} (also see our results).

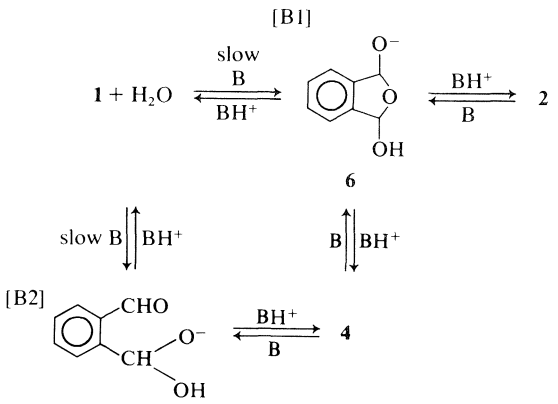


SCHEME 1

[A2] can be envisaged in which the slow general acid catalyzed water attack at one of the carbonyl groups is followed by rapid deprotonation to form the normal hydrate, the *gem*-diol **4**. Rapid (and presumably acid-catalyzed) cyclization of **4** followed by deprotonation of **5** leads to **2**. Two factors lead us to favor the stepwise pathway. Firstly, the Brønsted α coefficient for the hydration of **1** (0.52) is very similar to that measured by Bell *et al.* (23) for the hydration of acetaldehyde (0.54) under similar conditions. Secondly, our observed rates are similar to those measured by Sayer (10) for the hydration of *p*-nitrobenzaldehyde.[8] Since both of these latter cases involve formation of the *gem*-diol, we propose our mechanism also proceeds via formation of **4**. If the concerted pathway [A1] were preferred, one would expect some rate enhancement to be observed. Finally, Powell and Rexford (27) observed that when **1** was dissolved in ethanol, the disappearance of the uv carbonyl absorption band showed biphasic behavior; these authors proposed the intermediacy of the mono-hemiacetal which then went on to form the bis-hemiacetal although 3-ethoxyphthalan-1-ol might be the product of this reaction.

The analogous pathways for the base-catalyzed reaction are outlined in Scheme 2. Again Jencks (28) has proposed that catalysis of the forward reaction corresponds to true general base catalysis. Although our evidence is rather limited here, the similarity of the Brønsted β coefficients observed for the hydration of **1** (0.51) and acetaldehyde (0.45) (23), leads us to favor the stepwise pathway [B2] via the *gem*-diol **4** over the concerted pathway [B1].

The susceptibility of the hydration to catalysis by zinc(II) ions was investigated briefly. Carbonic anhydrase catalyzes the hydration of acetaldehyde (29) and the pyridine carboxaldehydes (30) as well as carbon dioxide, and is known to contain a hydrated zinc ion at the active site (31). Although the enzyme has been the subject of many investigations, the exact function of the zinc is not known. We find the hydration of **1** to be only weakly accelerated by Zn(II); a plot of k_{obs} vs. [$ZnSO_4$] (not shown) at pH 5.1 is linear from 0.10 to 1.0 *M* $ZnSO_4$ with a slope of $k_{Zn} = (2.30 \pm 0.12) \times 10^{-2}\ M^{-1}s^{-1}$. The reaction is only five-fold faster in 1.0 *M* $ZnSO_4$ than in water at this pH. This rate constant is not consistent with general acid catalysis by the hydrated ion ($pK_a = 9.6$ (32)) but rather suggests that the metal ion is providing some electrostatic polarization of the carbonyl group facilitating nucleophilic attack by water. Although weak catalysis of the hydration of aldehydes by zinc ions alone has been observed previously (33, 34), cooperative catalysis by zinc and acetate or pyridine is rather more pronounced (34). However, we did not investigate further such catalysis for **1**.



SCHEME 2

General Comments on Carbonyl Hydration

A modified Taft equation [6] has been proposed (35) to correlate the hydration equilibrium constants, K_{H_2O}, with the Taft σ^* substituent constants:

$$[6] \quad \log_{10} K_{H_2O} = 1.70 \sum\sigma^* + 2.03\,\Delta - 2.81$$

where Δ is a factor which distinguishes the behavior of aldehydes and ketones ($\Delta = 0$ for ketones, 1 for aldehydes, and 2 for formaldehyde). Thus, ketones are normally less hydrated than aldehydes owing to an electronic *and* an adjacent bond interaction (hyperconjugative) effect. Steric effects are concluded to be unimportant (35). This equation correlates the available K_{H_2O} data fairly well for aliphatic aldehydes and ketones of widely varying structure. Electron-withdrawing substituents favor hydration. However, aromatic carbonyl compounds have K_{H_2O} values 10^3-fold lower than this equation would predict.[9]

[8]We thank Dr. J. P. Guthrie for making this observation.

[9]Benzaldehyde is predicted by [6] to have a K_{H_2O} of 11.8 whereas the currently accepted value is near 1×10^{-2} (7, 8).

TABLE 6. Thermodynamic data for the hydration of some carbonyl compounds[a]

Compound	K_{H_2O}[b]	ΔG_{hyd}[c,d]	ΔH_{hyd}[d] (ΔH_{hyd}/(calcd.))[d,e]	ΔS_{hyd}[f]	Ref.
CH_2O	2.27×10^3	−4.58	−5.7		
			−8.0 (−8.0)	(−11)[g]	37
			−14.6		
CH_3CHO	1.06	−0.03	−5.6 (−5.6)	−19	38

[g]Calculated using the value of −8.0 kcal/mol for ΔH_{hyd}.
[h]Value not available.
[i]Value estimated by Greenzaid (7).
[j]4-Pyridine carboxaldehyde.

This must be due to the conjugative stabilization of the carbonyl group with the aromatic ring, a factor which this equation does not consider. This factor of 10^3 in K_{H_2O} corresponds to a stabilization free energy of 4.1 kcal/mol. Although the lack of solubility in water of aromatic carbonyl compounds hampers detection of the hydrate, it is clear that even moderately strong electron-withdrawing substituents do not favor hydration to any appreciable extent (see our results for the 1,3- and 1,4-dialdehydes). The K_{H_2O} value for *p*-nitrobenzaldehyde has been measured to be 0.15 (9) and 0.25 (10). Thus, the K_{H_2O} value of 7.7 for **1** is 10^2-fold larger than one would predict for normal hydration and the unique cyclic structure **2** of the hydrate is not totally unexpected.

In view of the results for **1**, we collected, for comparison purposes, thermodynamic data for the hydration of a variety of carbonyl compounds (Table 6). Much of the data is experimental but we have also included values for the enthalpy of hydration (ΔH_{hyd}) calculated by applying Benson's group additivity rules (36) to the normal hydration reaction or, for **1**, to the formation of **2**. Despite the fact that these calculated values refer to the gas phase, agreement with experimental values, where these are available, is good. Exceptions may occur where the carbonyl compound has remote electronic effects not considered in the calculation. Thus, the calculated ΔH_{hyd} value for both acetone and 1,3-dimethoxy acetone is −3.3 kcal/mol and that for the aromatic aldehydes (except **1**) is −3.7 kcal/mol. Where experimental ΔH_{hyd} data were not available, we have used the calculated value to evaluate ΔS_{hyd}.

Some general trends in the thermodynamic data may be noted. From the first three entries, it is clear that the increasingly unfavorable hydration observed as the hydrogens of formaldehyde are progressively replaced by methyl groups is reflected in both the ΔH_{hyd} and ΔS_{hyd} terms. The more extensive hydration of 1,3-dimethoxyacetone relative to acetone is determined mainly by the more exothermic (by 2.6 kcal/mol) ΔH_{hyd} term; the ΔS_{hyd} is similar to that estimated for acetone. Although the data for benzaldehyde are estimated, our calculations again reveal that much of the less favorable ΔG_{hyd} is reflected in the ΔH_{hyd} term while the ΔS_{hyd} is only 2 eu more negative than that for acetaldehyde. On the other hand, the appreciable hydration of 4-pyridine carboxaldehyde is determined by the much less negative ΔS_{hyd} relative to the other aldehydes while the ΔH_{hyd} is remarkably close to that estimated for an aromatic aldehyde. Obviously, there appears to be no correlation between the ΔH_{hyd} and ΔS_{hyd} terms (i.e., no isoequilibrium relationship exists) and the degree of hydration may be determined by either one or both of these terms. Finally, the extensive hydration of **1** is determined solely by the ΔH_{hyd} term which is some 5.2 kcal/mol more exothermic than that estimated for benzaldehyde. An inventory of bonds broken and made during hydration reveals that hydration of **1** to form **2** *should* be more than twice as exothermic as that to form the *gem*-diol **4**. The ΔS_{hyd} term is, in fact, 5–7 eu more negative than that observed or calculated for the other aldehydes, a result in accord with the loss of two rotational degrees of freedom accompanying ring formation.

Acknowledgements

We are pleased to acknowledge the technical assistance of Ms. Christine Sibley who processed much of the kinetic data and Mr. John Van Ingen of the Atlantic Regional Laboratory of the National Research Council of Canada who recorded the

variable temperature nmr spectra. We thank Dr. O. S. Tee and Dr. J. A. Pincock for valuable comments on parts of the work. The financial assistance of the National Research Council of Canada in the form of an operating grant (to R.S.M.) and a Negotiated Regional Development Grant is also gratefully acknowledged.

R. PHILIPPE, G. DELMAS, and PHUONG NGUYEN HONG. Can. J. Chem. **57**, 517 (1979).

Excess heats of the following mixtures of trialkylamines and tetraalkyl tin compounds with branched and linear alkanes have been measured at 25°C: five trialkylamines NR_3 (R = C_2H_5, C_3H_7, C_4H_9, $C_{10}H_{21}$, $C_{12}H_{25}$) with six linear alkanes, *n*-C_5, *n*-C_6, *n*-C_8, *n*-C_{10}, *n*-C_{12}, *n*-C_{16}, and three highly branched alkanes, 2,2,4-trimethylpentane, 2,2,4,6,6-pentamethylheptane, and 2,2,4,4,6,8,8-heptamethylnonane (br-C_{16}). Further measurements were carried out on tetrapropyl tin ($SnPr_4$) with *n*-C_8, *n*-C_{16}, and br-C_{16}.

Measurements were made to obtain more information on the heats of disordering of long chain compounds and on an exothermic contribution to the heats coming possibly from the sterically hindered character of one of the components of the mixture. The three short-chain trialkylamines have large heats with the linear long alkanes and small heats with the branched alkanes. On the other hand, the two long-chain trialkylamines have very small heats with linear alkanes and large heats with the branched alkanes. These results are interpreted as indicating no change of liquid or solution 'structure' when two ordered compounds (long alkanes and long-chain amines) are mixed but a change of 'structure' when an ordered compound (long alkane or long-chain amine) is mixed with a non-ordered one (branched alkane or short-chain amine). The heat of disordering of *n*-hexadecane is obtained with many order breakers and found to depend to some extent on the expansion coefficient of the order breaker. H^E values for the series of the shorter NR_3 do not vary regularly with molecular weight but are smaller for the propyl (and possibly the ethyl) derivative. Similarly, H^E of $SnPr_4$ in *n*-C_{16}, br-C_{16}, and *n*-C_8 are much lower than the corresponding heats with $SnEt_4$ and $SnBut_4$. This is attributed to the presence of the exothermic contribution to the heats, H^E(steric hindrance). The X_{12} parameter of the Flory theory has been calculated and is interpreted in terms of the disorder and steric hindrance contributions to the heats.

R. PHILIPPE, G. DELMAS et PHUONG NGUYEN HONG. Can. J. Chem. **57**, 517 (1979).

Nous avons mesuré les chaleurs de mélange d'amines trisubstituées et de composés d'étain tétrasubstitués avec des alcanes linéaires et ramifiés à 25°C. Les composés utilisés étaient les suivants: cinq amines NR_3 (R = C_2H_5, C_3H_7, C_4H_9, $C_{10}H_{21}$, $C_{12}H_{25}$) six alcanes linéaires *n*-C_5, *n*-C_6, *n*-C_8, *n*-C_{10}, *n*-C_{12}, *n*-C_{16} et trois alcanes très ramifiés 2,2,4-trimethylpentane, 2,2,4,6,6-pentamethylheptane et 2,2,4,4,6,8,8-heptamethylnonane (br-C_{16}). Les systèmes *n*-C_8, *n*-C_{16} et br-C_{16} avec le trétrapropylétain ($SnPr_4$) ont également été mesurés.

Les systèmes ont été choisis dans le but d'obtenir plus d'information (1) sur la chaleur de désordre des composés en chaine et (2) sur une contribution exothermique aux chaleurs associée à l'empêchement stérique présent dans un des constituants du mélange. Les amines globulaires à courtes chaines ont des chaleurs de mélange élevées avec les alcanes linéaires et faibles avec les alcanes ramifiés. Par ailleurs, les deux amines à longue chaine ont de très petites chaleurs avec les alcanes linéaires et de grandes chaleurs avec les alcanes branchés. L'interprétation de ce résultat est la suivante: la "structure" de la solution est semblable à celle des liquides purs quand deux composés ordonnés (alcanes ou amines à longue chaine) sont mélangés mais elle est différente si un composé ordonné est mélangé à un composé non-ordonné (alcane ramifié ou amine à courte chaine). La chaleur de désordre de l'hexadecane linéaire obtenue à partir de différents destructeurs d'ordre semble dépendre de l'état d'expansion du destructeur d'ordre. Les valeurs des chaleurs ne varient pas régulièrement avec le poids moléculaire du composé NR_3 dans la série mais sont plus faibles pour le dérivé propylé et peut-être éthylé. De la même façon, les chaleurs avec *n*-C_{16} et *n*-C_8 du composé $SnPr_4$ sont inférieures à celles obtenues avec $SnEt_4$ et $SnBut_4$. Cet effet est attribué à la présence d'une contribution exothermique H^E(empêchement stérique). Le paramètre X_{12} de la théorie de Flory a été calculé et interprété en termes de ces deux contributions.

Introduction

In the case of the heats of mixing of non-polar mixtures, the importance of the difference in chemical nature of the two components has been recognized early and taken into account by several theories (1*a*). The difference of size and shape of the two components which influences the chemical positive contribution to the heats has been analysed and written in terms of surface fractions (1*b*, *d*). Contributions to the heats arising from non-zero volume of mixing have been calculated (1*c*). Theories, introduced in the last twenty years (Prigogine (2), Patterson (3*a*), Flory (4)), stress the importance of the difference of state of expansion (or free volume) of the two components mixed. In systems where this difference is large, negative contributions to H^E, V^E, and TS^E are found experimentally and can be calculated from equations of state for the liquids and the solution. Solution properties of mixtures (5–10) consisting of molecules of different shapes, such as globular and linear alkanes or multibranched compounds like MR_4 (M = C, Sn, or Si), have shown that another contribution depending on the shape of the molecule should be added. In the case of the heats of mixing, this contribution can be a positive term, related to the destruction of orientational order (5–8) or a negative one, namely, the condensation or steric hindrance term (5–10) or a combination of the two. In many instances, the total heat, either positive (3*b*, 5, 6) or negative (11), is constituted principally by these effects. Our aim is to obtain more information on the role of the shape of the molecules. Thermodynamic data (8–9) and depolarized Rayleigh scattering (12) on long-chain compounds, pure and in solution, are in agreement with the hypothesis that the 'structure' of the liquid is very sensitive to the molecular shape. Due to the anisotropy of the molecule, a long *n*-alkane keeps in the liquid state some of the order it had in the solid state. The chains are oriented one along the other in order to maximize the Van der Waals interaction along the chain. A branched alkane, being more isotropic, does not have such orientational order. The relatively large endothermic heats, obtained when a long alkane is mixed with a branched one, comes from the heat (H^E_{dis}) associated with the disordering of the chains of the long alkane, i.e. with the disappearance, in the solution, of the 'structure' which existed in the pure liquid. The much smaller heats evolved when two branched alkanes are mixed, are explained by the lack of correlations of orientations in a liquid consisting of globular molecules and consequent lack of the heat of disordering. This work presents the results of H^E of trialkylamines with linear and branched alkanes. The investigation is rather similar to those made on the SnR_4 compounds (5, 6). However, the use of the trialkylamines as probes of the alkanes has seemed to us worthwhile for other reasons: (*1*) the magnitude of the heats can give the balance of the polar and non-polar contributions in the case of the shorter members of the NR_3 series, (*2*) comparison of the heats of the trisubstituted compounds like NR_3 with those of the tetrasubstituted SnR_4 (this work and refs. 5 and 6) could show evidence of *intra*molecular correlations of orientations present in long-chain SnR_4 although less important in long-chain NR_3 compounds, (*3*) measurements of the thermal pressure coefficient on the pure compounds appear to show a correlation between high P^* values and steric hindrance within the molecule as seen by heats of mixing. Heats measured on another series could confirm the correlation.

Three important systems have been added, namely, $SnPr_4$ with *n*-C_8, *n*-C_{16}, and br-C_{16}. In the previous work on the SnR_4 + alkane systems (5), the SnR_4 molecules were used as order breakers of the alkanes due to their globular shape. Knowledge of the heats with every member was not expected to give supplementary information, so that heats were obtained with the methyl, ethyl, and butyl derivatives only. However, because of the unexpected values of the heats with $SnPr_4$ when mixed with $SnLaur_4$ and $SnOct_4$, it was decided that the heats of $SnPr_4$ with some alkanes should be measured, values of which are published here and compared to those obtained previously with $SnMe_4$, $SnPr_4$, and $SnBut_4$.

H^E results are given on the following 41 systems at 25°C: five trialkylamines NR_3 (R = C_2H_5, C_3H_7, C_4H_9, $C_{10}H_{21}$, $C_{12}H_{25}$) with six linear alkanes (C_5, C_6, C_8, C_{10}, C_{12}, C_{16}) and three highly branched alkanes in C_8 (2,2,4-trimethylpentane (br-C_8)) in C_{12} (2,2,4,6,6-pentamethylheptane (br-C_{12})), in C_{16} (2,2,4,4,6,8,8-heptamethylnonane (br-C_{16})); one SnR_4 ($SnPr_4$) with two linear alkanes, *n*-C_8 and *n*-C_{16}, and one branched alkane, (br-C_{16}). The abbreviated terms NEt_3, NPr_3, $NBut_3$, $NDec_3$, $NLaur_3$ are used in the text.

Experimental

Apparatus

The heats of mixing were measured using a tilting Tian-Calvet calorimeter. Details of the measurements, the cells, and the calibration can be found in refs. 5 and 14, and with the reference system (cyclohexane + hexane) our points agree within 2% of the published value (15). It was found useful to employ another reference system, benzene + CCl_4 (16), for which the heats seem to be less dependent on the purity of the compounds. Our results agree with the published value within 3%. The experimental heats of H^E are fitted to the following equation where x is the mole fraction:

$$[1] \qquad H^E\,(\text{J/mol}) = x_1x_2(ax_1^2 + bx_1 + c)$$

br-C_{16}	0.7819	0.857	0.912	396.6	237.84	0.766

The curves are obtained from five to ten experimental points. In most cases, the difference between the experimental points and the calculated curve is less than 1%, but it could reach 5% for a few points with volatile components.

Chemicals

The alkanes and the lower amines were obtained from the same companies as in previous work (13).

Free Volume Theory

Parameters for the Pure Components

Densities, expansion coefficients, and thermal pressure coefficients have been found in the literature (17) for the alkanes and measured for the amines (13). Their values are listed in Table 1 together with the reduction parameters for the pressure P^*, for the volume V^* obtained from the experimental quantities, and from an equation of state for the liquid (3, 4). V^* can be construed as the core volume or the molar volume at 0 K.

Surface-to-volume Parameters

Models similar to those in general use for the alkanes (18) have been applied and are detailed in ref. 13 which also reports measurements on the pure components.

Calculation of the Free Volume Term

The free volume term depends only on the difference between the reduced volume of the pure components. We have chosen to apply an approximate (3) form of the Prigogine–Flory theory which separates the interactional and free volume contributions. The free volume contribution $H^E_{f.v.}$ is defined as

$$[2]\quad H^E_{f.v.}/(x_1U_1^* + x_2U_2^*) = \tilde{C}_p(\tilde{T}_U)(\psi_1\tilde{T}_1 + \psi_2\tilde{T}_2 - \tilde{T}_U)$$

Here $\tilde{T}_U$ is the average reduced temperature for the solution appropriate to the energy $\tilde{U}$ and is defined by:

$$\tilde{U}(\tilde{T}_U) = \psi_1\tilde{U}(\tilde{T}_1) + \psi_2\tilde{U}(\tilde{T}_2)$$

With the Van der Waals model, $\tilde{U} = -1/\tilde{v}$, so that the volume corresponding to $\tilde{T}_U$ is

$$1/\tilde{v}_U = \psi_1/\tilde{v}_1 + \psi_2/\tilde{v}_2$$

with

$$\psi_1 = x_1U_1^*/(x_1U_1^* + x_2U_2^*)$$

In this model, the reduced volume of the pure components is obtained from their expansion coefficients α and

$$\tilde{v}^{1/3} = (\tfrac{4}{3}\alpha T + 1)/(\alpha T + 1)$$

The reduced temperature is calculated from their reduced volume and

$$\tilde{T} = \tilde{v}^{-1}(1 - \tilde{v}^{-1/3})$$

with

$$\tilde{C}_p(\tilde{T}_U) = (\tfrac{4}{3}\tilde{v}_U^{-1/3} - 1)^{-1}$$

The energy reducing parameter is

$$U^* = P^*V^*$$

$$P^* = \gamma\tilde{v}^2T$$

where γ is the thermal pressure coefficient. Equation [2] does not depend on the surface-to-volume ratio. In the Flory terminology, the interactional contribution, which is the difference between the experimental value of the heat and the free volume contribution, is expressed through the X_{12} parameter. In the present form, X_{12} is obtained by eq. [3]:

$$[3]\quad (H^E_{exp} - H^E_{f.v.})/(x_1U_1^* + x_2U_2^*) = (X_{12}/P_1^*)\theta_2\psi_1 f(\tilde{v})$$

[a]A negative X_{12} value is rare in non-polar systems. It is due to the absence of disordering and free volume contributions and to the negative heat due mainly to the steric hindrance effect.

$f(\tilde{v}) = (\tilde{v}^{-1} + \tilde{T}\tilde{C}_p)$ and is not very different from 1. ψ_1 and θ_2 ($= x_2V_2^*s_2/(x_1V_1^*s_1 + x_2V_2^*s_2)$) are used rather than the mole fractions, s_1 and s_2 are parameters calculated from a model characteristic of molecular shape. The units of X_{12} are energy per cm^3. The parameter $X_{12}s_1^{-1}$ tabulated in Table 2 for the concentration of the maximum is independent of the choice of 1 or 2 as a second component, i.e., $X_{12}s_1^{-1} = X_{21}s_2^{-1}$. The left side of eq. [3] does not depend on the s's while X_{12} and θ_2 do to some extent. $X_{12}s_1^{-1}$ also relies very little on the s's. For instance, a variation of 10% on s_1 will change $X_{12}s_1^{-1}$ by less than 2%. Because the $X_{12}s_1^{-1}$ values vary largely from one system to another, the discussion and interpretation of the results from these values are not sensitive to the exact choice of the s's.

Results and Discussion

Table 2 shows the experimental and calculated data for all the systems. The first columns give the maximum of the heats, H^E_{max}, the concentration of the maximum, and the three parameters of eq. [1]. The next column lists the experimental heats calculated per cm^3, $H^E_{max}/V^* = H^E_v$ (the core volume of the solution $V^* = x_1V_1^* + x_2V_2^*$ being used rather than the molar volume for the volume at maximum). The last two columns indicate the cal-

culated free volume terms and the parameter $X_{12}s_1^{-1}$ corresponding to H^E_{max}. Figure 1*a* shows H^E_v at the maximum for the three order-destroyer amines NEt_3, NPr_3, $NBut_3$, and Fig. 1*b* for the two ordered amines $NDec_3$ and $NLaur_3$ plotted against the number, *n*, of carbon atoms of the alkane. Comparison of Fig. 1 (H^E_v) with Fig. 2 ($X_{12}s_1^{-1}$) indicates that the trend of the experimental heats and that of the calculated parameter $X_{12}s_1^{-1}$, which corresponds to the heat minus the free volume term, are very similar. It has seemed worthwhile to present the two series of data since conclusions drawn from one or the other only may be misleading. On one hand, H^E_{exp} includes the free volume contribution which may represent a different proportion of H^E_{exp} from one system to another; on the other hand, $H^E_{f.v}$ and consequently X_{12} is calculated to be too large in systems with a large free volume difference (14) (see in Fig. 2 the rise of X_{12} for the long-chain amines from dodecane to octane while the corresponding H^E_{exp} hardly depends on the alkane chain length).

The characteristic features of the results are the

two following: (*1*) The magnitude of the heats for short- and long-chain amines confirms previous results on the SnR_4 and alkane systems: there is orientational order in long-chain compounds order which is destroyed by mixing with a globular molecule. H^E_{dis} is often the main contribution in these non-polar systems. (*2*) The negative steric hindrance contribution which lowers the experimental heats can be seen on the SnR_4 + alkane systems as well as on the SnR_4 + SnR_4 systems (10). The trialkyl amines (propyl or ethyl derivatives) appear to be also sterically hindered but the effect is much larger on the tin compounds (Fig. 3*b*) than on the NR_3 compounds (Fig. 3*a*).

The analysis of the data and the comparison of different systems raise other interesting points such as the concentration dependance of the heats (or of X_{12}), the value of the chemical term in similar compounds, the validity of the assumption that the different contributions are additive, the extent of the disordering of the ordered component in relation with the size and shape of the order breaker, the effect of the shape of the second component on the steric hindrance contribution. In the following discussion, some of the points come up but the con-

clusions are not as definitive as the two previously quoted. Furthermore, simplifying assumptions concerning these points have been put forward to make the conclusions less complex.

To obtain more information on the chemical contribution, we intend to study mixtures of homomorph compounds such as $NR_3 + HCR_3$ or $MR_4 + CR_4$. On the other hand, analysis of the concentration dependance of the heat (or of X_{12}) is likely to give physical insight and quantitative information about the balance of the different contributions at the extremes of the concentration range. This has not been reported in this paper but will be the subject of further work.

The experimental heats of mixing can be written formally as the sum of the different contributions:

$$[4] \quad H^E_{exp} = H^E_{chem} + H^E_{f.v.} + H^E_{dis} + H^E_{ster.hindr.}$$

In the present systems for which the contacts between unlike molecules is made of CH_2 and CH_3 groups, H^E_{chem} must be small enough. As the free volume contribution may be calculated (eq. [2]), the discussion of the experimental heats will be made in terms of the two other contributions, H^E_{dis} and $H^E_{ster.hindr.}$.

(A) Structure Effects

Order-destroyer Amines: NEt_3, NPr_3, $NBut_3$

The heats with the branched alkanes are small and almost independent of the branched alkane chain length, indicating that the four contributions in eq. [4] are small and that orientational order is absent in branched alkanes. The heats with the normal alkanes increase regularly with the chain length. This is in agreement with the existence of orientational order in the pure *n*-alkanes increasing regularly with chain length and then being destroyed by mixing with the globular NR_3 molecule. Values of the heats of disordering of the two chain alkanes *n*-C_{12} and *n*-C_{16} have been obtained in a manner similar to that described below for the long chain amines and are tabulated in the first two rows of Table 3. The extrapolation of H^E_{dis} found for *n*-C_{16} and *n*-C_{12} to short alkanes indicates as well as depolarized Rayleigh scattering (14) that *n*-C_7 has little orientational order at 25°C.

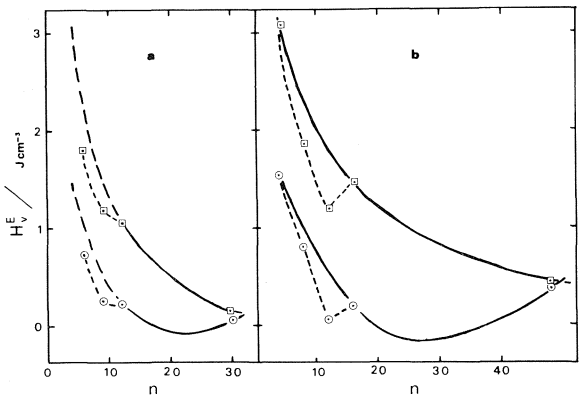

FIG. 3. H^E_v in J per cm^3 versus the atom carbon number of the non-alkane compound with □, *n*-C_{16}; and ○, *n*-C_8. (*a*) NR_3 series, (*b*) SnR_4 series. The lines are drawn through the points corresponding to the same alkane. In Fig. 2*b*, the propyl findings are from this work, the other SnR_4 results are from ref. 5.

Ordered Amines: $NDec_3$, $NLaur_3$

Quantitative evaluation of H^E_{dis}. Equation [4], which lists the contribution to the heats, can be written for two mixtures, one involving a linear alkane and the other a branched alkane of the same carbon atom number and with the same second component

$$[5] \quad H^E_{exp}(\text{linear}) = H^E_{chem} + H^E_{f.v.} + H^E_{dis} + H^E_{ster.hindr.}$$

$$H^E_{exp}(\text{branched}) = H^E_{chem} + H^E_{f.v.} + H^E_{ster.hindr.}$$

H^E_{dis} is assumed to be very small for a branched alkane mixture. Furthermore, if one assumes that the other contributions are either small (H^E_{chem}) and/or very similar for the linear and branched alkanes ($H^E_{f.v.}$ and $H^E_{ster.hindr.}$), one finds

$$[6] \quad H^E_{exp}(\text{linear}) - H^E_{exp}(\text{branched}) = H^E_{dis}$$

In other cases where there was no branched alkane available to give equations similar to [5] and [6], it was assumed that

$$[7] \quad H^E_{exp} = H^E_{dis}$$

which is a good approximation for mixtures of non-polar components whose expansion coefficients are not very different. Table 3 gives the values of H^E_{dis} for different order destroyers and different long-chain compounds obtained by either eq. [6] or [7]. These values are quite independent of any model or theory. Table 3 indicates that H^E_{dis} is relatively constant whatever order breaker is used for making the solution. For instance, H^E_{dis} for *n*-C_{16} obtained from eq. [6] varies between 1.14 and 1.37 J/cm^3 for five different order breakers. In the same way, H^E_{dis} derived from eq. [7] for $SnLaur_4$ varies between 1.22 and 1.28 J/cm^3 for five order breakers. This result justifies the simplified assumptions contained in eqs. [5] to [7]. Comparison of the orientational order of a linear alkane with *n* carbon atoms and that of an alkyl chain with the same length but attached to a large group (NR_2 or SnR_3) can be made. The dodecyl chains in $NLaur_3$ (1.1 J/cm$_3$) have orientational

order of the same magnitude as those of $SnLaur_4$ (1.2 J/cm^3). On the other hand, dodecane (H^E_{dis} = 0.8 J/cm^3) appears to have only about two-thirds the orientational order of the attached dodecyl chain (1.15 J/cm^3). This may be due to more mobility of the smaller molecule. Values of H^E_{dis} are higher than the average if the order breaker is a volatile compound (2,2-DMB or NEt_3), or lower if it is a sterically hindered compound ($SnPr_4$). These cases will be discussed later in the context of the $X_{12}s_1^{-1}$ parameter.

(B) Steric Hindrance Effect

Comparison with the SnR_4 Series

Some unexpected exothermic heats have been found for non-polar systems where one of the components of the mixture appears to be sterically hindered. This effect has been called either condensasation effect or steric hindrance effect. The corresponding negative contribution is $H^E_{ster.hindr.}$. An example of such a system is 3,3-diethylpentane + *n*-C_8 measured by Mathot and Prigogine (11) whose negative heat (−80 J/mol) could not be explained by the difference in free volume. In the SnR_4 series, the system $SnBut_4$ + br-C_{16} (−41 J/mol) (5) was also much more negative than expected. In this work, $SnPr_4$ + br-C_{16} (−84 J/mol) is another striking example of negative heats in non-polar systems which cannot be explained by the usual contribution, and particularly not by the difference in free volume. This steric hindrance contribution is likely to occur as well in systems where the total heat has become positive due to other contributions. In such cases, the experimental heat will be less positive than expected by comparison with other systems. As seen in Table 1, the same $SnPr_4$ molecule gives a heat of mixing of 266 J/mol with *n*-hexadecane. This large value is due to the disordering of the alkane chains by $SnPr_4$. However, the magnitude of the heat is not that which could be expected from those obtained with the other members of the series such as 522 ($SnMe_4$), 333 ($SnEt_4$), and 354 ($SnBut_4$). The expected value intermediate between the ethyl and butyl derivative would be about 350 while an interpolated value between the butyl and methyl derivative would be approximately 400 J/mol.

The irregular trend of the heats can be better seen in Fig. 3*b* where the heats H^E_v of *n*-C_{16} and *n*-C_8 with the different members of the series have been plotted against *n* the carbon atom number of the SnR_4 compound. It is concluded then that these systems with a lower H^E_v involving $SnPr_4$ and $SnEt_4$ have a sizeable value for the negative contribution $H^E_{ster.hindr.}$ which is larger than for the systems involving the methyl and butyl derivatives. Similar results have been found (10) in mixtures where $SnLaur_4$ and $SnOct_4$ are the second components instead of *n*-C_{16} and *n*-C_{10}.

The Amines Series

In Fig. 3*a*, H^E_v for the amines have been plotted against *n*, the carbon atom number of the NR_3 compound. Comparison between Fig. 3 *a* and *b* indicates that the steric hindrance contribution occurs for NPr_3 and possibly NEt_3 but is less important than in the SnR_4 series. The lack of data on NMe_3 causes the conclusions to be less sure than in the case of the SnR_4 compounds.

The molecular origin of this steric hindrance contribution is not very clear. It is possible that the low mobility of the sterically hindered compound diminishes that of the second component. An alternative explanation is the better packing in solution than in the pure state of the sterically hindered compounds. However, excess volumes obtained on these systems[2] do not seem more negative than expected as would be the case if the solution was packed better than the pure components. The similarity of shape between the two molecules which appear the most sterically

[2]Bernard Rield and G. Delmas. To be published.

hindered, 3,3-diethylpentane (or CEt_4) and $SnEt_4$, is worth noting. A semiquantitative evaluation of $H^E_{ster.hindr.}$ for five sterically hindered compounds and second components of different size have been given (21).

Effects of the State of Expansion of the Order Breaker

Comparison of the heat of disordering alone for different order breakers cannot be done by using only H^E_{dis} since, for instance, from 2,2-dimethylbutane to br-C_{16} the free volume contribution in the *n*-C_{16} mixtures diminishes rapidly. Instead, comparison can be made on the $X_{12}s_1^{-1}$ parameter which corresponds to the experimental heats from which the free volume term has been subtracted. $X_{12}s_1^{-1}$ (disorder) can be obtained (Table 4) as H^E_{dis} in two ways: either by subtracting the values obtained for the branched alkane from that calculated for the linear alkane (Fig. 4*a*) or directly from the $X_{12}s_1^{-1}$ tabulated in Table 2 (Fig. 4*b*, *c*). The reasonably small scatter of H^E_{dis} as seen in Table 3 or of $X_{12}s_1^{-1}$ in Table 4 is an indication that eqs. [5] and [6] are good assumptions for most of the order breakers. However, as X_{12} seemed to depend on the state of expansion of the order breaker, it has been plotted in Fig. 4 against the expansion coefficients of the order breaker. It is to be noted that the two methods of calculating $X_{12}s_1^{-1}$ (respectively, Fig. 4 *a*, *b*, and *c*) give the same trend, although there are fewer points on the *b* and *c* curves. The smooth dependence of $X_{12}s_1^{-1}$ (disorder) on α as seen in Fig. 4 may have two origins: (*1*) Smaller molecules, i.e. molecules with a large α, are more efficient order breakers than larger molecules, hence the increase of $X_{12}s_1^{-1}$ or of H^E_{dis} for large α. (*2*) The negative steric hindrance contribution increases for large, more sterically hindered molecules, the effect of which would give the same trend for $X_{12}s_1^{-1}$ with α as in the preceding case. Several points have been added on Fig. 4 using oligomers and polymers as order-destroyers. These points are with the dimer, tetramer, and the polymer of dimethylsiloxane (19) and polyisobutylene (14). Their $X_{12}s_1^{-1}$ (disorder) follows undoubtedly the main curve because the shape of the polymer segment is not very different from that of the branched alkane or of the other non-polymeric order breakers shown on the graph.

The $X_{12}s_1$ obtained with cyclohexane (⌓), $SnMe_4$ (□), and dibromoethane (●) are quite outside the general curve. The assumption needed to go from eq. [5] to eq. [6] is undoubtedly not valid in the case of these three order breakers. Excess heat capacities may give more understanding of these heats. It has been found[2] that cyclohexane and $SnMe_4$ have in common the unusual feature to give in decahydronaphthalene solutions excess heat capacities which change sign with concentration. C_p^E is positive in solutions rich in the globular component and negative in the other region.

Heats of mixing of the trialkyl with the linear and branched alkanes have given an answer to two of the three questions detailed in the Introduction. Firstly, the magnitude of the heats seems to indicate that in alkane solution the trialkylamines behave as non-polar compounds. A compensation of larger negative and positive terms to give these small heats is possible but not very likely. Secondly, the very similar magnitude of H^E_{dis} with $NLaur_3$ and $SnLaur_4$ indicates no extensive contribution of *intra*molecular correlations of orientations. Had it been the case, H^E_{dis} for the tetraalkyl derivative would perhaps have been twice as large as that of trialkyl. On the third point, i.e. the correlation in pure compounds of high P^* and high steric hindrance, it is not possible to give a definite answer since the steric hindrance effect is relatively small in NPr_3 and its P^* value is not very different from that of the other members of the series.

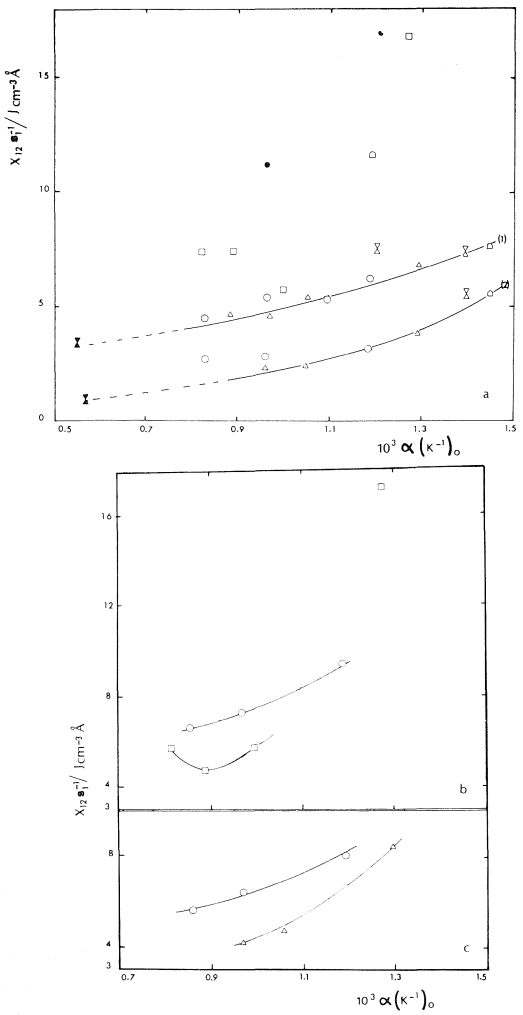

FIG. 4. $X_{12}s_1^{-1}$ (disorder) for long-chain compounds in J cm^{-3} Å versus α, the expansion coefficient of the order breaker. (*a*) Ordered compounds *n*-C_{16} (curve *1*) and *n*-C_{12} (curve *2*); (*b*) ordered compound, $SnLaur_4$; (*c*) ordered compound, $NLaur_3$. Symbols for the order breaker molecule: ⌓, 2,2-DMB; ○, br-C_n; △, NR_3; □, SnR_4; ⧖, dimer, tetramer, polymer of dimethylsiloxane (19); ⧗, polyisobutylene (14). The points outside curve (*1*) in Fig. 4*a* and *b* correspond to the solution in *n*-C_{16} compounds for which eq. [6] should not apply: □, $SnMe_4$; ⌓, cyclohexane ref. 3*b*; and ●, dibromoethane (20).

cis- and *trans*-Platinum compounds of substituted pyrimidines and their products from thiourea in Kurnakov's reaction

PI-CHANG KONG AND F. D. ROCHON

Département de chimie, Université du Québec à Montréal, C.P. 8888, Montréal (Qué.), Canada H3C 3P8

Received May 24, 1978

PI-CHANG KONG and F. D. ROCHON. Can. J. Chem. **57**, 526 (1979).

cis- and *trans*-$[Pt(pm)_2X_2]$ (where pm = 2-aminopyrimidine, 4-phenylpyrimidine, 4-methylpyrimidine and X = Cl, Br) were prepared and characterized. The *cis* compounds were isolated from the reaction of K_2PtCl_4 and pm in water, while *trans*-$[Pt(pm)_2X_2]$ was obtained by isomerization of *cis*-$[Pt(pm)_2X_2]$ in dimethylsulfoxide. The *cis*- and *trans*-isomers react with thiourea (tu) to give different products (Kurnakov's test).

$$cis\text{-}[Pt(pm)_2X_2] \xrightarrow{tu} [Pt(tu)_4]X_2$$

$$trans\text{-}[Pt(pm)_2X_2] \xrightarrow{tu} trans\text{-}[Pt(pm)_2(tu)_2]X_2$$

The complexes *trans*-$[Pt(pm)_2(tu)_2]X_2$ were isolated and characterized.

PI-CHANG KONG et F. D. ROCHON. Can. J. Chem. **57**, 526 (1979).

Les complexes *cis*- et *trans*-$[Pt(pm)_2X_2]$, où pm = amino-2 pyrimidine, phenyl-4 pyrimidine, méthyl-4 pyrimidine et X = Cl, Br, ont été préparés et caractérisés. Les composés *cis* ont été isolés de la réaction de K_2PtCl_4 avec pm dans l'eau, tandis que les composés *trans* ont été obtenus par l'isomérisation de *cis*-$[Pt(pm)_2Cl_2]$ dans le diméthylsulphoxyde. Les isomères *cis* et *trans* réagissent avec thiourée (tu) pour donner des produits différents (test de Kurnakov).

$$cis\text{-}[Pt(pm)_2X_2] \xrightarrow{tu} [Pt(tu)_4]X_2$$

$$trans\text{-}[Pt(pm)_2X_2] \xrightarrow{tu} trans\text{-}[Pt(pm)_2(tu)_2]X_2$$

Les complexes *trans*-$[Pt(pm)_2(tu)_2]X_2$ ont été isolés et caractérisés.

Introduction

The discovery that *cis*-$[Pt(NH_3)_2Cl_2]$ is an effective anti-tumor drug[1] has led a large research effort to synthesize complexes of the type *cis*-$[Pt(L)_2Cl_2]$ which would be active against a broad spectrum of tumor systems. Since *trans*-$[Pt(L)_2Cl_2]$ has no anti-tumor activity and *cis*-$[Pt(L)_2Cl_2]$ may isomerize in certain solvents to *trans*-isomers, the configuration assignments of the structures and the choice of solvents used for dissolving drugs are important. Recently, Stetsenko *et al.* (2) prepared two compounds from the reaction of K_2PtCl_4 with 2-aminopyrimidine and 2-amino-4-phenylpyrimidine in aqueous solution. The compounds have an experimental formula $[Pt(pm)_2Cl_2]$ (where pm = pyrimidine derivative). The compounds were assigned to have the *trans* configuration (2). This assignment suggests that the chemistry of pyrimidine with K_2PtCl_4 is not analogous to that of amines and pyridine which give the *cis*-isomers in the same conditions. However, the evidence used to assign the *trans* configuration to the pyrimidine complexes is not very conclusive. A more complete study of pyrimidine complexes was made in our laboratory in order to obtain more evidence for the assignment of the configuration. We have prepared the *cis*- and *trans*-isomers of $[Pt(pm)_2Cl_2]$ where pm = 2-aminopyrimidine (2AP), 4-phenylpyrimidine (4PhP), 4-methylpyrimidine (4MeP), and their bromo-analogs and we have found that the *cis*-isomer isomerizes to the *trans*-isomer in dimethylsulfoxide. The results of Kurnakov's test (3) on the isomers indicate that the previous assignment of the configuration was wrong.

[1]The most recent reports of the clinical status of the drug appear in a two-part issue of ref. 1.

Experimental

Microanalyses were performed by Chemalytics Inc., Tempe, AZ, U.S.A. Infrared spectra were measured as Nujol or hexachlorobutadiene mulls or KBr pellets on a Perkin-Elmer 621 grating spectrometer. Melting points were measured on a Fisher-Johns apparatus and are uncorrected.

The platinum salt was purchased from Johnson Matthey and Mallory and was recrystallised from water. 4-Phenylpyrimidine and 4-methylpyrimidine were obtained from Aldrich and used without further purification. 2-Aminopyrimidine (practical grade) from Eastman was purified twice from water by filtering its aqueous solution through charcoal.

0008-4042/79/050526-04$01.00/0

After recrystallization, the product was obtained as white crystals, mp 125°C (126°C (12)).

Solution of K_2PtBr_4

K_2PtCl_4 (0.83 g) and NaBr (0.5 g) were dissolved in 10 mL of water at room temperature. After 24 h the solution was ready to use.

cis-[*Pt(2AP)$_2$X$_2$*] (*X = Cl, Br*)

To an aqueous solution of K_2PtX_4 (0.83 g of K_2PtCl_4 in 10 mL of water or 10 mL solution of K_2PtBr_4) an aqueous solution of 2AP (0.6 g in 5 mL of water) was added. The resultant solution was left at room temperature for 5 h (X = Br, 3 h). The yellow precipitate was filtered off, washed with water, alcohol, and ether, and dried at 80°C under vacuum overnight. Yield 80% (65% X = Br).

cis-[*Pt(4PhP)$_2$Cl$_2$*]

4PhP (0.65 g) dissolved in 15 mL of alcohol was added to 0.415 g of K_2PtCl_4 dissolved in 15 mL of water. A yellow precipitate appeared after stirring the mixture at room temperature. After 2 h, the yellow precipitate was filtered off, washed with water and alcohol, and dried in a desiccator. When dried the product was dissolved in 5 mL dimethylformamide and filtered. Anhydrous ether (20 mL) was then added to the filtrate and a precipitate appeared immediately. The yellow precipitate was filtered, washed with ether, and dried at 100°C under vacuum overnight. Yield 50%.

cis-[*Pt(4PhP)$_2$Br$_2$*]

4PhP (1 g) dissolved in 15 mL of alcohol was added to 10 mL solution of K_2PtBr_4 at room temperature with stirring. Three hours later, the precipitate was filtered off, washed with water, alcohol, and ether, and dried at 80°C under vacuum overnight. Yield 60%.

cis-[*Pt(4MeP)$_2$Cl$_2$*]

4MeP (0.4 g) was added to a solution of 0.415 g of K_2PtCl_4 dissolved in 10 mL of H_2O at room temperature with stirring. One hour later, the precipitate was filtered off, washed with water, and dried at 80°C overnight. Yield 55%.

trans-[*Pt(pm)$_2$X$_2$*]

The *cis*-compound was dissolved in a minimum amount of dimethylsulfoxide (DMSO). The DMSO solution was heated at 65°C with stirring and 2 h later, the solution became cloudy. Three days later, the solution was cooled to room temperature. The precipitate was filtered off and washed with DMSO, alcohol, and ether. It was dried at 80°C under vacuum overnight. Yield 75%.

trans-[*Pt(pm)$_2$(tu)$_2$*]*Cl$_2$*

trans-[Pt(pm)$_2$Cl$_2$] (0.5 mmol) was suspended in 10 mL of dimethylformamide (DMF) with 0.38 g of thiourea (tu) and stirred overnight (pm = 2AP) or 10 h (pm = 4PhP). The yellow suspension became white. The compound was isolated by filtration and washed with DMF and ether. The compound was then dissolved in water and filtered in order to remove the small amount of starting material (water at room temperature for 2AP, at 80°C for 4PhP). The aqueous filtrate was evaporated to dryness with a rotatory evaporator and a water pump. The compound was dried at 80°C under vacuum overnight. Yield 65%.

trans-[*Pt(4PhP)$_2$(tu)$_2$*]*Br$_2$*

trans-[Pt(4PhP)$_2$Br$_2$] (0.5 mmol) was suspended in 10 mL of DMF with 0.38 g of thiourea and stirred overnight. The unreacted starting material was filtered off and a yellow-greenish filtrate was obtained. Ether (10 mL) was added to the filtrate and a white precipitate was obtained. The precipitate was isolated by filtration, washed with 20 mL of DMF–ether 1:1 mixture, in 4 portions. It was then washed with ether and dried at 80°C under vacuum overnight. Yield 70%.

Results and Discussion

K_2PtCl_4 mixed with nitrogen bases (L) such as pyridine and amine in aqueous solutions gives a yellow precipitate, *cis*-[Pt(L)$_2$Cl$_2$]. In similar conditions, pyrimidine with K_2PtCl_4 also gives a yellow precipitate with experimental formula [Pt(L)$_2$Cl$_2$]. By analogy to the chemistry of pyridine and amine, the pyrimidine complex should also have the *cis*-configuration. However, compounds of 2-aminopyrimidine and 2-amino-4-phenylpyrimidine prepared in aqueous solution were reported as having the *trans*-configuration (2). The configuration assignment was based on the following: (*a*) one Pt—Cl stretching band was observed in the infrared spectrum, (*b*) on heating the compounds with pyridine (py), pyrimidine was displaced and *trans*-[Pt(py)$_2$Cl$_2$] was obtained. Actually, these two evidences are not very conclusive: (*a*) we have repeated the reaction and noted that if the compound [Pt(2AP)$_2$Cl$_2$] is well dried, the Pt—Cl stretching is not a single band, but a doublet, (*b*) a final product, *trans*-[Pt(py)$_2$Cl$_2$], from the reaction between [Pt(pm)$_2$Cl$_2$] and pyridine was obtained, but it should not be used to justify the structure of the starting material, because isomerization can occur during the process of the reaction. For example, *cis*-[Pt(DMSO)$_2$Cl$_2$] (4) and *cis*-[M(py)$_2$Cl$_2$] (M = Pt (5) and Pd (6)) react with pyridine to give *trans*-[Pt(py)$_2$Cl$_2$]. To settle this controversy, both *cis*- and *trans*-isomers of [Pt(pm)$_2$Cl$_2$] are required. Usually, *trans*-isomers of pyridine and amine complexes are prepared as follows (7).

$$[Pt(L)_4]Cl_2 \xrightarrow[H_2O]{HCl} trans\text{-}[Pt(L)_2Cl_2]$$

[Pt(L)$_4$]Cl$_2$ can be obtained by refluxing *cis*- or *trans*-[Pt(L)$_2$Cl$_2$] with an excess of L. We tried this reaction to prepare [Pt(L)$_4$]Cl$_2$ from [Pt(L)$_2$Cl$_2$] (L = 2AP, 4PhP) without success.

A new method was found to prepare the *trans*-isomer. The compounds of pyrimidines, [Pt(pm)$_2$Cl$_2$], isolated from an aqueous solution according to ref. 2, were dissolved in DMSO at 65°C for 3 days. A lighter yellow precipitate was obtained. The results from the element analysis indicated that the experimental formula is the same as the starting material, [Pt(pm)$_2$Cl$_2$]. But there is a remarkable difference in their properties, especially their solubility in DMSO. The lighter yellow precipitate is, at least, 5 times less

*Calculated value in first row.

soluble than the starting material. The infrared spectra of the 4-methylpyrimidine complexes are shown in Fig. 1. The spectrum of the isomer from DMSO (*a*) showed one single sharp band at 345 cm^{-1} while the spectrum of the isomer from aqueous solution (*b*) showed two bands at 341 and 330 cm^{-1}. These bands are assigned as Pt—Cl stretching vibrations. The compounds of other pyrimidine derivatives showed the same Pt—Cl stretching as those of 4MeP. There are two single bands from 4MeP ligands at 390 and 510 cm^{-1} in Fig. 1*a*, while these two bands become doublets at 378, 390 and 500, 515 cm^{-1}, respectively, in Fig. 1*b*. Therefore the infrared spectra suggest that the isomer isolated from the DMSO solution is the *trans*-isomer while the starting material (isolated from K_2PtCl_4 and pm in aqueous solution) has the *cis* configuration. This method has been used to prepare pyridine and picoline compounds. *cis*-$[Pt(py)_2Cl_2]$ isolated from an aqueous solution was dissolved in DMSO and left at room temperature for 5 days. Water was then added to the DMSO solution and the precipitate formed proved to be *trans*-$[Pt(py)_2Cl_2]$ by infrared spectroscopy (8). From the infrared data and the isomerization of pyridine compounds in DMSO, the compounds with pyrimidine derivatives isolated from DMSO should be the *trans*-isomers.

Very fortunately, the two isomers respond to Kurnakov's test in dimethylformamide, i.e., *cis*- and *trans*-$[Pt(pm)_2X_2]$ react with thiourea (tu) to give different products (3).

$$[1] \qquad cis\text{-}[Pt(pm)_2X_2] \xrightarrow[DMF]{tu} [Pt(tu)_4]X_2$$

$$[2] \qquad trans\text{-}[Pt(pm)_2X_2] \xrightarrow[DMF]{tu} [Pt(pm)_2(tu)_2]X_2$$

The rate of the above reactions are quite different. Within 1 h, reaction [1] is complete and a clear yellow solution is obtained. However, 10 h is not enough for reaction [2].

The products from the above reactions can be distinguished by their elemental analyses and their infrared spectra. The configuration of the isomers can now be definitely assigned. The compound from the aqueous solution is the *cis*-isomer and the compound from DMSO is the *trans*-isomer.

Kurnakov's test was also tried in water and acetone at room temperature. Both reactions [1] and [2] were quite slow and only a small amount of product was obtained from the reactions. When the compounds were refluxed in water the test failed, both isomers gave $[Pt(tu)_4]Cl_2$. The test is reliable if the appropriate conditions and solvent are found and the compounds should be tested preferably in

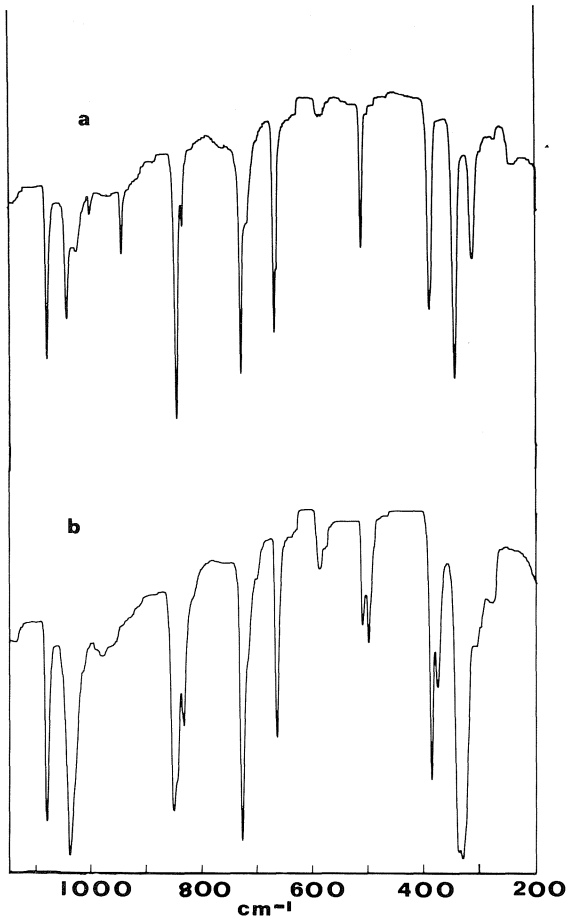

FIG. 1. Infrared spectra of (*a*) *cis*-[Pt(4MeP)$_2$Cl$_2$], (*b*) *trans*-[Pt(4MeP)$_2$Cl$_2$] in Nujol mull.

pairs. If the *trans*-isomer is refluxed in water without a parallel testing on the *cis*-isomer, it will be erroneously assigned as the *cis*-isomer based on reaction [1].

Because of the sterie hindrance of the phenyl group and the methyl group, the coordinating sites of 4PhP and 4MeP should be far from these groups, i.e. N_1. The binding site of 2-aminopyrimidine is N_1 (or N_3) rather than the amino group. Cytidine and cytosine derivatives coordinate to platinum through N_3 (9–11). The ν_{N-H} stretching of 2-aminopyrimidine is shifted to higher region upon complexation indicating that the amino group is not involved in the bonding.

In Fig. 1*a*, there is a band at 318 cm^{-1} which becomes a shoulder in *b* because of the broad Pt—Cl stretching very close to it. Free pyrimidine ligands do not have bands around this position. It is assigned as Pt—N stretching with comparison to the compounds of 4-methylpyridine having a Pt—N stretching band at 317 cm^{-1} (8).

In a previous work (5), we have found a method to prepare *trans*-[Pt(py)$_2$Cl$_2$] (py = pyridine and picoline) from DMF solution of *cis*-[Pt(py)$_2$Cl$_2$] and py. Pyrimidine compounds can also be made by this method. Crystals of *trans*-pyrimidine compounds were obtained from a DMF solution of *cis*-[Pt(pm)$_2$X$_2$] and pm at room temperature after 1 to 2 weeks.

A calorimetric dilution method was applied to the system benzoic acid in benzene at 25°C. Two different calorimeters, a batch calorimeter (at Guelph) and a flow microcalorimeter (at Sherbrooke), were used in this study. Our results were inconsistent with an ideal monomer–dimer model, which had been used in previous calorimetric studies on this and other similar systems. Our results were consistent with an ideal monomer–dimer–trimer model, for which we obtained: $K_2 = 625 \pm 100$ L/mol, $K_3 \simeq 10^4$ L^2/mol^2 for the dimerization and trimerization constants respectively, and $\Delta H_2^0 = -8.52 \pm 0.50$ kcal/mol, $\Delta H_3^0 = -13.48 \pm 2$ kcal/mol for the molar enthalpies of dimerization and trimerization, respectively.

On a appliqué une méthode de dilution calorimétrique au système acide benzoïque/benzène à 25°C. Deux calorimètres différents — un calorimètre à masse (à Guelph) et un microcalorimètre à écoulement (à Sherbrooke) — ont été utilisés dans cette étude. Nos résultats ne concordent pas avec un modèle idéal monomère–dimère qui avait été utilisé dans des études calorimétriques antérieures sur ce système et d'autres semblables. Nos résultats sont en accord avec un modèle idéal monomère dimère–trimère pour lequel on a obtenu des valeurs respectives de $K_2 = 625 \pm 100$ L/mol, $K_3 = 10^4$ L^2/mol^2 pour les constantes de dimérisation et de trimérisation et des valeurs respectives de $\Delta H_2^0 = -8.52 \pm 0.50$ kcal/mol, $\Delta H_3^0 = -13.48 \pm 2$ kcal/mol pour les enthalpies molaires de dimérisation et de trimérisation.

Introduction

Recently, a number of papers have appeared which describe a calorimetric dilution technique that enables one to determine the thermodynamic quantities ΔG^0, ΔH^0 (and ΔS^0) for self-association reactions that result from intermolecular hydrogen bonding (1–5). This technique is attractive because it is applicable to a wide variety of systems (5), and because it gives results rapidly. The method does, however, require the assumption that the heat evolved is due only to the change in the number of ideal molecular aggregates. When applied to carboxylic acids an ideal monomer–dimer model was invariably assumed (2, 3, 5).

Two fairly recent studies, however, cast doubt upon the validity of this model. In one (6) infrared data on the acetic acid – carbon tetrachloride system were investigated by the method of factor analysis. It was found that in all but the most dilute solutions species larger than dimers were present in appreciable concentrations. In a second article (7) it was found that monomers, dimers, and trimers were required to account for osmometric data on benzene solutions of long-chained carboxylic acids.

In view of these articles and the only fair agreement between the calorimetric results and those from others techniques for the benzoic acid in benzene system (5, 8–11), we considered it worthwhile to re-examine the calorimetric results. In the present work we used the results obtained from the heat of dilution values measured in two different laboratories. A batch calorimeter in Guelph and a Picker flow microcalorimeter in Sherbrooke were used.

Experimental

The benzene (Fisher, B-245 reagent grade) was purified and dried as described elsewhere (12), and stored over molecular sieves (Fisher, 4 Å). Traces of absorbed moisture in the benzoic acid (Analar, analytical reagent grade 99.9% assay) were removed by fusing in a platinum crucible at 135 ± 5°C. Two separate analyses on the final product by the sodium carbonate – sodium hydroxide method (13, 14) resulted in assay values of 99.97 and 100.00%.

At the University of Guelph, the heats of dilution (ΔH_{dil})

0008-4042/79/050530-08$01.00/0

were measured with a batch calorimeter, built by Dr. W. C. Duer, which is similar to one described in ref. 15. With this instrument, fragile glass ampoules (capacity of ~5 mL) fitted with capillary side-arms (designed to minimize solvent evaporation) were used for sample introduction. The heat of bulb breaking was found to be negligible. In all the experiments at Guelph the calorimeter vessel (volume of 200 mL) initially contained pure benzene and the ampoules contained a known weight of a benzoic acid – benzene stock solution. Different final concentrations of benzoic acid in benzene were achieved both by using different concentrations for the stock solutions, and by varying the quantity of stock solution in the ampoule.

The heats of dilution measured at the Université de Sherbrooke were obtained with the commercial version (Sodev Inc.) of the Picker flow microcalorimeter. The principle of this calorimeter is described in detail elsewhere (16, 17). The measurements were done at a dilution ratio $C_i/C_f \simeq 2$, where C_i and C_f are, respectively, the initial and final stoichiometric concentrations of benzoic acid in mol/L. Due to the strong concentration dependence of the relative apparent molar enthalpy ϕ_L in the low concentration region (Fig. 1) we measured most of the ΔH_{dil} on the flow system with $C_i \leq 0.1\ M$. The high sensitivity (1×10^{-6} °C) of the flow microcalorimeter allows such measurements with good precision, i.e., 0.5% or better.

The solutions were prepared by weight. Molality–molarity interconversions were made using solution densities, which were measured with a flow densimeter (18). The excess volume of mixing was found to be negligible.

The effect of the water content of the samples on the dilution data was checked and found to be appreciable, as already observed by Flitt and Jaycock and others (1, 19–21). Therefore special care was taken in both laboratories to minimize water contamination. This precaution was especially important in the flow experiments where the low concentration region was probed. The water content of all samples run on the flow system were therefore titrated before and after the dilution using an aquatest Karl Fischer titrimeter (Photovolt, model 702). We kept only the ΔH_{dil} values for samples with less than 25 ppm water, for reasons which are now explained.

A number of preliminary trial experiments were run with the flow calorimeter, in which water was deliberately added either to the solution, or to the solvent, or to both. Two concentrations of benzoic acid were used in these trials: 0.04 *m* and 0.40 *m*. With 450 ppm water in the solution, $\Delta\phi_L$ was found to increase (i.e. become more negative) with respect to the anhydrous situation by about 15%, for both the 0.04 *m* and the 0.40 *m* benzoic acid solutions. When 450 ppm water were present in both the solvent and the solution $\Delta\phi_L$ decreased by about 5% with the 0.04 *m* solution and it decreased by about 15% with the 0.40 *m* solution. In another experiment, where 120 ppm water were added to the 0.04 *m* solution, $\Delta\phi_L$ increased by about 2%. In still another set of preliminary experiments, two solutions of wet benzene containing 450 ppm and 120 ppm water (but no benzoic acid) were diluted with anhydrous benzene. The $\Delta\phi_L$ values observed in these trials were negligible with respect to our experimental uncertainty. These last experiments demonstrate that the effect of water on $\Delta\phi_L$ is due to changes in the extent of hydration of benzoic acid, rather than to the heat of dilution of water in benzene.

These observations made it imperative to reduce the water content of these solutions as far as possible. It was found, in practice, that by taking sufficient precautions it was possible in almost every run to reduce the total water content of our systems to 25 ppm or less. The water content of the solutions did not change significantly (the experimental uncertainty in the water analyses was 10 ppm) in the course of a dilution experiment. We found that when the water content of the solutions was within the range 0 to 25 ppm, the experimental $\Delta\phi_L$'s obtained from one run to the next were well within 0.50% of each other, which is our experimental uncertainty in $\Delta\phi_L$. Consequently we retained only those data obtained with the flow system where the water content was 0 to 25 ppm. The order of magnitude calculation given below provides a theoretical justification for the view that we can neglect the effect of water on our results provided the water content of our solutions is less than 25 ppm.

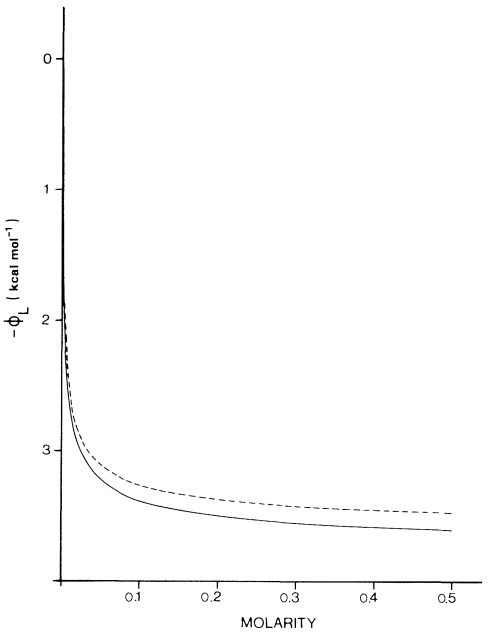

FIG. 1. Relative apparent molar enthalpy of benzoic acid in benzene at 25°C: solid line, this work; dashed line, calculated from K_2 and ΔH_2^0 of Woolley and Zaugg (5).

A previous study (which assumed a monomer–dimer model for the system benzoic acid in benzene) provides the following estimates for the hydration constants of benzoic acid in benzene at 25°C: $K_{11} = 12.4$ L/mol; $K_{12} = 248$ L^2/mol^2, $K_{21} = 582$ L^2/mol^2 where K_{11}, K_{12}, and K_{21} represent the hydration constants for the formation of the monomer-monohydrate, the monomer-dihydrate, and the dimer-monohydrate, respectively (22). In order to obtain an upper bound on the fractions of the benzoic acid species that were hydrated in our experiments with the flow calorimeter, we assume that all of the 25 ppm ($1.21 \times 10^{-3}\ M$) was in the form of free (i.e. nonbonded) water. Thus the maximum fraction of the benzoic acid monomer that can be hydrated in our solutions at 25°C is given by:

$$F = \frac{\text{Concentration of hydrated monomer}}{\text{Total monomer concentration}}$$

$$= \frac{\text{M}\cdot\text{H}_2\text{O} + \text{M}\cdot 2\text{H}_2\text{O}}{\text{M} + \text{M}\cdot\text{H}_2\text{O} + \text{M}\cdot 2\text{H}_2\text{O}}$$

$$= \frac{K_{11}[\text{H}_2\text{O}] + K_{12}[\text{H}_2\text{O}]^2}{1 + K_{11}[\text{H}_2\text{O}] + K_{12}[\text{H}_2\text{O}]^2}$$

[b] ΔH_{dil} is the heat of dilution.

or

$$F = 0.015$$

Similarly the maximum fraction of dimer that can be hydrated in our experiments is found to be 0.0011.

Thus by keeping the water content of the benzene solutions to 25 ppm or less we keep the extent of hydration very small indeed.

Results and Treatment of the Data

A total of 32 separate heat of dilution experiments were carried out in two runs with the batch calorimeter and 25 with the flow microcalorimeter. All the measurements were done at 25.0 ± 0.1°C. The raw data from both sets of experiments are entered in Tables 1 and 2.

It is conventional to report heat of dilution data in terms of ϕ_L. After several trial calculations, we found that the data obtained with the batch calorimeter did not extend sufficiently into the dilute concentration region (Fig. 1) to make such a reformulation either meaningful or useful. However, the data from the flow calorimeter did extend to low enough concentrations to make this re-formulation worthwhile. Therefore, the data in Table 2 were treated by a large-scale graphical interpolation procedure, similar to one that had been used previously in the Sher-

TABLE 3. Relative apparent molar enthalpy ($-\phi_L$) of benzoic acid in benzene at 25°C from a graphical interpolation procedure

0.07	3308	0.50	3604

brooke laboratory. The smoothed ϕ_L values so obtained are entered in Table 3. While a direct comparison of data in Tables 1 and 2 is not possible (because of the different concentration ranges involved and the difficulty of getting ϕ_L's from the data in Table 1) an indirect comparison (see text below and Table 4) indicated that the data from the two laboratories were consistent.

The principal source of error in the evaluation of ϕ_L stems from the required extrapolation to infinite dilution. While a large number of experiments on the flow system were run with $C_i < 0.1\ M$ in an attempt to minimize this uncertainty, a substantial residual error in the extrapolation remained. We estimate that the extrapolation led to an uncertainty of about ± 250 cal/mol in the absolute values of ϕ_L. The uncertainty in the values of $\Delta\phi_L$ was of course much less. We estimate that for $8 \times 10^{-4}\ M \leq C \leq 0.5\ M$, the values of $\Delta\phi_L$ are correct to $\pm 0.5\%$ or better.

Monomer–Dimer Model

Several methods can be used to obtain values for K_2 (the dimerization constant) and ΔH_2^0 (the enthalpy of dimerization) from heat of dilution data (1–3).

In this section we describe two methods that were applied to our data. For the dimerization equilibrium

$$2M \rightleftarrows D$$

wherein the monomers and dimers are each assumed to be ideal (see ref. 1 and below):

$$[1] \qquad K_2 = [D]/[M]^2$$

$$[2] \qquad [C] = [M] + 2[D]$$

where [C] is the stoichiometric concentration of the solute and [M] and [D] are the monomer and dimer concentrations, respectively (mol/L). Combining eqs. [1] and [2], one gets

$$[3] \qquad [D] = \{-1 + (1 + 8K_2[C])^{1/2}\}^2/16K_2$$

Method 1

ϕ_L can be related to the enthalpy of dimerization by the following equation

$$[4] \qquad [C]\phi_L = \Delta H_2^0[D]$$

Using eqs. [1] and [2], eq. [4] can be rearranged to give equation:

$$[5] \qquad \phi_L = \frac{\Delta H_2^0}{2} - \left(\frac{-\Delta H_2^0(-\phi_L)}{4K_2[C]}\right)^{1/2}$$

Thus a graph of ϕ_L vs. $(-\phi_L/[C])^{1/2}$ leads to the evaluation of ΔH_2^0 and K_2 from the intercept and the slope of the best linear fit. In fact, the plot of our ϕ_L results according to this equation shows a slight curve with values for $C < 0.1\ M$ as can be seen from Fig. 2. We will return to this point later. A linear least-squares fit gave $K_2 = 400$ L/mol and $\Delta H_2^0 = -7.6$ kcal/mol.

Method 2

It was found by experience that the values of ΔH_2^0 and K_2 that were obtained by method 1 were strongly dependent on the absolute values of ϕ_L which were used with eq. [5]. As explained previously, the absolute values of ϕ_L were subject to considerable

TABLE 4. K_2 and ΔH_2^0 for benzoic acid in benzene at 25°C calculated on the basis of an ideal monomer–dimer model

[a]'Method 1' and 'method 2' are described in text.
[b]These standard deviations were obtained from Professor Earl Woolley in a private communication.

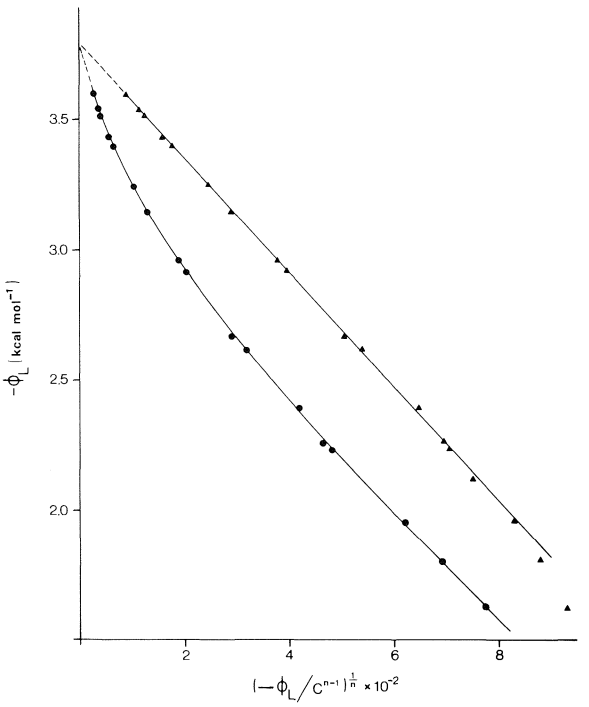

FIG. 2. Relative apparent molal enthalpy of benzoic acid in benzene at 25°C displayed as suggested by eq. [5] (monomer–dimer model, $n = 2$) and eq. [7] (monomer–trimer model, $n = 3$).

uncertainty due to the uncertainty in the extrapolation to infinite dilution. Therefore, it was desirable to treat our data by a second method. This method was applied to the data from both the batch and the flow calorimeters.

This method is an iterative procedure that can be summarized as follows: first an initial value for K_2 is chosen, and eq. [3] is used to calculate the change in the number of mole of dimers $\Delta n_D = n_f - n_i$ for each dilution experiment (the subscripts i and f refer to the initial and final states). Then the enthalpy of dimerization, ΔH_2^0, is computed by means of

$$[6]\ \Delta H_2^0 = \frac{q}{\Delta n_D} = \frac{\Delta H_{dil}}{n_f - n_i} = \frac{\Delta H_{dil}}{[D]_f V_f - [D]_i V_i}$$

where [D] means dimer concentration, V means volume, and q is the value of the measured heat change in the calorimeter.

The calculation is carried out for all the experimental values and subsequently an average and a standard deviation is obtained for ΔH_2^0. These calculations are repeated for a number of values of K_2. The 'best' values of K_2 and ΔH_2^0 were obtained from that pair of values for which the standard deviation of ΔH_2^0 was a minimum. When this procedure was applied to the data in Table 1 we obtained: $K_2 = 458$ L/mol; $\Delta H_2^0 = -7.7$ kcal/mol dimer. When applied to the data in Table 2 we found $K_2 = 500$ L/mol; $\Delta H_2^0 = -8.4$ kcal/mol dimer.

The values of K_2 and ΔH_2^0 from both methods are grouped together in Table 4, together with the values for these quantities reported previously by Woolley and Zaugg (5). These authors used the ϕ_L method on their calorimetric data which were obtained by a titrimetric procedure.

Several points are immediately apparent from the entries in Table 4. First the data obtained by the batch and the flow calorimeters in this work are mutually consistent, and they are both consistent with Woolley and Zaugg's data. Also, the uncertainties in this and in Woolley and Zaugg's work are of comparable magnitude. Thus the $\Delta\phi_L$'s obtained here and in Woolley's work are consistent. The discrepancy in the *absolute* ϕ_L values (apparent from Fig. 1) obtained in this and in Woolley's work is a consequence of the fact that accurate absolute ϕ_L values require very accurate data in the dilute solution regime. The titrimetric procedure used by Woolley and his collaborators inadequately probes this dilute solution region.

Of course, consistency of the above results really amounts to little more than a data check and certainly this consistency does not prove the validity of monomer–dimer model. Indeed we are prompted for several reasons to be suspicious of this model. First, other authors using methods as diverse as infrared spectroscopy (6) and osmometry (7) found that larger species in addition to dimers were required to account for their data on carboxylic acids in nonaqueous solvents. Second, the values listed in Table 4 for K_2 are somewhat lower than what is expected from previous studies involving other experimental techniques. This discrepancy is demonstrated by the point with the symbol ∇ in Fig. 3. We believe that the titrimetric calorimetric method employed by Woolley *et al.* gives more weight to the high concentration regime than do other experimental methods, so that the K_2 values extracted from the titrimetric data are too low. Third, we were bothered by the slight curvature, which we believe to be real, in the ϕ_L vs. $(-\phi_L/[C])^{1/2}$ plot (Fig. 2, upper graph). This curvature is apparent when a large scale graph is used. The scaling down and distortion that occurs on photographic reproduction makes this curvature unobservable in the upper graph of Fig. 2. We reasoned that if aggregates larger than dimers were present in our solutions, then the use of a monomer–dimer model should result in a concentration-dependent K_2. To test this idea we evaluated K_2 and ΔH_2^0 from ΔH_{dil} by applying method 2 to different concentration ranges. We split up our data from the batch

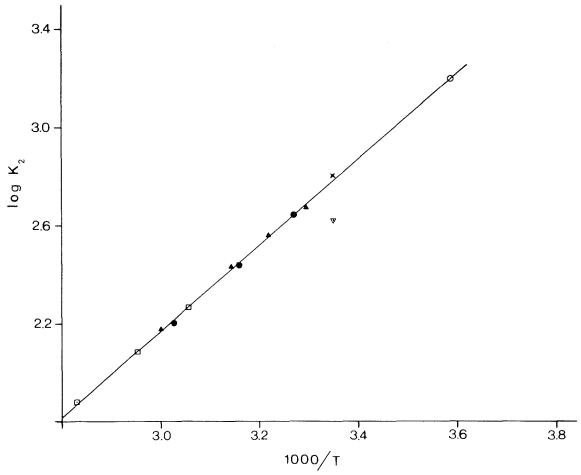

FIG. 3. Various values of K_2 (molar) for benzoic acid in benzene using the ideal monomer–dimer model: ▲, infrared (8); ●, isopiestic method (9); □, ebullioscopy (10); ○, cryoscopy (11); ▽, heat of dilution (5); ×, heat of dilution (this work with trimers included in the data treatment); solid line is linear least-squares line through all the values.

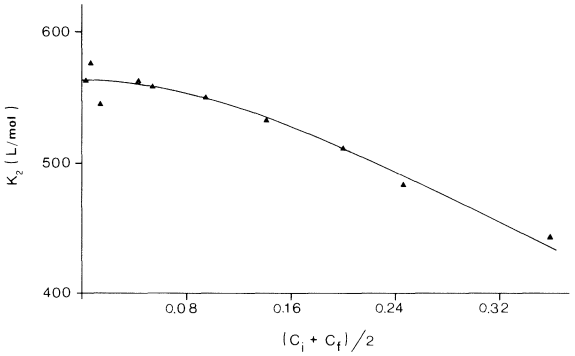

FIG. 4. The dimerization equilibrium constant (K_2) as a function of concentration.

calorimeter (Table 1) into two sets. In the first, the final solution concentration (i.e. the concentration of the solution in the calorimeter after the ampoule is broken) was always less than some selected value and in the second it was always greater than this value. The results of a number of such calculations clearly showed that K_2 dropped with increasing concentration. This concentration-dependence of K_2 is even more obvious with the data from the flow calorimeter (Table 2) since there the ΔH_{dil} were measured with solutions covering a wide range of initial concentrations, i.e., $0.0016\ M < C_i < 0.48\ M$. In Fig. 4, we plotted the value of K_2 calculated for each ΔH_{dil} (Table 2) using eqs. [6] and [3], assuming $\Delta H_2^0 = -8525$ cal/mol dimer (our 'best' value, details given below) and setting the concentration $C = (C_f + C_i)/2$. It is clear from Fig. 4 that when the ideal monomer–dimer is applied to our data, the values of K_2 that result are strongly concentration-dependent.

In view of these results, we considered it worthwhile to pursue other models, in an attempt to better account for our data.

Monomer–Trimer Model

This is an obvious alternative to the monomer–dimer model. Using the same approach as was taken in the monomer–dimer case (method 1) one can show that for the case of an ideal monomer–trimer equilibrium (1):

$$[7]\quad \phi_L = \frac{\Delta H_3^0}{3} - \tfrac{1}{3}(\Delta H_3^0)^{2/3}\left(\frac{1}{K_3}\right)^{1/3}\left(\frac{\phi_L}{[M]^2}\right)^{1/3}$$

where ΔH_3^0 is the molar enthalpy of trimerization and K_3 the trimerization constant. We applied eq. [7] to the data in Table 3; the results are plotted as the lower curve in Fig. 2. As is seen from Fig. 2, a very obvious curvature results. It was concluded that this model was clearly inconsistent with our data, and it was pursued no further.

Monomer–Dimer–Trimer Model

We next decided to fit our data to an ideal monomer–dimer–trimer model. This model is the simplest logical extension of the ideal monomer–dimer model and, as previously mentioned, it has been used to account for osmometric data on solutions of long-chained carboxylic acids in benzene (7). Of course in taking this approach we assume that the deviations we observed from the ideal monomer–dimer model are not due to non-ideality of the monomers and dimers themselves. While this is an unprovable assumption at present, it is consistent with much previous work in this area (e.g. see ref. 1 and references contained therein) and it is partially supported by the evidence that molecules that are geometrically similar to benzoic acid but do not have a carboxylic acid group (e.g. chlorobenzene) are very nearly ideal up to concentrations of $\sim 1\ M$ in non-aqueous solvents (1, 23). The approach described below is similar to one that has been previously described (4).

For the case where trimers are assumed to co-exist in equilibrium with monomers and dimers, the relevant equations (assuming all the species behave ideally) are:

$$[8]\quad [C] = [M] + 2K_2[M]^2 + 3K_3[M]^3$$

$$[9]\quad q = \Delta n_D \Delta H_2^0 + \Delta n_T \Delta H_3^0$$

$$[10]\quad [C]\phi_L = \Delta H_2^0[D] + \Delta H_3^0[T]$$

where the trimerization constant K_3 and the enthalpy of trimerization ΔH_3^0, refer to the process:

$$3M \rightleftarrows T$$

TABLE 5. Values of the dimerization constant (K_2), enthalpy of dimerization (ΔH_2^0), trimerization constant (K_3), and enthalpy of trimerization (ΔH_3^0) of benzoic acid in benzene at 25°C from heat of dilution measurements

Parameter	Value	
	Flow calorimeter	Batch calorimeter
K_2 (L/mol)	625[a]	—
ΔH_2^0 (cal/mol dimer)	−8 525[a]	—
K_3 (L²/mol²)	9 000[a]	—
ΔH_3^0 (cal/mol trimer)	−13 475 ± 100	−12 975 ± 435[b]

[a]See text for discussion of the uncertainties in these quantities.
[b]Calculated using $K_2 = 625$, $\Delta H_2^0 = -8525$, and $K_3 = 9000$.

In eq. [9], Δn_T is the change in the number of moles of trimers in a dilution experiment. To obtain unique values for the four constants K_2, K_3, ΔH_2^0, and ΔH_3^0 we proceeded in two steps. First, we divided the data in Table 2 into two sets, one with $C_i < 0.1$ M and the other with $C_i > 0.1$ M. Then we used an iterative procedure as follows. For the set $C_i < 0.1$ M we assume only monomers and dimers are present to get a first estimate of K_2 and ΔH_2^0. Then these values of K_2, ΔH_2^0 are used in the $C_i > 0.1$ M set to calculate a first estimate for K_3 and ΔH_3^0. These last values are now used to get an improved pair of values of K_2, ΔH_2^0, from the dilute range. The entire procedure is repeated until the values obtained for the four constants stabilize. As a final step, all the data in Table 2 are combined into one set and the iterative calculation is repeated, starting with the last values of the four constants, until the standard deviation (sd) for all the 25 points is minimum, where

$$\text{sd} \equiv \left[\frac{\sum_{i=1}^{25} (\Delta H_{dil}(\text{exp}) - \Delta H_{dil}(\text{calcd}))^2}{24}\right]^{1/2}$$

The values we thus obtained for the four constants are grouped in Table 5. Since it is not possible to obtain unique values for the four constants K_2, K_3, ΔH_2^0, ΔH_3^0 using the data from Table 1 alone, the stock solutions used being too concentrated, we utilized these newly obtained results ($K_2 = 625$ L/mol, $\Delta H_2^0 = -8525$ cal/mol dimer, $K_3 = 9000$ L²/mol²) to calculate a value for ΔH_3^0 using the batch calorimeter data. The value thus obtained for ΔH_3^0 is also entered in Table 5. As is seen from Table 5, both values of ΔH_3^0 agree to within their estimated standard deviations.

The entries in Table 5 provide a good fit to the data in Tables 1 to 3 in that the calculated values of ΔH_{dil} were found not to deviate in any systematic (i.e. concentration-dependent) way from the corresponding experimental values. In other words these values provide a good fit to sets of $\Delta\phi_L$ values that can be constructed from the ϕ_L values in Table 3.

The uncertainties in the values K_2 and ΔH_2^0 given in Table 5 are probably close to those that are deduced from the entries in Table 4 (i.e. sd $K_2 \sim \pm 100$; sd $\Delta H_2^0 \simeq 0.5$ kcal/mol dimer). It is much more difficult to assess, even roughly, the net uncertainties in K_3 and ΔH_3^0. (The values of ±100 and ±435 cal given in Table 5 for ΔH_3^0 are conditional uncertainties in that they depend on K_2, ΔH_2^0, and K_3 being perfectly correct.) This is because there is no concentration region in which trimers are the clearly predominant species. From unpublished trial calculations, however, we feel that ΔH_3^0 is probably correct to within 2 kcal, and that K_3 is of the right order of magnitude.

Discussion

Our values of K_2 and ΔH_2^0 calculated from the monomer–dimer–trimer model are in good agreement with those obtained from other work (Fig. 3). The slope ($d \log K_2/d(1/T)$) through all the points leads to $\Delta H_2^0 = -8.0$ kcal/mol dimer compared with −8.5 in the present work. Also our value for K_2 (625 L/mol) falls almost perfectly on the least-squares line.

It remains to account for the quasi-linearity of our ϕ_L vs. $(-\phi_L/C)^{1/2}$ plot (Fig. 2, upper graph). To get better insight into this type of plot, we evaluated ϕ_L and $(-\phi_L/C)^{1/2}$ using eq. [10] for different values of K_3, keeping K_2, ΔH_2^0, and ΔH_3^0 fixed at the values in Table 5. The results of these trial calculations showed that linearity of a ϕ_L vs. $(-\phi_L/C)^{1/2}$ plot is a poor criterion for the validity of the monomer–dimer model. For example, using $K_3 = 90\,000$ (i.e., 10 times our estimated value) which leads to an important relative contribution of trimers to the stoichiometric concentration (for $C = 0.10$, the fraction of acid in monomer:dimer:trimer form would be 0.06:0.42:0.52), the ϕ_L vs. $(-\phi_L/C)^{1/2}$ plot manifests only a slight curvature, which may, depending on the quality of the data, be considered almost negligible relative to experimental error.

Our value of ΔH_3^0 per mol ($\Delta H_3^0/3 = -4.49$ kcal/mol) is slightly more negative than ΔH_2^0 per

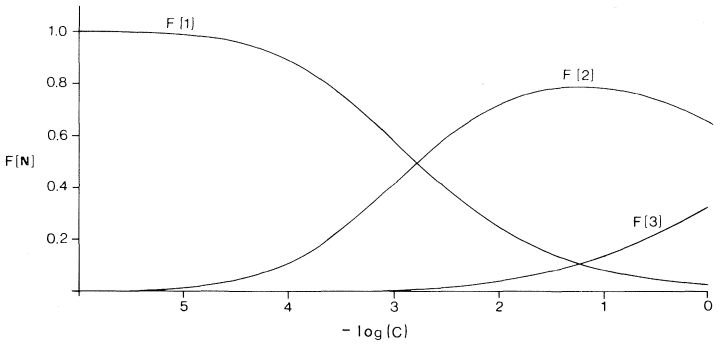

FIG. 5. $F(N)$ is the fraction of the stoichiometric benzoic acid concentration present as monomers, $F(1)$; dimers, $F(2)$; and trimers, $F(3)$. Curves obtained by eq. [8] with $K_2 = 625$ L/mol and $K_3 = 9000$ L^2/mol^2.

mol ($\Delta H_2^0/2 = -4.26$ kcal/mol). This trend in enthalpies has been noted for carboxylic acids in the gas phase (24), for long-chained carboxylic acid in benzene (7) and from quantum mechanical calculations (25). Also, our relative values of K_3 to K_2 are such that trimers make a significant contribution to the stoichiometric concentration for concentrations beyond 0.01 M. This is illustrated in Fig. 5, and is in line with what has been found for long-chained carboxylic acids in benzene (7) and for acetic acid in carbon tetrachloride (6).

We conclude, that except for very dilute solutions (i.e., less than 10^{-2} M), the ideal monomer–dimer model is of questionable value in the study of carboxylic acid self-association. For this reason, we believe that studies of H-bonding or self-association by the calorimetric dilution method have to be done in such a way that the dilute concentration region is well characterized, and this requires a highly sensitive microcalorimeter.

Modelling of interactions in solutions: alkali halides in DMSO

PEETER KRUUS AND BARBARA E. POPPE[1]

Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received September 6, 1978

PEETER KRUUS and BARBARA E. POPPE. Can. J. Chem. **57**, 538 (1979).

A model of solutions of alkali halides in DMSO is developed. Each ion is described by a radius, a charge, a polarizability, and an exponential repulsion parameter. Each molecule is described by a polarizability, charges, 6-12 energy parameters, and 6-12 distance parameters centered on each of the 10 atoms in the molecule. The model is applied to calculate (*i*) the vaporization energy of solvent molecules, (*ii*) single ion solvation energies and configurations of the solvating molecules, and (*iii*) the energy as a function of reaction coordinate for the formation of an ion pair. The energies and configurations are obtained by allowing the systems to relax to minimum energy configurations by allowing motion of the molecules. The results of (*i*) give a vaporization energy 60% of the experimental. The results of (*ii*) give solvation energies in reasonable agreement with the experimental, and configurations which are reasonable from the point of view of mobilities of ions. The results of (*iii*) show the presence of a distinct solvent separated ion pair which actually has an energy lower than the contact ion pair. Advantages and problems involved in using this approach to model solutions are discussed.

PEETER KRUUS et BARBARA E. POPPE. Can. J. Chem. **57**, 538 (1979).

On a développé un modèle pour les solutions d'halogénures alcalins dans le DMSO. On décrit chaque ion grâce à son rayon, à sa charge, à sa polarisabilité et à un paramètre de répulsion exponentielle. On décrit chaque molécule grâce à sa polarisabilité, et à des charges et des paramètres d'énergie de distance 6-12 dont le centre coincide avec chacun des 10 atomes de la molécule. On a appliqué le modèle pour calculer (*i*) l'énergie de vaporisation des molécules de solvant; (*ii*) les énergies de solvatation des ions uniques et les configurations des molécules solvatantes; et (*iii*) l'énergie en fonction des coordonnées de la réaction conduisant à la formation d'une paire d'ions. On a obtenu les énergies et les configurations en permettant au systèmes d'atteindre des configurations d'énergie minimale grâce au mouvement des molécules. Les résultats de (*i*) conduisent à une énergie de vaporisation qui est égale à 60% de la valeur expérimentale. Les résultats de (*ii*) conduisent à des énergies de solvatation qui sont en bon accord avec les valeurs expérimentales et à des configurations qui sont raisonnables du point de vue des mobilités des ions. Les résultats de (*iii*) indiquent la présence d'une paire d'ions définie qui est séparée par le solvant et dont l'énergie est plus faible que celle d'une paire d'ions en contact. On discute des avantages et des problèmes impliquées dans l'utilisation de cette approche à des solutions modèles.

[Traduit par le journal]

Introduction

Modelling of solutions can be approached from two extremes: by consideration of a large number of necessarily simple particles, or by detailed, quantum mechanical consideration of a necessarily small number of particles. Realistic models of solutions containing geometrically more complicated molecules can be difficult to achieve via either of these approaches. The configurations present in solutions can be quite sensitive to the detailed geometry of the molecules, so that description by spheres, ellipsoids, quadrupoles, etc. is not satisfactory. At the same time, it may be necessary to include several molecules in any realistic model of a solvated species, so that reasonably accurate quantum mechanical calculations are prohibitively expensive.

An approach intermediate to the two limiting approaches was introduced for dimethyl sulfoxide solutions in ref. 1, where the geometry of the solvent molecules was described in detail. Similar approaches have been used for calculations involving interactions of very large molecules (2), conformations (3), liquids (4), crystals (5), and hydration of ions (6), nonelectrolytes (7), and even macromolecules (8). The intermolecular potentials used in these cases vary, but include primarily r^{-1} terms between point charges on atoms, r^{-6} attractive dispersion terms, and repulsive terms (r^{-12} or exponential). The intermolecular potentials used are in several cases calculated with the aid of quantum mechanics (e.g. refs. 2, 3, 5, 6, 7), but the subsequent calculations involve only sums of pair potentials, with no further allowance for charge transfer or three body effects (9, 10).

[1]Present address: Bell Canada, Ottawa K1G 3J4.

0008-4042/79/050538-14$01.00/0

Various molecular models of solvation of ions are summarized in ref. 11. Solvation of ions by organic solvents have been modelled by an approach similar to the above (12), but only one acetonitrile molecule was considered. There have been several complete quantum mechanical calculations involving methanol (13), formic acid (14), acetonitrile (15), and other solvents (16), all using the CNDO/2 approach. The absolute values obtained are in some cases in very poor agreement with experiment (13, 14), and the stabilization energies between Li^+ and acetonitrile predicted in refs. 15 and 16 differ by 320 kJ mol^{-1}.

Large numbers of quantum mechanical calculations involving water molecules have been made (e.g. ref. 17). Classical calculations involving dipoles, induced dipoles, quadrupoles, polarization, dispersion, and repulsion (18) give results for hydration of alkali metal ions which are essentially the same as the quantum mechanical SCF calculations (19). The repulsion parameters in the calculations in ref. 18 were empirically selected, however.

Different approaches to modelling of solutions are put in perspective in ref. 20 where three approaches are compared for simple solvents (H_2O and NH_3). The calculations presented here would fall under the discrete model, with contributions of the same type as those in ref. 20: electrostatic, dispersion, repulsion, and polarization. No allowance for any charge transfer (donor–acceptor) effects (21) is allowed for. This model is simple enough so that a system of up to 2 ions and 16 dimethylsulfoxide (DMSO) can be considered. However, as in ref. 20, a statistical mechanical (e.g., Monte Carlo) treatment is not feasible for such a complex system due to lack of computer resources. Thus thermal effects are neglected, and systems are simply allowed to relax to a minimum energy configuration.

The results of such calculations for DMSO are presented here in three stages: (*i*) pure solvent, (*ii*) ion solvation, and (*iii*) ion pairing. DMSO was chosen as the solvent model molecule because several aspects of DMSO had been investigated previously (1). It is also an important substance in its own right (22) and may be useful as a standard solvent for electrolytes (23). Only systems with univalent spherical ions were considered here. The approach can be readily extended to structurally more complicated charged species and to other solvent species, as well as to mixed solvents.

Computations

(a) Model

The model of the DMSO molecule chosen is an extension of that in ref. 1, with the geometry of the molecule and the charges on the atoms the same (Table 1). The charges were calculated in ref. 1 using experimental data on DMSO, dimethylsulfide, and methane. The geometry of the DMSO molecule was that obtained from X-ray data (24).

In ref. 1, the polarization was described by 9 bond polarizabilities, each with a transverse and a longitudinal component (25). Here each DMSO molecule was assumed to have a scalar polarizability $\alpha = 8.37 \times 10^{-24}$ cm^3 (26) close to the sulfur atom (1.22 Å from the O atom along the dipole axis). The position of the scalar polarizability was chosen so that energies obtained in calculations with the scalar polarizability were close to those obtained with polarizabilities on each of the 9 bonds. The value of the polarizability used (8.37×10^{-24} cm^3) is a calculated value (26); it is somewhat lower than the value 9.32×10^{-24} cm^3 obtained by summing over the bond polarizabilities used in ref. 1, but somewhat higher than 7.97×10^{-24} cm^3 calculated from molecular volume and dielectric constant (27). The use of a scalar polarizability instead of 9 matrices saves considerable computational time.

Repulsive and dispersion forces between DMSO molecules were described by 6-12 distance and energy parameters positioned on the centres of the 10 atoms in each molecule (Table 1). These parameters were calculated so that the atom–atom energy minima were the same as those used for calculations of lattice energies of crystals of organic molecules (5). The distance parameters were obtained by noting the O---H distance (2.34 Å) in DMSO crystals (24), and from Lennard-Jones distance parameters of O_2, CS_2, and COS (25). Attempts to use an r^{-6} attraction and an exponential repulsion as in ref. 2 were discontinued because of the difficulty of specifying a precise energy minimum for the interaction in that mathematical form.

The radii and the polarizabilities of the ions are the same as those used in ref. 1, i.e. from refs. 28 and 29, respectively. The repulsions are assumed exponential, with the power 2.94 (Table 2) and the

$\boldsymbol{F}_{C,i} = q_C \boldsymbol{r}_{C,i}/r_{C,i}^3$

$E_{DIR} = \sum_{i,j} 0.082 \times 10^{-12} \exp[-3.98(r_{C;i,j} - (\sigma_{i,j} + \sigma_C))]$ (in erg) for $i = 1, 16; j = 1, 10$

$E_{AD} = E_{ADP} + E_{ADI} + E_{DIR}$

Expressions for E_{AD} contributions are analogous to those for E_{CD} contributions.

$E_{DD} = E_{PP} + E_{PI} + E_{II} + E_{LON} + E_{DDR}$

$E_{PP} = \frac{1}{2}\sum_{i,j}\sum_{k,l} q_{i,j}q_{k,l}/r_{i,j;k,l}$ $i = 1, 16; j = 1, 10; k = 1, 16; l = 1, 10; i \neq k$

$E_{PI} = -\sum_i \sum_{k,l} \boldsymbol{p}_i \cdot q_{k,l}\boldsymbol{r}_{i;k,l}/r_{i;k,l}^3$ $i = 1, 16; k = 1, 16; l = 1, 10; i \neq k$

$E_{II} = \sum_i \sum_k [\boldsymbol{p}_i \cdot \boldsymbol{p}_k/r_{i,k}^3 - 3(\boldsymbol{p}_i \cdot \boldsymbol{r}_{i,k})(\boldsymbol{p}_k \cdot \boldsymbol{r}_{i,k})/r_{i,k}^5]$ $i = 1, 16; k = 1, 16; i \neq k$

$E_{LON} = -\frac{1}{2}\sum_{i,j}\sum_{k,l} 4\varepsilon_{i,j}\varepsilon_{k,l}\left(\frac{\sigma_{i,j} + \sigma_{k,l}}{r_{i,j;k,l}}\right)^6$ $i = 1, 16; j = 1, 10; k = 1, 16; l = 1, 10; i \neq k$

$E_{DDR} = \frac{1}{2}\sum_{i,j}\sum_{k,l} 4\varepsilon_{i,j}\varepsilon_{k,l}\left(\frac{\sigma_{i,j} + \sigma_{k,l}}{r_{i,j;k,l}}\right)^{12}$ $i = 1, 16; j = 1, 10; k = 1, 16; l = 1, 10; i \neq k$

pre-exponential factor 0.243×10^{-12} erg chosen after ref. 28. Ion–atom repulsions are also assumed exponential with a power 3.98 (Table 2) taken following (30). A pre-exponential factor 0.082×10^{-12} erg $\simeq 2kT$ is chosen for ion–atom repulsion, as a repulsion of this order of magnitude would be expected when the ion and an atom are at their 'hard sphere' distance. A change in the pre-exponential factor is equivalent to a change in the ion and/or atom radii.

Table 2 lists the interactions which are included in the calculations. Induced dipoles p_i are assumed to be due to the ion fields only. Thus polarization of both the ions and other molecules due to fields of molecules are neglected. As pointed out in ref. 1, some additional terms are also neglected in dividing up the interaction between molecules in the field of ions into E_{PP}, E_{PI}, and E_{II}. A minimum distance of approach to the center of polarizability was specified to prevent an unrealistically large induced dipole moment for the case of small ions. The polarizability was assumed shielded by an amount equal to the distance (radius) parameter σ for sulfur.

The polarization of the molecules and ions is assumed linear, and any distortion of the geometry of DMSO molecules by the field is neglected. The DMSO are assumed rigid at all times, so that rotation of methyl groups is also not taken into account; the significance of this approximation is discussed in ref. 1. Other effects which are neglected are: (*i*) London dispersion forces between ions and molecules and (*ii*) any charge-transfer (21) or quantum mechanical effects.

The validity of the choice of the above model will be discussed following presentation of the results obtained using it. The parameters used were chosen

as far as possible from experimental data in the literature. There was no adjustment of these parameters during the calculations.

(b) Calculation Method

The strategy for the calculations is outlined in Fig. 1. Several different input files are used in the calculations to describe the initial positions of the DMSO molecules: (*i*) 16 DMSO's in the geometry of the crystal as determined by X-ray scattering; (*ii*) 16 DMSO's all at least 10 Å from the origin distributed approximately evenly around the origin; (*iii*) symmetrical configurations (trigonal, tetrahedral, trigonal bipyramid, octahedral) about the origin either 5 Å or 9 Å from the origin, and with dipoles pointing either into or out from the origin.

Since the energy contributions are calculated from atomic coordinates, then these must be specified. For a system of 16 molecules and 2 ions, the 3 dimensional coordinates of 162 particles must be given. However, when a new configuration is generated, the whole molecule must be moved; thus molecular coordinates are also necessary. The positions of individual atoms are described by cartesian coordinates, while the molecular configuration is described by the distance of the center of the molecule from the origin, the direction cosines of the vector from the origin to the molecule, the direction cosines of the permanent dipole of the molecule, and the direction cosines of the line between carbon atoms on a DMSO. These molecular coordinates make it easy to visualize the motion of molecules and to alter the position of molecules by editing input files.

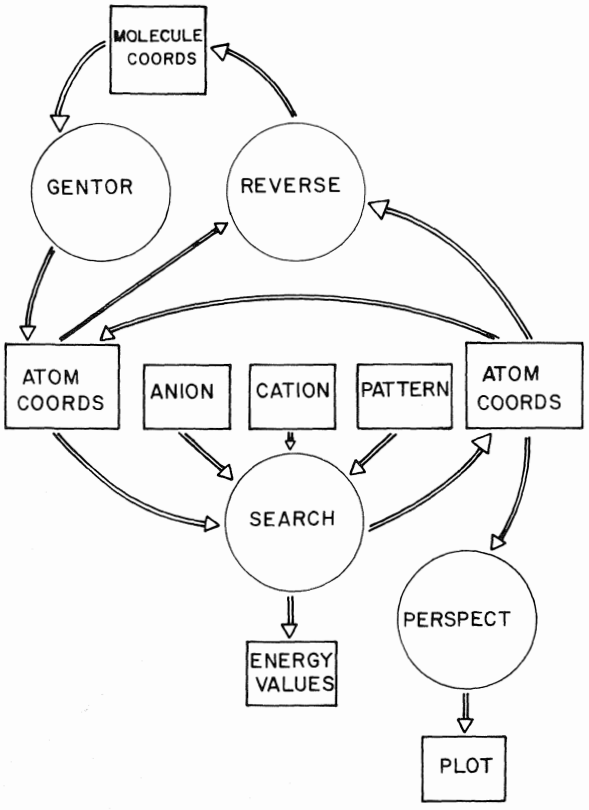

FIG. 1. Schematic diagram outlining the calculation strategy.

The relaxation of a configuration to an energy minimum is guided by a search pattern input file. This file specifies which molecule is to be moved, in which order the molecular coordinates of that DMSO are to be altered, the magnitude of a coordinate alteration, and the magnitude of the energy decrease to be considered significant enough to accept a new configuration. Temperature effects are thus neglected.

There is also an option in the search pattern to have the molecule interact with all other molecules, or only with those numbered less than itself. The latter routine is useful for building up an initial cluster of molecules containing fewer local minima. Since only one molecule at a time can be moved in this search pattern, configurations such as dimers removed from the main cluster are unlikely to break up if a molecule interacts with all its partners.

Achievement of an energy minimum for systems containing, e.g. an ion and 6 DMSO molecules, is fairly rapid, requiring at most 3 min CPU time to reach an equilibrium. The Xerox Sigma 9 computer has a CPU speed approximately 75% of the IBM/360-65. Several different minimizations with different initial coordinates and energy minimum search patterns are necessary to reasonably ensure that the configuration arrived at is not a subsidiary minimum.

When the system contains 16 molecules and 2 ions, at least 80 min CPU time is necessary to reach an energy minimum. This corresponds to the calculation of the energy of the order of 10 000 configurations at 0.42 s CPU time per configuration. Under the charge system used, the cost of obtaining the minimum energy configuration for a system of 2 ions and 16 molecules is of the order of $300. The core required for the calculations is not excessive, being only 32 000 bytes memory.

It was possible to view configurations on a screen in between steps, and to obtain hard copy plots of configurations (see Fig. 2). Figure 2 also gives the single molecules energies in units of -10^{-19} J. When a molecule is moved, it is sufficient to note the change in the energy contributions involving that molecule only, and not all molecules.

Results and Discussion

(a) Pure DMSO

Table 3 shows the results of calculations for systems of 2, 3, ..., 7, and 16DMSO molecules. In sys-

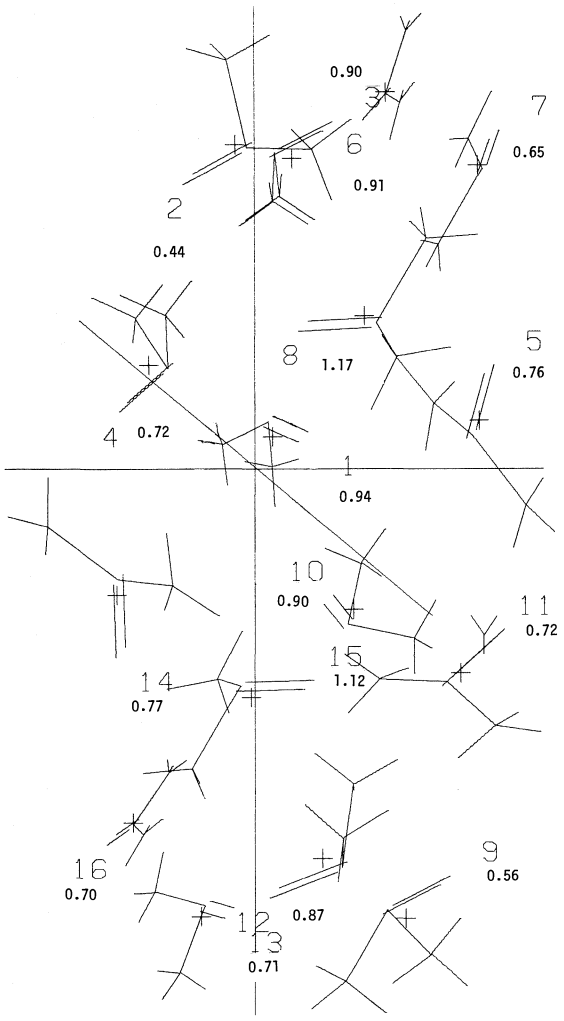

FIG. 2. The final (lowest energy) configuration of a system of 16DMSO molecules when the initial configuration consists of the experimentally determined crystal configuration. Energies of individual molecules in the configuration are given in units of -10^{-19} J.

tems with 2 to 7 molecules, the initial configuration consisted of molecule *1* near the origin and the others several Å away. A cluster of DMSO molecules was then formed by 'condensing' molecules one at a time onto the first. This cluster was then allowed to relax to its energy minimum.

For the system with 16 molecules, the initial configuration was the experimental crystal configuration (24). This was then allowed to relax to an energy minimum. The final minimum energy configuration achieved is shown in Fig. 2. The energies in -10^{-19} J of the individual molecules are shown beside the numbers labelling the molecules.

Table 3 indicates that contributions to the total energy from permanent charge distribution interactions (E_{PP}, Table 2) and London dispersion interactions (E_{LON}, Table 2) are of the same order of magnitude. Thus even in the case of quite polar molecules such as DMSO, dispersion forces are very significant. The repulsive (r^{-12}) term is separated out here from the 6-12 potential; often the sum of E_{LON} and E_{DDR} is considered as being the dispersion interaction. There are no further terms contributing to the total energy as there are no ions present and as the dipole moments p_i induced in the molecules are assumed to be due to ions only.

TABLE 3. Energy contribution in DMSO clusters (energies in 10^{-19} J)

Number of molecules	E_{TOT}	E_{PP}	E_{LON}	E_{DDR}
2	−0.23	−0.18	−0.13	+0.09
3	−0.42	−0.28	−0.31	+0.18

†Experimental crystal configuration.

The neglect of permanent-induced interactions for the systems in Table 3 will make the calculated energies less favourable. The mean nearest neighbour distance for the configuration in Fig. 2 is 4.18 Å. The energy of a DMSO molecule due to permanent charge and London interactions in such a case is of the order of -0.7×10^{-19} J. The greatest possible interaction energy between a dipole of 3.9 Debye and a polarizable entity of 8.4×10^{-24} cm^3 which are 4.18 Å apart is -0.10×10^{-19} J. Since the fields of nearest neighbours will have some cancellation effect, and since this most favourable orientation will not be achieved, the error due to neglect of permanent-induced interactions for the systems in Table 2 should be at most of the order of 10%.

The experimental energy of vapourization for DMSO is 50 kJ mol^{-1} (31). From the slope of E_{TOT} vs. number of DMSO (Table 2, Fig. 3), a value of 0.45×10^{-19} J molecule^{-1} = 27 kJ mol^{-1} is obtained for E_{vap} (really E for sublimation). Figure 2 indicates several surface molecules to have an energy of -0.7×10^{-19} J. Removal of such a molecule would mean an energy requirement of 42 kJ mol^{-1}. The 42 kJ mol^{-1} value is an activation energy for vapourization, so that when the cluster relaxes to fill the void, the net change is only 27 kJ mol^{-1}. Thus the calculations give an E_{vap} of the right order of magnitude but somewhat low. Calculation of such energies

TABLE 4. Ion solvation by DMSO molecules (energies in -10^{-19} J)

No. of DMSO	Energy for solvated species* = DMSO (α 8.37, σ ~2.8)	F^- (0.76, 1.19)	Cl^- (3.04, 1.65)	Br^- (4.28, 1.80)	I^- (6.54, 2.01)	H^+ (0.0, 0.10)	Li^+ (0.0, 0.90)	Na^+ (0.30, 1.21)	K^+ (1.23, 1.51)	Cs^+ (3.17, 1.80)

*Numbers in parentheses stand for ($\alpha/10^{-24}$ cm, σ/Å).

of vapourization or sublimation cannot be done very accurately given the limited amount of data used here (see, e.g., ref. 32). Detailed calculations of the lattice energy of benzene (10) also show how difficult it is to obtain agreement with experimental values in such cases. Thus the order of magnitude agreement with the experimental value should be considered satisfactory, and evidence that the model of the DMSO molecules used is likely to be quite realistic.

A cluster of 16DMSO molecules has a very large surface-to-volume ratio, and might therefore be considered as an inadequate model for a region of bulk liquid. However, the properties of a cluster of 16DMSO can already be reasonably well extrapolated from the properties of a cluster of 7DMSO as indicated by the data in Table 3.

The difference in the energy and configuration of the 'relaxed' cluster of 16DMSO and the DMSO in the regular crystal configuration is most likely primarily due to surface effects. The 16-molecule crystal used as an input configuration had no bulk molecules. When a very large number of DMSO are included in the calculation, then the regular crystal arrangement will be the lowest energy one. The computer resources available were, however, not sufficient to perform calculations involving more than 16 molecules, nor to allow for the repetitive units usually employed in Monte Carlo (MC) and molecular dynamics (MD) calculations to correct for surface effects.

The main emphasis in the calculations in part (*i*) is not to arrive at a definitive view of liquid DMSO, but simply to test the reasonableness of the model of the DMSO molecules chosen. A calculation such as this which neglects temperature effects cannot in any case describe a liquid properly. More sophisticated MC and MD calculations of liquids can include similar potentials, but then only of simpler molecules (2, 5), or else molecules where potentials are of a regular geometric shape (33, 34). The number of configurations used in these MC or MD calculations is at least an order of magnitude greater than the 10^4 feasible here.

(b) Ion Solvation

Table 4 and Fig. 3 summarize the results for ion solvation calculations. The DMSO column in Table 4 contains the same data as in Table 3, except that here a central DMSO is considered solvated by 1, 2, ..., 6 other DMSO's. All the energies in Table 4 are those for the lowest energy configuration of several configurations arrived at from different initial configurations and/or different patterns. At least 3 initial configurations were used for cases where there were 3 or more DMSO's: a symmetrical configuration close in, a symmetrical configuration 9 Å away, and an asymmetric configuration.

The configurations of the systems for which energies are available in Table 4 are not presented in detail here. To illustrate the type of information obtained, the plot of Cl^- with 5DMSO is shown in Fig. 4. The ion–DMSO distances and the orientations of the solvating DMSO's for this system are given in Table 5. Figure 5 summarizes the configurational data for the ions with 6DMSO's. The DMSO's are numbered in order of increasing distance from the ion and the distance–number relationship is plotted to indicate symmetry aspects of the solvating molecules.

Some examples of detailed energy contributions are listed in Table 6 in order to illustrate some aspects of the calculations.

The results in Table 4 and Fig. 3 are quite similar to the experimental results obtained for gas phase ion solvation by mass spectrometry (11, 12). Solvation of alkali metal ions by acetonitrile indicates that by the time the 5th solvent molecule is added, there is little dependence of the incremental enthalpy on the type of ion. In Fig. 3, this corresponds to the observation that the slopes of the curves of the energy vs. number of molecules are essentially the same from

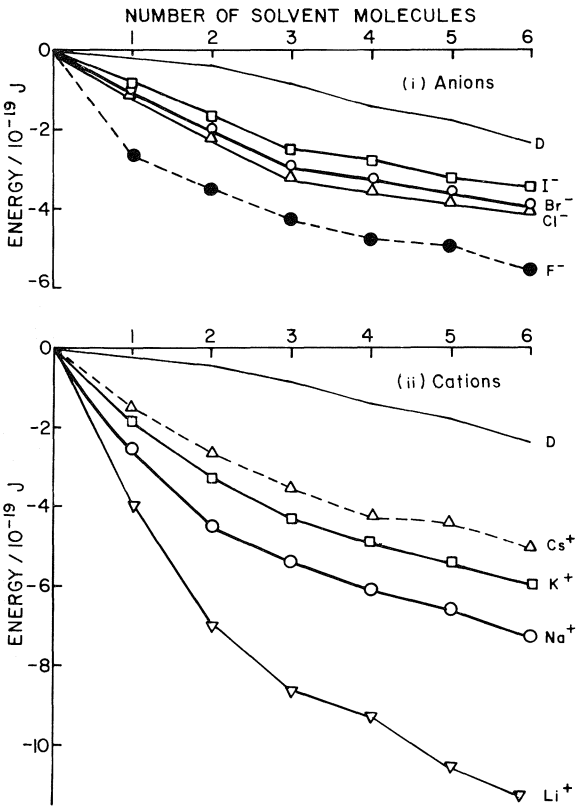

FIG. 3. Energies of DMSO clusters (data in Table 4).

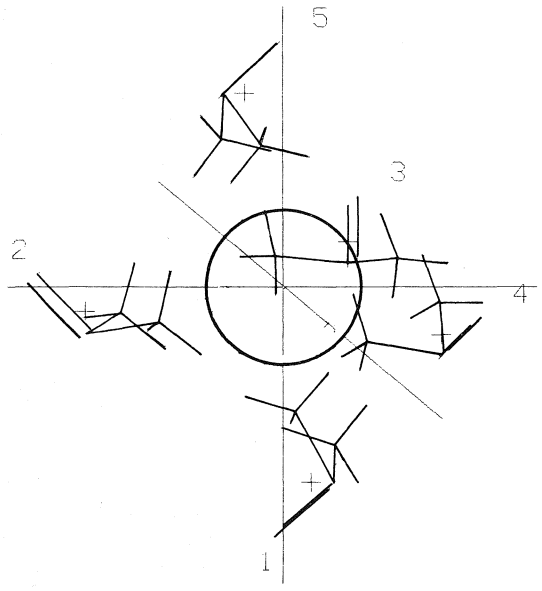

FIG. 4. Lowest energy configuration of Cl^- with 5DMSO (Table 5 and system 2 in Table 6).

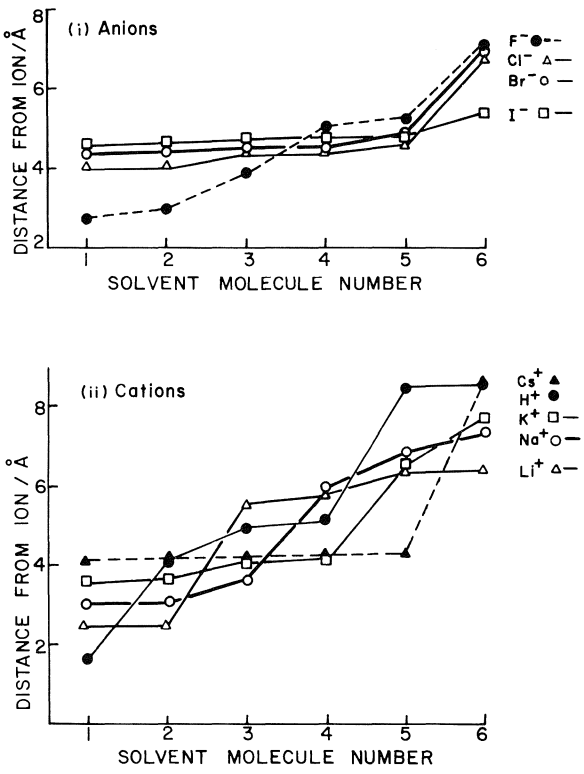

FIG. 5. Distribution of ion–DMSO distances for ions solvated by 6DMSO molecules.

4DMSO's onward for most ions. These slopes are also close to the slope of the energy vs. number of DMSO's curve for the case of a DMSO in the center instead of an ion. Thus from the point of view of energy, a relatively small number of solvent molecules are needed to describe a major proportion of the solvation of the ion.

Energies of solvation can be calculated for the ions from the data in Table 4. These are calculated by taking the values in the last row less the value of the energy of 6DMSO's (-1.79×10^{-19} J) and then adding a contribution from the Born energy of in-

teraction with the remainder of the solvent

$$[1] \quad E_{Born} = -\frac{q^2}{2r_B}\left(1 - \frac{1}{\varepsilon} - \frac{T}{\varepsilon}\left(\frac{\partial \ln \varepsilon}{\partial T}\right)_p\right)$$

where r_B is the radius of a sphere containing the ion solvated with 6DMSO's. From Fig. 5 this can be estimated as $\simeq 7$ Å giving $E_{Born} \simeq 103$ kJ mol^{-1}.

Figure 5 suggests that in the case of anions and Cs^+, a well-defined primary solvation shell containing 5DMSO is formed. Thus the anion calculations were done with the ion plus 5DMSO energies. The most reasonable radius for the Born energy calculations in this case is 5.6 Å.

There is considerable difficulty in making a precise assessment of the effective radius of the solvated ions. Thus the Born energy contributions could have an error of up to ±20 kJ mol^{-1}. In principle, the volume of the solvated ions can be obtained from the geometry of the configurations, e.g. Fig. 4, and partial molal volumes of ion could be obtained. However, the overall volume of a configuration such as that in Fig. 4 must be obtained to an accuracy of better than 7% for a Cl^- with 5DMSO if a molal volume of 25 cm^3 mol^{-1} (23) is to be detected, as the molar volume of DMSO is 71 cm^3 mol^{-1}.

Table 7 shows the resulting calculated solvation energies compared to the experimentally determined solvation enthalpies. The classical Born solvation energy (= solvation enthalpy) is also shown. The calculated solvation energies for Na^+, K^+, and Cs^+ are all about 20 kJ mol^{-1} less favourable than the experimental ones. This is good agreement, considering the latitude possible in the choice of the radius used for the Born contribution calculations and the uncertainty in the experimental solvation energy (really enthalpy) due to uncertainty in determining single ion values. Such uncertainties are removed when E_{solv} of pairs of ions are considered.

Data for some Li and K salts are available in ref. 37. A comparison of these data is given in Table 8.

As can be seen in Table 8, there is some uncertainty regarding the experimental solvation enthalpy values, but consideration of Tables 7 and 8 together indicate that the solvation energy calculated here for the Li^+ ion is too great. This is very possibly due to a break-down of the model for small ions where electric fields are high. As can be seen in Table 6, row 8, induced contributions to the Li^+–DMSO energy are of the same order of magnitude as permanent charge contributions. Calculations with data from ref. 38 give second order hyperpolarizability contributions an order of magnitude less than the linear contributions in a field 2 to 3 Å from an ion (see Fig. 5). Nevertheless, the assumption of a single scalar polarizability seems suspect at such small ion–molecule distances, and the induced interactions are far greater for Li^+ than for the other alkali metal and halide ions (except H^+). Representing induced interactions by E_{PI} and E_{II} terms alone has also a maximum error when ions and molecules are close.

Tables 7 and 8 also suggest that the solvation energies calculated for the other ions, but especially the large anions (Cl^-, Br^-, I^-) are too small. The three calculated values for Cl^-, Br^-, and I^- in Table 7 are within 5% of the experimental values if the Fajans convention ($K^+ = F^-$) (36) is used, but this extreme case is unlikely, and would mean larger errors for Na^+, K^+, and Cs^+.

The calculated energies would become considerably greater if radii recently calculated from compressibility data (39) are used. The suggested radii are 1.41 Å for Cl^- (1.65 in Table 4), 1.55 Å for Br^- (1.80 in Table 4), and 1.72 for I^- (2.01 in Table 4). This means that the E_{solv} calculated for I^- with the new radius from (39) would be close to that listed for Br^- in Table 7, in better agreement with the experimental value. Similarly, the new calculated value for Br^- would be close to the old for Cl^-, again in better agreement with the experiment. This indicates how sensitive the calculations are to the choice of input data for the model. Other aspects may, however, be responsible for the low calculated values in Table 7 for Cl^-, Br^-, and I^-.

TABLE 8. Comparison of calculated and experimental solvation energies in DMSO (energies in $-$kJ mol^{-1})

Salt	E_{solv}(calcd) (Table 7)	E_{solv}(exp) from Ref. 37	E_{solv}(exp) from Ref. 35
LiCl	950	896	906
LiBr	934	871	890
LiI	914	841	866
KBr	607	689	699
KI	587	659	675

One of the energy contributions not taken into account in the calculations is the London dispersion attraction between ions and atoms in the molecule. A calculation of this contribution is difficult, as when ion–atom distances are of the order of or less than the ion radius, it is invalid to assume the r^{-6} interaction to be between the centers of the moieties. This contribution could, however, be considerable when ions with a large polarizability such as Cl^-, Br^-, and I^- are involved. Table 3 indicates the London attraction between two DMSO 4.18 Å apart to be -0.13×10^{-19} J. The I^- is 4.6 Å from 5DMSO molecules according to Fig. 5. Thus dispersion interactions could contribute of the order of

$$0.13 \times 10^{-19} \times 5 \times (6.5/8.4) \times (4.18/4.6)^6 \simeq 0.3 \times 10^{-19} \text{ J}$$

or 20 kJ mol^{-1} to the solvation energy of I^-.

Nuclear magnetic resonance results (40) suggest that I^- is strongly solvated in DMSO. Experimental nmr data can also be interpreted to give an idea of the dipole orientation of the solvating molecules (40). As indicated in Table 5, the dipoles are oriented quite radially for all 5 molecules. Inclusion of ion–atom dispersion forces may alter such geometry, as well as the energy of solvation.

The calculations here are completely classical electrostatic. Thus any charge-transfer (donor–acceptor) effects are neglected. Such an approximation is common both for calculations of pure liquids (2, 5) and ion–solvent clusters (41). Parker (42) estimates that donor–acceptor effects may account for less than 10% of the solvation energy for such systems. *Ab initio* molecular orbital calculations (43) indicate that the net quantum mechanical contributions to the solvation of F^- by 4 waters is small (<7%). This is, however, due to fortuitous near-cancellation of an exchange and a charge-transfer term. Thus donor–acceptor considerations may be quite considerable in cases where species such as I^- are involved.

The calculations for H^+ are of a qualitative nature only with the H^+ taken as a charge with radius 0.1 Å and zero polarizability. An interesting effect can, however, be noted from the data in Table 4 and Fig. 5, namely that the H^+ essentially 'belongs' to a single DMSO molecule. This predicts that the mobility of H^+ in DMSO should be of the same magnitude as that of a DMSO molecule. The λ_0 for H^+ in DMSO is obtained at 16.0 Ω^{-1} cm^2 mol^{-1} in ref. 44. This predicts a mobility u for H^+ of $16.0 \times 10^{-4}/(96\,500)^2 = 1.72 \times 10^{-13}$ m s^{-1} N^{-1}. The self-

diffusion coefficient for DMSO is 0.8×10^{-5} cm^2 s^{-1} (40). This corresponds to a mobility for the DMSO molecule of $0.8 \times 10^{-5} \times 10^{-4}/(8.314 \times 298) = 3.2 \times 10^{-13}$ m s^{-1} N^{-1}, somewhat greater than that for the H^+ ion, as is reasonable.

Values of λ_0 for the other ions considered can be found in refs. 45 and 23, with the effective Stokes radii calculated in ref. 45. Li^+, Na^+, K^+ have λ_0 values of 13.3, 14.2, and 14.8 Ω^{-1} cm^2 mol^{-1} respectively, corresponding to Stokes radii of 3.2, 3.0, and 2.9 Å, respectively; well above their crystal radii. The mobilities of these ions would be of the same order as that of H^+, i.e. somewhat lower than that of a DMSO molecule. The Cl^-, Br^-, and I^- have λ_0 of 24.1, 23.7, and 23.5 corresponding to Stokes radii of 1.73, 1.76, and 1.75, of the order of, or less than the radii listed in Table 4. This is another indication of weak solvation of anions by DMSO, contrary to the nmr interpretations (40).

As can be seen from Fig. 5, the larger ions (Cl^-, Br^-, I^-) and Cs^+ have lowest energy configurations which are quite symmetrical, with 5DMSO's in a definable first solvation shell. However, the smaller ions have increasingly asymmetric configurations, although a primary solvation shell of 4DMSO can be identified for K^+, 3 for Na^+, 2 for Li^+ and F^-, and a single DMSO for H^+. Approaches which assume symmetrical solvation shells, e.g. ref. 1, cannot therefore arrive at the lowest energy ion–solvent configurations. At the same time, energy minimum search patterns which 'condense' one molecule after another into an ion–solvent cluster (see Calculation Method) cannot arrive at some symmetric configurations without excessive computation time.

Some other aspects of ion–solvent interactions can be noted by reference to Table 6. Systems 4 and 5 indicate the importance of including polarizability contributions in the calculations. There is a change of 23% in the total energy when α is neglected. Inclusion of the polarizability gives a looser solvent structure around the ion, as the induced dipoles in the first shell solvent molecules cause repulsion.

Systems 6 and 7 in Table 6 indicate the difficulty of defining a definite minimum energy configuration for systems. System 6 has 3 first shell solvent molecules and one second shell, while system 7 has essentially 4 first shell molecules. The energy of 6 is lower because the decrease in repulsion between molecules as compared to the more crowded configuration in system 7 is more than sufficient to overcome the less favourable ion–solvent interaction. Such a trade-off between ion–molecule attraction and molecule–molecule repulsion is present throughout Table 6. The only consistently attractive molecule–molecule term is the London contribution. When it is excluded, the lowest energy system becomes a loose structure with 'streamers' of solvent molecules with head–tail–head–tail orientation coming from the ion.

(c) Ion Pairing of Alkali Halides in DMSO

A series of calculations were made utilizing the model to examine ion pairing of Na^+ and Br^- in DMSO. Figure 6 summarizes the results by presenting the total energy and the various contributions to it as a function of anion–cation distance r_{AC}. These results were obtained by fixing the cation and anion at various positions and allowing 16 DMSO molecules to relax about them into a minimum energy configuration. At least 80 min CPU time were required to reach a final configuration for a particular value of r_{AC}. Figure 7 shows an example of the final configuration obtained.

Two runs were made with $r_{AC} = 4$ Å with different patterns of motion for the molecules. Although the total energy is in reasonable agreement, the final configurations for the two runs are quite different as indicated by the different E_{AD}, E_{CD}, and E_{DD} values. The possible error in E_{TOT} is probably of the order of 1×10^{-19} J, i.e. E_{TOT} values could be lower by up to that amount. This is already of the order of $25kT$ at 298 K. Several more runs under different condi-

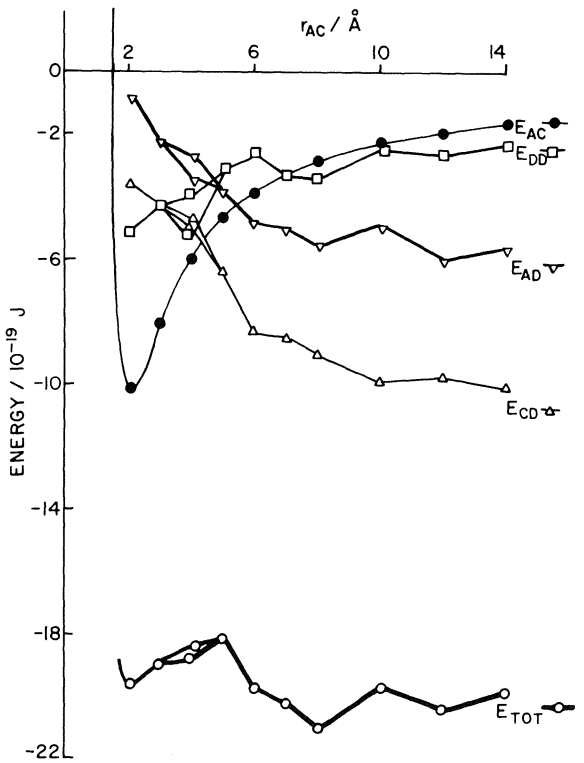

FIG. 6. Energies as a function of distance between Na^+ and Br^- with 16DMSO present.

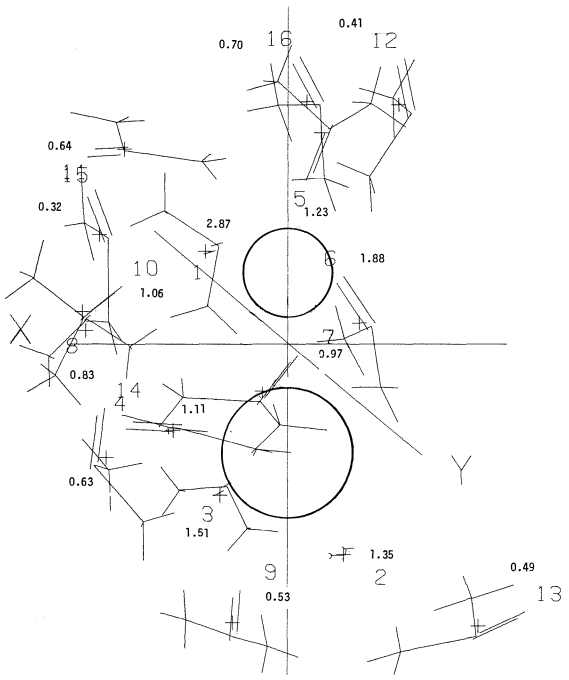

FIG. 7. Final (lowest energy) configuration of a system of 16DMSO and Na^+ and Br^- ions 5 Å apart. Energies of individual molecules in the configuration are given in units of -10^{-19} J.

tions would have to be necessary in order to test the reproducibility of the E_{TOT} values.

One source of error is the possibility of a molecule going into some subsidiary minimum. Some larger step sizes must be allowed for in the pattern governing the relaxation in order for a molecule to break out of a subsidiary energy minimum. It would be desirable to have a picture of the configuration appear at intervals during the relaxation (Fig. 1) so that molecules can be pulled out of obvious energy subminima.

The total energy indicates that the contact ion pair is not the lowest energy position, but instead a solvent separated ion pair with $r_{AC} \simeq 8$ Å. As can be seen from Fig. 7, it is not possible when $r_{AC} = 5$ Å for DMSO's to enter the space between the ions. At 8 Å, however, molecules can fit into this energetically favoured region. The anion and cation fields add constructively in this region, and give favourable ion–molecule energies.

The energy of a system with 16 molecules and the two ions at $r_{AC} = 14$ Å is considerably more favourable than that for two free ions. From Table 4, the energy of an Na^+ and a Br^-, each with 8DMSO molecules would be $(-8.12 - 4.88) \times 10^{-19}$ J $= -13 \times 10^{-19}$ J, considerably less favourable than the -20×10^{-19} J value. From systems 1 and 3 in Table 6 it can be seen that the E_{DD} terms are both repulsive. When $-2 \times 0.45 \times 10^{-19}$ J are added on to both terms to account for addition of two molecules, then the total E_{DD} is approximately zero. This is in agreement with the behaviour of E_{DD} in Fig. 6. As the ions approach, molecule–molecule interactions become more favourable. The value of E_{DD} with no ions present is -6.4×10^{-19} J, approximately where the E_{DD} curve extrapolates for completely overlapping ions ($r_{AC} = 0$).

The ion–molecule interactions terms become less favourable as r_{AC} decreases as there is greater cancellation of ion electric fields in regions other than the interior region. E_{AC} follows the curve postulated for two free gaseous ions in the model. Thus E_{TOT} is the sum of four major effects, two decreasing as r_{AC} decreases and two increasing.

It is likely that the calculations give unrealistically favourable energies for systems when ions have several molecules between them. Table 9 shows E_{CDI} and E_{ADI} contributions to be very large. This is because the fields of the ions add constructively in the interior region. Solvent molecules which would be aligned favourably in this field would give rise to fields opposing the ion fields. Since the induced dipoles are calculated using ion fields only, their magnitudes would be exaggerated giving rise to favourable E_{CDI}, E_{ADI} values.

The classical picture of such ion pairing involves generally smaller energy changes. The difference in energy $q^2/\varepsilon(1/r_1 - 1/r_2)$ in going from 8 Å to 2.1 Å is only 0.2×10^{-19} erg using the continuum value 46.7 for the dielectric constant ε. As indicated in Fig. 7, however, there are no molecules between the ions at $r_{AC} \leq 5$ Å.

Figure 6 indicates that the model predicts the existence of a solvent separated ion pair, and an activation energy for formation of a contact ion pair. This activation energy is from Fig. 6 of the order of 3×10^{-19} J $\simeq 180$ kJ mol^{-1}, an unrealistically high value. It is, however, arrived at by subtraction of two large somewhat uncertain numbers.

The existence of a solvent separated species was postulated in explaining ultrasonic absorption results (46). However, in ultrasonic studies of HCl in DMSO (47), it was not necessary to postulate a solvent separated species. This can be explained by referring to Fig. 5. As the H^+ is essentially solvated by only one molecule, there is greater freedom for the Cl^- to approach it without formation of a distinct solvent separated species. The Na^+ is better shielded by relatively strongly held first solvation shell molecules and cannot as readily be approached by anions.

TABLE 9. Energy contributions to ion pairing of Na^+ and Br^- (energies in 10^{-19} J)

Parameter	Value for $r_{Na^+—Br^-}$ = 2.1 Å	5.0 Å	8.0 Å	14.0 Å
E_{TOT}	−19.62	−18.02	−21.01	−19.77
E_{AC}	−10.17	− 4.70	− 2.90	− 1.65
E_{ACP}	−10.99	− 4.61	− 2.88	− 1.65
E_{ACI}	− 2.72	− 0.08	− 0.01	− 0.00
E_{IIR}	+ 3.53	+ 0.00	+ 0.00	+ 0.00
E_{CD}	− 3.64	− 6.34	− 9.04	−10.09
E_{CDP}	− 1.97	− 3.77	− 4.82	− 6.26
E_{CDI}	− 2.20	− 3.49	− 5.18	− 4.71
E_{DIR}	+ 0.53	+ 0.91	+ 0.97	+ 0.83
E_{AD}	− 0.74	− 3.83	− 5.67	− 5.69
E_{ADP}	− 1.35	− 2.65	− 3.94	− 3.89

E_{DD}	− 5.07	− 3.16	− 3.41	− 2.34
E_{PP}	− 3.05	− 2.45	− 1.88	− 1.56
E_{PI}	− 0.96	− 0.59	− 0.97	− 0.10
E_{II}	+ 0.41	+ 1.00	+ 0.58	+ 0.97
E_{LON}	− 4.00	− 3.38	− 4.27	− 5.05
E_{DDR}	+ 2.53	+ 2.24	+ 3.13	+ 3.39

It was indicated that the choice of the radius for the ions was of great importance in arriving at ion solvation energies. It can be seen from Fig. 6 that the shape of the ion–ion potential (E_{AC}) is of crucial importance in determining the relative energies of the contact and solvent separated ion pairs, or even the existence of a distinct solvent separated ion pair.

The repulsive potential exponent used seems to be in agreement with later work (48), and the inclusion of an r^{-6} term seems not to be necessary (48). There is some question about the correct values to be used for the radii (39) and the polarizability (49, 50). The best comparison of the E_{AC} here would be with that of Woodcock (51) for gaseous alkali halides. The potential used in (51) also has an r^{-1} term, an r^{-4} term, and exponential term which is more complex. The Na^+Br^- potential has a minimum of -8.8×10^{-19} J at 2.5 Å, as compared with -10×10^{-19} J at 2.1 Å here. However, the more recent potential in ref. 52 shows differences from the potentials in ref. 51 which approach that used here (i.e. deeper, further in).

More accurate ion–atom potentials, including dispersion force contributions, would also be desirable, both in calculation of ion pairing and ion solvation phenomena. Such problems have been considered, e.g. ref. 53, but no reasonable simple mathematical forms are presented for the potential. Curves for the Cl^-—Ar potential (53) show, however, that the dispersion energy is approximately one quarter of the induced energy at the energy minimum, i.e. they are not negligible.

Individual contributions to the energy calculated here are listed in Table 9. None of the contributions considered are negligible, and different terms dominate at different values of r_{AC}. Thus it does not seem wise to simplify the calculations by excluding any contribution, and it seems desirable to add some.

Conclusions

The DMSO results discussed here indicate that valuable information regarding ion–solvent and ion pairing interaction can be obtained by this calculation method. Solvation energies, as well as configurations of likely ion–solvent and ion–ion structures, can be obtained with a reasonable amount of computer time. The results obtained are in good agreement with available experimental data, especially considering the fact that really no adjustable parameters were used in the calculations. The position of the scalar polarizability was chosen to reproduce results obtained using bond polarizabilities, but its value was not adjusted. This type of calculation procedure can be generalized to include solvents other than DMSO and more complex ions.

The point charges used to describe the molecule in the energy calculations can be obtained from quantum mechanical calculations, or from experimental data regarding that molecule and others containing common functional groups or bonds (1). The latter approach would seem advantageous for larger species where accurate quantum mechanical calculations are difficult to perform. It may be desirable to extend the point-charge model by also including point

charges in places other than atom centers, e.g. to describe lone pair electrons, or to give a directionality when hydrogen bonding should be included.

Dispersion and repulsion contributions are best described by 6-12 atom centered potentials. Parameters for these potentials are now quite readily available from calculations done on molecules of biological interest, e.g. refs. 3, 5. It seems desirable to extend consideration of dispersion interactions to include ion–atom contributions. A model of an r^{-6} interaction between the centers of an atom and a large ion will not be very accurate however.

Polarizability effects in the molecule cannot be neglected. For most purposes, it seems satisfactory to describe polarizability by one judiciously placed scalar polarizability for the whole molecule. For molecules larger than DMSO, it may, however, be necessary to distribute the polarizability in several places in the molecule, e.g. in the bond centers as in ref. 1. This results in a considerable increase in computation time.

Polarizability effects in the case of small ions seem to be overestimated. This could be alleviated by introducing a hyperpolarizability (i.e., setting $p_i = \alpha F - \beta F^2$). Hyperpolarizability would in any case have to be considered if multivalent ions are to be included. The addition of a second order term in the field may also be a method for compensating for terms left out by describing induced effects solely by E_{PI} and E_{II}. As pointed out in ref. 1, several higher order terms are left out, and these can achieve non-negligible values when ion–molecule distances are small.

It may be unsatisfactory to assume the induced dipoles in molecules to be due to ion fields only. If several aligned polar molecules are considered, then the contribution of the molecule fields may also be considerable. Inclusion of this in the calculations would increase the computation time considerably.

The choice of ion–ion and ion–molecule interactions can have considerable influence on the results. It seems feasible to describe ion–ion interactions reasonably by an r^{-1}, an r^{-4}, and an exponential repulsion term with the factor in the exponent being $\simeq 3$. An r^{-6} term can be added if dispersion interactions involving ions are to be considered. Ion–molecule (really ion–atom) interactions should be extended to include an r^{-6} term. The pre-exponential factor (i.e. the effective size) and the factor in the exponent (i.e. the effective compressibility of the interaction) are more doubtful for the ion–atom case.

The calculation method to arrive at the lowest energy configuration must be such that both symmetric and asymmetric configurations are possible. If only one molecule at a time is moved, this means that at least two patterns for the energy minimum search must be used: (*i*) where molecules are 'condensed' one by one into an ion–solvent cluster and (*ii*), where molecules begin in a symmetric configuration and relax to a minimum energy configuration.

In these calculations, the effect of temperature was neglected. The cut-off for meaningful configurational changes was set at 10^{-23} J $\simeq 5 \times 10^{-3} kT$, so that the precision of the energy of a configuration was $\pm 5 \times 10^{-3} kT$. However, in most cases, the uncertainty in the minimum energy which could be achieved was probably $\gtrsim kT$ (for $T = 298$ K) due to the possibility of subsidiary minima. Thus Monte Carlo calculations were not thought worthwhile, considering the order of magnitude or more of computer time which would have been required. In principle, either Monte Carlo or molecular dynamics simulations are possible for these systems, but with such a large increase in computation time that it would defeat the original intention of an inexpensive, generally usable calculation scheme. The minimum energy configurations obtained here would in MC and/or MD calculations be averaged with many other configurations. The configurations with higher energy would be averaged in with a probability $\exp(\Delta E/kT)$.

The calculations described here cannot readily take into account charge-transfer (donor–acceptor) effects. On any charge transfer, the charge distribution in the species involves changes, so that the complete description of the species must be altered. For systems where charge-transfer effects are minimal, the calculation system described seems quite useful. Copies of the programs used can be obtained from P.K.

Ipso chlorination of 4-alkylphenols. Formation of 4-alkyl-4-chlorocyclohexa-2,5-dienones

ALFRED FISCHER AND GEORGE NARAYANAN HENDERSON

Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received September 5, 1978

ALFRED FISCHER and GEORGE NARAYANAN HENDERSON. Can. J. Chem. **57**, 552 (1979).

Chlorination of 4-methyl-, 4-ethyl-, 4-isopropyl-, and 4-*tert*-butylphenol, and of substituted 4-methylphenols, with chlorine in acetic anhydride gives 4-chloro-4-methyl-, 4-chloro-4-ethyl-, 4-chloro-4-isopropyl-, and 4-chloro-4-*tert*-butylcyclohexa-2,5-dien-1-one, and substituted 4-chloro-4-methylcyclohexa-2,5-dien-1-ones, respectively, in yields ranging from 19 to 100%.

ALFRED FISCHER et GEORGE NARAYANAN HENDERSON. Can. J. Chem. **57**, 552 (1979).

La chloration, par le chlore dans l'anhydride acétique, des méthyl-4 éthyl-4, isopropyl-4 et *tert*-butyl-4 phénols et de méthyl-4 phénols substitués conduit respectivement aux chloro-4 méthyl-4, chloro-4 éthyl-4, chloro-4 isopropyl-4 et chloro-4 *tert*-butyl-4 cyclohexadiène-2,5 ones-1 et aux chloro-4 méthyl-4 cyclohexadiène-2,5 ones-1 substituées avec des rendements allant de 19 à 100%.

[Traduit par le journal]

The formation of halo cyclohexadienones in the bromination and chlorination of cresols, xylenols, and trimethylphenol was recognized by Zincke over 80 years ago.[1] Although Auwers subsequently proposed nonketonic structures for these compounds, the dienone structures have long been accepted and modern spectroscopic methods have established them conclusively (2, 4). A very large number of halo cyclohexadienones are now known (e.g., 23 4-halocyclohexa-2,5-dienones are indexed in Vol. 86 of Chemical Abstracts). However, all but a very few of these are derived from phenols which are either fully substituted in the reactive *ortho* and *para* positions or, if the substrate phenol is not 2,4,6-trisubstituted, it becomes so through halogenation in the course of formation of the dienone (none of the 23 cyclohexa-2,5-dienones mentioned above is less than tetrasubstituted). Thus, it is not surprising that the view became current that the halo cyclohexadienones were only formed after prior nuclear halogenation of the phenol substrates (1) and that even in quite recent studies of the chlorination of phenols to form (poly)chlorocyclohexadienones the technique of exhaustive chlorination has been used without apparent consideration of the possibility of formation of the less substituted compounds (4, 5). Halocyclohexadienones occur in both the fully-conjugated *ortho* (i.e., 2,4-dienone) and cross-conjugated *para* (2,5-dienone) series, the 2,5-dienones being more stable than their 2,4-isomers (2).

In the present work we have synthesised a number of simple 4-chloro-2,5-dienones. These compounds are of interest as substrates for dienone–phenol rearrangement studies (cf. ref. 6) and also, in view of their functionalized nature, as potential intermediates for synthetic studies. The formation of the dienones is also of interest in relation to studies of 'abnormal' or 'non-conventional' pathways in reactions of aromatic substrates with electrophiles (7, 8). Of the compounds synthesised in the present work only 4-chloro-4-methylcyclohexa-2,5-dienone (9) and 4-chloro-3,4-dimethylcyclohexa-2,5-dienone (10, 11) have been reported previously. Bromocyclohexadienones were obtained by bromination of phenols with molecular bromine in solvents such as acetic acid, ether, hexane, and carbon tetrachloride, in the presence of a suitable basic species, which is required to accept the proton from the hydroxyl group (1, 2). Chlorocyclohexadienones were obtained by chlorination of phenols with chlorine in acetic acid or aqueous acetic acid (4, 11, 12–14), carbon tetrachloride (12), chloroform (15), ether (16), and in the solid state (17). Other chlorinating agents such as alkyl hypochlorites (13, 18, 19), sulfuryl chloride (15), hypochlorous acid (19), and antimony pentachloride (9) have been used. These reactions, with the exception of the last, were carried out at ambient or elevated temperatures and resulted in the formation of the mixtures of polychlorinated cyclohexadienones and cyclohexenones. Our objective was to prepare the 4-chlorocyclohexa-2,5-dienones under conditions such that

[1]Formation of halocyclohexadienones has been reviewed by Ershov *et al.* (1) and by Waring (2). References to the early literature may be found in ref. 1. Ershov and Volod'kin have themselves made extensive contributions to the study of the formation of halo dienones, e.g. ref. 3.

Results and Discussion

Preliminary nmr studies of the chlorination of *p*-cresol with chlorine in a variety of solvents showed that the maximum yield (~33%) of 4-chloro-4-methylcyclohexa-2,5-dienone (**1**) was obtained in acetic anhydride. Good yields were also obtained in mixtures of acetic anhydride and acetic acid, chloroform, or ether, and also in aqueous acetic acid, chloroform, and pyridine–chloroform. Less dienone was obtained in neat ether and yields in methanol, dioxane, and acetonitrile were poor. Chlorination with sulfuryl chloride in acetic anhydride also gave a good yield of **1** and a similar yield of **1** was obtained when chlorine was used in the presence of a catalytic amount of iodine. In chlorination with molecular chlorine the yield of dienone measured at −40°C was not reduced when the temperature was subsequently raised, in one case to 35°C. When the ratio of the amount of chlorine to *p*-cresol was raised above 1:1 the total yield of dienones increased and 2,4-dichloro-4-methylcyclohexa-2,5-dienone (**5**) was obtained in addition to **1**. Preparative-scale (~0.1 mol) experiments confirmed these observations. Chlorination of *p*-cresol in acetic anhydride gave a 31% yield of dienone **1**. Chlorination in ether gave 20% of the dienone but chlorination in ether (1 dm^3 per mole of *p*-cresol) containing 16% acetic anhydride gave almost the same yield (29%) as in neat acetic anhydride and was more convenient for large scale preparations. Chlorination in aqueous acetic acid (1:3 v/v) gave a similar yield of dienone to that using ether – acetic anhydride. Chlorination using a mole ratio of chlorine to *p*-cresol of 1:1 gave a higher yield (34%) of dienone than did the normal 0.9:1 ratio but this included a small amount of 2,4-dichloro-4-methylcyclohexa-2,5-dienone. When the mole ratio of chlorine was increased to 1.5:1 the yield of dienones increased to 54% of which half was the dichloro compound. Separation of dienone **1** from accompanying phenols was more straightforward than the separation of the dienones **1** and **5**. For this reason we chose to use a chlorine to substrate ratio of 0.9:1 in the general preparative method, thus reducing the opportunity for dichlorination to occur. Apart from the preliminary reactions with *p*-cresol reactions were carried out by mixing the reactants at −78°C and then raising the temperature to −20°C. This was to minimize the possibility of dichlorination as a result of reaction occurring before complete mixing of the reactants. The low reaction temperature ruled out the use of acetic acid as solvent and the reactions were generally done in acetic anhydride. In a large-scale preparation (2 mol) use of the mixed solvent 16% acetic anhydride in ether made for a more convenient work-up.

Chlorination of the substituted phenols gave the corresponding 4-chlorocyclohexa-2,5-dienones in yields ranging from 19% (for **4**) to 100% (for **10**). In general the chlorophenol substitution products were also formed but these were removed by absorption on alumina in the process of isolating the dienones and were not themselves isolated and identified. 2,4-Dichloro-4-methylcyclohexa-2,5-dienone (**5**) was obtained, in addition to **1**, and was isolated and characterised from the chlorination of *p*-cresol using a chlorine to substrate ratio of 1.5:1.

The structures of the dienones are clearly established by their spectra. Infrared absorptions at 1675 (C=O) and 1640 cm^{-1} (C=C) in the spectrum of **1** confirm the presence of the conjugated enone system. The ^1H nmr shows that there are four vinylic protons (AB quartet) consisting of two pairs, the members of each pair being chemically identical. Thus the enone is a dienone and specifically a 2,5-dienone, with a plane of symmetry, rather than a less symmetrical 2,4-dienone. The ^{13}C nmr spectrum confirms the presence of two pairs of olefinic carbons, a quaternary carbon, and carbonyl carbon. These can only be accommodated by the 2,5-dienone structure. Similar arguments can be adduced to support the assigned structures for **2**, **3**, **4**, and **10**. The symmetry argument cannot be applied to distinguish between the *ortho*- and *para*-dienone structures in the cases of **5**, **6**, **7**, **8**, and **9**. However, it is apparent that the methyl group which appears at ~30 ppm in the ^{13}C nmr spectra must be attached to a quaternary carbon atom and thus **5**, **7**, **8**, and **9** must be 2,5-dienones. This is confirmed by the fact that this methyl group appears as a singlet in the ^1H nmr spectrum. In the *ortho*-dienone structure this methyl group would be attached to an unsaturated carbon and be split by a vinylic proton(s). Finally the close correspondence between the absorptions of groups in similar environments in both the ^1H and ^{13}C nmr spectra of **6** and **10** and more generally between **6** and the other 2,5-

dienones establishes that **6** must be a 2,5-dienone. Thus in the ^{13}C spectrum of **6** the methyl groups appear at almost exactly the same positions as those in **10**, indicative of the close structural similarity.

It is evident that in chlorination of phenols with molecular chlorine attack at a substituted *para* position is competitive with attack at an unsubstituted *ortho* position.[2] Furthermore it would appear that attack at a substituted *para* position is dominant over attack at a substituted *ortho* position: no *ortho* dienones were obtained from 2,4-disubstituted phenols and mesitol gave the 2,5-dienone as the sole product.[3] However since *para* dienones are known to be more stable than *ortho* dienones (2) it is possible that an initially formed *ortho* dienone is rapidly equilibrated to its more stable *para* isomer. A further illustration of the difficulty of forming *ortho* dienones in chlorination was provided by the failure of both 2,6-dimethylphenol and 2,5-dimethylphenol to form dienones (see below). The latter example is particularly significant since we have shown that this phenol gives a 90% yield of 2,5-dimethyl-2-nitrocyclohexadienone on nitration in acetic anhydride.[4]

Nilsson and co-workers (9) obtained **1** in close to quantitative yield on chlorination of *p*-cresol with a massive excess of antimony pentachloride in dichloromethane at $-60°C$. We were able to obtain a good yield of **1** following their procedure but the work-up proved troublesome and it was found necessary to centrifuge the mixture to separate the organic and aqueous phases. An added disadvantage of the method is the large amount of antimony pentachloride required. Hussain (10) obtained **9** as well as 4,6-dichloro- and 2,4,6-trichloro-3,4-dimethylcyclohexa-2,5-dienones on chlorination of 3,4-dimethylphenol with 3 mol of *tert*-butyl hypochlorite in 90% acetic acid. It was claimed that no dienones were formed when one and two moles of the chlorinating agent were used, but it seems more likely that **9** was formed under these conditions but was not noticed. de la Mare and co-workers (11) subsequently obtained **9** on chlorination of 3,4-dimethylphenol with molecular chlorine in acetic acid. They did not obtain the compound pure and stated that it is unstable and that it decomposes in acetic acid to a mixture of 3,4-dimethylphenol and 2-chloro-4,5-dimethyl phenol. We have found that the crystalline compound, like the other dienones, is quite stable in the pure state at ambient temperature and that a solution of the dienone in acetic acid did not react over a period of one week. de la Mare *et al.* (11) also observed a trichlorocyclohexenone in the products of chlorination of 3,4-dimethylphenol and they proposed that it is an intermediate in the formation of 2,4-dichloro-4,5-dimethylcyclohexa-2,5-dienone. Under our conditions we did not observe the formation of any trichlorocyclohexenones. A likely route to the dichlorocyclohexadienone is from the further chlorination at the substituted *para* position of the chlorophenol produced by *ortho* chlorination.

In addition to those for *p*-cresol preliminary nmr scale experiments were also carried out on the other phenol precursors to the dienones **2**–**4** and **6**–**10** to establish the conditions for the subsequent 0.1-mol scale dienone preparations. Yields of dienones were generally consistent with those obtained in the larger scale experiments. Nuclear magnetic resonance scale experiments were also carried out on 2,5-dimethyl-, 2,6-dimethyl-, 4-chloro-, 2,4-dichloro-, and 3-methyl-4-chlorophenol. In no case was any dienone detected. The dimethylphenols have been discussed above. In the cases of the chlorophenols it appears that substitution at the unsubstituted *ortho* position(s) occurs more readily than addition to the *para* position which is *ipso* to chlorine. Dienones have been formed from chlorophenols but only when the chlorophenols had no unsubstituted positions *ortho* or *para* to the hydroxyl group (4, 5, 12, 13, 19). For nitration, positions *ipso* and *meta* to chlorine are of comparable reactivity: $i_f^{Cl}:m_f^{Cl} = 1:1\text{–}2$ (20, 21). Chlorination, for which $\rho = -10$ (22), is more sensitive to small differences in substituent electronic effects than is nitration, for which $\rho = -6$ (22). Even so, some chlorination ($\sim 25\%$) should occur *ipso* to chlorine in *p*-chlorophenol and the fact that it does not suggests some specific *ipso* deactivation in chlorination. Even *p*-cresol is less susceptible to chlorination at the 4-position than expected. Phenol is chlorinated to about the same extent at the *ortho* and *para* positions (23) i.e., the *para* position is twice as reactive as an *ortho* position. For nitration $i_f^{Me}:m_f^{Me} = 2\text{–}4:1$ (24). Thus the methyl group is more activating at the *ipso* than the *meta* position and hence *p*-cresol should be chlorinated to a greater extent at the 4-position *ipso* to methyl than at the unsubstituted 2-position. In fact the 2- and 4- positions in *p*-cresol appear to be equally reactive towards chlorine with only one-third of the product arising from *ipso* attack. The lower than expected reactivity of *ipso* positions towards chlorination is also consistent with the behaviour of hydrocarbon substrates in chlorination. *p*-Xylene, 1,2,3,5-tetramethylbenzene (isodurene), and 5-*tert*-butyl-1,2,3-trimethylbenzene all give good

[2]It has been stated (9) that "chlorination of *p*-alkylated phenols with the traditional chlorinating agents usually gives *o*-chlorophenols..." with the intended and clearly incorrect implication that 4-chlorodienones are not formed.

[3]A 5% yield of *ortho* dienone would have been detected in the crude chlorination product from 2,4-dimethyl- and 2,4,6-trimethylphenol.

[4]Unpublished work.

yields of diene adducts in nitration (25). However, no adducts could be detected on chlorination nor were any side-chain products formed (which would point to the intermediate formation of an *ipso*-cyclohexadienyl cation intermediate (25)). It is of course also possible that an initially formed *ipso*-chlorocyclohexadienyl cation could revert to the reactants or rearrange to the non-*ipso* cation, precursor to the nuclear chlorination product, without forming adduct.

Nuclear magnetic resonance scale experiments were also carried out using *p*-cresyl acetate and *p*-methylanisole as substrates. These compounds were so much less reactive than the phenols that under conditions under which *p*-cresol reacted completely they were largely unreacted, although a small amount of dienone was formed in each case.

Experimental

4-Methyl, 4-ethyl-, 4-isopropyl-, 4-*tert*-butyl-, 2,4-dimethyl-, 2-*tert*-butyl-4-methyl-, 2-bromo-4-methyl-, 3,4-dimethyl-, and 2,4,6-trimethylphenol were from Aldrich. Alumina was Camag basic, activity I.

Infrared spectra were obtained on a Pye-Unicam SP1000 or a Perkin-Elmer 337 spectrophotometer. ^{1}H nuclear magnetic resonance spectra at 90 MHz were determined using a Perkin-Elmer R32 spectrometer. ^{13}C nmr spectra at 15.1 MHz were obtained with a Nicolet TT-14 spectrometer. Mass spectra were obtained on a Hitachi Perkin-Elmer RMU 7 spectrometer. High pressure liquid chromatography was carried out with a Waters Prep LC/System 500.

Nuclear Magnetic Resonance Scale Experiments

Chlorine (24 cm^3, 1 mmol) was injected from a hypodermic syringe into a solution of the substrate (1 mmol) in the appropriate solvent (400 mm^3) in an nmr tube at −78°C and the nmr spectra were recorded at −40°C and at successively higher temperatures until reaction was observed. Some experiments were carried out on a 0.5-mmol scale.

Chlorination of p-*Cresol: 4-Chloro-4-methylcyclohexa-2,5-dien-1-one (**1**) and 2,4-Dichloro-4-methylcyclohexa-2,5-dien-1-one (**5**)*

Chlorine (2.2 dm^3, 0.09 mol) was bubbled over 2 min, into a stirred solution of *p*-cresol (10.8 g, 0.1 mol) in acetic anhydride (200 cm^3) at −78°C. After 10 min the reaction mixture was warmed to −20°C for 15 min and then cooled to −78°C and poured into ether (1.5 dm^3) at −78°C. Ammonia was condensed into the vigorously stirred ether solution, which was cooled in solid carbon dioxide – acetone, at a rate such that the temperature did not rise above −65°C. Excess ammonia was aspirated and the mixture allowed to warm to 0°C. The solution was washed (×5) with ice water, dried ($MgSO_4$), and the solvent evaporated. The crude product (13.8 g) contained 28% of a single dienone (31% yield based on chlorine), 62% of chlorophenol(s), and 10% of *p*-cresol, by nmr. Filtration of a pentane solution of the mixture through 20 times its weight of basic alumina and elution with ether gave the pure dienone (when ether solutions of the residue were used two filtrations through alumina were required for purification). The 4-chloro-4-methylcyclohexa-2,5-dienone gave a positive Beilstein test (26)[5] and had ir: 1675 (C=O), 1640 (C=C), 708 cm^{-1} (C—Cl); ^{1}H nmr ($CDCl_3$) δ: 1.69 (s, 3, CH_3), 6.16(d, 2, J = 10 Hz, 2-*H* and 6-*H*), 6.95 ppm (d, 2, J = 10 Hz, 3-*H* and 5-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 29.4 (*C*H$_3$), 59.9 (*C*-4), 126.5 (*C*-2 and *C*-6), 149.5 (*C*-3 and *C*-5), 184.1 ppm (*C*-1); ms (70 eV) *m/e* (relative intensity): 144 (20) and 142.022 (57, M_r ($^{12}C_7{}^1H_7{}^{35}Cl^{16}O$): 142.019), 108 (68), 107 (100, M − Cl), 79 (30), 77 (35).

Similar chlorinations were carried out in ether (18% dienone, 20% yield), 16% acetic anhydride in ether (26%, 29% yield) and, with a 1:1 mole ratio of chlorine to *p*-cresol, in acetic anhydride (34% dienone(s)) and, at −10°C, in aqueous acetic acid (1:3 v/v) (31% dienones).[6] Chlorination was also carried out with sulfuryl chloride by adding the chloride (7.3 cm^3, 0.09 mol) over 15 min to a solution of *p*-cresol (10.8 g, 0.1 mol) in acetic anhydride (200 cm^3), with stirring, at −78°C. After a further 15 min the mixture was warmed to −20°C, maintained at that temperature for 15 min and worked up in the usual manner to yield the mixture of the dienone (31%, 34% yield) and phenols. Chlorination with antimony pentachloride (9) was carried out by adding a solution of *p*-cresol (9.0 g, 0.083 mol) in dichloromethane (250 cm^3) at −50°C over 2 h to a solution of antimony pentachloride (60 cm^3, 0.47 mol) in dichloromethane (150 cm^3) at −70°C. The mixture was stirred for 10 min at −60°C, cooled to −78°C, and cold methanol (50 cm^3) was added dropwise keeping the temperature below −70°C. The mixture was poured into water (200 cm^3). The sticky mass produced could not be filtered (as called for in the literature procedure) and it was centrifuged to separate the organic layer, which was then washed with phosphate buffer (pH 6), diluted with ether, and washed (×3) with water. After drying and removal of the solvent the product (9.8 g) contained dienone (86%) and phenols (14%). Pure dienone (7.3 g) was obtained on passage of an ethereal solution of the crude dienone through alumina.

Chlorination of *p*-cresol in aqueous acetic acid with 1.5:1 mole ratio of chlorine to substrate gave a product containing both **1** (27%) and **5** (27%). High pressure liquid chromatography on silica using ether solvent afforded the mixed phenols, the mono- and the dichlorodienones. The 2,4-dichloro-4-methylcyclohexa-2,5-dienone (**5**) was further purified by filtration through basic alumina and had ir: 1680 (C=O) 1640 (C=C), 727 (C—Cl), 660 cm^{-1} (C—Cl); ^{1}H nmr ($CDCl_3$) δ: 1.86 (s, 3, CH_3), 6.27 (d, 1, J_{56} = 10 Hz, 6-*H*), 6.97 (dd, 1, J_{35} = 2.7 Hz, J_{56} = 10 Hz, 5-*H*), 7.12 ppm (d, 1, J_{35} = 2.7 Hz, 3-*H*); irradiation of the 6-*H* resonance at 6.27 collapsed the 5-H quartet to a doublet and irradiation of the 5-*H* resonance at 6.97 collapsed the 6-*H* doublet to a singlet; ^{13}C nmr ($CDCl_3$) δ_C: 29.5 (4-*C*H$_3$), 61.0 (*C*-4), 125.4 (*C*-6), 145.4 (*C*-3), 149.8 (*C*-5), 177.4 ppm (*C*-1); *C*-2 was not detected; ms (70 eV) *m/e* (relative intensity): 178 (20) and 175.981 (32, M_r ($^{12}C_7{}^1H_6{}^{35}Cl_2{}^{16}O$): 175.980), 144 (25), 143 (22), 142 (70), 141 (60), 113 (20), 108 (14), 107 (100), 78 (15), 77 (65).

*4-Chloro-4-ethylcyclohexa-2,5-dien-1-one (**2**)*

Chlorination of *p*-ethylphenol (12.2 g, 0.1 mol) in acetic anhydride gave crude product (14.9 g) containing 49% (54% yield) of dienone. Filtration of a solution in ether through basic alumina gave 4-chloro-4-ethylcyclohexa-2,5-dienone (**2**) as an oil; ir: 1672 (C=O), 1635 (C=C), 870 cm^{-1} (C—Cl); ^{1}H nmr ($CDCl_3$) δ: 0.96 (t, 3, J = 7.0 Hz, CH_2CH_3), 2.12 (q, 2, J = 7.0 Hz, CH_2CH_3), 6.25 (d, 2, J = 10 Hz, 2-*H* and 6-*H*), 6.88 ppm (d, 2, J = 10 Hz, 3-*H* and 5-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 9.3 (CH_2CH_3), 35.3 (CH_2CH_3), 63.8 (*C*-4), 127.9 (*C*-2 and *C*-6), 148.6 (*C*-3 and *C*-5), 184.6 ppm (*C*-1); ms (70 eV) *m/e* (relative intensity): 156.035 (22, M_r($^{12}C_8{}^1H_9{}^{35}Cl^{16}O$):

[5]All of the chlorodienones gave a positive Beilstein test (26).

[6]Chlorinations in ether and aqueous acetic acid were worked up by washing with cold bicarbonate solution.

156.034), 141 (12), 130 (14), 128 (38), 122 (37), 121 (22), 113 (18), 107 (100), 93 (40), 91 (35), 78 (15), 77 (65).

*4-Chloro-4-isopropylcyclohexa-2,5-dien-1-one (**3**)*

Chlorination of *p*-isopropylphenol (13.6 g, 0.1 mol) in acetic anhydride gave crude product (16.4 g) containing 35% (39% yield) of dienone. Filtration of a solution in ether through basic alumina gave 4-chloro-4-isopropylcyclohexa-2,5-dienone (**3**) as an oil; ir: 1675 (C=O), 1635 (C=C), 870 cm^{-1} (C—Cl); ^1H nmr ($CDCl_3$) δ: 1.06 (d, 6, J = 7 Hz, $CH(CH_3)_2$), 2.23 (septet, 1, $CH(CH_3)_2$), 6.26 (d, 2, J = 10 Hz, 2-*H* and 6-*H*), 6.92 ppm (d, 2, J = 10 Hz, 3-*H* and 5-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 17.7 ($CH(CH_3)_2$), 38.5 ($CH(CH_3)_2$), 67.4 (*C*-4), 128.2 (*C*-2 and *C*-6), 147.6 (*C*-3 and *C*-5), 184.7 ppm (*C*-1); ms (70 eV) *m/e* (relative intensity): 170.049 (6, $M_r(^{12}C_9{}^1H_{11}{}^{35}Cl{}^{16}O)$: 170.050), 155 (19, $M - CH_3$), 136 (35), 130 (32) and 128 (100, $M - C_3H_6$), 121 (94), 107 (13), 103 (12), 91 (42), 77 (16).

*4-*tert*-Butyl-4-chlorocyclohexa-2,5-dien-1-one (**4**)*

Chlorination of *p-tert*-butylphenol (15 g, 0.1 mol) in acetic anhydride gave crude product (17.2 g) containing 17% (19% yield) of dienone. Filtration of a solution in pentane through alumina and elution with ether gave 4-*tert*-butyl-4-chlorocyclohexa-2,5-dienone (**4**), which was recrystallized from pentane as colourless needles, mp 60°C; ir (Nujol): 1680 (C=O), 1660 (C=C), 872 cm^{-1} (C—Cl); ^1H nmr ($CDCl_3$) δ: 1.12 (s, 9, $C(CH_3)_3$), 6.24 (d, 2, J = 10 Hz, 2-*H* and 6-*H*), 7.05 ppm (d, 2, J = 10 Hz, 3-*H* and 5-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 25.6 ($C(CH_3)_3$), 39.4 ($C(CH_3)_3$), 70.5 (*C*-4), 127.8 (*C*-2 and *C*-6), 147.7 (*C*-3 and *C*-5), 184.6 ppm (*C*-1); ms (70 eV) *m/e* (relative intensity): 184.068 (3, $M_r(^{12}C_{10}{}^1H_{13}{}^{35}Cl{}^{16}O)$: 184.065), 169 (14, $M - CH_3$), 150 (15), 135 (45), 128 (22), 107 (20), 91 (19), 77 (15), 57 (100, $C(CH_3)_3{}^+$). *Anal.* calcd. for $C_{10}H_{13}ClO$: C 65.04, H 7.10; found: C 65.40, H 7.28.

*4-Chloro-2,4-dimethylcyclohexa-2,5-dien-1-one (**6**)*

Chlorination of 2,4-dimethylphenol (12.2 g, 0.1 mol) in acetic anhydride gave crude product (14.4 g) containing 45% (50% yield) of dienone. Filtration of a solution in ether through alumina gave 4-chloro-2,4-dimethylcyclohexa-2,4-dienone (**6**) as an oil; ir: 1670 (C=O), 1647 (C=C), 890 cm^{-1} (C—Cl); ^1H nmr ($CDCl_3$) δ: 1.79 (s, 3, 4-CH_3), 1.88 (d, 3, J = 1.5 Hz, 2-CH_3), 6.15 (d, 1, J_{56} = 10 Hz, 6-*H*), 6.73 (m, 1, 3-*H*), 6.91 ppm (dd, 1, J_{35} = 3 Hz, J_{56} = 10 Hz, 5-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 15.6 (2-CH_3), 29.7 (4-CH_3), 61.0 (*C*-4), 126.3 (*C*-6), 133.4 (*C*-2), 145.2 (*C*-3), 149.4 (*C*-5), 184.9 ppm (*C*-1); ms (70 eV) *m/e* (relative intensity): 158 (19) and 156.035 (58, $M_r(^{12}C_8{}^1H_9{}^{35}Cl{}^{16}O)$: 156.034), 141 (5, $M - CH_3$), 128 (25), 122 (75), 121 (100, M − Cl), 107 (57), 93 (30), 91 (55), 78 (15), 77 (45).

*2-*tert*-Butyl-4-chloro-4-methylcyclohexa-2,5-dien-1-one (**7**)*

Chlorination of 2-*tert*-butyl-4-methylphenol (16.4 g, 0.1 mol) in acetic anhydride gave crude product (18.3 g) containing 48% (53% yield) of the dienone. Filtration of a solution in pentane through alumina and elution with ether gave 2-*tert*-butyl-4-chloro-4-methylcyclohexa-2,5-dienone (**7**), obtained as pale yellow crystals after recrystallization from pentane, mp 39°C; ir (Nujol): 1667 (C=O), 1640 (C=C), 840 (cm^{-1}) (C—Cl); ^1H nmr ($CDCl_3$) δ: 1.22(s, 9, $C(CH_3)_3$), 1.79 (s, 3, 4-CH_3), 6.07 (d, 1, J_{56} = 10 Hz, 6-*H*), 6.69 (d, 1, J_{35} = 3 Hz, 3-*H*), 6.83 ppm (dd, 1, J_{35} = 3 Hz, J_{56} = 10 Hz, 5-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 28.8 ($C(CH_3)_3$), 30.2 (4-CH_3), 34.4 ($C(CH_3)_3$), 61.5(*C*-4), 128.2 (*C*-6), 143.5 (*C*-2 and *C*-3) 147.2 (*C*-5), 184.4 ppm (*C*-1); ms (70 eV) *m/e* (relative intensity): 198.070 (3, $M_r(^{12}C_{11}{}^1H_{15}{}^{35}Cl{}^{16}O)$: 198.081), 183 (10, $M - CH_3$), 164 (36), 163 (41, M − Cl), 162 (24), 150 (86), 148 (22), 135 (16), 122 (20), 121 (100), 107 (18), 105 (20), 91 (24), 77 (26). *Anal.* calcd. for $C_{11}H_{15}ClO$: C 66.50, H 7.61; found: C 66.09, H 7.65.

*2-Bromo-4-chloro-4-methylcyclohexa-2,5-dien-1-one (**8**)*

Chlorination of 2-bromo-4-methylphenol (18.7 g, 0.1 mol) in acetic anhydride gave crude product (20.7 g) containing 44% (49% yield) of dienone. Filtration of a solution in ether through alumina followed by recrystallization from ether–pentane at −20°C gave 2-bromo-4-chloro-4-methylcyclohexa-2,5-dienone (**8**), mp 55°C; ir (Nujol): 1660 (C=O), 1600 (C=C), 915, 835 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.83 (s, 3, 4-CH_3), 6.28 (d, 1, J_{56} = 10 Hz, 6-*H*), 6.96 (dd, 1, J_{35} = 2.5 Hz, J_{56} = 10 Hz, 5-*H*), 7.38 ppm (d, J_{35} = 2.5 Hz, 3-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 29.2 (4-CH_3), 61.5 (*C*-4), 123.9 (*C*-2), 124.9 (*C*-6), 149.5 and 149.7 (*C*-3 and *C*-5), 177.1 ppm (*C*-1); ms (70 eV) *m/e* (relative intensity): 222 (3) and 219.934 (3, $M_r(^{12}C_7{}^1H_6{}^{79}Br{}^{35}Cl{}^{16}O)$: 219.929), 188 (70), 187 (40), 186 (74), 185 (37), 143 (27), 142 (11), 141 (73), 113 (15), 108 (12), 107 (100), 79 (15), 78 (60), 77 (75). *Anal.* calcd. for C_7H_6BrClO: C 37.96, H 2.73; found: C 37.93, H 2.77.

The presence of a significant amount of 2-bromo-*p*-cresol (*m/e*: 188 (62), 187 (23), 186 (62), 185 (20), 108 (20), 107 (100), 79 (13), 78 (24), 77 (42)) is evident in the mass spectrum. This must arise from thermolysis of the dienone within the mass spectrometer since no phenol could be detected by either ^1H nmr or ^{13}C nmr.

*4-Chloro-3,4-dimethylcyclohexa-2,5-dien-1-one (**9**)*

Chlorination of 3,4-dimethylphenol (12.2 g, 0.1 mol) in acetic anhydride gave crude product (15.0 g) which contained 41% (46% yield) of dienone. Filtration of a solution in ether through alumina followed by crystallization from ether gave 4-chloro-3,4-dimethylcyclohexa-2,5-dienone (**9**) as colourless crystals, mp 51°C; ir (Nujol): 1675 (C=O), 1630 (C=C), 887 cm^{-1} (C—Cl); ^1H nmr ($CDCl_3$) δ: 1.77 (s, 3, 4-CH_3), 2.17 (s, 3, 3-CH_3), 6.09 (broad s, 1, 2-*H*), 6.16 (dd 1, J_{26} = 1.5 Hz, J_{56} = 9 Hz, 6-*H*), 6.94 ppm (d, 1, J = 9 Hz, 5-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 19.3 (3-CH_3), 28.3 (4-CH_3), 62.8 (*C*-4), 125.6 and 126.4 (*C*-2 and *C*-6), 150.3 (*C*-5), 157.7 (*C*-3), 185.1 ppm (*C*-1); ms (70 eV) *m/e* (relative intensity): 158 (14) and 156.034 (42, $M_r(^{12}C_8{}^1H_9{}^{35}Cl{}^{16}O)$: 156.034), 141 (7), 130 (24), 128 (69), 122 (71), 121 (100), 120 (19), 107 (72), 93 (70), 92 (19), 91 (93), 78 (18), 77 (95). *Anal.* calcd. for C_8H_9ClO: C 61.35, H 5.79; found: C 61.34, H 5.93.

*4-Chloro-2,4,6-trimethylcyclohexa-2,5-dien-1-one (**10**)*

Chlorination of 2,4,6-trimethylphenol (13.6 g, 0.1 mol) in acetic anhydride gave crude product containing 90% dienone (100% yield) and 10% of the unreacted phenol. Filtration of a solution in ether through alumina at 0°C, followed by crystallization from pentane at −20°C, gave 4-chloro-2,4,6-trimethylcyclohexa-2,5-dienone (**10**) as colourless crystals, mp 32°C; ir (Nujol): 1675 (C=O), 1647 (C=C), 900 cm^{-1} (C—Cl); ^1H nmr ($CDCl_3$) δ: 1.76 (s, 3, 4-CH_3), 1.88 (s, 6, 2-CH_3 and 6-CH_3), 6.73 ppm (s, 2, 3-*H* and 5-*H*); ^{13}C nmr ($CDCl_3$) δ_C: 15.7 (2-CH_3 and 6-CH_3), 30.1 (4-CH_3), 61.5 (*C*-4), 133.0 (*C*-2 and *C*-6), 145.1 (C-3 and C-5), 182.8 ppm (*C*-1); ms (70 eV) *m/e* (relative intensity): 172 (12) and 170.046 (34, $M_r(^{12}C_9{}^1H_{11}{}^{35}Cl{}^{16}O)$: 170.048), 169 (18), 136 (100), 135 (82), 121 (67), 107 (18), 105 (16), 91 (52), 79 (20), 77 (16). *Anal.* calcd. for $C_9H_{11}ClO$: C 63.35, H 6.50; found: C 63.65, H 6.55.

The reactions of arenesulphonyl azides with tetrahydropyrido[1,2-*a*]indoles have been examined. Compounds formed by elimination and by ring enlargement are obtained, including a compound with a novel zwitterion structure. The structure of this compound has been determined by X-ray crystallography.

T. Stanley Cameron, Ruth E. Cordes, Aris Terzis, A. Sydney Bailey et Peter W. Scott. Can. J. Chem. **57**, 558 (1979).

On a étudié les réactions des azotures d'arènesulfonyles avec les tétrahydropyrido[1,2-*a*]-indoles. On a obtenu des composés, résultant d'une élimination accompagnée d'une extension de cycle, parmi lesquels se trouve un composé comportant une nouvelle structure zwittérionique. On a déterminé la structure de ce composé par diffraction de rayons-X.

[Traduit par le journal]

We have described the reactions of arenesulphonyl azides with *N*-methyltetrahydrocarbazole (**1**) (1) and with the pyridocarbazole derivative (**2**) (2). It was of interest to extend this work by investigating the reactions of a tetrahydropyrido[1,2-*a*]indole and we chose the known (3) dimethyl derivative **3**; we also examined the reactions of the isomeric structure (**4**; R = H and R = Me) since the reactions of simple indolizines with azides have been reported (4). Compound **3** was prepared by the known route (3) via compound **5**; compounds **4**; R = H (5) and **4**; R = Me (6) were synthesised from 2-bromocyclohexanone.

Compound **3** was treated with *p*-chlorobenzenesulphonyl azide ($CbsN_3$) in chloroform solution and yielded two products (plus polymeric materials). The compounds were *p*-chlorobenzenesulphonamide and an unstable oil (50% yield) which darkened rapidly and could not be analysed. Structure **6** is supported by the nmr, mass, and uv spectra of the compound. The nmr spectral values are in good agreement with those reported (7) for compound **7**. We consider that compound **6** arises via the intermediates **8** and **9** although it is possible that **10** is formed as an intermediate (cf. the formation (1) of **11** from **1**) and the loss of $TsNH_2$ from **12** (8) to form **13**.

To determine if olefin formation occurred with simple alkylindoles containing a secondary alkyl group at position (2), the reactions of 1,3-dimethyl-2-isopropylindole (**15**) with tosyl azide was examined (**15** was obtained by hydrogenation of **14** (9)). The major product (yield 57%) was the 1:2 reaction product **16**. This structure was supported by its physical properties and by hydrolysis of **16** to form **18**. Compound **16** arises by addition of a second molecule of azide to **17** followed by ring enlargement (1, 10). Two other compounds were isolated from the reaction, *p*-toluenesulphonamide and the olefin **14** (yield 10%). The olefin arises from **17** by loss of $TsNH_2$ (cf. the formation of **6**). These observations suggest that the elimination of $TsNH_2$ from the cyclic intermediate **9** occurs faster than the attack of TsN_3 whilst for the acyclic compound **17** the converse occurs. It is impossible for compound **3** to give rise to ring-enlarged quinoline structures of type **16** by addition of second molecule of azide to **9** since such products would contain a '*meta*' bridge.

1,2,3,4-Tetrahydropyrido[1,2-*a*]indole (**4**; R = H) reacted smoothly with $CbsN_3$ giving a high yield of the azo compound (**20**) with its characteristic uv spectrum (4). The reaction of **4**; R = Me with $CbsN_3$ was more complex, tlc showing many products; only one compound was obtained crystalline (yield 23%). The ir spectrum of the compound showed the presence of a C=N—Cbs group (1620 cm^{-1}) and the absence of an NH group. We considered that the compound had structure **23** arising from **4** via **21** and **22**. With small quantities available it was decided to carry out an X-ray determination since crystals were suitable. It has been found that

0008-4042/79/050558-07$01.00/0

structure **23** originally considered is incorrect and the compound has the 'ionic' structure **25** and probably arises via **24**. The presence of the pyridinium ring explains the signals at very low field in the n.m.r. spectrum of the compound and the negatively charged NSO_2Ar group explains why the signals of the $SO_2C_6H_4$—Cl group have moved upfield from these 'normal' positions.

Crystal Structure of ***25***

Crystal data:

$C_{19}H_{19}ClN_2O_2S$ fw = 374.89

Monoclinic, $P2_1/c$, $a = 9.591(3)$, $b = 21.081(8)$, $c = 8.939(3)$ Å, $\beta = 90.75(3)$, $V = 1807.2$ Å^3, $Z = 4$, $\rho_c = 1.377$ g cm^{-3} (18 ± 2°C; $CuK_{\alpha 1}$, $\lambda = 1.54051$ Å (carbon monochromator) $\mu = 29.40$), $F(000) = 784$.

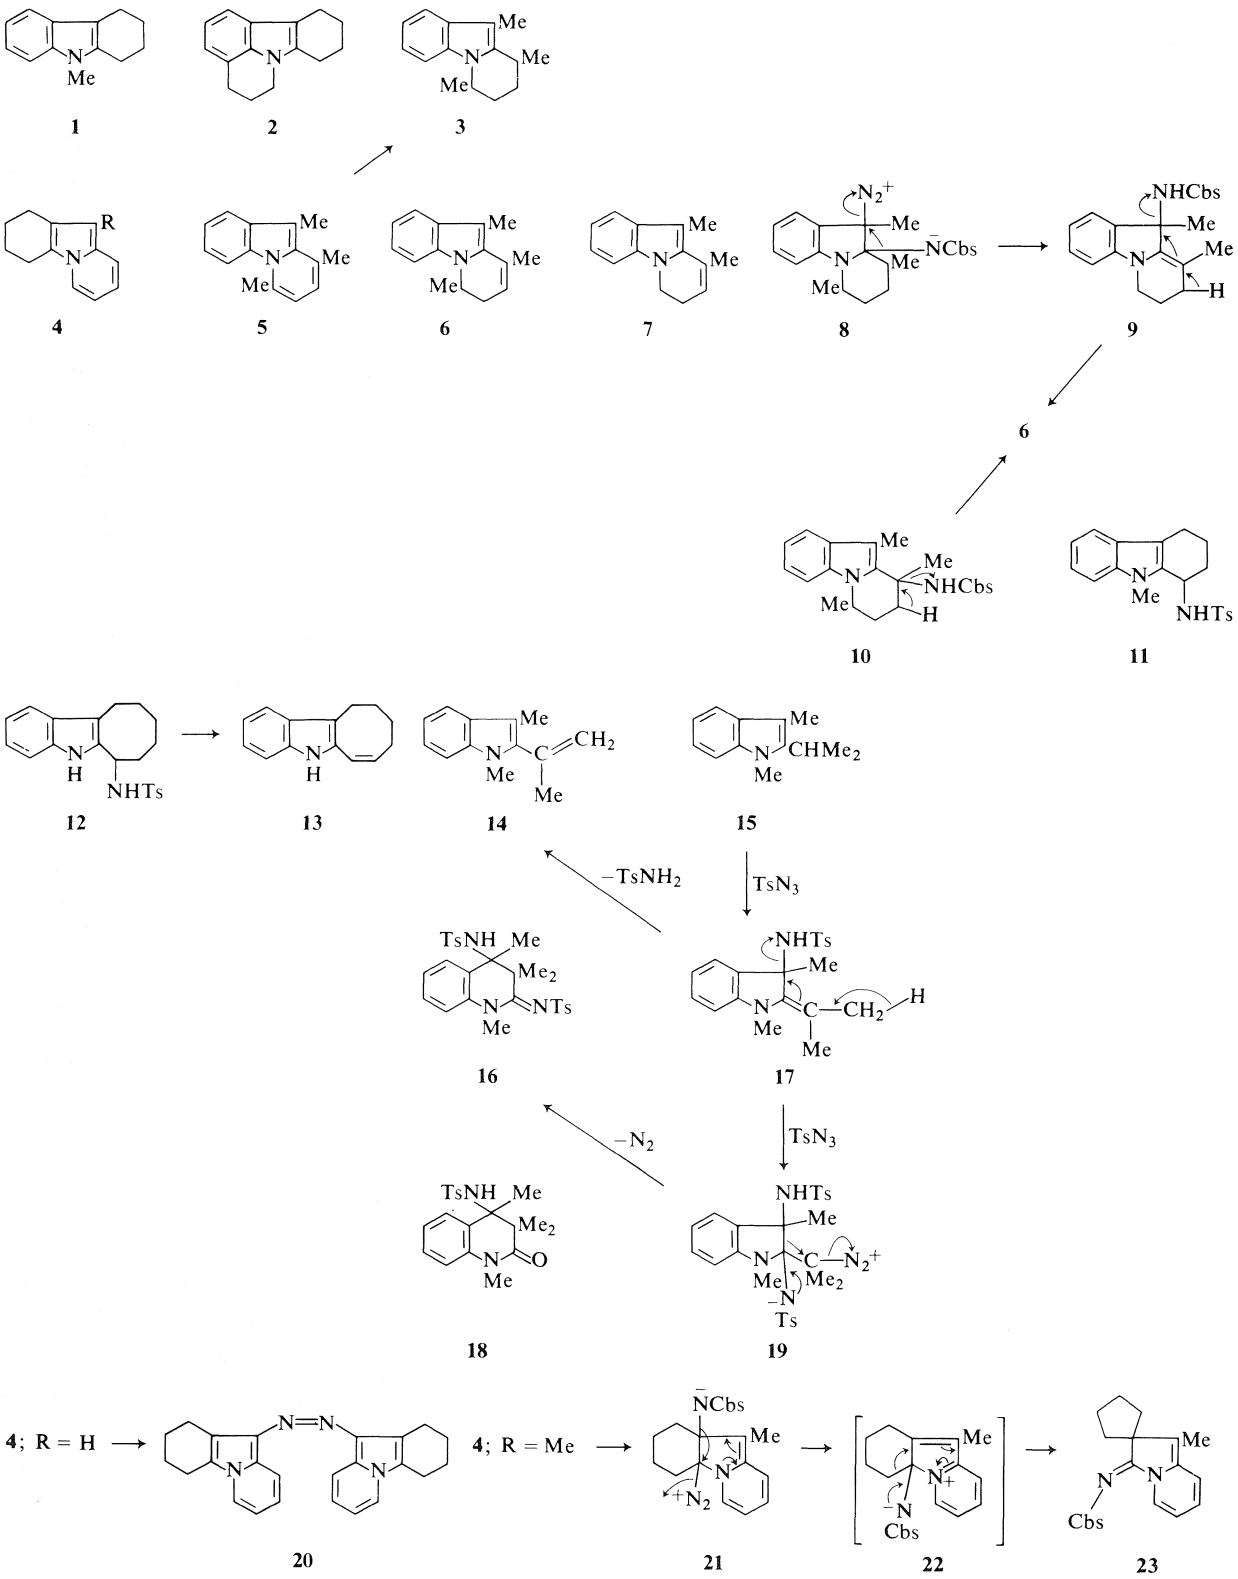
The cell dimensions (refined from 12 general reflections with 2θ between 70–76°) and intensities of 2786 independent reflections were measured on a Picker FACS-1 four circle diffractometer with an ω − 2θ scan and 2θ values between 4 and 120°. The minimum base-width was 2.2°. Three standard reflections were measured every 58 reflections. The intensity of these three reflections decreased steadily throughout the data collection but could be adjusted to a standard scale by a least-squares fit ($\sigma = 0.015$) to a first order decay; from the counting statistics the ratio of esd to reflection of these standards was 0.019. The data were reduced to $|F_o|$ by the routine procedure. No absorption or extinction corrections were applied. The scattering factors for neutral atoms were taken from ref. 11; they were corrected for the real part of the anomalous dispersion. Reflections with $|E| > 1.2$ were used to solve the structure by an application of the tangent formula that examined $4096 = 2^{12}$ sets of starting phases and successively eliminated all but the most likely. This program is part of an X-ray system written by Sheldrick (12). The position of all but the hydrogen atoms were found on the E map with the lowest Karle R factor (13).

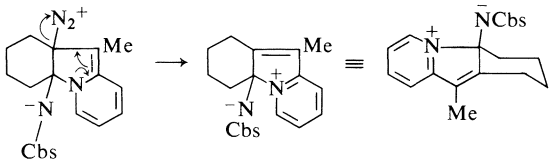
The structure was refined by large-block least-squares ($\sum(\Delta|F|)^2 = \min$) initially with isotropic temperature factors using only the 2031 reflections with $I > 3\sigma(I)$. The atomic parameters for those hydrogen atoms with positions defined by the molecule were calculated and the remainder were located from a difference Fourier synthesis calculated when the conventional R was 0.13. The subsequent refinement with anisotropic temperature factors converged[1] with $R = 0.0518$. The hydrogens of the methyl group appeared to be disordered with at least two preferred locations. The methyl group was therefore refined as a rigid body (12) (see below). The least-squares weights were calculated from $w = 1/(\sigma^2|F_o| - 0.00043|F_o|^2)$, where σ is the weight for each reflection derived from the diffractometer counting statistics. The atomic coordinates are given in Table 1 and the interatomic distances and interbond angles are listed in Table 2. Figure 1 shows a single molecule and Fig. 2 gives its packing within the unit cell.

The crystal was found to be constructed from isolated molecules which contained a *p*-chlorophenylsulphone group bonded through a nitrogen atom to a hexahydropyrido[1,2-*a*]indole system (Fig. 1). The S—N(1), N(1)—C(3), C(3)—N(2), and N(2)—C(5) distances are 1.563(3), 1.432(4), 1.531(4), and 1.335(4) Å, respectively. A formal S=N double bond has been reported (14) at 1.52(2) and a S—NH— single bond at 1.635(8) in a tolylsulphenylamino group that has an sp^3 carbon atom bonded to the third valency at nitrogen (15). The N(1)—C(3) bond length is shorter than that normally quoted (16) (1.472(5)) for a bond between an sp^2 nitrogen and an sp^3 carbon, whereas the C(3)—N(2) length (1.531(4)) is very much longer. The N(2)—C(5) and N(2)—C(9) bonds of 1.335(4) and 1.362(4) are similar to those observed in pyridine derivatives (17). The two S—O bond lengths, 1.449(2) and 1.453(3), are slightly longer than those normally observed in this type of molecule (15). The nitrogen atom N(2) therefore formally forms four bonds and is positively charged, and the $-SO_2N$ group has a balancing negative charge which is situated predominantly upon the nitrogen atom. This can be written as the zwitterion **25**. A sulimido)pyridinium ylide has been observed (18) before and here too the negative charge is found on the sulphonyl nitrogen atoms. In this case though no X-ray structure has been determined.

The hexahydropyrido[1,2-*a*]indole fragment of the molecule has two six-membered rings separated by a five-membered ring. One six-membered ring, attached at C(2) and C(3), is largely saturated and has the chair conformation. The C(1)—C(2) bond, however, which is part of the adjoining five-membered ring has a length of 1.337(4) Å and is clearly a double bond. The angle C(3)—C(2)—C(14) is 115.6(3)° and compares with the mean internal angle of 110.8° for this ring. The C—C—C—C torsional angles around this ring (Table 3) have an absolute value which varies between 60.4° (C(14)—C(2)—C(3)—C(11)) and 52.5° (C(2)—C(14)—C(13)—C(12)), with a mean value of 56.6° so that the introduction of an sp^2 carbon at C(2) only slightly distorts the ring. The five-

[1]A list of structure factors (Table 4) and complete atomic parameters is available at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.





24 25

membered ring has a mean deviation from the least-squares best plane of 0.010 Å. As already noted, C(1)—C(2) is a double bond and is conjugated to the other six-membered ring, which is aromatic, through bond C(1)—C(9). This bond has a length of 1.459(4) Å which compares with 1.480 Å for the central bond in buta-1,3-diene (19). The hydrogen atoms of the methyl group at C(10) appeared in the difference map to have two alternative orientations, so in the refinement the whole CH_3 group was treated as a rigid body and was permitted to rotate about the C(1)—C(10) bond (12). These hydrogen atoms were constrained (20) to have equal temperature factors and to have a site occupation which summed to one for the two groups. The two possible methyl orientations refined with one rotated 38.6° about C(1)—C(10) with respect to the other. The six-membered ring attached at C(9) and N(2) is aromatic with a mean

the five-membered ring has a double bond in it (C(1)—C(2)) this probably introduces strain at the ring junction thus lengthening the common bond.

The distances in the *p*-chlorosulphonyl group are unexceptional. The sulphur–carbon distance of 1.792(3) compares with 1.776(4) in the *p*-toluenesulphonate ion (21) and the carbon chlorine bond length of 1.747(4) compares with 1.780(8) in 1-(2-chloro-4-dimethylaminophenyl)-2-nitroethylene (22).

Experimental

Infrared spectra were determined for Nujol mulls, uv spectra for solutions in ethanol, and nmr spectra for solutions in $CDCl_3$ unless otherwise stated. Chromatography (tlc and column) was carried out using silica–$CHCl_3$ unless otherwise stated. Solutions were dried using $MgSO_4$.

*6,7-Dihydro-6,9,10-trimethylpyrido[1,2-a]indole (**6**)*

6,9,10-Trimethylpyrido[1,2-*a*]indole **5** had mp 134–134.5°C (yield 70%) (lit. (3) mp 134°C); τ: 1.83 (1H, d, J = 8 Hz), 2.24 (1H, d, J = 8 Hz), 2.50–2.90 (2H, m), 3.54 (1H, q, J = 7 and 1 Hz C(8)H), 3.98 (1H, q, J = 7 and 1 Hz C(7)H), 7.12 (3H, sbr, C(6)CH_3), 7.25 (3H, s, C(10)CH_3), and 7.36 (3H, sbr, C(9)CH_3), these assignments were confirmed by decoupling experiments. Hydrogenation of **5** (3) afforded **1**, mp 75–79°C (lit. (3) mp 76–80°C); τ: 2.40–2.95 (4H, m), 5.3–5.65 (1H, m,

C(6)H), 6.65–6.95 (1 H, m, C(9)H), 7.70 (3H, s, C(10)CH_3), 7.85–8.35 (4H, m, C(7)H_2 + C(8)H_2), 8.50 (3H, d, J = 8 Hz, C(6)CH_3), and 8.62 (3H, d, J = 8 Hz, C(9)CH_3); assignment of C(6) and C(9) Me group signals was made by decoupling experiments on the corresponding methine signals; *m/e* (relative intensity): 213 (M^+, 100), 199 (30), 198 (95), and 182(15). A solution of this compound (1.1 g) in chloroform (20 mL) containing $CbsN_3$ (1.1 g) was kept in the dark for 4 weeks. Chromatography gave **6** (0.55 g), stable at 0°C; ν_{max}: 210, 235(sh), 254(sh), 263(infl), 307, 319(sh), 336(infl) nm (ε 21 500, 15 500, 9600, 6500, 15 500, 14 200, and 5050); ν_{max} (liquid film): 740 and 1465 cm^{-1}; τ: 2.4–2.6 (1H, m), 2.7–3.1 (3H, m), 4.35–4.6 (1H, m, C(8)H), 5.25–5.6 (1H, m, C(6)H), 7.0–8.0 (2H, m, C(7)H_2) 7.54 (3H, s, C(10)CH_3), 7.65–7.85 (3H, m, C(9)CH_3), and 8.86 (3H, d, J = 7 Hz, C(6)CH_3); irradiation of the signal at 8.86 showed that it was coupled to C(6)H; irradiation of the signal 7.75 showed that it was coupled to the vinyl proton, the complexity of the signals in **7** has been noted (7); *m/e* (relative intensity): 211 (M^+, 100), 196 (M − CH_3, 60, m* 182), 181 (196 − CH_3, 58, m* 167), and 196 (4). Further elution gave *p*-chlorobenzenesulphonamide (0.4 g) and a black tar (0.5 g).

The Reaction of 1,3-Dimethyl-2-isopropylindole with Azides

Hydrogenation (Pd/C, EtOH) of the olefin **14** afforded **15**, bp 130–140°C/0.2 Torr, mp 22–23°C; λ_{max}: 230, 281(infl), 286, and 293 nm (ε 41 100, 7900, 8900, and 8800); τ: 2.4–3.05 (4H, m), 6.33(3H, s, NCH_3), 6.68 (1H, heptet, J = 7 Hz, $CHMe_2$), 7.68 (3H, s, C—CH_3), and 8.62 (6H, d, J = 7 Hz, C(CH_3)$_2$); *m/e* (relative intensity): 187 (M^+, 55), 173 (16), 172 (M − CH_3, 100, m* 158), and 157 (172 − CH_3, 17, m* 143.3). *Anal.* calcd. for $C_{13}H_{17}N$: C 83.4, H 9.1, N 7.5; found: C 83.2, H 9.0, N 7.4. A mixture of this indole (1.0 g) and tosyl azide (2.1 g) was kept for 24 h at room temperature. Methanol (3 mL) was then added and 3 days later the solid was collected and recrystallised from methanol (yield 57%). 1,2,3,4-Tetrahydro 1,3,3,4-tetramethyl-4-*p*-tolylsulphonylamino-2-*p*-tolylsulphonyliminoquinoline **16** formed colourless rods, mp 230–232°C; λ_{max}: 222 and 282 nm (ε 26 900 and 18 000); ν_{max}: 1555 and 3230 cm^{-1}; τ: (DMSO) 2.24 (2H, d, J = 9 Hz), 2.35 (1H, s, NH, exchanged with D_2O), 2.65 (2H, d, J = 9 Hz), 2.50–3.10 (8H, m), 6.57 (3H, s, NCH_3), 7.58 and 7.63 (each 3H, s, 2 × $TsCH_3$), 8.40 (3H, s, CH_3), 8.72 (3H, s, CCH_3), and 9.28 (3H, s, CCH_3); *m/e* (relative intensity): 525 (M^+, 4), 461 (M − SO_2, 18, m* 405), 446 (13), 370 (25), 291 (60), 199 (63), and 147 (100). *Anal.* calcd. for $C_{27}H_{31}N_3O_4S_2$: C 61.7, H 5.9, N 8.0, S 12.2; found: C 61.6, H 5.9, N 8.0, S 12.0. Chromatography of the mother liquors afforded starting material (0.09 g), tosyl azide (0.1 g), and the olefin **14** (0.1 g) identical (tlc, ir, nmr) with an authentic sample. Hydrolysis of **16** (0.5 g) by boiling in EtOH (20 mL) with aqueous NaOH (10 mL, 2 M) for 1 h followed by dilution and extraction ($CHCl_3$) gave 1,2,3,4-tetrahydro-1,3,3,4-tetramethyl-4-*p*-tolylsulphonylaminoquinolin-2-one (**18**) (yield 75%) needles, from benzene–cyclohexane, mp 175–175°C; λ_{max}: 233 and 256 nm (ε 20 900 and 16 100); ν_{max}: 1660 and 3280 cm^{-1}; τ: 2.35–2.50 (1H, m), 2.70–3.15 (6H, m), 3.45–3.65 (1H, m), 5.17 (1H, s, NH, exchanged with D_2O), 7.12 (3H, s, NCH_3), 7.65 (3H, s, $TsCH_3$), 8.15 (3H, s, C—CH_3), 8.63 (3H, s, C—CH_3), and 9.16 (3H, s, C—CH_3); *m/e* (relative intensity): 372 (M^+, 23) 302 (M − (CH_3)$_2$CCO, 11, m* 245.2), 202 (M − TsNH, 17), 147 (302 − Ts, 100, m* at 71.5); and 132 (7). *Anal.* calcd. for $C_{20}H_{24}N_2O_3S$: C 64.5, H 6.5, N 7.5; found: C 64.6, H 6.5, N 7.3.

The Reactions of **4**; *R = H and* **4**; *R = Me with Azides*

1,2,3,4-Tetrahydropyrido[1,2-*a*]indole (**4**; *R = H*) had mp 54.5–55°C (lit. (5) mp 52°C); *m/e* (relative intensity): 171 (M^+, 57), 170 (26), 144 (13), and 143 (100, m* 119.6). Compound **4**; R = Me had mp 52–53°C (lit. (6) mp 41–43°C; *m/e* (relative intensity): 185 (M^+, 100), 184 (73), 158 (22), and 157 ($M - C_2H_4$, 100, m* 133). The indolizine **4**; R = H (0.85 g) was dissolved in chloroform (10 mL) and $CbsN_3$ (1.1 g) added. Seven days later the solid (yield 77%) was collected and recrystallised from chloroform. Blood-red needles mp > 340°C; λ_{max}: 260, 468(sh), and 504 nm (ε 16 600, 22 100, and 22 500); ν_{max}: 1503, 1528(w), and 1625(w) cm^{-1}; the compound was too insoluble to allow an nmr determination in $CHCl_3$ or DMSO; in TFA τ: 1.01 (1H, d, J = 7 Hz), 1.25–1.8 (4 H, m), 2.9–3.5 (3H, m), 4.45–4.8 (1H, m), and 6.5–8.7 (15H, m); *m/e* (relative intensity): 368 (M^+, 8), 186 (13), 171 (40), 157 (15), and 143 (100). *Anal.* calcd. for $C_{24}H_{24}N_4$: C 78.2, H 6.5, N 15.2; found: C 78.1, H 6.6, N 15.0. A solution of the indolizine **4**; R = Me (0.92 g) in chloroform (10 mL) containing $CbsN_3$ (1.1 g) was kept at room temperature for 15 weeks. The solvent was removed and methanol (5 mL) added. The solid (0.07 g) which separated was recrystallised (EtOAc–MeOH).

1,2,3,4-Tetrahydro-10-methyl-4a-*p*-tolylsulphonylaminopyridol[1,2-*a*]indole **25** formed colourless rods, EtOAc–MeOH, mp 199–200°C; λ_{max}: 213, 248, and 325 nm (ε 19 400, 17 400, and 4850); ν_{max}: 1620 cm^{-1}; τ: 1.14 (1H, d, J = 8 Hz), 1.75–1.95 (1H, m), and 2.35–2.9 (6H, m), 7.4–9.0 (8H, m), 7.88 (3H, s, CCH_3); *m/e* (relative intensity): 374 (M^+, 10), 200 (17), 199 (M – Cbs, 100, m* 106), 185 (15), 184 (28), and 183 (23). *Anal.* calcd. for $C_{19}H_{19}ClN_2O_2S$: C 60.9, H 5.1, N 7.5, Cl 9.3; found: C 60.7, H 5.3, N 7.5, Cl 9.0.

The mother liquors were concentrated and the residues chromatographed (SiO_2; MeOH), affording more compound **25** (0.35 g).

Reçu le 5 juin 1978

HUGUES MÉNARD et JACQUES DUBOIS. Can. J. Chem. **57**, 565 (1979).

A l'aide d'un capillaire en polyéthylène comme électrode polarographique, il a été mis en évidence la formation d'une goutte de mercure ayant un col cylindrique anormal. Mathématiquement ce col est justifié mais chimiquement nous devons opérer en milieu NaOH afin d'avoir formation d'oxyde mercurique.

HUGUES MÉNARD and JACQUES DUBOIS. Can. J. Chem. **57**, 565 (1979).

Using a polyethylene capillary as polarographic electrode we could notice the formation of a mercury drop with an abnormal cylindric neck. This can be justified mathematically but chemically we must use NaOH so as to have the formation of mercuric oxide.

Introduction

La mise au point d'un capillaire en polyéthylène (1) pour l'application, comme électrode de travail en polarographie, dans des milieux extrêmements corrosifs au verre (tels le fluorure d'hydrogène et les solutions de soudes concentrées) a permis de mettre en évidence une formation d'une goutte de mercure ayant une géométrie complexe.

Partie expérimentale

Une solution de NaOH 1 *M* (A.C.S. Fischer Scientific Company) a été préparée avec de l'eau bidistillée. Une cellule en verre contenant un système à trois électrodes a été utilisée. L'électrode de référence est de calomel saturé avec double jonction et l'électrode auxiliaire est de platine. Un potentiostat tacussel type PRT 30-0.1 a permi d'y appliquer les différents potentiels d'oxydation.

Résultats

En effet dans une solution de NaOH 1 *M* et à des potentiels ≤ 0.0 V par rapport à une électrode de calomel saturé, c'est-à-dire à des potentiels d'oxydation, nous avons photographié (fig. 1), à des intervalles de temps de l'ordre de 3 s, la formation d'une goutte de mercure au bout d'un capillaire de polyéthylène. D'une goutte normale (fig. 1*a*) de mercure, nous avons après avoir atteint une masse critique, formation d'un col cylindrique qui devient extrêmement long par rapport à la goutte, (fig. 1 *b*, *c*, *d*, *e*). La longueur limite du col cylindrique de mercure dépend du potentiel appliqué à l'électrode et de la concentration de la soude.

Il est à remarquer qu'une diminution de la tête d'hydrostatique du mercure peut arrêter l'écoulement du liquide et fixer la goutte dans l'espace. De plus, un montage approprié assure l'élimination des vibrations mécaniques.

Discussion

Selon Armstrong et coll. (2), il y aurait formation à la surface de l'électrode d'une couche de HgO ayant une bonne conductivité électrique. De plus, selon Cotton et Wilkinson (3) l'oxyde de mercure possèderait une structure de chaîne en zigzag —Hg—O—Hg— avec une liaison de Hg—O = 2.03 Å et des angles de 109° pour HgOHg et 179° pour OHgO.

Il est en outre possible de fournir une justification mathématique pour ce phénomène. De façon précise nous allons, dans ce qui va suivre, présenter une équation mathématique devant être satisfaite par le profil de la goutte et nous allons vérifier comment cette équation nous permet de conclure que la présence d'un col est possible.

Fixons un temps t quelconque (après le début de formation de la goutte, mais avant sa chute). Désignons par h la hauteur de la goutte en ce temps et par r le rayon du capillaire.

Afin de concilier les faits qu'expérimentalement on observe une goutte suspendue et qu'il est habituel de dénoter par x (resp. z) les quantités mesurées horizontalement (resp. verticalement) avec le fait que mathématiquement une fonction n'est bien définie que si à chaque valeur de la variable indépendante on associe une et une seule valeur de la fonction, nous allons utiliser un système d'axes rectangulaires (z,x) ayant pour origine le point inférieur de la goutte et où cette fois z apparaît en abcisse et x en ordonnée. Utilisant cette convention tout à fait naturelle la

0008-4042/79/050565-03$01.00/0

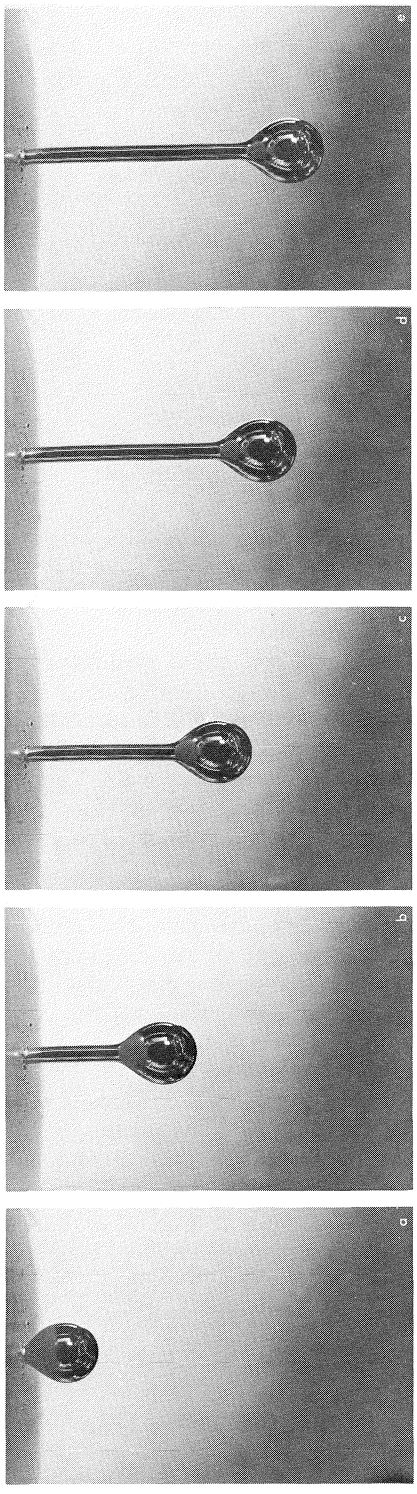

FIG. 1. Formation d'une goutte de mercure dans NaOH 1.0 *M*: (*a*) temps: 3 s; (*b*) temps: 6 s; (*c*) temps: 9 s; (*d*) temps: 12 s; (*e*) temps: 15 s.

goutte est alors délimitée par une surface de révolution engendrée par une fonction non négative, notée $X(z)$ at appelée la fonction profil, dont la valeur est nulle sur les intervalles $[-\infty, 0]$ et $[h, \infty]$ et qui est telle que $X(h) = r$ (voir fig. 2). Notons au passage que $X(z)$ dénote la valeur de la fonction profil au point z et que selon une coutume bien établie nous prendrons la liberté d'écrire tout simplement X à la place de $X(z)$ lorsque le contexte montrera clairement que X est une fonction de z.

Posons g = constante d'accélération due à la gravité; ρ_1 = masse spécifique du mercure; ρ_2 = masse spécifique de la solution de NaOH; σ = tension superficielle; R = rayon du cercle osculateur à la fonction profil au point (0,0); $V(z)$ = volume de révolution (dépendant de z) déterminé par la fonction profil restreinte à l'intervalle $[0,z]$; c'est-à-dire

$$[1] \qquad V(z) = \pi \int_0^z X^2(s)\mathrm{d}s$$

et $\theta(z)$ = angle (dépendant de z) formé au point $(z,X(z))$ par la normale (pointée extérieurement) à la fonction $X(z)$ et la verticale; c'est-à-dire

$$[2] \qquad \cos\theta(z) = [1 + (\dot{X}(z))^2]^{-1/2}$$

Dans ce travail, $\dot{X}$, $\ddot{X}$ désignent les dérivées (par rapport à z) première et seconde respectivement de la fonction $X(z)$. A nouveau lorsqu'il y a lieu de bien faire ressortir que ces dérivées dépendent de la variable z, on prendra le soin d'écrire $\dot{X}(z)$ et $\ddot{X}(z)$.

Une approche générale à la mise au point d'une méthode pour déterminer la tension superficielle à partir de la masse et du profil d'une goutte formée à l'extrémité d'un capillaire est présentée dans l'article de Badiali, Cachet, Cachet et Lestrade (4). Cette méthode est basée sur une relation rigoureuse qui doit exister entre la tension superficielle σ et la masse de la goutte. En supposant (ce que nous ferons nous aussi) que les pressions au sein des fluides ne varient qu'avec le champ de gravitation, les con-

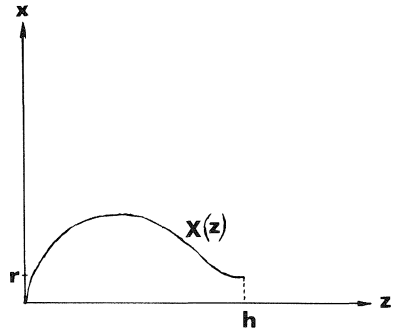

FIG. 2. Schéma de la goutte de mercure avant 3 s.

ditions d'équilibre mécanique de la goutte permettent d'établir que la fonction profil $X(z)$ doit satisfaire pour toute valeur de $z \in [0,h]$ l'équation de base suivante:

$$[3] \quad 2\pi\sigma X(z)\cos\theta(z) = g(\rho_1 - \rho_2)V(z) + \pi[X(z)]^2\,[(2\sigma/R) - g(\rho_1 - \rho_2)z]$$

Cette éq. [3] est précisément l'éq. [4] de la réf. 4 en page 744 et nous renvoyons le lecteur à cet article pour y trouver les détails conduisant à son établissement.

Maintenant si dans l'équation intégro-différentielle [3] on remplace $\cos\theta(z)$ et $V(z)$ par leurs expressions données en [2] et [1] respectivement et si on dérive par rapport à la variable z l'équation ainsi fournie, on obtient que la fonction profil satisfait l'équation différentielle:

$$[4] \quad X\dot{X}\ddot{X} = \dot{X}\left[1 + \dot{X}^2 - X\left[\frac{2}{R} - \frac{g}{\sigma}(\rho_1 - \rho_2)z\right] \times (1 + \dot{X}^2)^{3/2}\right]$$

ainsi que les conditions $X(0) = 0$, $X(h) = r$ et $\dot{X}(h) = 0$. Observons de plus que dans [3] et [4] R est relié à $X(z)$ par la formule:

$$[5] \qquad R^{-1} = \lim_{z\to 0^+} \frac{|\ddot{X}(z)|}{[1 + (\dot{X}(z))^2]^{3/2}}$$

Le point important pour nous consiste à observer que chacune des éqs [3] ou [4] fournit un modèle mathématique qui permet la formation d'une goutte avec un col. Afin de vérifier ceci, il nous faut montrer qu'étant donné h_1, $0 < h_1 < h$, et une fonction $X(z)$ satisfaisant [3] ou [4] sur l'intervalle $[0,h_1]$ et dont la valeur est constante et égale à r sur l'intervalle $[h_1,h]$ (voir fig. 3) il suit que $X(z)$ satisfait aussi [3] ou [4] sur l'intervalle $[0,h]$.

En effet, pour chaque valeur de $z \in [h_1,h]$ on a alors $\cos\theta(z) = 1$, $X(z) = r$, $V(z) = V(h_1) + \pi r^2(z - h_1)$. Utilisant maintenant le fait que [3] est vérifiée pour $z = h_1$ on obtient

$$[6] \quad 2\pi r\sigma = g(\rho_1 - \rho_2)V(h_1) + \pi r^2\,[(2\sigma/R) - g(\rho_1 - \rho_2)h_1]$$

ce qui peut être écrit sous la forme:

$$[7] \quad 2\pi r\sigma = g(\rho_1 - \rho_2)[V(h_1) + \pi r^2(z - h_1)] + \pi r^2[(2\sigma/R) - g(\rho_1 - \rho_2)z]$$

Or l'éq. [7] montre précisément que [3] est satisfaite également pour $z \in [h_1,h]$. D'autre part, l'éq. [4] indique bien que toute fonction $X(z)$ constante sur un intervalle satisfait cette équation sur cet intervalle car alors $\dot{X} \equiv 0$ sur l'intervalle en question.

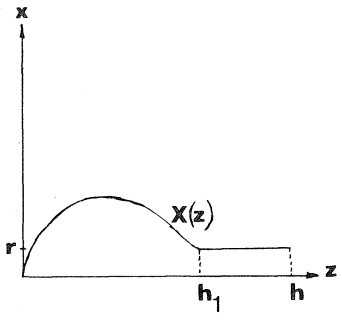

FIG. 3. Schéma de la goutte après 3 s.

Conclusions

En conclusion, nous pouvons faire remarquer qu'en milieux hallogénures ce phénomène de col n'est pas enregistré mais que, par contre, en milieu sulfure nous obtenons la formation d'une goutte similaire à celle présentée ici.

Devant la complexité de ce phénomène, l'identification par voie spectroscopique et la détermination de la tension interfaciale permettront d'identifier le film à la surface de l'électrode et de définir son importance.

Enfin le modèle mathématique présenté montre bien que la formation d'un col cylindrique est théoriquement possible et qu'il y a lieu de s'attendre à ce que le phénomène soit effectivement observé sous certaines conditions expérimentales. Malheureusement les équations fondamentales du modèle, les éqs [3] ou [4], sont trop complexes pour permettre la détermination d'une formule analytique pour la fonction profil $X(z)$ et ainsi arriver à prédire la forme d'une goutte. D'autre part nous n'avons pas réussi à déterminer la (les) relation(s) qui doit (doivent) exister entre les paramètres expérimentaux ρ_1, ρ_2 et σ pour que les éqs [3] ou [4] permettent de prédire la formation d'un col. Cette question importante reste ouverte pour le moment.

An experimental technique for the measurement of the rate of formation and removal of atomic oxygen in an active glow discharge is described. The concentration of atomic oxygen was monitored with a mass spectrometer by sampling the gases flowing through the discharge. The rate of removal of oxygen atoms was found to be first order in atomic oxygen and 10 to 100 times faster than the corresponding recombination rate in the afterglow region. The measured rates of atom production are in agreement with those calculated by assuming electron impact dissociation of ground state molecular oxygen. The atoms are removed by a wall recombination process.

The ability of trace amounts of certain gases to enhance significantly the extent of dissociation in an electric discharge in oxygen has been studied. Only those added gases which contain a hydrogen or nitrogen atom are effective in enhancing the yield of atomic oxygen. For each hydrogen atom introduced into the oxygen stream about 300 extra oxygen atoms could be produced. This 'catalytic' effect is shown to be due to a marked decrease in the rate of recombination of O-atoms at the walls of the discharge tube. Whatever small change that occurs in the rate of O-atom production can be easily accounted for by a change in the energy distribution of the electrons in the discharge due to the effect of the additives.

MOTILAL D. COSTA, PRESTON A. ZULIANI et JACQUES M. DECKERS. Can. J. Chem. **57**, 568 (1979).

On décrit une technique expérimentale permettant de mesurer le taux de formation et d'enlèvement d'oxygène atomique actif dans une décharge électrique sous pression réduite. On a évalué la concentration de l'oxygène atomique par spectrométrie de masse en prélevant des échantillons de gaz s'écoulant à travers la décharge électrique. On a trouvé que le taux d'enlèvement des atomes d'oxygène est du premier ordre en oxygène atomique et est environ 10 à 100 fois plus rapide que le taux de recombinaison correspondant dans la région de la phosphorescence qui suit la décharge électrique. Les taux de production pour les atomes mesurés sont en accord avec ceux calculés en faisant l'hypothèse qu'il y a dissociation, sous impact électronique, de l'oxygène moléculaire dans son état fondamental. Les atomes sont enlevés par un processus de combinaison au niveau des parois.

On a étudié la propriété qu'ont certains gaz à l'état de trace d'augmenter d'une façon importante le taux de dissociation de l'oxygène sous l'influence d'une décharge électrique. Parmi les gaz additionnés, seuls ceux qui contiennent des atomes d'hydrogène ou d'azote sont efficaces pour rehausser le rendement en oxygène atomique. Pour chaque atome d'hydrogène introduit dans un courant d'oxygène, il se produit environ 300 atomes d'oxygène en supplément. On a montré que cet effet catalytique est dû à une diminution sensible du taux de recombinaison des atomes d'oxygène près des parois du tube de la décharge. Tout changement mineur dans le taux de production des atomes d'oxygène peut être expliqué par un changement dans la distribution d'énergie des électrons dans la décharge électrique dû à l'effet d'additifs.

1. Introduction

There is much controversy concerning the mechanisms for atom production and removal in discharges in diatomic gases. It has been argued that the production of oxygen atoms occurs by a stepwise process involving some unspecified metastable species as an intermediate, a reaction sequence which has been postulated to occur in nitrogen discharges (Baker *et al.* (1), Young and St. John (2)). Others (Kaufman and Kelso (3, 4), Linnett and Marsden (5)) have felt that catalytic production schemes in-

0008-4042/79/050568-12$01.00/0

volving trace impurities are responsible for the atom production. More recently, Kaufman (6) has proposed that the main atom production term in discharges in O_2, N_2, and H_2 involves the simple electron impact dissociation of the ground state molecules. While this proposal has not met with universal acceptance, at least for N_2, it seemed to us to be an attractive possibility for oxygen discharges. Kaufman (6) has also suggested that the wall recombination of atoms might be very much faster in the active discharge than in the afterglow and could be the dominant removal term.

In this paper we describe an experimental design which permits the sampling of an active discharge. The sampled products and intermediates are analysed continuously by mass-spectrometry. The measured profiles of atomic oxygen concentration versus time are then used for kinetic analysis in order to determine the dominant reaction mechanism.

Although discharges are commonly used to generate atoms for other studies, very little is known about parameters controlling the atom concentration in the discharge effluent. It has long been realized that addition of small amounts of other gases causes large increases in the extent of dissociation in diatomic gases. We report our studies of the effect of addition of small amounts of gases on the oxygen atom concentration in the discharge. Those effects have been extensively studied in the case of hydrogen and nitrogen (7, 8). However, surprisingly little is known in the case of oxygen. We will show that the dominant effect of these added gases is to inhibit the atom recombination process rather than to affect the atom production process.

2. Experimental

The experimental apparatus is illustrated schematically in Fig. 1. The gas or gas mixture which was to be studied was passed through a liquid nitrogen cold trap to remove traces of water vapor. The gas flow system was all glass and metal and the use of mercury was strictly avoided. The flow rates of the gases were measured with Hastings flow transducers. The average stream velocity of the gas $\bar{V}_s$ through the discharge was calculated from the total flow rate, the pressure in the discharge, and the tube diameter. The discharge was sustained in a U-shaped Pyrex glass tube with an inside diameter of 12.7 mm. A moveable anode was located in one of the arms of the U-tube. A small (0.07 mm radius) 'leak' was located in a thin glass membrane at the tip of a glass cone near the bottom of the U-tube in line with the anode. The gas entered the discharge tube upstream of the anode. A pressure transducer was used to record the pressure at a tap-off located 3 cm downstream of the leak. A small platinum wire probe was located about 1 cm downstream of the pinhole and was used to measure the floating potential in the discharge near the sampling orifice. A further side-arm in the anode region contained an additional electrode. When desired, a discharge could be struck between this electrode and the anode; in this case the mass spectrometer

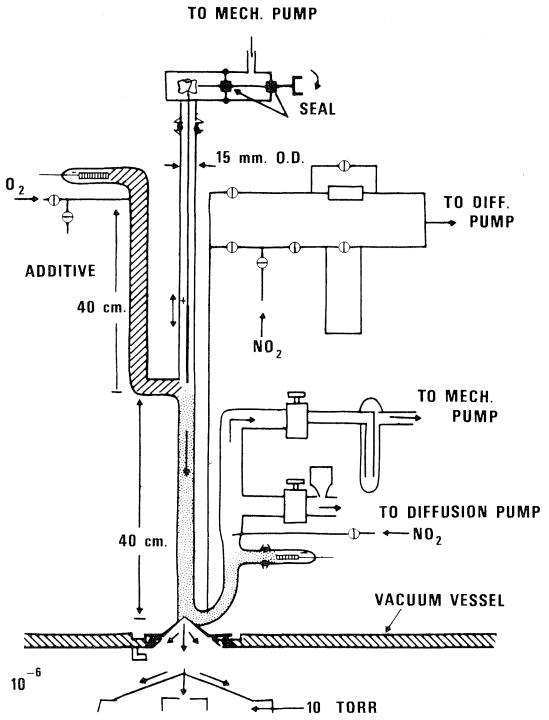

FIG. 1. Schematic of apparatus.

leak would be located in the afterglow region so that the afterglow atom concentrations could be measured directly. It was calculated that about 0.5% of the gas flowed through the sampling orifice.

The gas discharge was sustained by a regulated 5000 V power supply. The discharge was 'floated' in such a manner as to maintain the plasma in the vicinity of the pinhole very slightly negative with respect to the grounded mass spectrometer to prevent positive ions, formed in the discharge, from entering the mass spectrometer.

The electrodes were fashioned from copper. Care was taken that no detectable anode sputtering occurred in the positive column of the discharge during the reported runs. In particular, frequent cleaning of the discharge tube with nitric acid followed by copious rinsing with distilled water ensured that no complications occurred due to sputtering of electrode material on the walls. The cathode was a hollow cylinder located in a side-arm well downstream from the region in which measurements were taken.

The sample of discharged gas which had passed through the pinhole travelled about 6 cm in a 10^{-6} Torr environment before part of it flowed through a 2 mm diameter aperture at the apex of a second chamber which housed the mass spectrometer. The pressure in this chamber was maintained at less than 10^{-7} Torr by using differential pumping and liquid nitrogen cooling. An Extranuclear Laboratories high efficiency ionizer, quadrupole mass spectrometer, and 14 stage particle multiplier were used to analyze the gases.

The molecular beam emanating from the discharge was mechanically chopped at 400 Hz and the resulting ac signal was recovered by phase sensitive detection. By setting the

electron energy in the ionizer just below the threshold for the dissociative ionization of O_2, the relative concentration of O-atoms formed in the discharge could be measured as a function of experimental parameters. These concentrations were then converted to absolute O-atom concentrations by calibrating the mass spectrometer using the NO_2 titration technique. Titration experiments were always performed in the afterglow region of the discharge using the side-arm electrode, as it was found that, in the active discharge, the NO/NO_2 were also subjected to partial decomposition (see sections 3.6 and 4.4) which might affect the results of the titration.

3. Results and Interpretation

3.1 General

The fundamental measurement in this work involved the determination of the concentration of atomic oxygen as a function of distance between the pinhole and the anode location in either ultrapure oxygen or in oxygen to which measured trace amounts of another gas had been added. Simultaneously the potential at the floating probe was recorded. The mass spectrometric signal versus distance profile was then converted into atomic concentration versus time by taking into account the calibration factor of the mass spectrometer, the gas flow, the pressure, and the diameter of the discharge tube. A sample graph is shown in Fig. 2. The slope of the floating potential versus distance curve gave a measure of the electric field in the positive column of the discharge (9). After a discharge was struck, it was noticed that measured quantities such as the mass spectrometric signal, the potential at the electrodes, or the current through the discharge would drift, reaching a steady value after a couple of hours. All measurements reported are taken under the 'steady' conditions. Each time one or more of the discharge operating parameters were altered, it was necessary to wait from 5 min to as much as 1 h before a new steady measurement could be recorded.

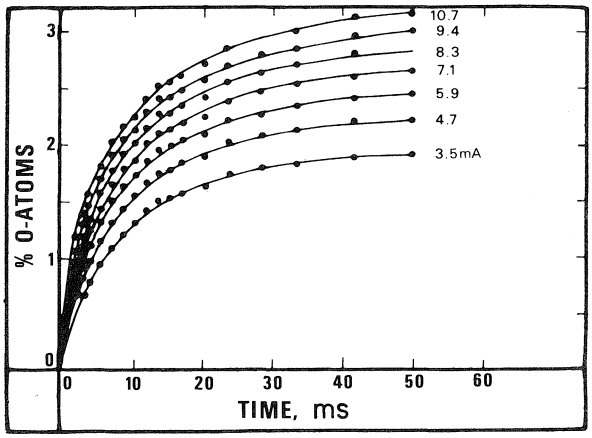

FIG. 2. Plot of % oxygen atoms produced versus time spent in the discharge for various currents (P = 0.798 Torr, $\bar{V}_s$ = 7.25 m s^{-1}).

3.2 Ultrapure Oxygen

The oxygen atom concentration was found to rise monotonically with the residence time of the gas in the discharge to achieve a final steady-state value $[O]_{ss}$. Plots of ln $([O]_{ss} - [O])/[O]_{ss}$ versus time were linear demonstrating that the rise was exponential and that the oxygen atom concentration at any time could be described by an equation of the type

$$[1] \qquad [O] = [O]_{ss}\{1 - \exp(-k_w t)\}$$

Here k_w is an arbitrary constant which is obtained from the slope of the logarithmic plot. A sample graph is shown in Fig. 3.

Let us now test the hypothesis that the O-atoms are being produced by simple electron impact dissociation with rate constant k_T and removed by a first order wall recombination process with rate constant k_w. Then

$$[2] \qquad O_2(X^3\Sigma_g^-) + e^* \xrightarrow{k_T} 2O(^3P) + e$$

$$[3] \qquad O(^3P) \xrightarrow{k_w} \tfrac{1}{2}O_2(X)$$

$$[4] \qquad d[O]/dt = 2k_T n_e[O_2] - k_w[O]$$

where n_e is the electron concentration. Integrating, one gets

$$[5] \qquad [O] = (2k_T n_e[O_2]/k_w)(1 - \exp -k_w t)$$

We can immediately see that this mechanism is consistent with the observed [O] versus t profiles where k_w is the first order removal rate constant and

$$[6] \qquad [O]_{ss} = 2k_T n_e[O]_2/k_w$$

We now attempt to test this mechanism further by calculating $[O]_{ss}$ from eq. [6] and comparing the calculated variation of $[O]_{ss}$ with discharge current and pressure with the experimentally determined profiles.

3.3 Variation of $[O]_{ss}$ versus Current and Pressure

Two of the parameters in eq. [6] necessary to calculate $[O]_{ss}$ are readily available. $[O_2]$ was determined by measuring the discharge pressure while k_w could be determined from the slope of the plots as shown in Fig. 3. In actual practice, k_w was determined by a least-squares fit to the [O] versus t data with corrections being made for back diffusion.[2]

Values for the electron concentration, n_e, were obtained using the equation

$$[7] \qquad I = n_e e v_e A$$

where I is the discharge current, A the tube cross section, e the electronic charge, and v_e the electron drift velocity. To obtain n_e as a function of discharge

[2]For details see Zuliani's Ph.D. thesis (11).

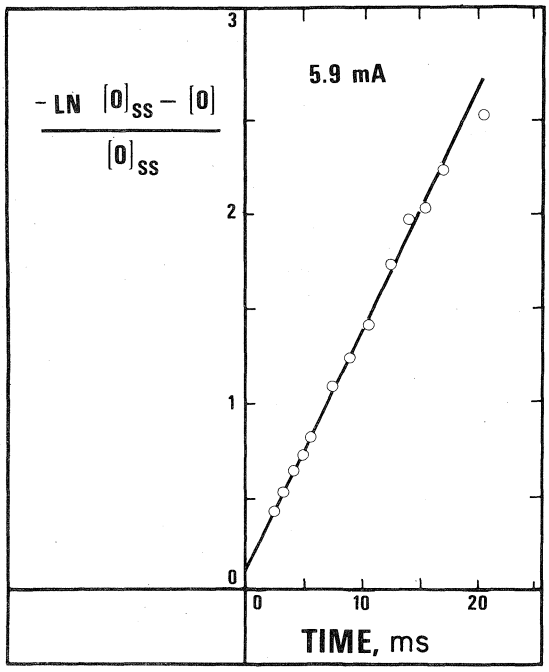

FIG. 3. Logarithmic plot of $([O_{ss}] - [O])/[O]_{ss}$ versus time spent in the discharge ($P = 0.798$ Torr, $\bar{V}_s = 7.25$ m s^{-1}).

current and pressure, it was necessary to measure the electric field as a function of these parameters. This was done using either the Langmuir probe and/or the moving anode technique (9). The electron concentration n_e could be calculated from $X_e = n_e v_e$ where the drift velocities were taken from Hake and Phelps (10) and X_e is the electric field.

Finally, k_T was calculated from the expression

$$[8] \qquad k_T = \int_0^\infty f(\varepsilon) Q(\varepsilon) \left(\frac{2}{m_e}\right)^{1/2} d\varepsilon$$

where $f(\varepsilon)$ is the electron energy distribution function, $Q(\varepsilon)$ the electron impact cross section for reaction [2], while ε and m_e are the energy and mass of the electron, respectively.

Actually, reaction [2] is a composite of three reactions:

$$[9] \qquad \begin{aligned} O_2(X^3\Sigma_g^-) + e^*(>4.5\text{ eV}) &\rightarrow O(^3P) + O(^3P) \\ O_2(X^3\Sigma_g^-) + e^*(>8.0\text{ eV}) &\rightarrow O(^3P) + O(^1D) \\ O_2(X^3\Sigma_g^-) + e^*(>9.7\text{ eV}) &\rightarrow O(^1D) + O(^1D) \end{aligned}$$

The cross sections for these three reactions are available as a function of the electron energy (10).

In this laboratory Rundle *et al.* (9) measured the electron energy distribution function over a limited range of discharge pressure. For extrapolating beyond this range, we assumed a Druyvesteyn energy distribution (16) since, where comparison was possible, this was a closer approximation to the measured distribution than was an equilibrium distribution.

The differences between values of k_T calculated by using a Druyvesteyn energy distribution versus those calculated using the functional form determined by Rundle *et al.* (9) were smaller than the experimental uncertainties.

In Fig. 4, we illustrate the effect of current on k_w and $[O]_{ss}$, while in Fig. 5 the effect of pressure on $[O]_{ss}$ is shown. The values of an expanded set of measurements of k_w obtained similarly (using a different oxygen supply) are tabulated as a function of pressure and current in Table 1. The magnitudes of the back diffusion correction, expressed as a percentage of k_w, are given in parentheses underneath the values of k_w. The effect of pressure on k_w is illustrated in Fig. 6.

In Fig. 7, the measured and calculated values for the % oxygen dissociation are presented for ultrapure oxygen. The agreement between calculated and experimental values is within a factor of 2 for the whole range of pressures investigated and provides further confirmation of the interpretation of the data.

3.4 Addition of Foreign Gases: General

Wherever hydrogen or nitrogen containing gas was added to the oxygen flow, the oxygen atom concentration in the discharge rose significantly and reached a new steady-state value after a certain time (usually a matter of a few minutes). When the flow of foreign gas was stopped, the atom yield started to decrease immediately, returning to its original 'steady' value after about an hour.

Results could be presented in two ways depending on the type of information desired. Recombination

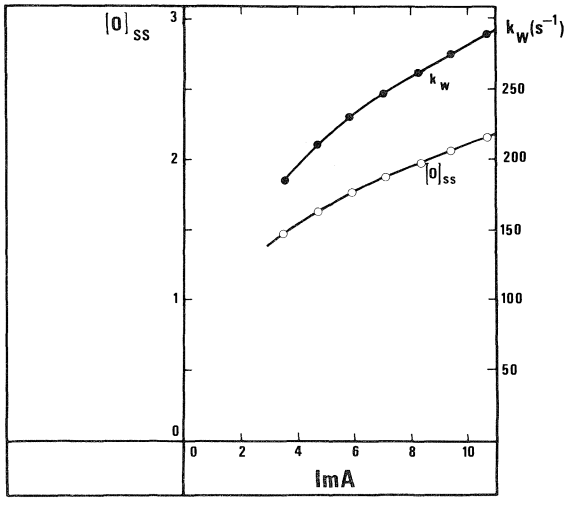

FIG. 4. Plot of % atomic oxygen in the steady state (○) and k_w (●) versus current ($P = 0.798$ Torr, $\bar{V}_s = 7.25$ m s^{-1}).

*T = 340 K was used as the gas temperature in order to calculate $\bar{V}_s$ and k_w for all results, $\bar{V}_s$ is the average gas stream velocity in the discharge tube. The numbers in parentheses are the magnitudes of the back diffusion correction, expressed as a % of k_w.

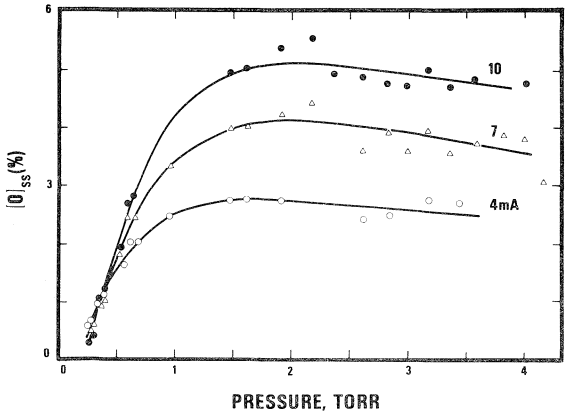

FIG. 5. Plot of % atomic oxygen in the steady state versus discharge pressure at various currents ($\bar{V}_s$ = ~3 m s^{-1}).

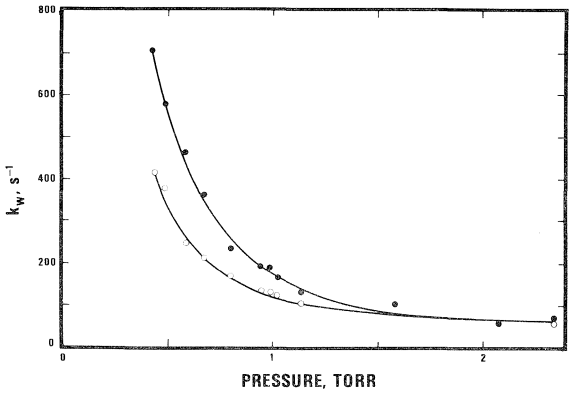

FIG. 6. Plot of k_w versus pressure at two values of the discharge current: ○, 3 mA, ●, 8 mA.

rate constants could be obtained for a given gas/additive ratio from the plotting procedure outlined in section 3.2. Alternately, the percent dissociation of O_2 could be plotted versus the percent of added gas, hence describing the effect of the additive on the overall oxygen atom concentration. In Fig. 8, we plot the percent dissociation versus the concentration of various additives in parts per million. In Fig. 9 the range of added gas is increased. It is immediately obvious from an examination of these curves that, even for very small amounts of gas added, several hundred additional oxygen atoms are produced per molecule of added gas. In fact, the slopes of the curves in Figs. 8 and 9 are equal to the number of oxygen atoms produced per added molecule; this slope is defined as the 'catalytic efficiency' of the additive gas. As can be seen from Figs. 8 and 9, the oxygen atom concentration rises sharply for small concentrations of the 'catalyst' (0–30 ppm) and less rapidly at larger concentrations. The catalytic efficiency is thus very large initially and decreases monotonically with increasing additive gas concentration. In Table 2 the

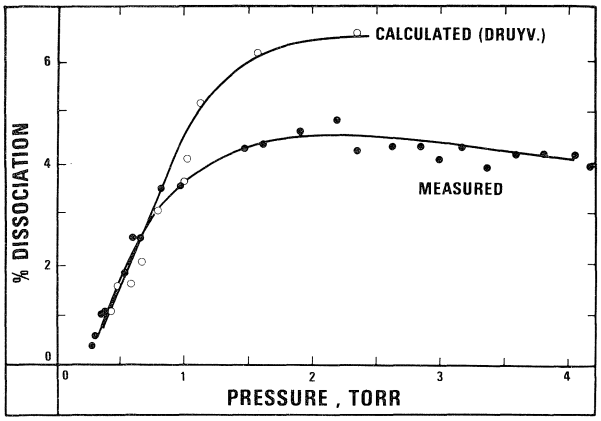

FIG. 7. Calculated and measured plots of extent of dissociation versus pressure at 8 mA in ultrapure oxygen (~10 ppm impurities). $\bar{V}_s = 6.8$ m s^{-1}.

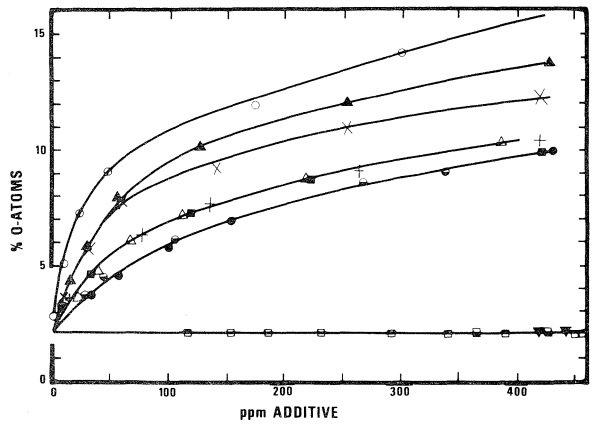

FIG. 8. Plot of % atomic oxygen produced versus concentration of additives in ppm. $P = 1.21$ Torr, $\bar{V}_s = 1.96$ m s^{-1} (at 8 mA), $T = 340$ K (at 8 mA). Symbols: NO, ◒; C_2H_4, +; H_2, ●; C_2H_2, △; CH_4, ■; C_4H_6 (1,2-butadiene), ▲; C_2H_6, ×; $(CH_3)_4C$, ○; CO, ▼; CO_2, ⬓; Ne, Kr, Xe, Ar, □.

initial slope has been tabulated in for a number of additive gases at various currents. In Table 3 the slope is plotted at the 0.1% additive level. A comparison of the values in these two tables illustrates the decrease in efficiency.

3.5 Hydrocarbon Additives

Plots of the percent of oxygen atoms produced versus the percent hydrocarbon added are characterized by very steep initial rises which gradually level off. For very large additions (~0.5%), the catalytic efficiencies assume negative values: the concentration of oxygen atoms in the discharge decreases upon further hydrocarbon additions. This decrease in the oxygen atom concentration is wholly accounted for by the consumption of the atoms by reaction with the hydrocarbons and their reaction

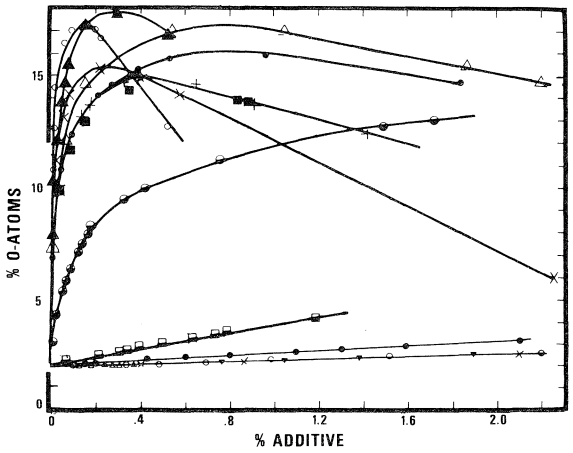

FIG. 9. Plot of % atomic oxygen produced versus concentration of additives in %. $P = 1.21$ Torr, $\bar{V}_s = 1.96$ m s^{-1} (at mA), $T = 340$ K (8 mA). Symbols: (upper range) NO, ◒; C_2H_4, +; H_2, ●; C_4H_6, ▲; CH_4, ■; $(CH_3)_4C$, ○; C_2H_6, ×; (lower range) He, △; CO, ●; Ne, ▼; CO_2, ⬓; Kr, ○; Ar, ×.

products. A plot of the catalytic efficiency of some gases is shown as function of current in Fig. 10.

3.6 Nitrogen Containing Additives

Plots of O atom concentration versus the concentration of nitrogen containing additives are shown in Figs. 11, 12.

3.7 Inert Gases, CO, CO_2

Plots of $[O]_{ss}$ versus percent of added inert gases are shown in Figs. 8, 9. Although these gases were quite ineffective in enhancing the atom yield, a finite slope was measured. For He, Ar, Kr, and Ne, this slope was <0.3 oxygen atom per inert gas atom. For CO the slope was ≤ 0.6, while for CO_2 it was ≤ 2 oxygen atom per impurity added. These low efficiencies are quite likely due to the small amounts of water present as an impurity in the gases.

4. Discussion

4.1 General

We wish to emphasize here that the sampling pinhole was located in the active discharge and not in the afterglow region. The only purpose of the additional electrode located in the side-arm was for establishing on an absolute scale the O atom concentration through the NO titration technique. Luminosity due to the discharge itself and the partial decomposition due to reactions interfered with the measurement when it was attempted in the active discharge.

Results in a given discharge tube were very reproducible, especially when trace amounts of catalytic gases were added. However, because of the extreme sensitivity of $[O]_{ss}$ to trace impurities in highly purified oxygen, it would be expected that

TABLE 2. The catalytic efficiency of added gases as a function of the discharge current

*P = 1.21 Torr, 8 mA, T = 340 K, V_s = 1.96 m s^{-1}, and residence time in the discharge = 163 ms.

different $[O]_{ss}$ values might be obtained in different laboratories, or indeed, with different oxygen cylinders, due to slightly different impurity levels. Hence, great care should be taken in lifting O-atom concentration to be used for other purposes.

In fact, at one time, after having run a discharge through oxygen – carbon monoxide mixtures for some time, it was no longer possible to obtain the very high values of k_w observed before this set of experiments was performed. Close examination of the discharge tube wall revealed that it was coated with a very thin brownish-black film. This film could not be removed by running the discharge for many hours through pure oxygen. Only after cleaning with concentrated HNO_3 mixed with HCl was the film removed and the original k_w values reproduced. Black particles (probably some form of polymeric carbon) were suspended in the solution. No further analysis of the phenomenon was attempted.

4.2 Pure Oxygen

The proposed mechanism predicts an [O] versus t profile which rises exponentially to a steady-state value in agreement with experiment. Moreover, calculations of the absolute value of $[O]_{ss}$ from eq. [6] agree to within a factor of 3 with the experimental values. This is within the uncertainty limits of the cross sections, the electron concentrations, and the energy distribution function used in the calculation.

Figure 13 shows that $[O]_{ss}$ increases strongly with current at high pressures, but decreases with current

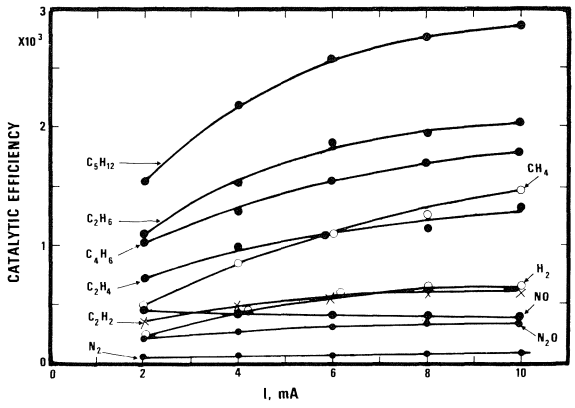

FIG. 10. Plot of the number of oxygen atoms produced for each foreign gas molecule added ('catalytic efficiency') versus the current for different gases (initial slope method). $P = 1.21$ Torr, $\bar{V}_s = 1.96$ m s^{-1}.

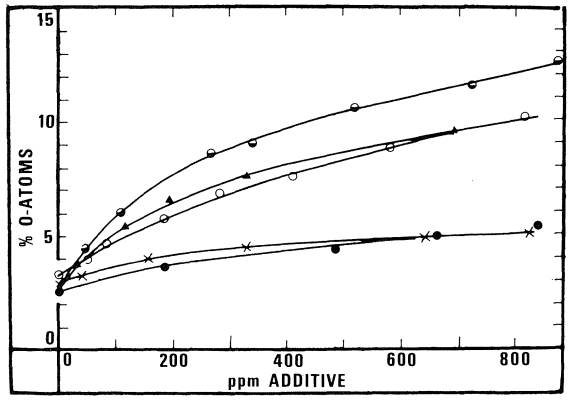

FIG. 11. Plot of % oxygen atoms produced versus the concentration of added catalyst for several gases which contain N atoms. $P = 1.21$ Torr, $\bar{V}_s = 1.96$ m s^{-1}. Symbols: NO_2, ○; NO, ◒; N_2, ×, ●; N_2O, ▲.

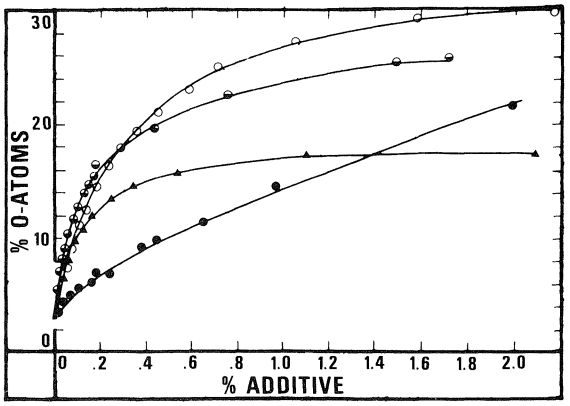

FIG. 12. Plot of % oxygen atoms produced versus the concentration (larger amounts) of added catalyst for several gases which contain N atoms. $P = 1.21$ Torr, $\bar{V}_s = 1.96$ m s^{-1}. Symbols as in Fig. 11.

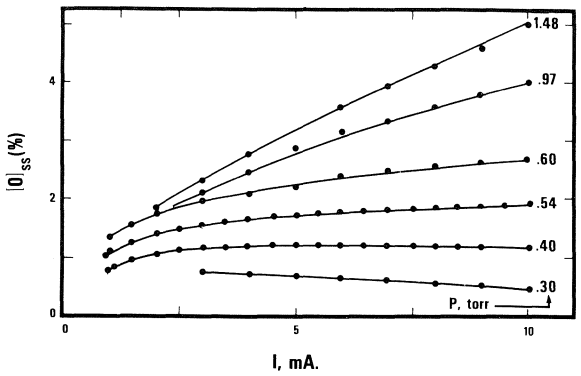

FIG. 13. Plot of $[O]_{ss}$ versus current at various pressures. $\bar{V}_s \sim 3$ m s^{-1}.

at low pressures. To determine whether the postulated mechanism is consistent with the observed trend, we may rearrange eq. [6] and use eq. [7]:

$$[10] \quad k_w[O]_{ss} = 2k_T[O_2]I/eV_eA = (\text{Constant}) \times I$$

Thus, this mechanism will explain the measured current dependence of $[O]_{ss}$ only if all plots of $k_w[O]_{ss}$ versus I are linear with zero intercept. Such behaviour was always observed, as can be seen in Fig. 14 where the product $k_w[O]_{ss} = \theta$ is shown at three pressures. The extrapolation to zero current intersects the origin within experimental uncertainty.

The calculations also predicted that the percent dissociation of O_2 should increase with increasing pressure, passing through a broad maximum from 2–4 Torr. As is shown in Fig. 7, this is in agreement with experiment. (The predicted curve was calculated using Hake and Phelps dissociation cross sections

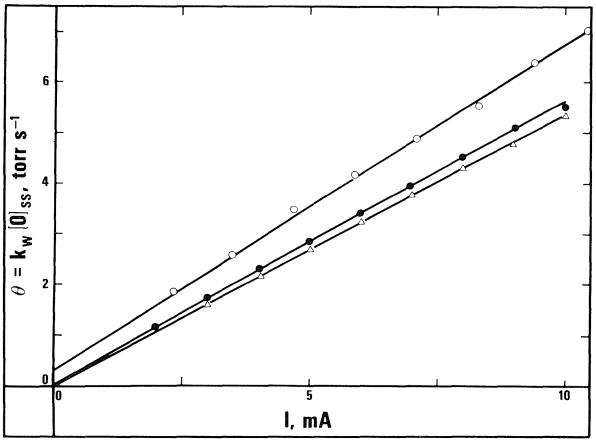

FIG. 14. Plot of $\theta = k_w[O]_{ss}$ versus current: $P = 0.59$ Torr, $\bar{V}_s = 7.8$ m s^{-1}; $P = 0.95$ Torr, $\bar{V}_s = 6.2$ m s^{-1}; $P = 1.2$ Torr, $\bar{V}_s = 5.2$ m s^{-1}.

(10) and drift velocities and assuming a Druyvesteyn energy distribution (16).)

Attempts have been made, without success, to correlate the value of k_w with known or suggested gas phase reactions to explain the observed first order removal of atomic oxygen. The fact that when the setting of an experimental parameter such as pressure, flow rate, or current was altered a significant lag time occurred for steady measurements is clear indication that wall effects play a dominant role in controlling the discharge.

The various observations related so far, especially those involving the observed inability to obtain very high k_w values when the walls of the discharge tube were coated with the brown-black deposit, establish quite unambiguously that the first order removal of O atoms is a wall process.

4.3 Hydrocarbon Additives

As the number of hydrogen atoms present in the additive gas molecule increases, the catalytic efficiency increases. Figure 15 shows a plot of the catalytic efficiency versus the number of hydrogen atoms in the additive molecule. The straight line obtained through the points has a slope of 300 oxygen atoms produced per hydrogen atom in the additive gas molecule. Since hydrocarbons added to the discharge decompose to form H_2 and CO as the dominant reaction products (13) this result is reasonable. As Figs. 8 and 9 show, H_2 is highly effective at increasing the atom yield in the discharge while CO and CO_2 are rather ineffective.

Winkler (7) has suggested that the catalytic efficiency of additives in enhancing the nitrogen atom yield in a N_2 discharge can be correlated with the molecular complexity of the additives. Such a plot is shown in Fig. 16. The correlation obtained with the number of hydrogen atoms is certainly better than the correlation obtained with the number of internal degrees of freedom. It is probable that for the much shorter residence times used by Winkler, the added hydrocarbons were only partially decomposed.

In Fig. 10, the catalytic efficiency, as calculated from the initial slope, is shown to increase with current in a non-linear fashion. For species containing the same number of hydrogen atoms (H_2, C_2H_2; CH_4, C_2H_4; C_2H_6, C_4H_6), the decrease at lower currents is greatest for those species which decompose most slowly in the discharge (H_2, CH_4, C_2H_6). The increased catalytic efficiencies at high currents may thus simply be the results of a greater conversion of the added hydrocarbon to hydrogen or its oxydation products.

4.4 Nitrogen Containing Impurities

Plots of the oxygen atom concentration versus the concentration of nitrogen containing additives are similar to those obtained when using hydrogen additives except that no maxima are observed for additions of up to 10%. Instead, the oxygen atom concentration increases monotonically with impurity concentration. Since oxygen atoms are not consumed by a reaction with nitrogen containing species, no maxima are expected.

From Figs. 11 and 12, it is apparent that the catalytic efficiency decreases less rapidly with increasing additive concentration in the case of nitrogen containing species than for hydrogen containing ones. It is also obvious that no correlation exists between the number of nitrogen atoms in the additive molecules and the catalytic efficiency. This is consis-

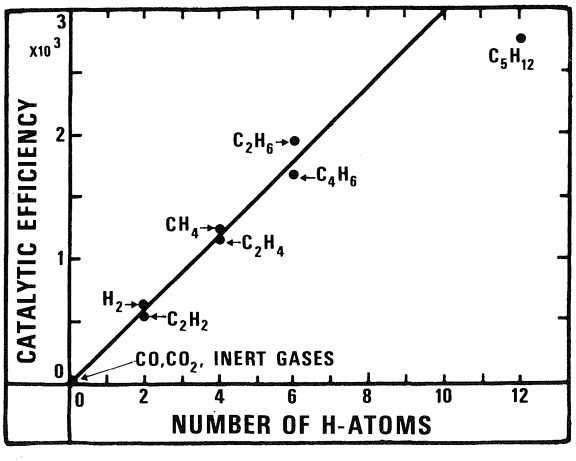

FIG. 15. Plot of the number of oxygen atoms produced for each foreign gas molecule added ('catalytic efficiency') versus the number of H-atoms in the additive. P = 1.21 Torr, $\bar{V}_s$ = 1.96 m s^{-1}; I = 8 mA.

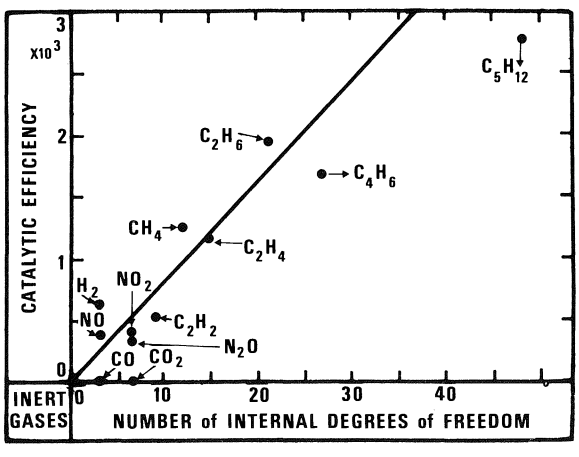

FIG. 16. Plot of the number of oxygen atoms produced for each foreign gas molecule added ('catalytic efficiency') versus the number of internal degrees of freedom in the additive. (Conditions as in Fig. 13.)

tent with the fact that interconversion between the nitrogen additives occurs: (*1*) NO addition: 50–60% remains intact; the remainder is converted to N_2. (*2*) N_2 addition: 95% remains intact; the remainder is converted to NO. (*3*) N_2O addition: 20% remains intact; 25% is converted to NO; 55% is converted to N_2. (*4*) NO_2 addition: 0% remains intact; 50% is converted to N_2; 50% is converted to NO.

Thus, if X% of NO, N_2, and N_2O were added to the discharges, then taking the stoichiometry into account, one would expect $X/2$%, $X/10$%, and $X/2$%, respectively, of NO to be present in the discharge. Thus the ratio of the percent NO present for each of these gases is approximately the same as the ratio of the catalytic efficiencies ($\sim$10:2:9 for NO, N_2, and N_2O, respectively). This suggests that either NO or some species proportional to the NO concentration (perhaps NO^+) is the active species.

5. Discussion

5.1

The remarkable enhancement in [O] when trace amounts of certain gases are added to an oxygen discharge must be ascribed either to the enhanced production or to the decreased removal of atoms (or a combination of these).

By measuring the time development of the oxygen atom concentration in the discharge, one can separate the effects due to the production and removal processes. When presenting the data, we have postulated that oxygen atoms in the discharge are produced by direct electron impact dissociation of ground state molecules while the atoms are removed by a first order process [2], [3].

Figure 17 illustrates the dependence of both $[O]_{ss}$ and k_w on concentration of added NO. Similar results were obtained with other catalytic gases. The marked enhancement in the atom concentration is seen to be accompanied by an equivalent decrease in the removal rate constant k_w. This established quite unequivocally that the production term $k_w[O]_{ss}$, from eq. [10], is independent of [NO] within the experimental error.

These results provide striking evidence that the catalytic effects are almost entirely the result of a decreased removal rate of atoms and not as a result of changes in electron energy distribution nor of catalytic production sequences. Indeed, measurements of the ratio of the electric field over gas density, E/N, which is a measure of the electron properties, were found to decrease by less than 2% for addition of hydrocarbons of up to 10% to the oxygen discharge. On this basis alone, one would have expected a decrease in the atomic oxygen production.

We have also attempted to account for the removal

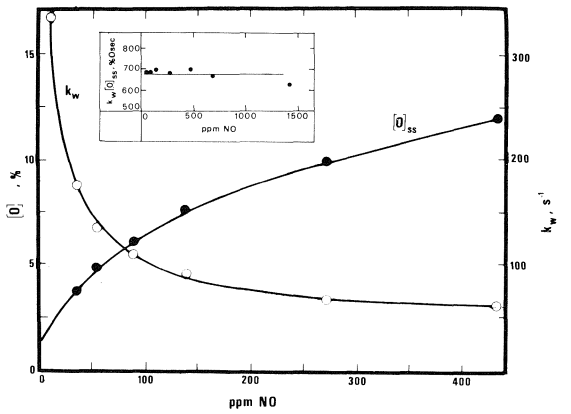

FIG. 17. Plots of $[O]_{ss}$ and k_w versus the concentration of added NO. P = 1.20 Torr, V_s = 5.64 m s^{-1}, I = 8 mA.

process via ion molecule processes. Although some of those processes have very large rate constants, the concentration of the various species, especially ions, are very small at the rather low current densities at which these experiments were carried out. Because of the low concentrations, none of the processes for which calculations were attempted had rates which were even within 1% of the measured rates, and almost all were many orders of magnitude lower.

Even when large amounts of nitrogen additives were present and that it was suspected that NO or NO^+ might play a significant role in the removal process, the results of calculated rates were too low to account for the k_w observed.

It is a well-known fact that because of the ambipolar diffusion which sustains the positive column of a glow discharge (17) the walls are coated with a layer of electrons while the core of the column contains a slightly positive charge. It is believed that when ultrapure oxygen is fed into the discharge, the walls are 'cleaned' from most impurities by this electron bombardment and many active sites are then formed on which oxygen atoms can condense. Because of the large number of electrons, these atoms should be fairly mobile and, hence, recombine efficiently. The catalytic efficiency of impurities is then explained by either accepting that the impurities (especially H, probably as OH) will preferentially be adsorbed at the active sites and thus poison them for oxygen recombination, or alternately, that the presence of those foreign molecules on the surface would inhibit significantly the diffusion of adsorbed O atoms, thus reducing the rate of recombination.

The rather long times elapsing before a new steady measurement could be taken after a change in either composition or some of the discharge parameter are consistent with this interpretation.

TABLE 4. Comparison of (O-atoms produced)/(catalyst molecules added) with results of other workers

Catalyst	Catalyst efficiency			
	Brown (ref. 8)	Kaufman (ref. 7)	Present study	
			0.01% addition	Initial slope
He, Ar	—	<0.2	<0.3	<0.3
CO_2	—	<0.2	<2	<2
NO	—	40–45	~300	~400
N_2	80–100	80–90	30–70	30–80
N_2O	—	80–90	150–300	200–350
H_2	150–200	160–200	130–400	200–650

5.2 Comparison With Other Results

In Table 4 the catalytic efficiencies in oxygen are compared with those found in the literature.

The studies of Kaufman and Kelso (3) and Brown (14) were conducted using nearly identical conditions in their microwave discharges and yielded similar results. Brown (14) also reports that the catalytic efficiency of H_2O is about 90 to 130 oxygen atoms produced per H_2O molecule added.

It is apparent that the catalytic efficiencies measured here are somewhat larger than those reported by Kaufman and Kelso. The difference is especially apparent in the case of NO.

The major difference between the experiments by Kaufman and Kelso and those reported here is that a microwave discharge was used in the former study while an electrode discharge was used in this study. Kaufman and Kelso used the NO_2 titration technique downstream of the discharge to measure O-atom concentrations and assumed that this was equivalent to the concentration in the discharge (i.e., they assumed that there was no large removal term at the end of the discharge as Kaufman (15) has more recently postulated).

Since the measurements in the present study were done at a slightly greater pressure (1.2 Torr compared to 0.8 Torr), higher catalytic efficiencies would be expected since both studies indicate that the efficiency increases with pressure. Also, Kaufman's catalytic efficiencies were reported for additions of 0.01% to 0.05% impurity. Since in the present study it was found that the catalytic efficiency decreases with impurity concentration the values from the present study for 0.01% impurity are best used for comparison.

6. Conclusions

We have been able to quantitatively measure the concentration of atomic oxygen in an active glow discharge. Concentration–time profiles have established that the atom production is a dissociative excitation of the oxygen molecule under electron impact. The recombination of atomic oxygen obeys first order kinetics and appears to occur at the walls of the discharge tube. This removal is more than two orders of magnitude faster than that occurring in the after-glow region. This observation was originally presented as a suggestion by Kaufman (15) and is thus confirmed experimentally. The variation of the recombination constant with pressure and current is in good agreement with calculations, taking into account the uncertainties with which these quantities are known.

We have further established that the rate of production of atomic oxygen is not significantly altered when a foreign gas is added to the oxygen stream, but that the rate of atom removal is decreased by up to two orders of magnitude (possibly more) leading to a very large increase in the atomic oxygen concentration. Most effective are hydrogen containing compounds while nitrogen containing species are less effective. Other compounds do not appear to have a significant influence. All evidence indicates that the removal step is a wall process. The increase in oxygen atom concentration is then the result of the deactivation of the recombination at the wall.

Self-adduct formation in the extraction of cobalt(II) chelates of certain 8-quinolinols

ARVIND T. RANE AND KASHINATH S. BHATKI[1]

Received January 31, 1978[2]

ARVIND T. RANE and KASHINATH S. BHATKI. Can. J. Chem. **57**, 580 (1979).

Equilibrium distribution ratios have been determined for the extraction of cobalt(II) with 8-quinolinol and its 2-methyl-, 4-methyl-, 5-chloro-, and 5-nitro- analogues into chloroform as a function of pH and reagent concentration at ambient temperature. Except in the case of 2-methyl-8-quinolinol, which formed a simple 1:2 chelate, the extractable complexes were mono-adducts, that is, 1:2 chelates to which a third molecule of the reagent was coordinated. The overall formation constants of the cobalt chelates in aqueous solution were determined. A linear correlationship was observed between the formation constants, adduct formation constants, and the basicity of the reagent. This dependence could be used to predict, based on known data, the stabilities of not yet studied complexes of cobalt with this family of ligands. The distribution coefficients of the chelates and the chelate adducts are discussed in terms of structural influences. A penta-coordinate, square pyramidal structure has been proposed for the self-adducts of cobalt(II) with 8-quinolinols (except 2-methyl analogue).

ARVIND T. RANE et KASHINATH S. BHATKI. Can. J. Chem. **57**, 580 (1979).

On a déterminé les rapports des équilibres de distribution pour l'extraction du cobalt(II) par le quinoléinol-2 et ses dérivés méthyl-2, méthyl-4, chloro-5 et nitro-5 dans le chloroforme, en fonction du pH et de la concentration du réactif, à température ambiante. A l'exception du cas du méthyl-2 quinoléinol-8 qui forme un chélate 1:2 simple, les complexes qui peuvent être extraits sont des mono-adduits, soit des chélates 1:2 auxquels une troisième molécule vient se coordonner. On a déterminé les constantes globales de formation des chélates de cobalt en solution aqueuse. On a remarqué une relation linéaire entre les constantes, les constantes de formation des adduits et la basicité du réactif; on pourrait utiliser cette relation pour prédire, à l'aide de données connues, les stabilités de complexes qui ne sont pas connus du cobalt avec ces familles de ligands. On discute des coefficients de distribution des chélates et des adduits de chélates en termes de facteurs structuraux. On propose la présence d'une structure penta-coordonnée à pyramide carrée pour les auto-adduits du cobalt(II) avec les quinoléinols-8 (à l'exception de l'analogue méthylé en 2).

[Traduit par le journal]

Introduction

In his review, Stary (1) reported the extraction and colorimetric determination of metals with 8-quinolinol (oxine). We reported recently (2) the extraction of the self-adduct of nickel(II) with oxine and its analogues from the aqueous phase with chloroform. Our successful attempts to determine the adduct formation constants spectrophotometrically in a single phase, chloroform, are also described (3). Both these studies (2, 3) confirmed the penta-coordinate square pyramidal structure for the self-adduct of nickel with oxines, except its 2-methyl analogue.

During his comprehensive study of several metal ions, Stary (4) recorded the extraction of Co(II) as a cobalt-oxinate adduct, $CoQ_2 \cdot 2H_2O$; whereas, Oki and others (5, 6) observed that the extraction of cobalt from perchlorate solutions occurred as $CoQ_2 \cdot HQ$. In order to resolve these controversies we attempted the extraction of cobalt with oxine and extended the study to know more about the influences of steric hindering groups present in the ligand on the formation of the adduct. This is described in the sequel.

Experimental

Apparatus

The shaking assembly, radioactive counting, and pH measurements have been described earlier (2).

Material

AR grade 8-quinolinol (E. Merck), 2-methyl-8-quinolinol (8-quinaldine, Fluka), 5-chloro-8-quinolinol (Aldrich), and 5-nitro-8-quinolinol (K and K) were recrystallised from absolute alcohol. This gave products having melting points 73, 74, 126, and 179°C, respectively, very close to the literature reported value. The 4-methyl-8-quinolinol was synthesized from *o*-aminophenol and methyl-vinyl ketone and purified as described previously (2).

Carrier-free cobalt-58 ($t_{1/2}$ = 72 days) activity was supplied by Isotope Division, B.A.R.C., Trombay as a solution of cobalt chloride. The activity was sufficiently diluted with distilled water to give 6×10^5 cts min^{-1} mL^{-1} and 0.2 mL aliquots were taken every time from this stock solution for the distribution study. A set of Clark and Lubs buffer solutions were prepared with pH varying successively by 0.2 units.

[2]Revision received October 12, 1978.

0008-4042/79/050580-06$01.00/0

Requisite amounts of sodium perchlorate were added to the buffers to maintain a constant ionic strength at 0.25 *M*.

Procedure

Five millilitres of buffered cobalt-58 solution at a constant ionic strength ($\mu = 0.25$) at various pH (3.0–8.0), and 5 mL of the reagent solution of varying concentration (10^{-4} to 1.0 *M*) in chloroform, were equilibrated by shaking for 30 min. After the shaking was over, the mixtures were centrifuged and equal volumes of both phases were pipetted out in suitable counting tubes and counted for radioactivity separately at a constant and a reproducible geometry.

Results and Discussion

The extraction of a simple chelate is generally described by a plot of log *D* vs. pH, at a constant reagent concentration in the organic phase. These plots essentially consist of two linear portions; the log *D* increasing initially in the lower pH region with a slope *n*, the number of protons released on chelate formation and then eventually reaching a constant, pH-independent value, determined by K_{DC}, the distribution coefficient of the chelate. At a higher value of the reagent concentration, the entire curve shifts to the left, i.e. to a lower pH region, without alteration of either the slope or the value of the maximum log *D*, which remains equal to log K_{DC}. This situation changes when the extractable complex is not a simple chelate but an adduct. The adduct reagent concentration then influences the entire extraction curve. An increase in reagent concentration then causes the plateau region of the curve to shift to a higher log *D*, the initial linear portion of the curve shifting to a lower pH, without changing its slope. In Fig. 1 are shown the extraction curves (log *D* vs. pH) of cobalt(II) for the reagent 8-quinolinol (HQ) and its four substituted derivatives: 2-methyl-, 4-methyl-, 5-chloro-, and 5-nitro-. Various plots (drawn manually) in each part (Fig. 1*A*, 1*B* etc.) correspond to a different reagent concentration. The slopes of these plots are almost 2, indicating that in each of these extractions two protons are released on the formation of the extractable complex (7). In Fig. 1*A*, *C*, *D*, and *E*, the plateau region of each curve shifts to higher log *D*, indicating the formation of an adduct with the increase in adduct reagent concentration, whereas in the case of 2-methyl-8-quinolinol (Fig. 1*B*), all the curves in the higher pH region merge, indicating the absence of an adduct in the extraction system.

Plots of log *D* vs. the logarithm of the reagent concentration, log $[HQ]_0$, were constructed for the extraction of cobalt(II) with 8-quinolinols, and are shown in Fig. 2. The slopes of these plots show the number of reagent molecules incorporated in the extractable complex. The behaviour of the 2-methyl-8-quinolinol extraction indicates that the extractable

complex is a simple 1:2 chelate since two reagent molecules per cobalt ion are involved in the extraction. In other cases (Fig. 2*A*, *C*, *D*, and *E*), however, the slope of three of these plots indicates the additional reagent molecule utilised for the formation of a mono-adduct, e.g. $CoQ_2 \cdot HQ$.

These plots in Fig. 2 show a number of curves in each portion *A*, *B*, *C*, etc. These are drawn for various pH values from the data in plots of Fig. 1. It is interesting to note from these curves that at lower reagent concentration, the slopes (Fig. 2*A*, *C*, *D*, *E*) approach a value of 2 indicating the absence of the adduct. The slopes subsequently increase to 3 with the increase in reagent concentration showing that the adduct formation has taken place. In the case of 2-methyl-8-quinolinol (Fig. 2*B*), the slope remains 2 throughout, thus confirming the absence of any adduct in this system.

The distribution ratio D for the extraction of cobalt by oxine or its analogue is then given by (2, 7)

$$D = \frac{[Co]_0}{[Co]} = \frac{[CoQ_2]_0 + [CoQ_2 \cdot aHQ]_0}{[Co^{2+}] + [CoQ^+] + [CoQ_2] + [CoQ_2 \cdot aHQ]}$$

The equation can be modified when the adduct formation predominates over the simple CoQ_2 of the adduct complexes, $a = 1$ to $a = a$. The value of a can then be determined from the plot of log D vs. log $[HQ]_0$. Since two reagent molecules are involved in the formation of a simple 1:2 chelate, the slope of the resulting line should be $(2 + 0)$ as $a = 0$. It is seen from Fig. 2 that the value of a for 8-quinolinol, 4-methyl-, 5-chloro-, and 5-nitro-8-quinolinol systems is unity and for the 2-methyl-8-quinolinol system it is zero, i.e. no adduct formation is involved in the extraction of the cobalt chelate of 2-methyl-8-quinolinol, whereas a mono-adduct is involved in other chelates.

At lower concentrations of HQ when the formation of a simple 1:2 chelate cannot be ignored and at the lower pH range where Co^{2+} predominates in the aqueous phase, the distribution ratio D is then given by (2, 7)

$$D = \frac{K_{ex}[HQ]_0^2}{[H]^2}[1 + K_{AD_0}[HQ]_0^a]$$

where

$$K_{ex} = K_1 K_2 K_{DC} K_a / K_{DR}^2$$

K_{DC} and K_{DR} being the distribution coefficients of cobalt chelate and HQ, respectively; K_a being the dissociation constant of the reagent and K_{AD_0} the adduct formation constant.

The plot of log D vs. log $[HQ]_0$ gives two straight lines (2), the intersection of which gives the value for the adduct formation constant in the organic phase.

$$\log K_{AD_0} = -a \log [HQ]_0$$

at the intersection.

A plot of log $D[H]^2/[HQ]_0^2$ against log $[HQ]_0$ takes into account the variation both in pH and in the reagent concentrations simultaneously (8). Such a plot gives two straight lines. The horizontal line corresponds to log D = log K_{ex} and the line of slope a shows the number of neutral reagent molecules involved in the self-adduct formation. The intersection

of these lines gives the adduct formation constant, log K_{AD_0} (Fig. 3). Results for 2-methyl-8-quinolinol are also given in Fig. 3. The entire curve in the case of 2-methyl analogue is parallel to log $[HQ]_0$ axis indicating the absence of adduct formation in this case.

The overall formation constants, K_1K_2 or K_f, of the chelates may be evaluated from the extraction constant, K_{ex}, the K_{DR} and K_a values being obtained from the literature (9, 10).

Alternatively, a plot of log $D - a \log [HQ]_0$ vs. $-\log [Q^-]$ or pQ^-, where $[Q^-]$ represents the corresponding quinolinol anion concentration in the aqueous phase, takes into account the variations in the pH and the reagent concentration simultaneously giving two straight lines. The log K_f values may be obtained (7) from the intersection of the two lines, i.e. $pQ^- = \frac{1}{2} \log K_f$.

Such plots were constructed for 8-quinolinol, 4-methyl-, 5-chloro-, and 5-nitro-8-quinolinols and are shown in Fig. 4 while a plot for 2-methyl-8-quinolinol is given in Fig. 5. In these plots (except 2-methyl-), the value of $a = 1$ and the value of a, for a simple 1:2 chelate, such as that formed by cobalt(II) with 2-methyl-8-quinolinol, is zero. Figure 5 shows a plot of log D vs. pQ^- instead of

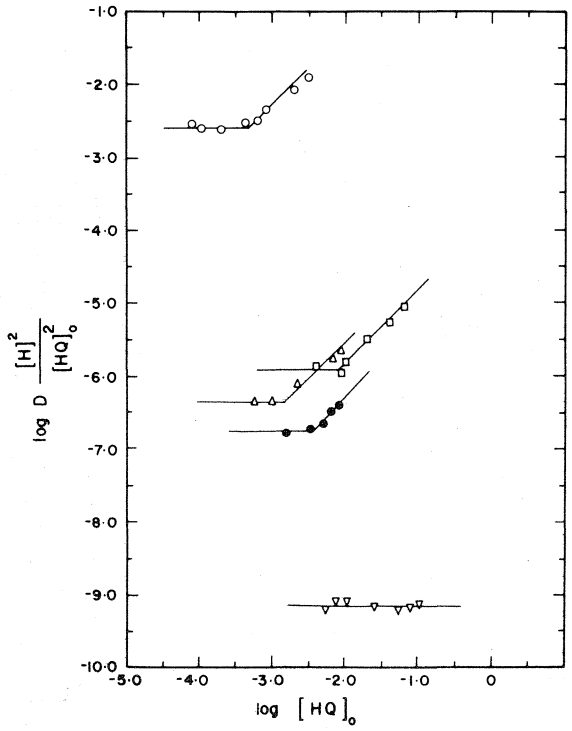

FIG. 3. log $D[H]^2/[HQ]_0^2$ vs. log $[HQ]_0$: ○, 5-NO_2-8-HQ; □, 8-HQ; △, 4-Me-8-HQ; ●, 5-Cl-8-HQ; ▽, 2Me-8-HQ.

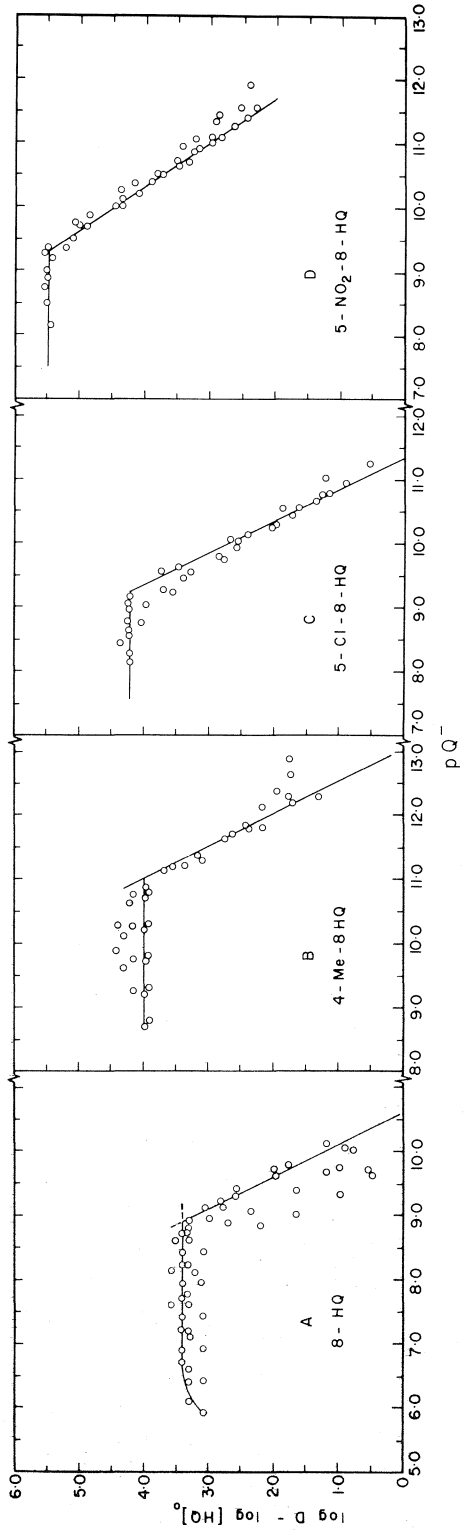

FIG. 4. log D − log $[HQ]_0$ vs. pQ^-: (*A*), 8-quinolinol; (*B*), 4-methyl-8-quinolinol; (*C*), 5-chloro-8-quinolinol; (*D*), 5-nitro-8-quinolinol.

log D − log $[HQ]_0$ vs. pQ^-. All these curves were plotted manually.

Table 1 gives the summary of equilibrium constants for cobalt chelates of 8-quinolinol and its substituted products.

This study has also shown a similar difference between the behaviour of cobalt(II) with 2-methyl-8-quinolinol from other 8-quinolinols as in the case of nickel (2) and zinc (7). The reason for this difference is that the extraction of the simple chelate results from the steric hindrance to the adduct formation exerted by the substituent in the 2-position. Substitution at a particular position in the chelating molecule not only alters its basic strength, and the stability of the complex it forms as well, but also introduces steric effects. This is very well shown by the difference in the extraction behaviour of cobalt(II) by 2-methyl- and 4-methyl-8-quinolinols. The steric hindrance offered by the 2-methyl- group in the case of cobalt(II) is similar to the earlier findings observed in the extraction of nickel(II) (2).

In Fig. 2 a slope of 3 obtained in the plots of log D vs. log $[HQ]_0$ indicates that to each atom of cobalt are attached three molecules of the reagent, HQ. Whereas, only two protons are liberated in the course of extraction, as seen from the log D vs. pH plot (Fig. 1). It is obvious that 8-quinolinol is playing a dual role, firstly, by coordinating with cobalt as a bidentate ligand, forming a 1:2 chelate, and secondly, as an unidentate ligand in the adduct formation. The slope of 2 in the log D vs. pH plot indicates that cobalt is extracted as Co(II). It has been shown (6) that Co(III) complex can be extracted in the presence of 0.8 M hydrogen peroxide, and identified spectrophotometrically by the shift in the spectrum, presumably with respect to that of Co(II) complex. However, in the normal course oxidation of the Co(II) complex can readily be avoided if the extraction is carried out with a large excess of oxine solutions and in the absence of any oxidizing agents, such as hydrogen peroxide. Large excess of oxine prevents the oxidation of Co(II) to Co(III) in the complex. The possibility of formation of a self-adduct in Co(III) has not been reported so far.

When the logarithm of the chelate formation constants were plotted against pK_a values of the 8-quinolinols (where $pK_a = pK_{a_1} + pK_{a_2}$), the overall basicity of the donor atoms, a linear correlationship was observed (Fig. 6). In the same figure, a similar plot was constructed between the adduct formation constants and the pK_a values of the reagents. In this case also a linear dependence was observed. This dependence may be used to estimate, based on known data, the stabilities of not yet experimentally studied complexes in this series of ligands. It is seen from Fig. 6 that the chelate formation constants and the adduct formation constants are almost constant over

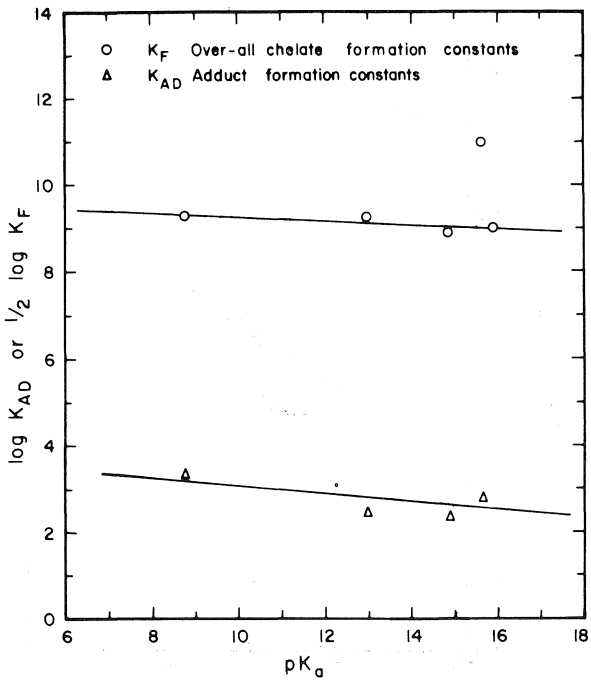

FIG. 6. Correlationship between adduct formation constants, chelate formation constants, and the basicities of the chelating agents: ○, log K_f; △, log K_{AD}.

TABLE 1. Summary of equilibrium constants for cobalt(II) chelates of 8-quinolinol and substituted 8-quinolinols at 28 ± 2°C

Substituted 8-quinolinol	log K_{ex}	log K_{AD_0}	log K_{DC}	$pK_{a_1} + pK_{a_2}$	log K_{DR}	log K_f
Parent	−5.93	2.10	1.28	14.9	2.64	17.8
2-Methyl-	−9.15	No adduct formation	1.30	15.9	3.22	18.1
4-Methyl-	−6.35	2.85	1.40	15.66	3.27	22.0
5-Chloro-	−6.75	2.45	1.73	13.00	3.32	18.55
5-Nitro-	−2.60	3.35	2.08	8.79	2.64	18.6

a wide range of pK_a values. This can be explained as follows: an adduct is formed between a Lewis base of the donor as well as the Lewis acid of the acceptor, the metal chelate. The Lewis acidity of the metal after chelation decreases with the increasing stability of the chelate. The overall effect would be a much smaller net decrease in the adduct formation constants for a relatively large increase in the reagent basicity. The 2-methyl- group in 8-quinaldine, however, does not produce any adverse effect on the linearity of the plot.

From the data obtained in the present study, it is presumed that cobalt(II) forms a penta-coordinate structure as observed in nickel (2) and zinc (7). During the extraction of Co(II) by oxine, the water molecules are pushed out of the coordination sphere and are replaced by the third molecule of the excess of the ligand present. The two molecules of 8-quinolinol form the square base of a pyramid and the unidentate ligand is in the axial position of the pyramid (point group C_{4v}) (11). The extracted species are presumably the anhydrous penta-coordinate adducts, except in the case of 8-quinaldine, where it forms a simple coplanar 1:2 complex, i.e. the base of the pyramid.

Presence of perchlorate ions, added to keep the ionic strength constant, does not produce any appreciable influence on the extraction of Co(II) by oxine. This was ascertained in a separate experiment, by varying the ClO_4^- concentration.

Received October 10, 1978

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **57**, 586 (1979).

Details of the synthesis and physical properties of $H_2NCH_2CH_2O \cdot GaMe_2$ are given. The compound crystallizes in the tetragonal space group $P4_3$, $a = 12.2771(2)$, $c = 9.7345(4)$ Å, $Z = 8$. The structure was solved by Patterson and Fourier syntheses and was refined by full-matrix least-squares procedures to a final R value of 0.028 and R_w of 0.036 for 1378 reflections with $I \geq 3\sigma(I)$. The structure consists of monomeric molecules containing tetrahedrally-coordinated gallium atoms. Molecules are linked by an extensive network of N—H...O hydrogen bonds. Bond lengths (corrected for libration) are: Ga—O, 1.916(5) and 1.917(4), Ga—N, 2.056(6) and 2.072(6), and Ga—C, 1.962–1.974(8–9) Å.

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **57**, 586 (1979).

On rapporte les détails relatifs à la synthèse et aux propriétés physiques du $H_2NCH_2CH_2O \cdot GaMe_2$. Le composé cristallise dans le groupe d'espace tétragonal $P4_3$, $a = 12.2771(2)$, $c = 9.7345(4)$ Å, $Z = 8$. On a résolu la structure par des synthèses de Patterson et de Fourier et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur finale de R de 0.028 et de R_w de 0.036 pour 1378 réflexions avec $I \geq 3\sigma(I)$. La structure comprend des molécules monomères contenant des atomes de gallium tétracoordonnées. Les molécules sont liées entre-elles par de nombreuses liaisons hydrogène N—H...O. Les longueurs des liaisons (corrigées pour les librations) sont: Ga—O, 1.916(5) et 1.917(4), Ga—N, 2.056(6) et 2.072(6) et Ga—C, 1.962–1.974(8–9) Å.

[Traduit par le journal]

Introduction

A previous report (1) characterized the *N*,*N*-dimethylethanolaminogallium dimethyl dimer, $[Me_2NCH_2CH_2O \cdot GaMe_2]_2$, as a compound containing five-coordinate gallium atoms with distorted trigonal bipyramidal geometry. The present account details the synthesis and crystal structure determination of the ethanolaminogallium dimethyl compound, $H_2NCH_2CH_2O \cdot GaMe_2$, and compares the results with those previously obtained for similar boron complexes, $H_2NCH_2CH_2O \cdot BPh_2$ (2, 3) and $H_2NCH_2CH_2O \cdot B(p\text{-}RC_6H_4)_2$, where R = F (4) and R = Me (3), and for other similar gallium dimethyl complexes (1, 5).

Experimental

Starting Materials

Ethanolamine was refluxed over anhydrous $CaSO_4$ and distilled prior to use. Gallium trimethyl was prepared as described previously (6). Benzene solvent was dried by refluxing over molten potassium followed by distillation. All materials were handled in a glove-box filled with dry nitrogen or on a standard vacuum line.

Ethanolaminogallium Dimethyl, $H_2NCH_2CH_2O \cdot GaMe_2$

Ethanolamine (0.771 g, 12.64 mmol) was reacted with gallium trimethyl (1.451 g, 12.64 mmol) in refluxing benzene solvent until cessation of methane gas evolution.

$$H_2NCH_2CH_2OH + GaMe_3 \xrightarrow[\text{reflux}]{C_6H_6} H_2NCH_2CH_2O \cdot GaMe_2 + MeH$$

After removal of solvent from the clear product solution, the desired compound was isolated as an extremely air and moisture sensitive white solid. *Anal.* calcd. for $H_2NCH_2CH_2O \cdot GaMe_2$: C 30.1, H 7.5, N 8.8; found: C 29.9, H 7.0, N 8.5.

The ir spectrum in Nujol showed strong bands in the ν_{Ga-C} region of the spectrum at 573 and 533 cm^{-1}. A strong δ_{N-H} band at 1620 cm^{-1} was also a prominent feature but the ν_{N-H} region of the spectrum, ~3300 cm^{-1}, was not clearly resolved.

The ^1H nmr spectrum in C_6D_6 solution showed two well resolved triplets for the two CH_2 groups at $\tau = 6.66$ and 7.83 ppm ($J_{HCCH} \approx 5$ Hz), a broad NH_2 signal at $\tau = 9.09$ ppm, and a sharp singlet for the $GaMe_2$ group at $\tau = 10.13$ ppm. (All signals refer to $\tau_{C_6H_6} = 2.84$ ppm.) The sharp $GaMe_2$ signal indicates a fluxional ring in the C_6D_6 solution.

The mass spectrum of the compound, in addition to a strong signal corresponding to the monomer ion minus a methyl group, displayed strong signals at higher mass numbers corresponding to Ga_2- and Ga_3-containing moieties.

Crystalline samples suitable for X-ray study were obtained by slow sublimation in evacuated tubes. Selected crystals were positioned in capillaries under a nitrogen atmosphere to avoid atmospheric interference and to prevent sublimation within the capillary tube during the collection of X-ray data. The tubes were flame-sealed.

X-ray Crystallographic Analysis of Ethanolaminogallium Dimethyl

The crystal was mounted in a general orientation and had

0008-4042/79/050586-05$01.00/0

dimensions of ca. 0.20 × 0.32 × 0.50 mm. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections measured on a diffractometer with Cu K_α radiation (λ = 1.54184 Å). Crystal data (at 22°C) are:

$C_4H_{12}GaNO$ fw = 159.87
Tetragonal, a = 12.2771(2), c = 9.7345(4) Å, V = 1467.3(1) Å^3, Z = 8 (two molecules per asymmetric unit), ρ_c = 1.448 g cm^{-3}, $F(000)$ = 656, μ(Cu K_α) = 47.5 cm^{-1}. Absent reflections: $00l$, $l \neq 4n$. Space $P4_1$ (C_4^2, No. 76) or $P4_3$ (C_4^4, No. 78); the latter was confirmed by structure analysis for the particular crystal used.

Intensities were measured with nickel-filtered Cu K_α radiation on an Enraf-Nonius CAD4-F diffractometer. An ω scan at 0.91–6.71° min^{-1} over a range of (0.90 + 0.15 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 150°. The intensities of three check reflections, measured every 3600 s throughout the data collection, did not vary by more than 1%. After data reduction, an absorption correction was applied using the Gaussian integration method (7, 8). Transmission factors ranged from 0.265 to 0.444. Of the 1604 independent reflections measured, 1378 (86%) had intensities greater than $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = background count.

The positions of the two independent gallium atoms were determined from the Patterson function and those of O, N, and C atoms from a subsequent difference map. After full-matrix least-squares refinement of all non-hydrogen atoms with anisotropic thermal parameters to R = 0.041, a difference map gave positions for 18 of the 24 hydrogen atoms (all of those not located were methyl hydrogens, but at least one hydrogen on each methyl group was located). The remaining hydrogen positions were calculated by assuming ideal geometries. Attempts to refine the methyl hydrogen positions did not give satisfactory results and thus these atoms were left fixed in calculated positions during the final stages of refinement. The other 12 hydrogen atoms were included in the refinement with isotropic thermal parameters. The scattering factors of ref. 9 were used for non-hydrogen atoms and those of ref. 10 for hydrogen atoms. Anomalous scattering factors from ref. 11 were used for the non-hydrogen atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. An isotropic Type I extinction correction (Thornley–Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (12–14). The final value of g was 0.34(3) × 10^4. Convergence was reached at R = 0.028 and R_w = 0.036 for 1378 reflections with $I > 3\sigma(I)$. For all 1604 reflections R = 0.035 and R_w = 0.037.

Hamilton's test (15) was applied to the R factor ratios resulting from parallel refinements carried out in $P4_1$ and $P4_3$. For observed planes only, $R(P4_1)/R(P4_3) = 1.011$ and $R_w(P4_1)/R_w(P4_3) = 1.019$, indicating that $P4_3$ is the correct space group at a confidence level of > 99.5%.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.18 and 1.39σ, respectively. The mean error in an observation of unit weight was 1.0654. A final difference map showed maximum fluctuation of ±0.4 e Å^{-3}. The final positional and thermal parameters appear in Tables 1 and 2[1] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (16) using the computer program MGTLS.[1] The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0037 Å^2. Analyses were successful for each of the two independent molecules (rms ΔU_{ij} = 0.0034 and 0.0035 Å^2 for the molecules containing Ga(1) and Ga(2), respectively). The appropriate bond distances have been corrected for libration (17), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths are shown in Fig. 1 and are listed in Table 3[1] along with uncorrected values (corrections were +0.007–0.014, mean 0.010 Å). Corrected bond angles do not differ by more than 1σ from the uncorrected values in Table 4. Intra-annular torsion angles are given in Table 5.

[1]The thermal motion analysis, structure factor table, and Tables 2 (thermal parameters) and 3 (bond lengths) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

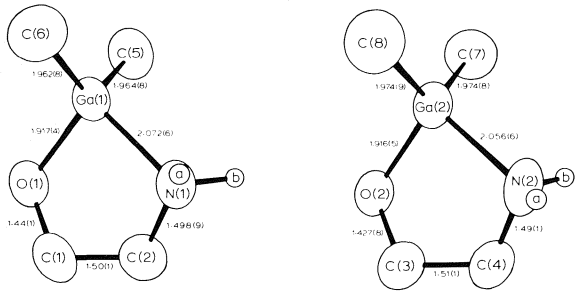

FIG. 1. The two independent molecules of ethanolaminogallium dimethyl. 50% probability thermal ellipsoids are shown for non-hydrogen atoms. Bond lengths are in Å (mean N—H = 0.89(18), C—H = 1.03(12) Å).

Results and Discussion

The reaction between ethanolamine and gallium trimethyl was investigated in connection with a series of anionic ethanolaminopyrazolylgallate ligands which were under study (18, 19). It was well known that gallium trimethyl would react with 'active hydrogen'-containing compounds to undergo methane elimination and produce associated gallium-containing species. The fact that enthanolamine bears 'active hydrogen' atoms on both the nitrogen and oxygen ends of the molecule prompted us to substantiate our prediction that the hydroxyl hydrogen would react preferentially in a 1:1 stoichiometric reaction leaving the amino group intact. Thus it is known that molecules with amino groups coordinated to gallium trimethyl require elevated temperatures for elimination of methane whereas molecules with hydroxyl groups coordinated to the gallium alkyls eliminate alkane much more readily at lower temperatures (20). The isolation of the title compound left no doubt that the preferential reaction was indeed occurring and this fact paved the way for the syntheses of the numerous complexes already reported incorporating the ethanolamino moiety in chelating anionic gallate ligands (19, 21).

The crystal structure of $H_2NCH_2CH_2O{\cdot}GaMe_2$ (Fig. 2) consists of discrete monomeric molecules (two per asymmetric unit) which display the gallium atoms in distorted tetrahedral environments. The individual monomer units are each linked to four others by an extensive network of N—H...O hydrogen bonds (see Table 6). Evidently this hydrogen bonding is quite strong since fragments containing two and three gallium atoms have been identified in the mass spectrum of the compound. Molecules of the related boron compounds $H_2NCH_2CH_2O{\cdot}BAr_2$ (Ar = C_6H_5, *p*-FC_6H_4, and *p*-$CH_3C_6H_4$) are also linked by N—H...O hydrogen bonds, but due to the bulky aromatic substituents attached to the boron atom only one of the protons bonded to nitrogen is involved in N—H...O hydrogen bonding. Apart from the hydrogen bonds, the packing is dominated by van der Waals contacts between hydrogen atoms with several H...H distances between 2.23 and 2.50 Å. The structure is quite different from those of the *N*,*N*-dimethylethanolamino derivatives $[Me_2NCH_2CH_2O{\cdot}GaR_2]_2$ (R = H or Me), which consist of well-separated dimeric units containing five-coordinate gallium atoms (1).

The two independent molecules (Fig. 1) are nearly identical; there are no significant differences between corresponding bond lengths but there are small but significant differences in some bond angles and torsion angles (see Tables 3–5). The gallium atoms are

N(2)—H(N2b) . . . O(1)[4]	2.09(7)	2.907(6)	148(6)	121(2), 102(2)

*H...O(1)...H 86(3)°, H...O(2)...H 80(2)°. Superscripts refer to atoms at positions: [1] $1-x, 1-y, z-1/2$; [2] $1-y, x, z-1/4$; [3] $1-y, x-1, z-1/4$; [4] $x-1, y, z$.

four-coordinate with distorted tetrahedral coordination geometry; bond angles at gallium range from 86.9(2) (O—Ga—N) to 124.4(4)° (C—Ga—C). The Ga—O and Ga—C distances are normal for tetrahedral gallium (22–24) and very similar to equatorial Ga—O and Ga—C distances for trigonal bipyramidal gallium (1, 5). As in the boron compounds (2–4) the bonds to nitrogen are somewhat long, 2.056(6) and 2.072(6) Å, compared to values of 1.971–2.042 Å previously observed for tetrahedral Ga—N bonds (22–24 and references therein). The Ga—N bonds in the five-coordinate dimers $[Me_2NCH_2CH_2O{\cdot}GaR_2]_2$ (1) are axial with lengths of 2.279(3) Å for R = H and 2.479(4) Å for R = Me.

The geometry of the ethanolamino moiety is very similar to that observed for the boron compounds. The only significant difference is the O—C bond length which has a mean[2] value of 1.412(2) Å in the boron compounds and a mean value of 1.435(7) Å in the present structure. This may be due to the involvement of the oxygen in a second N—H...O hydrogen bond in the present study. The O—C distances in the dimers $[Me_2NCH_2CH_2O{\cdot}GaR_2]_2$ are significantly shorter at 1.369(5) and 1.384(7) Å, but the oxygen is trivalent, being bound to a carbon and two gallium atoms.

[2]Here and elsewhere in this report mean values are weighted means with rms deviations from the mean in parentheses.

Band resolution of optical spectra of solvated electrons in water, alcohols, and tetrahydrofuran[1]

FANG-YUAN JOU AND GORDON R. FREEMAN

Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 14, 1978

FANG-YUAN JOU and GORDON R. FREEMAN. Can. J. Chem. **57**, 591 (1979).

The optical absorption spectra of solvated electrons in water, alcohols, and tetrahydrofuran are empirically resolved into two Gaussian bands and a continuum tail. The first Gaussian band covers most of the low energy side of the spectrum. The second Gaussian band lies at an energy slightly above that of the absorption maximum of the total spectrum. With the exception of *tert*-butyl alcohol, in water and alcohols the following were observed: (*a*) the first Gaussian bands have the same half-width, but the oscillator strength in water is about double that in an alcohol; (*b*) the second Gaussian bands have similar half-widths and oscillator strengths; (*c*) the continuum tails have similar half-widths, yet that in water possesses only about one third as much oscillator strength as one in an alcohol. In *tert*-butyl alcohol and tetrahydrofuran the first Gaussian band and the continuum tail each carry nearly half of the total oscillator strength.

FANG-YUAN JOU et GORDON R. FREEMAN. Can. J. Chem. **57**, 591 (1979).

Les spectres d'absorbtion optique des électrons solvatés dans l'eau, les alcools et le tétrahydrofuranne peuvent être résolus empiriquement en deux courbes gaussiennes et en une queue continue. La première courbe gaussienne recouvre presque toute la partie de faible énergie du spectre. La deuxième courbe gaussienne se trouve à une énergie légèrement supérieure au maximum d'absorbtion du spectre global. A l'exception du *tert*-butanol, on observe généralement avec l'eau et les alcools, les faits suivants: (*a*) les largeurs à demi-hauteur des premières courbes gaussiennes sont approximativement les mêmes; la force de l'oscillateur dans l'eau est approximativement deux fois celle dans l'alcool; (*b*) les largeurs à demi-hauteur et les forces des oscillateurs des deuxièmes courbes gaussiennes sont semblables; (*c*) les largeurs à demi-qauteur des queues continues sont semblables; toutefois la force de l'oscillateur de celle de l'eau est environ trois fois moindre que celle d'un alcool. Dans le *tert*-butanol et le tétrahydrofuranne la force de l'oscillateur de la première courbe gaussienne est approximativement égal à cela de la queue continue.

Introduction

Theoretical treatments of the optical absorption spectrum of solvated electrons in polar liquids have been moderately successful in rationalizing the transition energy at the absorption maximum, but have failed to explain the breadth and skewness of the band (1–3). Semi-empirical models for fitting the band shape help to provide a qualitative understanding of the spectrum (4, 5). Recent theoretical work (6) supports the suggestion (4) that the broad spectrum is comprised of overlapping bands for a small number of bound–bound transitions, with a tail towards high energies due to bound–continuum transitions.

In view of the Gaussian shape of the Franck–Condon factor (7) which governs the band shape of a bound–bound transition, the whole spectrum of solvated electrons was previously resolved into two Gaussian bands and a continuum tail (8). The empirical fitting requires extended measurement of the wings of the spectrum. Therefore, we have measured the spectra over wide ranges of wavelength in water, alcohols, and tetrahydrofuran. The results of the resolution are reported herein.

Experimental

The materials, purification, and optical system were described elsewhere (8–10). Ethanolamine (scintillation grade) was from Eastman Kodak Co. The purification was the same as for a normal alcohol but under reduced pressure.

The whole solvated electron spectrum in water and ethanolamine and the partial spectra at $\lambda > 900$ nm and $\lambda < 500$ nm in methanol, ethanol, 1-propanol, and 1-butanol, and that at $\lambda < 1000$ nm in tetrahydrofuran (THF) were measured in a 1.5 cm spectrosil cell. The ultraviolet and visible portions in water and alcohols were measured with 100 ns pulses (6×10^{16} eV/g) and those in THF with 1.0 μs pulses (30×10^{16} eV/g). The infrared portion in water and alcohols was measured with 1.0 μs pulses. Appropriate Corning glass filters were placed in front of the optical cell and the monochromator.

The operation of the 1P28 uv detector was limited to a light input of 1.0 ± 0.2 V, as the linearity was good only in this range (deviation ~2%). The high voltage was varied between 600–900 V, depending upon wavelength. The slits of the monochromator were kept at constant widths.

The irradiation temperature was 26 ± 1°C, except for THF which was − 99°C.

Results

The absorbance measured after a 0.1 μs pulse was not corrected for decay during the pulse, but that after a 1.0 μs pulse was corrected according to first-order decay kinetics and square pulse. The rate constant was taken from the first half-life of the observed maximum absorbance of individual pulse. At $\lambda < 400$ nm (700 nm in THF) correction was also made for radical absorption (9). The parameters of the optical absorption spectra of solvated electron in ethanolamine, water, alcohols, and THF are listed in Table 1 in which E_{Amax} (eV) is the energy at maximum absorption, $W_{1/2}$ (eV) is the width at half-peak height, i.e., half-width, and $G\varepsilon_{max}$ is the product of the free ion yield in (100 eV)$^{-1}$ and the decadic molar extinction coefficient in M^{-1} cm^{-1}. The half-width was separated to the blue, W_b, and red, W_r, sides of the absorption maximum. The ratio W_b/W_r shows the asymmetry of the spectrum.

Fitting the spectrum with a combined Gaussian–Lorentzian shape function (11) is satisfactory in water and aqueous solution (8, 11) for absorbances larger than 10% of the maximum absorbance, A_{max}, and in ethers (9, 12) for absorbances larger than one third of A_{max}. The fitting is, however, not satisfactory in alcohols (8). In general, all or most of the red side of a spectrum of solvated electrons follows the Gaussian shape function.

Lugo and Delahay (4) have previously resolved the solvated electron spectrum into several Gaussian bands, each having the same width, and a continuum tail. Since each band represents an ensemble of electronic and vibronic broadening, be it homogeneous or inhomogeneous, of many individual transition lines, they need not have the same width. Therefore, in the present spectrum fitting, the overlapping Gaussian bands are not restricted to having a same half-width.

The fitting starts from the low energy side of the spectrum. The Gaussian equation for the ith band is transformed to a linear form:

$$[1] \quad \ln A = \ln A_{max,i} - (\ln 2/g_i^2)(E_i - E)^2 \quad \text{for } E < E_i,\ i = 1, 2$$

where A is the absorbance at energy E (eV), E_i (eV) is the energy at maximum absorbance, $A_{max,i}$, and g_i is half of the width of the ith band at $0.5A_{max,i}$. E_i is varied and the correlation factor calculated. The final values of E_i, g_i, and $A_{max,i}$ are obtained from the equation that provides the largest correlation factor. Absorbances entering the least-squares fitting have in general at least 4% of the maximum. The first

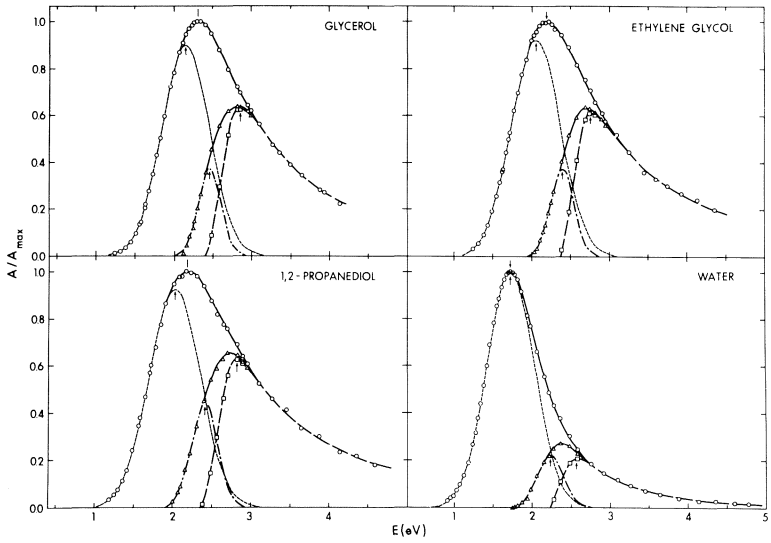

FIG. 2. Band resolution in glycerol, ethylene glycol, 1,2-propanediol, and water at 26°C. Symbols as in Fig. 1.

Gaussian is subtracted from the whole spectrum to obtain a remainder, which is then fitted with a second Gaussian. A third Gaussian, if it exists, would have a very narrow width. Therefore, the whole spectrum is resolved into only two Gaussians and a high energy tail. The resolution of the optical spectrum in ethanolamine at 26°C is shown in Fig. 1. The resolution was also done for spectra of solvated electrons in glycerol, ethylene glycol, 1,2-propanediol, water (Fig. 2), methanol, ethanol, 1-propanol, 1-butanol (Fig. 3), 1-octanol, 2-propanol, *tert*-butyl alcohol, and THF (Fig. 4). In *tert*-butyl alcohol and THF the experimental data on the low energy side are not extensive enough. The resolutions of these two spectra are tentative.

In water and all alcohols the widths at half-height of the first and second Gaussian bands are $2g_i = 0.71 \pm 0.07$ eV and 0.37 ± 0.08 eV, respectively, and the width at half-height of the high energy tail about 1.0 ± 0.2 eV.[2] If the optical excitation on the low energy side of the spectrum corresponds to a bound–bound transition, then the presently obtained Gaussian shape justifies the semi-classical Franck–Condon factor due to vibronic broadening (6, 7). The high energy tail has a rather steep rise on its low energy side. It is quite similar to the band shape of a theoretically calculated bound–continuum transition (13, 14). Therefore, the high energy tail is believed to be a bound–continuum transition. From the onset of the high energy tail, the threshold energy of photoionization of the solvated electrons (E_0) could be estimated. The threshold energy is 1.7 eV in ethanolamine, 2.4 eV in multihydric alcohols, 2.2 eV in water, 2.0–2.1 eV in normal monohydric alcohols, 1.8 eV in 2-propanol, and 1.5 eV in *tert*-butyl alcohol. These energies lie $\sim$0.1–0.3 eV above E_{Amax} of the overall spectrum in alcohols and 0.5 eV above in water. In THF the first Gaussian band has the same half-width as that of the second Gaussian band in alcohols. The second Gaussian band in THF is very small. The threshold energy of photoionization is 0.95 eV, which locates 0.18 eV higher than E_{Amax}. The parameters of the Gaussian bands and the continuum tail of each spectrum are listed in Table 2.

The high energy sides of the spectra were tested to see whether they follow a simple exponential law: $A/A_{\text{max}} \propto E^{-\alpha}$, where α is a constant and may be obtained from the slope of the plot $\ln(A/A_{\text{max}})$ vs. $\ln E$. Straight lines were obtained for $A/A_{\text{max}} \leq 0.6 \pm 0.1$. The value of α is 4.4 in water, $(8 \pm 1)/3$ in alcohols, and 2.2 in THF. The spectrum at the high energy side in ethanol at 77 K (15) and in 3-methyloctane at 127 K (16) were also examined. The fitting is $A/A_{\text{max}} = 41.26E^{-3.77}$ from 3.0 eV to 6.0 eV for the former and $0.54E^{-2.19}$ from 0.9 to 2.1 eV for the latter. The value of α is not 8/3 or 3 for electrons in

[2]The analysis includes the possibility that $g_1 = g_2$, but the best fit of the band shape always gave $g_2 < g_1$. The earlier assumption that $g_1 = g_2$ (4) was only tolerable if the measured band lacked most of the low energy side. When the present analysis was applied to spectra measured for the same solvent in different types of apparatus, such as a high pressure apparatus and a variable temperature apparatus, the values of g_1 at a given T and P were reproducible within 2–10%, while those of g_2 were reproducible within 20%.

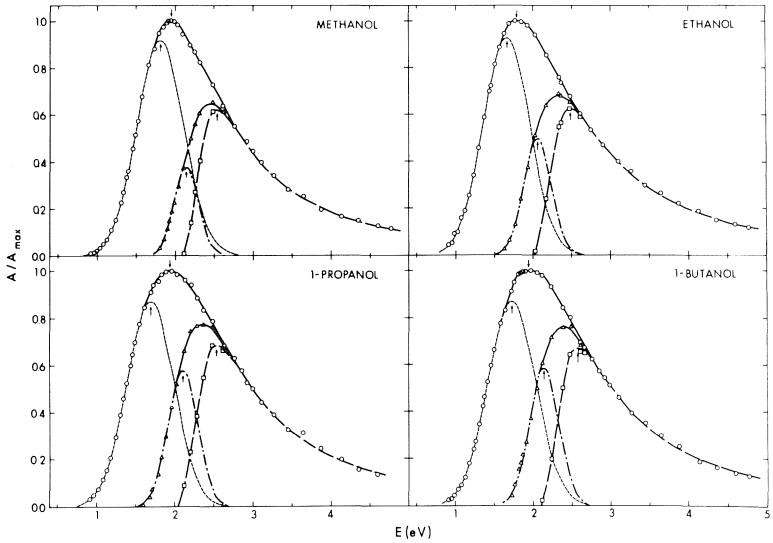

FIG. 3. Band resolution in methanol, ethanol, 1-propanol, and 1-butanol at 26°C. Symbols as in Fig. 1.

all solvents, as suggested earlier (4); the variations from 2.2 to 4.4 mentioned above are well outside of the experimental uncertainty.

Discussion

The optical absorption spectra reported here cover a wide range of spectral region. Both sides of each spectrum maximum extend to the observation limit of our optical system. All the spectra have the well known broad, asymmetric shape and no noticeable fine structure. A cut-off energy, which is characteristic of bound–continuum transitions (ref. 13, sect. 74, refs. 14, 17), is not observed in the *ascending* part of the spectrum. The difference between Gaussian and (linear) cut-off shapes is most clearly visible at $A/A_{max} < 0.2$ on the low energy side (see Figs. 2 and 3). Theoretical studies of solvated electrons (1–6, 18) still do not conform with the experimental line shape. The studies of temperature dependence of the spectrum in ethers (9) and pressure dependence in alcohols (8) showed that the half-width of a spectrum is less informative about the nature of the transition than are the separate widths on the two sides of the band maximum.

The whole band was empirically resolved into two Gaussian bands and a continuum tail. The first

[a] E = band maximum, g = half of the width at half-height, A = relative absorbance, f = percentage of oscillator strength. Subscript 1 indicates first Gaussian band, 2 indicates second Gaussian band, c indicates continuum tail, E_0 = threshold energy of bound–continuum transition, α = descending power of A/A_{max} vs. E curve.

Gaussian band is a bound–bound transition. This proposition is based on the fact that in the photobleaching studies of trapped electrons in organic glasses (15, 19, 20), ice (21), and liquid methanol (22), the quantum yield is very low with photon energies at the red side of the absorption spectrum. This phenomenon was also observed by photoconductivity (23–26) and stimulated luminescence (27). It could be explained that the excited electron in the energy region of the first Gaussian band could still be bound by the same potential well. The small photoresponse that is observed in this energy region (15, 19–27) could arise from thermal agitation or tunnelling from the excited state to the continuum.

The second Gaussian band which lies slightly above E_{Amax} could be due to transition to higher excited states. This was speculated in theoretical studies but was concluded not to contribute significantly to the total width (1). Indeed, this band contributes only about 10% of the total oscillator strength (Table 2). Huang *et al.* (24, 25) postulated a possible second transition band of which the final state is in the continuum, on the basis that there was no temperature dependence of photobleaching yield and photocurrent in methyltetrahydrofuran and 3-methylhexane glasses. However, the latter work involved a double photon process, so the transition presumably passed through an intermediate state.

The continuum tail is characterized by a rapidly ascending and slowly descending A vs. E curve. The slope of both sides lies between those in neutral and negative hydrogen atoms (13). The overall band shape is very similar to the photoionization spectrum due to direct bound–continuum transition (28). The band maximum is higher than E_{Amax} by about 0.6 ± 0.1 eV in alcohols, 0.9 eV in water, and 0.4 eV in THF. This band resembles, in relative position, the detrapping curves of photobleaching yield (15, 19–21), photoconductivity (23–26), and stimulated luminescence intensity (27). The cut-off energy, i.e., threshold energy of the bound–continuum transition, was obtained by linear extrapolation of the low energy side of the continuum (Table 2).

By analogy with the hydrogen atom spectrum, the first Gaussian band is due to $1s \rightarrow 2p$ transition, the second Gaussian band to $1s \rightarrow 3p$ transition, and the high energy tail to $1s \rightarrow$ continuum. The widths come from the Franck–Condon factor (7). For hydrogen atoms the oscillator strength was calculated (ref. 13, sect. 63) to be $f_{1s\rightarrow 2p} = 42\%$, $f_{1s\rightarrow 3p} = 8\%$, and $f_{others} = 50\%$. In all alcohol liquids except *tert*-butyl alcohol the first Gaussian band carries ~33%, the second one ~10%, and the high energy tail ~55% of the total measured oscillator strength. In water the distribution of oscillator strength is 69, 8, and 23%, respectively. In *tert*-butyl alcohol and THF the first Gaussian band and the high energy tail each contribute nearly half of the total oscillator strength. It is to be noted that the first and second Gaussian bands both extend into the high energy tail due to phonon broadening effect (29). The overlapping portion between the two Gaussian bands and the high energy tail is about 2–4% each of the total strength. This may account for the 4% bound–continuum transition in aqueous glass with a photon energy on the red side of the first Gaussian band (30).

If a Slater type of $1S$ wave function, $\psi(1S) = (\beta^3/\pi)^{1/2} \exp(-\beta r)$, represents the ground state orbi-

tal of the solvated electron which is bound by a coulomb force $-\beta/r$, then the threshold energy for bound–continuum transition is $E_0 = \beta^2/2$ au. The unit of effective charge, β, is calculated to be 0.35 in ethanolamine, 0.42 in multihydric alcohols, 0.40 in water, 0.39 in normal alcohols, 0.36 in 2-propanol, 0.33 in *tert*-butyl alcohol, and 0.26 in THF. These values are, incidentally, very similar to the optimum ones calculated from the semi-continuum model with coordination number 4: 0.40 (31)[3] and 0.41 in water (2), 0.38 in methanol (2), and 0.36 in ethanol (2).[4] The effective charge obtained from the empirical resolution is always smaller than that which would arise from a long range polarization potential $\beta_p = 1/D_{op} - 1/D_{st}$, where D_{op} and D_{st} are the optical and static dielectric constants, respectively (32). According to the virial theorem and uncertainty principle, the uncertainty in position of the solvated electron should not be less than 1.3 Å in multihydric and normal alcohols and water, 1.4 Å in ethanolamine and 2-propanol, 1.5 Å in *tert*-butyl alcohol, and 1.9 Å in THF. The diameter of the void calculated in ref. 2 is 1.1 Å in water, 1.4 Å in methanol, and 1.5 Å in ethanol.

The length of the alkyl group in normal alcohols has been shown to have the effect of increasing the transition intensity on the high energy side, comparing with water (8). The empirical band resolution shows that the second Gaussian band has twice and the continuum tail three times the intensity in alcohols as in water, although the respective half-widths are similar in the different solvents (Figs. 2, 3, and 4). However, the overall half-width does not increase beyond 1-propanol (Table 1).

To compare the distribution of oscillator strength through the whole spectrum, the usual formula of oscillator strength f

$$[2] \qquad f = 3.49 \times 10^{-5} \int \varepsilon_E \, dE$$

was rearranged to

$$[3] \quad f = 3.49 \times 10^{-5} \varepsilon_{max} W_{1/2} \times \int_{-\infty}^{\infty} \left(\frac{\varepsilon_E}{\varepsilon_{max}}\right) d\left(\frac{E - E_{Amax}}{W_{1/2}}\right)$$

where ε_E (M^{-1} cm^{-1}) is the decadic molar absorbance at photon energy E (eV). The integral in [3] is shown in Fig. 5 for solvated electrons in water, 1-propanol, and 2-propanol at 26°C and THF at −99°C. It shows that water contributes more strength on the low energy side, and organic liquids more on the high energy side. The value of the integral is not constant, being 1.3 in water, 1.4 in normal and multihydric alcohols, 1.5 in ethanolamine and branched alcohols, and 1.7 in THF. These are to be compared with 1.06 for a Gaussian curve and 1.57 for a Lorentzian curve. The values of $\varepsilon_{max} W_{1/2}$ (see [3]) reported in the literature (8, 9, 33–36) range over a factor of two, partly due to the uncertainty in the value of ε_{max}. The most acceptable one is for water (35, 36), i.e.

$$\varepsilon_{max} W_{1/2} = 1.9 \times 10^4 \times 0.85 = 1.6 \times 10^4 \, M^{-1} \, \text{cm}^{-1} \, \text{eV}$$

which leads to $f = 0.73$. In normal alcohols (8, 36) ε_{max} was reported to be $1.0 \times 10^4 \, M^{-1} \, \text{cm}^{-1}$, giving $\varepsilon_{max} W_{1/2} = 1.4$ to $1.6 \times 10^4 \, M^{-1} \, \text{cm}^{-1}$ eV and $f = 0.67$ in methanol, 0.72 in ethanol, 0.76 in 1-propanol, and 0.75 in 1-butanol. If the same ε_{max} is applied to other alcohols then $f = 0.75$ in 1-octanol, 0.72 in 2-propanol, 0.68 in glycerol, 0.73 in ethylene glycol, and 0.74 in 1,2-propanediol. The most probable value of oscillator strength in water and alcohols is, therefore, $f = 0.72 \pm 0.05$.

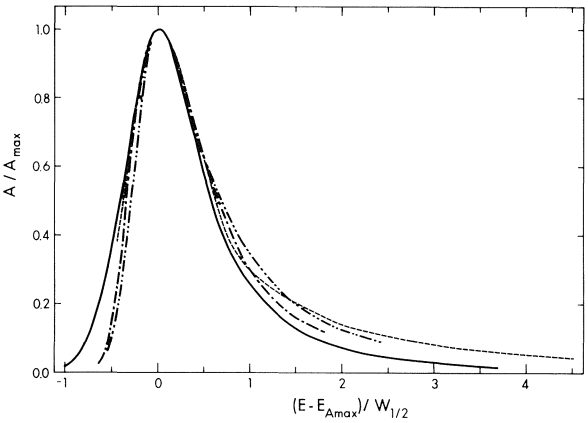

FIG. 5. Oscillator strength distribution of solvated electrons in water (—), 1-propanol (-·-·-·-), and 2-propanol (-···-) at 26°C and THF (---) at −99°C.

[3]Quasi-free energy $V_0 = 0.0$ eV.

[4]$V_0 = -1.0$ eV in water, −0.2 eV in methanol, and +0.2 eV in ethanol.

Dichotomous reactions of thioketones with tetracarbonylferrate

HOWARD ALPER, BERNARD MARCHAND, AND MASATO TANAKA
Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received October 26, 1978

HOWARD ALPER, BERNARD MARCHAND, and MASATO TANAKA. Can. J. Chem. **57**, 598 (1979).

Treatment of nonenolizable and enolizable thioketones, first with disodium tetracarbonylferrate and then with an acid chloride, affords saturated and unsaturated thioesters, respectively. Mechanisms are proposed for these different reactions.

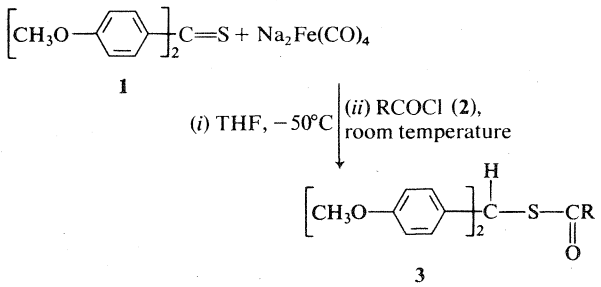
HOWARD ALPER, BERNARD MARCHAND et MASATO TANAKA. Can. J. Chem. **57**, 598 (1979).

Si l'on traite respectivement des thiocétones qui peuvent être énolisées et d'autres qui ne peuvent pas l'être par du tétracarbonylferrate de disodium puis par un chlorure d'acide, on obtient des thioesters saturés et insaturés. On propose des mécanismes pour ces diverses réactions.

[Traduit par le journal]

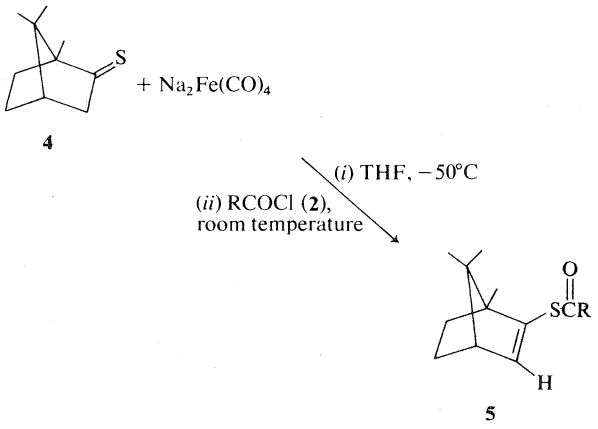
The reactions of thioketones with nucleophiles represent an intriguing aspect of the chemistry of these sulfur compounds. Thiophilic and carbophilic additions have been described in the literature (1). One of us has recently observed that the cyclopentadienylmetal carbonyl anions, $C_5H_5M(CO)_n^-$ (M = Mo, W, n = 3; M = Fe, n = 2), can effect desulfurization and coupling of thiobenzophenones to give fulvenes (2). We now wish to report on the dichotomous reactions of thioketones with disodium tetracarbonylferrate, a reagent of demonstrated (3) value in several areas of synthetic organic chemistry.

Disodium tetracarbonylferrate, generated from iron pentacarbonyl and sodium amalgam (4), was reacted with a nonenolizable thione such as 4,4′-dimethoxythiobenzophenone (**1**) in tetrahydrofuran (THF) at −50°C. Subsequent addition of an acid chloride (**2**) and work-up affords the thioesters **3** in



modest yields (R = CH_3, 20% yield, ir(ν_{CO}) 1690 cm^{-1}, nmr($CDCl_3$) δ 5.73 (s, 1H, CHS), ms (*m/e*) 302; R = Ph, 27% yield, ir(ν_{CO}) 1665 cm^{-1}, nmr($CDCl_3$) δ 6.01 (s, 1H, CHS), ms (*m/e*) 364). Adamantanethione, a nonenolizable cycloalkyl thione, reacted in a similar manner with tetracarbonylferrate and benzoyl chloride to give the analogous thioester in 40% yield (ir(ν_{CO}) 1665 cm^{-1}, ms (*m/e*) 272).

When an enolizable thione such as thiocamphor (**4**) was reacted under identical conditions as described for nonenolizable thioketones, unsaturated thioesters (**5**) were formed in 52–62% yields. Saturated thioesters were not detected in any of these reactions. The yields of **5**, together with pertinent spectral data for these new compounds, are listed in Table 1.



Saturated thioesters (**3**) may arise from initial thiophilic addition of the metal carbonyl dianion to a nonenolizable thione (e.g. **1**) to give the dianion **6**

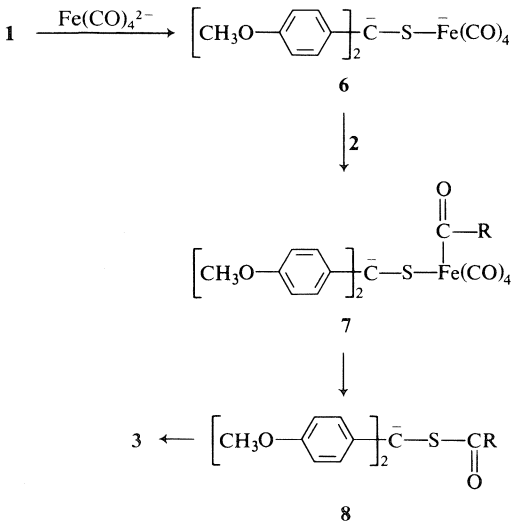
[a]Neat.
[b]The data cited are those for the vinylic proton which appears as a doublet (J = 3–4 Hz). The nmr spectra were recorded in $CDCl_3$, with TMS as an internal standard.

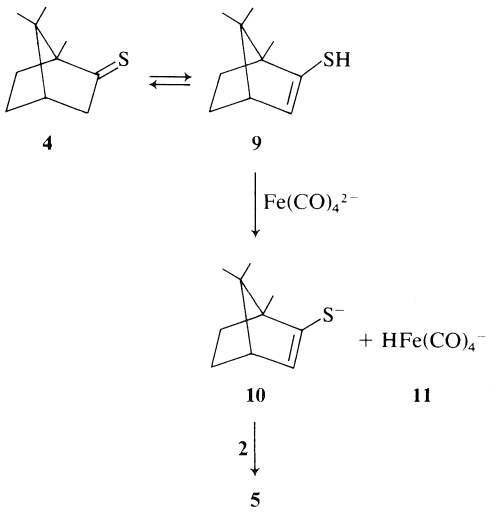
(Scheme 1). Acylation of the latter with an acid chloride (**2**), followed by reductive elimination to **8** (the $Fe(CO)_4$ formed trimerizes to $Fe_3(CO)_{12}$) and protonation would afford **3**. Some evidence for **7** comes from the reaction of **1** with $Fe(CO)_4^{2-}$ and **2**, followed by 1-bromo-2-methylpropane, which alkylates at the benzylic position.



SCHEME 1

The results for thiocamphor clearly show that tetracarbonylferrate is a sufficiently strong base to effect proton removal from an enolizable thione, or its thioenol tautomer (**9**), to form the thioenolate anion **10** and the hydridotetracarbonylferrate anion **11** (3) (Scheme 2). The unsaturated thioester **5** would then result from reaction of **10** with the appropriate acid chloride **2**.

Related to the results for thiocamphor are some very recent findings by Werstiuk and Andrews (5). They showed that the *exo* and *endo* protons of thiocamphor (**4**) undergo NaOD catalyzed deuterium exchange at a considerably faster rate than the



SCHEME 2

corresponding protons of camphor. We have observed that although, as noted above, $Fe(CO)_4^{2-}$ readily abstracts a proton from thiocamphor, camphor is inert to the metal carbonyl dianion.

The following general procedure was used. Iron pentacarbonyl (4.0 mL) in THF (7.5 mL) was added, over a 2-h period, at 0°C, to sodium amalgam (3.5 mL) in THF (10 mL). Excess amalgam was removed, the stirred solution was cooled to −50°C, and then the thioketone (9.9 mmol) in THF (5 mL) was added. The mixture was allowed to warm, with stirring, to room temperature. The acid chloride (**2**, 2.5 equiv.) was added and the reaction mixture was stirred for a short time, concentrated to approximately one-fifth its volume, and then treated with ether (60 mL). The solution was washed successively with water (15 mL), 10% sodium bicarbonate (10 mL), and water (15 mL). The dried organic phase was then chromatographed on silica gel (60–220 mesh, elution with benzene or 1:1 hexane–benzene) or fractionally distilled to give pure **3** or **5**.

[Traduit par le journal]

The mechanism involving electron transfer in the photoreductions of ketones by tertiary amines has remained controversial in recent years. Cohen and co-workers (1) initially suggested that amines react with excited carbonyl compounds via an electron transfer mechanism followed by a proton transfer from the amine radical cation. The earlier CIDEP results obtained in the photoreduction of quinones by amines were interpreted in terms of this electron transfer mechanism followed by a hydrogen transfer from the alcoholic solvent to the amine radical cation (see, for example, ref. 2). Subsequently, McLauchlan and Sealy (3) have demonstrated that in the CIDEP system involving the photoreduction of benzophenone by amine in the presence of biacetyl the primary process does not involve electron transfer. On the other hand, Wong (4) has recently concluded from his CIDEP experiments of the photoreduction of naphthoquinone by pyridine and by tertiary triethyl amine that the primary process is a hydrogen abstraction reaction in the first case and it becomes an electron transfer reaction in the latter case. Similarly, the early CIDNP results in the photoreduction of benzophenone by amines were interpreted based on an electron transfer mechanism (5). Further studies by Roth and co-workers (6) have revealed that the electron transfer mechanism is operative only when the amine used is the 1,4-diazobicyclo[2.2.2]octane. The CIDEP and CIDNP applications to photochemistry have been reviewed recently by Wan (7).

Flash photolysis with optical detection has also been applied to study the electron transfer mechanism in the ketone–amine systems (8). Arimitsu and co-workers (8) have reported that among a number of amines quenching the triplet benzophenone, only the *N*,*N*-dialkylanilines produce radical ions. Although esr spectroscopy is now commonly used to follow photochemical reactions in solution and to identify the transient intermediates, it has not been possible to confirm the presence and the fate of the counter amine radical cation in the ketone–amine photochemical systems.

We wish to report here the first high resolution esr observations of contact ammonium ion-pairs of hexafluoroacetone and the radical anion of α,α,α-trifluoroacetophenone.[1] While the results will shed some light on the controversial electron transfer

[1]A charged ion aggregate involving the ammonium cation and a ninhydrin anion radical, in rapid equilibrium with the free ninhydrin anion radical and the tetraalkylammonium salt, has been proposed to account for the variation of esr parameters as a function of the ammonium salt concentration (9).

The mechanism involving electron transfer in the photoreductions of ketones by tertiary amines has remained controversial in recent years. Cohen and co-workers (1) initially suggested that amines react with excited carbonyl compounds via an electron transfer mechanism followed by a proton transfer from the amine radical cation. The earlier CIDEP results obtained in the photoreduction of quinones by amines were interpreted in terms of this electron transfer mechanism followed by a hydrogen transfer from the alcoholic solvent to the amine radical cation (see, for example, ref. 2). Subsequently, McLauchlan and Sealy (3) have demonstrated that in the CIDEP system involving the photoreduction of benzophenone by amine in the presence of biacetyl the primary process does not involve electron transfer. On the other hand, Wong (4) has recently concluded from his CIDEP experiments of the photoreduction of naphthoquinone by pyridine and by tertiary triethyl amine that the primary process is a hydrogen abstraction reaction in the first case and it becomes an electron transfer reaction in the latter case. Similarly, the early CIDNP results in the photoreduction of benzophenone by amines were interpreted based on an electron transfer mechanism (5). Further studies by Roth and co-workers (6) have revealed that the electron transfer mechanism is operative only when the amine used is the 1,4-diazobicyclo[2.2.2]octane. The CIDEP and CIDNP applications to photochemistry have been reviewed recently by Wan (7).

Flash photolysis with optical detection has also been applied to study the electron transfer mechanism in the ketone–amine systems (8). Arimitsu and co-workers (8) have reported that among a number of amines quenching the triplet benzophenone, only the *N*,*N*-dialkylanilines produce radical ions. Although esr spectroscopy is now commonly used to follow photochemical reactions in solution and to identify the transient intermediates, it has not been possible to confirm the presence and the fate of the counter amine radical cation in the ketone–amine photochemical systems.

We wish to report here the first high resolution esr observations of contact ammonium ion-pairs of hexafluoroacetone and the radical anion of α,α,α-trifluoroacetophenone.[1] While the results will shed some light on the controversial electron transfer

[1]A charged ion aggregate involving the ammonium cation and a ninhydrin anion radical, in rapid equilibrium with the free ninhydrin anion radical and the tetraalkylammonium salt, has been proposed to account for the variation of esr parameters as a function of the ammonium salt concentration (9).

0008-4042/79/050600-03$01.00/0

mechanism in the ketone–amine photochemical reactions, the esr characterization of the here-to-fore elusive ammonium ion-pairs should be of wider interest to chemistry in general.

When a degassed cyclopropane solution of hexafluoroacetone and triethylamine was uv-irradiated within the esr cavity of a E-3 spectrometer at −78°C, a well resolved spectrum was observed (Fig. 1). The volume ratio of the sample solution was 1:1:5 for hexafluoroacetone, triethylamine, and cyclopropane, respectively. The experimental technique has been previously described (10). The spectrum in Fig. 1*a* represents a septet with only the major 5 group showing on scale. The septet can be unambiguously assigned to the six fluorines by comparison with the known fluorine splitting in the hexafluoroacetone ketyl generated electrochemically (11). The inserts with an expanded scale in Fig. 1*b* further resolve the triplet (1:1:1) splitting due to the nitrogen nucleus ^{14}N, $I = 1$. Additional but partially resolved second-order fluorine splittings are also observed which were predicted by Fessenden (12). The spectrum is therefore assigned to the contact ammonium ion-pair of the hexafluoroacetone. The esr parameters are listed in Table 1.

The contact ammonium ion-pair is produced probably via the following scheme:

$$[1]\quad (CF_3)_2C{=}O + h\nu \overset{ISC}{\rightsquigarrow} {}^3[(CF_3)_2C{=}O]$$

$$[2]\quad {}^3[(CF_3)_2C{=}O] + R_3N \rightarrow [R_3\dot{N}^{+}\,{}^{-}\dot{O}{-}C(CF_3)_2] \rightarrow R_2N\dot{C}HCH_3 + (CF_3)_2\dot{C}OH$$

$$[3]\quad (CF_3)_2\dot{C}OH + R_3N \rightarrow (CF_3)_2C\dot{O}^{-}\,{}^{+}NHR_3$$

(Ion-pair I)

Reactions [2] and [3] have been postulated for other ketone–amine systems by Davidson and co-workers (13) and recently by McLauchlan and Sealy (3). The ion-pair (I) formed in reaction [3] can be either a contact pair or a 'solvent separated' pair (14), depending upon the solvent involved. For example, contact ion-pairs of phenanthroquinone were normally observed in THF but the contact ion-pair would dissociate in a more polar solvent such as DMF. In the ammonium ion-pair case, a non-polar cyclopropane solvent had to be used because the ion-pair would dissociate even in the commonly used THF solvent. Thus, only the esr spectrum of the hexafluoroacetone radical anion was observed (Fig. 1*c* and Table 1) in THF. The choice of the proper solvent was probably the main reason why the contact ammonium ion-pairs had escaped esr observation until now.

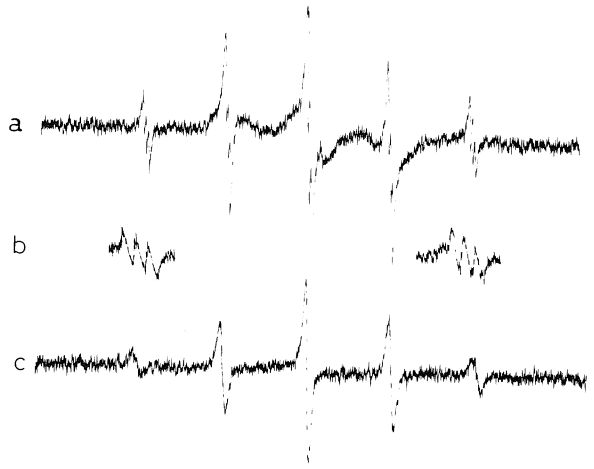

FIG. 1. Electron spin resonance spectra obtained during the photolyses of hexafluoroacetone and triethylamine in (*a*) cyclopropane at −78°C, (*b*) cyclopropane at −78°C but with an expanded scale (×4), (*c*) THF at −78°C.

Although the ketyl radical can be produced via an intermolecular hydrogen abstraction (15)

$$[4]\quad {}^3[(CF_3)_2C{=}O] + \text{cyclo-}C_3H_6 \rightarrow (CF_3)_2\dot{C}OH + \dot{C}_3H_5$$

this process is unlikely to compete favourably with the most efficient amine quenching reaction in [2]. Furthermore, the dissociation of the $(CF_3)_2\dot{C}OH$ radical into the radical anion $(CF_3)_2CO^{\dot{-}}$ and H^+ in the absence of amine was not observed even in the presence of added alkali metal salts such as the metal tetraphenylborate. In the presence of a tertiary amine, it is thought that the ionization in reaction [3] requires the formation of a complex in which the hydrogen bonding is essential between the ketyl radical and the nitrogen atom of the amine.

The effect of solvent on the observation of ammonium ion-pairs also depends upon the individual ketone used. When a THF solution of α,α,α-trifluoroacetophenone and triethylamine was photolyzed within an esr cavity, a contact ammonium ion-pair was readily observed. In addition to the well known pattern of the hyperfine splittings of the trifluoroacetophenone radical anion, the nitrogen triplet splitting was resolved (Table 1). However, if acetonitrile was used as the solvent such as in the CIDNP experiments, no contact ammonium ion-pair could be observed. If a THF solution of the unsubstituted acetophenone and triethylamine was irradiated, again no ammonium ion-pair was observed. It appears that a trifluoromethyl group next to a carbonyl is essential for the formation and observation of a 'stable' ammonium ion-pair, but this is not always sufficient. A series of compounds, CF_3-

TABLE 1. Electron spin resonance parameters of contact ammonium ion-pairs of $(CF_3)_2CO$ and trifluoroacetophenone

Ion-pair (or radicals)	Solvent	T (°C)	a_N (G)	a_F	a_H^o	a_H^m	a_H^p	a_H^{OH}

$COCH_2COX$, with X = CH_3, CF_3, and $\underset{S}{\square}$ have been systematically studied in their photoreduction by amines in THF and none led to the observation of the contact ammonium ion-pair. Perhaps an exceptionally electron-deficient carbonyl group such as that in the hexafluoroacetone and the trifluoroacetophenone is the prerequisite for the formation of a 'stable' ammonium ion-pair.

Finally, we point out that the type of amines used also plays an important role in the observation of the contact ammonium ion-pair. Thus, in the photoreduction of trifluoroacetophenone by amines in THF, triethylamine, tributylamine, and triamylamine all yield contact ammonium ion-pairs while trimethylamine does not lead to formation of the ion-pair.

Further investigation of these contact ammonium ion-pairs in photochemical systems including CIDEP experiments is in progress.

The crystal and molelcular structure of benzil bisthiosemicarbazonatocopper(II) and the antitumour mechanism of related compounds

GORDON W. BUSHNELL AND ANNIE Y. M. TSANG
Chemistry Department, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received September 1, 1978

GORDON W. BUSHNELL and ANNIE Y. M. TSANG. Can. J. Chem. **57**, 603 (1979).

The crystal structure of benzil bisthiosemicarbazonatocopper(II) has been solved and refined to an *R*-value of 0.082. The dark red triclinic crystal has cell dimensions a = 960.8(4), b = 1090.7(6), c = 895.8(4) pm, α = 106.23°(4), β = 92.36°(7), γ = 99.50°(7), and belongs to space group $P\bar{1}$ with two molecules per cell. The measured and calculated densities are 1.571 and 1.568 g cm^{-3}, respectively, using $C_{16}H_{14}CuN_6S_2$ (mol. wt. 417.99). The copper coordination is significantly non-planar. The five non-hydrogen atoms of each original thiosemicarbazide molecule lie close to planes set at a dihedral angle of 8.9°. The fold is away from the origin and the neighbouring molecule. Bond lengths to copper are: Cu—S(1) = 223.7(3), Cu—S(2) = 223.4(3), Cu—N(13) = 197.1(6), Cu—N(23) = 197.0(7) pm. The bond angles at the Cu atom are S(1)—Cu—S(2) = 108.62°(9), N(13)—Cu—N(23) = 81.1°(3), N(13)—Cu—S(1) = 85.1°(2), and N(23)—Cu—S(2) = 85.0°(2). The first and second phenyl rings are at 100.3° and 93.0° to the mean Cu coordination plane, which is at a perpendicular distance of 330 pm from a similar plane in the inverse molecule. Intermolecular double hydrogen bonding occurs at each side of the complex between the uncoordinated nitrogen atoms, thus linking the molecules into parallel ribbons.

GORDON W. BUSHNELL et ANNIE Y. M. TSANG. Can. J. Chem. **57**, 603 (1979).

On a résolu la structure cristalline du benzyl bisthiosemicarbonato cuivre(II) et on l'a affinée jusqu'à une valeur de R de 0.082. Les dimensions de la maille du cristal triclinique rouge foncé sont a = 960.8(4), b = 1090.7(6), c = 895.8(4) pm, α = 106.23°(4), β = 92.36°(7), γ = 99.50°(7); il appartient au groupe d'espace $P\bar{1}$ et compte deux molécules par maille. Se basant sur une formule moléculaire $C_{16}H_{14}CuN_6S_2$ (masse mol. 417.99), les densités mesurées et calculées sont respectivement 1.571 et 1.568 g cm^{-3}. La coordination du cuivre est loin d'être planaire. Les cinq atomes qui ne sont pas des hydrogènes de chacune des molécules de thiosemicarbazide originales se trouvent dans des plans formant un angle dièdre de 8.9°. Le plissement s'éloigne de l'origine et de la molécule voisine. Les longueurs des liaisons avec le cuivre sont: Cu—S(1) = 223.7(3), Cu—S(2) = 223.4(3), Cu—N(13) = 197.1(6), Cu—N(23) = 197.0(7) pm. Les angles de valence au niveau de l'atome du cuivre sont S(1)—Cu—S(2) = 108.62°(9), N(13)—Cu—N(23) = 81.1°(3), N(13)—Cu—S(1) = 85.1°(2) et N(23)—Cu—S(2) = 85.0°(2). Les premier et deuxième noyaux phényles sont respectivement à des angles de 100.3° et 93.0° par rapport au plan moyen de coordination du cuivre qui est lui même à une distance perpendiculaire de 330 pm d'un plan semblable dans la molécule inverse. Il se produit une liaison hydrogène intermoléculaire double de chaque côté du complexe entre les atomes d'azote qui ne sont pas coordonnées; il y a donc une liaison de molécules en rubans parallèles.
[Traduit par le journal]

Introduction

Thiosemicarbazide reacts with a wide variety of aldehydes and ketones to form thiosemicarbazones, which may be used as ligands. Compounds formed in this way are structurally interesting, since both sulfur and nitrogen atoms may be involved in the coordination, thus invoking the *a* or *b* character of the metallic centre. The chemistry of the transition metal complexes of thiosemicarbazide and thiosemicarbazones has been reviewed (1). Certain of the

0008-4042/79/060603-05$01.00/0

copper(II) compounds of this kind have significant antitumour activity, thus 3-ethoxy-2-oxobutyraldehyde bisthiosemicarbazonatocopper(II) (abbreviated CuKTS) is effective against the Walker 256 carcinosarcoma in rats (2, 3). Binding to DNA and RNA has been established for the *N*-methylisatin β-thiosemicarbazone copper complexes (4). Inhibition of the RNA directed DNA polymerase in the virion by thiosemicarbazone copper(II) complexes prevents malignant transformation by the Rous sarcoma virus (5).

While remarkable progress in understanding the antitumour activity of these copper complexes has been made by biological methods, the chemistry remains obscure in detail. The substances administered in animal tests have often been the free ligands, and one of the early postulated mechanisms was that of removal or translocation of essential metal ions involved in biological processes (6). The work of Petering and VanGiessen (7) has shown that in the case of CuKTS it is the complex which is active. It is recognised that the transport of the complex in the body depends on the balance between hydro- and lipophilic properties and on solubility, which are substituent dependent properties. Methylation of the terminal $-NH_2$ group in a thiosemicarbazone will affect the hydrogen bonding. Booth and Sartorelli suggest that CuKTS interferes with the incorporation of thymine into DNA (8). It has also been suggested that CuKTS interacts with cellular thiols, such as those in co-enzyme A and dihydrolipoate (9–11). Petering has suggested that reduction to the cuprous state may be involved (12). The crystal structures of CuKTS and the free ligand H_2KTS have been completed (12). In order to get more insight into the antitumour mechanism of these compounds, we decided to investigate benzil bisthiosemicarbazonatocopper(II) by chemical and crystallographic methods.

Experimental

Thiosemicarbazide was recrystallised from water. Preparation of benzil bisthiosemicarbazone has been described (13). The title compound was prepared by adding 1 mmol of $CuCl_2 \cdot 2H_2O$ in water to 1 mmol of benzil ditsc in 20 mL of dimethylformamide (dmf) slowly with stirring. The reddish brown powder precipitates on addition of water. Washed with dilute HCl, water, hot EtOH, and acetone. Yield 0.31 g. *Anal.* calcd. for $C_{16}H_{14}CuN_6S_2$: C 45.98, H 3.38, N 20.11; found: C 45.95, H 3.33, N 20.36, mp 250°C; uv/visible spectrum: $\lambda_{max} = 313$ nm, $\varepsilon = 2.2 \times 10^4$, shoulder at 360 nm, $\lambda_{max} = 510$ nm, $\varepsilon = 3.8 \times 10^3$, shoulder at 565 nm. Crystals were grown by diffusion of water from gelatin into a dmf solution of the complex. Preliminary photographic work on Weissenberg and precession cameras using CuK_α radiation gave a unit cell $a = 960$, $b = 1200$, $c = 895$ pm, $\alpha = 119°$, $\beta = 88°$, $\lambda = 100°$. Picker 4-circle diffractometer measurements of 16 pairs of reflections centered at $\pm 2\theta$, Delaunay reduction (transformation matrix: $-1,0,0$; $0,-1,-1$; $0,0,1$) and least-squares refinement of the cell gave $a = 960.8(4)$, $b = 1090.7(6)$, $c = 895.8(4)$ pm, $\alpha = 106.23°(4)$, $\beta = 92.36°(7)$, $\gamma = 99.50°(7)$. The cell volume is 0.8852(7) nm^3, density = 1.571 g cm^{-3} (flotation) and 1.568 g cm^{-3} (calcd.) with 2 molecules per cell. The linear absorption coefficient for MoK_α radiation, $\lambda = 71.069$ pm, was 15.19 cm^{-1}. The crystal shape is defined by perpendicular distances of six faces from a central origin: {1,0,0}, 0.0328; {0,1,−1}, 0.123; {0,1,0}, 0.458 mm. The goniometer head axis was parallel to the length of the crystal. Intensity measurements were done on the 4-circle diffractometer controlled by a PDP 11/10 minicomputer, scanning in 50 steps of 0.04° in 2θ, and counting for 1 s per step and for 25 s at each extremity. Three standards −900, 0–50, and 0–55 were measured at intervals of 50 reflections. The measurements (total scanned = 3583) were complete to $2\theta = 50°$. There was no visible or X-ray evidence of crystal decomposition. Analysis of the standards gave a mean instability constant of 0.023 which was used to get $\sigma(I)$. 2307 reflections and 210 standards for which $I/\sigma(I) > 3$ were retained. Lorentz, polarisation, and instrument variation factors were applied. Corrections for absorption used Gaussian quadrature (14) and a $4 \times 6 \times 4$ grid. The transmission range was 0.70 to 0.91. After sorting and merging, 2164 reflections remained in the data file.

Structure Determination

The structure was solved by the use of the Patterson function. The programs used were supplied by Penfold (15) and are based on ORFLS, FORDAP, ORTEP, and ORFFE. The atomic scattering factors were those of Cromer and Waber (16). All atoms were assumed to be uncharged, and the copper atom was treated as an anomalous scatterer (17). The *R* value was 0.46 with Cu only. The lighter atoms were found by difference syntheses. The full-matrix least-squares refinement, minimising $w(|F_o| - |F_c|)^2$, was uneventful. The weights derived from counting statistics were not completely satisfactory, so a weighting scheme was devised: $w = (A + Bx + Cx^2 + Dx^3)^{-1}$ where $x = |F_o|$, $A = 5.2830$, $B = -4.4944 \times 10^{-1}$, $C = 2.9134 \times 10^{-2}$, $D = -1.2204 \times 10^{-4}$. This gave approximate constancy of $\Sigma w \Delta^2$ in sets of reflections grouped according to $|F_o|$ or $\sin\theta/\lambda$. The refinement converged at $R = 0.082$, $R_w = 0.105$ with a maximum (change/error) ratio of 0.21. Most of the hydrogen atoms were located in the final difference map, including those involved in the hydrogen bonding. The maximum peak height was 1.38×10^{-6} electrons pm^{-3} near to the Cu atom. Tables containing the structure factors and the anisotropic temperature parameters are in the Depository of Unpublished Data.[1]

Results

Fractional atomic coordinates are given in Table 1.

Figure 1 shows the molecule with labels, bond lengths, and angles. The right and left halves of the figure are closely similar. The benzene rings are normal. The bonds C(12)—C(22), C(12)—C(13), and C(22)—C(23) are predominantly single (C—C = 154 pm, C=C = 134 pm). The lengths of the bonds running from N(11) to C(12) and from N(21) to C(22) suggest multiple bonding with partial delocalisation (C=N heterocyclic = 135 pm, C—N = 147 pm, N=N = 125 pm, N—N = 146 pm). Alternate bonds C(12)—N(13), N(12)—C(11) are shorter on the left hand side, but on the right of the diagram this alternation is a little less convincing. However,

*Reference 12.

copper coordination group Cu, S(1), S(2), N(13), and N(23) is non-planar with deviations from the mean plane being −0.8, 1.3, 1.0, 4.5, and 10.5 pm, respectively. The angles between the first and second phenyl groups and the mean coordination plane were 100.3° and 93.0°, respectively. The mean coordination plane is 165 pm from the origin and hence 330 pm from its parallel and symmetrically related neighbour. All three five-membered rings containing Cu are non-planar. The five non-hydrogen atoms of each original thiosemicarbazide molecule are close to planarity (χ^2 = 29.4 and 12.6). These groups are set at a dihedral angle of 8.9°, with the coordination plane folded away from the origin and the neighbouring molecule, as can be seen in Fig. 2.

Table 3 gives the crystal packing results for the title compound. The copper atom has in addition to its distorted square coordination, an S(2)′ neighbour at a distance of 345.4(3) pm on one side only. Relevant bond angles are: S(1)—Cu—S(2)′ = 98.87°(8), S(2)—Cu—S(2)′ = 101.53°(9), N(13)—Cu—S(2)′ = 77.7°(2), N(23)—Cu—S(2)′ = 81.6°(2). Viewed perpendicular to the mean coordination planes, S(2)′ lies approximately over the centroid of the Cu, N(13), N(23) triangle. In Fig. 2, atom labels can be assigned using this information. In contrast the copper atom in CuKTS has neighbouring sulfur atoms on both sides of the coordination plane at distances of 310.1 and 331.2 pm (12).

Row 2 of Table 3 gives the hydrogen bonds present in the crystal structure. Use of Fig. 2 with mental c translations is recommended. Double hydrogen bonds link the molecules into polymeric ribbons. The hydrogen bonding in crystalline CuKTS involves the oxygen atom of the disordered ethoxy side chain. A sulfur atom also functions weakly as an H acceptor. The strongest hydrogen bond in CuKTS is a single one between a terminal NH_2 group and the central nitrogen of a thiosemicarbazonato moiety. There is therefore some resemblance between the two structures with respect to hydrogen bonding, and the differences can be ascribed to the side chain.

Comparison of the crystal structures of the title compound and CuKTS leads us to suggest that the

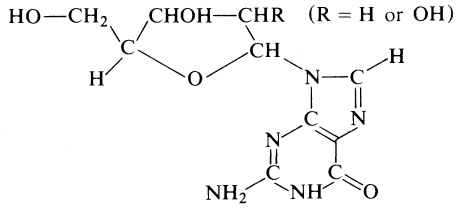
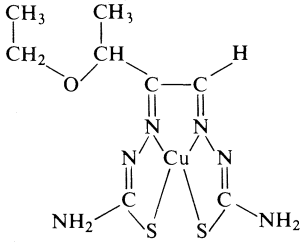
bonding of sulfur to the axial copper sites is probably not totally dominant over the forces of double H-bonding. Hydrogen bonding may be an important factor in the antitumour mechanism. Adenine, guanine, and cytosine all have amine groups adjacent to unprotonated ring nitrogen atoms, and are thus well equipped to form double H-bonds with the bis(thiosemicarbazone)copper(II) complexes. We have also noticed a structural similarity between CuKTS and the nucleosides formed from guanine and ribose or deoxyribose:





It seems from the literature that the particular effectiveness of CuKTS was discovered from animal testing studies, and that the above structural analogy has not been previously noticed. There are many thiosemicarbazone copper(II) complexes which have some antitumour activity, for which no such structural analogy can be drawn. Nevertheless, the relationship is a curious one, and warrants further investigation by crystallographic methods.

GÉRARD DOUHÉRET and MAURICE MORÉNAS. Can. J. Chem. **57**, 608 (1979).

Dielectric constants of water + glycol (mono-, di-, tri-, and tetraethyleneglycol) mixtures have been measured at 298.15 K over the entire composition range. The mixtures involving monoethyleneglycol have also been studied at temperatures from 308.15 to 288.15 K. Calculated deviations from ideality are always positive and show one maximum. Related properties have been computed: polarizability volume and excess polarizability volume, correlation factor of mixtures, and dipole moments of both components using the Mecke–Reuter treatment. Results support conclusions previously deduced from excess and partial molar volumes; they suggest that the addition of glycol molecules gives rise to a slight enhancement of the water-lattice in the water-rich region, followed by a progressive destructuring; the ether functions do not seem to play a prominent role.

GÉRARD DOUHÉRET et MAURICE MORÉNAS. Can. J. Chem. **57**, 608 (1979).

On a mesuré les constantes diélectriques de mélanges eau + glycol (mono-, di-, tri- et tétraéthylèneglycol), à 298.15 K, sur toute l'étendue de composition. Les mélanges eau + monoéthylèneglycol ont été également étudiés dans la gamme de température 288.15–308.15 K. Les écarts à la loi d'idéalité ont été calculés: ils sont toujours positifs et présentent un seul maximum. La polarisabilité et la polarisabilité d'excès, ainsi que le facteur de corrélation ont également été calculés, de même que le moment dipolaire de chacun des composés des mélanges binaires, ceci par le traitement de Mecke–Reuter. Tous ces résultats confirment les conclusions résultant des données précédemment obtenues relatives aux volumes d'excès et aux volumes molaires partiels: ils suggèrent que l'addition de molécules de glycol donne lieu à une augmentation modérée de la structuration du réseau de l'eau dans les régions riches en constituant aqueux, suivie d'une déstructuration progressive; les fonctions éther-oxyde ne paraissent pas jouer un rôle prédominant.

Introduction

In a previous systematic work on the physical and thermodynamic properties of mixtures of water + polyethyleneglycol [CH_2OH—(CH_2—CH_2O—)$_n$-CH_2OH]: n = 0, 1,2-ethanediol; n = 1, 2,2′-oxybis-ethanol; n = 2, 2,2′-[1,2-ethanediylbis(oxy)]bis-ethanol; n = 3, 2,2′-[oxybis-(2,1-ethanediyloxy)]bis-ethanol (more commonly known as mono-, di-, tri-, and tetraethyleneglycol, respectively), the acid–base properties of some of these mixtures were first investigated over the organic component mole fraction range x = 0 to 0.6 (1). Later, excess and partial molal volumes have been calculated over the whole composition range (2). These results suggest that a slight enhancement of the three-dimensional water-lattice may develop in the water-rich region, its magnitude increasing with the size of the hydrocarbon chain.

It seems worthwhile to support the foregoing conclusion by examining departures from ideality of other physical properties. The knowledge of the dielectric constant and of related excess properties appeared to us as an adequate approach to estimate the water–polyethyleneglycol interactions (3, 4). Therefore, the dielectric constants and the refractive indices were determined at 298.15 K for n = 0 to 3; the temperature effect was studied for n = 0 only. The dielectric constant deviations from ideality were computed using Decroocq's formula involving volume fractions (5). Using these results and the corresponding densities (2), the polarizability volumes, the excess polarizability volumes, the correlation factors, and the dipole moments have been calculated, following the Fröhlich theory (6) and the Mecke–Reuter treatment (7).

Experimental

Apparatus and Method

Dielectric constant measurements were carried out, at 1.8 MHz, by the heterodyne beat method with a Wissenschaftliche-Technische Werkstätten DK03 Dekameter.[2] The thermostated (±0.05 K) measuring cells (MFL-2 and MFL-3 type) were adequate to cover the dielectric-constant range (ε = 19 to 82) of water + glycol at relevant temperatures.[3] It

[3]Complete set of the actual experimental data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

0008-4042/79/060608-06$01.00/0

was checked that a good overlapping was obtained when passing from MFL-3 (ε_r = 20–90) to MFL-2 (ε_r = 7–24) measuring cells, the difference lying always within the experimental accuracy of the equipment. Reproducibility of measurements was approximately equal to ± 0.1 dielectric-constant unit. The cells were previously calibrated at 298.15 K with standard pure liquids: water, nitrobenzene, acetone, and ethylene chloride, in accordance with the manufacturer's specifications and with Natl. Bur. Stand. circular 514 (8). The results obtained for pure solvents are in very good agreement (within 0.1 unit) with the data published by Koizumi and Hanai (9); they are also in satisfactory agreement with results of Levin and Podlovchenko (10) although a systematic difference (~ 0.5 unit) is observed between the two sets of values, the difference being a little greater than the experimental accuracy of the equipment. Åkerlöf (11) published the first set of measurements on water + monoethyleneglycol covering the whole range of concentration. However, his data for the pure components show serious discrepancies with our results as well as with those of Koizumi and Hanai (9) and those of Levin and Podlovchenko (10). Furthermore, the discrepancy becomes larger as the concentration of glycol increases; it is thus likely that some systematic error has occurred in his measurements.

Refractive index measurements were carried out at 288.15, 298.15, and 308.15 K by means of a thermostated Abbé refractometer. Thermoregulation was the same as for dielectric constant measurements. Values were obtained for Na-D light (wave length: 589.3 nm). The reproductibility was as good as 0.0001. Comparison with literature data (12) for pure ethyleneglycol shows very good agreement.

Chemicals

Chemicals were used as follows.

Water was purified by means of a demineralizer. Its conductivity was always less than $1.0 \times 10^{-6}\ \Omega^{-1}\ cm^{-1}$. It was stored under previously purified dry nitrogen.

Ethyleneglycol and its derivatives were prepared from commercial best grade Fluka products. They were first dried over dehydrating agents and then fractionally distilled. The glycols were distilled under reduced pressure and the middle fraction was dried over anhydrous Na_2SO_4 for several days. The material was then redistilled and stored under nitrogen. The final products had a specific conductance less than $5 \times 10^{-7}\ \Omega^{-1}\ cm^{-1}$. The water content was measured, for all samples, by the Karl–Fischer method, and was always found to be less than 0.01%.

Mixtures were made up by weight using Mettler B5 and B6 balances, correcting for the vacuum. Samples of the mixtures have been thoroughly degassed so as to avoid air bubbles, the solubility of nitrogen in the mixtures being lower than that in the pure solvents.

Results

Dielectric Constants

Smoothing values for the dielectric constant on the whole organic component mole fraction range (x_2 = 0 to 1) are given by the following equation:

$$[1] \qquad \varepsilon_r = \sum_{i=0}^{6} a_i x_2^{\,i}$$

whose coefficients, obtained by a least-squares method, are summarized in Table 1.[3]

Deviations from ideality are determined by

$$[2] \qquad \varepsilon_r^{E} = \varepsilon_r - \varepsilon_r^{id}$$

where ε_r^{E} and ε_r^{id} are, respectively, the excess and the ideal dielectric constants. As shown by Fialkov (13), ε_r^{id} must be defined on the volume fraction scale (under certain conditions shown by Decroocq (5)). Thus we can write

$$[3] \qquad \varepsilon_r^{E} = \varepsilon_r - (1 - \phi)\varepsilon_r(1) - \phi\varepsilon_r(2)$$

where $\varepsilon_r(1)$ and $\varepsilon_r(2)$ are the dielectric constants of water and polyethyleneglycol, respectively, ϕ is the volume fraction defined on the partial molar volume basis (14)

$$[4] \qquad \phi = x_2 \overline{V}_2 / \{(1 - x_2)\overline{V}_1 + x_2 \overline{V}_2\}$$

$\overline{V}_2$ and $\overline{V}_1$ being the water and polyethyleneglycol partial molar volumes, respectively.

These excess dielectric constants characterize the water–polyethyleneglycol interactions; among them one can quote the dipole–dipole interactions and the H-bonded complexes. Figure 1 represents the changes of the excess dielectric constant when x_2 is allowed to vary over the entire composition range.

Polarizability Volumes

The static dielectric constant, $\varepsilon_r(\phi)$, of mixtures is used to calculate the polarizability volume $P(\phi)$ from the Kirkwood–Fröhlich equation:

$$[5] \qquad P(\phi) = [\varepsilon_r(\phi) - \{n(\phi)\}^2][2\varepsilon_r(\phi) + \{n(\phi)\}^2]V(\phi)/9\varepsilon_r(\phi)$$

where $V(\phi)$ is the molar volume of the mixture and $n(\phi)$ the refractive index. Some authors consider it sufficiently accurate to make a linear interpolation of $n(\phi)$ between the refractive index of the two pure liquids. However, to obtain higher accuracy we have measured refractive indices of all considered water–glycol systems at the relevant temperatures.[3] Smoothing values for the refractive index are given by

$$[6] \qquad n_D = \sum_{i=0}^{6} a_i' x_2^{\,i}$$

whose coefficients, also obtained by a least-squares method, are summarized in Table 2. Polarizability volume shows how the framework of a molecule (electrons and nuclei) is modified by an external electric field.

The variations of the excess polarizability volume in terms of x_2 are shown in Fig. 2. This excess function is calculated by an equation analogous to [2], where volume fractions have been substituted by mole fractions.

Correlation Factors

Polarizability volumes lead further to the calculation of the correlation factor g, as pointed out by Kirkwood (15) in a general theory of the dielectric polarization of polar liquids (16). This factor tends to clarify the role of hindered molecular rotation; it shows how the contribution of the individual molecular dipoles to the dielectric constant of a liquid is modified in terms of the correlation in the orientation of the neighbouring molecules. The correlation factor g has been calculated from the Fröhlich theory (6), using the following equation:

$$[7]\quad g=\frac{[\varepsilon_r(\phi)-\{n(\phi)\}^2][2\varepsilon_r(\phi)+\{n(\phi)\}^2]9kTV(\phi)\varepsilon_0}{\varepsilon_r(\phi)[\{n(\phi)\}^2+2]^2 4\pi L[\mu^g(\phi)]^2}$$

where k and L are, respectively, Boltzmann's and Avogadro's constants, ε_0 is the permittivity of vacuum, while μ^g represents the gas-phase dipole moment of the considered solvent. The rule of additivity has been applied to get the gas-phase dipole moment $\mu^g(\phi)$ from the pure components gas-phase dipole moments $\mu^g(1)$ and $\mu^g(2)$.

The $\mu^g(1)$ and $\mu^g(2)$ values relative to water and monoethyleneglycol were taken from the literature (17). For the higher homologs, an empirical equation given by Smyth (18) has been used to supply the lack of experimental data; it relates the dipole moment, μ^s, in the solvent S to that in the gas-phase, μ^g, through the following relationship:

$$[8] \qquad \mu^s = \mu^g\{1 + C[\varepsilon_r(S) - 1]\}$$

where $\varepsilon_r(S)$ is the dielectric constant of the solvent S and C is an empirical constant to which Müller (19) attributed the value 0.038. Smyth (18) has shown that this equation is valid for many substances. It should also be emphasized that gas-phase dipole moments are insensitive to temperature changes over a wide range. Consequently, the gas-phase dipole moments of the glycols were calculated from eq. [8], using the μ^s data determined for the glycols in dioxane solutions (20). Results relative to the different glycols are: $n = 0$, $\mu = 2.28$ D; $n = 1$, $\mu = 2.57$ D; $n = 2$, $\mu = 2.86$ D; $n = 3$, $\mu = 3.11$ D.

In comparison with the value given by ref. 17 for $n = 0$, 2.28 D, a very good agreement is observed.

The correlation factor for all systems continuously but slowly decreases as the mole fraction, x_2, goes from 0 to 1. Coefficients of the equation:

$$[9] \qquad g = \sum_{i=0}^{4} A_i x_2^{\,i}$$

are given in Table 3.

Dipole Moments

Finally, the dipole moments of both components of the mixtures were calculated from dielectric constant, refractive index, and density measurements. The Mecke–Reuter relationship [7], which takes into account the Onsager treatment of the reaction field of a molecule (16) allows the calculation of the dipole moment μ_2 by the following equation:

$$[10] \qquad \mu_2^{\,2} = [(\varepsilon_r, \text{app.})_2 - n_2^{\,2}]\left[2 + \frac{n_2^{\,2}}{\varepsilon_r(\phi)}\right] \times [9kTV_2\varepsilon_0/L]F/[n_2^{\,2} + 2]^2$$

If $(\varepsilon_r, \text{app.})_2$ is an apparent dielectric constant defined as

$$[11] \qquad (\varepsilon_r, \text{app.})_2 = [\varepsilon_r(\phi) - (1 - \phi)(\varepsilon_r)_1]/\phi$$

then, F, a correction factor is given as:

$$[12] \qquad F = 1 + XY$$

where

$$[13] \qquad X = \frac{[(\varepsilon_r, \text{app.})_2 - (\varepsilon_r)_1](1 - \phi_2)}{[2\varepsilon_r(\phi) + n_1^{\,2}][(\varepsilon_r, \text{app.})_2 - n_2^{\,2}]}$$

and

$$[14] \qquad Y = \frac{(n_2^{\,2} - n_1^{\,2})[2\varepsilon_r(\phi) + n_1^{\,4}/(\varepsilon_r)_1]}{2\varepsilon_r(\phi) + (\varepsilon_r)_1} - \frac{[(\varepsilon_r)_1 - n_1^{\,2}]n_1^{\,2}}{(\varepsilon_r)_1}$$

Parallel formulae can be written for the component 1.

Dipole moments are reported in Table 3, together with correlation factors; they too obey an equation of the type [9] whose coefficients A_0 to A_4 and standard deviation, σ_r, are given.

Discussion

Excess dielectric constants are positive for all the systems considered here. The magnitude of the extrema increases from mono- to triethyleneglycol (Fig. 1); at the same time, it is shifted towards water-rich region. No simple temperature dependence is observed for the water + monoethyleneglycol system: we observe a minimum at 298.15 K which is shifted towards the water-rich region when temperature is decreased.

The excess polarizability volumes are always positive too, showing the same trends as ε_r^E when the same variables, x_2 and T, are considered. It means that the strength of interactions between water and glycol is augmented when passing to higher homologs or when temperature is decreased. It appears therefore that the structure of separate components is somewhat distorted, because of the increasing disparity of the shapes of the neighbouring molecules in the different mixtures. This can be related to the phenomenon of hydrophobic hydration which is likely to occur at the same extent the hydrocarbon chains are able to counterbalance the dissociative power of polar groups, the ether oxygen atom developing a comparatively weak interaction with water (21–23).

If we now refer to the excess and partial molal volumes of these systems (2), the same remarks are valid relative to the deviations from ideality; one should nevertheless notice the slightly different concentration at which the extrema of V^E, ε_r^E, and P^E appear. The ordinates and abscissae of all extrema are summarized in Table 4.

If we consider now the variations of correlation factor, g, in terms of x_2, a slow decrease is generally observed over the whole range of concentration except for the water–monoethyleneglycol and water–diethyleneglycol systems, where a quasi-constancy of g occurs in the water-rich region ($x_2 < 0.3$–0.4), indicating that the number of neighbouring dipoles decreases, i.e. that the water molecules are progressively replaced by glycol molecules, whose correlation factor is lower. A flat maximum has also been postulated for water + monoethyleneglycol system by Hasted (24). The decrease of g suggests a progressive destructuring of the tetrahedral water-lattice. However, because of the initial slow decrease, or quasi-constancy, one cannot exclude a slight enhancement of the water-structure in the water-rich region. However, there is no point of comparison between such systems and the rapid decrease of g in water + acetonitrile mixtures (3), for which no enhancement of the aqueous structure was assumed to take place.

A supplementary argument to support this assumption lies in the variations of the dipole moments of glycols in the different systems. Except for the system water–triethyleneglycol, a maximum of μ_2 is observed, which was never the case for the above quoted water + acetonitrile solvents.

The above conclusions support a previous interpretation issued of the volumetric properties of these

binary solvents. Water–glycol systems may be classified in an intermediate position between systems like water + acetonitrile mixtures, where the role of the functional group is prominent compared to that of the hydrocarbon chain, and more structured systems, for example water + monohydric compounds, homologs of glycols; as a matter of fact, the hydrocarbon chain has to counterbalance to a far less extent the influence of polar hydroxy groups, due to the presence of ether functions.

Nuclear analogs of β-lactam antibiotics. XII. 2-Oxodesthiocephalosporins[1]

ALAIN MARTEL,[2] TERRENCE WILLIAM DOYLE,[3,4] AND BING-YU LUH

Bristol Laboratories of Canada, 100 Industrial Boulevard, Candiac, P.Q., Canada J5R 1J1

Received September 7, 1978

ALAIN MARTEL, TERRENCE WILLIAM DOYLE, and BING-YU LUH. Can. J. Chem. **57**, 614 (1979).

Epoxidation of Δ^2-1-carbacephems **2** followed by base treatment gave the allylic alcohols **4**. Oxidation of **4** gave the 2-keto-Δ^3-carbacephem **9** which could be reduced to the isomeric allylic alcohol **7**. Conversion of these intermediates to a series of biologically active cephalosporin analogs **13***g–l* and **14** is described.

ALAIN MARTEL, TERRENCE WILLIAM DOYLE et BING-YU LUH. Can. J. Chem. **57**, 614 (1979).

L'époxydation des Δ^2-carbacéphèmes-1 (**2**) suivie d'une réaction en milieu basique conduit aux alcools allyliques **4**. L'oxydation de **4** fournit les céto-2 Δ^3-carbacéphèmes **9** que l'on peut réduire en alcools allyliques isomères **7**. On décrit la transformation de ces intermédiaires en une série d'analogues (**13***g–l* et **14**) de céphalosporines biologiquement actifs.

[Traduit par le journal]

Previously, the syntheses of 1-carbacephalosporins carrying carboxylic acid, carboxylic acid ester, and bromo substituents at C(2) were described (1, 2). In view of the observation that increased antibacterial activity was seen in the 2-hetero-atom substituted analogs as the ability of the hetero atom to donate electrons to the chromophore was decreased, we were interested in the synthesis of an analog in which an electron withdrawing group would be placed at C(2).[5] For this purpose the carbonyl function was chosen as our target, e.g., **1** with X = C=O.

As we reported earlier, attempts to displace a 2-bromo function so as to give other 2-substituents, were disappointing (2). Consequently, an alternate approach departing from the Δ^2 ester **2***a* was devised. To provide a variety of ester functions which could be cleaved subsequently under mild conditions the conversion of the acid **2***b* (2) to the esters **2***c–e* was carried out.

Thus treatment of **2***b* with *tert*-butyl acetate in the presence of a catalytic amount of 60% perchloric acid gave **2***c* in 80% yield as well as recovered starting material in 18% yield (3). The conversion of **2***b* to **2***d* and **2***e* was carried out via treatment of the acid with the appropriate chloroformates so as to form the mixed anhydrides followed by thermal carbon dioxide extrusion. The yields of **2***d* and **2***e* were 89 and 62%, respectively.

FIG. 1. Nuclear analogs of cephalosporins.

We reasoned that formation of the epoxide from compounds **2***a–e* followed by base treatment would yield the allylic alcohols **4** which by suitable manipulation could be converted to the desired target molecules (Scheme 1). Treatment of **2***a*, **2***c*, and **2***e* with *m*-chloroperbenzoic acid gave the desired epoxides **3***a–c* in good yield. In the case of **2***a* and **2***e* the only detectable products were the α-epoxides **3***a* and **3***c*, respectively. The epoxidation of **2***c* gave an excellent yield of the α-epoxide (91%) and an additional amount of material containing the β-epoxide **5** as a minor constituent (35–40% of the mixture). The assignment of the α configuration to the epoxides **3***a–c* is based upon the nmr spectra of these materials. An analysis of the coupling constants for **3***a–c* of the C(6) proton indicates that the most probable conformation for these molecules is that shown for **3***A* in Fig. 2. This, coupled with the fact that the proton at C(2) appears as a triplet (J = 2.3 Hz), establishes the configuration as α.

As expected, treatment of the α-epoxides **3***a–c* with DBN in methylene chloride gave the desired allylic alcohols **4***a–c* in 83, 93.5, and 100% yields, respectively. An examination of the proton nmr of the

[1]For Part X of this series see Ref. 1.

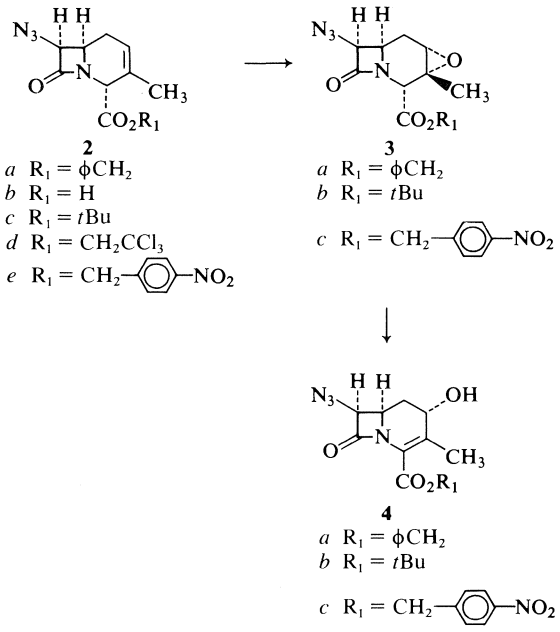

SCHEME 1

alcohols revealed that the C(2) proton appears at ~4.2 δ in **4***a*, **4***b*, and **4***c*. The coupling constants and coupling pattern are consistent with a pseudoaxial configuration for the alcohol as illustrated in Fig. 2. In an attempt to determine whether or not base-catalysed rearrangement of the β-epoxide would lead to the β-alcohol, the mixture of **3***b* and its isomer **5** was treated with DBN as for **3***b* alone. A quantitative yield of **4***b* was obtained based on the amount of **3***b* in the starting mixture. The only other detectable product was the pyridine derivative **6** obtained in 50% yield based on the amount of **5** estimated to have been present in the isomer mixture. No trace of the β-allylic alcohol **7** could be detected (Scheme 2). The

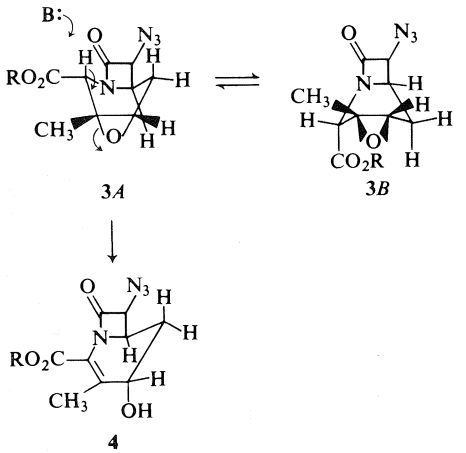

FIG. 2. Base elimination of d-epoxide.

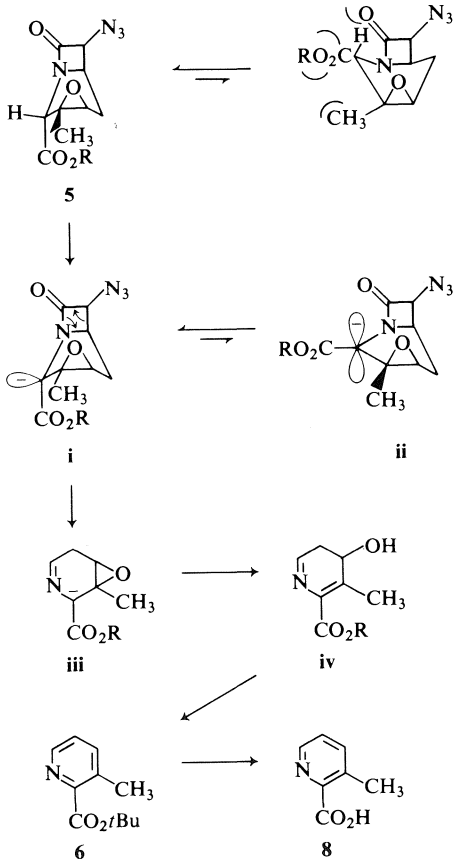
structure of **6** is based on its ir and nmr spectra and its conversion to the carboxylic acid **8** a known compound (4). The formation of **6** rather than **7** on treatment of **5** with DBN may be due to the fact that the departing hydrogen and the epoxide are not transdiaxially oriented in the base catalysed abstraction of the C(4) proton in either of the two possible conformations of **5**. Proton abstraction would give the anion (**i**) which would have to either invert or become trigonal to give **ii** to effect rearrangement. A trigonal intermediate would have severe *gauche* interactions between the C(3)-methyl, C(4)-ester groups, and the β-lactam carbonyl, and the process of inversion would necessarily go through such a sterically hindered transition state. We propose that intermediate **i** instead undergoes a retro-cycloaddition to give **iii** which then rearranges to give **iv**. Dehydration of **iv** would give the observed product **6**. No attempt to trap the azidoketene which would be expected as a by-product in this reaction was made owing to the difficulty in obtaining **5**.

The preparation of the β-allylic alcohol **7** was carried out via oxidation of the α-alcohol to the

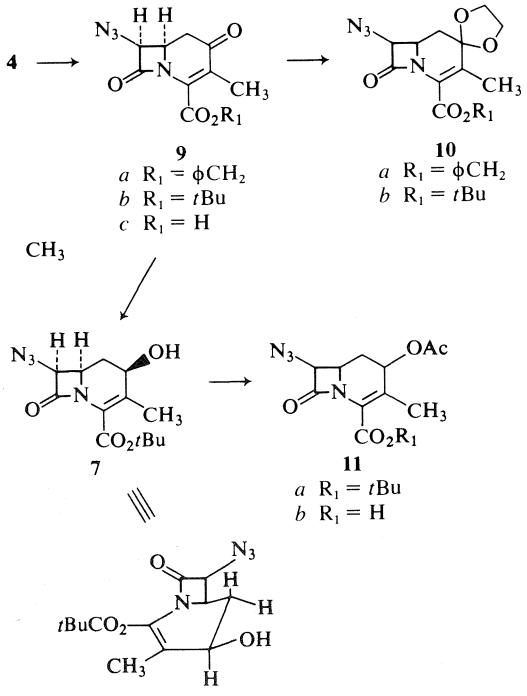


SCHEME 2

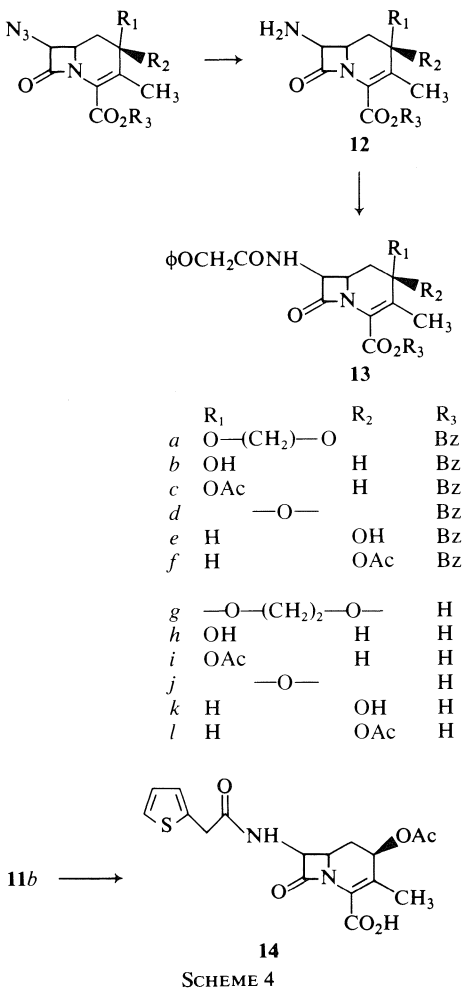
ketone followed by reduction. The oxidation of **4***a* to **9***a* was effected by the use of activated manganese dioxide in 41% yield. In view of the low yield of **9***a* obtained, an alternative oxidizing agent for the conversion of **4***b* to **9***b* was sought. Treatment of **4***b* with *N*-chlorosuccinimide – dimethyl sulfide in methylene chloride (5) gave, after work up, the desired ketone **9***b* in 75% yield. As a test of the stability of the 2-ketocarbacephalosporin system to acid, the removal of the *tert*-butyl ester of **9***b* was studied next. Treatment of **9***b* with trifluoroacetic acid gave the acid **9***c* in 98% yield, thus indicating the suitability of the *tert*-butyl ester protecting group in this series. Anticipating that protection of the ketone might well be desirable, the conversion of **9***a* and **9***b* to their respective ketals **10***a* and **10***b* was carried out. Treatment of **9***a* and **9***b* with ethylene glycol and a trace of *p*-toluenesulfonic acid at reflux in benzene, converted them to **10***a* and **10***b*, respectively, in moderate yields. Reduction of **9***b* with sodium borohydride gave the β-allylic alcohol **7** as the sole product of the reaction (97% yield). Conversion of **7** to its acetate **11***a* proceeded readily in 65% yield. The ester **11***a* was deblocked as the conversion of **9***b* to **9***c* to give **11***b* in good yield (Scheme 3). The structures of compounds **7**, **11***a*, and **11***b* were evident from their nmr spectra and are consistent with a β-allylic alcohol in the pseudoequatorial position.

The conversion of the azido esters to the appropriate 7-β-amido acids **13***g–l* was carried out in the usual fashion (1, 2). Reduction of **10***a* and **4***a* with hydrogen sulfide – triethylamine gave the amines **12***a* and **12***b*, respectively. These were coupled with phenoxyacetic acid using *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ) to give **13***a* and **13***b*, respectively, in 56 and 77% yields (6). Acetylation of **13***b* gave the acetate **13***c* (91.5%). Oxidation of **13***b* with manganese dioxide yielded **13***d* (63.5%) which was reduced to **13***e* using sodium borohydride (92%). Acetylation of **13***e* gave the acetate **13***f* (83%). With the esters **13***a–f* in hand, these were converted to the carboxylic acids **13***g–l* via hydrogenation using 10% palladium-on-carbon in ethyl acetate (Scheme 4).

As expected, **13***j* exhibited enhanced bioactivity in comparison to the parent 1-carbacephalosporin system whereas the alcohols **13***h* and **13***k* were less active and of approximately equal potency. The acetates exhibited quite different activity, **13***i* being inactive while **13***l* was close in potency to the ketone



SCHEME 3



SCHEME 4

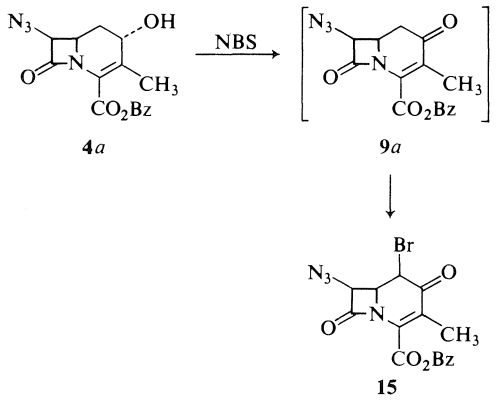


FIG. 3. NBS bromination of **4***a*.

13*j*. We speculate that the lack of activity for **13***i* may have been due to inactivation via solvolysis to a 4-hydroxy-Δ^2-desthiocephem by analogy with our results in the 2-bromo case (2).[6]

In view of the activity of **13***l*, the preparation of an analog having a side chain other than phenoxyacetamido was carried out. Thus **11***b* was treated with trimethylchlorosilane and triethylamine followed by hydrogen sulfide. The solution was evaporated to remove excess hydrogen sulfide and an equivalent of triethylamine added, followed by 2-thienylacetyl chloride. Work up gave the desired amide **14** in 70% yield from **11***b*.

The promising activity of **13***j*, **13***l*, and **14** encouraged us to attempt the preparation of a 3-acetoxymethyl analog of **13***j*. Attempts to brominate the C(3)-methyl function of **4***a* using *N*-bromosuccinimide (NBS) (Fig. 3) led to oxidation of the C(2) alcohol to the ketone followed by bromination at the C(1) position. Use of 1 equiv. of NBS gave a mixture of **4***a* and **15** in approximately equimolar amounts. Evidently oxidation of **4***a* to **9***a* occurs more slowly than the bromination of **9***a* to **15**. To avoid this side reaction, it was decided to protect the allylic alcohol in **4***b*. Treatment of **4***b* with 2,2,2-trichloroethyl chloroformate and 1,5-diazobicyclo[4.3.0]-5-nonene gave the carbonate **16** in 85% yield.

Treatment of **16** with NBS gave the crude bromomethyl compound **17** which was converted to the acetoxymethyl compound **18** by treatment with sodium acetate in dimethylformamide. The overall yield was 59.5% from **16**. The azido function was converted to the amine using hydrogen sulfide – triethylamine and the amine converted to the 2-thienylacetamide **20** in 53% yield from **18**. Cleavage of the 2,2,2-trichloroethyl carbonate with zinc dust in acetic acid proceeded smoothly (94% yield) to give the alcohol **21** (7). Oxidation of **21** with manganese dioxide gave two products. In addition to a low yield of the desired 2-keto compound **22** (25%) there was obtained traces of an overoxidation product **23** in which the methylene α to the thienyl group was oxidized to the ketone.

All attempts to remove the *tert*-butyl ester function of **22** led to decomposition of the material. In view of the publication of a more facile route to the 3-acetoxymethylcarbacephams by the Merck Laboratories, further work in this series was abandoned (8).

An extensive discussion of the biological activities of the compounds discussed in this and earlier papers of the series will be forthcoming.

Experimental

The infrared spectra were recorded on a Unicam SP-200G grating ir spectrophotometer. The uv spectra were recorded on a Unicam SP-800 uv spectrophotometer. The nmr spectra were determined on a Varian A60-A spectrometer using tetramethyl silane as an internal standard. Melting points are uncorrected except where noted and were determined on a Gallenkamp melting point apparatus. The analyses were performed by Micro-Tech Laboratories, Skokie, IL.

tert-Butyl 3-Methyl-7-β-azido-Δ²-desthiocephem-4-carboxylate (2c)

To a solution of 2.50 g (11.25 mmol) of **2***b* in 75 mL of *tert*-butyl acetate was added 2 drops of 60% perchloric acid. The solution was let stand 6 days at ambient temperature (20–25°C). The solution was evaporated and the residue partitioned between ether and 10% sodium bicarbonate. The organic phase was washed twice with additional sodium bicarbonate solution, dried over sodium sulfate, and evaporated to yield 2.50 g (80%) of **2***c*, mp 69.5–70°C. The basic extracts were made acidic with 10% hydrochloric acid and extracted with methylene chloride. The extracts were dried over sodium sulfate and evaporated to yield 0.45 g of **2***b* (18%); ir ($CHCl_3$): 2110, 1765, 1730 cm^{-1}.

*2,2,2-Trichloroethyl 3-Methyl-7-β-azido-Δ^2-desthiocephem-4-carboxylate (**2**d)*

To a solution of 1.0 g (4.50 mmol) of **2***b* in 30 mL methylene chloride at −15°C (ice–methanol) was added 1 g (4.73 mmol) of 2,2,2-trichloroethyl chloroformate dropwise over 5 min. To this was added 0.366 mL pyridine in 15 mL methylene chloride over 10 min. The solution was stirred at −15°C for 1 h, then for 1 h at 25°C, and finally it was refluxed 1 h. The solution was poured into ice – 10% hydrochloric acid and the solution extracted with ether. The extracts were washed with 10% hydrochloric acid, water, sodium bicarbonate, and brine. The washed extracts were dried over sodium sulfate and evaporated to yield 1.41 g (89%) of **2***d*, mp 68.5°C (corrected) after recrystallization from petroleum ether (30–60°C).

p-*Nitrobenzyl 3-Methyl-7-β-azido-Δ^2-desthiocephem-4-carboxylate (**2**e)*

Treatment of 1.0 g (4.5 mmol) of **2***b* with 1.0 g (4.65 mmol) *p*-nitrobenzyl chloroformate and 0.366 mL pyridine as in the preparation of **2***d* gave 1.0 g of **2***e* (62%), mp 118–119°C. From the basic extracts there was recovered 0.36 g of **2***b* (36%); ir ($CHCl_3$): 2120, 1765, 1750 cm^{-1}.

*Preparation of **3**a–c*

*Compound **3**a*

To a solution of 2.4 g (7.3 mmol) of **2***a* in 30 mL CH_2Cl_2 was added 1.6 g (9.25 mmol, 85%) of *m*-chloroperbenzoic acid at 0–5°C (ice bath). The solution was left at 4°C for 24 h, after which it was diluted with 20 mL ether, washed with 10% aqueous $Na_2S_2O_3$ (2 × 20 mL), 10% $NaHCO_3$ (2 × 20 mL), and brine (2 × 20 mL). The organic layer was dried over Na_2SO_4 and evaporated to give an oily oxide which crystallized out on trituration with ether. Filtration gave 1.7 g (68%) of crystalline **3***a*, mp 108.5–109.5°C; ir ($CHCl_3$): 2110, 1765, 1753 cm^{-1}.

*Compound **3**b*

Treatment of 5.0 g (18.65 mmol) of **2***c* with 7.3 g of *m*-chloroperbenzoic acid as in the preparation of **3***a* gave an oil which on trituration with ether yielded 5.0 g (91%) of pure α-epoxide **3***b*, mp 121–121.5°C; ir ($CHCl_3$): 2110, 1762, 1740 cm^{-1}.

From the mother liquors an additional 400 mg of oil was obtained, the nmr spectrum of which indicated that the oil consisted of a mixture of the α- and β-epoxides plus a small amount of **2***c*. Chromatography of the oil on silica gel (15% water, w/w) using chloroform as an eluent gave 300 mg of a mixture of α- and β-isomers of the epoxide (5:3 ratio).

*Compound **3**c*

Treatment of 1 g (2.80 mmol) of **2***e* with 0.80 g (4 mmol) of *m*-chloroperbenzoic acid as in the preparation of **3***a* gave 800 mg (77%) of **3***c*, mp 117.5–118°C, recrystallized from chloroform–ether; ir ($CHCl_3$): 2110, 1770, 1750 cm^{-1}.

*Benzyl 2-α-Hydroxy-3-methyl-7-β-azido-Δ^3-desthiocephem-4-carboxylate (**4**a)*

To a cold (0–5°C) solution of 1.7 g (5.2 mmol) epoxide **3***a* in 30 mL CH_2Cl_2 was added dropwise 0.65 g DBN (5.2 mmol) in 10 mL CH_2Cl_2 over a 15-min period. Stirring was continued for 2 h at 0°C. The solution was diluted with 20 mL ether, washed with 10% HCl (1 × 50 mL), brine (3 × 20 mL), dried over Na_2SO_4, and evaporated. The oily residue upon trituration with ether crystallized. Filtration gave 1.4 g (83%) of crystalline **4***a*, mp 152–153°C; ir ($CHCl_3$): 3610, 3420, 2110, 1777, 1725, 1635(w) cm^{-1}.

tert-*Butyl 2-α-Hydroxy-3-methyl-7-β-azido-Δ^3-desthiocephem-4-carboxylate (**4**b)*

Treatment of 294 mg (1 mmol) of **3***b* (pure α-isomer) with 124 mg (1 mmol) DBN as in the above example gave 275 mg (93.5%) of **4***b*, mp 140.5–141°C, crystallized from ether; ir ($CHCl_3$): 3580(s), 3400, 2110, 1780, 1720, 1640(w) cm^{-1}.

p-*Nitrobenzyl 2-α-Hydroxy-3-methyl-7-β-azido-Δ^3-desthiocephem-4-carboxylate (**4**c)*

Treatment of 800 mg (2.14 mmol) of **3***c* with 100 mg (0.8 mmol) DBN as in the above example yielded 800 mg (100%) of **4***c*, mp 163.5–164°C, crystallized from ether; ir ($CHCl_3$): 3590(s), 3420(b), 2110, 1773, 1725, 1605 cm^{-1}.

*Benzyl 2-Keto-3-methyl-7-β-azido-Δ^3-desthiocephem-4-carboxylate (**9**a)*

To a solution of 500 mg (1.5 mmol) allylic alcohol **4***a* in 30 mL CH_2Cl_2 was added 2 g activated manganese dioxide. The mixture was stirred for 2 h at room temperature then checked by tlc. The reaction was brought to completion by further addition of 2 g activated MnO_2 and stirring 3 h more. The MnO_2 was filtered through Celite and the solvent evaporated. The residue crystallized upon trituration with ether. Filtration gave 200 mg (41%) crystalline **9***a*, mp 105.5–106.5°C; ir ($CHCl_3$): 2110, 1785, 1730, 1680, 1605(w) cm^{-1}.

tert-*Butyl 2-Keto-3-methyl-7-β-azido-Δ^3-desthiocephem-4-carboxylate (**9**b)*

To a suspension of 5.20 g (40 mmol) of *N*-chlorosuccinimide in 100 mL dry toluene was added 5 mL of dimethyl sulfide at −25°C. To this was added 1.60 g (5.45 mmol) of **4***b* in one portion and the solution was stirred 3 h at −15°C. To the solution was added 11 mL of triethylamine in 20 mL petroleum ether over 10 min. The cooling bath was removed and the solution stirred 10 min. To the solution was added 100 mL ether and it was washed with 5% hydrochloric acid, water, brine, dried over sodium sulfate, and evaporated to give an oil which crystallized on trituration with ether. Filtration yielded 1.20 g (74%), mp 117–118°C, of **9***b*; ir ($CHCl_3$): 2110, 1782, 1722, 1675, 1600 cm^{-1}.

*2-Keto-3-methyl-7-β-azido-Δ^3-desthiocephem-4-carboxylic Acid (**9**c)*

A solution of 200 mg (0.68 mmol) of **9***b* in 10 mL trifluoroacetic acid was evaporated to dryness at 40°C at reduced pressure. This procedure was repeated four times until the nmr spectrum of the residue indicated complete loss of the *tert*-butyl group. Trituration of the residue with chloroform induced crystallization. Filtration yielded 161 mg (98%) of **9***c*, mp 145–147°C (decomposition); ir (Nujol mull): 2110, 1780, 1725, 1640, 1595 cm^{-1}.

*Preparation of **10**a*

A solution of 300 mg (0.9 mmol) of **9***a* and 500 mg ethylene glycol in 50 mL benzene with ~25 mg *p*-toluenesulfonic acid added as a catalyst was refluxed for 48 h under a Dean–Stark trap. The solution was poured into water and extracted with ether. The combined extracts were washed with water, 5% sodium bicarbonate, and brine. After drying over sodium sulfate the extracts were evaporated. Trituration of the residual oil with ether and filtration gave 230 mg (67.5%) of **10***a*, mp 120–121°C; ir ($CHCl_3$): 2110, 1777, 1730, 1630(w) cm^{-1}.

*Preparation of **10**b*

Treatment of 100 mg (0.34 mmol) of **5***b* with 150 mg ethylene glycol as in the preparation of **6***a* gave 75 mg (65%) of **10***b*, mp 150–150.5°C; ir ($CHCl_3$): 2110, 1775, 1720 cm^{-1}.

*Preparation of **16***

To a solution of 5.56 g (18.9 mmol) of **4***b* in 100 mL methylene chloride at 0°C was added 4.14 g (19.5 mmol) 2,2,2-trichloroethyl chloroformate followed by 4.41 g (35.5 mmol)

DBN in 20 mL methylene chloride over 1 h. The solution was stirred 4 h at 25°C and washed with 10% hydrochloric acid, dried over sodium sulfate, and evaporated to give 7.4 g (84%) of **16** on trituration of the residual oil with ether, mp 145–145.5°C; ir ($CHCl_3$): 2110, 1775, 1765, 1755(s), 1720 cm^{-1}.

tert-*Butyl 2-β-Hydroxy-3-methyl-7-β-azido-Δ³-desthiocephem-4-carboxylate (**7**)*

To a solution of 1.20 g (4.12 mmol) of **9***b* in 40 mL tetrahydrofuran (~1% water added) at −15°C was added 81.5 mg (2.14 mmol) of sodium borohydride. The solution was stirred 30 min at −15°C and poured into 50 mL brine – 5 mL 10% hydrochloric acid. The organic phase was separated and the aqueous layer extracted with ether. The combined extracts were dried over sodium sulfate and evaporated to yield 1.15 g (97%) of **7** as an oil; ir (film): 3420(b), 2110, 1765, 1715, 1630(w) cm^{-1}.

tert-*Butyl 2-β-Acetoxy-3-methyl-7-β-azido-Δ³-desthiocephem-4-carboxylate (**11**a)*

A solution of 1.20 g (4.08 mmol) of **7** in 5 mL acetic anhydride and 7 mL pyridine was stirred 17 h at 25°C. The solution was poured into 50 mL of ice cold 10% hydrochloric acid and extracted four times with 50-mL portions of ether. The extracts were dried over sodium sulfate and evaporated. Trituration of the residual oil with ether gave 900 mg (65%) of **11***a*, mp 112–113.5°C; ir ($CHCl_3$): 2110, 1776, 1725 cm^{-1}.

*2-β-Acetoxy-3-methyl-7-β-azido-Δ³-desthiocephem-4-carboxylic acid (**11**b)*

Treatment of 500 mg (1.49 mmol) of **11***a* with trifluoroacetic acid according to the procedure given for the conversion of **9***b* to **9***c* gave 396 mg (95%) of **11***b*, mp 168–170°C (with decomposition) recrystallized from acetone; ir (Nujol mull): 2120, 2110, 1760, 1750(s), 1730, 1645 cm^{-1}.

*Preparation of **6***

To a solution of 294 mg (1 mmol) of a mixture of epoxides **3***b* and **5** (63% **3***b* and 37% **5**) in 10 mL methylene chloride at 0–5°C (ice bath) was added 124 mg (1 mmol) DBN in 5 mL methylene chloride over 5 min. The solution was stirred 1 h at 0–5°C followed by 1.5 h at 25°C. The solvent was evaporated and the residue was taken up in 25 mL ether. The ethereal layer was washed with 10 mL 5% hydrochloric acid, 5 mL water, and 25 mL brine. The organic phase was dried over magnesium sulfate and evaporated to give 275 mg of an oil. This oil was partitioned between 25 mL ether and 10 mL 10% hydrochloric acid. The acidic extract was made basic with sodium sulfate and extracted with methylene chloride (4 × 10 mL). The extracts were dried over sodium sulfate and evaporated to yield 36 mg of **6** (50.5% based on amount of β-epoxide **5** in starting material) as an oil; ir (neat): 1720, 1570  , 1370, 1310, 1260, 1235, 1175, 1140, 1105, 855, 815, 795, 725, 670 cm^{-1}.

The nonbasic ethereal layer was dried over sodium sulfate and evaporated to yield 229 mg of an oil which gave 151 mg of **4***b* on trituration with ether, identical with an authentic sample. From the mother liquors an additional 35 mg of **4***b* was isolated in slightly less pure form. The combined yield was 186 mg (100% based on the amount of α-epoxide in starting mixture).

*Hydrolysis of **6***

Treatment of 41 mg (0.212 mmol) of **6** with trifluoroacetic acid according to the procedure given for the conversion of **9***b* to **9***c* gave **7** as its trifluoroacetate salt. The salt was treated with 5 mL of a saturated methanolic solution of sodium bicarbonate at 25°C, and the solution was evaporated to dryness. The residue was extracted with chloroform to yield 7 mg of **7** which crystallized from chloroform, mp 100–106°C (lit. (4) mp 111°C).

*Preparation of **13**a*

Treatment of 220 mg (0.60 mmol) of **10***a* in 20 mL methylene chloride with hydrogen sulfide – triethylamine followed by coupling of the amine thus obtained with phenoxyacetic acid using EEDQ in the usual fashion (see preparation of **13***b*) gave 160 mg (56%) of **13***a*, mp 140–140.5°C; ir ($CHCl_3$): 3420, 1775, 1730, 1692, 1520, 1495 cm^{-1}.

*Benzyl 2-α-Hydroxy-3-methyl-7-β-(phenoxyacetamido)-Δ³-desthiocephem-4-carboxylate (**13**b)*

A solution of 1.40 g (4.27 mmol) of azide **4***a* in 30 mL CH_2Cl_2 was cooled to 0°C in an ice bath, then 1.8 mL TEA was added after which a stream of H_2S gas was bubbled through the solution for 15 min. The cooling bath was removed and the solution stirred 1 h. The solvent was evaporated and the residue pumped under high vacuum.

The crude amine was redissolved in 30 ml CH_2Cl_2 and cooled to 0°C. Then 1 g (6.66 mmol) phenoxyacetic acid and 1.5 g (6.08 mmol) EEDQ were added. The solution was let stand at 4°C for 17 h, washed with 10% HCl, saturated $NaHCO_3$ solution, brine, and dried over Na_2SO_4. Evaporation gave residue which crystallized out on trituration with CH_2Cl_2. Filtration gave 1.4 g (77%) of crystalline **13***b*, mp 176–176.5°C; ir ($CHCl_3$): 3600, 3420, 1770, 1725, 1690, 1530, 1495 cm^{-1}.

*Benzyl 2-α-Acetoxy-3-methyl-7-β-(phenoxyacetamido)-Δ³-desthiocephem-4-carboxylate (**13**c)*

Treatment of 100 mg (0.236 mmol) of **13***b* with acetic anhydride – pyridine (2 mL – 3 mL) as in the preparation of **11***a* gave 100 mg (91.5%) of pure **13***c*, mp 153.5–154°C, crystallized from ether; ir ($CHCl_3$): 3410, 1772, 1736 (1725 sh), 1690, 1520, 1495 cm^{-1}.

*Benzyl 2-Keto-3-methyl-7-β-(phenoxyacetamido)-Δ³-desthiocephem-4-carboxylate (**13**d)*

Treatment of 600 mg (1.43 mmol) of **13***b* in 80 mL methylene chloride with 5 g activated manganese dioxide for 5 h at 20°C gave 380 mg (63.5%) of **13***d*, mp 174.5–175°C; ir ($CHCl_3$): 3410, 1780, 1730, 1680 (1690s), 1520, 1495 cm^{-1}.

*Benzyl 2-β-Hydroxy-3-methyl-7-β-(phenoxyacetamido)-Δ³-desthiocephem-4-carboxylate (**13**e)*

Reduction of 380 mg (0.91 mmol) of **13***d* in 20 mL tetrahydrofuran (2% water) with 18.5 mg (0.475 mmol) sodium borohydride as in the preparation of **8** gave 350 mg (92%) of **13***e*, mp 152–153°C, on trituration of the reaction residue with ether; ir ($CHCl_3$): 3510, 3430, 3340, 1760, 1705, 1680, 1520, 1470 cm^{-1}.

*Benzyl 2-β-Acetoxy-3-methyl-7-β-(phenoxyacetamido)-Δ³-desthiocephem-4-carboxylate (**13**f)*

From 175 mg (0.415 mmol) of **13***e* was obtained 160 mg (83%) of **13***f*, mp 173–174°C, by the method previously described; ir ($CHCl_3$): 3410, 1775, 1730, 1685, 1520, 1495 cm^{-1}.

*Preparation of **13**g*

Hydrogenation of 130 mg (0.272 mmol) of **13***a* over 160 mg 10% Pd/C in 50 mL ethylacetate at 5 psi for 7 min gave 114 mg crude **13***g*. Recrystallization from methylene chloride gave 86 mg (81%) of pure **13***g*, mp 163–164°C (with decomposition); ir (Nujol mull): 2500–3600, 3340, 1775, 1685, 1670, 1520, 1495 cm^{-1}.

*2-α-Hydroxy-3-methyl-7-β-(phenoxyacetamido)-Δ³-desthiocephem-4-carboxylic Acid (**13**h)*

Reduction of 200 mg (0.472 mmol) of **13***b* as in the above example gave 120 mg (86%) of **13***h*, mp 151.5–152.5°C (with

decomposition), recrystallized from acetone; ir (Nujol mull): 3440, 3310, 2500–3600, 1763, 1730, 1710, 1645, 1545, 1495 cm^{-1}.

*2-α-Acetoxy-3-methyl-7-β-(phenoxyacetamido)-Δ^3-desthiocephem-4-carboxylic Acid (**13**i)*

Reduction of 200 mg (0.430 mmol) of **13***c* as in the previous examples gave 150 mg (90%) of **13***i*, mp 126.5–127.5°C (with decomposition), recrystallized from ether; ir (Nujol mull): 2500–3600, 3310, 1777, 1738, 1692, 1677 cm^{-1}.

*2-Keto-3-methyl-7-β-(phenoxyacetamido)-Δ^3-desthiocephem-4-carboxylic Acid (**13**j)*

Reduction of 150 mg (0.355 mmol) of **13***d* as in the previous example gave 89 mg (69%) of **13***j*, mp 162–162.5°C (with decomposition), recrystallized from acetone–ether; ir (Nujol mull): 2500–3600, 3340, 1760, 1725, 1683, 1655 cm^{-1}.

*2-β-Hydroxy-3-methyl-7-β-(phenoxyacetamido)-Δ^3-desthiocephem-4-carboxylic Acid (**13**k)*

Reduction of 175 mg (0.415 mmol) of **13***e* as in the previous examples gave 100 mg (70%) of **13***k*, mp 125.5–126.5°C (with decomposition), crystallized from ether; ir (Nujol mull): 2500–3600, 3480, 3300, 1765, 1695, 1655 cm^{-1}.

*2-β-Acetoxy-3-methyl-7-β-(phenoxyacetamido)-Δ^3-desthiocephem-4-carboxylic Acid (**13**l)*

Reduction of 140 mg (0.300 mmol) of **13***f* in the usual manner gave 80 mg (68%) of **13***l*, mp 133.5–135.5°C (with decomposition), crystallized from ether; ir (Nujol mull): 3600–2500, 3440(b), 3320, 1750, 1710, 1635 cm^{-1}.

*2-β-Acetoxy-3-methyl-7-β-(2′-thienylacetamido)-Δ^3-desthiocephem-4-carboxylic Acid (**14**)*

To a solution of 371 mg (1.325 mmol) of **11***b* in 10 mL methylene chloride at 0°C was added 0.146 g (1.34 mmol) trimethyl chlorosilane. To this was added 0.136 g (1.35 mmol) triethylamine in 2 mL methylene chloride and the solution was stirred for 10 min. To the stirred solution was added 0.5 mL triethylamine and hydrogen sulfide gas was passed through the solution for 10 min. The mixture was stirred at 0–5°C for 80 min after which the solvent was removed by evaporation. The semisolid residue was taken up in 10 mL methylene chloride to which 0.3 mL triethylamine had been added. The solution was cooled to 0–5°C and a solution of 270 mg (1.68 mmol) 2-thienylacetyl chloride in 4 mL of methylene chloride was added dropwise over 30 min. The solution was stirred 17 h at 25°C. To this was added 20 mL 5% hydrochloric acid and the solution was stirred for 15 min. The organic phase was removed, dried over sodium sulfate, and evaporated to give a residue which crystallized on trituration with ether. Filtration gave 351 mg (70%) of **14**, mp 169–170°C, recrystallized from acetone; ir (Nujol mull): 2500–3600, 3270, 1780, 1728, 1690, 1645, 1530 cm^{-1}.

tert-*Butyl 2-α-(2′,2′,2′-Trichloroethylcarbonate)-3-acetoxymethyl-7-β-azido-Δ^3-desthiocephem-4-carboxylate (**8**)*

A suspension of 1.79 g (3.82 mmol) of **16** and 1.0 g (5.6 mmol) of *N*-bromosuccinimide in 100 mL carbon tetrachloride was refluxed 25 min. The solution was washed with 5% sodium thiosulfate solution, water, and brine. The solution was then dried over sodium sulfate and evaporated to give 2.10 g of crude **17**.

The crude **17** was taken up in 20 mL of dry dimethylformamide at 0°C and 400 mg sodium acetate was added. The solution was stirred 4.5 h at 25°C and poured onto ice water. The aqueous solution was extracted with ether and the extracts were washed with water and brine then dried over sodium sulfate. Evaporation of the solution gave an oil which was chromatographed on 20 g of silica gel (15% water w/w) using benzene then benzene–ether (19:1) as eluent to yield 1.10 g (59.5%) of **18** as an oil; ir ($CHCl_3$): 2110, 1785, 1755, 1733 cm^{-1}.

tert-*Butyl 2-α-(2′,2′,2′-Trichloroethylcarbonate)-3-acetoxymethyl-7-β-(2′′-thienylacetamido)-Δ^3-desthiocephem-4-carboxylate (**20**)*

Reduction of 1.0 g (1.94 mmol) of **18** in methylene chloride using triethylamine – hydrogen sulfide in the usual manner gave the amine **19** which was taken up in 50 mL methylene chloride and cooled to 0°C. To this was added 350 mg (2.46 mmol) thienylacetic acid followed by 570 mg (2.30 mmol) EEDQ. The solution was let stand 18 h at 4°C and worked up as in the preparation of **13***b*. Trituration of the residual oil with benzene gave 650 mg (52.5%) of **20**, mp 131.5–132°C; ir ($CHCl_3$): 3320, 1780, 1755, 1730, 1680, 1510 cm^{-1}.

tert-*Butyl 2-α-Hydroxy-3-acetoxymethyl-7-β-(2′-thienylacetamido)-Δ^3-desthiocephem-4-carboxylate (**21**)*

To a solution of 920 mg (1.44 mmol) of **20** in 20 mL 90% acetic acid was added 7 g activated zinc powder. The suspension was stirred for 3 h, filtered through Celite, and the filtrate was diluted to 200 mL with ether. The solution was washed with water (3 × 50 mL), 10% sodium bicarbonate solution to neutrality, and finally with brine. The solution was dried over sodium sulfate and evaporated to give 620 mg (94%) of **21**, mp 145.5–147°C, crystallized from ether; ir ($CHCl_3$): 3400, 3320, 1780, 1725, 1680, 1515 cm^{-1}.

tert-*Butyl 2-Keto-3-acetoxymethyl-7-β-(2′-thienylacetamido)-Δ^3-desthiocephem-4-carboxylate (**22**)*

To a solution of 650 mg (1.35 mmol) of **20** in 25 mL methylene chloride under nitrogen was added 4 g manganese dioxide. The suspension was stirred for 36 h at 25°C and the MnO_2 removed by filtration and the filtrate was evaporated. The residual oil was chromatographed on 20 g silica gel (10% H_2O, w/w) using benzene as eluent. The solvent was slowly changed to benzene–ether then ether. The first compound which eluted from the column (benzene–ether, 19:1) was **23**. A total of 30 mg was obtained, mp 178–179°C.

Further elution of the column (benzene–ether, 9:1) gave 167 mg (25.5%) of the desired compound **22**, mp 155–156°C; ir ($CHCl_3$): 3400, 1777, 1720, 1685, 1598(w), 1500 cm^{-1}.

Mechanisms of bromination of uracil derivatives. 4.[1] Formation of adducts in acidic aqueous solutions and their dehydration to 5-bromouracils

OSWALD S. TEE[2] AND SUJIT BANERJEE

Department of Chemistry, Concordia University, Montreal, P.Q., Canada H3G 1M8

Received July 31, 1978

OSWALD S. TEE and SUJIT BANERJEE. Can. J. Chem. **57**, 626 (1979).

The reactions of bromine with uracil, 1-methyluracil, 3-methyluracil, and with 1,3-dimethyluracil in 0.125–2.0 *M* aqueous sulfuric acid have been examined. Under these conditions *rapid* attack by bromine upon the uracil leads to the formation of an observable intermediate, a 5-bromo-5,6-dihydro-6-hydroxyuracil, which subsequently undergoes *slow* acid-catalyzed dehydration to the appropriate 5-bromouracil. The intermediates derived from uracil and 3-methyluracil also show acid independent dehydration. The dehydration of the adduct derived from 6-methyluracil proceeds much more rapidly and so precludes observation of that adduct. The dehydrations show significant primary isotope effects for the rupture of C(5)—H bonds of the intermediates. The mechanistic implications of these results are discussed.

OSWALD S. TEE et SUJIT BANERJEE. Can. J. Chem. **57**, 626 (1979).

On a étudié la réaction du brome avec l'uracil et les méthyl-1, méthyl-3 et diméthyl-1,3 uraciles en solution dans de l'acide sulfurique aqueux à 0.125–2.0 *M*. Dans ces conditions, il se produit une attaque *rapide* de l'uracile par le brome qui conduit à la formation d'un intermédiaire qui peut être mis en évidence, le bromo-5 dihydro-5,6 hydroxy-6 uracile, et qui subit une déshydratation acido-catalysée en bromo-5 uracile approprié. Les intermédiaires provenant de l'uracile et du méthyl-3 uracile se déshydratent aussi par un mécanisme n'impliquant pas d'acide. La déshydratation de l'adduit provenant du méthyl-6 uracile se produit beaucoup plus rapidement; on ne peut donc pas le mettre en évidence. Les déshydratations présentent des effets isotopiques primaires importants pour la scission de la liaison C(5)—H de ces intermédiaires. On discute des implications mécanistiques de ces résultats.

[Traduit par le journal]

Introduction

The occurrence of uracil (**1**, $R_1 = R_2 = H$) and thymine (5-methyluracil) in nucleic acids (4), and the biological activity of 5-halouracils (4) has stimulated much work on the chemistry of these pyrimidines (5). However, only recently have there been mechanistic studies of some of their reactions with electrophiles. Johnson *et al.* (6) studied the nitration of some simple uracils in sulfuric acid, and the hydrogen–deuterium exchange of various uracil derivatives in acidic and basic deuterium oxide has been studied by several workers (7, 8; 9 and references therein).

Prior to our bromination studies (1–3) there does not appear to have been any kinetic studies of the halogenation of uracils. Wang (10) proposed that uracil and 1,3-dimethyluracil (**1**, $R_1 = R_2 = H$ and Me) react rapidly with bromine in aqueous solution to yield intermediates (**2**) which subsequently undergo dehydration to the corresponding 5-bromouracil **3** (see eq. [1]). These products also react with aqueous bromine to give isolable 5,5,-dibromo-5,6-dihydro-6-hydroxyuracils **4** (5, 10, 11) which have structures very similar to those of the proposed intermediates **2**.

In strong acid the derivatives **4** revert to 5-bromouracils **3** by the loss of HOBr (10). In a recent paper we discussed the kinetics of this type of reaction for the 6-methyluracil analogue of **4** (2).

Moore and Anderson (11) made observations which are not totally explicable in terms of the sequence **1** → **2** → **3** → **4**. They carried out potentiometric and spectrophotometric titrations of uracils with bromine in an aqueous acetate buffer of pH 4.7. They found that 1,3-dimethyluracil (**1**, $R_1 = R_2 =$ Me) and uridine (**1**, R_1 = ribosyl, $R_2 = H$) react

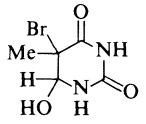
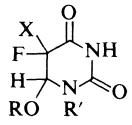
0008-4042/79/060626-09$01.00/0

with 1 mol equiv. of bromine to give, it was presumed, intermediates **2**. The conversion of **2** to 5-bromouracils **3** was then achieved by heating or by treatment with acid. In contrast, they found that uracil reacts with 2 mol equiv. of bromine and appears to give, in succession, 5-bromouracil (**3**, $R_1 = R_2 = H$) and its 5,5-dibromo derivative (**4**, $R_1 = R_2 = H$). Thus for two uracils possessing a substituent at N_1 the step **2** → **3** appeared to be quite slow, whereas for uracil the steps **1** → **3** → **4** all seem to occur fairly rapidly.

The literature now contains a fair amount of evidence which is supportive of the postulated intermediates **2**. As already mentioned, the related 5,5-dibromo derivatives **4** are isolable (5, 10, 11). More recently, Nofre and co-workers (12) have carried out ir and ^{1}Hmr spectral studies of a variety of dihydrouracils. Among these were the thymine adduct **5**, the

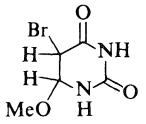


5

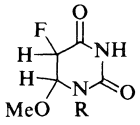


6

5,5-dibromo derivative **4** ($R_1 = R_2 = H$) and, more importantly, the adduct **2** ($R_1 = R_2 = Me$) (12*c*). Unfortunately they do not report (12*c*) how this adduct was made. Addition of various hypohalites to 5-fluorouracils gives adducts **6** (13). Likewise the 6-methoxy adduct **7** was prepared by addition of methyl hypobromite to 1-methyluracil (**1**, $R_1 = Me$, $R_2 = H$) and its ^{1}Hmr spectrum was reported (14).



7



8

Quite recently Robins and co-workers (15) have accomplished synthetically useful fluorinations of uracil derivatives using trifluoromethyl hypofluorite in trichlorofluoromethane and methanol. Their initial products are the adducts **8**, which upon treatment with base undergo elimination of methanol to give good yields of 5-fluorouracils. It was shown (15) that the fluorine and methoxyl group of **8** have a *cis* relationship. On the other hand, in the adduct **6** (X = Br, R = Me, R′ = H), prepared from 5-fluorouracil, the bromine and the methoxyl are *trans* (15). Likewise, it appears that bromine and hydroxyl are *trans* in the thymine adduct **5** and in the 1,3-dimethyluracil adduct **2** ($R_1 = R_2 = Me$) (12).

We have undertaken kinetics studies of the bromination of uracils with a view to defining more precisely the mechanistic features. Previously published work concerned debrominations analogous to **4** → **3** (2) and the bromination of 6-azauracils (3). The main thrust of the present work was to establish the intermediacy of structures **2** and to study their conversion to the substitution products **3**. A preliminary account of this work has appeared (1).

Results and Discussion

We chose as substrates for our study uracil (**1**, $R_1 = R_2 = H$), 1-methyluracil (**1**, $R_1 = Me$, $R_2 = H$), 3-methyluracil (**1**, $R_1 = H$, $R_2 = Me$), and 1,3-dimethyluracil (**1**, $R_1 = R_2 = Me$). Some additional experiments were carried out using 6-methyluracil (**14**).

Titration Studies

We first carried out spectrophotometric titrations similar to those of Moore and Anderson (11) upon the four uracil substrates (**1**, R_1, R_2 = H, Me). In agreement with their observations (11) we found that at *low* acidity (<0.05 *M* sulfuric acid) uracils possessing a substituent on N_1 (**1**, $R_1 = Me$, $R_2 = H$ or Me) undergo a rapid 1:1 reaction with bromine, whereas uracils bearing hydrogen on N_1 (**1**, $R_1 = H$, $R_2 = H$ or Me) react with 2 mol equivs. In addition, however, we found that at *high* acidity (>0.05 *M* sulfuric acid) all four uracils **1** undergo a 1:1 reaction. The uv absorptions due to bromine and the uracil are extinguished rapidly but the appearance of absorptions appropriate to the 5-bromouracils **3** occurs relatively slowly. Thus at high acidity all four uracils **1** react rapidly with bromine to form intermediates which undergo subsequent slow conversion to the corresponding substitution products **3**. The intermediates could have structures **2**, as proposed by Wang (10), and be formed from **1** via **9** as shown in [2]. Confirmation of the intermediacy of **2** was provided by the following nmr studies.

[2]

Proton Magnetic Resonance Spectra

The four uracil substrates **1** ($R_1 = H$ or Me, $R_2 = H$ or Me) show very simple spectra (Table 1) (5*b*). Upon addition of bromine to aqueous solutions of the substrates their absorptions are replaced by ones at higher field attributable to the proposed intermediates **2** (see Table 1). The 5- and 6-hydrogens

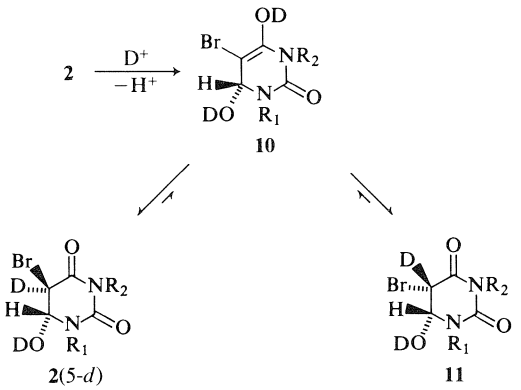
of **2** appear as doublets at δ ~ 4.5 and ~5.1, respectively. The coupling ($J_{5,6}$ ~ 2.3 Hz) between them was confirmed by spin–spin decoupling experiments. In addition, adducts **2** generated from 5-deuteriouracils lacked the signal at δ ~4.5 and the 6-hydrogen simply appeared as a singlet. Signals for *N*-methyl protons appear at δ 3.1–3.2.

These observations are very much what are to be expected for structures **2** when one considers the available literature (12–15) on similar compounds. For comparative purposes Table 1 contains literature data for three compounds: **2** ($R_1 = R_2$ = Me), **5**, and **7**. We also have observed the thymine adduct **5** but were unable to observe an adduct derived from 6-methyluracil which undergoes dehydration quite quickly (*vide infra*).

As mentioned earlier, Nofre and co-workers (12) have concluded that the bromine and hydroxyl are *trans* in the thymine adduct **5** and in the adduct **2** ($R_1 = R_2$ = Me). In view of the similarity of their chemical shifts and particularly of coupling constants ($J_{5,6}$ ~ 2.3 Hz) it appears that all of the adducts **2** have this stereochemical relationship.

In time the ^{1}Hmr signals due to the intermediates **2** decay and are replaced by signals of the 5-bromouracils (**3**). However, at the same time as **2** converts to **3** there are minor spectral changes which suggest that other processes are occurring. The intensity of the 5H doublet of **2** diminishes somewhat faster than that of the 6H doublet, even though the area of 6H resonances maintain a constant ratio to the area of appropriate *N*-methyl signals. These observations suggest that the 5-hydrogen of **2** undergoes slow exchange with the deuterated medium to produce **2** (5-*d*) [3]. Consistent with this interpretation the spectra show the appearance of a singlet in the centre

[3]



of the 6H doublet. More noticeable, however, is a singlet 3–4 Hz downfield of the 6H doublet which appears, reaches a maximum and then disappears with the appearance of the 5-bromouracil **3**. There is a similar growth and decay of an additional singlet in the *N*-methyl region. These last two observations we attribute to the formation of the diastereomer **11** with bromine and deuteroxyl *cis* to one another, and with deuterium at the 5-position (since no new peaks appear in the region of the 5H).

All of the above observations may be rationalized by enolization leading to concomitant exchange and diastereomerization as shown in [3]. In this acid-catalyzed loss of the 5-hydrogen of **2** (Br and OD *trans*) leads to the enol **10**. Ketonization of **10** can lead to either of the diastereomers **2** (5-*d*) or **11**.

We attempted to follow the kinetics of the ^{1}Hmr spectral changes to support the above rationalization and to find out the importance of the processes [3] relative to the conversion of **2** → **3**. Unfortunately the small differences in peak positions, and the ease with which the 5-bromo products **3** crystallize out of

solution prevented accurate measurements.[3] However, since we observed significant isotope effects for the conversion of **2** → **3** followed by uv spectrophotometry (next section), isotopic exchange of **2** must be slower than **2** → **3**.

As further evidence for the identity of the adducts **2**, addition of potassium iodide to the ^{1}Hmr solutions results in the regeneration of the starting uracil **1** and in the formation of iodine (eqs. [4] and [5]).

[4] $$\mathbf{2} + I^- + H^+ \rightarrow \mathbf{1} + IBr + H_2O$$

[5] $$IBr + I^- \rightarrow I_2 + Br^-$$

There are several precedents for this type of conversion in the literature. Iodide ion converts the 5,5-dibromo derivatives of barbituric acid, uracil, 6-methyluracil, and 4,6-dihydroxypyrimidine to their respective monobromo derivatives (2, 5). Also we have shown that the analogous bromide ion induced debrominations of the dibromo derivatives of 4,6-dihydroxypyrimidine and 6-methyluracil are acid catalyzed (eq. [6] and Scheme 1) (2).

[6] $$\mathbf{19} \underset{H_2O,\,-H^+}{\overset{H^+,\,-H_2O}{\rightleftharpoons}} \mathbf{18} \xrightarrow{Br^-} \mathbf{17} + Br_2$$

In summary, ^{1}Hmr studies fully support the intermediacy of the adducts **2** in the bromination of the uracils **1** in acidic media. There is some evidence of concomitant diastereomerization and isotopic exchange of **2** but in view of the observation of primary isotope effects these processes occur more slowly than the dehydration of **2** to **3**.

Kinetics

The titration studies described earlier established that in strongly acidic media (>0.05 *M* H_2SO_4) all four uracil substrates **1** react rapidly with bromine[4] in a 1:1 reaction but that the 5-bromouracils **3** appear only slowly. On the basis of the ^{1}Hmr studies the intermediates between **1** and **3** have structures **2**.

The slow appearance of the 5-bromouracils (**3**) follows first-order kinetics and the pseudo-first-order rate constants (k_{obs}) are independent of the initial concentrations of uracil **1** and of bromine. Thus the formation of the intermediates **2** is irreversible. The acidity dependence of k_{obs} values for various uracils are presented in Table 2.

For the intermediates **2** derived from 1-methyluracil (**1**, R_1 = Me, R_2 = H) and from 1,3-dimethyluracil (**1**, R_1 = R_3 = Me) the rates of appearance of the corresponding 5-bromouracils increase linearly with the acidity function H_0 (Fig. 1). The least-squares correlation lines are as follows.

For 1-methyluracil

[7] $$\log k_{obs} = -4.60 - 1.13H_0 \; (r = 0.9997)$$

For 1,3-dimethyluracil

[8] $$\log k_{obs} = -4.28 - 1.20H_0 \; (r = 0.9995)$$

Intermediates derived from 5-deuterio-1,3-dimethyluracil undergo dehydration more slowly, and give a primary kinetic isotope effect $k_H/k_D \simeq 3.4$ (see Table 2) for rupture of the C(5)—H bond.

The above results are compatible with the dehydration **2** → **3** having rate-determining deprotonation of the cation **9** (by water) formed in a pre-equilibrium from **2** (eq. [9]). Assuming [**2**] ≫ [**9**]

[9] 
which is justified by the ^{1}Hmr studies, the mechanism shown in [9] requires that

[10] $$k_{obs} = k_1 h_x / K$$

and

[11] $$\log k_{obs} = \log k_1 + pK - H_x$$

where $K = [\mathbf{2}]h_x/[\mathbf{9}]$ and $H_x = -\log h_x$ is the acidity function governing the equilibrium. Clearly the correlation lines (eqs. [7] and [8]) are compatible with [11] in view of the known linear relationships between acidity functions (16).

The acidity dependences of the rates of appearance of 5-bromouracils from the intermediates **2** derived from uracil (**1**, R_1 = R_2 = H) and from 3-methyluracil (**1**, R_1 = H, R_2 = Me) are decidedly non-linear (see Fig. 2). At the highest acidities the slopes against H_0 approach −1, whereas at the lowest acidities they approach zero. Thus it appears that

[3]In general, observation of the adducts **2** in D_2O is not without its difficulties. Some of the uracils **1** are not particularly soluble; the 5-bromouracils **3** even less so. Thus as **2** converts to **3** the latter often crystallize out. Moreover, the acidity of the medium is difficult to control because of the large amount of hydrobromic acid produced in the initial reaction **1** + Br_2 → **2**. If one starts out with an acidic medium the total acidity becomes such as to make the conversion **2** → **3** fairly fast since this conversion is acid catalyzed (*vide infra*). Consequently we chose to start with essentially neutral D_2O which becomes acidic due to the production of DBr.

[4]Using the stopped-flow method we have recently shown that bromine attack upon uracil and upon 1,3-dimethyluracil has $k_2 = 5 \times 10^4$ and 10^5 M^{-1} s^{-1}, respectively. O. S. Tee and C. G. Berks. Unpublished results.

[a]At 30°C. Each k_{obs} is the average of two or three determinations.
[b]Gives a primary kinetic isotope (k_H/k_D) of 4.32.
[c]Gives k_H/k_D = 3.37.
[d]Gives k_H/k_D = 3.49.
[e]Gives k_H/k_D = 2.42.

k_{obs} is made up of an acid dependent term and an acid independent term (k_0 say). For the appearance of 5-bromouracil we estimate $k_0 = 7.9 \times 10^{-6}\ s^{-1}$ and for the appearance of 5-bromo-3-methyluracil

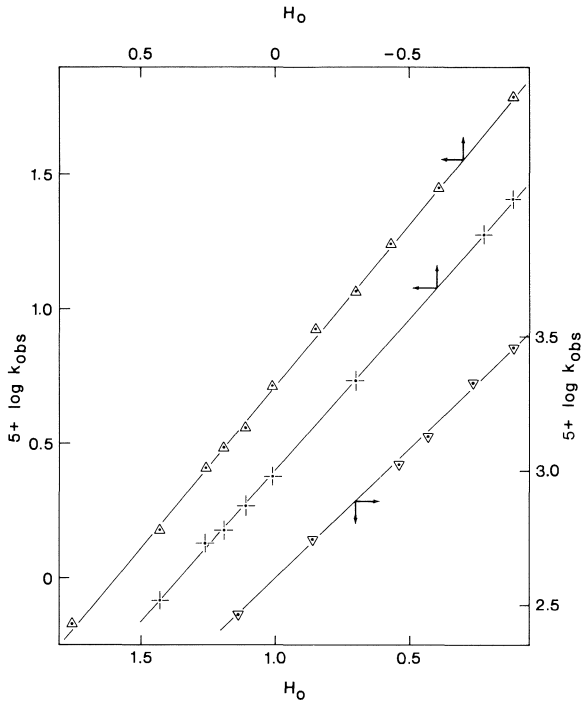

FIG. 1. Acidity dependence of k_{obs} for the formation of 5-bromouracils (**3** and **17**): △ for **3**($R_1 = R_2$ = Me) and + for **3**(R_1 = Me, $R_2 = H$), upper and lefthand scales; ▽ for **17**, lower and righthand scales.

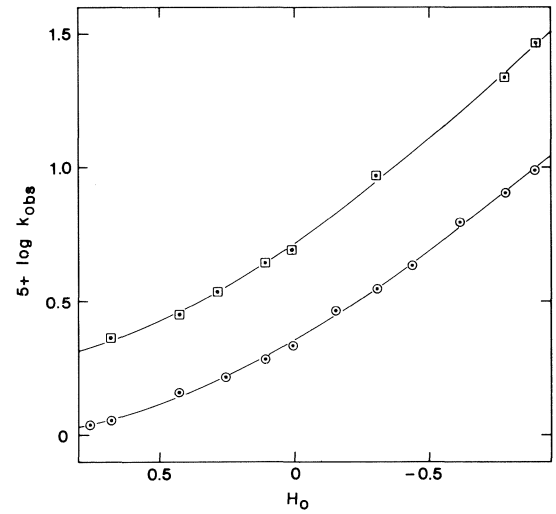

FIG. 2. Acidity dependence of k_{obs} for the formation of 5-bromouracils (**3**): □ for **3**($R_1 = H$, R_2 = Me) and ○ for **3**($R_1 = R_2 = H$).

$k_0 = 1.46 \times 10^{-5}\ s^{-1}$. Using these values the quantity $\log(k_{obs} - k_0)$ varies linearly with acidity as shown in [12] and [13].

For uracil

[12] $\log(k_{obs} - k_0) = -4.83 - 0.90H_0$ ($r = 0.9993$)

For 3-methyluracil

[13] $\log(k_{obs} - k_0) = -4.43 - 0.98H_0$ ($r = 0.9993$)

In 2 *M* sulfuric acid the intermediate derived from 5-deuteriouracil undergoes dehydration more slowly (see Table 2) and leads to $k_H/k_D = 4.32$.

In view of the similarity of the acidity dependences expressed by [12] and [13] to those of [7] and [8], and the observation of a primary isotope effect, it is reasonable to propose that the acid dependent components of the k_{obs} values for the formation of 5-bromouracil (**3**, $R_1 = R_2 = H$) and of 5-bromo-3-methyluracil (**3**, $R_1 = H$, $R_2 = Me$) are also due to the operation of mechanism [9]. The acid independent terms (k_0) may be due to either (or both) of two processes: (*a*) removal of the 5-hydrogen of cation **9** ($R_1 = H$) by hydroxide ion; (*b*) removal of the 5-hydrogen of the free base form of **9** (viz. structure

[14] 
12) by water. The first of these seems unlikely. If process (*a*) operated on cations **9** ($R_1 = H$), one would expect it to operate on cations **9** ($R_1 = Me$) also but the data for **2** → → **3** ($R_1 = Me$) show no evidence of a k_0 term. Furthermore, under our reaction conditions $[OH^-] < 10^{-13}$ *M* and [**9**] < 10^{-4} *M*, and so even if attack by hydroxide on **9** ($R_1 = H$) were diffusion controlled ($\sim 10^{10}\ M^{-1}\ s^{-1}$) the pseudo-first-order rate constant for process (*a*) would be $<10^{-7}\ s^{-1}$, whereas the observed k_0 is about $10^{-5}\ s^{-1}$.

For these reasons we favour process (*b*) in which the unstable tautomer **12** is deprotonated by water to give the anion **13** of the product (see [14]). Since the pK_a of 5-bromouracil (**3**, $R_1 = R_2 = H$) is 8.0 (5*a*, *b*) the anions **13** are reasonably stable and the proposal of **12** → **13** is not unreasonable.

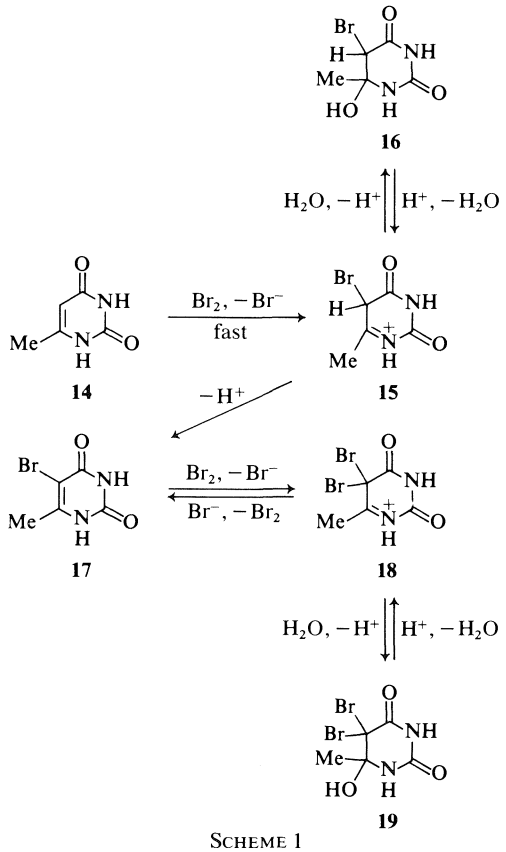
The bromination of 6-methyluracil (**14**) (Scheme 1) in sulfuric acid solutions appears to be considerably more complicated than that of the uracils **1**. The formation of 5-bromo-6-methyluracil (**17**) occurs in three distinct time frames. Immediately after mixing bromine with an equivalent amount of **14** in solution there is a rapid appearance of absorptions appropriate to **17**. This is followed by a slower ($t_{1/2}$ = 24 s in 0.5 *M* H_2SO_4) build-up of **17**. Finally, there is a much slower reaction, the rate of which is acid dependent and dependent upon bromide ion concentration ($t_{1/2}$ = 770 min, at $[Br^-] = 0.0036$ *M*, in 0.5 *M* H_2SO_4) which also yields 5-bromo-6-methyluracil **17**. This last step was dealt with in an earlier paper (2) and was shown to be due to the conversion of the 5,5-dibromo derivative **19** to **17** and bromine, the liberated bromine reacting with unreacted 6-methyluracil to produce more **17**.

The initial absorbance increase observed immediately after mixing bromine with an excess of **14** occurs too quickly to be followed by conventional means. However, the second process leading to the formation of 5-bromo-6-methyluracil **17** is easily monitored. Pseudo-first-order rate constants which were obtained are presented in Table 2 and plotted against H_0 in Fig. 1. They increase linearly with acidity according to [15].

For 6-methyluracil

[15] $\log k_{obs} = -1.44 - 0.96H_0$ ($r = 0.9992$)

This acidity dependence we ascribe to acid-catalyzed dehydration of the intermediate **16** by way of the



SCHEME 1

cation **15**. Partially or totally rate-determining deprotonation of **15** is supported by the observation of a primary kinetic isotope effect of 2.42 (see Table 2).

The steps **16** $\rightleftarrows$ **15** $\rightarrow$ **17** are in essence the same as those in mechanism [9] which was postulated earlier. However, the intermediate **16** derived from 6-methyluracil undergoes dehydration about 2500 times as fast as the intermediate (**2**, $R_1 = R_2 = H$) derived from uracil (**1**, $R_1 = R_2 = H$). This is perfectly reasonable in terms of the proposed mechanisms in that the formation of cation **15** from intermediate **16** should be more facile than the formation of **9** from **2** due to the electronic and steric effects of the 6-methyl group.

We presume that the adduct **16** arises by way of capture of water by the cation **15** formed initially by attack of bromine upon 6-methyluracil **14** (Scheme 1). This sequence is analogous to that proposed for the formation of the adducts **2** (eq. [2]). Moreover, the intermediacy of cation **15** can explain the rapid initial formation of 5-bromo-6-methyluracil (**17**) as well as the slower reaction we have measured and have ascribed to the dehydration of the adduct **16**.

The cation **15**, formed rapidly from bromine and 6-methyluracil **14**, may be partitioned between **16** and **17**. That is, it may be captured by water (k_{16}) to give the adduct **16** or it may be deprotonated by water (k_{17}) to give **17** (eq. [16]).[5] Clearly the kinetic

[16] $$\mathbf{14} + Br_2 \rightarrow \mathbf{15} \begin{matrix} \xrightarrow{k_{16}} \mathbf{16} \\ \xrightarrow{k_{17}} \mathbf{17} \end{matrix}$$

behaviour which is observed will depend upon the relative magnitudes of the first-order rate constants k_{16} and k_{17}. If they are of comparable magnitude there should be an initial relatively fast increase in absorbance due to **17** arising directly from **15** followed by a slower increase due to the slow acid-catalyzed dehydration of **16**. This is the sort of behaviour that we have observed.

The ratio k_{17}/k_{16} may be estimated from the ratio [**17**]/[**16**] before significant dehydration of **16**. At this stage the absorbance at the analytical wavelength[6] is due to **17**[5] and so [**17**] = $A_0/\varepsilon l$. The concentration of **16** may be estimated from the amount of **17** formed subsequently during the slow conversion of **16** to **17** and so [**16**] = $(A_\infty - A_0)\varepsilon l$. Accordingly the partition ratio may be obtained from

[17] $$k_{17}/k_{16} = [\mathbf{17}]/[\mathbf{16}] = A_0/(A_\infty - A_0)$$

Insertion of appropriate numerical values into [17] yields $k_{17}^{H}/k_{16} = 0.938$ (average of two values in 0.5 *M* H_2SO_4) for the 5-protio cation **15**.

For the cation **15** derived from 5-deuterio-6-methyluracil the rate constant k_{16} should be essentially unaffected, whereas k_{17} should be reduced due to a primary isotope effect. In agreement with this we find that $k_{17}^{D}/k_{16} = 0.219$ (averages of two values in 0.5 *M* H_2SO_4). From this ratio and that in the previous paragraph the isotope effect on k_{17} appears to be $k_{17}^{H}/k_{17}^{D} = 0.938/0.219 = 4.28$.

This value is similar to the kinetic isotope effect of 4.32 found for the dehydration of the adduct **2** ($R_1 = R_2 = H$) derived from uracil (Table 2) but higher than the value of 2.42 obtained directly from rate constants of the appearance of **17** (Table 2). This apparent discrepancy is removed when one takes account of the relative values of k_{16} and k_{17} (eq. [16]). Since these rate constants are of similar magnitude, the k_{17} step (**15** $\rightarrow$ **17**) is only partially rate determining in the overall dehydration of the adduct **16**, and consequently its isotope effect is attenuated.

Consider the proposed mechanism for the dehydration of **16** (eq. [18]).

[18] $$\mathbf{16} + H^+ \underset{k_{16}}{\overset{k_{15}}{\rightleftarrows}} \mathbf{15} \xrightarrow{k_{17}} \mathbf{17}$$

For a steady-state concentration of the reactive cation **15** this mechanism requires

$$k_{obs}^{H} = k_{15}k_{17}^{H}[H^+]/(k_{16} + k_{17}^{H})$$

for the 5-protio system and

$$k_{obs}^{D} = k_{15}k_{17}^{D}[H^+]/(k_{16} + k_{17}^{D})$$

for the 5-deuterio system. Division of these two equations leads to

[19] $$\frac{k_{obs}^{H}}{k_{obs}^{D}} = \frac{k_{17}^{H}}{k_{17}^{D}} \frac{(1 + k_{17}^{D}/k_{16})}{(1 + k_{17}^{H}/k_{16})}$$

Insertion of appropriate values from above into [19] gives

$$k_{obs}^{H}/k_{obs}^{D} = 4.28\,(1.219)/(1.938) = 2.69$$

which is in reasonable agreement with the value of 2.42 obtained directly from the measurement of rate constants.

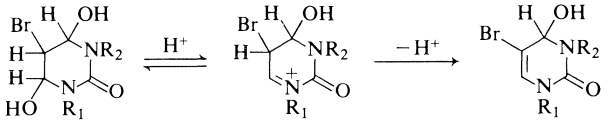
Overall the observed spectral changes, rate con-

[5]Under the conditions of our kinetic experiments the formation of the 5,5-dibromo derivative **19** should be negligible since we used [**14**] > [Br_2] and **14** reacts more rapidly with bromine than **17** (2).

[6]The appearance of **17** was monitored at a wavelength where only it absorbs significantly and so ε is the extinction coefficient of **17** at the analytical wavelength. A_0 was estimated by least-squares analysis of ln $(A_\infty - A)$ vs. time, the same analysis providing the rate constant for the appearance of **17** (Table 2).

stants and the effects of isotopic substitution upon them are consistent with mechanism [18] and with $k_{16} \sim k_{17}$. Together with earlier results (2) they provide good evidence for the total mechanism set out in Scheme 1.

The acidity function behaviours exhibited by the rate data in Table 2 are similar to what we have observed in related systems. In the present work we have slopes against H_0 of −0.90, −0.96, −0.98, −1.13, and −1.20 (see [12], [15], [13], [7], and [8]). Analysis of the rate data (17) for the acid-catalyzed dehydration of the adducts **20** gives slopes of −0.93, −1.02, and −1.10. For the acid-catalyzed debromination of the 5,5-dibromo derivative **19** (eq. [6])



20 (R_1, R_2 = H or Me)

the slope is −1.20 (2). These similarities in behaviour add further support to our interpretation of the rate data in Table 2.

Conclusions

On the basis of the evidence presented above we propose that in strongly acidic aqueous media (>0.05 *M* sulfuric acid) simple uracils **1** undergo monobromination by the mechanism set out in Scheme 2. In this, initial *rapid* attack by bromine[4] leads to the formation of observable intermediates **2**, as originally proposed by Wang (10). These intermediates undergo slow acid-catalyzed dehydration **2** ⇄ **9** → **3**, with deprotonation of the cation **9** being rate determining. At low acidities intermediates **2** bearing hydrogen at N_1 (i.e. R_1 = H) also undergo dehydration by way of the neutral species **12**, that is, by the pathway **2** ⇄ **9** ⇄ **12** → **13** ⇄ **3**.

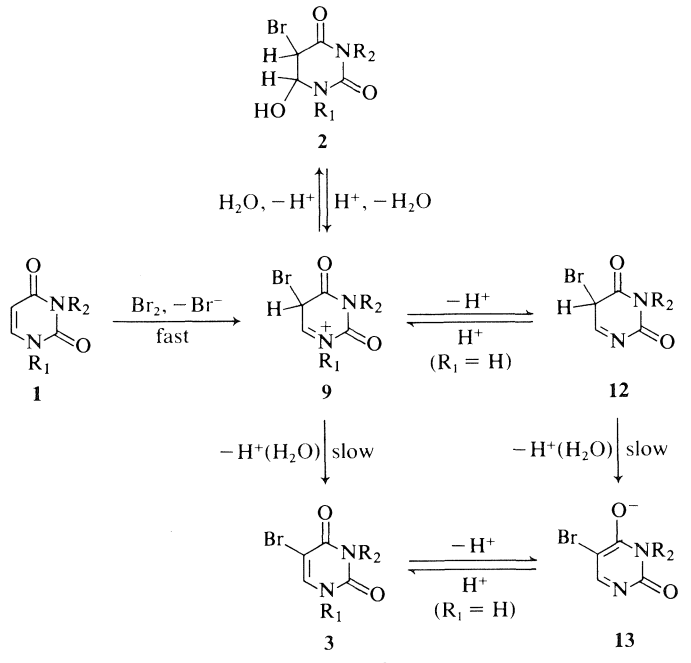
The reaction of 6-methyluracil **14** with bromine occurs via similar pathways as shown in Scheme 1. However, in this case it appears that deprotonation of the cation **15** and its capture by water (leading to **16**) are of comparable magnitude. As a consequence the deprotonation **15** → **16** is only partially rate determining and a reduced primary isotope effect is observed.

Experimental

The uracils used in this study were obtained from commercial sources and recrystallized before their use. The following compounds were prepared by literature methods: 5-deuteriouracil (8), 5-deuterio-1,3-dimethyluracil (8), 5-bromouracil (10), 5-bromo-1,3-dimethyluracil (10), 5-bromo-6-methyluracil (18), 5-bromo-6-hydroxy-5-methyldihydrouracil (19), and 5,5-dibromo-6-hydroxydihydrouracil (10).

5,5-Dibromo-6-hydroxy-6-methyldihydrouracil

Bromine (3.2 g, 20 mmol) was added to a suspension of 6-methyluracil (1.26 g, 10 mmol) in 15 mL of water. The mixture was stirred for 30 min, then refrigerated, and the solid was filtered off. Recrystallization from acetone–ligroin gave 2.28 g (88%) of the dibromo compound (20), mp 232–234°C (darkens above 200°C). *Anal.* calcd. for $C_5H_6N_2O_3Br_2$: C 19.89, H 2.00, N 9.28, Br 52.93; found: C 19.74, H 1.88, N 9.22, Br 52.85.



SCHEME 2

5-Deuterio-6-methyluracil

This was prepared from 6-methyluracil in 88% yield and with an isotopic purity above 95% using the literature method (8) reported for the deuteriation of uracil.

Kinetic Procedures

These were essentially the same as those used in earlier work (17), as were those used in the preparation of the sulfuric acid and the bromine solutions. The rate of appearance of the 5-bromouracils was monitored at wavelengths where only they absorb significantly (280–300 nm). Initial uracil concentrations were about 10^{-3} M; bromine concentrations slightly less. The cell holders of the Cary 14 spectrophotometer were thermostatted at 30°C as previously.

The higher values of the acidity function H_0 were interpolated from those given by Johnson *et al.* (21) as described before (17). To provide a continuous scale down into the 'pH' region H_0 values were calculated from the published log I values and the known pK_a of *p*-nitroaniline (21).

Proton Magnetic Resonance Spectra

Spectra of the uracils and their adducts were obtained in deuterated media using a Varian A-60 spectrometer (see Table 1 and footnote 3).

The conformation and reorientation of enclathrated 1,2-dichloroethane[1]

S. K. GARG, D. W. DAVIDSON, S. R. GOUGH, AND J. A. RIPMEESTER

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received July 20, 1978

S. K. GARG, D. W. DAVIDSON, S. R. GOUGH, and J. A. RIPMEESTER. Can. J. Chem. **57**, 635 (1979).

The rigid-lattice nmr line shape of the four-proton system in 1,2-dihaloethanes has been obtained by spectral simulation as a function of dihedral angle (ϕ) and used to show that 1,2-dichloroethane is encaged in the structure II hydrate in a *gauche* configuration with $\phi = 60 \pm 3°$. Very broad low-temperature dielectric absorption is associated with an average activation energy of 0.87 kcal/mol for guest-molecule reorientation.

S. K. GARG, D. W. DAVIDSON, S. R. GOUGH et J. A. RIPMEESTER. Can. J. Chem. **57**, 635 (1979).

On a déterminé l'allure des bandes rmn du système à quatre protons des dihalo-1,2 éthanes dans des réseaux solides; on a obtenu ces résultats en simulant les spectres en fonction des angles dièdres (ϕ) et on les a utilisés pour montrer que le dichloro-1,2 éthane est inséré dans l'hydrate de structure II dans une configuration *gauche* avec un $\phi = 60 \pm 3°$. Une absorbtion très large à basse température est associée à une énergie d'activation moyenne de 0.87 kcal/mol pour la réorientation de la molécule-hôte.

[Traduit par le journal]

Rotational isomerization of 1,2-dihaloethanes has long been a popular subject of study (see, for example, ref. 1). We show here that the shape of the rigid-lattice nmr spectrum of the four-proton system in these molecules is sensitive to the molecular configuration and may be used to determine the dihedral angle in the solid state.

A modified LAOCOON program (2) was used to simulate the four-proton spectrum of the polycrystalline powder as a function of dihedral angle. Figure 1 gives calculated derivative spectra for a number of dihedral angles (taken as zero for the *cis* or *syn* configuration) with the following molecular parameters assumed: $r_{CH} = 1.10$ Å, $r_{CC} = 1.51$ Å, all angles at C = 109.5°. These spectra have been subjected to Gaussian broadening, a relatively small value of β (0.5 G) being used to bring out clearly the spectral features. The shape is least perturbed from the doublet shape of the isolated proton pair for ϕ near 90° and most perturbed for the *cis* configuration. A pronounced central dip in the absorption occurs at all angles except those near 60°. It is clear that the angular dependence of the line shape may be used to determine the dihedral angle with considerable accuracy, provided that intermolecular broadening is sufficiently small and that the line shape is not appreciably perturbed (as it likely is for 1,2-difluoroethane) by magnetic interaction with the halogen atoms of the same molecule.

Rigid-lattice proton resonance line shapes have been recorded for 1,2-dichloroethane (*a*) in the solid solution with perdeuterated 1,2-dichloroethane and (*b*) in a D_2O clathrate hydrate lattice. Failure of 1,2-dichloroethane to form a clathrate hydrate by itself has been reported several times (3–5), although a hydrate of the doubtful (6) composition $C_2H_4Cl_2 \cdot 34H_2O$ has recently been reported to be formed in the presence of air (7). In the presence of H_2S a structure II double hydrate is readily formed (8), with 1,2-dichloroethane incorporated in the 16-hedral cages. Enclathration of this relatively large molecule may be expected to modify considerably the molecular conformation.

Figure 2 shows the proton spectrum of $C_2H_4Cl_2$ in solid solution in $C_2D_4Cl_2$ (99 at.% D) as recorded with a marginal oscillator and phase-sensitive detection. The narrow central line, whose relative amplitude decreases with increase in concentration of $C_2H_4Cl_2$, is attributed to $C_2D_3HCl_2$ impurity in the $C_2D_4Cl_2$. Otherwise the spectrum agrees well with that calculated for the *trans* (or *anti*) conformation ($\phi = 180°$) shown as the lowermost spectrum of Fig. 2. Solid 1,2-dichloroethane is well known to consist exclusively of the *trans* form (9).

The double hydrate of 1,2-dichloroethane and D_2S (98 at.% D) was prepared with D_2O (99.7 at.% D) by the procedure used to prepare neopentane–D_2S D_2O hydrate (10). Its spectrum (Fig. 3, lower curve) was recorded at very low temperatures to ensure the absence of motional narrowing. The well-defined central peak cannot be ascribed to $C_2H_4Cl_2$ and, in common with a similar feature in the spectra

[1]NRCC No. 17144.

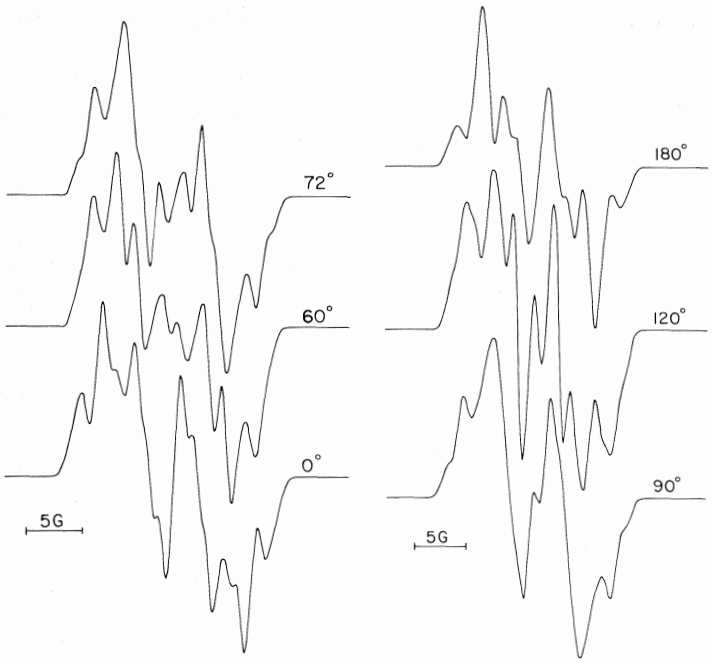

FIG. 1. Calculated derivative ^1H nmr spectrum of a 1,2-dihaloethane as a function of angle of rotation from the *cis* form.

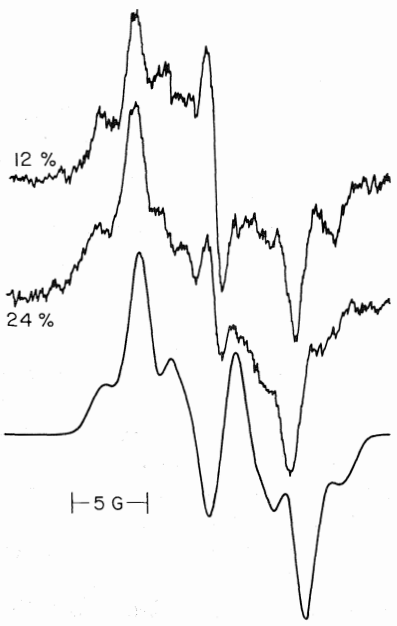

FIG. 2. Proton magnetic resonance spectra of 12 and 24% solutions of $C_2H_4Cl_2$ in $C_2D_4Cl_2$ recorded at ~57 MHz and 112 K. The bottom spectrum was calculated for the *trans* form and $\beta = 0.65$ G.

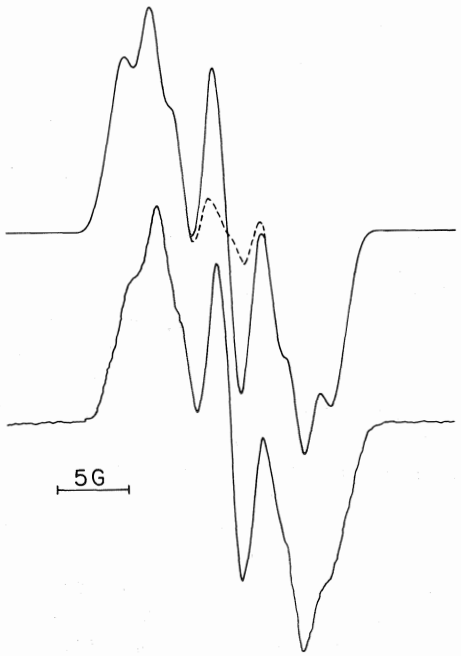

FIG. 3. Comparison of experimental ^1H nmr spectrum (below) of 1,2-dichloroethane–D_2S deuteriohydrate at ~20 MHz and 2.5 K and simulated rigid-lattice spectrum (above) with $\phi = 60°$ and HDO represented by an added central line.

of other deuteriohydrates (11), must be assigned to HDO. The remaining features may be satisfactorily assigned to 1,2-dichloroethane in which ϕ is close to 60°. The upper curve of Fig. 3 was calculated for this *gauche* conformation and $\beta = 0.65$ G, with the addition of a central (HDO) line of width $\beta = 0.75$ G and an integrated intensity 3.2% of that contributed by $C_2H_4Cl_2$. This magnitude corresponds to the presence of 0.36 at.% H in the D_2O.

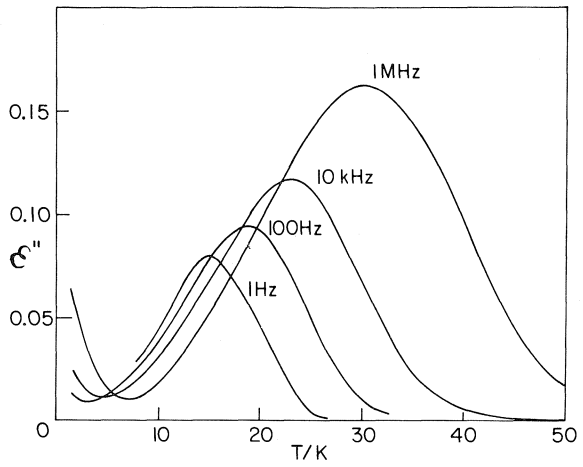

FIG. 4. Dielectric loss at low temperatures in 1,2-dichloroethane–H_2S hydrate.

The agreement between experimental and simulated spectra is decidedly poorer at angles only a few degrees removed from 60°. With due allowance for uncertainties in the assumptions made with respect to bond lengths and angles, Gaussian broadening, and neglect of conformation-dependent coupling of the protons to the chlorine nuclei, the average dihedral angle appears to be defined as $60 \pm 3°$. The configuration of the enclathrated molecule is thus not only entirely different from the *trans* form found in solid 1,2-dichloroethane but also differs from the *gauche* form which (together with the dominant *trans* form) occurs in the vapor (12). Electron diffraction studies have shown the dihedral angle of the vapor-phase *gauche* conformation to be $72 \pm 3°$ (13). Overlap repulsion of Cl atoms by water molecules in the cage walls undoubtedly plays the major role in modifying the conformation of the enclathrated molecule. The mean 'free diameter' of the 16-hedral cage is about 6.9 Å (14), whereas the van der Waals dimension of 1,2-dichloroethane through the Cl atoms is 8.1 Å for $\phi = 180°$, 7.2 Å for 72°, and 7.0 Å for 60°.

For the geometrically similar *n*-butane molecule, the *trans* form is also too large to be encaged: dielectric measurements have shown the presence of a dipolar *gauche* conformation for enclathrated *n*-butane (10). Results of low-temperature measurements of dielectric loss in the $C_2H_4Cl_2$–H_2S double hydrate are shown in Fig. 4. The rise in ε'' with decrease of temperature below 5 K arises from H_2S (10), the remaining frequency-dependent loss from 1,2-dichloroethane. From the variation of the temperature of maximum ε'' with frequency, an 'activation energy' of 0.87 kcal/mol for reorientation of 1,2-dichloroethane is obtained. The loss peak is exceptionally broad even for a hydrate-enclathrated molecule. It may be that the two loss peaks shown by *n*-butane (10), a dominant peak arising from molecular reorientation and a lower-temperature peak possibly associated with conformational interchange, are not distinguishable for 1,2-dichloroethane.

Received August 4, 1978

RAFIK O. LOUTFY, IAN W. J. STILL, MICHAEL THOMPSON, and TOONG S. LEONG. Can. J. Chem. **57**, 638 (1979).

The gas phase ionization potentials, electrochemical redox potentials and spectroscopic properties of a series of thiochroman-4-one and thiochromone derivatives have been studied. A dramatic shift in the energies of the lowest vacant and highest occupied molecular orbitals of the parent thiochromanone as a function of the addition of a double bond and/or oxidation of the sulphur atom was observed. This shift in energy of the molecular orbitals was reflected in their spectroscopic characteristics. The lowest singlet (and triplet) state of compounds **1–3** in solution is π,π^* in nature, while that of compounds **4–6** is n,π^*. These results are best explained in terms of substituent effects on the energetics of the acetophenone moiety. The change in the nature of the lowest excited state from π,π^* (**1–3**) to n,π^* (**4–6**) should result in quite different types of photochemistry for the two series.

A linear free-energy relationship between the singlet and triplet energies and the absolute difference between the oxidation and reduction potentials of the two series was found. These correlations have been utilized to estimate the half-wave oxidation potentials of compounds **3–6**. A correlation was found to exist between the gas phase ionization potential and the solution electrochemical oxidation potential.

RAFIK O. LOUTFY, IAN W. J. STILL, MICHAEL THOMPSON et TOONG S. LEONG. Can. J. Chem. **57**, 638 (1979).

On a étudié les potentiels d'ionisation en phase gazeuse, les potentiels d'oxydo-réduction électrochimiques et les propriétés spectroscopiques d'une série de dérivés de la thiochromanone-4 et de la thiochromone. On a observé des changements importants dans les énergies des orbitales moléculaires basse vacances (BV) et hautes occupées (HO) de la thiochromanone fondamentale lors de l'addition d'une double liaison et/ou lors de l'oxydation de l'atome de soufre. Ces déplacements dans les énergies des orbitales moléculaires se reflètent dans leurs caractéristiques spectroscopiques. La nature de l'état singulet (et triplet) le plus bas pour les composés **1** à **3** en solution est π,π^* alors que pour les composés **4** à **6**, elle est de n,π^*. On explique ces résultats en termes d'effets de substituants sur les niveaux énergétiques de la portion acétophénone. Le fait que la nature de l'état excité le plus faible passe de π,π^* (**1** à **3**) à n,π^* (**4** à **6**) doit être le résultat de types de photochimie assez différents pour chacune des séries.

On a noté une relation linéaire d'énergie libre entre les énergies singulet et triplet et la différence absolue entre les potentiels d'oxydation et de réduction des deux séries. On peut utiliser ces corrélations afin d'évaluer le potentiel d'oxydation à demi-vague des composés **3** à **6**. On a trouvé qu'il existe une corrélation entre le potentiel d'oxydation en phase gazeuse et le potentiel d'oxydation électrochimique en solution.

[Traduit par le journal]

Introduction

Recent years have seen the development of the use of electrochemical redox and gas phase ionization potential data to interpret photochemical reactions in which the excited states undergo electron or charge transfer processes (1). In order to understand these processes, it is necessary to know not only the excitation energy of the electrons, but also the oxidation and reduction potentials of the interacting molecules, which provide a convenient method for determining the absolute values of the energy levels of these molecules. A desire to develop the connection between spectroscopic and electrochemical data (2), coupled with our previous interest in the photochemical behavior of thiochroman-4-one derivatives (3, 4), prompted us to examine the gas phase ionization and electrochemical redox potentials, and the absorption and luminescence properties for a series of simple thiochromanones and thiochromones, **1–6** (Fig. 1).

0008-4042/79/060638-07$01.00/0

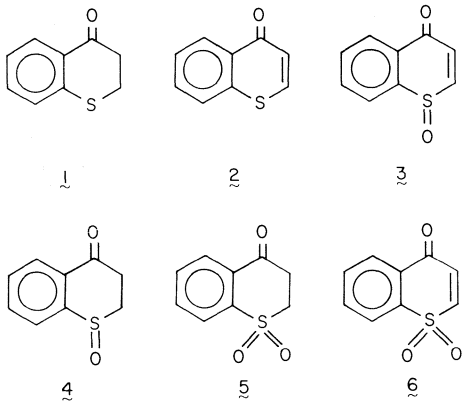

FIG. 1. The chemical structures of the thiochroman-4-one and thiochromone derivatives studied.

Interestingly, thiochromone 1-oxide (**3**), unlike other members of this series, had never been reported previously and proved to be inaccessible from thiochromone using standard oxidative procedures. Only recently did we successfully obtain thiochromone 1-oxide by a less direct route (5).

The objective of this study was, first, to carry out a molecular orbital assignment and to elucidate the nature of the singlet and triplet excited states in order to gain further insight into the photochemical behavior of this interesting series and, secondly, to establish the relationship between the lowest excited state energies and the electrochemical and gas phase parameters. These correlations were utilized (*a*) to predict the n,π* triplet energies of compounds **1**–**3**, which are undetectable by experimental spectroscopy, and (*b*) to estimate the oxidation potentials and gas phase ionization potentials of **4** and **5**, for which we were unable to obtain satisfactory photoelectron spectra because of their relative involatility.

Experimental

Thiochroman-4-one (97%) (**1**) is commercially available from Aldrich Chemical Co., Inc. and was further purified by column chromatography. Thiochromone (**2**) was prepared from **1** by dehydrogenation, as described previously (6). Thiochroman-4-one 1-oxide (**4**) and the two sulphones (**5**, **6**) were prepared by the respective oxidative procedures already described (3, 4). Thiochromone 1-oxide (**3**) was synthesized from thiochroman-4-one by a non-oxidative procedure which we have recently reported (5).

Electrochemistry

A Princeton Applied Research (PAR) model 174A polarographic analyzer, equipped with a drop mercury electrode or a Beckman 2 mm platinum button electrode model 39281, was employed for the polarographic reduction and voltammetric oxidation analysis.

The electrochemical cell assembly consisted of a PAR model 9301 and 9300, cell base and cover, with the mercury drop electrode as cathode and a platinum wire auxiliary electrode as anode. A Brinkmann model EA410 saturated calomel electrode, making contact via a PAR model 9361 non-aqueous liquid junction bridge, served as the reference electrode. For oxidation potential measurements a platinum disc electrode was employed as an anode and a Pt wire as auxiliary counter electrode.

The electrolyte, tetra-*n*-butylammonium perchlorate (TBAP), was polarographic grade and dried in a vacuum oven at 100°C for 6 h prior to use. Spectral grade methylene chloride was distilled from P_2O_5 before use. Methylene chloride was chosen as the solvent for a number of reasons. It is an excellent, yet relatively inert, solvent for a wide variety of organic compounds, it has an exceptionally wide potential window for the appropriate redox measurements, it is aprotic, and it has a low dielectric constant. Direct current (dc), normal pulse (np), and differential pulse polarograms were obtained from 0.05 m*M* solutions of compounds **1**–**6** in 0.1 *M* TBAP – methylene chloride. Measurements were performed at room temperature (22°C) under a dried argon atmosphere.

Absorption and Luminescence Spectroscopy

Ultraviolet absorption spectra were recorded on a Cary 17 spectrophotometer in spectral grade 2-methyltetrahydrofuran, methanol, methylene chloride, and acetonitrile.

Emission spectra were recorded on a Perkin-Elmer PMF4 spectrofluorimeter. Phosphorimetry was carried out using a conventional phosphorescence attachment at 77 K in 2-methyltetrahydrofuran. The luminescence excitation spectra were recorded in ratio mode. The quantum yield of luminescence was not determined.

Photoelectron Spectroscopy

The ultraviolet photoelectron spectra of compounds **1**, **2**, **3**, and **6** were recorded on the magnetic spectrometer described previously (7). The He(I) resonance line of 21.22 eV was used as the excitation source and spectra were calibrated against xenon lines at 12.13 and 13.44 eV, and the argon signal at 15.76 eV.

Results and Discussion

Gas Phase Ionization Potentials

The vertical ionization potentials obtained from the spectra of compounds **1**, **2**, **3**, and **6** shown in Fig. 2 are given in Table 1. The spectrum of **1** can be rationalized by consideration of previous analyses of the spectra of thioanisole (8) and substituted acetophenones (9). The spectrum of thioanisole in the lower IP region is discussed in terms of a 'p-model', i.e., delocalization of the sulphur lone-pair into the aromatic π-system. This results in the splitting of the parent benzene e_{1g} orbitals at 9.23 eV into three bands in thioanisole at 8.07 eV (significant sulphur character), 9.28 eV (largely unperturbed benzene π-antisymmetric orbital), and 10.14 eV (orbital of significant benzene π-symmetric character). The spectrum of *o*-methylacetophenone exhibits overlapping bands in the region 9.15–9.70 eV. The acetyl n-orbital IP occurs at 9.32 eV. The highest occupied orbital is given as the aromatic ring π-orbital at 9.15 eV. Thus we could expect for **1** four events at IP less than (approximately) 10.5 eV. The spectrum

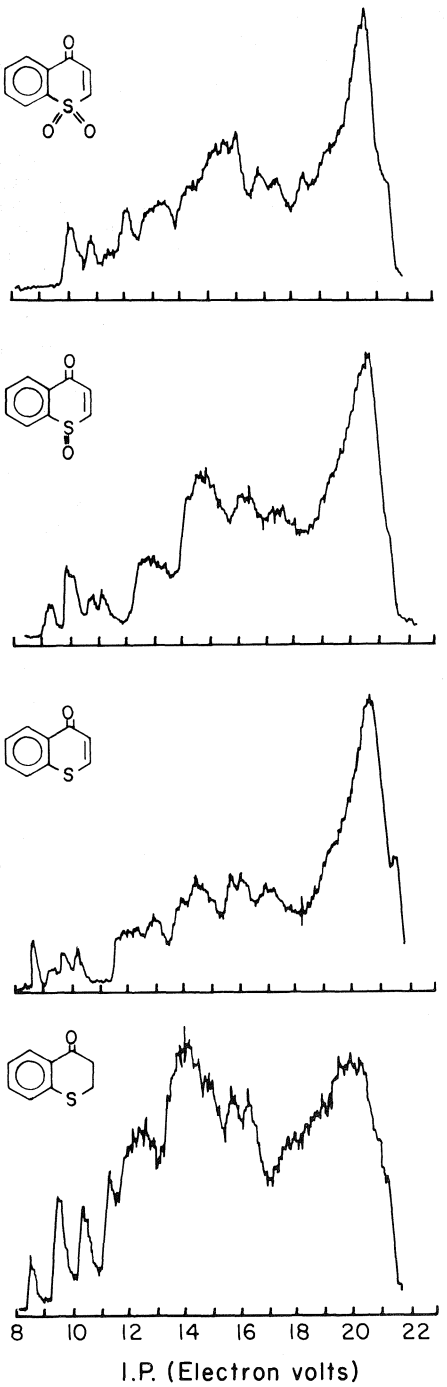

FIG. 2. Photoelectron spectra of compounds **1**, **2**, **3**, and **6**.

actually shows three bands in this region. However, the cross-section of the second peak suggests that this band contains two ionizations. Consideration of the above leads us to the conclusion that the band at 8.53 eV arises from a π-orbital with significant sulphur contribution. The composite band at 9.70 eV can be assigned to ionization of benzene-π and oxygen n-orbitals and the peak at 10.41 eV to the other of the split benzene e_{1g} orbitals. The appropriate π-IP's for **1** are greater than those for thioanisole, undoubtedly due to the presence of the electron-accepting carbonyl group. The oxygen n-ionization of 9.70 eV probably reflects the resultant effect of the sulphur atom and the increment in negative charge on the >C=O group due to electron migration from the benzene ring.

With regard to the spectrum of **2**, the addition of a further π-orbital to the situation described above for **1** will likely result in an additional ionization event in the region of 8.5–11.0 eV (10). The spectrum actually shows four peaks in this area. Therefore, the extra π-orbital is either overlapped in the lower IP region or is a component of the broad peak centred at 12.1 eV which has an adiabatic IP of about 11.4 eV. The peak at 8.68 eV can clearly be assigned to the π orbital with significant sulphur character.

As for the spectrum of **3**, the picture must now be modified to take account of a further factor expected to increase spectral complexity, the S=O bond. Previous results for alkyl-substituted sulphoxides (11) showed that the highest occupied orbital is the sulphur lone-pair (8.2–9.6 eV) followed by the S=O π-orbital (9.2–10.2 eV) and further oxygen lone-pair (11.2–12.9 eV). The spectrum of **3** shows four peaks in the range 9.0–11.5 eV. The intensity of the second peak (9.90 eV) clearly indicates that there is more than one ionization event associated with it. It seems reasonable, therefore, to assign the first band at 9.24 eV to a π-orbital of significant sulphur character and some oxygen character. As expected, the value is shifted to higher IP with the formation of the sulphur–oxygen bond. Furthermore, it is expected that the benzene e_{1g} orbitals will be shifted further to higher IP by the presence of the S=O bond. Clearly, the relatively intense peak at 9.90 eV arises in part from an ionization of one or both of these orbitals. The complexity of the spectrum prevents us from making further assignments.

Since the first ionization potential of methyl phenyl sulphone at 9.74 eV has been assigned to benzene πe_{1g} orbitals (12), it is tempting to assign the first peak in the spectrum of **6** (9.93 eV) to the related orbitals in that compound. However, the carbonyl lone-pair level is also expected to have a similar energy. Further evidence is thus required to make a positive assignment of this band. This was provided by an examination of the electrochemical and spectroscopic properties of the molecules studied in this work.

TABLE 1. Vertical ionization potentials measured by ultraviolet photoelectron spectroscopy (eV)

Compound	Ionization potential										
	1	2	3	4	5	6	7	8	9	10	11

Polarographic Reduction and Voltammetric Oxidation

Figure 3 shows typical differential pulse and dc polarograms of compounds **1**, **4**, and **5** in methylene chloride, with TBAP as supporting electrolyte. The half-wave reduction potentials, $E_{1/2}^{red}$, for the first wave, are included in Table 2. (In all cases the limiting current was diffusion-limited, the number of electrons transferred was 1, and the electron transfer coefficient, α, was 0.5.) The $E_{1/2}^{red}$ values, which relate to the energy of the lowest vacant molecular orbital (π^*), become progressively anodic from the sulphides, through the sulphoxides to the sulphones. This anodic shift of the reduction potentials is typical of acetophenones substituted with electron-withdrawing groups (13).

A typical voltammogram, that of compound **2** in methylene chloride is shown in Fig. 4. No cathodic wave was observed, indicating an irreversible electron transfer process. The oxidation peak shifted by 60 mV (anodic) on increase of the scan rate by 10-fold. A plot of the anodic peak current versus the square root of the scan rate yields a straight line with a slope of 1. These results are in agreement with an irreversible one-electron transfer electrode process with a transfer coefficient of 0.5. The half-wave oxidation potentials for compounds **1** and **2** are included in Table 2.

ultraviolet absorption spectra, recorded at ambient temperature in 2-methyltetrahydrofuran (2-MTHF), are given in Table 3 for compounds **1**–**6**. The spectra of all compounds in methanol, methylene chloride, or acetonitrile were identical to those obtained from the aforementioned solvent, with the single exception that **3** showed a shoulder at 368 nm in methanol.

Relatively strong fluorescence emission was observed for compound **1** in methylene chloride solution at ambient temperature (λ_{max}^{F}, 415 nm). Fluorescence from other members of the series was weak and difficult to determine. However, every compound exhibited relatively strong phosphorescence in 2-MTHF glass at 77 K. The phosphorescence emission from **1** and **2** is slightly structured (e.g., Fig. 5) and resembles luminescence from triplet π,π* states of aromatic ketones. Compounds **4**, **5**, and **6** show structured phosphorescence (e.g., Fig. 6) typical of n,π* triplet states of aromatic ketones. Compound **3** exhibited a unique low energy non-structured phosphorescence. The energies of the lowest excited triplet states of compounds **1**–**6** are included in Table 3.

Correlation between Gas-phase and Solution Ionization Energies

The effects of substituents on the redox potentials of molecules have been extensively studied during the past decade and several review articles and books have been written (14). Similarly, the effects of substituents on the gas phase ionization potential of molecules have also been reported (15, 16). On the other hand, few examinations of the interrelation between the gas phase ionization potential and the solution $E_{1/2}^{ox}$ are available (17–22). This is mainly due to the fact that reversible one-electron electrochemical oxidation potential data are scarce and also due to difficulties in allowing for the junction potential. Ionization potentials of some organic molecules are difficult to determine (e.g., **4** and **5**). Although ionization potentials have been calculated by

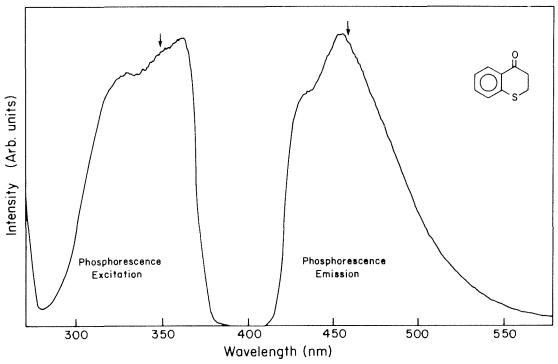

FIG. 5. Phosphorescence emission and excitation of thiochroman-4-one **1** in 2-MTHF at 77 K. The arrows indicate the wavelengths of excitation and monitoring.

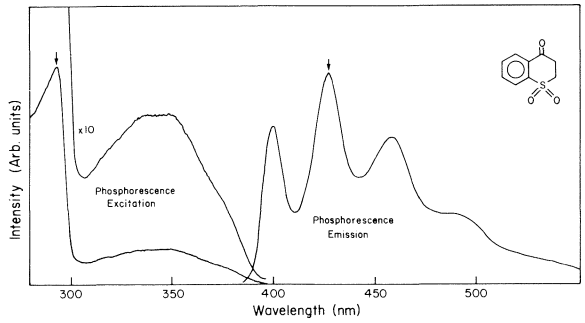

FIG. 6. Phosphorescence emission and excitation of thiochroman-4-one 1,1-dioxide **5** in 2-MTHF at 77 K. The emission is representative of the series **4**, **5**, and **6**.

studying charge transfer spectra, it would be useful to have another easily accessible experimental measure of relative ionization potentials.

It is well-known that half-wave oxidation potentials of organic compounds are closely related to the energy of their highest occupied molecular orbitals (23). This in turn is related to the gas-phase IP of a molecule by the expression

$$[1] \qquad E_{1/2}{}^{ox} = IP + \Delta F_S{}^{+} + E_{RE}{}^{0}$$

where $E_{RE}{}^{0}$ is a constant which includes the free energy of the electron in the reference electrode versus an electron *in vacuo* at infinity ($E^0 = -4.38$ V for the standard calomel electrode) (24), and $\Delta F_S{}^{+}$ is the differential real solvation energy of the radical cation (22). It is interesting to note that use of eq. [1] and the data of Table 2 results in a solvation energy of -2.34 eV for compounds **1** and **2**. This value is typical for molecules with relatively well-delocalized electron charge distribution and is consistent with the assignment of the first IP as being due to ionization of a π-orbital with significant sulphur character. The oxidation potentials of compounds **3** and **6** can be computed from their first IP's and eq. [1], assuming the same solvation energy found for compounds **1** and **2** applies. These values are shown in Table 2.

Correlation of Excited State Energies and Redox Potentials

The single configuration formula for the singlet and triplet excitation energies, E_S and E_T, respectively, can be given by the following equations (25):

$$[2] \qquad E_S = \varepsilon_1 - \varepsilon_2 - J_{12} + 2K_{12}$$

$$[3] \qquad E_T = \varepsilon_1 - \varepsilon_2 - J_{12}$$

where ε_1 and ε_2 are the energies of the highest occupied and lowest vacant molecular orbitals, respectively, J_{12} is the coulomb repulsion integral, and K_{12} is the exchange integral. A distinction must be made between the energy of the lowest vacant MO of a molecule when occupied by an electron after excitation and the energy of the empty orbital in a closed shell configuration. This difference, in the case of a singlet excited state, is $-J_{12} + 2K_{12}$ and for the triplet state is given by $-J_{12}$. Since the electrochemical half-wave oxidation and reduction potentials are related to the energies of the highest occupied (ε_1) and lowest vacant (ε_2) molecular orbitals, respectively, then the singlet and triplet excitation energies[1] can be given in terms of electrochemical redox potentials, as indicated below (2).

$$[4] \qquad E_S = a(E_{1/2}{}^{ox} - E_{1/2}{}^{red} - J_{12}{}^{s} + 2K_{12}{}^{s})$$

$$[5] \qquad E_T = b(E_{1/2}{}^{ox} - E_{1/2}{}^{red} - J_{12}{}^{s})$$

According to eq. [4], a linear relationship should exist between the absolute difference of the oxidation and reduction potentials and the energy of the singlet excited state for a series of closely related molecules, provided that the sum of the coulomb repulsion and the exchange integral is constant or varies in a regular manner within the series. Similarly, according to eq. [5], the existence of a linear free energy relationship between the redox properties of a series of molecules and their triplet energies is expected, provided that the coulomb repulsion integral is constant.

It was recently reported that a linear relationship exists between the n,π* triplet energies of a series of acetophenone derivatives and their half-wave reduction potentials (13). This correlation is only possible if both J_{12} and ε_1, or their difference, remain constant throughout the series. If we consider that the compounds **1**–**6** are simply derivatives of acetophenone, then it is possible to predict their n,π* triplet energies using the following equation (13):

$$[6] \qquad E_{T(n,\pi^*)} = -0.42(E_{1/2}\,(\text{V vs. sce}) - 0.33) + 2.3\ \text{eV}$$

The n,π* triplet energies of compounds **1**–**6**, calculated using eq. [6] from their experimental $E_{1/2}{}^{red}$ values, are shown in Table 3, along with the experimentally obtained triplet energies. It can be seen that the agreement between the calculated and experimental values is excellent for compounds **4**, **5**, and **6** which all possess a lowest n,π* triplet state. However, the triplet energies of compounds **1**, **2**, and **3** do not fit the above correlation. This strongly indicates that the lowest triplet transition of these compounds is a π → π* transition rather than a n → π* transition.

The singlet–triplet splitting energy (ΔE_{S-T}) is generally of the order of 1 eV for π,π* singlet–

[1]Where *a* and *b* are proportionality constants which, in most cases, were found to be near unity (1, 2).

triplet states and 0.2–0.5 eV for n,π* states. The mean value of ΔE_{S-T} for compounds **1**, **2**, and **3** is 0.83 eV, while that for compounds **4**, **5**, and **6** is 0.23 eV (Table 3). These results are in agreement with the assignment that **1**, **2**, and **3** possess π,π* lowest singlet and triplet states, while compounds **4**, **5**, and **6** have n,π* lowest singlet and triplet states.

According to eq. [5], the triplet energies of a series of structurally similar molecules should correlate with the absolute difference between their oxidation and reduction potentials. The data of Tables 2 and 3 show that such a correlation exists for compounds **1** **2**, and **3**. Although the oxidation potentials for compounds **4**, **5**, and **6** could not be measured experimentally, eq. [5] can be used to estimate the term $(E_{1/2}{}^{ox} - E_{1/2}{}^{red})$ and therefore the $E_{1/2}{}^{ox}$ values, through use of the experimentally determined $E_T(n,\pi^*)$ results and a value for $J_{1/2}{}^{s}$ of 1.25 eV (2). The $E_{1/2}{}^{ox}$ values are included in Table 2. It is interesting to note that, as expected, their values are beyond the experimentally attainable electrochemical potential limit.

The apparent difference between the lowest energy triplet states of compounds **3** and **6** (π,π* versus n,π*) is particularly interesting in the light of the observed differences in photochemical reactivity of these two compounds.[2] This, and related aspects of the photochemical behavior of these molecules, will be the subject of a forthcoming publication.

Conclusions

The gas phase ionization and the solution electrochemical oxidation–reduction potentials of a series of simple thiochromanones and thiochromones **1–6** have been determined. The highest occupied molecular orbital for compounds **1–3** was assigned as a π-orbital with significant sulphur character. This assignment was confirmed from the study of the ultraviolet absorption and phosphorescence spectra, where the lowest singlet and triplet states of **1–3** were found to involve π → π* transitions.

The photoelectron spectrum of compound **6** was too complex to make a definite assignment and those of **4** and **5** were experimentally unattainable. From the spectroscopic and electrochemical investigation of compounds **4–6**, the lowest singlets and triplets are clearly n,π* in nature. Therefore, the highest occupied molecular orbital in these cases is attributable to the n-orbital of the carbonyl group. A correlation between the n,π* triplet energies and the absolute difference between the oxidation and reduction potentials was utilized to estimate the half-wave oxidation potential of compounds **3–6**. Likewise, a correlation between IP and $E_{1/2}{}^{ox}$ was used to estimate the ionization potentials of compounds **4** and **5**.

A stereoselective synthesis of sucrose.[1] Part II.[2] Theoretical and chemical considerations

BERT FRASER-REID AND DAVID ERLE ILEY[3]

Guelph–Waterloo Centre for Graduate Work in Chemistry, Waterloo Campus, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received June 29, 1978

BERT FRASER-REID and DAVID ERLE ILEY. Can. J. Chem. **57**, 645 (1979).

Under the agency of an iodonium ion, the tertiary anomeric hydroxyl of tetraacetyl fructofuranose adds stereoselectively in a 1,4 sense, to a pyranoid 4,6-*O*-benzylidenated conjugated diene receptor. The resulting disaccharide, isolated in 45% yield, is an hex-2-enopyranoside possessing an allylic primary iodide which can be oxidised to an aldehyde either directly or after hydrolysis to the allylic primary alcohol. The aldehyde is decarbonylated and the unsubstituted hex-2-enopyranoside formed undergoes hydroxylation giving exclusively the *manno*-diol. After protecting the equatorial hydroxyl as the benzoate ester, the axial 2-hydroxyl group is inverted via oxidation followed by borohydride reduction. Acetylation gives the known 4,6-*O*-benzylidene hexaacetyl derivative of sucrose, which is identified by mixture melting point.

BERT FRASER-REID et DAVID ERLE ILEY. Can. J. Chem. **57**, 645 (1979).

Sous l'influence d'un ion iodonium, le groupe hydroxyle anomère tertiaire du tétraacétyl du fructose s'additionne en 1,4 d'une façon stéréosélective, sur le récepteur diénique conjugué d'un pyrannoïde portant un groupe *O*-benzylidène en 4,6. On a isolé le disaccharide qui en résulte avec un rendement de 45%; il s'agit d'un hexèno-2 pyrannoside portant un iodure allylique primaire qui peut être oxydé en aldéhyde soit directement soit après hydrolyse en alcool allylique primaire. On peut décarbonylé l'aldéhyde; l'hexèno-2 pyrannoside non-substitué qui en résulte subit une hydroxylation conduisant uniquement au diol-*manno*. Après avoir protégé l'hydroxyle équatorial par un groupe benzoyle, on provoque une inversion du groupe hydroxyle axial en position 2 par une oxydation suivie d'une réduction au borohydrure de sodium. Une acétylation fournit le dérivé *O*-benzylidène-4,6 hexaacétylé connu que l'on identifie par son point de fusion.

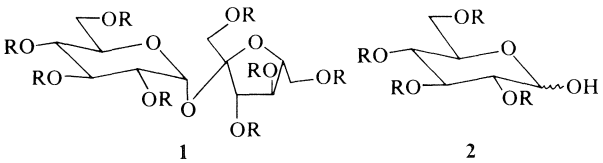
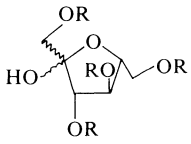
Introduction[4]

Sucrose (**1***a*) is the compound produced commercially in greatest quantity with the highest degree of purity.[5] In spite of this fact, the compound presented organic chemists with two challenges (*a*) determining its structure and (*b*) achieving its synthesis, both of which were met only a generation ago. For the majority of natural products, realization of the second objective would have concomitantly dispensed with the first. However, in the case of sucrose this was not the case. It had been known for decades that the components were glucose (**2***a*) and fructose (**3***a*) but



1
a R = H
b R = Ac
c R = Me

2
a R = H
b R = Ac
c R = Me



3
a R = H
b R = Ac
c R = Me
d R = $PhCH_2$

the nature of the anomeric linkages continually baffled organic chemists[6] and indeed was not promulgated (4) until five years *after* the first chemical synthesis had been announced by Lemieux and Huber (5).

[1]Dedicated to Professor Sir Derek Barton on the occasion of his 60th birthday.

[2]For Part I, see the preliminary account of this work (6).

[3]Holder of the NRCC Studentship 1973–1975. Taken from the M.Sc. Thesis of D.E.I., University of Waterloo, 1975. Present address: Ontario Hydro, W. P. Dobson Laboratories, 800 Kipling Ave., Toronto, Ont.

[4]In disaccharides such as **21**α, **21**β, **22**α, **32**β, etc., the 'α' or 'β' refers to the anomeric configuration of the *furanose* moiety, since the linkage of the pyranose anomeric centre is always 'α.' Use of **21**, **22**, **32**, etc., indicates a mixture of anomers at the furanose centre.

[5]Table sugar has a melting point of 183–185°C. The analytically pure material melts at 185–186°C. The annual production of sucrose is in excess of 60 million tons (1).

[6]Proof of the anomeric configurations by crystallographic methods had been obtained (2, 3).

0008-4042/79/060645-08$01.00/0

In 1975 we made a preliminary announcement of a new synthesis of sucrose in which all of the steps involved proceeded with complete stereoselectivity (6). In addition, the synthesis introduced a novel method for uniting two saccharides by a procedure which generated intermediates which were themselves interesting synthons for branched-chain and modified sugars.

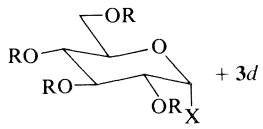
Our synthesis (6) was predicated upon the stereoselective methoxybromination of the diene **8** (*vide infra*). However, we were cognisant of the fact that the stereochemical course of reactions at the anomeric centre of sugars frequently change when one goes from simpler to more complex alcohols (see, for example, ref. 7) (*vide infra*). The chemical manipulations were therefore undertaken with a high degree of faith and chemical vindication came only with the final isolation of a crystalline derivative of sucrose, **32**β.[4] However, while proceeding in this way, extensive spectroscopic studies were made on our intermediates which provide independent proof of structure. Thus in this paper we describe the chemical details of our synthesis and in the accompanying paper (8) the spectroscopic studies are considered.

Background

The simplest conception of a synthesis of sucrose involves the direct dehydrative union of appropriately protected glucosyl and fructosyl derivatives and this was indeed the approach in the earliest attempts. However, the acetates **2***b* and **3***b* could not be united to give octaacetyl sucrose **1***b* (9). Interestingly a more recent attempt using the methylated counterparts (**2***c* and **3***c*) and zinc chloride gave ~7% of **1***c* (10).

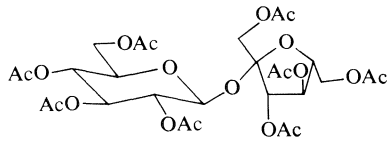
However, such direct condensations allow no control over the stereo- or regiochemistry of the process, so that myriad products were obtained (9*d*). This could be overcome by specifically activating the anomeric centre of one of the units. Traditionally such activation is achieved with glycosyl halides such as **4** which are usually stable, crystalline, well-characterised products. By contrast, the halide derived from **3** is, understandably, exceedingly unstable (9*b*). Thus most efforts have utilized glucosyl halides (**4**) and fructosyl alcohols (**3**). However, reaction of **4***a* with **3***b* gave the β-D-pyranoside **5** (isosucrose) (11) a result which reflects the participation of the C-2 acetoxy group of **4***a* in the reaction (12). Accordingly when nonparticipating benzyl groups were utilized (**4***b* + **3***d*) sucrose was obtained in 4.5% yield (13).

The above-described successful approaches to sucrose are in fact predated by Lemieux's historic breakthrough (5) in which the activated partner was the α-epoxy ether Brigl's anhydride (**6**). The synthesis

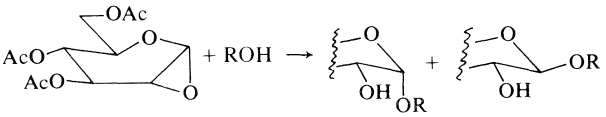


4

a R = Ac, X = Br
b R = $PhCH_2$, X = Cl



5



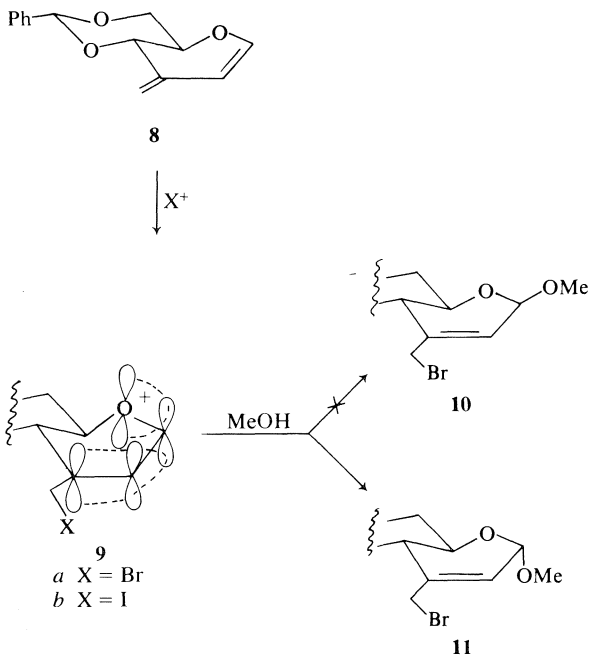
6 **7α** **7β**

was the climax of a series of studies in which it was observed that in the reactions of **6** with alcohols, the proportion of the anomers, **7**α and **7**β in the products increased as the residue R got more and more bulky. Thus use of the exceedingly bulky alcohol **3***b* led to an 8.8% yield of sucrose octaacetate (**1***b*) (5).

The three successful syntheses (5, 10, 13) above also give varying amounts of the β-linked isosucrose (e.g., **5**), a result which reflects the lack of stereoselectivity in the reaction at the glucosyl centre. Clearly, therefore, there are unfavourable stereoelectronic influences to be overcome in forging the link between the two saccharide units.

A method of some promise emanated from the observation (Scheme 1) that the novel diene **8** underwent methoxybromination to give α-product **11** quantitatively and exclusively (14). Predominant, although not exclusive, axial addition might have been anticipated since bromination of **8** would produce the highly delocalized allyl oxocarbonium ion **9***a*. Entry of the alcohol at the electron-deficient centre at C-1 could occur from above, leading to the β product **10**, or below, leading to the α product **11**. The latter allows for greater continuous overlap in going from the transition state to product and is therefore more favourable. This principle was originally enunciated by Corey in order to rationalize the initial formation of the axial halide as the kinetic product in the α-halogenation of ketones (15). However the first formed glycoside here, **11**, has the benefit of the anomeric effect (12, 16) and is therefore the preferred product.

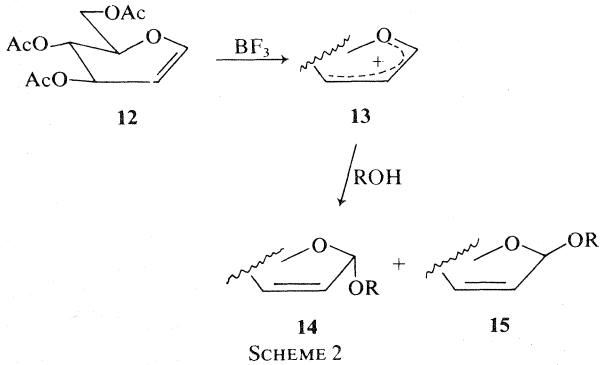
To these favourable electronic considerations must be added the encouraging stereochemical circum-



SCHEME 1

stance arising from the planar nature of the ion **9**, so that there are no obstacles in the path of the incoming nucleophile. The total prognosis, therefore, augured well for the addition of the troublesome tertiary alcohol of **3***b* to the α-face of **9**. With this secured the other functional groups would then be added subsequently.

We were mindful of the fact that a similar intermediate **13** can be invoked for the Ferrier reaction,[7] Scheme 2, which also gives a predominance of α-glycoside **14** (17). The use of this procedure for the proposed synthesis would be even more appropriate than our own (Scheme 1), since unlike **11**, compound **14** does not have the extra carbon at C-3 to be subsequently removed. However, our efforts to bring about the reaction of triacetyl glucal (**12**) (13)

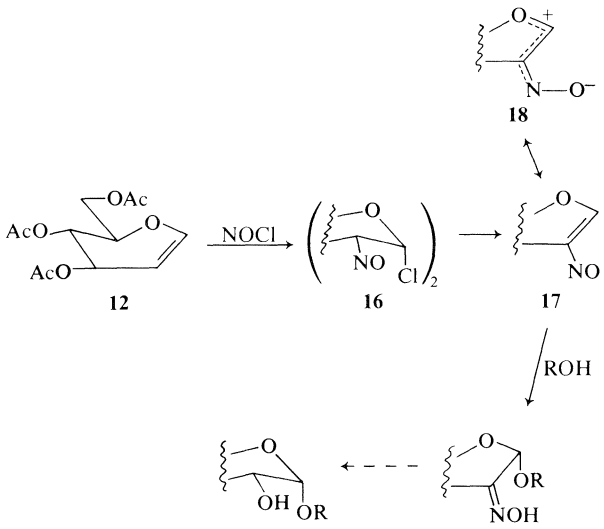


SCHEME 2

[7]However, see refs. 17 and 18 for further discussion.

and tetraacetyl fructose (**3***b*) under the standard Ferrier conditions went completely unrewarded. This was not entirely surprising since it had been reported that **12** undergoes self-condensation rather than glycosidation, when a sugar was used in Scheme 2 in the hope of forming a disaccharide (18).

The Lemieux–Nagabhushan reaction (Scheme 3) is currently widely used for the synthesis of α-glycosides, e.g., **7**α (ref. 19 and references cited therein). Interestingly, the intermediate in these reactions is the nitroso glycal **17**, a canonical form of which is the dipolar species **18** which bears a critical resemblance to **9** and **13**. However, attempts to glycosylate **16** with **3***d* were also unsuccessful in our hands.

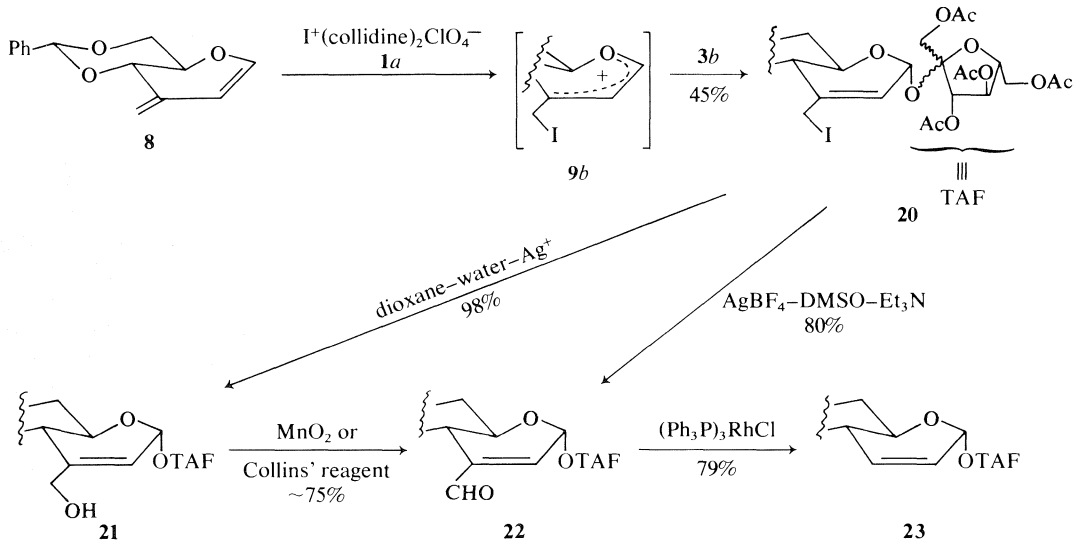


SCHEME 3

The Synthesis[4] (Schemes 4 and 5)

Although the halogen-promoted condensation of the diene **8** and methanol (Scheme 1) had proceeded so efficiently, it was found that with tetraacetyl fructose (**3***b*), the outcome was not encouraging. Reaction of equimolar amounts of **8**, **3***b*, and iodine in chloroform containing silver acetate or silver oxide, did afford a new product which according to tlc monitors had been formed immediately. However its concentration was low and attempts to increase its production either by use of excess iodine or by prolonged reaction times had the opposite effect. The reactive nature of the iodide in **20** was considered to be the cause of the extreme lability, but attempts to stabilize the product by solvolysis to the acetate ($Et_4N^+AcO^-$, benzene) led to decomposition.

The use of iodonium dicollidine perchlorate (**19**; $I^+(collidine)_2ClO_4^-$) as a ready source of iodonium



SCHEME 4

ions has been developed by Lemieux and Morgan (20) and it seemed ideal for our purposes particularly because of the nonnucleophilic counterion. With chloroform as solvent, the condensation product was formed but again it decomposed. However the condensation proceeded smoothly in benzene and the product (**20**) could be isolated in 45% yield (Scheme 4).

There were two other components in the product and one of these proved, upon isolation, to be unreacted tetraacetyl fructose (**3***b*). The other had the same R_f value as the diene **8** but it was different. Unfortunately it proved to be unstable and decomposed upon attempts to isolate it chromatographically, liberating molecular iodine.

The foregoing indicates that **20** was the only reaction product arising from the union of **8** and **3***b*. In view of its high reactivity, **20** was immediately solvolysed to the allylic alcohol **21**.

We had planned to remove the 'extra' carbon by decarbonylation (21) of the aldehyde **22** to give the alkene **23**. To this end, the alcohol was oxidised smoothly with either manganese dioxide or Collins' reagent (22). Alternatively, the iodide **20** could be oxidised directly to **22** by the procedure of Ganem and Boeckman (23).

It was our expectation based on the precedent in Scheme 1, that the orientation at C-1 of the pyranose residue of the condensation product **20** would be exclusively α, but since the tetraacetyl fructose (**3***b*) used was a mixture of α and β anomers, we expected to obtain two products differing in the anomeric configuration of the furanose portion. Indeed, patient, repeated silica column chromatography of the alcohol **21** and aldehyde **22** did afford the components **21**α, **21**β, **22**α, and **22**β which were all noncrystalline. Their identities were cross-checked by oxidation whereby **21**α gave **22**α, and **21**β gave **22**β, and their structures were confirmed spectroscopically (8).

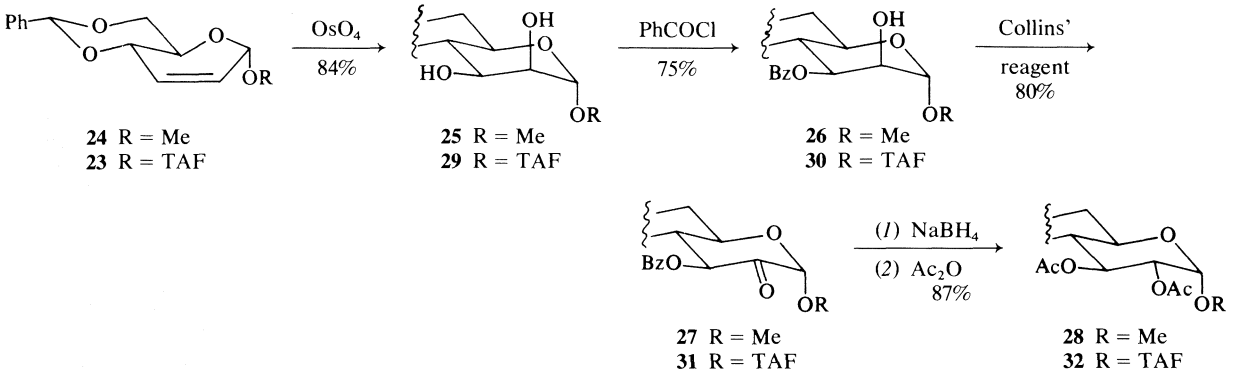
The demands of these fractionations were so daunting that it was decided to use the mixtures (**21**–**23**) of furanose anomers in the hope that a more opportune stage for separation would arise subsequently.

The task was now to add equatorially oriented hydroxyl groups to the olefinic centres of **23**. A model study was carried out on the related monosaccharide **24** (Scheme 5) and it was advantageous that the transformation products **25** (24), **26** (25), and **27** (26) had already been reported in the literature. Thus the conversion of **24** into **28** was examined by us, and an overall yield of 45% was achieved.[8]

Accordingly, osmylation (24) of the alkene **23** gave the diol **29** in 75% yield. The problem of inverting the configuration at C-2 was solved by taking advantage of the greater reactivity of the equatorial hydroxyl group towards acylation (25). Thus benzoylation of **29** at −30°C in pyridine – methylene chloride solution (1:1) gave **30** (75%), which was oxidised with Collins' reagent (22) to **31** (80%). The latter was treated with excess sodium borohydride in methanol (27) and the product acetylated to give **32** (87%).

4,6-*O*-Benzylidenesucrose (**32**β) has recently been prepared by Khan by treating sucrose (**1***a*) with benzal bromide followed by acetic anhydride (28). Nucleation of our synthetic substance **32** with a

[8]This study was carried out by D. J. Balcarras as part of his year IV research project, University of Waterloo, Waterloo, Ont., 1974.



SCHEME 5

sample of the material obtained from Dr. Khan caused fractional crystallisation of the desired **32**β, identified as such by mixture melting point and microanalytical data.

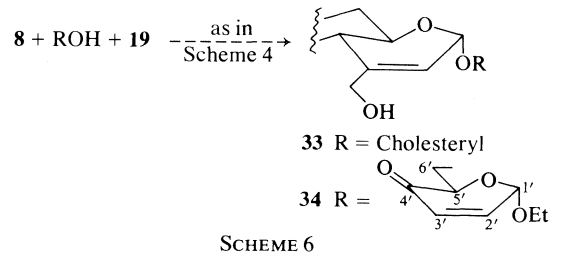
Since **32**β can be debenzylidenated and converted to sucrose (**1***a*) or its octaacetate (**1***b*) the foregoing constitutes a total synthesis of sucrose.

In view of the fact that the intermediate (**13**) in the Ferrier reaction (17) (Scheme 2) and that (**9**) in our reaction (Scheme 1) are both allyl oxocarbonium ions, the complete failure of the former to react with the alcohol **3***b* is deserving of comment. The major difference between **9** and **13** is the C-3 substituent but the electron-withdrawing nature of the halomethyl group should make **9** *less stable* than **13** and concomitantly *less* prone to react with the hindered alcohol (**3***d*). A more probable reason might be sought in the differing conditions utilized in the two procedures. Thus the Lewis acid catalyst used in the Ferrier reaction undoubtedly complexes with the hydroxyl group of the alcohol thereby increasing its bulk and reducing its nucleophilicity.

In the light of the failure of the tertiary alcohol **3***b* to undergo the other α-glycosylation reactions summarized in Schemes 2 and 3 (*vide supra*), it appeared that the haloalkoxylation procedure would be even more efficient with less hindered alcohols.

An interesting alcohol for the test is cholesterol which undergoes both the Ferrier (Scheme 2) and Lemieux–Nagabhushan (Scheme 3) reactions. Accordingly, reaction of diene **8** with cholesterol as in Scheme 4 gave a product which was isolated chromatographically. The derived alcohol **33** (Scheme 6) was characterized as the benzoate. The α configuration was assigned on the basis of the H-1 absorption (5.21 ppm) which corresponds well with that (5.18 ppm) for the analogue **14** (R = cholesteryl). The yield of the latter from the Ferrier reaction (Scheme 2) was 50% (17); of **7**α (R = cholesteryl) in the Lemieux–Nagabhushan reaction (Scheme 3), 73.5% (29); and of **33** (Scheme 5), 84%.

The α-enone alcohol (cf. **34**) is a sensitive substance (30) and should therefore provide a test for the mildness of the condensation. In fact the iodinated disaccharide was obtained quantitatively as was the alcohol **34**. The latter was a crystalline material and its configuration was assigned on the basis of H-1 (5.12 ppm).



SCHEME 6

Experimental

General

The progress of all reactions was followed by thin-layer chromatography (tlc) which was performed on 5 cm × 20 cm and/or 20 cm × 20 cm glass plates coated with silica gel (HF-254, E. Merck) to a thickness of 0.3 mm. The chromatograms were first viewed under ultraviolet light, then sprayed with concentrated sulfuric acid, and finally heated in an oven at 110°C. Column chromatography was performed using silica gel 60 particle size 0.063–0.20 mm (70–230 mesh ASTM, E. Merck). Melting points were determined in capillary tubes in a Mel-Temp block and are uncorrected. Elemental analyses were performed by Microanalyses Laboratory, Toronto, Ont.

All solvents were removed on a rotary evaporator under reduced pressure at 40°C and the residues dried under high vacuum.

*Methyl 4,6-*O*-Benzylidene-1,2,3-trideoxy-3-*C*-methylene-*D*-erythro-hex-1-enopyranoside (**8**)*

The diene **8** was prepared by one of the six synthetic routes developed in our laboratory (31).

*1,3,4,6-Tetra-*O*-acetyl-*D*-fructofuranose (**3**b)*

The tetraacetate **3***b* was prepared from inulin by the method of Binkley and Wolfrom (**9***d*).

1′,3′,4′,6′-Tetra-O-*acetyl*-α *and* β-D-*fructofuranosyl 4,6*-O-*Benzylidene-2,3-dideoxy-3*-C-*(iodomethyl)*-α-D-erythro-*hex-2-enopyranoside (**20**)*

Freshly prepared (20) iodonium dicollidine perchlorate, **19** (1.40 g, 3.0 mmol) was added in small portions, over a 20-min period, to a solution of the diene **8** (460 mg, 2.0 mmol) and tetraacetyl fructofuranose (**3***b*) (3.48 g, 10.0 mmol) in anhydrous benzene (46 mL). During this time, the reaction mixture turned a light yellow colour as the powdery iodonium ion complex was consumed and replaced by microcrystalline collidinium perchlorate. The excess reagent was precipitated by the addition of diethyl ether (50 mL) to the reaction mixture. The solids formed were removed by filtration through a bed of Celite. The filter cake was washed with more diethyl ether and the filtrate extracted with saturated aqueous sodium thiosulfate, 5% hydrochloric acid, saturated aqueous sodium bicarbonate, and water. The organic layer was dried (Na_2SO_4) and concentrated to yield a syrupy residue which was immediately subjected to silica column chromatography. Elution with ethyl acetate – petroleum ether (30–60°C) (1:1) gave the material with R_f 0.48 in the same solvent system; yield 635 mg (45%). This compound which was judged by nmr to be the title compound, **20** (8), was unstable and decomposed at room temperature overnight or in the freezer (−15°C) within several days.

1′,3′,4′,6′-Tetra-O-*acetyl*-α *and* β-D-*fructofuranosyl 4,6*-O-*Benzylidene-2,3-dideoxy-3*-C-*(hydroxymethyl)*-α-D-erythro-*hex-2-enopyranoside (**21**)*

The iodide **20** (635 mg, 0.902 mmol) was dissolved in 25% aqueous dioxane (75 mL) and treated with silver carbonate (2.5 g, 9.0 mmol) and 1 *M* silver perchlorate (2.3 mL, 2.3 mmol). The mixture was stirred for 4 h at room temperature after which time tlc showed that an homogeneous product had formed (R_f 0.26, ethyl acetate – petroleum ether (30–60°C) (1:1)). The silver salts were removed by filtration through a bed of Celite and the filter cake was washed with chloroform (75 mL). The filtrate was extracted with water (50 mL). This aqueous extract was washed once with chloroform (75 mL). The combined organic layers were extracted with water, dried (Na_2SO_4), and concentrated to afford the title compound; yield 525 mg (98%). Compound **21** was resolved into its two anomers **21**α and **21**β by repeated silica column chromatography with diethyl ether – benzene (1:1) as eluant. These were converted into the aldehydes **22**α and **22**β, respectively, by oxidation with chromium trioxide – dipyridine complex in methylene chloride.

Spectroscopic data for **21**, **21**α, and **21**β are presented in the accompanying paper (8).

1′,3′,4′,6′-Tetra-O-*acetyl*-α- *and* β-D-*fructofuranosyl 4,6*-O-*Benzylidene-2,3-dideoxy-3*-C-*formyl*-α-D-erythro-*hex-2-enopyranoside (**22**)*

Method A

The allylic alcohol **21** (525 mg, 0.884 mmol) was dissolved in anhydrous methylene chloride (50 mL) and treated with chromium trioxide – dipyridine complex (22) (2.72 g, 10.6 mmol). Thin-layer chromatography showed that after 1 h, a faster running product had formed (R_f 0.34, ethyl acetate – petroleum ether (30–60°C) (1:1)). The reaction mixture was diluted with diethyl ether (50 mL) and the solid residue formed was removed by filtration through a bed of Celite. The filter cake was washed with diethyl ether and the filtrate was extracted with 5% hydrochloric acid, saturated aqueous sodium bicarbonate, and water. The dried (Na_2SO_4) organic layer after concentration afforded the title compound; yield 398 mg (76%). Compound **22** was resolved into **22**α and **22**β by silica column chromatography with diethyl ether – benzene (1:1) as eluant.

Method B

A solution of the allylic alcohol **21** (164 mg, 0.276 mmol) and manganese dioxide (1.4 g) in tetrahydrofuran (32 mL) was stirred at room temperature for 48 h. The manganese dioxide was removed by filtration through a bed of Celite and the filtrate evaporated to give the aldehyde **22**; yield 119 mg (73%). This material had physical properties identical to those of the material prepared by method A.

Method C (23)

The iodide **20** (95 mg, 0.135 mmol) was dissolved in anhydrous dimethyl sulfoxide (0.5 mL) and treated with silver tetrafluoroborate (39.5 mg, 0.203 mmol). The reaction mixture was stirred at room temperature for 10 min during which time a yellow precipitate formed. Anhydrous triethyl amine (0.05 mL) was added to the reaction mixture and stirring was continued for another 5 min. (*Caution*: Stirring with triethyl amine for periods longer than 5 min caused partial deacetylation of the product.) The aldehyde **22** was isolated by extraction with diethyl ether (3 × 20 mL). The combined extracts were washed with water (3 × 20 mL), dried (Na_2SO_4), and concentrated to afford **22**; yield 64 mg (80%).

For **22**: ir ν_{max}: 1670 (trisubstituted olefin), 1705 (α,β-unsaturated aldehyde), 1745 (OAc), 2860, 2920 (aldehyde) cm^{-1}.

Additional spectroscopic data for **22**, **22**α, and **22**β are presented in the accompanying paper (8).

1′,3′,4′,6′-Tetra-O-*acetyl*-α- *and* β-D-*fructofuranosyl 4,6*-O-*Benzylidene-2,3-dideoxy*-α-D-erythro-*hex-2-enopyranoside (**23**)*

A solution of the aldehyde **22** (398 mg, 0.672 mmol) in anhydrous benzene (40 mL) was stirred with tris(triphenylphosphine)chlororhodium (21) at 80°C for 1 h. Thin-layer chromatography then showed that an homogeneous product had formed (R_f 0.44, ethyl acetate – petroleum ether (30–60°C) 1:1)). During this time, the reaction mixture changed from the burgundy colour of the starting complex to the beige colour of the carbonylated complex. The reaction mixture was concentrated and treated with either diethyl ether or ethanol. The inorganic complex which precipitated was removed by filtration. The filtrate was concentrated and purified from some residual inorganic material by filtration down a short column of silica gel. Elution with ethyl acetate – petroleum ether (30–60°C) (1:1 gave syrupy **23**; yield 300 mg (79%)). The absence of the aldehyde group was readily apparent from nmr and ir spectra. Additional spectroscopic data for **23** are presented in the accompanying paper (8).

1′,3′,4′,6′-Tetra-O-*acetyl*-α- *and* β-D-*fructofuranosyl 4,6*-O-*Benzylidene*-α-D-*mannopyranoside (**29**)*

A 0.10 *M* solution of osmium tetroxide in pyridine and a solution of sodium bisulfite (1.8 g) in water (30 mL) and pyridine (20 mL) were prepared for use in the hydroxylation experiments. The olefin **23** (120 mg, 0.213 mmol) was allowed to react with the solution of osmium tetroxide (2.4 mL, 0.24 mmol) for 20 h at room temperature. As the reaction proceeded, the colour of the mixture turned from light yellow to dark brown or black. This colour change was accompanied by the precipitation of the pyridine-complexed osmate ester of the olefin. The latter was decomposed by the addition of a portion of the sodium bisulfite solution (3.4 mL) and stirring continued for another 4 h. The resulting orange solution was extracted with methylene chloride (6 × 10 mL) and the extract dried (Na_2SO_4) and concentrated to give syrupy

homogeneous **29**; yield 107 mg (84%) (R_f 0.12, ethyl acetate – petroleum ether (30–60°C) (1:1) or R_f 0.44, ethyl acetate).

The mass spectrum of **29** showed peaks at *m/e* 251 (hexopyranosyl cation), 331 (ketofuranosyl cation), and those characteristic of benzylidene acetals (see ref. 8). In the infrared: ν_{max}: 3300–3650 (OH) cm^{-1}.

*1′,3′,4′,6′-Tetra-*O*-acetyl-α and* β-D-*fructofuranosyl 2,3-di-*O*-Acetyl-4,6-*O*-benzylidene-*α-D-*glucopyranoside (**32**)—Synthetic 4,6-*O*-Benzylidenesucrose Hexaacetate (**32**β)*

A solution of benzoyl chloride (0.15 mL, 1.79 mmol) in anhydrous methylene chloride (20 mL) was prepared. The diol **29** (107 mg, 0.179 mmol) was dissolved in anhydrous pyridine (2 mL) and cooled to −30°C. To this solution was added a portion of the above benzoyl chloride solution (2 mL) representing one equivalent of that reagent. After stirring for 5 h, tlc showed that a trace unreacted starting material and that an homogeneous product (R_f 0.34, ethyl acetate – petroleum ether (30–60°C) (1:1)) had formed. A slight excess of the benzoyl chloride solution (0.05 mL) was added and stirring continued for another 5 h. The product (**30**) was isolated by conventional chloroform extraction procedures; yield 94 mg (75%).

A portion of this material (70 mg, 0.10 mmol) was oxidized with chromium trioxide – dipyridine complex (22) (1.5 g) in methylene chloride (15 mL). The product (**31**) was isolated in the usual manner; yield 56 mg (80%).

The latter was dissolved in methanol (30 mL) and treated with excess sodium borohydride (600 mg). The mixture was stirred for 4 h at room temperature and the excess reagent was then destroyed by dropwise addition of acetic acid. The mixture was concentrated to dryness and the resulting residue was dissolved in anhydrous pyridine (15 mL), cooled to 0°C, and allowed to react with acetic anhydride (15 mL) overnight. The reaction mixture was cooled in ice and the excess reagent destroyed by dropwise addition of methanol. The mixture was extracted several times with chloroform and the extracts were washed with dilute hydrochloric acid, aqueous sodium bicarbonate and then dried Na_2SO_4. The product (**32**) 44 mg (87%) was homogeneous on tlc and had an R_f value identical with that of an authentic sample of **32**β (28) (R_f 0.30, benzene – diethyl ether (1:1)). The mass spectrum of **32** showed peaks at *m/e*: 632 (M), 335 (hexopyranosyl cation), 331 (ketofuranosyl cation), and those characteristic of benzylidene acetals (see ref. 8).

Nucleation of a solution of **32** in diethyl ether – petroleum ether with an authentic sample of **32**β kindly supplied by Dr. Khan (28) afforded the desired material, mp 162–164°C; mixture mp 161.5–163°C; authentic sample mp 162.5–164°C. *Anal.* calcd. for $C_{31}H_{38}O_{17}$: C 54.55, H 5.61; found: C 54.71, H 5.64. Additional spectroscopic data for **32** and **32**β are presented in the accompanying paper (8).

*Cholesteryl 4,6-*O*-Benzylidene-2,3-dideoxy-3-*C*-(hydroxymethyl)-*α-D-*erythro-hex-2-enopyranoside (**33**) and its Benzoyl Derivative*

Iodonium dicollidine perchlorate (**19**) (20) (352 mg, 0.75 mmol) was added in portions over 20 min to a solution of the diene **8** (115 mg, 1.0 mmol) and cholesterol (387 mg, 1.0 mmol) in anhydrous benzene (10 mL). The reaction mixture was worked up as previously described above for **20**. The product (R_f 0.70, ethyl acetate – petroleum ether (30–60°C) (1:4)) was isolated by silica column chromatography (yield 310 mg, 84%) and was immediately dissolved in dioxane (37 mL) and water (5 mL) and treated with silver carbonate (1.38 g) and 1 *M* silver perchlorate (5 mL). The mixture was stirred at room temperature for 4 h after which time tlc showed that an homogeneous product had formed (R_f 0.25, ethyl acetate – petroleum ether (30–60°C) (1:4)). The product **33** was isolated as previously described for **21**; yield 249 mg (95%). This compound jelled on all attempts at crystallization and was therefore characterized as its benzoate ester, prepared in 90% yield via standard procedures.

In the mass spectrum of **33**, no molecular ion was observed but peaks at *m/e* 351 and 385 owing to cleavage of the glycosidic bond were readily apparent (8). Also present were the peaks characteristic of benzylidene acetals. In the infrared: ν_{max}: 1740 (aryl ester) cm^{-1}.

The ^{1}Hmr spectrum of **33** at 60 MHz showed ($CDCl_3$, TMS) δ: 0.5–2.6 (m, 44, cholesteryl protons), 3.6–4.6 (m, 4, H-4, H-5, H-6a, H-6e), 5.0 (m, 2, benzoxymethyl), 5.21 (m, 1, H-1), 5.36 (m, 1, cholesterylic olefin), 5.60 (s, 1, benzylidene methine), 5.80 (m, 1, H-2), 7.2–8.2 (m, 10, aromatic protons).

The benzoate of **33** was recrystallized from ethanol; mp 132–134°C. *Anal.* calcd. for $C_{48}H_{64}O_6$: C 78.22, H 8.75; found: C 78.39, H 8.59.

*Ethyl 2,3-Dideoxy-6-*O*-(4,6-*O*-benzylidene-2,3-dideoxy-3-*C*-(hydroxymethyl)-*α-D-*erythro-hex-2-enopyranosyl)-*α-D-glycero-*hex-2-enopyranosid-4-ulose (**34**)*

Iodonium dicollidine perchlorate (**19**) (20) (352 mg, 0.75 mmol) was added in portions over a period of 29 min to a solution of the diene **8** (115 mg, 0.50 mmol) the enone **97** (30) (172 mg, 1.0 mmol) in anhydrous benzene (10 mL). The reaction mixture was worked-up as previously described for **20** and the product (R_f 0.47, ethyl acetate – petroleum ether (30–60°C) (1:1)) was isolated by silica column chromatography; yield 264 mg (100%). The material was immediately dissolved in dioxane (26 mL) and water (5 mL) and treated with silver carbonate (1.38 g) and 1 *M* silver perchlorate (5 mL) at room temperature for 3 h after which time tlc showed that an homogeneous product had formed (R_f 0.26, ethyl acetate – petroleum ether (30–60°C) (1:1)). The product (**34**) was isolated as previously described; yield 210 mg (100%).

In the mass spectrum of **34**, peaks were observed at *m/e*: 419 (M + 1), 418 (M), 401 (M + 1 − H_2O), 400 (M − H_2O), 374 (M + 1 − OEt), 373 (M − OEt), and those characteristic of benzylidene acetals (8). Also prevalent were the peaks due to cleavage of the disaccharide linkage (i.e., *m/e* 247 and 171).

The ^{1}Hmr spectrum of **34** at 60 MHz showed ($CDCl_3$, TMS) δ: 1.25 (t, 3, OCH_2CH_3), 1.92 (bs, 1, exchangeable OH), 3.4–4.8 (m, 11, hydroxymethyl, H-4, H-5, H-6a, H-6e, OCH_2CH_3, H-5′, H-6a′, H-6e′), 5.12 (m, 1, H-1), 5.17 (d, 1, H-1′, $J_{1',2'}$ = 5.0 Hz), 5.60 (s, 1, benzylidene methine), 5.71 (m, 1, H-2′), 6.15 (d, 1, H-3′, $J_{2',3'}$ = 10.0 Hz), 6.92 (dd, 1, H-2′), 7.2–7.7 (m, 5, aromatic protons).

Compound **34** was recrystallized from diethyl ether – petroleum ether (30–60°C); mp 97–99°C. *Anal.* calcd. for $C_{22}H_{26}O_8$: C 63.15, H 6.26; found: C 63.12, H 6.37.

A stereoselective synthesis of sucrose.[1] Part III.[2] Spectroscopic analyses of key intermediates

DAVID ERLE ILEY[3] AND BERT FRASER-REID

Guelph–Waterloo Centre for Graduate Work in Chemistry, Waterloo Campus, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received June 29, 1978

DAVID ERLE ILEY and BERT FRASER-REID. Can. J. Chem. **57**, 653 (1979).

Condensation of the diene **1** with the α,β-anomeric mixture of tetraacetyl fructofuranose and processing of the resulting product gives rise to a series of disaccharides, **5**, **6**, and **7**, each of which is a mixture of two substances differing only in the anomeric configuration at the fructosyl centre, the linkage at the pyranosyl moiety being α in all cases. This conclusion is reached by careful comparison of the ^{1}Hmr and ^{13}Cmr spectra of these disaccharides with those of a number of fructofuranose derivatives. There are interesting correlations in configuration, conformation, and optical rotation.

DAVID ERLE ILEY et BERT FRASER-REID. Can. J. Chem. **57**, 653 1979).

La condensation du diène **1** avec le mélange des anomères α et β du tétraacétyl fructofurannose et la transformation du produit qui en résulte donne lieu à la série de disaccharides **5**, **6** et **7**; dans chaque cas, il s'agit d'un mélange de deux produits qui ne diffèrent que par la configuration du carbone anomère de la portion fructoyle puisque la liaison avec la moitié pyrannosyle est α dans tous les cas. On peut tirer cette conclusion en se basant sur une comparaison soignée des spectres rmn du ^{1}H et du ^{13}C de ces disaccharides avec ceux d'un certain nombre de dérivés fructofurannoses. On peut déduire des corrélations intéressantes concernant la configuration, la conformation et la rotation optique.

[Traduit par le journal]

In the accompanying paper (1) we gave details of a novel synthesis of sucrose. In spite of the theoretical considerations upon which the synthetic plan was devised, we were assured of the validity of our approach only at the final stages when a substance having the sucrosyl skeleton was finally isolated. Admittedly, the halogen-promoted addition of methanol to the diene **1** to give the α-glycoside **3** exclusively, was a promising precedent (2). However it is known that with glycosidation reactions, changing from simple to complex alcohols sometimes causes drastic variations not only in the stereochemistry (see, for example, ref. 3) but even in the pattern of the reaction (4). Thus unquestioning reliance upon our precedent seemed ill-advised and we therefore sought assurances by making detailed spectroscopic analyses of our key intermediates. Many of the latter are interesting in their own right, for being highly functionalised and amenable to diverse chemical manipulations they are promising synthons for the preparation of branched-chain and other modified sugars. In this paper we therefore describe various aspects of these spectroscopic studies.

Reaction of diene **1** with tetraacetyl fructose **2**, in the presence of iodonium dicollidine perchlorate gave the iodide **4** which was immediately solvolysed to the alcohol **5**. Oxidation of the latter gave the aldehyde **6**, decarbonylation of which gave the alkene **7** (1). The structures of these key intermediates were

studied by mass spectroscopy, and proton and carbon-13 magnetic resonance.

Experimental

Proton magnetic resonance (^{1}Hmr) spectra were determined, unless otherwise stated, in deuteriochloroform containing 1% tetramethylsilane (TMS) as internal standard with either a Varian T-60 or Varian HR-220 spectrometer.[4] Coupling constants were obtained by measuring the spacings of spectra judged to be first order. Infrared (ir) spectra were determined on a Beckman model IR-10 spectrometer using 0.1-mm sodium chloride solution cells, chloroform being the solvent used. Mass spectra were determined on a Hitachi mass spectrometer model RMU-6E. Carbon-13 nuclear magnetic resonance (^{13}Cmr) spectra were recorded on a Bruker HX-90 spectrometer, operating at 22.63 MHz and equipped with a Nicolet 1083 instrument computer for Fourier transform spectroscopy.[5] The spectra were recorded in deuteriochloroform. The latter showed its characteristic absorptions at 78.5, 77.2, and 75.7 ppm downfield from tetramethylsilane.

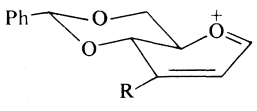
Optical rotations were measured on a Carl Zeiss model LEP nür 370740 Lichtelektrisches Präzisionpolarimeter at 546 and 578 nm at 23°C.

Most of the compounds described in this paper are benzylidene acetals. The benzylidene group was detected by a five-proton multiplet at about 7.40 ppm (aromatic) and a one-proton singlet at about 5.60 ppm (H-7, benzylidene methine) in the ^{1}Hmr spectra. At 60 MHz the H_4, H_5, H_{6a}, and H_{6e} resonances formed a multiplet at about 3.7–4.6 ppm. The mass spectra of benzylidene acetals show, characteristically, peaks at *m/e*: 149 ($PhCHOCH_2CHO^+$), 106 ($PhCHO^+$), 105 ($PhCO^+$), 91 ($C_7H_7^+$), and 77 ($C_6H_5^+$). The compounds studied were obtained as described in the accompanying paper (1).

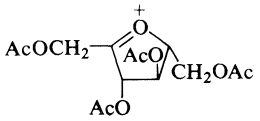
Results and Discussion

Mass Spectra

The mass spectra of **5** and **6** gave molecular ions



8 R = CH_2OH *m/e* 247
9 R = CHO *m/e* 245
10 R = H *m/e* 217



m/e 331
11

at *m/e* 594 and 592, respectively. Although the conventional electron impact mass spectrum of **7** failed to produce a molecular ion, field ionization mass spectroscopy showed a molecular ion at *m/e* 564 and chemical ionization mass spectroscopy gave a large peak at 582 representing the $M + NH_4^+$ ion corresponding to *m/e* 564.

The most readily observed fragmentation of these glycosides is cleavage of the glycosidic bond (5). Thus the mass spectra of **5**, **6**, and **7** showed peaks at *m/e*: 247, 245, and 217 attributed, respectively, to the hexopyranosyl cations **8**, **9**, and **10**, and all the spectra contained a relatively intense peak at *m/e* 331 for the ketofuranosyl cation **11**.

^{1}H Nuclear Magnetic Resonance Spectra

The Pyranosyl Moiety

It was anticipated that the chemical shift of H-1 of the simple hex-2-enopyranosides **12**α and **12**β (6) (Fig. 1) could be used as a probe for the determination of the configuration at the anomeric carbon of the pyranosyl residue of the olefinic disaccharides. Thus if the condensation reaction (Scheme 1) had proceeded stereoselectively to give only the α adduct, the H-1 resonance should appear around 4.9 ppm as against 5.3 ppm for the β adduct.

Unfortunately, the 60 MHz spectra of **5**, **6**, and **7** were not resolved well enough in the region of interest to allow such analyses and it was therefore necessary to study the model compounds **12**α, **12**β, **2**, **13**α, and **13**β at 220 MHz in an effort to sort out the complex disaccharide spectra.

The 220 MHz ^{1}Hmr data for **12**α and **12**β in deuterated chloroform, benzene, and pyridine solutions in Table 1 reveal that the different solvents caused only minor variations in chemical shift and that all the spectra were well resolved.

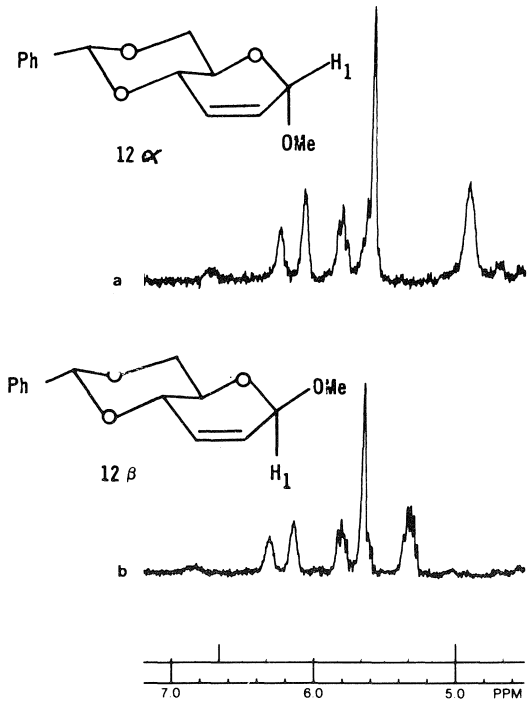


FIG. 1. The H-1 region of the ^{1}Hmr spectra (220 MHz) of compounds **12**α and **12**β.

[4]We are indebted to Dr. A. A. Grey of the Canadian 220 MHz NMR Centre for determining the 220 MHz spectra and for his help in their interpretation.

[5]We are indebted to Professor J. K. Saunders of the Université de Sherbrooke for determining the ^{13}Cmr spectra and for his help in their interpretation.

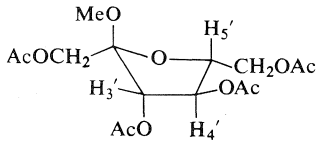
The 220 MHz ^{1}Hmr spectra of the methyl fructofuranoside derivatives **13**α and **13**β (7) were more difficult to analyze completely. Fortunately in both spectra the area of interest (4.8–6.0 ppm) was not obscured by the complex absorptions for H-1_a′, H-1_b′, H-5′, H-6_a′, and H-6_b′[6] occurring between 3.8 and 4.8 ppm. The results of the analysis of the area of interest are reported in Table 2 and the spectra in deuteriochloroform are displayed in Fig. 2.

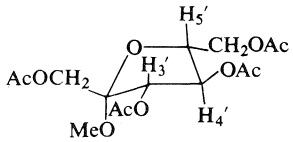
These data can be used to determine the conformation of the furanose rings in **13**α and **13**β. Since $J_{4',5'}$ is the same (5.0 Hz) in both of these compounds but $J_{3',4'}$ is different, it seems probable, on the basis of Karplus considerations (8), that in the conformations of **13**α and **13**β, the dihedral angles must be the same for H-4′ and H-5′ but different for H-3′ and H-4′. The *E*-2 conformations shown for these substances accommodate these parameters. These conformational preferences can be rationalized by noting that because of the anomeric effect, the glycosidic oxygens will favour quasi-axial orientations (9) in both forms, and that the bulky acetoxymethyl groups should prefer to occupy quasi-equatorial orientations. It is noteworthy that in these conformations eclipsing interactions of large substituents are minimised.



13α

$\phi_{3',4'} \simeq 100°$; $J_{3',4'} = 2.0$ Hz

$\phi_{4',5'} \simeq 120°$; $J_{4',5'} = 5.0$ Hz



13β

$\phi_{3',4'} \simeq 140°$; $J_{3',4'} = 7.0$ Hz

$\phi_{4',5'} \simeq 120°$; $J_{4',5'} = 5.0$ Hz

The purpose of the foregoing model studies was to gain a better basis for analyzing the spectra of the disaccharides. It was hoped that the condensation of **1** and **2** would produce only two diastereomers arising from the presence of both the α and β anomeric forms of **5**. After prolonged efforts, it was found possible to resolve **5** into two components by chromatographic fractionation but the required procedure was so tedious that only small amounts of pure **5**α and **5**β could be accumulated. Unfortunately, these did not crystallize but their ^{1}Hmr spectra at 220 MHz were recorded.

Although the spectra were extremely complex, the 4.8–6.0 ppm regions displayed in Fig. 3 could be partially analyzed on a first-order basis. A visual comparison of the H-3′ and H-4′ resonances in Figs. 2 and 3 was undertaken to permit the assignment of configuration of the fructofuranosyl residues as shown in **5**α and **5**β. Thus, the slower running component **5**α was judged to possess the α-fructofuranosyl residue. The similar coupling constants, $J_{3',4'}$ and $J_{4',5'}$ (see Tables 2 and 3) in **5**α and **13**α imply that the furanose ring in the disaccharide **5**α is also in the *E*-2 conformation as was deduced above for **13**α. In contrast, the faster running component,

[6]The primed numbers will be used to refer to positions in the fructofuranose residue.

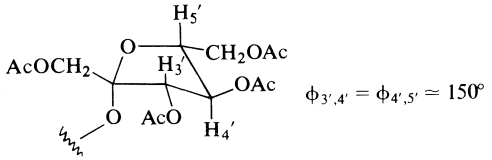
13β	7.0	5.0

5β, can be seen to have a different conformation than **13**β, since H-4′ appears as a triplet in the former compound. The *E*-4 conformation as expressed in **14**, for the furanose ring in the disaccharide **5**β may



$\phi_{3',4'} = \phi_{4',5'} \simeq 150°$

14 (≡**5**β)

be assigned on the basis of the fact that the β-fructofuranosyl residue of sucrose exists in this form (10). This conformation accounts for the large coupling constants observed for $J_{3',4'}$ and $J_{4',5'}$ in **5**β. Hence the dihedral angle for H-3′ and H-4′ is the same as that for H-4′ and H-5′.

Attempts were made to obtain information about H-1 and H-2 of the pyranosyl moiety in **5**α and **5**β, and some relevant data are assembled in Table 3. It was assumed that the resonances for these protons were buried ~5.6 ppm (Fig. 3) but changing the solvent to benzene-d_6 proved to be ineffective.

Fortunately this problem was solved when it was found that the α,β-unsaturated aldehyde **6** was also resolvable (with considerable difficulty) into two components, namely **6**α and **6**β. These compounds also failed to crystallize but gave good ^{1}Hmr spectra. The region of interest, 4.8–6.0 ppm, is displayed in Fig. 4 and the results of the spectral analysis are reported in Table 3. Inspection of the H-3′ and H-4′ resonances clearly shows that **6**α and **6**β have the structures as shown with respect to the fructofuranose rings. Distinct absorptions for H-1 and H-2 of **6**α and **6**β can be seen, although their chemical shifts cannot be used to infer the anomeric configuration. In both compounds, H-1 appears as a broad signal but H-2 appears as a triplet. The coupling

constants $J_{1,2}$ and $J_{2,4}$ are the same as in the monomer **12**α (cf. Tables 1 and 2) and thus it can be concluded that in both of these compounds, the linkage at the pyranosyl residue is α. This result in turn confirmed the original supposition (1) that the alkoxy halogenation of the diene **1** proceeds stereoselectively giving α adducts exclusively.

Additional correlation of structure was obtained when the alcohols **5**α and **5**β were oxidized independently by chromium trioxidedipyridine complex in methylene chloride and gave products identical with **6**α and **6**β, respectively (1).

^{13}C *Nuclear Magnetic Resonance Spectra*

Added proof for the α configuration of the hex-2-enopyranosyl moiety of the disaccharides **5**, **6**, and **7** was sought from their ^{13}C nuclear magnetic resonance spectra. The correlation of the ^{13}C spectral peaks of a complex molecule with those of the constituent monomers has recently been utilised with great effectiveness by Wenkert and co-workers (11) in a study of tobramycin and related antibiotics of the kanamycin family.

The Pyranosyl Moiety

For the problem at hand, the monomeric derivatives **12**α, **12**β, **2**, **13**α and **13**β were subjected to ^{13}Cmr analysis. The natural abundance ^{13}C signals in the spectra of the compounds studied were assigned to specific carbons by means of the following procedures: (*a*) off-resonance decoupling techniques, (*b*) application of known chemical shift rules (12), and (*c*) comparison with the results of related studies from the literature (13).

A study of the ^{13}Cmr data for the olefins **12**α and **12**β (Table 4) reveals that there are very large chemical shift differences between the two anomers for C-5 ($\Delta\delta = -6.6$ ppm) and C-1 ($\Delta\delta = -3.1$ ppm). The former observation is by far the more important and is a direct consequence of the manifestation of the 'γ steric effect' (12*b*) also known as the 'steric compression shift' (12*a*). Interestingly, a similar trend is observed for the conformationally more labile derivatives **15** and **16** (see Table 4). This is

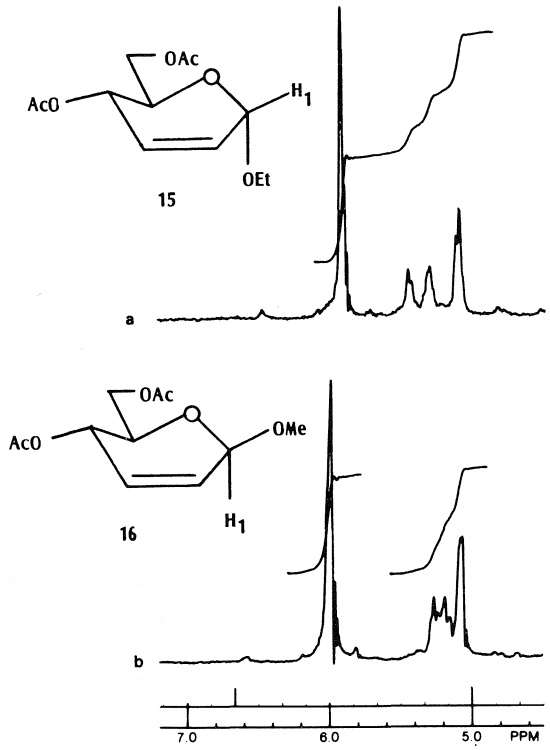

FIG. 5. The H-1 region of the ^{1}Hmr spectra (220 MHz) of compounds **15** and **16**.

11	129.0	129.0	0	—	—	—
14	55.8	54.8	+1.0	—	—	—

noteworthy because the chemical shifts of H-1 in the proton spectra of **15** and **16** are so close that this data cannot be used to diagnose the anomeric configuration of these and structurally related compounds (see Fig. 5).

Thus the ^{13}C chemical shifts of C-1 and C-5 in the α anomers of hex-2-enopyranosides are shielded relative to the corresponding resonances in the β anomers. These observations lay the groundwork for the structural analysis of the related disaccharides with respect to the hex-2-enopyranosyl moiety.

The Furanosyl Moiety

The ^{13}Cmr spectrum of 1,3,4,6-tetra-*O*-acetyl-D-fructofuranose (**2**) was recorded as a model for the fructofuranosyl moiety of the structurally related disaccharides. The spectrum showed two distinct and clearly defined sets of resonances of different intensities. The two peaks at 103.9 and 101.5 ppm (see Table 5) were assigned to the anomeric carbons of the α and β anomers, respectively. This is in keeping with the recent assignment of the absolute anomeric configuration of the di-D-fructose anhydrides (13*d*) based on the observation that the ^{13}C chemical shift of the anomeric carbon of the α anomer of D-fructofuranosyl residues always resonates downfield from its β counterpart. Integration of these peaks revealed that the α to β ratio was 46:54. Thus, the predominant furanose anomer has the C-2′ hydroxymethyl group and the C-3′ hydroxyl group in a *trans* relationship as previously noted (13*a–c*).

The remaining 10 signals were readily assignable to the α or β anomer by their relative intensities. The signal at 63.3 ppm was assigned to C-1′ of **2α** because of the expected shielding effect of the C-3′ acetoxy group. C-6′ of **2α** was therefore the signal at 64.4 ppm. The signal at 64.8 ppm was assigned to C-6′ of **2β** because inversion at the anomeric centre would not greatly affect the chemical shift of C-6′. The only remaining methylene carbon at 65.3 ppm was therefore C-1′ of **2β**.

With regard to the three secondary carbons of **2α**, C-3′ and C-4′ should be the least and most shielded, respectively. Inversion of the anomeric centre should not affect C-4′ and C-5′ appreciably, and these carbons would therefore have similar chemical shifts in both **2α** and **2β**. On the other hand, C-3′ is greatly affected by inversion at the anomeric centre. Thus the large Δδ value of +4.3 ppm is immediately identified with C-3′.

To confirm these assignments the spectra of **13α** and **13β** were recorded and analyzed. The results (see Table 5) compare favourably and follow the expected trends. Also worthy of mention is the excel-

TABLE 5. ^{13}C chemical shifts for some fructofuranose derivatives

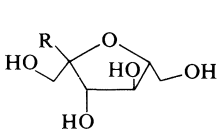
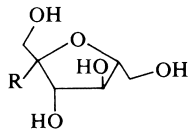
[b]The methoxy peaks in these compounds resonated at 48.7 (13α) and 49.8 (13β).

lent agreement of our assignments with those of Que and Gray (13*c*). Their assignments for α-D-fructofuranose (**17**α) and β-D-fructofuranose (**17**β) (see Table 5) were based on a study of the structurally related compound 2,5-anhydro-D-glucitol (**18**) and 2,5-anhydro-D-mannitol (**19**). It might also be noted



17α R = OH
18 R = H



17β R = OH
19 R = H

that the resonances of **17**α assigned by Que and Gray (13*c*) have virtually the same chemical shifts as the β-D-fructofuranosyl resonances of sucrose recorded by Dorman and Roberts (14). The only discrepancy between our results and those of Que and Gray is in the assignment of the methylene carbons of **17**β. If their C-1′ and C-6′ assignments were reversed, then a more favourable comparison of Δδ values would result (i.e., for C-1′, Δδ = −1.7 vs. +0.2 cf. −2.0 and for C-6′, Δδ = −0.7 vs. −1.3 cf. −0.4).

Thus the ^{13}C chemical shifts of C-2′ and C-3′ in the β anomers of fructofuranoses are shielded relative to the corresponding resonances in the α anomers and this allows the ready assignment of the anomeric configuration of these derivatives.

^{13}C magnetic resonance analyses of **5**, **6**, and **7** revealed the presence of only two components arising from the presence of the α and β anomers in the furanose ring. The chemical shifts of C-5 in these compounds affirm the α linkages in the hex-2-enopyranosyl moieties. *As there are no other methine peaks in this region, the chemical shift of C-5 becomes totally diagnostic of the anomeric configuration of these compounds.* Accordingly, there are signals at 63.2 ppm in **5**, 64.4 ppm in **6**, and 63.5 ppm in **7** corresponding to the one at 63.9 ppm in the related monomer **12**α but none (ca. 70.5 ppm) corresponding to the β anomer, **12**β.

For C-1, signals were observed at 87.8 ppm in **5**, 87.5 ppm in **6**, and 87.9 ppm in **7**. These chemical shifts are shielded compared to that of C-1 in **12**α (cf. 96.1 ppm). This is attributable to the steric compression of C-1 caused by the attachment of the fructofuranosyl moiety.

2′	107.9	102.7
3′	82.1	73.6
4′	77.9	75.6
5′	79.2	77.7
6′	63.0	63.1

A detailed analysis of the spectra of **5**, **6**, and **7** was not attempted, however; the two components of **6**, viz. **6**α and **6**β, were analyzed. The ^{13}C data for these two diastereomers are presented in Table 6. The resonances followed the expected trends observed in Tables 4 and 5. The anomeric configuration at C-1 was α as described above. The assignment of the anomeric configuration of the fructofuranose ring in **6**α and **6**β was readily made. The peaks at 102.7 and 73.6 ppm for C-2′ and C-3′ of **6**β were observed at higher field than the corresponding resonances, 107.9 and 82.1 ppm, for **6**α.

In conclusion, the ^{13}C spectral data proved unam-

biguously, that **6**α was 1′,3′,4′,6′-tetra-*O*-acetyl-α-D-fructofuranosyl 4,6-*O*-benzylidene-2,3-dideoxy-3-*C*-formyl-α-D-*erythro*-hex-2-enopyranoside and that **6**β was 1′,3′,4′,6′-tetra-*O*-acetyl-β-D-fructofuranosyl 4,6-*O*-benzylidene-2,3-dideoxy-3-*C*-formyl-α-D-*erythro*-hex-2-enopyranoside.

Optical Rotation

Another interesting correlation between the disaccharides **6**α and **6**β and the fructofuranosides **13**α and **13**β is in their relative specific rotations. Inspection of Table 7 reveals that these compounds, and the known compounds listed, follow the trend that

those derivatives possessing the α-fructofuranosyl residue all are more dextrorotatory than the corresponding β anomers.

Spectral Comparisons of Synthetic and Authentic Derivatives of Sucrose

Because of the extreme difficulty (*vide supra*) in separating the desired component (**5**β or **6**β) from the anomer (**5**α or **6**α), it was decided to test the feasibility of our planned route on the mixture **7**. If successful, the final product would contain sucrose in addition to one of its isomers, and spectroscopic verification of this fact would be extremely encouraging. Fortunately, 4,6-*O*-benzylidenesucrose hexaacetate (**20**β), a compound well correlated with our synthetic plan, was described by Khan (15). Compound **7** was therefore converted to **20** (1) and spectroscopic comparisons were undertaken.

The 3.0–6.0 ppm regions of the 220 MHz ^{1}Hmr spectra of authentic **20**β and the synthetic mixture **20** determined in deuteriochloroform and benzene-d_6 are shown in Figs. 6 and 7, respectively. In the case of the former, signals for H-1, H-2, and H-3 were assigned on a first-order basis for **20**β (Fig. 6*a*) and these signals were clearly recognisable in the synthetic mixture **20** (Fig. 6*b*).

With benzene-d_6 as solvent, the comparison was much more fulfilling, since discrete signals were observed for H-1, H-2, H-3, H-3′, H-4′, and H-7 of **20**β, the assignments being made on a first-order basis (Fig. 7*a*). Appropriately, these signals could all be identified in the synthetic mixture, **20** (Fig. 7*b*), thereby confirming that sucrose was present in the mixture.

It proved possible to obtain a crystalline sample of the synthetic material **20**β by nucleation with the authentic material (1).

Artificial carbohydrate antigens: synthesis of rhamnose disaccharides common to *Shigella flexneri O*-antigen determinants[1]

DAVID R. BUNDLE AND STAFFAN JOSEPHSON[2]

Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received September 12, 1978

DAVID R. BUNDLE and STAFFAN JOSEPHSON. Can. J. Chem. **57**, 662 (1979).

Three disaccharides containing α-linked rhamnopyranoside units have been synthesised in a form suitable for covalent linkage to protein. The artificial antigens obtained in this manner represent structural elements similar to portions of the repeating unit of the *Shigella flexneri O*-antigen. The glycosylation reactions leading to the disaccharides utilised silver trifluoromethanesulphonate and *N,N*-tetramethylurea, or *sym*-collidine, conditions which generated the three 1,2-*trans*-linked glycosides in high yield and stereospecificity. The blocking groups used in these syntheses are consistent with further chain extension to tri- and tetrasaccharides. 2-Acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-glucopyranosyl chloride and the 1,2-oxazoline derivative obtained from it were not effective in glycosylating the C-2 position of partially blocked rhamnopyranoside but 3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-D-glucosyl bromide gave the desired 1,2-*trans*-2-amino-2-deoxyglucoside in good yield. Selective conversion of the phthalimido group to an acetamido function in the presence of an ester function was achieved, thereby extending the utility of the phthalimido protecting group to sequential oligosaccharide synthesis, in which 2-acetamido-2-deoxy-β-D-glucosides are internal units. Proton nmr evidence in support of the *exo*-anomeric effect is presented.

DAVID R. BUNDLE et STAFFAN JOSEPHSON. Can. J. Chem. **57**, 662 (1979).

On a synthétisé trois disaccharides contenant des unités rhamnopyrannosides qui portent une liaison α et qui sont présents sous une forme appropriée à la formation d'une liaison covalente avec une protéine. Les antigènes artificiels obtenus de cette manière correspondent à des éléments de structures semblables à ceux de portions de l'unité de base du *O*-antigène du *Shigella flexneri*. Les réactions de glycosylation conduisant aux disaccharides font appel au trifluorométhanesulfonate et à la *N,N*-tétraméthylurée ou à la *sym*-collidine; ces conditions conduisent aux trois glycosides liés *trans*-1,2 avec de bons rendements et une haute stéréospécificité. Les groupes bloqueurs utilisés dans ces synthèses sont compatibles avec des extensions subséquentes des chaînes vers des tri- et des tétrasaccharides. Les chlorure de l'acétamido-2 tri-*O*-acétyl-3,4,6 désoxy-2 α-D-glycopyrannosyle et le dérivé oxazoline-1,2 qui en dérive ne sont pas des agents efficaces pour provoquer la glycosylation en position C-2 d'un rhamnopyrannoside partiellement bloqué; toutefois le bromure de tri-*O*-acétyl-3,4,6 désoxy-2 phtalimido-2 D-glycosyle conduit au glucoside *trans*-1,2 amino-2 désoxy-2 avec un bon rendement. La transformation sélective du groupe phtalimido en fonction acétamido en présence d'une fonction ester a pu être réalisée; ce résultat étend le champ d'application du groupe protecteur phtalimido à la synthèse séquencielle d'oligosaccharides dans lesquels les unités internes sont des acétamido-2 désoxy-2β D-glucosides. On présente des données de rmn du proton qui sont en accord avec un effet anomérique *exo*.

[Traduit par le journal]

Introduction

Structural studies of the lipopolysaccharides (LPS) from various strains of *Shigella flexneri* indicate a basic tetrasaccharide repeating unit common to all serogroups (1–5). The simplest structure is that of strain Y (3) which possesses the structure

$$\text{-}[\text{-}3)\text{-}\beta\text{-D-GlcNAc}p(1\rightarrow 2)\text{-}\alpha\text{-L-Rha}p(1\rightarrow 2)\text{-}\alpha\text{-L-Rha}p(1\rightarrow 3)\text{-}\alpha\text{-L-Rha}p(1\text{-}]_n$$

Other strains of *S. flexneri* possess LPS with different glycosyl or acyl substitution patterns upon this basic structure (4, 5). The serological classification of *S. flexneri* finds its basis in this variability of fine structure. The serogroup Y polysaccharide is a high molecular weight antigen containing approximately 40 repeating units (3). Since this polysaccharide has neither charged groups nor side chains which are known (6–8) to direct the synthesis of antibody complementary to these features, the structural units that constitute the immunodominant regions are not immediately obvious. It is known from published data (9, 10) that linear charged polysaccharides ellicit antibody populations with specificities for different portions of the polysaccharide structure. Extensive studies of the dextrans (11, 12) show that

[1]NRCC No. 17121.
[2]NRCC Research Associate.

0008-4042/79/060662-07$01.00/0

there is heterogeneity with respect to the specificity for α1,3 or α1,6 linkages and in the size of the combining site. Although the Y polysaccharide would be expected to exhibit similar immunogenic properties, the occurrence of several 1,2-glycosidic linkages (13) might be imagined to render a particular region of the repeating unit more 'accessible' to cell surface receptors responsible for initiating the process of antibody synthesis in vivo. Little is known of such immunodominant features of *S. flexneri.*

The objective of the work currently in progress in this laboratory and reported in part here is to investigate the immunodominant regions of *S. flexneri* by the use of artificial antigens. Advances in glycoside synthesis in conjunction with modern methods of artificial antigen synthesis (14, 15) and conformational analysis provide particularly attractive tools to probe this question. Oligosaccharides possessing 6-deoxyhexopyranosides were chosen for study in the expectation that high resolution nmr would provide important insights into the conformational basis of serological specificity (14). In addition synthetic oligosaccharides hold promise as diagnostic reagents either via artificial antigens (14) or immunoabsorbents. In this context we report the synthesis of three disaccharides in a form suitable for covalent linkage to proteins or solid supports. The blocking sequences employed are consistent with our ultimate goals, the syntheses of tri- and tetrasaccharide antigens which are currently in progress.

Results and Discussion

The three disaccharides, which are the object of this synthetic work are exclusively glycosides of the 1,2-*trans*-linked type. Each disaccharide has been synthesised as its 8-methoxycarbonyloctyl glycoside to allow subsequent covalent attachment to protein after removal of blocking groups. This necessitates the formation of two glycoside linkages both consistent with those portions of the LPS antigen to which the artificial antigen correspond. Consequently the three disaccharides required were of the following structure

α-L-Rha*p*(1 → 3)β-D-GlcNAc*p*(1 → R)

α-L-Rha*p*(1 → 2)α-L-Rha*p*(1 → R)

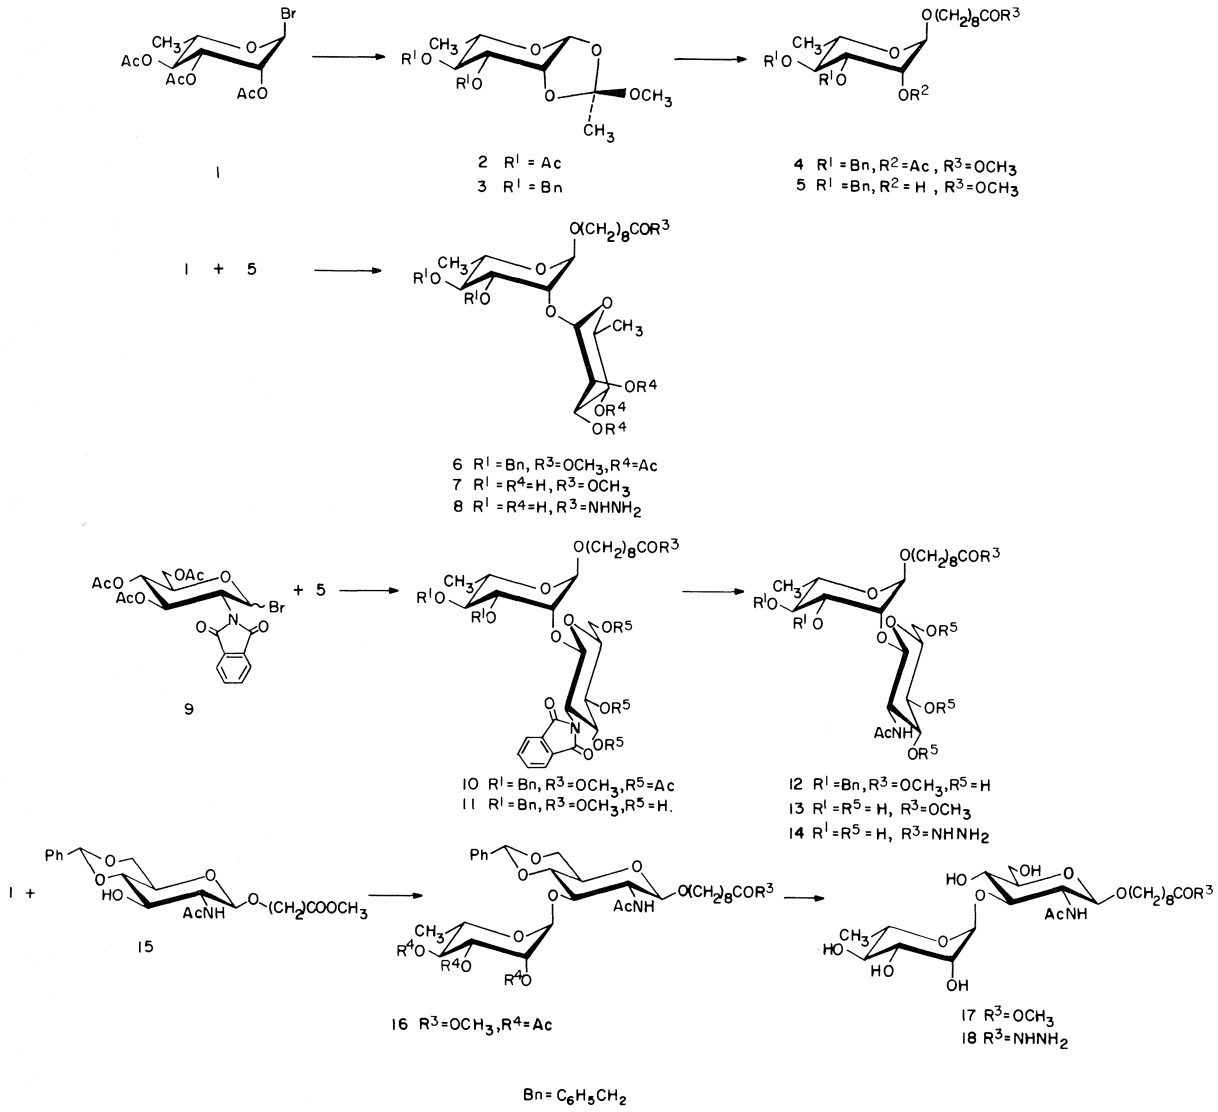
β-D-GlcNAc*p*(1 → 2)α-L-Rha*p*(1 → R)

where $R = O(CH_2)_8CO_2CH_3$ referred to here and elsewhere (15) as the 'bridging' or 'linking arm.'

The initial stage of the synthesis of 2-acetamido-2-deoxy-3-*O*-(α-L-rhamnopyranosyl)-β-D-glucopyranoside (**17**) required a 2-acetamido-2-deoxy-β-D-glucopyranoside selectively blocked at the 4 and 6 positions. The 4,6-*O*-benzylidene derivative **15** used in this work was previously synthesized by Lemieux *et al.* (14) as a precursor to Lewis-a blood-group antigens. The attachment of an α-linked rhamnopyranoside residue at the 3-position was a comparatively straight forward step. Although per-*O*-acetyl-α-rhamnopyranosyl and α-D-mannopyranosyl bromides are known to yield significant amounts of orthoester under Koenigs–Knorr conditions (16, 17), Helfrich conditions usually alleviate this problem (18) and indeed disaccharide **16** was synthesised in 52% yield by this procedure. Silver trifluoromethanesulphonate(triflate)tetramethylurea has been shown by Hanessian and Banoub (19) to be effective for 1,2-*trans*-glycoside synthesis. Related work utilising silver triflate – *sym*-collidine in conjunction with the phthalimido group as a limited participating group at C-2 establish these as conditions of choice for 2-amino-2-deoxyglycoside synthesis (20). The latter conditions lead to ortho ester formation when per-*O*-acetylated glycosyl bromides are used as the glycosylating species (Banoub and Bundle (28)) whereas glycosides result when the weaker base tetramethylurea is substituted for *sym*-collidine. When the protected glycoside **15** was reacted with **1** under these conditions (silver triflate – tetramethylurea) the yield of **16** was 67%, an increase from the 52% yield obtained with mercuric cyanide as the promotor. Since silver triflate – tetramethylurea effectively avoids the problem of ortho ester formation due to the acidic nature of these conditions, this procedure was used in all subsequent glycosylations leading to α-L-rhamnopyranosidic bonds.

The synthesis of 2-*O*-(α-L-rhamnopyranosyl)-α-L-rhamnopyranoside (**7**) resolved itself into the selective blocking of positions C-3 and C-4 of 8-methoxycarbonyloctyl-α-L-rhamnopyranoside. These protecting groups were required to be 'persistent' to allow the synthesis of a trisaccharide antigen, wherein, a β-linked 2-acetamido-2-deoxy-D-glucopyranose sugar could be linked to C-2 of the terminal rhamnose of disaccharide **7**.[3] This objective was most conveniently achieved by utilising the approach of Garegg and co-workers (21), in which a 1,2-ortho ester (**2**) is benzylated to give the derivative **3** which may be used directly to give the glycoside **4** using standard orthoester glycosylation procedures (22). Conversion of the acetate **4** to the alcohol **5** followed by reaction with **1** using silver triflate as promoter provided disaccharide **6** in 76% yield. Attempts to prepare the analogous 2-*O*-linked glucosamide (**12**) by

[3]Paper in preparation.



reaction of 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-glucopyranosyl chloride or the oxazoline derived from this compound with partially blocked rhamnoside **5** were not successful. However, using the conditions described by Lemieux and co-workers (20) the bromide **9** reacted with rhamnopyranoside **5** to give the expected glucosaminide **10** in 70% yield.

The deblocking of disaccharide **10** provided important findings which should allow the uses of the phthalimido protecting group in sequential oligosaccharide synthesis, where the glucosaminyl residue is not the terminal sugar. The approach to synthetic carbohydrate antigens developed by Lemieux *et al.* (14) and utilising the alcohol 8-methoxycarbonyloctanol has synthetic convenience in addition to the important biological effects associated with the choice of a nine carbon atom 'bridging arm' (15). However, the ester function of the bridging arm must be compatible with all reaction conditions, blocking, glycosylation and removal of protecting groups. In this connection it may be appreciated that strongly reducing conditions such as $LiAlH_4$, B_2H_6, or alkaline conditions, both of which destroy the ester function, must be avoided. The ester function is required to be converted to a hydrazide, e.g., **8**, **14**, or **18** in the final step preceding antigen preparation (cf. 13, 14). Conversion of the phthalimido function of **11** to a 2-amino-2-deoxy glucoside with hydrazine was anticipated to replace the 8-methoxy carbonyloctyl function by its hydrazide derivative, thereby necessitating selective *N*-acetylation to provide **14**. However, it was found that the phthalimido

group can be selectively converted by hydrazine without affecting the ester function. In addition it was found that catalytic de-*O*-acetylation of compound **10** by sodium in methanol proceeds smoothly without conversion of the phthalimido group to a 2′-carboxybenzamido function as reported by Baker *et al.* (23). When the disaccharide **11** was refluxed with hydrazine hydrate in ethanol, an 80% yield of the desired product **12** was obtained. Clearly the finding, that the phthalimido function is stable to conventional de-*O*-acetylation procedures and that the amino blocking group may be removed without destroying the essential ester function of the 'spacer' or 'bridging arm' permits manipulation of the glucosaminide residue such that another sugar may be attached at C-3, C-4, or C-6 positions with suitable ester or acetal blocking groups.

All compounds synthesised were characterised by both ^{1}H nmr and ^{13}C nmr. The results of the latter, particularly, establish the stereochemistry of the reaction products. The most striking feature of the ^{1}H nmr data was the 0.6 ppm upfield shift of the H-6′ protons of disaccharide **16**. That this is due to the influence of the aromatic ring of the benzylidene acetal and not to other conformational reasons was indicated by conversion of **16** to the 4,6-isopropylidene ketal. Both this ketal and the de-*O*-benzylidenated, tri-*O*-acetyl-rhamnopyranosyl-glucosaminide showed 'normal' shifts, $\delta \simeq 1.2$ ppm for the H-6′ protons. Consideration of the *exo*-anomeric effect with respect to orientation of the glucosamine residue about the C-1′ to glycosidic oxygen bond (torsional angle ϕ) indicates two possible staggered arrangements, one of which, with the C(1′)—C(2′) bond antiparallel to the O(1′)—C(3) bond, is predicted to be the more stable rotamer (24). The direction of chemical shift for the H-6′ protons indicates that they must lie close to the centre of the aromatic ring. Examination of molecular models shows that for the H-6′ protons to remain in this orientation it is necessary to restrict not only ϕ but also the second torsional angle, ψ, used to define disaccharide conformation at the glycosidic linkage. In fact the rotamer about O(1′)—C(3) that maintains the exocyclic methyl group in maximum overlap with the aromatic nucleus is that in which the C(3)—H(3) bond nearly eclipses the C(1′)—O(1′) bond. A similar conformation has been predicted from hard-sphere calculations based on the *exo*-anomeric effect for cyclohexyl-α-D-glucopyranosides (24). The ^{13}C nmr spectra for compound **16** show a related but opposite chemical shift for the C-6′ carbon. In other respects the ^{13}C nmr spectra of the compounds reported are consistent with the structures synthesised and do not warrant further comment at present.

Experimental

Thin-layer chromatography was performed with Merck precoated silica gel 60 F-254 plates and the detection of compounds was achieved by quenching of uv fluorescence and with 5% sulphuric acid in ethanol. Column chromatography utilised silica gel G60 (70–230 mesh) and redistilled solvents. The loading on all columns was 1:100 unless otherwise indicated. Skellysolve B refers to hexane supplied by Getty Refining and Marketing Company, Tulsa, OK. Palladium 10% on charcoal was purchased from Engelhard Industries, Newark, NJ. Solvents were purified and dried according to standard procedures (25). Processed solutions were dried over anhydrous sodium sulphate and solvent removal was achieved with bath temperatures 40°C or lower unless otherwise stated. Melting points were determined on a Fisher-Johns apparatus and are uncorrected. Optical rotations at the sodium-D-line were measured in a 1-dm cell at room temperature (20–23°C). Carbon-13 and ^{1}H nmr spectra were recorded at 20 and 79.9 MHz, respectively, in the pulsed Fourier transform mode on a Varian CFT-20 spectrometer. Proton chemical shifts are expressed relative to 1% tetramethylsilane (TMS) for deuteriochloroform, acetone-d_6 and methanol-d_4. Carbon-13 shifts are expressed relative to internal TMS in methanol-d_4 and assignments of ^{13}C resonances are tentative.

*3,4-Di-*O*-acetyl-1,2-*O*-(methoxyethylidene)*-β-L-*rhamnopyranose (2)*

Anhydrous methanol (19 mL, 469 mmol) was added to a stirred solution of 164.8 g (467 mmol) of 2,3,4-tri-*O*-acetyl-α-L-rhamnopyranosyl bromide (**1**) (26) in 235 mL of 2,6-lutidine. After 48 h at room temperature absolute chloroform (250 mL) was added and after 16 h **1** had been consumed. Filtration and quenching of the filtrate in cold water (1 L) followed by addition of 1 *M* hydrochloric acid to pH 8 produced an oil which was extracted with ethyl acetate (3 × 200 mL). The combined extracts were washed with water (3 × 300 mL), dried, concentrated, and the syrup taken up in ether – Skellysolve B. Crystallisation overnight at 4°C gave 53.6 g and a further 30.9 g on retreatment of the mother liquors. Both samples had mp 86–87°C, $[\alpha]_D$ 34.4° (*c* 1.0, $CHCl_3$) (mp 84–86°C, lit. (27) $[\alpha]_D$ 34.7° ($CHCl_3$)), and were pure by ^{1}H nmr (single isomer, *exo*-OCH_3) and by analysis; ^{1}H nmr ($CDCl_3$) δ: 1.19 (d, 3H, H-6), 1.68 (s, 3H, CH_3-C), 2.03 (s, 3H, CH_3CO), 2.07 (s, 3H, CH_3CO), 3.22 (s, 3H, CH_3O), 3.27–3.61 (m, 1H, H-5) 4.53 (dd, $J_{1,2} = 2.5$ Hz, $J_{2,3} = 4.0$ Hz, 1H, H-2), 4.99 (m, 2H, H-3, H-4), 5.26 (d, $J_{1,2} = 2.5$ Hz, 1H, H-1). *Anal.* calcd. for $C_{13}H_{20}O_8$: C 51.31, H 6.63; found: C 51.32, H 6.80.

The mother liquors contained 45 g of material which may be used directly as a syrup in the next step without significant decreases in yield. The purity of this material by ^{1}H nmr was approximately 90%.

*3,4-Di-*O*-benzyl-1,2-*O*-(methoxyethylidene)*-β-L-*rhamnopyranose (3)*

Crystalline **2** (50.9 g, 167 mmol) dissolved in dry methanol (200 mL) was treated with 100 mL of ammonia saturated methanol and left for 48 h at room temperature under anhydrous conditions. The crystalline residue obtained when this solution was evaporated could be recrystallised from ethyl acetate – Skellysolve B but was most conveniently dried as a solid mass and used directly. This solid (34.7 g), after drying under vacuum over phosphorous pentoxide, was dissolved in dry DMF (200 mL) and added slowly to a suspension of sodium hydride (16 g, 667 mmol) in 250 mL of DMF. Benzyl bromide (60 mL, 491 mmol) was added dropwise to the solid mixture formed by the addition of ortho ester to sodium hydride. The benzyl bromide was added over 30 min with

cooling to keep the reaction at approximately 20°C. The solution was then left stirring for 18 h and worked up by addition of methanol 50 mL. After 1 h the clear solution was poured into water (1 L) and brought to pH 8 with 1 *M* hydrochloric acid. Ethyl acetate (200 mL) was added and the aqueous phase extracted with ethyl acetate (2 × 200 mL). After washing with water (2 × 200 mL) the organic phase was dried, concentrated, and dissolved in ether – Skellysolve B. On standing at 4°C crystals (42.7 g, 64%) were deposited, mp 110–111°C, $[\alpha]_D$ 0.6° (*c* 1.0, $CHCl_3$). A further 3 g of material was obtained upon crystallisation of the mother liquors, mp 109–111°C, total yield 68%; ^{1}H nmr ($CDCl_3$) δ: 1.31 (d, 3H, H-6), 1.73 (s, 3H, CH_3-C), 3.27 (s, 3H, CH_3O), 3.27–3.79 (m, 3H, H-3, H-4, H-5) 4.38 (dd, $J_{2,3}$ = 4.0 Hz, $J_{1,2}$ = 2.5 Hz, 1H, H-2), 4.53–5.02 (m, 4H, $CH_2\phi$), 5.26 (d, $J_{1,2}$ = 2.5 Hz, 1H, H-1). *Anal.* calcd. for $C_{23}H_{28}O_6$: C 68.98, H 7.05; found: C 69.13, H 7.10.

*8-Methoxycarbonyloctyl 3,4-Di-*O*-benzyl-α-*L*-rhamnopyranoside (**5**)*

Ortho ester **3** (18.0 g) was refluxed for 30 min with 8-methoxycarbonyloctanol (9 g) in acetonitrile (200 mL) containing mercuric bromide (100 mg). The solvent was then distilled off leaving a light brown syrup to which dichloromethane (500 mL) was added. Following extraction with ice cold water (300 mL) the solution was dried, evaporated, and a small sample of the resulting syrup was chromatographed on silica gel using Skellysolve B – ethyl acetate (3:1) to provide pure **4** as a syrup, $[\alpha]_D$ −23.3° (*c* 1.1, $CHCl_3$); ^{1}H nmr ($CDCl_3$) δ: 0.9–1.7 (m, 15H, H-6 and —$(CH_2)_6$—), 2.12 (s, 3H, CH_3CO), 2.28 (t, 2H, CH_2CO—), 3.63 (s, 3H, —OCH_3), 3.20–4.25 (m, 4H, ring protons and OCH_2), 4.33–5.01 (m, 6H, —$CH_2\phi$ and ring protons), 5.32 (dd, $J_{1,2}$ = 1.8 Hz, $J_{2,3}$ = 3.4 Hz, 1H, H-2); ^{13}C nmr (CD_3OD) δ: 98.7 (Cl), 81.1, 80.9 ($OCH_2\phi$), 76.1 (C4), 72.7 (C2), 70.3 (C3), 68.8 (2C, C5 and OCH_2), 18.3 (C6).

The remaining portion of **4** was deacetylated directly in methanol (500 mL) containing a catalytic amount of sodium. Deionisation with Rexyn 101 (H^+) resin, concentration, and chromatography on a column of silica gel (1200 g) with Skellysolve B – ethyl acetate (1:1) gave pure **5** (14.5 g) and 3.0 g of methyl 3,4-di-*O*-benzyl-α-L-rhamnopyranoside. Pure, homogeneous syrup **5** had $[\alpha]_D$ −24.2° (*c* 1.0, $CHCl_3$); ^{1}H nmr ($CDCl_3$) δ: 0.90–1.75 (m, 15H, H-6 and —$(CH_2)_6$—), 2.30 (t, 2H, CH_2CO), 2.50 (d, 1H, OH), 3.62 (s, 3H, OCH_3), 3.23–4.18 (m, 7H, OCH_2 and ring protons), 4.43–5.01 (m, 4H, CH_2O), 7.23–7.27 (m, 10H, aromatic); ^{13}C nmr (CD_3OD) δ: 101.3 (C1), 81.1, 80.9 ($OCH_2\phi$), 76.0 (C4), 72.3 (C3), 69.1 (C2), 68.8 (OCH_2), 68.4 (C5), 18.3 (C6). *Anal.* calcd. for $C_{30}H_{42}O_7$: C 70.01, H 8.23; found: C 69.90, H 8.30.

*8-Methoxycarbonyloctyl 2-*O*-(2,3,4-Tri-*O*-acetyl-α-L-rhamnopyranosyl)-3,4-di-*O*-benzyl-α-L-rhamnopyranoside (**6**)*

The partially protected glycoside **5** (2.0 g, 3:9 mmol) was dissolved in dichloromethane (35 mL) containing silver triflate (1.9 g, 7.5 mmol) and tetramethylurea (3.6 mL, 30 mmol). This solution was cooled to −70°C and 2,3,4-tri-*O*-rhamnopyranosyl bromide (**1**) (2.4 g, 6.8 mmol) (26) dissolved in dichloromethane (15 mL) was added dropwise with stirring. The reaction was allowed to warm to room temperature overnight and then filtered. Following extraction with saturated sodium bicarbonate (20 mL), the concentrated syrup was purified on a silica gel column with Skellysolve B – ethyl acetate (2:1) as solvent. Pure disaccharide, **6** (2.0 g) was obtained in 73% yield $[\alpha]_D$ −42.7° (*c* 0.9, $CHCl_3$), R_f 0.48 (Skellysolve B – ethyl acetate, 2:1); ^{1}H nmr ($CDCl_3$) δ: 1.0–1.8 (m, 18H, H-6, H-6′, and —$(CH_2)_6$—), 1.95 (s, 3H, CH_3CO—), 2.02 (s, 3H, CH_3CO—), 2.06 (s, 3H, CH_3CO—), 2.28 (t, 2H, CH_2CO—), 3.56 (s, 3H, OCH_3), 3.10–4.16 (m, 7H, OCH_2 and ring protons), 4.45–5.51 (m, 7H, $OCH_2\phi$ and ring protons), 7.06–7.36 (m, 10H, aromatic); ^{13}C nmr (CD_3OD) δ: 100.3 (C1′), 99.8 (C1), 81.0, 80.7 ($CH_2\phi$), 77.3 (C2), 76.1 (C4), 73.1 (C3), 72.0 (C4′), 70.8 (C3′), 70.5 (C2′), 69.1 (OCH_2), 68.5 (C5), 68.0 (C5′), 18.2 (C6), 17.6 (C6′).

*8-Methoxycarbonyloctyl 2-*O*-(α-L-Rhamnopyranosyl)-α-L-rhamnopyranoside (**7**)*

Compound **6** (1.5 g) in methanol (200 mL) containing a catalytic amount of sodium was left for 16 h at room temperature. The syrup, obtained after removal of sodium ions with Rexyn 101 (H^+) resin, filtration, and evaporation, was dissolved in acetic acid (100 mL) and hydrogenated with palladium, 10% on charcoal (0.5 g), at 70 psi for 3 h. Filtration and co-evaporation with toluene (3 × 150 mL) followed by column chromatography on silica gel with the solvent, ethyl acetate – methanol – water (85:10:5) gave pure **7** (0.7 g, yield 74%), $[\alpha]_D$ −60.5° (*c* 1.0, methanol), R_f 0.40 (solvent 85:10:5 as above); ^{1}H nmr (acetone-d_6 δ: 1.19 (d, $J_{5,6}$ = 6 Hz, H-6), 1.22 (d, $J_{5,6}$ = 6 Hz, H-6′), 1.0–1.75 (m, 18 H, —$(CH_2)_6$—), 2.25 (t, 2H, CH_2CO), 3.60 (s, 3H, CH_3O), 3.10–4.16 (m, ring protons), 4.74 (bs, 1H, H-1′) 4.93 (bs, 1H, H-1); ^{13}C nmr (CD_3OD) δ: 103.9 (C1), 100.1 (C1′), 80.2 (C2), 74.1 (C4), 73.7 (C4′), 72.1 (C3), 72.0 (C3′), 71.8 (C2′), 70.0 (C5), 69.6 (OCH_2), 68.4 (C5′), 18.0 (C6), 17.8 (C6′).

*8-Hydrazinocarbonyloctyl 2-*O*-(α-L-Rhamnopyranosyl)-α-L-rhamnopyranoside (**8**)*

The fully deblocked disaccharide **7** (0.5 g) in ethanol solution (3 mL) was treated with hydrazine hydrate (0.5 g) at room temperature for 60 h. After evaporation and codistillation with ethanol, the solid residue was dried under vacuum. Purification on a column of silica gel with dichloromethane–methanol (1:1) gave pure **8** (0.45 g, 90% yield), $[\alpha]_D$ −53.6 (*c* 1.0, methanol), R_f 0.51 (1:1, as above); ^{1}H nmr (D_2O) δ: 1.1–1.9 (m, 18H, H-6, H-6′, —$(CH_2)_6$—), 2.20 (t, 2H, CH_2CO), 3.18–4.56 (m, 10H, ring protons, —CH_2O), 4.86 (bs, 1H, H-1′), 4.96 (bs, 1H, H-1). *Anal.* calcd. for $C_{21}H_{40}N_2O_{10}$: C 52.49, H 8.39, N 5.82; found: C 52.50, H 8.59, N 5.69.

*8-Methoxycarbonyloctyl 2-*O*-(3,4,6-Tri-*O*-acetyl-2-deoxy-2-pthalimido-β-D-glucopyranosyl)-3,4-di-*O*-benzyl-α-L-rhamnopyranoside (**10**)*

The partially benzylated rhamnopyranoside **5** (1.40 g, 2.7 mmol) was dissolved in dichloromethane (30 mL) together with collidine (0.37 g, 3.3 mmol) and silver triflate (0.85 g, 3.3 mmol). The solution was maintained under a dry nitrogen atmosphere and cooled to −40°C. The bromo sugar **9** (1.6 g, 3.2 mmol), prepared according to Lemieux and co-workers (20), dissolved in dichloromethane (20 mL) was added dropwise to the cooled solution of **5** and allowed to warm to room temperature overnight with constant stirring. After filtration, extraction of the filtrate with 3% hydrochloric acid, saturated sodium bicarbonate, and water, the solution was dried and evaporated. The product was purified on silica gel with Skellysolve B – ethyl acetate (1:1) as solvent to give pure **10** (1.75 g, 70% yield), $[\alpha]_D$ +8.0° (*c* 1.0, $CHCl_3$), R_f 0.58 (solvent as for column chromatography); ^{1}H nmr (CD_3OD) δ: 0.85–1.70 (m, 15H, H-6 and —$(CH_2)_6$—), 1.86 (s, 3H, CH_3CO), 2.02 (s, 3H, CH_3CO), 2.07 (s, 3H, CH_3CO), 2.25 (t, 2H, CH_2CO), 3.53 (s, 3H, CH_3O), 2.75–3.68 (m, 5H, ring protons, OCH_2), 3.68–4.57 (m, 9H, $OCH_2\phi$, ring protons), 4.67 (d, $J_{1,2}$ = 8 Hz, 1H, H-1′), 5.99 (t, $J_{2,3}$ = 9 Hz, 1H, H-3′), 6.85–7.86 (m, 14H, aromatic); ^{13}C nmr (CD_3OD) δ: 101.8 (Cl′), 100.1 (C1), 81.6, 79.6 ($OCH_2\phi$), 78.8 (C2), 75.8 (C5′),

73.2 (C4), 72.8 (C3′), 71.4 (C4′), 70.5 (C3), 69.0 (OCH_2), 68.3 (C5), 63.0 (C6′), 55.9 (C2′), 18.2 (C6).

*8-Methoxycarbonyloctyl 2-O-(2-Deoxy-2-phthalimido-β-D-glucopyranosyl)-3,4-di-O-benzyl-β-L-rhamnopyranoside (**11**)*

The fully protected disaccharide **10** (0.45 g, 0.48 mmol) was dissolved in methanol (70 mL) and a catalytic amount of freshly prepared sodium in methanol was added. The reaction was stirred overnight at room temperature, sodium ions were removed with Rexyn 101 (H^+) resin and the syrup was chromatographed using chloroform–methanol (7:1) with silica gel. Pure de-*O*-acetylated product **11** (0.35 g) was obtained in 90% yield, $[\alpha]_D$ −19.9° (*c* 1.1, methanol), R_f 0.54 (chloroform–methanol 7:1), mp 126–128°C (recrystallised from ether); ^{1}H nmr (CD_3OD) δ: 1.07 (d, 3H, H-6), 1.15–1.65 (m, 12H, —$(CH_2)_6$—), 2.23 (t, 2H, CH_2CO), 3.57 (s, 3H, CH_3O), 4.69 (d, $J_{1,2}$ = 2 Hz, 1H, H-1), 5.20 (d, $J_{1,2}$ = 8 Hz, 1H, H-1′), 6.80–7.90 (m, 14H, aromatic), 2.70–4.58 (remaining protons); ^{13}C nmr (CD_3OD) δ: 101.4 (C1′), 100.3 (C1), 81.8, 79.7 ($OCH_2\phi$), 78.6 (C2), 77.9 (C3′), 75.9 (C5′), 73.0 (C4), 72.5 (C3), 71.9 (C4′), 69.0 (OCH_2), 68.3 (C5), 62.6 (C6′), 58.6 (C2′), 18.1 (C6). *Anal.* calcd. for $C_{44}H_{55}NO_{13}$: C 65.58, H 6.88, N 1.74; found: C 65.46, H 6.89, N 1.88.

*8-Methoxycarbonyloctyl 2-O-(2-Acetamido-2-deoxy-β-D-glucopyranosyl)-3,4-di-O-benzyl-α-L-rhamnopyranoside (**12**)*

Compound **11** (0.35 g, 0.43 mmol) in ethanol (20 mL) was boiled with hydrazine hydrate (0.18 g of an 85% solution, 3 mmol) for 2 h. The reaction was monitored by tlc with chloroform–methanol (7:1) as solvent. In this system starting material possessed R_f 0.54 and the free amino derivative R_f 0.42. The solution was evaporated and thoroughly dried to remove traces of hydrazine. The product was then dissolved in methanol–water (1:1, 10 mL) and acetic anhydride (1 mL) was added. The solution was then stirred at room temperature overnight. Concentration followed by silica gel column chromatography with chloroform–methanol (7:1) gave pure **12** (0.25 g, 80% yield), $[\alpha]_D$ −8.8° (*c* 1.1, CH_3OH), R_f 0.52 (chloroform–methanol 7:1); ^{1}H nmr (CD_3OD) δ: 1.10–1.70 (m, 15H, H-6 and —$(CH_2)_6$—), 1.83 (s, 3H, CH_3CONH), 2.28 (t, 2H, CH_2CO), 3.52 (s, 3H, CH_3O), 7.00–7.80 (m, 10H, aromatic), 3.15–5.00 (remaining protons); ^{13}C nmr (CD_3OD) δ: 104.1 (C1′), 100.4 (C1), 81.7, 80.7 ($OCH_2\phi$) 77.8 (C2), 77.8 (C3′), 76.2 (C5′), 75.8 (C4), 73.1 (C3), 71.8 (C4′), 69.1 (OCH_2), 68.4 (C5), 62.6 (C6′), 57.9 (C2′), 18.3 (C6). *Anal.* calcd. for $C_{38}H_{55}NO_{12}$: C 63.58, H 7.72, N 1.95; found: C 63.46, H 7.63, N 1.85.

*8-Methoxycarbonyloctyl 2-O-(2-Acetamido-2-deoxy-β-D-glucopyranosyl)-α-L-rhamnopyranoside (**13**)*

Compound **12** (0.25 g, 0.35 mmol) was dissolved in acetic acid (50 mL) and palladium-on-charcoal (0.25 g) was added, the solution was hydrogenated at 70 psi for 3 h, filtered, and evaporated. The product was purified by column chromatography on silica gel with the solvent ethyl acetate – methanol – water (85:10:5) to give pure disaccharide **13** (0.17 g, 90% yield), $[\alpha]_D$ −25.4° (*c* 1.1, CH_3OH), R_f 0.18 (85:10:5); ^{1}H nmr (CD_3OD) δ: 1.10–1.75 (m, 15H, H-6 and —$(CH_2)_6$—), 1.99 (s, 3H, CH_3CONH), 2.29 (t, 2H, CH_2CO), 3.58 (s, 3H, CH_3O), 4.61 (d, $J_{1,2}$ = 8 Hz, 1H, H-1′), 4.84 (d, $J_{1,2}$ = 2 Hz, 1H, H-1), 3.15–4.35 (m, remaining protons); ^{13}C nmr (CD_3OD) δ: 104.3 (C1′), 100.3 (C1), 81.0 (C2), 77.8 (C3′), 76.2 (C5′), 74.1 (C4), 72.1 (C4′), 71.8 (C3), 69.6 (OCH_2), 68.5 (C5), 62.5 (C6′), 57.9 (C2′), 17.9 (C6). *Anal.* calcd. for $C_{24}H_{43}NO_{12}$: C 53.62, H 8.06, N 2.61; found: C 53.46, H 7.85, N 2.61.

*8-Hydrazinocarbonyloctyl 2-O-(2-Acetamido-2-deoxy-β-D-glucopyranosyl)-α-L-rhamnopyranoside (**14**)*

The fully deblocked disaccharide, **13** (0.3 g) in ethanol solution (3 mL) was treated with hydrazine hydrate (0.5 g) at room temperature for 60 h. After evaporation and codistillation with ethanol the residue was dried under vacuum. Purification on a column of silica gel with dichloromethane–methanol (1:1) gave pure **14** (0.27 g, 90% yield), $[\alpha]_D$ −21.5° (*c* 1.0, CH_3OH), R_f = 0.52 (dichloromethane–methanol 1:1); ^{1}H nmr (CD_3OD) δ: 1.23 (d, $J_{5,6}$ = 5.9 Hz, 3H, H-6), 1.0–1.75 (m, 12H, —$(CH_2)_6$—), 2.00 (s, 3H, CH_3CONH), 2.14 (t, 2H, CH_2CO), 4.63 (d, $J_{1,2}$ = 7.8 Hz, 1H, H-1′), 4.87 (d, $J_{1,2}$ = 1.5 Hz, 1H, H-1), 3.20–4.20 (m, remaining protons). *Anal.* calcd. for $C_{23}H_{43}N_3O_{11}$: C 51.39, H 8.06, N 7.82; found: C 51.25, H 8.21, N 7.63.

*8-Methoxycarbonyloctyl 2-Acetamido-3-O-(2,3,4-tri-O-acetyl-α-L-rhamnopyranosyl)-4,6-O-benzylidene-2-deoxy-β-D-glucopyranoside (**16**)*

(A) Mercuric Cyanide

The glucosaminide **15** (2.6 g, 5.4 mmol) was dissolved in dry acetonitrile (75 mL) containing mercuric cyanide (1.5 g, 5.9 mmol) and to this stirred solution maintained under an atmosphere of dry nitrogen was added dropwise a solution of a 2,3,4-tri-*O*-acetyl-α-L-rhamnopyranosyl bromide (**1**) (2.1 g, 6.0 mmol) (26) in acetonitrile (20 mL). After 16 h dichloromethane was added and the solution was extracted once with water, sodium bicarbonate, and again with water. Purification of the syrup obtained after solvent removal on a column of silica gel with the solvent ethyl acetate – Skellysolve B (3:1) gave pure **16** (2.1 g, 52% yield), $[\alpha]_D$ −41.8° (*c* 1.1, $CHCl_3$), R_f 0.62 (3:1), mp 149–151°C (recrystallised from ethyl acetate – Skellysolve B); ^{1}H nmr ($CDCl_3$) δ: 0.61 (d, $J_{5,6}$ = 6.5 Hz, 3H, H-6), 1.0–1.75 (m, 12H, —$(CH_2)_6$—), 1.90–1.95 (d, 9H, CH_3CO), 2.07 (s, 3H, CH_3CO), 2.20 (t, 2H, CH_2CO), 3.64 (s, 3H, CH_3O), 4.78 (d, $J_{1,2}$ = 2 Hz, 1H, H-1′), 4.93 (d, $J_{1,2}$ = 8 Hz, 1H, H-1), 5.46 (s, 1H, acetal H), 6.03 (bd, 1H, NH), 7.0–7.5 (m, 5H, aromatic), 2.85–5.35 (remaining protons); ^{13}C nmr (CD_3OD) δ: 103.2 (C1), 102.8 ($CH\phi$), 99.1 (C1′), 81.1 (C4), 78.3 (C3), 72.5 (C5), 71.7 (C4), 70.8 (C3′), 70.1 (C2′), 69.7 (OCH_2), 67.7 (C5′), 67.4 (C6), 57.5 (C2), 17.0 (C6′). *Anal.* calcd. for $C_{37}H_{53}NO_{15}$: C 59.11, H 7.11, N 1.86; found: C 58.89, H 7.15, N 1.98.

(B) Silver Triflate

Compound **15** (1.8 g, 3.8 mmol) was dissolved in dichloromethane (50 mL) together with silver triflate (1.6 g, 6.3 mmol) and tetramethylurea (3 mL, 25 mmol). The stirred solution was cooled to −40°C under a dry nitrogen atmosphere and the bromo sugar **1** (2.0 g, 5.7 mmol) in dichloromethane solution (20 mL) was added dropwise. The reaction mixture was allowed to warm to room temperature over 16 h. The reaction was worked up as described in A. After chromatography the yield of pure **16** was 1.9 g, 67%. The physical constants and ^{1}H nmr data were identical to those above.

*8-Methoxycarbonyloctyl 2-Acetamido-2-deoxy-3-O-(α-L-rhamnopyranosyl)-β-D-glucopyranoside (**17**)*

The disaccharide **16** (1.9 g, 2.5 mmol) was dissolved in methanol (200 mL) containing a catalytic amount of sodium. After 16 h the solution was deionised and concentrated. The residue was dissolved in 10 mL of 90% aqueous trifluoroacetic acid at 0°C and left for 45 min. Evaporation and codistillation with ethanol gave **17** which crystallized from ethanol – ethyl

acetate. Crystals of **17** (1.0 g, yield 77%) were collected, $[\alpha]_D$ −48.9° (*c* 1.2, CH_3OH), R_f 0.45 (dichloromethane–methanol 1:1), mp 175–177°C (recrystallized from ethanol–ethyl acetate 3:1); ^1H nmr (CD_3OD) δ: 1.10–1.75 (m, 15H, H-6′ and —$(CH_2)_6$—), 1.96 (s, 3H, CH_3CO), 2.28 (t, 2H, CH_2CO), 3.62 (s, 3H, CH_3O), 4.39 (d, $J_{1,2}$ = 8.0 Hz, 1H, H-1), 4.82 (d, $J_{1',2'}$ = 1.8 Hz, 1H, H-1′), 3.10–4.27 (remaining protons); ^{13}C nmr (CD_3OD) δ: 103.3 (C1), 102.3 (C1′), 83.8 (C3), 77.9 (C5), 73.8 (C4), 72.6 (C4′), 72.2 (C3′), 70.8 (C2′), 70.6 (C5′), 70.4 (OCH_2), 62.8 (C6), 56.9 (C2), 17.9 (C6′). *Anal.* calcd. for $C_{24}H_{43}NO_{12}$: C 53.62, H 8.06, N 2.61; found: C 53.33, H 8.10, N 2.80.

*8-Hydrazinocarbonyloctyl 2-Acetamido-2-deoxy-3-O-(α-L-rhamnopyranosyl)-β-D-glucopyranoside (**18**)*

The deblocked disaccharide **17** (0.50 g) was dissolved in ethanol (5 mL) containing hydrazine hydrate (0.5 g); the solution was stirred for 48 h, then evaporated and dried under high vacuum. Recrystallisation from ethanol gave pure **18** (0.45 g, 90% yield), $[\alpha]_D$ −48.3° (*c* 1.1, CH_3OH), R_f 0.54 (dichloromethane–methanol 1:1), mp 184–187°C (recrystallized from ethanol); ^1H nmr (CD_3OD) δ: 1.21 (d, $J_{5,6}$ = 6.3 Hz, H-6′), 1.05–1.70 (m, 15H, —$(CH_2)_6$— and H-6′), 1.95 (s, 3H, CH_3CONH), 2.12 (t, 2H, CH_2CO), 4.39 (d, $J_{1,2}$ = 8 Hz, 1H, H-1), 4.79 (d, 1H, H-1′), 3.15–4.27 (remaining protons). *Anal.* calcd. for $C_{23}H_{43}N_3O_{11}$: C 51.39, H 8.06, N 7.82; found: C 51.53, H 8.25, N 7.63.

ARNOLD JARCZEWSKI, PRZEMYSLAW PRUSZYNSKI, and KENNETH T. LEFFEK. Can. J. Chem. **57**, 669 (1979).

The proton transfer reaction between 2,4,6-trinitrotoluene and 1,1′,3,3′-tetramethylguanidine in dimethylformamide solvent shows a large primary deuterium isotope effect, $k_H/k_D = 24.3$ at 0°C and 16.9 at 20°C. The enthalpy of activation difference $(\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger}) = 2.6 \pm 0.4$ kcal mol^{-1} and the entropy of activation difference $(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger}) = 3.4 \pm 1.3$ cal mol^{-1} K^{-1}. This isotope effect, when fitted to Bell's equation, indicates that there is a considerable contribution to this reaction from tunnelling of the proton through the potential energy barrier.

ARNOLD JARCZEWSKI, PRZEMYSLAW PRUSZYNSKI et KENNETH T. LEFFEK. Can. J. Chem. **57**, 669 (1979).

La réaction de transfert de proton entre le trinitro-2,4,6 toluène et la tétraméthyl-1,1′,3,3′ guanidine dans le diméthylformamide comme solvant est accompagnée d'un effet isotopique primaire important, $k_H/k_D = 24.3$ à 0°C et 16.9 à 20°C. Les différences d'enthalpie d'activation $(\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger})$ et d'entropie d'activation $(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger})$ sont respectivement 2.6 ± 0.4 kcal mol^{-1} et 3.4 ± 1.3 cal mol^{-1} K^{-1}. Lorsqu'on insère ces valeurs d'effets isotopiques dans l'équation de Bell, on en déduit que l'effet de tunnel du proton à travers la barrière à l'énergie potentielle contribue d'une façon importante à la réaction.

[Traduit par le journal]

Introduction

The reaction of 2,4,6-trinitrotoluene (TNT) with 1,1′,3,3′-tetramethylguanidine (TMG) gives, in polar aprotic solvents, the purple anion of TNT (1), the absorption maxima and molar absorptivities of which are very similar to those observed by Buncel *et al.* (2) for the reaction of TNT with ethoxide ion in ethanol. Despite some opposing views (3–6), it now appears established (1, 2, 7) that the proton transfer reaction takes place to form the anion under appropriate conditions, free of competing reactions such as nucleophilic attack on the benzene ring and radical anion formation.

The observation of a kinetic isotope effect, $k_H/k_D \simeq 7$ for the formation of the purple TNT anion upon treatment with ethoxide ion in ethanol (2), 8.4 for isopropoxide in isopropanol (9), and 8 for *tert*-butoxide in *tert*-butyl alcohol (10), have been reinforced by k_H/k_D values of 20.4 and 13.7 for the TMG reaction in acetonitrile and benzonitrile, respectively (1). Consistent with this primary kinetic isotope Buncel *et al.* (11) showed that TNT exchanged the hydrogens of the methyl group completely after 30 min at room temperature in alkaline 90% DMF – 10% D_2O.

This paper is a development of the previous work (1) on the reaction of TNT with tetramethylguanidine in polar aprotic solvents. Caldin *et al.* (12–16) have demonstrated large kinetic isotope effects in weakly polar solvents for reactions of this base and have suggested that in less polar solvents the lack of solvent reorganization accompanying the proton transfer allows proton tunnelling through the energy barrier which increases the isotope effect. In more polar solvents, some solvent reorganization takes place during proton transfer which increases the effective mass of the proton and thereby greatly reduces tunnelling. DMF was chosen as the solvent on the basis that it is a more bulky molecule than the nitriles already studied and therefore might reorganize to a lesser extent during the activation process of the proton transfer. Thus, even though DMF has the same dielectric constant as acetonitrile it should allow a greater contribution from the tunnel effect and therefore a larger isotopic rate ratio.

Results and Discussion

The reaction between TNT (1.5×10^{-5} *M*) and TMG ranging in concentration from 5×10^{-4} to 5×10^{-3} *M* in DMF gives the purple anion. No

0008-4042/79/060669-04$01.00/0

brown product, originally described by Caldin *et al.* (7), was observed. A careful examination of the possibility of side reactions has been made previously (1) for the reaction in acetonitrile and benzonitrile from which it was concluded that any competitive reactions to the proton transfer were negligible under these conditions. The absorption maxima for the product of the reaction in DMF are identical to those observed in acetonitrile (1) and the molar absorptivities differ by only about 5%. The maxima are 377 nm ($\varepsilon = 8500$ L mol^{-1} cm^{-1}), 526 nm ($\varepsilon = 13800$ L mol^{-1} cm^{-1}), and 645 nm ($\varepsilon = 6800$ L mol^{-1} cm^{-1}). The equilibrium constant K_{25} was calculated as 1800 L mol^{-1} from the slope of the plot [S]/OD vs. 1/[B] shown in Fig. 1 for the relationship shown in [1] where [S] is the initial

$$[1] \qquad [S]/\mathrm{OD} = \frac{1}{K\varepsilon}\frac{1}{[B]} + \frac{1}{\varepsilon}$$

concentration of TNT, [B] that of TMG, and OD is the optical density at 526 nm.

This equation was derived on the assumption that the anion and protonated base products exist in DMF solvent as an ion pair. If this assumption were not valid the plot in Fig. 1 would show a curvature.

Pseudo-first-order rate constants (k_1) were determined from runs carried out with excess base in which the change in optical density with time was monitored. A good fit to the first-order equation was found for both the proton and the deuteron transfer. The k_1 values were plotted against the base concentration and the slopes of these plots afforded the second-order rate constants. These are shown in Table 1 for both TNT and TNT-d_3. The error limits quoted are standard deviations. The second-order constants in DMF are greater than those observed in benzonitrile and acetonitrile (1) by factors of about 2 and 5, respectively. The activation parameters derived from the second-order rate constants are given in Table 2. For the proton transfer, $\Delta H^{\ddagger}$ in DMF is the same as that observed in benzonitrile and about 2.5 kcal mol^{-1} greater than that observed in acetonitrile. The rate differences are, therefore, due to an overriding entropy of activation effect. In acetonitrile ($\Delta S^{\ddagger} = -31.4$ cal mol^{-1} K^{-1}) the entropy of activation is about 12 cal mol^{-1} K^{-1} more negative than in DMF, from which it can be concluded that the DMF transition state solvation shell is less ordered than the acetonitrile solvation shell, i.e., that solvent reorganization is less complete in DMF.

The primary isotope effects in DMF are large, well in excess of the rate ratio of 7 at 300 K expected from the loss of zero-point energy associated with the C—H stretching vibration which is converted into a

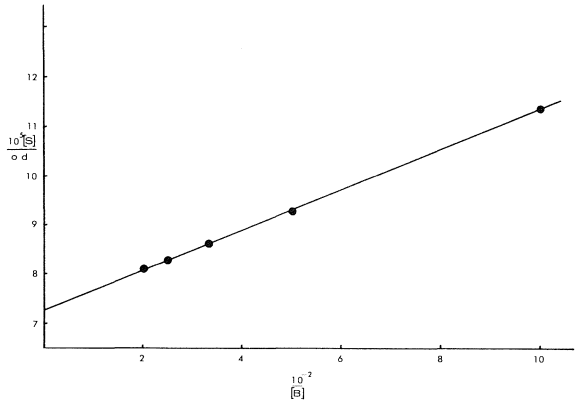

FIG. 1. Plot of 10^{-2}/[B] vs. 10^5[S]/OD for the reaction of 2,4,6-trinitrotoluene with 1,1′,3,3′-tetramethylguanidine in dimethylformamide solvent at 25°C.

translation during proton transfer. The value of $k_H/k_D = 16.9$ at 293 K falls between the 19.2 observed in acetonitrile and 13.1 in benzonitrile (1). Thus, we do not find a greater rate ratio as postulated from the solvent effect. However, from the isotope effects on the activation parameters, collated in Table 3, there does appear to be a larger tunnelling contribution in DMF, since the enthalpy of activation difference is much larger than the 1.1 kcal mol^{-1} arising from the loss of the stretching vibration.

These results confirm the general phenomenon of large isotope effects for TMG observed by Caldin and Mateo (5) with 4-nitrophenylnitromethane as substrate. Only acetonitrile is common to both sets of data and for this solvent the isotope effects on the activation parameters are very similar.

A_D/A_H	5.6	0.78	0.44

*From ref. 1.

In the extreme case of a complete loss of the C—H stretching frequency and two C–H bending frequencies during the activation process, the maximum isotope effect on the activation parameters is 2.1 kcal mol^{-1} for $\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger}$, 1.4 cal mol^{-1} K^{-1} for $\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger}$ and $A_D/A_H = 2.0$. Since our results in DMF solvent are in excess of these maximum values, it is assumed that there is a significant contribution from the tunnel effect. The results were fitted to Bell's equation (17–19) for a parabolic potential energy barrier, using the technique of Caldin and Mateo (13). For comparison, the tunnelling correction was also calculated for the isotope effects observed for the proton transfer reaction from 4-nitrophenylnitromethane to 1,8-bis(dimethylamino)naphthalene in *tert*-butyl alcohol solvent (20). For this reaction $k_H/k_D = 3.0$ at 30°C, $(\Delta H_D^{\ddagger} - \Delta H_H^{\ddagger}) = 1.1 \pm 0.7$ kcal mol^{-1} and $(\Delta S_D^{\ddagger} - \Delta S_H^{\ddagger}) = 1.5 \pm 2.3$ cal mol^{-1} K^{-1}, from which we concluded that there was probably no contribution from proton tunnelling (20). The tunnelling calculation is basically a trial and error fit of three parameters, E_H and E_D, the activation energies corrected for the tunnel effect for the protium and deuterated substrate, and $2b$, the width of the barrier at the base, to Bell's equation. The value of $E_D - E_H$ was limited to a maximum of 1.3 kcal mol^{-1}. The values of these parameters which give the best fit with the measured k_H/k_D over the temperature range are given in Table 4. The calculated parameters confirm the qualitative conclusion that the tunnelling contribution is important in the TNT reaction but insignificant in the reaction 4-NPNM with 1,8-bis(dimethyl)aminonaphthalene. In making these computations we have ignored the secondary isotope effect which arises from the fact that in the deuterated substrate only one of the three deuterium atoms is transferred. It is known that secondary effects of this type bring about a rate constant change of about 12 to 18% per D (21–23). However, they are difficult to measure in the presence of the primary effect and the uncertainties in the results are of the same magnitude as the secondary isotope effect itself, so it is impossible to measure the temperature dependence of the secondary effect in order to obtain the value of this effect on the activation parameters. Thus, although one can correct the rate ratio, using an estimated 15% per D atom for the secondary effect, this correction cannot be incorporated into the tunnel effect calculation which uses activation energies. Therefore, to make our computations directly comparable to those of Caldin and Mateo (13), we have followed the same method and ignored the secondary isotope effect, but we have allowed the activation energy difference to be as large as 1.3 kcal mol^{-1}, slightly larger than predicted by the loss of the C—H stretching frequency. For the TNT reaction, the values in Table 4 for the barrier width $2b$ and parameters C_t, ν_t, and $E_{H_{obs}}/E_H$ are very similar to those of a number of reactions, tabulated by Caldin (24), in which tunnelling is believed to be important. They are also very similar to those calculated by Caldin *et al.* (13) for 4-NPNM reacting with TMG in solvents such as tetrahydrofuran, dichloromethane and acetonitrile.

In contrast the reaction of 4-NPNM with 1,8-bis(dimethylamino)naphthalene yields a wide barrier of 3.3 Å and a correspondingly small curvature at the apex of the barrier C_t, with $E_{H_{obs}}/E_H$ close to unity. The different behaviour between the two bases may be correlated with the hybridization at the nitrogen atom to which the proton or deuteron is being transferred. As previously noted by Caldin *et al.* (14, 15) the larger isotope effects can be attributed to the smaller barrier widths with the more compact sp^2 hybridized orbitals at the nitrogen of TMG.

Experimental

Materials

2,4,6-Trinitrotoluene (TNT) was purified by repeated crystallization from ethanol with charcoal until a constant melting point of 81°C was reached. The purity of TNT was tested by ir and nmr methods (methyl protons δ 2.75 ppm, benzene ring protons δ 8.95 ppm in the ratio 3:2). The values obtained were in a good agreement with the literature.

Deuterated 2,4,6-trinitrotoluene (TNT-d_3) was obtained by reacting 0.1 *M* NaOD with 0.2 *M* TNT in a mixed solvent DMF–D_2O (90:10 v/v). Neutralization of this purple solution was effected after 2 h with a few drops of concentrated deuterium chloride in D_2O. The yellow solution was poured into an excess of D_2O, yellow crystals being obtained. This material was then recrystallized from deuterated ethanol and evaporated to dryness under vacuum. This procedure was carried out three times yielding deuterated material containing more than 96% D on the aliphatic carbon atom, as judged from the nmr spectrum. The peak at δ 2.75 ppm disappeared. The melting point of the TNT-d_3 was 80.5–81°C.

N,*N*-Dimethylformamide (DMF) was purified by the method of Zaugg and Schaefer (25).

*C_t is the curvature at the top of the barrier, ν_t is the frequency corresponding to the barrier dimensions.
†Reference 20.

1,1′,3,3′-Tetramethylguanidine (TMG) (Eastman) was dried over KOH, fractionally distilled over BaO under N_2, and collected at 161°C.

Kinetic Measurements

The kinetic measurements were carried with a Specord UV-VIS spectrophotometer equipped with a thermostating device to keep the cell temperature constant within 0.1°C.

The first-order rate constants (k_1) were obtained using considerable excess of the base. The values of k_1 were calculated according to the Guggenheim method (8). The following concentrations of the solutions were used: TNT, 1.5×10^{-5} *M* and TMG, 5×10^{-4} to 5×10^{-3} *M*. From the first-order rate constants (k_1), the k_2 values were calculated as a slope of the plot of k_1 against base concentration. The calculated second-order rate constants (k_2) were used for the Arrhenius relation of log $k_2 = f(1/T)$ from which, applying the transition state equation, the activation parameters ΔH^{+}, ΔS^{+}, and A were evaluated.

Both the second-order rate constants and the activation parameters were computed by the least-squares method.

Laboratoire d'Etude des Interactions Solutés–Solvants, Université de Clermont, B.P. 45, 63170 Aubière, France

Received August 8, 1978

NICOLE MOREL-DESROSIERS and JEAN-PIERRE MOREL. Can. J. Chem. **57**, 673 (1979).

The standard molar volumes, the standard molar enthalpies of solution, and the limiting conductivities have been determined for potassium and tetrabutylammonium adamantylcarboxylates in water and heavy water, at 298.15 K. The temperature dependence of the volume and of the conductivity of the potassium salt has also been studied. The results are compared with those relative to potassium acetate. The change of the methyl group for the adamantyl one does not follow the behaviour normally expected for the transfer of hydrophobic solutes from water to heavy water.

NICOLE MOREL-DESROSIERS et JEAN-PIERRE MOREL. Can. J. Chem. **57**, 673 (1979).

Les volumes molaires standard, les enthalpies molaires standard de solution et les conductivités limites de l'adamantylcarboxylate de potassium et de l'adamantylcarboxylate de tétrabutylammonium ont été déterminés dans l'eau et dans l'eau lourde, à 298.15 K. Le volume et la conductivité du sel de potassium ont aussi été étudiés en fonction de la température. Les résultats ont été comparés à ceux relatifs à l'acétate de potassium. Le remplacement du groupe méthyle par le groupe adamantyle n'a pas l'effet normalement attendu lors du transfert de solutés hydrophobes de l'eau à l'eau lourde.

Introduction

During the last twenty years, much attention has been devoted to the study of hydrophobic phenomenon. Completely apolar molecules like the rare gases and the alkanes induce purely hydrophobic phenomenon when dissolved in water. Unfortunately, these solutes are so sparingly soluble in water that their solution properties are very difficult to measure and hence the paucity of such studies in the literature. This problem is usually circumvented by studying alkyl derivatives. As pointed out by Franks (1), alkyl derivatives that possess only one simple polar site are believed to behave like "soluble hydrocarbons", their functional group providing only a minor contribution to the thermodynamic properties of a homologous series (2). Carboxylates, however, seem to be an exception to this rule. On the other hand, these solutes are likely to represent closely what is encountered in proteins where the hydrophobic groups are usually in the neighbourhood of electrostatic entities. Therefore, despite the difficulty in interpreting their properties, the carboxylates should be interesting solutes.

Very few studies have been done on these systems. Snell and Greyson (3) have measured the heats of transfer and the free energies of transfer of the series sodium formate to sodium caproate from water to heavy water; the hydration properties of this particular transfer are believed "to be useful in reaching definite conclusions about hydrophobic interactions" (4). From the sign and magnitude of the transfer entropies they deduced that there was a transition from structure breaking to structure making in passing from sodium formate to sodium caproate. More recently, Lucas and Le Bail (5) measured the volumes and the heat capacities of transfer of sodium adamantylcarboxylate from water to heavy water and studied the ^1H nmr and Raman spectra of the potassium salt. The volumes of transfer did not give them significant structural information whereas the heat capacity results allowed them to consider sodium adamantylcarboxylate a structure former relative to sodium *tert*-butylcarboxylate. On the other hand, from their spectroscopic results potassium adamantylcarboxylate appeared to be a net structure breaker relative to smaller potassium *tert*-butylcarboxylate. Lucas and Bury (6) have also tried to measure the enthalpies of transfer of sodium adamantylcarboxylate from water to heavy water.

The adamantylcarboxylate anion (Fig. 1) is a very interesting solute and this has led us to precisely determine some of its properties in water and in heavy water. In order to have confidence in the ionic data, we have measured the properties of potassium and of tetrabutylammonium adamantylcarboxylates, the additivity rule serving as a check of the results. The standard volumes, expansivities (obtained for potassium adamantylcarboxylate only, from the temperature dependence of the volume), enthalpies of solution, and limiting conductivities were deter-

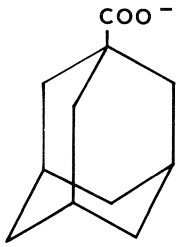

FIG. 1. The 1-adamantylcarboxylate anion.

mined at 298.15 K in water and in heavy water. As we intend to compare the adamantylcarboxylate to the acetate, we have also measured the conductivities of potassium acetate in water and in heavy water, at 298.15 K.

Experimental

The adamantylcarboxylates were prepared by stoichiometric neutralization of adamantylcarboxylic acid (Fluka, purum) with Bu_4NOH and KOH. The potassium salt (KAd) was recrystallized in water and dried under vacuum at 410 K during many days. The tetrabutylammonium salt (Bu_4NAd), obtained from the tetrabutylammonium methoxide in methanol (7), was recrystallized in ethyl acetate and dried under vacuum at 350 K during many days. The potassium acetate (KAc) (Prolabo) was recrystallized in anhydrous ethanol and dried under vacuum at 373 K. All solutions were prepared by weight with triply distilled water or with heavy water 99.8% minimum. For conductivity measurements, the solution concentration was varied by successively diluting the initial solution, using the Mettler DP11/DP101 weighing burette. Because of their hygroscopic nature, all manipulations of the salts were carried out under nitrogen atmosphere.

The conductivities, the densities, and the enthalpies of solution were measured with a Beckman RC-18-A conductivity bridge using a Tacussel CM 02 probe, a Picker flow differential densimeter, and a L.K.B. calorimeter, respectively, following the procedures described elsewhere (8–10). The conductivity cell was calibrated with aqueous KCl solutions on the concentration range suitable for our study (8). The solvent conductivity κ_0 is of the order of $2 \times 10^{-6}\ \Omega^{-1}\ cm^{-1}$. The uncertainty of our density measurements is about 3×10^{-6} g cm^{-3}. The densities of heavy water at 288.15, 298.15, and 308.15 K were determined relative to those of pure water; we have obtained 1.105728, 1.104278, and 1.101559 g cm^{-3}, respectively, using Kell's data for pure water (18). These results are in excellent agreement with the values of Millero *et al.* (15).

Results

The apparent molal volumes ϕ_v were derived from

$$[1] \qquad \phi_v = M_r/\rho + 1000(\rho_0 - \rho)/m\rho_0\rho$$

where M_r is the solute molecular weight, m is the molality, ρ and ρ_0 are the densities of the solution and the pure solvent, respectively. They were determined in the concentration range 0.02–0.08 m, at 298.15 K for KAc and for Bu_4NAd and at 288.15 K, 298.15 K, and 308.15 K for KAd in water and in heavy water.[2] The results are fitted to an equation of the type

$$[2] \qquad \phi_v = V^\theta + A_v(m\rho_0)^{0.5} + B_v m$$

where V^θ is the standard molar volume, A_v is the Debye–Hückel limiting slope, and B_v is an empirical constant determined from the experimental results. We have used for 1:1 electrolytes in H_2O and in D_2O the A_v parameters calculated by Perron *et al.* (11). We estimate the uncertainty in V^θ, including the error likely to arise from the extrapolation, to be less than 0.5 cm^3 mol^{-1}. From the temperature dependence of the standard molar volumes we have roughly estimated the standard molar expansivity $E^\theta = \partial V^\theta/\partial T$ of KAd in water and in heavy water, at 298.15 K.

The enthalpies of solution in H_2O and in D_2O were measured at concentrations around 0.015 m for KAd and 0.003 m for Bu_4NAd, at 298.15 K. The concentration dependence being generally similar in both solvents (11), we can assume the transfer functions at these concentrations to be approximately equal to the standard transfer enthalpies ΔH_{tr}^θ.

The conductivities were measured in the concentration range 0.001–0.01 m, at 298.15 K for KAc and Bu_4NAd and at 288.15 K, 298.15 K, and 308.15 K for KAd.[2] The limiting conductivities Λ^0 were obtained from the equation of Fuoss–Onsager, as described by Juillard *et al.* (8). The parameters of the equation were calculated at 288.15 K, 298.15 K, and 308.15 K using the dielectric constants of water and of heavy water as given by Malmberg and Maryott (12) and by Malmberg (13), respectively, and the viscosities as a function of temperature as given by Stokes and Mills (14) for water and by Millero *et al.* (15) for heavy water. The uncertainty in the limiting conductivities is of the order of 0.3 Ω^{-1} cm^2 mol^{-1}.

All these results are shown in Tables 1 and 2.

The additivity rule can be used as a check of some of our results. We have compared, for instance, the thermodynamic property differences between Bu_4NAd and KAd with that between Bu_4NBr and KBr. The differences of standard volumes in water and in heavy water agree to better than 0.5 cm^3 mol^{-1}, using the data of Perron *et al.* (11) for Bu_4NBr and that of Fortier *et al.* (16) for KBr. The differences of standard transfer enthalpies from water to heavy water agree to 0.3 kJ mol^{-1}, using Friedman and Krishnan's (4) compiled data. Using their ionic enthalpies of transfer, one would then predict an enthalpy of transfer of NaAd of 0.1 kJ mol^{-1} instead of the anomalously

[b]$\Delta H_{tr}^0(H_2O \rightarrow D_2O) = 0.4_5$ kJ mol^{-1} (obtained from a value for NaAc (3, 6) by using the ionic transfer enthalpies (4) of K^+ and Na^+).

TABLE 2. Temperature dependence of the standard molar volumes, of the B_v parameters, and of the limiting conductivities of KAd in water and in heavy water

Property	Solvent	Value at 288.15 K	298.15 K	308.15 K
V^0 ($cm^3\ mol^{-1}$)	H_2O	141.8	143.9	145.5
	D_2O	140.1	142.3	144.5
B_v ($cm^3\ mol^{-2}$)	H_2O	−2.4	−1.9	0.3
	D_2O	−9.6	−4.5	−1.9
Λ^0 ($\Omega^{-1}\ cm^2\ mol^{-1}$)	H_2O	78.6	98.1	119.0
	D_2O	63.6	81.9	100.7

large value of 4.6 kJ mol^{-1} given by Lucas and Bury (6).

Juillard *et al.* (8) give a value of 114.6 Ω^{-1} cm^2 mol^{-1} for the limiting conductivity of KAc. Their result is directly comparable with ours since both were extrapolated in the same way. The agreement is not perfect but this is not surprising with this type of electrolyte. However, we shall expect the comparison of our results in H_2O and D_2O to be relatively better as long as both sets of measurements are rigorously made under the same conditions.

Discussion

To gain a better understanding of anion–solvent interactions, it is desirable to evaluate the individual ionic contributions to the observed solvent isotope effect. This was done using the volume and the enthalpy of transfer for K^+ from water to heavy water (4) and the limiting ionic conductivity of K^+ in water and in heavy water (17). The transfer property data for acetate and adamantylcarboxylate anions are listed in Table 3.

TABLE 3. Ionic properties relative to the acetate and to the adamantylcarboxylate in water and in heavy water, at 298.15 K

Property	Value Ac^-	Ad^-
$\Delta V_{tr}^0(H_2O \rightarrow D_2O)$ ($cm^3\ mol^{-1}$)	−1.1	−1.9
$\Delta H_{tr}^0(H_2O \rightarrow D_2O)$ ($kJ\ mol^{-1}$)	−2.4	−2.4
λ^0 (H_2O) ($\Omega^{-1}\ cm^2\ mol^{-1}$)	40.5	24.6
λ^0 (D_2O) ($\Omega^{-1}\ cm^2\ mol^{-1}$)	32.1	20.5

The anionic volumes of transfer are negative and changing the methyl for the adamantyl group results in a more negative volume of transfer. The strong electrostriction associated with the $—COO^-$ group is probably responsible for the negative sign, as observed with the halides (4). The alkyl structural behaviour should attenuate this effect since the volumes of transfer of hydrophobic solutes are expected to be positive (4); furthermore, the cavity contribution to the volume of transfer ($H_2O \rightarrow D_2O$) of an alkyl group is positive and increases with the

TABLE 4. Ionic Walden products of the acetate and of the adamantylcarboxylate in H_2O and in D_2O

(*a*) Temperature dependence of the Walden product of adamantylcarboxylate in water

Walden product	Value at 288.15 K	Value at 298.15 K	Value at 308.15 K
$\lambda^o\eta_o$	0.217	0.219	0.219
$(\lambda^o\eta_o)_T/(\lambda^o\eta_o)_{288.15\,K}$	1	1.009	1.009

(*b*) Solvent-isotope effect on the Walden products of the acetate and of the adamantylcarboxylate, at 298.15 K

Walden product	Value Ac^-	Value Ad^-
$\lambda^o\eta_o(H_2O)$	0.360	0.219
$\lambda^o\eta_o(D_2O)$	0.352	0.225

alkyl size (19). Surprisingly, we observe the opposite effect when we increase the size of the alkyl group attached to the carboxylate.

The anionic enthalpies of transfer are negative; this was expected since, although for different reasons, both the strongly electrostatic anions and the hydrophobic groups give a negative enthalpy of transfer from water to heavy water (4). Amazingly, the ionic enthalpies of transfer seem independent of the spherical alkyl size, the large adamantyl group apparently perturbing the solvent as much as the small methyl group. Snell and Greyson (3), on the other hand, have observed a slight dependence with the increase of the linear alkyl chain, the ionic enthalpies of transfer varying from -2.2 to -2.9 kJ mol^{-1} by going from the methyl to the pentylcarboxylate.

In Table 4 we have listed the ionic limiting conductivity – solvent viscosity products (Walden products) of adamantylcarboxylate in water at 288.15 K, 298.15 K, and 308.15 K, calculated by using the viscosity of pure water as a function of temperature (14) and the ionic limiting conductivities of K^+ at 288.15 K (interpolated), 298.15 K, and 308.15 K (interpolated) of Kay and Evans (17). We have also listed the Walden products of the acetate and adamantylcarboxylate anions in H_2O and in D_2O, at 298.15 K. Structural information is usually obtained from the ratio of the Walden products at two temperatures or in two solvents. We have thus reported in Table 4 the ratio of the Walden product of adamantylcarboxylate in H_2O at temperature T over the Walden product at 288.15 K. We have also given the ratio of the Walden products in D_2O and in H_2O for the acetate and for the adamantylcarboxylate. The temperature dependence of the former is very slightly positive. This could be interpreted according to the classical models as reflecting the behaviour of a slightly hydrophobic solute. It could also mean that, of the two contributions involved, the carboxylate (electrostatic) one and the alkyl group (hydrophobic) one, the latter is more temperature dependent than the former. However, such small effects are hardly significant if we take into account the uncertainty in the limiting conductivities. Surprisingly, the ratio of the Walden products in D_2O and in H_2O is smaller than unity for the acetate and greater than unity for the adamantylcarboxylate. The classical interpretation of this ratio, which is based on the fact that there is more structural order in D_2O than in H_2O at the same temperature (17), implies the acetate is a structure former whereas the adamantylcarboxylate is a structure breaker, in apparent contradiction with what was just observed with the temperature effect. This unexpected conclusion and what was observed with the volumes and the enthalpies of transfer probably reflect the fact that the classical interpretations are not suitable for this type of solute. One reason for this could be that the 'structural' influences of both parts of the solute, the carboxylate one and the alkyl one, are not necessarily additive. This seems very important and should be kept in mind when studying biological systems since in proteins, for instance, alkyl groups are very often in the field of highly electrostatic entities. The comparison of the hydrophobic contribution of such alkyl groups with what is observed when we dissolve rare gases or hydrocarbons in pure water thus does not seem very helpful, the environment of these 'hydrophobic' entities being completely different.

Excess properties of cumene + *p*-dioxane system at 30°C

HORACIO N. SÓLIMO,[1] SILVIA DEL V. ALONSO, and MIGUEL KATZ

Cátedra de Físicoquímica, Facultad de Ciencias Exactas y Tecnología, Universidad Nacional de Tucumán, Tucumán, Argentina

Received December 16, 1977[2]

HORACIO N. SÓLIMO, SILVIA DEL V. ALONSO, and MIGUEL KATZ. Can. J. Chem. **57**, 678 (1979).

Densities, viscosities, enthalpies, and magnetic susceptibilities at 30°C were determined for the system cumene + *p*-dioxane. From the experimental results, the excess viscosity, excess enthalpy, excess volume, and excess molar magnetic susceptibility were calculated. The excess functions show deviations from the additivity law. An attempt has been made to explain the observed deviations on the basis of intermolecular interactions.

HORACIO N. SÓLIMO, SILVIA DEL V. ALONSO et MIGUEL KATZ. Can. J. Chem. **57**, 678 (1979).

On a déterminé les densités, les viscosités, les enthalpies et les susceptibilités magnétiques du système cumène/*p*-dioxanne, à 30°C. A l'aide de ces données expérimentales, on a calculé les viscosité, enthalpie, volume et susceptibilité magnétique molaires en excès. Les fonctions d'excès ne suivent pas la loi de l'additivité. On a essayé d'expliquer les déviations observées en se basant sur les interactions intermoléculaires.

[Traduit par le journal]

Introduction

The excess properties such as: η^E (excess viscosity), h^E (excess molar enthalpy), v^E (excess molar volume), and $\chi_M{}^E$ (excess molar diamagnetic susceptibility) have been studied to obtain information about the type and degree of interaction between molecules of the components. This is a continuation of our investigation of the thermodynamic properties of binary liquid mixtures (1, 2).

Densities, viscosities, enthalpies, and magnetic susceptibilities for the cumene + *p*-dioxane (C + D) system at different molar fraction were measured at 30°C, where one component (D) is non-polar and the other (C) weakly polar, without association in the pure state.

The diamagnetic molar susceptibility of the mixture is correlated with the molecular polarizability of the pure components by the Boyer–Donzelot equation (3).

Experimental

The methods used in our laboratory for the densities, viscosities, and enthalpies of binary liquid mixtures have been described previously (4).

Magnetic Susceptibility

The magnetic susceptibility was determined by a Gouy method using a Mettler H20T balance. Measurements have been made in a 9 kG magnetic field. The Gouy force ranged from 10 to 15 mg and the accuracy of its determination was estimated to be ±0.01 mg. Water twice distilled from alkaline permanganate ($\chi = -0.720 \times 10^{-6}$ cgs/g) and mercury tetrathiocyanate cobalt ($\chi = 16.49 \times 10^{-6}$ cgs/g) (5) were used as reference substances.

Materials and Solutions

Cumene and *p*-dioxane, Fluka p.a., were fractionally distilled over sodium under reduced pressure, and the middle colorless fraction was collected.

Mixtures were prepared by mixing weighed amounts of the pure liquids. Caution was taken to prevent evaporation.

Results

The experimental results for the pure liquids are reported in Table 1 along with the values from the literature for comparison.

The excess thermodynamic functions were calculated with the following equations:

$$[1] \qquad \eta^E = \eta - (x_1\eta_1 + x_2\eta_2)$$

$$[2] \qquad h^E = h_M - (x_1h_1 + x_2h_2)$$

$$[3] \qquad v^E = v - (x_1v_1 + x_2v_2)$$

$$[4] \qquad \chi^E = \chi_M - (x_1\chi_1 + x_2\chi_2)$$

where η, η_1, and η_2 = viscosity of the mixture and of the pure components; h_M, h_1, and h_2 = molar enthalpy of the mixture and of the pure components; v, v_1, and v_2 = molar volume of the mixture and of the pure components; χ_M, χ_1, and χ_2 = molar diamagnetic susceptibility of the mixture and of the pure components.

The molar volume of the mixture is defined by:

$$[5] \qquad v = (x_1M_1 + x_2M_2)/\rho$$

where M_1 and M_2 are the molecular weights of the components and ρ the density of the solution.

The experimental densities, viscosities, and molar enthalpies for the C + D systems were measured at different molar fractions, over a wide range of concentration.[3]

The diamagnetic susceptibility was related with the molecular polarizability by the Boyer–Donzelot equation (3), for organic pure compounds:

$$[6] \qquad \chi_i = f(n_i'\alpha_i)^{1/2}$$

For mixtures, we can assume to a first approximation that the additivity law for molar diamagnetic susceptibility is correct, then

$$[7] \qquad \chi_M = f\sum x_i(n_i'\alpha_i)^{1/2}$$

where f = constant = -3.46×10^6; n_i' = effective number of electrons, α_i = molecular polarizability of the component i. This effective number of electrons could be calculated by:

$$n_i' = n_i - n_0$$

where n_i = valence electrons of the component i and n_0 = characteristic constant for every family of substances (cumene = 10 and *p*-dioxane = 3.4).

The molar diamagnetic susceptibilities of the binary systems were measured over a wide range of concentration and compared with those calculated with eq. [7].[3]

The agreement between the observed and calculated values (e.g., for $x_C = 0.5059$: $\chi_M(\text{exp}) = -70.11 \times 10^{-6}$ cgs mol^{-1}; $\chi_M(\text{calcd}) = -71.90 \times 10^{-6}$ cgs mol^{-1}) points to the validity of the additivity law for this mixture.[3]

Each set of results was fitted with a Redlich–Kister (6) form of the type

$$[8] \qquad X^E = x_1(1 - x_1)\sum_{j=1}^{n} a_j x_1{}^{j-1}$$

where X^E represents the excess property under consideration; a_j = polynomial coefficients, and n = polynomial degree. The method of least-squares was used to determine the values of the coefficients a_j. In each case, the optimum number of coefficients was ascertained from an examination of the variation of the standard error of estimate with n:

$$[9] \qquad \sigma_x = [\sum(X^E{}_{obs} - X^E{}_{calcd}{}^2/(n_{obs} - n)]^{1/2}$$

where n_{obs} is the number of measurements.

The values adopted for the coefficients a_j (calculated with an IBM 1620 computer) and the standard error of the estimate associated with the use of [8] are summarized in Table 2.

Figures 1, 2, 3, and 4 show the experimental values obtained for the excess properties as a function of the molar fraction of cumene. The continuous curves were calculated from [8] using these values for the coefficients.

[3]Complete set of the actual experimental data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

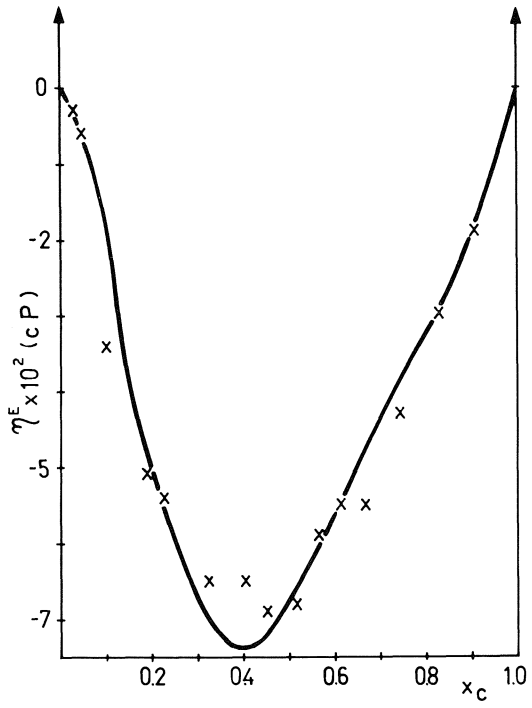

FIG. 1. Excess viscosity at 30°C for the C + D system. Experimental results: ×; continuous curve was calculated from eq. [8].

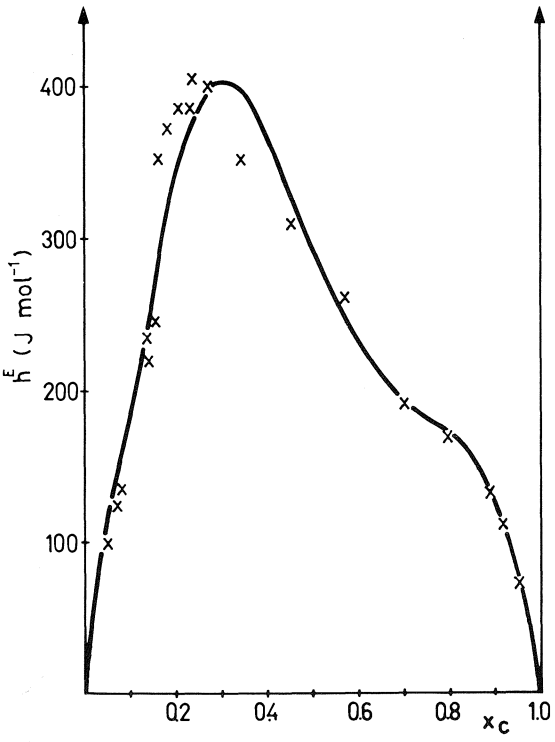

FIG. 2. Excess molar enthalpy at 30°C for the C + D system. Experimental results: ×; continuous curve was calculated from eq. [8].

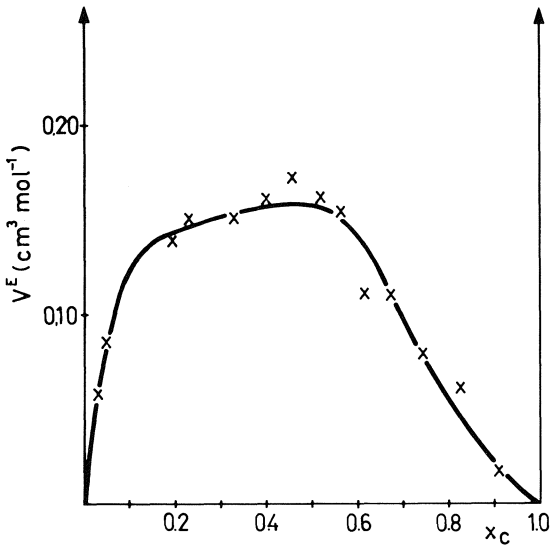

FIG. 3. Excess molar volume at 30°C for the C + D system. Experimental results: ×; continuous curve was calculated from eq. [8].

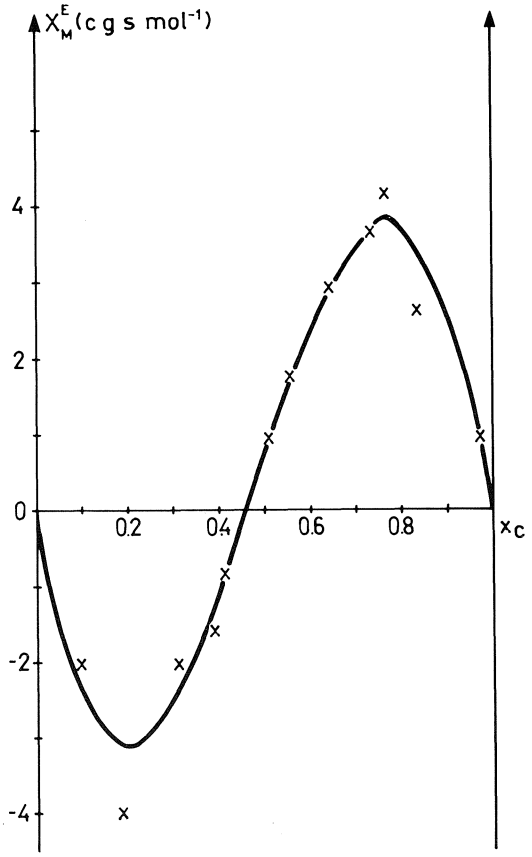

FIG. 4. Excess molar magnetic susceptibility for the C + D system. Experimental results: ×; continuous curve was calculated from eq. [8].

Discussion

Figure 1 shows negative excess viscosity for this system over the whole concentration range. Taking into account that neither of the components exhibits hydrogen bonding in the pure state, dispersion forces are dominant (7). However, since the minimum of the curve η^E vs. x_C is well marked, evidence of interaction between the molecules of different kinds is clear (8).

More quantitatively, evidence of this interaction is established taking into account h^E for C + *n*-heptane mixtures (h^E_{max}/J mol^{-1} (298 K) ~ 500) (9) and for D + cyclohexane mixtures (h^E_{max}/J mol^{-1} (298 K) ~ 1600) (10). The rather small h^E for C + D mixtures (h^E_{max}/J mol^{-1} (303 K) ~ 400) indicates that the interaction between C + D leads to a large decrease in h^E of about 1700 J mol^{-1} (1600 + 500 − 400 = 1700). This is not surprising since D gives rise to complex formation (n-π type or dipole-induced dipole type) with even non-polar molecules like benzene and CCl_4 with cumene, due to the inductive effect of the isopropyl group, the complex should be stronger.

Almost similar reasoning can be made for v^E: the contraction resulting in mixing C with D largely compensates the positive contribution observed ($v^E > 0$) in D and hydrocarbon mixtures (10).

In the case of mixtures in which one component is non-polar and the other weakly polar, the force field is envisaged as a superposition of a weak angular dependent field on a centrally spherical one (11). The cumene has a high polarizability and when it is mixed with *p*-dioxane there arises an induced dipole interaction because of the presence of these polarizable weakly polar molecules, and as expected gives rise to negative deviations in χ_M which produce a negative χ^E. As the concentration of cumene is increased there is an inversion at $x_C \sim 0.5$, which could be explained by the so-called "ring effect" (12) which causes an increase in the value of χ_M, that is, positive χ^E.

Halogen-bridged complexes of platinum(II) and their reactions with dimethylformamide

PI-CHANG KONG AND F. D. ROCHON

Département de chimie, Université du Québec à Montréal, C.P. 8888, Montréal (Qué.), Canada H3C 3P8

Received June 14, 1978

PI-CHANG KONG and F. D. ROCHON. Can. J. Chem. **57**, 682 (1979).

Bridged compounds, $[Pt(L)Cl_2]_2$ (L = pyridine, picoline, and lutidine) have been prepared from the reactions between $K[Pt(L)Cl_3]$ and perchloric acid. The molecular weight measurements indicate that they are dimers in chloroform solutions. When $[Pt(L)Cl_2]_2$ is dissolved in dimethylformamide (DMF), $[Pt(L)(DMF)Cl_2]$ is formed and has been isolated. Infrared and nmr studies have shown that DMF is coordinated to platinum through the oxygen atom.

PI-CHANG KONG et F. D. ROCHON. Can. J. Chem. **57**, 682 (1979).

Des composés à ponts $[Pt(L)Cl_2]_2$ (L = pyridine, picoline et lutidine) ont été préparés par la réaction entre $K[Pt(L)Cl_3]$ et l'acide perchlorique. Les mesures de poids moléculaires indiquent que les composés sont des dimères en solution dans le chloroforme. Lorsque $[Pt(L)Cl_2]_2$ est dissout dans le diméthylformamide (DMF), $[Pt(DMF)(L)Cl_2]$ est formé et a été isolé. Des études de spectroscopie infrarouge et de rmn ont montré que le site de coordination du DMF est l'atome d'oxygène.

Introduction

General methods for the preparation of halogen-bridged complexes of platinum of the type $[Pt(L)Cl_2]_2$ were developed by Chatt and Venanzi (1). Two of these methods can be used to prepare amine or pyridine complexes. The first method is the thermal decomposition of olefin complexes:

$$2trans\text{-}[Pt(olefin)(L)Cl_2] \rightarrow [Pt(L)Cl_2]_2 + 2olefin$$

The reaction is very slow and requires a week to several months to obtain a reasonable yield of products. Complexes of piperidine, 4-*n*-pentylpyridine, 4-*n*-nonylpyridine, and toluidine were prepared by this method. The method was later modified. *trans*-$[Pt(acetylene)(L)Cl_2]$ was used and the rate of reaction was increased. However, only the bridged compound with pyridine has been prepared (2). The second method is the decomposition of acids:

$$2H[Pt(L)Cl_3] \rightarrow [Pt(L)Cl_2]_2 + 2HCl$$

The authors have pointed out that the method was strictly limited because the starting material is not very common. Only $[Pt(NH_3)Cl_2]_2$ has been prepared by this method.

Recently, we have developed a method to prepare salts, $K[Pt(L)Cl_3]$ (3), which can be readily converted to acid $H[Pt(L)Cl_3]$. Therefore the limitation of the second method no longer exists. A series of bridged complexes with various pyridine derivatives have been prepared and are described in this paper.

The bridged bonds can be easily cleaved even by weak nucleophiles which cannot displace chlorides from $PtCl_4^{2-}$. For example, when $[Pt(L)Cl_2]_2$ is dissolved in dimethylformamide (DMF), $[Pt(L)(DMF)Cl_2]$ is produced and can be isolated. These compounds are also discussed.

Experimental

Microanalyses were done by Chemalytics Inc., Tempe, AZ, U.S.A., and molecular weight measurements were done by Galbraith Laboratories, Inc., Knoxville, TN. Melting points were measured on a Fisher-Johns apparatus and are uncorrected. Nuclear magnetic resonance spectra were taken on a Perkin-Elmer R-12 spectrometer. Infrared spectra were measured on a Perkin-Elmer 621 grating spectrometer.

The platinum salt, K_2PtCl_4, was obtained from Johnson Matthey & Co. Limited. Pyridine (py), picoline (pic), and lutidine (lut) were purchased from Aldrich and Eastman and used without further purification. All the complexes were dried at 65°C under vacuum in the presence of P_2O_5.

Preparation of the Bridged Chloro Complexes

The freshly prepared salt, $K[Pt(L)Cl_3]$ (3) (0.4–0.5 g), was dissolved in a minimum amount of water and then 10 mL of $HClO_4$ (0.2 *M*) was added. The solution was allowed to stand at room temperature overnight and the $KClO_4$ was then filtered off. The filtrate was evaporated nearly to dryness and the red-yellow product was collected by filtration, washed with cold water, and dried. If the washings were still very yellow, more product was obtained by evaporating again to dryness.

Preparation of DMF Compounds

The bridged compound was dissolved in a minimum amount of DMF. The solution was allowed to stand 30 min and was then evaporated to dryness. The yellow product was washed with ether, collected by filtration, and dried. The yield is almost quantitative.

Results and Discussion

The Bridged Compounds

These compounds are reddish yellow. Their analytical data and melting points are listed in Table 1. They are soluble in most common organic solvents, such as chloroform, acetone, and tetra-

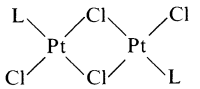
*The upper values represent the theoretical values.

hydrofuran. Compounds with substituted pyridine are soluble in benzene. All of them are insoluble in water. The measurements of molecular weight indicate that the compounds are dimers in chloroform solution (Table 1).

A crystallographic study of the 2,6-lutidine compound was done in our laboratory (4), and the results showed that it has the *trans*-configuration.



The dimers slowly form potassium salts $K[Pt(L)Cl_3]$ in the presence of potassium chloride in acidic solution. When the dimers are dissolved in DMF, solvated compounds characterized as $[Pt(L)(DMF)Cl_2]$ are obtained (see next section). When $[Pt(L)(DMF)Cl_2]$ is dissolved in chloroform, $[Pt(L)Cl_2]_2$ is partially formed. Crystals of $[Pt(2,6\text{-lutidine})Cl_2]_2$ were obtained from a dichloromethane solution of $[Pt(2,6\text{-lut})(DMF)Cl_2]$ at room temperature. Similarly Chatt and Venanzi found that [(4-*n*-pentylpyridine)(2,6-dibromo-4-*n*-dodecylaniline)dichloroplatinum] lost the aniline derivative in tetrachloromethane solution (5). It seems therefore that the bridged complexes are moderately favored in non-coordinating solvents, even in the presence of weak nucleophiles like DMF and aniline.

In acetone, the bridged complex of piperidine reacts with 4-*n*-pentylamine to give a mixture of *cis* and *trans* isomers, using stoichiometric proportions at room temperature or with an excess of ligand in boiling acetone (5). The mechanism of the reactions is uncertain. Using stoichiometric proportions at room temperature, we have found that the product of the reaction between $[Pt(py)Cl_2]_2$ and pyridine in DMF is *cis*-$[Pt(py)_2Cl_2]$.

In a previous work (3), we have found that *cis*-$[Pt(py)_2Cl_2]$ isomerized to *trans*-$[Pt(py)_2Cl_2]$ in the presence of pyridine at 80°C in DMF and that the reaction is not reversible. We may now conclude that in these cleavage reactions, the *cis*-compounds are first formed and the *trans*-compounds are formed from the subsequent isomerization of the *cis*-isomer.

DMF Compounds

DMF compounds can be obtained by the following two reactions:

$$[1]\quad [Pt(L)Cl_2]_2 + 2DMF \xrightarrow{DMF} 2[Pt(L)(DMF)Cl_2]$$

$$[2]\quad K[Pt(L)Cl_3] + AgNO_3 + DMF \rightarrow [Pt(L)(DMF)Cl_2] + AgCl\downarrow + KNO_3$$

The DMF compounds are soluble in many organic solvents. In chloroform a mixture of two compounds is in equilibrium.

$$2[Pt(L)(DMF)Cl_2] \rightleftharpoons [Pt(L)Cl_2]_2 + 2DMF$$

The nmr spectra showed that the complexed DMF and the free DMF are in equal amounts in chloroform solution. No free pyridine (L) was found. When the chloroform was evaporated the above reaction shifted to the left except for the 2,6-lutidine complex where both compounds were obtained.

The ir spectra of the DMF compounds in Nujol mull showed that the carbonyl stretching of DMF is lowered by 20–40 cm^{-1} (Table 2) indicating that the oxygen atom is the donor atom. The same conclusion was made for $[Pt(DMF)_2Cl_2]$ and $[Pt(DMA)_2Cl_2]$ (DMA = dimethylacetamide) by an infrared study (6). The nmr spectra of $[Pt(Py\text{-}d_5)(DMF)Cl_2]$ also indicated that the oxygen atom is the donor atom (Fig. 1). The aldehyde proton of DMF shifted from 8.15 to 8.35 ppm with a coupling constant of 40 Hz with ^{195}Pt while the methyl group on the nitrogen atom has no coupling. If nitrogen was the donor

[b]From ref. 6.

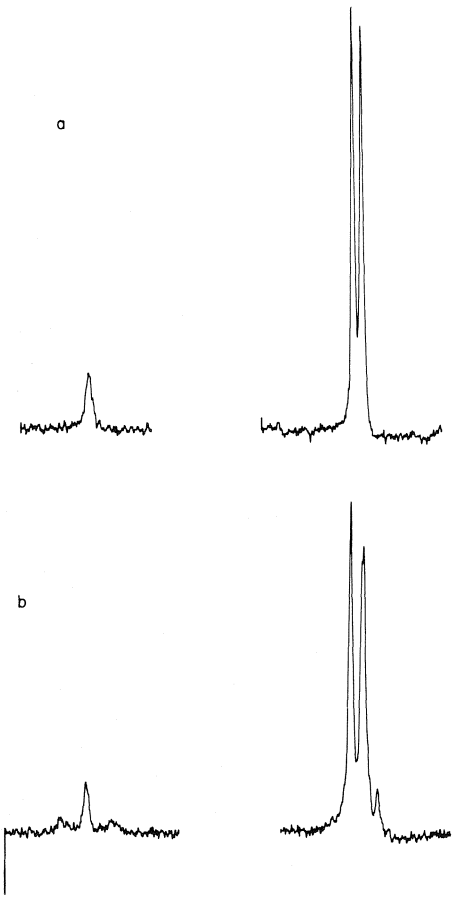

FIG. 1. Nuclear magnetic resonance spectra of (*a*) DMF and (*b*) $[Pt(Py\text{-}d_5)(DMF)Cl_2]$ in chloroform solution. Because C_5D_5N was used the signal of the aldehyde proton of DMF can be clearly observed, and shifted from 8.15 to 8.35 ppm with coupling of 40 Hz. The signals of the methyl groups shifted from 2.95 to 3.10 ppm. In (*b*) a small amount of dissociated DMF can be observed from the signals of the methyl group.

atom, the methyl group should have a coupling constant with ^{195}Pt of about 40 Hz like *N*-methyl-aminoacid in platinum compounds (7). The crystal structure of *trans*-$[Pt(2,6\text{-lutidine})(DMF)Cl_2]$ is presently being studied by X-ray diffraction in our laboratory. The results have confirmed that DMF is bonded to platinum through the oxygen atom (8).

Both *trans*- and *cis*-$[Pt(L)_2Cl_2]$ (L = py, 2-pic, or 4-pic) can be obtained from the reaction of $[Pt(L)(DMF)Cl_2]$ and L in DMF or $CHCl_3$ at room temperature (Pt:L = 1:1, conc. 0.05 *M* and time 1.5 h). The yield of *cis*-$[Pt(L)_2Cl_2]$ is quite low (20%). If an excess of L is used or if the time of the reaction is longer (5 h), only *trans*-$[Pt(L)_2Cl_2]$ is obtained. *trans*-$[Pt(2,6\text{-lut})(DMF)Cl_2]$ can be recovered from a DMF solution in the presence of an excess of 2,6-lut.

Determination of $\Delta H^0_{f298}(C_6F_{10},g)$ and $\Delta H^0_{f298}(C_6F_{12},g)$ from studies of the combustion of decafluorocyclohexene and dodecafluorocyclohexane in oxygen and calculation of the resonance energy of hexafluorobenzene

STANLEY JAMES W. PRICE[1] AND HENRY J. SAPIANO

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received September 7, 1978

STANLEY JAMES W. PRICE and HENRY J. SAPIANO. Can. J. Chem. **57**, 685 (1979).

The heats of formation of decafluorocyclohexene and dodecafluorocyclohexane have been determined by the direct combustion method previously developed and used for hexafluorobenzene and related compounds. The combustion of decafluorocyclohexene and dodecafluorocyclohexane formed the reaction products CO_2, CF_4, and F_2. In both cases a portion of the compound remained unburned. The unburned material was collected and quantitatively determined gravimetrically. A material balance was obtained for carbon and fluorine on the basis of CO_2, CF_4, and F_2 and the amount of unburned compound. With a ten-fold excess of oxygen, the average CO_2-to-CF_4 molar ratios for C_6F_{10} and C_6F_{12} are 2.03 ± 0.01 and 1.35 ± 0.01, respectively. The values obtained for the heats of formation are $\Delta H^0_{f298}(C_6F_{10},g) = -1906.6 \pm 7.2$ kJ mol^{-1} and $\Delta H^0_{f298}(C_6F_{12},g) = -2368.9 \pm 7.6$ kJ mol^{-1}. ΔH^0_{f298} for the reaction $C_6F_{10(g)} + F_{2(g)} \rightarrow C_6F_{12(g)}$ was calculated to be -462.3 ± 14.8 kJ mol^{-1} and the 'resonance energy' of C_6F_6 is estimated at -36.4 kJ mol^{-1}.

STANLEY JAMES W. PRICE et HENRY J. SAPIANO. Can. J. Chem. **57**, 685 (1979).

On a déterminé les chaleurs de formation du décafluorocyclohexène et du dodécafluorocyclohexane par la méthode de combustion directe développée antérieurement et utilisée pour l'hexafluorobenzène et des composés apparentés. La combustion du décafluorocyclohexène et du dodécafluorocyclohexane conduit au CO_2, au CF_4 et au F_2 comme produits de la réaction. Dans chacun des cas, une partie du produit est réfractaire à la combustion. On récupère le produit qui n'a pas réagi et on le détermine quantitativement par gravimétrie. On peut établir un bilan pour le carbone et le fluor en se basant sur les quantités de CO_2, de CF_4 et de F_2 obtenues et de produit récupéré. Lorsque l'excès d'oxygène est égal à 10 fois la quantité requise, les rapports molaires de CO_2 et de CF_4 pour le C_6F_{10} et le C_6F_{12} sont respectivement 2.03 ± 0.01 et 1.35 ± 0.01. Les valeurs obtenues pour les chaleurs de formation sont $\Delta H^0_{f298}(C_6F_{10},g) = -1906.6 \pm 7.2$ kJ mol^{-1} et $\Delta H^0_{f298}(C_6F_{12},g) = -2368.9 \pm 7.6$ kJ mol^{-1}. On a calculé que le ΔH^0_{f298} de la réaction $C_6F_{10(g)} + F_{2(g)} \rightarrow C_6F_{12(g)}$ est -462.3 ± 14.8 kJ mol^{-1} et on évalue à -36.4 kJ mol^{-1} l'énergie de résonance du C_6F_6.

[Traduit par le journal]

Introduction

To date no thermodynamic study for the heat of formation of C_6F_{12} has been reported. The combustion of C_6F_{10} in polyester bags has been reported by Cox and co-workers (1). To ensure complete combustion hydrogen-containing organic materials were added to the crucible. The approach taken in this study involves open dish combustion under anhydrous conditions and without auxiliary materials (2–5). This method has been adopted for the combustion of decafluorocyclohexene and of dodecafluorocyclohexane through the use of a steel crucible in a steel bomb. In each case some parent compound remained unburned but the only combustion products were CO_2, F_2, and CF_4. The quantity of unburned material was determined gravimetrically.

Experimental

Materials

(i) Decafluorocyclohexene

C_6F_{10} obtained from the Imperial Smelting Corporation was purified by preparative-scale gas chromatography. The final product had the following physical properties (the values in parentheses are those reported by the manufacturer) (6) bp = 53°C (53°C), $n_D^{25} = 1.29$ (1.29). Analysis by gas chromatography (6 ft. × 1/8 in. od Durapak *n*-octane/Porasil C, 100–200 mesh, N_2, 60 cm^3/min, column temperature 110°C, flame ionization detection) showed the presence of three impurities which represented a maximum of 0.02% of the sample. The impurities were collected and analyzed by mass spectrometry and nmr. They were identified to be $C_6F_{11}H$, C_6F_8, and $C_6F_{10}H_2$.

Vapour pressure measurements were made over the range of 4°C to 46°C. The data are adequately represented by

$$[1] \quad \log_{10} P\,(\text{cm}) = 10.474 - 1783.3/T - 1.236 \log_{10} T$$

[1]To whom all correspondence should be addressed.

0008-4042/79/060685-04$01.00/0

The resulting heat of vapourization and average heat capacity differences (vapour–liquid) are $\Delta H^0_{298} = 30.96$ kJ mol^{-1} and $\langle \Delta C_p, 4°C–46°C \rangle = -10.3$ J deg^{-1} mol^{-1}. The heat of vapourization is in good agreement with the value of 30.75 kJ mol^{-1} reported by Cox *et al.* (1).

(ii) Dodecafluorocyclohexane

C_6F_{12} obtained from the Imperial Smelting Corporation was used without further purification. Analysis by gas chromatography (same conditions as for C_6F_{10}) showed the presence of a minor impurity which represents a maximum of 0.01% of the sample. Vapour pressure measurements were made over the range 1°C to 49°C. The data can be adequately represented by:

$$[2] \quad \log_{10} P\,(\text{cm}) = 5.4180 - 1781.7/T + 0.7799 \log_{10} T$$

The resulting heat of sublimation and average heat capacity difference (vapour–solid) are $\Delta H^0_{298} = 35.98$ kJ mol^{-1} and $\langle \Delta C_p, 1°C–49°C \rangle = +6.49$ J deg^{-1} mol^{-1}.

(iii) CO_2, CF_4, F_2

CO_2, CF_4, and F_2 were obtained from the Matheson Chemical Company and were used without further purification.

Apparatus and Calorimetric Procedure

The apparatus and procedure used for the main combustion process were identical to those used for C_6F_5Br (5). A Parr model 1004C steel bomb and steel crucible were again used for the combustion process.

The rate of loss of C_6F_{10} and C_6F_{12} from the steel crucible in which they were weighed were 0.833 mg s^{-1} and 0.667 mg s^{-1}, respectively. The time between weighing the crucible containing the sample and closing the bomb was such that less than 1.7% of the total sample for C_6F_{10} and 1.3% for C_6F_{12} were lost by evaporation. The correction for the evaporation is estimated to be accurate to better than ±3%. The error generated by the correction procedure for C_6F_{10} and C_6F_{12} should therefore be less than ±0.05% and ±0.04%, respectively.

It must be remembered that the C_6F_{10} and C_6F_{12} samples are not contained in any way and that combustion occurs in a 320 cm^3 bomb with an initial temperature of 23.5°C and an initial pressure of 450 psi. The experimental procedure therefore involves the combustion of 1.23 g C_6F_{10} vapour and $(w - 1.23)$ g C_6F_{10} liquid where w = weight of C_6F_{10} sample in grams and the combustion of 1.18 g C_6F_{12} vapour and $(w - 1.18)$ g C_6F_{12} solid where w = weight of C_6F_{12} sample in grams. This means that on the average approximately 74% of the C_6F_{10} and 67% of the C_6F_{12} are in the vapour state before combustion.

Analysis of Reaction Products

The analytical procedures for CO_2, CF_4, and F_2 have been described elsewhere (2–5). The unburned material was collected in a glass U-trap which was immersed in an acetone – dry ice bath. The quantity of unburned material was determined gravimetrically. Mass spectra were obtained using a Varian MAT CH5-DF spectrometer controlled by an INCOS computer system. A Bausch and Lomb Spectronic 100 was used to determine iron with 1,10-phenanthroline (7).

Results and Discussion

In the combustion of C_6F_{10} and C_6F_{12} in the steel bomb it was observed that the formation of a green coloration was less extensive inside the bomb in both cases as compared with the amount observed in the study of C_6F_5Br (5). The amount of Fe(II) and Fe(III) fluorides after combustion of C_6F_{10} and C_6F_{12} was determined using a colorimetric procedure (7). In both cases the quantity found was 1.23 ± 0.01 mg. Approximately 80% of the iron fluoride was FeF_2. The correction to the heat of formation of C_6F_{10} and C_6F_{12} caused by the formation of FeF_2 and FeF_3 was less than 1.5 kJ mol^{-1} and 1.6 kJ mol^{-1}, respectively.

Apart from the small quantities of iron fluoride the products of combustion were CO_2, CF_4, and F_2. These products were identified and quantitatively determined in the same manner reported for the products of combustion of C_6F_6 (2), except that in the gas chromatographic procedure the silica gel column was replaced with a Porapak Q column.

The column used was a 6 ft. × 1/4 in. od Porapak Q column (25°C, He carrier, 48 cm^3/min). Calibrations were carried out using O_2–CF_4 and O_2–CO_2 mixtures. If pure CO_2 is used the CO_2 calibration is unaffected. If pure CF_4 is used the net result is that the relative response factor for CF_4 is increased by 3.5% resulting in values for $\Delta H^0_{f298}(C_6F_{10},g)$ and $\Delta H^0_{f298}(C_6F_{12},g)$ which are about 35.6 kJ mol^{-1} and 50.2 kJ mol^{-1} too high, respectively.

Gas chromatographic and mass spectrometric analyses indicate that observed unburned material in the study of both C_6F_{10} and C_6F_{12} is a portion of the original material. The mass spectrum of unburned C_6F_{12} was compared with that of an authentic sample and with API 0201 (8). No literature spectra could be found for C_6F_{10}. Table 1 presents the major peaks (R.A. > 4% base peak) for both an authentic sample and the recovered unburned material.

TABLE 1. Main peaks (R.A. > 4% base peak) for C_6F_{10} and for unburned material from the combustion of C_6F_{10} (isotope peaks omitted)

The total material balance based on CO_2, CF_4, F_2, and unburned material was in general low by about 0.25%. This was shown to be due to small losses from the trapping systems used to recover the unburned material. Subsequent thermochemical calculations were therefore based on the CO_2–CF_4 recovery.

From the material balance shown in Table 2 along with the average CO_2/CF_4 molar ratio reaction [3] may be written to represent the combustion of decafluorocyclohexene

[3] $C_6F_{10} + 4.024O_2 \rightarrow 4.024CO_2 + 1.976CF_4 + 1.048F_2$

From the material balance shown in Table 3 along with the average CO_2/CF_4 molar ratio reaction [4] may be written to represent the combustion of dodecafluorocyclohexane

[4] $C_6F_{12} + 3.452O_2 \rightarrow 3.452CO_2 + 2.548CF_4 + 0.904F_2$

In treating a complex mixture of products possible interactions between the compounds must be taken into account. No detectable heat of mixing was observed when F_2, O_2, CF_4, and CO_2 were mixed under anhydrous conditions (4).

In carrying out the thermochemical calculations the following heats of formations have been used; CO_2(g), −393.512 kJ mol^{-1} (9); and CF_4(g), −933.0 kJ mol^{-1} (10).

Based on the preceding data and an estimated correction to standard state of 3.4 kJ mol^{-1}, $\Delta H^0_{f298}(C_6F_{10},g) = -1906.6 \pm 7.2$ kJ mol^{-1}. The previously reported values −1881.1 kJ mol^{-1} (1) and −1935.1 kJ mol^{-1} (11) were based on ΔH^0_{f298} (HF·20H_2O) = −316.44 and −322.00 kJ mol^{-1}, respectively. Hubbard's work (12) would seem to support the latter value which leaves a discrepancy of about 28 kJ mol^{-1} between the present result and that of Cox and Pilcher (11).

The value for $\Delta H^0_{f298}(C_6F_{12},g)$ based on the above data and an estimated correction to standard state of 2.9 kJ mol^{-1} is -2368.9 ± 7.6 kJ mol^{-1}.

It is possible from the present data and from the heat of formation of hexafluorobenzene to calculate the enthalpies of reactions [5] and [6]

[5] $C_6F_{10}(g) + F_2(g) \rightarrow C_6F_{12}(g)$

[6] $C_6F_6(g) + 3F_2(g) \rightarrow C_6F_{12}(g)$

and subsequently to calculate a value for the 'resonance energy' of hexafluorobenzene (defined as $\Delta H^0_{298}(Rx[6]) - 3\Delta H^0_{298}(Rx[5])$. Based on ΔH^0_{f298}-(C_6F_6,g) = −945.6 kJ mol^{-1} (4) this 'resonance energy' is found to be −36.4 kJ mol^{-1}, implying little difference in energy between hexafluorobenzene and the hypothetical triene. This conclusion

seems to be in agreement with 'destabilization' calculations by Cox *et al.* (13) which show that the destabilizing effects of the C—F dipoles do not seem to be significantly moderated by any 'resonance' effect.

It is interesting to note that if the values of Cox *et al.* for $\Delta H^0_{f298}(C_6F_{10},g)$ (11) and $\Delta H^0_{f298}(C_6F_6,g)$ (13) are used the calculated 'resonance energy' is -112.1 kJ mol^{-1}. However, if the enthalpies used here are recalculated using the older NBS selected value of $\Delta H^0_{f298}(HF{\cdot}20H_2O) = -319.16$ kJ mol^{-1} (9) rather than the more recent result of Hubbard, -322.1 kJ mol^{-1} (12), then the resonance energy is -44.7 kJ mol^{-1} and $\Delta H^0_{f298}(C_6F_{10},g) = -1908.1$ kJ mol^{-1}, both in good agreement with the present work. Although the implication here is far from conclusive it may indicate that further study of the heats of formation of aqueous HF solutions is needed.

A shock-tube study of ammonia pyrolysis

JOHN E. DOVE AND WING S. NIP[1]

Department of Chemistry, Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received October 11, 1977[2]

JOHN E. DOVE and WING S. NIP. Can. J. Chem. **57**, 689 (1979).

The pyrolysis of NH_3 was studied behind reflected shock waves at temperatures 2500–3000 K, using mass spectrometric analysis of dynamically sampled gas. The initial mixtures contained 0.14% to 6% NH_3, with Kr as diluent, at total gas concentrations of about 2×10^{-6} mol cm^{-3}. Concentration profiles of NH_3, NH_2, NH, and N_2 were measured. It was found that the apparent rate coefficient for overall removal of NH_3 is increased by increasing the initial NH_3 concentration, but is decreased by addition of H_2. Addition of H_2 also suppressed NH, but left the NH_2 concentration relatively unchanged. A close correlation was found between NH_2 concentration and N_2 formation rate, indicating that NH_2 participates in the reaction which produces N_2.

The experimental results are consistent with a chain mechanism in which NH_3 is removed by unimolecular decomposition and by attack by H, NH, and NH_2. Computer analysis yields a rate constant of $1.2 \times 10^{16} \exp(-91\,000 \text{ cal mol}^{-1}/RT)$ cm^3 mol^{-1} s^{-1} for the unimolecular process.

JOHN E. DOVE et WING S. NIP. Can. J. Chem. **57**, 689 (1979).

Faisant appel à la spectrométrie de masse d'échantillons de gaz prélevés d'une façon dynamique, on a étudié la pyrolyse du NH_3, derrière des ondes de choc réfléchies, à des températures de 2500 à 3000 K. A des concentrations totales de gaz de 2×10^{-6} mol/cm^3, les mélanges initiaux contiennent de 0.14 à 6% de NH_3 lorsqu'on utilise du Kr pour diluer. On a mesuré les profils de concentration de NH_3, NH_2, NH et N_2. On a trouvé que le coefficient de vitesse apparent pour l'élimination globale de NH_3 augmente avec une augmentation de la concentration initiale du NH_3 mais qu'il diminue avec une addition de H_2. L'addition de H_2 supprime aussi la formation de NH mais influence peu la concentration de NH_2. On a trouvé une corrélation étroite entre la concentration de NH_2 et le taux de formation de N_2; ceci indique que le NH_2 participe à la réaction qui produit le N_2.

Les résultats expérimentaux sont en accord avec un mécanisme en chaîne dans lequel le NH_3 est éliminé par une décomposition unimoléculaire et par des attaques par H, NH et NH_2. Une analyse par ordinateur permet d'obtenir une constante de vitesse de $1.2 \times 10^{16} \times \exp(-91\,000 \text{ cal mol}^{-1}/RT)$ cm^3 mol^{-1} s^{-1} pour le processus unimoléculaire.

[Traduit par le journal]

Introduction

The thermal decomposition of gaseous ammonia provides a potentially interesting and important test case for the theory of unimolecular reactions. This decomposition has indeed already been the subject of a number of experimental studies (1–8), from which it is evident that the overall reaction is influenced by secondary processes. However, the reaction mechanism is by no means clear, and consequently it is difficult to deduce the unimolecular rate constant unambiguously from the observed kinetics.

Table 1 summarizes the literature values for the overall decomposition rate coefficient, k_D. There has been some doubt about the form of the overall rate equation. Jacobs (1) found orders of 1.5 and 0.5 with respect to NH_3 and diluent, respectively. Johnson (4), on the other hand, found that the rate was first order in NH_3 and zero order in diluent concentration. However, the variation in diluent concentration by these two workers was less than 50%, and hence their statements about the diluent concentration dependence should be viewed with caution. Most of the recent studies are in agreement that, at the total gas concentrations typical of shock-tube experiments, the overall rate is first order in NH_3 and first order in diluent, so that

$$-\mathrm{d}[NH_3]/\mathrm{d}t = k_D[NH_3][M]$$

The study by Michel and Wagner (2) over a 120-fold variation in NH_3 concentration, and an 8-fold variation in diluent concentration, is particularly convincing in this respect.

The values of k_D found by different workers vary substantially; e.g. at 2500 K, Takeyama and Miyama (5) report a value 6.3 times larger than that of Bradley *et al.* (6). However, the observed temperature dependences (Table 1) are all about 80 kcal mol^{-1}, which

*$k_D = -([NH_3]^{-1}[M]^{-1}(d[NH_3]/dt))$ except in refs. 1 and 4; units in cm^3 mol^{-1} s^{-1} with the activation energy in cal mol^{-1}. [M] = diluent gas concentration.
†In ref. 1, $k_D = -([NH_3]^{-1.5}[M]^{-0.5}(d[NH_3]/dt))$.
‡In ref. 4, $k_D = -([NH_3]^{-1}(d[NH_3]/dt))$ in s^{-1}.

is much lower than the N—H bond dissociation energy of 103 kcal mol^{-1}. There are several ways of explaining this difference between the activation energy and the exothermicity:

(*i*) If the unimolecular dissociation step

[1] $NH_3 + M \rightarrow NH_2 + H + M$ $\quad \Delta H_0^0 = 103$ kcal mol^{-1}

is rate-determining for the overall reaction, the lowering in activation energy could be ascribed to unimolecular fall-off. The lowering appears, however, to be rather large to be wholly explained in this way.

(*ii*) While it is usually assumed in the literature that the products of the unimolecular step are NH_2 and H, the formation of NH and H_2 is thermochemically somewhat more favourable:

[2] $NH_3 + M \rightarrow NH + H_2 + M$ $\quad \Delta H_0^0 \simeq 91$ kcal mol^{-1}

Allowing for some unimolecular fall-off, this endothermicity appears to fit the observed activation energy quite well.

(*iii*) An alternative is that the decomposition is a chain reaction, or at least that secondary reactions of lower activation energy also influence the rate of NH_3 removal. The occurrence of a chain reaction is supported by the results of Takeyama and Miyama (5), who observed an induction period in the pyrolysis process below 2400 K. The nature of the secondary reactions is by no means clear. Previously, it has usually been assumed (on the basis of low temperature rate data) that H atoms do not react with NH_3. This forced Bradley *et al.* (6) to conclude that the chain carrier must be NH_2. They proposed the following mechanism

[1] $NH_3 + M \rightarrow NH_2 + H + M$

[3] $NH_2 + NH_3 \rightarrow N_2H_3 + H_2$

[4] $N_2H_3 \xrightarrow{(M)} NH + NH_2$

[7′] $NH_2 + NH_2 \rightarrow$ products

However, it is now known (9) that H atoms do react with NH_3 at high temperatures. The mechanism of Bradley *et al.* therefore needs further examination.

Haluk (7) used a theoretical rate coefficient from the literature (10, 11) from a Johnston and Parr type of calculation, for the reaction of H with NH_3, and concluded that most of the secondary reactions must be carried out by H atoms. He proposed the following mechanism:

[1*a*] $NH_3 + Ar \rightarrow NH_2 + H + Ar$

[5] $H + NH_3 \rightarrow H_2 + NH_2$

[6] $H + NH_2 \rightarrow H_2 + NH$

[7] $NH_2 + NH_2 \rightarrow NH + NH_3$

[8*a*] $H + H + Ar \rightarrow H_2 + Ar$

[9] $NH + NH \rightarrow N_2 + H_2$

[10] $NH_2 + NH_2 \rightarrow N_2 + H_2 + H_2$

However, the theoretical value which he chose for k_5 is so much larger than all of the experimental values that it is almost certainly wrong. Hence he most probably overestimates the importance of H atoms. Johnson (4) also proposed that H atoms are important in ammonia pyrolysis, based on his finding that addition of H_2 increased the decomposition rate. However, his analyses were not conclusive.

NH has not been suggested as an important intermediate in the pyrolysis mechanism. Nevertheless, studies of its behaviour in NH_3 pyrolysis have been reported by three research groups (6, 8, 12) who agreed in proposing that NH was derived from NH_2, rather than from the direct decomposition of NH_3 into NH and H_2. However, there was no agreement about the observed kinetic behaviour. Bradley *et al.* (6) found that the NH concentration, measured by infrared emission, rose parabolically

$$[NH] = k[NH_3]^2[Ar]t^2$$

They proposed the following mechanism for formation of NH

[3] $$NH_2 + NH_3 \rightarrow N_2H_3 + H_2$$

[4] $$N_2H_3 \xrightarrow{(M)} NH + NH_2$$

which is consistent with their overall mechanism mentioned earlier. Cann and Kash (12) and Genich, Zhirnov, and Manelis (8) studied the ultraviolet emission of NH, and found an initial linear rather than parabolic rise:

$$d[NH]/dt = k'[NH_3]_0^2$$

However, this emission from electronically excited NH is apparently non-thermal, and it may well bear no direct relationship to the concentration of electronic ground state NH.

Evidently, there is still considerable uncertainty about the decomposition mechanism, and in particular about the possible role of radical intermediates. For this reason, we have made a shock-tube kinetic study using mass spectrometric detection. This method gives concentration versus time profiles of reactant, products, and some major intermediates, and therefore yields a very good overview of the processes taking place.

Experimental

Apparatus

The basic apparatus and detailed experimental procedure have been described previously (13) so that only a brief account will be given here. The equipment included a stainless steel shock tube coupled to a time-of-flight mass spectrometer. The hot reacting gas was sampled from the reflected shock region directly into the ion source of the mass spectrometer. A set of mass spectra, recorded sequentially from oscilloscopes at intervals of typically 15 to 25 μs, constituted the basic kinetic data from each experiment. The speed of the incident shock wave was measured by timing it over 4 successive intervals, using digital time interval meters of 0.1 μs resolution. The temperature, pressure, and density behind the reflected shock wave were then calculated from the shock speed (extrapolated to the end wall of the shock tube) using standard thermodynamic data (14) and computational methods.

Before commencing each experiment, the shock tube was pumped down to a pressure less than 10^{-5} Torr, measured by a hot filament ion gauge. Since NH_3 is polar and tends to adsorb on stainless steel, the shock tube was then flushed with ammonia, pumped down to about 1×10^{-3} Torr, and flushed with the reaction mixture before every experiment.

Before the present study, several significant changes were made to the original apparatus (13), as follows:

(*a*) A predynode gating circuit (15), designed in this laboratory, was added to the electron multiplier of the mass spectrometer. This allowed the very large mass peaks due to the diluent gas to be eliminated before amplification in the multiplier. The electron multiplier could then be operated at larger gain without danger of non-linearity due to saturation effects.

(*b*) The inlet cylinder to the differential pumping baffle in the flight tube of the mass spectrometer was replaced by a cylindrical grid. This change reduced the pressure build-up in front of the baffle which was the cause of a slight collision broadening of mass peaks found in earlier work with this instrument.

(*c*) The original glass manifold and gas handling system were replaced by a bakable all stainless steel system. Gas pressure measurements were made by a Texas Instruments quartz spiral gauge which was calibrated by the National Research Council of Canada.

Experimental Gases

Kinetic experiments were made with four mixtures: mixture 1: 6.2% NH_3, 5.0% Ar, 88.7% Kr; mixture 2: 6.0% NH_3, 1.2% H_2, 5.6% Ar, 87.2% Kr; mixture 3: 6.1% NH_3, 5.8% H_2, 6.4% Ar, 81.7% Kr; mixture 4: 0.14% NH_3, 0.16% Ar, 99.70% Kr. The mixtures were made up by manometric measurement of partial pressures. No further analysis was made of the mixture composition, but the purity was checked mass spectrometrically.

Unless otherwise stated, the gases used were obtained from Matheson of Canada: NH_3: "anhydrous" grade, 99.99% pure. The gas was further purified by fractional distillation from liquid nitrogen and from a dry ice – acetone bath at about −40°C. H_2: "ultra high purity" grade, 99.999%, used without further purification. Ar: "research purity" grade, 99.9999%, used without further purification. Kr: "research purity" grade, 99.99%, from Air Products and Chemicals Ltd., used without further purification. The only significant impurities were other inert gases. N_2: "high purity" grade, 99.99%, from Canadian Oxygen Ltd., used without further purification. (Used for calibration only.)

Mass Spectrometric Data

For measurements of the time-dependent NH_3 and N_2 concentration in the kinetic experiments, Ar was used as an internal standard, i.e. the mass peak heights were measured relative to the Ar^+ peak. Absolute concentrations could then be obtained using the appropriate relative sensitivity factors and the known Ar concentration. This procedure, rather than reliance on the measurement of absolute peak heights, was used to find concentrations because of its insensitivity to slight variations, from experiment to experiment, in the performance of the mass spectrometer and in the behaviour of the flow through the sampling orifice. The relative sensitivity factors were measured using known mixtures in shock wave experiments under conditions as close as possible to those of the kinetic experiments themselves; the gas temperature in the calibration experiments was, of course, kept low enough for the extent of reaction to be insignificant.

To follow the concentration profiles of NH_3, H_2, and NH, the electron beam energy was set at 25.0 eV. However, when NH_2 was being studied, the electron energy was lowered to 13.0 eV to avoid interference from the fragmentation of NH_3^+. (The appearance potential (16) of NH_2^+ from NH_3 is 16.0 eV.) With such a low energy, it is impossible to use Ar^+ as an internal standard, since the ionization potential of Ar is 15.8 eV. Therefore the NH_2^+ mass peaks were standardized to the NH_3^+ peak at time zero. (The height of NH_3^+ at time zero was obtained by extrapolation from the NH_3^+ peak in the first mass spectrum after arrival of the shock wave, knowing the decay rate of the ammonia peaks.) The question of mass spectrometer sensitivity to NH and NH_2 is discussed below.

Results

Kinetic experiments were carried out at temperatures of 2500 to 3000 K and total gas concentrations of about 1.7×10^{-6} mol cm^{-3}. The resulting mass spectrometric observations are summarized below.

Ammonia Analysis

In all of the mixtures studied, the NH_3 profile followed a pseudo-first order decay, to within experimental accuracy. Expressing the rate of de-

composition in the form

$$-\frac{d[NH_3]}{dt} = k_D[NH_3]([Kr] + [H_2]_0 + [Ar])$$

a second order decomposition rate coefficient k_D could be defined for each experiment. Arrhenius plots of k_D for the four mixtures are given in Figs. 1 and 2. The corresponding Arrhenius expressions are:

$$k_D(6\%\ NH_3) = 10^{15.78\pm0.59} \times \exp(-78\,400 \pm 7\,200/RT)$$

$$k_D(6\%\ NH_3, 1.2\%\ H_2) = 10^{13.80\pm0.25} \times \exp(-56\,800 \pm 6\,000/RT)$$

$$k_D(6\%\ NH_3, 6\%\ H_2) = 10^{13.96\pm0.63} \times \exp(-60\,300 \pm 8\,000/RT)$$

$$k_D(0.14\%\ NH_3) = 10^{16.08\pm0.67} \times \exp(-89\,500 \pm 8\,600/RT)$$

in $cm^3\ mol^{-1}\ s^{-1}$, with activation energies in cal mol^{-1}. The quoted uncertainties are standard deviations.

It will be seen from Fig. 1 that addition of NH_3 increases k_D. This implies that, over a large range of NH_3 concentrations, the reaction is not strictly first order with respect to $[NH_3]$. As shown by Fig. 2, addition of H_2 progressively decreases k_D.

NH_2 Analysis

As explained above, NH_2^+ mass peaks were standardized to NH_3^+. Because there appeared to be no reliable way of measuring a sensitivity factor for NH_2 relative to NH_3, the data presented in Fig. 3 assume a relative sensitivity of unity. Since the ionization potential (16) of NH_2 (11.4 eV) is higher than that of NH_3 (10.4 eV) and is fairly close to the electron energy used (13.0 eV), the NH_2 concentration deduced in this way is very probably an underestimate. Nevertheless the shapes of the NH_2 profiles are expected to be correct. Moreover, as shown later, a knowledge of the relative concentrations of NH_2 in different mixtures is useful in determining the reaction mechanism.

Because the concentration of NH_2 was small, the results from experiments with similar temperatures were grouped and averaged to reduce scatter. A typical NH_2 profile is shown in Fig. 3. Comparison of results from mixtures 1 and 3 showed that addition

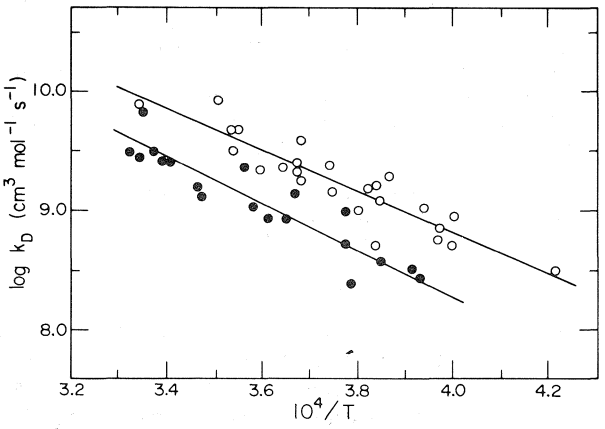

FIG. 1. Arrhenius plot of k_D, the rate constant for overall removal of NH_3, for NH_3/Kr mixtures: upper line and open points, 6.2% NH_3 in Kr; lower line and solid points, 0.14% NH_3 in Kr.

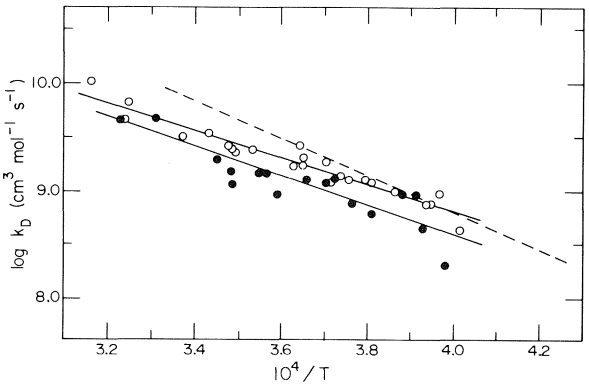

FIG. 2. Arrhenius plots showing how addition of H_2 progressively reduces k_D in ammonia pyrolysis: dashed line, k_D for 6.2% NH_3 in Kr (cf. Fig. 1); upper solid line and open points, k_D for 6.0% NH_3 + 1.2% H_2 in Kr; lower solid line and solid points, k_D for 6.1% NH_3 + 5.8% H_2 in Kr.

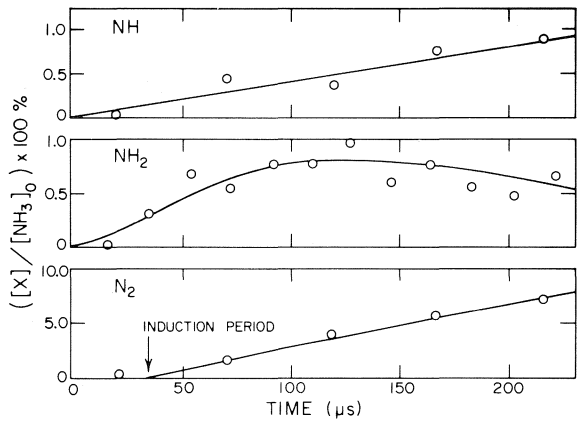

FIG. 3. Typical NH, NH_2, and N_2 concentration profiles in pyrolysis of mixture 1 (6.2% NH_3 in Kr). T = 2511 K. Total gas concentration = 1.7×10^{-6} mol cm^{-3}. The arrow on the lowest profile indicates the end of the induction period for N_2 formation. (The NH_2 and NH profiles use an arbitrary mass spectrometric sensitivity factor of unity, relative to NH_3; see the text for discussion of the actual sensitivity.)

of H_2 has very little effect on the NH_2 profiles over the present temperature range.

NH Analysis

The NH concentration profiles were deduced from the 25 eV experiments, corrected for NH_3^+ fragmentation. Fortunately this correction is found to be very small

$$([NH^+]_{fragment}/[NH_3^+]) = 0.03$$

No corrections were made for NH_2^+ fragmentation, because the mass 16 peak (NH_2^+) in these experiments could be accounted for almost entirely by NH_3^+ fragmentation; this implies that the contribution of NH_2 to mass 16 in the 25 eV experiments was very small and its contribution to mass 15 (NH^+) is probably even smaller. The data in Fig. 3 assume that the mass spectrometric sensitivity to NH is the same as to NH_3. This assumption under the present conditions is expected to be good to within a factor of two (17), since the electron beam energy is substantially higher than the ionization potentials of both species. Scatter of data again forced grouping of experiments under similar conditions.

In the 6% NH_3 mixture, the NH concentration shows a linear rise (Fig. 3) and falls slowly. This agrees with the observations of Cann and Kash rather than those of Bradley *et al.* Addition of hydrogen (1.2 mol%) reduced the concentration of NH; with an initial hydrogen concentration of 6 mol% the concentration of NH was below the detectability limit. This suppression of NH on addition of H_2 was also observed by Bradley *et al.* The fact that the NH concentration can be suppressed to below the detectability limit with the NH_2 concentration relatively unchanged confirms that the NH^+ from 6% NH_3 mixture was not formed from NH_2^+ by fragmentation.

N_2 Analysis

The N_2 profiles (Fig. 3) show an induction period before the N_2 concentration rises linearly. We define the induction period τ as the time between the shock arrival and the linear extrapolation of the N_2 concentration to the time axis. A plot of log τ vs. $1/T$ is shown in Fig. 4. Addition of hydrogen (6 mol%) decreases the induction period slightly, but has very little effect on the rate of linear rise (Fig. 5). Because of the limited number of mixtures, it is not possible to determine the dependence of the N_2 growth rate on $[NH_3]$ and [M].

Other Species

Masses 14, 29, 30, 31, and 32, corresponding to N, N_2H, N_2H_2, N_2H_3, and N_2H_4, were searched for but not found. The nitrogen mass balance was very good for the low temperature (<2700 K) experiments both

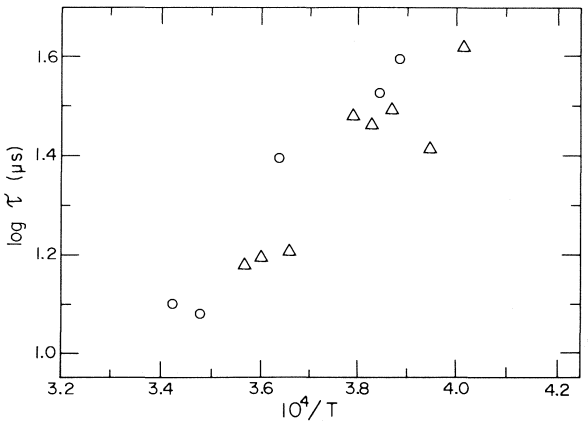

FIG. 4. Plot of the logarithm of τ, the induction period for N_2 formation, against $10^4/T$, in ammonia pyrolysis. ○, mixture 1 (6.2% NH_3 in Kr); △, mixture 3 (6.1% NH_3 + 5.8% H_2 in Kr).

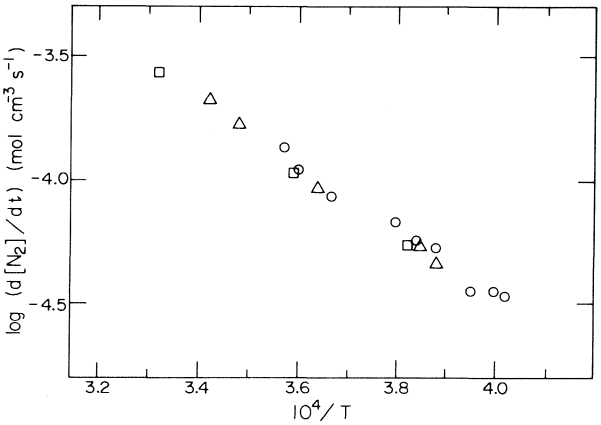

FIG. 5. Plot of log (rate of linear rise of $[N_2]$) against $10^4/T$ in NH_3 pyrolysis. Total gas concentration $\simeq 1.7 \times 10^{-6}$ mol cm^{-3}. ○, Mixture 1; □, mixture 2; △, mixture 3.

with and without H_2 in the initial mixture. At high temperatures the N balance was less satisfactory especially over long periods of time, although over 80% of the N was still recovered at times less than 100 μs. The cause of this discrepancy is not known. It is quite unlikely that there exist N-containing species other than those already mentioned. The relative sensitivity of N_2 to Ar has been found to be independent of temperature, and the mass peaks remained reasonably well shaped (i.e., there was no sign of pressure broadening of peaks). Because of this discrepancy, the results of high temperature experiments at times beyond 100 μs must be viewed with caution. Most of our kinetic analysis was done on the early part of the reaction, so that there should not be a serious effect on our conclusions.

Concentration profiles of H_2 and H atoms would be very useful in studying the reaction mechanism.

Unfortunately, the very low sensitivity of the mass spectrometer to these species made it impossible to obtain useful information about them.

Discussion

Values of k_D

Figure 6 shows that our second order decomposition rate coefficients k_D for mixtures 1 and 4 fall essentially in the range of previous observations. However, the present work is the first one using Kr as diluent, so that exact agreement with studies using Ar diluent is, in any case, not necessarily to be expected. The work of Michel and Wagner (2) and our own measurements with mixture 4 are the only two studies using very low NH_3 mole fractions. Comparison of these two studies implies that Ar is twice as efficient as Kr in decomposing NH_3 over the temperature range 2500–3000 K as far as the effect on k_D is concerned.

The factor of three difference in k_D obtained between our mixtures 1 and 4 is too large to be dismissed as probably due to experimental scatter. One possible explanation is the NH_3 has a much larger collision efficiency than Kr in decomposing ammonia.

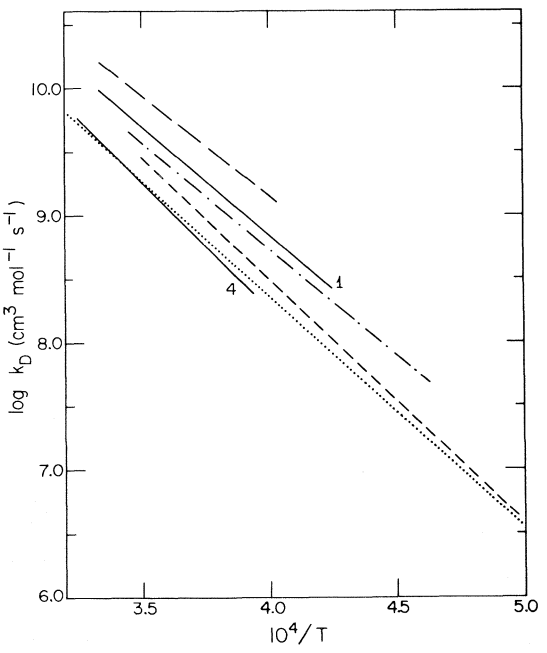

FIG. 6. Comparison of our results for k_D, the overall rate coefficient for NH_3 removal, with literature values. — *1*, this work, mixture 1 (6.2% NH_3 in Kr); — *4*, this work, mixture 4 (0.14% NH_3 in Kr; – – –, Takeyama and Miyama (5); ····· Michel and Wagner (2); - - -, Henrici (3); · · ·, Bradley *et al.* (6). For clarity, Haluk's line (7) has been omitted. It is essentially coincident with that of Bradley *et al.* in the range $10^4/T = 3.4$–5.0.

To explain the whole of the difference in this manner would require that NH_3 be about 40 times as efficient as Kr. An alternative is that secondary reactions become important at higher NH_3 concentrations; this explanation is supported by the slight decrease in activation energy when the NH_3 mole fraction is increased, implying the participation of other reactions of lower activation energy.

One possibility is that the reaction occurs by the following type of mechanism:

$$NH_3 + M \rightarrow A + P_1$$

$$A + NH_3 \rightarrow P_2 + P_3$$

where P_1, P_2, and P_3 are species which do not react with NH_3. Two mechanisms of this type are:

Mechanism 1

[1] $NH_3 + M \rightarrow H + NH_2 + M$

$\Delta H_0^0 \simeq 103$ kcal mol^{-1}

[5] $H + NH_3 \rightarrow NH_2 + H_2$

$\Delta H_0^0 \simeq 1$ kcal mol^{-1}

[10] $NH_2 + NH_2 \rightarrow N_2 + H_2 + H_2$

$\Delta H_0^0 \simeq -84$ kcal mol^{-1}

or

Mechanism 2

[2] $NH_3 + M \rightarrow NH + H_2 + M$

$\Delta H_0^0 \simeq 91$ kcal mol^{-1}

[−7] $NH + NH_3 \rightarrow NH_2 + NH_2$

$\Delta H_0^0 \simeq 15$ kcal mol^{-1}

[10] $NH_2 + NH_2 \rightarrow N_2 + H_2 + H_2$

$\Delta H_0^0 \simeq -84$ kcal mol^{-1}

However, this type of mechanism increases the rate of NH_3 removal by at most a factor of two. In order to explain entirely in terms of secondary reactions the finding that $k_D(6\%\ NH_3)/k_D(0.14\%\ NH_3) \simeq 3$, one must introduce also a reaction between NH_2 and NH_3. Of the two reactions

[3] $NH_2 + NH_3 \rightarrow N_2H_3 + H_2$

$\Delta H_0^0 \simeq 19$ kcal mol^{-1}

and

[11] $NH_2 + NH_3 \rightarrow N_2H_4 + H$

$\Delta H_0^0 \simeq 46$ kcal mol^{-1}

reaction [3] is favoured on thermochemical grounds.

N_2H_3 can break up by either of

[4] $N_2H_3 + M \rightarrow NH_2 + NH + M$

$\Delta H_0^0 \simeq 72$ kcal mol^{-1}

or

[12] $N_2H_3 + M \rightarrow N_2H_2 + H + M$

$\Delta H_0^0 \simeq 54$ kcal mol^{-1}

The products of either reaction (H or NH) can react with NH_3 to regenerate NH_2, thus constituting a chain.

The fact that successive additions of H_2 to the initial mixture decrease the overall decomposition rate (Fig. 2) also suggests a chain process. Mechanism 2 cannot be correct since it would predict no effect of addition of H_2, as long as the reverse of reaction [2] is slow, which is the case under the present conditions. Mechanism 1 predicts that under no conditions can the addition of H_2 decrease k_D by more than a factor of 2, whereas we find that, at high temperatures, the actual factor exceeds 3 (Fig. 2).

It thus appears that neither mechanism 1 nor mechanism 2 (and hence no combination of the two) can fully explain our values of k_D. We must therefore analyze the effects of introducing a reaction between NH_2 and NH_3, which will inevitably lead to a chain reaction. At this point we disagree with Haluk (7), who considered that such a reaction was not necessary in order to explain his results. However, we support the suggestion by Bradley *et al.* (6) of such a reaction, and the conclusion that the overall activation energy of about 80 kcal mol^{-1} does not represent exactly the activation energy of the primary step.

Reactions of NH

Our results for mixtures 1 and 2 show a linear rise in NH concentration followed by a drop, agreeing with the results of Cann and Kash but in conflict with the parabolic rise observed by Bradley *et al.* Cann and Kash found that the growth of NH follows a relationship

$$\frac{d[NH]}{dt} = k'[NH_3]_0^2$$

with

$$k' = 4.8 \times 10^{12} \exp\left(\frac{-23\,900}{T}\right) \text{cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$$

Assuming the same dependence on ammonia concentration, Table 2 compares values of the rate coefficient k' computed from the present work and from the results of Cann and Kash. The scatter of experimental data forced grouping of a large number of experiments to obtain any reasonable estimate of the rates, hence the very few experimental points available for comparison. Agreement between the present work and Cann and Kash's data is very good, especially the two low temperature points.

TABLE 2. Apparent rate constant for NH formation. Comparison with results of Cann and Kash (12)

Temperature (K)	k' (cm^3 mol^{-1} s^{-1})	
	Cann and Kash	This work
2513	3.6×10^8	3.9×10^8
2563	4.4×10^8	4.3×10^8
2788	9.1×10^8	7.6×10^8

Addition of hydrogen to the reaction mixture suppresses the growth of NH. NH can only be formed from NH_2 or by splitting NH_3 into NH and H_2. In the NH_2 analysis, it was shown that addition of H_2 does not affect the NH_2 concentration profiles much; thus it is fairly safe to assume that the rate of formation of NH is not much affected by the addition of H_2. Presumably therefore the lowering of NH concentration is due to removal by reaction with H_2, probably by

[−6] $NH + H_2 \rightarrow NH_2 + H$

The other possible reaction with H_2, the combination reaction

[−2] $NH + H_2 + M \rightarrow NH_3 + M$

is probably a three body process and very slow. The formation and removal of NH can therefore be represented by

$$\xrightarrow{F} NH$$

[−6] $NH + H_2 \rightarrow NH_2 + H$

where F is the rate of production of NH. A value of F can be read from the early part of a profile of [NH] against time in the absence of added H_2. Then for mixture 2 (6% NH_3, 1.2% H_2), at a time in the very early part of the reaction, we can write

$$\frac{d[NH]}{dt} = F - k_{-6}[NH][H_2]_0$$

Using values of d[NH]/dt from mixture 2, we get

$$k_{-6} = 1.8 \times 10^{12} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1} \text{ at } 2601 \text{ K}$$

$$= 2.2 \times 10^{12} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1} \text{ at } 2788 \text{ K}$$

This simple analysis does not require a knowledge of the absolute sensitivity of the mass spectrometer to NH. k_{-6} deduced this way is expected to be accurate to within a factor of 3, the errors being mainly due to the uncertainty in determining the slope of the [NH] profile in the very early part of the reaction. This value of k_{-6} appears to be the first based on experimental measurements. There are theoretical calculations by Mayer and Schieler (10, 18) which agree well with the

present measurements; the closest agreement is with the results of (18*b*) which are 20% below our values at both 2601 and 2788 K. Calculations using k_{-6} indicate that in mixture 3, with 5.8% H_2, the concentration of NH should be too small to be observed, as was found in our experiments.

The above analysis predicts that addition of H_2 will convert NH to NH_2 through reaction [−6]. The resultant increase in $[NH_2]$ will be small, as observed experimentally, because even before adding H_2, the NH concentration is already substantially below that of NH_2, especially at short reaction times. Note that, as discussed above, our NH_2 profiles (cf. Fig. 3) should be multiplied by a factor which is almost certainly greater than unity; the computer analysis outlined later indicates that the factor is about 5.

Mechanism of N_2 Formation

A very interesting problem in ammonia pyrolysis is the mechanism of formation of molecular nitrogen. In principle, N_2 can be formed from mutual or cross combination of any of the species NH, NH_2, and NH_3. Comparison of the concentration profiles of these species with those for N_2 allows us to test which processes may be important.

In the previous section, we showed that addition of 6% H_2 to the initial reaction mixture drastically reduces the concentration of NH but has very little effect on N_2. This observation eliminates all reactions involving NH as the main source of N_2 in ammonia pyrolysis. The other possibilities are

[13] $$NH_2 + NH_2 \rightarrow \cdots \rightarrow N_2$$

[14] $$NH_2 + NH_3 \rightarrow \cdots \rightarrow N_2$$

[15] $$NH_3 + NH_3 \rightarrow \cdots \rightarrow N_2$$

Reaction [15] must be rejected as a major source of N_2 because it predicts a maximum rate of production of N_2 at the start of the reaction, contrary to our experimental observations. Reaction [13] predicts a very strong correlation between the induction period τ for the formation of N_2 and the build up of NH_2 radicals. Since only a small fraction of the NH_3 is decomposed during the induction period, reaction [14] also predicts a correlation between τ and the build up of NH_2 radicals. Figure 7 shows that, for either reaction [13] or [14], the correlation is very satisfactory.

The tests can be carried one step further. If most of the N_2 comes from the recombination of NH_2, reaction [13], then

$$(d[N_2])/dt = k_{13}[NH_2]^2$$

and

$$[N_2] = k_{13}\int_0^t [NH_2]^2\, dt$$

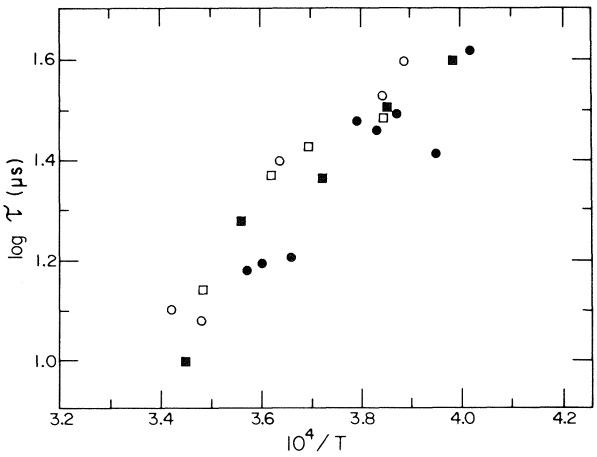

FIG. 7. Comparison of induction period τ for N_2 formation with time taken for $[NH_2]$ to reach 40% of its maximum value. Mixture 1 (6.2% NH_3 in Kr): ○, induction period τ; □, time t to reach 40% of maximum $[NH_2]$. Mixture 3 (6.1% NH_3 + 5.8% H_2 in Kr): ●, induction period τ; ■, time t to reach 40% of maximum $[NH_2]$.

Thus the concentration of N_2 at any time t should be proportional to the area under a $[NH_2]^2$ vs. time plot. Similarly, if one assumes that reaction [14] is the major producer of N_2, then

$$[N_2] = k_{14}\int_0^t [NH_2][NH_3]\, dt$$

and the concentration of N_2 at time t would be proportional to the area under a graph of $[NH_2] \times [NH_3]$ against t. The above two comparisons were made for mixtures 1 and 3. Satisfactory correlations were found assuming either reaction [13] or [14]. An example of the comparisons is shown in Fig. 8. We cannot decide at this stage whether reaction [13] or reaction [14] is responsible for the production of N_2 in the pyrolysis of ammonia.

It should be noted that our results do not rule out the possibility that NH contributes to the formation of N_2 in ammonia pyrolysis, but they do show that a major route to N_2 involves NH_2 and not NH.

The details of reactions [13] and [14] will now be considered. The reaction of two NH_2 radicals is often believed to lead to disproportionation to NH_3 and NH

[7] $$NH_2 + NH_2 \rightarrow NH_3 + NH$$

$$\Delta H_0^0 \simeq -11 \text{ kcal mol}^{-1}$$

However, if reaction [13] leads to N_2, then there must be a significant probability that a collision of two NH_2 radicals leads to products different from those of reaction [7], e.g.

[16] $$NH_2 + NH_2 \rightarrow N_2H_2 + H_2$$

$$\Delta H_0^0 \simeq -50 \text{ kcal mol}^{-1}$$

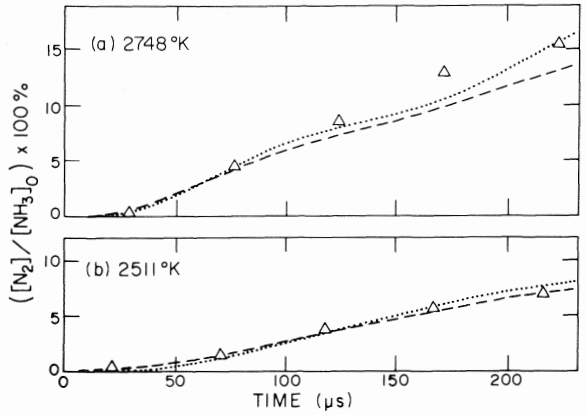

FIG. 8. An example of the comparison of the experimentally measured N_2 profiles with the time integrals of $[NH_2]^2$ and $[NH_2][NH_3]$. (*a*) Mixture 3 (6.1% NH_3 + 5.8% H_2 in Kr), $T = 2748$ K. (*b*) Mixture 1 (6.2% NH_3 in Kr), $T = 2511$ K. · · ·, $k\int[NH_2]^2\,dt$. - - -, $k'\int[NH_2][NH_3]\,dt$. k and k' were treated as adjustable parameters.

followed by

$$[17] \qquad N_2H_2 \xrightarrow{M} N_2 + H_2 \qquad \Delta H_0^0 \simeq -50 \text{ kcal mol}^{-1}$$

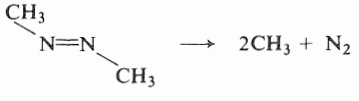
However, Michel and Wagner (2) suggested that N_2H_2 splits into N_2H and H. The sequence leading to N_2 formation would then be

$$[16] \qquad NH_2 + NH_2 \rightarrow N_2H_2 + H_2 \qquad \Delta H_0^0 \simeq -34 \text{ kcal mol}^{-1}$$

$$[18] \qquad N_2H_2 \rightarrow N_2H + H \qquad \Delta H_0^0 \simeq 82 \text{ kcal mol}^{-1}$$

$$[19] \qquad N_2H \rightarrow N_2 + H \qquad \Delta H_0^0 \simeq -28 \text{ kcal mol}^{-1}$$

Even though Michel and Wagner's suggestion does not alter the present argument about the source of the N_2, it will affect the overall kinetics of pyrolysis because it implies that the combination of NH_2 radicals is a chain propagation step rather than a termination reaction. One drawback of the above sequence is that it includes the highly endothermic reaction [18] which would be fairly slow. Possibly therefore reactions [18] and [19] occur in a single concerted process which would be much less endothermic. Azomethane, a close relative of N_2H_2, forms two radicals



$$\longrightarrow 2CH_3 + N_2$$

apparently in a single step. However, Willis and Back (19) have studied the thermal decomposition of N_2H_2 at room temperature and found that free radical mechanisms are not important in the process. This tends to suggest that N_2H_2 does not split into N_2 and H atoms.

The most plausible reaction sequence for producing N_2 from NH_2 + NH_3 (reaction [14]) is

$$[3] \qquad NH_2 + NH_3 \rightarrow N_2H_3 + H_2 \qquad \Delta H_0^0 \simeq 17 \text{ kcal mol}^{-1}$$

$$[19] \qquad N_2H_3 + M \rightarrow N_2 + H_2 + H + M \qquad \Delta H_0^0 \simeq 4 \text{ kcal mol}^{-1}$$

Reaction [19] may not occur as written but may involve splitting off H and H_2 in two separate steps.

Computer Simulations

In order to study the kinetics of this system further, we have calculated concentration profiles by computer integration of the reaction rate equations, using different assumed mechanisms, and have compared these profiles with our experimental results. A serious handicap is that, not only are the rate coefficients of most of the elementary reactions quite unknown, but also there is considerable uncertainty about the thermochemistry of some of the chemical species (e.g. refs. 14, 20–25). Uncertainties in the thermochemistry, and hence in the equilibrium constants, introduce additional uncertainties into the kinetic analysis, since a standard procedure is to use the rate quotient law to calculate a reverse rate constant from the forward rate constant and the equilibrium constant.

Because it is not feasible to make a computer simulation analysis of every individual experiment, we represented our results by four sets of concentration profiles of NH_3, N_2, NH_2, and NH (each of which was the average of many experiments): (*a*) mixture 1 (6% NH_3, 94% diluent) at 2511 K, (*b*) mixture 1 at 2792 K, (*c*) mixture 3 (6% NH_3, 6% H_2, 88% diluent) at 2600 K, (*d*) mixture 3 at 2873 K, together with the following ratios of k_D for mixtures 1 and 4: (*e*) $k_D(6\%\,NH_3)/k_D(0.14\%\,NH_3) = 3.6$ at 2511 K, and (*f*) $k_D(6\%\,NH_3)/k_D(0.14\%\,NH_3) = 2.9$ at 2792 K. These data were chosen because their temperatures are fairly close to the middle of the experimental range, where the quality of the results is best, yet the temperature spread is large enough to allow the temperature dependence of the kinetics to be studied. Thermodynamic data from the JANAF Tables (14) were used in the computations.

Results

After a very large number of trials using various combinations of the elementary reactions discussed above, we found that a good fit to our chosen NH_3,

TABLE 3. Reaction rate coefficients and equilibrium constants used in computer fitting of experimental results*

*Rate coefficients are in cm^3 mol s units, with activation energies in cal mol^{-1}. Equilibrium constants for reactions [3] and [4] are estimates; others are taken from ref. 14.

†This work; obtained after numerous trials.

‡Thermochemical data suggest that the activation energy is too low; it can be increased to 20 kcal mol^{-1}, with corresponding reduction in A_4, without significantly worsening the fit.

(*b*) Set No. 2 is the same as No. 1 except for

$k_1 = 8.00\times10^{15}\exp(-89\,500/RT)$

$k_2 = 5.51\times10^{11}\exp(-91\,000/RT)$

$k_3 = 1.40\times10^{14}\exp(-28\,300/RT)$

(*c*) Set No. 3 is the same as No. 1 except for

$k_1 = 8.00\times10^{10}\exp(-89\,500/RT)$

$k_2 = 1.10\times10^{16}\exp(-89\,500/RT)$

$k_3 = 1.00\times10^{12}T^{0.5}\exp(-21\,567/RT)$

NH_2, and N_2 profiles, and to the k_D ratios of (*e*) and (*f*) above, could be obtained using the following mechanism with the rate data of Table 3:

[1] $NH_3 + M \rightleftarrows NH_2 + H + M$

[2] $NH_3 + M \rightleftarrows NH + H_2 + M$

[3] $NH_2 + NH_3 \rightleftarrows N_2H_3 + H_2$

[4] $N_2H_3 + M \rightleftarrows NH + NH_2 + M$

[5] $H + NH_3 \rightleftarrows H_2 + NH_2$

[6] $H + NH_2 \rightleftarrows H_2 + NH$

[7] $NH_2 + NH_2 \rightleftarrows NH + NH_3$

[8] $H + H + M \rightleftarrows H_2 + M$

[9] $NH + NH \rightleftarrows N_2 + H_2$

[10] $NH_2 + NH_2 \rightleftarrows N_2 + H_2 + H_2$

where, as discussed above, reaction [10] may take place in more than one stage. To get this agreement, the experimental NH_2 profiles had to be multiplied by 5, a factor which is very reasonable in view of the considerations about ionization potential discussed above. Two variations of this set of rate coefficients, which gave very similar fits, are also included in Table 3.

Discussion

The results in Table 3 must be viewed with caution for two reasons. Firstly, in a system with so many unknown parameters, there could well be other ways of fitting our rate data. Secondly, for one species, namely NH, the computed and measured profiles do not agree very well (Fig. 9). The discrepancies in shape of the NH profiles are more disturbing than the differences in magnitude, since the latter could be due to uncertainties in the sensitivity of the mass spectrometer to this unstable species. Therefore, there seems to be a real possibility that an important reaction involving NH has been omitted from our mechanism, or that one or more of the rate constants in Table 3 are wrong. However, a very substantial computer study of this problem did not give a better fit.

Because of the doubts expressed above, we will not discuss in detail the results in Table 3. However, we will briefly comment on two points of general importance which emerge from our calculations, namely, the predicted overall rate law and the rate of the unimolecular initiation step.

Kinetics of the Overall Reaction

An important question is why, if there is a chain mechanism as we suggest, most workers have found the rate equation to be

$$-d[NH_3]/dt = k_D[NH_3][M]$$

To test this, we ran computer simulations, using the first set of rate data from Table 3, for initial compositions in the range 0.08% to 20% NH_3. k_D was calculated from the time Δt for $[NH_3]$ to fall to 85%

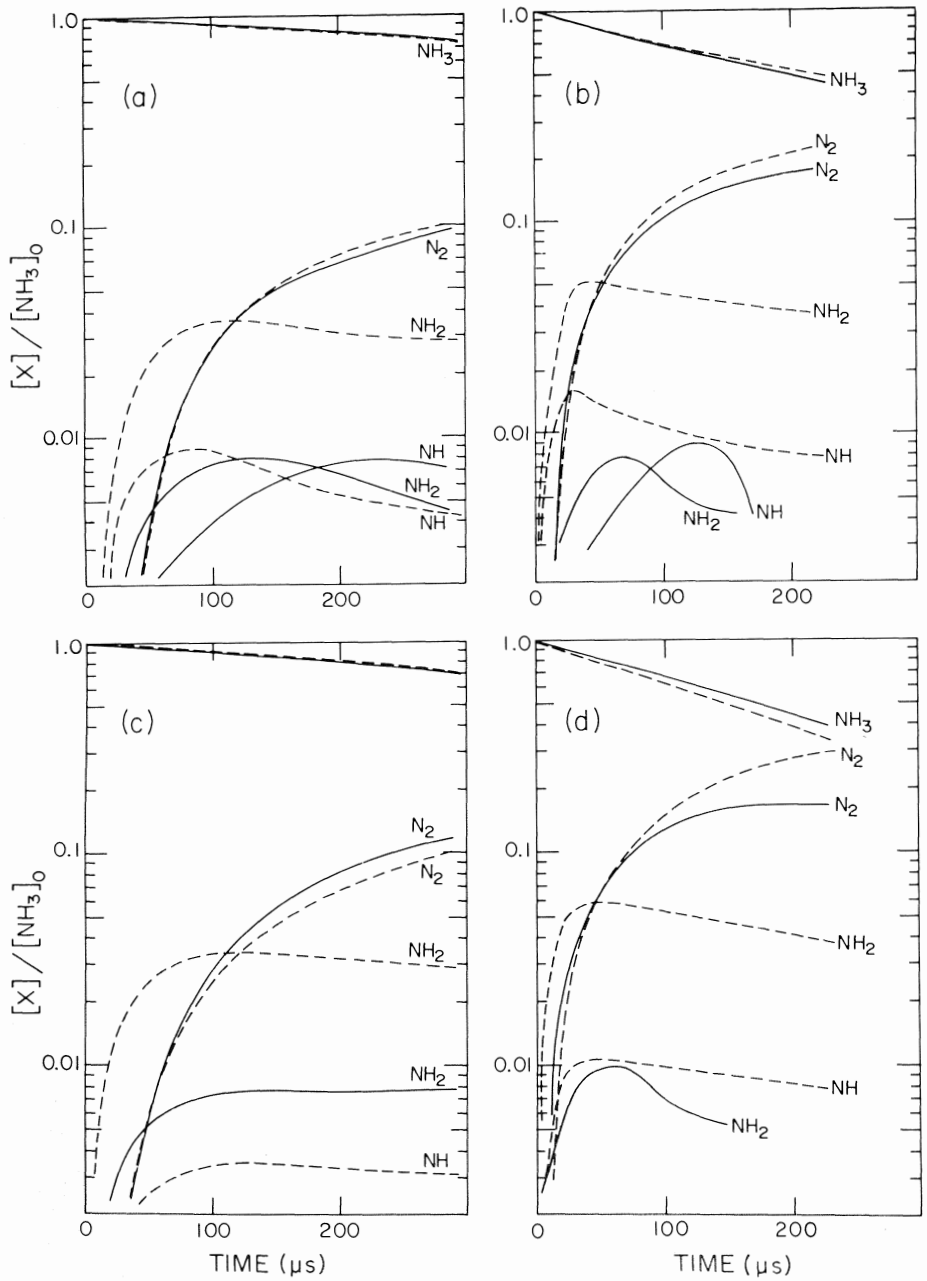

FIG. 9. Example of comparison of measured (solid lines) and computer simulated (dashed lines) concentration profiles in NH_3 pyrolysis. Computed profiles of species which were not measured have been omitted. All simulations showed $[N_2H_3]/[NH_3]_0 < 10^{-3}$. These simulations used the reaction scheme [1] to [10] in the text, including both forward and reverse processes, with the first set of rate coefficients of Table 3. In these diagrams, the experimental NH_2 profiles are those obtained using an arbitrary sensitivity factor of unity, relative to NH_3; as discussed in the text, these profiles should be multiplied by a factor of approximately 5, for comparison with the computed values. (*a*) Mixture 1 (6.2% NH_3) at 2511 K. [M] = 1.5×10^{-6} mol cm^{-3}. Note that the experimental and computed NH_3 profiles coincide. (*b*) Mixture 1 at 2792 K. [M] = 1.6×10^{-6} mol cm^{-3}. (*c*) Mixture 3 (6.1% NH_3 + 5.8% H_2) at 2600 K. [M] = 1.7×10^{-6} mol cm^{-3}. (*d*) Mixture 3 at 2873 K. [M] = 1.8×10^{-6} mol cm^{-3}.

of $[NH_3]_0$, i.e. $k_D = -(\ln 0.85)/[M]\Delta t$. The results (Fig. 10) agree with our observed variation in k_D between mixtures 1 and 4, and they suggest that the reason why most other workers did not see such a variation was either that they did not change $[NH_3]_0$ sufficiently, or that their NH_3 percentages fell in the range where k_D remains fairly constant. Thus Bradley *et al.* (6) used 5 to 20% NH_3; the resulting variation in k_D would be 40%, well within experimental scatter. Even though Michel and Wagner (2) varied the composition from 0.11% to 1.5% NH_3, we predict that k_D would only change by a factor of 2, again within experimental scatter. An exception to these comments seems to be the work of Jacobs, who used 1% and 8% NH_3. Assuming a rate law of the form

$$-d[NH_3]/dt = k[NH_3]^x[M]^y$$

our simulations predict that Jacobs would find $x = 1.36$, which is close to the value of 1.5 which he reported.

The Initiation Reaction

Our simulations could not distinguish between channels [1] and [2] for the initiation step. Irrespective of whether NH or NH_2 is produced initially, secondary reactions will rapidly shuffle these radicals.

The discussion in the previous section indicates that, while our mechanism may not reproduce all details of the secondary processes, it does adequately represent the way in which k_D increases with increasing $[NH_3]$. Therefore, it appears that we have succeeded in separating the effects of initiation and secondary reactions, so that our rate constant for the unimolecular initiation process should be fairly accurate. Our simulations, and comparison of results from mixtures 1 and 4, indicate an activation energy slightly larger than 89.5 kcal mol^{-1}. We propose

$$k_1 + k_2 = 1.2 \times 10^{16} \times \exp(-91\,000/RT)\ cm^3\ mol^{-1}\ s^{-1}$$

which we expect to be correct to within a factor of 2 under the conditions of our experiments. This expression is about 25% lower than k_D for mixture 4, 0.14% NH_3, at 2500–3000 K. Thus our analysis indicates that in this mixture, our measured k_D was not strongly influenced by secondary reactions.

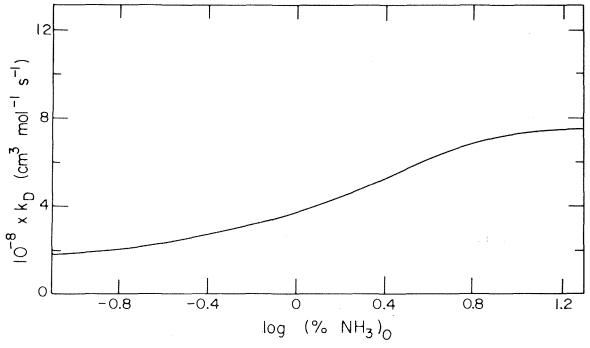

FIG. 10. Computed values of k_D, the second order rate coefficient for overall removal of NH_3, at 2511 K as a function of initial mole percentage of NH_3. The reaction mechanism used was reactions [1] to [10], with the first set of rate coefficients of Table 3.

Since the unimolecular reaction is almost certainly very close to its low pressure limit, it is interesting to compare our rate constant with the calculated strong collision value. We assume that $k_1 \gg k_2$ and that the minimum critical energy is the endothermicity of reaction [1], 101.7 kcal mol^{-1}. Using the recently published method of Troe (29), with molecular data from refs. 14 and 30, we calculate strong collision rate constants of 4.15×10^9 and 9.21×10^{10} cm^3 mol^{-1} s^{-1} at 2500 and 3000 K. Comparison with our experimentally derived values yields a collision efficiency β_c of 0.032 at 2500 K and 0.031 at 3000 K. These values of β_c are similar to those found (29) for the unimolecular dissociation of a number of other small polyatomic molecules in this temperature range, and they add further evidence that the strong collision assumption should not be used in the theoretical analysis of unimolecular rates at high temperatures.

Conclusions

Our experimental studies and analysis lead to the following main conclusions:

(*a*) The pyrolysis of ammonia is a chain reaction initiated by the unimolecular decomposition of NH_3. In the absence of added H_2, NH_3 is also removed by reaction with H, NH, and NH_2. Addition of H_2 markedly reduces the concentration of NH.

(*b*) Measurements of the effect of added H_2 show that the rate constant of the reaction

$$[-6] \qquad NH + H_2 \rightarrow NH_2 + H$$

is about 2×10^{12} cm^3 mol^{-1} s^{-1} in the temperature range 2600–2800 K.

(*c*) The principal reaction leading to N_2 is the recombination of NH_2 radicals or the reaction between NH_2 and NH_3. Our analysis slightly favours the first of these alternatives. Reactions involving NH are substantially less important in forming N_2.

(*d*) The rate constant of the unimolecular initiation step, at total gas concentrations of about 1.7×10^{-6} mol cm^{-3} is

$$k = 1.2 \times 10^{16} \exp(-91\,000/RT)\ cm^3\ mol^{-1}\ s^{-1}$$

with the activation energy in cal mol^{-1}. If this rate constant applies to the reaction

$$NH_3 + Kr \rightarrow NH_2 + H + Kr$$

then Kr has a collision efficiency of about 0.03 in the dissociation of NH_3 at 2500–3000 K.

Evidence for the existence of complex ions in mixed solutions of indium trichloride and ammonium chloride

ALAN N. CAMPBELL

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received June 9, 1978

ALAN N. CAMPBELL. Can. J. Chem. **57**, 702 (1979).

The conductances, densities, and viscosities of concentrated solutions of ammonium chloride in water, at 25°C, have been determined with good agreement with existing conductance data. The same data have been obtained for mixed solutions of indium trichloride and ammonium chloride. The fact that the conductance is always much less than the sum of the individual conductances, in some cases less than that of indium chloride alone, points to the existence of a complex in solution.

ALAN N. CAMPBELL. Can. J. Chem. **57**, 702 (1979).

On a déterminé les conductivité, les densités et les viscosités de solutions concentrées de chlorure d'ammonium dans l'eau à 25°C; les valeurs obtenues sont en bon accord avec les données de conductivité existantes. On a aussi obtenu les mêmes données pour des solutions mixtes de chlorures d'indium et d'ammonium. Le fait que les conductivités des mélanges sont toujours plus faibles que la somme des conductivités individuelles et dans quelques cas plus faibles que celle du chlorure d'indium seul, suggère l'existence d'un complexe en solution.

[Traduit par le journal]

Introduction

It has been shown (1) that indium trichloride forms a double salt with ammonium chloride, whose formula is $2NH_4Cl{\cdot}InCl_3{\cdot}H_2O$. It is usually assumed that double salts, when dissolved in water, dissociate completely into their individual ions but so great is the tendency of indium chloride to form double salts with the chlorides of the metals of Groups 1 and 2 of the Periodic Table, that it is possible that when some of the indium chloride double salts dissolve to form concentrated solutions, a complex anion may exist in solution. In the case of the double salt quoted above the first result of solution could be

$$[1] \qquad 2NH_4Cl \cdot InCl_3 \rightarrow In^{3+} + ((NH_4Cl)_2{\cdot}Cl_3)^{3-}$$

followed on dilution by

$$[2] \qquad ((NH_4Cl)_2Cl_3)^{3-} \rightarrow 2NH_4^+ + 5Cl^-$$

Or, alternatively

$$[3] \qquad In(NH_4)_2Cl_5 \rightarrow (In(NH_4)_2Cl_4)^+ + Cl^-$$

followed on dilution by

$$[4] \qquad (In(NH_4)_2Cl_4)^+ \rightarrow 2NH_4^+ + In^{3+} + 4Cl^-$$

The method of investigation chosen by the author was that of conductance. If the double salt dissociates completely into its constituent single salts, then, apart from the inevitable effect on the activity due to the presence of the common ion, the measured conductance should be approximately equal to the sum of the individual conductances. A marked deviation from additivity should indicate complex ion formation. Such deviation was found; indeed, the conductance of a mixture of indium chloride and ammonium chloride is sometimes less than that of indium chloride alone.

Experimental

The methods of determining conductance are well known and have frequently been described by the author (2). Density was determined with a large pyknometer (capacity 50 cm^3) and therefore density figures are only good to four decimals but this is amply sufficient for the present purpose. Viscosity was determined with the viscometer of Cannon and Fenske. The product $\Lambda\eta$ (equivalent conductance multiplied by viscosity) offers a better comparison than the simple conductance.

The conductance of ammonium chloride in water at 25°C has been determined from 0.1 *N* to 0.01 *N* by Longsworth (3) and from 5.252 *N* to 0.1019 *N* by Wishaw and Stokes (4). Wishaw and Stokes have long been interested, in common with the present author, in the conductances of concentrated solutions, and have offered an equation for the expression of conductance as a function of concentration which, whatever its theoretical basis or lack of it, does in fact represent the conductance very well.

The author has repeated the work of Wishaw and Stokes on ammonium chloride and at the same time determined the density, viscosity, and apparent molal volume. The results are reproduced in Table 1. Equivalent conductance and conductance–viscosity products are shown in Fig. 1.

Although the conductances of indium trichloride solutions were determined previously (2), the measurements were now repeated with the same results. A weighed amount of ammonium chloride was then added and the conductance redetermined. The specific conductance of indium chloride was then subtracted from the specific conductance of the mixed solution and the apparent conductance of the ammonium chloride obtained, on the assumption that that of the indium

*N = equivalent molarity, d = density (with respect to water at 4°C), η = viscosity, κ = specific conductance, Λ = equivalent conductance, ϕ_V = apparent molal volume of NH_4Cl. Volume (solid NH_4Cl) = 35.03.

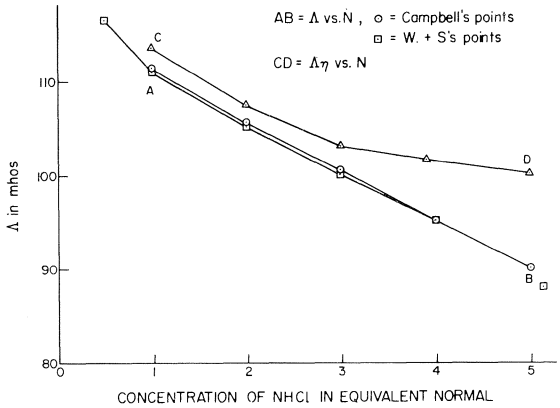

FIG. 1. Equivalent conductance and equivalent conductance × viscosity of NH_4Cl in water vs. $\sqrt{c}$.

chloride did not change. Actually, of course, it must change, the conductance measured being the sum of those of the ions In^{3+}, Cl^-, NH_4^+, and complex ions, but the assumption is only a basis of reference.

Discussion

Table 1, when compared with the results of Wishaw and Stokes (4), shows that the present results are in good agreement. If anything, the present results are a shade higher and this gives better agreement with the calculated results of Wishaw and Stokes. The apparent volumes are not of high accuracy since they rest on density determinations of only four decimal accuracy, but they show that the apparent volume decreases with dilution and approaches that of solid ammonium chloride. This is to be expected if ammonium chloride is completely ionized in the lattice.

Table 2 shows that with strong indium trichloride (13.73 N), addition of only 0.1 N ammonium chloride produces a conductance less than that of indium chloride alone. With 4.916 N indium chloride, the effect is similar. If Λ for 15.78 N indium chloride is multiplied by the viscosity of the mixed solution, containing 15.78 N indium chloride and

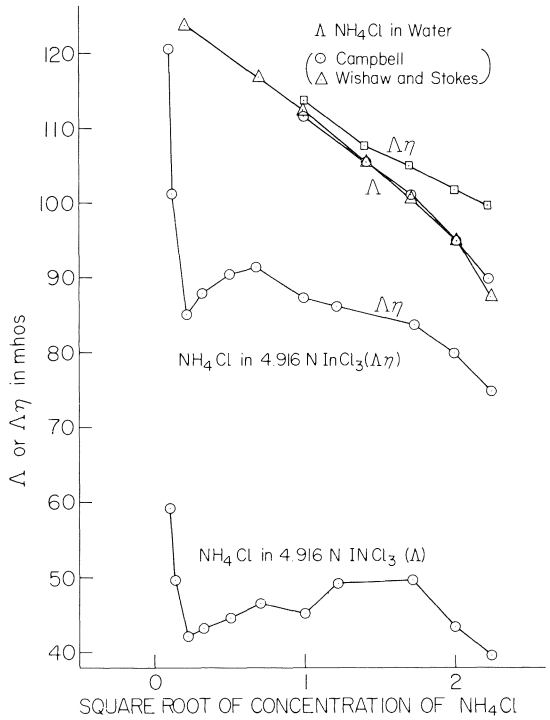

FIG. 2. Equivalent conductance and equivalent conductance × viscosity of NH_4Cl in $InCl_3$ solutions of fixed concentration vs. $\sqrt{c}$.

0.25 N ammonium chloride (1.406 × 21.3 = 29.95) the value of the product is much greater than the value (15.22) for the mixed solution, in other words, the presence of 0.25 N of NH_4Cl has greatly increased the viscosity without adding to the conductance. The value of the (apparent) equivalent conductance of ammonium chloride remains roughly constant over the concentration range 0.05 N to 0.5 N, and this is no doubt connected with an equilibrium of the form:

$$2NH_4^+ + In^{3+} + 4Cl^- \rightleftharpoons [In(NH_4)_2Cl_4]^+$$

With 13.73 N, the very great increase in viscosity

TABLE 2. Corresponding data for mixed solutions of indium trichloride and ammonium chloride, the indium trichloride being always 13.73 *N*, except for the last two concentrations where it was 15.78 *N*. The experiments could not be carried beyond 0.5 *N* NH_4Cl, as this represents the extent of solubility of NH_4Cl in such highly concentrated indium chloride

Received June 14, 1978

ALAN N. CAMPBELL. Can. J. Chem. **57**, 705 (1979).

The density up to 257°C and the vapour pressure up to 189°C of dimethylsulfoxide have been determined directly. Dimethylsulfoxide decomposes below the critical temperature, but by indirect methods the (hypothetical) critical density is found to be

$$\rho_c = 0.366 \text{ g/cm}^3$$

or

$$V_c = 237.7 \text{ cm}^3$$

The vapour pressure measurements yield a molar heat of evaporation of 10.84 kcal/mol or 138.7 cal/g.

ALAN N. CAMPBELL. Can. J. Chem. **57**, 705 (1979).

On a déterminé, par des méthodes directes, la densité du diméthylsulfoxyde jusqu'à 257°C et sa tension de vapeur jusqu'à 189°C. Le diméthylsulfoxyde se décompose à une température inférieure à sa température critique; par des méthodes indirectes, on a toutefois pu calculer que la densité critique (hypothétique) est

$$\rho_c = 0.366 \text{ g/cm}^3$$

ou

$$V_c = 237.7 \text{ cm}^3$$

A partir des mesures de tension de vapeur, on peut évaluer une chaleur molaire d'évaporation de 10.84 kcal/mol ou 138.7 cal/g.

[Traduit par le journal]

Introduction

It should be said at the outset that it is not possible to determine directly the critical constants because of decomposition. It is, however, possible to arrive at an approximation to the critical density and in the attempt to do so good values of the vapour pressure and density have been obtained.

Experimental

The dimethylsulfoxide used was a Fisher product (certified A.C.S.). A small quantity was dried by standing over molecular sieves, as recommended by Perrin, Armarego, and Perrin (1), but this produced no change in the freezing point or density: for subsequent work, the product was used without further purification.

For the determination of density, all the customary precautions of the best pyknometry were used, viz. a large, but not too large, pyknometer (50 cm^3 capacity). The thermostat temperature was constant to ± 0.01°C, as determined with a Beckmann thermometer, which had been standardised against a standard platinum resistance thermometer. The pyknometer was left in the balance case for a fixed time before weighing. Conductance water was used for the calibration and buoyancy was eliminated by using an identical pyknometer as a counterpoise. Under these circumstances, it is usual to claim an accuracy of 0.0001 in the density, say 0.0003.

Above 92°C, density was obtained with a dilatometer, consisting of a bulb and graduated capillary: the apparatus was evacuated and sealed to prevent boiling of the liquid. The rise in the capillary was measured with a cathetometer reading to 0.01 cm. Measurements with the dilatometer are somewhat less accurate, since they depend on the accuracy of the cathetometer. An accuracy of 0.001 is claimed.

Vapour pressure was measured with a closed manometer up to a pressure of 78.1 cm of mercury and a temperature of 189°C. The DMSO in the manometer was repeatedly frozen, pumped down on a high vacuum line, melted, and the operation repeated. The manometer itself was flamed to remove occluded moisture from the glass. The accuracy is estimated as 0.1 cm. This means that for pressures less than 1.0 mm the error is high. Direct observation is not a good method for such low vapour pressures. Densities are given in Table 1 and vapour pressures in Table 2.

Results

Density has been determined by various investigators, at temperatures ranging from 20 to 80°C (2–4). The measurements of this paper extend to 257°C. Despite the wide range of temperature and the fact that density determinations above 92°C were made with a dilatometer, it was found that the results can be represented quite accurately by the equation:

$$d_t = d_{25}(1 - \alpha\Delta t - \beta(\Delta\tau)^2)$$

where

$$\Delta t = t - 25$$

When the experimental results were offered to the

186	459	2.179	74.3	1.871
187	460	2.174	74.3	1.871
188	461	2.169	76.1	1.881
189	462	2.164	78.1	1.893

computer, it obtained for the constants:

$$\alpha = 0.97514 \times 10^{-3}$$

$$\beta = 0.4400 \times 10^{-6}$$

The average discrepancy between calculated and observed results is 0.03966% and the maximum deviation is 0.8360% at 188°C. Table 1 gives the experimental results together with the densities calculated from the above equation for the temperatures of previous workers. Considering the conditions of experiment, the agreement is good, except that the previous figure for 20°C is obviously too high. The discrepancies between observed and calculated results are small and vary in algebraic sign.

It is surprising that so little work has been done on the vapour pressure of DMSO. The only work discovered by the author is that of Teichmann and Ziebarth (5), who give the vapour pressure as $p =$ 16 mm at 79.80°C and 12 mm at 72.50°C, and that of Douglas (6). Douglas determined the vapour pressure of DMSO over the temperature range 20 to 50°C. Comparing his results with those of this work, we have

Douglas	Campbell
3.07 Torr (t = 50°C)	7.10 Torr (t = 65°C)
2.27 Torr (t = 45°C)	0.95 Torr (t = 44°C)

Considering that the present method was the direct observation of a mercury column in a manometer and that of Douglas the more delicate one of the air-saturation method, the agreement is good enough. Perhaps Douglas' results may be low, since his method of saturating the air is hardly sufficient, according to modern technique. Douglas used the Kirchhoff equation to express his results:

$$\log p = A - B/T + C \log T \text{ (his } C \text{ is negative)}$$

Using Douglas' constants to calculate the vapour pressure at the experimental temperatures of this paper, very poor agreement results, e.g. at 189°C which is generally agreed to be the normal boiling temperature, the vapour pressure is calculated to be 1051 mm, instead of 760 mm. But this, of course, is not a criticism of Douglas, since his equation only purports to cover the range 20 to 50°C.

Discussion

The Kirchhoff equation assumes a constant ΔH_{vap} over the temperature range, but ΔH_{vap} is not constant. Nevertheless, the Kirchhoff equation satisfactorily describes the behaviour of many liquids over a wide range of temperature. For instance, mercury, ethanol, mesitylene, acetone, cyclohexane, and ether give very good straight line plots for log *p* vs. $1000/T$ over the temperature range 0 to 160°C, though ΔH_{vap} is not constant. The constant B of the Kirchhoff equation is proportional to ΔH_{vap}, but ΔH_{vap} is not constant. The slope of the log *p* vs. $1/T$ plot must therefore give a mean value of ΔH_{vap} over the temperature range. Compensating factors must account for the straightness of the plot. This criti-

cism applies to all ΔH values obtained from vapour pressure plots.

The results of Table 2 when plotted in the form of log p vs. $1/T$ give a good straight line. From the slope of the straight line, the heat of evaporation results as $\Delta H = 10.84 \pm 0.2$ kcal/mol (as a mean value over the range 25 to 189°C). Similar treatment of Douglas' (6) results gives 12.64 kcal over the range 20 to 50°C. A single and often quoted direct experimental determination for the heat of evaporation at the boiling point is that of Prückner (7) who gives 13.67 kcal. The application of Trouton's rule gives $\Delta H = 9.26$ kcal but Trouton's rule is only an approximation. The Nernst–Bingham rule: $\Delta S = 17 + 0.011T$ gives $\Delta S = 22.082$, and hence $\Delta H = 10.20$ kcal/mol.

TABLE 3. Data for the application of Hakala's rule*

t (°C)	$(r + \rho)/2$	$(r - \rho)^{10/3}$
25	0.5480	1.3578
48	0.5365	1.2647
61	0.5312	1.2231
72	0.5257	1.1815
92	0.5161	1.1106
116	0.5019	1.0112
172	0.4734	0.8248
188	0.4637	0.7662

*The above results are expressed graphically in Fig. 1. The intercept of the straight line = $\rho_c = 0.366$ g/cm³. From the slope, $k = 0.133$. V_c/mol = 237.7 cm³.

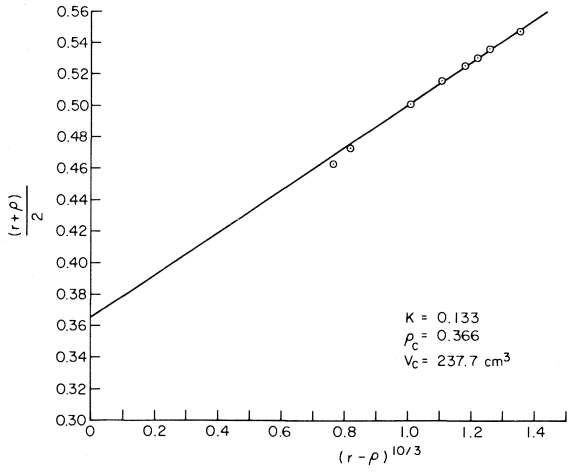

FIG. 1. Plot of $(r + \rho)/2$ vs. $(r - \rho)^{10/3}$.

The law of the rectilinear diameter while giving a straight line plot for the mean density of orthobaric liquid and vapour, for most of the temperature rise, is liable to bend in a distressing manner just before the critical temperature is reached. A modification of the rectilinear diameter rule by Hakala (8) has been found very successful. According to Sheehan (9) "In general, values of P_c found by this linear extrapolation agree with traditional methods; even when the densities are one hundred degrees from T_c, the values of P_c are correct within one percent." The rule takes the form:

$$(r + \rho)/2 = \rho_c + k(r - \rho)^{10/3}$$

where r = liquid density, ρ = density of saturated vapour, k = empirical constant, ρ_c = critical density.

In applying Hakala's rule to the present results, the density of the vapour up to 189°C and a vapour pressure of 1 atm was calculated from the observed vapour pressures and the ideal gas law: any deviations from ideal behaviour would not be significant, since the density of the vapour is so small in comparison with that of the liquid. The results are given in Table 3.

COMMUNICATION

A total synthesis of (−)-khusimone[1]

HSING-JANG LIU AND WING HONG CHAN

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received November 24, 1978

HSING-JANG LIU and WING HONG CHAN. Can. J. Chem. **57**, 708 (1979).

A total synthesis of (−)-khusimone (**1**), an odoriferous norsesquiterpenoid ketone, has been achieved in 16 steps from the ammonium salt of *l*-10-camphorsulfonic acid.

HSING-JANG LIU et WING HONG CHAN. Can. J. Chem. **57**, 708 (1979).

On a réalisé la synthèse totale de la (−)-khusimone (**1**), une cétone norsesquiterpénique odoriférante, en 16 étapes à partir du sel d'ammonium de l'acide *l*-camphresulfonique-10.

[Traduit par le journal]

The norsesquiterpenoid (−)-khusimone, a highly odoriferous ketone found in vetiver oil (1, 2), has been shown to possess the tricyclic skeleton and absolute stereochemistry depicted in formula **1** (1) by spectroscopic and chemical evidence. Recently, Büchi and co-workers (3) reported an elegant total synthesis of its racemic modification using an intramolecular Diels–Alder approach. We wish to describe an efficient photochemical route leading to the naturally occurring ketone in optically active form.

(−)-α-Campholenic acid (**2**),[2] prepared in 50% yield from the commercially available *l*-10-camphorsulfonic acid ammonium salt by fusion with solid potassium hydroxide,[3] was esterified with methyl iodide and potassium carbonate in acetone (5). Ozonolysis of the resulting ester **3** followed by reductive work up using triphenylphosphine (6) gave keto aldehyde **4** which was smoothly cyclized by means of *p*-toluenesulfonic acid in refluxing benzene. The product **5** obtained in 70% yield from **2** was subsequently irradiated (450-W Hanovia high-pressure quartz mercury vapor lamp and Pyrex filter) with 1,1-diethoxyethene (7, 8) in benzene at room temperature for 3 h. The photocycloaddition proceeded with complete regioselectivity to give an inseparable mixture of at least two diastereomers (four sets of partially superimposed —OCH_2— quartets at δ 3.39 region in the nmr spectrum) of the head-to-tail adduct **6**.[4] When hydrolyzed with dilute hydrochloric acid in acetone, the mixture afforded, as the only products, two diastereomeric diketones **7** and **8**[5] (total 80% yield from **5**) in a ratio of 5:8. In the nmr spectra, the minor isomer showed two singlets at δ 1.21 and 0.97 for the *gem*-dimethyl group whereas the corresponding signals of the major isomer, which was obtained as a solid (mp 127–128°C), appeared at δ 1.12 and 1.06. The larger Δδ observed for the minor product suggested its structure was **7** (and thus that of the major isomer was **8**) as the most important contribution conformation could be represented by formula **7***a* in which the α-faced methyl is shielded and the β-methyl deshielded respectively by the cyclobutanone and the cyclohexanone carbonyl. These tentative structural assignments were substantiated by subsequent transformations. Direct conversion of diketone **8** to **7** was attempted without success using a variety of conditions which were expected to induce epimerization at both ring junction centers. However the desired isomerization could be achieved by a two-step sequence as follows. Treatment of diketone **8** with pyridinium bromide perbromide in acetic acid gave a 70% yield of unsaturated ketone **9** which was reduced to diketones **7** and **8** (3:2; 65% yield)[6] with zinc in acetic acid (9) at room temperature.

Before the incorporation of the required *exo*-

[1]Dedicated to Professor K. Wiesner on the occasion of his 60th birthday.

[2]All compounds were adequately characterized by spectroscopic methods (ir, nmr, and ms) and by exact mass measurement and/or elemental analysis.

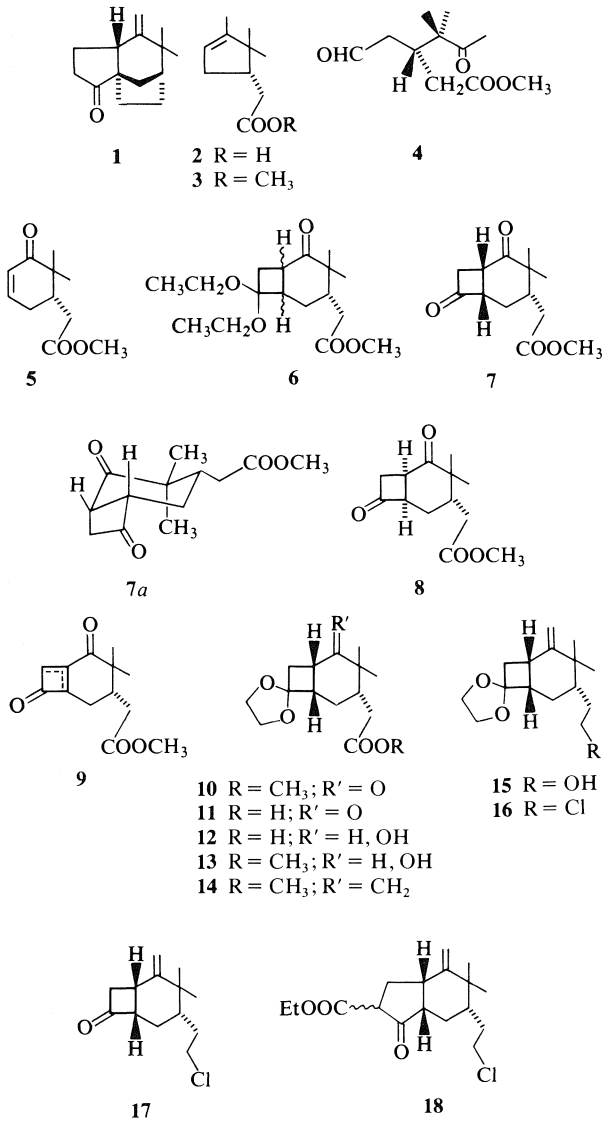
[3]The published procedure (4) for the degradation of the sodium salt of *d,l*-10-camphorsulfonic acid to α-campholenic acid was used.

[4]The regioselectivity and the orientation of the photocycloaddition follow from the result obtained from the subsequent hydrolysis of the photoadduct.

[5]Regardless of the ring junction stereochemistry of the precursors, a *cis* ring juncture could be readily assigned to these compounds on the basis of reported observations (8).

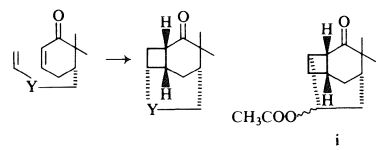
[6]Our original plan was to introduce the desired stereochemistry more efficiently by the following intramolecular photochemical process:

0008-4042/79/060708-02$01.00/0



methylene group into diketone **7**, its cyclobutanone carbonyl was protected by means of selective transketalization with 2-ethyl-2-methyl-1,3-dioxolane at 95°C using *p*-toluenesulfonic acid as a catalyst. Hydrolysis of ester **10** with 2 *N* aqueous sodium hydroxide in refluxing methanol followed by treatment of the resulting acid **11** sequentially with 1 equiv. of sodium hydride and a fivefold excess of methyl magnesium bromide gave rise to hydroxy acid **12** which was esterified with diazomethane to afford hydroxy ester **13** (71% yield from **7**). On treatment with thionyl chloride and pyridine in benzene, hydroxy ester **13** underwent dehydration cleanly with exclusive formation of the exocyclic double bond as expected[7] and ester **14** was isolated in 89% yield. Ester **14** was reduced with lithium aluminum hydride and the resulting alcohol **15** converted by phosphorus oxychloride in pyridine to the corresponding chloride **16** in 70% yield over two steps. Hydrolysis of chloride **16** was effected by treatment with dilute hydrochloric acid to give quantitatively keto chloride **17**.

The transformation of keto chloride **17** to (−)-khusimone (**1**) requires two primary operations: one-carbon expansion of the cyclobutanone ring and cyclization. Each was accomplished by a single step. Boron trifluoride catalyzed ring expansion of keto chloride **17** with ethyl diazoacetate (10, 11) proceeded with high regioselectivity by the expected migration of the less substituted α-carbon (11, 12) to give keto ester **18** as the predominant product in 59% yield. When heated at reflux with 1 *N* sodium hydroxide in ethanol, keto ester **18** underwent concomitant decarbethoxylation and ring closure giving rise to (−)-khusimone (**1**) in 61% yield, which was shown to be identical in all respects with the natural material.



Of several suitable compounds studied, only one (Y = $CHOOCCH_3$) underwent intramolecular cycloaddition but in an undesirable head-to-head fashion to give keto acetate **i**.

The polarized Raman spectrum of *s*-trioxane has been measured in single-crystal phase I, the melt, and the chloroform-*d* solution and the measurements used to improve the assignments, particularly in the C—H stretching region.

M. NAKAHARA, P. T. T. WONG et E. WHALLEY. Can. J. Chem. **57**, 711 (1979).

On a mesuré le spectre Raman polarisé du *s*-trioxanne sous forme de cristal unique en phase I, de produit fondu et en solution dans le chloroforme-*d*; on a utilisé les mesures pour améliorer les attributions, en particulier dans la région de vibration de valence C—H.

[Traduit par le journal]

Introduction

It has recently been shown by a detailed analysis (1) of the infrared (2) and Raman (1) spectra under pressure that the puckered ring of trithiane, a six-membered ring compound $(CH_2S)_3$, is greatly flattened at 18 kbar, and by extrapolation appears to become flat at ~40 kbar. A few years ago, Brasch *et al.* (3) reported that when trioxane was squeezed between diamond anvils to pressures of the magnitude of 40 kbar its spectrum changed markedly at a change of phase that occurred (2) in a piston-cylinder apparatus at a nominal pressure of 27 kbar on increasing the load, and 8 kbar on decreasing, and several bands lost all or most of their intensity in the high-pressure phase. On releasing the pressure, the high-pressure spectrum persisted until at least 10 kbar, but was reported to revert to the low-pressure spectrum when the pressure was fully released. When a "single" crystal of trioxane was squeezed, the high-pressure phase was formed with considerable orientation, as shown by the strong polarization of the absorption spectrum of several bands. It was tentatively suggested, without a detailed analysis, that trioxane became flat under pressure.

As trithiane becomes flat under pressure (1), it is certainly expected that trioxane would become flat also, perhaps at a higher pressure than trithiane. However, a detailed analysis of the spectroscopic effects of flattening (4) suggested that the current assignment (5) of the spectrum and the observed effects of pressure were not consistent with flattening. This statement was also true (1) of the spectrum of trithiane as originally assigned, but several of the assignments could be changed in a reasonable manner to make the effect of pressure on the infrared spectrum agree with flattening.

It seemed that the assignment of trioxane could not be changed in a similar way, but nevertheless, there were some uncertainties in the assignment, and it seemed worth verifying by recording the polarized Raman spectra of a single crystal. In addition, the polarized spectra of the melt and of a solution in chloroform-*d* have been obtained. The spectra will also provide a basis for discussing the Raman spectrum of the high-pressure phase trioxane II, a phase which was first observed by Brasch *et al.* (3). As we shall see, the Raman spectrum of trioxane II (6) also helps to interpret that of trioxane I.

The vibrational spectra of trioxane have been investigated previously in the infrared for the gas (5, 7–10, 11), carbon tetrachloride solution (5, 7, 12), liquid (5, 11), and single crystal (5), and in the Raman

using a mercury source for the liquid (9), carbon tetrachloride solution (13), and crystal (9).

Experimental Methods and Results

Experimental Methods

Practical grade *s*-trioxane was supplied by the Eastman Kodak Co. Single crystals were made by heating the solid to about 70°C in a bottle and storing at room temperature, 21.5°C. The vapor slowly condensed on the upper part of the wall to form clear long crystals. Single crystals were distinguished from polycrystals by the polarized Raman spectrum. The long axis of a crystal was assumed to coincide with the crystallographic *c* axis as has been observed by several workers (5, 14, 15), and the ends of the crystals were cut approximately perpendicular to the axis. The crystals were sealed in 3-mm-diameter glass tubes and mounted near the spectrometer slit, and were oriented to give the maximum intensity of the appropriate polarized components of several strong bands near 3000 cm^{-1}. Melt and solution samples were made by sealing trioxane either alone or with chloroform-*d* in a 3-mm-diameter glass tube. The melt was made by heating the tube to ~70°C with an air gun.

The Raman spectra were obtained using the 5145-Å argon line from a Coherent Radiation Laboratories model 52 argon-ion laser and a Jarrel–Ash model 25-300 spectrometer, using a 90° scattering angle. The polarization properties were measured using a half-wave plate for the exciting light and a polarization scrambler and an analyzer for the scattered light. They were checked by measuring the carbon tetrachloride bands (16). The intensity of the laser beam was ~1 W for the melt and solution spectra, and was reduced to ~300 mW for the single-crystal spectra to prevent sublimation. For the final spectra, the spectral slit width was 2.9 cm^{-1}, time constant 10 s, and scanning speed 10 cm^{-1} min^{-1}. The spectrum of a neon lamp (17) was recorded with several of the spectra, and the neon lines and the stronger plasma lines of the laser were used to calibrate the frequencies. Sharp bands were reproducible to ±0.2–0.3 cm^{-1}, and all are reported to ±1 cm^{-1}.

Results

Polarized spectra were run on 5 different single crystals. The polarized spectra of the crystal in the range 4000–200 cm^{-1} are shown in Fig. 1, in which the *a* and *a'* directions are perpendicular to the *c* axis of the crystal and to one another, and selected regions are shown on an expanded scale in Fig. 2. The polarized spectra in the region of the lattice vibrations are shown in Fig. 3. No laser Raman spectrum of liquid trioxane appears to have been published and so polarized spectra are shown in Fig. 4. The frequencies and peak intensities for the crystal are summarized in Table 1. The frequencies, qualitative relative intensities, and depolarization ratios for the liquid at ~70°C and the 0.3 *M* solution in chloroform-*d* are summarized in Table 2.

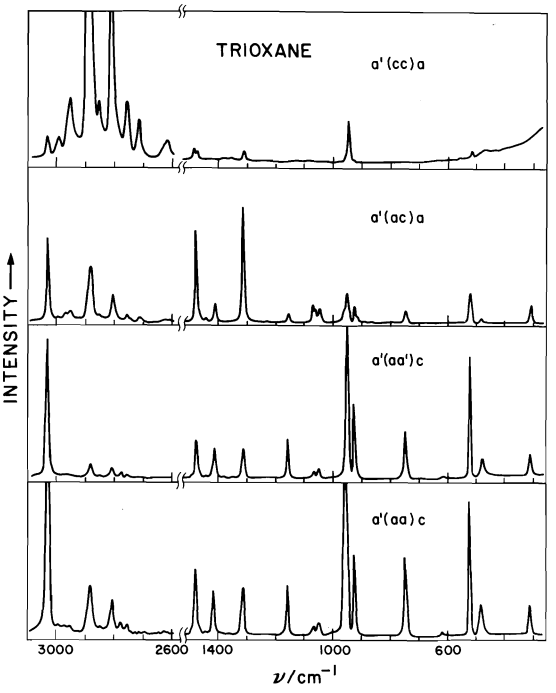

FIG. 1. Polarized Raman spectra of single-crystal trioxane in the range 4000–200 cm^{-1}. The polarizations are indicated in the frames. The scanning speed was 20 cm^{-1} min^{-1}, maximum counting rate 2000 s^{-1}, and time constant 2 s.

The Raman spectrum of polycrystalline trioxane has been reported by Stair and Nielsen (9) using mercury excitation, and their frequencies and assigned species are summarized in Table 1. The two measurements agree well, although Stair and Nielsen's experiments were not sensitive enough to detect some of the weaker bands.

The Raman spectrum of the lattice vibrations of the single crystal has recently been reported by Thomas (18). Our spectra agree with his except that the band he reported at 64 cm^{-1} was found at 69 cm^{-1} in this work, and he did not report the 54-cm^{-1} band although it seems to be present as a weak shoulder in his *cc* and *bc* spectra.

The infrared spectrum has been studied several times in the gas (5, 7–10), liquid (5, 12), and solution in carbon tetrachloride (5, 7, 11). Single crystals have been studied in the infrared by Kobayashi *et al.* (5), and a selection of their frequencies, particularly those assigned to the fundamentals, qualitative intensities, and polarizations are summarized in Table 1. Our frequencies agree reasonably well with

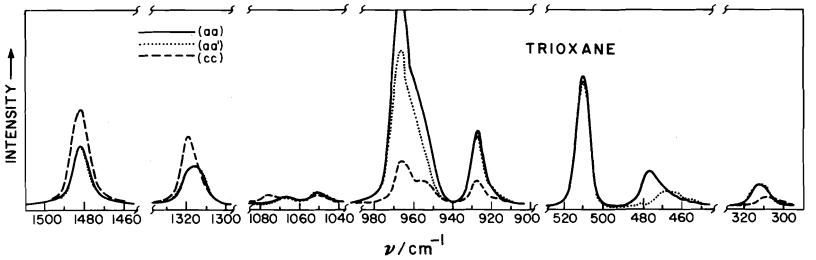

FIG. 2. Expanded polarized Raman spectra of single-crystal trioxane in selected frequency regions. The polarizations are indicated in the frames. The scanning speed was 10 cm^{-1} min^{-1}, maximum counting rate 2000 s^{-1}, and time constant 10 s.

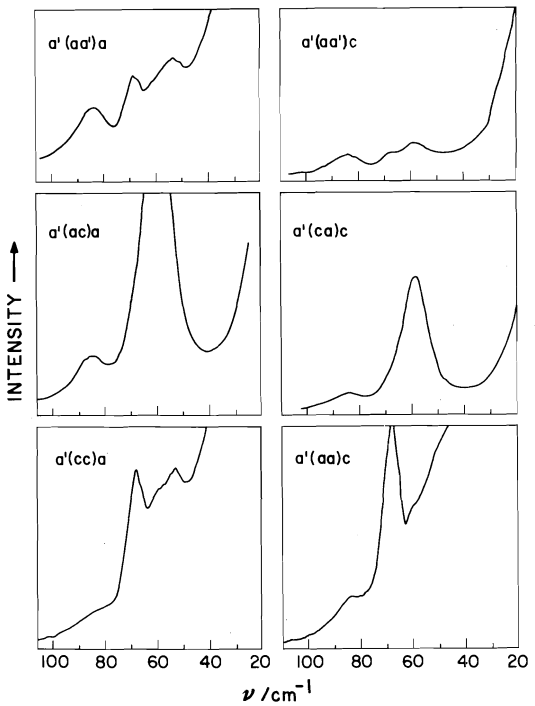

FIG. 3. Polarized Raman spectra of single-crystal trioxane in the region of the lattice vibrations. The polarizations are indicated in the frames. The scanning speed was 5 cm^{-1} min^{-1}, maximum counting rate 1000 s^{-1}, and time constant 40 s.

theirs except for the band that appears to be at 486 cm^{-1} in the Raman spectrum and 469 cm^{-1} in the infrared. It will be discussed in the following section.

Symmetry Assignment

The isolated trioxane molecule has symmetry C_{3v}. It has thirty fundamental vibrations which form the reducible representation $7A_1 + 3A_2 + 10E$. The A_1 and E vibrations are active in both the infrared and Raman spectra, and the A_2 vibrations are inactive in both. The crystal belongs to space group $R3c$, C_{3v}^6 with two molecules in the unit cell on sites of symmetry C_3 (14, 15). Under C_3 site symmetry, the distinction between A_1 and A_2 species disappears and both become A, and are active in both infrared and Raman. Under the unit-cell symmetry, each of the A vibrations splits by intermolecular coupling into an A_1 and an A_2 vibration, and only the A_1 vibrations are active. The E vibrations of the isolated molecule remain E under the site group, and each gives rise to two E vibrations which differ in frequency by the effects of intermolecular coupling. Thus, the A_1 vibrations of the isolated molecule remain active as A_1 vibrations in the crystal, the A_2 vibrations give A_1 vibrations and are presumably weakly active, and the E vibrations double. The intermolecular coupling is probably small, and the two coupled E vibrations probably differ little in frequency.

In the infrared, the A_1 vibrations are polarized parallel to the crystallographic c axis and the E vibrations parallel to a,b. In the Raman, the scattering matrix for the A_1 vibrations has the form

$$\begin{pmatrix} a & \cdot & \cdot \\ \cdot & a & \cdot \\ \cdot & \cdot & b \end{pmatrix}$$

and for the E vibrations the forms

$$\begin{pmatrix} c & \cdot & \cdot \\ \cdot & -c & d \\ \cdot & d & \cdot \end{pmatrix} \quad \text{and} \quad \begin{pmatrix} \cdot & -c & -d \\ -c & \cdot & \cdot \\ -d & \cdot & \cdot \end{pmatrix}$$

(19). The A_1 vibrations, therefore, occur in *aa* and *cc* polarizations only. The E vibrations occur in all polarizations except *cc*, and the *aa* and *ab* polarized spectra have the same intensity.

The Raman bands of the single crystal can therefore be assigned to their symmetry species as in Table 1. The assignment is straightforward for most bands. Several bands had strong *aa* and *aa'* components and a weak *cc* component. The *cc* component could be either an A_1 component or leakage, and an A_1 component was deduced only if the *aa* and *aa'* intensities were significantly different. There is no evidence that the coupled E vibrations derived from a particular E vibration of the isolated molecule differ significantly in frequency.

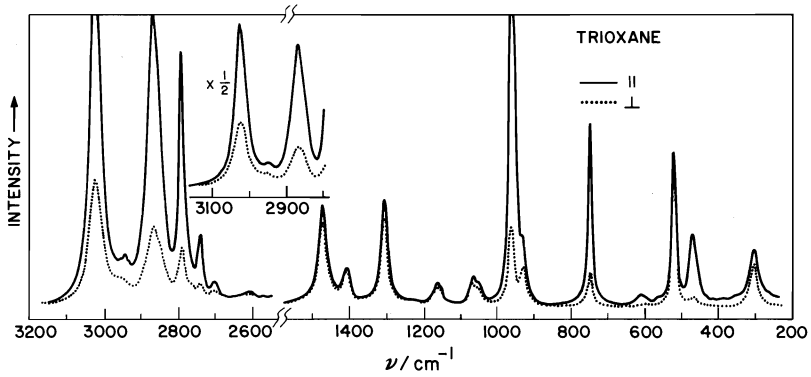

FIG. 4. Raman spectrum of liquid trioxane at ~70°C polarized parallel (∥), perpendicular (⊥) to the electric vector of the exciting light. The inset spectra are selected regions of the main spectra with the intensity scale reduced to one half. The scanning speed was 20 cm^{-1} min^{-1}, maximum counting rate 5000 s^{-1}, and time constant 2 s.

The species assigned by Kobayashi *et al.* (5) from their polarized infrared spectra of single crystals agree with ours, with a few exceptions which will be discussed below. The species assigned to the bands in the pure liquid and in solution based on the Raman polarization agree with the crystal assignments, again with a few apparent exceptions which will be discussed below.

The 3033-cm^{-1} Raman band of single-crystal trioxane has strong and nearly equal *aa* and *aa'* components. The *E* vibration, for which *aa* and *aa'* intensities are the same, dominates and the evidence for an A_1 vibration, i.e. that the *aa* and *aa'* components are not equal and there is a significant *cc* component, is not overwhelming. The Raman band of the liquid has a depolarization ratio of 0.29 and so has significant contribution from the A_1 band. The infrared spectrum is nearly all perpendicularly polarized, and so is due to the *E* vibration, and the A_1 is very weak at best. In the Raman spectrum (6) of trioxane II, a high-pressure phase which is produced at pressures about ~27 kbar at 22°C (2), most of the bands that are undoubtedly degenerate are split into two approximately equal components and none of the A_1 bands is split. No doubt the C_3 molecular axis is absent. The band at ~3033 cm^{-1} is split into two unequal parts, which can be interpreted as a strong doublet at 3037 and 3027 cm^{-1} derived from an *E* band and an A_1 component about 5 cm^{-1} lower than the mean *E* frequency of 3032 cm^{-1}, i.e., at ~3027 cm^{-1}. The spectrum of trioxane I is therefore probably due to a strong *E* vibration at 3033 cm^{-1} in both infrared and Raman and a weak A_1 vibration at ~3028 cm^{-1} in both infrared and Raman. In the polarized Raman spectrum the weak A_1 component seems to be dominated by leaked *E* spectra and the difference of frequencies is not evident.

The 2888-cm^{-1} Raman band of the single crystal is mainly the A_1 vibration, which agrees with the spectrum of the melt, and is largely *cc* polarized. In the infrared, there are clearly two bands, an A_1 at 2883 cm^{-1} and an *E* at 2877 cm^{-1}. In the Raman spectrum of trioxane II (6), there is a strong band and two weak sidebands. The sidebands are no doubt due to the split *E* vibration, and their mean frequency is ~6 cm^{-1} below that of the A_1. It seems likely, therefore, that the A_1 vibration of trioxane I is at 2888 cm^{-1} and the *E* components at ~2882 cm^{-1}. Apart from a frequency shift of 5 cm^{-1}, these agree with the infrared spectra.

Three of the combination bands, at 2855, 2630, and 1076 cm^{-1}, appear to have different species in the infrared and Raman spectra. Perhaps the two spectra see different combinations.

The 966- and 746-cm^{-1} bands appear to have significant A_1 and *E* contributions in the single-crystal Raman spectra, but to be only A_1 in the infrared. Their depolarization ratios in the liquid are 0.00 and 0.06 respectively. It seems likely that the apparently significant *E* component is due to leakage caused by imperfect alignment of the crystal and unwanted reflections and refractions.

The band at 480 cm^{-1} is clearly asymmetric in the Raman spectrum, and appears to consist of an A_1 band at 486 cm^{-1} and a weaker *E* band at 477 cm^{-1}. In the infrared (5), only a strong A_1 band at 469 cm^{-1} was reported.

The infrared spectrum has therefore been carefully recorded on a Perkin-Elmer model 521 infrared spectrometer. It is a broad asymmetric band, as is the Raman band, centered at about 475 cm^{-1}, and appears to be composed of two bands centered at ~484 and ~472 cm^{-1}, as does the Raman spectrum. However, according to Kobayashi *et al*'s. (5) Fig. 4, there is no perpendicularly polarized infrared band in this region, and the explanation of this discrepancy is not known.

[h]This is a weak band and the polarizations are uncertain.

The Raman-active intermolecular rotational vibrations form the representation $A_1 + 2E$ and the only active translational vibration belongs to species E. They can be assigned as in Table 1. Thomas (18) assigned his 64-cm^{-1} band to the E species, but there seems little doubt that it is the A_1 band.

Discussion

Vibrational Assignment

The CH_2 stretching vibrations of the isolated molecule form the reducible representation $2A_1 + 2E$, of which $A_1 + E$ is caused by each of the symmetric and asymmetric stretches. When coupled in the crystal, each forms the reducible representation $A_1 + A_2 + 2E$, of which the A_2 vibration is inactive.

The coupling between the C—H stretches within a CH_2 group is expected to be much greater than the coupling between CH_2 groups, and so the designation symmetric and asymmetric should be a good approximation. The doubling of the E vibrations due to intermolecular coupling is probably

[a]Abbreviations are as for Table 1.

small, and so in a first approximation the symmetric and the asymmetric stretches each give an A_1 and two overlapping E Raman-active vibrations. The scattering matrices of the four CH_2 vibrations were calculated assuming that the polarizability of the C—H bond was cylindrically symmetrical. For simplicity, the C—H bonds were assumed to be parallel to or at the tetrahedral angle to the c axis, and the effective masses of the symmetric and asymmetric motions have been assumed equal. The predicted relative intensities of the Raman polarizations and the depolarization ratios are summarized in Table 3. The relative infrared intensities have been calculated assuming that the dipole-moment derivative for the stretching of the C—H bond is parallel to the bond direction. They are also summarized in Table 3.

Kobayashi *et al.* (5) assigned the E and A_1 asymmetric stretches to bands at 3031 and 2883 cm^{-1}, respectively, although their vibrational analysis predicted that their frequencies differed by only 4 cm^{-1}, which agrees with two other calculations (10, 20). Pickett and Strauss (10) assigned the 3025-cm^{-1} vapor band to the overlapping asymmetric stretches, and the 2850-cm^{-1} band to the symmetric stretches. Clark and Hewitt (20) assigned the asymmetric stretches to 3030 and 2852 cm^{-1} and the symmetric stretches to 2852 and 2790 cm^{-1}. Kobayashi *et al.* (5) also assigned the E and A_1 symmetric stretches to the widely spaced bands 2877 and 2807 cm^{-1} in spite of a calculated difference of only 1 cm^{-1}. The polarized infrared spectra shown in their Fig. 7 show that the 2883-cm^{-1} band has a strong A_1 component and a somewhat weaker E. The 3031-cm^{-1} band contains a very strong E component, and the A_1 component is so weak that it might be due to leakage. The Raman spectrum is, however, quite clear in requiring both A_1 and E components. The final assignment is summarized in Table 3.

The predicted polarizations agree qualitatively with experiment when the different experimental arrangements for the different polarizations are allowed for. For example, the ratio of *aa'* and *ca* intensities for the two E bands is predicted to be 4. It is about 4 for the asymmetric, and the symmetric is probably dominated by leakage of the A_1 band. The *cc* component of the A_1 symmetric band is predicted to be much stronger than the *aa*, as is observed. The *aa* component of both the symmetric and the asymmetric bands is predicted to be dominated by the E vibration, which is true for the

TABLE 3. Predicted relative intensities of the C—H stretching bands of single-crystal trioxane in the Raman and infrared spectra

		Raman[a,b]					Infrared[a,b]	
Band	Assigned frequency, cm^{-1}	*aa*	*aa'*	*ac*	*cc*	ρ[c]	*a*	*c*

E (CH_2 asymm. st.)	3033	$16(1 - r)^2$	$16(1 - r)^2$	$3(1 - r)^2$	0	¾	1	0

[a]The factor $(4/3)\alpha_{\parallel}'^2$ multiplies the entries in the *aa*, *aa'*, *ac*, and *cc* columns for the Raman, and $24\mu'^2$ multiplies the columns *a* and *c* for the infrared.
[b]$r = \alpha_{\perp}'/\alpha_{\parallel}'$, $\alpha_{\perp}' = \partial\alpha_{\perp}/\partial r_{CH}$, $\alpha_{\parallel}' = \partial\alpha_{\parallel}/\partial r_{CH}$, $\alpha_{\perp}$ and $\alpha_{\parallel}$ are the components of the polarizability tensor perpendicular and parallel respectively to the bond axis, r_{CH} = C—H distance, $\mu' = \partial\mu/\partial r_{CH}$, μ = dipole moment.
[c]For the liquid.
[d]Approximately, assuming $r \ll 1$.

asymmetric; the E symmetric band is weak, and has unknown leakage from the strong cc of the A_1 band. The cc component of the A_1 symmetric band is predicted to be stronger than the A_1 asymmetric; it is about 10 times or more stronger.

The depolarization ratio of the combined asymmetric stretching vibrations was calculated as 0.38, independent of r. The experimental value for the pure liquid was 0.29, and for the solution in chloroform-d was 0.20. For the symmetric band the predicted values are $\frac{1}{3}$ for $r = 0$ and 0.13 for $r = 0.25$. The experimental values were 0.14 for the pure liquid and 0.10 for the solution. The agreement is reasonable.

In the infrared spectrum, the A_1 asymmetric stretch is predicted to be twice as strong as the E, and the E symmetric stretch to be twice as strong as the A_1. In fact, the relative intensities (5) are the inverse of the predicted, for reasons that are not understood.

All the other bands observed in the 3-μm region in the infrared and Raman spectra must be combinations. Several of them are quite strong in both the Raman and infrared, and are probably in Fermi resonance with the fundamentals. While assignments can be suggested for several combinations, there is no evidence that they are correct except the approximate coincidence of frequencies, and this is not reliable if several bands are in Fermi resonance, as seems to be so.

Kobayashi *et al.* (5) proposed a complete vibrational assignment of the molecule based on a normal coordinate analysis, and Pickett and Strauss (10, 21) have analyzed the ring vibrations that have significant internal rotation. Except in the C—H stretching region discussed above, our spectra do not require any revision of these assignments, except that the $A_1\nu_3$ internal rotation is at 484 cm^{-1} instead of 469 cm^{-1}. The companion E band at $\sim$477 cm^{-1} is presumably a combination, but there is no obvious candidate for it.

The catalytic reaction between carbon monoxide and nitrous oxide over chromium(III) oxide

BORDAN W. KRUPAY[1] AND ROBERT A. ROSS

Department of Chemistry, Lakehead University, Thunder Bay, Ont., Canada P7B 5E1

Received September 12, 1978

BORDAN W. KRUPAY and ROBERT A. ROSS. Can. J. Chem. **57**, 718 (1979).

The catalytic reaction between carbon monoxide and nitrous oxide over chromium(III) oxide has been investigated in a continuous flow system at atmospheric pressure from 525 to 583 K. Two kinetic regions with apparent activation energies of 172 ± 4 kJ mol^{-1} (525 to 559 K) and 239 ± 4 kJ mol^{-1} (565 to 583 K) were observed. The rate-controlling step in both regions was associated with the formation of an intermediate carbonate-like species during the consecutive decompositions of two nitrous oxide molecules. In the region of higher apparent activation energy, the presence of polymeric surface chromate groups may influence the reactivity of any carbonate-like intermediate and the subsequent desorption of carbon dioxide thereby leaving a vacant site for nitrous oxide decomposition.

BORDAN W. KRUPAY et ROBERT A. ROSS. Can. J. Chem. **57**, 718 (1979).

On a étudié la réaction catalytique du monoxyde de carbone avec l'oxyde nitreux sur de l'oxyde de chrome(III) dans un système à écoulement continu, à la pression atmosphérique, entre 525 et 583 K. On a observé deux régions cinétiques des énergies d'activation apparentes de 172 ± 4 kJ mol^{-1} (525 à 559 K) et 239 ± 4 kJ mol^{-1} (565 à 583 K). L'étape qui détermine la vitesse dans chaque région est associée à la formation d'une espèce intermédiaire ressemblant à un carbonate au cours des décomposition consécutives de deux molécules d'oxyde nitreux. Dans la région associée avec l'énergie d'activation apparente la plus élevée, la présence de groupes chromates polymères à la surface peut influencer la réactivité de tout intermédiaire ressemblant à un carbonate et la désorbtion subséquente du dioxyde de carbone qui laisse ainsi un site vacant pour la décomposition de l'oxyde nitreux.

[Traduit par le journal]

Introduction

The catalytic reduction of nitric oxide by carbon monoxide has received considerable attention (1). In regard to the relative activities of various transition metal oxides, the oxides of iron and chromium were more effective catalysts than those of nickel, cobalt, and manganese (2); a finding which differs from the usual pattern associated with oxidation reactions (3) although in later work (4, 5), the oxides of copper, cobalt, and manganese were reported to be most active. Further, it has been proposed that catalysis of the CO/NO reaction may proceed by an associative mechanism or if by a stepwise (regenerative) scheme oxide reduction would not be rate-determining (6).

Fewer studies have been reported on the catalytic reaction between carbon monoxide and nitrous oxide, a reaction which carries less immediate technological import. Reactivity patterns for the first row transition metal oxides (7) have suggested that three possible key contributory processes may explain catalysis: (*a*) the adsorption and reaction of carbon monoxide via a cyclic transition state involving the metal/oxygen bond, (*b*) the destabilization of a surface carbonate intermediate, and (*c*) the desorption of carbon dioxide which may be adsorbed on two surface sites.

The present study with chromium(III) oxide is a further contribution to kinetic work on the catalysis of the CO/N_2O reaction on transition metal oxides and also provides an opportunity to assess the general applicability of earlier hypotheses (7, 8).

Experimental

The catalytic reaction between carbon monoxide and nitrous oxide was examined in a differential-reactor flow system (9, 10) at atmospheric pressure. High-purity helium was used as the carrier gas in the flow system and Beckman GC-5 gas chromatograph. Nitrogen, carbon monoxide, carbon dioxide, and nitrous oxide were analyzed by a thermal conductivity bridge using stainless steel columns, 183 × 0.32 cm od, packed with 61 cm "Carbosieve B" and the remainder with "Poropak Q" at a column temperature of 353 K which was sufficient to resolve all components.

The standard reacting gas mixture consisted of carbon monoxide and nitrous oxide at a partial pressure of 5.33 kPa (40 Torr). "Blank" runs confirmed that reaction on the quartz wool and reactor walls reached 1% at 853 K which was 270 K above the highest temperature of catalysis. Preliminary experiments with the oxide catalysts established that diffusion phenomena (11, 12) did not influence the rate measurements at a total gas flow rate of 350 mL min^{-1} (NTP).

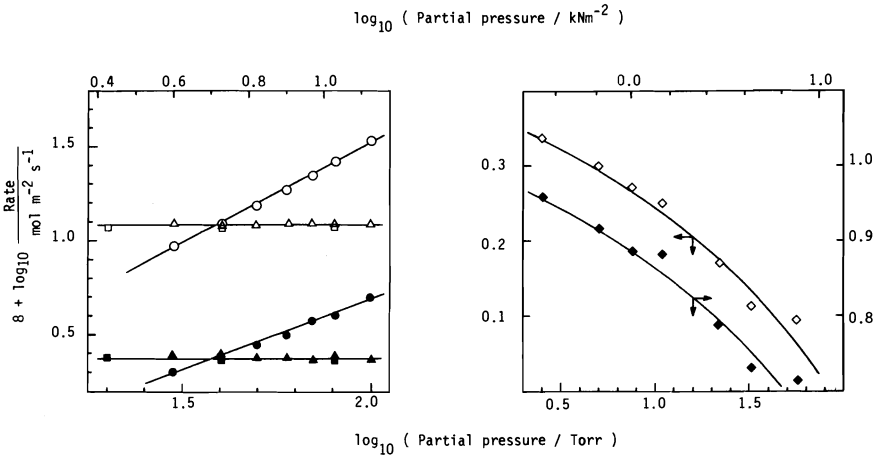

FIG. 1. The effects of variations in the partial pressures of carbon monoxide (△, ▲), nitrous oxide (○, ●), nitrogen (□, ■), and carbon dioxide (◇, ◆) on the catalytic CO/N_2O reaction on chromium(III) oxide at 567 and 545 K, respectively.

Chromium(III) oxide (99% w/w, Alfa Inorganics Inc.) was pelletized in a 1.27 cm die at 3 tons for 2 min and then calcined at 873 K for 10 h to increase tensile strength. After coarse crushing and sieving, particles with a 1–2 mm diameter were used for catalysis. The catalyst was heated in the reactor in flowing helium at 853 K for 30 min and then at 583 K for 3 h in the reacting gas mixture to establish steady catalyst activity. The conversion level at the highest temperature was 13.1%.

After the kinetic studies were completed, the surface area was 3 $m^2\ g^{-1}$ and bulk volume 0.65 $cm^3\ g^{-1}$. X-ray powder diffraction photographs before and after exposure to the standard gas mixture, consisting of 5.33 kPa each of carbon monoxide and nitrous oxide, did not reveal any changes in catalyst composition.

Carbon monoxide (C.P.; 99.5% minimum), carbon dioxide (Coleman; 99.99%), nitrogen (super-pure; 99.99%), nitrous oxide (99.9% minimum), and helium (high purity; 99.995%) were used as supplied.

Results

The reaction rate order with respect to carbon monoxide was determined at 545 and 567 K in the partial pressure range 4.00 to 13.3 kPa with nitrous oxide fixed at 5.33 kPa. At both temperatures, the reaction rate was independent of variations in the carbon monoxide partial pressure (Fig. 1).

The partial pressure of nitrous oxide was varied from 4.00 to 13.3 kPa with carbon monoxide maintained constant at 5.33 kPa. At 567 K, the reaction rate order with respect to nitrous oxide was 1.0 while at 545 K, a value of 0.8 was calculated (Fig. 1).

With the partial pressures of carbon monoxide and nitrous oxide each fixed at 5.33 kPa, the carbon dioxide partial pressure was varied from 0.33 to 5.79 kPa in individual experiments at 578 and 545 K. At both temperatures, the rate of reaction was retarded with increasing carbon dioxide partial pressure. The range of variation in the CO_2 partial pressure added to the reaction gas stream was much higher than the level of CO_2 produced from the CO/N_2O mixture. On this basis, the rate order for the gas was computed at the lowest CO_2 partial pressures and found to be -0.2 at both 578 and 545 K. The reaction rate was independent of variations in nitrogen partial pressure at both temperatures from 2.67 to 10.7 kPa. Thus, the rate of the reaction, r (mol $m^{-2}\ s^{-1}$), can be expressed as

$$[1] \qquad r = kP_{N_2O}{}^{1.0}/P_{CO_2}{}^{0.2} \quad \text{at 567 K}$$

and

$$[2] \qquad r = kP_{N_2O}{}^{0.8}/P_{CO_2}{}^{0.2} \quad \text{at 545 K}$$

Steady catalytic activity was attained at 583 K after 3 h with the standard gas mixture. Temperature was then progressively decreased from 583 to 525 K in 6 K intervals. Rate constants were calculated from the integrated forms of eq. [2] in the lower temperature region and eq. [1] at higher temperatures. The Arrhenius plot exhibited two apparent activation energies: 172 ± 4 kJ mol^{-1} from 525 to 559 K and 239 ± 4 kJ mol^{-1} from 565 to 583 K (Fig. 2).

Discussion

Infrared spectroscopic studies (13) indicate that α-Cr_2O_3 belongs to a class of oxidation catalysts that does not possess a metal/oxygen bond having double-bond character as evidenced by the absence of an infrared absorption band in the region near 1000–900 cm^{-1}. However, under oxidizing conditions, Cr_2O_3 can be oxidized to CrO_3 which does have some Cr—O double bond character. The catalytic properties are related to calcination tem-

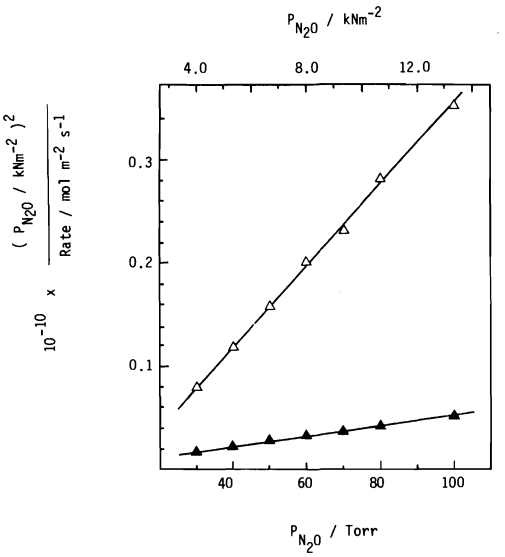

FIG. 3. Nitrous oxide rate order results plotted according to eq. [3] at 545 (△) and 567 K (▲) for the catalytic CO/N_2O reaction on chromium(III) oxide.

perature (14) while the extent of surface dehydration influences the sorption of carbon monoxide (15). Chromium(III) oxide exhibits intrinsic p-type semiconductivity (16) and lattice oxygen does not appear to be involved in catalytic oxidation (17, 18).

The rate order results were analyzed by testing various Langmuir–Hinshelwood kinetic expressions (19, 20). Correlations based on statistical fitting have been discussed (21, 22) and, in view of recent findings (23) regarding their interpretation, their use has been adopted as a general guide to the nature of the surface reaction. Only one kinetic expression accommodated both nitrous oxide and carbon dioxide rate order results:

$$[3] \qquad r = kP_{N_2O}\theta_{N_2O}$$

where

$$\theta_{N_2O} = aP_{N_2O}/(1 + aP_{N_2O} + b\sqrt{P_{CO_2}})$$

The relationship was valid for both components at 545 and 565 K (Figs. 3 and 4).

Since the experimental reaction rate was zero order with respect to carbon monoxide partial pressure, the adsorption and reaction of CO would necessarily be rapid relative to nitrous oxide. The form of eq. [3] may be interpreted to indicate that the rate-controlling step is associated with the formation of a surface carbonate-like intermediate which has been previously detected in calorimetric studies of carbon monoxide, carbon dioxide, and oxygen adsorption (24) on Cr_2O_3 and, more

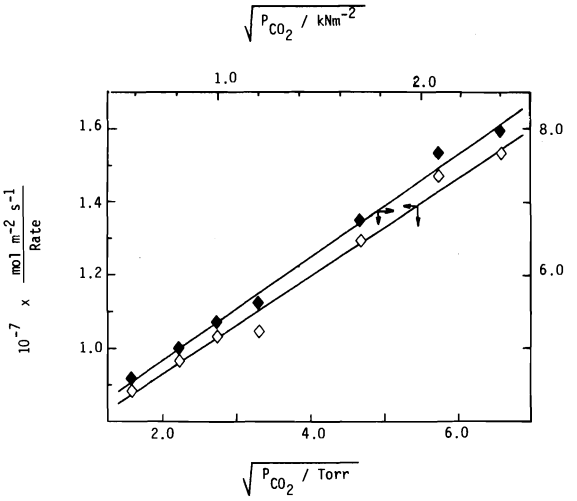

FIG. 4. Carbon dioxide rate order results for the CO/N_2O reaction on chromium(III) oxide at 545 K (◆) and 567 K (◇) plotted according to eq. [3].

specifically, could be the surface reaction involving nitrous oxide during the formation of this intermediate. In this respect, the value of the apparent activation energy, E_A, for the CO/N_2O reaction was 172 ± 4 kJ mol^{-1} (525 to 559 K) in good agreement with that reported for nitrous oxide decomposition (25) on Cr_2O_3, 167 kJ mol^{-1}, albeit in a 200 K higher temperature range when the decomposition of adsorbed nitrous oxide was proposed as the rate-determining step. The overall rate was associated

with the number of reaction sites available for N_2O decomposition determined by the inhibitory effect of adsorbed oxygen.

The formation of surface carbonates has been detected by infrared spectroscopy during the adsorption of carbon dioxide on α-Cr_2O_3 (26). The nature of the surface species depends on the degree of dehydration and the amount of CO_2 not removed at 473 K increases with activation time and temperature since bidentate carbonates formed on highly dehydrated surfaces are more strongly held than bicarbonates that predominate at low dehydration levels. Since the catalytic reaction rate is independent of CO partial pressure, the reactions involving N_2O may be proposed to intervene after the adsorption of carbon monoxide at a reactive site which has been identified as Cr^{3+} (15, 18). A surface scheme involving the simultaneous reaction between the reactants as adsorbed species does not seem likely since then the denominator of the kinetic expression should be squared (27). Further, the interaction between CO and N_2O yielding the intermediate carbonate-like species must proceed on specific sites since the introduction of CO_2 into the reacting gas mixture does not augment the catalytic reaction rate in the manner observed with Co_3O_4 (8).

The slight increase in rate order with respect to nitrous oxide partial pressure from 0.8 at 545 K to 1.0 at 567 K would not usually be regarded as significant but it did occur in step with the increase in apparent activation energy from 172 $\pm$ 4 kJ mol^{-1} (525 to 559 K) to 239 $\pm$ 4 kJ mol^{-1} (565 to 583 K) and hence may be associated with a variation in the surface reactivity of nitrous oxide. However, although the rate order was consistently zero with respect to carbon monoxide partial pressure at all temperatures, there remains the possibility that a change in the reactivity of this relatively strongly adsorbed reactant could occur within the two temperature zones. In this respect, correlations of E_A values obtained for the CO/N_2O reaction over 3*d* metal oxides with metal/oxygen bond polarization (7) and length (28) suggest that the adsorption of carbon monoxide via a cyclic intermediate does contribute to the catalytic reaction although the strengths of the metal/oxygen bonds may predominate in controlling the overall course of catalysis.

Oxygen desorption studies have revealed two surface oxygen states for Cr_2O_3 with desorption activation energies reported as 155 and 197 kJ mol^{-1} (29) and 146 and 230 kJ mol^{-1} (24). The non-uniformity of the surface oxygen of chromium(III) oxide has been examined by isotopic exchange (30) and samples annealed at 873 K exhibited parallel exchange with two types of surface oxygen species. The variation in non-uniformity and the amount of exchangeable oxygen on the surface was related to the presence of hexavalent chromium. Increase of temperature favoured the preponderance of polymeric surface chromate groups (14, 31) which possessed stronger metal/oxygen bonds resulting in higher activation energies for isotopic oxygen exchange and variations in the strength and form of the surface complex arising from CO_2 adsorption.

For the CO/N_2O reaction, the change in the apparent activation energy may be associated with a change in the bonding level of the catalyst metal/oxygen bond which could influence the reactivities of the reactants and also the ease of CO_2 desorption. Thus, the rate-determining step in the lower temperature region would be associated with the adsorption and decomposition of nitrous oxide and, at higher temperatures, the increase in activation energy would be related to a change in mechanism, similar to that observed in the catalytic oxidation of carbon monoxide (6), from an associative to a regenerative scheme. Finally, polymeric surface chromate groups would be expected to influence the decomposition of any carbonate-like intermediate as well as the desorption of carbon dioxide which relates in turn to the availability of vacant sites for nitrous oxide decomposition.

Passage des phosphorinènes aux hexadiényl-3,5-phosphines: un nouveau type de coordinat P(III)-diène pour les métaux de transition

FRANÇOIS MATHEY ET CATHERINE SANTINI

Equipe IRCHA-CNRS, 2-8 rue Henry Dunant, BP no 28, 94320 Thiais, France

Reçu le 19 juillet 1978

FRANÇOIS MATHEY et CATHERINE SANTINI. Can. J. Chem. **57**, 723 (1979).

La réaction du tertiobutyllithium sur la phényl-1-phosphorinanone-4 fournit un mélange d'alcools isomères qui sont partiellement séparés sous forme de sulfures. Ce mélange est déshydraté par P_4S_{10} pour fournir le sulfure de phényl-1-tertiobutyl-4-phosphorinène-3. Ce sulfure donne avec le nickélocène et l'iodure d'allyle un complexe P(III) → Ni(II) qui réagit avec $P(OMe)_3$ pour donner un sel de méthyl-phényl-phosphorinènium. Ce sel conduit par action du butyllithium et de la cyclohexanone à un produit à chaîne ouverte, l'oxyde d'hexadiényl-3,5-phosphine correspondant. Cet oxyde est réduit par $HSiCl_3$ et la phosphine obtenue est caractérisée sous forme de complexe avec $Fe(CO)_4$. Le sulfure de phosphorinène est métallé sur C(2) par le butyllithium dans le THF. Le dérivé lithié réagit avec l'acétone pour donner un mélange d'alcools "*cis*" et "*trans*" séparés et pleinement caractérisés. Des variations significatives des couplages ^2J(H–P), ^3J(H–P) et des fréquences ir ν(OH), ν(P═S) sont observées entre les deux isomères. Le mélange d'alcools "*cis*"–"*trans*" est déshydraté pour fournir un diène endo-exocyclique qui ne s'isomérise pas par réaction avec $Fe_3(CO)_{12}$. En fait, on observe une réduction-complexation du groupement P═S. Le lithio-2-phosphorinène réagit aussi avec l'iode pour donner un dimère ponté.

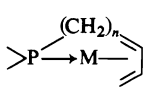
FRANÇOIS MATHEY and CATHERINE SANTINI. Can. J. Chem. **57**, 723 (1979).

The reaction of tertbutyllithium with 1-phenylphosphorinan-4-one yields a mixture of isomeric alcohols which are partly separated as their P-sulfides. This mixture is dehydrated by P_4S_{10} to afford 1-phenyl-4-tertbutylphosphorin-3-ene sulfide. This sulfide with nickelocene and allyl iodide gives a P(III) → Ni(II) complex which reacts with $P(OMe)_3$ to yield a methylphenylphosphorinenium salt. This salt with BuLi and cyclohexanone gives the corresponding open chain product, i.e. a hexa-3,5-dienylphosphine oxide. This oxide is reduced by $HSiCl_3$ to the corresponding phosphine which is characterized as its P → $Fe(CO)_4$ complex. The phosphorinene sulfide is metalated on C(2) by *n*-butyllithium in THF. The lithium derivative with acetone yields a mixture of '*cis*' and '*trans*' alcohols which are separated and fully characterized. Significant variations of ^2J(H–P), ^3J(H–P) coupling constants and ν(OH), ν(P═S) ir frequencies are observed between the two isomers. The mixture of '*cis*' and '*trans*' alcohols is dehydrated to give a endo-exocyclic diene which is not isomerized when reacted with $Fe_3(CO)_{12}$. A reduction-complexation of the P═S group is observed instead. The 2-lithiophosphorinene is also reacted with iodine to afford a bridged dimer.

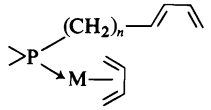
Introduction

Les diènes conjugués comme les dérivés du phosphore trivalent font partie des quelques coordinats fondamentaux utilisés dans la chimie des métaux de transition. Cette constatation suffirait à expliquer l'intérêt que nous portons aux systèmes du type

Avec un choix convenable de la valeur de *n*, ce genre de coordinat peut acquérir des propriétés chélatantes ou, du moins favoriser la création de liaisons métal–métal car le phosphore peut devenir suffisamment proche spatialement du système diénique. On peut alors espérer obtenir des complexes du type I dans lequel M désigne un centre mono- ou polymétallique:



(I)



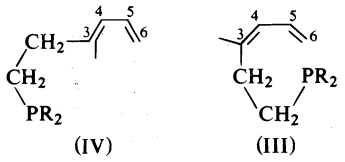
(II)

Des complexes d'un type apparenté ont d'ailleurs été décrits dans des cas particuliers (1, 2).

En présence d'un autre diène en excès, (I) pourrait évoluer pour donner réversiblement des complexes du type (II). Voir par exemple à ce sujet, les travaux de Caïs (3) sur les équilibres diène libre – diène complexé par $Fe(CO)_3$. Notons simplement que l'effet stabilisant de la chélation sur la liaison métal–diène dans (I) peut défavoriser la formation de (II). On conçoit néanmoins tout l'intérêt de tels systèmes pour catalyser certaines transformations des composés diéniques. L'étude des modèles de Dreiding mon-

0008-4042/79/070723-06$01.00/0

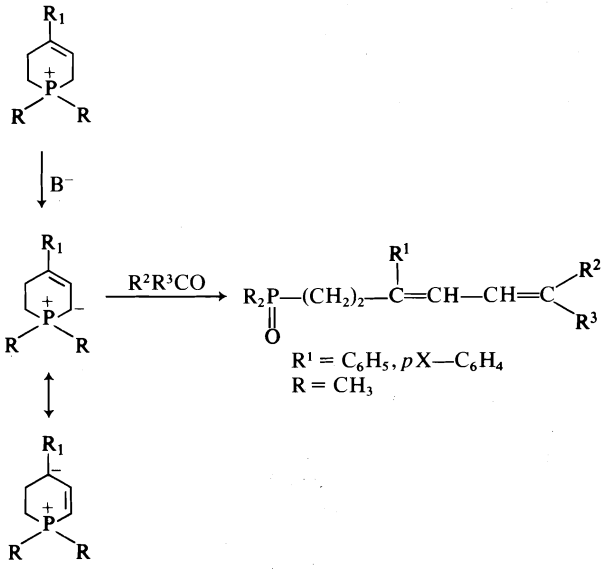
tre que l'obtention de complexes tels que (I) ne peut se produire que si $n \geq 2$. Dans le cas des hexadiényl-3,5-phosphines ($n = 2$) il faut en outre que le substituant $-(CH_2)_2PR_2$ et la double liaison $C_5{=}C_6$ soient en position "*cis*" (structure III) par rapport à la double liaison $C_3{=}C_4$ et non en position "*trans*" (structure IV).



(dans III et IV les échelles ne sont pas respectées). Nous avons donc entrepris l'étude de quelques voies possibles d'accès aux hexadiényl-3,5-phosphines de structure "*cis*". Ce mémoire décrit nos premiers travaux synthétiques effectués dans cette optique.

Accès aux hexadiényl-3,5-phosphines

Pour respecter les conditions structurales imposées, nous avons fondé notre approche sur les travaux de Lednicer (4) qui a montré que les sels de phosphorinénium-3 possédant un substituant arylique R^1 en position 4 réagissaient sur les dérivés carbonylés en présence de base pour fournir des oxydes d'hexadiényl-3,5-phosphines dont la disposition "*cis*" était imposée par la nature cyclique du produit de départ:



Le choix d'un substituant R^1 arylique est essentiel car, comme il se conjugue avec la double liaison du cycle, il facilite la synthèse du sel de phosphorinénium et permet un déroulement normal de la condensation de Wittig en diminuant le poids statistique de la forme mésomère de l'ylure. Cependant, nous nous sommes refusés à un tel choix car nous ne voulions pas désactiver le diène par des substituants électroattracteurs ni introduire des possibilités de coordination parasite faisant intervenir les doubles liaisons et le cycle benzénique de R^1. Pour éviter néanmoins une attaque du dérivé carbonylé sur la position 4 de l'ylure, nous avons choisi un substituant R^1 encombrant, le tertiobutyle. Ce choix nous a obligé en fait, à modifier de fond en comble le schéma réactionnel décrit par Lednicer. La séquence finalement retenue est décrite dans la fig. 1.

Nous avons fait réagir la phényl-1-phosphorinanone-4 (5) sur le tertiobutyllithium. Comme Quin dans un cas analogue (6), nous avons obtenu deux alcools isomères **1** + **2** avec un rendement quasi quantitatif.

Les deux isomères n'ont pas été séparés mais leur existence se manifeste par la présence de deux signaux *t*-Bu en rmn du proton situés respectivement à 0.75 et 0.95 ppm dans le rapport approximatif 2:1 ($CDCl_3$, TMS). On notera que la différence de déplacement chimique des protons des tertiobutyles est nettement plus importante dans ces alcools

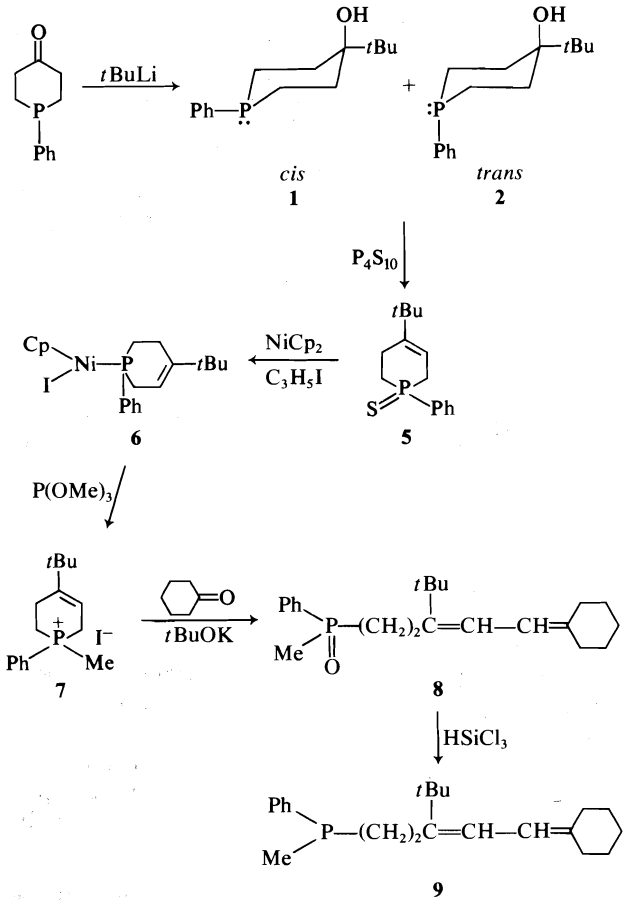


FIG. 1. La séquence finalement retenue.

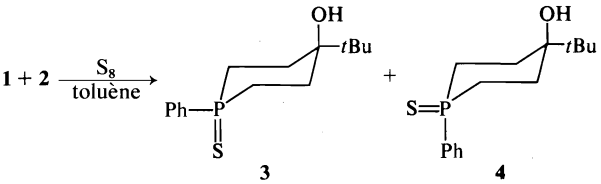
P-phénylés que dans leurs homologues P-méthylés préparés par Quin. Après sulfuration dans le toluène à chaud, nous avons pu, par contre, séparer partiellement les isomères par chromatographie sur gel de silice (éluant: pentane–éther 1:3). Le produit passant en tête a été isolé à l'état pur et complètement caractérisé notamment par rmn ^1H, ^{13}C et ^{31}P.



Nous lui attribuons la structure "*cis*" **3** (par rapport aux substituants phényle et hydroxy) par analogie avec les travaux de Quin sur des sulfures analogues (7) parce que son signal phosphore ($CDCl_3$, H_3PO_4 85%, δ positif à champ faible) est plus déblindé que celui du deuxième isomère auquel nous attribuons la structure "*trans*" **4** mais que nous n'avons pu isoler à l'état pur: $\delta^{31}P$ (**3**) = 34.4 ppm; $\delta^{31}P$ (**4**) = 31 ppm.

Pour déshydrater le mélange d'alcools **1** et **2**, nous avions à notre disposition trois techniques décrites dans la littérature. La première utilise l'acide chlorhydrique concentré dans le xylène au reflux (8), la deuxième l'acide *para*-toluènesulfonique dans les mêmes conditions (4) et la troisième l'alumine vers 400°C en phase vapeur (9). Les deux premières techniques ne nous ont donné aucun résultat; pour des raisons non éclaircies cette déshydratation s'avère en fait très difficile à effectuer. La troisième technique nécessite l'utilisation de quantités importantes d'alcool; nous n'avons pu l'employer malgré un essai préliminaire encourageant. Nous avons donc dû développer un nouveau procédé de déshydratation utilisant le pentasulfure de phosphore dans le toluène à reflux pendant 2 h. Evidemment, il n'est pas question dans ces conditions, de respecter la trivalence du phosphore et nous obtenons finalement le sulfure de phosphorinène-3 **5** avec un rendement de 45% (nous assurons la conversion complète du P(III) en P(IV)=S en ajoutant un peu de soufre dans le milieu réactionnel). Le spectre ir de **5** (KBr) comprend une bande d'absorption C=C faible à 1640 cm^{-1} et une bande P=S forte à 585 cm^{-1}. Le spectre rmn ^1H montre un singulet à 1.14 ppm correspondant au *t*Bu et un doublet de triplet correspondant au CH éthylénique centré à 5.91 ppm ^3J(H–H) = 6 Hz; ^3J(H–P) = 25.3 Hz. Le pic de résonance du phosphore apparaît à 31.9 ppm.

Pour convertir ce sulfure **5** en sel de phosphorinénium, la solution évidente consistait à le réduire en phosphine puis à quaternariser cette phosphine. Pour éviter toute migration ou destruction de la double liaison, nous avons préféré utiliser la technique très douce de la réduction-complexation des sulfures de phosphines par le nickelocène en présence d'iodure d'allyle (10). La réaction est conduite dans le benzène à 40°C, pendant 3 h. Le complexe **6** obtenu avec un rendement de 85% se présente sous la forme d'une huile rouge caractérisée par analyse élémentaire C, H, Ni et par rmn du proton ($CDCl_3$). Les résonances des protons du tertiobutyle et du cyclopentadiènyle apparaissent sous la forme de singulets fins respectivement à 0.99 et 5.27 ppm. Après découplage des CH_2, le proton éthylénique donne un doublet situé à 5.56 ppm (^3J(H–P) = 17.2 Hz). Enfin, après découplage du CH éthylénique, le CH_2P allylique se présente sous la forme d'un pseudo-doublet élargi à 3.03 ppm (^2J(H–P) = 9 Hz). Le complexe **6** a ensuite été détruit par le triméthylphosphite en excès pour donner directement l'iodure de phényl-1-méthyl-1-phosphorinénium correspondant: **7** avec un rendement de 83%. L'iodure de méthyle nécessaire à la quaternarisation provient de l'attaque par $P(OMe)_3$ du motif Ni—I du complexe intermédiaire $(C_5H_5)Ni(I)[P(OMe)_3]$ suivant un schéma qui rappelle celui de la réaction d'Arbuzov: voir réf. 11. Le spectre rmn de **7** ($CDCl_3$, TMS externe) comprend le pic de résonance des protons du tertiobutyle à 1.03 ppm, un doublet dû à CH_3P à 2.52 ppm (^2J(H–P) = 14 Hz) et un doublet de triplet centré à 5.64 ppm (^3J(H–P) = 22 Hz; ^3J(H–H) = 5 Hz) correspondant à la résonance du proton éthylénique.

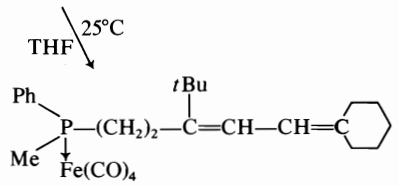
L'iodure **7** réagit sur la cyclohexanone dans le THF en présence de *t*BuOK suivant la technique de Lednicer pour fournir l'oxyde diénique attendu **8** (rendement 61%). Son spectre de rmn ($CDCl_3$, TMS interne) montre un premier singulet à 1.03 ppm dû aux protons du tertiobutyle, un singulet élargi à 1.53 dû aux trois CH_2 cyclohexaniques non liés à la double liaison, un doublet dû au CH_3P à 1.72 ppm (^2J(H–P) = 12.8 Hz) et un système AB à 5.57 et 6.08 ppm ^3J(H–H) = 11.4 Hz dû aux deux protons éthyléniques. Le pic de résonance du phosphore apparaît à 37.2 ppm. Le spectre de masse (70 eV, 90°C) comprend le pic moléculaire de *m/e* 344. Enfin on observe dans le spectre ir (KBr) une bande moyenne d'absorption à 1600 cm^{-1}: ν(C=C) et une bande intense à 1180 cm^{-1}: ν(P=O).

La réduction de cet oxyde **8** par $HSiCl_3$ conduit à la phosphine correspondante **9** avec un rendement de 52% en produit distillé. Nous n'observons aucune hydrogénation détectable du système diénique contrairement à ce qui est constaté avec les oxydes de butadiénylphosphines (12).

Le spectre rmn de **9** est très semblable à celui de **8**. La principale différence est visible au niveau du

CH_3P qui se présente sous la forme d'un doublet à 1.31 ppm (^2J(H–P) = 2 Hz). Le phosphore apparaît à −33.5 ppm. L'unicité du signal phosphore suggère qu'il n'y a pas hydrogénation partielle du système diènique. Pour parfaire la caractérisation de **9**, nous avons préparé son complexe avec le fer-tétracarbonyle **10** par réaction avec $Fe(CO)_4(THF)$ (13):

9 + $Fe(CO)_4(THF)$



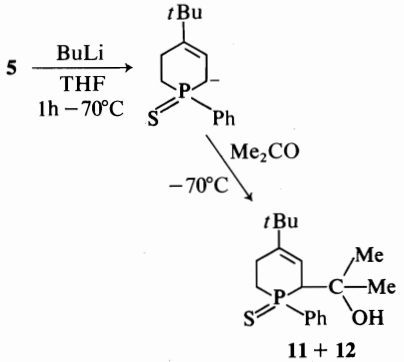
Rdt ~ 72%

10

La complexation se traduit par un déblindage très important du phosphore: $\delta^{31}P$ (**10**) = 51.3 ppm. Le spectre rmn ^1H ($CDCl_3$, TMS externe) ressemble beaucoup à celui de l'oxyde **8**: le tertiobutyle apparaît à 1.10 ppm, les CH_2 cyclohexaniques à 1.61 ppm, le doublet CH_3P à 1.95 ppm (^2J(H–P) = 9.9 Hz) et les protons éthyléniques à 5.73 et 6.17 ppm (^3J(H–H) = 11.4 Hz). A l'évidence donc le système diénique ne participe pas à la complexation du fer. Le spectre ir (cyclohexane) comprend 4 bandes d'absorption dûes aux CO à 2047, 1974, 1937 et 1933 cm^{-1}. Enfin le spectre de masse (70 eV, 80°C) comprend le pic moléculaire de *m/e* 496 et les différents pics correspondant à la perte des 4 CO, ce qui établit définitivement la formule.

Essais parallèles

A partir du sulfure **5**, nous avons également essayé de synthétiser le système diénique recherché à l'aide d'une réaction de Horner. Nous avons donc métallé **5** par le butyllithium dans le THF à −70°C puis condensé le dérivé métallé obtenu avec l'acétone. La condensation s'effectue uniquement sur la position 2 et conduit au mélange d'alcools diastéréoisomères: **11** + **12**:



Rdt global 53%

11 + **12**

Les deux diastéréoisomères ont pu être séparés sur colonne de gel de silice. Ils sont présents en quantités sensiblement équivalentes. Les données rmn du proton sont les suivantes: **11**: δ = 1.13 (s, *t*Bu); 1.27 (s, Me); 1.35 (s, Me); 3.08 (dd, ^2J(H–P) 10.7, ^3J(H–H) 4.2, C_2*H); 4.58 (s, OH); 5.84 (dd, ^3J(H–P) 20.6, =CH) ppm. **12**: δ = 0.91 (s, Me); 1.19 (s, *t*Bu); 1.27 (s, Me); 3.11 (dd, ^2J(H–P) 20.5, ^3J(H–H) 4.5, C_2*H); 3.75 (s, OH); 5.62 (dd, ^3J(H–P) 9.7, =CH) ppm.

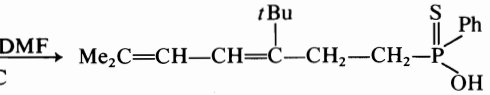
Lorsqu'on compare les données rmn de **11** et de **12**, on constate une forte variation des couplages ^2J(H–P) et ^3J(H–P) alors que le couplage ^3J(H–H) reste sensiblement constant. Compte tenu des données de la littérature (14) nous attribuons la structure "*cis*" (fonction carbinol en "*cis*" du P=S) à l'isomère possèdant le plus petit couplage ^2J(H–P) et le plus grand couplage ^3J(H–P) c'est à dire **11**.

Les spectres ir de **11** et **12** viennent à l'appui de cette interprétation: **11**: ν(OH) = 3400 cm^{-1} (pastille KBr ou solution CCl_4 à 2 concentrations); ν(P=S) = 596 cm^{-1}. **12**: ν(OH) = 3370 cm^{-1} (pastille KBr), 3410 cm^{-1} (solution CCl_4 à 2 concentrations); ν(P=S) = 638 cm^{-1}.

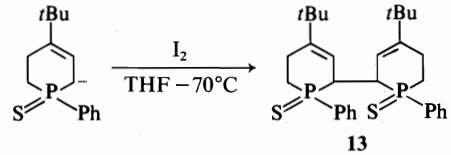
Dans **11**, l'abaissement de la fréquence de vibration ν(P=S) et la valeur constante de la fréquence de vibration ν(OH) en fonction de la concentration suggère la présence d'une liaison intramoléculaire OH...S=P.

La non sélectivité de la métallation permet de penser que le lithium n'est pas chélaté par le soufre dans l'organométallique intermédiaire.

Soumis à l'action de NaH à chaud, dans la diméthylformamide, **11** ne nous a pas fourni le produit diénique attendu:

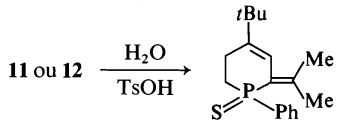


Nous avons donc abandonné cette voie. Auparavant, nous avons toutefois tenté la conversion de **5** en dihydrophosphorine en mettant à profit sa métallation aisée. Les dihydrophosphorines sont en effet des précurseurs des phosphorines elles-mêmes (15). Nous avons donc fait réagir l'anion dérivé de **5** sur l'iode. L'analyse C, H et la spectrométrie de masse (70 eV, 160°C: *m/e* 526, M, 30%; *m/e* 263, M/2, 100%) indiquent clairement que nous avons en fait obtenu le produit de pontage **13** et non le dérivé iodé dont la déshydrohalogénation nous aurait permis de préparer une dihydrophosphorine:



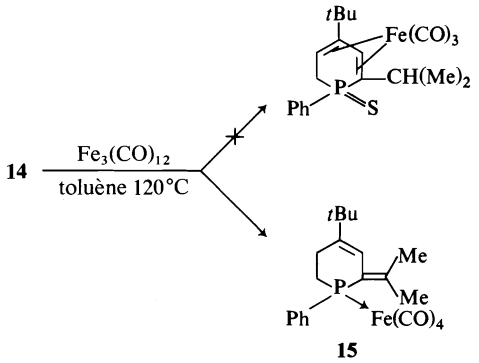
13

Nous avons effectué une deuxième approche plus indirecte. Par chauffage dans le toluène avec de l'acide paratoluène-sulfonique, les alcools **11** ou **12** se déshydratent sans difficulté:



14

Le système diénique de **11**, compte tenu de sa géométrie, ne peut donner le complexe π avec $Fe(CO)_3$. Par contre, la dihydrophosphorine qui dérive de **14** par isomérisation peut fournir un tel complexe. Nous avons donc pensé que **11**, chauffé en présence de $Fe_3(CO)_{12}$, conduirait au complexe de cette dihydrophosphorine. En fait, nous avons observé non une isomérisation mais une simple réduction-complexation du P=S conduisant au complexe P → $Fe(CO)_4$ **15** selon un schéma déjà observé avec des sulfures de phosphines plus classiques (16):



15

Conclusion

La préparation des hexadiènyl-3,5-phosphines de structure *cis* à partir des sels de phosphorinénium s'avère être un schéma viable. Cependant, pour exploiter pleinement cette voie, il nous faudra auparavant simplifier l'accès aux cycles phosphorinènes. A cette condition, nous pourrons probablement développer une intéressante chimie des complexes de métaux de transition avec ce type de coordinats.

Partie expérimentale

Toutes les réactions sont effectuées sous courant d'argon. Les points de fusion ont été déterminés au banc Kofler. Les spectres ir ont été enregistrés à l'aide d'un spectrophotomètre Perkin-Elmer 457 en pastille KBr, la position des bandes d'absorption est exprimée en cm^{-1}. Les spectres de masse ont été mesurés à l'aide d'un appareil MS 30 (AEI). Les analyses élémentaires ont été effectuées au service de Microanalyse de l'IRCHA (Vert le Petit). Les spectres de rmn (dans le deutério chloroforme) ont été enregistrés pour le proton sur appareils Perkin-Elmer R12 et R24 à 60 MHz et JEOL PS 100 FT à 100 MHz; pour le phosphore et le carbone sur JEOL PS 100 FT à respectivement 36.447 MHz et 22.63 MHz. Les déplacements chimiques sont comptés positivement à champ faible des références (TMS pour ^1H et ^{13}C, H_3PO_4 (85%, en capillaire) pour ^{31}P). Les chromatographies sont effectuées sur colonne de gel de silice (70–230 mesh).

La phényl-1-phosphorinanone-4 a été synthétisée comme décrit dans la littérature (5).

*Phényl-1-terbutyl-4-phosphorinanol-4 (**1** + **2**)*

A une suspension de 2.40 g (1.25×10^{-2} mol) de phényl-1-phosphorinanone-4 dans 50 cm^3 d'éther éthylique, refroidie à environ −50°C, sont ajoutés 20 cm^3 d'une solution 0.66 molaire de tertiobutyllithium. En fin d'addition, le milieu réactionnel est porté au reflux de l'éther pendant 3 h. Après hydrolyse acide, puis décantation, la phase organique est séchée sur Na_2SO_4 puis distillée, conduisant à 1.6 g (52%) du mélange d'isomères **1** + **2** (le rendement du produit brut est quantitatif) [Eb 130–135°C, *p*: 0.4 mm Hg] − *F* = 90°C. Analyse trouvé pour $C_{15}H_{23}OP$: C 71.68, H 9.27; calc.: C 71.97, H 9.26. ir: ν(OH) à 3400 cm^{-1}.

*Sulfure de phényl-1-terbutyl-4-phosphorinanol-4 (**3** + **4**)*

Dans 20 cm^3 de benzène, 1.4 g du mélange d'isomères (**1** + **2**) (cette étape peut être réalisée sur l'alcool (**1** + **2**) brut) et 1.5 g de soufre sont chauffés à reflux du solvant pendant 2 h. Le rendement est quantitatif. Par chromatographie sur colonne (silice 100 g, éluant éther éthylique 3 volumes; pentane 1 volume, fractions 20 cm^3) seuls 70 mg de l'isomère **3** ont pu être obtenus purs (fractions 15, 16, 17), les autres fractions étant des mélanges de **3** et **4** (*F*: 164°C (isomère pur)). Analyse trouvé pour $C_{15}H_{23}OPS$: C 63.78, H 8.14; calc.: C 63.82, H 8.15. ir ν(OH): 3430 F ν(P=S): 585 F. rmn: **3**: 1.08 [s, *t*Bu]; 1.55 [s, OH]; **4**: 0.9 [s, *t*Bu]; 1.82 [s, OH]. ^{13}C (isomère pur) δ_{COH}: 74.5 δ_{PCH_2}: 27.2 $^1J_{PC}$: 43.4 Hz $\delta C_{3,5}$: 26.2 ppm.

*Sulfure de phényl-1-terbutyl-4-phosphorinène-3 (**5**)*

Une suspension de 4.62 g (1.85×10^{-2} mol) de {**1** + **2**}, 13 g (2.9×10^{-2} mol) de pentasulfure de phosphore et 1 g (3.1×10^{-2} mol) de soufre dans 100 cm^3 de toluène est chauffée au reflux du solvant 3 h. Après filtration de l'excès de P_4S_{10}, le milieu réactionnel est agité vigoureusement (agitation mécanique) pendant 1 h avec une solution saturée en $NaHCO_3$. Après décantation, la phase organique est séchée sur Na_2SO_4, concentrée puis chromatographiée (silice 150 g, éluant: éther éthylique 1 volume, pentane 3 volumes) conduisant à 2.2 g (ρ = 45%) du produit attendu: ce rendement optimal a été obtenu pour des quantités de l'ordre de 4 g en alcool (**1** + **2**); pour des quantités supérieures (7 → 15 g) il a toujours été inférieur [≃30%]. F: 60°C. Analyse trouvé pour $C_{15}H_{21}PS$: C 68.28, H 8.05; calc.: C 68.15, H 7.95.

*Iodure de η⁵-cyclopentadiényl[phényl-1-terbutyl-4-phosphorinène-3] nickel(II) (**6**)*

Une solution de 1.6 g (6×10^{-3} mol) de **5**, 3.4 g de nickelocène (1.8×10^{-2} mol) et 0.85 cm^3 d'iodure d'allyle dans 100 cm^3 de benzène est chauffée à 40°C pendant 3 h. Après filtration de l'insoluble noir puis concentration, le résidu est chromatographié sur colonne de gel de silice (40 g éluant benzène). Passent en tête des impuretés organiques, puis le complexe dont la progression est aisément suivie grâce à sa coloration rouge sombre. Cette chromatographie est réalisée sous argon. Après évaporation du solvant 2.2 g (ρ: 85%) de complexe sont isolés. Analyse trouve: C 49.95, H 5.50, Ni 12.0; calc.: C 49.73, H 5.42, Ni 12.15.

*Iodure de phényl-1-méthyl-1-terbutyl-4-phosphorinen-3-ium (**7**)*

A une solution de 0.7 g (1.45×10^{-3} mol) de complexe **6** dans 50 cm^3 de benzène sont ajoutés, sous argon et avec une forte agitation, 0.6 g (4.85×10^{-3} mol) de triméthylphosphite. La solution est *agitée* 24 h à la température ambiante dans un

Erlenmeyer hermétiquement bouché. Les cristaux obtenus sont filtrés et lavés à l'éther −0.46 g (ρ: 83%) du sel de phosphonium sont obtenus. F: 153°C. Analyse trouvé pour $C_{16}H_{24}IP$: C 50.66, H 6.42; calc.: C 51.53, H 6.41. ir ν(C=C) 1635 et 1580 cm^{-1}.

*Oxyde de méthyl, phényl, (cyclohexylydène-5-terbutyl-3) pentèn-3-yl-phosphine (**8**)*

Un mélange de 1.6 g (4.27×10^{-3} mol) de **7**, 1 g de terbutylate de potassium et 1 cm^3 de cyclohexanone est chauffé à reflux du tétrahydrofuranne (fraîchement distillé sur Na/ϕ_2CO) pendant 20 h. Après évaporation du solvant le résidu marron est repris avec 100 cm^3 d'eau acidulée et 100 cm^3 de chlorure de méthylène. La phase organique après lavage à l'eau jusqu'à pH neutre, est séchée puis concentrée. Le résidu est chromatographié (45 g de silice éluant acétate d'éthyle 95 alcool méthylique 5) conduisant à 0.9 g (61%) de l'oxyde attendu. F: 92°C. Analyse trouvé pour $C_{22}H_{33}OP$: C 75.69, H 9.09; calc.: C 76.7, H 9.65. ir ν(C=C): 1590, 1600 ep, m. ν(P=O) = 1180 F.

*Méthyl, phényl, (cyclohexylydène-5-terbutyl-3) pentèn-3-yl-phosphine (**9**)*

0.4 g (1.16×10^{-3} mol) de **8** et 1 cm^3 de trichlorosilane dans 50 cm^3 de toluène sont chauffés à 120°C pendant 2 à 3 h. Après évaporation du toluène et de l'excès de $HSiCl_3$, le résidu est lavé au benzène puis avec une solution désoxygénée de carbonate de sodium afin d'éliminer les traces résiduelles de $HSiCl_3$. Après décantation, la phase organique est séchée puis concentrée; 0.2 g (53%) de phosphine sont obtenus après distillation à 160°C (p = 0.2 mm de Hg) dans un four tubulaire GKR.50 Bucchi.

*[Méthyl, phényl, (cyclohexylydène-5-terbutyl-3) pentèn-3-yl phosphine] tétracarbonyl fer (0) (**10**)*

Sous atmosphère d'oxyde de carbone, 0.6 g (1.65×10^{-3} mol) de fer nonacarbonyle et de phosphine brute **9** dans 80 cm^3 de tétrahydrofuranne (fraîchement distillé sur Na/ϕ_2CO) sont agités 3 h à 25°C. La solution orangée obtenue est concentrée puis chromatographiée (silice 40 g éluant hexane 90 benzène 10). 0.62 g (ρ = 72% par rapport à l'oxyde de phosphine **8**) du complexe 1:1 sont ainsi obtenus (huile jaune) spectre de masse (80°C, 70 eV) M 496, (M—CO) 468 et (M—2CO): 440. ir: ν(CO): 2047 F, 1971 F, 1930 TF.L, ν(C=C) 1600 f large rmn: 1.95 [d, ^2J(H–P): 9.9 Hz, Me] δ_A: 5.73, δ_B: 6.17 (système AB, =CH).

*Sulfure de phényl-1 (α-hydroxyisopropyl)-2-tertbutyl-4-phosphorinène-3 (**11** et **12**)*

A une solution (1.25 g, 4.73×10^{-3} mol) de **5** dans 50 cm^3 de tétrahydrofuranne (fraîchement distillé sur Na/ϕ_2CO)), refroidie à −78°C, sont ajoutés 3 cm^3 d'une solution hexanique de butyllithium (N = 1.75). La réaction de métallation se caractérisant par une coloration orange foncé du milieu, est spontanée. Cependant, le milieu réactionnel est lentement réchauffé à la température ambiante puis agité à cette température 30 min. Le milieu est, de nouveau refroidi à −78°C et 1 cm^3 d'acétone (fraîchement distillée sur P_2O_5) est ajouté, entraînant une décoloration quasi-spontanée du milieu. Après réchauffement à la température ambiante, le solvant est évaporé, le résidu repris avec 50 cm^3 d'eau acidulée puis 100 cm^3 de chlorure de méthylène. La phase organique, après lavage avec 3 × 20 cm^3 d'eau, est décantée, séchée sur Na_2SO_4 puis concentrée. Par chromatographie sur colonne (50 g silice éluant éther éthylique 1 volume: pentane 3 volumes), on obtient d'abord **11** (0.4 g), puis le mélange **11** + **12** (0.2 g), puis **12** (0.2 g), soit un rendement global de 53%, alors que 0.4 g de **5** sont recouvrés. F: **11**: 82°C; **12**: 118°C. Analyse (sur **11**) trouvé pour $C_{18}H_{27}OPS$: C 66.89, H 8.63; calc.: C 67.08, H 8.44. rmn: $\delta^{31}P$ (**11**) 33.56; $\delta^{31}P$ (**12**) 35.74/H_3PO_4).

*Bis[thio-1-phényl-1-terbutyl-4-phosphorinèn-3-yl-2] (**13**)*

La réaction de métallation est réalisée comme ci-dessus avec 2.2 g (8.3×10^{-3} mol) de **5** et 6 cm^3 d'une solution héxanique de butyllithium (2 N). Puis 2.5 g (9.8×10^{-3} mol) d'iode dans 20 cm^3 de tétrahydrofuranne sont ajoutés au milieu réactionnel qui est ensuite lentement réchauffé à la température ambiante. Après 1 h 30 min d'agitation, le milieu réactionnel est lavé avec une solution de bisulfite de sodium. Après évaporation du solvant, le résidu est repris au chlorure de méthylène (50 cm^3) et à l'eau (20 cm^3). La phase organique (après décantation) est séchée sur Na_2SO_4, concentrée puis chromatographiée (100 g silice, éluant: éther éthylique 1 volume, pentane 3 volumes). 0.43 g (20%) du produit ponté sont ainsi obtenus. F 210°C. Analyse trouvé pour $C_{30}H_{40}P_2S_2$: C 68.62, H 7.65; calc.: C 68.41, H 7.65. ir ν(C=C) 1635f, 1580, et 1560f ν(P=S) 600 cm^{-1}. rmn: δ = 6 ppm (dd, ^3J(H–P): 22 Hz, =CH).

*Sulfure de phényl-1-méthyléthylydène-2-terbutyl-4-phosphorinène-3 (**14**)*

En présence d'une quantité catalytique d'acide p-toluène sulfonique 0.25 g de **11** ou **12** sont chauffés à reflux du toluène pendant 2 h. Après évaporation du solvant, le résidu est chromatographié (40 g de silice éluant éther éthylique 1 volume, pentane 3 volumes) conduisant à 0.2 g (85%) du produit déshydraté F = 88°C. Analyse trouvé pour $C_{18}H_{25}SP$: C 70.61, H 8.29; calc.: C 71.07, H 8.27. ir ν(C=C): 1635f, 1575m large. rmn: 1.13 (s, tBu); 1.8 (d, ^5J(H–P): 1.5 Hz, Me); 1.93 (d, ^5J(H–P) = 1.5 Hz, Me); 6.45 (d, ^3J(H–P) = 24.3 Hz, =CH).

*[Phényl-1-méthyléthylydène-2-terbutyl-4-phosphorinène-3] tétracarbonyl fer (0) (**15**)*

0.2 g (0.65×10^{-3} mol) de **14** et 0.5 g (1×10^{-3} mol) de fer dodécacarbonyle dans 50 cm^3 de toluène sont chauffés à reflux du solvant pendant 2 h. Après filtration d'un précipité noir, la solution orangée obtenue est concentrée puis chromatographiée (silice 40 g éluant hexane 90 benzène 10) 0.240 g (ρ = 82%) du complexe sont isolés. ir (décaline) ν(CO): 2020F, 1955F, 1920FL (KBr) ν(C=C): 1570F. rmn: 1.1 (s, tBu); 1.66 (s, Me); 1.96 (s, Me); 6.29 [d, ^3J(H–P) = 20 Hz, =CH] $\delta^{31}P$: 41.34/H_3PO_4, spectre de masse [70°C, 70 eV]: m/e 440 (M); 412 (M—CO); 384 (M—2CO); 356 (M—3CO); 328 (M—4CO); pic de base à 257.

DANIEL KOST, H. BERNHARD SCHLEGEL, DAVID JOHN MITCHELL, and SAUL WOLFE. Can. J. Chem. **57**, 729 (1979).

The quantitative PMO analysis of the *ab initio* wavefunction of a molecule A—B is based upon a partitioning of the Fock matrix elements of this wavefunction to obtain the fragments A and B, followed by computation of the stabilizing and destabilizing orbital interactions between the orbitals of these fragments that contribute to the HOMO of A—B. However, when one or both of the fragments is NH_2 or a congeneric species, neither the $3a_1$ nor the $1b_1$ orbital of this fragment is appropriate for overlap with the second fragment, and the PMO analysis cannot be performed. A solution to this problem is proposed, and has been tested by application to various conformational properties of methylamine.

DANIEL KOST, H. BERNHARD SCHLEGEL, DAVID JOHN MITCHELL et SAUL WOLFE. Can. J. Chem. **57**, 729 (1979).

L'analyse quantitative PMO de la fonction d'onde *ab initio* de la molécule A—B est basée sur une partition des éléments de la matrice de Fock de cette fonction d'onde en vue d'obtenir les fragments A et B suivie par une évaluation des interactions orbitalaires stabilisantes et déstabilisantes entre les orbitales de ces fragments qui contribuent à la OM haute occupée de A—B. Toutefois si l'un ou les deux fragment est NH_2 ou une espèce congénère, ni l'orbitale $3a_1$ ni l'orbitale $1b_1$ de ce fragment n'est appropriée pour un recouvrement avec le deuxième fragment et l'on ne peut pas réaliser une analyse PMO. On propose une solution à ce problème et on l'a vérifié en l'appliquant à diverses propriétés conformationnelles de la méthylamine.
[Traduit par le journal]

The concept of the functional group has long been a part of the language of organic chemistry. In terms of this concept, 'chemical intuition' might be described as the ability to predict the properties of a molecule from a knowledge of the number, location, and different kinds of functional groups that are present.

Molecular orbital calculations also lead to predictions concerning molecular properties, but the notion of functional groups does not emerge naturally from such work. This has made it difficult to convey the results of theory in a manner compatible with chemical intuition.

Significant progress on this communication problem has been made recently, as a result of the observation that molecular orbitals can often be expressed qualitatively as a linear combination of a small number of canonical 'group orbitals' which recur from molecule to molecule (1). Using the language of perturbational molecular orbital (PMO) theory (2) to estimate the stabilizing and/or destabilizing effects associated with these linear combinations (orbital interactions) it has become possible, in principle (3), to treat the behaviour of every molecular orbital of a molecule in a manner that closely parallels the traditional conception of functional group interactions. For practical reasons, however, it has seemed desirable to focus attention upon the interactions that lead to certain specific molecular orbitals. In particular, it is of interest to consider the interactions in the highest occupied molecular orbital (HOMO), because trends in calculated total energies from one system to another are very often parallelled by trends in the energy of the HOMO (4).

The PMO interpretation of a molecular orbital calculation on the general system A—B, which contains the functional groups A and B, will, therefore, require the following information: (*i*) a knowledge of the nature, origin, and energies of the canonical orbitals of A and of B; (*ii*) a knowledge of the electron occupancies of these orbitals; (*iii*) a knowledge of which orbitals of A and of B contribute to the HOMO of A—B.

In several recent publications (5–9), we have de-

0008-4042/79/070729-04$01.00/0

scribed a quantitative PMO analysis of *ab initio* SCF-MO wavefunctions, in which the required information is obtained by a partitioning of the Fock matrix elements of these wavefunctions. The computer program for the analysis of A—B, with the fragmentation A···B, provides the orbitals of A and of B, their energies (e_i^0) and occupancies (i.e., gross populations), the interaction matrix elements, Δ_{ij}, the overlap integrals, S_{ij}, and an expansion of each of the molecular orbitals of A—B in terms of the fragment orbitals of A and of B. Equations [1] and [2] are then employed (5) to calculate, respectively, the stabilizing (i.e., doubly occupied with unoccupied) and destabilizing (i.e., doubly occupied with doubly occupied) interactions associated with the fragment orbitals that contribute to the HOMO of A—B.

$$[1]\quad \Delta e_{ij} = 2(\Delta_{ij} - S_{ij}e_i^0)^2/(e_i^0 - e_j^0)$$

$$[2]\quad \Delta e_{ij} = 2S_{ij}[-2\Delta_{ij} + (e_i^0 + e_j^0)S_{ij}]/(1 - S_{ij})^2$$

The molecules treated in this manner include ethane (5), propylene (5), $(CH_3)_2X$ (6), the dimethyl- (7) and difluoroethylenes (8), and XCH_2YH (X = CH_3, H_2N, HO, F, Cl; Y = O, S) (9). The results for these molecules have been characterized by the following general features: (*i*) the HOMO is comprised mainly of a linear combination of π-type and π*-type group orbitals and (where applicable) *p*-type lone pairs; (*ii*) the electron occupancies of these orbitals are either very close to 2 or very close to 0; (*iii*) the energy differences, from conformation to conformation or from molecule to molecule, that are calculated by application of eqs. [1] and [2], are close to the calculated total energy differences.

It has now been found that this quantitative procedure requires modification when the HOMO of the molecule contains a significant contribution from a hybrid lone pair orbital, as is the case in amines and their congeners. The purpose of this paper is to explain why the problem exists, and to provide a solution to it which otherwise retains the features of the general method.

Consider a molecule of ammonia, oriented as in Fig. 1, with one hydrogen on the *x*-axis of the coordinate system. If the fragmentation $H_2N\cdots H_x$ is performed, the amino group that results has the set of canonical orbitals shown in Fig. 1 as σ, π, n_σ, and n_π, and 7 valence electrons. The lower lying σ and π orbitals are each doubly occupied, leaving three electrons to populate n_σ and n_π. Our intuition suggests that one of these orbitals should be doubly occupied, and the other should be singly occupied. Moreover, the doubly occupied orbital should point in the direction of the lone pair of ammonia; and the singly occupied orbital should be directed along the *x*-axis, because it will form the bond to H_x. It is clear, however, that neither n_σ nor n_π meets these latter requirements. The quantitative PMO treatment of ammonia in the manner just described[1] leads to NH_2 orbitals corresponding to σ, π, n_σ, and n_π, and the electron occupancies of n_σ and n_π are found to be approximately 1.5 in each case. Equations [1] and [2] are, therefore, not applicable.

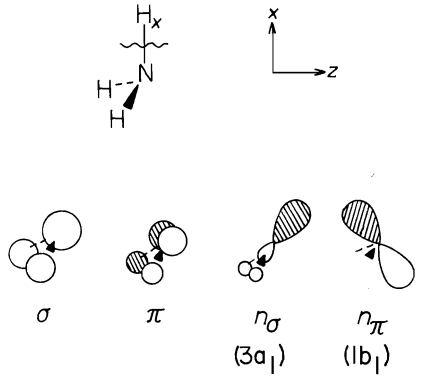

FIG. 1. The canonical orbitals of the NH_2 fragment of ammonia.

The problem arises because the C_{2v} axis of the NH_2 fragment does not coincide with the H_2N—H_x bond axis. This leads to significant overlap of H_x with both n_σ and n_π. As discussed in ref. 5, orbital occupancy depends upon the overlap between the fragment orbitals, because the gross population (Q_p) of an orbital ϕ_p^0 is defined as

$$[3]\quad Q_p = Q_{pp} + \sum_{i \neq p} Q_{pi}$$

where

$$[4]\quad Q_{pi} = 2\sum_n^{occ} S_{pi}T_{pn}T_{in}$$

with T the matrix that expresses the molecular orbitals in the fragment orbital basis. Fragment orbitals with populations close to 1.5 might be regarded as linear combinations of filled (population close to 2) and half-filled (population close to 1) orbitals. Therefore, one solution to the problem might consist of 'unmixing' these orbitals manually by taking a linear combination to form two new fragment orbitals with populations ca. 1 and ca. 2.

Alternatively, such a linear combination might be based upon the overlap properties of the two fragment orbitals. For any 2 × 2 rotation of a pair of orbitals ϕ_p^0 and ϕ_q^0 of one fragment, one has the

[1]All calculations were performed at the STO-3G level on a Burroughs B6700 computer, using a locally modified version of GAUSSIAN 70, and the optimized geometries reported in ref. 10.

result

$$[5] \qquad S'_{ip} = S_{ip} \cos\theta - S_{iq} \sin\theta$$

$$[6] \qquad S'_{iq} = S_{ip} \sin\theta + S_{iq} \cos\theta$$

where ϕ_i^0 is an orbital of the second fragment and S' is the overlap matrix after transformation. The sum of the squares of these overlap integrals with all n orbitals of the second fragment is invariant under the transformation, i.e.,

$$\sum_i^n (S'_{ip}{}^2 + S'_{iq}{}^2) = \sum_i^n \{(S_{ip} \cos\theta - S_{iq} \sin\theta)^2 + (S_{ip} \sin\theta + S_{iq} \cos\theta)^2\} = \sum_i^n (S_{ip}{}^2 + S_{iq}{}^2)$$

The angle θ should then be chosen so that $\sum_i^n S'_{ip}{}^2$ is maximized (while $\sum_i^n S'_{ip}{}^2$ is minimized), with the result that $\phi_p^{0'}$ more closely approximates the singly occupied σ-bonding orbital between the fragments, and $\phi_q^{0'}$ describes the lone pair orbital.

Application of this latter procedure to the $n_\sigma(3a_1)$ and $n_\pi(1b_1)$ orbitals of Fig. 1 leads to the hybrid fragment orbitals shown in Fig. 2. As can be seen, one of these is nearly aligned with the bond axis, and the other is nearly aligned with the C_{3v} symmetry axis of the molecule. In addition, the transformation has changed the electron occupancies, from 1.686 and 1.565 in n_σ and n_π, respectively, to 1.256 for the orbital on the bond axis and 1.996 for the orbital on the symmetry axis.

Methylamine

Figure 3 shows the effects of this transformation procedure upon the $3a_1$ and $1b_1$ fragment orbitals of the amino group of methylamine in its staggered conformation. As a result of the transformation, the computation of the destabilizing and stabilizing interactions between the nitrogen 'lone pair' ($4a'$) and the π_z and π_z^* methyl group orbitals becomes feasible. These are the only doubly occupied and unoccupied fragment orbitals that contribute to the HOMO. It is noteworthy that, since the axis of the methyl group coincides with the C—N bond axis, transformation of the orbitals of this fragment is not necessary, as is evident from the gross populations: π_z, 1.998; π_z^*, 0.019; π_x, 1.025.

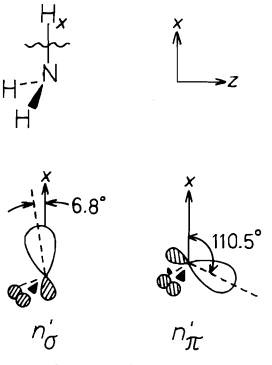

FIG. 2. Transformation of the n_σ and n_π canonical orbitals of the NH_2 fragment of ammonia based upon the criterion of maximization of the overlap of one of these orbitals with the fragmented H.

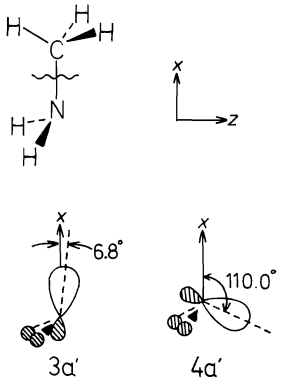

FIG. 3. The transformed n_σ and n_π orbitals of the NH_2 fragment of methylamine in its staggered conformation.

The quantitative PMO analysis of methylamine will, therefore, be based upon the interaction diagram shown in Fig. 4, which contains a destabilizing interaction between N_{lp} and π_z, and a stabilizing interaction between N_{lp} and π_z^*. The energies of these fragment orbitals, and the calculated interaction energies in the staggered and eclipsed conformations, are collected in Table 1. In terms of this analysis, the staggered conformation is found to be less destabilized by 0.20 kcal/mol, and more stabilized by 0.34 kcal/mol, than the eclipsed conformation.

The (N_{lp}–π_z^*) interaction is shown in Fig. 5. As a result of this interaction, antibonding CH regions become populated, and the CH bonds are weakened.

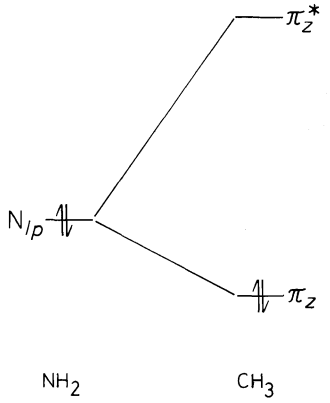

FIG. 4. Interaction diagram for the PMO analysis of methylamine.

TABLE 1. Quantitative PMO analysis of methylamine

Conformation	Fragment orbital	e_i^0 (au)	Interaction energy (kcal/mol) N_{lp}–π	Interaction energy (kcal/mol) N_{lp}–π^*
Staggered[a]	N_{lp}	−0.3592		
	π_{CH_3}	−0.5314	20.43	−4.95
	$\pi_{CH_3}^*$	0.6801		
Eclipsed[b]	N_{lp}	−0.3561		
	π_{CH_3}	−0.5274	20.63	−4.61
	$\pi_{CH_3}^*$	0.6780

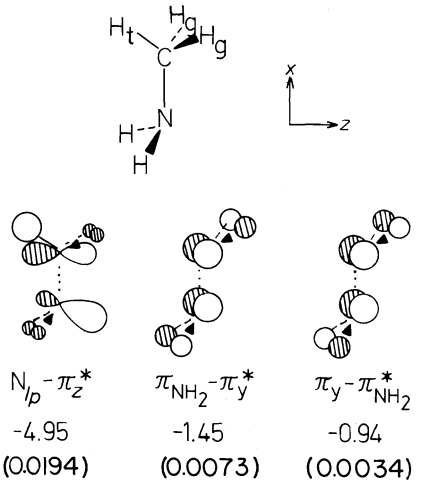

FIG. 5. The (N_{lp}–π_z^*), (π_{NH_2}–π_y^*), and (π_y–$\pi_{NH_2}^*$) orbital interactions in the staggered conformation of methylamine, and the values calculated for these interactions in kcal/mol. The numbers in parentheses are the gross populations of the π^* orbitals.

However, since H_t has a larger atomic orbital coefficient in π_z^* than does H_g, the C—H_t bond is weakened preferentially (11). An experimental manifestation of this effect is found in the Bohlmann bands (12), which appear in the infrared spectrum of methylamine (13).

Although they do not contribute to the HOMO, two other orbital interactions, shown in Fig. 5 as (π_{NH_2}–π_y^*) and (π_y–$\pi_{NH_2}^*$), also lead to weakening of CH bonds. In the (π_{NH_2}–π_y^*) interaction, the charge transfer is to antibonding C—H_g regions; this leads to preferential weakening of the C—H_g bonds. In the (π_y–$\pi_{NH_2}^*$) interaction, the charge transfer is from *bonding* C—H_g regions; this also weakens the C—H_g bonds preferentially. The values computed for the three orbital interactions are included in Fig. 5, together with the gross populations of the three π^* orbitals. These populations reflect the amount of charge transfer which occurs in each case. As can be seen, the (N_{lp}–π_z^*) interaction, which contributes to the HOMO, and weakens C—H_t preferentially, is significantly larger than the other two. This indicates that the Bohlmann band phenomenon has been predicted by a quantitative PMO analysis which is based upon examination of the interactions in the HOMO.

Chemical and microbiological remote functionalisation of (+)- and (−)-bornyl acetate[1]

MALCOLM S. ALLEN, NICHOLAS DARBY, PHILLIP SALISBURY, ELIN R. SIGURDSON, AND THOMAS MONEY

Chemistry Department, The University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received September 26, 1978

MALCOLM S. ALLEN, NICHOLAS DARBY, PHILLIP SALISBURY, ELIN R. SIGURDSON, and THOMAS MONEY. Can. J. Chem. **57**, 733 (1979).

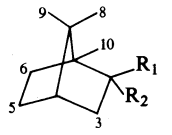
Chemical oxidation of (−)-bornyl acetate provides a mixture of 3-, 5-, and 6-oxobornyl acetate, whereas microbiological hydroxylation with cultures of *Helminthosporium sativum* gives a mixture of 2,3-, 2,6-, and 2,5-bornanediols. In each case the reaction occurs preferentially at the C(5) position. Microbiological hydroxylation of (+)-bornyl acetate with *H. sativum* occurs almost exclusively at the C(5) position. Regiospecific hydroxylation of (+)- or (−)-bornyl acetate with cultures of *Fusarium culmorum* also occurs at the C(5) position but without concomitant hydrolysis of the acetoxy group.

MALCOLM S. ALLEN, NICHOLAS DARBY, PHILLIP SALISBURY, ELIN R. SIGURDSON et THOMAS MONEY. Can. J. Chem. **57**, 733 (1979).

L'oxydation chimique de l'acétate du (−)-bornyle conduit à un mélange des acétates des oxo-3, -5 et -6 bornyles; l'hydroxylation microbiologique par des cultures d'*Helminthosporium sativum* fournit un mélange des bornane-diols-2,3 -2,6 et -2,5. Dans chaque cas, la réaction se produit préférentiellement en position C(5). L'hydroxylation microbiologique de l'acétate du (+)-bornyle par le *H. sativum* se produit presqu'exclusivement en position C(5). L'hydroxylation régiospécifique des acétates des (+)- ou (−)-bornyles par des cultures de *Fusarium culmorum* se produit aussi en position C(5); elle n'est toutefois pas accompagnée d'une hydrolyse du groupe acétoxy.

[Traduit par le journal]

As part of our synthetic studies (2 and references cited therein) in the monoterpenoid and sesquiterpenoid area we have considered the possibility of using remote oxidation or hydroxylation reactions to convert commercially available or synthetically accessible mono- and sesquiterpenoids to more complex, oxygenated derivatives. Our interest in this approach to terpenoid synthesis was prompted by a consideration of biosynthetic evidence which demonstrates that the introduction of hydroxyl or carbonyl groups into unactivated positions (i.e., remote from activating functionality) is a characteristic feature of many biosynthetic sequences. In addition there are many reports in the literature which indicate that transformations of this type can be accomplished in the laboratory using microbiological (3) or chemical techniques (4). Since our immediate synthetic objectives were dependent on the synthesis of 2,5-disubstituted bornane (camphane) derivatives we directed our initial attention to the direct remote oxidation or hydroxylation of bornyl (**1**) and isobornyl acetate (**2**).[2]



1 $R_1 = H, R_2 = OAc$
2 $R_1 = OAc, R_2 = H$

Remote Oxidation of (−)-Bornyl Acetate (1) with CrO_3/HOAc or CrO_3/HOAc/Ac_2O

Several reports in the literature have established that oxidation of bornyl acetate with CrO_3/HOAc (6) or CrO_3/Ac_2O/HOAc (7) provides 5-oxobornyl acetate (**3**) and its 6-oxo isomer (**8**) in ~15–35% yield. In our initial investigations we reexamined this remarkable transformation to assess its potential use in synthetic and biosynthetic studies.

Oxidation of (−)-bornyl acetate (**1**) with CrO_3/Ac_2O/HOAc (7) for 7 days at 0–25°C provided a mixture of products which was partially purified and separated into components by crystallisation, column chromatography, and/or preparative glc. The major product (~40% yield, see Table 1), readily isolated by crystallisation, was identified as 5-oxobornyl acetate (**3**) (7*c*) on the basis of its spectroscopic properties and conversion to 5-oxoborneol (**4**), 5-*exo*-hydroxyborneol (**5**) (7*c*), and bornan-2,5-dione (**6**) (7*c*). Minor components of the reaction mixture were identified as 5-*exo*-acetoxybornyl acetate (**7**), 6-

[1]The results described in this paper were previously reported in preliminary communications (1).

[2]Remote oxidation of isobornyl acetate (**2**) (5; M. S. Allen, D. H. Hunter, and T. Money. Unpublished observations) and its use in the synthesis of nojigiku alcohol and monoterpenoid analogs of *cis*-sativenediol, *trans*-sativenediol, and helminthosporal will be described in later papers (17).

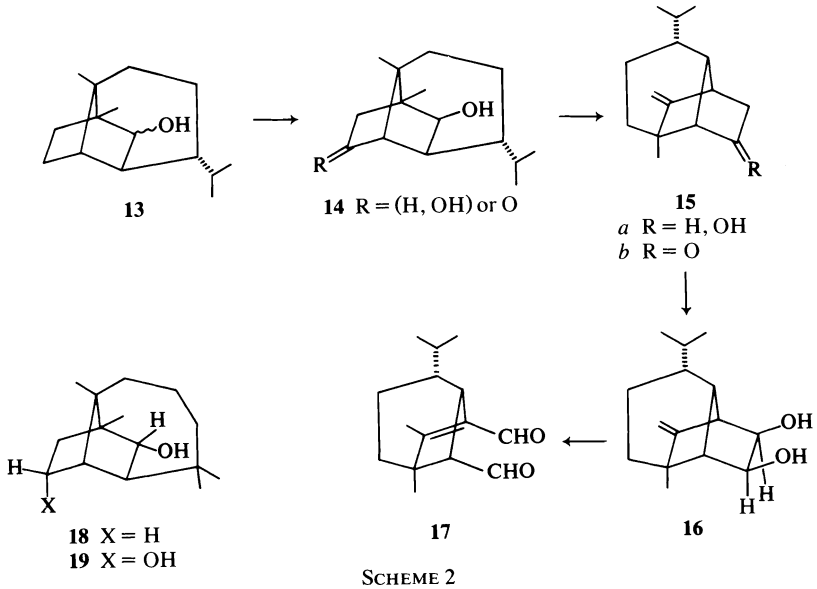
oxobornyl acetate (**8**), and 3-oxobornyl acetate (**11**) by chemical correlation with bornan-2,6-dione (**10**),[3] 6-*endo*-hydroxyborneol (**9**), bornan-2,5-dione (**6**),[3] and 3-*exo*-hydroxyborneol (**12**) (8) (Scheme 1). The stereochemistry of the acetoxy group in **7** was established by its nmr spectrum and its synthesis from 5-*exo*-hydroxyborneol (**5**). Oxidation of (−)-bornyl acetate with CrO_3/HOAc (6) produced a similar mixture of products in lower yield (Table 1).

[3]Bornane-2,5-dione (6) and bornane-2,6-dione (10 and references cited therein) were also identified as minor components of the oxidation process.

Microbiological Hydroxylation of (−)- and (+)-Bornyl Acetate

The regiospecificity of the oxidative transformation described above led us to consider that a similar functionalisation of the C(5) position in more complex camphane systems could occur during the biosynthesis of several groups of sesquiterpenoids. For



13 **14** R = (H, OH) or O **15** *a* R = H, OH *b* R = O **16** **17** **18** X = H **19** X = OH

SCHEME 2

TABLE 2. Hydroxylation of (−)-bornyl acetate (**5**) by *H. sativum*[4]

Product	Yield (%)[a]		
(−)-5-*exo*-Hydroxyborneol (**5**)	17	24	29
(−)-5-*endo*-Hydroxyborneol (**20**)	6	10	8

example introduction of oxygen functionality into an ylangobornane derivative (**13**; OH *endo* or *exo*), followed by Wagner–Meerwein rearrangement of **14** to a 5-oxo- (**15***a*) or 5-hydroxysativene (**15***b*) could be involved in the biosynthesis of *cis*-sativenediol (**16**), helminthosporal (**17**), and related compounds produced by *Helminthosporium sativum* (cf. ref. 9) (Scheme 2).[4] Similarly we considered that the final step (?) in the biosynthesis of culmorin (**19**) (cf. ref. 10), a metabolite of *Fusarium culmorum*, could involve C(5)-hydroxylation of longiborneol (**18**) or a suitable derivative. A result of these biosynthetic considerations is the prediction that *H. sativum* and *F. culmorum* contain a C(5)-hydroxylase which may be capable of introducing oxygen functionality at the C(5) position in compounds such as borneol[5] or more complex compounds such as longiborneol, etc. Support for these predictions is described below.

Hydroxylation of (−)- and (+)-Bornyl Acetate with H. sativum[4]

(−)-Bornyl acetate (**1**) was added to 3-day-old cultures of *H. sativum* and, after 7–10 days, ether extraction of the broth provided (−)-borneol and a mixture of bornanediols which were separated by column chromatography. On the basis of their nmr spectra and chemical correlation with products obtained in the chemical oxidation of **1**, the various microbiological products were identified as (−)-5-*exo*-hydroxyborneol (**5**) (major), (−)-5-*endo*-hydroxyborneol (**20**), (−)-6-*exo*-hydroxyborneol (**21**), and (−)-3-*exo*-hydroxyborneol (**12**) (8). The overall yield of diols was ~50% and the relative proportions of 2,5-, 2,3-, and 2,6- isomers (~5:2:1) was calculated from glc analysis of their diacetates (Table 2).[6,7]

When (+)-bornyl acetate (**22**) was used as substrate with *H. sativum* the regiospecificity of hydroxylation increased considerably and the only major products were (+)-5-*exo*- (**23**) and (+)-*endo*-hydroxylborneol (**24**).[8] The yield of diols **23** and **24** was ~35–65% and their relative proportion, as

[4]Now classified as *Bipolaris sorokiniana*.

[5]Previous studies (3*a*, *b*) have shown that the methylene groups of camphor, fenchone, and isofenchone can be hydroxylated by microorganisms or animals.

[6]Other minor components of the reaction mixture have been tentatively identified as 6-ketoborneol and bornane-2,8-diol.

[7]We are unable to provide a satisfactory explanation for the variation in relative yields of products in successive microbiological experiments (see Tables 2 and 3).

[8]The only other reaction product, (+)-3-*exo*-hydroxyborneol (**25**) was formed in ~2% yield (see Table 3).

TABLE 3. Hydroxylation of (+)-bornyl acetate (**22**) by *H. sativum*

SCHEME 3

determined by glc and nmr of the corresponding diacetates, varied from ~2.5:1 to ~7:1 (Table 3).[7]

Hydroxylation of (−)- and (+)-Bornyl Acetate with F. culmorum

Addition of (−)-bornyl acetate (**1**) to 7-day-old cultures of *F. culmorum* and work-up after 18 days provided 5-*exo*-hydroxybornyl acetate (**26**) as the only major product (~12% yield). The identity of this product was established by its spectroscopic properties and by its conversion to (−)-5-*exo*-acetoxybornyl acetate (**7**) and 5-oxobornyl acetate (**3**). An almost identical result was obtained when (+)-bornyl acetate (**22**) was used as substrate (Scheme 3).

The efficiency, regiospecificity, and stereoselectivity of the microbiological hydroxylations described above compare favourably with microbial transformations of other terpenoids (3*a–e*). In addition the regiospecificity of hydroxylation of (+)-bornyl acetate by *H. sativum* and the ability of *F. culmorum* to hydroxylate at C(5) while leaving the C(2)-acetoxy group intact[9] could be of value in subsequent synthetic studies.

[9]Preliminary observations (R. Zerr. Unpublished results) indicate that *F. culmorum* converts isobornyl acetate (2) to 5-hydroxyisobornyl acetate. Hence 5-oxo-isobornyl acetate is accessible by a microbiological route which complements the laboratory synthesis involving direct oxidation with CrO_3/HOAc/Ac_2O (5; M. S. Allen, D. H. Hunter, and T. Money. Unpublished results).

The remarkable correspondence in regiospecificity between the chemical and microbiological reactions described above probably reflects the greater accessibility of the C(5) position towards oxidising agents or enzymic systems. We have suggested a similar explanation for the partial regiospecificity of other direct remote oxidation reactions (11).

Experimental

Chromium trioxide (Mallinckrodt, Technical grade 99.75%), (−)-bornyl acetate (Aldrich Chemical Company), and (+)-camphor (Eastman Organic Chemicals) were used as received. (+)-Bornyl acetate, $[\alpha]_D$ +43.2° (*c* 2.47, $CHCl_3$), was prepared by calcium – liquid ammonia reduction (12) of (+)-camphor followed by column chromatography (alumina) and acetylation. Pyridine was dried over potassium hydroxide pellets before use and methylene chloride for pyridinium chlorochromate oxidations was dried by distillation from phosphorus pentoxide.

Nuclear magnetic resonance spectra were recorded at 100 MHz using either a Varian HA-100 or XL-100 machine, or the HA-100 magnet with Bruker TT23 console and Nicolet 16 K computer. Infrared spectra were recorded with Perkin Elmer 137 or 710A instruments.

Column chromatography was performed with aluminium oxide Woelm neutral, for column chromatography (ICN Pharmaceuticals) or with silicic acid, 100 mesh (Mallinckrodt). Alumina was deactivated to grade III before use. Thin-layer chromatography plates were made from silica gel GF-254 for tlc (E. Merck) and were visualised by spraying with a saturated solution of ceric sulphate in 12 *N* aqueous sulphuric acid followed by heating.

Gas–liquid chromatography was performed with either a Varian Aerograph model 90-P or Hewlett-Packard HP5831A

instrument, using thermal conductivity and flame ionisation detectors respectively. Analytical glc on the Varian instrument was conducted with 6 ft × 0.25 in. stainless steel columns using 3% SE-30, 10% OV-210, or 20% DEGS stationary phases on 60–80 or 80–100 mesh Chromosorb W. Preparative glc was performed with a 10 ft × 0.375 in. stainless steel column with 20% DEGS as the stationary phase on 60–80 mesh Chromosorb W. Mass spectra were recorded at 70 eV with a Varian/MAT CH4B spectrometer and high resolution mass measurements were determined with a Kratos-AEI MS50 instrument. Gas–liquid chromatography on the Hewlett-Packard instrument was performed with 6 ft × 0.125 in. stainless steel columns, using 3% OV-17, and 10% Carbowax stationary phases on 80–100 mesh Chromosorb W-HP support.

Optical rotations were measured with a Perkin-Elmer 141 or 241MC instrument and microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver.

Oxidation of (−)-Bornyl Acetate with Chromium Trioxide in Acetic Anhydride – Acetic Acid

A solution of (−)-bornyl acetate (**1**) (60 g, 0.31 mol) in glacial acetic acid (260 mL) and acetic anhydride (115 mL) was cooled to 0°C. The solution was stirred and maintained at 0°C while a solution of chromium trioxide (85 g, 0.85 mol, 2.1 equiv.) in acetic anhydride (135 mL) was added in several portions over 24 h. After this time the mixture was allowed to warm to room temperature and stirring was continued at this temperature for a further 6 days. The green viscous reaction mixture was dissolved in water (2500 mL), extracted with ether (3 × 650 mL), using filtration through Celite 535 to aid phase separation, and the ether extracts washed successively with water, excess aqueous sodium bicarbonate, and saturated aqueous sodium chloride. Drying (Na_2SO_4) and evaporation provided a viscous yellow oil. Separation of the oxidation products (27.2 g; bp 90–96°C/0.85 Torr) from recovered starting material was achieved by fractional distillation *in vacuo*.

Typical Oxidation Procedure using Chromium Trioxide in Glacial Acetic Acid

A solution of (−)-bornyl acetate (**1**) (20 g, 0.10 mol) in glacial acetic acid (30 mL) was stirred and heated to reflux while a slurry of chromium trioxide (50 g, 0.50 mol, 3.75 equiv.) in glacial acetic acid (70 mL) was cautiously added in small portions over 40–80 min. A further portion of glacial acetic acid (70 mL) was used to wash the oxidising agent into the reaction vessel. Heating and stirring were continued for 30–80 min and the solution was cooled, diluted with water (600 mL), and extracted with ether (3 × 350 mL). The ether extracts were washed successively with excess aqueous sodium bicarbonate and saturated aqueous sodium chloride, dried (Na_2SO_4), and evaporated to give a pale yellow viscous oil. Separation of the oxidation products (7.3 g; bp 89–90°C/0.8 Torr) from unreacted starting material was achieved by fractional distillation *in vacuo*.

*Isolation of (−)-5-Oxobornyl Acetate (**3**)*

The fractionally distilled product from the oxidation of (−)-bornyl acetate with chromium trioxide in acetic acid readily crystallised upon standing at −20°C. Washing with ice-cold hexane followed by crystallisation from hexane gave (−)-*5-oxobornyl acetate* (**3**) as a colourless solid, mp 78°C (lit. (7*b*) mp 78°C, lit. (7*c*) mp 74–76°C); $[\alpha]_D^{25}$ −102.6° (*c* 1.96, $CHCl_3$) (lit. (7*c*) $[\alpha]_D$ −97° in $CHCl_3$)); ν_{max} (CCl_4): 1745, 1235, 1035 cm^{-1}; δ ($CDCl_3$): 0.94, 1.00, 1.01 (3H each, s, CH_3), 1.30 (1H, d of d, *J* = 3.5 and 14 Hz, 3-*endo*-H, collapses to d, *J* = 14 Hz, upon irradiation at 5.06 δ), 2.03 (3H, s, CH_3CO_2—), 2.16 (1H, d, *J* = 5 Hz, C(4)-H), 2.35–2.75 (2H, overlapping of d, *J* = 18 Hz (6 *endo*-H) and multiplet (3-*exo*-H), collapsing to d of d, *J* = 14 and 5 Hz, upon irradiation at 5.06 δ), 5.06 (1H, multiplet, collapsing to dd, *J* ~ 9 and 1–2 Hz, upon irradiation at 1.30 δ, 2-*exo*-H); *m/e* (relative intensity): 210(M^+, 24), 168(84), 124(36), 111(23), 109(32), 108(40), 107(34), 43(100), 41(24).

*(−)-5-Oxoborneol (**4**)*

A mixture of (−)-5-oxobornyl acetate (**3**) (1.00 g) and sodium carbonate decahydrate (1.37 g) in methanol (4 mL) and water (7 mL) was briefly heated to reflux and then allowed to stand for 48 h. The mixture was diluted with water, extracted with ether several times, and the ether extracts washed with water, dried (Na_2SO_4), and evaporated. Recrystallisation from cyclohexane gave (−)-*5-oxoborneol* (**4**) as a colourless solid (0.65 g, 81%), mp 239–241°C (sealed capillary) (lit. (7*c*) mp 247–248°C); $[\alpha]_D^{25}$ −87.0° (*c* 1.55, $CHCl_3$) (lit. (7*c*) $[\alpha]_D$ −74° in $CHCl_3$); ν_{max} ($CHCl_3$): 3630, 3480, 1745, 1035 cm^{-1}; δ ($CDCl_3$): 0.91, 0.95, 1.00 (3H each, s, CH_3), 1.27 (1H, d of d, *J* = 14 and 3.5 Hz, 3-*endo*-H), 1.86 (1H, d with fine coupling, *J* = 18 Hz, 6-*exo*-H), 2.13 (1H, d, *J* = 5 Hz, 4-H), 2.3–2.75 (2H, overlapping of doublet, *J* = 18 Hz, 6-*endo*-H, and of multiplet, 3-*exo*-H), 4.20 (1H, multiplet, 2-*exo*-H): d of d at 1.27 δ collapses to d (*J* = 14 Hz) upon irradiation of 4.20 δ; d with fine coupling at 1.86 δ collapses to d (*J* = 18 Hz) upon irradiation at 4.20 δ; *m/e* (relative intensity): 168(M^+, 49), 125(49), 124(100), 109(46), 71(30), 70(39), 55(32), 41(44).

*(−)-5-*exo-*Hydroxyborneol (**5**)*

To a freshly prepared solution of lithium trimethoxy aluminum hydride (13) (11.2 mmol) in tetrahydrofuran (25 mL), stirred under nitrogen at 0°C, was added a solution of 5-oxobornyl acetate (**3**) (250 mg, 1.2 mmol) in tetrahydrofuran (5 mL). Stirring was continued for 30 min at 0°C, then for 17 h at room temperature. Ether (25 mL) was added, followed by just sufficient water to decompose the excess reducing agent and produce a white, easily filtered precipitate. Filtration of the product followed by evaporation of the filtrate and crystallisation from benzene provided (−)-5-*exo*-hydroxyborneol (**5**) as a colourless solid (169 mg, 84%), mp 258–259°C (sealed capillary); $[\alpha]_D^{27}$ −16.3° (*c* 0.81, $CHCl_3$); ν_{max} ($CHCl_3$): 3650, 1040 cm^{-1}; δ ($CDCl_3$): 0.76, 0.81, 1.04 (3H each, s, CH_3), 1.25–1.50 (1H, multiplet), 1.73 (1H, d, *J* = 5 Hz, 4-H), 2.1–2.5 (2H, multiplet), 3.83 (2H, multiplet, 2-*exo*-H and 5-*endo*-H); *m/e* (relative intensity): 170(M^+, 4) 137(18), 126(29), 125(47), 111(100), 109(59), 83(17), 55(18), 43(22), 41(26). *Anal.* calcd. for $C_{10}H_{18}O_2$: C 70.55, H 10.66; found: C 70.50, H 10.76.

*(−)-5-*exo-*Acetoxybornyl Acetate (**7**)*

A solution of (−)-5-*exo*-hydroxyborneol (**6**) (50 mg) in pyridine (1.6 mL, dried by standing over potassium hydroxide pellets) and acetic anhydride (0.4 mL) was heated at 90°C with stirring while under nitrogen for 19 h. The mixture was diluted with water, extracted three times with ether, and the ether extracts washed successively with 1 *N* aqueous hydrochloric acid (excess), water, excess aqueous sodium bicarbonate, and saturated aqueous sodium chloride. The ether extracts were then dried (Na_2SO_4) and evaporated to give (−)-5-*exo*-acetoxybornyl acetate (**7**) as an almost colourless viscous oil (72 mg, 97%). Purification by preparative glc (30% SE-30) gave a colourless viscous oil; $[\alpha]_D^{27}$ −13.6° (*c* 1.49, $CHCl_3$); ν_{max} (CCl_4): 1740, 1230, 1030 cm^{-1}; δ ($CDCl_3$): 0.85, 0.90, 1.01 (3H each, s, CH_3), 1.49 (1H, multiplet), 1.88 (1H, d, *J* = 5 Hz, 4-H), 1.97 and 2.00 (3H each, s, CH_3CO_2—), 2.2–2.6 (2H, multiplet), 4.63 (1H, d of d, 5-*endo*-H), 4.78 (1H, multiplet, 2-*exo*-H); *m/e* (relative intensity): 254(M^+, 25), 195(30), 168(24), 152(27), 137(27), 135(27), 134(70), 126(30), 119(57),

109(73), 108(63), 93(37), 43(100). *Anal.* calcd. for $C_{14}H_{22}O_4$: C 66.12, H 8.72; found: C 66.16, H 8.67.

*Isolation of 6-Oxobornyl Acetate (**8**), 3-Oxobornyl Acetate (**11**), and 5-*exo*-Acetoxybornyl Acetate (**7**)*

The fractionally distilled oxidation product from the oxidation of bornyl acetate with chromium trioxide in acetic acid and acetic anhydride was cooled to −20°C for 7 days to promote crystallisation of 5-oxobornyl acetate (**3**). This was removed by filtration and the mother liquors subjected to column chromatography on silica gel (2.0 g of substrate, 200 g of silica gel deactivated to grade III; eluted with 15% ether in hexane). Two fractions were obtained, each of which was a mixture of two main components by glc (20% DEGS). Each component was isolated by preparative glc. Preparative glc (30% SE-30) of the more rapidly eluted fraction (0.42 g) provided 3-oxobornyl acetate (**11**) and 5-*exo*-acetoxybornyl acetate (**7**) in order of increasing retention time.

3-Oxobornyl acetate (**11**) was obtained as a colourless partially crystalline solid, a single component on tlc (silica gel, ether – petroleum ether 1:2) and glc (3% SE-30 and 5% QF-1); $[\alpha]_D^{25}$ −42.50° (*c* 1.0, $CHCl_3$); ν_{max} (CCl_4): 1755, 1250, 1060 cm^{-1}; δ ($CDCl_3$): 0.98 and 1.01 (6H and 3H respectively, s, CH_3), 2.11 (3H, s, CH_3CO_2—), 2.29 (1H, d, J = 5 Hz, 4-H) 5.19 (1 H, fine coupling, 2-*exo*-H); *m/e* (relative intensity): 210(M^+, 23), 168(39), 123(33), 122(18), 113(14), 81(14), 71(18), 69(12), 58(10), 55(13), 43(100); *Mol. Wt.* calcd. for $C_{12}H_{18}O_3$: 210.1256; found (mass spectrometry): 210.1237.

5-exo-*Acetoxybornyl acetate* (**7**) was obtained as a colourless viscous oil, identical with material from the acetylation of 5-*exo*-hydroxyborneol (**5**) by tlc (silica gel, ether – petroleum ether 1:1) and glc (3% SE-30 and 20% DEGS), as well as by nmr ($CDCl_3$) and ir (CCl_4) spectrometry.

Preparative glc (30% QF-1) of the less rapidly eluted fraction (1.31 g) provided 6-oxobornyl acetate (**8**) and 5-oxobornyl acetate (**3**) in order of increasing retention time.

6-Oxobornyl acetate (**8**) was isolated as a colourless partially crystalline solid, providing colourless crystals from hexane, mp 62–62.5°C; $[\alpha]_D^{25}$ +31.42° (*c* 1.13, $CHCl_3$); ν_{max} (CCl_4): 1750, 1245, 1075, 1050 cm^{-1}; δ ($CDCl_3$): 0.85, 0.94, 1.04 (3H each, s, CH_3), 1.27 (1H, d of d, J = 14 and 3 Hz, collapsing to d, J = 14 Hz, upon irradiation at 5.13 δ, 3-*endo*-H), 1.99 (3H, s, CH_3CO_2—), 5.13 (1H, d of d, J = 9 and 3 Hz, 2-*exo*-H); *m/e* (relative intensity): 210(M^+, 5), 168(46), 167(27), 153(100), 150(19), 121(21), 109(19), 108(58), 107(29), 43(39), 41(18). *Anal.* calcd. for $C_{12}H_{18}O_3$: C 68.55, H 8.63; found: C 68.49, H 8.55.

5-Oxobornyl acetate (**3**) was isolated as a colourless crystalline solid, identical with material previously isolated from the chromium trioxide – acetic acid oxidation of bornyl acetate by tlc (silica gel, ether – petroleum ether 1:2), glc (3% SE-30 and 5% QF-1), as well as by nmr ($CDCl_3$) and ir (CCl_4) spectrometry.

6-endo-*Hydroxyborneol* (**9**)

To a solution of 6-oxobornyl acetate (**8**) (81 mg) in dry ether (2 mL), stirred under nitrogen at −78°C, was added lithium aluminum hydride (37 mg, 3.4 equiv.) in three portions over 15 min. After stirring at −78°C for a further 3 h the mixture was allowed to warm to room temperature and the stirring continued for a further 19 h. Just sufficient water was added to decompose the aluminum salts to a readily filtered precipitate and the mixture was filtered and the filtrate evaporated. This provided a colourless viscous oil which was purified by column chromatography on silica gel (9 g, deactivated to grade III, and eluted with ether – petroleum ether 1:2). This gave 6-*endo*-hydroxyborneol (**9**) (53 mg, 81%), mp 258–260°C (from hexane) (sealed capillary); $[\alpha]_D^{25}$ −0.05 ± 0.06° (*c* 3.46, $CHCl_3$); ν_{max} (1% in $CHCl_3$): 3620, 3480, 1130, 1060 cm^{-1}; δ ($CDCl_3$): 0.84 (6H, s, C(8)- and C(9)-CH_3), 1.06 (3H, s, C(10)-CH_3), 1.34 (2H, d of d, J = 12.5 and 2.5 Hz; collapsing to d, J = 12.5 Hz, upon irradiation at 4.25 δ; collapsing to d, J = 2–3 Hz, upon irradiation at 2.47 δ; 3-*endo*- and 5-*endo*-H), 1.75 (1H, t, J = 5 Hz, collapsing to s upon irradiation at 2.47 δ, C(4)-H), 2.47 (2H, multiplet (d of d of d), J = 12.5, 9.5, and 5 Hz; collapsing to d of d, J = 12.5 and 5 Hz upon irradiation at 4.25 δ; collapsing to d of d, J = 12.5 and 9.5 Hz, upon irradiation at 1.75 δ; collapsing to d of d, J = 9.5 and 5 Hz upon irradiation at 1.34 δ; 3-*exo*- and 5-*exo*-H), 4.25 (2H, d, of d, J = 9.5 and 2.5 Hz, collapsing to doublet, J = 9.5 Hz, upon irradiation at 1.34 δ; collapsing to broad singlet upon irradiation at 2.47 δ; 2-*exo*- and 6-*exo*-H); δ (C_6D_6): 0.64 (6H, s, C(8)- and C(9)-CH_3), 1.08 (3H, s, C(10)-CH_3), 1.25–1.6 (3H, complex, 3-*endo*-, 5-*endo*-, and C(4)-H), 2.33 (2H, m, 3-*exo*- and 5-*exo*-H), 4.19 (2H, m, 2-*exo*- and 6-*exo*-H); δ (CCl_4): 0.82 (6H, s, C(8)- and C(9)-CH_3), 0.98 (3H, s, C(10)-CH_3), 1.30 (2H, poorly resolved d of d, J = 2–3 and 13 Hz, 3-*endo*- and 5-*endo*-H), 1.68 (1H, t, J = 4.5 Hz, C(4)-H), 2.39 (2H, m, 3-*exo*- and 5-*exo*-H), 4.12 (2H, poorly resolved d of d, J = 2–3 and 10 Hz, 2-*exo*- and 6-*exo*-H); *m/e* (relative intensity): 109(17), 108(100), 95(9), 93(18), 68(5), 55(5), 43(6), 41(112), no molecular ion visible. *Anal.* calcd. for $C_{10}H_{18}O_2$: C 70.55, H 10.66; found: C 70.56, H 10.74.

(−)-3-exo-*Hydroxyborneol* (**12**)

To a solution of 3-oxobornyl acetate (**11**) (approximately 10 mg) in dry ether (1 mL), stirred at −78°C under nitrogen, was added lithium aluminum hydride (22 mg). Stirring was continued at −78°C for 4 h then at 25°C for 18 h, and the mixture was worked up by adding just sufficient water to decompose the aluminum salts to a readily filterable precipitate. Filtration and evaporation of the ether followed by column chromatography (silica gel, 0.5 g, elution with ether – petroleum ether 1:2) provided (−)-3-*exo*-hydroxyborneol (**12**). The physical constants and spectroscopic and glc characteristics of this product were identical to those recorded for the sample of **12** isolated from *H. sativum* (*vide infra*).

*Oxidation of (−)-5-Oxoborneol (**4**) and (−)-5*-exo-*Hydroxyborneol (**5**)*

Treatment of (−)-5-oxoborneol (**4**) or (−)-5-*exo*-hydroxyborneol (**5**) with pyridinium chlorochromate (14) in methylene chloride at room temperature for 4–5 h provided (−)-bornane-2,5-dione (**6**) in ~80% yield; mp 207–209°C; $[\alpha]_D$ −113°. The product had the same ir (CCl_4), nmr (CCl_4 and C_6D_6), tlc (silica gel, petroleum ether – ether 1:1), and glc (3% SE-30, Carbowax C-20M, and 20% DEGS)[9] characteristics as authentic (+)-bornane-2,5-dione prepared from (+)-camphor.

Oxidation of 6-endo-*Hydroxyborneol (**9**)*

Treatment of 6-*endo*-hydroxyborneol (**9**) (11 mg) with pyridinium chlorochromate in CH_2Cl_2 (14) for 6 h gave, after preparative glc (20% DEGS), bornane-2,6-dione (**10**) as a colourless solid (31% yield) with the same spectroscopic and glc characteristics as authentic bornane-2,6-dione prepared from (+)-camphor (*vide infra*).

(+)-Bornane-2,5-dione and Bornane-2,6-dione

Oxidation of (+)-camphor with chromium trioxide in acetic acid – acetic anhydride according to the literature procedure (15) provided a mixture of bornanediones (~7% yield) which were separated by preparative glc (30% SE-30).[10]

Bornane-2,6-dione (**10**) of shorter retention time, crystallised

[10]10% Carbowax C-20M resolves 2,3-, 2,5-, and 2,6-bornanediones; 20% DEGS separates 2,6-dione from the 2,3- and 2,5-diones; and 3% SE-30 separates 2,5-dione from the 2,3- and 2,6-diones.

from hexane, mp 190–192°C (sealed capillary) (lit. (15) mp 194–195°C, lit. (16) mp 192–193°C); $[\alpha]_D$ +0.7° (*c* 2.59, $CHCl_3$); ν_{max} (CCl_4): 1770, 1735 cm^{-1}; δ ($CDCl_3$): 0.95 (3H, s), 0.99 (6H, s); δ (C_6D_6): 0.48 (6H, s), 0.97 (3H, s) 1.80 (1H, t, J = 5 Hz, C(4)-H); *m/e* (relative intensity): 166(M^+, 96), 123(38) 109(38), 97(61), 95(48), 83(40), 81(52), 69(65), 41(100), 39(52).

(+)-Bornane-2,5-dione (enantiomer of **6**) crystallised from hexane, mp 210–211°C (sealed capillary) (lit. (7*c*) mp 213–214°C); $[\alpha]_D^{26}$ +115° (*c* 1.71, $CHCl_3$); ν_{max} (CCl_4): 1755 cm^{-1}; δ ($CDCl_3$): 0.97 (3H, s), 1.05 (6H, s); *m/e* (relative intensity): 166(M^+, 93), 123(54), 95(37), 83(59), 81(31), 69(78), 67(23), 53(25), 41(100).

Fermentation with H. sativum

Helminthosporium sativum[11] was grown in 1-L Erlenmeyer flasks each containing modified Czapek-Dox medium (200 mL) (water (200 mL), sucrose (6 g), sodium nitrate (0.4 g), yeast extract (0.2 g), potassium dihydrogen phosphate (0.2 g), potassium chloride (0.1 g), magnesium sulphate heptahydrate (0.1 g), iron(III) (0.1 mg), zinc(II) (0.1 mg), manganese(II) (0.05 mg), and copper(II) (0.1 mg)) on a rotary shaker (106 rpm) at 26°C. After 3 days (+)- or (−)-bornyl acetate was added (0.2 g per flask). After a further 7–10 days the mycelium was separated by filtration and the culture filtrate extracted with ether, using a continuous extraction apparatus, for 3 days. The ether extract was dried (Na_2SO_4) and evaporated to provide the crude fermentation product.

Isolation of Hydroxyborneols ***5***, ***20***, ***21***, *and* ***12***

The crude fermentation product (2.0 g) from fermentation with (−)-bornyl acetate (~2 g) as substrate was purified by column chromatography on silicic acid (50 g). After elution of the less strongly absorbed material (0.4 g) with chloroform, the hydroxyborneols were removed as a mixture (1.2 g) with 3% methanol in chloroform. A portion of this mixture of hydroxyborneols (0.5 g) was purified further by several cycles of column chromatography (silica gel, deactivated to grade III, 100:1 ratio of adsorbant to substrate, eluted with ether – petroleum ether 1:1 then 2:1). This provided fractions that were sufficiently pure in each of the four hydroxyborneols for them to be purified by recrystallisation from benzene.

(−)-5-exo-*Hydroxyborneol* (**5**) (135 mg), mp 257–259°C (sealed capillary); $[\alpha]_D^{27}$ −15.9° (*c* 0.94, $CHCl_3$), identical to previously characterised 5-*exo*-hydroxyborneol (**5**) (*vide supra*) by nmr ($CDCl_3$), ir ($CHCl_3$ and Nujol mull), mass spectrometry as well as by tlc and mixture melting point.

(−)-5-endo-*Hydroxyborneol* (**20**) (37 mg), mp 244.5–245.5°C (sealed capillary); $[\alpha]_D^{25}$ −33.25° (*c* 0.8, $CHCl_3$); ν_{max} ($CHCl_3$): 3600, 3450, 1060 cm^{-1}; δ ($CDCl_3$): 0.82 (3H, s, CH_3), 0.91 (6H, s, CH_3), 1.6–1.85 (4H, complex), 1.9–2.4 (1H, complex), 4.06 (1H, d of d, J = 4 and 10 Hz, 2-*exo*-H), 4.44 (1H, complex, 5-*exo*-H); *m/e* (relative intensity): 170(M^+, 30), 152(30), 137(63), 111(50), 109(100), 108(84), 95(31), 41(27), 32(23). *Anal.* calcd. for $C_{10}H_{18}O_2$: C 70.55, H 10.66; found: C 70.73, H 10.60.

(−)-6-exo-*Hydroxyborneol* (**21**) (18 mg), mp 268–270.5°C (sealed capillary); $[\alpha]_D^{25}$ −56.4° (*c* 0.96, CH_3CN); ν_{max} ($CHCl_3$): 3600, 1070, 1050 cm^{-1}; δ ($CDCl_3$): 0.82, 0.95, 1.03 (3H each, s, CH_3), 1.6–1.95 (3H, complex), 2.0–2.4 (1H, complex), 4.04 (1H, d of d, J = 10 and 4 Hz, 2-*exo*-H) 4.33 (1H, m, 6-*endo*-H); *m/e* (relative intensity): 170(M^+, 1), 111(17), 109(41), 108(100), 95(16), 93(18), 55(13), 43(18), 41(23). *Anal.* calcd. for $C_{10}H_{18}O_2$: C 70.55, H 10.66; found: C 70.41, H 10.50.

[11]Subculture from single spore of culture isolated by Dr. Stanley Chinn (Canada Agricultural Research Station, Saskatoon, Sask.) from wheat (subculture sent to ATCC).

(−)-3-exo-*Hydroxyborneol* (**12**) (17 mg), mp 247–240°C (sealed capillary); $[\alpha]_D^{25}$ −19.4° (*c* 0.66, $CHCl_3$); ν_{max} ($CHCl_3$): 3650, 3470, 1060, 1050 cm^{-1} (cf. ref. 8*b*); δ ($CDCl_3$): 0.86, 0.89, and 1.09 (3H each, s, CH_3), 1.65–2.0 (3H, complex), 3.55 (1H, d, J = 2Hz, 3-*endo*-H), 3.97 (1H, m, 2-*exo*-H); the nmr spectrum in pyridine-d_5 with a trace of D_2O is identical to published spectrum (8*a*); *m/e* (relative intensity): 170(M^+, 3), 152(31), 123(18), 111(67), 109(32), 108(35), 95(100), 81(29), 69(25), 60(18), 55(18), 43(22), 41(28), 32(19), 31(18). *Anal.* calcd. for $C_{10}H_{18}O_2$: C 70.55, H 10.66; found: C 70.41, H 10.76.

5-exo-, 5-endo-, 6-exo-, *and* 3-exo-*Acetoxybornyl Acetates*

Hydroxyborneol **5**, **20**, **21**, or **12**, (5–15 mg) was stirred with pyridine – acetic anhydride (4:1, 2 mL) at 90°C under nitrogen for 18–21 h. After dilution with water (10 mL) and extraction with ether (3 × 5 mL), the ether extracts were washed successively with excess 1 *N* aqueous hydrochloric acid, water, excess saturated aqueous sodium bicarbonate, and saturated aqueous sodium chloride. Removal of solvent provided the appropriate acetoxybornyl acetate in almost quantitative yield.

5-exo-*Acetoxybornyl acetate* (**7**) was identical by tlc (silica gel, ether – petroleum ether 1:1) and glc (3% SE-30 and 20% DEGS) as well as nmr ($CDCl_3$), ir (CCl_4), and mass spectrometry to material isolated from chemical oxidation of bornyl acetate (*vide supra*).

5-endo-*Acetoxybornyl acetate* derived from **20**; ν_{max} (CCl_4): 1740, 1240 cm^{-1}; δ ($CDCl_3$): 0.83 (3H, s, CH_3), 0.97 (6H, s, CH_3), 2.07 and 2.10 (3H each, s, CH_3CO_2), 4.94 (1H, d of d, J = 9 and 3.5 Hz, 2-*exo*-H), 5.15 (1H, m, 5-*exo*-H); *m/e* (relative intensity): 254(M^+, 21), 195(73), 152(32), 137(27), 135(40), 134(27), 119(48), 109(53), 108(41), 93(43), 43(100), 32(25).

6-exo-*Acetoxybornyl acetate* derived from **21**; ν_{max} (CCl_4) 1740, 1235, 1060, 1040 cm^{-1}; δ ($CDCl_3$): 0.89, 0.93, and 1.03 (3H each, s, CH_3), 2.05 and 2.08 (3H each, s, CH_3CO_2—), 4.99 (1H, d of d, J = 10 and 3.5 Hz, 2-*exo*- or 6-*endo*-H), 5.31 (1H, d of d, J = 7.5 and 4 Hz, 2-*exo*- or 6-*endo*-H); *m/e* (relative intensity): 254(M^+, 15), 212(6), 197(6), 194(5), 152(14), 134(9), 119(12), 109(16), 108(100), 95(6), 93(9), 43(34), 41(7), 32(16).

3-exo-*Acetoxybornyl acetate* derived from **12**; ν_{max} (CCl_4): 1740, 1240, 1045 cm^{-1}; δ ($CDCl_3$): 0.87, 0.88, and 1.08 (3H each, s, CH_3) 2.06 and 2.10 (3H each, s, CH_3CO_2), 4.50 (1H, d, J = 3 Hz, 3-*endo*-H), 5.21 (1H, m, 2-*exo*-H); *m/e* (relative intensity): 254(M^+, 4), 152(51), 137(22), 135(28), 134(44), 124(10), 123(23), 119(29), 109(20), 108(13), 102(24), 96(10), 95(48), 83(14), 81(12), 80(22), 43(100), 41(14).

Oxidation of (−)-5-endo-*Hydroxyborneol (**20**)*

Treatment of 5-*endo*-hydroxyborneol (**20**) (8 mg) with pyridinium chlorochromate (14) for 6 h gave (−)-bornane-2,5-dione as a colourless solid (6 mg, 76% yield); nmr (in CCl_4 and C_6D_6), ir (CCl_4), tlc (silica gel, ether – petroleum ether 1:1), and glc (3% SE-30, 10% Carbowax C-20M, and 20% DEGS) characteristics identical to those of authentic bornane-2,5-dione (*vide supra*).

Oxidation of 6-exo-*Hydroxyborneol (**21**)*

Treatment of 6-*exo*-hydroxyborneol (**21**) (10 mg) with pyridinium chlorochromate (14) for 6 h gave bornane-2,6-dione (**10**) as a colourless solid after preparative glc purification (20% DEGS); nmr ($CDCl_3$ and C_6D_6), ir (CCl_4) spectra of this specimen of **10** were identical to those recorded for the authentic compound prepared from camphor (*vide supra*).

*Hydroxylation of (+)-Bornyl Acetate (**22**) by* H. sativum

The reaction product from fermentations using (+)-bornyl acetate (**22**) as substrate was acetylated and then analysed by comparing the nmr and glc characteristics with the diacetates derived from hydroxyborneols **5**, **20**, **21**, and **12** (*vide supra*).

The results obtained from four experiments indicated that the original microbiological product was a mixture of (+)-5-*exo*-hydroxyborneol (**23**), (+)-5-*endo*-hydroxyborneol (**24**), and (+)-3-*exo*-hydroxyborneol (**25**). The yields of diols from four separate fermentations are shown in Table 3.

Quantitative Gas–Liquid Chromatographic Analysis of H. sativum *Products*

Analysis of Fermentation Extracts Directly

This was performed on a Varian Aerograph model 90-P chromatograph fitted with TC detector and analytical 20% DEGS column, using 10–100 μL injections of solutions in ethyl acetate. With a column oven temperature of ~130°C the absolute quantity of hydroxyborneols was determined by injecting known quantities of the fermentation products and comparing the area of the peak corresponding to the hydroxyborneols with that arising from the injection of known quantities of pure 5-*exo*-hydroxyborneol as a standard. In the same way, using a column oven temperature of ~70°C and (−)-bornyl acetate as standard, it was possible to determine the absolute quantities of bornyl acetate and borneol. All injections were performed several times to ensure reproducibility of the results, and fermentation peak areas were only compared with those of standards that had been injected immediately beforehand.

Analysis of Acetylated Fermentation Extracts

Fermentation extracts were acetylated in the usual way and the acetylated products were analysed by glc (analytical 3% SE-30 column at ~100°C). The absolute quantities of acetoxybornyl acetates were determined by using 5-*exo*-acetoxybornyl acetate (**13**) as a standard, taking the same precautions that are described above. The identity of the peaks in the glc analysis was confirmed by isolation (preparative glc, 30% SE-30) and nmr analysis of the isolated components.

Fermentation with F. culmorum

Fusarium culmorum[12] was grown in 4-L Erlenmeyer flasks each containing Raulin–Thom medium (1 L) (water (1 L), glucose (50 g), tartaric acid (2.7 g), ammonium tartrate (2.7 g), ammonium phosphate $NH_4H_2PO_4$ (0.4 g), potassium carbonate (0.4 g), magnesium carbonate 0.27 g), ammonium sulphate (0.17 g), zinc sulphate heptahydrate (0.047 g), and ferrous sulphate heptahydrate (0.047 g)) on a rotary shaker (120 rpm) at 26°C. After 7 days, (+)- or (−)-bornyl acetate was added (1.0 g per flask). After a further 18 days the mycelium was separated by filtration and the culture filtrate extracted with ether using a continuous extraction apparatus for 3 days. The ether extract was dried (Na_2SO_4) and evaporated to provide the crude fermentation product.

*Isolation of 5-*exo*-Hydroxybornyl Acetate (**26**)*

The crude fermentation product (3.01 g) was purified by column chromatography (silicic acid, 180 g). Elution with $CHCl_3$ provided 5-*exo*-hydroxybornylacetate (**26**) (900 mg; 97% pure by glc); ν_{max} ($CHCl_3$): 3600, 1720, 1250, and 1040 cm^{-1}; δ ($CHCl_3$): 0.84, 0.86, 1.09 (3H each, s, CH_3), 1.99 (3H, s, CH_3CO_2—) 3.84 (1H, d of d, J = 7.5 and 3 Hz, 5-*endo*-H), 4.76 (1H, m, 2-*exo*-H).

*5-*exo*-Acetoxybornyl Acetate (**7**)*

5-*exo*-Hydroxybornyl acetate (**26**) (41 mg), isolated in 96% purity (glc, 10% Carbowax C-20M TPA) from silicic acid chromatography of the crude fermentation product, was stirred at 90°C under a nitrogen atmosphere with pyridine–acetic anhydride (4:1, 2 mL) for 22 h. The reaction mixture was diluted with water (10 mL), extracted with ether (3 × 5 mL), and the ether layers washed with excess aqueous 1 *N* hydrochloric acid, water, excess saturated aqueous sodium bicarbonate, and saturated aqueous sodium chloride. Removal of solvent provided 5-exo-*acetoxybornyl acetate* (**7**), identical by tlc (silica gel, ether – petroleum ether 1:2), glc (3% OV-17 and 10% Carbowax C-20M; HP-5831A), and by nmr ($CDCl_3$) and ir ($CHCl_3$) spectrometry to material prepared previously by lithium trimethoxy aluminum hydride reduction of 5-oxobornyl acetate (**3**) followed by acetylation (*vide supra*).

*Oxidation of 5-*exo*-Hydroxybornyl Acetate (**26**)*

Treatment of 5-*exo*-hydroxybornyl acetate (**26**) (46 mg) with pyridinium chlorochromate (14) for 7 h gave 5-oxobornyl acetate (**3**) (41 mg), identical by tlc (silica gel, ether – petroleum ether 1:2) and glc (3% OV-17 and 10% Carbowax C-20M TPA; HP-5831A) and by nmr ($CDCl_3$) and ir ($CHCl_3$) spectrometry with authentic material isolated from the oxidation of bornyl acetate with chromium trioxide – acetic acid (*vide supra*).

Quantitative Gas–Liquid Chromatographic analysis of F. Culmorum *Products*

Quantitative glc analysis of the fermentation products of (+)- and (−)-bornyl acetate was performed using (−)-camphorquinone as an added internal standard. The relative detector responses to borneol, bornyl acetate, 5-*exo*-hydroxybornyl acetate, and (−)-camphorquinone were determined by injection of a mixture of known quantities of the four substrates (10% Carbowax C-20M TPA; HP-5831A); an average of three determinations was taken. By injection of a mixture of a known quantity of the fermentation product and a known quantity of camphorquinone (10% Carbowax C-20M TPA; HP-5831A) the relative peak areas, after correction for the detector response, were used to determine the absolute quantities of borneol, bornyl acetate, and 5-*exo*-hydroxybornyl acetate; an average of two determinations was taken.

[12]Subculture of culture No. CBS 171.28 obtained from Centraal-bureau voor Schimmelcultures, Baarn, Holland.

Synthesis and absolute configuration of nojigiku alcohol

NICHOLAS DARBY, NANCY LAMB, AND THOMAS MONEY
Chemistry Department, The University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received September 26, 1978

NICHOLAS DARBY, NANCY LAMB, and THOMAS MONEY. Can. J. Chem. **57**, 742 (1979).

The structure, absolute configuration and physical constants of nojigiku alcohol ((+)-6-*exo*-hydroxycamphene) and derivatives have been established by synthesis from (−)-isobornyl acetate.

NICHOLAS DARBY, NANCY LAMB et THOMAS MONEY. Can. J. Chem. **57**, 742 (1979).

On a déterminé la structure, la configuration absolue et les constantes physiques de l'alcool nojigiku ((+)-hydroxy-6 *exo*-camphène) et de ses dérivés grâce à une synthèse à partir de l'acétate du (−)-isobornyle.

[Traduit par le journal]

Nojigiku alcohol (**10**) (6-*exo*-hydroxycamphene), a metabolite of *Chrysanthemum japonense* (1), has previously been synthesised in low yield from camphene (2) and tricyclene (3). Our interest in applying remote oxidation techniques to the synthesis of various mono- and sesquiterpenoids has resulted in an alternative synthesis of this naturally occurring camphene derivative.

Remote oxidation of (−)-isobornyl acetate (**2**) with CrO_3/HOAc/Ac_2O provided a mixture (4:1) of 5-ketoisobornyl acetate (**3**) and its 6-keto isomer (**4**) in ~55% yield (4). Treatment of this mixture with SeO_2 gave 5,6-diketoisobornyl acetate (**5**) (50% yield) which underwent regiospecific and stereoselective reduction with Zn/HOAc (5–7) to provide 6-*endo*-hydroxy-5-ketoisobornyl acetate (**6**) (~82% yield).

The regiospecificity and stereoselectivity of the latter reaction was established by nmr and chemical evidence. For example the nmr of **6** showed absorption at 6.15 τ which is almost identical to that found in 2-*endo*-hydroxyepicamphor (**13**) (5–7) and differs markedly from the C(3)-*exo*-hydrogen absorption (5.78 τ) in 3-*endo*-hydroxycamphor (**14**) (5, 6). The presence of a C(6)-*endo*-hydroxy group in **6** is also supported by the fact that the C(2)-*endo*-hydrogen (4.75 τ) is shifted downfield from its expected position (cf. isobornyl acetate, C*H*OAc, 5.43 τ). This effect of a C(6)-*endo*-hydroxyl on the neighbouring C(2)-*endo*-hydrogen in bornane systems is also evident when the nmr of isoborneol (**15**) and 6-*endo*-hydroxyisoborneol (**16**) or isobornyl acetate (**2**) and 6-*endo*-hydroxyisobornyl acetate (**7**) are compared (8). Chemical evidence for the structure of **6** was obtained by an alternative synthesis involving low-yield α-hydroxylation (MoO_5/HMPA/C_5H_5N) (9) of 5-ketoisobornyl acetate (**3**). In addition reduction of the derived thioketal (*vide infra*) followed by hydrolysis provided 6-*endo*-hydroxyisoborneol (**16**), a compound whose structure has been confirmed by nmr evidence and oxidation to 2,6-bornanedione (8).

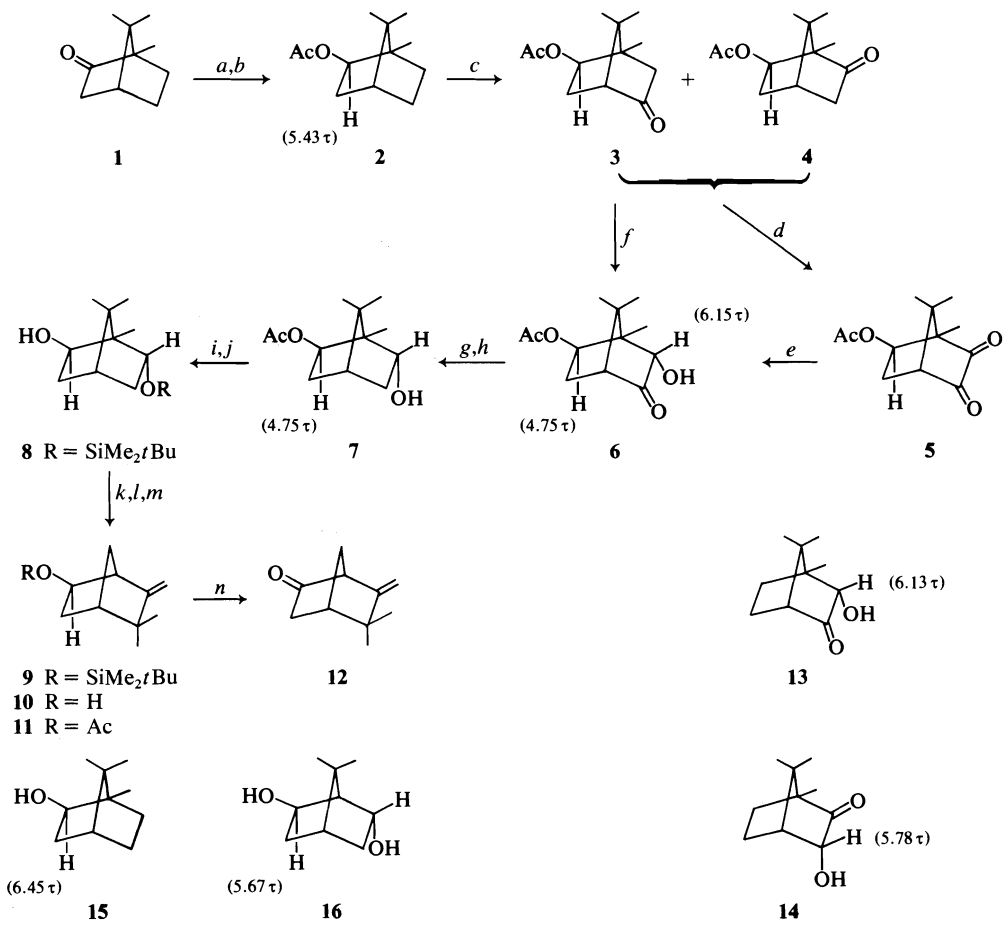
The regiospecificity of the Zn/HOAc reduction of 5,6-diketoisobornyl acetate (**5**) was totally unexpected since the analogous reaction involving camphorquinone provides a mixture (2:1) of 2-*endo*-hydroxyepicamphor (**13**) and 3-*endo*-hydroxycamphor (**14**) (5). We conclude, therefore, that the regiospecificity of the Zn/HOAc reduction of 5,6-diketoisobornyl acetate (**5**) is probably due to some unknown directing effect of the C(2)-acetate group.

Thioketalisation of **6** followed by reduction (Raney Ni) gave 6-*endo*-hydroxyisobornyl acetate (**7**) (14) which was converted to the *tert*-butyldimethylsilyl (TBDMS) (10) ether and subsequently hydrolysed (Na_2CO_3/MeOH) to hydroxyether **8** in 50% overall yield. Wagner–Meerwein rearrangement (MsCl/C_5H_5N) of **8** followed by removal of the TBDMS group with Bu_4NF/THF or HOAc/H_2O/THF (3:1:1) provided nojigiku alcohol (**10**) (1), mp 67.5–69.5°C (sealed tube), sublimation point 52°C (lit. (1) mp 52–53°C, lit. (2*c*) mp 59.5–60°C); $[\alpha]_D$ +58.6° (*c* 1.33, $CHCl_3$), +60.4° (*c* 1.16, $CHCl_3$) (lit. (1) $[\alpha]_D$ +12° (*c* 1.1, $CHCl_3$), lit. (2*c*) $[\alpha]_D$ +9°).

Although the nmr and ir spectra of our synthetic material are identical to those of the natural compound (12)[1] the specific rotation of **10** (measured at different concentrations and on two different instruments (Perkin Elmer 141 and 241MC)) was significantly different from the value quoted in the literature. Similar differences were noted for the corresponding acetate (**11**) (1), $[\alpha]_D$ +37.6° (*c* 1.11, $CHCl_3$) (lit. (1) $[\alpha]_D$ +20.9° (*c* 0.58, $CHCl_3$), +11.6° (*c* 1.20, $CHCl_3$)) and ketone (**12**) (1), mp 73.5–

[1]We are grateful to Dr. A. Matsuo and co-workers (Hiroshima University) for providing us with ir and nmr spectra of nojigiku alcohol.

0008-4042/79/070742-05$01.00/0



(*a*) $LiAlH_4$; (*b*) Ac_2O/C_5H_5N; (*c*) $CrO_3/Ac_2O/HOAc$; (*d*) SeO_2; (*e*) Zn/HOAc; (*f*) $MoO_5/HMPA/C_5H_5N$; (*g*) $(CH_2SH)_2/BF_3 \cdot Et_2O$; (*h*) Raney Ni; (*i*) $tBuMe_2SiCl$/imidazole; (*j*) KOH/EtOH; (*k*) $MsCl/C_5H_5N/\Delta$; (*l*) Bu_4NF/THF; (*m*) Ac_2O/C_5H_5N; (*n*) $CrO_3/C_5H_5N/HCl$

75.5°C (sealed tube), sublimation point 40°C; $[\alpha]_D$ +155.3° (*c* 0.91, $CHCl_3$) (lit. (1) mp 47–48°C; lit. (1) $[\alpha]_D$ +33.7° (*c* 0.86, $CHCl_3$)). Regeneration of 6-*exo*-hydroxycamphene (**10**), $[\alpha]_D$ +58.86° (*c* 0.88, $CHCl_3$), from acetate **11** and its subsequent oxidation to ketone **12**, $[\alpha]_D$ +158.2° (*c* 0.79, $CHCl_3$), provided further support for the authenticity of the physical constants we have recorded for these compounds.[2] Gas–liquid chromatographic evidence (see Experimental) demonstrated that the synthetic alcohol **10** was pure and the absence of common chemical shifts in the nmr spectra of **10** and its enantiomer, measured in the presence of a chiral shift reagent (TFMC-Eu) (13), indicated that our synthetic alcohol **10** was also optically pure. We conclude, therefore, that the specific rotation of (+)-6-*exo*-hydroxycamphene (nojigiku alcohol) (**10**) falls within the range, +55 to 61° (see Experimental). This conclusion is relevant to recent studies on the free radical benzoyloxylation of camphene (2*c*) since the mechanism proposed for that reaction was based, to some extent, on the assumption that the specific rotation of pure 6-*exo*-hydroxycamphene is approximately +12°.

Experimental

Unless otherwise stated the following are implied. Melting points (mp) were determined on a Kofler micro heating stage or a Thomas Hoover capillary melting point apparatus and are uncorrected. Gas chromatography was carried out on either a Hewlett-Packard model 5831A gas chromatograph using 6 ft × $\frac{1}{8}$ in. columns and nitrogen as carrier gas, or a Varian Aerograph model 90-P with 5 ft × $\frac{1}{4}$ in. columns and helium as carrier gas. The following columns were employed.

[2](−)-6-*exo*-hydroxycamphene, (−)-6-acetoxycamphene, and (−)-6-oxocamphene, synthesised from (−)-camphor by the route outlined above, have specific rotations numerically equivalent to those of the enantiomers (9–11).

Column	Dimensions	Stationary phase	Support	Mesh	
A	6 ft × ⅛ in.	3% OV17	Chromosorb W (HP)	80–100	Hewlett-Packard 5831A
B	6 ft × ⅛ in.	3% OV101	Chromosorb W (HP)	80–100	
C	6 ft × ⅛ in.	3% OV210	Chromosorb W (HP)	80–100	
D	6 ft × ⅛ in.	10% DEGS	Chromosorb W (HP)	80–100	
E	6 ft × ⅛ in.	10% Carbowax	Chromosorb W (HP)	80–100	
F	5 ft × ¼ in.	3% SE30	Varaport 30	100–120	Varian 90-P
G	5 ft × ¼ in.	20% DEGS	Chromosorb W	80–100	

Carrier gas flow rate for ¼ in. columns was about 60 mL/min and for ⅛ in. columns about 35 mL/min. The 60 MHz nmr spectra were recorded on a Varian Associates model T-60 whereas 100 MHz spectra were recorded on Varian Associates model HA-100 or XL-100. Signal positions are given in the Tiers tau scale (τ) with tetramethylsilane (TMS) as an internal reference. Signal multiplicity and integrated area are indicated in parentheses. Infrared spectra were recorded on a Perkin-Elmer 137 spectrophotometer and optical rotations were measured with either a Perkin-Elmer model 141 or 241 MC polarimeter. Low resolution mass spectra were recorded on a Varian/Mat model CH4B mass spectrometer and high resolution mass spectra were determined on the AEI model MS902 or model MS 50 instrument. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver. All the solvents used for nmr, ir, and optical rotations were of Spectral grade. Zinc dust purchased from Fisher Scientific Company.

*(−)-Isoborneol (**15**)*

(+)-Camphor (**1**) (40.0 g, 0.26 mmol) (Eastman Kodak Co., $[\alpha]_D^{25}$ +41.2° (*c* 1.06, $CHCl_3$)) in dry THF (~100 mL) was added dropwise (1 h) to a stirred suspension of lithium aluminum hydride (10.0 g, 0.26 mmol) in dry tetrahydrofuran (100 mL) at 0–5°C. The reaction mixture was then stirred at 0°C for 4 h and excess lithium aluminum hydride hydrolysed by dropwise addition of water (10 mL), followed by 2 *N* sodium hydroxide (10 mL) and then water (40 mL). The white precipitate was filtered off, washed with ether and the combined filtrates dried with anhydrous magnesium sulphate. Removal of the solvent gave a colorless crystalline product (40 g) which was shown, by glc analysis (column *D*; carrier gas, nitrogen; flow rate 38 mL/min; 120°C), to be a mixture of (−)-isoborneol (retention time 3.49 min) (92%) and borneol (retention time 4.17 min) (8%). Recrystallization of the crude product from petroleum ether (30–60°C) provided isoborneol (98% pure by glc); τ (CCl_4): 6.49 (dd, 1H, J = 7.0 and 2.0 Hz), 9.02, 9.16, and 9.21 (three singlets, 9H); ν_{max} (CCl_4): 3790, 3500, 2850 and 2800, 1070 cm^{-1}.

*(−)-Isobornyl Acetate (**2**)*

A mixture of (−)-isoborneol (37.0 g, 0.24 mol), acetic anhydride (43.0 g, 0.42 mol), and dry pyridine (120 mL) was heated at 100°C under nitrogen for 11 h. The reaction mixture was cooled, diluted with water, and extracted with ether. The combined ether extract was washed with water, 2 *N* hydrochloric acid, water, saturated sodium bicarbonate, and dried over anhydrous magnesium sulphate. Removal of solvent followed by distillation (43–50°C/0.05 Torr) provided isobornyl acetate (**2**) as a colorless oil (45 g, 96% yield); τ (CCl_4): 5.44 (m, 1H), 8.10 (s, 3H), 9.06, 9.20 and 9.21 (3 singlets, 9H); ν_{max} (CCl_4): 2900, 2850, 1740, and 1245 cm^{-1}; *m/e*: 194(M^+), 154, 136; $[\alpha]_D$ −51.8° (*c* 1.29, $CHCl_3$) (lit. (11) $[\alpha]_D$ −50.2° (EtOH)).

*Oxidation of (−)-Isobornyl Acetate (**2**)*

Chromium trioxide (80.0 g, 0.80 mol) in acetic anhydride (140 mL) was slowly added (2 h) to a cooled (ice bath) and vigorously stirred solution of (−)-isobornyl acetate (**2**) (45.0 g, 0.23 mol) in glacial acetic acid (200 mL) and acetic anhydride (100 mL). The reaction mixture was then stirred for 8 days at room temperature, diluted with water, and extracted with ether. (The heavy emulsion formed during extraction was broken up by filtration through Celite.) The combined ether extract was neutralized with sodium carbonate and then washed successively with water, 3 *N* hydrochloric acid, water, saturated sodium bicarbonate, water, and dried over anhydrous magnesium sulphate. Removal of solvent and glc analysis of the crude oily product (36 g) showed that it was mainly a mixture of unreacted isobornyl acetate, 6-oxoisobornyl acetate (**4**) (retention time 7.19 min), and 5-oxoisobornyl acetate (**3**) (retention time 7.79 min) (column *A*, carrier gas, nitrogen; flow rate 41 mL/min; 110°C). Fractional distillation, using a 5-in. Vigreux column, gave a mixture of 5- and 6-oxoisobornyl acetate (about 4:1 by glc) (19.6 g, 40% yield); τ (CCl_4): 5.36 (dd, J = 7.5, 4.0 Hz), 5.14 (dd, J = 7.0, 4.5 Hz), 7.98 (s, 3H), 8.01 (s, 3H), 8.86, 8.89, 9.01, 9.05, 9.15, and 9.16 (six singlets, tertiary methyls); ν_{max} (CCl_4): 2900, 2750, 1750, 1235 cm^{-1}.

*(+)-5,6-Dioxoisobornyl Acetate (**5**)*

A mixture of 5- and 6-oxoisobornyl acetate (0.79 g, 3.75 mmol) was dissolved in acetic anhydride (1.0 mL, 10 mmol). Selenium dioxide (1.63 g, 14.6 mmol) was added and the stirred reaction mixture was refluxed for 18 h. After cooling to room temperature, the mixture was diluted with ether and the precipitate of selenium filtered and washed with ether. The filtrate was washed with water, saturated sodium bicarbonate, water, and dried over anhydrous magnesium sulphate. Removal of solvent gave an orange coloured product (0.72 g) which was chromatographed on silica gel (activity grade III). Elution with ether – petroleum ether (30–60°C) (30:70), followed by crystallisation from petroleum ether (30–60°C) gave (+)-5,6-dioxoisobornyl acetate (**5**) (0.36 g, 53% yield) as a yellow crystalline solid, mp 101–103°C, 97.5–99.5°C (sealed tube) (lit. (4) mp 95–96°C); $[\alpha]_D^{25}$ +37.3° (*c* 1.35, $CHCl_3$); τ (CCl_4): 5.26 (dd, 1H, J = 8.0 and 4.0 Hz), 7.31 (dd, 1H, J = 5.0 and 1.0 Hz), 8.00 (s, 3H), 8.80, 8.98, and 9.11 (three singlets, 9H); ν_{max} (CCl_4): 2900, 1825, 1780, 1760, 1230, 1200 cm^{-1}; *m/e* (relative intensity): 224(M^+, 9), 196(5), 154(5), 141(18), 136(50), 127(18), 121(45), 115(4), 111(9), 109(14), 108(18), 99(100). *Mol. Wt.* calcd. for $C_{12}H_{16}O_4$: 224.1049; found (high resolution mass spectrometry): 224.1050.

*(−)-5-Oxo-6-*endo*-hydroxyisobornyl Acetate (**6**)*

Zinc dust (0.40 g, 6.15 mmol) was added to a cooled solution of (+)-5,6-dioxoisobornyl acetate (**5**) (0.37 g, 1.65 mmol) in acetic acid (14 mL) and water (3 mL). The yellow color of the solution disappeared within 10 min and the reaction mixture was stirred at 0°C for 1 h. The filtrate obtained after removal of zinc dust was diluted with water, neutralized with sodium carbonate, and extracted with ether. Removal of solvent gave a pale yellow oil (0.4 g) which on short-path distillation (bulb-to-bulb, 120–160°C/0.05 Torr) afforded (**6**) as colorless crystals

(0.31 g, 82% yield), mp 120–122°C (from petroleum ether (30–60°C) – ether); $[\alpha]_D^{25}$ −68.0°(*c* 0.50, $CHCl_3$); τ (CCl_4): (dd, 1H, J = 7.0 and 4.5 Hz), 6.15 (d, 1H, J = 1.5 Hz), 6.75 (bs, 1H, exchanged with D_2O), 7.99 (s, 3H), 8.85, 8.91, and 9.03 (three singlets, 9H); ν_{max}: 3520, 2900, 1760, 1240 cm^{-1}; *m/e* (relative intensity): 226(M^+ 2), 198(18), 184(1), 167(3), 151(2), 138(100), 129(52), 123(55), 109(18). *Mol. Wt.* calcd. for $C_{12}H_{18}O_4$: 226.1204; found (high resolution mass spectrometry): 226.1204. *Anal.* calcd. for $C_{12}H_{18}O_4$: C 63.70, H 8.02; found: C 63.59, H 7.94.

(−)-6-endo-*Hydroxyisobornyl Acetate (7)*

To a solution of (−)-5-oxo-6-*endo*-hydroxyisobornyl acetate (**6**) (205 mg, 0.91 mmol) in 1,2-ethanedithiol (4 mL) was added freshly distilled boron trifluoride etherate (4 drops). A fine white precipitate was formed after 15 min and the reaction mixture was stirred at room temperature for 22 h. Water was added and the mixture was extracted with ether. Work-up in the usual way followed by removal of excess ethanedithiol by distillation (60–75°C/0.5 Torr) gave the ethylene thioketal as a colorless oil (233 mg, crude yield 85%). The crude product was distilled (bulb-to-bulb, 150–160°C/0.05 Torr) to give colorless crystals which on crystallization from petroleum ether (30–60°C) – ether, provided pure thioketal of (**6**), mp 102–104°C; τ (CCl_4): 5.22 (dd, 1H, J = 8.0 and 5.0 Hz) 6.14 (bs, 1H, $w_{1/2}$ = 10 Hz), 6.70–7.00 (m, 4H), 8.09 (s, 3H), 8.85, 9.00, and 9.16 (three singlets, 9H); ν_{max} (CCl_4): 3500, 2900, 1750, 1245 cm^{-1}; *m/e* (relative intensity): 302(M^+, 30), 274(20), 258(30), 242(5), 214(6), 186(100), 173(10), 168(30), 159(40), 134(20), 131(40), 126(20), 119(20), 111(20), 109(40). *Mol. Wt.* calcd. for $C_{14}H_{22}O_3S_2$: 302.1011; found (high resolution mass spectrometry): 302.1002. *Anal.* calcd. for $C_{14}H_{22}O_3S_2$: C 55.60, H 7.33, S 21.20; found: C 55.37, H 7.56, S 21.10.

In general the intermediate ethylene thioketal of **6** was desulfurized without purification. A slurry of Raney nickel (3 g) (Grace Davidson Chemical Co.) in ethanol was added to the ethylene thioketal of **6** (106 mg, 0.35 mmol) and the mixture refluxed for 1 h. Catalyst was removed from the cooled reaction mixture and the filtrate was concentrated by removal of most of the solvent. The residue was dissolved in ether and after washing (saturated sodium chloride) and drying (anhydrous magnesium sulphate) removal of solvent gave colorless solid (75 mg). Crystallization from petroleum ether (30–60°C) afforded 6-*endo*-hydroxyisobornyl acetate (**7**) (57 mg, 80% yield), $[\alpha]_D$ −70.7° (*c* 0.55, $CHCl_3$) (lit. (14) $[\alpha]_D$ −59.7° (*c* 1.5, $CHCl_3$)), mp 94.5°C (sublimation point ~80°C) (lit. (14) mp 94–94.5°C); τ (CCl_4): 4.72 (dd, 1H, J = 9.5 and 3.5 Hz), 8.06 (s, 3H), 9.05 and 9.18 (two singlets, 9H); ν_{max} (CCl_4): 3580, 2900, 1755, 1250 cm^{-1}; *m/e* (relative intensity): 212(M^+, 4), 194(1), 170(8), 155(18), 152(8), 137(6), 119(4), 108(100). *Mol. Wt.* calcd. for $C_{12}H_{20}O_3$: 212.1412; found (high resolution mass spectrometry): 212.1401. *Anal.* calcd. for $C_{12}H_{20}O_3$: C 67.89, H 9.50; found: C 68.07, H 9.53.

6-endo-tert-*Butyldimethylsilyloxyisoborneol (8)*

A mixture of (−)-6-*endo*-hydroxyisobornyl acetate (**7**) (400 mg, 1.88 mmol), *tert*-butyldimethylsilyl chloride (470 mg, 3.11 mmol) (Aldrich Chemical Co.), and imidazole (510 mg, 7.50 mmol) in dry dimethylformamide (10 mL) was heated at 85°C under nitrogen for 20 h. The reaction mixture was cooled, poured into water, and the solution extracted with a mixture (1:1) of ether and petroleum ether (30–60°C). Removal of solvent gave crude *tert*-butyldimethylsilyloxyisobornyl acetate (768 mg) which was hydrolysed without purification. A mixture of the acetate (730 mg) and potassium hydroxide (400 mg, 7.14 mmol) in 95% ethanol (15 mL) was refluxed for 1½ h. After cooling to room temperature part of the solvent was removed under reduced pressure and the residue dissolved in water and extracted with ether. The combined ether extract was washed thoroughly with water and dried over anhydrous magnesium sulphate. Removal of the solvent followed by column chromatography of the product on silica gel (activity grade III) yielded **8** as colorless solid (509 mg, 95% yield). Part of the product was sublimed (oil bath temperature 90°C, atmospheric pressure) to give **8** as colorless crystals, mp 77.0–78.0°C, sublimation point ~50°C; τ ($CDCl_3$, without TMS): 5.68 (dd, 1H, J = 7.0 and 4.0 Hz), 6.10 (dd, 1H, J = 10.0 and 3.5 Hz), 9.01, 9.12, 9.15, and 9.21 (four singlets, 18H, tertiary methyls), 10.02 and 10.04 (two singlets, 6H, $—SiCH_3$); ν_{max} (CCl_4): 3700, 3500, 3000, 1250 cm^{-1}; *m/e* (relative intensity): 284(M^+, 9), 269(23), 227(32), 151(100), 135(27), 123(18), 109(91). *Mol. Wt.* calcd. for $C_{16}H_{32}O_2Si$: 284.2171; found (high resolution mass spectrometry): 284.2184. *Anal.* calcd. for $C_{16}H_{32}O_2Si$: C 67.54, H 11.34; found: C 67.52, H 11.21.

6-exo-tert-*Butyldimethylsilyloxycamphene (9)*

6-*endo*-*tert*-Butyldimethylsilyloxyisoborneol (**8**) (509 mg; 1.79 mmol) in dry pyridine (15 mL) was treated with mesyl chloride (920 mg, 8.07 mmol) at room temperature under nitrogen for 15 min and then refluxed for 10 h. The resulting dark brown solution was cooled, diluted with water, and extracted with ether. The combined ether extract was washed with water and dried over anhydrous magnesium sulphate. Removal of solvent and chromatography of product (1.76 g) on silica gel (activity grade III) gave **9** as a colorless oil (192 mg, 40% yield); τ ($CDCl_3$, without TMS): 5.18 (bs, 1H), 5.40 (bs, 1H), 6.30 (dd, 1H, J = 7.0 and 3.0 Hz), 7.46 (bs, 1H), 9.00 (s, 3H), 9.05 (s, 3H), 9.15 (s, 9H), 10.00 (s, 6H); ν_{max} (CCl_4): 2950, 2900, 1650, 1460, 1360, 1260, 890 cm^{-1}; *m/e* (relative intensity): 266(M^+, 0.6), 251(4), 209(100), 191(6), 179(6), 165(6), 153(5), 135(13). *Mol. Wt.* calcd. for $C_{16}H_{30}OSi$: 266.2065; found (high resolution mass spectrometry): 266.2052.

Elution of the silica gel column with ether gave about 10 mg of colorless crystals with nmr, tlc, and glc characteristics of 6-*exo*-hydroxycamphene (nojigiku alcohol) (*vide infra*).

(+)-6-exo-*Hydroxycamphene (Nojigiku Alcohol) (10)*

Method A

6-*exo*-*tert*-Butyldimethylsilyloxycamphene (139 mg, 0.52 mmol) in dry tetrahydrofuran (10 mL) was stirred with tetra-*n*-butylammonium fluoride (10) (200 mg, 0.76 mmol) under helium in a dry box at room temperature for 15 min. Water was added, the solution extracted with ether, and the combined organic extracts washed with water and dried over anhydrous magnesium sulphate. Removal of solvent followed by column chromatography of product (165 mg) on silica gel (activity grade III) (4 g) provided compound **10** as colorless crystals (78 mg). Sublimation (oil bath temperature 70°C, atmospheric pressure) afforded **10** as colorless needles (62 mg, 78% yield), mp 67.5–69.5°C (sealed tube), sublimation point 52.0°C (lit. (1) mp 52–53°C, lit. (2*c*, 3*b*) mp 59.5–60°C, lit. (2*b*) mp 58–59°C, lit. (3*a*) mp 54–55°C); $[\alpha]_D^{25}$ +58.6° (*c* 1.33, $CHCl_3$), (lit. (1) $[\alpha]_D$ +12.0° (*c* 1.1, $CHCl_3$), lit. (2*c*) $[\alpha]_D^{20}$ +9°); τ (CCl_4): 5.21 (bs, 1H), 5.43 (bs, 1H), 6.29 (dd, 1H, J = 6.0 and 3.0 Hz), 7.48 (bs, $w_{1/2}$ = 4.0 Hz, 1H), 8.98 (s, 3H), and 9.30 (s, 3H); ν_{max} (CCl_4): 3700, 3400, 2900, 1670, 1060, 890 cm^{-1}; *m/e* (relative intensity): 152(M^+, 5), 137(7), 135(5), 134(2), 121(10), 119(12), 108(100). *Mol. Wt.* calcd. for $C_{10}H_{16}O$: 152.1201; found (high resolution mass spectrometry): 152.1209. *Anal.* calcd. for $C_{10}H_{16}O$: C 78.90, H 10.59; found: C 79.00, H 10.72.

The sublimed material was shown to be homogeneous on tlc (silica gel GF 254 with $CaSO_4$) and on various glc columns: 3% OV17 (90°C, from 120–200°C), 3% OV101 (90°C, from

120–200°C), 10% OV210 (from 120–200°C), 10% DEGS (from 120–170°C), and 10% Carbowax (from 90–200°C).

Method B

6-*exo*-*tert*-Butyldimethylsilyloxycamphene (**9**) (116.8 mg, 0.43 mmol) was dissolved in a mixture (10 mL) of acetic acid – water – THF (3:1:1). The solution was stirred at room temperature for 11 h then neutralized with sodium carbonate and extracted with ether. Work-up in the usual way afforded a colourless product (116.4 mg) which on column chromatography on silica gel (grade III) (4 g), elution with 10% ether–petroleum ether (30–60°C) provided (+)-6-*exo*-hydroxycamphene (62.0 mg, 94% yield) as colourless needles. Spectral data, glc retention time, tlc, R_f value, and specific rotation were identical to those of 6-*exo*-hydroxycamphene (**10**) prepared by method A.

*(+)-6-*exo*-Acetoxycamphene (**11**)*

A solution of (+)-6-*exo*-hydroxycamphene (**10**) (21.4 mg, 0.14 mmol) in acetic anhydride (100 mg, 0.99 mmol) and dry pyridine (10 mL) was heated at 100°C under nitrogen for 9 h. After cooling the reaction mixture was diluted with water and extracted with ether. Work-up in the usual way gave yellow oil (24 mg) which was chromatographed on silica gel (grade III) (2 g) to provide **11** as a colorless oil (19.6 mg, 72% yield); $[\alpha]_D^{25}$ +37.6° (*c* 1.11, $CHCl_3$) (lit. (1) $[\alpha]_D$ +20.9° (*c* 0.58, $CHCl_3$), +11.6° (*c* 1.20, $CHCl_3$)); τ (CCl_4): 5.08 (s, 1H), 5.35 (s, 1H), 5.56 (dd, 1H, J = 8.0 and 3.5 Hz), 7.30 (bs, $w_{1/2}$ = 4 Hz, 1H), 8.09 (s, 3H), 8.97 (s, 3H), 8.99 (s, 3H); ν_{max} (CCl_4): 2900, 1740, 1240, 1230, 895 cm^{-1}; *m/e* (relative intensity): 194(M^+, 21), 179(3), 150(100), 134(13), 119(13), 107(76). *Mol. Wt.* calcd. for $C_{12}H_{18}O_2$: 194.1306; found (high resolution mass spectrometry): 194.1320. *Anal.* calcd. for $C_{12}H_{18}O_2$: C 74.19, H 9.34; found: C 74.17, H 9.20.

*(+)-6-Oxocamphene (**12**)*

A solution of 6-*exo*-hydroxycamphene (**10**) (26.5 mg, 0.17 mmol) in methylene chloride (3 mL) was added to a suspension of pyridinium chlorochromate (12) (132 mg, 1.44 mmol) in methylene chloride (spectral grade) (3 mL). A dark brown precipitate was formed after 5 min and the reaction mixture was stirred at room temperature for 2 h. Filtration through a short Florisil column followed by removal of solvent from the filtrate gave a pale yellow oil (37 mg). Column chromatography of this oily product on silica gel (grade III) (3 g) afforded **12** as crystals (21 mg, 80% yield) which, on sublimation (bath temperature 50°C), provided colorless needles, mp 73.5–75.5°C (sealed tube), sublimation point 40°C (lit. (1) mp 47–49°C, lit. (2*b*) mp 65–70°C, lit. (3*a*) mp 75–76°C); $[\alpha]_D^{25}$ +158.2° (*c* 0.79, $CHCl_3$) (lit. (1) $[\alpha]_D$ +33.7° (*c* 0.86, $CHCl_3$); τ (CCl_4): 5.00 (bs, 1H), 5.25 (bs, 1H), 7.04 (bs, 1H), 8.81 (s, 3H), and 8.88 (s, 3H); ν_{max} (CCl_4): 2850, 1750, 1660, 895 cm^{-1}; *m/e* (relative intensity): 150(M^+, 100), 135(42), 121(25), 107(67), 106(83). *Mol. Wt.* calcd. for $C_{10}H_{14}O$: 150.1045; found (high resolution mass spectrometry): 150.1033. *Anal.* calcd. for $C_{10}H_{14}O$: C 79.95, H 9.39; found: C 79.72, H 9.25.

*(−)-6-*endo*-Hydroxyisoborneol (**16**)*

A mixture of (−)-6-*endo*-hydroxyisobornyl acetate (**7**) (74.5 mg, 0.35 mmol) and $Na_2CO_3 \cdot H_2O$ (100 mg, 0.8 mmol) in 5 mL methanol–water (1:1) was refluxed for 22 h. The reaction mixture was cooled and extracted with ether. Removal of solvent and crystallisation of the product from ether – petroleum ether (30–60°C) provided 6-*endo*-hydroxyisoborneol (**16**) (syn. 6-*exo*-hydroxyborneol) as colourless needles (see ref. 8 for physical constants).

Novel lyotropic mesophases that spontaneously orient in magnetic fields have been prepared using hexadecylpyridinium chloride and hexadecyltrimethylammonium bromide as well as, in limited regions, mixtures of the two detergents. These mesophases of type II provide the opportunity to study the behaviour of oriented water (DOH) at the hydrophobic interface, sodium ions, and the effect on hydrocarbon chain motions of variations in composition of the constituent bilayers formed by the mixed detergent systems. The pyridinium head group is especially accessible to definitive studies using deuterium magnetic resonance spectra of specifically deuteriated ring and adjacent hydrocarbon chain segments. Such investigations reveal the lack of cylindrical symmetry of motion about the extended chain axis near the pyridinium head group.

The deuterium resonance of the HOD species shows that both pyridinium and trimethylammonium head groups have a very small orienting effect on the adjacent water, which appears to be indifferent to the choice of these chemical identities. This is understandable in terms of the lack of hydrogen bonding to these moieties. Sodium ions also exhibit small quadrupole splittings in all systems studied here and thus probably play a passive role in the interface chemistry and structure.

LEONARD W. REEVES, ALAN S. TRACEY et MARCELLINE M. TRACEY. Can. J. Chem. **57**, 747 (1979).

On a préparé de nouvelles mésophases lyotropes qui s'orientent spontanément dans des champs magnétiques en utilisant du chlorure d'hexadécylpyridinium et du bromure d'hexadécyltriméthylammonium ainsi que, dans des régions limitées, des mélanges des deux détergents. Les mésophases de type II permettent d'étudier le comportement d'eau (DOH) orienté à l'interface hydrophobe, d'ions sodium et l'effet sur les mouvements de la chaîne hydrocarbonée de variations dans la composition des doubles couches constituantes formées par les systèmes de détergents mixtes. Le groupe pyridinium est particulièrement accessible pour des études définitives utilisant les spectres de résonance magnétique de cycles deutérés d'une façon spécifique et de segments de chaînes hydrocarbonées adjacentes. De telles études révèlent le manque de symétrie cylindrique dans le mouvement autour de l'axe prolongé de la chaîne près du groupe pyridinium.

La résonance du deutérium des espèces DOH montre que les groupes pyridinium ainsi que triméthylammonium ont un effet très faible sur l'orientation de l'eau adjacente qui semble être indifférente au choix de ces entités chimiques. On peut comprendre ce comportement en termes d'un manque de liaisons hydrogène vers ces moitiés. Les ions sodium présentent aussi de faibles couplages quadrupolaires dans tous les systèmes étudiées ici et jouent probablement un rôle insignifiant dans la chimie interfaciale et dans la structure.

[Traduit par le journal]

Introduction

The behaviour of water, alkali ions, halide ions, and hydrocarbon chains as a function of surfactant headgroup as well as the behaviour of the headgroups themselves are topics of considerable interest in various branches of chemistry, particularly those of colloid and interface chemistry, biochemistry of membranes, and the chemistry of lytropic liquid crystalline materials for which disciplines there are various broad areas of overlap.

One facet of lyotropic mesomorphic systems which has been of interest is how headgroups determine the motional behaviour of the hydrocarbon chains to which they are attached and also how they affect that of other alkyl chains with which they are associated in the bilayer. It has been found, for instance, that a carboxyl headgroup has a significantly greater restrictive effect on the hydrocarbon chain motions of neighbouring chains than does a trimethylammonium group (1). On the other hand, motions of individual chains are governed to a large extent by their respective headgroups (1, 2).

The headgroups of surfactants such as decyltrimethylammonium, decylsulfate, decylammonium,

0008-4042/79/070747-07$01.00/0

dodecanoate and others are all rather simple and as a result, using nuclear magnetic resonance techniques, it is often difficult to obtain information concerning the polar groups themselves. It has been found that liquid crystalline mesophases which spontaneously align in the magnetic field of an nmr spectrometer can be prepared from aqueous solutions of either hexadecylpyridinium chloride or hexadecyltrimethylammonium bromide (3). The pyridinium group is particularly useful since two order parameters may be measured for the pyridinium ring. None or only one such parameter may be obtained in most other cases. This headgroup is also of interest because of the inherently very large diamagnetic anisotropy of the aromatic ring compared to that of a hexadecyl chain. One question in this regard was whether the aromatic ring would cause a 90° rotation of the director from similar mesophases with the $-N(CH_3)_3$ headgroup since the diagmagnetic anisotropy of aromatic systems is opposite to that of hydrocarbon chains.

To investigate the behaviour of these two mesophases, the partially averaged deuterium quadrupole splittings from specifically and perdeuterated detergents and deuterated water as well as sodium quadrupole splittings from added sodium ions were utilized. Mixed detergent mesophases were also studied.

Results and Discussion

Lyotropic mesophases which are aligned by the magnetic fields of nmr spectrometers are readily prepared from both hexadecylpyridinium chloride and hexadecyltrimethylammonium bromide. Moreover, throughout a limited region the two mesophases can be prepared with the same molar proportions of all components, i.e., detergent, sodium chloride, decanol, and water. They may also be mixed in all proportions to give a mesophase with the same superstructure.

Preliminary experiments showed that both mesophases were of type II, that is, the directors are aligned perpendicular to the magnetic field (4, 5). This was established simply by observing the deuterium signal from a deuterated component of the mesophase and finding that spinning the sample tube in an iron core spectrometer had no effect on the deuterium doublet splitting. Type I mesophases align with their directors parallel to the magnetic field (4, 5) and spinning the sample provides a two dimensional powder spectrum immediately after cessation of spinning (6).

Several features of these mesophases were investigated. The anisotropic motions of the long hydrocarbon chains as determined from deuterium magnetic resonance of deuterated derivatives were of interest. Various properties of the pyridinium headgroup were investigated, particularly its alignment in these detergent systems. Some structural features of the pyridinium ring were determined.

Deuterium magnetic resonance studies of specifically or perdeuterated compounds in mesomorphic materials have proven to be of considerable value for obtaining degrees of order of micro-axes of such materials (1–11). This arises because the deuterium quadrupole splitting is generally not averaged to zero in liquid crystalline materials and the residual splitting is determined by the alignment of that material in the magnetic field. Quadrupole splittings arise from the presence of electric field gradients and the deuterium splitting, $\Delta\nu$, is given by the expression [1].

$$[1] \qquad \Delta\nu = \tfrac{3}{2}Q_D[S_{zz}^0 + (\eta/3)(S_{xx}^0 - S_{yy}^0)]$$

where Q_D is the deuterium quadrupole coupling constant, η given the asymmetry in the electric field gradients, and S_{zz}^0, S_{yy}^0, and S_{xx}^0 give the alignment of a coordinate system in which the Z^0 axis coincides with the major axis of the electric field gradient. For deuterated hydrocarbons the major axis of the field gradient is very close to the carbon–deuterium bond axis and is generally assumed to coincide with that axis. For saturated systems it is usually assumed that the asymmetry in the electric field gradient is negligibly small, the measured value for instance being less than 0.01 in deuterated cyclohexane (12). Assuming the two above conditions, eq. [1] reduces to [2]

$$[2] \qquad \Delta\nu = (3/2)Q_D S_{CD}$$

where S_{CD} gives the alignment of the carbon–deuterium bond in the magnetic field.

For aromatic systems the asymmetry parameter is not negligible, having values in the order of 0.04 to 0.06 (12, 13). In this particular case we are concerned with the alignment of the pyridinium group as a unit. If we adopt a pyridinium fixed coordinate system such as shown in Fig. 1, then by simple coordinate transformation we can obtain the expressions [3], [4], and [5] (14)

$$[3] \quad \Delta\nu_1 = \tfrac{3}{2}Q_{D_1}[S_{zz} - \cos^2\gamma_1(S_{zz} - S_{yy}) + (\eta_1/3)(2S_{yy} + S_{zz} + \cos^2\gamma_1(S_{zz} - S_{yy}))]$$

$$[4] \quad \Delta\nu_2 = \tfrac{3}{2}Q_{D_2}[S_{zz} - \cos^2\gamma_2(S_{zz} - S_{yy}) + (\eta_2/3)(2S_{yy} + S_{zz} + \cos^2\gamma_2(S_{zz} - S_{yy}))]$$

$$[5] \quad \Delta\nu_3 = \tfrac{3}{2}Q_{D_3}[S_{zz} + (\eta_3/3)(2S_{yy} + S_{zz})]$$

where S_{xx}, S_{yy}, and S_{zz} are the order parameters for a coordinate system fixed in the pyridinium ring. Since any differences between the quadrupole coupling constants, Q_{D_i}, and asymmetry parameters, η_i, will be unimportant, we can subtract [5] from [3] and [4]

TABLE 1. Deuterium quadrupole splittings from the perdeuterated pyridinium group in various concentrations in the mixed hexadecylpyridinium/hexadecyltrimethylammonium mesophase. Deuterium splitting from specifically labelled decanol are included as are the experimental ratios for cos γ_2/cos γ_1 (see Fig. 1) (HDPCl = hexadecylpyridinium chloride)

Composition		Quadrupole splittings (kHz)						
		Pyridinium*				Decanol-1,1,2,2-d_4†		Water*
Phase	Mol% HDPCl in total detergent	$\Delta\nu_{1,5}$	$\Delta\nu_{2,4}$	$\Delta\nu_3$	(cos γ_2/cos γ_1)	$\Delta\nu_1$	$\Delta\nu_2$	$\Delta\nu$
1	4.7	6.972	9.341	−8.911	1.0720	15.05	14.10	0.019
2	25.4	5.961	7.988	−7.680	1.0717	12.78	12.06	—
3	49.9	4.697	6.27	−6.27	1.069	9.64 (broad)		0.020
4	75.2	4.700	6.24	−6.24	1.068	9.62 (broad)		0.024

*Errors in quadrupole splittings from non-overlapping transitions are estimated to be less than 5 Hz.
†Errors in quadrupole splittings are estimated to be less than 1%.

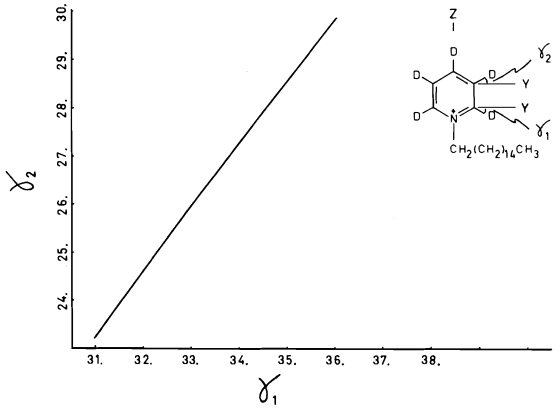

FIG. 1. The relationship between the angles γ_1 and γ_2 which are defined relative to a molecular fixed coordinate system is shown.

to obtain eqs. [6] and [7]

$$[6] \quad 2(\Delta\nu_1 - \Delta\nu_3) = Q_D \cos^2 \gamma_1 (S_{zz} - S_{yy})(\eta - 3)$$

$$[7] \quad 2(\Delta\nu_2 - \Delta\nu_3) = Q_D \cos^2 \gamma_2 (S_{zz} - S_{yy})(\eta - 3)$$

from which it is clear that

$$[8] \quad (\Delta\nu_1 - \Delta\nu_3)/(\Delta\nu_2 - \Delta\nu_3) = \cos^2 \gamma_1 / \cos^2 \gamma_2$$

Equations [3] to [7] by themselves are not particularly useful because of the large number of unknown parameters required. The quadrupole coupling constants may be estimated to be about 185 kHz (12, 13, 15) and the asymmetry parameter about 0.05 (12). The exact values are not critical but even so the above estimates are unlikely to be in error by more than 5.0 kHz and 0.01 in Q_D and η, respectively. The parameter S_{zz}, the alignment of the C_2 symmetry axis of the pyridinium, may be estimated reasonably well by neglecting η but from only deuterium quadrupole splittings no estimate of S_{yy} can be obtained without structural assumptions, i.e. either of the angles γ_1 or γ_2 which are related by eq. [8]. Equation [8] is a particularly useful expression since with even rather crude angle assumptions it will establish the relative signs of the quadrupole splittings. Specifically deuterated compounds were used to ascertain the proper assignments of quadrupole splittings.

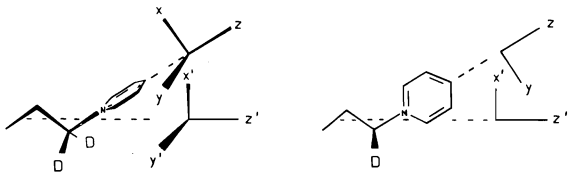
Table 1 gives various deuterium splittings obtained from the pyridinium ring and as a reference, the deuterium splitting from decanol deuterated in the 1,2 positions. The ratio, cos γ_2/cos γ_1, is also given. In this case it should be noted that often transitions from deuteriums 2 and 3 overlap so that individual resonances were not observed and as a consequence the mean frequency was assigned to the splittings. Even so, the agreement between the various mesophases is extremely good. It is clear from the results that in order to obtain a constant ratio of cosines, the quadrupole splitting $\Delta\nu_3$ is of opposite sign to those of positions 1 and 2. The ratio obtained from only the completely resolved spectra (entries 1 and 2 from Table 1) is 1.0718 ± 0.0002 and the angles corresponding to this ratio are plotted in Fig. 1. The results shown in Fig. 1 demonstrate that the two angles must differ by 6 or 7°. Since the angular distortion from the 30° of a hexagon is caused mostly by the fact that the C—N bond is shorter than the C—C bond, it can be expected that γ_1 is greater than 30° while γ_2 is less than that value. If we make the following assumptions $\gamma_2 = 28°$, $\eta = 0.05$, and $Q_D = 185$ kHz we can determine from Fig. 1 that $\gamma_1 = 34.5°$ and from eqs. [5] and [7] and the specific quadrupole splittings $\Delta\nu_{1,5} = 7.208$ kHz and $\Delta\nu_3 = -9.731$ kHz that $S_{zz} = -0.0363$, $S_{yy} = 0.0552$, and finally $S_{xx} = -0.0189$. Note that relative signs of the order parameters are given, not absolute values. The value determined for S_{zz} is insensitive to the angle assumed for γ_2. S_{yy} depends on that value, increasing in magnitude about 3–4% for each 1° increment in angle assumed. For our purposes this effect is not important unless there is a very large error in the assumed angle.

We can now do a coordinate transformation from a coordinate system locked to the pyridinium headgroup to a new system fixed with respect to an axis located in the first methylene segment of the hexadecylpyridinium ion as depicted below.

The two coordinate systems are related by eq. [9]

$$[9] \quad S_{zz} = \cos^2 \phi_{zz} S_{zz}' + \cos^2 \phi_{yy} S_{yy}' + \cos^2 \phi_{xx} S_{xx}'$$

and similar expressions for S_{yy} and S_{xx} which combined with the trace relationship that $S_{xx} + S_{yy} + S_{zz} = 0$ give the following values for conformation A shown. $S_{xx}' = -0.0014$, $S_{yy}' = 0.0552$, and $S_{zz}' = -0.0538$. These values are extremely small, providing a calculated methylene quadrupole splitting about one-half that observed experimentally. Thus conformation A is probably not very important.



A B

Order parameters from conformation B give S_{xx}', S_{yy}', and S_{zz}' equal to $+0.1467$, -0.0189, and -0.1278, respectively. These are closer to experimental values.

The above transformation has been made in order to determine whether the pyridinium with its attached hydrocarbon chain behaves as an effectively cylindrically symmetric system at the headgroup. For this symmetry and an S_{zz}' of -0.1278, S_{xx}' and S_{yy}' should both equal $+0.0639$. Clearly this condition is not even approximately true at the pyridinium position. Different structural assumptions will change the calculated parameters, particularly because the pyridinium residue can rotate. However, if conformation B represents the dominant rotamer as is suggested by the values computed for S_{xx}', S_{yy}', and S_{zz}' the deuterium quadrupole splitting at the methylene group of position 1 can be calculated. The values are 16.3 kHz and 9.3 kHz using effective cylindrical symmetry from S_{zz}' and noncylindrical symmetry, respectively. The observed value is 11.71 kHz for the methylene splitting in the particular case corresponding to the pyridinium values previously used. The agreement is not particularly good. However, when we note the unusual and large increase in methylene quadrupole splitting by going from position 1 to 2, i.e., 11.71 kHz compared to 14.06 kHz, one sees that this latter value at the plateau of the order profile is in much better accord with an effective axial symmetry, a view which is supported by the fact that the 14 kHz splitting extends from methylene 2 to 9 inclusive. The lack of exact agreement in this latter case probably reflects the fact that the pyridinium is not fixed with respect to these methylenes but undergo hindered rotation about the C—N axis. Under the assumption that S_{zz}' is determined by the 14.06 kHz splitting, i.e. $S_{zz}' = -0.1103$, the parameters S_{xx}' and S_{yy}' may be determined for the α-methylene from the $\Delta\nu$ of 11.71 kHz and eq. [2] in conjunction with eq. [9]. The order parameters obtained are 0.0828, 0.0275, and -0.1103 for S_{xx}', S_{yy}', and S_{zz}', respectively. These calculations indicate strongly that there is a large deviation from axial symmetry at the α-methylene.

Referring again to Table 1, a comparison of the results from the specifically deuterated pyridinium ring in the various mixed mesophases shows that the mixing of the detergents has little effect on the alignment. The decanol specifically substituted in the 1 and 2 positions does show a small effect from the changing compositions. In the hexadecylpyridinium mesophase the two decanol resonances are well resolved. This contrasts with the results from the hexadecyltrimethylammonium phase where only one signal was observed for the two positions. Mixing of the detergents revealed a gradual collapse in separation between the splittings on going from the one extreme to the other. This gradual collapse coupled with the lack of significant change in the alignment of the pyridinium indicated that nothing extraordinary occurred to the micellar superstructure or the interface when mixing the two detergents, indeed the integrity of the mesophase is preserved.

Investigation of sodium ions and deuterated water showed that species in the aqueous region were also insensitive to changes in composition of the mesophase. Unfortunately deuterium resonance of deuterated water was not very helpful because of the very small water splittings, typically less than 30 Hz. This, however, does show that water associated with the cationic headgroups is essentially isotropic, particularly when one bears in mind the large differences in shape between pyridinium and trimethylammonium. Nuclear magnetic resonance spectra from the sodium ion showed that its behaviour was virtually unaffected by the replacement of one detergent with the other. The sodium quadrupole splittings changed very little on going from the extreme of one mesophase to the other (Table 2). Because of the similarity of the results from the various mixed mesophases it was decided to investigate the chain motion of the hexadecyl chains only at the two extremes of composition.

Methylene quadrupole splittings serve as a good indicator of the relative motion of the various methylene segments in the same chain. Figure 2

TABLE 2. Sodium quadrupole splittings for the various mixed mesophases indicated. The sodium splittings increase in magnitude as the sample warms from room temperature to magnet temperature (32°C) (HDTMABr = hexadecyltrimethylammonium bromide, HDPCl = hexadecylpyridinium chloride)

*Errors in quadrupole splittings are estimated to be less than 1%.

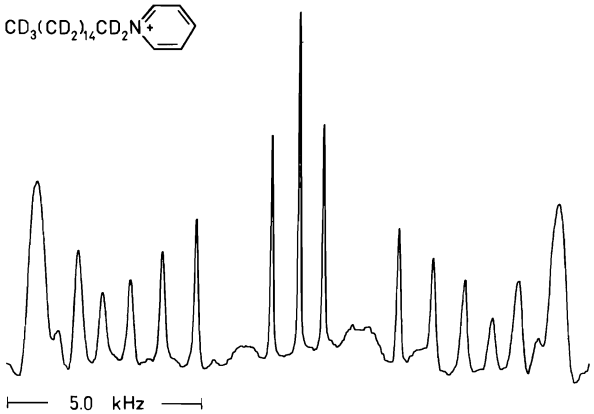

FIG. 2. A deuterium magnetic resonance spectrum from the perdeuterated chain of hexadecylpyridinium in a lyotropic mesophase.

shows a spectrum from a perdeuterated hexadecyl chain attached to the pyridinium headgroup. The relative linewidth of the intense outer transitions, which arise from superimposed methylene quadrupole splittings, compared to the other transitions show the small range of values over which those splittings are spread. Table 3 gives the measured deuterium quadrupole splittings from the various methylene groups for the hexadecylpyridinium mesophase. The values for the hexadecylpyridinium as a minor component in a hexadecyltrimethylammonium phase are included as are the corresponding results for the perdeuterated hexadecyl chain of the trimethylammonium derivative. The splittings for decanol, which is a minor component in the mesophases, are also given. Note that the values reported in Tables 1 and 3 are for a dilute ($\sim 10\%$ by weight) labelled component in total detergent.

The magnitudes of the splittings from the various components of the mesophases are all similar and provide minimal information concerning the relative chain motions. However, information can be extracted from these splittings by obtaining their ratios. Typically this is done by dividing all the methylene quadrupole splittings from a particular chain by the value obtained for the terminal methyl group. The advantage of these ratios is that the contributions to the deuterium quadrupole splittings which arise because of rigid body motions of the chain cancel. The resultant chain profiles provide information concerning the internal motion of the hydrocarbon chains and in particular allow comparisons to be drawn between different chains and between different mesophases (1). Figure 3 shows the chain motion profiles for the three components of the two mesophases investigated, 15.1 and 87.5 mol% hexadecylpyridinium chloride in total detergent, the second detergent of course being hexadecyltrimethylammonium bromide. A major feature of the hexadecyl chain profile from the pyridinium salt is the value for the ratio between the methyl and the plateau methylene quadrupole splittings. This ratio is 8.4 in the pyridinium mesophase and rises to 10.1 where hexadecylpyridinium is associated mainly with the trimethyl derivative. A ratio of three is expected for a rigid rapidly rotating chain. This value becomes larger with increase in chain flexibility which is related to the increased probability for random *gauche* rotamers to occur near the terminal positions of the hydrocarbon chains.

Figure 3 clearly shows that this ratio for the hexadecyl chain of hexadecylpyridinium increases as the pyridinium is diluted in trimethylammonium thus indicating more freedom for the formation of isolated *gauche* rotamers. A similar but opposite behaviour for the trimethylammonium's hexadecyl chain is also observed. The results indicate that in this latter case the hexadecyl chain is least restricted in its motion when in the pyridinium phase but becomes much more restricted with an increasing

TABLE 3. Deuterium quadrupole splitting from perdeuterated hexadecyl hydrocarbon chains and perdeuterated decanol. The mole fraction of hexadecylpyridinium chloride (HDPCl) in total detergent is also indicated for the various mesophases

*Errors in quadrupole splittings are estimated to be less than 1%.

proportion of hexadecyltrimethylammonium. The relative motional freedom of the two chains have interchanged on going from the one extreme to the other. This type of behaviour has not been observed previously but since in both cases hexadecyl chains are being observed, this change in relative motion must be determined by the headgroup through both its own orienting influence and through its interaction with its neighbours. The very flat hexadecyl chain profile for the trimethylammonium derivative strongly suggests that only one order parameter is required for a description of its alignment, at least in the plateau region.

The chain profiles for deuterated decanol are relatively insensitive to the composition of the mesophase as is evident from Fig. 3. Of particular interest here is the fact that decanol, having a chain only ten carbons long, is significantly shorter than the other chains which are sixteen carbons long. As a consequence if the hydroxyl group is in the interface then effectively the whole decyl chain is confined to the highly aligned portion of the bilayer, i.e., the methylene quadrupole splittings from the hexadecyl chains begin dropping at carbon 10. This should have a substantial effect on the chain profile as compared to the profile from other mesophases prepared from shorter chain detergents such as decylammonium, decylsulfate, or dodecanoate, for example. In such mesophases the plateau to methyl splitting ratio varies from about 7 to 9 to compare with the value here of 6. Even this value is surprisingly large but probably results from the fact that the detergent headgroups are quite bulky and allow the chains to retain considerable motional freedom. In mesophases containing decyltrimethylammonium bromide, compared to hexadecyltrimethylammonium here, the ratios for decanol are the largest so far observed, being about 9 (1).

Recently the importance of pure components for the preparation of lyotropic liquid crystals was strongly stressed, the authors having difficulty in reproducing previously published results (19). Unfortunately those same authors used "commercially supplied detergents" without "purification". Commercial detergents simply are much too impure and generally three if not more recrystallizations from distilled solvents are required to obtain good reproducibility of results.

Experimental

Perdeuterated hexadecanoic acid was prepared using an adaption of the process of Stenhagen and Dinh-Nguyen (16). Adam's catalyst, PtO_2 (3.67 g in 50 mL D_2O), was reduced with D_2 gas under 1–2 atm pressure. The mixture was transferred with 100 mL D_2O to a stainless steel pressure vessel cooled in an ice/water bath, and Na_2O_2 (2.32 g) was added slowly. Potassium hexadecanoate (20 g) was added, followed by an

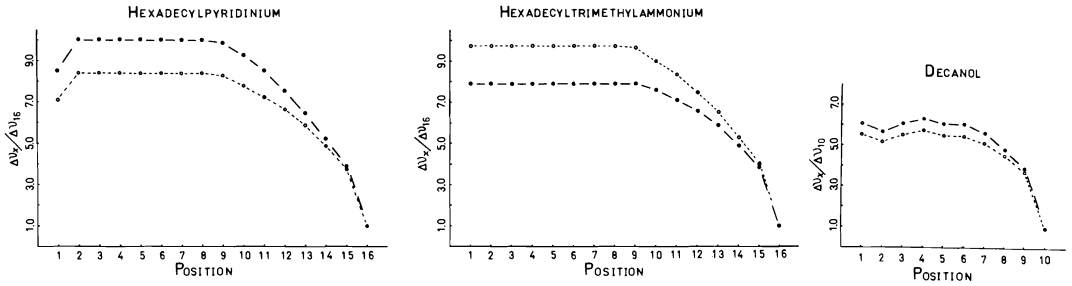

FIG. 3. Chain motion profiles for the three amphiphile components of the lyotropic mesophases. ○, 85 mol% hexadecylpyridinium chloride in total detergent; ●, 15 mol% hexadecylpyridinium chloride in total detergent. The second detergent is hexadecyltrimethylammonium bromide.

additional 75 mL D_2O. The vessel was equipped with a magnetic spin bar, then sealed, frozen in Dry Ice, and evacuated. The reaction mixture was heated, with stirring, using a salt bath (sodium nitrite:potassium nitrate 7:10 by weight) at 220°C for 10 days. The contents were acidified with HCl, and the acid extracted into $CHCl_3$. The chloroform layer was filtered to remove the spent platinum and the solvent removed under reduced pressure using a Buchi rotary evaporator. The acid was then distilled under reduced pressure. Approximately a 90% exchange of deuterium for hydrogen was obtained in 95% yield.

1-Hexadecyl-d_{33}-pyridinium Chloride

Perdeuterated hexadecanoic acid was converted to the acid chloride with thionyl chloride and the acid chloride reduced with $LiAlD_4$ to give the perdeuterated hexadecanol. The alcohol was converted to the bromide with constantly boiling HBr (17). Hexadecylpyridinium bromide was prepared by warming on a hot plate for $1\frac{1}{2}$ h equal molar proportions of hexadecylbromide and pyridine. The bromide was recrystallized from ethylacetate.

1-Hexadecylpyridinium bromide was dissolved in methanol and a slight molar excess of Ag_2O was added. (Water added at this point caused rapid decomposition of the pyridinium salt.) After the mixture was stirred for 1/2 h, the solution was filtered and the filtrate acidified with HCl. The methanol was removed under reduced pressure and the 1-hexadecylpyridinium chloride was crystallized from ethylacetate.

1-Hexadecyl-d_{33}-trimethylammonium Iodide

Perdeuterated hexadecanol was converted to the hexadecyliodide with red phosphorus and iodine using standard techniques (18). The iodide (3.6 g) was added to methanol (100 mL) and trimethyl amine (16 mL of a 25% solution in water) was added. The reaction mixture was stirred overnight at room temperature. Methanol and water were removed under reduced pressure and the resulting salt was crystallized from ethylacetate/ethanol. The corresponding chloride and bromide were prepared from the iodide by the Ag_2O method above. All salts were crystallized from ethylacetate.

Acknowledgements

We are thankful to the National Research Council of Canada for its financial support for this work and to Keith Radley for indicating to us that hexadecyltrimethylammonium bromide forms a liquid crystalline solution which spontaneously aligns in the magnetic field of an nmr spectrometer.

Nuclear magnetic resonance studies of the solvation of phosphorus(V) selenides, 1,2-bis(diphenylphosphino)ethane, and tris(dimethylamino)phosphine telluride by sulfur dioxide[1,2]

PHILIP A. W. DEAN

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received September 12, 1978

PHILIP A. W. DEAN. Can. J. Chem. **57**, 754 (1979).

^{31}P and ^{77}Se nmr spectra have been measured for a range of phosphorus(V) selenides, diphosphorus(V) diselenides, and triphosphorus(V) triselenides in the inert solvent CH_2Cl_2 and in liquid SO_2. Significant roughly-correlated reductions in $|^1J(PSe)|$ and deshielding of the ^{77}Se resonance accompany change of solvent from CH_2Cl_2 to SO_2. These changes are shown to arise from 1:1 phosphorus(V) selenide:SO_2 donor:acceptor complex formation. Approximate thermodynamic constants for the formation of the complexes have been determined and possible structures for the 1:1 complexes with the diphosphorus(V) diselenides discussed. It is shown from ^1H and ^{31}P nmr spectral changes that $Ph_2P(CH_2)_2PPh_2$ forms a 1:1 complex with SO_2, and approximate thermodynamic data for the SO_2 complexation of the diphosphine have been established. Complexation is indicated by changes in both $|^1J(PTe)|$ and δ_P when $(Me_2N)_3PTe$ is dissolved in SO_2, but the chemical reactivity of this system precluded detailed study.

PHILIP A. W. DEAN. Can. J. Chem. **57**, 754 (1979).

On a déterminé les spectres rmn du ^{31}P et du ^{77}Se d'un certain nombre de sélénures de phosphore(V), de disélénures de diphosphore(V) et de trisélénures de triphosphore(V) dans le solvant inerte CH_2Cl_2 et dans le SO_2 liquide. Un changement de solvent de CH_2Cl_2 à SO_2 s'accompagne de réductions marquées qui présente une corrélation grossière des $|^1J(PSe)|$ et des déblindages de la résonance du ^{77}Se. On a montré que ces changements sont dus à la formation d'un complexe 1:1 donneur:accepteur sélénure de phosphore(V):SO_2. On a déterminé les constantes thermodynamiques approximatives pour la formation des complexes et on discute des structures possibles des complexes 1:1 avec les disélénures de diphosphore. On a montré, grâce aux changements dans les spectres rmn du ^1H et du ^{31}P, que le $PH_2P(CH_2)_2PPH_2$ forme un complexe 1:1 avec le SO_2 et on a déterminé les données thermodynamiques approximatives pour la complexation de la diphosphine par le SO_2. La complexation est révélée par des changements à la fois dans $|^1J(PTe)|$ et dans le δ_P lorsqu'on dissout du $(Me_2N)_3PTe$ dans le SO_2; la réactivité chimique de ce système ne permet par une étude plus détaillée.

Introduction

Our studies of the complexation of phosphorus(V) selenides by metal ions in liquid sulfur dioxide (1–3) have, of necessity, required an nmr spectroscopic investigation of the ligands alone in this medium. Previously, this class of ligands has been studied in "inert" media by both ^{31}P (4–7) and ^{77}Se (7) nmr. Where there is overlap, our data are in agreement with earlier work, but we find that use of SO_2 as solvent leads to significantly different ^{31}P and ^{77}Se nmr parameters. Our results, and their interpretation in terms of specific SO_2-solvation of the phosphorus(V) selenides are presented here.

To further study the generality of SO_2-solvation of "soft" donors, we have also investigated the interaction of $Ph_2P(CH_2)_2PPh_2$ and $(Me_2N)_3PTe$ with SO_2. In an earlier ^{13}C nmr study, it was shown that SO_2 acts as an acceptor towards triphenylphosphine (1).

Results

In most cases, the ^{31}P and ^{77}Se nmr spectra of the compounds examined could be analyzed readily. The ^{77}Se satellites in the ^{31}P-{H} spectra, and the ^{77}Se-{H} spectra of monophosphorus(V) monoselenides, diphosphine monoselenides, and diphosphorus(V) diselenides are the appropriate parts of AX, AMX, and AA'X (ABX if the (experimentally unobserved) selenium isotope effect is included) spectra, X being ^{77}Se. Because of the zero values of $^4J(P–P)$ and $^5J(P–Se)$, $(Ph_2P(Se)CH_2)_3CMe$ gives rise to an AX spectrum. $Ph_2P(Se)(CH_2)_2(Se)PPh(CH_2)_2$-$P(Se)Ph_2$ gives rise to two sets of ^{77}Se satellites in the ^{31}P-{H} spectrum: the AB_2 part of an AB_2X spectrum from $Ph_2P(Se)(CH_2)_2(^{77}Se)PPh(CH_2)_2$-

[a]Reproducibility $\approx \pm 1$ Hz; $^1J(PSe)$ is known to be negative for phosphorus(V) selenides (7).
[b]Measured relative to external $OP(OMe)_3$ in $(CD_3)_2CO$ and corrected for susceptibility difference; downfield shifts positive.
[c]In pure $SeP(OMe)_3$, $|^1J(PSe)| = 961$ Hz.
[d]In $CHCl_3$, $|^1J(PSe)| = 731 \pm 2$; in acetone, $|^1J(PSe)| \sim 742$ Hz.
[e]In pure $SePMePh_2$, $|^1J(PSe)| = 728$ Hz.
[f]$|^2J(PP)| = 14.7$ Hz in CH_2Cl_2, 13.5 Hz in SO_2. $|^3J(PSe)| \sim 1.9$ Hz in both solvents.
[g]$^3J(PP) = \pm 64.9$ Hz in CH_2Cl_2, ± 66.2 Hz in SO_2. $^4J(PSe) = \mp 0.5$ Hz in both solvents.
[h]$^3J(PP) = \pm 62.6$ Hz; $^4J(P_{terminal}\text{–}Se) = \mp 4.1 \pm 1.0$ Hz; $^4J(P_{central}\text{–}Se) = \mp 1.4 \pm 0.8$ Hz.
[i]$^3J(PP) = \pm 63.9$ Hz; $^4J(P_{terminal}\text{–}Se) = 0.1 \pm 0.5$ Hz; $^4J(P_{central}\text{–}Se) = \mp 0.9 \pm 0.4$ Hz.

$P(Se)Ph_2$, and the AA′B (or ABC) part of an AA′BX spectrum (or ABCX spectrum with an isotope effect included) from $Ph_2P(^{77}Se)(CH_2)_2(Se)PPh(CH_2)_2P(Se)Ph_2$. In this case, the centreband obscured much of the satellite spectrum and only an approximate analysis was possible.

In Table 1 are presented ^{31}P nmr spectral parameters for the phosphorus(V) selenides in the inert solvent CH_2Cl_2 and in SO_2. Table 2 shows the analogous ^{77}Se nmr data for those compounds in Table 1 which were sufficiently soluble in the two solvents to make the measurement worthwhile.

The ^{31}P chemical shifts and one-bond phosphorus–selenium coupling constants of the selenides in SO_2 solution were independent of concentration, suggesting complete solute–solvent interaction in this medium. The stoichiometry of the interaction was determined for several representative selenides by measurement of the variation of δ_P and/or $^1J(PSe)$ as a function of SO_2/selenide in the systems selenide–SO_2–CH_2Cl_2 and computer-analysis of the titration curves. In all cases, even for the diphosphine diselenides, 1:1 complex formation is indicated; approximate stability constants and enthalpies and entropies of formation are given in Table 3.

To assess the extent of interaction between the two $Ph_2P(Se)$ groups of the diphosphorus(V) diselenides, the ^{31}P and ^{77}Se nmr spectra of $Ph_2P(CH_2)_nPPh_2$, $Ph_2P(Se)(CH_2)_nPPh_2$, and $Ph_2P(Se)(CH_2)_nP(Se)Ph_2$ ($n = 1$–6) have been obtained for CH_2Cl_2 solutions of equilibrium mixtures of the

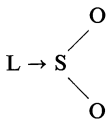
[b]Calculated from Δ^1J(PSe) for consistency.

three components. The comparison is made in Table 4. The data show the sensitivity of the nmr parameters to the proximity of a second phosphorus-containing group to be in the order δ_P, $\delta_{Se} < |^{1 \text{ or } (n+2)}J(PSe)| < |^{(n+1)}J(PP)|$, the least sensitive parameters suggesting virtually independent action of the two end groups at $n \geq 2$, the most sensitive at $n \geq 5$. On chemical evidence, the distribution of selenium when equimolar amounts of $Ph_2P(CH_2)_2PPh_2$ and Se react, it has been suggested that independent behaviour occurs when $n \sim 2$ (8).

The sensitivity of δ_{Se} and $|^1J(PSe)|$ but not δ_P to complexation of the selenides by SO_2 suggests that the selenium atom is the site of the interaction. The yellow colour of the phosphorus(V) selenide – SO_2 solutions is indicative of acceptor behaviour by sulfur dioxide (9). In addition, the solid, approximately 1:1, yellow adduct between $SeP(o\text{-}C_6H_4Me)_3$ and SO_2 shows $\nu(SO)_{sym}$ at 1134 ± 2 cm^{-1} in the Raman spectrum, in the range expected for



(pyramidal) coordination (10). (For comparison, the pyramidal ISO_2^- ion in $[PPh_3Bz](ISO_2)$ has $\nu(SO)_{sym}$ at 1123 cm^{-1} (10).) Clearly, the sulfur atom of SO_2 is acting as an acceptor in the selenide–SO_2 adducts.

The well-known (11) deceptively-simple, second-order, 'triplet' signal given by the aliphatic protons of $Ph_2P(CH_2)_2PPh_2$ dissolved in an inert solvent changes markedly when the compound is dissolved in liquid SO_2 (Fig. 1). The equivalence of the two phosphorus atoms is maintained, at least on a time-average, and the 'filling in' of the aliphatic triplet signal is consistent with either a reduction in $|^3J(PP)|$ or an increase in $|^2J(PH) - {}^3J(PH)|$, or both. Now oxidation or quaternization of phosphorus(III) is known to cause $^2J(PH)$ to become more negative and the positive $^3J(PH)$ to become more positive (12) while $|^3J(PP)|$ has been shown to increase on oxida-

Temperature (K)	K_1 (M^{-1}) [a]	$\frac{10^2\sigma}{\Delta\delta_{P,max}}$	Standard enthalpy and entropy of formation
308 [b]	0.09	3.8	$\Delta H^0 \approx -4.9$ kJ mol^{-1}
228	0.23	2.4	$\Delta S^0 \approx -42$ J mol^{-1} K^{-1}

[a] For method of calculation see Experimental section.
[b] Some oxidation of the diphosphine is evident at 308 K.

tion (13). The lower spectrum in Fig. 1 is thus consistent with complexation of the diphosphine at phosphorus, with the concomitant changes in the geminal and vicinal phosphorus–hydrogen coupling constants. Accordingly, the deshielding of the ^{31}P nmr signal of $Ph_2P(CH_2)_2PPh_2$ in SO_2 solution (3.89 ppm at 308 K, 17.99 ppm at 228 K relative to δ_P for CH_2Cl_2 solution) is assumed to result from complexation of the diphosphine. A ^{31}P chemical shift titration of $Ph_2P(CH_2)_2PPh_2$ with SO_2 in CH_2Cl_2 gives shifts consistent with the formation of a 1:1 complex; the stability and approximate enthalpy and entropy of formation are shown in Table 5. Some error in the value of K_1 at 308 K must be expected because SO_2-oxidation of the phosphine, an example of a well-studied general phenomenon (14), occurs at this temperature. On long standing at 308 K, the yellow colour of $Ph_2P(CH_2)_2PPh_2$—SO_2—CH_2Cl_2 solutions is discharged.

As indicated in Table 6, both $^1J(^{31}P–^{123}Te)$ and $^1J(^{31}P–^{125}Te)$ are visible in the ^{31}P nmr spectrum of colourless solutions of $(Me_2N)_3PTe$ in CH_2Cl_2. In the blood-red solutions of the telluride in SO_2, some decomposition occurs even at 228 K, giving broader lines, but a greatly reduced $^{31}P–^{125}Te$ satellite splitting is evident (Table 6). Attempts to ascertain the stoichiometry and stability of the $(Me_2N)_3PTe$—SO_2 adduct were thwarted by the evident decom-

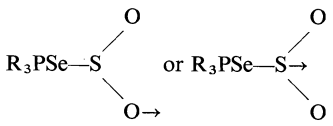
position occurring in CH_2Cl_2 solutions of $(Me_2N)_3PTe$ with SO_2 at 228 K. If, as expected by analogy with $(Me_2N)_3PSe$, a 1:1 complex is formed, K_1 appears to be of the order 0.1–1 M^{-1}, but the 1:1 stoichiometry could not be firmly established.

Discussion

Our results are consistent with all the phosphorus(V) selenides studied being completely complexed in liquid SO_2 to give 1:1 Lewis acid:Lewis base adducts containing a sulfur–selenium bond. To our knowledge, the only other example of SO_2 acting as an acceptor to a selenium-donor ligand is in the recently-reported $[NCSeSO_2]^-$ anion (10). It seems likely, however, that such behaviour by SO_2 is general. Thus it cannot safely be assumed that in SO_2 solution *direct* donation from a selenium-donor to an acceptor will always occur: *indirect* donation, e.g. via



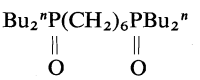
is a possibility needing consideration.

General medium effects on δ_P and $|^1J(PSe)|$ have been neglected, and only empirical allowance for changes in activity with system composition is made in calculation of the stability constants in Table 3. Nonetheless the degree of agreement between expected and found values, indicated by $10^2\sigma$/range, varies from reasonable to very good suggesting that the K_1's determined are good approximations. The SO_2 – phosphine selenide complexes are evidently weakly formed,[3] though their stability increases as expected with increasing electron-releasing ability of the substituents on phosphorus. The diphosphine diselenides $Ph_2P(Se)(CH_2)_nP(Se)Ph_2$ show insignificant change in K_1 for n = 1, 2, 4, or 6.

The SO_2 solutions provide an unusual opportunity to study the effects of complexation of a wide range of different phosphorus(V) selenides with a common acceptor, the solvent molecule. From the data in Table 1, it is clear that in the ^{31}P nmr spectrum a reduction in $|^1J(PSe)|$ from its value in an inert solvent is the most uniform indication of complexation: noticeable reductions in this coupling constant occur even when changes in δ_P are very small. In the ^{77}Se nmr spectrum, a large downfield shift from the free ligand (i.e. inert solvent) value accompanies complexation. Interestingly, there is a fair correlation between the changes in $|^1J(PSe)|$ and the changes in δ_{Se} accompanying complexation by SO_2, as shown in Fig. 1.[4] Such a correlation seems reasonable since both coupling constants involving ^{77}Se (16, 17) and ^{77}Se chemical shifts (18) are thought to depend on the nature and the number of the lone pairs of electrons on selenium.

In general, it seems that the more easily obtained ^{31}P spectra should provide a satisfactory indication of complexation of the phosphorus(V) selenides. However, when SO_2 or another acceptor solvent is used, the changes in $|^1J(PSe)|$ could be small, as the magnitude of this coupling will already have been reduced by complexation with the solvent.

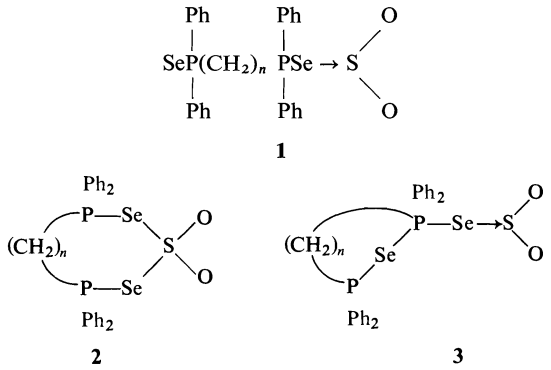
The formation of only 1:1 complexes by all the diphosphine diselenides, $SePPh_2(CH_2)_nPh_2PSe$ (n = 1, 2, 4, 6) is perplexing. The $Ph_2P(Se)$ group is known to be electron-withdrawing (19), so that 1:1 complex formation at short aliphatic chain lengths is not surprising. However, as discussed above, the two $Ph_2P(Se)$ groups are certainly spectroscopically independent at n = 6 (see Table 4) and may act independently chemically at n = 2. It should be noted though that the two ends of



do not act independently upon protonation in nitromethane, the two pK_a's being 11.6 and 4.7 (20). In the present examples, the formation of a simple one-ended 1:1 complex (**1**) appears favoured by the

[3]For comparison, Zingaro and co-workers (15*a*) find K_1 to be 2.40 × 10^3 M^{-1} for $Ph_3PSe{\cdot}I_2$ in $CHCl_3$ at 308 K, while Bruno *et al.* (15*b*) find K_1 for $(Me_2N)_3PSe{\cdot}I_2$ to be 12 900 ± 650 M^{-1} under the same conditions.

[4]It should be noted that data for complexes of phosphorus(V) selenides with acceptors other than SO_2 do not correlate with the data for the SO_2 complexes, e.g., we find $\Delta|^1J(PSe)| = 306$ Hz and $\Delta\delta_{Se} \approx 387$ ppm at 308 K when $(MeSeP(NMe_2)_3)^+$ is formed from MeI and $SeP(NMe_2)_3$ in SO_2.



1 **2** **3**

thermodynamic data (Table 3) but from the spectroscopic results is most unlikely. The *exchange-averaged* values of $\Delta\delta_{Se}$ and $|^1J(PSe)|$ are in the ranges 155.5–222.7 ppm and 34–53 Hz, respectively, which means that complexation by SO_2 would have to produce changes in $\Delta\delta_{Se}$ of ca. 301–445 ppm and in $|^1J(PSe)|$ of ca. 68–106 Hz at the donor site: the largest of these changes, at least, would be anomalously high compared with the other data in Fig. 2. Thus ring-closure either by chelation as in **2**, or internally, perhaps as in **3**, must be occurring.[5] In either event, it is surprising that neither the thermodynamic data (Table 3) nor the spectroscopic data (Fig. 2) are anomalous. The nature of the 1:1 complexes of diphosphine diselenides and SO_2 must remain an open question.

The analogues of structures **1** and **2** are possibilities for the 1:1 complex of $Ph_2P(CH_2)_2PPh_2$ and SO_2, and the present data do not permit a choice. The stability of the diphosphine adduct is only a little less than those of the diphosphine diselenides, and like the selenides the diphosphine is apparently totally complexed in liquid SO_2. Earlier, it has been suggested on the basis of ^{13}C nmr data that PPh_3 is totally complexed in SO_2 (1). The earlier data for the system PPh_3—SO_2—CS_2 can be used to estimate that K_1 for $Ph_3P{\cdot}SO_2$ is ca. 0.03 M^{-1} at 305 K.[6] For both PPh_3 and $Ph_2P(CH_2)_2PPh_2$ adducts with SO_2, the formation of phosphorus–sulfur bond is indicated, supporting a previous suggestion (14*a*) that SO_2-oxidation of phosphines and related phosphorus(III) species proceeds through $R_3P \rightarrow SO_2$ adducts.

Both the blood-red colour of solutions of $TeP(NMe_2)_3$ in SO_2 or SO_2—CH_2Cl_2 and the remarkable changes in the ^{31}P spectral parameters which occur when the telluride is dissolved in an SO_2-containing medium (Table 6) are good evidence that an SO_2–$TeP(NMe_2)_3$ interaction occurs. Unfortunately the chemical instability of the system precluded more detailed characterization. However, the formation of a tellurium-to-SO_2 bond seems very likely from the large reduction in $^1J(PTe)$ occurring in SO_2 as solvent.

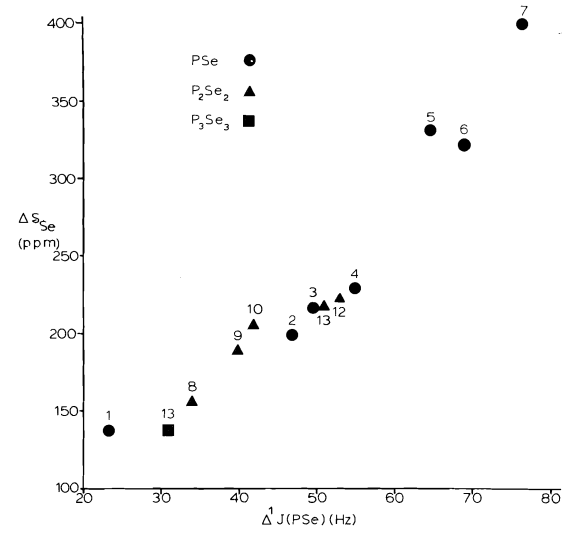


FIG. 2. Relationship between the downfield shift of the ^{77}Se resonance and the decrease in the magnitude of $^1J(PSe)$ occurring at 308 K when some phosphorus(V) selenides are dissolved in liquid SO_2 instead of CH_2Cl_2 (*1* = $SeP(OMe)_3$; *2* = $SePPh_3$; *3* = $SeP(p\text{-}C_6H_4Me)_3$; *4* = $SePMePh_2$; *5* = $SeP(C_6H_{11})_3$; *6* = $SePEt_3$; *7* = $SeP(NMe_2)_3$; *8–12* = $[SePPh_2]_2(CH_2)_n$, *n* = 1–5, respectively; *13* = $[SePPh_2CH_2]_3CMe$).

Experimental

Materials

Triethylphosphine (PCR, Inc.), tri-*o*-tolylphosphine (PCR, Inc.), tri-*p*-tolylphosphine (Eastman Chemicals), bis(diphenylphosphino)methane (PCR, Inc.), 1,3-bis(diphenylphosphino)propane (Strem Chemicals, Inc.), 1,5-bis(diphenylphosphino)pentane (Strem Chemicals, Inc.), 1,6-bis(diphenylphosphino)hexane (Strem Chemicals, Inc.), 1,1,1-tris(diphenylphosphinomethyl)ethane (Strem Chemicals, Inc.), bis(2-diphenylphosphinoethyl)phenylphosphine (Strem Chemicals, Inc.), and methyldiphenylphosphine (prepared by D. Stephan of this Department by Grignard synthesis) showed no significant impurities in their ^{31}P nmr spectra and were used as received, as was the CS_2 adduct of tricyclohexylphosphine (Strem Chemicals, Inc.). Triphenylphosphine (Eastman Kodak Co.) was recrystallized from ethanol, and both trimethylphosphite (Strem Chemicals, Inc.) and tris(dimethylamino)phosphine (Aldrich Chemical Co., Inc.) were purified by distillation under reduced pressure.

Literature methods were used in the synthesis and purification of 1,2-bis(diphenylphosphino)ethane (22) and 1,4-bis(diphenylphosphino)butane (23).

Trimethylselenophosphate, $(MeO)_3PSe$, was prepared by the direct reaction of a slight excess of finely-powdered selenium with freshly-distilled trimethylphosphite under a dry nitrogen atmosphere (24). The supernatant liquid showed no significant

[5]Intramolecular association similar to **3** has been suggested earlier to account for the anomalous vibrational spectra of tetrakis(diphenylphosphinoselenoyl and -thioyl)methanes (21).

[6]Such a calculation also shows that $^1J(P\text{–}C_1)$ must change sign on complexation of PPh_3 by SO_2.

impurity by either ^1H or ^{31}P nmr and was used without further purification. Crude tris(dimethylamino)phosphine selenide was prepared in a like manner (25). Purification was achieved by sublimation followed by dissolution in liquid SO_2, filtration, and removal of volatiles *in vacuo*. All of the other phosphorus(V) selenides were synthesized by refluxing a benzene solution of the phosphine with excess selenium shot under nitrogen (26). Methyldiphenylphosphine selenide was purified by reduced pressure distillation (27). The solid selenides were purified by recrystallization. (The solvents used were ethanol (for $SePEt_3$ and $SeP(C_6H_{11})_3$), benzene (for $SePPh_3$ and $(SePPh_2)_2(CH_2)_n$ (n = 3–6)), and *n*-butanol (for $SeP(o\text{-}C_6H_4Me)_3$, $SeP(p\text{-}C_6H_4Me)_3$, $(SePPh_2)_2(CH_2)_n$ (n = 1 or 2), $(SePPh_2CH_2)_3CMe$ and $[SePPh_2(CH_2)_2]P(SePh)$.) The two triselenides are new compounds; they are characterized by the spectral data reported in this paper and by their melting points (247–249 and 208–210°C(uncorr), for $(SePPh_2CH_2)_3CMe$ and $[SePPh_2(CH_2)_2]P(SePh)$ respectively).

Crude tris(dimethylamino)phosphine telluride was prepared by reaction of a slight excess of finely-powdered tellurium with freshly-distilled tris(dimethylamino)phosphine for 3 h in a sealed tube at 437 K (25, 28). Unreacted $P(NMe_2)_3$ was removed by pumping *in vacuo*. (This removal is crucial because rapid tellurium exchange between $P(NMe_2)_3$ and $TeP(NMe_2)_3$ is known to occur (29).) Excess tellurium was removed by filtration of a CH_2Cl_2 solution of the pumped product. Removal of the solvent *in vacuo* gave a straw-coloured product showing no significant impurities by either ^1H or ^{31}P nmr.

$(MeSeP(NMe_2)_3)I$ was prepared *in situ* in SO_2 by the direct reaction of MeI and $SeP(NMe_2)_3$ (30, 31). (^1H (30, 31) and partial ^{31}P (31) nmr spectra of this compound have been reported.) Methylene chloride (Fisher Scientific Co., Certified Grade) was dried by standing over 3A molecular sieves and used without additional purification. Sulfur dioxide (Matheson Anhydrous Grade) was dried by standing in the gas phase over 3A molecular sieves for 12–24 h.

Raman Spectrum

The Raman spectrum of solid $SeP(o\text{-}C_6H_4Me)_3$ 0.63 SO_2 in a melting point capillary was obtained using a Cary 82 Spectrometer and excitation by the 5145 Å line of an Ar^+ laser.

Nuclear Magnetic Resonance Spectra

All nmr spectra were obtained using a Varian XL-100-12 spectrometer system equipped with the Gyrocode Observe accessary.

^{31}P and ^{77}Se spectra were measured with samples in a 10 mm hand-made sample tube within a 12 mm precision nmr tube, the external lock material (and, for ^{31}P, the reference) being in the annulus. Generally a 32 K transform was used.

For ^{31}P, the lock/reference was a 2% solution of $OP(OMe)_3$ in $(CD_3)_2CO$ ($\delta_{OP(OMe)_3} = \delta_{H_3PO_4} - 1.72$ ppm). Typically, selenium satellites in the spectra of 0.1–0.2 *M* samples were clearly visible after 250–500 ca. 60° pulses at 8–10 min^{-1}. For ^{77}Se, the lock substance was either $(CD_3)_2CO$ or D_2O, and referencing to neat $SeP(OMe)_3$ was by sample interchange ($\delta_{SeP(OMe)_3} = \delta_{SeMe_2} + 396.1$ ppm (7)). For this nucleus, pulses of ca. 20° were used. The repetition rate was 10 min^{-1} for solutions in CH_2Cl_2; in these cases 1000–4000 transients gave acceptable spectra when the sample concentration was 0.1–0.2 *M*. In SO_2 solutions T_1, not unexpectedly, seems much longer: poorer spectra could be obtained in the same number of transients at 3 min^{-1}. The ^{77}Se nmr spectra of $Ph_2P(CH_2)_n$-PPh_2—Se_8 equilibrium mixtures (Table 4) were obtained from samples having a total phosphine concentration of ca. 0.5 *M*, as were the spectra of $SeP(C_6H_{11})_3$, $Ph_2P(Se)(CH_2)_n$—$P(Se)Ph_2$ (n = 4 or 5), and $(Ph_2P(Se)CH_2)_3CMe$ in SO_2.

Temperatures were measured using a Doric Trendicator Type 400 thermocouple thermometer, with a stationary probe. The temperature controller of the nmr spectrometer was able to hold 228 K to better than ±1 K.

Preparation of Nuclear Magnetic Resonance Samples

^1H nmr samples were made up in standard 5 mm od nmr tubes. ^{31}P and ^{77}Se samples were prepared in tubes made from 10 mm od standard wall Pyrex tubing. Those tubes which were to contain SO_2 had attached a length of 9 mm od special wall tubing to allow their connection to a vacuum system via 3/8 in. Ultratorr fittings. The solid components were added to the tubes by weight, and the CH_2Cl_2, if any, by volume. Samples without SO_2 were sealed with plastic pressure caps. For those which did contain SO_2, known amounts of the gas were condensed in from a calibrated conventional glass-and-Teflon vacuum line before flame-sealing at the special wall tubing.

The composition of each sample was determined from its total weight. Sample volumes at 308 and 228 K were found by measurement of the weight at room temperature of the same volume of CH_2Cl_2 (density 1.33 g cm^{-3}).

Analysis of Exchange-averaged Chemical Shift/Coupling Constant Titration Curves

The composition of each sample was corrected for the amount of SO_2 in the headspace, assuming ideal behaviour Incremental chemical shifts were corrected for changes in the magnetic susceptibility of the solutions with composition.

Titration curves of the exchange-averaged chemical shift and/or coupling constant versus SO_2/L were analyzed using the program LISA (32). The chemical shifts and coupling constants in SO_2 as solvent were independent of concentration, suggesting virtually complete complexation. Therefore SO_2/L for such solutions was arbitrarily set at 9999.99999 to ensure that the predicted curve passed close to these points and hence to obtain the best fit over the whole range of composition. The K_1's given in Table 3 were calculated in this way, and we take the reasonable to very good fits to justify the treatment. However, our conclusions regarding the formation of 1:1 complexes does not depend on inclusion of the point for neat SO_2.

It should be noted that in all cases examined $|^1J(PSe)|$ was temperature dependent, being smaller at lower temperatures. In the analysis of the data, the incremental changes for the appropriate temperature were used. At 228 K the values of $|^1J(PSe)|$(Hz) are: $SeP(OMe)_3$: 949 (CH_2Cl_2), 914 (SO_2); $SePEt_3$: 674 (CH_2Cl_2), 585 (SO_2); $SeP(NMe_2)_3$: 778 (CH_2Cl_2), 675 (SO_2); $Ph_2P(Se)CH_2P(Se)Ph_2$: 746 (CH_2Cl_2), 696 (SO_2); $Ph_2P(Se)(CH_2)_4P(Se)Ph_2$: 717 ($CH_2Cl_2$), 646 ($SO_2$).

Spectral Analysis

The ^{77}Se satellite spectra in the ^{31}P-{H} nmr spectrum of $Ph_2P(Se)(CH_2)_2(Se)PPh(CH_2)_2P(Se)Ph_2$ were analyzed iteratively using the program LAOCN3(33). The values of $^1J(PSe)$ (Table 1) were insensitive to small changes in $^4J(PSe)$.

Acknowledgements

The author is grateful to Eva E. Schlahetka for preliminary work on the $(Me_2N)_3PSe$ and $(Me_2N)_3$-PTe systems, and to Mary Hughes for the preparation of some of the selenides and for assistance with the computations. Dr. Bill Dawson (University of South Carolina) is thanked for helpful discussions on several aspects of ^{77}Se nmr, and Mrs. Heather Schroeder for expert technical assistance in obtaining some of the nmr spectra. The National Research Council of Canada kindly supported this research.

Mercury(II) cyanide complexes of bulky phosphines. Preparation, characterization, and spectral studies

RAM G. GOEL, WILLIAM P. HENRY, AND WILLIAM O. OGINI

Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received September 12, 1978

RAM G. GOEL, WILLIAM P. HENRY, and WILLIAM O. OGINI. Can. J. Chem. **57**, 762 (1979).

Mercury(II) cyanide forms 1:2 complexes with triphenylphosphine and tri-*p*-tolylphosphine. Both 1:1 and 1:2 complexes are formed with tricyclohexylphosphine but only the 1:1 complex is obtained with tri-*tert*-butylphosphine, and no complex is formed with tri-*o*-tolylphosphine. The complexes have been characterized by elemental analyses and by infrared and Raman spectral measurements. Their behaviour in solution has been investigated by conductance, molecular weight, and ^{31}P nmr measurements. The infrared and Raman data for the 1:2 complexes are in accord with a pseudotetrahedral structure of C_{2v} skeletal symmetry. At least one of the 1:1 complexes is indicated to have a dimeric structure involving terminal and bridging CN ligands. The C≡N, Hg—CN, and Hg—P stretching frequencies and the ^{31}P—^{199}Hg spin–spin coupling for the complexes are discussed.

RAM G. GOEL, WILLIAM P. HENRY et WILLIAM O. OGINI. Can. J. Chem. **57**, 762 (1979).

Le cyanure de mercure(II) forme des complexes 1:2 avec la triphénylphosphine et la tri-*p*-tolylphosphine. Il se forme des complexes 1:1 ainsi que 1:2 avec la tricyclohexylphosphine alors que l'on n'obtient que des complexes 1:1 avec la tri-*tert*-butylphosphine; il ne se forme aucun complexe avec la tri-*o*-tolylphosphine. On a caractérisé les complexes grâces à leurs analyses centésimales et à leurs spectres infrarouges et Raman. On a étudié leur comportement en solution par des mesures de conductivité, de leurs poids moléculaires et de leurs spectres rmn ^{31}P. Les données infrarouge et Raman concernant les complexes 1:2 sont en accord avec une structure pseudotétraédrique de symétrie de squelette C_{2v}. Il semble qu'au moins un des complexes comporte une structure dimère impliquant des ligands CN terminaux servant de ponts. On discute des fréquences de vibration C≡N, Hg—CN et Hg—P ainsi que des couplages spin–spin ^{31}P—^{199}Hg des complexes.

Introduction

Mercury(II) halides are known to form a variety of complexes(I) with tertiary phosphines (1) and a number of spectroscopic (2–10) as well as crystallographic studies (11, 12) on these complexes have been reported recently. An investigation on triphenylphosphine complexes of mercury(II) pseudohalides showed that, unlike mercury(II) halides, mercury(II) cyanide forms only a 1:2 complex (13). In another study (5), both 1:1 and 1:2 complexes of mercury(II) cyanide were obtained with trimethylphosphine. Apart from these studies no report has appeared on phosphine complexes of mercury(II) cyanide.

In continuation of our investigations on metal complexes of sterically hindered phosphines we have undertaken a systematic study of phosphine complexes of mercury(II) (7, 8, 14) and other d^{10} metals (15, 16). In the present work complexes of mercury(II) cyanide with tri-*tert*-butyl-, tricyclohexyl-, tri-*o*-tolyl-, and tri-*p*-tolylphosphines were investigated. In view of very limited information reported for the triphenylphosphine complex (13), it was also included in the study.

Results and Discussion

Like mercury(II) halides, mercury(II) cyanide forms only 1:1 complex with tri-*tert*-butylphosphine (7) and both 1:1 and 1:2 complexes with tricyclohexylphosphine (4). However, unlike mercury(II) halides, mercury(II) cyanide does not form any complex with tri-*o*-tolylphosphine (7). This is indeed due to the large steric requirement and relatively low basicity of tri-*o*-tolylphosphine. In agreement with the observation of previous workers (13), only 1:2 complexes could be isolated with triphenylphosphine as well as with tri-*p*-tolylphosphine.

The analytical, molecular weight, and conductance data for the complexes included in the present study are recorded in Table 1. All the complexes are white, air-stable solids, soluble in polar solvents such as dichloromethane, acetone, or acetonitrile. As shown by the conductance data, the complexes do not ionize to any significant extent in acetonitrile. The complexes $[(p\text{-tolyl})_3P]_2Hg(CN)_2$ and $(Cy_3P)_2Hg(CN)_2$ exist as undissociated molecular species in dichloromethane but significant dissociation is indicated for the complex $(Ph_3P)_2Hg(CN)_2$. The com-

§In benzene.

plex $Cy_3PHg(CN)_2$ has a dimeric constitution in benzene. The molecular weight data for both $Cy_3PHg(CN)_2$ and $(t\text{-Bu})_3PHg(CN)_2$, in dichloromethane, are explicable in terms of partial dissociation of the dimeric species into monomers.

Vibrational Spectral Studies

Vibrational spectra for the complexes $(Ph_3P)_2HgX_2$ and $(Cy_3P)_2HgX_2$, X = Cl, Br, and I, are in accord with a pseudotetrahedral structure of C_{2v} skeletal symmetry (2, 10) and such a structure has been established for the complex $(Ph_3P)_2Hg(SCN)_2$ by a X-ray diffraction study (17). The infrared and Raman data for the dicyanobis(phosphine)mercury(II) complexes are also consistent with a pseudotetrahedral structure. The mercury–halogen stretching and bending frequencies (2, 10) for the dihalobis(phosphine)mercury(II) complexes are very similar to those for the corresponding HgX_4^{2-} complexes (18). The C≡N and Hg—CN stretching and the Hg—CN bending frequencies for the dicyanobis(phosphine)mercury(II) complexes are also found to be very similar to those for the cyano complex $Hg(CN)_4^{2-}$ (19).

The Raman spectrum of solid $[(p\text{-tolyl})_3P]_2Hg(CN)_2$, in the C≡N stretching region, showed a strong band at 2146 cm^{-1} and a weak band at 2141 cm^{-1}. A strong Raman band at 2143 cm^{-1} and a weak Raman band at 2130 cm^{-1} were observed for the complex $(Cy_3P)_2Hg(CN)_2$, and a very strong, broad Raman band at 2140 cm^{-1} was observed for $(Ph_3P)_2Hg(CN)_2$. The infrared bands due to the C≡N stretching frequencies for all three complexes were very weak. Two very weak infrared bands were observed at 2145 and 2130 cm^{-1} for $[(p\text{-tolyl})_3P]_2Hg(CN)_2$ but only a very weak band at ca. 2140 cm^{-1} was observed for the triphenylphosphine and tricyclohexylphosphine complexes. Therefore, the previously reported assignment (13) for the C≡N stretching frequency for the $(Ph_3P)_2Hg(CN)_2$ complex appears to be erroneous.

Previously reported assignments (13) for the Hg—P and Hg—CN stretching frequencies and the Hg—CN bending frequency for the $(Ph_3P)_2Hg(CN)_2$ complex are also indicated to be erroneous. The 432 and 395 cm^{-1} infrared bands assigned to the Hg—P and Hg—CN stretching frequencies, respectively, are in fact due to the internal vibrations of triphenylphosphine (20). Our infrared and Raman data show that the skeletal vibrations for the dicyanobis(phosphine)mercury(II) complexes occur in the region below 400 cm^{-1}. The observed infrared bands in the 400–130 cm^{-1} region and the Raman bands in the 400–100 cm^{-1} region for the three complexes, in the solid state, together with their assignment are listed in Table 2. The proposed assignments for the Hg—CN stretching and bending frequencies for the complexes follow from those for $Hg(CN)_4^{2-}$ (19). As discussed later, the ^{31}P—^{199}Hg spin–spin coupling constants for the mercury(II) cyanide complexes are of the same order of magnitude as those for the mercury(II) iodide complexes. Since the Hg—P stretching frequencies for the $(Ph_3P)_2HgI_2$ and $(Cy_3P)_2HgI_2$ complexes are indicated (2, 10) to occur in the 100–90 cm^{-1} region, the Hg—P stretching frequencies for the corresponding cyano complexes are expected to fall below 100 cm^{-1}.

For the complex $(Me_3P)_2Hg(CN)_2$ (5), an infrared band at 311 cm^{-1} has been assigned to the Hg—CN stretching frequency and a Raman band at 329 cm^{-1} has been assigned to the Hg—P stretching frequency. Our results suggest that the aforementioned bands are due to the antisymmetric and symmetric Hg—CN stretching frequencies, respectively. The CN stretching frequencies reported for the trimethylphosphine complex (5) are comparable to those observed in the present work.

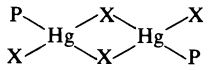
skeletal symmetry as shown below is indicated for the 1:1 triphenylphosphine[1] (2, 10) and tricyclohexylphosphine (10) complexes of mercury(II) halides.



As shown by molecular weight measurement, the complex $Cy_3PHg(CN)_2$ is undoubtedly a dimer in benzene. The observed CN stretching frequencies for this complex in the solid state as well as in solution are in accord with the presence of terminal and bridging CN groups. Its infrared spectrum, in the solid state, showed weak bands at 2180 and 2146 cm^{-1}, and its Raman spectrum showed a strong band at 2149 cm^{-1} and a weak band at 2179 cm^{-1}. The higher frequency bands can be attributed to the bridging CN groups (21, 22) and the lower frequency bands to the terminal CN groups. Infrared measurements in chloroform showed that the CN stretching frequencies in solution are virtually identical to those observed in the solid state. Thus, the solid state structure of the complex appears to be maintained in solution. The infrared spectrum of $Cy_3PHg(CN)_2$, in the low frequency region (400–130 cm^{-1}), showed bands at 344 (m, b), 270 (m, b), and 230 (w, b) cm^{-1} which can be attributed to the vibrations involving Hg—CN bonds. The 344 cm^{-1} band can be assigned to the terminal Hg—CN stretching frequency but it is difficult to make clearcut assignments for the other two infrared bands. The Raman spectrum of $Cy_3PHg(CN)_2$ in the region below 400 cm^{-1} was not very informative.

In the C≡N stretching region, a medium infrared band at 2157 cm^{-1} and a strong Raman band at 2152 cm^{-1} were observed for the complex $(t\text{-Bu})_3PHg(CN)_2$, in the solid state. The infrared frequency was not altered when the complex was dissolved in dichloromethane. The observed frequencies attributable to the skeletal vibrations of the complex include infrared bands at 335 (m, b), 281 (mw), 273 (mw), and 170 (mw, b) cm^{-1} and the Raman bands at 336 (w) and 112 (s) cm^{-1}. The 335 cm^{-1} infrared band and the 336 cm^{-1} Raman bands can be assigned to the terminal Hg—CN stretching frequency. The 112 cm^{-1} Raman band is similar to that observed for the iodo complex $(t\text{-Bu})_3PHgI_2$ (7) and is assigned to the Hg—P stretching frequency.

Although definitive structural conclusions for the 1:1 complexes must await X-ray diffraction studies, the molecular weight and vibrational spectral data for the complex $Cy_3PHg(CN)_2$ are consistent with a dimeric structure involving bridging and terminal CN groups and tetrahedrally coordinated mercury atoms.

^{31}P *Nuclear Magnetic Resonance Studies*

The ^{31}P nmr data for the 1:2 as well as 1:1 complexes at ambient temperature and at 183 K are given in Table 3. As shown by the data in Table 3, the ^{31}P nmr spectra of the complexes of less basic and less bulky phosphines, i.e., triphenylphosphine and tri-*p*-tolylphosphine, consisted of a single peak at

[1]The structure of Ph_3PHgCl_2 has been established by a crystal structure determination (11).

TABLE 3. ^{31}P nmr data*

Compound	δ (ppm)		Δδ (ppm)		$J(^{31}P–^{199}Hg)$ (Hz)	
	Amb. temp.	183 K	Amb. temp.	183 K	Amb. temp.	183 K
$(Ph_3P)_2Hg(CN)_2$	12.6	18.7	18.4	27.7	—	2645

ambient temperature whereas the spectra for the tricyclohexylphosphine and tri-*tert*-butylphosphine complexes showed a main peak and two satellite peaks due to $^{31}P—^{199}Hg$ spin–spin coupling. The satellites due to $^{31}P—^{199}Hg$ spin–spin coupling for the $(Ph_3P)_2Hg(CN)_2$ and $(p\text{-tolyl})_3PHg(CN)_2$ complexes were observed when the spectra were recorded at 183 K. The solution behaviour of mercury(II) cyanide complexes is thus very similar to that of the corresponding halide complexes (8). The ^{31}P nmr spectra of the triphenylphosphine and tri-*p*-tolylphosphine complexes containing excess phosphine gave a single resonance peak even at 183 K, showing that the rate of phosphine exchange is increased markedly by the presence of free phosphine. The ^{31}P nmr spectrum of an equimolar mixture of the 1:1 complex, $Cy_3PHg(CN)_2$, and free phosphine, at ambient temperature, was identical to that of the 1:2 complex, $(Cy_3P)_2Hg(CN)_2$. Addition of another equivalent of phosphine, however, gave a spectrum showing only a single resonance peak. Upon cooling the solution to 183 K the spectrum showed characteristic peaks of the 1:2 complex and free phosphine. From these results we conclude that the phosphine exchange occurs via an associative mechanism.

The $J(^{31}P–^{199}Hg)$ values for the three non-labile complexes increase with a decrease in temperature and the largest increase is observed for the $Cy_3PHg(CN)_2$ complex. Increase in the $^{31}P—^{199}Hg$ spin–spin coupling with decreasing temperature is also observed for complexes of mercury(II) halides (9) and carboxylates (14). The increase in the $^{31}P—^{199}Hg$ spin–spin coupling for the mercury(II) halide complexes (9) has been explained in terms of decrease in the rate of phosphine exchange with decreasing temperatures. However, we believe that further investigations are required to explain the temperature dependence of the $^{31}P—^{199}Hg$ spin–spin coupling. Such studies are underway in our laboratory.

For the 1:2 complexes, the $^{31}P—^{199}Hg$ spin–spin coupling increases markedly with increasing basicity of the phosphine but the increase in the coordination chemical shift is not substantial. The $J(^{31}P–^{199}Hg)$ values for the 1:2 complexes $(Ph_3P)_2HgX_2$ and $(Cy_3P)_2HgX_2$, where X = Cl, Br, I, and CN, follow the order Cl > Br > I > CN. However, the coordination chemical shifts for the cyano complexes in both series are larger than those for the iodo complexes. These observations as well as our recent ^{31}P nmr data on mercury(II) carboxylates (14) show that the correlations between the $^{31}P—^{199}Hg$ spin–spin coupling and the coordination chemical shifts observed in previous studies (3, 8) are fortuitous.

In agreement with the ^{31}P nmr data for the complexes of mercury(II) halides (3, 8, 9) and carboxylates (14), the $J(^{31}P–^{199}Hg)$ value for the 1:1 complex, $Cy_3PHg(CN)_2$, is much higher than that for the 1:2 complex, $(Cy_3P)_2Hg(CN)_2$. The $J(^{31}P–^{199}Hg)$ values for the complexes in the series Cy_3PHgX_2, where X = Cl, Br, I, CN, follow the sequence Cl > Br > CN > I. The $J(^{31}P–^{199}Hg)$ values for the tri-*tert*-butylphosphine complexes also vary in the above order.

^{31}P nmr measurements on ethanol solutions containing mercury(II) cyanide and tri-*o*-tolylphosphine in 1:1, 1:2, and 1:10 mole ratios showed only the resonance signal due to free phosphine at ambient temperature as well as at 183 K indicating lack of any interaction between mercury(II) cyanide and the phosphine.

Experimental Section

Materials

Tri-*tert*-butylphosphine was prepared and purified as described previously (23). Triphenylphosphine (Eastman Kodak) was recrystallized twice from hot ethanol. Tricyclohexyl- and tri(*p*-tolyl)phosphines (Pressure Chemical) were used without further purification. The purity of phosphines was checked by their infrared and ^1H and ^{31}P nmr spectra. Mercury(II) cyanide was reagent grade. Ethanol was dried by refluxing over magnesium and subsequent distillation. Acetonitrile was treated with phosphorus pentoxide and distilled over potassium carbonate. Other solvents were reagent grade.

Physical Measurements

Elemental analyses were performed by M-H-W Laboratories, Garden City, MI. Molecular weights were determined by Galbraith Laboratories, Knoxville, TN. Conductances were determined at 25°C with a Yellow Springs Instrument con-

ductivity bridge using a cell with platinized platinum electrodes. The infrared spectra (4000–130 cm^{-1}) were recorded on a Perkin-Elmer 180 double beam spectrophotometer. Solid samples were prepared as mulls in Nujol, and KRS-5 and polyethylene discs were used for spectral measurements. Sealed sodium chloride cells were used for measuring the spectra in solution. Raman spectra were recorded on a Jarrel-Ash Raman spectrometer using the 5145 Å excitation of an argon ion laser (Spectra Physics). The samples were powdered and sealed in glass capillary tubes. ^{31}P nmr spectra were obtained with a Bruker WP-60 FT spectrometer at 24.3 MHz using 85% H_3PO_4 as external reference. The spectra were recorded at ambient temperature and at 183 K.

*Preparation of Complexes of Triphenylphosphine and Tri-*p*-tolylphosphine*

$Hg(CN)_2$ (0.100 mmol) was dissolved in 20 mL ethanol and this solution was added dropwise, with constant stirring, to an ethanol solution of the phosphine (2.00 mmol). The mixture was refluxed for 1 h. Upon cooling, a white precipitate was obtained which was filtered off and recrystallized from a mixture of dichloromethane and petroleum ether. Yields: over 80%. Reaction of mercury(II) cyanide and phosphine in 1:1 mole ratio afforded a mixture of 1:2 complex and mercury(II) cyanide.

*Preparation of Complexes of Tricyclohexylphosphine and Tri-*tert*-butylphosphine*

The phosphines were handled under an atmosphere of *oxygen-free* dry nitrogen in a controlled atmosphere glove-box. Stoichiometric amount of mercury(II) cyanide was added to the solution of phosphine in dichloromethane and the mixture was stirred to give a clear solution which was concentrated in vacuum. Upon adding hexane (in excess) to the above solution a white precipitate of the complex was formed which was filtered off. The complex $Cy_3PHg(CN)_2$ was recrystallized from benzene and the tri-*tert*-butylphosphine complex was recrystallized from a mixture of dichloromethane and hexane. The 1:2 complex $(Cy_3P)_2Hg(CN)_2$ was recrystallized from an ice-cold solution in ethanol. Reaction of $Hg(CN)_2$ and $(t\text{-}Bu)_3P$ in 1:2 mole ratio also gave 1:1 complex. Yields: ~80%.

*Attempted Preparation of Tri-*o*-tolylphosphine Complexes*

Mercury(II) cyanide and phosphine in 1:1 and 1:2 mole ratios were dissolved in alcohol, acetone, or dimethylacetamide and the solutions were refluxed for several hours. In each case, a mixture of mercury(II) cyanide and phosphine was recovered upon removal of the solvent.

Syntheses and spectroscopic study of a new series of mixed-ligand complexes of As(III) and Sb(III) with dithio-ligands

FADEL M-N. KHEIRI, CONSTANTINOS A. TSIPIS, CHRISTOS L. TSIAMIS, AND GEORGE E. MANOUSSAKIS[1]

Laboratory of Inorganic Chemistry, University of Thessaloniki, Thessaloniki, Greece

Received September 12, 1978

FADEL M-N. KHEIRI, CONSTANTINOS A. TSIPIS, CHRISTOS L. TSIAMIS, and GEORGE E. MANOUSSAKIS. Can. J. Chem. **57**, 767 (1979).

Seventeen new mixed-ligand complexes of As(III) and Sb(III) with dithio-ligands have been prepared and studied. The preparation of the mixed-ligand complexes has been made by reacting the corresponding iodobis(dialkyldithiocarbamate) complexes with either CS_2 and HNR_2 or the sodium salt of the dithiocarbamate. Alteration of the second method facilitated the preparation of the mixed-ligand dithiocarbamate–xanthate complexes of Sb(III) whereas the analogous arsenic compounds have not been isolated. The study of these new compounds reveals that their stability depends on the nature of both ligand and central atom. The spectroscopic data of the compounds are discussed and compared with those of similar complexes of Bi(III).

FADEL M-N. KHEIRI, CONSTANTINOS A. TSIPIS, CHRISTOS L. TSIAMIS et GEORGE E. MANOUSSAKIS. Can. J. Chem. **57**, 767 (1979).

On a préparé et étudié dix-sept nouveaux complexes avec des ligands mixtes du As(III) et du Sb(III) avec des ligands disulfurés. On a préparé les complexes avec des ligands mixtes en faisant réagir les complexes iodobis(dialkyldithiocarbamate) correspondants soit avec du CS_2 et du HNR_2 ou le sel de sodium du dithiocarbamate. Une modification de la seconde méthode a facilité la préparation des complexes avec les ligands mixtes, dithiocarbamate–xanthate, du Sb(III) alors que l'on n'a pas pu isoler les composés analogues de l'arsenic. L'étude de ces nouveaux complexes révèle que leur stabilité dépend à la fois de la nature du ligand et de l'atome central. On discute des données spectroscopiques et on les compare avec celles de complexes semblables du Bi(III).

[Traduit par le journal]

Introduction

In previous papers (1, 2) we have reported the syntheses and study of some new mixed-ligand complexes of Fe(III) and Bi(III) with dithio-ligands. In the course of our studies on metal complexes with sulfur containing ligands, it seemed interesting to investigate the effect of the different size and electronegativity of the central atom on the stability and the electronic properties of the mixed-ligand dithio-complexes. In this paper we report the results concerning the preparation and study of some new mixed-ligand complexes of As(III) and Sb(III) with dithio-ligands and compare their properties with those of the Bi(III) analogues.

Experimental

Materials

The sodium dialkyldithiocarbamate salts, the potassium *O*-ethylxanthate, the iodobis(dialkyldithiocarbamate) complexes of As(III) and Sb(III) and the As(III) and Sb(III) *O*-ethylxanthates were prepared by previously reported methods (3–7).

Synthesis of the Mixed-ligand Complexes

The following two general methods were applied for the preparation of the mixed-ligand complexes of As(III) and Sb(III) of the general formula $M(R_2'dtc)(R_2dtc)_2$.

Method A

The preparation was carried out into a three-necked flask equipped with a magnetic stirrer, a reflux condenser, and a separatory funnel. Into the flask were charged 2.0 mmol of the iodobis(dialkyldithiocarbamato)arsine or -stibine, 2.0 mmol of CS_2 and 100 cm^3 of CCl_4 as a solvent.

To the resulting suspension 4.0 mmol of the amine ($R_2'NH$), dissolved in $\sim$30 cm^3 of CCl_4, were added slowly under continuous stirring in a period of 0.5 h.

The mixture was refluxed for 4–5 h and after cooling it was filtered. The filtrate was condensed up to a small volume ($\sim$30 cm^3) and upon addition of ethanol the mixed-ligand dithio-complex was precipitated as a crystalline solid. The products obtained were purified by dissolving them in a small volume of $CHCl_3$ or benzene and reprecipitating by adding methanol or petroleum ether.

Method B

The reaction was run into a conical flask. Into the flask were charged 3.0 mmol of the iodobis(dialkyldithiocarbamato)arsine (or -stibine) suspended into 60 cm^3 of chloroform. Then 3.0 mmol of sodium dialkyldithiocarbamate salt, dissolved in 15 cm^3 of ethanol, were added to the suspension slowly, under continuous magnetic stirring. The reaction mixture was left for 1 h at room temperature and then was filtered in order to remove the insoluble potassium iodide formed. The filtrate was condensed up to a small volume ($\sim$20 cm^3) and upon addition of ethanol or petroleum ether the mixed-ligand dithio-complex

[1]To whom all correspondence should be addressed.

0008-4042/79/070767-06$01.00/0

was precipitated. The crude product obtained was purified as described in method A.

The synthesis of the mixed-ligand dithiocarbamate–xanthate complexes of antimony has been done according to the following method. To a suspension of 2.5 mmol of iodobis(dialkyldithiocarbamato)stibine in 60 cm^3 of chloroform, 2.5 mmol of potassium *O*-ethylxanthate, dissolved in 10 cm^3 of ethanol, were added slowly under continuous stirring. The reaction mixture was left at room temperature for 1 h and then was filtered. The filtrate was condensed up to a small volume ($\sim$20 cm^3) and the mixed-ligand complex was precipitated by addition of petroleum ether. The crude product was purified by dissolving it in a small volume of benzene and reprecipitating by adding petroleum ether.

Measurements

Infrared spectra were recorded in the region of 4000–650 cm^{-1} with a Perkin-Elmer 257 spectrophotometer. Proton nmr spectra were obtained with a Varian A 60A (60 MHz) spectrometer in $CDCl_3$ and C_6H_6 solutions, using TMS as an internal standard. Electronic spectra in the region 200–1000 nm were measured at ca. 30°C using a Zeiss PMQII spectrophotometer. Solutions in chloroform were used in 1 cm "suprasil" cells fitted with Teflon stoppers, with pure solvent in the reference cell. Mass spectra were measured on an RMU-6L Hitachi Perkin-Elmer mass spectrometer with ionisation source of AT-2p type operating at $\sim$70 eV. Molecular weights in solution were determined using a Perkin-Elmer Model 115 molecular weight apparatus at a concentration ranging from 3×10^{-3} to 6×10^{-4} mol/kg in chloroform.

Results and Discussion

Seventeen new mixed-ligand complexes of arsenic and antimony with dithio-ligands have been prepared by reacting the iodobis(dialkyldithiocarbamate) complexes of As(III) and Sb(III) with sodium dialkyldithiocarbamate salts according to the following general equation

$$Na(R_2'dtc) + M(R_2dtc)_2I \rightarrow M(R_2'dtc)(R_2dtc)_2 + NaI$$

where M = As or Sb, $R_2'dtc$ = Et_2dtc, Pyrrdtc, Bz_2dtc, THPyrdtc, and R_2dtc = Et_2dtc, Pyrrdtc, Pipdtc (Et = C_2H_5, Pyrr = $(CH_2)_4N$, Bz = C_6H_5-CH_2, THPyr =  N, Pip = $(CH_2)_5N$).

These complexes can also be prepared by reacting the iodo-complexes with carbon disulfide and the amine (HNR_2') in one step according to the reaction:

$$2R_2'NH + CS_2 + M(R_2dtc)_2I \rightarrow M(R_2'dtc)(R_2dtc)_2 + R_2'NH{\cdot}HI$$

This method cannot be applied for the preparation of the mixed-ligand complexes, whenever the amine is the dibenzylamine.

The iodobis(dialkyldithiocarbamate) complexes of Sb(III) also react with potassium *O*-ethylxanthate to give the mixed-ligand dithiocarbamate–xanthate complexes according to the reaction:

$$Sb(R_2dtc)_2I + K(EtXanth) \rightarrow Sb(EtXanth)(R_2dtc)_2 + KI$$

where EtXanth = $EtOCSS^-$ and R_2dtc = Et_2dtc or Pyrrdtc.

However, in the case of the arsenic compounds, it was not possible to obtain mixed-ligand dithiocarbamate–xanthate complexes, as the products of the second reaction were the corresponding tris(dialkyldithiocarbamate) and tris(*O*-ethylxanthate) complexes of arsenic.

This may be due to a disproportionation reaction which undergoes the mixed-ligand dithiocarbamate–xanthate complexes of arsenic formed possibly as intermediates:

$$3As(EtXanth)(R_2dtc)_2 \rightleftharpoons 2As(R_2dtc)_3 + As(EtXanth)_3$$

In order to support the above idea, some ligand exchange experiments were performed. The tris(dialkyldithiocarbamate) and tris(*O*-ethylxanthate) complexes of arsenic were dissolved in $CHCl_3$ in a mole ratio 2:1 and the mixture was refluxed for several hours. From the reaction mixture only the starting materials were isolated.

The mixed-ligand dithio-complexes of arsenic and antimony are stable in air, in solid state as well as in solution. All the complexes are soluble in chloroform, methylene chloride, and benzene, and insoluble in methanol, ethanol, petroleum ether, and water. The analytical data and some physical properties of the complexes are given in Table 1.

Infrared Spectra

The thioureide band (1460–1500 cm^{-1}) of the complexes studied is a composite band, containing the frequencies of the C···N bonds of both types of the dithiocarbamato ligands. The maximum of these bands corresponds to the C···N stretching frequency of the dithiocarbamato ligand, which is in higher proportion in the molecule of the mixed-ligand complex. The stretching frequency of the C···N bond of the other ligand appears as a shoulder. Generally, there is no significant influence of the nature of the central atom on the position of the thioureide band.

There are some bands in the region 800–1000 cm^{-1} which are attributed (8) to the C···S stretching vibration of both types of the dithiocarbamato ligands. The position of these bands is about the same as those of the corresponding simple tris(dialkyldithiocarbamate) complexes. In the mixed-ligand dithiocarbamate–xanthate complexes of antimony, the C···S stretching frequencies of the xanthate moiety are higher than those of the dithiocarbamate group.

The asymmetric stretching vibration of the C···O bond of the xanthate group appears in the region of 1200–1300 cm^{-1} and depends heavily on the nature of the central atom (9–13). As the electronegativity of

†Figures in parentheses are the theoretical calculated values.

the central atom decreases, the band is shifted to lower frequencies. This dependence is more pronounced than that of the C⋯N bond of the dithiocarbamate ligand.

The C⋯O frequency for the mixed-ligand dithiocarbamate–xanthate complexes is lower than that for the corresponding tris(*O*-ethylxanthate) complexes. That would be expected for the dithiocarbamate group which, as a stronger electron donor, increases the electron density on the central atom. Thus the latter reduces the electron releasing ability of the xanthate group.

Proton Nuclear Magnetic Resonance Spectra

The ^1H nmr chemical shifts (τ, ppm) of the mixed-ligand complexes of As(III) and Sb(III) with dithio-ligands are given in Table 2.

There is a remarkable difference in the ^1H nmr spectra of the mixed-ligand complexes concerning the dithiocarbamate and xanthate ligands. In the xanthate ligand, as its electron releasing ability increases, the proton chemical shifts are moved to lower frequencies, while in the dithiocarbamate ligand only the protons, the most distant from the nitrogen atom, are deshielded. This can be explained on the basis of the different location of the protons in the shielding or deshielding cone, which is the consequence of the magnetic anisotropy of the C⋯O and C⋯N bonds in the xanthate and dithiocarbamate ligands, respectively. This explanation also holds true for the analogous behaviour observed (2) in the mixed-ligand Bi(III) dithio-complexes.

In benzene solution the usual Aromatic Solvent Induced Shift (ASIS) was observed. This is attributed to the formation of weak collision complexes between the solute and solvent molecules (14). In the mixed-

*Figures in parentheses are the τ values for the benzene solutions.

† 
ligand dithiocarbamate complexes, the observed ASIS has approximately the same magnitude as that in the case of the tris-derivatives. This observation supports the notion that, in a complex, each dithiocarbamate ligand acts as an independent centre for electrophilic attack from the benzene molecules (14). The ASIS in the mixed-ligand dithiocarbamate–xanthate complexes is smaller than in the previous cases. The different ASIS between the xanthate and dithiocarbamate ligands is attributed to the different orientation of the attached benzene molecule as this orientation is dependent on the stereochemistry of the ligand and the magnitude of the positive charge on the oxygen or the nitrogen atom respectively.

Electronic Spectra

As shown in Table 3 the compounds gave, as expected (15), intense bands at approximately 255, 310, and 360 nm. Most authors (16–18) agree that the intense band near 255 nm, band I, should be assigned to intraligand $\pi^* \leftarrow \pi$ transition of the N⋯C⋯S group. In the mixed-ligand dithiocarbamate–xanthate complexes this band partly obscures the band at λ_{max} 245 nm due to an $\sigma^* \leftarrow \eta$ electronic transition of the xanthate moiety (19). Band II is attributed to a $\pi^* \leftarrow \pi$ transition of the S⋯C⋯S group. This band, which appears as a shoulder in dithiocarbamate and mixed dithiocarbamate complexes, exhibits a characteristic λ_{max} and a blue shift

in the case of xanthate complexes. The same observations can be made for band III which is attributed to either an $\pi^* \leftarrow \eta$ transition located on the sulfur atom or a *d*-orbital ← ligand transition (5, 19, 20).

Mass Spectra

The mass spectra (ms) of the mixed-ligand dithiocarbamate and dithiocarbamate–xanthate complexes were obtained over a temperature range as these complexes might undergo a thermolytic decomposition at elevated temperatures (250–300°C). In common with dithiocarbamate and xanthate complexes, the molecular ion was not observed. Again, at the lower end of the temperature range, the base peak appeared at $(m/e) = 76$ attributed to the $|CS_2|^{+\cdot}$ ion. As the temperature was raised the fragmentation pattern changed and this was accompanied by a change in peak intensity. There was a sharp increase in the intensity of peaks attributed to ions $|CS|^{+\cdot}$, $|CO|^{+\cdot}$, $|R|^+$, $|R'|^+$. This and the appearance of sulfides of the general formula As_nS_m, Sb_nS_m, where $n, m = 1, 2, 3, 4$, are in support of a pyrolytic decomposition taking place (21). The mass spectra of a representative complex at different temperatures are given in Table 4.

The salient feature of the mass spectra of the dithiocarbamate–xanthate complexes is that no peak could be assigned to fragments containing the xan-

thate moiety bonded to the central ion. This is in support of the widely held opinion that the xanthate ligand is a weaker chelating agent than the dithiocarbamate.

Etude des complexes du tungsténe(VI) dans l'excès de acide malique

ANTONIO CERVILLA, AURELIO BELTRAN ET JOSÉ BELTRAN
Département de Chimie Inorganique, Faculté de Sciences, Université de Valencia, Espagne
Reçu le 10 août 1978

ANTONIO CERVILLA, AURELIO BELTRAN et JOSÉ BELTRAN. Can. J. Chem. **57**, 773 (1979).

L'étude polarimétrique des complexes de W(VI) avec l'acide malique montre, en présence d'un excès d'acide malique (H_2M), l'existance de trois complexes différents. La stoechiométrie et le degré de condensation de ces complexes sont fonction du pH. Les resultats obtenus indiquent que l'acide malique et l'acide tartrique montrent un comportement analogue. La constante de formation du complexe $[O_2W(OH)_2(M_2)]^{4-}$ a été determinée par deux méthodes différents.

ANTONIO CERVILLA, AURELIO BELTRAN, and JOSÉ BELTRAN. Can. J. Chem. **57**, 773 (1979).

The complex formation between W(VI) and malic acid (H_2M) has been investigated polarimetrically in excess malic acid. The formation of three different complexes is confirmed. The stoichiometry and the degree of condensation of these complexes can vary depending on the acidity. Furthermore, the results obtained show that both tartaric and malic acids behave similarly in forming complexes with W(VI). The formation constant of the complex $[O_2W(OH)_2(M_2)]^{4-}$ has been determined by two different methods.

Introduction

Le pouvoir rotatoire du tartrate ou malate neutre n'est pas modifié par l'addition de WO_4^{2-}, ce qui preuve qu'il ne se forme pas de complexe dans cettes conditions. Par contre, on a observé depuis longtemps (1) que l'acidification du mélange provoque une augmentation importante de son pouvoir rotatoire, ce qui indique la formation de complexes.

Desal (2) étudie les variations du pouvoir rotatoire en fonction de la neutralisation progressive des mélanges d'acide tungstique et d'acide 1(+)-tartrique ou 1(−)-malique. Avec l'acide tartrique, Desal ne reconnait qu'un seul complexe tungsto-tartrique (TWO_2Na_2), dextrogyre. Par contre, avec l'acide malique, les courbes polarimétriques de neutralisation misent en évidence deux groupes de complexes. Un complexe tungsto-dimalique levogyre ($M_2WO_2Na_2$) et un complexe ditungsto-malique destrogyre ($MWO_2(OH)Na_2WO_4H_2$). Il n'existe pas de complexes dans lesquels le rapport M/W = 1/1.

En 1961, Baillie et Brown (3) montrent, à partir des mesures polarimétriques de neutralisation des mélanges d'acide tungstique et d'acide 1(+)-tartrique ou 1(−)-malique, l'existence de trois espèces, avec un degré différent de protonation, donc le rapport M/W est toujours égale a 1/1.

Face à ces conclusions assez divergentes, dans un travail précedant (4), nous avons fait l'étude des complexes du W(VI) avec l'acide 1(+)-tartrique, en utilisant une méthode polarimétrique décrite par Viossat (5).

Les résultats obtenus sont partiellement en accord avec d'autres récemment parus dans la réf. 6.

Avec le propos de deduire l'influence des groupes alcooliques dans les complexes qui forme le W(VI) avec l'acide tartrique, dans ce travail nous allons étudier les complexes qui se forment avec l'acide malique.

Il faut remarquer, d'accord avec un travail publié en avance (7), que l'acide tartrique forme les espèces complexes antérieurement cités, indépendamment de la concentration de W(VI). Tout au contraire, il semble que l'acide malique forme des espèces complexes en l'excès de cet acide, différents a ceux qui se forment en présénce d'un excès de W(VI). Dans ce travail nous n'allons nous occuper que des complexes formés en excès d'acide malique.

Mise en évidence des différents complexes

Dans la fig. 1 (courbe *A*) on a porté le pouvoir rotatoire, face au pH pendant la neutralisation d'une disolution de H_2M 0.1 *M* avec NaOH.

Cette courbe *A* es très influenciée par la addition de Na_2WO_4 à la disolution initial de H_2M (courbe *B*, fig. 1). La concentration de Na_2WO_4 correspondant à la courbe *B* est de 4×10^{-3} *M*, c'est-à-dire $H_2M/WO_4^{2-} = 25$. Dans cette courbe *B* apparaisent superposées les rotations dues aux complexes existants et à l'excès d'acide malique.

Comme nous verrons après, la relation M/W dans les complexes formés ne sera pas plus grande de 2/1. Pourtant, l'excès d'acide malique ne sera jamais inferieur à 23 fois la concentration de WO_4^{2-} présente. Pour cela et etant donné que le pouvoir rotatoire de l'acide malique est très inférieur à celui des complexes formés, on peut déduir, avec une erreur négligeable, que la différence entre les courbes *A* et *B* (courbe *C*, fig. 1) répresente la

0008-4042/79/070773-04$01.00/0

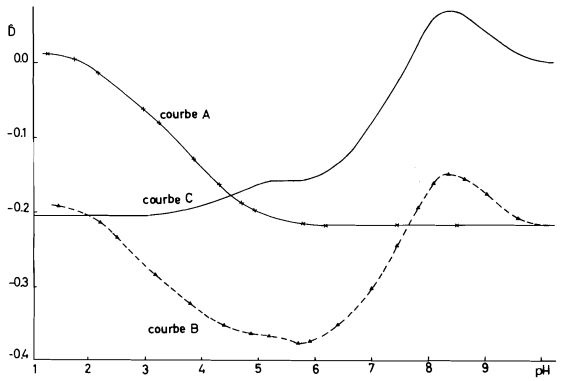

FIG. 1. $\hat{D} = f(\text{pH})$ à $\lambda = 436$ nm. Courbe A: H_2M seul 0.1 M. Courbe B: WO_4^{2-} 4×10^{-3} M + H_2M 0.1 M. Courbe C: courbe A − courbe B.

variation du pouvoir rotatoire avec le pH, dû aux complexes formés.

On peut deceler, à partir de la forme presentée par la courbe C, l'existance de trois zones distinctes. Ces trois zones correspondront à trois complexes différents.

Zone A: *pH compris entre 10 et 8.5*

Les courbes A et B (fig. 1) coincident à partir du pH égal à 10, ceci nous indiquerai l'absence de complexes pour les pH supérieurs à celui-ci. L'addition d'acide $HClO_4$ produit une montée brusque du pouvoir rotatoire, cela nous montre la formation d'un complexe que nous appellerons I. Au pH 8.5 on observe sur la courbe C un maximum, ceci indique que tout le W(VI) est complexé sous la forme I puisqu'il existe un excès de ions malate.

Les variations du pouvoir rotatoire dû aux complexes formés, courbe C, varient entre 0.000 et 0.072 pour des pH 10.0 et 8.5 respectivement. Cette variation servira à la détermination des ions H^+ necessaires au passage des ions WO_4^{2-} au complexe I, suivant la reaction:

$$WO_4^{2-} + nH^+ + zM^{2-} \rightleftarrows (1/a)I$$

où la valeur du paramètre a est lié au degré de condensation du complexe. En appelant α la fraction molaire de I formée, C la concentration total de W(VI), et en appliquant la loi d'action de masse à l'équilibre précédant, on obtient:

$$[1] \quad \log K + (1/a)\log a - \log C(1/a - 1) + z \log (M^{2-}) = \text{cte} = n\text{pH} + \log \alpha^{1/a}/(1 - \alpha)$$

Pour des valeurs de C et (M^{2-}) constants la connaissance des valeurs de α permet le calcul de la fonction $\log \alpha^{1/a}/(1 - \alpha)$ pour différents valeurs de a. Si on porte cette fonction envers le pH on obtient une série de courbes, la seule qui satisfait l'équation précédente est la droite, dont la pente détermine la valeur de n.

Les valeurs de α, pour un pH fixé, sont calculés à partir de la relation: $\hat{D} = \alpha \hat{D}_I = 0.072\alpha$; où $\hat{D}_I = \hat{D}(\text{pH} = 8.5)$ et $\alpha = 1$.

Sur la fig. 2 sont representées les courbes correspondant aux valeurs de a 1, 1/2 et 2. La seule droite correspond au valeur de $a = 1$, une pente de -1.98 et ordonnée à l'origine 19.83. On peut donc conclure que le complexe I est un monomère, dont la formation nécessite $2H^+/W$.

On peut calculer le rapport M/W present dans l'espèce I par la méthode de la droite d'Asmus (8).

Chaque échantillon a 1 mL de Na_2WO_4 0.2 M dans un volume total de 50 mL ($a_0 = 4 \times 10^{-3}$ M) et volumes croissants de H_2M ($b_0 = 2$ M). On ajoute à chaque échantillon la quantité necessaire de NaOH pour obtenir un pH de 8.5.

Dans la fig. 3 on represente $1/V^n$ face à $1/\hat{D}$, où $\hat{D}$ est le pouvoir rotatoire mesuré moins celui correspondant à l'acide malique qui èxiste. Dans cette graphique on peut voir que la ligne droite obtenue correspond à une valeur de $n = 2$, ce qu'indique que la rapport M/W dans l'espèce I est égal à 2/1. Ce resultat nous améne à la conclusion de que la formation du complexe I peut donc être représentée par l'equilibre suivant:

$$WO_4^{2-} + 2M^{2-} + 2H^+ \rightleftarrows [O_2W(OH)_2(M_2)]^{4-}$$

La droite obtenue quand on represente $1/V^n$ face à $1/\hat{D}$, a une ordonnée à l'origine de -0.0126. De ce valeur on déduit que la constante de formation du complexe $[O_2W(OH)_2(M_2)]^{4-}$ est de $K = 1.27 \times 10^{23}$.

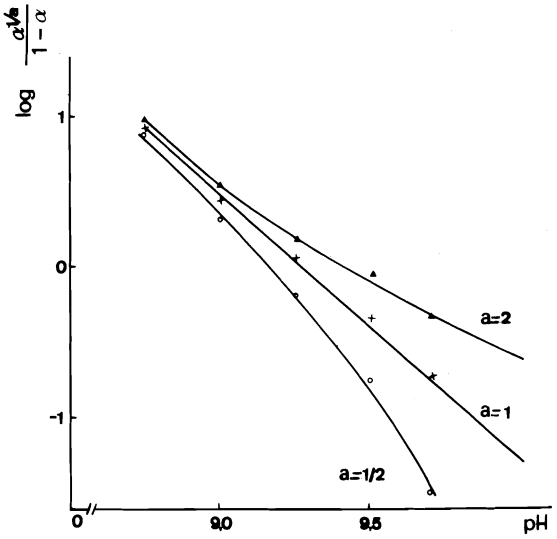

FIG. 2. $\log \alpha^{1/a}/(1 - \alpha) = f(\text{pH})$; pH compris entre 10 et 8.5.

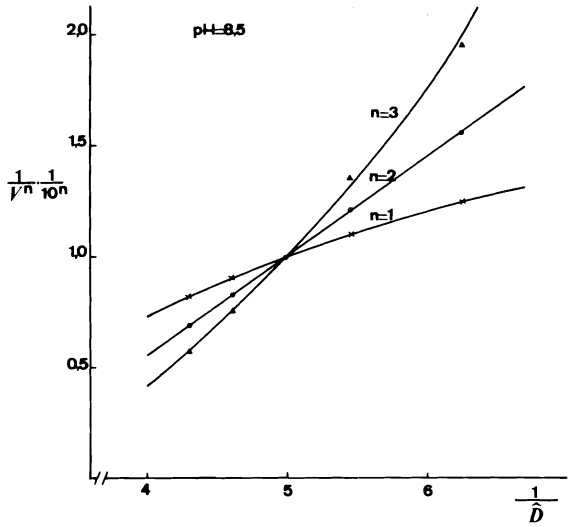

FIG. 3. Calcul de la relation M/W present à l'espèce I par la méthode de la droite d'Asmus. $V_t = 50$ mL, $a_0 = 4 \times 10^{-3}$ M, $b_0 = 2$ M, force ionique 1 M ($NaClO_4$). pH = 8.5, $\lambda = 365$ nm.

Également l'éq. [1] permet le calcul de K, puisqu'on connaît $(M^{2-}) = 0.1$ M, $C = 4 \times 10^{-3}$ M, $a = 1$, $z = 2$ et ordonnée à l'origine de la droite obtenue quand on represente $\log \alpha/(1 - \alpha) = f(\text{pH})$ égale à 20.63. On obtient la valeur de $K = 4.26 \times 10^{22}$. Cette valeur de K est comparable à celle obtenue avec la méthode d'Asmus.

Zone B: *pH compris entre 8.5 et 5.5*

Dans cette zone une diminution du pH entraîne une diminution du pouvoir rotatoire. Ceci indiquerai la formation d'une nouvelle espèce que nous apellerons II. Comme précédemment, l'équilibre:

$$[O_2W(OH)_2(M_2)]^{4-} + m\text{H}^+ \leftrightharpoons (1/b)\text{II}$$

a été suivi polarimétriquement. Il faut noter que la fraction molaire, β, de II est liée au pouvoir rotatoire du mélange $NaWO_4/25H_2M$ en fonction du pH, suivant l'équation: $\hat{D} = \hat{D}_I(1 - \beta) + D_{II}\beta$. La fig. 1 (courbe C) fournit, pour $\lambda = 436$ nm, les valeurs $\hat{D}_I = 0.072$ et $\hat{D}_{II} = 0.162$ degrés.

Avec le même raisonnement utilisé pour l'étude de la zone A il ressort, que la seule valeur de b satisfactoire est 2. La droite $\log \beta^{1/2}/(1 - \beta) = f(\text{pH})$ a une pente de -1.02.

Ces resultats montrent que l'espèce II est un dimère dont l'équilibre de formation peut s'exprimer:

$$[O_2W(OH)_2(M_2)]^{4-} + \text{H}^+ \leftrightharpoons (1/2)\text{II}$$

Pour le calcul de la relation M/W present à l'espèce II, nous avons appliqué, de façon similaire à celle de l'apartat A, la méthode de la droite d'Asmus, en excès d'acide malique et pH égal a 5.5.

En représentant $1/V^n$ face a $1/\hat{D}$ on obtient une droite pour $n = 1$, ce qu'indique que la espèce levogyre II presente un rapport M/W = 1/1 et son équilibre de formation, à partir de l'espèce I, on peut représenter par l'équation:

$$[O_2W(OH)_2(M_2)]^{4-} + \text{H}^+ \leftrightharpoons (1/2)[O_3W_2(OH)_4(M_2)]^{2-} + M^{2-} + (1/2)H_2O$$

Zone C: *pH compris entre 5.5 et 3.2*

Le pouvoir rotatoire dans cette zone diminue, apparaissant un minime au pH 3.2. L'espèce II doit se transformer dans une autre, III, suivant l'équilibre:

$$[O_3W_2(OH)_4(M_2)]^{2-} + p\text{H}^+ \leftrightharpoons (1/c)\text{III}$$

La constance des valeurs de $\hat{D}$, pour les pH inférieurs à 3.2, indique que l'espèce III est la seule stable dans cette zone.

L'étude de l'équilibre de formation de la espèce III a besoin des valeurs de γ, fraction de $[O_3W_2(OH)_4(M_2)]^{2-}$ transformée en III, calculées avec l'équation: $\hat{D} = \hat{D}_{II}(1 - \gamma) + \hat{D}_{III}\gamma = -0.162 \times (1 - \gamma) - 0.206\gamma$.

La fonction $\log \gamma^{1/c}/(1 - \gamma)$ face au pH donne une droite pour $c = 1$, dont la pente est de -0.96.

Ce résultat indique que les complexes II et III ont le même degré de condensation, c'est-à-dire il s'agit de deux espèces dimères.

La méthode d'Asmus, appliquée à pH 2.5, en excès d'acide malique nous indique aussi que le rapport M/W est égal à 1/1 pour l'espèce III.

Ainsi, l'équilibre de formation de cette espèce, à partir de $[O_3W_2(OH)_4(M_2)]^{2-}$, on peut écrire:

$$[O_3W_2(OH)_4(M_2)]^{2-} + \text{H}^+ \leftrightharpoons [HO_3W_2(OH)_4(M_2)]^-$$

Conclusion

En excès d'acide malique, le W(VI) forme un complexe tungsto-dimalique destrogyre et deux tungsto-malique levogyres. La formation de ces espèces, à partir de WO_4^{2-} et M^{2-}, necessite 2, 2, et 2.5 H^+/W respectivement.

Nous avons comprobé, aussi, que le degré de condensation de l'espèce $[O_2W(OH)_2(M_2)]^{4-}$ est 1, tandis que les autre deux, de stoechiométrie 1:1, son dimères.

De ce résultats on peut conclure que l'acide malique montre un comportement analogue à celui de l'acide tartrique (4).

La constant de formation de l'espèce $[O_2W(OH)_2(M_2)]^{4-}$ a été deduite par deux méthodes différents. De la valeur obtenue on déduit que cette complexe est plus stable que celle formée par l'acide tartrique ($K = 1.07 \times 10^{18}$) (4, 6).

Données expérimentales

Le pouvoir rotatoire des échantillons a été mesuré à l'aide d'un polarimétre photoélectrique Perkin-Elmer Mod. 141, à sortie digitale. La precision des mesures est de ± 0.002 degrés.

La cellule est thermostatée à 30 $\pm$ 0.05°C et a une longeur de 10 $\pm$ 0.002 cm. L'appareil permet effectuer les mesures à cinq longeurs d'onde différents (589, 578, 546, 436, 365 nm). Les résultats obtenus pour chacune de ces longeurs d'onde son comparables dans tous les cas.

Les pH sont mesurés à l'aide d'un pHmétre Radiometer 26, à 30°C. La force ionique des solutions est maintenue constante et égale à 1 à l'aide de $NaClO_4$.

Determination of rates of hydrogen atom reactions with alkenes at 298 K by a double modulation technique[1]

K. OKA[2] AND R. J. CVETANOVIĆ

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received August 28, 1978

K. OKA and R. J. CVETANOVIĆ. Can. J. Chem. **57**, 777 (1979).

Hydrogen atoms and HgH radicals are the two precursors of the HNO($^1A''$) chemiluminescence in the mercury photosensitized reaction of gaseous mixtures of H_2, NO, and Hg and are responsible, respectively, for its slow and fast decaying component. The total intensity of the chemiluminescence is decreased when an olefin is added to the gaseous mixture and, with an excess of the olefin added, 85% of the luminescence is eliminated. This fraction corresponds to the slow component of the chemiluminescence, due to the reaction H + NO + M → HNO* + M, while the residual 15% is due to the reaction HgH + NO → HNO* + Hg. The magnitudes of the decrease of chemiluminescence intensity and of the increase of the rate of decay of its slow component at a given concentration of an added olefin provide information on the rate of H atom reaction with the olefin.

Relative values of the rate constants of H atom reactions with ethylene, propene, 1-butene, *cis*-2-butene, *trans*-2-butene, isobutene, and 1,3-butadiene have been determined in the present work from the observed dependence of the luminescence intensity on olefin concentration. At the same time, the absolute values of these rate constants have been determined from the relation between the decay rate of the slower component of the chemiluminescence and olefin concentration. The relative and the absolute values of the rate constants are compared with each other, to check their mutual consistency, and with the available relative and absolute values in the literature.

K. OKA et R. J. CVETANOVIĆ. Can. J. Chem. **57**, 777 (1979).

Les atomes de H et les radicaux HgH sont les deux précurseurs de la chemiluminescence HNO($^1A''$) dans la réaction photosensibilisée au mercure de mélanges gazeux de H_2, NO et Hg et ils sont les causes respectives des composantes lentes et rapides de la décroissance. L'addition d'un alcène aux mélanges gazeux produit une diminution de l'intensité totale de la chemiluminescence; si on ajoute un excès d'alcène, 85% de la luminescence est éliminée. Cette fraction correspond à la composante lente de la chemiluminescence due à la réaction H + NO + M → HNO* + M, alors que le 15% résiduel est dû à la réaction HgH + NO → HNO* + Hg. Les amplitudes des diminutions des intensités de la chemiluminescence et de l'augmentation du taux de décroissance de sa composante lente à une concentration donnée d'un alcène ajouté fournissent des renseignements concernant la vitesse de la réaction de l'atome de H avec l'oléfine.

Les valeurs relatives des constantes de vitesse des réactions des atomes H avec de l'éthylène, du propène, du butène-1, du butène-2 *cis*, du butène-2 *trans*, de l'isobutène et du butadiène-1,3 ont été evaluées dans ce travail en observant l'effet de la concentration en oléfine sur l'intensité de la luminescence. A la fois, on a évalué les valeurs absolues de ces constantes de vitesse en utilisant la relation qui existe entre le taux de décroissance de la composante plus lente de la chemiluminescence et la concentration en oléfine. On a comparé les valeurs relatives et absolues, soit les unes avec les autres pour vérifier leur accord mutuel, soit avec les valeurs relatives et absolues qui sont disponibles dans la littérature.

[Traduit par le journal]

Introduction

The chemiluminescence observed in the mercury photosensitized reaction of gaseous mixtures of H_2, NO, and Hg has been studied previously (1–3) and it has been established that it consists of two distinct components, decaying at very different rates. The two precursors of the chemiluminescence are H atoms and HgH radicals, which are both the primary products of the reaction of Hg6($^3P_1$) with H_2. The excited molecules which luminesce, HNO($^1A''$), are formed simultaneously by the following two reactions

[1] $$HgH + NO \rightarrow HNO + Hg$$

[2] $$H + NO + M \rightarrow HNO + M$$

and emit light in the 600–800 nm spectral region.

Since the decay rate of reaction [1] is 2–3 orders of magnitude faster than that of reaction [2], the individual decay rates can be evaluated by the

[1]NRCC No. 17168

[2]NRCC Research Associate.

0008-4042/79/070777-08$01.00/0

double modulation technique, in which the illuminating 253.7 nm radiation is modulated simultaneously at two different modulation frequencies.

In the experiments carried out, variation of the concentration of the olefin added to the gaseous mixture of H_2, NO, and Hg caused variations both in the intensity and in the decay rate of the chemiluminescence which were measured using the double modulation technique (1–3). The relative and the absolute values of the rate constants of reactions of H atoms with olefins were evaluated, respectively, from the observed variations in the intensity and in the decay rate of the slower component of the chemiluminescence as functions of the concentrations of the reactants. Although there is a considerable amount of information in the literature both on the relative and the absolute values of the rate constants of the reactions of H atoms with simple olefins, there are some substantial discrepancies between data from different sources. In view of these discrepancies, further determinations, especially when they can be done by entirely different techniques, are still necessary. The present results represent a new contribution of this kind.

Experimental

The experimental arrangement was the same as described previously (1–3).

The gases used were Matheson U.H.P. hydrogen, C.P. nitric oxide, propene, isobutene and *cis*-2-butene, and Phillips ethylene, *trans*-2-butene, 1-butene, and 1,3-butadiene. All the olefins used were research grade products. NO was passed through a column of freshly activated Linde Molecular Sieve 13× to remove any traces of NO_2. The range of H_2 flow rates (f.r.$_{H_2}$) was 3.0–6.5 × 10^{-4} mol s^{-1}.

The basic quantities measured have been the amplitudes of the modulated signals of the 253.7 nm incident radiation and of the chemiluminescence at the low frequency of 10 Hz and at higher frequencies in the kHz region. The three experimental parameters measured, x_0, x, and y, are, respectively, the relative values of the intensities of the total luminescence (x_0) and of the in-phase (x) and $-90°$ out-of-phase (y) components of the luminescence modulated in the kHz frequency region. The value of x_0 was measured at 10 Hz, since at this low modulation frequency the total luminescence intensity is to a good approximation confined to the in-phase component. The precise definitions and derivation of the relevant rate expressions are given in our earlier papers (1–3).

The luminescence measured is the sum of two processes, i.e., of a slow and a fast decaying component. The decay rate (m_{II}) of the slow luminescence is therefore given by the equation (1)

$$[I] \qquad m_{II} = 2\pi\nu_m C_{II} y/(x_0 - x)$$

where ν_m is the modulation frequency in the kHz region. The correction term C_{II} is a function of the ratio m_{II}/m_I of the decay rates of the slow (m_{II}) and the fast (m_I) luminescence (1). The latter corresponds to the decay rate of HgH, by reaction with NO or thermal decomposition, and is given by the equation

$$[II] \qquad m_I = k_{HgH+NO}[NO] + k_{HgH+M}[M]$$

where [M] is the total concentration. The rate constants k_{HgH+NO} and k_{HgH+M} have been measured before (3). Since the correction term C_{II} is close to unity (0.9–1) for the experimental conditions used and its dependence on m_{II}/m_I is very small, a simple procedure for evaluating m_{II} is to assume initially that $C_{II} = 1$ and calculate with it the first approximate value of m_{II}, which is then used to obtain an improved value of C_{II} and from it the final value of m_{II}.

Results

A. Luminescence Intensity in the Presence and Absence of Olefins

Luminescence intensity (x_0) in the absence of olefins is approximately proportional to the mole fraction of H_2 and inversely proportional to the total pressure (P). The inverse proportionality to P indicates that, at the pressures used, the quenching of $HNO(^1A'')$ is much faster than the light emitting process and a correction for this effect can be made simply by multiplying x_0 by P. The proportionality to the H_2 mole fraction is due to partial removal of Hg*, i.e., of $Hg6(^3P_1)$, by quenching with NO (and with the olefins, when added), a correction for which can be made by multiplying x_0 by F. This correction factor is given by

$$F = 1 + (k_{Hg^*+NO}[NO] + k_{Hg^*+Ol}[Ol])/k_{Hg^*+H_2}[H_2]$$

where Ol stands for the olefin and the relative values of the quenching rate constants ($k_{Hg^*+NO}/k_{Hg^*+H_2}$ and $k_{Hg^*+Ol}/k_{Hg^*+H_2}$) are taken from the literature (4). The product x_0PF represents therefore the luminescence intensity corrected for the above two quenching processes. x_0PF is to first approximation independent of P and [NO] in the absence of olefins.

Figure 1 shows the corrected luminescence intensity, x_0PF, plotted as a function of [NO][M′] for various experimental conditions. [M′] is the effective concentration of the third body for reaction [II], i.e.

$$[III] \qquad [M'] = [H_2] + (k_{2,NO}/k_{2,H_2})[NO] + (k_{2,Ol}/k_{2,H_2})[Ol]$$

where [Ol] is the concentration of the olefin added, k_{2,H_2}, $k_{2,NO}$, and $k_{2,Ol}$ are the rate constants of reaction [2] for H_2,NO and olefin, respectively, as the third body. The value of $k_{2,NO}/k_{2,H_2}$ has been obtained in previous work (2). The last term in eq. [III] is very small in the present study because $[H_2] > [NO] > [Ol]$.

Luminescence intensity decreases very strongly when 1,3-butadiene is added, as shown in Fig. 1 by half filled circles (◐). Since most of the H atoms are

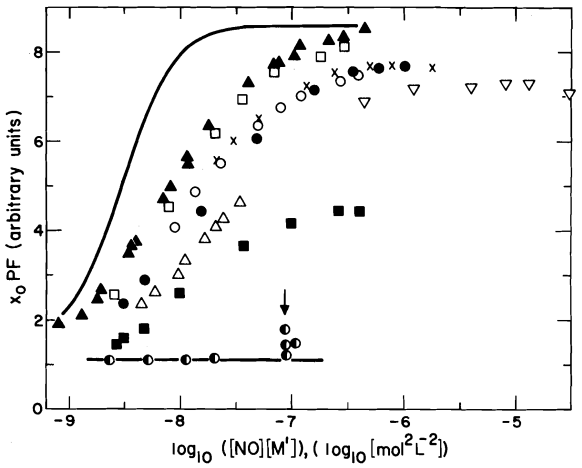

FIG. 1. Plots for several experimental conditions of the corrected luminescence intensity, x_0PF, as a function of [NO][M'] in the presence (◐) and absence (other symbols) of added 1,3-butadiene. The experimental conditions are: ○, P = 50 Torr, $I_{253.7\text{ nm}} = 8 \times 10^{13}$ photons s^{-1}, the flow rate of H_2 is f.r.$_{H_2} = 5 \times 10^{-4}$ mol s^{-1}, $P_{Hg} = 1.8 \times 10^{-13}$ Torr, T = 298 K; ▲, light intensity changed to $I_{253.7\text{ nm}} = 3 \times 10^{13}$ photons s^{-1}; □, $I_{253.7\text{ nm}} = 0.8 \times 10^{13}$ photons s^{-1}; ●, f.r.$_{H_2}$ changed to f.r.$_{H_2} = 1.6 \times 10^{-4}$ mol s^{-1}; ■, $P_{Hg} = 4.8 \times 10^{-4}$ Torr; △, P_{Total} = 20 Torr; ×, P_{Total} = 100 Torr; ▽, P_{Total} = 300 Torr; ◐, 1,3-butadiene is added, [1,3-C_4H_6] = 7×10^{-6} mol/L. The arrow indicates experimental points for [1,3-C_4H_6] varying from 2.7×10^{-5} to 16×10^{-5} mol/L, with the highest point corresponding to the lowest butadiene concentration. The horizontal line at x_0PF = 1.1 is the estimated net luminescence intensity of HNO* from reaction [1] (HgH + NO → HNO* + Hg). The solid line is the 'theoretical' curve, obtained assuming absence of any secondary consumption of H atoms.

then scavenged by the added olefin, the residual luminescence is due to the reaction of HgH with NO (reaction [1]). Removal of H atoms by olefins evidently competes efficiently with their termolecular combination with NO. Nevertheless, at large [NO], luminescence intensity increases slightly when the concentration of the 1,3-butadiene added is substantially smaller (as shown by the four experimental points in the region indicated by the arrow in Fig. 1) because of the less complete scavenging of H atoms by the olefin in this case.

The intensity of the chemiluminescence from HgH reaction with NO has been estimated by subtracting from the observed total intensity in the presence of 1,3-butadiene the small contribution of the luminescence from any residual (unscavenged) H + NO reaction. It is found to be independent of [NO][M'] under the experimental conditions used and is indicated by the horizontal line at x_0PF = 1.1 in Fig. 1.

In the absence of olefins the intensity of the luminescence increases with increasing [NO][M'] and reaches a plateau value at large [NO][M'], as shown in Fig. 1. The magnitude of the plateau value attained depends on the experimental conditions used. Since the transmittance of the 253.7 nm radiation increases with decreasing Hg vapor pressure, the small plateau value at small [Hg], as shown in Fig. 1 by filled squares (■), is due to the decreased light absorption in the cell.

At 50 and 100 Torr pressure, indicated, respectively, by open circles and crosses (○ and ×) in Fig. 1, the intensities fall approximately on the same curve. Under these conditions the intensity is independent of the flow rate of the gaseous mixture, except at small [NO][M'], as shown by filled circles (●).

The absorbance of the 253.7 nm line varies with the total pressure in the reaction cell and maximum absorption was found to occur between about 50 and 100 Torr. Both at 25 and 300 Torr the absorbance decreases slightly because of a mismatch between the lamp emission and the absorption contours of the 253.7 nm line. A slight reduction of the luminescence intensity at 25 and 300 Torr may therefore be partly due to the reduced absorbance of the 253.7 nm light. Since the luminescence intensity is small at 300 Torr, the errors in the measurements of the background luminescence also affect somewhat the values of x_0. At 25 Torr, the decrease of intensity is probably partly due to the loss of H atoms by diffusion to the cell wall and recombination on it.

As shown in Fig. 1 by filled triangles and open squares (▲ and □), the plateau value is slightly larger when the light intensity is decreased, although the curvature does not change. A potential cause for this slight increase is the secondary consumption of H atoms by reaction with some of the products (HNO, HgH, etc.). Another reason may be a slight change of the alignment of the optical path of the 253.7 nm radiation since a rough wire mesh was used to decrease its intensity.

The 'theoretical' curve (the solid curve in Fig. 1) was obtained in the following manner. The value of x_0 is defined as the ratio of the amplitudes of modulation at 10 Hz of the luminescence and of the 253.7 nm incident radiation and is proportional to $\cos \theta_{10}$, where θ_{10} is the phase shift at 10 Hz between the luminescence and the incident radiation. For the purpose of calculating the theoretical curve, it was assumed that the secondary consumption of H atoms is negligibly small so that their pseudo-first order decay rate is simply given by k_2[NO][M']. In view of this, the values of θ_{10} were obtained directly from the relation $\tan \theta_{10} = 2\pi \times 10/k_2$[NO][M']

and were used to calculate the values of x_0PF for the solid curve in Fig. 1. At larger values of [NO][M′], the modulation frequency of 10 Hz is much smaller than k_2[NO][M′] and θ_{10} is therefore negligibly small so that the theoretical curve is at a plateau value (since $\cos\theta_{10} \approx 1$). At smaller values of [NO][M′] this is no longer the case, the calculated value of θ_{10} begins to increase and the theoretical curve declines by a factor approximately equal to $\cos\theta_{10}$. (The value of this factor is actually slightly larger than $\cos\theta_{10}$ because of the contribution of the very fast decaying luminescence, due to the HgH + NO reaction.)

All the experimental points plotted in Fig. 1 are seen to be shifted to the right from the 'theoretical' curve, i.e., to the larger values of [NO][M′]. This shift indicates the occurrence of some secondary H atom consuming reactions, which are in fact responsible for the decrease in luminescence intensity at smaller values of [NO][M′]. It is actually found experimentally (1) that in this region θ_{10} remains small (and thus $\cos\theta_{10} \approx 1$). The reason for this is that θ_{10} is not determined by k_2[NO][M′] alone, as assumed above in the calculation of the 'theoretical' curve in Fig. 1, but by the substantially larger (at small [NO][M′]) sum k_2[NO][M′] + k', where k' is the pseudo-first order rate of consumption of H atoms in secondary reactions. Therefore, although the value of the $\cos\theta_{10}$ factor does not decline, the intensity nevertheless declines at smaller [NO][M′] because the secondary consumption of H atoms, i.e., the ratio k'/k_2[NO][M′], is relatively large. The intensity of luminescence is reduced by the factor equal to k_2[NO][M′]/(k_2[NO][M′] + k'). Assuming that k' is a constant, it is estimated from the trends in Fig. 1 that k' is about 1.5–2.0 × 10^2 s^{-1}.

B. Relative Rates of H Atom Reactions with Olefins

In the presence of olefins the intensity of the luminescence decreases with increasing olefin concentration. The ratios of the intensities in the presence of olefins and in their absence are plotted in Fig. 2 as functions of $\log_{10}$ ([Ol]/[NO][M′]). The x_0PF values used are corrected for the slight consumption of H atoms in secondary reactions, but this correction is very small in this case since large NO concentrations, in the range 0.6–6 × 10^{-4} mol/L, were used in the experiments. After this correction, the ratio of the intensities is given by

$$[\text{IV}]\quad \frac{x_0PF}{(x_0PF)_{[\text{Ol}]=0}} = a + (1-a)\left\{1 + \frac{k_{\text{H+Ol}}}{k_2}\frac{[\text{Ol}]}{[\text{NO}][\text{M}']}\right\}^{-1}$$

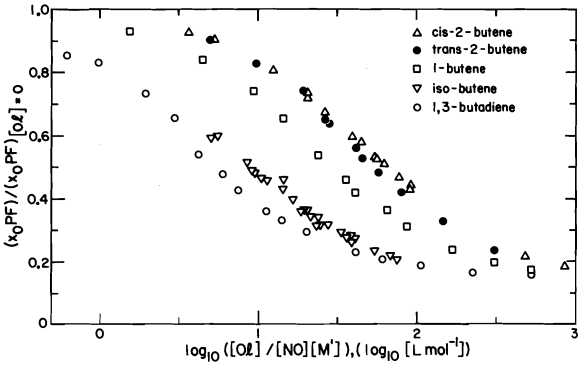

FIG. 2. Ratios of the corrected luminescence intensities in the presence and absence of olefin, $(x_0PF)/(x_0PF)_{[\text{Ol}]=0}$, plotted as a function of $\log_{10}$ [Ol]/[NO][M′] at 50 Torr total pressure for several C_4 olefins (△, *cis*-2-butene; ●, *trans*-2-butene; □, 1-butene; ▽, isobutene; ○, 1,3-butadiene. The luminescence intensities are corrected for the effect of the total pressure (P), the quenching of Hg6($^3P_1$) by NO and olefins (F), and the secondary consumption of H atoms).

where a is the ratio of the intensity of the chemiluminescence due to the HgH + NO reaction (reaction [1]) to the total intensity. As shown in Fig. 2, the ratios $(x_0PF)/(x_0PF)_{[\text{Ol}]=0}$ decrease with increasing [Ol]/[NO][M′] and level off at a lower plateau value of about 0.16, corresponding to the fraction of the luminescence intensity due to the HgH + NO reaction. A rough estimate of the value of $k_{\text{H+Ol}}/k_2$ is therefore given by the value of [NO][M′]/[Ol] in Fig. 2 at which $(x_0PF)/(x_0PF)_{[\text{Ol}]=0} = (a+1)/2$.

Better estimates of $k_{\text{H+Ol}}/k_2$ and of a can be obtained from the plots of the following rearranged linear form of eq. [IV].

$$[\text{V}]\quad \left\{1 - \frac{(x_0PF)}{(x_0PF)_{[\text{Ol}]=0}}\right\}\frac{[\text{NO}][\text{M}']}{[\text{Ol}]} = \frac{k_{\text{H+Ol}}}{k_2}\left\{\frac{(x_0PF)}{(x_0PF)_{[\text{Ol}]=0}} - a\right\}$$

In accordance with eq. [V], plots of $\{1 - (x_0PF)/(x_0PF)_{[\text{Ol}]=0}\}$[NO][M′]/[Ol] vs. $(x_0PF)/(x_0PF)_{[\text{Ol}]=0}$ are found to be linear. The x-intercepts give the values of a and the slopes of $k_{\text{H+Ol}}/k_2$. The values obtained are listed in Table 1 for several olefins. Since k_2 is constant, the values of $k_{\text{H+Ol}}/k_2$ provide the relative rate constants of the H atom reactions with olefins.

C. Absolute Rate Constants of the H Atom Reactions with Olefins

The rate of decay (m_{II}) of the slow decaying luminescence (due to the H atom reaction with NO), as defined by eq. [I], is close to the pseudo-first order

rate of decay of H atoms under the conditions used, i.e.

[VI] $$m_{II} = k_2[NO][M'] + k_{H+OI}[OI] + k'$$

As will be discussed below, k', the rate of secondary consumption of H atoms, can be assumed to be negligibly small at larger [NO][M']. The slopes of the plots such as shown in Fig. 3 of $m_{II}/N[O][M']$ vs. [OI]/[NO][M'] provide then the absolute values of k_{H+OI}. The values obtained are listed in Table 2.

As discussed in our earlier paper (2), a slight experimental uncertainty may arise because of a probable small difference in the sensitivity of signal measurements at 10 Hz and in the kHz region of the modulation frequencies. However, since the exact magnitude of this sensitivity change is not known, the overall uncertainty in m_{II} is almost entirely due to it and much less to the random errors. In view of this, the uncertainties in k_{H+OI} shown in Table 2 have been evaluated as the differences between the observed values of the slopes of the plots in Fig. 3 and the corresponding values after allowing for a potential 1% error in x_0 due to the difference between the signal measurement sensitivities at 10 Hz and in the kHz region. From the analysis of x,y-semicircles in our previous work (2), we estimate approximately that the overall uncertainties in k_{H+OI} are probably within a factor of 3 of the uncertainties given in Table 2. It may be noticed that these uncertainties are 2–3 times larger than that for k_{H+NO+M} in the absence of olefins.

The experimental data for the plots of $m_{II}/[NO][M']$ vs. [OI]/[NO][M'] (such as shown in Fig. 3) were obtained in most cases (except at very large [OI]/[NO][M']) by varying olefin concentration without changing NO concentration. If k' is independent of [OI], its effect on the values of k_{H+OI} can be neglected. In any case, although the exact

magnitude of the effect of k' is not certain, it is probably not as large as the uncertainty due to the potential sensitivity change discussed above.

Discussion

The relative rate constants listed in Table 1 can be compared with the absolute values in Table 2 by taking $k_2 = 1.56 \times 10^{10}$ L^2 mol^{-2} s^{-1}, the value determined in our earlier work. The comparison is made in Table 3, which lists the two sets of the k_{H+OI} values and, in the last column, their ratios. It is seen that in most cases the indirectly obtained values (set B) differ from the directly determined absolute values (set A) by less than about 10%, with only one difference of 13% and one of 19%. The two sets of values are therefore mutually consistent within the likely combined experimental uncertainties. Nevertheless, the set A values are somewhat preferable, because of their more direct method of determination, and will be used further below for comparison with the data in the literature.

The data in Tables 1–3 show that the value of the

rate constant for H reaction with ethylene is pressure dependent. Initial formation of vibrationally excited ('hot') alkyl radicals in the exothermic addition of H atoms to olefins has been known for a long time (5) and it has been recognized that at low pressures they may undergo unimolecular decomposition (6) including back decomposition into H and the (original or isomerized) olefin (6–9). To what extent such back decomposition occurs in a particular system depends on the nature of the moderating gases present and their pressures. Kurylo, Peterson, and Braun (10*a*, *b*) have carried out detailed kinetic studies of the effect of pressure, using helium as the moderating gas, on the k_{H+O1} values for ethylene (10*a*) and propylene (10*b*). However, it is not possible to utilize their results directly to assess reaction systems with other moderating gases, which are expected to be more efficient deactivators of vibrational excitation than is helium. Since in the present work the uncertainties of the measurements become large at pressures greater than about 200 Torr, a detailed experimental study of the pressure dependence of k_{H+O1} was not feasible. It is probable that the value of the rate constant for ethylene obtained at the highest pressure of the moderating gas used (100 Torr H_2) may still be somewhat below the high pressure limiting value. It is possible that the value for propylene may also be slightly below the high pressure limiting value although the difference, if any, would be expected to be much smaller in this case because of the greater number of degrees of freedom and thus a longer life time of the 'hot' propyl radicals initially formed. Additional information on this point may be provided by the comparison with the literature values of the rate constants given further below.

The relative rate data for 1,3-butadiene in Table 1 may appear to suggest that there is a slight pressure dependence of the rate constant. However, the effect is very small and close to the experimental uncertainty. Furthermore, it is not confirmed by the absolute rate constants for 1,3-butadiene in Table 2, which seem to be pressure independent within the experimental scatter. The slight decrease in the value of the rate constant for 1,3-butadiene at 20 Torr after a three-fold decrease of light intensity is also uncertain because of the weaker luminescence signals and increased experimental errors at the reduced light intensity.

The present values of k_{H+O1} are compared in Table 4 with the corresponding values taken from some of the more comprehensive sets of data in the literature. The values of k_{H+O1} from different sources are listed in the chronological order of the year of publication. The three sets of relative rate constants obtained previously in this laboratory (12, 15, 16) and those of Yang (13) have been converted to absolute values in the following manner. Woolley and Cvetanović's (WC) values of k_{H+O1}, which have been measured relative to the rate constant of the reaction of H with H_2S at 25°C, have been converted to the absolute values in column 5 of Table 4 by taking the now available (and Natl. Bur. Stand. recommended (19)) value $k_{H+H_2S} = 7.77 \times 10^9$ exp

$(-860/T)$ L mol^{-1} s^{-1} of Kurylo, Peterson, and Braun (10*c*). Since this and the other three sets of relative rate constants in Table 4 (JC, Y, and CD, in columns 2, 3, and 6, respectively) have all been obtained in the presence of high pressures of relatively efficient moderating gases (CO_2, n-C_4H_{10}, C_3H_8, H_2), it is reasonable to assume that the $k_{H+propylene}$ values must all be very close to the high pressure limiting value. The WC value $k_{H+propylene} = 8.3 \times 10^8$ L mol^{-1} s^{-1} (column 5) was therefore used to convert the JC, Y, and CD relative data to absolute values. It is evident that the absolute rate constants in the JC and CD sets in Table 4 would remain unaltered if the conversions to absolute values were based on the WC rate constant for isobutene instead of for propylene. However, Yang's set of values (column 3) would be substantially altered, since, as has been pointed out before (15), it is not quantitatively consistent with the other sets of values in Table 4 although it clearly shows qualitatively similar trends. Similarly, the AMR values in column 1, obtained in the pioneering work of Allen, Melville, and Robb (11) by the ingeneous molybdenum trioxide technique, although very much of the right order of magnitude, show some quantitative disparities.

The absolute values of k_{H+OI} obtained in the present work, listed in the last column of Table 4, are, within the combined experimental uncertainties, consistent with the other data in the table (apart from some deviations of the AMR and Y data mentioned above and allowing for the fact that some of the values for ethylene and propylene are below the high pressure limiting values). The agreement with the previous three sets of relative determinations in this laboratory (JC, WC, and CD) is particularly good. The present value for propylene turns out to be identical with the WC value. Since the latter is believed to have been obtained under conditions required for the high pressure limiting value, the agreement suggests that the present value corresponds also to the high pressure limit. The difference of about 15% from the KPB high pressure extrapolated value for propylene (column 7) is probably not larger than the combined experimental error. The present value for ethylene is probably below the high pressure limit, as already mentioned. This may perhaps be also true for the JC, WC, and CD ethylene values and is no doubt so for the CKMY value (column 8). The KPB ethylene value of 8.2 $\times 10^8$ L mol^{-1} s^{-1} (column 7) provides a high pressure limit for this rate constant. However, Hikida, Eyre, and Dorfman (20) obtained a (seemingly) pressure independent value of 5.5×10^8, which could possibly be scaled up at most to 6.5×10^8 L mol^{-1} s^{-1} by applying KPB's empirical expression to extrapolate from 1500 Torr to infinite He pressure. KPB quote (10*c*) the results of Yokota (21) which seem to indicate a high pressure limit of 7.0×10^8 L mol^{-1} s^{-1}. Thus, there may still be an uncertainty of the order of about 10% in the high pressure limit of the H + C_2H_4 constant.

A current modulation technique has been developed for the determination of kinetic information in glow discharges through flowing gases. A low frequency sinusoidal modulation superimposed on the dc discharge current produces modulations in the electron density and radical concentrations. Measurements of the amplitudes and phase shifts of radical concentrations can be used to elucidate reaction mechanisms and to determine rate constants for some reaction processes.

The kinetic response of discharge chemical phenomena to an applied current modulation is discussed for several general types of reaction mechanisms. Rates of O atom production and removal measured in a current modulated O_2 glow discharge are compared to rates measured in a dc glow discharge. The excellent agreement of these two sets of results provides an experimental foundation for the current modulation method.

JOHN N. SMITH, MOTILAL D. COSTA et JACQUES M. DECKERS. Can. J. Chem. **57**, 785 (1979).

On a développé une technique de modulation de courant afin de tirer des informations cinétiques des décharges électriques à travers des courants gazeux. Si on superpose une modulation sinusoidale de basse fréquence à un courant de décharge cd il se produit une modulation de la densité électronique et des concentrations radicalaires. On peut utiliser des mesures d'amplitudes et de déplacements de phase des concentrations radicalaires pour élucider les mécanismes réactionnels et pour déterminer les constantes de vitesse de quelques processus réactionnels.

On présente une discussion relative à la réponse cinétique du phénomène de décharge chimique à une modification de courant appliqué pour plusieurs types généraux de mécanismes réactionnels. On a comparé les vitesses de production et d'enlèvement d'atomes de O mesurées dans une décharge électrique de O_2 modulée par un courant avec celles mesurées dans une décharge électrique cd. Le bon accord entre ces deux séries de valeurs fournit une base expérimentale pour la méthode de modulation de courant.

1. Introduction

For some time the kinetics of reactions occurring in glow discharges have been investigated in this laboratory (1). In order to determine additional information on the kinetics of reaction processes occurring in the glow discharge, a low frequency sinusoidal modulation has been superimposed on the dc current through the discharge. The rates of electron–molecule reactions are thereby modulated and the resulting response of the system to the applied modulation depends on the nature of the reaction mechanism. Observations of the perturbations thus produced in the concentrations of reactants, intermediates, or products can be used to elucidate the reaction mechanism and to determine the value of the rate constants.

Bair *et al.* (2) have previously employed a chemical modulation technique in their detection of free radical absorption spectra in a pulsed electrical discharge. Most other applications of chemical modulation techniques to gas phase systems have employed modulation of the intensity of the exciting light source in photolysis experiments. Burnnett and Melville (3) have discussed the theory of the rotating sector method as applied to the study of (free radical) chain reactions initiated in a photochemical system. Metcalfe (4) has measured the rates of consecutive and competing reactions in modulated fluorescence experiments. Johnston *et al.* (5) applied chemical modulation techniques to photolysis experiments in which the absorption spectrum of reactive interme-

0008-4042/79/070785-11$01.00/0

diates was measured. Atkinson and Cvetanović obtained modulated concentrations of $O(^3P)$ atoms from the reaction $Hg(^3P) + N_2O \rightarrow O(^3P)$ and obtained kinetic information about the reactions of these O atoms with various substances (6), using phase shift techniques. For a review and further discussion of these techniques, see ref. 7.

In this paper we describe an experimental system designed to measure the amplitude and phase shift of radical concentrations in a current modulated oxygen glow discharge. We then discuss the equations which predict the kinetic response of a glow discharge to modulation of the current for several general types of reaction mechanisms. Finally, the experimental validity of the method is established for a two-step reaction mechanism.

2. Experimental

Most of the apparatus used in the experiments has been described previously (1, 8, 9). The modifications which have been made are in the electrical circuitry which controls the discharge current. Briefly, gas flows through a discharge tube which contains moveable electrodes. A pinhole located in the core of the tube allows us to sample the gas and analyze it mass-spectrometrically. The discharge power supply was operated to keep the location of the sampling hole near zero potential. The ac modulation was superimposed on the dc component through an especially designed unit. The frequency could be adjusted from 0 to 1000 Hz with less than 1% harmonic distortion.

The modulated output signal from the mass spectrometer was amplified and applied to the input of a 100 channel analog analyzer (PAR TDH-9 waveform educator). The amplitude of the observed signal and its phase relative to the applied current modulation could be measured graphically from a strip chart recording of the analyzer output or electronically, with a PAR lock-in phase detector. It was established that the phase angles between the signals measured by both methods did not differ by more than 1 deg.

To ensure that the amplification and detection system did not introduce a phase shift or distortion into the measured signal, a sinusoidal voltage was imposed on one of the focusing lenses of the mass spectrometer, with the discharge operating in the dc mode. It was verified by amplification and analysis of the resulting signal that no measureable phase shift or distortion was introduced into the mass spectrometer output signal.

3. Theory

3.1 General

The rates of electron molecule interactions in the positive column of the discharge can be described by the expression (10, 11)

$$[1] \quad dn_{ij}/dt = n_i n_e \int f(E) Q_{ij}(2E/m)^{1/2}\, dE = k_{ij} n_i n_e$$

where n_i is the concentration of molecules in state i, n_e is the electron concentration, j is the state populated in the collision, $Q_{ij}(E)$ is the cross section for the process, and $f(E)dE$ is the fraction of electrons having energy between E and $E + dE$. k_{ij} is the equivalent of a rate constant in chemical kinetics as applied to an inelastic collision between an electron and a molecule. It is shown below that, within experimental error, for discharges through oxygen, the electron energy distribution function, $f(E)$, remains invariant when a small modulation is superimposed on the dc current. If $f(E)$ remains constant, k_{ij} also remains constant while the current is modulated. Under some conditions, modulation of the current will produce both a modulation in the electron density and thus in the rates of electron–molecule interactions. From the analysis presented in this paper, it will become apparent that measurements of the phase shifts and amplitudes thus produced in radical concentrations can be used to characterize special features of the reaction mechanisms and to evaluate rate constants for specific steps in the mechanism.

3.2 Modulation of the Discharge Current, Experimental

We shall consider the case of a glow discharge with the electrodes positioned at each end of a cylindrical glass tube. The gas flows in the direction of the cathode with a stream velocity, v_s. For small stream velocities, we neglect the spatial pressure and temperature gradients and we assume the gas glow to be piston (plug) flow. The gas residence time, t_g, at a distance, d, in the discharge tube is then given by

$$[2] \quad t_g = d/v_s$$

A sinusoidal modulation, having a relative amplitude, α, and angular frequency, ω, is imposed on the dc current, i_0. The dependence of the current, i, on time, t, is given by

$$[3] \quad i = i_0(1 + \alpha \sin \omega t)$$

The total (integrated) current density to which a volume element of gas is exposed during its passage through the discharge tube is a function of both the gas residence time, t_g, associated with that volume element of gas and the phase angle, ωt, of the current density. Consequently, the rates of reactions occurring in each volume element of gas are also functions of t_g and ωt. In a steady state flow system, radical concentrations at a given point in the discharge corresponding to a given gas residence time, t_g, will be modulated and for some mechanisms, phase shifted with respect to the current modulation, as volume elements associated with different current phase angles pass the observation point.

3.3 Criteria for the Validity of the Method

The applicability of the current modulation technique to glow discharge systems depends on the following two criteria which will now be discussed.

Criterion 1: A sinusoidal modulation imposed on the dc current produces a modulation of identical phase and amplitude in the electron density through the discharge

Because no measurements of n_e have been made in the current modulated discharge, the validity of the above criterion must be judged indirectly. There is evidence from measurements conducted in a dc discharge that this criterion is valid under certain conditions.

Rundle *et al.* (12) employed a microwave absorption technique to measure the average electron concentration in the positive column of a dc oxygen glow discharge. They showed that n_e is directly proportional to the current density for $i = 2$–10 mA (at a pressure of 1 Torr) within the limits of the precision of their measurements.

The current density in the discharge, j, is equal to the flux of electrons through unit cross section of the discharge tube and is given by

$$[4] \qquad j = i/A_x = n_e e v_d$$

where v_d is the electron drift velocity, which itself depends on the electron energy distribution function, e is the electron charge, and A_x is the cross sectional area of the discharge tube. If v_d remains constant as i is varied then the electron density must vary directly with the current. The dependence of v_d on the ratio of the experimental parameters, E/N, where E is the electric field and N is the gas number density, has been measured for different gases by means of electron drift tube experiments (13, 14). Measurements of E/N in our laboratory show that this ratio varies by less than 2% in an oxygen discharge and by less than 5% in a nitrogen discharge as the current is varied from 2 mA to 10 mA in discharge tubes having a cross sectional area of 1.22 cm^2. It can be inferred from these results that, within the indicated limits, the drift velocity is nearly independent of the current at low pressures; thus n_e is directly proportional to the current to a good approximation.

At very low frequencies the current-modulated discharge can be considered as a dc discharge in which the current is slowly varied with time. Since the production and loss rates of electrons in the positive column are in balance, the ability of the electron concentration to follow the current modulation is determined both by the rate of loss of electrons through ambipolar diffusion to the walls of the discharge and by the local rate of production of electrons in the positive column. If these rates are large compared to the modulation frequency the electron density will follow the current modulation. Ambipolar diffusion leads to an apparent first order removal of the electrons with a time constant of the order of 10^{-5} s^{-1} (15) in discharges through gases such as oxygen and nitrogen. The pseudo first order rate of production of electrons by electron impact with ground state molecules is of the order of $10^6 n_e$ s^{-1} in oxygen and nitrogen discharges at the pressure of 1 Torr (14). For frequencies under 500 Hz, the phase shift induced in n_e by production and loss processes will then be less than 1 deg and, hence, negligible to a good approximation. Criterion 1 should be valid over the frequency range of 1–500 Hz.

It follows then that the electron density in the discharge is given by

$$[5] \qquad n_e = (i_0/A_x e v_d)(1 + \alpha \sin \omega t)$$
$$= n_e^0(1 + \alpha \sin \omega t)$$

where n_e^0 is the electron density in the dc discharge.

Criterion 2: The electron energy distribution and hence the average electron energy remain constant as the current density is varied through the range 1.8–10 mA/cm^2

Rundle and co-workers' (11) measurements of E and $f(E)$ in an oxygen glow discharge show that $f(E)$ does not depend on the current within the range of 2–10 mA. Therefore, the above criterion is valid for a dc discharge through oxygen.

The ability of the electrons to maintain the same E and $f(E)$ in a current modulated discharge depends on the electron relaxation time. The relaxation time can be considered to be the time taken for an ensemble of electrons to reestablish the original energy distribution after a perturbation in one or more of the parameters controlling it. We have estimated this to be of the order 10^{-5} s (or smaller) in the active discharge. Criterion 2 should, therefore, be valid for low frequencies (< 500 Hz) for discharges in which $f(E)$ is independent of the current.

Although criterion 2 is valid for the oxygen discharge, the same cannot be said for the nitrogen discharge and possibly other types of discharges. Chenery's (16) attempted measurements of $f(E)$ in the nitrogen discharge show that $f(E)$ depends more on the current than was the case in oxygen. Under these conditions, the applicability of the current modulation technique to the nitrogen discharge is limited by the possible failure of the system to conform to criterion 2.

It should be borne in mind that the drift velocity is mainly dependent on that part of the electron energy distribution which is most highly populated. Because the electron density at high energies is a small fraction of the total electron concentration, large variations in the high energy part of $f(E)$ correspond to relatively small changes in the drift velocity, and criterion 1 should remain valid.

4. Analysis of Some Reaction Mechanisms

In this section, eq. [6], for n_e in the current modulated discharge, is introduced into the rate equations for several simple reaction mechanisms which are typical of chemical processes in the discharge. Equations are determined for the phase shifts and amplitudes of radical concentrations as functions of the experimental parameters. It is shown by this analysis that phase shift measurements can be used not only to determine rate constants for some reaction processes but also to distinguish between various possible mechanisms.

4.1 Mechanism 1

A radical X_j is produced by electron impact with a reactant species X_i; X_j is then deactivated in a first order process

$$[6] \qquad X_i + e \xrightarrow{k_1} X_j + e$$

$$[7] \qquad X_j \xrightarrow{k_2} X_i$$

We shall assume that the depletion of X_i is small and its concentration, $[X_i]$, remains approximately equal to the initial concentration, $[X_i^0]$. The rate equation governing $[X_j]$ is

$$[8] \qquad d[X_j]/dt = k_1[X_i^0]n_e - k_2[X_j]$$

Substituting eq. [5] for n_e into the above equation, we obtain

$$[9] \quad d[X_j]/dt = k_1 n_e^0[X_i^0](1 + \alpha \sin \omega t) - k_2[X_j]$$

Integration of this equation gives

$$[10] \quad [X_j] = \frac{k_1 n_e^0}{k_2}[X_i]\left[1 + \frac{\alpha k_2}{\omega^2 + k_2^2} \times (k_2 \sin \omega t - \omega \cos \omega t)\right] + C \exp(-k_2 t)$$

where C is an integration constant. Integration over the gas residence time is accomplished by using the integration limits $t - t_g$ and t. C is evaluated and the resulting expression substituted in the above equation to give a complicated algebraic expression for $[X_j]$. Simplification of this expression for $[X_j]$ is accomplished by solving the following equation for a, A, and θ.

$$[11] \qquad [X_j] = a(1 + A \sin(\omega t - \theta))$$

to give

$$[12] \quad a = (k_1 n_e^0/k_2)[X_i^0][1 - \exp(-k_2 t_g)]$$

$$[13] \quad A = \frac{\alpha}{(1 + \omega^2/k_2^2)^{1/2}} \times \frac{[1 - 2\exp(-k_2 t_g)\cos \omega t_g + \exp(-2k_2 t_g)]^{1/2}}{1 - \exp(-2k_2 t_g)}$$

$$[14] \quad \theta = \arctan \omega/k_2 - \arctan \frac{\sin \omega t_g}{\exp k_2 t_g - \cos \omega t_g}$$

At each point in the discharge characterized by a given gas residence time, t_g, $[X_j]$ is a sinusoidal function of t, having an amplitude A and lagging n_e by a phase shift, θ.

For values of t_g which are large compared to k_2^{-1} (corresponding to large distances in the discharge tube), the terms in the above equations dependent on t_g become negligibly small and the above equations simplify to

$$[15] \qquad \theta = \arctan(\omega/k_2)$$

$$[16] \qquad A = \alpha/(1 + \omega^2/k_2^2)^{1/2}$$

Under this condition, $t_g \gg k_2^{-1}$, a pseudo steady state (PSS) is attained in the concentration of X_j. A measurement of either A or θ in this region of the discharge can be used to determine k_2 from the above equations. Empirically, it can be shown that the most accurate measurements of k_2 can be made in the frequency range $k_2 < \omega/2\pi < 10k_2$; the frequency should be of the same order of magnitude as the reciprocal lifetime of X_j. Because we are only concerned with low frequency modulation of the current, the most useful applications of this technique to glow discharge are the measurements of the lifetimes of long lived metastable species and to the elucidation of reaction mechanisms which involve metastable species.

The dependence of θ and the ratio A/α, on t_g and distance in the discharge (at a stream velocity, $v_s = 2.8\ ms^{-1}$) for values of k_2 ranging from $2\ s^{-1}$ to $200\ s^{-1}$ is illustrated in Figs. 1 and 2. The maxima and minimum which appear in both sets of curves become more pronounced for smaller values of k_2.

The dependence of θ and A/α on t_g is determined by the values of the experimental parameters, and k_2, and by the nature of the reaction mechanism. It can be shown that many different types of reaction mechanisms will give the pseudo steady state values of θ and A/α shown in Figs. 1 and 2, but these same mechanisms will give different profiles of θ and A/α as a function of t_g. Measurements made in the discharge region preceding the onset of a pseudo steady state (a region that has previously been neglected in chemical modulation experiments) provide a means of verifying the nature of the reaction mechanism

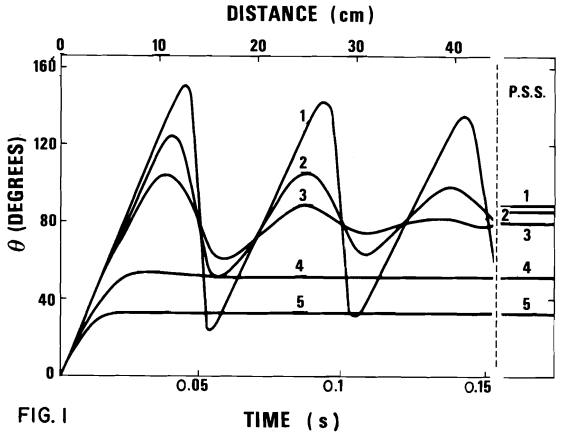

FIG. 1

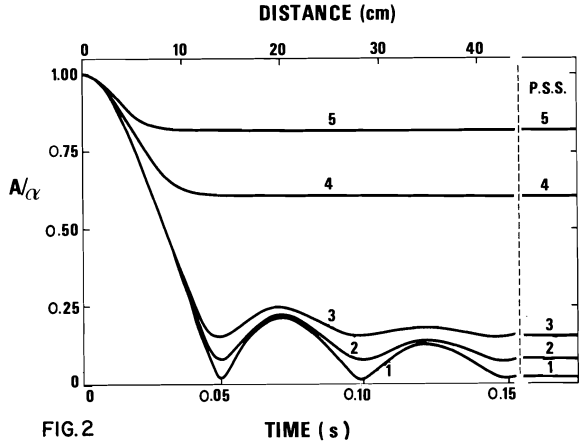

FIG. 2

and checking the values of rate constants measured in the pseudo steady state region.

4.2 Mechanism 2

If, in addition to the electron impact excitation and the first order removal of X_j, we also assume that de-excitation occurs via a superelastic collision with an electron, the phase shift and amplitude equations take a different form. This reaction sequence is described by

$$[17] \qquad X_i + e \xrightarrow{k_1} X_j + e$$

$$[18] \qquad X_j \xrightarrow{k_2} X_i$$

$$[19] \qquad X_j + e \xrightarrow{k_3} X_i + e$$

The concentration of X_j is governed by the rate equation:

$$[20] \quad d[X_j]/dt = k_1 n_e [X_i] - (k_2 + k_3 n_e)[X_j]$$

No restriction is placed on the concentration of X_j other than the conservation of mass:

$$[21] \qquad [X_i^0] = [X_i] + [X_j]$$

where $[X_i^0]$ is the total initial concentration. Substitution of $[X_i]$ in eq. [20] from the above equation allows us to eliminate $[X_i]$ from the former equation. Combining this equation with [6] then gives the rate equation for $[X_j]$ in the current modulated discharge. The integrated form of this rate equation simplifies considerably in the pseudo steady region of the discharge (large values of t_g) to give:

$$[22] \quad [X_j] = \frac{k_1 n_e^0 [X_i^0]}{k_2 + (k_1 + k_3) n_e^0} \times [1 + A \sin(\omega t - \theta)]$$

where $[X_j]$ is phase shifted (with respect to n_e) by an angle θ.

$$[23] \qquad \theta = \arctan \omega / [k_2 + (k_1 + k_3) n_e^0]$$

and has an amplitude A

$$[24] \quad A = \alpha k_2 / \{\omega^2 + [k_2 + (k_1 + k_3) n_e^0]^2\}^{1/2}$$

The rate equation for $[X_j]$ was integrated with the use of a series expansion. Higher order terms in α^n, where $n \geq 2$, are neglected in this calculation for the case in which the amplitude of the current, α, is small, $\alpha \ll 1$. This condition must be met experimentally to insure the applicability of the above equations to experimental results. The above equations can be solved simultaneously for measured values of θ and A in the pseudo steady state, and for a given frequency ω, to determine the value of k_2 and $(k_1 + k_3)n_e^0$. For the case in which $k_1 \ll k_3$ both the first order and electron impact removal rate constants, k_2 and $k_3 n_e^0$ can be measured by this method.

4.2.1 Phase Shift Dependence on Time

Phase shift and amplitude versus time curves should prove particularly useful for distinguishing between reaction mechanisms which generate similar results in the pseudo steady state. For example, phase shift versus time curves, determined by numerical integration of the rate equations for Mechanism 2, are shown in Fig. 3. The phase shift in the pseudo steady state (eq. [23]) of 78° is determined solely by the magnitude of $k_2 + k_3 n_e^0$ (for the case $k_1 \ll k_3$) which in this case is 50 s^{-1}. However, as the rate constant ratio, $k_3 n_e^0 / k_2$, is varied from 0

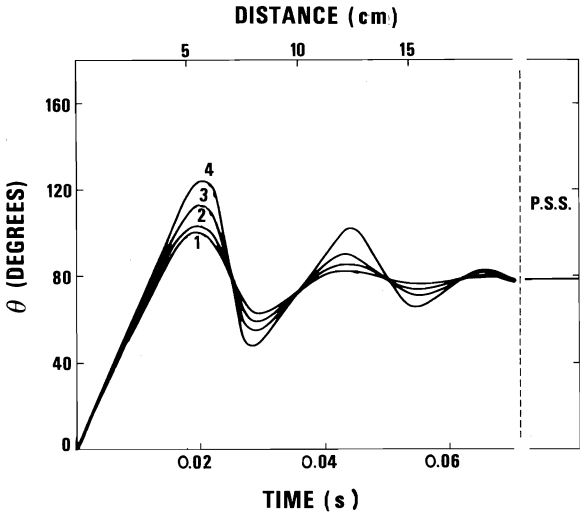

FIG. 3. Phase shift of $[X_j]$ versus distance in the discharge (mechanism 2): $v_s = 2.8$ m s^{-1}, $\nu = 40$ Hz, $n_e^0 = 5 \times 10^9$ cm^{-3}, $\alpha = 0.2$, $k_1 = 10^{-11}$ cm^3 s^{-1}; $k_2 = 50$ s^{-1}, $k_3 = 0$ (curve 1); $k_2 = 37.5$ s^{-1}, $k_3 = 2.5 \times 10^{-9}$ cm^3 s^{-1} (curve 2); $k_2 = 25$ s^{-1}, $k_3 = 5 \times 10^{-9}$ cm^3 s^{-1} (curve 3); $k_2 = 12.5$ s^{-1}, $k_3 = 7.5 \times 10^{-9}$ cm^3 s^{-1}.

to 3, the peak phase shift decreases from 125° to 90°. Measurements of the peak phase shift provide an additional experimental observable which in this case can be used to determine the relative values of $k_3 n_e^0$ and k_2.

4.2.2 Modulation of $[X_i]$: *Negative Phase Shifts*

Due to the conservation of mass (eq. [21]) $[X_i]$ is also modulated and phase shifted. The phase shift, θ, of $[X_i]$ in the pseudo steady state is given by

$$[25] \quad \theta = -180° + \arctan \omega/[k_2 + (k_1 + k_3)n_e^0]$$

for $\alpha \ll 1$ and has the amplitude A

[26]
$$A = \frac{\alpha k_1 n_e^0 k_2}{\{\omega^2 + [k_2 + (k_1 + k_3)n_e^0]^2\}^{1/2}(k_2 + k_3 n_e^0)}$$

The phase shift of $[X_i]$ is negative; the waveform of $[X_i]$ precedes that of n_e. Phase shifts in the first and second quadrants are defined as positive phase shifts while those in the third and fourth quadrants are defined as negative phase shifts. In general, the phase shifts of the concentrations of reaction intermediates and short lived states excited from reaction intermediates will be positive. On the other hand, the concentrations of reactants and short lived states excited directly from the reactant species will be negatively phase shifted.

Phase shifts of both types have been observed in this laboratory in the nitrogen glow discharge (7). A low frequency modulation superimposed on the discharge current resulted in modulations in the intensities of both the first positive system ($B^3\Pi_g$–$A^3\Sigma_u^+$) and the second positive system ($C^3\Pi_u$–$B^3\Pi_g$). The former intensities, proportional to the populations of the vibrational levels of the $B^3\Pi_g$ state, were positively phase shifted. It follows from these results that the $B^3\Pi_g$ state must be populated from a long lived intermediate. The intensities of the second positive system, proportional to the populations of the vibrational levels of the $C^3\Pi_u$ state, were negatively phase shifted. This result indicates that the $C^3\Pi_u$ state is excited mainly by electron impact from the ground electronic state which itself is depopulated by excitation processes.

4.3 Mechanism 3

Here, we consider the case of a short lived excited state, X_j^*, produced both by an electron impact reaction and by a first order (or pseudo first order) process from a long lived intermediate, X_j.

$$[27] \quad X_i + e \xrightarrow{k_1} X_j + e$$

$$[28] \quad X_j \xrightarrow{k_2} X_i$$

$$[29] \quad X_j + e \xrightarrow{k_3} X_j^* + e$$

$$[30] \quad X_j (+ M) \xrightarrow{k_4} X_j^* (+ M)$$

$$[31] \quad X_j^* \xrightarrow{k_5} X_j^{**} + h\nu$$

Because X_j^* is a short lived excited state, it radiates in the same region of the discharge in which it is produced, and its concentration, proportional to the emission intensity, I, is also proportional to the rate of production of X_j^* by reactions [29] and [30]

$$[32] \quad I = h\nu \sim [X_j^*] \sim (k_3 n_e + k_4)[X_j]$$

Hence, modulations in $[X_j]$ are reflected by modulations in the emission intensity I.

For the case $k_2 > k_3 n_e^0 + k_4$, $[X_j]$ is given by eq. [11], discussed for mechanism 1. If we substitute eq. [11] in the above expression for I and neglect higher order harmonic terms, for the case $\alpha \ll 1$, then we obtain an expression proportional to I in the pseudo steady state region.

The phase shift, θ, of I is

$$[33] \quad \theta = \arctan \left[\frac{k_2}{\omega} + \left(\frac{\omega}{k_2} + \frac{k_2}{\omega} \right) \times \left(1 + \frac{k_4}{k_3 n_e^0} \right)^{-1} \right]^{-1}$$

and the amplitude, A, is

$$[34] \quad A = \alpha\left(1 + \frac{\omega^2}{k_2{}^2}\right)^{-1/2} \times \left[1 + \left(3 + \frac{\omega^2}{k_2{}^2}\right)\left(1 + \frac{k_4}{k_3 n_e{}^0}\right)^{-1}\right]^{1/2}$$

The dependence of A and θ on the ratio, ω/k_2, for different ratios of the rate constants, $k_4/k_3n_e{}^0$, is shown in Figs. 4 and 5.

If $X_j{}^*$ is excited only by a first order or pseudo first order process, ($k_3n_e{}^0 = 0$), then the phase shift of both I and $X_j{}^*$ shows the same dependence on frequency as does the phase shift of X_j and approaches a value of 90° at high frequencies. On the other hand, if any of the production of $X_j{}^*$ occurs by electron impact with X_j, then the phase shift must approach 0° at high frequencies.

For large values of ω/k_2, the amplitude (eq. [34]) attains a constant value

$$[35] \quad A = \left(1 + \frac{k_4}{k_3 n_e{}^0}\right)^{-1/2}$$

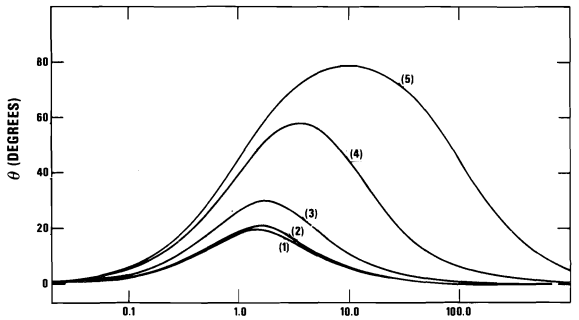

FIG. 4

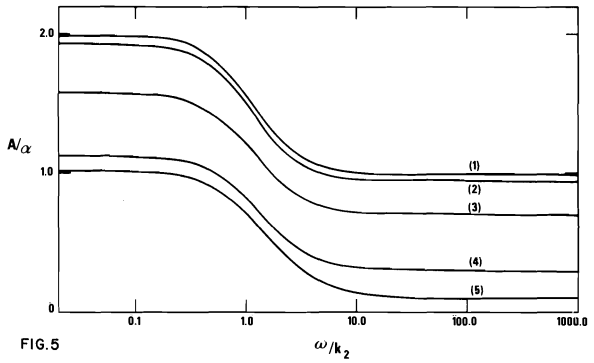

FIG. 5

FIG. 4. Phase shift, θ, of $[X_j{}^*]$ versus ω/k_2 (mechanism 3): $k_4/k_3n_e{}^0 = 0.01$ (curve 1), 0.1 (curve 2), 1 (curve 3), 10 (curve 4), 100 (curve 5).

FIG. 5. Ratio of amplitude A of $X_j{}^*$ to the amplitude α of n_e versus ω/k (mechanism 3), conditions are the same as in Fig. 4.

which is independent of the value of k_2. A measurement of the amplitude of $X_j{}^*$ at high frequencies provides a direct measurement of the rate constant ratio, $k_4/k_3n_e{}^0$.

This result illustrates an important application of chemical modulation techniques. At frequencies which are large compared to the removal rate constants for intermediate species (in this case, X_j; the amplitude of X_j approaches a value of 0 (see eqs. [16] and [34])). But eq. [35] shows that A attains a constant value different from 0 for ω going to infinity. Measurements of the amplitude of the concentration of short lived excited states at high frequencies provide a direct measurement of the relative rates of excitation of these states by first order and electron impact processes, regardless of how many intermediate states are involved in the reaction mechanism. It would be impossible to determine this type of kinetic information from measurements performed in a dc discharge unless the reaction mechanism was simple and well defined. Clearly, kinetic information can be obtained by measurements of the limiting high frequency phase shift and amplitude of modulated radical concentrations.

The phase shift, θ_{max}, at the maximum of the curves in Fig. 4 is given by

$$[36] \quad \theta_{max} = \arctan\left[\frac{1 + k_4/k_3n_e{}^0}{2(2 + k_4/k_3n_e{}^0)}\right]^{1/2}$$

A measurement of this quantity, for this specific mechanism, is sufficient to determine the rate constant ratio, $k_4/k_3n_e{}^0$.

The frequency, ω_{max}, at which this maximum occurs is given by

$$[37] \quad \omega_{max} = k_2(2 + k_4/k_3n_e{}^0)^{1/2}$$

The value of k_2 can be determined from a measurement of ω_{max}, and the ratio $k_4/k_3n_e{}^0$.

An interesting case is that for which $k_3n_e{}^0 \gg k_4$ (curve 1 in Figs. 4 and 5). Here, ω_{max} is given by

$$[38] \quad \omega_{max} = 2^{1/2}k_2$$

and the phase shift at the maximum is

$$[39] \quad \theta_{max} = \arctan 1/2\sqrt{2} = 19.5°$$

The position of the maximum is determined solely by the value of k_2; the largest possible phase shift in the pseudo steady state becomes 19.5°. Measurements of θ and A as a function of the frequency can be used to both identify this particular mechanism and also to determine values of the rate constants k_2 and the ratio $k_4/k_3n_e{}^0$.

Other reaction mechanisms can be treated in a

similar manner to those discussed above. In most cases approximate solutions for θ and A in the pseudo steady state can be readily obtained. However, when extremely complex mechanisms are considered, it becomes more convenient to use computer methods to determine the phase shift and amplitude by integrating numerically the rate equations corresponding to an assumed mechanism.

4.4 Conclusions

For a limited number of reaction mechanisms, rate constants can be deduced from measurements of radical concentrations as a function of the gas residence time in the dc current discharge. The analogous experiment in the current modulated discharge is the measurement of the phase shift of a radical concentration as a function of the frequency in the pseudo steady state region. This shift in emphasis from gas residence time (a calculated parameter which is poorly defined under many experimental conditions in flow tubes) to the frequency (an experimental parameter which can be accurately determined) allows for greater flexibility and accuracy in the measurement of rate constants in glow discharges.

Measurements performed in the dc current discharge are only useful for the case in which the reaction mechanism is simple and well established. Phase shifts and amplitudes are dimensionless parameters which have physical significance, regardless of the complexity of the reaction mechanism. Consequently, measurements performed in a current modulated discharge can be used to elucidate complex mechanisms for cases in which dc current techniques can provide only marginal kinetic information.

Another advantage of current modulation techniques is that phase shift and amplitude measurements in the pseudo steady state region are independent of the gas stream velocity. Although there are spatial concentration gradients in this region of the discharge, as there are along the entire length of the discharge, the phase shift and amplitude of radical concentrations will be identical in each volume element of gas in the pseudo steady state. This follows from the definition of PSS as being the discharge region in which the radical amplitude and θ attain constant values. Although there may be spatial concentration gradients in this region as there are in the dc discharge, the phase and amplitude of the modulated concentrations are identical in each volume element of gas. Hence, it is unnecessary to make any assumption regarding the nature of the gas flow (such as the commonly employed assumption of plug flow) to determine accurate rate constants. Since phase shifts and amplitudes in the pseudo steady state are unaffected by radial or axial gradients in the stream velocity, corrections for these gradients, which must be applied to measurements performed in a dc current discharge, need not be considered for experiments in a current modulated discharge.

The application of chemical modulation techniques to a gas flow discharge system provides an additional experimental observable, the peak phase shift (defined as the maximum phase shift measured along the length of the discharge). For many mechanisms, this quantity exhibits an entirely different dependence on frequency compared to the phase shift measured in the pseudo steady state region. In contrast to the pseudo steady state parameters, transient phenomena such as the peak phase shift are dependent on the gas flow profile. The phase shift peaks predicted theoretically may be distorted as a consequence of stream velocity gradients and diffusion of metastable species. Measurements of the peak phase shift can provide kinetic information in a manner which has not been considered in previous applications of chemical modulation techniques.

5. Experimental Testing of the Current Modulated Technique

5.1 General

The mechanism for the production and removal of O atoms in a flowing oxygen glow discharge was determined in this laboratory. Mass spectrometric measurements (1) of the atom concentration profile in the active discharge have established that the atoms are produced by direct electron impact dissociation of the molecule and removed by a process first order in the atom concentration

$$[40] \qquad O_2 + e \xrightarrow{k_1} O + O + e$$

$$[41] \qquad O \xrightarrow{k_w} \tfrac{1}{2}O_2$$

The magnitude of the removal rate constant, k_w, was found to be from 10 to 100 times larger than the corresponding value in the afterglow. In the present study measurements obtained in a dc glow discharge have been compared by investigating the kinetics of O-atom formation using the current modulated technique, under otherwise identical experimental conditions. This mechanism is of the type discussed in section 4.1 where X_i is O_2 and X_j the O atom. The response of the important measured quantities are given by eqs. [13]–[16], where $k_2 = k_w$.

The concentration of oxygen atoms thus can be visualized as consisting of two parts: a dc component which is identical to that in a dc current discharge and a modulated component with a relative amplitude, A, which is phase-shifted with respect to n_e by a phase angle θ. Both θ and A are functions of the

residence time t, and rate constant k_2 in addition to the modulation parameters. By flowing ultrapure oxygen through the discharge tube and adjusting the energy of the ionizing electron beam of the mass spectrometer so as to ionize O atoms (but not O_2), one can obtain a measure of X_j as a function of the resident time in the discharge (1) and hence determine k_w. Alternately, phase angles and amplitudes of the modulated atom concentration could be obtained experimentally at various values of the gas residence time as a function of the applied frequency and amplitude of modulation.

Within the limits of detection, the modulation induced in the oxygen atom concentration was found to be sinusoidal and consequently could be described by a phase shift and an amplitude of the fundamental frequency only. Any phase shift introduced by the flight time of the atoms in the molecular beam between the sampling orifice and the mass spectrometer could be determined by operating the discharge in the dc mode and chopping the molecular beam at the appropriate frequency.

5.2 Results

The dependence of the phase shift and relative amplitude of the modulation in the oxygen atom concentration is plotted against time in the discharge in Figs. 6 and 7. As the applied frequency was increased, the relative amplitude was found to decrease while the phase shift increased. At large values of time both the phase shift and relative amplitude assumed a constant value.

The theoretical phase shifts and amplitude of the oxygen atom concentration for the postulated mechanism were fitted to the experimental points. The only nonexperimental parameter available for this fitting procedure is the value of k_w. The best fit of the experimental and calculated points was obtained for a value of k_w of 280 s^{-1} for any value of the gas residence time t.

At large values of t_g the equations for the calculated phase shift and relative amplitude simplify to [15] and [16]. Note that both θ and A for this special case are independent of t in the pseudo steady state region of the discharge.

Figures 8 and 9 show the dependence of both the phase shift and relative amplitude as a function of the applied frequency. As the frequency is increased the phase shift asymptotically approaches a value of 90° while the relative amplitude decreases to a value of 0°. Excellent agreement is thus obtained between the calculated and experimental values for the entire experimental frequency range (10–500 Hz).

A value of the first order recombination rate constant was also determined in the dc discharge. The technique consisted of monitoring the [O] as a function of gas residence time. A plot of $\ln([O]_{ss} - [O]_t)/[O]_{ss}$ versus t yielded a straight line with a sloped (k_w) of 330 s^{-1} (Fig. 10). This value is in good agreement with that determined using the current modulated technique.

In Fig. 11 the value of k_w determined at various frequencies from a reading in the PSS is plotted. This shows that the value of k_w thus obtained is independent of frequency.

The excellent fit obtained for both the θ and A over the entire range of experimental parameters and the good agreement obtained between the rate constant determined using both methods is taken as evidence for the correctness of the postulated mechanism and hence the soundness of the current modulated tech-

nique. It should be noted that the suggested mechanism was the only one among the many tested which predicted the correct variations of the phase shift and relative amplitude with the experimental parameters.

These results illustrate convincingly several advantages of using the current modulated technique over the DC technique in the determination of k_w. Since both the phase shift and relative amplitude in the pseudo steady state are exclusive functions of k_w and modulation parameters (α,ν) the value of k_w can be determined from either of these measurements in this region of the discharge. The experimental errors associated with the determination of k_2 from measurements associated with short residence times of a dc current discharge are thus eliminated.

The enol content of simple carbonyl compounds: a kinetic approach

J. PETER GUTHRIE[1]

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received June 16, 1978

J. PETER GUTHRIE. Can. J. Chem. **57**, 797 (1979).

Following a suggestion of Lienhard and Wang, we demonstrate that the enol content of simple carbonyl compounds can be estimated as the ratio of the rate constants for acid-catalyzed enolization of the carbonyl compound and acid-catalyzed hydrolysis of the corresponding methyl enol ether. Values so estimated are in excellent agreement with those determined by our thermochemical method. Sufficient data are available for the following; compound, pK_{Enol}: acetaldehyde, 4.7; propionaldehyde, 4.2; isobutyraldehyde, 2.7; acetone, 7.0; cyclopentanone, 6.7; cyclohexanone, 5.3; cycloheptanone, 7.2; cyclooctanone, 6.6; *p*-nitroacetophenone, 4.9; *p*-bromoacetophenone, 6.2; acetophenone, 6.6; *p*-methylacetophenone, 7.0; *p*-methoxyacetophenone, 7.3; and by estimating the rate constants for enolization, the following; indanone, 7; 2-phenyl-2-propanone, 4; cyclopropyl methyl ketone, 8; chloroacetaldehyde, 2 (corrected for hydration); phenylacetaldehyde, 2.

J. PETER GUTHRIE. Can. J. Chem. **57**, 797 (1979).

A la suite de la suggestion de Lienhard et Wang, on démontre que l'on peut évaluer le taux d'énol dans des composés carbonylés simples en faisant le rapport des constantes de vitesse de l'énolisation acido-catalysée du composé carbonylé et de l'hydrolyse acido-catalysée de l'éther énolique méthylique correspondant. Les valeurs évaluées de cette manière sont en excellent accord avec celles déterminées par notre méthode thermochimique. Des données suffisantes sont disponibles dans les cas suivants; composé, pK_{enol}; acétaldéhyde, 4.7; propionaldéhyde 4.2; isobutyraldéhyde, 2.7; acétone, 7.0; cyclopentanone, 6.7; cyclohexanone, 5.3; cycloheptanone, 7.2; cyclooctanone, 6.6; *p*-nitroacétophénone, 4.9; *p*-bromoacétophénone, 6.2; acétophénone, 6.6; *p*-méthylacétophénone, 7.0; *p*-méthoxyacétophénone, 7.3; et si l'on fait une évaluation des constantes de vitesse de l'énolisation, les données seraient aussi disponibles pour les cas suivants; indanone, 7; phényl-2 propanone-2, 4; cyclopropylméthylcétone, 8; chloroacétaldéhyde, 2 (corrigé pour l'hydratation); phénylacétaldéhyde, 2.

[Traduit par le journal]

Introduction

Although the question of the enol content of simple carbonyl compounds has been addressed at intervals for a long time (1–5), the problems involved in obtaining an unambiguous answer have remained formidable (3, 6). Recently (7) we reported a thermochemical method which appeared to offer a general and unambiguous answer to this problem. In the course of the investigations leading to the thermochemical method, we found that a quite independent method of comparable generality exists but has not been exploited. This method is based upon the work of Lienhard and Wang (8), who pointed out, in an investigation of the mechanism of hydrolysis of enol ethers, that the accepted mechanism for general-acid-catalyzed enolization of a ketone (and therefore for the ketonization of an enol) requires that the rate constants for general-acid-catalyzed hydrolysis of an enol ether must be approximately equal to the rate constant for the general-acid-catalyzed ketonization of the corresponding enol, if protonation of the enol ether on carbon is the rate-determining step. Lienhard and Wang demonstrated that this identity obtains for cyclohexanone and drew the appropriate mechanistic conclusions.

It is obvious that if this approximate identity is generally valid, then from the rate of acid-catalyzed hydrolysis of an enol ether (equal to the rate of ketonization of the enol) and the rate of acid-catalyzed enolization of the corresponding keto tautomer one can determine the enol content of the carbonyl compound. It is curious that although this has been recognized (9, 10) there seems to have been no real attempt to utilize this potentially very powerful method. One serious difficulty hindering the acceptance of this method is the dearth of simple compounds, for which the enol content is known, which could be used to test the method. With a set of equilibrium constants for enolization determined by our thermochemical method (7) now in hand, it is possible to demonstrate that the kinetic method implicit in the work of Lienhard and Wang (8) is indeed quite general and has the potential for great

[1]Alfred P. Sloan Fellow, 1975–1979.

0008-4042/79/070797-06$01.00/0

utility.[2] The available data are already sufficient to show that the method can not be exactly correct (which was hardly to be expected), since the rate constant for acid-catalyzed hydrolysis of an alkyl enol ether depends upon the nature of the alkyl group (11). The rate factors are fairly small for simple alkyl groups, so that these facts do not invalidate the method but simply demonstrate an inherent imprecision.

Results and Discussion

In Table 1 are summarized the available data for acid-catalyzed enolizations of carbonyl compounds and hydrolysis of the corresponding enol ethers. The list is believed to be essentially complete for hydrolyses of methyl enol ethers (some other compounds which differ only in the alkyl or substituted aryl substituent and are closely similar to related compounds in Table 1 have been studied; these other compounds are referred to in the table) but is less complete for acid-catalyzed enolization, for which there are numerous compounds for which the enol ether has not been studied.

Table 1 reports only rate constants for methyl enol ethers (some of which are estimated from the corresponding ethyl enol ethers); although in a few thoroughly studied enol ether systems a variety of other alkyl or aryl groups have been present in place of methyl (or ethyl), this restriction does not reduce the number of carbonyl compounds considered.

Assuming that the rate constant for acid-catalyzed hydrolysis of an enol ether is the same as the rate constant for ketonization of the corresponding enol, the equilibrium constant for enolization can be calculated as the ratio of the rate constant for enolization to the rate constant for hydrolysis. It is convenient to use $pK_{Enol} = -\log K_{Enol}$ as a measure of the tendency of a carbonyl compound to enolize. These values are also found in Table 1. This method for estimating K_{Enol} as the ratio of rate constants will be referred to as the 'kinetic method' in this paper.

For 1-methoxypropene both the methyl and ethyl ethers of both *E* and *Z* isomers have been studied (11). As is generally the case the ethyl ethers are about twice as reactive as the corresponding methyl ethers. The *Z* isomers are about three times as reactive as the corresponding *E* isomers. This difference in reactivity is not a reflection of differences in stability of the two isomers because the equilibrium constant for geometrical isomerization is 1.2 (12). Assuming that the proton transfer to (or from) carbon is the rate-determining step for ketonization (or enolization), the observed rate constant for enolization is the sum of the rate constants for formation of the *E* and the *Z* enol, and the corresponding overall rate of ketonization is given by:

$$k_{ketonization} = (k^{E\text{-Enol}}_{ketonization} + k^{Z\text{-Enol}}_{ketonization} \cdot K_{Z/E})/(1 + K_{Z/E})$$

$$K_{Z/E} = [Z\text{-Enol}]/[E\text{-Enol}]$$

For all cases except the alkyl isopropenyl ethers where both ethyl and methyl ethers have been studied the methyl ether is the less reactive by a factor of about twofold. The average value for the five cases excluding alkyl isopropenyl ethers is $k_{OMe}:k_{OEt} = 0.48 \pm 0.05$. In contrast to this pattern, the value for k_{H^+} reported for methyl isopropenyl ether (13) is larger than the value for ethyl isopropenyl ether (11, 14). The experiments were done in different laboratories, under slightly different conditions (0.04 as opposed to 0.08 *M* ionic strength); the most likely source of the discrepancy is that the rate constant for the methyl ether is based upon experiments done in phosphate buffers where the hydronium ion catalyzed reaction makes only a small contribution to the observed rate, although the errors are claimed to be only 1.3%. For methyl isopropenyl ether and for 1-methoxycyclopentene rate constants for acid-catalyzed hydrolysis were estimated from the observed rate constants for the ethyl ethers (11) and the average value of 0.48 for the methyl to ethyl rate ratio. In the case of methyl isopropenyl ether we consider that this estimated value is probably the better one to use.

The data supporting the value of the methyl to ethyl rate ratio are collected in Table S-I, which has been placed in the Depository for Unpublished Data.[3]

Rate constants for enolization of the aldehydes were taken from the work of Talvik and Hiidmaa (15) and are observed rate constants for the equilibrium mixture of aldehyde and hydrate, not corrected for number of enolizable hydrogens. There appear to have been no studies of the enolization of cycloalkanones in water except for the studies of cyclohexanone by Lienhard and Wang (8). Schechter *et al.*

[2]A referee has pointed out that on *a priori* grounds one might have expected that the method would not work since hydroxy and alkoxy should differ in their ability to stabilize a developing positive charge. However since the rate constants for acid-catalyzed hydrolysis of an enol ether or ketonization of the corresponding enol are in fact approximately equal (8) it seems clear that this difference is really quite small.

[3]Copies of material on deposit may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

(16) studied a series of cycloalkanones in 90% acetic acid with HCl as catalyst. We have estimated the rate constants for the other cycloalkanones in water from these data assuming that the relative rates in water at 25°C will be the same as in 90% acetic acid at 20°C.

The rate constant for the acid catalyzed enolization of acetophenone was taken from studies at 25°C using 0.053 or 0.109 *M* H_2SO_4 as catalyst (1). Rate constants for ring-substituted acetophenones were calculated from this value assuming that relative rates will be approximately the same as those for a study at 30°C in 1.39 *M* $HClO_4$ (18).

A number of enol ethers have been studied in 80:20 dioxane–water (19–21); these rate constants have been corrected to pure water as solvent by taking advantage of the linear free energy relation between rate constants in dioxane–water and water. This relation can be expressed as

$$\log k_{water} = 1.244 + 0.971 \log k_{dioxane-water}$$

with a correlation coefficient of 0.992. The rate constants upon which the correlation is based, as well as the corrected rate constants for all compounds studied in dioxane–water are found in Table S-II, which has been placed in the Depository for Unpublished Data.[3]

It is of interest to attempt to estimate the enol content for the final group of compounds in Table 1, for which only the rate of hydrolysis for the enol ether is available. For indanone, the observation that acetone and cyclopentanone have very similar rates of enolization suggests that indanone will be very similar to acetophenone, with a rate constant of ca. 10^{-5} M^{-1} s^{-1}. Although there has been no investigation of the enolization of phenylpropanone under conditions where the reaction is unambiguously acid catalyzed reaction of the ketone, an investigation of exchange in acetic acid (22) showed that the methylene position in 1-phenyl-2-propanone exchanged faster than either position in butanone; comparison with rates of acid-catalyzed enolization for butanone in water (23) suggests that the rate constant for phenyl propanone is about 10^{-4} M^{-1} s^{-1}. The rate constant for enolization of the keto tautomer of chloroacetaldehyde can be estimated from the rate constant for acetaldehyde by using the rate ratio for chloroacetone to acetone. The rate constants for acid-catalyzed enolization (in the case of chloroacetone, expressed in terms of the keto form, corrected for hydration) have been measured at 15°C (24, 25). Taking the observed values at $H_0 = 0.0$ as the desired second-order rate constants (in both cases plots of log k_{obs} vs. H_0 are linear with unit slope in this H_0 region), one finds that the rate constants are 1.4×10^{-6} M^{-1} s^{-1} for chloroacetone (24) and

$5.0 \times 10^{-6}\ M^{-1}\ s^{-1}$ for acetone (25). Thus one estimates that the rate constant for enolization of the keto tautomer of chloroacetaldehyde will be ca. $10^{-6}\ M^{-1}\ s^{-1}$; the apparent rate constant would be slower because of the extensive formation of hydrate to be expected: $K_{hydration} = 10$, estimated from ref. 26. The apparent rate constant for enolization of an equilibrium mixture of chloroacetaldehyde and its hydrate would be about $10^{-7}\ M^{-1}\ s^{-1}$.

These estimated rate constants lead to predicted values of pK_{Enol} shown in Table 1; of particular interest are the predictions for 1-phenyl-2-propanone, for which $pK_{Enol} = 4$; chloroacetaldehyde, for which $pK_{Enol} = 2$, although hydration would lead to an apparent value (for K^{app}_{Enol} = [Enol]/([Aldehyde] + [Hydrate])) of $pK^{app}_{Enol} = 3$; and phenylacetaldehyde, for which $pK_{Enol} = 2$. For the closely related 2-phenylpropanal, the enol content in DMSO at 60°C is about 10% (27). Since one expects that the extra methyl group might well favor the enol, this result is not inconsistent with our prediction.

Table 2 compares the results from the application of the 'kinetic method' with those from our thermochemical method and also with the various values reported by other laboratories, using more direct methods. It must be borne in mind that the earlier attempts to use halogen titrations were probably subject to systematic errors (3, 6); furthermore the latest attempts to use halogen titration (3, 28) lead to values which are sometimes in disagreement with expectations based upon the overall chemical behaviour of the systems concerned (9, 10).

For cyclohexanone the agreement with Bell's measured value is good, but for cyclopentanone the agreement is very poor; the discrepancy amounts to two orders of magnitude. Hine and Arata (9, 10) have pointed out that Bell's result for cyclopentanone is inconsistent with a considerable body of information concerning relative behaviour of five- and six-membered ring compounds; one is reluctantly driven to consider the possibility that Bell's result is in error. This is extremely serious since if one of the values reported is in error, the other cannot be trusted entirely and there remains *no* firmly established and directly measured equilibrium constant for enolization of a simple carbonyl compound. For acetone the value which we obtain is consistent with the limit placed by Bell's work. The other recent investigation of the enol content of acetone was by Toullec and Dubois (4, 5), who measured the rate of halogenation of acetone under acidic conditions where tautomerization was rapid and the rate-determining step was reaction of enol with halogen. They concluded that the reaction occurred at the diffusion controlled limit from the identity of the rate constants for chlorine, bromine and iodine. Using a rate constant for diffusion controlled reaction of $1 \times 10^{10}\ M^{-1}\ s^{-1}$ (29) one obtains an equilibrium constant for enolization of 1.5×10^{-9} (7*b*).

This corresponds to a pK_{Enol} of 8.8, which is disturbingly far from the values estimated by our methods. As Dubois and Toullec (5) point out, their value is only approximate, because of uncertainties concerning the appropriate values of the parameters used to estimate the rate of diffusion. It is difficult to estimate the uncertainty in the pK_{Enol} values calculated by the 'kinetic method' but it should be less than 1 pK unit. (Although the reasons for choosing the estimated value for k_{OMe} for 2-methoxypropene continue to seem convincing it should be noted that the value from ref. 13 would give a $pK_{Enol} = 7.5$, in closer agreement with the value of Dubois and Toullec (6).)

Novack and Loudon (28) have reported measurements, in 40% *tert*-butyl alcohol – water, of the enol content of cyclopentanone and acetophenone (28). It is most disturbing that they obtain the same value for cyclopentanone as was reported by Bell and Smith (3), in view of the arguments mentioned above for thinking that this value is out of line with other chemistry of cyclopentanone. For acetophenone the value which Novack and Loudon report is not consistent with the pK_a^{Enol} which they report (28) on the basis of independent experiments studying the aminolysis of enol esters and the value of pK_a^{Keto} which can be derived (7*b*) from Bartlett and Vincent's (30, 31) studies of the rate of chlorination. Consequently we are led to propose that there is some systematic error in the halogenation titration used by Bell and Smith (3) and also by Novack and Loudon (28), which is not associated with trace impurities, although it may be associated with products of reactions induced under the experimental conditions.

The agreement between the 'kinetic method' and the thermochemical method is clearly excellent. Since the two approaches are entirely independent, this agreement tends to increase confidence in both methods.

Conclusions

The 'kinetic method' leads to reliable values of pK_{Enol}, is quite general, and for many simple carbonyl compounds may be the method of choice. It would be exceedingly valuable to have rate constants for the hydrolysis of a greater range of enol ethers, incorporating more of the structural features (halogen, alkyl, aryl, alkoxy, etc., substituents) important in synthetic applications of enolization.

Received September 29, 1978

LOIS M. BROWNE, R. E. KLINCK, and J. B. STOTHERS. Can. J. Chem. **57**, 803 (1979).

The ^{13}Cmr spectra of 5β,10β-dimethyldecalin, 10β-decal-5β-ol, and 10β-methyldecal-5β-ol have been examined as a function of temperature to determine the barriers to conformational inversion. Lineshape fitting was employed to extract rate data from which the thermodynamic parameters governing the inversion processes were extracted. Comparison of these results with those obtained by molecular mechanics calculations indicates that the barrier for chair-twist to twist-twist interconversion dominates the conformational inversion profile.

LOIS M. BROWNE, R. E. KLINCK et J. B. STOTHERS. Can. J. Chem. **57**, 803 (1979).

On a déterminé les spectres rmn ^{13}C des diméthyl-5β,10β décaline, 10β-décalol-5β et méthyl-10β décalol-5β en fonction de la température dans le but d'évaluer les barrières à l'inversion conformationnelle. On a utilisé la technique de la superposition des formes des pics pour en tirer les données à partir desquelles on a pu évaluer les paramètres thermodynamiques qui gouvernent les processus d'inversion. Une comparaison de ces résultats avec ceux obtenus grâce à des calculs de mécanique moléculaire indique que la barrière à l'interconversion chaise-croisée à croisée-croisée domine le profil de l'inversion conformationnelle.

[Traduit par le journal]

Introduction

Conformational inversion of the *cis*-decalin ring system [1] has been the subject of several nmr investigations (1–5). Gerig and Roberts (1) used ^{19}Fmr spectra to measure the inversion barriers for a series of 2,2-difluoro substituted *cis*-decalins whereas Altman *et al.* (2) analyzed the ^{1}Hmr spectra of *cis*-decalins bearing $-CH_2R$ substituents at the ring junction to estimate the barriers. More recently, the utility of ^{13}Cmr for such determinations has been demonstrated (3–5). In addition to their barrier determinations Gerig and Roberts (1) carried out potential energy calculations to obtain an energy profile for the inversion process. Their calculations showed the chair-chair (*CC*) conformation to be the preferred ground state, as expected, with the major barrier involving a half-chair-twist ($\frac{1}{2}CT$) form (see Fig. 1). The symmetrical boat-boat (*BB*) conformation was found not to represent a significant barrier to inversion, i.e., $A > B$ in Fig. 1. Because inversion from one *CC* form to the other requires passage through two equivalent $\frac{1}{2}CT$ forms a transmission coefficient (κ) of 0.5 has been used in the Eyring treatment of the rate constants in the more recent studies (3–5).

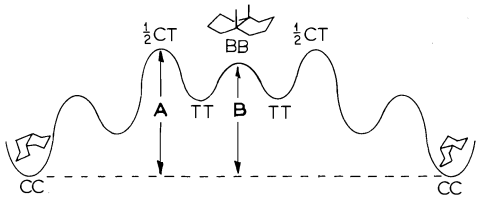

FIG. 1. Energy profile for the conformational inversion of the *cis*-decalin skeleton.

During the study of ^{13}C shieldings in a series of *cis*-decalins, we decided to investigate the inversion barriers for examples with substituents at the ring junction. It was felt that such substitution should increase the energy of the symmetrical *BB* form and in disubstituted derivatives perhaps alter the profile for inversion such that this form constitutes the highest point, i.e., $A < B$ in Fig. 1. If this were the case, a κ value of 0.5 would be inappropriate in the Eyring analysis. To provide a comparison with the observed energy barriers and to obtain an energy profile for the inversion process, molecular mechanics calculations have been examined.

Three substituted *cis*-decalins, 10β-decal-5β-ol (**1***a*), 10β-methyldecal-5β-ol (**1***b*), and 5β,10β-dimethyl-

1*e*	Me	H

decalin (**1***c*) were chosen for study. Molecular mechanics calculations were also carried out for *cis*-decalin (**1***d*) and its 5β-methyl analog (**1***e*), experimental barriers for which had been determined previously by ^{13}Cmr (4, 5). During the course of this work, inversion parameters were published for **1***b* (5) and these provide an independent check for the present experimental results.

Experimental

Materials

*10β-Decal-5β-ol (**1**a)*

This alcohol, mp 52–56°C, was prepared as described by Huckel *et al.* (6).

*10β-Methyldecal-5β-ol (**1**b)*

A mixture of 4β,5β-epoxy-10β-methyldecal-3-one (0.108 g), prepared by the method of Kuehne and Nelson (7), hydrazine hydrate (0.25 mL), glacial acetic acid (2 drops), and methanol (2 mL) was stirred at room temperature for 2 h. After dilution with water (5 mL), the mixture was extracted with pentane. The pentane extract was washed successively with buffer pH 5, $NaHCO_3$ solution, brine, and dried over $MgSO_4$. The solvent was removed by distillation at atmospheric pressure to give Δ^3-10β-methyldecal-5β-ol (0.086 g, 87% yield). This alcohol had the following properties: ir (neat): 3460, 1655, 940, 910 cm^{-1}; ^{1}Hmr ($CDCl_3$)δ: 1.00 (s, 3H, 10-CH_3), 5.49 (d of t, 1H, J = 1, 5 Hz, 4-H), 5.74 (d of t, 1H, $J \sim 2$, 5 Hz, 3-H); (C_5D_5N)δ: 1.20 (s, 3H, 10-CH_3); *Exact mass* calcd. for $C_{11}H_{18}O$: 166.1358; found (high resolution ms): 166.1354.

This octalol (0.050 g), triethylamine (1 drop), and ether was hydrogenated over 5% Pd/C in a Parr hydrogenator at 40 psi for 1 h. The solution was filtered through a small plug of silica gel and the solvent removed to give **1***b* (0.050 g). Its spectral data agree with those reported (8): ir (neat): 3470 cm^{-1}; ^{1}Hmr ($CDCl_3$)δ: 0.98 (s, 3H, 10-CH_3); (C_5D_5N)δ: 1.11 (s, 3H, 10-CH_3). *Exact mass* calcd. for $C_{11}H_{20}O$: 168.1514; found (high resolution ms): 168.1509.

*5β,10β-Dimethyldecalin (**1**c)*

Methyllithium (0.55 g, 30 mL, 0.7 *M*) was added to a cooled, stirred solution of cuprous iodide (2.48 g) in ether (50 mL). After stirring at 0°C for 10 min, Δ^4-10β-methyldecal-3-one (1.25 g) in ether (20 mL) was added over 30 min. Stirring was continued for 1 h and then the reaction was quenched with saturated NH_4Cl solution. The two-phase system was stirred rapidly for 10 min, filtered *in vacuo*, and the layers separated. The aqueous fraction was extracted with ether (3 × 20 mL) and the combined extracts dried over $MgSO_4$. Removal of the ether afforded 1.0 g of product from which 5β,10β-dimethyldecal-3-one (0.74 g, 54% yield) was isolated by chromatography over silica gel. This material had the following properties: mp 108–120°C (lit. (9) mp 108–118°C); ir (CCl_4): 1715 cm^{-1}; ^{1}Hmr (CCl_4)δ: 0.89 (s, 3H), 1.02 (s, 3H); *Exact mass* calcd. for $C_{12}H_{20}O$: 180.1515; found (high resolution ms): 180.1510.

Reduction of the carbonyl group of this ketone was accomplished using the Huang–Minlon modification of the Wolff–Kishner reaction as described by Ireland *et al.* (10) to yield **1***c* in 54% yield. This hydrocarbon exhibited essentially the same properties as those reported for **1***c* by Ireland *et al.* (10). The observed mp of 55–70°C, however, indicated contamination with a small amount of the *trans* isomer since the melting range is the same as that reported for a similar mixture (10). The ^{13}C spectra of **1***c* confirmed that the compound was >95% pure and the requisite data were readily obtained.

Spectra

Methylene-d_2 chloride employed as the solvent for this study was obtained from Merck, Sharp and Dohme, Canada and used without further purification. Solution concentrations ranged from 5–8 mol%.

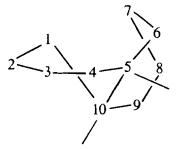
The spectra were obtained with a Varian XL 100-15 system equipped with variable temperature accessories and operated in the FT mode using the solvent signal for a lock. Probe temperatures were monitored before and after the collection of each spectrum with a thermocouple placed in a sample tube containing toluene. Temperature measurements should be reliable to ±1°C. Initially spectral widths of 2500 Hz were used to follow the temperature dependence of the spectra from −60 to +100°C, to obtain zero exchange separations and approximate coalescence temperatures and to identify the optimum temperature ranges for the spectra required for complete lineshape analysis. Subsequent spectra were recorded from 0 to 100°C at 10° intervals with smaller steps in the region of coalescences. Spectral widths of 800 Hz (8 K transforms) spanned the signals for exchanging carbons. For lineshape fitting, 100 Hz portions of these spectra were used in conjunction with the EXCHG program to obtain the best fits (11).

The ^{13}C shielding data for these derivatives will be presented and discussed with the results for several other *cis*-decalins in a forthcoming paper.

Molecular Mechanics Calculations

The Allinger MM1 program with the 1973 force field parameters (12) was used to investigate the energy profile for the inversion process. Input coordinates were generated with COORD 4 (13) using 109.5°C for the tetrahedral angle and the following bond lengths: C—C, 1.54 Å; C—H, 1.10 Å; C—O, 1.44 Å; O—H, 0.94 and 0.5 Å for an oxygen lone pair. The energies of the *BB*, *TT*, and ½*CT* forms (see Fig. 1) relative to that of the *CC* conformation were computed. A symmetrical *BB* conformation requires a X—C—C—Y dihedral angle of 0°C. It was necessary to restrict the motion of these atoms to maintain this condition. For **1***c* and **1***d*, this restriction resulted in eclipsing the 2-hydrogens with those on C-3 as well as the 7-hydrogens with those on C-8. For the other, less symmetrical cases, however, eclipsing interactions did not occur about the C-2,-3 and C-7,-8 bonds. Without these restrictions energy

minimization led to structures consistent with twist-twist (*TT*) conformations. A symmetrical *BB* arrangement constitutes an energy maximum between the *TT* forms and less symmetric species of lower energy are probably involved in the actual interconversion between *TT* forms. Thus, the values calculated for barrier *B* represent upper limits. For the $\frac{1}{2}CT$ forms, there are three possible conformers which represent six different cases for **1**, X ≠ Y; each was investigated using input coordinates obtained from the aforementioned bond lengths and typical dihedral angles available from calculations for cyclohexane. Since these forms represent energy maxima, restriction of the motions of certain atoms was necessary to fix the conformation. Initially, the motion of the carbons in the half-chair (C-1,-2,-3,-4,-5 and -10 in $\frac{1}{2}CT$-**1**) were constrained to obtain a first approximation of the energy for each form. Removal of the constraint for C-5 or -10 maintained the $\frac{1}{2}CT$ form but, in most cases, removal of the restrictions on both C-5 and -10 led, after minimization, to inappropriate conformations of much lower energy, for example, to a *TT* form. Although, in principle, all possible $\frac{1}{2}CT$ forms could be attained, the $\frac{1}{2}CT$-**1** conformation is



$\frac{1}{2}CT$-**1**

required to proceed to a symmetrical *BB* form and, in general, it was found that this form has the lower calculated energy. The values computed for the $\frac{1}{2}CT$-**1** forms were used in each case for the estimates of barrier *A* in Fig. 1.

Results and Discussion

Rate constants for the inversion process were obtained for all pairs of exchanging carbons in each of **1***a–c*. Because there are significant differences in the coalescence temperatures for the various exchanging nuclei it was possible to cover a wide temperature range without resorting to the use of data only from very fast or very slow exchange rates (4). For each case, from 15 to 27 rate constants were utilized in the Eyring and Arrhenius treatments (see Fig. 2). The results are summarized in Table 1 which includes published data for **1***d* and *e* for comparison. Agreement with recently reported parameters for **1***c* (5) is excellent indicating a negligible solvent effect since the latter data were obtained for the neat liquid. Although the experimental $\Delta H^{\ddagger}$ values for the disubstituted derivatives are greater than those for *cis*-decalin and the mono-

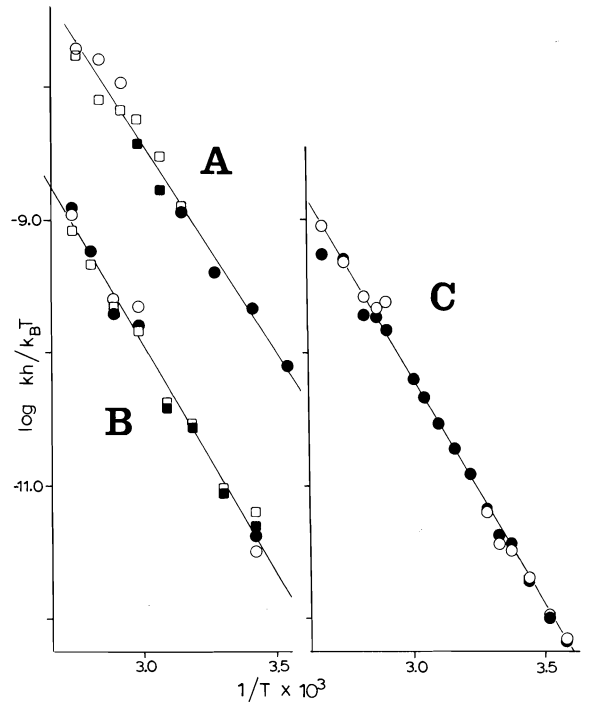


FIG. 2. Eyring plots from the data for the exchanging sites is **1***a* (*A*), **1***b* (*B*), and **1***c* (*C*).

substituted derivatives, no conclusion regarding the relative magnitudes of the barriers *A* and *B* for these cases can be drawn from these results alone. It may be noted that the observed $\Delta S^{\ddagger}$ values do not exhibit a regular variation as had been reported previously (2) for the change from symmetrical to unsymmetrical substitution at the ring junction. The activation energies, E_{act}, for inversion of **1***a–d* are listed for comparison with the results of the molecular mechanics calculations, which are included in Table 1 in terms of the barriers *A* and *B*. For all cases, it was found that $A > B$ indicating that passage through the $\frac{1}{2}CT$ conformation represents the dominant barrier to inversion, in agreement with the original conclusion of Gerig and Roberts (1) for *cis*-decalin itself. It had been suggested (5) that the presence of bulky substituents at both ring junction positions could render $B > A$ because of a greater destabilization of the *BB* form through the eclipsing interaction of these substituents. However, the present results indicate that this is not the case for two methyl groups. For the disubstituted derivatives there is a significant increase in the calculated value for barrier *B* but there is a concomitant increase for barrier *A* involving the $\frac{1}{2}CT$ form. Clearly, destabilizing interactions of the substituents with the ring skeleton are comparable to the eclipsing interactions. For the hydrocarbons reasonable agreement

is observed between the calculated values for barrier *A* and the experimental E_{act} values with the calculated results tending to be somewhat greater. A comparison of the energies for the same conformation for the three hydrocarbons indicates that the major effect of methyl substitution is to alter the bending and compression contributions to the total strain energy. This is consistent with the finding that skeletal changes in the ring system resulting from methyl substitution dominate the energy profile rather than the eclipsing interactions in the *BB* forms.

Since the force field parameters for hetero atoms are not so well refined as those for carbon and hydrogen, agreement between calculated and experimental inversion barriers cannot be expected to be as good for the decalols as found for the hydrocarbons. The strain energies for the various decalol conformers seem to differ but slightly from those for the hydrocarbons indicating that the parameters for oxygen are inadequate. In contrast to the findings for the hydrocarbons, the major differences for the decalols appear to arise from contributions calculated for the van der Waals interactions. In any event, the general tendency is the same, namely, $A > B$ for the two decalols.

Since, in each case, the difference between the calculated values for the two barriers is at least 5 kcal/mol, one can conclude that passage through the $\frac{1}{2}CT$ conformation represents the dominant barrier to conformational inversion in each of these systems. Thus, a transmission coefficient of 0.5 is required for the Eyring treatment of the rate data. It remains to be established whether bulkier substituents can render the *BB* form dominant in the energy profile.

Spin–spin coupling constants between side-chain and ring fluorine nuclei in some benzotrifluoride, benzal fluoride, and benzyl fluoride derivatives: coupling mechanisms

TED SCHAEFER, WALTER NIEMCZURA, CHIU-MING WONG, AND KIRK MARAT

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received September 27, 1978

TED SCHAEFER, WALTER NIEMCZURA, CHIU-MING WONG, and KIRK MARAT. Can. J. Chem. **57**, 807 (1979).

A complete analysis of the ^1H and ^{19}F nmr spectra of 2,5- and 3,4-difluorobenzotrifluoride, together with multiple resonance experiments, yields the signs and magnitudes of the long-range $^{19}F,^{19}F$ and $^1H,^{19}F$ spin–spin coupling constants. The coupling mechanisms are discussed. In particular, the coupling over six bonds, $^6J_p^{F,CF_3}$, whose sign is interpretable in terms of a σ–π mechanism, is too large in magnitude when compared to $^6J_p^{H,CH_3}$, $^6J_p^{F,CH_3}$, and $^6J_p^{H,CF_3}$ in the analogous compounds. These latter three couplings are consistent in sign and magnitude with what is known about hyperfine interaction constants. The magnitudes of $^6J_p^{F,CF_3}$ are reported for 4-fluorobenzotrifluoride, 3-amino-4-fluorobenzotrifluoride, 3-nitro-4-fluorobenzotrifluoride, as are $^6J_p^{F,F}$ values for *p*-fluorobenzal fluoride and *p*-fluorobenzyl fluoride. In contrast to $^6J_p^{H,CH}$ and $^6J_p^{F,CH}$, it seems unlikely that, unless its coupling mechanism becomes more precisely understood, $^6J_p^{F,CF}$ will be a reliable indicator of conformational preferences.

TED SCHAEFER, WALTER NIEMCZURA, CHIU-MING WONG et KIRK MARAT. Can. J. Chem. **57**, 807 (1979).

Une analyse complète des spectres rmn du ^1H et du ^{19}F des difluoro-2,5 (et 3,4) benzotrifluorures, de concert avec des expériences de résonance multiple, permet de déterminer les signes et les amplitudes des constantes de couplage spin–spin $^{19}F,^{19}F$ et $^1H,^{19}F$ à longue distance. En particulier l'amplitude du couplage à travers six liaisons, $^6J_p^{F,CF_3}$, dont on peut interpréter le signe en termes d'un mécanisme σ–π, est trop grande comparée aux $^6J_p^{H,CH_3}$, $^6J_p^{F,CH_3}$ et $^6J_p^{H,CF_3}$ observées dans les composés semblables. Les trois derniers couplages sont en accord, tant en ce qui a trait au signe qu'à l'amplitude, avec ce qui est connu concernant les constantes d'interactions hyperfines. On rapporte les amplitudes des $^6J_p^{F,CF_3}$ des fluoro-4, amino-3 fluoro-4 et nitro-3 fluoro-4 benzotrifluorures de même que les $^6J_p^{F,F}$ des fluorures de *p*-fluorobenzal et de *p*-fluorobenzyle. Par opposition aux $^6J_p^{H,CH}$ et $^6J_p^{F,CH}$, il est peu probable, que les $^6J_p^{F,CF}$ puissent êtres utilisés comme indicateurs surs des préférences conformationnelles à moins qu'on arrive à une meilleure compréhension de leur mécanisme de couplage.

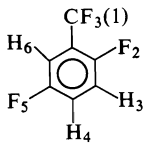
[Traduit par le journal]

Introduction

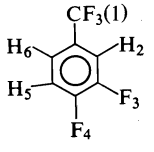
The σ–π electron contributions to the long-range spin–spin coupling constants over four, five, and six bonds, $J_{o,m,p}^{H,CH_3}$ and $J_{o,m,p}^{F,CH_3}$, in toluene derivatives have been discussed in some detail (1–12). In addition to their intrinsic interest as indicators of electronic structure, some of these couplings are useful in the determination of conformational preferences and, indeed, of internal barriers to rotation in benzene derivatives (13–16).

On the other hand, the signs and magnitudes of $J_{o,m,p}^{F,CF_3}$ in benzotrifluoride derivatives have been less thoroughly investigated (17–23). This paper briefly reports on these parameters for 2,5-difluorobenzotrifluoride, (**1**) and for 3,4-difluorobenzotrifluoride (**2**).

In addition some spectral parameters, useful in the discussion of **1** and **2**, are given for *p*-trifluoromethylbenzotrifluoride and 3-nitro-4-methylbenzotrifluoride; for *p*-fluorobenzotrifluoride and its



1



2

3-amino and 3-nitro derivatives; and for *p*-fluorobenzal fluoride and *p*-fluorobenzyl fluoride.

Experimental

The preparation of **1** involved repeated nitration and diazotization of benzotrifluoride whereas that of **2** necessitated a diazotization of 3-amino-4-fluorobenzotrifluoride (Pierce Chemical Co.). The details of the syntheses are in ref. 24*a*.

The preparation of 3-nitro-4-methylbenzotrifluoride involved 10 g of the benzoic acid (Aldrich Chemical Co.) and 26.7 g of SF_4, heated to 150°C/12 h in a 150 mL steel cylinder. The product, 6 g, 29% yield, distilled at 178°C/100 Torr.

The *p*-fluorobenzal fluoride was prepared from 1.1 g of the aldehyde (Pierce Chemical Co.) and 3.8 g of SF_4 by heating in a 75 mL steel cylinder, 125°C/17 h. The product was trap-to-trap distilled. No boiling point was determined but the ^1H nmr

spectrum gave the characteristic triplet components for the side-chain proton ($^2J^{H,F} = 56.4$ Hz).

The *p*-fluorobenzyl fluoride was prepared in a similar way from *p*-fluorobenzyl alcohol (Aldrich Chemical Co.) and gave the characteristic doublet components for the side-chain protons in the ^1H nmr spectrum. The physical properties of a series of benzyl fluoride derivatives, including the *p*-fluoro compound, have been described (24*b*).

Degassed samples of **1** and **2** in benzene-d_6 (details in footnotes to Table 1) had their ^1H nmr and ^{19}F nmr spectra calibrated on HA100 and DA60I spectrometers, respectively. Calibration markers, obtained by reading sweep and manual oscillator frequencies, were placed at 2 to 5 Hz intervals. Repeated calibrations were performed in the *frequency sweep mode* at spectral dispersions of 1 and/or 2 Hz/cm and at sweep rates of 0.02 and 0.01 Hz/s. Probe temperatures were determined by means of a thermocouple.

Weak irradiation experiments (25) on the ^{19}F nmr spectra were performed in the usual manner.

The ^1H nmr spectrum at 100 MHz of a 20 vol% solution of 3-nitro-4-methylbenzotrifluoride was also recorded and calibrated in the manner described above; 50 vol% solutions in C_6D_6 of all other compounds contained internal CF_3CCl_3 and TMS. Degassed samples were used to record and calibrate ^1H nmr and ^{19}F nmr spectra as described for **1** and **2**. An exception was *p*-trifluoromethylbenzotrifluoride (Chemical Procurements Co.) which was used as 95 vol% solution in CF_3CCl_3.

INDO MO FPT calculations (26) were performed on an IBM 370/158 system, using standard geometries (27).

Results and Discussions

Spectral Analysis of 1 and 2

These were performed with the computer program LAME (28, 29). The ^1H nmr spectra at 100 MHz were analyzed first. The parameters obtained in this way were used in an iterative analysis of the ^{19}F spectra at 56.4 MHz. The spectral parameters from the latter analysis were again used in an iterative analysis of the ^1H spectra. The final parameters satisfactorily reproduced the 60 MHz ^1H nmr spectra of **1**.

The spectral parameters are found in Table 1. Good agreement between the parameter sets is evident; the numbers in parentheses are *five* times the standard deviations. Iterations were not performed on the peaks from the CF_3 groups, severe overlap of peaks yielding ambiguities in their

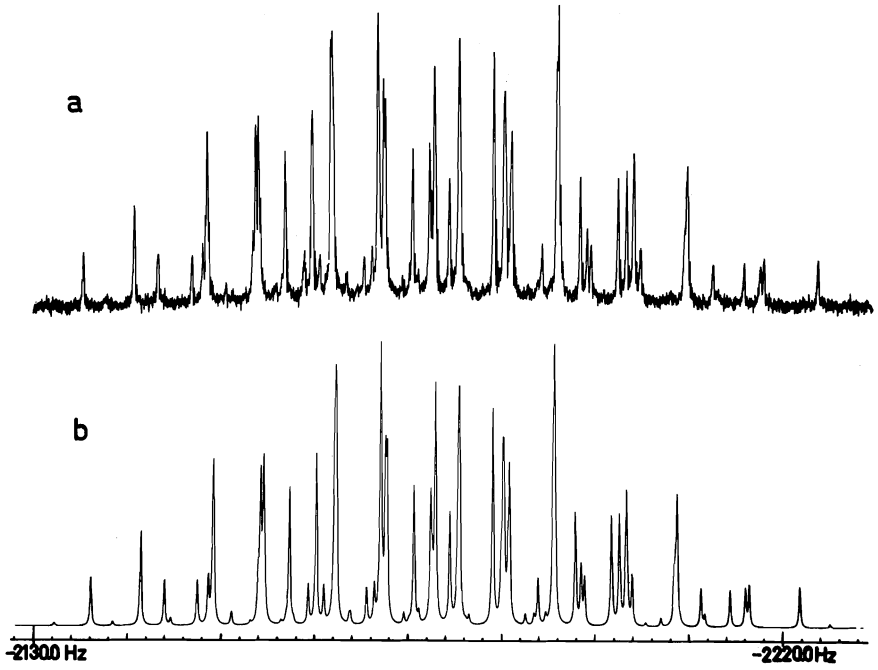

FIG. 1. The ^{19}F nmr spectrum of F-2 in 2,5-difluorobenzotrifluoride, **1**, observed at 56.44 MHz at 30 K for a 50 vol% solution in benzene-d_6 is shown in *a*. In *b* the calculated spectrum is displayed, employing the parameters in Table 1. The scale refers to frequencies to high field of the internal lock, CF_3CCl_3.

frequencies. However, the calculated spectra for these groups bore every resemblance to the observed spectra.

Figure 1 gives an example of observed and calculated ^{19}F nmr spectra, those of F-2 in **1**. Figure 2 displays the ^{19}F spectrum of the CF_3 group of **1**.

Relative Sign Determinations in 1 and 2

Sutcliffe and co-workers (20, 23) have given a series of detailed descriptions of double resonance experiments designed to determine the signs of $^{19}F,^{19}F$ coupling constants in fluoroaromatic compounds. Our experiments are very similar and will not be described in detail; complete descriptions can be found in ref. 24*a*. In particular, the present series of double irradiations showed that $^4J_o^{F,CF_3}/^5J_p^{F,F} > 0$, $^4J_o^{F,CF_3}/^5J_m^{F,CF_3} > 0$, $^6J_p^{F,CF_3}/^3J_o^{F,F} < 0$, $^5J_m^{F,CF_3}/J_o^{F,F} < 0$, $^5J_m^{F,CF_3}/^6J_p^{F,CF_3} > 0$, $^4J_m^{H,F}/^5J_p^{H,F} < 0$. As, invariably (30), $^5J_p^{F,F} > 0$, $^3J_o^{F,F} < 0$, $^4J_m^{H,F} > 0$, the signs in Table 1 follow.

A number of the double resonance spectra were calculated by the computer program DOR (31), modified to accommodate eight nuclei. Good agreement with experimental spectra was found.

The Spectral Analysis of p-*Fluorobenzal Fluoride*

In the ^1H nmr spectrum at 100 MHz, 288 transitions were assigned, leading to a root-mean-square

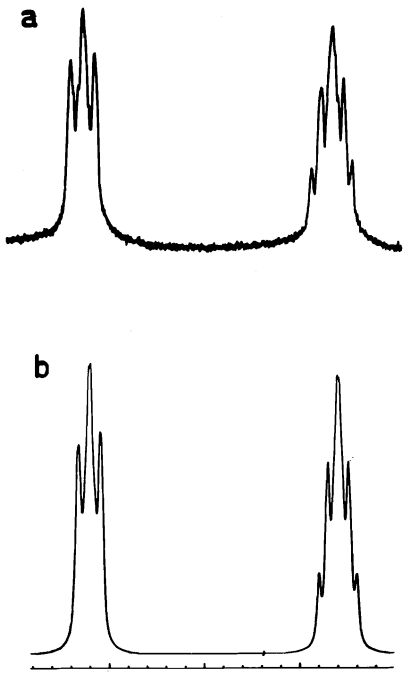

FIG. 2. The observed, *a*, and calculated, *b*, ^{19}F nmr spectrum of the CF_3 group in **1** (see Fig. 1). Each small division on the scale represents 1 Hz. The midpoint of the spectrum falls at 1108.5 Hz to low field of internal CF_3CCl_3.

deviation of 0.02 Hz between calculated and observed peaks. However, there exist three correlation coefficients greater than 0.5 in this analysis. There were also some curious intensity anomalies, which could not be removed despite considerable effort, suggesting unknown errors in at least some of the parameters. Consequently, the spectral parameters are not tabulated here.

However, the ^{19}F nmr spectrum did yield $^{6}J_{p}^{F,CF_2}$ as $\pm 3.45 \pm 0.05$ Hz, certain, even though the ring ^{19}F peaks overlapped one of the two bands ($^{2}J^{H,F} = 56.4$ Hz) from the CF_2H group. Because benzal fluoride itself has been satisfactorily analyzed (32), the analysis of *p*-fluorobenzal fluoride was terminated at this stage.

The ^{19}F spectrum of *p*-fluorobenzyl fluoride yielded $^{6}J_{p}^{F,F}$ as $\pm 5.8 \pm 0.2$ Hz.

$^{7}J_{p}^{CH_3,CF_3}$ *in 3-Nitro-4-methylbenzotrifluoride*

A full analysis was not made and attempts to determine the sign of $^{7}J^{CH_3,CF_3}$ were unsuccessful. However, a partial analysis indicates that this coupling is $\pm 0.76 \pm 0.05$ Hz, assumed positive.

$^{6}J_{p}^{F,CF_3}$ *in* p-*Fluorobenzotrifluoride and its 3-Amino and 3-Nitro Derivatives*

Again, the spectra were not fully analyzed. However, it was clear that $^{6}J_{p}^{F,CF_3}$ had the values given in Table 2, where the ^{19}F chemical shifts are also found.

$^{7}J^{CF_3,CF_3}$ *in* p-*Trifluoromethylbenzotrifluoride*

Because $^{4}J_{o}^{H,CF_3}$ and $^{5}J_{m}^{H,CF_3}$ are nearly of the same magnitude but of opposite sign (33), the ^{13}C side bands in the ^{19}F nmr spectrum at 56.4 MHz are (somewhat distorted) quartets arising from long-range $^{19}F,^{19}F$ coupling. $^{7}J_{p}^{CF_3,CF_3}$ is 0.85 ± 0.05 Hz, very likely positive. $^{1}J^{^{13}C,\,^{19}F}$ is 271.9 ± 0.4 Hz in magnitude, close to the literature value (34). The ^{19}F chemical shift is 1012 Hz (17.93 ppm) to low field of CF_3CCl_3.

The ^{19}F *Chemical Shifts*

If the ^{19}F shift in fluorobenzene is taken as 31.0 ppm to high field of CF_3CCl_3 and that in $C_6H_5CF_3$ is 18.4 ppm to low field of CF_3CCl_3(35), then the observed shifts in Table 2 are compatible with known substituent perturbations (35). The ring ^{19}F shifts in **1** agree closely with earlier observations (36). Although the chemical shifts in the ring follow the common substituent effects, in that electron donating substituents cause increased shielding, the ^{19}F shifts of the CF_3 group display the opposite trend (36, 37). A similar but more marked substituent dependence for the CH_2F group has been discussed periodically, if not explained (38–40).

The CF_2H group displays a shift similar to that of ring fluorine nuclei (Table 2) and this can lead to overlapping bands.

TABLE 2. Fluorine chemical shifts[a] in ppm relative to internal CF_3CCl_3 and $^{19}F,^{19}F$ coupling constants over six or seven bonds

Compound[b]	Ring F	CF_3	$^{6,7}J$
4-F, 1-CF_3	−26.13	19.45	1.97 (2)
4-F, 3-NO_2, 1-CF_3	−30.63	18.84	1.67 (4)
4-F, 3-NH_2, 1-CF_3	−49.63	19.53	1.96 (2)
2,5-diF, 1-CF_3	−38.56 (F-2) −35.28 (F-5)	19.64	—
3,4-diF, 1-CF_3	−53.50 (F-3) −50.54 (F-4)	19.01	+1.89 (2)
1,4-diCF_3[c]	—	17.93	0.80 (5)
4-F, 1-CF_2H	−28.22	−27.72[d]	3.45 (5)
4-F, 1-CFH_2	—	−126.3[d]	5.8 (2)[e]

[a]A negative sign indicates a shift to high field of CF_3CCl_3.
[b]50 vol% in benzene-d_6, containing also 5 vol% TMS and 5 vol% CF_3CCl_3.
[c]95 vol% in CF_3CCl_3.
[d]Shift of the CF_2H group or of the CFH_2 group.
[e]Coupling constants are in Hz, the uncertainty in the last place being given in parentheses.

The Coupling Constants Within the Ring

There are no exceptional magnitudes of these couplings and the reader is referred to refs. 41–43 for full discussions.

Long-range $^{19}F,C^{19}F_3$ *Couplings*

Over Six Bonds, $^{6}J_{p}^{F,CF_3}$

$^{6}J_{p}^{F,CF_3}$ is +1.89 Hz in **2**; tentatively, and now very likely, +1.33 Hz in perfluorotoluene (23). This coupling equals ± 1.97 Hz in 4-fluorobenzotrifluoride, ± 1.96 Hz in the 3-amino derivative, and sinks to ± 1.67 Hz in the 3-nitro derivative. In view of the known sign for **1**, these couplings are very likely positive. The following observations are pertinent.

In contrast to $^{6}J_{p}^{H,CH_3} = -0.62$ Hz and $^{6}J_{p}^{F,CH_3} = 1.12$ Hz in toluene (8) and *p*-fluorotoluene (15), respectively, it seems unlikely that $^{6}J_{p}^{F,CF_3}$ can be interpreted in terms of a *simple* σ–π mechanism (2). For such a mechanism, $J_{p}^{H,CH_3} \propto Q_{CF}Q_{CCH}$, where the Q parameters are hyperfine interaction constants between an electron in an aromatic π orbital and the proton or fluorine nucleus. $Q_{CF} > 0$ (44) and an appropriate value is 41.1 G, derived from nickel(II) aminotroponeimineate derivatives in which a small spin density is delocalized into the *p*-fluorophenyl groups (45). Q_{CH} is −22.5 G, so that $^{6}J_{p}^{H,CH_3}/^{6}J_{p}^{F,CH_3} = -0.62/1.12 = -0.55 = -22.5/41.1$, as expected for a σ–π coupling mechanism.

However, $^{6}J_{p}^{H,CF_3}$ in benzotrifluoride is −0.64 Hz (32) and, if this coupling is also dominated by a σ–π mechanism, it follows that $^{6}J_{p}^{F,CF_3}$ in *p*-fluorobenzotrifluoride should equal $-0.64(41.1/-22.5)$ or 1.17 Hz. Yet its value is 1.97 Hz. It is tempting to attribute this result to a large increase in Q_{CF} relative to

p-fluorotoluene and to argue that the reduction to 1.67 Hz in 3-nitro-4-fluorobenzotrifluoride is caused by a polarization of the C—F bond by the *ortho* nitro group. Because Q_{CF} is a composite term, dependent on the extension of the π-electron system to the fluorine atom (44), such an interpretation has its attraction.

It is then difficult to account for the very small changes (10% or less) in $^6J_p^{F,CH_3}$ observed in *p*-fluorotoluene (2, 15), 2-fluoro-5-methylpyridine (3), 5-fluoro-2-methylpyridine (3), and in some *p*-fluorotoluene derivatives (2), these results being consistent with very minor changes in Q_{CF} (Q_{CH} is also largely substituent independent, $^6J_p^{H,CH_3}$ being invariant in toluene (8), tetrachlorotoluene (11), and some polynitrotoluenes (12)).

On the other hand, $^6J_p^{F,CF_3}$ is rather insensitive to amino or fluoro substituents placed *ortho* to the C—F bond (Table 2).

INDO MO FPT calculations of the type previously described for toluene (5) and benzotrifluoride (46) gave a $\sin^2\theta$ dependence for $^6J_p^{F,CF_3}$ (θ is the angle by which the exocyclic C—H or C—F bond twists out of the benzene plane), thereby implying a σ–π mechanism. Because the barrier to internal rotation in benzotrifluoride is only 0.010 kcal/mol (47), the average value of $\sin^2\theta$ is 0.5. The calculations yield $^6J_p^{F,CF_3}$ as 2.8 Hz, an overestimate probably attributable to the parameters employed for the CF_3 group (46).

That a σ–π mechanism is at least partially operative, is supported by our observations of $^6J_p^{F,CF}$ as $\pm 3.45 \pm 0.05$ and $\pm 5.8 \pm 0.2$ Hz, respectively, in *p*-fluorobenzal fluoride and *p*-fluorobenzyl fluoride. The decrease in magnitude of $^6J_p^{F,CF}$ on successive substitution to CH_2F, CHF_2, and CF_3 groups is expected if the group orbitals become successively lower in energy and interact to a lesser degree with the π electron system (48, 49).

Returning to Q_{CCF}, it is interesting that $^6J_p^{H,CF_3}$ is −0.62 Hz in **1** and is −0.64 Hz in benzotrifluoride, i.e., the same as $^6J_p^{H,CH_3}$ in toluene; suggesting that $Q_{CCF} \sim Q_{CCH}$ if $^6J_p^{H,CF_3}$ is due solely to a σ–π mechanism. One test of this mechanism involves the very reasonable assumption that coupling constants over seven bonds arise from a σ–π mechanism. $^7J_p^{CH_3,CF_3}$ is 0.76 ± 0.05 Hz in 3-nitro-4-methylbenzotrifluoride, implying a positive σ electron contribution[1] of +0.1 to +0.2 Hz to $^6J_p^{H,CF_3}$.

A further test involves the 0.85 ± 0.05 Hz measured for $^7J^{CF_3,CF_3}$ in 4-trifluoromethylbenzotrifluoride. These results indicate $Q_{CCF}/Q_{CCH} \sim 0.85/0.76 = 1.1 \pm 0.1$, close to the ratio of unity derived for the neutral $CF_3CH_2\cdot$ and $CH_3CH_2\cdot$ radicals (51, 52). It appears that $^6J_p^{H,CF_3}$ contains a σ electron component of 0.15 ± 0.05 Hz.

In consequence, it seems that the large value of $^6J_p^{F,CF_3}$ in *p*-fluorobenzotrifluoride could be attributed to a large σ electron component of $+0.7 \pm 0.1$ Hz present only in the F,CF_3 combination; a rather unsatisfactory situation.

In summary, whereas $^6J_p^{H,CH_3}$ and $^6J_p^{F,CH_3}$ are interpretable in terms of a simple σ–π electron coupling mechanism, which is rather insensitive to ring substitution, $^6J_p^{F,CF_3}$ is larger than expected in *p*-fluorobenzotrifluoride on this basis and displays a peculiar substituent dependence. The successful use of $^6J_p^{F,CF}$ in aromatic compounds in the derivation of preferred conformations and of internal rotation barriers (50) is therefore unlikely.

Over Five Bonds, $^5J_m^{F,CF_3}$

In toluene (5) and 3-fluorotoluene (10), $^5J_m^{H,CH_3}$ and $^5J_m^{F,CH_3}$ can be interpreted as composites of σ and σ–π electron coupling mechanisms. The σ contributions are positive. The σ–π contribution to $^5J_m^{H,CH_3}$ is also positive because, although Q_{CH} and Q_{CCH} are of opposite sign, the induced π electron spin density at C-3 is negative (a result of electron correlation, the spin densities at C-2 and C-4 being positive), as discussed previously (10). On the other hand, the σ–π contribution to $^5J_m^{F,CH_3}$ is negative because Q_{CF} and Q_{CCH} have the same sign, positive, and this contribution outweighs the σ electron component, resulting in a negative $^5J_m^{F,CH_3}$.

In **1** and **2**, respectively, $^5J_m^{F,CF_3}$ is 0.56 and 0.86 Hz. By analogy to $^5J_m^{F,CH_3}$ and noting that Q_{CF} and Q_{CCF} are both positive, it follows that the negative σ–π electron component is outweighed by a positive σ contribution. INDO MO FPT calculations on $^5J_m^{F,CH_3}$ in 3-fluorotoluene reproduce the model behaviour very well (10), predicting substantial negative values at $\theta = 90°$ and large positive values as θ approaches 180° (all-*trans* conformation). Similar calculations on **1** and **2** show the same qualitative behaviour[2] (the plots are entirely similar to that in Fig. 3 of ref. 10) and suggest that the two-component model is adequate.

In perfluorotoluene (23), $^5J_m^{F,CF_3}$ is +0.62 Hz, implying that substituent perturbations will not change the sign of this coupling constant.

Over Four Bonds, $^4J_o^{F,CF_3}$

This coupling of 13.1 Hz in **1** is an example of a 'through-space' coupling, discussed in detail by Sutcliffe and co-workers (21, 23). They point out that its attribution to a predominant Fermi contact mechanism (53) is unsatisfactory. We note here that

[1]A σ electron contribution of +0.3 Hz to $^6J_p^{H,CF_2}$ in benzal fluoride is indicated (50) by this methyl group replacement technique (4).

[2]Details are given in ref. (24*a*), where calculations on $^6J_p^{F,CF_3}$ and $^4J_o^{F,CF_3}$ are also tabulated.

our INDO MO FPT calculations confirm their criticism, the calculated average coupling being of the same magnitude as ${}^6J_p^{F,CF_3}$ with a maximum at $\theta = 90°$. In other words, the Fermi contact contribution is calculated by INDO MO FPT to have a large σ–π component.

Conclusions

The long-range coupling constants over six bonds between methyl protons and *para* ring protons or fluorine nuclei in toluene and *p*-fluorotoluene, and perhaps between fluorine nuclei and ring protons in benzotrifluoride, are satisfactorily interpreted in terms of a σ–π electron coupling mechanism in which $Q_{CH} > 0$, $Q_{CCH} \sim Q_{CCF} > 0$, and $Q_{CF} > 0$. By way of contrast, the corresponding six-bond coupling between fluorine nuclei in *p*-fluorobenzotrifluoride, although of the sign expected for a σ–π mechanism, is much too large to be consistent with the other six-bond couplings. The six-bond fluorine–fluorine coupling constants involving CR_2F and CRF_2 groups are unlikely to be very reliable conformational indicators.

Synthèse et étude du rearrangement SR ⇋ NR des diazoles-1,3 : alkyl-1 alkylthio-2 (allylthio, arylthio, cycloalkylthio) imidazoles. Partie I. Synthèse et études physicochimiques

JACKY KISTER,[1] GEORGES ASSEF,[1] GILBERT MILLE[2] ET JACQUES METZGER[1]

Faculté des Sciences et Techniques, Aix-Marseille III, Rue Henri Poincaré – Saint Jérôme, 13397, Marseille, France

Reçu le 2 octobre 1978

JACKY KISTER, GEORGES ASSEF, GILBERT MILLE et JACQUES METZGER. Can. J. Chem. **57**, 813 (1979).

Nous avons étudié la synthèse et le réarrangement SR ⇋ NR de thioéthers des séries imidazoliques *N*- et *S*-substituées (60 composés). Les études physicochimiques complètes des thioéthers, thiones, catalyseurs de réarrangement et des éventuels produits d'hydrolyse ont été effectuées, ainsi que l'étude des cinétiques de réarrangement SR ⇋ NR à diverses températures. Ces résultats de réarrangement et d'hydrolyse ont été comparés à ceux des alkyl-1 méthylthio-2 Δ-2-imidazolines et alkyl-1 méthylthio-2 Δ-2-tétrahydropyrimidines. Les effets électroniques et stériques sont discutés. Dans cette première partie nous présentons uniquement l'aspect synthétique et les résultats des études physicochimiques.

JACKY KISTER, GEORGES ASSEF, GILBERT MILLE, and JACQUES METZGER. Can. J. Chem. **57**, 813 (1979).

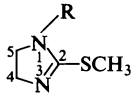
The synthesis and the SR ⇋ NR rearrangement of thioethers in the *N*- and *S*-substituted imidazolic series have been studied (60 compounds). The physicochemical studies of the thioethers and mercapto compounds, catalysts of the rearrangement, and of the eventual hydrolysis products have been carried out and the kinetics of rearrangement have been examined at several temperatures. The rearrangement and hydrolysis results are compared with those of 1-alkyl-2-methylthio-Δ-2-imidazolines and 1-alkyl-2-methylthio-Δ-2-tetrahydropyrimidines and the electronic and steric effects are discussed. In this first part the synthetic aspect and physicochemicals results are presented.

Introduction

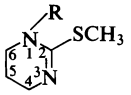
Dans le cadre d'une étude générale sur un procédé photographique non argentique à haute résolution (1–3), nous avons récemment rapporté la préparation et l'étude du réarrangement SR ⇋ NR des méthyl-1 méthylthio-2 imidazole, imidazoline et tétrahydropyrimidine et des réactions secondaires s'y rattachant (2–5).

Plusieurs études concernant des thioéthers de séries azahétérocycliques montrent que le taux de réarrangement SR ⇋ NR (comme la quaternisation des thioéthers) est notablement influencé par la nature de l'hétérocycle et sa substitution (6–13). Dans cette optique nous nous sommes intéressés dans un premier temps à l'influence de la *N*-substitution sur le réarrangement de composés des séries apparues comme les plus réactives dès 1974 (2): les séries imidazolinique et tétrahydropyrimidinique (3, 7, 14) (fig. 1)

Cependant l'existence de réactions parasites gênantes pour le procédé photographique (2) et provoquant soit un réarrangement parallèle, soit une dégradation du cycle, a orienté nos travaux vers des séries moins rapides *a priori*, mais présentant l'avantage de ne pas être le siège de réactions secondaires importantes (2).



Alkyl-1 méthylthio-2 Δ-2-imidazoline (C_2)



Alkyl-1 méthylthio-2 Δ-2-tétrahydropyrimidine (C_3)

FIG. 1. Les séries imidazolinique et tétrahydropyrimidinique.

Ainsi il nous a semblé intéressant d'entreprendre la synthèse et l'étude du réarrangement de thioéthers imidazoliques *N*- et *S*-substitués, ainsi que de divers composés substitués en position 4 et 5 (3, 7). Les composés **5**, **6** et **7** (fig. 2) sont donc susceptibles de présenter des différences intéressantes avec leurs homologues méthylés en position 1 et 2 et leurs homologues des séries saturées à cinq ou six chaînons.

L'analyse des résultats des réactions de réarrange-

ment SR ⇋ NR nous a permis de comparer les effets de cycle et de substitution pour ces séries hétérocycliques de type diazole-1,3 et diazine-1,3 (14*b*). Une étude plus générale des relations qui existent entre le taux de réarrangement et le pK_a des thioéthers est menée sur des composés hétérocycliques benzocondensés, aromatiques ou saturés à cinq ou six chaînons (fig. 3) et permet une analyse cohérente des effets structuraux, effets de cycle, de champ, de substitution (3). Cette généralisation fera l'objet d'un mémoire indépendant (15).

Partie théorique

Synthèse des thioéthers ***5***, ***6*** *et* ***7***

La synthèse de ces thioéthers procède soit par alkylation des thiones **1** et **2** suivie d'une neutralisation de l'iodhydrate **3** et **4** (schéma 1), soit par une réaction de catalyse polyphasique menée sur ces thiones (schéma 2). Nous avons donc été amenés à synthétiser initialement des thiones de type **1** et **2**.

Synthèse des thiones de type ***1*** *et* ***2***

La synthèse des alkyl-1 Δ-4-imidazolinethiones-2 substituées ou non en position 4 et 5 est beaucoup plus complexe que celle de leurs homologues en séries imidazolinique et tétrahydropyrimidinique (14).

(*a*) Ces composés sont accessibles par chauffage d'α-hydroxycétones ou α-hydroxyaldéhydes et de thiourées convenablement substituées (16–21) (schéma 3). Cette méthode a été appliquée pour la thione **2** ($R_1 = R_4 = R_5$ = Me) conduisant au triméthyl-1,4,5 méthylthio-2 imidazole et triméthyl-1,4,5 isopropylthio-2 imidazole. Récemment Lespagnol *et al.* (22) a préparé les alkyl-4 (5) Δ-4-imidazolinethiones-2, par la méthode de synthèse qui consiste à faire réagir, comme l'avaient fait Posner et coll. (23), des α-aminocétones ou α-aminoaldéhydes sur des dérivés de l'acide thiocyanique.

(*b*) Les composés de type alkyl-1 Δ-4-imidazolinethiones-2 non substituées en position 4 et 5 peuvent être obtenus par réaction d'un isothiocyanate d'alkyle (éthyle, phényle) sur l'aminoacétaldéhyde

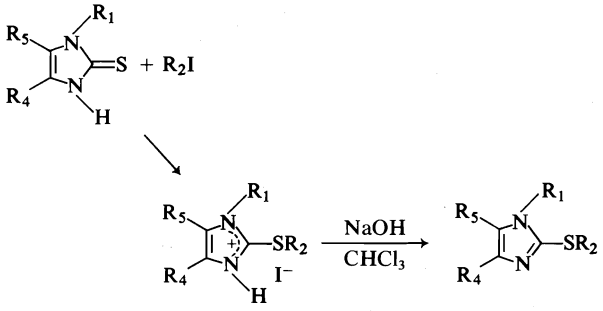

SCHÉMA 1

diéthylacétal, selon la méthode de Wohl et Marckwald (24–26) (schéma 4), ou par la méthode de Jones et Kovtunovskaya (27, 28) par action du thiocyanate de potassium et de l'acide chlorhydrique sur les

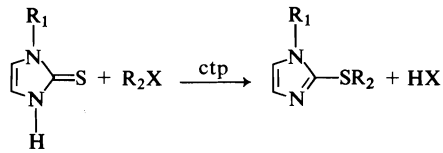

SCHÉMA 2

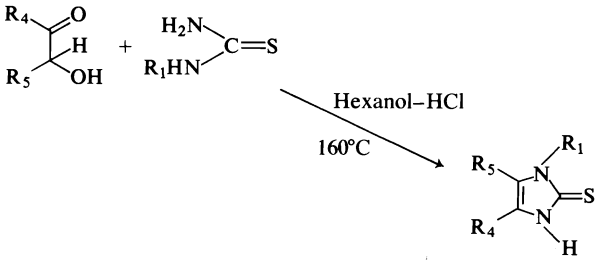

SCHÉMA 3

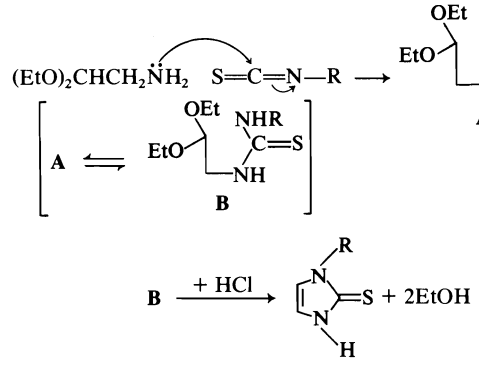

SCHÉMA 4

N-alkylaminoacétaldéhyde diéthylacétals (éthyle, isopropyle, tertiobutyle) précédemment synthétisés par action d'amines primaires sur les bromoacétaldéhyde diéthylacétals (27, 29–32) (schéma 5 et synthèse des intermédiaires). La méthode de Wohl et Marckwald est directement utilisable pour les seuls isothiocyanates commerciaux substitués par un groupement éthyle ou phényle. La synthèse du phénylaminoacétaldéhyde diéthylacétal ayant échouée nous avons synthétisé directement la phényl-1 Δ-4-imidazolinethione-2 par cette méthode.

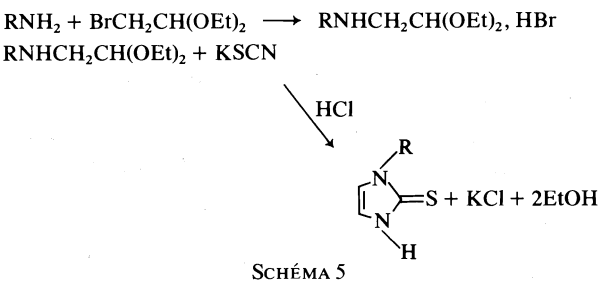

SCHÉMA 5

En 1932, Easson et Pyman (33) ont utilisé une variante de la réaction précédente, comportant une étape supplémentaire. Ils préparaient d'abord un acétylcarbamide qui réagissait ensuite sur une alkylamine pour donner un diéthylacétal d'aldéhyde α-isothiocyanate.

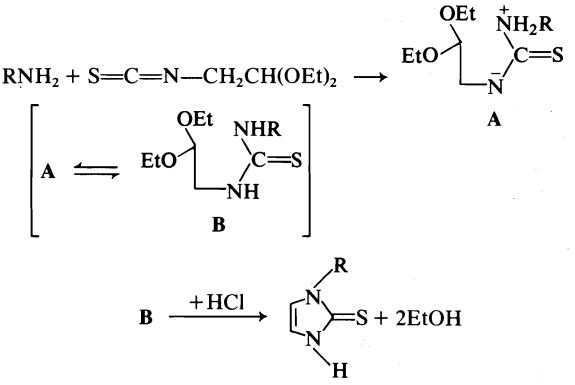

SCHÉMA 6

D'autres auteurs (34) ont utilisé la méthode de Easson et Pyman (33) en préparant d'abord l'acétal de l'aldéhyde α-isothiocyanate par action de l'aminoacétaldéhyde diéthylacétal sur le sulfure de carbone, suivant le schéma 7.

SCHÉMA 7

Nous citerons à titre d'exemple la méthode utilisant des intermédiaires ayant un groupe carboxylate en position 5, méthode surtout développée par Jones (35). Le mécanisme de cette réaction est donné par le schéma 8. Il existe encore diverses autres méthodes moins utilisées (21, 36–39).

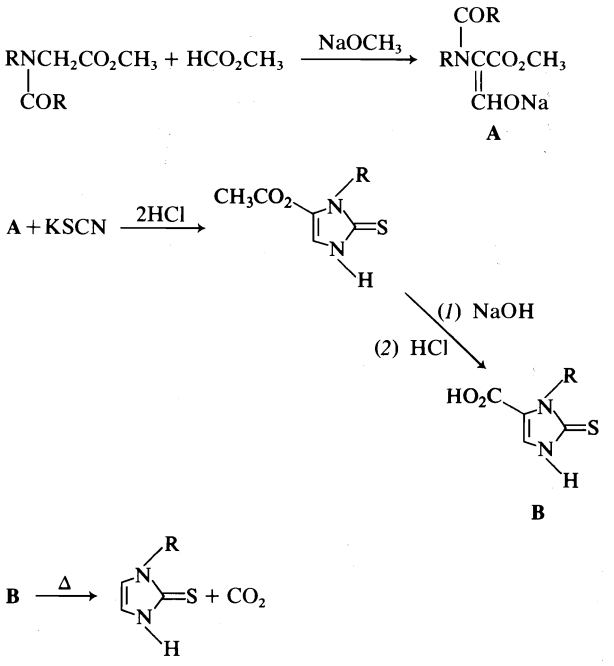

SCHÉMA 8

Synthèse des thioéthers ***5***, ***6*** *et* ***7***

(*a*) Par quaternisation à froid avec l'iodure de méthyle dans l'acétone anhydre, nous isolons les iodhydrates **3** et **4** qui conduisent aux thioéthers par déprotonation basique dans des conditions analogues à celles décrites pour les alkyl-1 méthylthio-2 Δ-2-imidazolines et Δ-2-tétrahydropyrimidines (14). Seuls les iodhydrates **3** ont été isolés et étudiés. Les iodhydrates **4** n'ont pas été isolés, la réaction en deux étapes ayant lieu dans le même ballon.

(*b*) *Malgré une optimisation poussée* des synthèses intermédiaires, nous préférons à ce schéma en deux étapes (rendement global >70%), la technique de catalyse interfaciale (ctp) (40). Outre le gain de temps puisque la synthèse est réalisée en une étape, s'ajoute aussi un gain de pureté puisque le produit *S*-alkylé est obtenu de manière univoque sans réactivité de l'atome d'azote (schéma 2). Ce point de vue doit cependant être complété, par le fait que la réaction de *S*-alkylation est univoque en série aromatique, tandis qu'en série saturée, la *S*-alkylation est accompagnée d'environ 5% de *N*-alkylation. Cette réactivité particulière de l'anion ambident NCS a été vérifiée sur les Δ-4-thiazolinethiones-2 et Δ-4-imidazolinethiones-2 (41–42). Les rendements obtenus sont plus faibles quand on utilise des halogénures d'alkyle à longue chaîne (40). La méthode peut utiliser des bromures ou chlorures d'alkyle, les iodures conduisant à une inhibition du catalyseur.

Indiquons schématiquement le principe de la catalyse par transfert de phase qui est appliquée ici: un système biphasique, contenant une solution aqueuse d'un hydroxyde d'ammonium quaternaire (obtenu *in situ* par réaction d'un sel d'ammonium quaternaire avec une solution de soude concentrée) et une solution organique d'agent alkylant (halogénure d'alkyle) et de substrat (), est mis en réaction par agitation et chauffage (40–45). En fin de réaction, le mélange réactionnel est refroidi et laissé au repos. La phase organique contenant le produit attendu est alors séparée puis traitée de manière conventionnelle.

Le choix du solvant de la réaction et du sel quaternaire catalyseur a été effectué lors d'études antérieures menées sur la *N*-alkylation des imidazoles et pyrazoles (43). Le solvant doit favoriser au maximum l'extraction de l'espèce $NR_4^+ OH^-$, ne pas être réactif et permettre les conditions de température et de solubilité des réactifs. Le benzène est le plus souvent utilisé. Le système biphasique étant fixé, le catalyseur utilisé est le bromure de tétrabutylammonium (commercial) à la concentration de 4% en mole par mole de substrat.

La catalyse interfaciale apparaît donc dans notre cas comme une méthode de choix pour l'obtention de dérivés *N*,*S*-alkylés, à partir de thiones ayant un ou plusieurs hydrogènes mobiles, permettant la formation d'anions ambidents N—C—O ou N—C—S. Dans le cas de la Δ-4-imidazolinethione-2 non substituée, deux protons mobiles sont présents dans la molécule et l'on peut obtenir des *N*,*S*-alkylations.[3] La Δ-4-imidazolinethione-2 étant commerciale, l'on juge bien de l'intérêt de ces *N*,*S*-alkylations qui font éviter les synthèses délicates des alkyl-1 Δ-4-imidazolinethiones-2. Cette technique a été appliquée à la synthèse du triméthyl-1,4,5 méthylthio-2 imidazole à partir de la triméthyl-1,4,5 Δ-4-imidazolinethione-2.

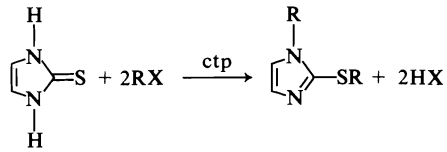

SCHÉMA 9

Par contre la catalyse par transfert de phase n'est pas utilisable quand on veut fixer en position 2 un groupe acétonyle. En présence de soude, la réaction de Darzens avec la chloroacétone devient prépondérante (46, 47); nous avons synthétisé le méthyl-1 acétonylthio-2 imidazole en deux étapes par le mode de synthèse classique (48). Cependant ces substrats intéressants par le gain de réarrangement en phase liquide ne seront pas utilisables en phase adsorbée (support solide du procédé photographique) du fait d'une complexation parasite du groupement acétonyle provoquant une diminution notable du taux de réarrangement.

Les conditions de réaction et caractéristiques physiques et physicochimiques des composés **1**–**7** sont rassemblées dans les tableaux 1–3. La synthèse des intermédiaires est donnée dans la partie expérimentale.

Synthèse des catalyseurs et thiones de réarrangement

La réaction de réarrangement que nous étudions est une réaction autocatalytique ionique contrôlable thermiquement et dont le schéma général (schéma 10) est le suivant.

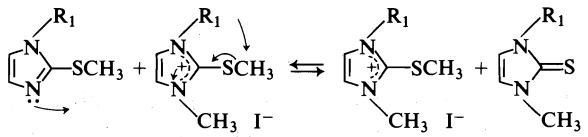

SCHÉMA 10

Nous avons donc synthétisé et purifié les catalyseurs utilisés: les sels quaternaires **9**. La synthèse correspond toujours à une alkylation par l'iodure de

§Spectre enregistré dans CH_2Cl_2.

méthyle, la quaternisation se faisant sur l'azote N_3 et non sur le soufre exocyclique. Lorsque la quaternisation est trop lente à température ambiante, les catalyseurs sont obtenus par fusion du thioéther et d'un net excès d'iodure de méthyle sans solvant, puis recristallisés dans l'éthanol et parfaitement séchés. Les caractéristiques physiques et physicochimiques des sels **9** et **10** sont rassamblées dans le tableau 5.

De la même façon certaines thiones de type **8** ont été isolées directement par réaction de réarrangement des thioéthers. Les caractéristiques physiques et physicochimiques sont rassemblées dans le tableau 4.

D'une façon générale, les études de spectrométrie ultraviolette (49), infrarouge (50) et de résonance magnétique nucléaire du carbone-13 (51) ont fait l'objet de mémoires indépendants. L'étude des réactions de réarrangement SR ⇋ NR et l'analyse des effets structuraux fera l'objet de la seconde partie de ce mémoire (14*b*). Les effets de substitution sur l'azote N_1, le soufre S_2 et en position 4 et 5 seront discutés ainsi que les effets de température et de catalyseur.

Dans l'analyse des résultats nous étudierons les relations pK_a/réarrangement pour les thioéthers de la série C_1 imidazolique et nous les comparerons à ceux déjà exposés des séries C_2 imidazolinique et C_3 tétrahydropyrimidinique. Les diverses réactions parasites, issues de l'hydrolyse des thioéthers (réarrangement parasite et réactions de dégradations) seront étudiées.

Partie expérimentale

Les points de fusion ont été déterminés au banc Kofler. Les spectres rmn du ^1H ont été enregistrés sur des appareils du type Varian HA 100 et JEOL C 60 H. Sauf indications contraires, les spectres ont été enregistrés dans le chloroforme deutérié à une concentration de 10% avec le tétraméthylsilane comme référence interne. Les déplacements chimiques sont donnés en ppm par rapport au TMS (s, singulet; d, doublet; t, triplet; q, quadruplet; qd, quadruplet dedoublé; m, multiplet). Les spectres infrarouges ont été enregistrés à l'état solide entre 4000 et 400 cm^{-1} sous forme de pastille KBr ou KI à l'aide d'un spectrographe Perkin-Elmer modèle 225. Les échantillons liquides ont été étudiés sous une épaisseur de 15 μ dans des cellules scellées à lame de bromure de potassium. Les spectres ultraviolets ont été enregistrés dans l'éthanol sur un spectrophotomètre Cary 14.

Synthèse des intermediaires

Synthèse d'alkyl-1 aminoacétaldéhyde diéthylacétal

Les aminoacétaldéhydes *N*-substitués sont obtenus en chauffant en ampoule scellée à haute température pendant 24 h un chloro- ou un bromoacétaldéhyde diéthylacétal avec un excès d'amine primaire. Comme l'ont décrit déjà Knorr (29) et Paal et Gember (30), ainsi que d'autres auteurs (27, 31, 32), il se forme d'abord un bromhydrate qui sera libéré par une solution de potasse à 50%. Les aminoacétaldéhyde diéthylacétals sont ensuite distillés avant leur utilisation ultérieure en vue de l'obtention des alkyl-1 Δ-4-imidazolinethiones-2 (C_1). Le mécanisme est décrit par le schéma 11.

SCHÉMA 11

Préparation du N-*éthylaminoacétaldéhyde diéthylacétal (27, 29, 30, 32, 36)*

L'éthylamine ayant une température d'ébullition de 16°C on prendra soin de tremper les ampoules dans une solution d'acétone–carboglace. Dans une ampoule préalablement refroidie, on place 0.2 mol (40 g) de bromoacétaldéhyde diéthylacétal et très rapidement à l'aide d'une seringue on ajoute 0.6 mol (27 g) d'éthylamine. L'ampoule est rapidement scellée et placée ensuite dans une gaine métallique que l'on met dans une étuve thermostatée à 140°C pendant 24 h. Souvent le produit cristallise sur les parois de l'ampoule. On ajoute ensuite 70 cm^3 d'une solution de potasse à 50%. On filtre le bromure de potassium formé, décante et récupère la phase organique. L'excès d'amine dans le cas de la tertiobutyl et isopropylamine est distillé sous pression réduite puis on distille l'alkyl aminoacétaldéhyde diéthylacétal. Par une voie analogue nous avons synthétisé les substrats suivants.

Composé **1** $\left(\begin{smallmatrix} a & b & c & d & e & f & g \\ CH_3CH_2NHCH_2CH(OCH_2CH_3)_2 \end{smallmatrix}\right)$—Rendement 50%; pé 90°C/20 Torr; rmn ^1H: a 1.10 (t), b 2.60 (q), d 2.65 (d), e 4.55 (t), f 3.60 (qd), g 1.20 (t).

Composé **2** $\left(\begin{smallmatrix} a & b & c & d & e & f \\ CH_3CH_2N(CH_2CH(OCH_2CH_3)_2)_2 \end{smallmatrix}\right)$—Rendement 10%; pé 160°C/20 Torr; rmn ^1H ($CDCl_3$/TMS): a 1.05 (t), b 2.60 (q), d 4.50 (t), c 2.63 (d), e 2.60 (qd), f 1.19 (t).

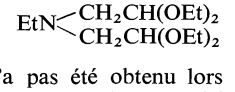
Composé **3** $\left(\begin{smallmatrix} a & b & c & d & e & f & g \\ (CH_3)_2CHNHCH_2CH(OCH_2CH_3)_2 \end{smallmatrix}\right)$—Rendement 80%, pé 88°C/21 Torr; rmn ^1H ($CDCl_3$/TMS): a 1.03 (d), b 2.72 (s), d 2.65 (d), e 4.52 (t), f 3.60 (qd), g 1.20 (t).

Composé **4** $\left(\begin{smallmatrix} a & b & c & d & e & f \\ (CH_3)_3NHCH_2CH(OCH_2CH_3)_2 \end{smallmatrix}\right)$—Rendement 80%; pé 193°C/760 Torr; rmn ^1H ($CDCl_3$/TMS): a 1.10 (s), d 4.55 (t), c 2.65 (d), e 3.60 (qd), f 1.20 (t).

Remarques

Contrairement aux auteurs précédents (26–32), lors de la distillation du *N*-éthylaminoacétaldéhyde diéthylacétal, nous avons isolé un sous produit (**2**) ayant une température d'ébullition de 160°C/20 Torr, 25% à côté du produit attendu qui bout à 90°C/20 Torr (**1**).

La spectrométrie de masse et la résonance magnétique nucléaire du proton nous ont permis de déterminer la structure de ce sous produit:



Ce sous produit n'a pas été obtenu lors de la synthèse de l'isopropyl et du *tert*-butylaminoacétaldéhyde diéthylacétal à cause de la gêne stérique qui interdit la double condensation.

Une expérience supplémentaire d'optimisation de cette étape de synthèse a été effectuée en utilisant un rapport 5:1 d'amine – bromoacétaldéhyde diéthylacétal au lieu du rapport 3:1 de l'expérience précédente. Ainsi nous avons obtenu le produit **B** (schéma 11) avec quelques traces de **C**.

Par la même méthode, nous avons tenté de synthétiser le phénylaminoacétaldéhyde diéthylacétal. A plusieurs reprises les ampoules scellées ont explosé. Etant moins nucléophile que ses homologues aliphatiques, l'aniline réagit moins bien sur le bromoacétaldéhyde. Ce dernier (pé 50°C/760 Torr) se trouve très rapidement à 140°C dans l'ampoule avant même de réagir sur l'amine, il se crée une forte surpression suivie d'explosion. Par contre les amines aliphatiques étant très réactives, le bromoacétaldéhyde a déjà réagi sur l'amine avant même que l'ampoule ait atteint 140°C.

Nous avons enfin effectué la réaction en autoclave sous pression à diverses températures: nous n'avons recueilli que des goudrons dont l'analyse par chromatographie en couche mince a décelé quelques traces du produit **B** (schéma 11). Ce mode expérimental, inexploitable dans ce cas, nous a obligé à rechercher une autre voie de synthèse. Nous avons donc effectué la synthèse directe de la phényl-1 Δ-4-imidazolinethione-2 par la méthode de Wohl et Marckwald, l'éthyl et le phényl isothiocyanate étant commerciaux (Fluka A.6).

Synthèse de la phényl-1 Δ-4-imidazolinethione-2

Dans un réacteur mini d'un vibreur et d'un réfrigérant on place 0.75 mol (100 g) d'aminoacétaldéhyde diéthylacétal, on ajoute goutte à goutte 0.83 (100 cm^3) de phényl isothiocyanate en 20 min. Un précipité blanc se forme et la température du réacteur passe de 50 à 80°C en fin d'addition. On ajoute 300 cm^3 d'éthanol et on laisse 2 H à reflux. Le rendement brut après filtration et séchage est de 80%.

Synthèse de la tert-*butyl-1 Δ-4-imidazolinethione-2*

Dans un réacteur de 1 L muni d'un vibreur et d'un réfrigérant ascendant, on place 0.40 mol (75.6 g) de *N-tert*-butylaminoacétaldéhyde diéthylacétal en solution dans 400 cm^3 d'alcool absolu. On ajoute 0.48 mol (48 g) de thiocyanate de potassium et 200 cm^3 d'acide chlorhydrique 2 *N*. Le mélange réactionnel est mis à reflux pendant une nuit. On évapore ensuite le solvant et récupère le résidu solide. On le solubilise dans une solution de soude diluée, le traite avec du charbon actif pendant 30 min à reflux. On filtre le charbon, reprécipite le solide avec une solution diluée d'acide chlorhydrique. Le produit obtenu par filtration est recristallisé dans un mélange acétone–éther 50:50.

Synthèse de l'iodure de tert-*butyl-1 méthylthio-2 imidazolium*

Dans un bicol de 1 L surmonté d'un réfrigérant ascendant et d'une ampoule à brome, muni d'un agitateur mécanique, on place 0.40 mol (72.4 g) de *tert*-butyl-1 Δ-4-imidazolinethione-2 dans 700 cm^3 d'acétone anhydre. On ajoute lentement 0.42 mol (59.64 g) d'iodure de méthyle. On laisse sous agitation à température ambiante pendant 3 h. Le solide obtenu est filtré, puis recristallisé dans de l'éthanol absolu.

Synthèse de la tert-*butyl-1 méthylthio-2 imidazole*

Dans un réacteur de 2 L muni d'un vibreur et d'un réfrigérant ascendant, on place 0.30 mol (89.4 g) d'iodure de *tert*-butyl-1 méthylthio-2 imidazolium en suspension dans 1 L d'éther anhydre. On ajoute une quantité stoéchiométrique de soude pulvérisée. On chauffe à reflux pendant 4 h. On filtre ensuite l'iodure de sodium formé, évapore le solvant et distille sous pression réduite.

Synthèse de la tert-*butyl-1 méthyl-3 Δ-4-imidazolinethione-2*

On place dans une ampoule 0.05 mol de *tert*-butyl-1 méthylthio-2 imidazole et on ajoute 3% mol d'iode pulvérisée. L'ampoule scellée est placée dans une gaine métallique à l'étuve à 140°C pendant 24 h. La thione obtenue est purifiée par chromatographie préparative. On peut isoler directement la thione lors des expériences de réarrangement classique catalysées par le sel quaternaire correspondant.

Synthèse de l'iodure de tert-*butyl-1 méthylthio-2 méthyl-3 imidazolium*

On place 0.05 mol de *tert*-butyl-1 méthylthio-2 imidazole dans un microballon avec 0.09 mol d'iodure de méthyle dans l'acétone anhydre et on laisse sous agitation à température

ambiante pendant 3 h. Le sel obtenu est ensuite recristallisé dans l'éthanol absolu.

Synthèse par catalyse polyphasique (ctp)

S-*Alkylation de la méthyl-1 Δ-4-imidazolinethione-2*

Procédure générale (40)—0.05 mol (5.71 g) de méthyl-1 Δ-4-imidazolinethione-2, 0.05 mol de bromure d'alkyle et 0.97 g (0.003 mol, 6% mol par rapport au thioéther) de bromure de tétrabutylammonium sont placés dans 150 mL de benzène et 15 mL de soude (40%). Le mélange est agité pendant 6 h au minimum à 60°C. La phase organique est séparée, séchée et concentrée et le résidu est distillé ou recristallisé (40).

NS-*Dialkylation*

NS-*Dibutylation de la Δ-4-imidazolinethione-2*—5.01 g (0.05 mol) de Δ-4-imidazolinethione-2, 13.7 g (0.1 mol) de bromo-1 butane et 1.95 g (0.006 mol) de bromure de tétrabutylammonium sont placés dans 150 mL de benzène et 15 mL de soude (40%). Le mélange est agité 6 h à 60°C, puis la phase organique est séparée, séchée et le solvant est évaporé. Le produit brut est obtenu avec un rendement de 80% (8.51 g) et analysé par rmn ^{1}H (40).

N,S-*Diéthylation de la Δ-4-imidazolinethione-2*—Dans les mêmes conditions avec 2.5 équiv. de bromure d'éthyle on recueille après 12 h à température ambiante, 67% de composé *N,S*-diéthylé (5.5 g) et 2% de composé *N,N'*-diéthylé. L'analyse a été effectuée par spectrométrie de masse (40).

Synthèse du méthyl-1 acétonylthio-2 imidazole

Une mixture de 7.5 de méthyl-1 Δ-4-imidazolinethione-2 et 6.8 g de chloracétone est placée dans 400 cm^3 de butanone-2. Après 3 h de reflux et évaporation partielle du solvant, refroidissement et filtration, on obtient le chlorhydrate que l'on reprend par l'eau et que l'on neutralise par une solution de carbonate saturé. On extrait au chloroforme et on sèche sur sulfate de sodium. Après évaporation du solvant de distillation, on recueille le thioéther (pé 104°C/2 Torr; rendement 25%) (3, 48).

Synthèse de la triméthyl-1,4,5 Δ-4-imidazolinethione-2

Une mixture de 0.2 mol de *N*-méthylthiourée et 0.2 mol d'acétoïne est mis à reflux 12 h dans 100 mL de pentanol-1[4] ou hexanol-1 (16). Après distillation azéotropique, le mélange est refroidi. Le solide formé est recristallisé dans l'éthanol. Le rendement est de 25% (pf 216°C). La purification est effectuée par chromatographie préparative (C_6H_6–AcEt 80:20) sur silice.

Synthèse de la tétraméthyl-1,3,4,5 Δ-4-imidazolinethione-2

La thione est obtenue par chauffage à reflux d'un mélange équimoléculaire de *N,N'*-diméthylthiourée et d'acétoïne dans l'hexanol-1 (16).

Reçu le 2 octobre 1978

JACKY KISTER, GEORGES ASSEF, GILBERT MILLE et JACQUES METZGER. Can. J. Chem. **57**, 822 (1979).

Les études cinétiques de la réaction de réarrangement SR ⇋ NR ont été réalisées à diverses températures sur les composés de type alkyl-1 alkylthio (ou allylthio, arylthio, cycloalkylthio)-2 imidazoles. Ces études de réarrangement et d'hydrolyse ont été comparées à celles menées sur les alkyl-1 méthylthio-2 Δ-2-imidazolines et Δ-2-tétrahydropyrimidines. Les effets électroniques et stériques sont discutés et un parallèle pK_a–réarrangement est proposé. La limite de ce parallèle est d'ordre structural, due à des interactions stériques directes (effet *ortho*) ou indirectes (déformation de cycle) ou à des modifications géométriques des hétérocycles étudiés (cycles à cinq ou six chaînons). L'ensemble de ces résultats a permis le choix cohérent du substrat d'amplification d'un procédé photographique non conventionnel.

JACKY KISTER, GEORGES ASSEF, GILBERT MILLE, and JACQUES METZGER. Can. J. Chem. **57**, 822 (1979).

The kinetics of the SR ⇋ NR rearrangement reaction for a series of 1-alkyl-2-alkylthio (or allylthio, arylthio, cycloalkylthio) imidazoles has been studied at various temperatures. The rearrangement and hydrolysis results have been compared with those of 1-alkyl-2-methylthio-Δ-2-imidazolines and 1-alkyl-2-methylthio-Δ-2-tetrahydropyrimidines. Electronic and steric effects are discussed and a parallel between pK_a and rearrangement is proposed. The limit of this parallel is either a structural effect such as direct (*ortho* effect) or indirect (cycle deformation) steric interactions or geometric modifications of the heterocycles studied (five- or six-membered cycles). All these results permitted the coherent choice of the amplification compound of a nonconventional photographic process.

Introduction

Dans un premier mémoire nous avons décrit la synthèse et les études physicochimiques des alkyl-1 alkylthio-2 (ou allylthio, arylthio, cycloalkylthio) imidazoles (1).

Récemment nous avons rapporté l'étude du réarrangement SR ⇋ NR des méthyl-1 méthylthio-2 imidazole, Δ-2-imidazoline et Δ-2-tétrahydropyrimidine, ainsi que les réactions secondaires s'y rattachant (2–5). Ces études sont liées au développement d'un procédé photographique non argentique dans lequel la réaction de réarrangement SR ⇋ NR constitue l'étape d'amplification du signal photochimique primaire (2, 3, 6).

Plusieurs travaux concernant des thioéthers de séries azahétérocycliques montrent l'influence de la nature de l'hétérocycle et de sa substitution sur le taux de réarrangement (7–13). Recherchant des conditions d'amplification du signal photographique assez douces, nous nous sommes intéressés dans un premier temps à l'influence de la *N*-substitution sur le réarrangement de composés des séries apparues comme les plus réactives dès 1974 (2): les séries imidazolinique et tétrahydropyrimidine (3, 14, 15).

L'existence de réactions secondaires parasites provoquant, soit un réarrangement parasite, soit une suite de réactions de dégradation, a orienté nos travaux vers des séries moins réactives *a priori*, mais présentant l'avantage de ne pas être le siège de réactions secondaires importantes (2, 5). Ainsi nous avons synthétisé les thioéthers de la série imidazolique, en faisant varier la substitution de l'azote N_1, du soufre S_2 et éventuellement des positions 4 et 5 de l'hétérocycle (fig. 1) (13, 14). Les thioéthers **5**, **6** et **7** sont donc susceptibles de présenter des différences intéressantes avec leurs homologues méthylés en position 1 et 2 et leurs homologues des séries saturés à cinq ou six chaînons. L'analyse des résultats de cinétique du réarrangement SR ⇋ NR nous permet de comparer les effets de substitution pour les divers hétérocycles à cinq ou six chaînons et par là même, d'analyser l'effet du cycle.

Une étude plus générale des relations qui existent entre le taux de réarrangement et le pK_a des thioéthers menée sur des composés hétérocycliques ben-

zocondensés, aromatiques ou saturés à cinq ou six chaînons rend possible une analyse cohérente des effets structuraux (effet de cycle, de champ, de substitution) (3). Cette généralisation fera l'objet d'un mémoire indépendant (16).

Etude du réarrangement autocatalytique ionique SR⇋NR des thioéthers 5, 6 et 7

Généralités

Le mécanisme de cette réaction est identique à celui décrit pour les alkyl-1 méthylthio-2 Δ-2-imidazolines et Δ-2-tétrahydropyrimidines (2–4, 14 et 15). Bien que plusieurs mécanismes aient été discutés (2–5, 7–15), c'est celui de type Chambonnet et d'Amico qui a été adopté (2, 7). Le réarrangement SR ⇋ NR est donc un réarrangement autocatalytique ionique contrôlable thermiquement pouvant être schématisé de la façon répresentée dans le schéma 1. Cette réaction correspond à un mécanisme de substitution nucléophile bimoléculaire (S_N2). Le caractère intermoléculaire et la réversibilité du réarrangement ont été étudiés (9) en série thiazolique. Dans le cas des diazoles et diazines-1,3, nous avons vérifié ce

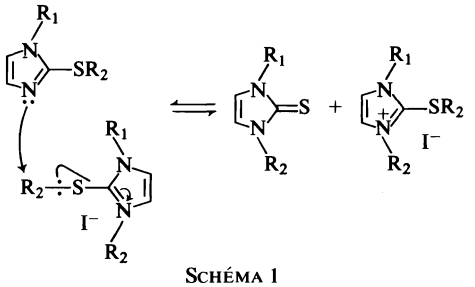

SCHÉMA 1

caractère intermoléculaire de la réaction. Celle-ci est bien réversible, mais pratiquement déplacée vers la forme thione. Nous avons vérifié la non élimination du groupe migrant en étudiant la réaction de réarrangement du méthyl-1 isopropylthio-2 imidazole en présence de 3% mol d'iodure de méthyl-1 isopropylthio-2 isopropyl-3 imidazolium. Nous n'avons observé que du produit résultant de la S_N2, sans aucune trace de produit d'élimination (12, 14).

Les thioéthers **5**, **6** et **7** examinés sont généralement purifiés par distillation sur potasse et conservés sur potasse afin d'éviter les réactions parasites dues à l'eau résiduelle (2–5, 14, 15). Pour chaque substrat nous contrôlons la stabilité thermique en vérifiant ainsi l'existence et l'importance des réactions parasites. Rappelons que le méthyl-1 acétonylthio-2 imidazole ne peut être purifié et conservé sur potasse du fait de la possibilité de réaction de Darzens (17–18). Cette même réaction ne permet pas la synthèse de ce thioéther par catalyse par transfert de phase (1). Nous effectuerons donc à diverses températures la cinétique de réarrangement des substrats d'amplification suivants: alkyl-1 (aryl-1) méthylthio-2 imidazoles, **5**; méthyl-1 alkylthio-2 (benzylthio...) imidazoles, **6**; et triméthyl-1,4,5 méthylthio-2 imidazole, **7**.

Conditions d'étude du réarrangement SR ⇋ NR

Elles sont du même type que celles retenues pour l'étude des thioéthers des séries imidazolinique et tétrahydropyrimidinique (2–5, 14–15). Les études sur les thiazolines étaient réalisées en ampoules scellées à l'étuve, en présence d'iodure de méthyle formant *in situ* le sel quaternaire, véritable catalyseur de la réaction (8, 9).

Ici, nous étudions la cinétique de migration S → N d'une façon différente: les transpositions sont réalisées dans un microballon ouvert, la phase liquide étant continuellement agitée et maintenue à une température régulée (2–4). Le catalyseur utilisé sera toujours le véritable catalyseur correspondant au sel quaternaire issu de la quaternisation par l'iodure de méthyle du thioéther étudié (1). Ces catalyseurs (**9** et **10**) qui sont donc les sels quater-

naires iodés des thioéthers sont les plus efficaces (9, 14), ils sont synthétisés, isolés et purifiés par double recristallisation dans l'éthanol anhydre (1). L'influence de l'anion associé du catalyseur sera étudiée pour le méthyl-1 méthylthio-2 imidazole. Le taux de catalyseur retenu pour l'étude cinétique est de 3% mol.

Nous avons recherché différents modes de dosage. Le dosage par spectrométrie ultraviolette s'est avéré inutilisable par suite de la grande analogie entre les spectres ultraviolets des formes thioéthers **5**, **6** et **7** et thiones de transposition **8** dans le cas des diazoles et diazines-1,3 (1, 19). Nous avons envisagé un mode de dosage par spectrographie de masse utilisable en phase adsorbée en présence de semi-conducteur et de liant (conditions technologiques liées au procédé photographique). L'étude en phase liquide a montré la possibilité théorique de réarrangement, mais le manque de précision, dû au mélange hétérogène entre thioéther (le plus souvent liquide) et thione (solide) nous a obligé à revenir au mode classique de dosage par résonance magnétique nucléaire du proton mis au point en 1974 (2, 4).

Lors de la transposition, des prélèvements sont effectués à intervalles de temps réguliers et la réaction est subitement arrêtée après chaque prélèvement par refroidissement. La précision de ce dosage est de l'ordre de 3%. Les quantités de thioéther utilisées par étude cinétique sont de 1 g, permettant ainsi six prélèvements.

Le calcul du taux de réarrangement s'effectue par l'étude en rmn du ^1H de la disparition de la bande du groupe SMe ou SR du thioéther en faveur de l'apparition de la bande NMe ou NR de la thione (2–4).[3] Les tableaux 1 et 2 et la fig. 2 donnent les taux

[3]Toutes les caractéristiques de synthèse et caractéristiques physico-chimiques nécessaires à l'étude et au dosage du réarrangement des thioéthers en thiones sont indiquées dans la réf. 1.

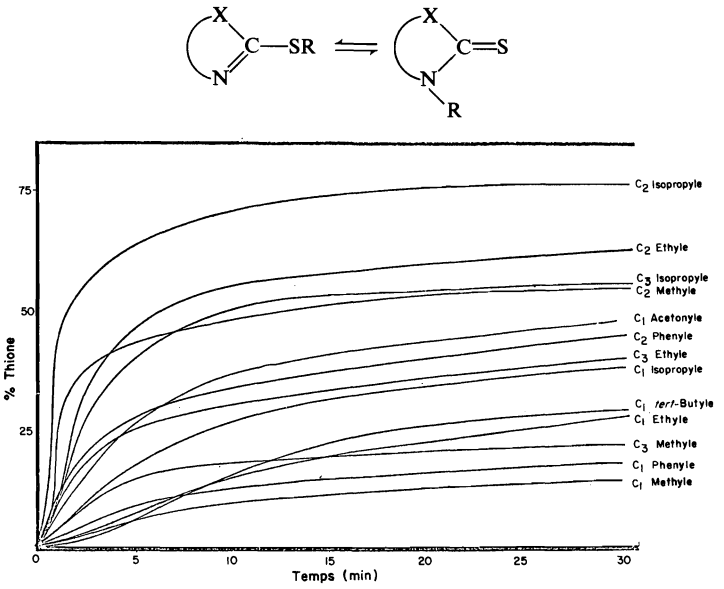

FIG. 2. Pourcentage de thione en fonction du temps, du substituant R_1 sur N_1 et du cycle ($T = 120°C$): cas des alkyl-1 methylthio-2 imidazoles, des alkyl-1 methylthio Δ-2-imidazolines et des alkyl-1 methylthio-2 Δ-2-tétrahydropyrimidines.

de réarrangement en thione en fonction du temps, de la température et de la structure du thioéther.

Phénomènes secondaires

Quand les thioéthers ne sont pas purifiés et conservés sur potasse ou quand ces substrats sont en présence d'eau, deux types de réactions parasites sont mises en évidence: *le réarrangement parasite* et les *réactions de dégradation* (2–5, 14–16). L'existence d'un intermédiaire tétraêdrique en équilibre avec un hydroxyde d'ammonium quaternaire **11** formé par hydrolyse des thioéthers a été démontrée en 1974 (2, 4) et généralisée aux composés des séries diazolique et diazinique-1,3 *N*-substituées (3, 5, 14, 15). La structure du sel **11** est proche de celle des sels **3** et **4**, intermédiaires de synthèse des thioéthers **5**, **6** et **7** obtenus à partir des thiones **1** et **2** (1). Nous ne rappelerons donc que les conclusions intéressant les composés diazoliques-1,3.

L'étude de la stabilité thermique (sans catalyseur) de ces substrats nous a permis de montrer que les réactions "*sans catalyseur*" sont en réalité des réactions autocatalytiques ioniques de type Chambonnet (7) catalysées par un sel parasite formé *in situ* par hydrolyse lente du thioéther. Le mécanisme a déjà été décrit (2–5, 14–15). Alors qu'un thioéther distillé sur potasse reste stable à 140°C (cf. tableau 1), l'adjonction de traces de sel formé par hydrolyse et préalablement isolé et identifié, provoque un *réarrangement parasite* qui conduit aux thiones de transposition classique **8** (2, 4).

L'étude des thioéthers imidazoliniques et tétrahydropyrimidiniques, nous a permis de proposer un mécanisme général de compétition entre cette voie de catalyse parasite et des voies de dégradations passant par un intermédiaire tétraêdrique (2–5, 14–15) (schéma 2).

Nous avons déjà montré que la prépondérance de l'une ou de l'autre voie dépend de la structure et de la substitution de l'hétérocycle (2, 3, 14). Dans le cas des composés imidazoliques, seule la voie *1* → *2* a pu être mise en évidence. Aucun composé de dégrada-

SCHÉMA 2. Réactions parasites: la voie *1* → *2* correspond à la catalyse parasite; les voies *1* → *3* → *4*, *1* → *3* → *5*, *1* → *3* → *6*, ... correspondent aux voies de dégradation.

tion n'a été identifié et les intermédiaires **D** et **E** n'ont pas été isolés. Contrairement aux composés imidazoliniques et tétrahydropyrimidiniques (2–4, 14–15), ces réactions parasites sont de faibles importances et la purification par simple distillation sur potasse permet d'obtenir une très bonne stabilité par chauffage (tableaux 1 et 2). Nous verrons que la substitution peut intervenir directement sur l'importance et l'existence de cette catalyse parasite

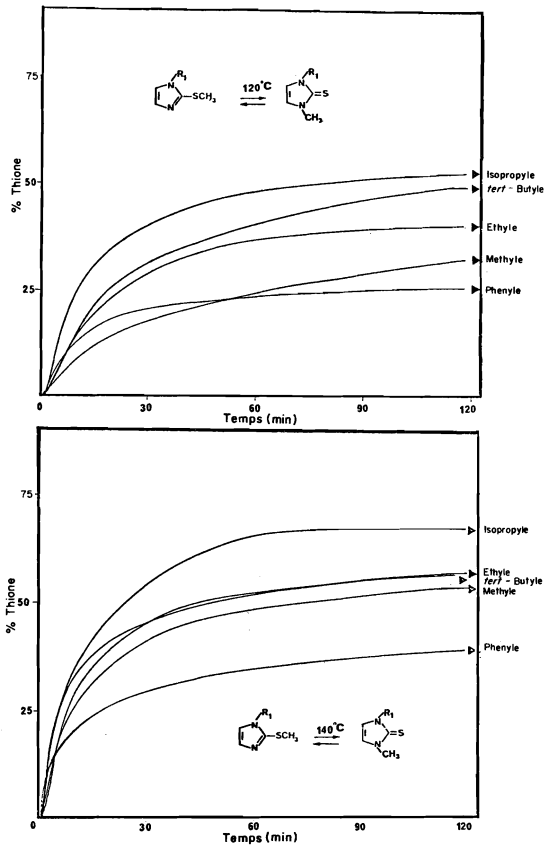

FIG. 3. Pourcentage de thione en fonction du temps et du substituant sur N_1 à 120 et 140°C: cas des alkyl (aryl)-1 méthylthio-2 imidazoles.

comme nous l'avons déjà démontré pour les alkyl-1 méthylthio-2 Δ-2-imidazolines et Δ-2-tétrahydropyrimidines (14–15).

Interprétation des résultats

Etude du réarrangement SR ⇋ NR: modifications structurales

Une analyse des tableaux 1 et 2 et des courbes *1–4* montre bien la variation du taux de réarrangement SR ⇋ NR en fonction de la substitution en position N_1 et S_2 et en fonction de la grandeur ou de l'aromaticité du cycle.

Influence du substituant R_1 fixé sur l'azote N_1 (fig. 3)

Au sein d'une même famille, nous notons une augmentation du taux de réarrangement en thione allant du méthyle à l'isopropyle, puis une décroissance pour les groupements *tert*-butyle et phényle en position 1.

La croissance du taux de réarrangement des groupements méthyle, éthyle et isopropyle s'explique par un effet électronique dû au groupement alkyle R_1. Cet effet inductif donneur du groupement R_1 tend à augmenter la densité électronique sur l'azote N_3 et ainsi renforce la nucléophilie de cet azote N_3. *A une augmentation du pK_a correspond une augmentation du taux de réarrangement.* L'abaissement du taux de thione transposée dans le cas du *tert*-butyle est dû à une gêne stérique qui l'emporte sur l'effet inductif. L'étude de rmn du ^{13}C confirme bien cette déformation du cycle diazolique (20).

Comme le montre le schéma 3, on peut penser que les substituants méthylthio sont repoussés par les groupements *tert*-butyle et ainsi les méthylthio du substrat et du catalyseur entrent en interaction. L'abaissement dans le cas du composé porteur du phényle en position N_1 est dû à un effet électronique. Ce groupement a tendance à attirer les électrons de l'azote N_3 pour se conjuguer avec l'ensemble du cycle. *Ainsi à un abaissement de pK_a correspond un abaissement du taux de réarrangement.* L'augmenta-

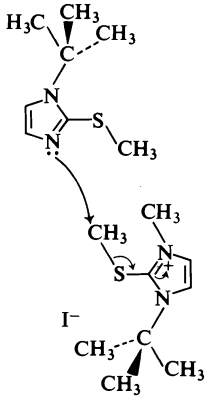

SCHÉMA 3

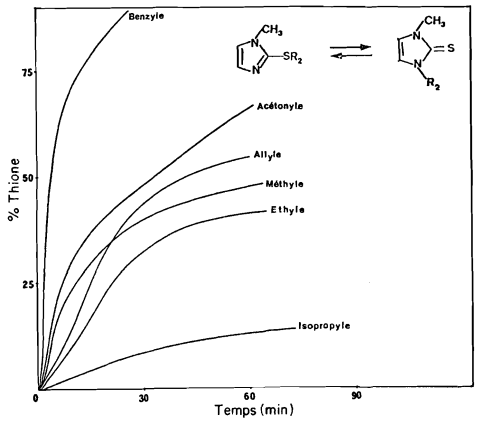

FIG. 4. Pourcentage de thione en fonction du temps et du substituant R_2 sur le soufre (T = 140°C): cas des méthyl-1 alkylthio (allylthio, acétonylthio et benzylthio)-2 imidazoles.

tion du taux de réarrangement pour R_1 = isopropyle est due à l'augmentation de l'effet inductif, la gêne stérique étant atténuée du fait d'une configuration privilégiée.

Influence du substituant R_2 fixé sur le soufre (fig. 4)

Dans le cas où R_2 = éthyle et isopropyle, nous observons une baisse du taux de réarrangement, baisse beaucoup plus significative pour l'isopropyle. Le réarrangement SR ⇌ NR se faisant par mécanisme S_N2, l'attaque du substrat se fera d'autant plus difficilement que le groupement R_2 est encombrant.

Dans le cas d'un groupement benzyle, nous constatons un accroissement du taux de réarrangement. La réaction S_N2 passe par un état de transition de type Y --- C --- X. Toute insaturation sur le carbone en α du carbone central augmente la stabilité de l'intermédiaire par une possibilité de conjugaison et par là même, influe sur la réactivité du substrat.

Pour le substrat substitué par un groupement allylthio, comme précédemment, l'intermédiaire réactionnel est stabilisé par conjugaison, la stabilisation étant inférieure à celle du méthyl-1 benzylthio-2 imidazole. Remarquons que le substrat chauffé seul sans catalyseur, donne un taux de réarrangement important. En accord avec Hayami et coll. (21) nous pouvons admettre qu'un mécanisme concerté se superpose à la réaction S_N2.

Le cas de la substitution par un groupement acétonyle est un peu plus délicat. En phase liquide ce substituant provoque un accroissement du taux de réarrangement. Ainsi le méthyl-1 méthylthio-2 imidazole donne 42% de thione à 140°C en 30 min et le méthyl-1 acétonylthio-2 imidazole donne 47% dans les mêmes conditions. Cet effet est classique et vérifié aussi pour les séries imidazolinique et tétrahydropyrimidinique. Cependant en phase adsorbée sur semi-conducteur (oxyde de titane type anastase AT_1 (Thann et Mulhouse)), le taux de réarrangement devient inférieur à celui du méthyl-1 méthylthio-2 imidazole par stabilisation du groupe migrant par complexation (3).

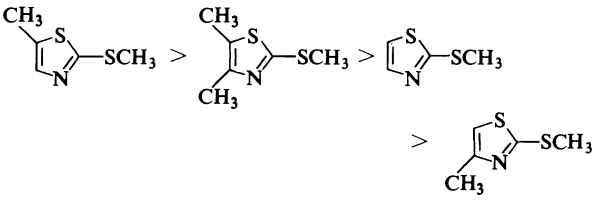
Influence des substituants fixés en position 4 et 5

Indépendamment des variations de substituants en position 1 et 2, nous pouvons étudier l'influence des substituants en position 4 et 5. L'analyse qui en résulte diffère fondamentalement des effets de pK_a. Ainsi, lors d'une étude afférente au doublet de l'azote dans la série du thiazole, conduite simultanément par une étude cinétique d'alcoylation et une étude d'équilibre de protonation, Chanon *et al.* (22) dégage deux effets de substitution.

Les premiers sont les effets électroniques transmis par le squelette, qui peuvent augmenter la réactivité au niveau du doublet de l'azote (cas du méthylthio-2 méthyl-5 thiazole), ou la diminuer (cas du méthylthio-2 thiazole). Ces effets sont additifs et sont traduits directement par le pK_a (3).

Le second effet est transmis à travers l'espace et il est de nature stérique. Dans le cas d'encombrement *ortho/ortho*, les effets sont exaltés par rapport à ce qu'on aurait pu attendre par simple additivité. Ainsi en position 4, l'influence d'un méthyle est remarquable: par son effet électronique, il devrait augmenter la constante de vitesse de quaternisation et le taux de réarrangement comme il augmente le pK_a. Au contraire, l'effet stérique provoque une diminution de la constante de vitesse et du taux de réarrangement.

On retrouve alors l'ordre de quaternisation et de réarrangement suivant (les deux réactions étant de type S_N2):



De tels effets de substitution seront particulièrement intéressants au niveau du choix de substrat de réarrangement dans la *série imidazolique*. Nous avons vérifié cet aspect prévisionnel en étudiant les composés **b** et **c**. Ainsi le méthyl-1 méthylthio-2 imidazole (pK_a = 5.5) donne 48% de thione à 140°C en 60 min et le triméthyl-1,4,5 méthylthio-2 imidazole (pK_a = 6.68) donne 57% dans les mêmes conditions (**b** > **c**).[4]

[4]La détermination des pK_a des divers hétérocycles étudiés a été réalisée par corrélations ou approximation à partir des composés étudiés par Perrin (23), Katritzky et Lagowski (24), Chanon *et al.* (22), Kjellin et Sandström (25), Deady (26) et Gonzalez (27). On retrouvera une étude complète des pK_a dans les références (3, 16, 28).

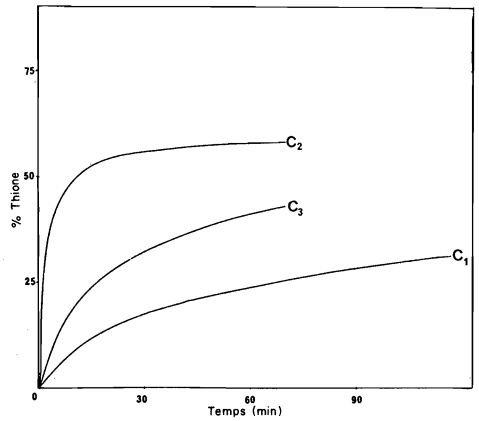


FIG. 5. Pourcentage de thione en fonction du temps et du cycle: cas des méthyl-1 méthylthio-2 imidazole (C_1), des méthyl-1 méthylthio-2 Δ-2-imidazoline (C_2) et des méthyl-1 méthylthio-2 Δ-2-tétrahydropyrimidine (C_3).

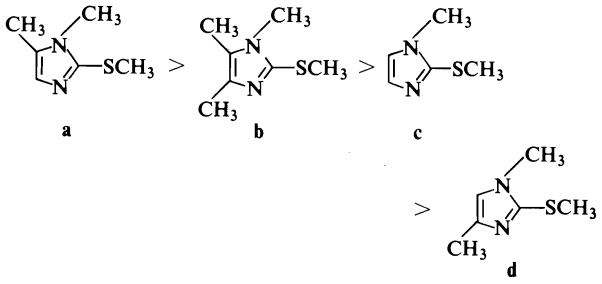
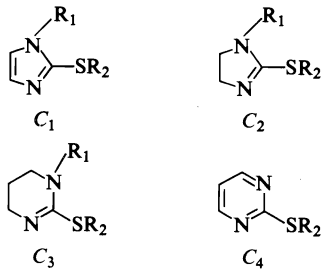
L'effet accélérateur (pK_a) est nuancé par l'effet ralentisseur de l'*ortho*-substitution (effet stérique):



Effet de cycle (*figs. 2 et 5*)

On peut raisonner de la même façon pour les cycles saturés à cinq et six chaînons et les effets de substitution 44′/55′ en série imidazolinique. Toujours dans le même esprit, regardons le passage d'un cycle à cinq à un cycle à six chaînons:



L'échelle des pK_a de ces composés (3, 16, 28) correspond à $C_3 > C_2 \gg C_1 > C_4$. L'ordre expérimental de réarrangement (3) correspond à $C_2 > C_3 \gg C_1$. Si nous observons ces échelles, nous constatons un fort accroissement du taux de réarrangement par passage des séries C_1 à C_2. Cet accroissement correspond à une augmentation importante du pK_a. Par contre l'étude des composés de la série des tétrahydropyrimidines (C_3) fait intervenir un facteur stérique supplémentaire, qui est le passage du cycle à cinq au cycle à six chaînons. La principale différence observée dans ces séries est donc une modification structurale. Il semble donc que le parallèle pK_a–réarrangement ne puisse être appliqué qu'à des structures comparables. Cette remarque avait déjà été faite par Deady (26) et Chanon *et al.* (9) lors de la comparaison de thiazoles et pyridines. La série pyrimidinique (C_4) présente pour le réarrangement des effets de pK_a et des effets stériques (six chaînons) défavorables. Synthétisés par catalyse par transfert de phase (29) ces composés ont un taux de migration S → N pratiquement nul en 1 h à 140°C (3).

Le parallèle pK_a–réarrangement est évident. Comme la quaternisation, le réarrangement est une réaction de type S_N2. Toute corrélation établie pour la quaternisation sera donc applicable à l'optimisation du substrat d'amplification. Nous venons de voir que l'effet de substitution en N_1 répond aussi au parallèle pK_a–réarrangement. Les limites à ce parallèle sont des limites stériques qui peuvent être indirectes ($R_1 = t$Bu) ou directes (*ortho*-substitution). Cependant à partir des figs 1 et 4, on constate que les séries C_2 et C_3 (15) sont plus sensibles à la *N*-substitution que la série C_1. Dans la série aromatique les effets électroniques sont beaucoup plus dilués que dans les séries imidazolinique et tétrahydropyrimidinique, où la délocalisation électronique se limite aux azotes N_1 et N_3. Cette observation est vérifiée en particulier par les études de rmn du carbone-13 (20) au niveau de l'effet de la *N*-substitution sur les carbones 2 et 5 ou 2 et 6 dans les séries à cinq ou six chaînons, et principalement, dans le cas particulier du groupement *tert*-butyle.

En réaction de réarrangement comme en rmn du ^{13}C, ou en spectroscopie ultraviolette (19), l'écart observé entre les thioéthers **5** ou thiones **1** et **8** substitués par les groupements éthyle, isopropyle et *tert*-butyle est maximum pour les séries imidazolinique et tétrahydropyrimidinique.

Effets de température sur le taux de réarrangement (*fig. 6*)

La fig. 6 et le tableau 1 traduisent ces effets. Les thioéthers de la série imidazolinique (C_1) étant moins réactifs que ceux des séries imidazolinique (C_2) et tétrahydropyrimidinique (C_3), les études sont le plus souvent menées à 140°C (15).

Effets des catalyseurs (*influence de l'anion associé*)

Ces effets ont déjà été discutés en série thiazolique (9); c'est d'ailleurs ce qui avait orienté le choix *de nos sels quaternaires* ***9*** *et* ***10****, comme catalyseurs optimum: "les iodures de méthyl-3 azolium."*

Nous avons étudié le réarrangement SR ⇌ NR du méthyl-1 méthylthio-2 imidazole à 140°C catalysé

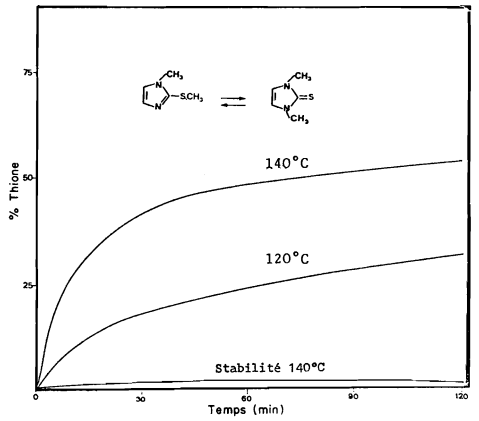


FIG. 6. Pourcentage de thione en fonction du temps et de la température: cas du méthyl-1 méthylthio-2 imidazole.

par les sels de type iodure, tosylate, chlorure de diméthyl-1,3 méthylthio-2 imidazolium (3% mol).

La réaction de réarrangement étant une réaction de type S_N2, nous retrouvons l'échelle établie pour la quaternisation ..... $I^- > TSO^- > Cl^-$ ..... Expérimentalement nous obtenons un taux de 50% en 1 h pour l'iodure, 37% en 1 h pour le tosylate et 10% en 1 h pour le chlorure.

Ces mêmes expériences effectuées en présence d'iode ou de tosylate de méthyle (3% mol) en ampoule scellée à 140°C donnent les résultats suivants: 80% de réarrangement en 2 h pour l'iode et 25% de réarrangement en 2 h pour le tosylate de méthyle.

Ces résultats sont proches de ceux obtenus par Chanon *et al.* en série thiazolique (9). L'explication de ces résultats est purement mécanistique et suggère la présence de légère quantité d'iodure de méthyle libre dans le milieu (9).

Réactions parasites

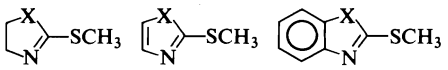
Contrairement aux thioéthers des séries imidazolinique et tétrahydropyrimidinique (4, 5, 15) aucun intermédiaire de type **11** ou composés de dégradation de type **12** n'a été isolé ou identifié en phase liquide.

Seule la voie de catalyse parasite *1,2* (schéma 2) a pu être mise en évidence (tableau 1). Cependant, d'une façon générale cette réaction parasite est trés faible et une simple distillation sur potasse limite le "back-ground" à 3%. Le taux de réarrangement sans catalyseur pour les benzylthio-2 et allylthio-2 imidazoles, traduit un mécanisme de migration différent de la réaction de réarrangement du type Chambonnet mécanisme concerté (21), réaction de Claisen ou Chapman. Il semble que cette hydrolyse parasite soit favorisée par les mêmes conditions que celles qui favorisent le réarrangement, cependant les variations de réactivité des thioéthers vis-à-vis de l'eau sont beaucoup plus importantes pour les séries imidazolinique et tétrahydropyrimidinique. Ces réactions parasites peuvent devenir très importantes sur support semi-conducteur selon la nature et la variété cristalline du support (TiO_2AT ou RL, ZnO, Al_2O_3, SiO_2, etc.).

Ainsi les composés de dégradation $\mathbf{E}_i$ (schéma 2) ont été identifiés sur support TiO_2AT (oxyde de titane anastase, Thann et Mulhouse). Le choix du support est donc un critère important pour la réalisation des expériences photographiques utilisant la réaction de réarrangement SR ⇋ NR comme réaction d'amplification (réf. 3 et renvoi 5).

Généralisation et conclusion

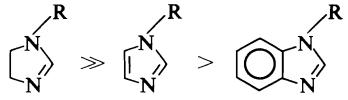
Les divers effets de cycle, de substitution, de champ (hétéroatome en position 1) etc., ont été étudiés systématiquement pour des thioéthers aromatiques, saturés ou benzocondensés à cinq ou six chaînons (3, 16).



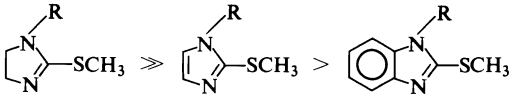
X = O, S, NR

Le parallèle pK_a–réarrangement est alors vérifié pour l'ensemble des substrats hétérocycliques.

Ainsi pour les diazoles-1,3 (X = NR), on observe que l'échelle de pK_a (3, 16, 28) est:



l'échelle de réarrangement observée (3, 16) est:



L'ensemble des résultats présentés dans ce mémoire pour les séries imidazolique et pyrimidinique, ainsi que ceux des séries imidazolinique et tétrahydropyrimidinique (15) permet le choix cohérent du substrat de réarrangement qui sera le substrat d'amplification du procédé photographique (2, 3, 6). La limite du parallèle pK_a–réarrangement permettant cette optimisation du substrat d'amplification du procédé photographique est bien d'ordre structural. Elle peut être due à des interactions stériques directes (effet *ortho*) ou indirectes (déformation de cycle) ou à des modifications géométriques des hétérocycles étudiés (cycles à six ou cinq chaînons).

Received October 13, 1978

DAVID GRILLER, PETER SCHMID, and KEITH U. INGOLD. Can. J. Chem. **57**, 831 (1979).

The rate constant for the irreversible cyclization of the 4-cyanobutyl radical to the cyclopentiminyl radical, $k_c^{C\equiv N}$, has been measured from −52 to 12°C by kinetic epr spectroscopy. The temperature dependence of this rate constant can be represented by,

$$\log (k_c^{C\equiv N}/s^{-1}) = (9.9 \pm 1.0) - (8.6 \pm 1.0)/\theta$$

where $\theta = 2.3RT$ kcal/mol. This rearrangement is somewhat slower than the analogous cyclizations of the 5-hexenyl and 5-hexynyl radicals.

DAVID GRILLER, PETER SCHMID et KEITH U. INGOLD. Can. J. Chem. **57**, 831 (1979).

On a mesuré les constantes de vitesse de la cyclisation irréversible du radical cyano-4 butyle en radical cyclopentiminyle, $k_c^{C\equiv N}$, à des températures allant de −52 à 12°C en faisant appel à la spectroscopie rpe. On peut représenter la relation entre la constante de vitesse et la température grâce à l'équation

$$\log (k_c^{C\equiv N}/s^{-1}) = (9.9 \pm 1.0) - (8.6 \pm 1.0)/\theta$$

où $\theta = 2.3RT$ kcal/mol. Cette transposition est un peu plus lente que les cyclisations analogues des radicaux hexényle-5 et hexynyle-5.

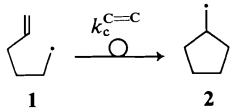
Introduction

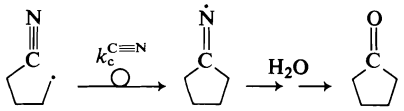
Free-radical ring closure reactions occur when a suitably constituted radical undergoes intramolecular addition to an unsaturated function. Many such reactions are known, the most thoroughly studied being the cyclization of 5-hexenyl, **1**, to form cyclopentylmethyl, **2** (for recent reviews of ring closure



1 **2**

reactions see ref. 1). This rearrangement first achieved prominence as a quantitative probe for the presence of primary alkyl radicals in reaction systems (1). Subsequently, the rate constant for this cyclization, $k_c^{C=C}$, was determined by a 'classical' procedure at 25°C (2) and later by kinetic epr spectroscopy over a range of temperatures (3, 4). This reaction is frequently employed to determine the rates at which primary alkyls react with suitable molecules (4, 5).

Many analogs of the 5-hexenyl cyclization have been reported (1) but the rate constants for these reactions have, at best, been determined only by competitive methods and generally at a single temperature (see for example ref. 6). A particularly interesting rearrangement belonging to this general class of radical cyclization was first described in 1975 by Ogibin *et al.* (7) who found that cyclopentanone was produced in high yield when 4-cyanobutyl, **3**, was generated in an aqueous medium. Clearly, the cyclopentylketiminyl radical, **4**, must be an intermediate



3 **4**

in this reaction (7, 8). Trapping experiments with Cu^{II} indicated that cyclization was rapid (7, 8).

Although there are some examples of intermolecular (9) and of intramolecular (10, 11) addition of alkyl radicals to alkyl nitriles there do not appear to have been any measurements of the rates of such processes. We wished, therefore, to measure $k_c^{C\equiv N}$ and compare its magnitude with that of $k_c^{C=C}$ which we had previously determined (2–4). However, the kinetic epr technique (3, 4) can be applied *only* if rearrangement is irreversible, i.e., only if **4** ⇌ **3**. To check this point it was necessary to generate **4** in some direct manner from a cyclopentyl precursor. The usual route to ketiminyls, which involves hydrogen abstraction from ketimines (12), was inapplicable since cyclopentylketimine appears to be unknown. Other routes to ketiminyl radicals are known (13, 14) but none of those we investigated proved suitable.

In 1977 Cooper *et al.* (15) reported that photochemically generated *tert*-butoxy radicals reacted

[1]Issued as NRCC No. 17204.

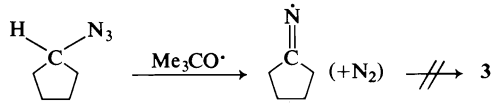
0008-4042/79/070831-04$01.00/0

with alkyl azides to produce iminyl radicals 'cleanly' and at concentrations suitable for epr spectroscopic study. This procedure worked well with cyclopentyl azide and, over the temperature range (−10 to 40°C, *vide infra*), the epr spectrum of the cyclopentylketiminyl was entirely free of the 4-cyanobutyl spectrum. Thus, conditions can be found where the **3** ⟶ **4** cyclization is irreversible.[3]



In the present paper we report measurements of $k_c^{C\equiv N}$ and derive Arrhenius parameters for this cyclization.[4]

Experimental

The kinetic epr method which is used to measure the rates of unimolecular radical reactions has been described previously (3, 4, 17). Radicals **3** and **4** were generated photochemically in solution in isooctane directly in the cavity of a Varian E-4 epr spectrometer under conditions of slow flow (0.2 mL/min). Radical **4** was generated as described above. Radical **3** was generated by bromine abstraction from 5-bromovaleronitrile using tri-*n*-butyltin radicals generated by photolysis of hexa-*n*-butylditin.

$$BrCH_2(CH_2)_3CN \xrightarrow{n Bu_3Sn\cdot} {\cdot}CH_2(CH_2)_3CN$$

Materials

5-Bromovaleronitrile was prepared from tetramethylene bromide and potassium cyanide according to the procedure of Leonard and Wildman (18). Distillation yielded a colorless liquid (bp 111°C/15 Torr (lit. (18) bp 114–115°C/12 Torr)) which was purified by preparative vpc before use. This compound was rather immiscible with isooctane and it was therefore used at concentrations ≤0.05 *M*. Cyclopentyl azide was prepared from cyclopentyl bromide and sodium azide in diethyleneglycolmonomethyl ether according to the procedure of Lieber *et al.* (19) and was purified by distillation (bp 62°C/50 Torr (lit. (19), bp 72°C/77 Torr)). This compound was used at a concentration of 0.01 *M*.

All other compounds were commercial materials that were purified by standard methods before use.

Results

Electron Paramagnetic Resonance Spectra

Bromine abstraction from 5-bromovaleronitrile at temperatures ≤ −70°C gave only **3**. This radical showed a spectrum typical of a primary alkyl, viz., $g = 2.00237 \pm 5 \times 10^{-5}$, $a^{H_\alpha}(2H) = 21.75 \pm 0.05$, $a^{H_\beta}(2H) = 27.50 \pm 0.05$, $a^{H_\gamma}(2H) = 0.55 \pm 0.05$ G at −10°C. At higher temperatures the spectrum of **4** appeared and this was the only radical observable at temperatures ≥17°C. The epr parameters for **4** generated from cyclopentyl azide at −7°C are: $g = 2.00300 \pm 1 \times 10^{-5}$, $a^N = 9.40 \pm 0.05$, $a^{H_\alpha}(4H) = 4.43 \pm 0.05$, $a^{H_\beta}(4H) = 1.94 \pm 0.05$ G. It is noteworthy that the epr signal due to **4** has much sharper lines than that due to **3**. In the kinetic experiments **3** was monitored at a modulation amplitude of 1.6 G and **4** at 0.16 G.

Steady-state Kinetic Measurements

Absolute concentrations of **3** and **4** were measured under conditions of steady photolysis in the temperature range (−57 to 12°C) where both radicals could be detected when **3** was generated from 5-bromovaleronitrile. From these concentrations the rate constant ratio, $k_c^{C\equiv N}/2k_t^4$ can be determined from the expression (3, 4)

$$k_c^{C\equiv N}/2k_t^4 = [\mathbf{4}](1 + [\mathbf{4}]/[\mathbf{3}])$$

where $2k_t^4$ is the rate constant for the bimolecular self-reaction of **4**, provided this reaction is diffusion controlled.[5] The results of these experiments are summarized in Table 1.

Measurement of $2k_t^4$

This rate constant was determined in the usual way (22) by monitoring the decay of **4** when the light was chopped by a rapidly rotating sectored disc. At 18.5°C this radical was found to decay with 'clean' second-order kinetics. The measured rate constant for decay, $2k_t^4 = 5.9 \times 10^9\ M^{-1}\ s^{-1}$, indicates that this reaction is diffusion controlled, just as we would expect for this sterically unhindered ketiminyl (12). The variation of $2k_t^4$ with temperature was computed from the temperature coefficient of viscosity of the solvent (21). It can be represented by

$$\log [2k_t^4(M^{-1}\ s^{-1})] = 11.56 - 2.42/\theta$$

where $\theta = 2.303\ RT$ kcal/mol. Values of $2k_t^4$ calculated from this relation have been used to calculate the values of $k_c^{C\equiv N}$ which have been listed in Table 1.

Discussion

The rate constant for cyclization of 4-cyanobutyl can be represented[6] by

$$\log (k_c^{C\equiv N}/s^{-1}) = (9.9 \pm 1.0) - (8.6 \pm 1.0)/\theta$$

[3]The ring opening reaction **4** ⟶ **3** does occur in the gas phase at temperatures >250°C (16).

[4]The rate constant for this reaction has also been determined at −10°C by Dr. B. P. Roberts (private communication) using the kinetic epr method.

[5]The actual requirement is that $2k_t^4$ be equal to the rate constant for the bimolecular reaction between **3** and **4** (3, 4, 17). Since the latter reaction involves unhindered radicals it will certainly be diffusion controlled (see e.g., refs. 2–4, 20, 21).

[6]The error limits given for the *A* factor and activation energy reflect the uncertainty introduced when extrapolating beyond the experimental temperature range to determine the activation energy and *A* factor. Within the experimental range the error in $k_c^{C\equiv N}$ is reasonably small and is probably not greater than a factor of 2 or 3.

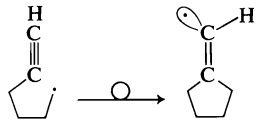
[a]Held to within ±0.5K during the course of each measurement.

which yields $k_c^{C\equiv N} = 4.0 \times 10^3\ s^{-1}$ at 25°C and $4.0 \times 10^4\ s^{-1}$ at 80°C. For comparison, the rate constant for the 5-hexenyl cyclization can be represented by (4)

$$\log (k_c^{C=C}/s^{-1}) = (9.5 \pm 1.1) - (6.1 \pm 1.1)/\theta$$

which yields, $k_c^{C=C} = 1.1 \times 10^5\ s^{-1}$ at 25°C and $5.3 \times 10^5\ s^{-1}$ at 80°C. The rate constant for cyclization of the 5-hexynyl radical, i.e., **5**⟶**6**, has been



5 **6**

estimated to be $1.2 \times 10^5\ s^{-1}$ at 80°C.[7] The cyclizations of **1**, **3**, and **5**, therefore proceed at rates which are not grossly dissimilar and the differences in rate can probably *primarily* be attributed to differences in activation energy. The Arrhenius preexponential factors are smaller than might have been anticipated for such simple cyclizations (4).

It is not unreasonable that **1**, **3**, and **5**, should cyclize at similar rates since the reactants are structurally related and even their thermochemistry must be very similar. The latter point can be illustrated by considering the estimated thermochemistry of three model reactions, viz., hydrogen atom addition to ethylene, acetonitrile,[8] and acetylene. The following heats of formation, ΔH_f^0 (in kcal/mol), have been measured or estimated for the species involved in these three reactions: C_2H_4, 12.5 (23); $C_2H_5^{\bullet}$, 26.0 (24);[9] CH_3CN, 19.0 (25); $CH_3CH{=}N^{\bullet}$, 34.4 (26); C_2H_2, 54.2 (23); $H_2C{=}\dot{C}H$, 69.0 (26); $H^{\bullet}$, 52.1 (26). The three model reactions and their calculated exothermicities are:

$$H^{\bullet} + H_2C{=}CH_2 \rightarrow H_3C{-}\dot{C}H_2 \qquad -38.6\ \text{kcal/mol}$$

$$H^{\bullet} + CH_3C{\equiv}N \rightarrow CH_3CH{=}\dot{N} \qquad -36.7\ \text{kcal/mol}$$

$$H^{\bullet} + HC{\equiv}CH \rightarrow H_2C{=}\dot{C}H \qquad -37.3\ \text{kcal/mol}$$

Rates of cyclization of other analogs of 5-hexenyl are currently under investigation.

The effect of tetra-*n*-butylammonium bromide on the proton magnetic resonance of 1-X-2,4-dinitrobenzenes

D. R. McLaughlin and J. D. Reinheimer[1]

Department of Chemistry, The College of Wooster, Wooster, OH 44691, U.S.A.

Received September 5, 1978

D. R. McLaughlin and J. D. Reinheimer. Can. J. Chem. **57**, 835 (1979).

The chemical shifts of the ring protons of 1-X-2,4-dinitrobenzenes are changed with the addition of tetrabutylammonium bromide. In general, the chemical shift of proton 3 decreases with salt addition, that of proton 5 may increase or decrease, while that of proton 6 increases. Where X is an oxygen containing group, the changes are somewhat more pronounced.

D. R. McLaughlin et J. D. Reinheimer. Can. J. Chem. **57**, 835 (1979).

Les déplacements chimiques des protons aromatiques des dinitro-2,4 X-1 benzènes varient lors de l'addition de bromure de tétrabutylammonium. En général, le déplacement chimique du proton en 3 diminue par addition du sel; celui du proton en 6 augmente alors que celui du proton en 5 peut augmenter ou diminuer. Lorsque X est un groupement contenant un oxygène, les changements sont quelque peu plus prononcés.

[Traduit par le journal]

Introduction

In connection with our studies of salt effects on the rate of aromatic nucleophilic substitution reactions (1–3), we found the study of Hyne and Fabris (4). Hyne and Fabris suggested that tetrabutylammonium bromide and iodide associated with both the aryl ring and the nitro group of nitrobenzene as an ion pair. The anion was placed over the *meta* and *para* positions of the benzene ring. If it were a nucleophile, the anion would be well positioned to attack the ring and form a σ anionic complex (5). This study was an extension of Hyne and Fabris' work to a series of dinitro compounds.

Experimental

All spectra were taken in the solvent methylene chloride. The Varian T-60 was locked on the solvent peak and peak positions were determined by a frequency counter.

The samples were commercial chemicals which were recrystallized until the melting point range was 1°C and agreed with the literature melting point. The tetra-*n*-butylammonium bromide was recrystallized twice from benzene and then dried in an Abderhalden drying pistol for 24 h. Samples were sealed and stored in a desiccator over $CaSO_4$; mp 117–119°C, lit. (6) mp 118°C. The solvent was dried over $CaSO_4$ and distilled before use. Sample solutions were prepared by weighing the compound and diluting to volume in a 1-mL volumetric flask.

The effect of water was investigated as follows: a control sample of dried tetra-*n*-butylammonium bromide in CH_2Cl_2 was prepared by performing all manipulations in a plastic glove bag filled with dry nitrogen. The second sample was prepared from purified tetra-*n*-butylammonium bromide that had been on the laboratory bench for several days. The third sample was taken from the commercial tetra-*n*-butylammonium bromide sample. The spectra of 1-chloro-2,4-dinitrobenzene with each salt solution were identical within experimental error. Next, 2 drops of water were added to the dried sample in the nmr tube. After vigorous shaking, no change in nmr spectrum was noted.

[a]Chemical shifts were measured in Hz from TMS.

the dinitro series. In nitrobenzene, Hyne and Fabris (4) found that the change for the *ortho* position was very small, whereas the downfield changes for the *meta* and *para* protons were greater. Our data (Fig. 1 and Table 1) reveal an upfield change of chemical shift for proton 3 (*ortho* to both NO_2 and *meta* to X) with all X. The magnitude of this change is largest for X = OH, smallest for X = Cl and similar for all other X. For proton 5, (*ortho,para* to the NO_2 groups and *meta* to X), a small upfield change is observed for all X except the halogens. Again, the greatest change is found for the OH group. The halogens give rise to a slight downfield change. For proton 6 (*meta* to both NO_2 and *ortho* to X), the change is downfield for all X. The magnitude of this change is greatest for OH and OCH, large for F, and about the same for Cl, CH_3, and H. The chemical shift vs. concentration ratio plot is not linear in all cases; this is in contrast to Hyne and Fabris' data.

The chemical shift changes were attributed to an association of the tetrabutylammonium ion with a nitro group and the halide ion with the benzene ring. The fact that the dinitro compounds dissolved much more rapidly in tetrabutylammonium bromide solution than in pure solvent provides weak evidence for association.[2]

[2]A referee has suggested that the solubility rate statement does not clearly delineate between thermodynamic and kinetic data. A better experiment would have been the investigation of the change in solubility of dinitro compounds with added tetrabutylammonium bromide. We did not make this study; our qualitative observation was that the dinitro compound dissolved in salt solution after one or two inversions of the volumetric flask but a period of minutes and many inversions for solution in the pure solvent. The unstated assumption was that the rate of solution would depend on the relative unsaturation of the solution with respect to the dinitro compound. If the species that is in solution is a salt – dinitro compound complex, the concentration of dinitro compound would be low and its rate of solution correspondingly fast.

The crucial question is where the ions are positioned with respect to the aromatic ring. If the tetrabutylammonium salt were complexed to X, the 3 and 5 positions are symmetrically placed and their change in chemical shift should be quite similar. A survey of Fig. 1 shows that this is not the case. Association of the cation of potassium *tert*-butoxide with the nitro group of *o*- and *p*-fluoronitrobenzene was postulated by Del Cina *et al.* (7). Ehrlich and Popov (8) have demonstrated that a downfield shift of the Na^+ resonance occurs in an ion pair (Na^+, I^-). These data are indicative of an association of the Br^- with the aryl ring and the tetrabutylammonium cation with the nitro group. In short, they support the Hyne–Fabris model. Additional support may be found in the following result. If the cation were above the benzene ring, the ring current should affect the butyl protons. This chemical shift should move upfield with added salt. To eliminate any NO_2 group effect, the nmr spectra of tetrabutylammonium bromide with nitromethane (A), with 2,4-dinitrochlorobenzene (B), and with no added solute (C) were taken. The aliphatic spectra of A and C were identical, but B was slightly different. The chemical shifts of B were downfield. If this is a ring current effect, the cation must not be above the benzene ring; a reasonable position is at the NO_2 group. This experiment is not a definitive result, but it provides more support for the Hyne–Fabris model.

In summary, the tetrabutylammonium bromide is associated with the nitro group or groups and the benzene ring. We postulate, with Hyne and Fabris, the association of the cation with the nitro group and the anion with the electron deficient benzene ring.

Received September14, 1978

ALEXEI M. AFANASSIEV, KIYOSHI OKAZAKI, and GORDON R. FREEMAN. Can. J. Chem. **57**, 839 (1979).

The rate constants k_1 for the reaction of solvated electrons with allyl alcohol in a number of hydroxylic solvents differ by up to two orders of magnitude and decrease in the order *tert*-butyl alcohol > 2-propanol > 1-propanol ≈ ethanol > methanol ≈ ethylene glycol > water. In methanol and ethylene glycol the rate constants ($7 \times 10^7\ M^{-1}\ s^{-1}$ at 298 K) and activation energies (16 kJ/mol) are equal, in spite of a 32-fold difference in solvent viscosity (0.54 and 17.3 cP, respectively) and 3-fold difference in its activation energy (11 and 32 kJ/mol, respectively). The reaction in *tert*-butyl alcohol is nearly diffusion controlled and has a high activation energy that is characteristic of transport in that liquid ($E_1 = 31$ kJ/mol, $E_\eta = 39$ kJ/mol). The activation energies in the other alcohols are all 16 kJ/mol, and it is 14 kJ/mol in water. They do not correlate with transport properties. The solvent effect is connected primarily with the entropy of activation. The rate constants correlate with the solvated electron trap depth. When the electron affinity of the scavenger is small, a favorable configuration of solvent molecules about the electron/scavenger encounter pair is required for the electron jump to take place. The behavior of the rate parameters for propargyl alcohol is similar to that for allyl alcohol, but k_1, A_1, and E_1 are larger for the former. The ratio k(propargyl)/k(allyl) at 298 K equals 10.5 in water and decreases through the series, reaching 1.3 in *tert*-butyl alcohol. Rate parameters for several other scavengers are also reported.

ALEXEI M. AFANASSIEV, KIYOSHI OKAZAKI et GORDON R. FREEMAN. Can. J. Chem. **57**, 839 (1979).

Les constantes de vitesse k_1, pour la réaction d'électrons solvatés par le l'alcool allylique dans un certain nombre de solvants hydroxylés diffèrent par des facteurs allant jusqu'à 100 et diminuent dans l'ordre *tert*-butanol > propanol-2 > propanol-1 ≈ éthanol > méthanol ≈ éthylène glycol > eau. Dans le méthanol et l'éthylene glycol, les constantes de vitesse ($7 \times 10^7\ M^{-1}\ s^{-1}$ à 298 K) et les énergies d'activation (16 kJ/mol) sont égales mêmes s'il existe un rapport de 32 dans les viscosités des solvants (0.54 et 17.3 cP) et un rapport de 3 dans les énergies d'activation de viscosité (respectivement 11 et 32 kJ/mol). La réaction dans le *tert*-butanol est pratiquement contrôlée par la diffusion et possède une énergie d'activation élevée qui est caractéristique du transport dans ce liquide ($E_1 = 31$ kJ/mol, $E_\eta = 39$ kJ/mol). Dans tous les autres alcools, les énergies d'activation sont toutes égales à 16 kJ/mol; dans l'eau E_a est égale à 14 kJ/mol. Ces valeurs ne peuvent pas être reliées avec les propriétés de transport. L'effet de solvant est principalement lié à l'entropie d'activation. Il y a un corrélation entre les constantes de vitesse et les profondeurs des pièges des électron solvatés. Lorsque l'affinité électronique pour le soluté est faible, il faut une configuration favorable des molécules de solvant autour de la paire électron-soluté qui se rencontre pour que le saut électronique puisse s'effecteur. Le comportement des paramètres de vitesse pour l'alcool propargylique est semblable à celui de l'alcool allylique; les valeurs de k_1, A_1 et E_1 sont toutefois plus élevées

dans le premier cas. Le rapport k(propargyl)/k(allyl) à 298 K est égal à 10.5 dans l'eau et diminue pour toute la série pour atteindre une valeur de 1.3 dans le *tert*-butanol. On rapporte des paramètres de vitesse pour plusieurs autres solutés.

[Traduit par le journal]

Introduction

The temperature dependence of solvated electron reaction rates has not been extensively studied (1–9), in spite of the importance of the subject. Perhaps one reason for that was the near constance of the observed activation energies for rate constants that varied by several orders of magnitude (1–3). These results indicated that there were greater variations in the entropy than in the enthalpy effects, and kinetics models are usually more suited to considerations of the latter.

Recent measurements have turned up systems in which the differences between the reaction activation energies E_a are greater than the experimental uncertainty (2*d*, 3*b*). For efficient scavengers in a series of alcohols and glycerol/water mixtures, the activation energy for solvated electron reaction was related to that, E_η, of viscous flow: $E_a = \alpha E_\eta + \beta$, where $\alpha = 0.44$–0.65 and $\beta = 3$–12 kJ/mol (3*b*). In another study, E_a for the inefficient scavenger benzene was found to be nearly double that for more efficient scavengers (2*d*). However, the values of E_a for benzene and toluene in C_1–C_4 alcohols are all 25–33 kJ/mol, and do not reflect the two-fold variations in E_η and the activation energies of dipolar rotational relaxation (2*e*).

The present work is devoted to the study of the effect of temperature on the reactivity of solvated electrons with two inefficient scavengers, allyl and propargyl alcohols, in a series of hydroxylic solvents that have different molecular structures.

Experimental

Materials

Allyl alcohol (2-propen-1-ol, 99%) and propargyl alcohol (2-propyn-1-ol, 97%) were Analyzed grade from Aldrich Chemical Co. The solvents were water (triply distilled), methanol (Spectroanalyzed, Fisher Scientific Co.), ethanol (U.S.P. anhydrous 200 proof, U.S. Industrial Chemical Co.), 1- and 2-propanol (Analyzed or Spectral grade, 99+%, Aldrich Chemical Co.), *tert*-butyl alcohol (99.5%, Aldrich Chemical Co.), and ethylene glycol (99%, Fisher Scientific Co.).

Methanol, 1- and 2-propanol, *tert*-butyl alcohol, and allyl and propargyl alcohols were treated for 1 day under argon with sodium borohydride (1 g/L) at 40, 60, 50, 50, 65, and 40°C, respectively. The alcohol was then fractionated through an 80 × 2.3 cm column packed with glass helices. The middle 50% was collected and kept under argon. Allyl and propargyl alcohols were treated twice in this manner. An argon (UHP, Matheson Co.) pressure and syphon system was used to transfer the alcohol without contacting air.

Ethylene glycol was distilled under reduced pressure at ~100°C. The first 15% and last 35% fractions were discarded and the middle 50% kept under an atmosphere of UHP argon.

Ethanol was used as received (10), but was kept under argon.

Techniques

The methods of sample preparation (11), temperature control, irradiation, and optical measurement (12–14) were essentially the same as described in the indicated references. In brief, a 0.1 μs pulse of 1.8 MeV electrons delivered 1–2 × 10^{16} eV/g to the sample. The dosimeter was oxygen saturated 5 mM potassium thiocyanate, using $G\varepsilon(478\text{ nm}) = 2.1 \times 10^4$ (100 eV M cm)$^{-1}$ for $(SCN)_2^-$.

The temperature during an experiment at a given temperature was constant to within 1°C. The absorbed dose/cm^3 and solute concentration were adjusted for the change of solvent density with temperature (15).

In water, methanol, and ethanol optical measurements were made at the absorption maximum, λ_{emax}, of the solvated electron band at each temperature. In 1- and 2-propanol and in ethylene glycol the wavelength was held constant at the λ_{emax} for 298 K, respectively 645, 815, and 566 nm. For *tert*-butyl alcohol the use of the fast response detector prevented measurements being made at λ_{emax} (298 K) = 1220 nm, so 950 nm was used.

Results and Discussion

The Solvents

The quality of each alcohol solvent was assessed by measuring the first order decay constant of solvated electrons in the absence of added solute, at several temperatures over an ~80 deg range. Temperatures from 298 K downwards were used for the propanols, from 298 K upwards were used for ethylene glycol and *tert*-butyl alcohol, while those for methanol and ethanol straddled 298 K. When a decay curve displayed an initial faster decay portion (geminate reaction), only the first order tail was measured. For example, geminate reaction was observable for 3 μs in *tert*-butyl alcohol at 300 K, so the rate constant was then taken from the decay between 6 and 16 μs. The values of the rate constants at 298 K and of the Arrhenius parameters are listed for the different alcohols in Table 1. The alcohols compare favorably with the purest used earlier (2*d*, 16–18).

The activation energy for *tert*-butyl alcohol is double that for the other alcohols (Table 1).

The electron half life in the purified water was 20 μs at 298 K.

Reaction of e^-_{solv} with Allyl and Propargyl Alcohols

Pseudo first order decay constants of e^-_{solv} were measured for several different concentrations of a solute S at a given temperature. The value of the rate constant of reaction [1] was obtained from the slope

[1] $$e^-_{solv} + S \rightarrow \text{product}$$

of a plot of the first order constants against the solute concentration. The nature and quality of the results are illustrated by the decay constants obtained for the

methanolic solutions at different temperatures (Figs. 1 and 2).

Arrhenius plots of k_1 for allyl alcohol in the different solvents are shown in Fig. 3. The rate constant and activation energy are largest in *tert*-butyl alcohol. The activation energies in the other alcohols are all equal to about half that in *tert*-butyl alcohol. The rate constants at a given temperature decrease in the order 2-propanol > 1-propanol ≈ ethanol > methanol ≈ ethylene glycol. The rate constant and activation energy are smallest in water. Numerical values of k_1 at 298 K and of the Arrhenius parameters A_1 and E_1 are listed in Table 2.

The behavior of the rate constants for propargyl alcohol is similar to that for allyl alcohol (compare Figs. 4 and 3). The values of k_1 for the former are larger and tend to be grouped into two clusters. One cluster includes the solvents *tert*-butyl alcohol, 2-propanol, 1-propanol, and ethanol, while the other includes methanol, ethylene glycol, and water (Fig. 4). Values of k_1 at 298 K and of the Arrhenius parameters are listed in Table 2. The values of A_1 and E_1 are all larger for propargyl than for allyl alcohol.

There is no correlation between the activation energies of the reactions and those of transport in the liquids. The latter are related to those of dielectric relaxation (Table 2 and refs. 19–21) and shear viscosity (Table 2 and ref. 15). Consider, for example, the activation energies in ethylene glycol and methanol: E_1 differs by 10% or less in these two solvents, whereas E_η differs by a factor of 2.9 and E_τ by a factor of 1.8 (Table 2).

There is also no correlation between the values of the rate constants in the different solvents and their activation energies (Table 2). The solvent effect is

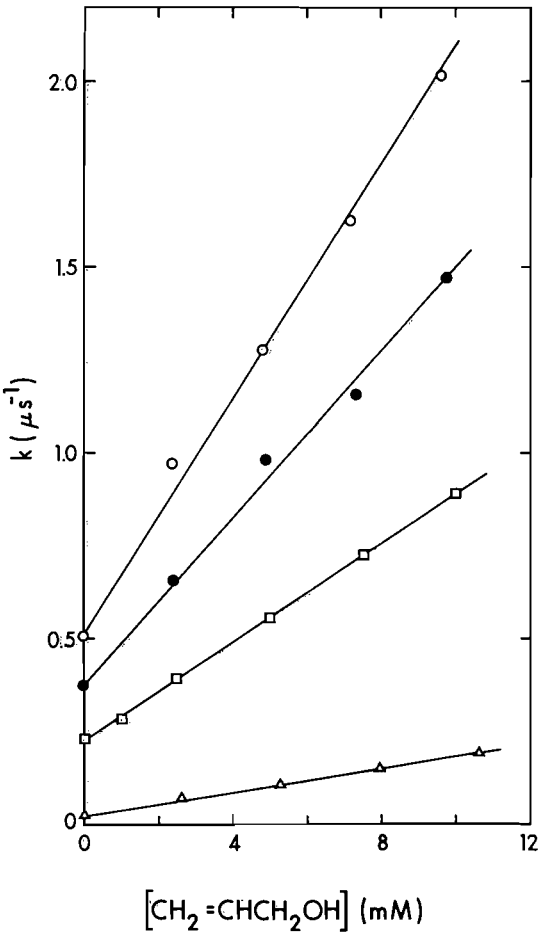

FIG. 1. Pseudo first order rate constants for the reaction of solvated electrons in methanolic solutions of allyl alcohol at 243 K (△), 298 K (□), 320 K (●), and 336 K (○).

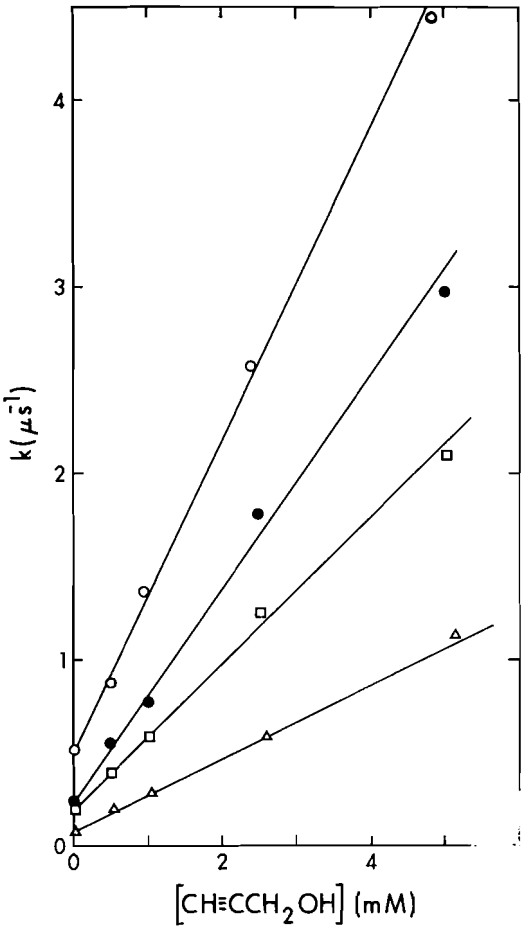

FIG. 2. Pseudo first order rate constants for the reaction of solvated electrons in methanolic solutions of propargyl alcohol at 273 K (△), 299 K (□), 310 K (●), and 333 K (○).

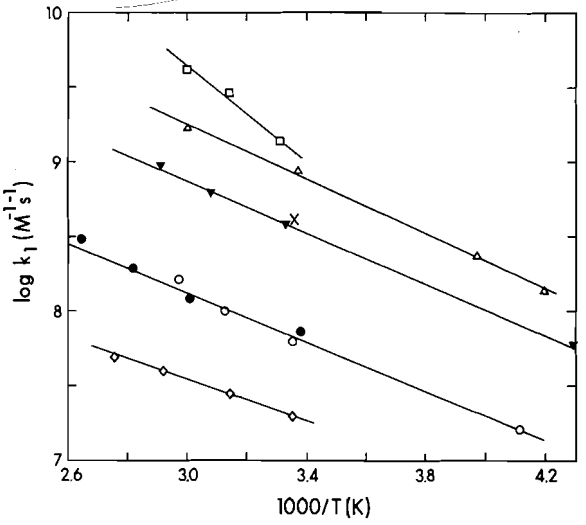

FIG. 3. Arrhenius plots of k_1 (M^{-1} s^{-1}) for allyl alcohol in water (◇), methanol (○), ethanol (▼), 1-propanol (×), 2-propanol (△), *tert*-butyl alcohol (□), and ethylene glycol (●).

therefore connected primarily with the entropy of activation.

The rate constant for propargyl alcohol is designated k_P and that for allyl alcohol k_A. The ratio k_P/k_A at 298 K equals 10 in water, in which the rate constants are smallest. As the values of k_A and k_P increase, their ratio tends to decrease. A plot of k_P/k_A against log k_A is shown in Fig. 5. The ratio extrapolates to unity at $k_A = 3 \times 10^9$ M^{-1} s^{-1}, which is the value one calculates for the diffusion controlled reaction using a reaction radius of 4 Å, a molecular diffusion coefficient of 3×10^{-6} cm^2/s (22) and an electron diffusion coefficient of 7×10^{-6} cm^2/s. This estimate for the diffusion coefficient of e^-_{solv} in *tert*-butyl alcohol at 298 K is consistent with earlier estimates of $2–8 \times 10^{-5}$ cm^2/s in methanol and $1–4 \times 10^{-5}$ cm^2/s in ethanol (23*a*, 24).[3]

The rate constants for these scavengers are largest in the alcohol in which the electron trap depth is the smallest, *tert*-butyl alcohol. Provided that the number of bound levels is similar for electrons solvated in different alcohols, the trap depth is related to the optical absorption energy (25). When the electron affinity of the scavenger is small, it is more difficult for an electron to jump from a deeper trap than from a shallower trap onto the scavenger molecule. The great breadth of the optical absorption band indicates that all the electrons are not in traps of the same depth in a given liquid. Electrons in the shallower traps have a greater probability of reacting per unit time than do those in deeper traps. We therefore choose as an indicator of the trap depth for kinetics purposes the quantity $E_r = (E_{\epsilon max} - W_r)$, where $E_{\epsilon max}$ is the energy at absorption maximum and W_r is the portion of the width at half height that is on the red side of $E_{\epsilon max}$ (13, 26). E_r is therefore the energy half way up the red side of the band. There is a significant correlation between log k_A and E_r in the alcohols (Fig. 6). Water lies well off the curve.

A plot of log k_A against $E_{\epsilon max}$ shows a poorer correlation than that in Fig. 6. The fact that E_r works better than $E_{\epsilon max}$ supports the heterogeneous broadening interpretation of the optical band in alcohols (27).

With the exception of the *tert*-butyl alcohol system, the activation energy of the reaction is nearly independent of E_r (Table 2). The solvent effect acts through the entropy of activation. A favorable configuration of solvent molecules about the electron/scavenger encounter pair is required for the electron jump to take place (28). The desired configuration would tend to stabilize the molecular anion and to

[3]Mobilities estimated from refs. 23 *b* and *c*.

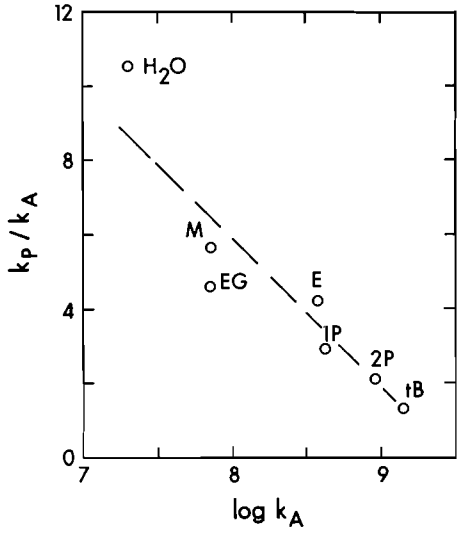

FIG. 5. Plot of k_P/k_A against log k_A, where k_P and k_A designate k_1 for propargyl and allyl alcohol, respectively, in a given solvent. T = 298 K.

make a less stable site for the electron in the solvent. The anion is probably finally stabilized by protonation (29).

[2] $$e^-_{solv} + S \rightleftharpoons S^-_{solv}$$

[3] $$S^-_{solv} + ROH \rightarrow SH + RO^-_{solv}$$

One may therefore write

[4] $$k_1 = k_2k_3/k_{-2}$$

Based upon earlier results in methanol and ethanol (29), one may predict that the overall volume of activation of process [1], $\Delta V_1^{\neq}$, is +3 cm^3/mol for allyl alcohol in methanol and +7 cm^3/mol in ethanol. For propargyl alcohol $\Delta V_1^{\neq}$ should be near 7 cm^3/mol in both solvents if the reaction mechanism is [2, 3].

The rate constants for propargyl alcohol are greater than those for allyl alcohol, which implies a greater electron affinity for the former. The values of k_P are therefore less sensitive to E_r than are those of k_A, so the ratio k_P/k_A increases with E_r (Fig. 6).

The value of k_1 in *tert*-butyl alcohol is near the diffusion controlled limit (Figs. 5 and 6). The large values of E_1 are caused mainly by the activation energy of diffusion in this solvent (compare E_1 with

TABLE 3. Energies and entropies of activation

Solvent	Allyl alcohol E_1 (kJ/mol)	Allyl alcohol $\Delta S_1^{\ddagger}$ (J/mol K)	Propargyl alcohol E_1 (kJ/mol)	Propargyl alcohol $\Delta S_1^{\ddagger}$ (J/mol K)

tert-Butyl alcohol	31	+33	36	+54

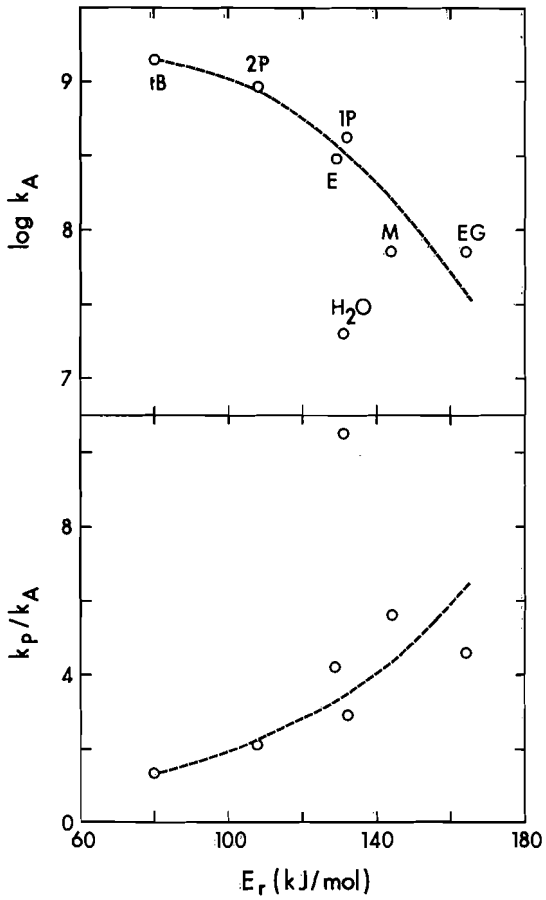

FIG. 6. Plots of log k_A and k_P/k_A against E_r (see Table 1).

E_η in Table 2). Transport has a higher activation energy in liquid branched chain compounds than in their straight chain counterparts (22, 30). The branched structure is more rigid and probably requires a greater amount of rearrangement of neighboring molecules to undergo a diffusion step.

Entropies of Activation

To estimate relative values of $\Delta S_1^{\ddagger}$ one may write

[5] $$\exp(-E_1/RT) \approx \exp(-\Delta H_1^{\ddagger}/RT)$$

and

[6] $$\log A_1 \approx \log(kT/h) + (\Delta S_1^{\ddagger}/2.3R)$$

At 298 K one has

[7] $$\log A_1 \approx 12.8 + (\Delta S_1^{\ddagger}/19)$$

where $\Delta S_1^{\ddagger}$ is in units of J/mol K. Values of $\Delta S_1^{\ddagger}$ so calculated are compared with E_1 in Table 3. The entropies vary relatively much more than do the energies of activation.

The capture of a solvated electron by a scavenger that has a low electron affinity is dependent upon the occurrence of a favorable configuration of solvent dipoles about the reaction site. A favorable configuration would increase the solvation energy of the molecular anion and decrease that of the electron. A more negative entropy of activation signifies the smaller probability of occurrence of a sufficiently favorable configuration.

Further interpretation of the positive and less negative values of ΔS_1 (less negative than, say, −20 J/mol K) requires knowledge of the parameter values for diffusion of e^-_{solv} and S. The value of k_1 can be divided into two components,

[8] $$k_1^{-1} = k_d^{-1} + k_r^{-1}$$

or

[9] $$\exp(\Delta G_1^{\ddagger}/RT) = \exp(\Delta G_d^{\ddagger}/RT) + \exp(\Delta G_r^{\ddagger}/RT)$$

where k_d and $\Delta G_d^{\ddagger}$ refer to the diffusion together of the reactants, while k_r and $\Delta G_r^{\ddagger}$ refer to the reaction of an encounter pair. Electron diffusion coefficients in alcohols are difficult to measure, but there is now great need of the information.

Other Scavengers

Rate parameters for a number of other scavengers in water, methanol, and ethanol are listed in Table 4. The smaller values of k_1 are limited by a large negative entropy of activation. However, acetonitrile has a high enthalpy of activation, which indicates that

Received August 14, 1978

S. SUNDER. Can. J. Chem. **57**, 846 (1979).

Raman spectra of the three solid phases of *tert*-butyl chloride-d_0 and -d_9 have been recorded for the regions of the intramolecular vibrations. The spectra of solid I are typical of those seen for plastic crystals and those of solid II of solids with partial orientational order. The transition from solid I to solid II results in the ordering of the three-fold molecular symmetry axes but the axes perpendicular to the molecular symmetry axes remain randomly oriented. The transition from solid II to III results in a more-or-less ordered structure. The spectra of phase III at 90 K suggest an ordered solid with the molecules on sites of symmetry C_s or C_1.

S. SUNDER. Can. J. Chem. **57**, 846 (1979).

On a enregistré les spectres Raman de trois phases solides du chlorure de *tert*-butyle-d_0 et -d_9 dans les régions des vibrations intramoléculaires. Les spectres du solide I sont typiques de ceux observés avec des cristaux plastiques alors que ceux du solide II se comparent à ceux de solides comportant un ordre partiel d'orientation. La transition d'un solide I en solide II provoque une orientation des axes tertiaires de symétrie moléculaire alors que les axes perpendiculaires aux axes de symétrie moléculaire restent orientés au hasard. La transition d'un solide II en III conduit à une structure plus ou moins orientée. Le spectre de la phase III à 90 K indique la présence d'un solide orienté comportant des molécules sur les sites de symétrie C_s ou C_1.

[Traduit par le journal]

Introduction

tert-Butyl chloride (TBC), $(CH_3)_3CCl$, is a globular molecule and shows two phase transitions in its solid state, with the I–II and II–III phase transitions occurring at 219.6 K and 183 K, respectively, under 1 atm pressure and its freezing point being 247.5 K (1). The three solid phases of TBC have been investigated using several physical techniques, e.g., heat capacity measurements (2–6), dielectric measurements (2, 3, 6, 7), nmr (8–10), nqr (11), ir (6), far-ir (12–14), X-ray diffraction (15–17), and more recently by inelastic neutron scattering (18). Their Raman spectra, however, have been reported only for the region below 100 cm^{-1}, i.e., only for the lattice modes (intermolecular vibrations) according to the information available to us (14). There seems to be general agreement about the nature of phase I (the high temperature phase), that it is plastic crystalline in nature and that molecules undergo hindered reorientations around all possible axes. Also, there seems to be agreement that at or below 90 K solid III has a fixed lattice. But there appears to be differences in opinion about the nature of solid II, and about that of solid III at temperatures above liquid air temperature. The nmr (10) and X-ray (17) data have been interpreted to indicate that the CCl bonds of the TBC molecules are fixed in solid II and the molecules can reorient about the molecular symmetry axis (CCl bond). Neutron scattering data, on the other hand, has been interpreted to suggest that the molecules can reorient both about the molecular symmetry axis and the axes perpendicular to it (18). Neutron scattering data did not suggest any molecular reorientations in phase III at temperatures around 173 K while the nmr data indicated the presence of molecular reorientations about the CCl bonds as well as the rotations of the methyl groups around the CC bonds at these temperatures in phase III. In light of the above interest in the solid phases of TBC we report here the Raman spectra of *tert*-butyl chloride-d_0 (TBC-d_0) and *tert*-butyl chloride-d_9 (TBC-d_9) in the regions of the intramolecular vibrations for their three solid phases, and discuss and compare the evidence obtained from Raman spectra regarding the structure, disorder, and molecular motions in the three solid phases with that derived from the other techniques. Earlier we presented a similar study of the three solid phases of *tert*-butyl bromide, a very closely related system (19–21).

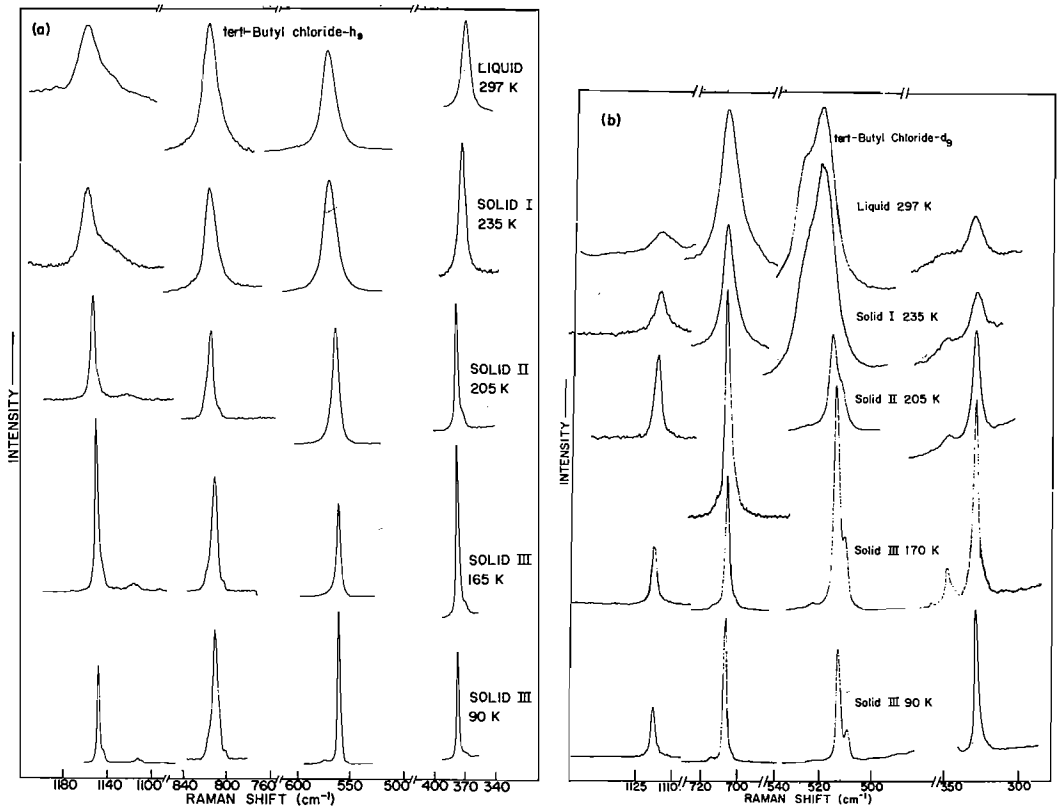

FIG. 1. Laser Raman spectra of the 'well-separated' A_1 modes of *tert*-butyl chloride in the liquid and the three solid phases using 4880 Å excitation: (*a*) *tert*-butyl chloride-d_0; (*b*) *tert*-butyl chloride-d_9.

Experimental

TBC-d_0 was obtained from B.D.H. Co. of England and was purified following the procedure of Baker and Smyth (2). TBC-d_9 was obtained from Merck, Sharp and Dohme of Canada and used without further purification. Its isotopic purity was better than 99% as indicated by its Raman spectra in the CH and CD stretching regions. The liquid samples were sealed in melting-point Pyrex capillaries (id 1 mm) and placed in an unsilvered vacuum jacketed transfer tube (22). Temperature control was achieved using a cold nitrogen gas stream flowing over a heater-sensor system in the transfer tube. The sample temperature was measured with a separate thermocouple placed near the sample and the reported temperatures are accurate to ± 3 K. The two transitions from phase I to II and from II to III were found to be spectroscopically complete when the solid samples were held for ~ 30 min at 205 K and 170 K, respectively (19, 21). Therefore all the spectra of phase II were recorded after the samples had been kept at 205 K for at least 40 min and the samples were held at 170 K for at least 40 min before recording any spectra of phase III.

The Raman scattering excited by the 4880 Å line from a Coherent Radiation 52 GA argon ion laser was recorded with a 90° scattering geometry using a Spex model 1400 dual monochromator, a photomultiplier tube (EMI 6256), and photon counting electronics. The laser output was filtered to remove extraneous emission lines and the power at the sample was about 250 mW. The frequency scale was calibrated using a neon lamp. No correction was applied to the observed intensities for the frequency-dependence of the instrument response.

Results

tert-Butyl chloride has $8A_1$ and $12E$ Raman active modes under C_{3v} molecular point group symmetry (19, 23–25). Assignment of the Raman bands of liquid TBC-d_0 and TBC-d_9 has been discussed in the literature (23–24). Here we have collected the bands due to the 'well-separated' and 'unambiguous' A_1 and E modes in Figs. 1 and 2, respectively, for the purpose of comparison. The assignment of the features in the CH_3 (CD_3) stretching and deformation regions are less certain due to the occurrence of several fundamentals and overtone/combination vibrations in these regions and the Fermi-resonance between them (19, 23–26). The spectra for these regions are shown in Fig. 3. The spectra of solid III are shown at two temperatures, at ~ 170 K, just below the II–III transition temperature, and at ~ 90 K, the lowest temperature used in this work. The spectra of phase III shown

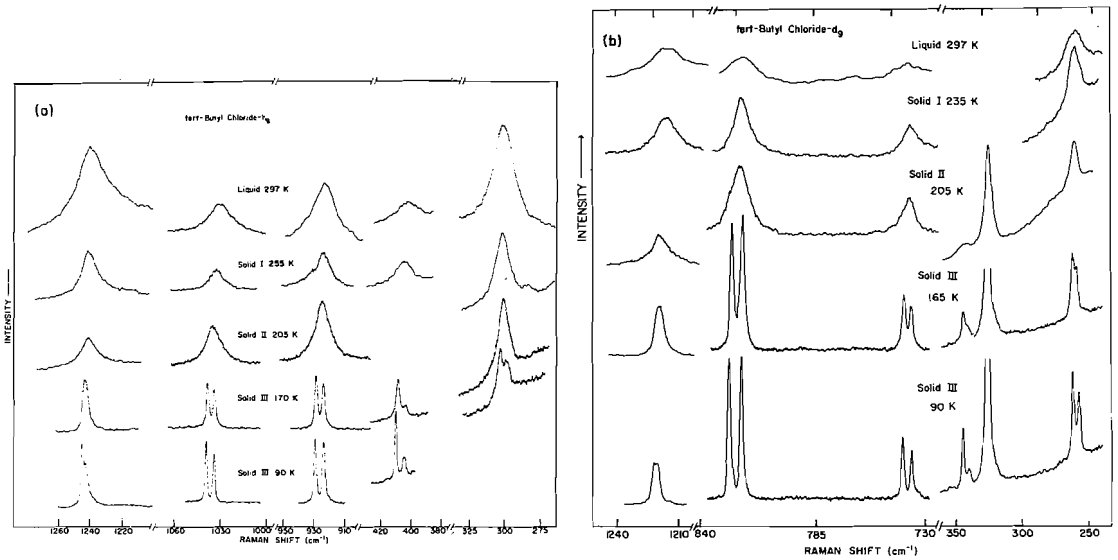

FIG. 2. Laser Raman spectra of the 'well-separated' E modes of *tert*-butyl chloride in the liquid and the three solid phases using 4880 Å excitation: (*a*) *tert*-butyl chloride-d_0; (*b*) *tert*-butyl chloride-d_9.

here are recorded at $\sim 1.5\ cm^{-1}$ spectral slitwidth, while those of the high temperature phases were recorded at $\sim 2.5\ cm^{-1}$ spectral slitwidth for better signal-to-noise ratio. The spectra of the high temperature phases were also studied at $\sim 1.5\ cm^{-1}$ resolution, but no additional features were observed. Here it may be mentioned that the spectra shown in Figs. 1–3 are photocopies of the original spectra and that the monochromator used was linear in wavelength. The Raman shifts of the observed features in the regions of the intramolecular fundamental vibrations are listed in Tables 1 and 2 for TBC-d_0 and TBC-d_9, respectively, for their three solid phases as well as the liquid phase. The frequency accuracy is believed to be $\pm 2\ cm^{-1}$ for the sharp features. These tables also contain the qualitative relative intensities of the observed features. The intensities are relative within the same phase. The spectra shown in Figs. 1–3 were recorded under different vertical expansions for the purpose of clearer presentation.

The spectra of solid I are very similar to those of the liquid (Figs. 1–3). The main exception to the above is that the shoulder on the high frequency side of the ν_7 band of TBC-d_9, at around $527\ cm^{-1}$, shows a marked decrease in its intensity in solid phase I. The feature was assigned to an H-impurity in ref. 24 but the progressive decrease in its intensity with the lowering of the temperature suggests that this feature probably arises from a 'difference transition' of TBC-d_9 itself and not from any impurity. The transition from solid I to solid II does not produce any marked change in the bands due to the E modes (Fig. 2) but it does cause a sharp decrease in the halfwidths of the bands due to the A_1 modes (Fig. 1). Each of the A_1 modes shows a single band in the solid II phase. Additional very weak features seen near some of the A_1 bands are believed to be due to the combinations and/or overtones. The features assigned to ν_1 in TBC-d_0 and to ν_1 and ν_2 in TBC-d_9 also show considerable sharpening in going from solid phase I to phase II (Fig. 3) which thus supports their assignment to A_1 modes. Transition from solid II to III is accompanied by the splitting of the bands due to the well separated E modes into two sharp bands (Fig. 2) while the bands due to the A_1 modes show no such splitting. Further cooling to 90 K does not produce any new splitting, but it does sharpen the features. The sharpening of the bands due to cooling in the phase III is maximum for the bands due to the methyl (methyl-d_3) torsion vibrations. A similar behaviour was seen for the corresponding bands in the far-ir (14).

Discussion

All three phases of TBC are isotopically grossly disordered due to the occurrence of chlorine as two isotopes, ^{35}Cl and ^{37}Cl, in a ratio of about 3:1. The isotopic splitting due to the two chlorine isotopes can be of significance mainly for the bands due to ν_7, ν_8, and ν_{23} according to the isotopic studies on TBC (27). However, no splitting or broadening is seen in the spectra, even in the bands due to these modes at ~ 90 K, which can be associated with the presence of two chlorine isotopes (Figs. 1 and 2).

[a]Raman shifts ($\Delta\nu$) are in wave numbers (cm^{-1}) and are listed only for the spectral region of intramolecular fundamental vibrations. s, m, w, v, sh, and br stand for strong, medium, weak, very, shoulder, and broad, respectively.
[b]Liquid data are from ref. 24.
[c]Possible combinations with a lattice mode, see ref. 14 for lattice vibrations in TBC.

Therefore we have assumed that the system is within the 'amalgamation limit' (28), and that the spectra due to the intramolecular vibrations can be qualitatively treated as though the disorder in the masses of chlorine atoms was not present (21, 29).

Solid phase I of TBC has been shown to be plastic crystalline, and its X-ray diffraction data indicated that the molecules occupy sites of cubic symmetry even though the molecular symmetry is only C_{3v} (15). Nuclear magnetic resonance (11),

[a]Raman shifts ($\Delta\nu$) are in wave numbers (cm^{-1}) and are listed only for the spectral region of intramolecular fundamental vibrations.

dielectric (6, 7), and more recently neutron scattering studies (18) have shown that the molecules can undergo hindered reorientations about all possible axes at rates greater than $10^9\ s^{-1}$ in solid I. The similarity between the spectra of the liquid and solid phase I is in agreement with the above conclusions that there is no loss of reorientational freedom in going from the liquid to solid I. Similar conclusions have been drawn from the vibrational spectra of other plastic crystals (19, 20, 22, 30–34). The 'large' halfwidth of the vibrational bands of the plastic crystals has been attributed to the disorder in their structure as well as to the reorientational motions of the molecules (19, 20, 22, 34). Both the molecular reorientations and the disorder in the orientations of the molecules contribute to the observed breadth of Raman bands in solid I of TBC, as was shown also for the plastic crystal phase of *tert*-butyl bromide (19, 20), a very similar system. Although all Raman bands are quite broad in the liquid and plastic crystal phase, it can be seen from Figs. 1–3 that the bands due to the A_1 modes are less broad than the bands due to the E modes at the same temperature. This is consistent with the facts that

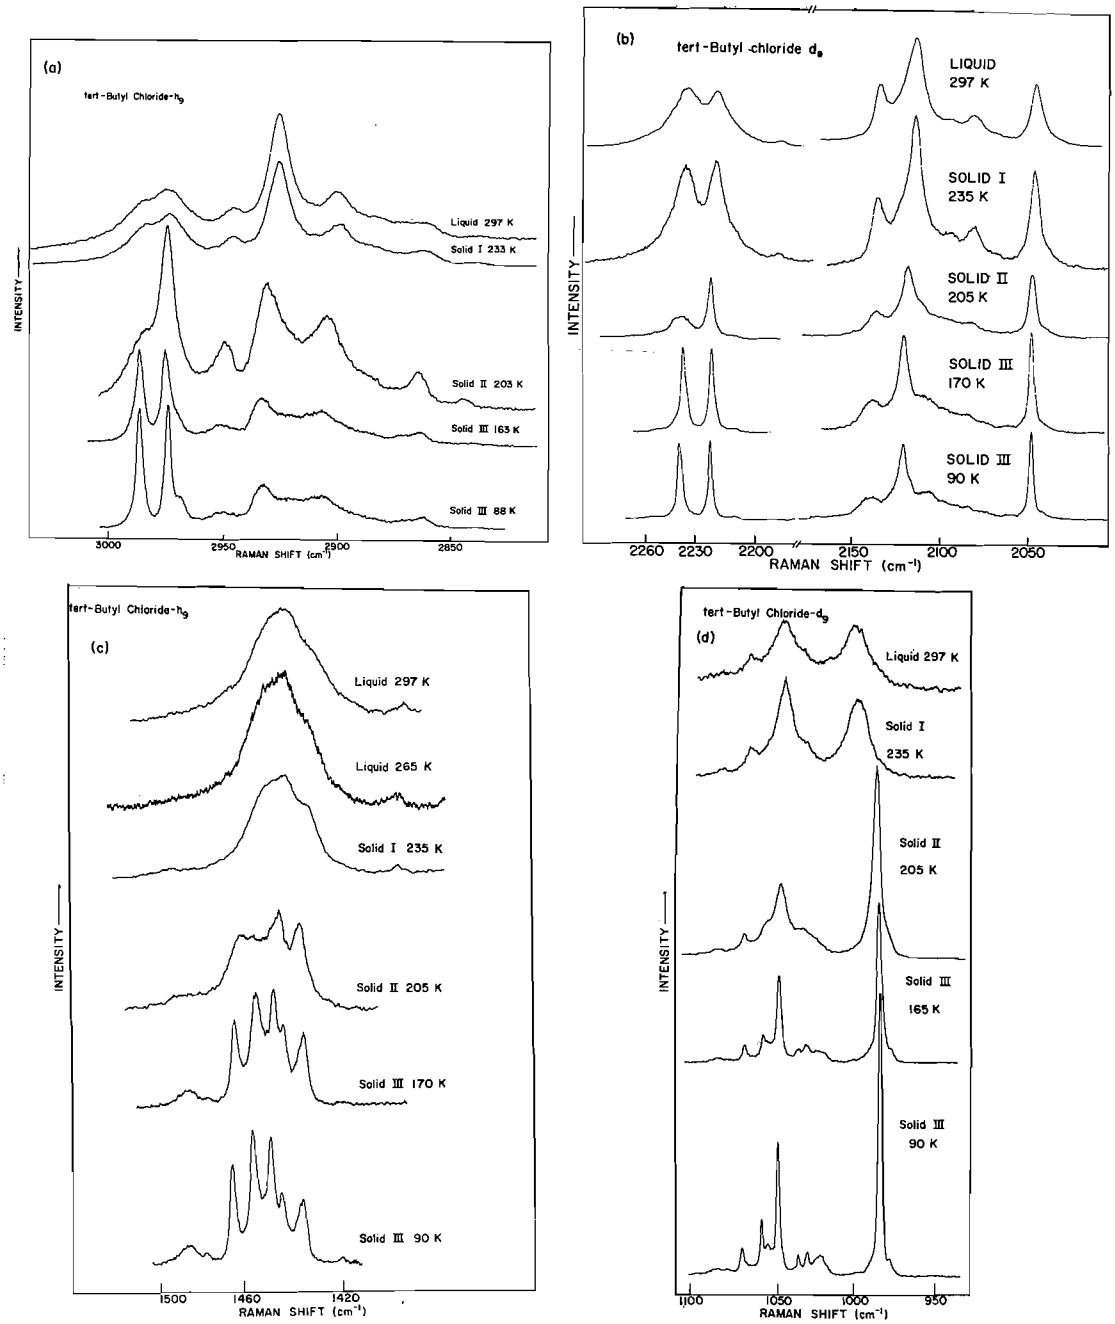

FIG. 3. Laser Raman spectra of the liquid and the three solid phases of *tert*-butyl chloride for the methyl (methyl-d_3) stretching and deformation regions using 4880 Å excitation: (*a*) CH_3 stretching vibrations in TBC-d_0; (*b*) CD_3 stretching vibrations in TBC-d_9; (*c*) CH_3 deformations in TBC-d_0; (*d*) CD_3 deformations in TBC-d_9.

(*a*) the reorientational motions of the molecules affect only the anisotropic part of Raman scattering, (*b*) the E mode bands are sensitive to both the tumbling motions of molecules (reorientations about the directions perpendicular to the molecular symmetry axis), and to the motions about the C_3 axis while the A_1 bands are sensitive only to the tumbling motions (34), and (*c*) the A_1 bands are polarized or partially polarized (24) and therefore the major contribution to their intensities is from the isotropic Raman scattering rather than the anisotropic Raman scattering.

The X-ray studies indicated that in solid phase II of TBC the dipolar axes of the molecules are ordered, but there is 'orientational disorder' about this axis (17). Sharp features seen for the A_1 modes (Fig. 1), and broad features seen for the E modes (Fig. 2) in the Raman spectra are consistent with these X-ray results. Similar spectral results have been obtained for other systems with similar partial orientational disorder, e.g. methyl ammonium halides (35) and *tert*-butyl bromide (19, 21). The sharpness of the features due to the A_1 modes suggests that the tumbling motion of the molecules in phase II indicated by the neutron scattering study, if present, is not able to affect the halfwidth of the A_1 bands to a significant extent.

The splitting of the bands due to the E modes into two sharp features in solid phase III (Fig. 2) suggests that the transition from phase II to III is accompanied by the ordering of the molecules in the directions perpendicular to the molecular symmetry (C_3) axes as well. The appearance of the bands due to the methyl torsion vibrations in the far-ir (14) and the Raman spectra at temperatures below the II–III transition temperature indicate that the methyl groups do not undergo 'free-rotation' in the solid phase III. At about 90 K, most of the observed features are quite sharp, indicating thereby that at this temperature the TBC lattice is not only fixed (10) but also *ordered*. The splitting of all the well-separated bands due to the E-modes into two sharp features while all the A_1 modes are showing only one feature indicates that the splitting of the E-modes is probably due to 'site-group-splitting'. This is possible only if the molecules are on sites of symmetry C_s or C_1 in solid III (19, 21). The 'absence' of 'factor-group-splitting' suggests that either there is only one molecule per 'unit-primitive-cell' or that the factor-group-splitting is less than the observed halfwidth of the bands, which at about 90 K is less than 3 cm^{-1} for most of the bands shown in Figs. 1 and 2. At present there are no published X-ray data about the structure of solid III to check the above conclusions (16).

Free energy relationship of the equilibrium ionization constants of disulfonyl carbon acids in 80% (w/w) dimethyl sulfoxide – water solvent at 25°C

THOMAS W. S. LEE AND KOK-PENG ANG

Department of Chemistry, University of Singapore, Bukit Timah Road, Singapore 10

Received September 27, 1978

THOMAS W. S. LEE and KOK-PENG ANG. Can. J. Chem. **57**, 853 (1979).

A series of eight carbon acids, α,α-bis(benzylsulfonyl)toluene and 7 substituted α,α-bis-(benzylsulfonyl)toluenes, was synthesized and their equilibrium ionization constants were determined by spectrophotometric measurement in 80% (w/w) dimethyl sulfoxide – water solvent at 25°C. From a plot of $-\log K$ versus σ for the 'well-behaved' substituents and σ^- for *para*-cyano and *para*-nitro substituents, a ρ value of 2.53 is obtained. The correlation coefficient is 0.99. Comparing this ρ value with the reported ρ value of 12 for the substituted toluenes in dimethyl sulfoxide, it shows that the acidities of the disulfonyl toluenes are at least 8 to 9 orders of magnitude less sensitive to substituent effects than are the acidities of substituted toluenes implying that, for disulfonyl toluenes, the negative charge on the benzylic carbon is extensively delocalised into the two adjacent sulfonyl groups.

THOMAS W. S. LEE et KOK-PENG ANG. Can. J. Chem. **57**, 853 (1979).

On a synthétisé une série d'acides comportant huit atomes de carbone, le α,α-bis-(benzylsulfonyl) toluène et 7 α,α-bis-(benzylsulfonyl) toluènes substitués et on a déterminé les constantes d'ionisation à l'équilibre par des mesures spectrophotométriques dans des solutions à 80% (p/p) de diméthylsulfoxyde dans l'eau à 25°C. A l'aide de la courbe de $-\log K$ versus σ dans le cas des substituants "se comportant bien" et σ^- pour les substituants *p*-cyano et *p*-nitro, on a pu obtenir une valeur de ρ de 2.53. Le coefficient de corrélation est 0.99. Une comparaison de cette valeur de ρ avec la valeur de ρ de 12 toluènes substitués en solution dans le diméthylsulfoxyde montre que les acidités des disulfonyltoluènes sont au moins 8 à 9 ordres de grandeur moins sensibles aux effets de substituants que les acidités des toluènes substitués; cette observation suggère que, dans les disulfonyltoluènes, la charge négative du carbone benzylique est fortement délocalisée par les deux groupes sulfonyles adjacents.

Introduction

Evidence for the acid-strengthening effect of sulfonyl group on the hydrogens attached to the α-carbon atom is compelling (1–6) but interpretation of the nature of this effect is not always unanimous. Some authors (1, 2, 5) have attributed the acidifying effect on the C—H to conjugative interaction between sulfur and the carbon atom presumably involving the sulfur *d*-orbitals while others (7, 8) have been skeptical of such an interaction.

The recent finding of Bordwell *et al.* (9) on the acidities of substituted toluenes has prompted us to report our results on the p*K* values and the Hammett plot of a series of substituted α,α-bis(benzylsulfonyl)-toluenes.

Experimental

Melting points were determined on a Thomas-Hoover capillary melting point apparatus. Microanalyses were performed by the Microanalytical Laboratory of the University. Infrared spectra were recorded on a Perkin-Elmer Model 337 spectrometer. Ultraviolet spectra were obtained on a Beckman DU-2 spectrophotometer coupled to a Hewlett-Packard 3465A multimeter for digital readout of the percentage transmission. Routine ^{1}H nmr spectra were recorded on a Perkin-Elmer R12B spectrometer with tetramethylsilane as internal standard.

Materials

Spectrophotometric grade dimethyl sulfoxide (Aldrich Chemical Co.) was used for preparing the solvent mixture. Buffer solutions were prepared from carbonate-free sodium hydroxide solution. Cresol red was purified according to the method of Baughman and Kreevoy (10).

Syntheses of bis(benzylsulfonyl)methane, **1**; α,α-bis(benzylsulfonyl)-*p*-xylene, **2**; α,α-bis(benzylsulfonyl)-*p*-fluorotoluene, **3**; α,α-bis(benzylsulfonyl)-*p*-chlorotoluene, **4**; α,α-bis(benzylsulfonyl)-*p*-bromotoluene, **5**; 4-[bis(benzylsulfonyl)-methyl]-benzonitrile, **7**; and α,α-bis(benzylsulfonyl)-*p*-nitrotoluene, **8** had been reported previously (6, 11).

α,α-Bis(benzylsulfonyl)-*m*-nitrotoluene, **6**, prepared by the same method as the *para* isomer: mp 214–215°C; ir ν_{max} (Nujol): 1320, 1150 cm^{-1} (SO_2); ^{1}H nmr (C_2D_6SO) δ 4.72, 4.88 (q, J = 13.8 Hz, 4H, benzylic H), 6.90 (s, 1H, CH), 7.40 (s, 10H, aromatic H), 7.68–8.50 (m, 4H, nitrophenyl H). *Anal.* calcd. for $C_{21}H_{19}NO_6S_2$: C 56.6, H 4.3, N 3.1, S 14.4; found: C 56.8, H 4.4, N 2.9, S 14.4.

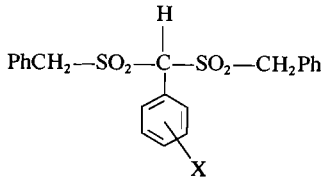
Spectrophotometric Measurements

All spectrophotometric measurements were made on triplicate solutions at 25°C using matched 1-cm silica cells. The temperature of the thermostated cell compartment was maintained at 25 ± 0.1°C and the temperature of the air-conditioned room was kept close to 25°C. The experimental details and methods of calculation of the p*K* values are given in ref. 6.

Results and Discussion

These disulfonyl carbon acids are all high-melting crystalline products with very low solubility in water. As a result, spectrophotometric measurements for uv

0008-4042/79/080853-03$01.00/0



1 X = H	**5** X = *p*-Br
2 = *p*-CH_3	**6** = *m*-NO_2
3 = *p*-F	**7** = *p*-CN
4 = *p*-Cl	**8** = *p*-NO_2

chromophores and p*K* values were all carried out in 80% (w/w) dimethyl sulfoxide – water solvent at 25°C.

Results of uv measurements of these compounds, in both acidic and anionic forms, are shown in Table 1. The equilibrium ionization constants of compounds **1** to **5** were determined by using the spectrophotometric indicator method (10, 12). Their p*K* values were calculated from the spectral data of cresol red indicator in buffer solutions containing a carbon acid and its salt. For compounds **6**, **7**, and **8**, their p*K* values were calculated from their spectral absorption data in acetate buffers (6). Each of these p*K* values, with a precision of ±0.02 p*K* unit, is an average of triplicate measurements at seven wavelengths near the λ_{max} of a chromophore; Table 2 gives a typical sample of the experimental data for compound **5**. The p*K* values of all the compounds studied are shown in Table 3.

A plot of these p*K* values against σ for the 'well-behaved' substituents and σ^- for *p*-cyano and *p*-nitro substituents yields a ρ value of 2.53 (Fig. 1). The correlation coefficient for the plot is 0.99 and the standard error is ±0.16. The need to use exalted substituent constants (σ^-) for *p*-cyano and *p*-nitro groups supports the expected effect of through conjugation between the benzylic carbanions and the two strongly electron-withdrawing substituents.

The ρ value of 2.53 for this plot is highly significant. It is remarkably low compared to the recently reported ρ value of 12 for the ionization of substituted toluenes in dimethyl sulfoxide at 25°C (9). Although it is reasonable to assume that our ρ value could have been slightly larger had it been determined in pure dimethyl sulfoxide (ρ value generally increases with less polar solvent because of decreasing degree of charge stabilization by solvation of the acid anion relative to the undissociated acid) (13), still the difference in the ρ values of the two systems would not likely be less than 8 or 9 units. The high sensitivity of the acidity of toluene to substituent effects was, in fact, long predicted by Dolman and Stewart (14) based on the argument that the equal electronegativity of the carbon atom at the reaction site and the carbon atoms of the aromatic ring permits extensive charge delocalization into the aryl ring of the benzylic anion. In view of this, it is apparent that the smaller charge density in the aryl ring of the disulfonyl benzylic anion, as evidenced by the much lower sensitivity of the acidity of disulfonyl toluene to substituent effects, must have been due to extensive electron withdrawal from the carbanion site by the two sulfonyl groups.

Although polarization and conformational con-

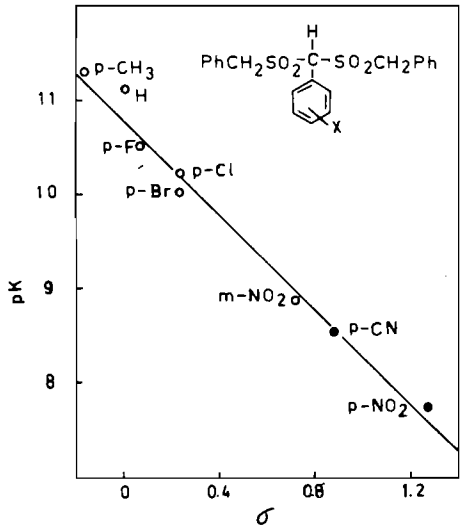

FIG. 1. pK values of disulfonyl toluenes vs. substituent constants: ○, σ values; ●, σ^- values.

straint may affect the charge distribution on the carbanion site, yet, without considering the conjugative effect it would be very difficult to justify the huge difference of over 28 pK units between the acidity of α,α-bis(benzylsulfonyl)toluene, **1** (pK = 11.1), and that of toluene (pK = 42) (9), assuming that the solvent effect is not likely to change the pK by more than 3 units (6).

In conclusion we believe that our results on the equilibrium ionizations of these disulfonyl carbon acids have quantitatively provided a strong evidence for the conjugative effect of sulfonyl group and this evidence is certainly in line with that of Bordwell *et al.* (5) who, based on the polar effect of trimethylammonio group $N(CH_3)_3^+$, suggested that the acidifying effect of sulfonyl group caused by polarization was small compared to that caused by conjugative interaction.

Salt desorption from surfaces of non-aqueous solvents

ROBERT AVEYARD AND YVONNE THOMPSON

Department of Chemistry, The University of Hull, Hull, England HU6 7RX

Received August 8, 1978

ROBERT AVEYARD and YVONNE THOMPSON. Can. J. Chem. **57**, 856 (1979).

Following previous studies of the desorption of salts from the surface of water, the desorption of several salts from various non-aqueous solvents has been investigated. Three protic and 3 dipolar-aprotic liquids were used. The surface properties of the solvents in the absence of electrolytes are discussed and it is observed that the molar excess surface entropies of the aprotic solvents are more positive than those of the protic solvents. Salt desorption, determined from measurements of surface tension, is discussed in terms of purely electrostatic models, and also ion solvation. The extent of salt desorption in systems where strong ion solvation exists is related to the thickness of the primary solvation sheath around the ions. In the present context water does not behave as an anomalous solvent but in a way similar to the other protic solvents.

ROBERT AVEYARD et YVONNE THOMPSON. Can. J. Chem. **57**, 856 (1979).

Suite à des études antérieures concernant la désorbtion de sels de la surface de l'eau, on a étudié la désorbtion de plusieurs sels de divers solvants non aqueux. On a utilisé trois liquides protiques et 3 liquides dipolaires aprotiques. On discute des propriétés superficielles des solvants en l'absence d'électrolytes et on observe que les entropies molaires de surface en excès dans le cas des solvants aprotiques sont plus positives que celles des solvants protiques. On discute de la désorbtion des sels, déterminée à partir de mesures de tensions superficielles, ainsi que de la solvation des ions, en termes de modèles strictement électrostatiques. Le taux de désorbtion des sels dans des systèmes où il existe une forte solvatation ionique est relié à l'épaisseur de la première couche de solvatation autour de ces ions. Dans le contexte actuel, l'eau ne se comporte pas d'une façon anormale mais plutôt d'une façon semblable à celle des autres solvants protiques.

Introduction

We have previously investigated the desorption of simple inorganic salts in aqueous solutions from both air–water and organic liquid – water interfaces in connection with a study of salt effects on non-ionic materials at interfaces (1–3). The present investigation is concerned with desorption of electrolytes from the surfaces of the organic solvents methanol, formamide, *N*-methylformamide, *N*,*N*-dimethylformamide, dimethylsulphoxide, and propylene carbonate. The salts studied are LiCl, LiBr, LiI, NaI, and KI. The choice of these systems has allowed us to consider the effects on desorption of ion solvation, and of changing the dielectric constant of the solvent from less than half to more than double that of water. A considerable interest in the physical chemistry of non-aqueous electrolyte solutions has grown up in recent years (4). Apart from providing a general insight, this has furnished some of the thermodynamic data necessary for a useful surface-chemical study of the solutions. The present work points the way to future investigations, which should prove to be an interesting facet of the study of non-aqueous solvents in general.

We note that a fair amount of work has previously been reported on non-aqueous electrolyte solutions in contact with liquid mercury (5, 6).

Experimental

Materials

Dimethylsulphoxide (DMSO), dimethylformamide (DMF), *N*-methylformamide (NMF), and propylene carbonate (PC) were all Aldrich (England) samples of greater than 99% purity, and the formamide (F), a BDH (England) sample, also had a minimum purity of 99%. DMSO, which had a water content as determined by nmr of 0.07 wt% (0.3 mol%) was used untreated. The DMF, which as supplied contained 0.58 wt% water, was stored over P_2O_5 for 3 days and distilled under a reduced pressure of N_2, and the final water content was 0.2 mol%. As bought, PC had a water content of 0.42 wt% which was reduced to undetectable levels by distillation at 76°C under a low pressure of N_2. NMF was allowed to stand over P_2O_5 for 48 h and then distilled at 94°C under N_2; no water was detectable in the final product. Molecular sieve 5A was used to dry F, which was subsequently distilled under N_2 at 116°C, and the distillate contained no detectable water. Finally, a pure sample of methanol (M) was prepared from "puriss" grade material by refluxing with I_2 and Mg and distilling at atmospheric pressure. The surface tension and density of each of the samples are listed in Table 1 together with reliable literature values, where available.

Lithium chloride, NaI, and KI, all AnalaR samples, were heated for 48 h in silica containers at 450°C and stored in a desiccator. Anhydrous LiBr and LiI (both 99+% pure) were from Alfa Products (U.S.A.) and were used without further treatment.

Measurement of Surface Tension

The drop-volume technique was used as described elsewhere (1), with the exception that the thermostatted tube housing the barrel of the drop-volume apparatus was initially purged with

*γ_0 in mN m^{-1}, ρ in g cm^{-3}; literature values of ρ taken from the compilation on p. 5 of ref. 4. Of the literature values of γ_0 for F, that given in ref. 10 is probably the more nearly correct since the sample was highly purified.

dry N_2 and then during measurements a steady stream of dry N_2 was passed. All solutions were prepared in a polythene glove bag (I2R, U.S.A.) filled with dry N_2. Surface tensions were reproducible to better than 0.1%.

The necessary densities, ρ, were determined to within $\pm 2 \times 10^{-4}$ g cm^{-3} using a 25 cm^3 density bottle. Densities of salt solutions were in all cases linear functions of salt molality, m_2, and densities were frequently interpolated from plots of ρ against m_2.

Results and Discussion

Surfaces of Pure Solvents

One of several factors which can influence the desorption of salts at liquid surfaces is the surface 'structuring' of the solvent. The solvents employed here all have high dielectric constants (>30) and can be classified as either protic or dipolar aprotic liquids. The surface tension, γ_0, of a solvent tells us little about the nature of that solvent in that both protic and aprotic solvents can have high or low surface tensions. Since we are concerned with the ordering of surface solvent molecules, 'surface entropies' are of more potential interest than γ_0. The excess surface entropy per unit area, s^σ, of a solvent is given by

$$[1] \qquad s^\sigma = -\mathrm{d}\gamma_0/\mathrm{d}T = s^s - \Gamma S_m$$

where s^s is the total entropy of the material (Γ moles) in unit area of surface, and S_m is the molar entropy of solvent in bulk. We have, where necessary, determined γ_0 as a function of T, the absolute temperature in the range 293 to 303 K (Table 2) and the (constant) values of s^σ are given in Table 3, together with s^σ for sulpholane (S), acetone (A), and ethylene glycol (EG) obtained from literature values of γ_0. As with γ_0, there is no obvious correlation between s^σ and solvent type. However, as a result of the different molecular sizes Γ varies from solvent to solvent. Assuming that the surface layer of solvent is monomolecular, we can calculate from the molar volume V_m of the liquid an approximate partial molar surface area, σ_m, and hence a *molar* surface excess entropy S_m^σ using

$$\sigma_m \simeq N_A^{1/3} V_m^{2/3}; \; S_m^\sigma = s^\sigma \sigma_m$$

where N_A is the Avogadro constant.

The quantity S_m^σ, which is the difference between the molar entropies of solvent in bulk and surface,

*Entropies obtained in the range 20 to 30°C except for sulpholane which is for 30 to 60°C, and methanol which is for 20 to 50°C. Values for M, EG, W, F, S, and A were obtained from γ_0 values reported in, respectively, refs. 11, 1, 12 ,10, 13, and 8.

is seen to be positive in all cases (Table 3). It is more positive for aprotic solvents as a group (between 16 and 18 J mol^{-1} K^{-1}) than for protic solvents (between 7 and 12 J mol^{-1} K^{-1}). Since protic solvents are probably more "structured" in bulk than are aprotic liquids (14) it seems likely that the surfaces of the protic solvents are more "structured" in an absolute sense than those of aprotic solvents.

The above arguments are not rigorous since, *inter alia*, we have assumed that the surface region is confined to a monolayer of solvent. More importantly we cannot deduce from thermodynamic data alone what form a "structured" surface will take. The most widely studied interface is that between air and water, and there now appears to be a consensus of opinion that the H-atoms of surface water molecules on average face the liquid phase, although the extent of orientation is not agreed. Surface potentials, $\Delta\chi$, of aqueous 1,1-electrolytes suggest that often, solvated anions approach the surface more closely than do cations, as might be expected from the direction of orientation of surface water. In the case of water then, information concerning the state of interfacial solvent, ion solvation in bulk, and surface potentials taken together furnishes a reasonable picture of the observed salt desorption (1). It will not be possible at present to use information regarding surface structure in non-aqueous solvents in this way since $\Delta\chi$ values for the relevant salt solutions are not available. As well as aiding in the understanding of salt desorption, however, surface potentials could be used in conjunction with desorption data to throw light upon the orientation of surface solvent. This remains an interesting possibility for the future.

General Observations of Salt Effects on Surface Tension

In all the systems investigated surface tension, γ, is, within experimental error, a linear function of salt molality, m_2.[1] Results have been fitted by the method of least-squares to

$$[2] \qquad \gamma = A + Bm_2$$

and the values of B (with rms errors) and of A are recorded in Table 4. Experimental points fall within ± 0.04 mN m^{-1} of the fitted lines except for γ_0 for the system LiCl/DMSO; in this case A differs from γ_0 by 0.06 mN m^{-1} which could mean that the initial slope of γ versus m_2 (below $m_2 \simeq 0.025$ mol kg^{-1}) is greater than the recorded value of B. The results for KI in PC are the least reliable since these were confined to $m_2 < 0.15$ mol kg^{-1} as a result of the low salt solubility. The most extensive results are those for LiCl in DMSO and in DMF.

The extent of salt desorption from concentrated solutions, and hence the increase in γ, depends on various factors in a complicated way. The solvation of ions and degree of ion association, which together are reflected in the electrolyte activity coefficients, are of obvious importance. One might also expect the solvent dielectric constant, and surface structure to play a role in the desorption. These factors will be discussed later, but in view of all this it is surprising that γ should be an apparently linear function of m_2. As might be expected, however, B values for a given salt (LiCl) in a series of solvents are not simply related to solvent type or to solvent properties such as dielectric constant, dipole moment, molecular size, or surface tension.

Application of Electrostatic Theory for Low Salt Concentrations

Theories based on the Coulombic repulsion of ions from the interface between two dielectrics give the limiting law for the variation of γ with concentration at high dilution. Our present results are for concentrated solutions but since γ varies linearly with m_2 for $m_2 \simeq 0.02$ mol kg^{-1} upwards, it is worthwhile to compare the predicted increments in γ with our experimental results. It should be remembered, however, that for a strictly valid comparison, experimental results for very low concentrations would be required.

Consider the interface between dielectrics α and β with dielectric constants ε_α and ε_β. A particle, carrying a charge e, in phase α and at a normal distance x from the interface, is repelled from that interface as if by a charge e' (the image charge) at a distance $2x$ in a medium of uniform dielectric constant ε_α. The image charge is given by $e' = e\lambda$ where

$$\lambda = (\varepsilon_\alpha - \varepsilon_\beta)/(\varepsilon_\alpha + \varepsilon_\beta)$$

In purely electrostatic theories of salt desorption (15) the electrolyte is supposed to consist of point charges, and each of the dielectrics is treated as a continuum. On this basis Bellemans (16) obtained the equation, written here for a 1,1-electrolyte,

$$[3] \quad \Delta\gamma = -\frac{69.38c_2}{\varepsilon_\alpha}\left\{\lambda \ln\left[\frac{4.20 \times 10^6 \lambda c_2^{1/2}}{(\varepsilon_\alpha T)^{3/2}}\right] - 0.35\lambda - (1+\lambda)\left[\ln 2 - \frac{1+\lambda}{2\lambda}\ln(1+\lambda)\right]\right\}$$

in which $\Delta\gamma = \gamma - \gamma_0$, and c_2 is the molarity (mol dm^{-3}) of salt and γ is in mN m^{-1}. For the case where $\varepsilon_\beta \simeq 1$ and $\varepsilon_\alpha \gg 1$ (i.e. $\lambda \simeq 1$), [3] reduces to the limiting form, given previously by Onsager and

[1]Data on surface tension are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Samaras (17),

$$[4]\quad \Delta\gamma = \frac{79.9}{\varepsilon_\alpha} c_2 \log \left\{ \frac{1.141 \times 10^{-13} (\varepsilon_\alpha T)^3}{c_2} \right\}$$

Equations [3] and [4] give differing values of $\Delta\gamma$ for the liquid/vapour interface ($\varepsilon_\beta = 1$), at higher concentrations ($c_2 > 10^{-2}$ mol dm^{-3}) and lower ε_α (<50). For $c_2 \gtrsim 0.01$ mol dm^{-3}, however, the predicted $\Delta\gamma$ are essentially equal for all ε_α relevant to the present study.

The comparisons between the theoretical $\Delta\gamma$ and $\Delta\gamma$ computed from values of B (Table 4) are shown in Fig. 1 for DMSO, F, NMF, and water (W). The agreement is surprisingly good for NMF, which has the highest ε_α (182) of the solvents studied, and quite reasonable, i.e. well within a factor of 2, for F ($\varepsilon_\alpha = 110$), W ($\varepsilon_\alpha = 78$), and DMSO ($\varepsilon_\alpha = 47$). For M ($\varepsilon_\alpha = 33$) and DMF ($\varepsilon_\alpha = 37$) the agreement, although less satisfactory, is still within a factor of 2 for $c_2 = 0.05$ mol dm^{-3}.

The equations, however, cannot be expected to hold for the more concentrated systems which have been the main concern in this work, and we now consider the results for solutions up to concentrations of 1 mol kg^{-1}.

The Surface Excess of Salts in Concentrated Solutions

The extent of salt desorption can be expressed in terms of the surface excess of salt Γ_2^σ. For a 1,1-electrolyte, A^+B^-, the Gibbs equation may be expressed (17) as

$$[5]\quad \Gamma_{A^+}{}^\sigma = \Gamma_{B^-}{}^\sigma = \Gamma_2{}^\sigma = -\frac{1}{2RT}\left(\frac{d\gamma}{d \ln a_\pm}\right)$$

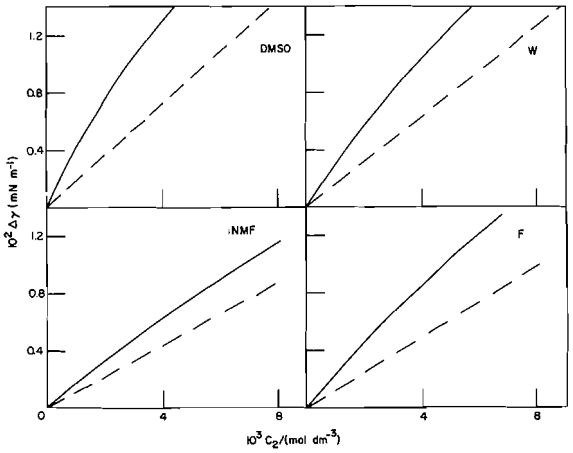

FIG. 1. Theoretical (full lines) and experimental (interpolated, see text) $\Delta\gamma$.

where the Γ^σ are surface excesses relative to a Gibbs dividing surface for which the excess of solvent is zero, and $a_\pm$ is the mean ionic activity of the salt. The availability of (molal) activity coefficients in the literature (4) was one of the main constraints on the choice of systems for study.

In Fig. 2 we have plotted surface tension increments, $\Delta\gamma$, against $-\ln a_\pm$ for LiCl in various solvents, including W (from ref. 1) for comparison. It is apparent that the $\Gamma_2{}^\sigma$ values are all negative, and vary with concentration. To compare behaviour it is necessary to choose a fixed (arbitrary) concentration, and we list in Table 5 values of $\Gamma_2{}^\sigma$ for $m_2 = 0.25$ mol kg^{-1}.

The most striking observation is that for LiCl, the desorption is stronger for the aprotic solvents (DMF

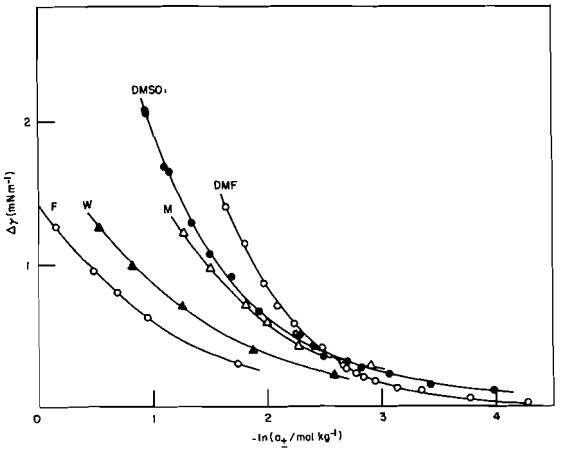

FIG. 2. Surface tension increments as a function of $-\ln a_{\pm}$ at 25°C for LiCl in various solvents.

and DMSO) than for the 3 protic solvents. In a simple picture it might be expected that the more strongly solvated an ion the more strongly it will be desorbed. However, it is known (14) that although Li^+ is similarly strongly solvated in all 5 solvents, Cl^- is much more strongly solvated in the protic solvents, where the desorption is small, than in the aprotic solvents.

A further observation is that the desorption of LiX (X = Cl^-, Br^-, I^-) from DMSO is similarly strong for all three halides although the halide ions are all weakly solvated in this solvent. It is possible that this arises from a preferential orientation of DMSO at the surface with the negative poles (O atoms) on average pointing into the bulk liquid and thus repelling anions from the surface. This however is purely speculative. We do not have at present any explanation of the order of desorption from PC of LiI and NaI; Li^+ is very much more strongly solvated by PC than is Na^+.

*Result not given for LiCl/NMF since activity coefficients not available.
†Obtained using results in ref. 1.
‡Obtained using activity coefficients for freezing point (≃2.5°C).

In order to gain a clearer insight into some of the above findings we now consider a more specific model for the desorption process.

The Ion-free Layer Approach to Desorption

Strongly solvated ions will approach a surface with their primary solvation layers intact. To a first approximation, therefore, we may assume in such cases that the ions meet an infinite potential barrier close to the surface, and that there is an ion-free layer of solvent, thickness δ, at the surface. For univalent ions δ is expected to be of the order of the diameter of a solvent molecule. This model, which is discussed elsewhere, leads to the form of the Gibbs equation (1, 18, 19),

$$[6] \qquad -d\gamma = c_1\delta d\mu_1$$

where c_1 is the concentration in mol vol^{-1}, subscript 1 refers to solvent, and μ is the chemical potential. The molal osmotic coefficient, φ, of a solution of 1,1-electrolyte is defined by (20)

$$[7] \qquad \ln a_1 = -2m_2M_1\phi$$

where M_1 is the molar mass (kg mol^{-1}) of solvent. Combination of eqs. [6] and [7] gives

$$[8] \qquad d\gamma = (2c_1\delta RTM_1)d(m_2\phi)$$

Noting that $c_1M_1 \simeq \rho_0$, the density of the solvent, δ is given to a reasonable approximation by

$$[9] \qquad \delta \simeq [d\gamma/d(m_2\phi)]/[2\rho_0RT]$$

Osmotic coefficients are not directly available for the systems of present interest and so have been obtained by graphical integration using the expression (20)

$$[10] \qquad \phi = 1 + m_2^{-1}\int_{m_2=0}^{m_2} m_2\, d\ln\gamma_{\pm}$$

and the mean molal activity coefficients, $\gamma_{\pm}$, given in the compilations of ref. 4. In the case of LiCl in DMF it was necessary to interpolate values of $\gamma_{\pm}$ for intermediate m_2 by the use of the equation (21)

$$[11] \qquad \ln\gamma_{\pm} + Am_2^{1/2}/(1 + m_2^{1/2}) = 2\beta m_2$$

where A = 3.572 for DMF at 25°C, and β is a constant. For LiI in PC the data were not available for the above analysis but over the concentration range of present interest ($0.05 < m_2 < 0.3$) $\gamma_{\pm}$ in this system is fairly constant (0.75 ± 0.02). For constant $\gamma_{\pm}$ it is readily shown from eq. [6] that

$$[12] \qquad \delta = (2\rho_0RT)^{-1}(d\gamma/dm_2)$$

Equation [12] has also been used to obtain a rough estimate of δ for LiCl in F where $\gamma_{\pm}$ is only available at the freezing point (≃ 2.5°C). It must be remarked

TABLE 6. Ion-free layer thickness δ and related parameters*

	Value							
	LiCl					LiI		LiBr
Parameter	DMSO	DMF	M	W	F	DMSO	PC	DMSO
δ	0.46	0.45	0.31	0.32	0.3	0.42	0.18	0.53
σ_{L-J}	0.51	0.52	0.37	0.28	0.38	0.51	0.52	0.51
r^+	0.43	0.42	0.38	0.28	0.35	0.43	(0.35)†	0.43
r^-	0.18	0.14	0.26	—	0.15	0.14	—	0.16

*All values in nm.
†The value listed is the uncorrected Stokes radius, which will be less than r^+.

in this case that for m_2 between 0.2 and 1 mol kg^{-1}, $\gamma_\pm$ varies between 0.94 and 1.11 and so the value of δ can only be taken as a very rough guide. Activity coefficients are not available at the required concentrations for LiCl in NMF, and our results for KI in PC extend only up to $m_2 \simeq 0.15$ mol kg^{-1} and are unsuitable for use in the above analysis.

Plots of $\Delta\gamma$ against $m_2\phi$ are shown for some of the systems investigated in Fig. 3 and good linearity is observed indicating the constancy of δ, values of which are given in Table 6. In some cases, the plots do not pass through the origin (e.g., LiCl in DMSO and in M as seen in Fig. 3) and it likely that δ values for low m_2 (<0.05 mol kg^{-1}) are somewhat larger than those given in Table 6. A similar situation is known to exist for various aqueous electrolytes (22).

Values of δ are now compared with quantities related to the size of solvent molecules. A reasonable measure of solvent molecule diameter is the Lennard-Jones σ parameter, σ_{L-J}, values of which (23) are given in Table 6. There is a very reasonable correspondence between δ and σ_{L-J} except in the case of LiI in PC, where it is known that I^- is only very weakly solvated and (relative to Li^+ in W) Li^+ is also weakly solvated (14).

The comparison of δ and σ_{L-J} makes no direct reference to any differences which exist between anions and cations. Perhaps a more informative approach is to compare δ with the solvodynamic radii of the ions. For all the systems represented in Table 6, except Li^+ and I^- in PC, and Cl^- in W, corrected Stokes radii, $r_s^\pm$, for anions and cations are available. If the crystallographic radius, $r_c^\pm$, is subtracted from $r_s^\pm$, an estimate is obtained for the thickness of the solvation sheath immediately surrounding an ion. The quantity $r_s^\pm - r_c^\pm$ is written in $r^\pm$ in Table 6; the values of Gourary and Adrian (24) were used for $r_c^\pm$, and the corrected Stokes radii were taken from refs. 20, 25, and 26.

The similarity between δ and r^+ is obvious; r^- is always considerably smaller than r^+. It appears then that for both the protic and the aprotic solvents it is the cation that is largely responsible for the extent

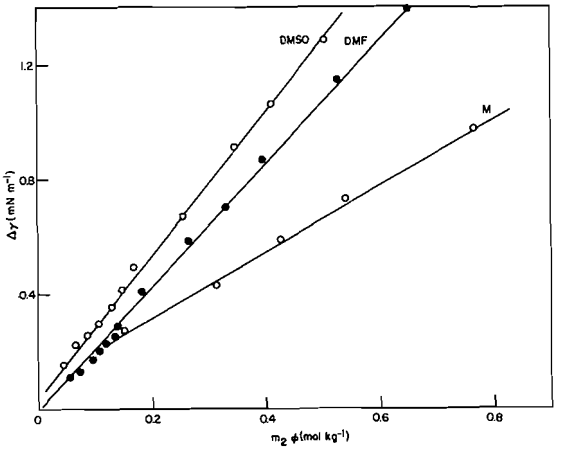

FIG. 3. Plots according to eq. [8] for LiCl in three solvents.

of salt desorption. The high Γ_2^σ (Table 5) for aprotic solvents is seen to result from the large molecular diameter of these liquids. Judging from the δ values the anions (with the exception of I in PC), though relatively weakly solvated, do not approach the surface significantly more closely than the cations. We have suggested earlier the possibility of a surface orientation of DMSO with the negative poles to the liquid phase; DMF is similar to DMSO in that the positive pole is shielded by 2 methyl groups, and it may also be oriented with the negative poles on average pointing into the liquid. There is evidence (27) that this is the orientation assumed by surface molecules of M. Water, however, is known to have the opposite orientation and so would not have the tendency to repel anions from the surface. Surface potentials indicate that halide ions do in fact approach the water surface more closely than do alkali metal cations, but in the case of LiCl, for which δ = 0.32 nm, we do not expect the segregation of anions and cations normal to the surface to be very great.

Conclusions

(*1*) The molar excess surface entropies of the protic solvents investigated are less positive than those of

the aprotic solvents. The results are consistent with the presence of a more highly structured surface layer in the protic solvents.

(*2*) There is no obvious correlation between the (constant) values of $d\gamma/dm_2$ for LiCl in various solvents, and the physical properties of these solvents.

(*3*) The electrostatic theories of Onsager and Samaras, and Bellemans, give reasonably good agreement with the (assumed) low concentration surface tension increments caused by the 1,1-electrolytes. The agreement is better for the solvents with the higher dielectric constants.

(*4*) The desorption of LiCl is smaller from the protic than from the aprotic solvents. This appears to result from the smaller molecular size of the former solvents as a group. The ion free layer thicknesses are comparable in most cases to the thickness of the cation primary solvation sheath and to the solvent molecular diameters.

(*5*) A very useful further insight into salt desorption in non-aqueous systems could be gained from surface potential measurements.

Photolyse du méthyl-2-butène-1, du méthyl-3-butène-1 et du *cis*-pentène-2 à 174, 163 et 147 nm

GUY J. COLLIN,[1] HÉLÈNE DESLAURIERS ET SYLVAIN AUCLAIR
Département des Sciences Pures, Université du Québec à Chicoutimi, Chicoutimi (Qué.), Canada G7H 2B1

Reçu le 30 octobre 1978

GUY J. COLLIN, HÉLÈNE DESLAURIERS et SYLVAIN AUCLAIR. Can. J. Chem. **57**, 863 (1979).

L'étude de la photolyse du méthyl-2-butène-1 (M2B1), du *cis*-pentène-2 (CP2) et du méthyl-3-butène-1 (M3B1) a été faite systématiquement à 163 nm, et l'effet de pression a été mesuré à la fois à 147, 163 et 174 nm. On observe que le processus majeur de fragmentation de ces trois oléfines est la rupture de la liaison C—C située en position β par rapport à la double liaison: $\Phi \simeq 0.9 \pm 0.1$. Le radical α-méthallyle obtenu dans le cas du M3B1 et du CP2 se fragmente partiellement à basse pression en butadiène-1,3 et en atome d'hydrogène. Le radical β-méthallyle produit lors de la photolyse du M2B1 se fragmente en allène et en un radical méthyle. Les rendements en butadiène-1,3 et en allène suivent la relation linéaire de type Stern–Volmer. Cela permet de déduire le rapport des constantes de dissociation et de stabilisation par collision, k_d/k_s, des radicaux α-méthallyles et β-méthallyles. On en conclut que la distribution de l'excès d'énergie du photon dans les fragments suit une (des) loi(s) particulière(s), cette loi n'étant pas statistique.

GUY J. COLLIN, HÉLÈNE DESLAURIERS, and SYLVAIN AUCLAIR. Can. J. Chem. **57**, 863 (1979).

Photolysis of 2-methyl-1-butene (M2B1), *cis*-2-pentene (CP2), and 3-methyl-1-butene (M3B1) has been systematically studied at 163 nm. Pressure effect has been measured at 147, 163, and 174 nm. The main fragmentation process of the photoexcited olefine is the C—C split of the bond located in position β relative to the double bond: $\Phi \simeq 0.9 \pm 0.1$. α-Methallyl radicals obtained in the M3B1 and CP2 photolysis decompose partly at low pressure, giving rise to the formation of 1,3-butadiene and hydrogen atoms. β-Methallyl radicals decompose also at low pressure into allene and methyl radicals. Butadiene and allene quantum yields follow the Stern–Volmer law, and this allows us to determine the ratio of the rate constant of dissociation relative to the rate constant of stabilization, k_d/k_s, through collision of the α- and β-methallyl radicals. From these values, we conclude that the excess of photon energy is not statistically distributed into the fragments, and that the decomposition process follows one (or several) particular law(s).

Introduction

Nous avons récemment étudié la photolyse des différents butènes vers 174 et vers 163 nm (1). La diversité des molécules étudiées n'a pas permis d'extraire le comportement général des oléfines photoexcitées dans ce domaine, bien que les travaux obtenus en photolyse éclair par d'autres laboratoires montrent l'importance quantitative de la scission des liaisons situées en position β par rapport à la double liaison (2, 3). Nous avons étendu nos précédentes études au méthyl-3-butène-1 (M3B1), *cis*-pentène-2 (CP2) et méthyl-2-butène-1 (M2B1), hydrocarbures qui possèdent chacun une liaison C—C en position β par rapport à la double liaison. En outre, nous sommes évidemment intéressés à connaître le comportement chimique des radicaux allyliques provenant de la scission de cette liaison. L'existence de certains radicaux a été éliminée lors de la photolyse des butènes (1). Nous présenterons ici des arguments définitifs qui justifient cette élimination.

[1]Auteur auquel toute correspondance devrait être envoyée.

Méthode expérimentale

Les méthodes expérimentales ont été largement décrites dans la littérature (1). C'est le cas des lampes d'irradiation au xénon (8.4 eV, 147 nm) (4), au brome (7.6 eV, 163 nm) (1*d*) ainsi que celle à l'azote (7.1 eV, 174 nm) (1*b*). L'origine et la préparation des échantillons a elle aussi été rapportée. Nous y avons apporté une modification quant à l'usage de l'iodure d'hydrogène et du sulfure d'hydrogène en utilisant les produits perdeutériés (Merck, Sharp and Dohme of Canada) car ils présentent une pureté moléculaire beaucoup plus grande que les produits commerciaux perhydrogénés correspondants. Etant donnée l'importance de la précision quant à la mesure des rendements quantiques dans l'établissement des courbes de type Stern–Volmer (voir plus loin), l'actinométrie dans ces cas a été faite de la façon suivante: dans chacun des cas, et ce chaque jour où ont été faites ces mesures, une irradiation du *cis*-butène-2 pur (133 N m^{-2}) a été faite au début et à la fin de la journée. Les photolyses des oléfines en C_5 faites en cours de journée ont été comparées à ces deux photolyses témoins (1*b*, *c*). En règle générale, la stabilité des lampes, ainsi que le positionnement de la lampe dans la cavité microonde maintient une fluctuation du débit de lampe inférieure à 5%.

Résultats

Les résultats sont indiqués dans les tableaux et les

0008-4042/79/080863-07$01.00/0

figures qui accompagnent le texte. Ils sont indiqués sous forme de rendements quantiques.

Cas du méthyl-2-butène-1 (M2B1) à 163.3 nm

Les produits majeurs obtenus dans la photolyse du produit pur sont l'éthane ($\Phi \geq 0.27$), l'allène ($\Phi \leq 0.16$), le méthane ($\Phi \leq 0.14$) ainsi qu'un certain nombre de produits qui apparaissent en quantités mineures ($\Phi \leq 0.05$) (tableau 1). En présence d'oxygène (10%), les rendements s'amenuisent: l'éthane, l'isobutane et le diméthyl-2,2-butane disparaissent. On a également indiqué dans le tableau 1 l'effet du D_2S ou de DI sur certains produits. Il faut ajouter en outre qu'en présence d'oxygène le rendement en méthane est constant entre 60 et 6600 N m^{-2}: $\Phi(CH_4) = 0.012 \pm 0.003$. L'addition de D_2S montre un rendement en isopentane de 0.18 ± 0.05 et en méthane de 1.5 ± 0.1. Finalement l'addition de DI ne donne pas de valeurs reproductibles. On note cependant une augmentation du rendement en méthane: $0.2 \leq \Phi_{DI}(CH_4) \leq 0.9$, en butène-2: $0.06 \leq \Phi_{DI}(C_4H_8\text{-}2) \leq 0.76$, dépendant de la pression totale du réacteur (133–7050 N m^{-2}) et du pourcentage moléculaire de DI. L'habileté qu'ont les atomes d'iode de réagir avec les oléfines (5) semble responsable de la disparition (?) du DI avant la fin de l'irradiation. On a noté en effet une isomérisation importante du M2B1 (6). A la fin de la photolyse de ces mélanges 40% de l'oléfine pouvait être isomérisée en méthyl-2-butène-2.

Finalement l'effet de pression observé est surtout important sur l'allène (fig. 1). Le tableau 1 montre un effet de pression qui semble présent sur plusieurs produits d'origine radicalaire. C'est le cas du méthane, de l'éthane, etc. Par contre les rendements en éthylène, propène et propyne ne sont pas ou peu affectés par l'augmentation de pression.

TABLEAU 1. Photolyse du méthyl-2-butène-1 pur à 163 nm[a]: rendements quantiques

Pression (N m^{-2})	12	133	1330	10 600
CH_4	0.040	0.058	0.095	0.14

[f]Produits peu ou pas affectés par la présence de DI ou de D_2S.

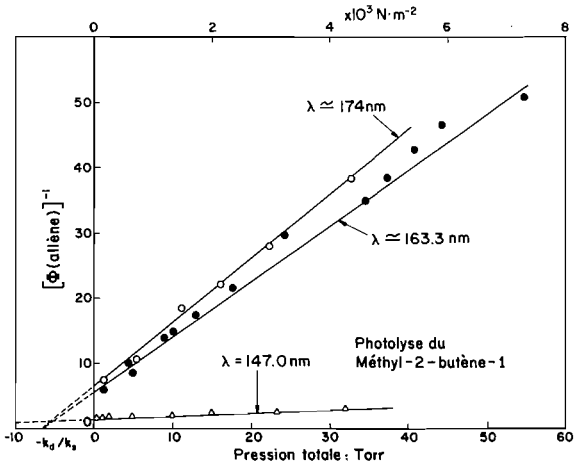

FIG. 1. Photolyse du méthyl-2-butène-1. Inverse du rendement quantique de l'allène en fonction de la pression à diverses longueurs d'onde.

Cas du méthyl-3-butène-1 (M3B1) à 163.3 nm

Les tableaux 2 et 3 résument les rendements quantiques des produits obtenus. Le comportement de ces rendements en présence d'additifs est similaire à celui déjà rapporté pour le M2B1. Par contre, on a eu ici aucune difficulté dans l'usage de DI comme intercepteur radicalaire. Tout au plus a-t-on observé une isomérisation marginale de l'oléfine. De l'accroissement des rendements en méthane et en isopentane, on a déduit facilement le rendement des radicaux CH_3 et C_5H_{11} en tenant compte de la réaction (7):

[1] $\quad R + XD \rightarrow RD + X \quad$ (où X = DS ou I)

Donc $\Phi(CH_3) \simeq 1.4$ et $\Phi(C_5H_{11}) \simeq 0.4$ à 133 N m^{-2}. De la même façon on peut déduire le rendement

TABLEAU 2. Photolyse du méthyl-3-butène-1 pur à 163 nm[a]: rendements quantiques

Pression (N m^{-2})	26	133	2660	6400	Note

[a]Incertitude relative: ± 10%.
[b]Rapport *trans*-butène-2/*cis*-butène-2 ≃ 2.0.
[c]Rapport *trans*-butène-2/*cis*-butène-2 ≃ 1.45.
[d]Rendements qui décroissent quand le pourcent de DI croît; les valeurs indiquées ont été mesurées à 10% de DI.
[e]n.m. = non mesuré.

en radicaux α-méthallyles:

[2*a*] $CH_3—\dot{C}H—\dot{C}H—CH_2 + XD \rightarrow C_4H_8\text{-}2 + X$

[2*b*] $CH_3—\dot{C}H—\dot{C}H—\dot{C}H_2 + XD \rightarrow C_4H_8\text{-}1 + X$

Ici la mesure exacte du rendement $\Phi(C_4H_7)$ est plus laborieuse. Tout d'abord, il faut noter que les *cis*- et *trans*-butène-2 sont formés en présence de 10% d'oxyde nitrique, via l'addition des atomes d'hydrogène libres sur le M3B1, suivis de la fragmentation du radical C_5H_{11} excité (8, 9)

[3] $H + M3B1 \rightarrow C_5H_{11}^*$

[4] $C_5H_{11}^* \rightarrow CH_3 + cis\text{-}$ ou $trans\text{-}C_4H_8\text{-}2$

[5] $C_5H_{11}^* + M \rightarrow M + C_5H_{11}$

La formation du butène par cette voie dépend de la pression et n'est appréciable qu'aux faibles pressions: $P \leq 133\ N\ m^{-2}$. En outre, pour des raisons analytiques, la séparation du butadiène-1,3 du butène-1 n'a pas été faite à toutes pressions. Cependant en soustrayant du total $\Phi(C_4H_6\text{-}1,3 + C_4H_8\text{-}1)$ la valeur $\Phi(C_4H_6\text{-}1,3)$ obtenue en présence d'oxyde nitrique, on peut tirer la valeur du rendement $\Phi(C_4H_7)$:

$$\Phi(C_4H_7) = \Phi_{DI}(C_4H_6\text{-}1,3 + C_4H_8\text{-}1) + \Phi_{DI}(C_4H_8\text{-}2) - \Phi_{NO}(C_4H_6\text{-}1,3) - \Phi_{NO}(C_4H_8\text{-}2)$$

D'où $\Phi(C_4H_7) = 0.26$, 0.61 et 0.83 à 133, 1330 et 6600 $N\ m^{-2}$. L'isomérisation du M3B1 en M2B2 n'a pas été observée à 133 $N\ m^{-2}$ ($\Phi(M2B2) \leq 0.02$). Par contre elle devient importante à 1330 ($\Phi \simeq 0.3$–0.8) et à 6600 $N\ m^{-2}$ ($\Phi \simeq 6$).

Finalement, l'effet de pression sur le rendement en butadiène-1,3 est indiqué à la fig. 2.

Cas du cis-*pentène-2 (CP2) à 163.3 nm*

Le tableau 4 indique les rendements des produits

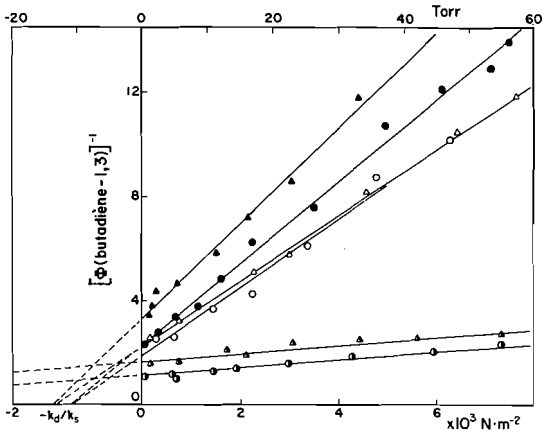

FIG. 2. Photolyse du M3B1 (●, ○, ◑) et du CP2 (▲, △, ◭). Inverse du rendement quantique en butadiène-1,3 en fonction de la pression à 174 (▲, ●), 163 (△, ○) et 147 nm (◭, ◑). Note: L'actinométrie n'a pas été rigoureusement faite dans le cas de la photolyse du CP2 à 174 nm (▲).

obtenus dans l'oléfine pure ou photolysée en présence d'additifs. Les résultats sont très semblables à ceux obtenus dans le cas du M3B1. On retrouve ici comme produit majeur, l'éthane qui disparaît en présence d'oxygène et le butadiène-1,3 qui a un rendement fortement sensible à l'augmentation de pression (fig. 2). DI augmente de façon importante les rendements en méthane, et en C_4H_8, avec une légère augmentation de l'éthylène et du propène.

Discussion

Réactions radicalaires

Dans ces systèmes, l'éthane dont la formation est perturbée de façon importante par la présence d'oxygène, d'oxyde nitrique ou d'iodure d'hydrogène, provient par voie radicalaire. Comme le butane normal n'apparaît jamais, et qu'en outre l'addition de DI ou de D_2S fait apparaître une quantité importante de méthane, la formation de l'éthane ne peut être attribuée qu'à la combinaison de radicaux méthyles. En outre, les autres produits majeurs mesurés en présence de DI sont les radicaux C_4H_7. Dans les systèmes sans additif on retrouve aussi les produits de combinaison des radicaux méthyles et C_4H_7. Ainsi dans le M3B1, le radical C_4H_7 a la structure α-méthallyle et les réactions de combinaison envisagée conduisent au M3B1, et aux *cis*- et *trans*-pentène-2. Il est intéressant de noter que le rapport *cis*-/*trans*-pentène-2 qui est voisin de 1.3 (tableau 2) est en accord avec celui connu dans la littérature (10, 11). Inversement, dans la photolyse du CP2, le M3B1 est un produit aussi attribuable aux mêmes réactions de combinaison. Comme on n'a pas mesuré le produit de la combinaison des radicaux C_4H_7 (les C_8H_{14}) il est difficile d'évaluer le rendement absolu en radicaux

TABLEAU 4. Photolyse du *cis*-pentène-2 à 163.3 nm (pur ou en présence d'additifs)[a]: rendements quantiques

H	0.18	0.40	0.28	0.16	n.m.[b]	n.m.[b]	n.m.[b]

[a]L'évaluation du rendement de chacun des radicaux est faite en tenant compte du rendement des produits sensibles à la présence de O_2 ou de NO, de l'effet de DI ou de D_2S (voir texte). L'incertitude relative est au moins 10%.
[b]n.m. = non mesuré.

α-méthallyles. Cependant, une estimation grossière à travers la loi statistique simple

$$R(A + B)^2/[R(A + A)\cdot R(B + B)] \simeq 4$$

où $R(A + A)$ est le rendement de la réaction de combinaison des radicaux méthyles, et $R(A + B)$ est celui de la réaction entre les radicaux méthyles et α-méthallyles, permet d'évaluer le rendement $\Phi(C_4H_7)$. Ce rendement, avec d'autres, est indiqué dans le tableau 5. Les autres radicaux observés sont aussi indiqués et proviennent essentiellement de la mesure de l'effet de DI. L'évaluation du rendement en radicaux méthyles est aussi faite en faisant la somme suivante (cas du M3B1)

$$\Phi(CH_3) = 2\Phi(C_2H_6) + \Phi(C_6H_{14}) \times 1.2 + \Phi(C_5H_{10}\text{-}2) \times 1.2 \quad (8\text{–}11)$$

En outre, l'évaluation du rendement en atomes d'hydrogène, à travers la mesure de l'isopentane (cas du M3B1 en présence de DI) est corrigée pour l'interception directe des atomes d'hydrogène par le DI (12).

Il reste un point d'intérêt qu'il faut soulever ici, c'est l'augmentation du rendement en méthane "radicalaire" avec l'augmentation de la pression de l'oléfine pure. A basse pression, où une part importante des radicaux C_4H_7 se fragmente (voir plus loin), la réaction majeure de disparition des radicaux méthyles est celle de combinaison $CH_3 + CH_3$. La réaction de combinaison $CH_3 + C_4H_7$ croît en importance au fur et à mesure que la pression croît. Par conséquent, la dismutation correspondante croît en importance, et explique qualitativement la croissance du rendement en méthane "radicalaire". Il existe une valeur du rapport k_{dismut}/k_{comb} pour la paire $CH_3 + \alpha\text{-}C_4H_7$: $\Delta(CH_3,\alpha\text{-}C_4H_7) = 0.02$ (11). Etant donnée la valeur du rendement en méthane "radicalaire" obtenue dans le cas du M3B1 et du CP2, cette valeur est insuffisante pour expliquer l'augmentation du rendement en méthane. Une valeur $\Delta(CH_3,\alpha\text{-}C_4H_7)$ de l'ordre de 0.2 serait plus convenable à moins que d'autres processus interfèrent comme par exemple la dismutation des radicaux méthyles et C_5H_{11}: $\Delta(CH_3,(CH_3)_2CH\text{—}\dot{C}H\text{—}CH_3) = 0.2$ ou 0.4 (8, 9) qui croît aussi en importance avec l'augmentation de pression.

Fragmentation des molécules photoexcitées

Le bilan complet qui vient d'être fait (tableau 5) montre sans ambiguités, l'importance des intermédiaires radicalaires que sont les radicaux méthyles et C_4H_7. Dans le cas du M3B1 et du CP2, le produit "moléculaire" formé en quantités majeures est le butadiène-1,3 suggérant le mécanisme suivant:

[6] $\text{M3B1 ou CP2} + h\nu \rightarrow C_5H_{10}^{**}$

[7] $C_5H_{10}^{**} \rightarrow CH_3 + \alpha\text{-}C_4H_7^*$

[8] $\alpha\text{-}C_4H_7^* \xrightarrow{k_d} H + C_4H_6\text{-}1,3$

[9] $\alpha\text{-}C_4H_7^* + M \xrightarrow{k_s} M + \alpha\text{-}C_4H_7$

Ainsi, si l'on ajoute au rendement du butadiène-1,3 celui des radicaux allyles mesuré à travers l'effet de DI on trouve que ces réactions, donc que la scission de la liaison C—C en position β de la molécule photoexcitée, comptent pour au moins 85% du total. Cette valeur est par défaut car il n'est pas exclu qu'une part mineure des radicaux allyles disparaît dans d'autres voies réactionnelles.

Dans le cas du M2B1, le bilan est plus difficile à réaliser, étant données les réactions secondaires déjà mentionnées des atomes d'iode. Néanmoins si l'on ajoute, le rendement de l'allène, à celui des radicaux β-méthallyles, on obtient une valeur au moins égale à 0.55 et pouvant être aussi élevée que 0.90: la scission de la liaison C—C en position β est encore prépondérante.

[10] $\text{M2B1} + h\nu \rightarrow C_5H_{10}^{**}$

[11] $C_5H_{10}^{**} \rightarrow CH_3 + \beta\text{-}C_4H_7^*$

[12] $\beta\text{-}C_4H_7^* \xrightarrow{k_d} CH_3 + C_3H_4 \text{ (allène)}$

[13] $\beta\text{-}C_4H_7^* + M \xrightarrow{k_s} M + \beta\text{-}C_4H_7$

Parmi les autres scissions possibles notables, il y a la scission de la liaison C—C en position α par rapport à la double liaison. La formation de radicaux propyles et du propène dans le cas du M3B1 en est un indice, de même que la formation de l'acétylène et des radicaux vinyles.

[14] $\text{M3B1}^{**} \rightarrow \text{s-}C_3H_7^* + C_2H_3^*$

[15] $\text{s-}C_3H_7^* \rightarrow C_3H_6 + H$

[16] $C_2H_3^* \rightarrow C_2H_2 + H$

Les deux dernières réactions sont, bien entendu, en compétition avec les réactions de stabilisation par collision de sorte que les sommes $\Phi(C_3H_7) + \Phi(C_3H_6)$ et $\Phi(C_2H_3) + \Phi(C_2H_2)$ donnent une valeur maximum au rendement de la scission de la liaison α(C—C). Ces deux valeurs sont 0.05 et 0.07 respectivement. Dans le cas du CP2, la mesure est un peu plus délicate, car il y a deux liaisons α(C—C). La somme $\Phi(C_2H_5) + \Phi(C_2H_4) \simeq 0.14$ correspond à la rupture d'une de ces liaisons. L'autre scission est difficilement appréciable car ses produits disparaissent dans la formation de produits par d'autres voies. Le fait que la chaleur de liaison α(C—CH_3) soit environ 3 kcal mol^{-1} plus énergétique que celle de la liaison α(C—C_2H_5) ne permet pas de dire si la rupture α(C—CH_3) se produit ou pas, bien qu'elle soit thermodynamiquement moins probable. Dans le cas du M2B1, on retrouve le même problème. La somme des rendements $\Phi(C_2H_5) + \Phi(C_2H_4) \simeq 0.12$ donne à nouveau une valeur maximum à la rupture de la liaison α(C—C_2H_5). Par contre, on n'a pas de moyen d'évaluer la rupture de la liaison α(C—CH_3). Disons seulement qu'un écart de 3 kcal mol^{-1} dans les énergies de liaisons, ΔH(C—CH_3) − ΔH(C—C_2H_5), donne une valeur $e^{-3000/RT}$ inférieure à 0.01. Cet argument tendrait à éliminer la scission de la liaison C—CH_3.

Il est intéressant de noter, cas du M3B1, que le rapport de la probabilité, *P*, de rupture de la liaison α(C—C_3H_7) par rapport à celle de la rupture de deux liaisons β(C—CH_3) est tel que

$$P[\alpha(\text{C—C})]/2P[\beta(\text{C—C})] = 0.06/2(0.90) = 1/7.5$$

Dans le cas du CP2, on obtient le rapport suivant:

$$P[\alpha(\text{C—C})]/P[\beta(\text{C—C})] \simeq 0.13/0.84 \simeq 1/6.5$$

Un rapport similaire peut être déduit dans le cas du M2B1, bien que la mesure exacte ne puisse être facilement obtenue à partir des résultats présentés ici. Lors de leur étude par photolyse éclair, Bayrakceken *et al.* (3) ont observé un rapport $P[\alpha(\text{C—C})]/P[\beta(\text{C—C})]$ de l'ordre de 1/13. Bien qu'il soit difficile de savoir comment cette valeur a été calculée, on peut penser à la possibilité d'un effet notable de la longueur d'onde: une énergie plus faible favorisant la rupture de la liaison β(?).

Les autres processus possibles, scission des liaisons C—H, ne sont pas directement visibles à la lumière des résultats. Les liaisons C—H en position β devraient être aussi plus fragiles que les autres liaisons C—H étant donnée l'énergie de résonance du radical allylique. Dans le cas du M3B1 ou du M2B1 on devrait trouver l'isoprène. En effet, les radicaux allyliques résultant conduisent à la formation de ce produit (13). Les techniques utilisées n'ont pas permis d'éclaircir ce point: le rendement en isoprène étant toujours non mesurable. Quand bien même il y aurait-il eu quelques traces d'isoprène, qu'il aurait aussi fallu compter avec les réactions possibles d'abstraction des radicaux chauds, tels que

[17] $CH_3^* + C_5H_{10} \rightarrow CH_4 + C_5H_9$

Les radicaux méthyles chauds sont probablement

produits dans la scission de la molécule photoexcitée (réaction [7]), les deux fragments emportant l'excès de l'énergie du photon.

On note cependant (cas du M3B1), qu'en présence de DI, on forme à 133 N m^{-2} une faible quantité de M2B2: $\Phi \simeq 0.02$. Cela peut indiquer une valeur maximum du rendement en radicaux α,α-diméthallyles, compte tenu des remarques faites à propos de l'isomérisation des oléfines catalysée par les atomes d'iode, et de l'attaque possible du M3B1 par des radicaux chauds. Donc, la scission de la liaison C—H en position β est un processus mineur: $\Phi \leq 0.02$.

Cette remarque a déjà été observée dans la photolyse directe du butène-1 (une autre oléfine ayant une liaison C—C en position β) à 185 nm (14), ainsi qu'à 174 nm (1*c*). On a cependant noté un accroissement de l'importance de cette scission avec l'augmentation de l'énergie du photon (1*c*).

Effet de longueur d'onde

L'analyse du rendement de l'allène (cas du M2B1) et du butadiène (cas du M3B1 et du CP2) en fonction de la pression, montre que les rendements de ces produits suivent une loi de type Stern–Volmer (15):

$$\frac{1}{\Phi(X)} = \frac{1}{\Phi_0(X)} + \frac{1}{\Phi_0(X)}\frac{k_s}{k_d}[M]$$

où $\Phi(X)$ et $\Phi_0(X)$ sont les rendements de l'allène ou du butadiène-1,3 à pression quelconque ou nulle respectivement; [M] tient lieu de pression. k_s et k_d sont les constantes de vitesse d'ordre 2 de stabilisation par collision et d'ordre 1 de fragmentation respectivement du radical précurseur du produit X: figs 1 et 2.

L'interception de ces droites avec l'axe des pressions donne la valeur du rapport $-k_d/k_s$ en unités de pression (tableau 6). On note que les rapports obtenus à 7.1 et 7.6 eV sont les mêmes pour chaque oléfine (à l'intérieur de l'incertitude expérimentale). Par contre, les valeurs obtenues à 8.4 eV sont nettement différentes. Les états électroniques impliqués dans la photoactivation des molécules sont peut-être différents. En fait on sait que l'émission obtenue avec les lampes à azote (7.1 eV) et à brome (7.6 eV) correspond à une bande d'absorption $\pi^* \leftarrow \pi$ tandis que celle de la lampe à xénon (8.4 eV) correspondrait plutôt à l'excitation d'électrons σ.

TABLEAU 6. Valeurs des rapports k_d/k_s (Torr) obtenus dans différents systèmes pour les radicaux α- et β-méthallyles

Radical	α-Méthallyle		β-Méthallyle
Activation photochimique indirecte du	M3B1	CP2	M2B1
7.1 eV	11.1	13.0	7.0
7.6	10.9	13.5	7.0
8.4	48	63	34.5
Activation chimique (réf. 16) ($H + CH_3—CH=C=CH_2$)		≃0.6	—

Une deuxième remarque concerne les valeurs identiques observées à 7.1 et à 7.6 eV. Malgré la différence d'énergie des photons incidents (≃11.5 kcal mol^{-1}), la constante de vitesse de dissociation du radical intermédiaire n'est pas affectée. En terme de la théorie RRK, cela implique que les intermédiaires ont la même énergie interne. Autrement dit, qu'ils soient formés à 7.1 ou à 7.6 eV, ils véhiculent la même quantité d'énergie interne. Cela va à l'encontre d'une distribution statistique de l'excès de l'énergie du photon dans les fragments (la statistique étant faite sur les degrés de liberté de vibration).

Finalement, la variation des valeurs obtenues pour une même énergie avec la structure du monomère traduit probablement entre autres (*a*) les variations des diamètres moléculaires des intermédiaires et des oléfines, (*b*) la différence dans la distribution de l'énergie dans les fragments qui obéit à d'autres lois que celle de la distribution statistique rapportée plus haut.

En outre, il faut ici rappeler que lors de la photolyse du butadiène-1,2 à 8.4 eV, Diaz et Doepker ont montré que le butadiène-1,3 provient de la fragmentation du radical α-méthallyle produit lors de l'addition des atomes d'hydrogène sur le butadiène-1,2 (16). En admettant que les atomes d'hydrogène sont thermiques;

[18] $H + C_4H_6\text{-}1,2 \rightarrow CH_3\dot{C}H—\dot{C}H—\dot{C}H_2{}^*$

$\Delta H = 250$ kJ mol^{-1}

La fragmentation de ces radicaux chimiquement activés suit une loi linéaire de type Stern–Volmer et le rapport k_d/k_s obtenu est voisin de 0.6 Torr. Hormis la différence mineure dans les diamètres de collision, il apparaît que la vitesse de décomposition des radicaux α-méthallyles obtenus lors de la photolyse du M3B1 et du CP2 est plus rapide en admettant, bien sûr, une constante de vitesse k_s identique dans chacun des cas.

Remerciements

Nous voulons spécialement remercier le ministère de l'Environnement du Canada, ainsi que l'Université du Québec pour l'aide généreuse accordée à ce projet.

Photolyse du propène et du méthyl-2-butène-2 vers 174 et à 163 nm

GUY J. COLLIN,[1] HÉLÈNE DESLAURIERS ET JOVETTE DESCHÊNES

Département des Sciences Pures, Université du Québec à Chicoutimi, Chicoutimi (Qué.), Canada G7H 2B1

Reçu le 30 octobre 1978

GUY J. COLLIN, HÉLÈNE DESLAURIERS et JOVETTE DESCHÊNES. Can. J. Chem. **57**, 870 (1979).

On a étudié la photolyse du propène à 163 nm et vers 174 nm, ainsi que celle du méthyl-2-butène-2 à 163 nm. A cette dernière longueur d'onde (7.6 eV), la molécule de propène photoexcitée se décompose principalement par rupture de la liaison β(C—H): $\Phi = 0.565$ et α(C—C): $\Phi = 0.335$. Le rapport β(C—H)/α(C—C) est donc voisin de 1.69. Dans le cas du méthyl-2-butène-2, les deux ruptures précédentes constituent encore la majorité des réactions de fragmentation de la molécule photoexcitée. Cependant le rapport est inversé: β(C—H)/α(C—C) $\simeq 0.58$. Ce rapport a également été mesuré pour le butène-2 dans un autre travail et il est voisin de l'unité. En outre, afin d'expliquer la formation de l'allène et du butadiène-1,3 dans la photolyse du méthyl-2-butène-2, on propose l'isomérisation des radicaux vinyliques intermédiaires en conformité avec les observations de Callear et Lee.

GUY J. COLLIN, HÉLÈNE DESLAURIERS, and JOVETTE DESCHÊNES. Can. J. Chem. **57**, 870 (1979).

We have studied the 163 nm photolysis of propene and of 2-methyl-2-butene and a few results on the 174 nm photolysis of propene are also included. At 163 nm (7.6 eV), the main decomposition processes of the photoexcited propene molecule are β(C—H) split ($\Phi = 0.565$) and α(C—C) split ($\Phi = 0.335$). Thus, the β(C—H)/α(C—C) ratio is close to 1.69. In the case of the photolysis of 2-methyl-2-butene, the same ratio is reversed: β(C—H)/α(C—C) $\simeq 0.58$. In another work, the ratio obtained in the photolysis of 2-butene was close to unity. Finally, in order to explain the allene and 1,3-butadiene formation in the photolysis of 2-methyl-2-butene, isomerisation of vinylic radical intermediates is proposed, in agreement with observations made by Callear and Lee.

Introduction

Dans la publication précédente (1), nous avons montré que la décomposition des molécules oléfiniques, photoexcitées dans la région de l'uv sous vide (vers 160 ± 15 nm), se fait principalement par le bris de la liaison C—C située en position β par rapport à la double liaison: $\Phi \simeq 0.9$. Cette scission libère un radical allylique et un radical alkyle. Dans ce présent rapport nous avons concentré notre attention sur la photodécomposition des oléfines qui n'ont pas de telle liaison β(C—C). Déjà, un certain nombre de rapports existent sur la photolyse du propène (2–4), du butène-2 (5, 6) et de l'isobutène (7–9). Cependant les observations qui y sont rapportées sont incomplètes: soit qu'il manque les rendements quantiques, soit que les mécanismes de fragmentation n'aient pu être clairement mis en évidence pour toutes sortes de raisons. En plus de l'étude systématique du propène et du méthyl-2-butène-2 à 7.1 et surtout à 7.6 eV, nous rediscuterons rapidement de certaines valeurs obtenues pour le butène-2.

Partie expérimentale

Les techniques expérimentales ont toutes été rapportées dans la littérature. Le propène est un produit de Matheson of Canada, "Research Grade" dont les impuretés principales sont: le propane: 105 ± 5 ppm, l'éthane: 4.48 ppm et l'éthylène: 2.67 ppm. Le méthyl-2-butène-2 est un produit "A.P.I." de pureté moléculaire affichée 99.4 ± 0.4%. Les impuretés observées sont: le méthyl-3-butène-1: 40.0 ppm, le méthyl-2-butène-1: 50.6 ppm, l'isoprène: 11.4 ppm et l'isopentane: 18.7 ppm. Les concentrations des impuretés varient légèrement d'un échantillon à l'autre (≤10%), ainsi que pour un échantillon entre le début et la fin de son utilisation. Les autres produits, les techniques ont été décrites ailleurs (1, 6, 9), de même que les lampes d'irradiation et l'actinométrie (6, 10). Il faut mentionner les précautions particulières prises pour l'actinométrie (1).

Les analyses ont été faites par chromatographie en phase gazeuse à l'aide d'un détecteur à double flammes ionisantes. La majorité des produits ont été analysés sur une colonne de squalane (6*c*). On a en outre utilisé une colonne d'alumine en programmation de température pour séparer le propane du propène, une colonne de *n*-octane/porasil C pour séparer le butène-1 de l'isobutène et du butadiène-1,3 (6*c*) et enfin une colonne de UCON LB 550 × 20% pour séparer l'allène du propène (11).

Résultats

Les résultats sont indiqués sous la forme de rendements quantiques dans les figures et les tableaux qui accompagnent le texte.

Cas du propène

La photolyse du propène est relativement simple, elle donne lieu, lorsque 5 à 10% d'oxyde nitrique sont ajoutés, à la formation de méthane ($\Phi(CH_4) = 0.05 \pm 0.01$ entre 66 et 26 600 N m^{-2}),[2] d'acétylène et

[1]Auteur auquel toute correspondance devrait être envoyée.

[2]133 N m^{-2} = 1 Torr.

0008-4042/79/080870-06$01.00/0

d'allène (fig. 1). Pour des raisons analytiques on n'a pas cherché à mesurer le propyne. Par contre, la photolyse du monomère pur (dégasé à la température de l'azote liquide) montre une variété de produits allant du méthane aux C_6. Parmi les produits principaux, on trouve ceux cités plus haut ainsi que l'isobutane, le méthyl-4-pentène-1 et le diméthyl-2,3-butane (tableau 1). L'addition de D_2S ou de DI (10 à 20%) au propène augmente de façon marquée les rendements en propane, méthane, éthylène et acétylène (tableau 2). Dans aucun de ces systèmes on a trouvé de quantités appréciables ($\Phi \leq 0.002$) de cyclopropane, méthylcyclopropane, vinylacétylène et de méthyl-3-butyne-1 quelle que soit la pression entre 66 et 26 600 N m^{-2}. Il faut en outre noter un effet de pression marqué sur le rendement en acétylène, éthylène et allène (fig. 1) ainsi que sur d'autres produits (tableau 1). Enfin, la photolyse à 174 nm, donne des résultats en tout point similaires à ceux rapportés ici. On n'a montré ici que les rendements en acétylène et en allène (fig. 1).

Cas du méthyl-2-butène-2 à 163 nm

La photolyse du méthyl-2-butène-2 donne aussi lieu à une variété importante de produits. En présence de 10% d'oxygène un certain nombre de produits ont des rendements indépendants de la pression entre 20 et 2600 N m^{-2}. Ce sont: le méthane: 0.033 ± 0.01, l'acétylène: 0.005 ± 0.002, l'éthylène: 0.015 ± 0.010 et le propène: 0.005 ± 0.002. Par contre les rendements en propyne, allène, butadiène-1,3 et isoprène ont des rendements qui décroissent avec la pression (fig. 2). Les rendements de ces produits extrapolés à pression nulle sont: Φ_0(propyne) $= 0.065 \pm 0.005$, Φ_0(allène) $= 0.022 \pm 0.002$, Φ_0(butadiène-1,3) $= 0.105 \pm 0.01$ et Φ_0(isoprène) $= 0.27 \pm 0.03$. L'addition de D_2S ou DI (10 à 20%) au méthyl-2-butène-2 n'a pas ou peu d'effet sur les rendements en acétylène, éthylène, propène, propyne et allène. Il augmente cependant de façon importante le rendement en méthane (tableau 3). On y observe aussi un rendement important en isopentane. L'effet avec DI est similaire à celui du D_2S bien que la reproductibilité expérimentale laisse à désirer ($\pm 25\%$). En particulier, dans ce cas on a observé une formation importante d'un composé dont le rendement croît très vite avec le pourcentage de DI ($0.2 \leq \Phi \leq 2.0$) et attribué à des réactions secondaires. On n'a pas poursuivi plus à fond l'étude de ce produit qui a le même temps de passage que l'isobutène ou le butadiène-1,3 sur la colonne de squalane.

Discussion

Cas du propène

L'analyse des résultats montre que la majorité des produits disparaît lorsque la photolyse est faite en présence d'oxyde nitrique, suggérant ainsi la nature

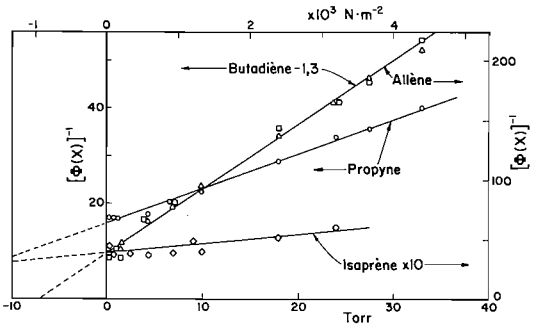

FIG. 2. Photolyse du méthyl-2-butène-2 à 163 nm. Inverse du rendement quantique en fonction de la pression totale du système: méthyl-2-butène-2:oxygène ou oxyde nitrique (1.0:0.10). Attention: les rendements en allène et en butadiène sont représentés par la même droite, mais non par le même axe des ordonnées.

radicalaire du mécanisme de leur formation. Les principaux produits en C_6 étant le diméthyl-2,3-butane et le méthyl-4-pentène-1, les intermédiaires radicalaires les plus probables sont les radicaux propyles secondaires et allyles. Il faut mentionner deux produits en C_4 issus des radicaux méthyles et allyles d'une part et méthyles et iso-propyles d'autre part et qui sont le butène-1 et l'isobutane respectivement. Compte tenu des rapports des constantes des réactions de dismutation et combinaison, k_d/k_c, donnés dans la littérature, on peut estimer à chaque pression le rendement quantique des radicaux.

$$\Phi(\text{iso-}C_3H_7) \geq 2\Phi(\text{diméthyl-2,3-butane}) \times 1.66 + \Phi(\text{méthyl-2-pentane}) + \Phi(\text{méthyl-4-pentène-1}) + \Phi(\text{isopentane}) \times 1.30 + \Phi(\text{isobutane}) \times 1.16 + \Phi(\text{méthyl-3-butène-1})$$

$$\Phi(n\text{-}C_3H_7) \simeq \Phi(\text{hexène-1}) + \Phi(\text{méthyl-2-pentane}) \times 1.41 + \Phi(n\text{-butane}) \times 1.05$$

$$\Phi(\text{allyl}) \geq \Phi(\text{hexène-1}) + 2\Phi(\text{hexadiène-1,5}) \times 1.01 + \Phi(\text{méthyl-4-pentène-1}) + \Phi(\text{pentadiène-1,4}) + \Phi(\text{butène-1})$$

$$\Phi(CH_3) \geq \Phi(n\text{-butane}) \times 1.06 + \Phi(\text{isobutane}) \times 1.16 + 2\Phi(\text{ethane}) + \Phi(\text{butène-1})$$

et

$$\Phi(C_2H_3) \simeq \Phi(\text{pentadiène-1,4}) + \Phi(\text{méthyl-3-butène-1})$$

Ces cinq relations sont discutables, puisque un bon nombre de rapports k_d/k_c sont inconnus (12). On peut estimer que les réactions de dismutation sont peu importantes bien que ce soit pas nécessairement le cas. Compte tenu des rendements des produits de combinaison, parmi ceux qui manquent, deux sont importants: celui se rapportant au couple méthyl + allyl et celui se rapportant au couple iso-propyl + allyl. Le premier couple produit la paire $CH_4 + C_3H_4$. La valeur du rendement en méthane radicalaire impose un rendement maximum de 0.03 à cette dismutation, c'est-à-dire le rendement en méthane radicalaire, diminué de celui provenant de la dismutation méthyl + iso-propyl calculable à partir de la formation de l'isobutane. L'autre couple est moins facilement accessible. La dismutation de ce couple conduit soit à la paire $C_3H_8 + C_3H_4$ soit à la paire $C_3H_6 + C_3H_6$. La première paire est de peu d'importance, car tout le propane formé est explicable par la dismutation des radicaux iso-propyles. Quant à l'autre paire, elle n'est pas accessible ici. Enfin ces relations n'expliquent pas le rendement important en ethylène et en acétylène qui sont inhibés par la présence d'oxyde nitrique et qui peuvent provenir via l'abstraction d'un atome d'hydrogène sur le monomère par le radical convenable.

TABLEAU 3. Effet de D_2S (20–30%)[a] dans la photolyse du méthyl-2-butène-2 à 163 nm: rendements quantiques

Pression totale[f]	150	700	1500
Méthane[b]	0.76	0.66	0.65
Isopentane[c]	0.60	0.56	0.60
Butène-2[d,b]	0.06	0.09	0.11
Méthylbutène[b,e]	0.07	0.08	0.10

[a]10% de D_2S sont insuffisants pour intercepter tous les radicaux méthyles: $\Phi(C_2H_6) = 0.11$ et $\Phi(CH_4) = 0.65$ à 150 N m^{-2}. Avec 20% et plus, $\Phi(C_2H_6) \leq 0.04$.
[b]Résultats similaires dans les mélanges C_5H_{10}:DI.
[c]En présence de DI, les valeurs Φ(iso-C_5H_{12}) sont plus faibles.
[d]Le rapport *trans*/*cis* $\simeq$ 2.0.
[e]Le rapport méthyl-2-butène-1/méthyl-3-butène-1 $\simeq$ 4.
[f]N m^{-2}.

Pour résoudre ce problème, DI et D_2S ont été utilisés pour intercepter les radicaux libres (tableau 2). Le rendement du produit XD obtenu en présence de DI ou de D_2S diminué de celui obtenu en présence de NO est attribué à la réaction.

[1] $$X + DI(D_2S) \rightarrow XD + I(DS)$$

Cette différence est donc égal au rendement du radical X. On trouve une bonne concordance entre les valeurs obtenues par cette méthode et ceux obtenus à l'aide des précédentes relations (tableau 4). Tout d'abord, les valeurs $\Phi(C_3H_7)$ obtenues par la méthode d'interception, sont un peu plus faibles que la somme Φ(iso-C_3H_7) + $\Phi(n\text{-}C_3H_7)$. Les atomes d'hydrogène sont les précurseurs de ces radicaux (voir plus loin) et sont partiellement interceptés par l'additif (13). Quant aux autres radicaux l'accord est acceptable. La formation des radicaux méthyles, vinyles et allyles est facilement compréhensible. Les radicaux propyles sont formés par addition des

TABLEAU 4. Photolyse du propène à 163 nm: rendements quantiques[a]

Pression ($N\ m^{-2}$)		Rendements des radicaux 133	1330	6650	13 300
$\Phi(iso\text{-}C_3H_7)$	A	0.90	0.85	0.82	0.82
$\Phi(n\text{-}C_3H_7)$	A	0.03	0.05	0.07	0.05
$\Phi(C_3H_7)$	DX	0.80	0.85	0.72	n.m.
Φ(allyl)	A	0.34	0.45	0.51	0.51
$\Phi(C_2H_3)$	A	0.064	0.084	0.079	0.071
	B	0.21	0.215	0.20	0.25
	DX	0.21	0.24	0.21	n.m.

	DX	0.43	0.42	0.40	n.m.

[a]A: déduit des 5 relations, photolyse du propène pur; DX: déduit de l'effet de D_2S ou de DI; B: valeurs obtenues en A augmentées du rendement en acétylène et en éthylène radicalaire (voir texte).

atomes d'hydrogène sur le monomère.

[2a] $H + C_3H_6 \rightleftarrows iso\text{-}C_3H_7^*$

[2b] $H + C_3H_6 \rightarrow n\text{-}C_3H_7$

$\Delta H = -143\ kJ\ mol^{-1}$

[2c] $H + C_3H_6 \rightarrow H_2 + C_3H_5$

où $k_{2b}/k_{2a} \simeq 0.06$ (13) et $k_{2c}/k_2 \simeq 0.04$ (12). Les radicaux iso- et n-C_3H_7 sont chimiquement excités et se décomposent à basse pression: la réaction [2a] est réversible et le radical n-$C_3H_7^*$ se décompose en radical méthyle et en éthylène (14).

[3] $n\text{-}C_3H_7^* \rightarrow CH_3 + C_2H_4$

$\Delta H = +96\ kJ\ mol^{-1}$

En admettant que les atomes d'hydrogène sont thermiques, la majorité (>99%) des radicaux isopropyles sont stabilisés par collision à une pression de 133 $N\ m^{-2}$. Par contre, il faut au moins une pression de 800–1000 $N\ m^{-2}$ pour stabiliser la moitié des radicaux n-propyles (14). A basse pression une part importante de l'éthylène est donc formé via la réaction [3]. Une autre possibilité de formation de l'éthylène est l'éjection d'un groupe méthylène par la molécule photoexcitée. On n'a pu mesurer de formation de méthyl-cyclopropane (addition d'un groupe méthylène sur le monomère) malgré qu'à 13 300 N m^{-2} une part importante de ce produit soit stabilisé par collision (15). A basse pression où le méthylcyclopropane s'isomérise en butènes linéaires (15), on n'observe que de faibles rendements en C_4H_8. En admettant qu'à 13 300 N m^{-2}, les radicaux n-propyles ne se fragmentent plus, la mesure du rendement en éthylène à cette pression donne une valeur limite à cette réaction

[4] $C_3H_6 + h\nu \rightarrow C_3H_6^{**}$

[5] $C_3H_6^{**} \rightarrow CH_2 + C_2H_4$

$\Phi \simeq 0.02$

Enfin le rendement en acétylène augmente ($\Delta\Phi \simeq 0.05$) lors de l'addition de D_2S ou de DI. Sur la base de la réaction [1], cette augmentation est attribuable au radical C_2H bien que dans ce cas l'efficacité puisse être douteuse (16). En l'absence, ou en présence de NO, ce radical réagit très rapidement avec le propène (17). Il se forme le vinylacétylène et un polymère. Cela explique pourquoi on n'observe pas le produit de combinaison entre les radicaux C_2H et iso-C_3H_7: le méthyl-3-butyne-1. Seule, la valeur obtenue en utilisant D_2S ou DI, donne une valeur fiable et suggère la réaction suivante

[6a ou b] $C_3H_6^{**} \rightarrow C_2H + (CH_4 + H)$ ou $(CH_3 + H_2)$

$\Phi \simeq 0.05$

L'allène est formé, même en présence d'oxyde nitrique. A basse pression, c'est le produit majeur et son rendement dépend fortement de la pression et suit une loi de type Stern–Volmer (18):

$$\Phi^{-1} = \Phi_0^{-1} + \Phi_0^{-1}(k_s/k_d)[M]$$

où Φ_0 et Φ sont les rendements quantiques à pression nulle et à pression P, k_s et k_d les constantes de vitesse de stabilisation par collision (d'ordre 2) et de décomposition (d'ordre 1) de l'intermédiaire qui précéde la formation de l'allène, et [M] est ici la pression du propène. L'intermédiaire probable de l'allène est le radical allyle. En effet, la somme Φ(allyle) + Φ(allène) = 0.565 ± 0.02 entre 133 et 13 300 N m^{-2}. La décomposition du monomère photoexcitée est quantitative dans ce domaine de pression; il n'est donc pas l'intermédiaire recherché.

[7] $C_3H_6^{**} \rightarrow H + \dot{C}H_2\text{—}\dot{C}H\text{—}\dot{C}H_2^*$

$\Phi = 0.565$

[8] $\dot{C}H_2\text{—}\dot{C}H\text{—}\dot{C}H_2^* \rightarrow H + CH_2{=}C{=}CH_2\ (k_d)$

[9] $\dot{C}H_2\text{—}\dot{C}H\text{—}\dot{C}H_2^* + M \rightarrow M + \dot{C}H_2\text{—}\dot{C}H\text{—}\dot{C}H_2\ (k_s)$

L'acétylène est aussi formé en présence d'oxyde nitrique, et son rendement suit aussi une loi de type Stern–Volmer et la somme $\Phi(C_2H_3) + \Phi(C_2H_2)$ est aussi constante dans le même domaine de pression: $\Phi(C_2H_3) + \Phi(C_2H_2) = 0.335 \pm 0.02$.

[10] $C_3H_6^{**} \rightarrow CH_3 + C_2H_3^*$

$\Phi = 0.335$

[11] $C_2H_3^* \rightarrow C_2H_2 + H$

[12] $C_2H_3^* + M \rightarrow M + C_2H_3$

Il reste finalement un produit formé en présence d'oxyde nitrique: le méthane. La réaction [6] a déjà été envisagée comme source de méthane. Cependant, une alternative est possible. Une émission simultanée de méthane et d'acétylène n'est pas

exclue.

[13] $C_3H_6^{**} \rightarrow CH_4 + C_2H_2$

Il est tentant de se baser sur les rendements en atomes hydrogène et en radicaux méthyles pour tenter de justifier ou d'éliminer l'une ou l'autre des réactions [6] et [13]. Cependant ces mesures ne permettent pas une précision expérimentale pour ce faire, bien qu'elles favorisent la réaction [6*a*], au détriment de [6*b*] et donc au détriment de [13] (tableau 5).

Il est intéressant de noter que le changement de longueur d'onde n'a pas d'effet sur le rendement en acétylène. Par contre, la formation d'allène est fortement influencée par ce changement (fig. 1). Alors que le rapport $k_d/k_s = 9.0$ Torr à 174 nm, il devient égal à 21.5 Torr à 163 nm. L'effet de l'énergie interne est évidemment visible sur la fragmentation du radical allyle.

Enfin, il faut noter que pour cette molécule qui n'a pas de liaison β(C—C), la scission principale est celle de la liaison β(C—H) suivie par celle de la liaison α(C—C) dans le rapport β(C—H)/α(C—C) = 1.69 ± 0.15. A 185 nm, ce rapport a été mesuré: 1.2 (4). A 147 nm, le mécanisme proposé est plus complexe et il n'est pas facile d'extraire ce rapport de résultats (2, 3) bien que la scission α(C—C) semble favorisée.

Cas du méthyl-2-butène-2

En présence de D_2S (tableau 3) les produits majeurs sont le méthane et l'isopentane. De façon similaire à ce qui a été dit pour la photolyse du propène, ces produits, via la réaction [1], proviennent des radicaux méthyles et C_5H_{11}

[14*a*] $H + (CH_3)_2C{=}CHCH_3 \rightarrow (CH_3)_2CCH_2CH_3^*$

[14*b*] $H + (CH_3)_2C{=}CHCH_3 \rightarrow (CH_3)_2CHCHCH_3^*$

Si les radicaux secondaires se fragmentent à très basse pression, à une pression supérieure à 133 N m^{-2} ils sont stabilisés par collision. Quant au radicaux tertiaires ils ne se décomposent pas dans les conditions présentes sauf si les atomes d'hydrogène véhiculent une part importante d'énergie cinétique. La quantité importante d'isopentane permet d'ignorer ces réactions de décomposition. En outre, même à 22 N m^{-2} le rendement $\Phi(C_4H_8\text{-}2)$ est inférieur à 0.015, confirmant le peu d'importance de cette fragmentation (19).

[15] $(CH_3)_2CHCHCH_3^* \rightarrow CH_3 + C_4H_8\text{-}2$

L'addition de D_2S augmente aussi les rendements du butène-2 et du méthyl-2-butène-1 et méthyl-3-butène-1 mais dans de moindres proportions. La réaction [1] suggère la présence de radicaux C_4H_7 et C_5H_9. Ausloos et coll. ont montré que l'hydrogène sulfuré n'intercepte pas les radicaux allyliques (20). Par conséquent, les radicaux C_4H_7 doivent avoir une structure vinylique: $CH_3C{=}CHCH_3$. Dans le cas de la formation du méthyl-2-butène-1 et méthyl-3-butène-1 les structures des radicaux C_5H_9 devraient être $CH{=}C(CH_3)C_2H_5$ et $(CH_3)_2CHC{=}CH_2$ ou $(CH_3)_2CHCH{=}CH$. Il n'est pas facile d'établir l'origine de ces radicaux (voir plus loin).

TABLEAU 5. Photodécomposition du propène à 163 nm

Réaction	$C_3H_6^{**} \rightarrow$	Φ
[7]	$C_3H_5^* + H \hookrightarrow CH_2{=}C{=}CH_2 + H$	0.565
[10]	$C_2H_3^* + CH_3 \hookrightarrow C_2H_2 + H$	0.335
[6*a*]	$C_2H + (CH_4 + H)$	≃0.05
[5]	$CH_2 + C_2H_4$	0.02
	Total	0.97

Parmi les produits "moléculaires", l'isoprène est le plus important, et demande la formation concurrente de deux atomes ou d'une molécule d'hydrogène. Le bilan global (voir plus loin) favorise sa scission en deux étapes, avec formation d'un intermédiaire allylique.

[16] $(CH_3)_2C{=}CHCH_3 + h\nu \rightarrow (CH_3)_2C{=}CHCH_3^{**}$

[17*a*] $(CH_3)_2C{=}CHCH_3^{**} \rightarrow (CH_3)_2\dot{C}\dot{C}H\dot{C}H^* + H$ (A)

[17*b*] $(CH_3)_2C{=}CHCH_3^{**} \rightarrow \dot{C}H_2\dot{C}(CH_3)\dot{C}HCH_3^* + H$ (B)

[18] A* ou B* → $CH_2{=}C(CH_3)CH{=}CH_2 + H$

[19] A* ou B* + M → M + A ou B

Ce mécanisme est basé sur le fait que le rendement en isoprène suit une loi de type Stern–Volmer (fig. 2). Les autres produits "moléculaires" importants que sont le propyne, l'allène et le butadiène-1,3 peuvent s'expliquer sur la base de rupture primaire d'une liaison α(C—C):

[20] $(CH_3)_2C{=}CHCH_3^{**} \rightarrow CH_3 + CH_3C{=}CHCH_3^*$

[21*a*] $CH_3C{=}C{-}CH_3^* \rightarrow CH_3C{\equiv}CH + CH_3$

[21*b*] $CH_3C{=}CHCH_3^* \rightarrow CH_3\dot{C}H\dot{C}H\dot{C}H_2^*$

[22] $CH_3\dot{C}H\dot{C}H\dot{C}H_2^* \rightarrow CH_2{=}CHCH{=}CH_2 + H$

et

[23] $(CH_3)_2C{=}CHCH_3^{**} \rightarrow (CH_3)_2C{=}CH^* + CH_3$

[24*a*] $(CH_3)_2C{=}CH^* \rightarrow CH_3C{\equiv}CH + CH_3$

[24*b*] $(CH_3)_2C{=}CH^* \rightarrow \dot{C}H_2\dot{C}(CH_3)\dot{C}H_2^*$

[25] $\dot{C}H_2\dot{C}(CH_3)\dot{C}H_2^* \rightarrow CH_2{=}C{=}CH_2 + CH_3$

Les réactions [21], [22], [24] et [25] sont bien sûr en compétition avec les réactions de stabilisation par collision. Il s'ensuit que les rendements en propyne, allène et butadiène-1,3 suivent la loi "Stern–Volmer" (fig. 2).

Les réactions d'isomérisation [21*b*] et [24*b*] ont été observées dans d'autres systèmes (21). Elles demandent la formation d'un complexe cyclique à quatre côtés, donc possédant une forte énergie interne. En particulier les radicaux β-méthallyles ont été observés dans la photolyse éclair de ce monomère (22). L'énergie disponible après la rupture primaire de la liaison α(C—C) est suffisante pour permettre à la réaction de passer par dessus la barrière de potentielle (23), bien que tous les radicaux C_4H_7 issus des réactions [20] et [23] peuvent ne pas avoir suffisemment d'énergie pour ce faire. En particulier, la présence de radicaux vinyliques C_4H_7 est l'indice qu'au moins une part des radicaux $CH_3C{=}CHCH_3$* ne s'isomérisent pas en structure allylique. Quant aux réactions [22] et [25] elles ont été proposées dans la publication précédente (1).

Finalement, il est intéressant d'essayer de mesurer l'importance relative de la scission β(C—H) par rapport à celle de la liaison α(C—C). Il n'est facile d'extraire le rapport β(C—H)/α(C—C) car tous les produits radicalaires n'ont pu être mesurés convenablement. Néanmoins, le rendement en atomes d'hydrogène -Φ(isopentane) obtenu en présence de D_2S- diminué du rendement des réactions (18) -Φ(isoprène)- et [22] -Φ(butadiène-1,3)- et en ajoutant le rendement des atomes d'hydrogène qui réagissent directement avec D_2S plutôt qu'avec le monomère, permet d'évaluer le rendement de la réaction [17]: Φ_{cal}(réaction [17]) $\simeq 0.35 \pm 0.05$. De la même manière, les réactions [20] et [23] peuvent être évaluées à partir de la mesure du rendement en radicaux méthyles en présence de D_2S, diminué du rendement en méthane "moléculaire", ainsi que de ceux des réactions [21*a*], [24*a*] et [25]. On trouve alors $\Phi([20]) + \Phi([23]) \simeq 0.60 \pm 0.05$. Le rapport β(C—H)/α(C—C) est donc égal à 0.58 ± 0.16. Ce rapport est l'inverse de celui obtenu avec le propène. Dans le cas du *cis*-butène-2, le même rapport était voisin de l'unité (1*c*). L'effet de substitution sur le groupe éthylénique, ou la grosseur de la molécule, a donc un rôle dans la scission de la molécule. Le remplacement successif d'un atome d'hydrogène par un radical méthyle semble affaiblir la liaison α(C—C) par rapport à la stabilité de la liaison β(C—H). On a également montré un effet de longueur d'onde dans le cas du *cis*-butène-2 (1*c*).

Remerciements

Nous aimerions remercier spécialement le Conseil de Recherches en Sciences Naturelles et en Génie du Canada, ainsi que le ministère de l'Education du Québec (programme FCAC) pour l'aide substantielle accordée à la réalisation de ce projet.

Etude de l'ion $HC_2O_4^-$ en solution aqueuse par spectrométrie infrarouge et Raman

M. JABER[1] ET F. BERTIN

Laboratoire de Chimie Analytique II, 43 boulevard du 11 Novembre 1918, Université de Lyon I, Villeurbanne, France

ET

M. T. FOREL

Laboratoire de Spectroscopie Infrarouge associé au C.N.R.S., Université de Bordeaux I, 351 Cours de la Libération, 33405 Talence, France

Reçu le 6 septembre 1978

M. JABER, F. BERTIN et M. T. FOREL. Can. J. Chem. **57**, 876 (1979).

Les auteurs ont examiné les solutions aqueuses de l'ion hydrogénooxalate par spectroscopie infrarouge et Raman. Ils montrent l'existence de l'équilibre entre une structure monomère plane liée par liaison hydrogène aux molécules d'eau du solvant et une forme associée. Un tel équilibre peut fournir une explication satisfaisante des spectres obtenus et de leur modification avec la température et la concentration. Un calcul de champ de forces de valence utilisant les coordonnées normales de l'ion $HC_2O_4^-$ supposé plan, permet de vérifier les attributions proposées pour la forme monomère de cet ion.

M. JABER, F. BERTIN, and M. T. FOREL. Can. J. Chem. **57**, 876 (1979).

The authors have investigated aqueous solution of the hydrogenooxalate ion by infrared and Raman spectroscopy. They show the existence of an equilibrium between a planar monomer structure linked by hydrogen bond to solvent molecules and an associated form. Such an equilibrium can provide a satisfactory explanation for the experimental spectra and their dependence upon temperature and concentration. The assignments for the monomeric form are supported by a normal coordinate analysis and by a calculation of the valence force field.

Introduction

L'étude structurale de l'ion $HC_2O_4^-$ à l'état cristallisé a déjà fait l'objet de plusieurs publications; nous ne résumerons que les plus importantes. Tellgren et Olovsson (1) montrent à partir des spectres de diffraction X du composé $NaHC_2O_4$, H_2O et de son dérivé deutérié que la maille cristalline est triclinique et que les ions $HC_2O_4^-$ s'associent en chaînes définies par l'intermédiaire d'une liaison hydrogène OH---O très courte (2.571 Å). Les molécules d'eau forment des ponts entre ces chaînes constituant ainsi des liaisons hydrogène longues (2.808 et 2.826 Å).

De Villepin et Novak (2–4) analysent les spectres infrarouges et Raman des hydrogénooxalates cristallisés de Li, Na et K, hydratés et anhydres, obtenus à deux températures différentes (température ambiante et $-180°C$). Ces auteurs proposent une attribution des bandes observées aussi bien pour les groupements oxalates que pour les molécules d'eau liées à ces groupements; pour justifier leurs attributions, les auteurs s'appuient sur les données cristallographiques de Tellgren et sur les modifications spectrales dues à la deutériation.

Nous avons étudié par spectrométrie Raman la dissociation de l'acide oxalique en solution aqueuse en fonction du pH, et identifié les bandes caractéristiques des trois espèces en équilibre: $H_2C_2O_4$, $HC_2O_4^-$ et $C_2O_4^{2-}$ (5). Dans ce mémoire nous discutons essentiellement les résultats obtenus pour $HC_2O_4^-$ en utilisant chaque fois que cela est possible les données de l'infrarouge. Nous comparerons les spectres de vibration de cet ion à ceux de l'ion $DC_2O_4^-$ en solution dans D_2O. Après avoir discuté les différents types d'association possibles pour ces ions en solution nous proposons une interprétation de leurs spectres et nous tentons de justifier nos hypothèses à l'aide d'un calcul de vibration.

Conditions expérimentales

Les solutions de $HC_2O_4^-$ 0.25 *M* sont préparées en neutralisant une seule acidité de l'acide oxalique par la potasse suivant un procédé déjà décrit (5).

Pour obtenir une concentration plus élevée en $HC_2O_4^-$ nous avons utilisé l'hydrogénooxalate de césium car il est soluble jusqu'à une concentration proche de 0.7 *M*. Ce sel est préparé par action, dans l'eau bouillante de l'acide oxalique sur le carbonate de césium introduits en quantités équimoléculaires; après dégagement du gaz carbonique il faut recristalliser le produit plusieurs fois pour obtenir des cristaux blancs de $CsHC_2O_4$. On redissout alors ces cristaux dans de l'eau distillée; la solution ainsi obtenue doit être assez rapidement utilisée car elle noircit après plusieurs jours.

[1]Boursier du C.N.R.S. Libanais.

TABLEAU 1. Fréquences infrarouge et Raman des ions $HC_2O_4^-$ et $DC_2O_4^-$ en solution aqueuse*

IR	H_2O					1240	1305?		1400?						1725
						F									F
	D_2O			855		1270			1415				1640	1700	1720
				f		e_p			m				TF	e_p	F
R	H_2O	453	725	868		1240	1305	1380	1410	1444					1725
		F	f	TF		tf	tf	m	m	m					F
	D_2O	450	685	853	950	1060	1270			1421		1560	1640	1700	1720
		F	f	TF	tf	tf	e_p			TF		tf	f	e_p	F

*TF: très forte; F: forte; m: moyenne; f: faible; tf: très faible; e_p: épaule.

Quelles que soient les solutions préparées, il est impossible d'isoler un domaine de pH dans lequel la concentration en ions $HC_2O_4^-$ représente plus que 91% de la concentration analytique totale; les 9% restants sont constitués d'ions $C_2O_4^{2-}$ ou de molécules $H_2C_2O_4$ non dissociées.

Les solutions de $DC_2O_4^-$ dans D_2O sont obtenues en dissolvant $Na_2C_2O_4$ anhydre, produit Merck pour analyse, dans D_2O (99.75%) et en acidifiant progressivement cette solution de départ par une solution de DCl, 7.8 *N* environ, dont la teneur en D_2O est de 99.5%. Les produits deutériés sont fournis par le C.E.A. Les manipulations sont réalisées dans une boite à gants. Les spectres infrarouges et Raman sont ceux de solutions 0.20 *M* de $NaDC_2O_4$.

Les spectres infrarouges sont enregistrés à la température ordinaire avec un spectromètre P.E. 457, en utilisant des cellules à liquide munies de fenêtres en Irtran II séparées par un joint de Téflon d'épaisseur 27 μm. Une cellule identique contenant le solvant (H_2O ou D_2O) est disposée sur le faisceau référence du spectromètre. Les domaines observables sont alors les suivants: 2000–1700 cm^{-1}, 1500–900 cm^{-1} dans H_2O et 2000–1300 cm^{-1} et 1100–800 cm^{-1} dans D_2O.

Les spectres Raman sont obtenus à l'aide d'un spectromètre CODERG PHO équipé d'un laser à argon ionisé; la raie excitatrice, 488 nm, fournit une puissance de 1 à 1.2 W. Les conditions moyennes d'enregistrement sont les suivantes: tension d'alimentation du photomultiplicateur 950 V, fentes 6 cm^{-1}, vitesse de défilement des réseaux 25 cm^{-1}/mn. Pour les spectres enregistrés à température ambiante, les solutions sont placées dans des cuves parallélepipédiques de 0.3 ou 1 mL. Pour enregistrer les spectres à différentes températures comprises entre 4 et 90°C on dispose l'une d'elles dans une jaquette cylindrique en verre dans laquelle circule de l'eau dont la température est maintenue constante par un thermostat.

Analyse des spectres

Le tableau 1 rassemble les fréquences ir et Raman caractéristiques des espèces $HC_2O_4^-$ et $DC_2O_4^-$ en solution.

Les spectres des solutions dont le pH est compris entre 2.1 et 2.4, domaine dans lequel ces espèces sont prépondérantes, présentent des bandes faibles dues aux molécules $H_2C_2O_4$ ou $D_2C_2O_4$ non dissociées ou à l'ion $C_2O_4^{2-}$ (5). Pour éviter toute confusion, ces bandes parasites sont identifiées en enregistrant les spectres de solutions très acides où $H_2C_2O_4$ et $D_2C_2O_4$ sont seuls et de solutions neutres où $C_2O_4^{2-}$ est totalement formé.

L'examen des spectres montre qu'il existe un grand nombre de coïncidences entre les fréquences infrarouges et Raman aussi bien pour $HC_2O_4^-$ que pour $DC_2O_4^-$. Toutes les bandes Raman sont polarisées donc si l'on admet que la molécule est plane, seuls les modes de vibration symétriques situés dans le plan sont observés. La modification fondamentale, en passant du composé hydrogéné ou deutérié, est le remplacement du quadruplet 1305–1380–1410–1444 cm^{-1} par trois bandes à 950, 1060 et 1421 cm^{-1}, cette dernière étant très intense.

Etude vibrationnelle du modèle monomère

Nous avons montré que la position des bandes Raman de $HC_2O_4^-$ reste fixe en fréquence malgré leur changement d'intensité corrélatif à la variation d'acidité du milieu. De plus nous avons vérifié que la hauteur de certaines bandes Raman est rigoureusement proportionnelle à la concentration de l'espèce $HC_2O_4^-$ en solution, calculée d'après les constantes de formation de l'acide oxalique. Ceci accrédite l'hypothèse de la formation d'une espèce de structure bien définie, au moins à température constante.

Si l'espèce qui se forme en solution est un ion monomère, plan, plus ou moins solvaté par les molécules d'eau, elle appartient au groupe de symétrie C_s et possède 11 vibrations de type A'.

Par analogie avec les attributions proposées par De Villepin et Novak (2, 3) pour l'hydrogénooxalate cristallisé, nous pouvons proposer une première interprétation des spectres Raman (tableau 2). Pour les spectres infrarouges la comparaison avec l'état solide est plus difficile par suite de l'étroitesse du domaine observable en solution aqueuse et des im-

précisions sur les maxima de certaines bandes, dues à la forte absorption du solvant.

Région 1800–1500 cm^{-1}

Dans H_2O la mise en évidence des bandes caractéristiques est difficile en raison de la large bande de diffusion à 1640 cm^{-1} due au solvant; on observe toutefois un maximum à 1725 cm^{-1}, déplacé par deutériation à 1720 cm^{-1} et attribuable à ν(C=O).

Dans D_2O une autre bande, affirmée par l'absence de celles caractéristiques de HOD (1450 cm^{-1}) et H_2O (1640 cm^{-1}) en milieu très acide et neutre, apparait à 1640 cm^{-1}; elle correspond au mode ν_a(COO) en accord avec les conclusions de De Villepin et Novak (2). Dans ce solvant on constate en outre la présence d'une bande faible à 1560 cm^{-1} et d'une épaule à 1700 cm^{-1}, difficilement attribuable à des vibrations du modèle monomère.

Région 1500–1000 cm^{-1}

Dans ce domaine de fréquences on attend trois bandes correspondant aux modes ν_s(COO), ν(C—O) et δ(OH) ou δ(OD), or le spectre du composé hydrogéné comporte cinq bandes dont l'une, située à 1240 cm^{-1} est probablement due à ν(C—O). Dans le cas du dérivé deutérié cette région perturbée par la bande intense de D_2O à 1204 cm^{-1}, présente quatre bandes (tableau 1). La vibration δ(OD) doit correspondre à l'une des fréquences observées à 1060 ou 950 cm^{-1}.

Région 1000–250 cm^{-1}

La raie Raman intense située à 868 cm^{-1} dans H_2O et à 853 cm^{-1} dans D_2O est attribuée à la vibration ν(C—C). Les bandes à 725 et 453 cm^{-1}, déplacées respectivement à 685 et 450 cm^{-1} par deutériation, correspondent respectivement à des déformations des groupements COOH et COO^-; on ne peut cependant préciser leurs modes.

Il apparait donc entre 1750 et 900 cm^{-1} un certain nombre de raies qui ne peuvent pas être attribuées aux vibrations du monomère plan. Il est très peu probable qu'elles proviennent de combinaisons car celles-ci sont généralement peu intenses en Raman. L'hypothèse d'une seule forme monoprotonée est donc insuffisante pour interpréter la totalité des fréquences expérimentales. Nous sommes donc amenés à supposer l'existence d'au moins deux formes en équilibre entre-elles. L'une est très probablement la forme monomère, l'autre serait alors associée, pour laquelle diverses structures seront envisagées.

Mise en évidence d'un équilibre d'association pour $HC_2O_4^-$ en solution

Afin de vérifier l'existence d'un équilibre, nous avons étudié l'influence de différents facteurs physiques et chimiques sur le spectre Raman de la solution. Celle-ci est maintenue à un pH voisin de 2.4 car l'espèce $HC_2O_4^-$ est alors majoritaire.

Influence de la température

Nous avons suivi de façon systématique l'évolution du spectre Raman de $HC_2O_4^-$ et $DC_2O_4^-$ en fonction de la température. Dans H_2O cet effet porte principalement sur les bandes du quadruplet 1305–1380–1410–1444 cm^{-1}. L'intensité des bandes à 1305 et 1410 cm^{-1} croît régulièrement avec la température (fig. 1). Comme cet effet doit être relié à la rupture des associations entre les groupements $HC_2O_4^-$ nous attribuons ces deux bandes à la forme monomère et celles à 1380 et 1444 cm^{-1} à une forme plus ou moins associée (tableau 2). Notons qu'il se produit simultanément des diminutions de fréquences de l'ordre de 5 cm^{-1}.

Aucune variation importante de l'intensité des bandes n'est observée pour les solutions deutériées. A 60°C on constate seulement que la raie intense à 1421 cm^{-1} s'est déplacée jusqu'à 1415 cm^{-1} et qu'elle semble présenter une épaule vers 1400 cm^{-1}.

Influence de la concentration

Nous avons enregistré le spectre d'une solution d'hydrogénooxalate de césium trois fois plus concentrée que la solution utilisée jusqu'à présent (0.7 *M*). On relève la présence d'une nouvelle bande très faible vers 600 cm^{-1} et on constate une légère diminution relative des intensités des bandes à 1305 et 1410 cm^{-1} par rapport à 1380 et 1444 cm^{-1} sans changement appréciable de fréquences. L'augmentation de concentration doit en effet conduire à un renforcement des associations au détriment de la forme monomère; ceci est donc compatible avec l'effet de température.

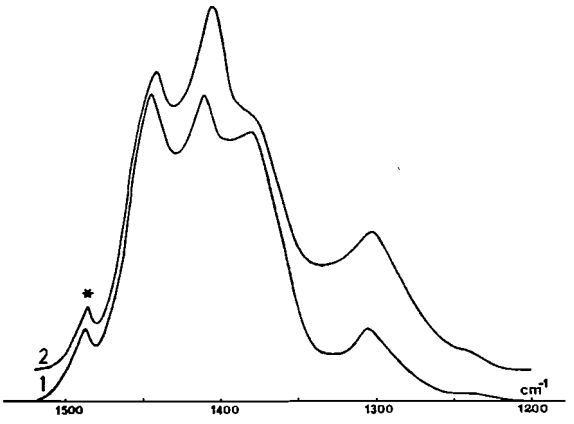

FIG. 1. Spectre Raman du composé $HC_2O_4^-$ en solution aqueuse, à deux températures différentes, dans la région 1200–1500 cm^{-1}. *1*: $T = 4°C$; *2*: $T = 90°C$. *Bande de $C_2O_4^{2-}$ à 1486 cm^{-1}.

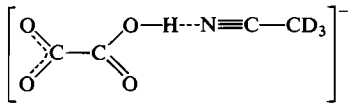
Influence de la nature du solvant

Nous avons suivi l'évolution du quadruplet Raman 1305–1380–1410–1444 cm^{-1} de l'ion $HC_2O_4^-$ en solution, en ajoutant à l'eau différents composés donneurs ou accepteurs de protons tels que $CHCl_3$, HCN, CD_3CN afin de modifier l'équilibre entre les formes. Ces solvants ne doivent pas posséder de bandes Raman intenses dans le domaine de fréquence étudié. Ainsi CH_3CN n'a pu être utilisé et a dû être remplacé par CD_3CN après avoir vérifié que l'échange deutérium–hydrogène était inexistant; CD_3CN possède cependant trois bandes entre 1250 et 1450 cm^{-1} dont deux à 1393 et 1451 cm^{-1} sont de très faible intensité, la troisième à 1281 cm^{-1} étant plus gênante.

L'addition de $CHCl_3$ ou de HCN n'apporte aucune information car le premier est très peu miscible à l'eau et le second ne parait pas interagir avec $HC_2O_4^-$. Par contre l'addition progressive, jusqu'à 28% en volume de CD_3CN à une solution d'hydrogénooxalate, 0.25 *M* provoque une augmentation régulière de l'intensité de la bande à 1410 cm^{-1}, qui s'abaisse à 1404 cm^{-1}, tandis que la bande à 1444 cm^{-1} se déplace à 1440 cm^{-1}. Il n'y a pas de modification mesurable des intensités des bandes à 1380 et 1444 cm^{-1}. L'évolution de la bande à 1305 cm^{-1} ne peut pas être chiffrée en raison de la présence à 1281 cm^{-1} de la raie plus intense de CD_3CN.

L'influence du CD_3CN peut s'interpréter par une compétition entre les formes associées de l'ion $HC_2O_4^-$ et une entité du type:

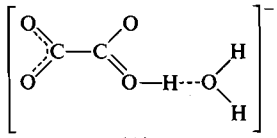


Les mêmes mesures effectuées pour les solutions de $NaDC_2O_4$ dans D_2O ne permettent pas de déceler des modifications significatives.

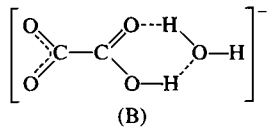
L'ensemble des résultats obtenus nous conduit à proposer une répartition des fréquences entre formes monomères et formes associées (tableau 2).

Proposition de structure pour l'espèce $HC_2O_4^-$ en solution aqueuse

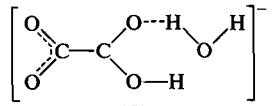
Pour la forme monomère, les interprétations de structures de Davies et Sutherland (11), Lascombe et coll. (12) et De Villepin et coll. (13, 14) concernant des monoacides carboxyliques en solution dans des mélanges H_2O–CCl_4 ou dans des solvants donneurs ou accepteurs de protons, nous conduisent à supposer la formation d'un hydrogénooxalate monomère, lié par liaison hydrogène aux molécules d'eau du solvant suivant les enchaînements (A), (B), (C) ou (D) envisagés par De Villepin et Lascombe:



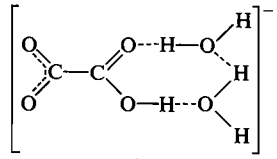
(A)



(B)



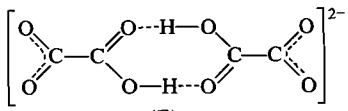
(C)



(D)

Pour la forme associée, à l'état cristallisé, De Villepin et Novak (2) admettent que l'association en chaînes longues, mises en évidence par Tellgren et Olovsson (1), permet d'expliquer leurs résultats spectroscopiques. En solution, la longueur des chaînes dépend du pH et on peut admettre que leur rupture entraîne des variations de fréquences ce qui est contraire aux observations expérimentales. La présence de telles chaînes est donc peu probable, ceci est confirmé par l'absence de certaines bandes observées sur les cristaux.

D'autre part une structure dimère fermée du type:



(E)

parait peu compatible avec les données spectroscopiques. En effet, d'après les travaux de plusieurs auteurs (6–10) si une telle structure dimère existe, elle présente un centre de symétrie et doit conduire à deux modes (C=O), l'un asymétrique actif en infrarouge et situé vers 1750 cm^{-1}, l'autre symétrique actif en Raman et vibrant entre 1650 et 1700 cm^{-1}. La coïncidence infrarouge Raman observée pour l'hydrogénooxalate à 1725 cm^{-1} (H_2O) et 1720 cm^{-1} (D_2O) rejette donc l'hypothèse du modèle (E).

L'existence d'une structure de dimères ouverts associés à des molécules d'eau suivant le schéma:

TABLEAU 2. Attribution des bandes Raman

Type de vibration	Monomère (A), (B) ou (D)		Associé (F) ou (G)		Résultats de De Villepin et Novak à l'état cristallisé (2)	
	H_2O	D_2O	H_2O	D_2O	$NaHC_2O_4.H_2O$	$NaDC_2O_4.D_2O$
ν(OH) ou ν(OD)	?	?	?	?		
ν(C═O)	1725	1720			1719	1720
$\nu_a(COO^-)$		1560 ou 1640		1640	1600	1632
$\nu_s(COO^-)$	1410	1400 ?	1444	1421	1416	1436

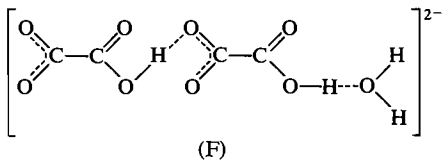
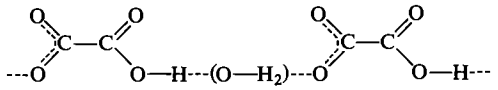
$\delta(OCO^-)$					597	592
$\delta(OCO^-)$					502	492
ou	453	450	453	450		
$\delta(OCO^-)$					479	481



(F)

ne peut être totalement exclue, mais la concentration d'une telle association doit être assez faible car le pouvoir solvatant de l'eau est tel que cette autoassociation ne devrait apparaître qu'à concentration élevée.

Il reste donc la possibilité d'association dipolaire entre les formes monomères liées par les molécules du solvant tel que:



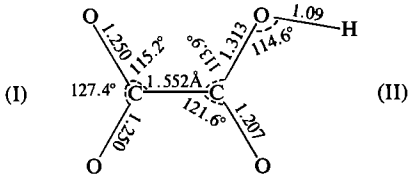
(G)

L'hypothèse d'un équilibre entre la forme monomère de type (A), (B) ou (D) et une association de type (F) et (G) peut expliquer les phénomènes observés par spectrométrie Raman.

Nous avons effectué un calcul des modes normaux des vibrations planes de l'ion $HC_2O_4^-$ monomère afin de préciser l'interprétation des spectres et d'expliquer les modifications de fréquence et d'intensité entrainées par la deutériation.

Calcul de vibration de l'ion $HC_2O_4^-$ pour la forme monomère

Le calcul a été réalisé par la méthode de Wilson et coll. (15) et les paramètres de structure utilisés pour calculer la matrice **G** sont ceux donnés par Tellgren et Olovsson (1). Nous les rappelons ci-dessous:



(I) (II)

Nous utilisons dans notre discussion la notation (I) et (II) pour désigner respectivement les groupes COO^- et COOH.

Choix du champ de force

Pour obtenir la matrice **F** de l'ion $HC_2O_4^-$ nous transférons 19 constantes de force provenant soit du champ de forces de valence du groupe —C—COO^- déduit des données spectrales de l'ion $^+NH_3$—CH_2—COO^- à l'état solide et en solution (16), soit du champ de force du groupement —COOH de l'acide formique à l'état gazeux (17). Les coordonnées utilisées pour le calcul sont les mêmes que celles des ions de référence. Nous disposons également des champs de forces proposés par Murata et Kawai (18, 19) pour l'ion $C_2O_4^{2-}$ et la molécule $H_2C_2O_4$; les constantes de force principales données par cet auteur et utilisées plus récemment par Bardet et Fleury (20) pour le même type de calcul sont du même ordre de grandeur de celles de Caillet et Destrade, excepté pour la liaison C—C.

Ce champ de force initial a été ajusté. Ainsi, la constante de force de la liaison C—C a été posée égale à 4.9 mdyn $Å^{-1}$. Nous avons augmenté les constantes de force de déformation δ(OH) et $\delta(OCO)_{II}$ et diminué celles des vibrateurs ν(C═O) et ν(C—O) du groupe COOH afin de tenir compte du changement d'état physique. Nous admettons que la constante de force du rocking du groupement COOH dont nous ne connaissons pas la fréquence de vibra-

TABLEAU 3. Constantes de forces pour l'hydrogénooxalate monomère plan. Les constantes de force de valence sont exprimées en mdyn $Å^{-1}$, celle de déformation en mdyn Å rad^{-2} et les interactions angles-liaison en mdyn rad^{-1}

§Constantes de forces nouvellement introduites.

tion est du même ordre de grandeur que celle du groupement COO^-. De plus, nous avons introduit deux constantes d'interactions supplémentaires numérotées 19 et 22 dont les valeurs sont ajustées par approximations successives. L'interaction 19, analogue à l'interaction ($\nu_{C=O}$, $\delta_{C—H}$) de l'acide formique, a pour effet de diminuer la fréquence $\nu(C=O)$ trop élevée avec le champ de forces initial. Il n'est pas possible de modifier davantage le champ de forces présenté dans le tableau 3 en raison de l'insuffisance des données expérimentales.

Résultats

Le tableau 4 regroupe les fréquences calculées et observées pour la forme monomère des ions $HC_2O_4^-$ et $DC_2O_4^-$. Il permet de comparer l'attribution initialement proposée à la répartition de l'énergie potentielle de chaque mode.

Fréquences calculées

La fréquence de l'élongation $\nu(C=O)$ de l'ion $HC_2O_4^-$ est supérieure de 3% à la valeur expérimentale. Seule l'introduction et l'ajustement des constantes d'interaction entre ce vibrateur et les déformations $r(OCO)_I$ et $r(OCO)_{II}$ permettraient d'améliorer l'accord entre le calcul et l'expérimental, mais les modes mettant surtout en jeu $r(OCO)_I$ et $r(OCO)_{II}$ sont inobservés pour l'ion $HC_2O_4^-$ en solution. Le problème est donc indéterminé.

Les modes situés à 1240 et 1305 cm^{-1} ($HC_2O_4^-$) et à 1270 cm^{-1} ($DC_2O_4^-$) sont calculés à des fréquences de 2 à 4% supérieures aux fréquences observées, mais le petit nombre de données expérimentales ne permet pas un affinement; quant au mode calculé à 1108 cm^{-1} pour $DC_2O_4^-$, il peut correspondre soit à la bande observée à 1060 cm^{-1}, primitivement attribuée aux formes associées, soit à une fréquence masquée par la très large bande de D_2O à 1204 cm^{-1}; les écarts sur $\delta(OH)$ et $\delta(OD)$ peuvent s'expliquer en partie par le fait que ces vibrations doivent être anharmoniques en raison des liaisons hydrogène.

Le calcul reproduit bien l'influence de la deutériation sur l'évolution des fréquences. En particulier $\nu_s(COO)_I$ s'abaisse alors que $\nu(C—O)$ augmente; ces variations sont dues aux couplages entre ces élongations et les déformations $\delta(OH)$ ou $\delta(OD)$.

Modes de vibrations

Dans l'ion $HC_2O_4^-$ le mode attribué à $\nu_s(COO)_I$ met également en jeu $\delta(OH)$ et $\nu(C—C)$; dans le composé deutérié la contribution de $\delta(OD)$ devient nulle alors que celles de $\nu(C—C)$ et $\nu_s(COO)_I$ augmentent. Ceci est cohérent avec l'exaltation de l'intensité diffusée à 1400–1421 cm^{-1}.

Les différences spectrales observées dans le domaine 1450–1300 cm^{-1} sont dues principalement aux modifications de couplage entre la vibration $\delta(OH)$ ou $\delta(OD)$ d'une part et les mouvements $\nu_s(COO)_I$, $\nu(C=O)$, $\delta(OCO)_I$, ... d'autre part.

Le mode de vibration calculé à 1360 cm^{-1} contient seulement 22% du $\delta(OH)$ tandis que la déformation $\delta(OD)$ participe pour 56% au mode situé à 1108 cm^{-1}.

La polarisation de la bande attribuée à $\nu_a(COO)_I$ s'explique par des élongations d'amplitudes différentes des deux liaisons C—O et par une mise en jeu de la liaison C—C.

Les modes situés vers 870 $\pm$ 10 cm^{-1} et attribués à $\nu(C—C)$ correspondent en fait à une élongation en phase de toutes les liaisons.

Enfin le mode observé vers 450 cm^{-1} correspond à une ouverture en phase des angles:

qui entraîne une contraction de la liaison C—C. La participation de ν(CC) explique la polarisation de la bande.

Conclusion

L'étude de la structure de l'ion $HC_2O_4^-$ en solution aqueuse par spectrométrie moléculaire, nous permet de mettre en évidence l'existence d'un équilibre d'association entre deux formes au moins; l'une d'entre elles, prépondérante à température élevée, est probablement de type monomère.

Le calcul de vibration, effectué en transférant les constantes de forces déjà connues pour les molécules voisines, confirme nos attributions. En effet les valeurs calculées sont en assez bon accord avec les résultats expérimentaux et reproduisent bien les variations spectroscopiques observées quand on passe de $HC_2O_4^-$ à $DC_2O_4^-$.

Stereoselective interaction of a tridentate Schiff base complex of nickel(II) and amino acids

B. ERNO AND R. B. JORDAN

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received September 12, 1978

B. ERNO and R. B. JORDAN. Can. J. Chem. **57**, 883 (1979).

It has been observed that a tridentate Schiff base complex of nickel(II), triaquotribenzo-[*b*,*f*,*j*][1.5.9]-triazacyclodecinenickel(II), commonly called (TRI)Ni$(OH_2)_3^{2+}$, shows substantial stereoselectivity on complexing with several amino acids. This provides a convenient way to resolve (TRI)Ni$(OH_2)_3^{2+}$ using histidine as a resolving agent, and either ion exchange or perchlorate salt crystallization techniques.

The resolved (TRI)Ni$(OH_2)_3^{2+}$ may then be used to resolve other amino acids or as a sensitive test of the stereochemistry of an amino acid. The test can be done on milligram quantities because of the insolubility of the complex perchlorate salt and because of the relatively large molecular rotation (2×10^5 deg at 283 nm) of (TRI)Ni$(OH_2)_3^{2+}$. The amino acid is easily released by treatment of the complex with dilute acid (pH $\approx$ 2). The procedure has been tested with histidine, tyrosine, methionine, and phenylglycine.

B. ERNO et R. B. JORDAN. Can. J. Chem. **57**, 883 (1979).

On a noté qu'un complexe entre du nickel(II) et une base de Schiff tridentate, triaquotribenzo[*b*,*f*,*j*][1.5.9]-triazacyclodécine nickel(II) généralement connue sous le nom de(TRI)Ni-$(OH_2)_3^{2+}$, présente une stéréosélectivité importante lors de sa complexation avec plusieurs acides aminés. Cette réaction fournit une méthode utile pour résoudre le (TRI)Ni$(OH_2)_3^{2+}$ faisant appel à l'histidine comme agent de résolution et des techniques d'échange d'ions ou de cristallisation du sel de perchlorate.

Le (TRI)Ni$(OH_2)_3^{2+}$ résolu peut alors être utilisé soit pour résoudre d'autres acides aminés soit comme une sonde sensible à la stéréochimie d'un acide aminé. Les essais peuvent être effectués sur des quantités de l'ordre du milligramme à cause de la faible solubilité du perchlorate du complexe et à cause de la rotation moléculaire relativement élevée (2×10^5 deg à 283 nm) du (TRI)Ni$(OH_2)_3^{2+}$. On peut regénérer facilement l'acide aminé en traitant le complexe avec de l'acide dilué (pH 2). On a évalué la méthode avec l'histidine, la tyrosine, la méthionine et la phénylglycine.

[Traduit par le journal]

Introduction

The observation of a stereoselective interaction of one optical isomer of a ligand by a metal ion generally requires the presence of a second ligand of specific stereochemistry on the metal ion. This second ligand should be stable, both stereochemically, and with respect to displacement from the metal ion. This ligand should also have sufficient steric bulk so that there is some interaction between the two ligands when complexed to the metal ion.

The tridentate Schiff base complex of nickel(II), triaquotribenzo[*b*,*f*,*j*][1.5.9]-triazacyclodecinenickel-(II), commonly, and hereinafter, referred to as (TRI)Ni$(OH_2)_3^{2+}$ (Fig. 1), seems to satisfy these requirements. The complex has been resolved (1) and is stable in aqueous solution at pH < 7. Observations are reported here on the interaction of this complex with histidine and several other amino acids.

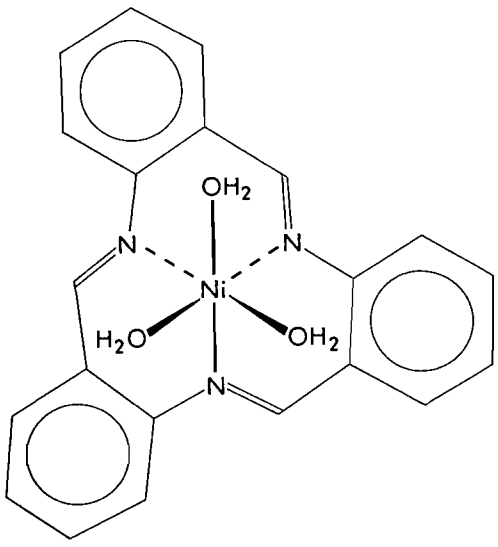

FIG. 1. Structure of (TRI)Ni$(OH_2)_3^{2+}$.

Experimental

Materials

The complex (TRI)Ni$(OH_2)_3(NO_3)_2$ was prepared by the method suggested by Taylor *et al.* (2). The method of Smith and Opie (3) was used to prepare *ortho*-aminobenzaldehyde, and this product was allowed to trimerize in dilute HCl as described by McGeachin (4). The trimer (1 g) was heated with an equimolar amount of Ni$(OH_2)_6(NO_3)_2$ in 40 mL of ethanol

0008-4042/79/080883-03$01.00/0

for 1 h. The initially green solution turned yellow-orange, and on cooling in ice yielded (TRI)Ni$(OH_2)_3(NO_3)_2$ (1.5 g).

The perchlorate salt was prepared by adding 10 mL of 3 *M* $NaClO_4$ to 1.5 g of the nitrate salt in 100 mL of warm (~50°C) water. The perchlorate salt was recrystallized twice from aqueous sodium perchlorate and dried under vacuum over calcium sulfate. *Anal.* calcd. for (TRI)Ni$(OH_2)_3(ClO_4)_2$: C 40.62, H 3.41, N 6.78; found: C 40.75, H 2.79, N 6.85. The electronic spectrum of the complex showed maxima at 315 nm and 275 nm, with molar absorbtivity coefficients of 1.18×10^4 dm^3 mol^{-1} cm^{-1} and 4.10×10^4 dm^3 mol^{-1} cm^{-1}, respectively, in agreement with previous results (1).

The histidine complex of $(TRI)Ni^{2+}$ was prepared as described in the Results section and characterized by the fact it could be converted to (TRI)Ni$(OH_2)_3^{2+}$ with aqueous acid, and by analysis. *Anal.* calcd. for (TRI)Ni(histidine)$(OH_2)(ClO_4)$: C 50.7, H 3.94, N 13.1; found: C 50.7, H 3.98, N 12.5.

The L-(+)-histidine (Nutritional Biochemicals) was recrystallized twice from 50% aqueous ethanol and dried over calcium sulfate. *Anal.* calcd. for $C_6H_9N_3O_2$: C 46.5, H 5.81, N 27.1; found: C 46.9, H 5.83, N 27.5. D-(−)-Histidine and D(−)-*d*-aminophenylacetic acid (D-(−)-*C*-phenylglycine) (Sigma Chemical Co.) were used as supplied, as were L-(−)-tyrosine (Eastman Organic Chemicals) and L-(+)-methionine (Aldrich Chemical Co.).

Instrumentation

Electronic spectra were recorded on a Cary 14 spectrophotometer. A Jasco Model ORD/UC-5 was used to measure ORD spectra, while routine optical rotations in the visible region were measured on a Perkin-Elmer 241 polarimeter.

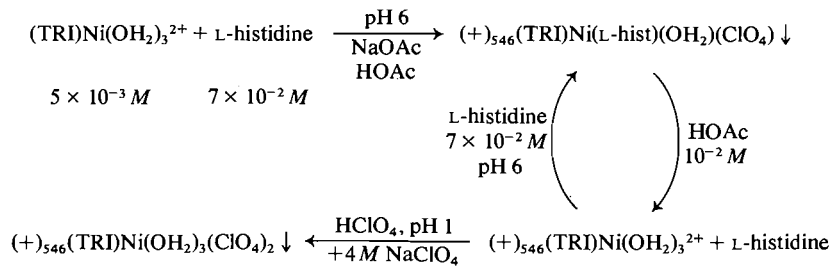
Solvent proton transverse relaxation times were measured on a Bruker SXP 4-100 spectrometer at 61 MHz. The standard 180°–τ–90° pulse sequence was used and the temperature was controlled at 25 ± 0.5°C with a standard Bruker temperature controller.

Results and Discussion

Preliminary examination of models indicated that there might be a steric interaction between histidine and the phenyl rings of (TRI) in a (TRI)Ni(histidine)$^+$ complex. As a resolving agent histidine also has the attraction of a cheap, widely available optical isomer. Subsequent studies have shown that (TRI)Ni$(OH_2)_3^{2+}$ can be resolved with L-(+)-histidine by either an ion exchange or a fractional crystallization method. The details are described below, but it is useful to bear in mind that the (TRI)Ni(histidine)$^+$ complex is rapidly dissociated in acidic solution (pH $\lesssim$ 2) to (TRI)Ni$(OH_2)_3^{2+}$, and that the perchlorate salt of the latter cation is almost quantitatively insoluble in solutions containing 3–4 *M* perchlorate ion.

In the ion exchange method a column (2 cm × 20 cm) of weak acid cation resin (Baker CGC-271) in the sodium ion form was charged with 50 mL of a solution containing 0.062 g (0.1 mmol) of (TRI)Ni$(OH_2)_3(ClO_4)_2$, and 0.077 g (0.5 mmol) of L-(+)-histidine free base in 0.04 *M* sodium acetate at pH 6. The column was eluted with increasing concentrations of sodium acetate (pH 6) always containing 10^{-2} *M* L-(+)-histidine. The complex moved down the column with 0.08 *M* sodium acetate, and was collected in six, 20 mL fractions. Each fraction was acidified (pH 1–2) with 6 *M* perchloric acid to convert the (TRI)Ni–histidine complex (yellow-orange) to (TRI)Ni$(OH_2)_3^{2+}$ (yellow). The ORD spectra of the acidic solutions showed that the first two fractions contained $(+)_{546}$(TRI)Ni$(OH_2)_3^{2+}$ and the last two contained $(-)_{546}$(TRI)Ni$(OH_2)_3^{2+}$. The product was recovered by adding 4 *M* sodium perchlorate to the acidic solutions to precipitate 12 mg of the $(+)_{546}$ isomer from the first two fractions and 9 mg of $(-)_{546}$ isomer from the last two fractions. The ORD spectrum of the $(+)_{546}$ isomer was essentially the same as that reported by Taylor and Busch. The maximum and minimum in the ORD spectrum of the $(+)_{546}$ isomer occurred at 254 nm and 283 nm, with molecular rotations of $+7.0 \times 10^4$ deg and -1.9×10^5 deg, respectively. The $(-)_{546}$ isomer gave corresponding molecular rotations of -6.8×10^4 deg and $+2.1 \times 10^5$ deg.

The precipitation method is shown in the following reaction scheme



The precipitate of (TRI)Ni(L-hist)$(OH_2)(ClO_4)$ was redissolved in 10^{-2} *M* HOAc (100 mL per mmol) and reprecipitated with an equal volume of L-(+)-histidine. A total of three precipitations was sufficient to produce no further change in optical activity of the product. The $(+)_{546}$(TRI)Ni$(OH_2)_3^{2+}$ product gave molecular rotations of $+6.5 \times 10^4$ deg and -2.0×10^5 deg at 254 nm and 283 nm, respectively, in good agreement with results from the ion exchange method. The $(-)_{546}$ isomer may be re-

covered by adding D-histidine to the filtrate from the first step with L-histidine.

Clearly the success of the precipitation method depends on the low solubility of the perchlorate salt of the (TRI)Ni^{2+}–histidine complex. The tetrafluoroborate salt is similarly insoluble, but the nitrate and chloride salts are too soluble to be used efficiently in the precipitation method.

On the other hand, the success of the ion exchange method implies that complex formation is stereoselective. An attempt has been made to measure the formation constants of the histidine complexes. Because (TRI)$Ni(OH_2)_3^{2+}$ is not stable in alkaline solution, the usual potentiometric titration method could not be used. A spectrophotometric method was investigated but the $\sim 10\%$ decrease in absorbance at 275 nm on complexing was too small to yield accurate measurements.

It was found that measurements of the solvent proton longitudinal relaxation rates (T_1^{-1}) as a function of ligand concentration could be used to calculate the formation constants. This method relies on the fact that histidine replaces rapidly exchanging water molecules (5) from (TRI)$Ni(OH_2)_3^{2+}$, and as these are replaced the effect of the paramagnetic complex on the solvent proton T_1^{-1} decreases proportionately. For example, at pH 6.2 and 25°C, the value of $(T_1^{-1})/[(TRI)Ni]_{total}$ decreases from ~ 550 s^{-1} M^{-1} to ~ 130 s^{-1} M^{-1} as the [histidine]/[(TRI)Ni] ratio increases from 0 to 2. The data analysis is directly analogous to that used in a spectrophotometric method. The results for the titration of racemic (TRI)$Ni(OH_2)_3^{2+}$ and L-(+)-histidine gave the logarithm of the formation constant as 7.26 ± 0.1, while $(-)_{546}$(TRI)$Ni(OH_2)_3^{2+}$ and D-(−)-histidine gave 7.42 ± 0.1. The differences are too small relative to the experimental uncertainty to show any definite difference in formation constants.

Since the stereoselectivity observed with histidine did not seem to be due to any dramatic formation constant differences it seemed possible that other amino acids might also demonstrate this effect. If this is the case (TRI)$Ni(OH_2)_3^{2+}$ could be a useful resolving agent for amino acids, or, because of its high molecular rotation, could be used to test for the presence of a particular stereoisomer. In fact stereoselectivity was shown by the amino acids tested.

As a general procedure a solution of 5×10^{-3} M (TRI)$Ni(OH_2)_3(ClO_4)_2$ and 3×10^{-3} M amino acid in dilute acid (e.g., 10^{-2} M acetic acid) was treated with sodium carbonate to a final pH of 6.2–6.5. Precipitate formation begins after a few minutes of stirring or a few drops of 4 M $NaClO_4$ may be added until precipitation begins. After cooling in ice for 2 h the precipitate may be collected by filtration or centrifugation depending on the scale of the experiment. For ORD measurements a 4×10^{-5} M solution of the product in 10^{-2} M $HClO_4$ in a 1 cm cell gave an easily measured rotation of $3–5 \times 10^{-2}$ deg at 283 nm. In the cases tested L-(+)-histidine, L-(−)-tyrosine, L-(+)-methionine, and D-(−)-*C*-phenylglycine the $(+)_{546}$ isomer of (TRI)Ni^{2+} was precipitated preferentially.

In summary it appears that the (TRI)$Ni(OH_2)_3^{2+}$–amino acid system shows a degree of stereoselectivity which can be useful in studies involving optical isomers of amino acids.

Reçu le 10 août 1978

JEAN-LUC PAYEN, JEAN DURAND, LOUIS COT et JEAN-LOUIS GALIGNE. Can. J. Chem. **57**, 886 (1979).

Le K_2PO_3F est orthorhombique, groupe d'espace *Pnma*, avec $a = 7.554(4)$, $b = 5.954(5)$, $c = 10.171(6)$ Å et $Z = 4$. On a mesuré les données d'intensité à l'aide d'un diffractomètre automatique muni d'une source de radiations CuK_α. On a déterminé la structure cristalline par analogie avec celle du K_2SO_4 et on a mis en évidence une interaction "F---K" importante. La valeur finale de R est de 0.065 pour 353 réflexions observées.

JEAN-LUC PAYEN, JEAN DURAND, LOUIS COT, and JEAN-LOUIS GALIGNE. Can. J. Chem. **57**, 886 (1979).

K_2PO_3F is orthorhombic, space group *Pnma*, with $a = 7.554(4)$, $b = 5.954(5)$, $c = 10.171(6)$ Å, and $Z = 4$. Intensity data have been measured on an automatic diffractometer with CuK_α radiation. The crystal structure was determined by analogy with that of K_2SO_4 and shows an important interaction 'F---K'. The final R index is 0.065 for 353 observed reflections.

Ce travail s'inscrit dans le cadre de l'étude systématique des composés oxyfluorés du phosphore V (1–9). Les résultats obtenus ont permis de montrer l'isostructuralité de certains composés sulfites et monofluorophosphates (anions à symétrie $3m$) d'une part puis de certains composés sulfates et fluoroberylattes (anions à symétrie $43m$) d'autre part (6). Il n'y a isotypie entre sulfates et monofluorophosphates que lors d'intéractions fortes "cation---fluor". Il était intéressant de déterminer la structure de K_2PO_3F, isotype de K_2SO_4, pour vérifier cette remarque sur un nouvel exemple.

Par ailleurs, K_2PO_3F est utilisé industriellement dans le cadre de la passivation des surfaces métalliques après phosphatation et avant peinture (7).

La résolution de la structure de K_2PO_3F avait été réalisée en 1958 par Robinson (10) mais, par suite du clivage des monocristaux utilisés, les résultats obtenus sont trop peu précis pour être utilisables ($R = 0.185$).

Partie expérimentale

Par cristallisation à 30°C d'une solution saturée de K_2PO_3F, nous avons obtenu des monocristaux en forme de bâtonnets. Ils sont stables à la température du laboratoire. Les constantes cristallographiques et le groupe d'espace ont été déterminés par les méthodes du monocristal. Les paramètres ont été affinés à partir des diffractogrammes de poudre enregistrés avec une précision de $\pm 1/100$ de degré θ. La masse volumique observée ρ_m a été mesurée par pycnométrie dans le benzène à 20.0 ± 0.1°C.

Z	4	4

L'étude structurale a été réalisée à partir d'un monocristal en forme de bâtonnet de $0.42 \times 0.18 \times 0.18$ mm³. Les mesures d'intensité ont été effectuées sur diffractomètre automatique Enraf–Nonius type CAD 3 avec la radiation CuK_α monochromatisée. 435 réflexions ont été mesurées jusqu'à un angle de Bragg θ égal à 60°.

Les réflexions de référence 013 et $01\bar{3}$ étaient repérées à intervalle régulier de 50 réflexions.

Les intensités ont été corrigées des effets de Lorentz polarisation. Les corrections d'absorption ont été effectuées en assimilant le bâtonnet à un cylindre et en utilisant les programmes permettant de traiter les cristaux cylindriques. Les 353 réflexions indépendantes pour lesquelles $\sigma(I)/I$ est inférieur à 0.3 ont été conservées.

Affinement de la structure

La structure a été résolue par isotypie avec le sulfate de potassium K_2SO_4 β forme basse température.

En début d'affinement les positions des atomes K,

*Expression du facteur de température: $T = \exp\ [-(\beta_{11}h^2 + \beta_{22}k^2 + \beta_{33}l^2 + 2\beta_{12}hk + 2\beta_{13}hl + 2\beta_{23}kl)]$.

P, O et F sont respectivement celles des atomes K, S et O de la molécule K_2SO_4.

Le groupement PO_3F^{2-} est symétrique par rapport au miroir *m* du groupe d'espace *Pnma* situé à $y = 1/4$ ou $y = 3/4$. Afin de pouvoir identifier l'atome de fluor, nous avons assimilé celui-ci à un atome d'oxygène. Dans le calcul d'affinement avec agitation thermique isotrope, un des 2 atomes d'oxygène en position 4*c* (c'est-à-dire dans le miroir *m*), voit son agitation thermique prendre une valeur nettement inférieure à celle de l'autre: il s'agit de l'atome de fluor ($Z = 9$). De plus un calcul de distances montre que la distance de cet atome au phosphore auquel il est lié est nettement supérieure à celle des trois autres atomes à ce phosphore.

A ce niveau le facteur de reliabilité se stabilise à $R = 0.112$. L'affinement s'est poursuivi avec agitation thermique anisotrope; R converge alors vers la valeur de 0.065 pour les 353 réflexions utilisées.

Les facteurs de diffusion atomique utilisés sont ceux donnés par Doyle et Turner pour K^+, P, O et F (11).

En fin d'affinement les positions atomiques ainsi que les coefficients d'agitation thermique anisotrope sont rassemblés dans le tableau 1.[1]

Description de la structure

La fig. 1 représente la projection de la structure sur le plan $y0z$. Les atomes K(1), K(2), P, O(1) et F sont dans les miroirs *m* situés à $y = 1/4$ et $y = 3/4$. Cet arrangement peut être décrit à partir de tétraèdres PO_3F^{2-} isolés et de cations K^+. Le tableau 2 rassemble les distances et angles interatomiques dans le tétraèdre PO_3F^{2-}.

L'atome de potassium K(1)—possède un environnement constitué par 9 atomes d'oxygène et un atome de fluor (fig. 2*a*): d'une part, 4 atomes d'oxygène O(2) et 2 atomes O(1) situés à des côtes voisines de $x = 0.173$; d'autre part, 3 atomes d'oxygène d'un tétraèdre PO_3F situés aux côtes x voisines de -0.200; enfin, l'atome de fluor d'un tétraèdre PO_3F situé à $x = 0.526$.

L'environnement de l'atome K(2)—est assuré par (fig. 2*b*): 6 atomes d'oxygène disposés en antiprisme déformés. Ces antiprismes se développent selon l'axe $0x$ en mettant une face en commun; 1 atome de fluor situé dans le plan *m*, à une distance F---K de 2.845 Å.

Les atomes d'oxygène O(1) et O(2)—possèdent un environnement octaédrique déformé constitué par un atome de phosphore auquel ils sont liés et à 5 atomes de potassium. (Les distances sont rassemblées dans les tableaux 2 et 3.)

Le fluor est environné—par 4 atomes de potassium et l'atome de phosphore auquel il est lié, avec cependant des interactions nettement différentes (fig. 3). Cet environnement est du type bipyramide trigonale: K(1) à 2.671(7) Å: distance voisine de la somme des rayons ioniques $K^+ + F^- = 2.69$ Å; K(2) à 2.845(8) Å: interaction moyenne; 2K(2) à 3.415(4) Å: interaction très faible.

Discussion

Il apparait que ce type d'arrangement se déduit directement de la structure K_2SO_4 β (12).

O(1)	0.3158	1/4	0.5459	2.920(8)
O(1)	−0.1842	1/4	0.9541	2.786(8)
O(2)	−0.2655	0.5404	0.6632	2.765(6)
O(2)	0.2345	−0.0404	0.8368	2.697(6)
O(2)	−0.2655	−0.0404	0.6632	2.765(6)
O(2)	0.2345	0.5404	0.8368	2.697(6)
F	0.0263	1/4	0.4414	2.845(8)

En effet, les atomes K(2) ont des projections sur le plan $y0z$ différentes quoique plus proches que dans K_2SO_4 β. Leur environnement est identique.

De plus K(1), P et F ont également des projections très voisines. L'axe ternaire du groupement PO_3F situé dans le miroir m fait un angle voisin de 10° avec l'axe $0x$.

Du fait de la distance K(1)---F = 2.671(7) Å (légèrement inférieure à la somme des rayons ioniques K^+ et F^- égale à 2.69 Å) la structure de K_2PO_3F est un exemple où l'atome de fluor de PO_3F^{2-} subit, de la part du cation voisin, une interaction forte.

Cet exemple montre l'isostructuralité entre monofluorophosphate et sulfate correspondant. Cette isostructuralité se retrouve pour l'ensemble des sels simples alcalins anhydres ainsi que pour les sels de formule $NaM_3(PO_3F)_2$ de structure glasérite. On constate alors que l'interaction métal alcalin---fluor est forte:

$$r_{K^+} + r_{F^-} = 2.671 \text{ Å pour } K_2PO_3F$$

$$r_{K^+} + r_{F^-} = 2.584 \text{ Å pour } NaK_3(PO_3F)_2$$

Par contre, lorsque la distance M^+---F^- est

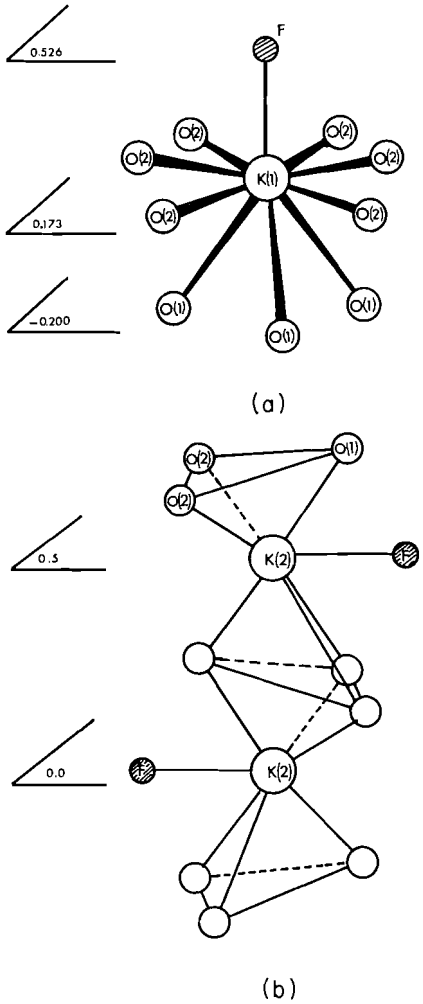

FIG. 2. (*a*) Environnement de l'atome de potassium K(1). (*b*) Environnement de l'atome de potassium K(2).

supérieure à la somme des rayons ioniques, cette intéraction est faible et les monofluorophosphates ne sont plus isostructuraux des sulfates correspondants. C'est en particulier le cas des sels doubles anhydres de la série lithium soit $LiMPO_3F$ (6). Dans ce dernier cas, les monofluorophosphates présentent des

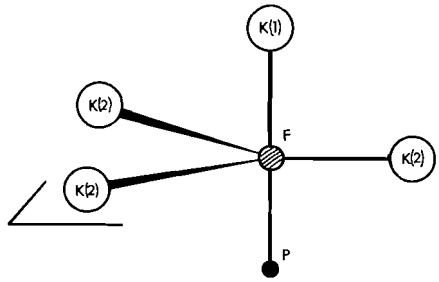

FIG. 3. Environnement de l'atome de fluor.

arrangements en couches tandis que les sulfates sont caractérisés par des structures en canaux.

La géométrie de l'anion PO_3F^{2-} (tableau 2) est de type C_{3v}; elle est comparable à celle trouvée dans la bibliographie (1–6 et 9), avec une distance P—F supérieure d'environ 0.1 Å par rapport à P—O. Il a été trouvé (13) un résultat identique pour l'anion SO_3F^-: S—O = 1.45 Å et S—F = 1.55 Å.

Chemistry of phenoxo complexes. VI. Reactions of phenoxocopper(I) complexes with carbon tetrachloride

JOHN F. HARROD AND PATRICK VAN GHELUWE
Chemistry Department, McGill University, Montreal, P.Q., Canada H3A 2K6

Received August 28, 1978

JOHN F. HARROD and PATRICK VAN GHELUWE. Can. J. Chem. **57**, 890 (1979).

The reactions of several substituted cuprous phenoxides with CCl_4 in acetonitrile were examined. Phenoxides without *ortho*-substituents usually gave high yields of tetraarylorthocarbonates. It is shown that the latter are also produced catalytically from sodium phenoxides and CCl_4 in the presence of small amounts of cuprous chloride. Cuprous phenoxides with *ortho*-chloro substituents, in the absence of facile hydrogen transfer agents, gave stable mixed oxidation state complexes of approximate composition: $Cu_2{}^{I}Cu^{II}Cl_2(OAr)_2$. In the presence of facile hydrogen atom transfer agents, such as free phenol or ascorbic acid, both the phenoxides without *ortho*-substituents and the *ortho*-chlorinated phenoxides gave moderate yields of triarylorthoformates. Some reactions of tritertbutylphenol and tritertbutylphenoxyl with copper complexes are described. The mechanisms of the various reactions are interpreted in terms of homo- and cross-coupling between phenoxyl and $\cdot CCl_3$ radicals.

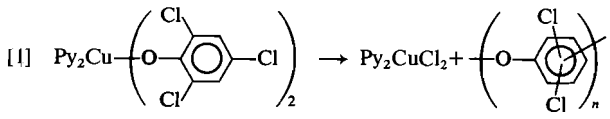
JOHN F. HARROD et PATRICK VAN GHELUWE. Can. J. Chem. **57**, 890 (1979).

On a étudié les réactions de plusieurs phénolates cuivreux substitués avec le CCl_4 dans l'acétonitrile. Les phénolates qui ne portent pas de substituants en *ortho* conduisent généralement à de bons rendements d'orthocarbonates de tétraaryles. On a montré que l'on peut aussi obtenir ces derniers par une réaction catalytique des phénolates de sodium et du CCl_4 en présence de faibles quantités de chlorures cuivreux. Les phénolates cuivreux portant un chlore en *ortho*, en l'absence d'agents permettant des transferts faciles d'hydrogènes, conduisent à des complexes stables comportant des états d'oxydation mixtes et de composition approximative $Cu_2{}^{I}Cu^{II}Cl_2(OAr)_2$. En présence d'agents permettant des transferts faciles d'atomes d'hydrogène, tels du phénol libre ou de l'acide ascorbique, les phénolates sans substituants en *ortho* de même que les phénolates portant des chlores en *ortho* conduisent à des rendements moyens d'orthoformates de triaryles. On décrit quelques réactions du tri-*tert*-butylphenol et du radical tri-*tert*-butylphenoxyle avec des complexes de cuivre. On interprète les mécanismes des diverses réactions en termes de couplages homolytiques et croisés entre les radicaux phénoxyle et $\cdot CCl_3$.

[Traduit par le journal]

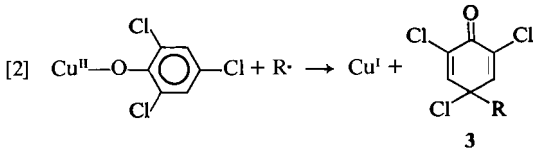
Introduction

An earlier paper (1) described a mechanistic study of reaction [1], first reported by Blanshard *et al.* (2).



1 **2**

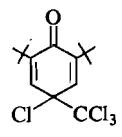
One conclusion of this study was that the initial step in reaction [1] is the homolytic ligand transfer from **1** to an initiator radical as depicted in [2] (1).



3

It was further suggested that one of the modes of participation of carbon tetrahalides in reaction [1] involved the formation and reaction of trihalomethyl radicals according to [2], to produce unstable trihalomethylcyclohexadienones, **3***a*, as intermediates (1).

Although a number of substituted trichloromethylcyclohexadienones have been synthesized, it is evident that their formation is favoured by alkyl substitution and strongly disfavoured by halogen substitution (3, 4). It is possible, however, that the latter empirical observation is the result of mechanistic rather than thermodynamic effects. To our knowledge there is a single reported example of a cyclohexadienone bearing both a chlorine and a trichloromethyl substituent on the same ring carbon.



4

This compound, **4**, was prepared by Pirkle and Koser and although no specific reference to its ther-

0008-4042/79/080890-09$01.00/0

mal stability was made, it is certainly of relatively long-term stability under ambient conditions (5). Thus, the plausibility of **3***a* as an unstable intermediate in reaction [1], catalyzed by carbon tetrachloride, remained open to question.

In order to further test the plausibility of **3***a* as an intermediate it was decided to take advantage of the well known tendency of copper(I) complexes to undergo reaction with carbon tetrachloride according to reaction [3] (6, 7).

[3] $$Cu^{I} + CCl_4 \rightarrow Cu^{II}Cl + {}^{\bullet}CCl_3$$

By using a phenoxocopper(I) complex in reaction [3] the possibility existed that both phenoxocopper(II) species and trichloromethyl radicals could be generated simultaneously in high concentration, thereby fulfilling all of the requirements for testing reaction [2]. The results of such a study are reported in the present paper.

Results

The results of the reactions studied may be classified in terms of the principal products obtained. These products are (*i*) aryl orthocarbonates, (*ii*) aryl orthoformates, (*iii*) cyclohexadienone derivatives. Only in the case of cuprous tritertbutylphenoxide was the anticipated trichloromethylcyclohexadienone obtained as the major product.

All of the reactions described below were carried out in acetonitrile except where otherwise stated. Acetonitrile is particularly appropriate for the *in situ* preparation of cuprous phenoxides by reaction of cuprous chloride with the appropriate sodium phenoxide.

Orthocarbonate-forming Reactions

As previously reported (8), certain cuprous phenoxides undergo smooth reaction with CCl_4 under ambient conditions to produce the corresponding tetraarylorthocarbonate as the principal product. The most important criteria for success in this reaction are the requirements that there be no *ortho*-substituents on the phenoxo group and that the substituents not be exceptionally reactive towards radical attack.

The operation of the first criterion is illustrated by the high yields of orthocarbonate from reaction of 3-methyl and 4-methylphenoxocopper(I), but very low yields from 2-methylphenoxocopper(I).[1] A similar result was obtained with the monochlorophenoxo analogues.

The operation of the second criterion is illustrated by the failure of any methoxy-substituted phenoxide to yield orthocarbonate. This failure seemed to be due to the extreme ease of hydrogen atom abstraction from the methyl group. The mixtures of products obtained in such reactions were not characterised.

Reactions of *ortho*-methylated phenoxide gave products typical of phenoxyl radical coupling. The usual complex mixture, typical of oxidative coupling (9), was obtained from 2-methylphenoxocopper(I). The 2,6-dimethylphenoxo complex reacted rapidly and cleanly according to reaction [4]:

[4] 
The precise fate of the $^{\bullet}CCl_3$ in reaction [4] was not determined. None of the reactions described herein was ever found to produce perchloroethane. A number of analyses by vpc all showed the presence of chloroform in solvent removed by distillation at the end of the reaction. It therefore seems reasonable to assume that $^{\bullet}CCl_3$ radicals are removed by hydrogen abstraction rather than coupling.

A reaction of dicopper(I) catecholate with CCl_4 produced the previously prepared bisphenylene orthocarbonate in good yield (10).

Since cuprous chloride is both a reactant and a product in the orthocarbonate forming reaction, it was anticipated that cuprous chloride would catalyse the reaction of a sodium phenoxide with CCl_4. A reaction in which an equimolar mixture of sodium 4-methylphenoxide and CCl_4 was reacted in the presence of 0.05 molar equivalents of cuprous chloride gave a high yield of orthocarbonate, thus confirming the expected catalysis.

Orthoformate-forming Reactions

The production of orthocarbonates described above only occurs in high yield under scrupulously anhydrous conditions. The use of undried acetonitrile as solvent led to the formation of triarylorthoformate as a major reaction product. Such reactions were also accompanied by precipitation of yellow cuprous oxide due to hydrolysis of the cuprous phenoxide.

An especially interesting case of orthoformate

[1]Although small amounts of orthoesters were detected in the reaction product by ir they were not successfully separated.

[d]The methine proton was coincident with the aromatic multiplet in this compound and was not assigned.

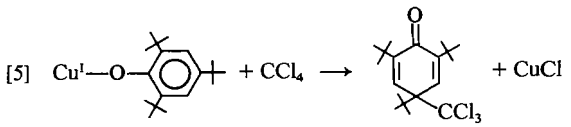
production was observed with cuprous 2,4,6-trichlorophenoxide. Under conditions normally used for the formation of orthocarbonate, the latter compound reacts to give a stable product of approximate composition $[Cu_2{}^{I}Cu^{II}Cl_2(OAr)_2]$. This reaction always leads to the production of a small amount of tris(trichlorophenyl)orthoformate and, by implication, cuprous chloride, thus rendering exact analysis of the Cu^{I}/Cu^{II} complex impossible. Equivalent results were obtained using cuprous pentachlorophenoxide.

When the products of reactions of excess CCl_4 with either cuprous pentachloro- or trichlorophenoxide were treated with a facile hydrogen atom transfer agent such as ascorbic acid, or a reducing phenol such as 2,6-xylenol, the intense reddish-brown colour was rapidly bleached and workup of the reaction mixture gave the polyhalophenyl orthoformate in substantial yield (see Table 1). Reduction of the reddish-brown mixed oxidation state complex with stannous chloride also resulted in rapid bleaching, but no orthoformate could be detected in the product.

When the ascorbic acid reduction of the reddish-brown material was carried out in the presence of carbene scavengers such as cyclohexene or norbornene, no dichlorocarbene adducts were detected and the formation of orthoformate proceeded normally.

Reactions Involving Tritertbutylphenoxyl Species

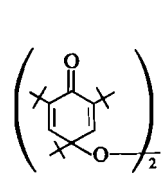
The reaction of cuprous 2,4,6-tritertbutylphenoxide with CCl_4 was quite different from those of relatively unhindered phenoxides. The reaction shown in [5] occurred rapidly and cleanly:



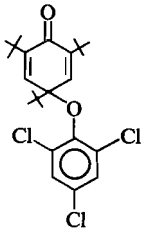
5

Since CuCl is generated in [5] and the cuprous phenoxide is easily formed from CuCl and sodium phenoxide, the cyclohexadienone can be synthesised in good yield from the reaction of CCl_4 and the sodium phenoxide in the presence of a catalytic amount of CuCl.

A reaction of equimolar amounts of 2,4,6-tritertbutylphenoxyl radical and cuprous trichlorophenoxide in the presence of CCl_4 also yielded **5** as the major product (ca. 50%). The remainder of the tertbutylphenoxyl radical was recovered as the peroxide, **6** (ca. 25%), and the quinol ether, **7** (ca. 25%). The product **6** resulted from oxygenation of unreacted radical during workup.



6



7

A similar reaction in which the tertbutylphenoxyl radical was replaced by 2,4,6-tritertbutylphenol resulted in a substantial increase in the yield of **7** at the expense of **5**.

No reaction occurred between tritertbutylphenoxyl and either bis(pyridine)bis(trichlorophenoxo)copper(II) or the mixed oxidation state product of the cuprous trichlorophenoxide/CCl_4 reaction.

Reaction [6] was found to proceed readily for X = Cl, but did not occur for X = CH_3COO, SCN, or OCH_3.

8

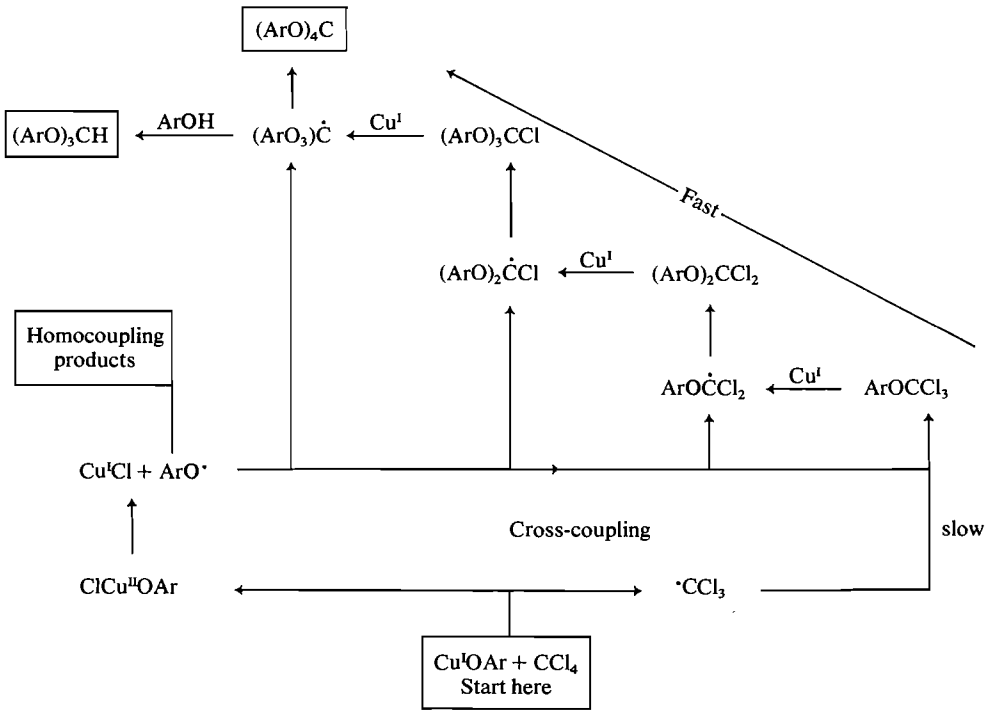
Discussion

Ortho Ester-forming Reactions

All of the experimental results described above can be accommodated by mechanisms involving free radicals. The production of ortho esters evidently occurs by an analogy of reaction [3] in which a copper(I)phenoxide generates a CCl_3 radical by chlorine atom abstraction from CCl_4 (see Scheme 1). If the phenoxide ligand is easily oxidised to the radical, such radical production should take place following oxidation of the Cu(I) by CCl_4. The simultaneously produced CCl_3 and phenoxyl radicals may undergo a number of different reactions, of which cross-coupling to produce an aryl trichloromethyl ether is presumably the precursor to ortho ester production. The fact that no mixed aryloxychloromethanes are observed in the ortho ester-producing reactions, even in the presence of a large excess of CCl_4, indicates that further substitutions into the trichloromethyl ethers are rapid compared to the initial substitution into CCl_4. The further substitutions could conceivably occur by simple nucleophilic attack by phenoxide (11) but the formation of orthoformates, as discussed below, is best explained on the assumption that they occur by a sequence of radical processes involving chlorine abstraction by copper(I).

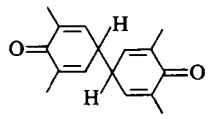
In the case of phenoxyl radicals that are unencumbered in the *ortho* positions the cross-coupling reaction to give ortho esters seems to occur with high efficiency. Alkyl substitution in the *ortho*-positions seems to favour homo-coupling of phenoxyl radicals relative to the cross-coupling reaction. This is probably a result of the reduced effectiveness of the bulky CCl_3 radical when it is competing with phenoxyl radical for a ring carbon position rather than for an unencumbered oxygen. Only in the case of the tritertbutylphenoxyl radical, where phenoxyl radical homocoupling is precluded, is carbon–carbon cross-coupling to CCl_3 observed.

The extreme rapidity of reaction [4] (complete



SCHEME 1. Production of ortho esters.

within a few minutes) suggests that phenoxyl radicals are generated in high concentration but that their rate of homo-coupling is much faster than either C—C, or C—O, coupling to trichloromethyl radicals. The stoichiometry of phenol production in the reaction also suggests that hydrogen abstraction from the primary coupling product, **9**, or its enol isomer, by phenoxyl radicals is fast compared to radical coupling, or to abstraction of hydrogen from solvent.



9

The formation of diphenoquinone rather than C—O coupled phenolic oligomers conforms to the generally accepted view that the diphenoquinone is the normal product of the coupling of 2,6-dimethylphenoxyl *free* radicals.

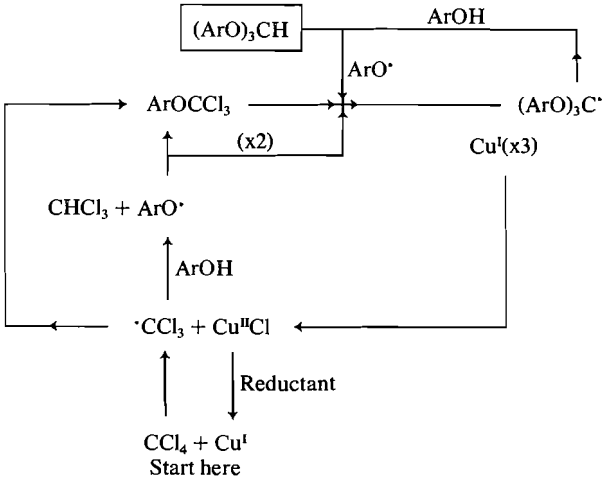
The observed formation of 2,4,6-trichlorophenyl orthoformate under certain reaction conditions proves that the steric impediment to cross-coupling at oxygen is not overly severe when both *ortho* positions are substituted with chlorine (in view of the similar steric size the same is surely true of methyl substituents). There is no doubt that the low stability of the homo-coupled phenoxyl dimers (either C—O or C—C) of the trichlorophenoxyl radical also directs the reaction towards orthoformate production. An examination of molecular models makes clear that orthocarbonate formation is sterically impossible in this case and it is expected that the triaryloxymethyl radicals will terminate by hydrogen atom abstraction. Even in the cases where there are no *ortho*-substituents the formation of orthoformate is observed when a facile hydrogen atom transfer agent, such as hydrolytically produced free phenol, is present. Since the mixed oxidation state products resulting from partial oxidation of cuprous penta- or trichlorophenoxides by CCl_4 are stable at room temperature, the generation of phenoxyl radicals in these systems most probably occurs via hydrogen atom abstraction from free phenol by other radicals in the system, and in particular by trichloromethyl radicals. Thus, in the absence of added hydrogen donor, a small amount of adventitious free phenol could yield phenoxyl radicals by hydrogen transfer to CCl_3 radicals generated by reaction [3].

The resulting phenoxyl radicals are then scavenged by cross-coupling with $CCl_3^{\cdot}$. The low yield of orthoformate results from the limited amount of $CCl_3^{\cdot}$ available and the inability of the phenoxide to recycle the Cu^{II} to Cu^{I} by reduction. These limiting factors are obviated by the addition of a protic reducing agent which can both recycle the Cu^{II} to Cu^{I} (thus ensuring a continuous supply of $CCl_3^{\cdot}$) and generate free phenol by protolysis of the phenoxide complexes (see Scheme 2).

The alternative possibility that orthoformate might be generated via insertion of dichlorocarbene into the O—H bond of free phenol is considered unlikely since no carbene derived products could be detected when the reactions were carried out in the presence of the carbene scavenger norbornene. It is not unlikely that dichlorocarbene might be extruded from an unstable trichloromethylcopper intermediate if it were formed. The present evidence provides little support for such a mechanism. The further possibility that orthoformate may arise from reaction of chloroform, resulting from hydrogen atom transfer to CCl_3 radicals, may be excluded on the grounds that chloroform was found to react only very slowly with cuprous phenoxides.

Reactions of Tritertbutylphenoxide and Tritertbutylphenol

All of the reactions of cuprous tritertbutylphenoxide and of tritertbutylphenol investigated in the present study gave products consistent with free radical mechanisms. The trichloromethylcyclohexadienone produced by reaction of cuprous tritertbutylphenoxide with CCl_4 is the expected product of cross-coupling between the phenoxyl radical and CCl_3 when steric hindrance precludes coupling at oxygen. The fact that only the 4-trichloromethyl derivative was isolated probably gives no clear indication of the stereoselectivity of the primary coupling process. The ^1H nmr spectrum of the crude reaction product indicated the presence of appreciable amounts of a 2-substituted cyclohexadienone. The failure to isolate such a compound may have been due to its spontaneous isomerisation to the more stable 4-isomer. The general failure to observe 2-substituted products from tritertbutylphenoxyl coupling reactions has previously been attributed to spontaneous isomerisation (12). The production of the quinol ether, **7**, in reactions of tritertbutylphenoxyl and tritertbutylphenol with cuprous trichlorophenoxide and CCl_4 is very likely due to protolysis of the cuprous trichlorophenoxide, followed by hydrogen abstraction from the free phenol to yield trichlorophenoxyl radicals. The reaction of tritertbutylphenoxyl with trichlorophenol is known to produce **7** in high yield (13). Since tritertbutylphenol introduces more protons into the system than the phenoxyl radical (where the protons come from hydroxylic impurities), it favours the formation of larger amounts of **7**.



SCHEME 2. Production of orthoformates from trichlorophenoxide.

The ligand abstraction reaction shown in [6], where X = Cl, is quite typical of ligand transfer reactions from cupric compounds to organic radicals (14); it is, we believe, the first such example involving an aryloxy radical. As such it raises some interesting speculation regarding the mechanisms of phenol substitution reactions mediated by metal complexes. For example, the well-known chlorination of phenols by cupric chloride is most simply explained by assuming the generation of a phenoxyl radical, followed by chlorine atom abstraction from $CuCl_2$ (15). Chlorine attachment at an unsubstituted *ortho-* or *para*-carbon would be followed by rapid enolisation to the phenol. In our study of reaction [6] it was also observed that use of $CuCl_2 \cdot 4H_2O$, rather than anhydrous $CuCl_2$, did not result in any decrease in the yield of **8**. Such behaviour parallels that of the reactions of alkyl radicals with copper(II) compounds, where the rates of transfer of chlorine or bromine atoms are very fast compared to reactions of ligands bonding through oxygen. The much higher reactivity of phenoxyl radicals towards chlorine ligand, rather than water or hydroxyl, also explains the relatively clean generation of monochlorophenol product in the copper catalyzed oxychlorination reaction [7] (16).

[7] 
Given the fact that chlorination can occur by ligand transfer it is reasonable to ask whether there is any condition under which hydroxylation can occur by a similar process, particularly in view of the important role played by metalloenzymes in biological hydroxylation (17). In a number of preliminary experiments we were unable to effect reaction [6] where X = CH_3O, CH_3COO, or CNS. Although the compound **7** was isolated from reactions of tritertbutylphenoxyl and tritertbutylphenol with cuprous trichlorophenoxide, its formation was more likely due to the known reaction of tritertbutylphenoxyl with free trichlorophenol (13) than to ligand transfer. An unequivocal resolution of the latter uncertainty is very difficult since solutions of tritertbutylphenoxyl radical are difficult to free of hydroxylic impurities. Since the lowering of oxidation potential of the metal by ligation to oxygen, rather than chloride, impairs transfer of oxygen bonded ligands, the problem may be solved by design of a more suitable non-reacting ligand environment about the copper (e.g., more polarisable ligands such as those found in copper-containing oxidases (17)).

Experimental

Solvents were generally of reagent grade. Hydrocarbons were freshly distilled from sodium benzophenone dianion before use. Acetonitrile was distilled from calcium hydride and stored over molecular sieves. Ethanol was dried with sodium and distilled under dry nitrogen prior to use. Phenols were obtained as reagent grade materials and subject to either a single recrystallisation or distillation prior to use. Cuprous chloride was prepared according to a standard procedure (18) and stored under vacuum.

Preparation of Cuprous Phenoxides

A sample of the appropriate sodium phenoxide was prepared by dissolution of sodium (2.3 g) in dry ethanol (150 mL) under nitrogen. Following dissolution of the sodium the phenol was added in slight excess (1.05 equivalent) and solvent was removed by distillation until solid began to appear. The remaining solvent and excess phenol were removed by heating at 90°C and 0.001 Torr for 16 h. The resulting sodium phenoxide was ground to a fine powder under dry nitrogen and used immediately.

Sodium phenoxide (100 mmol) in deoxygenated, dry acetonitrile (200 mL) was stirred to achieve a fine suspension and then cuprous chloride (100 mmol) was added. After stirring for 1 h the white precipitate was sometimes filtered off under nitrogen and identified as sodium chloride (ca. 5.8 g), but normally the NaCl was not removed and further reactions were carried out directly on the solution of cuprous phenoxide.

Preparation of Orthocarbonates

A solution of cuprous phenoxide, prepared as above, was treated with CCl_4 (9 mL; 100 mmol). On contact with the solution the CCl_4 initially generated an intense blue colour which almost instantly turned dark brown. After stirring for 12 h the brown colour was usually either completely discharged or considerably faded. Sodium chloride was removed by filtration and the filtrate was evaporated to dryness on a rotary evaporator to yield a white, sticky solid. Extraction of the solid with CCl_4 yielded insoluble CuCl (~100 mmol). The remaining solution contained essentially pure orthocarbonate in the cases of phenyl, 4-methylphenyl, 3-methylphenyl, and 4-chlorophenyl (by ^1H nmr). Evaporation of CCl_4 and recrystallisation from absolute ethanol gave the pure orthocarbonates in ca. 50% yield. The product from the reaction of cuprous 2-chlorophenoxide contained a considerable amount of phenol and some ortho ester (by ir). Removal of the phenol by vacuum sublimation and recrystallisation of the residue from ethanol gave a small amount of tris(2-chlorophenyl)

orthoformate (14% based on reactant phenol). Although the product of the cuprous 2-methylphenoxide reaction contained some ortho ester (by ir), neither orthocarbonate nor orthoformate was successfully isolated from the mixture of products.

A reaction of dicopper(I) catecholate (50 mmol) with CCl_4 (200 mmol) gave a dark green/black suspension with considerable evolution of heat. After stirring for 12 h the mixture was added to an excess of water, extracted with CH_2Cl_2, dried and evaporated to a dark brown viscous oil. The oil was deposited on a Florisil column and eluted with CH_2Cl_2 to yield pure bisphenylene orthocarbonate (50% yield).

Some properties of the orthocarbonates are summarised in Table 1.

Catalytic Synthesis of 4-Methylphenyl Orthocarbonate

To a stirred suspension of sodium 4-methylphenoxide (100 mmol) in acetonitrile (200 mL) was added cuprous chloride (5 mmol) and CCl_4 (100 mmol). After stirring for 12 h at room temperature the product was worked up as in the stoichiometric reaction and the yield of orthocarbonate was essentially the same.

Synthesis of 4-Methylphenyl Orthocarbonate in Wet Acetonitrile

The stoichiometric synthesis of 4-methylphenyl orthocarbonate was carried out using exactly the procedure described above, except for the use of reagent grade acetonitrile containing 0.2 to 0.3% water. Removal of a small amount of free phenol from the crude organic product by vacuum sublimation left a mixture of orthocarbonate and orthoformate in the ratio of 10:1 (by ^1H nmr).

Reaction of Cuprous 2,6-Dimethylphenoxide with CCl_4

Cuprous chloride (9.9 g) was added to a stirred suspension of sodium 2,6-dimethylphenoxide (14.4 g) in acetonitrile (100 mL). After 1 h CCl_4 (10 mL) was added. The mixture immediately turned dark brown, but after a few minutes the dark brown colour had completely faded to be replaced by the dark orange suspension of 2,2′,6,6′-tetramethyldiphenoquinone. The latter was filtered and washed with water to remove sodium chloride (yield: 5.8 g). The filtrate was evaporated to dryness and the resulting sludge was slurried with CCl_4 (100 mL). The precipitated CuCl was filtered off and the solution was evaporated to a brown oil. Sublimation of the oil under vacuum yielded xylenol (4.5 g) and left a dark brown tar (1.0 g) which contained a small amount of diphenoquinone together with other unidentified products.

Reactions of Cuprous 2,4,6-Trichlorophenoxide and Pentachlorophenoxide

Reactions of the title compounds with CCl_4 under the conditions described for orthocarbonate synthesis led to dark red-brown solutions of more or less indefinite stability at room temperature. The colour changes were much slower for the pentachlorophenoxide than for other phenoxides. Evaporation of the acetonitrile on a rotary evaporator gave an amorphous dark brown solid whose infrared spectrum was identical to that of the uncomplexed copper(II) trichloro- or pentachlorophenoxide (19).

Extraction of the solid derived from the trichlorophenoxide with ether yielded trichlorophenyl orthoformate in ca. 10% yield. Extraction of the solid derived from the pentachlorophenoxide with toluene yielded pentachlorophenyl orthoformate in ca. 10% yield.

Reactions in the Presence of Hydrogen Transfer Agents

A reaction of cuprous 4-methylphenoxide was carried out under the same conditions as the orthocarbonate synthesis but in the presence of one equivalent of 4-methylphenol. The crude organic product yielded cresol (77% based on total 4-methylphenoxyl) on vacuum sublimation and a residue containing only orthocarbonate and orthoformate in 2:1 molar ratio (by ^1H nmr) (50% based on sodium phenoxide).

A similar reaction with cuprous trichlorophenoxide and free trichlorophenol, using the same workup as that used in the stoichiometric orthocarbonate synthesis, yielded a crude organic product from which free phenol was sublimed (75% based on total trichlorophenoxyl) to leave essentially pure trichlorophenyl orthoformate (45% based on sodium phenoxide).

A solution of cuprous trichlorophenoxide, prepared from the sodium phenoxide (1.0 g) and cuprous chloride (0.46 g) in acetonitrile was reacted with CCl_4 (3 mL). 2,6-Dimethylphenol (0.58 g) was added and the solution was stirred until the dark brown colour was discharged. The precipitate was recovered and washed with water to yield 2,2′,6,6′-tetramethyldiphenoquinone (0.3 g). Evaporation of the filtrate to dryness and extraction with CCl_4 gave a crude organic fraction (1.1 g) containing mainly trichlorophenyl orthoformate, trichlorophenol, and xylenol. Removal of the phenols by vacuum sublimation left a residue consisting almost entirely of orthoformate (0.49 g; 44% yield).

Repetition of the latter reaction, but using ascorbic acid (0.88 g) in place of xylenol, resulted in a similar bleaching of the dark brown solution. The initial precipitate contained sodium chloride and unreacted ascorbic acid (only slightly soluble in CH_3CN). The CCl_4 extraction left a residue of CuCl mixed with dehydroascorbic acid. The CCl_4 soluble material was a mixture of trichlorophenol and trichlorophenyl orthoformate (0.91 g total weight). Removal of the phenol and recrystallisation of the residue from ethanol yield the pure orthoformate (0.36 g; 40%).

Synthesis of 2,4,6-Tritertbutyl-4-trichloromethylcyclohexa-2,5-dienone

Sodium tritertbutylphenoxide (1.29 g) was suspended in acetonitrile under nitrogen. Cuprous chloride (0.45 g) was added and the mixture was stirred for 1 h before addition of CCl_4 (5 mL). The mixture turned slowly from yellow, to green, to blue, and was left at room temperature several hours. The product was evaporated to dryness and the resulting green mass was extracted with CCl_4. Slow evaporation of the CCl_4 solution yields the product **5** as a pale yellow crystalline powder (1.38 g; 80%; mp 71–72°C, lit. 68–71°C (20)). *Anal.* calcd. for $C_{19}H_{29}OCl_3$: C 60.1, H 7.64, Cl 28.04; found: C 59.16, H 8.05, Cl 26.93. ^1H nmr (CCl_4): $\delta = 1.9$ (S, 27H); $\delta = 7.35$ (S, 2H); ir: $\nu_{C=O} = 1660$ and 1640 cm^{-1} (KBr pellet).

A small amount of the peroxide **6** was isolated by concentration of the mother liquor. This product had properties identical to those previously reported (12).

A catalytic reaction was carried out using the sodium phenoxide (0.7 g; 2.5 mmol) and CuCl (0.025 g; 0.25 mmol) in acetonitrile (40 mL) and an excess of CCl_4. After stirring at room temperature for 5 h a conversion of phenoxide to **5** of 65% was estimated by ^1H nmr.

Reaction of the Cuprous Trichlorophenoxide/CCl_4 Reaction Product with 2,4,6-Tritertbutylphenoxyl

A solution of cuprous trichlorophenoxide was prepared by reaction of the sodium phenoxide (1.1 g) and cuprous chloride (0.5 g) in acetonitrile (15 mL). Following a standard procedure (21), the phenoxyl radical was prepared under N_2 by stirring tritertbutylphenyl (2.0 g) with MnO_2 (6 g) in benzene (100 mL). The radical solution was introduced into the cuprous phenoxide by filtration through a Schlenk filter under pressure of N_2. Carbon tetrachloride (3 mL) was injected and the mixture was stirred for 1 h. The product was evaporated to dry-

*TCP = trichlorophenoxide; PCP = pentachlorophenoxide.

ness and extracted with hexane. Slow evaporation of the hexane solution yielded the trichloromethylcyclohexadienone, **5** (1.5 g, 51% based on tritertbutylphenol). The residual mother liquor was shown by ^1H nmr to contain the peroxide **6** and the quinol ether **7** in roughly equal amounts. The compound **7** was crystallised by concentration of the mother liquor and its identity confirmed by comparison of its properties with those cited in the literature (22).

A similar reaction in which the tritertbutylphenol was used directly, without preoxidation to the radical, yielded a crude product which was shown by ^1H nmr to contain **5** and **7** in roughly equal proportions and only a small amount of **6**.

Reaction of 2,4,6-Tritertbutylphenoxyl with $CuCl_2$

The radical was prepared by oxidation of the phenol (2.62 g) with MnO_2 (12 g) in benzene (100 mL). The radical solution was filtered into a solution of anhydrous $CuCl_2$ (2.0 g) in acetonitrile (50 mL). The blue colour of the radical was discharged on contact with the $CuCl_2$ solution and on completion of the addition the solution was dark green/brown. Filtration, to remove precipitated CuCl, and evaporation yielded a sticky, black solid which was extracted with hexane. Evaporation of the hexane extract yielded an oil (2.2 g) which was shown by nmr to be a mixture of 4-chloro-2,4,6-tritertbutylcyclohexa-2,5-dienone, **8** (70%), and 4-hydroxy-2,4,6-tritertbutylcyclohexa-2,5-dienone, **10** (30%). The compound **8** was recovered by recrystallisation of the mixture from absolute ethanol (mp: 89–90°C, lit.: 94–96°C (23)), ir (thin film) 1665, 1645, 1370, 920 cm^{-1}; ^1H nmr (CCl_4): $\delta = 1.6$ (S, 9H); $\delta = 1.79$ (S, 18H); $\delta = 7.1$ (S, 2H).

Examination of a sample of the reagent radical solution showed it to be contaminated with **10** before reaction with the $CuCl_2$.

Treatment of a solution of **8** with CuCl in acetonitrile led to the rapid appearance of a dark blue colour, indicating the reversibility of reaction [6].

Similar reactions of the phenoxyl radical were carried out with bis(pyridine)bis(trichlorophenoxo)copper(II) and a number of other simple copper compounds. In each case the peroxide **6** was isolated in high (>75%) yield following aerobic workup of the reaction mixture. No ligand transfer products were identified.

Analysis of the Cuprous Polyhalophenoxides/CCl_4 Reaction Products

Samples of cuprous trichloro- or pentachlorophenoxide were prepared in acetonitrile as described above. Following removal of acetonitrile the orthoformate was removed from the product by washing with either ether (trichlorophenoxide) or toluene (pentachlorophenoxide). The resulting dark brown, amorphous powders were then dried under vacuum.

An accurately weighed sample was hydrolyzed in dilute nitric acid and carefully extracted with ether to remove phenol. The ether solution was evaporated and the phenol residue was weighed. The ionic chloride content of the aqueous hydrolysate was determined by both a gravimetric AgCl determination (23*a*) and by the Fajans method (23*b*).

The total copper and the relative amounts of Cu(I) and Cu(II) were determined using a procedure described by Kochi (24). Elemental analyses for C, H, and Cl were performed by Schwartzkopf Microanalytical Ltd. The results of these analyses are shown in Table 2.

Reçu le 10 août 1978

CHRISTIAN ARCHER, JEAN DURAND, LOUIS COT et JEAN LOUIS GALIGNE. Can. J. Chem. **57**, 899 (1979).

L'étude cristallographique des sulfites de cations monovalents permet de mettre en évidence un plus grand nombre de composés isotypes des sels à anions C_{3v} (PO_3F^{2-}), que des sels à anions T_d (SO_4^{2-} ou BeF_4^{2-}): F de PO_3F^{2-} ou la paire libre de S^{IV} ne sont pas liés avec les atomes voisins.

$LiCsSO_3 \cdot 2H_2O$ cristallise dans le système monoclinique, $a = 11.927(7)$, $b = 5.670(3)$, $c = 4.828(2)$ Å, $\beta = 109.26(4)°$, $V = 308.2(9)$ Å^3, $\rho_o = 2.758(9)$ g/cm^3, $Z = 2$, $\rho_x = 2.771(6)$ g/cm^3 (20°C; MoKα, $d = 0.7107$ Å).

La structure est caractérisée par des chaînes de groupements de SO_3 et LiO_4 parallèles à l'axe *b*. Ces chaînes sont liées entre elles par un système de liaison hydrogène. L'anion SO_3^{2-} est pyramidal, le doublet libre de S^{4+} se localise sur l'axe ternaire. Les dimensions moyennes de l'ion sulfite sont: S—O = 1.526 Å et O—S—O = 105.4°. La valeur finale de *R* est 0.046.

CHRISTIAN ARCHER, JEAN DURAND, LOUIS COT, and JEAN LOUIS GALIGNE. Can. J. Chem. **57**, 899 (1979).

A crystallographic study of some monovalent cation sulfites allows us to propose a larger number of salt anions with C_{3v} symmetry (e.g., PO_3F^{2-}) than with T_d symmetry (SO_4^{2-} or BeF_4^{2-}). In PO_3F^{2-} the F atom and the lone pair of S^{IV} in SO_3^{2-} are not bonded to neighbouring atoms.

$LiCsSO_3 \cdot 2H_2O$ crystallises in the monoclinic system, $a = 11.927(7)$, $b = 5.670(3)$, $c = 4.828(2)$ Å, $\beta = 109.26(4)°$, $V = 308.2(9)$ Å^3, $\rho_o = 2.758(9)$ g/cm^3, $Z = 2$, $\rho_x = 2.771(6)$ g/cm^3 (20°C; MoKα, $d = 0.7107$ Å).

The structure is characterised by chains of SO_3 and LiO_4 groups parallel to the *b* axis. These chains are connected by a system of hydrogen bonds. The SO_3^{2-} anion is pyramidal with the sulphur lone pair on the ternary axis. The average dimensions of the sulfite ion are S—O = 1.526 Å and O—S—O = 105.4°. The final *R* value is 0.046.

Analogie avec les sels à anions tétraèdriques de symétrie T_d ou C_{3v}

Il existe une identité structurale très étroite entre $(NH_4)_2SO_3$, H_2O et $(NH_4)_2PO_3F \cdot H_2O$. Le doublet de S^{IV} de l'ion SO_3^{2-} occupe exactement la place de F^- de l'ion PO_3F^{2-} et a un volume sensiblement égal (1). L'atome de fluor excepté, tous les autres éléments occupent des positions identiques.

A côté de cet exemple particulièrement net où le doublet de S^{IV} a une activité stéréochimique analogue à celle de F^-, il était intéressant de préciser la cristallochimie des sulfites de cations monovalents, afin de définir leur isotypie avec les sels correspondants d'anions de symétrie C_{3v} (PO_3F^{2-}) ou T_d (SO_4^{2-} ou BeF_4^{2-}) et de mettre en évidence de nouveaux exemples où l'activité stéréochimique du S^{IV} soit comparable à celle de F^- ou de O^{2-}.

Nous avons pu préparer, puis identifier cristallographiquement plusieurs familles de sels simples et doubles, pour la plupart totalement inédits:

$M_2SO_3 \cdot xH_2O$ avec $x = 1$ si M = Li et NH_4
$x = 0$ si M = Li, Na, K, Rb, Cs

$LiMSO_3 \cdot xH_2O$ avec $x = 2$ si M = Rb ou Cs
$x = 1$ si M = K
$x = 0$ si M = K, Rb, Cs, NH_4

$NaM_3(SO_3)_2$ avec M = Rb et Tl

$Na_xK_{2-x}SO_3$ avec $0 \leq x \leq 2$

il s'agit d'une solution solide continue. Le principe de préparation des sulfites alcalins est le suivant (2). Pour les sels simples (*i*) formation du pyrosulfite $M_2S_2O_5$ par action du SO_2 sur la base correspon-

dante:

$$2MOH + 2SO_2 \rightarrow M_2S_2O_5 + H_2O$$

(*ii*) formation du sulfite M_2SO_3 par action de la base MOH sur le pyrosulfite:

$$M_2S_2O_5 + 2MOH \rightarrow 2M_2SO_3 + H_2O$$

Pour les sels doubles (*i*) action du SO_2 sur la base MOH:

$$2MOH + 2SO_2 \rightarrow M_2S_2O_5 + H_2O$$

(*ii*) action de la base MOH sur la pyrosulfite $M_2S_2O_5$:

$$M_2S_2O_5 + 2M'OH \rightarrow 2MM'SO_3 + H_2O$$

La solution est alors concentrée à chaud (60°C) puis portée à température inférieure à l'ambiante, entre 5 et 15°C. La cristallisation fait apparaître des monocristaux sous forme d'aiguille. Le contrôle de la pureté des produits se fait par dosage du groupement sulfite et caractérisation de l'ion SO_3^{2-} par spectroscopie d'absorption infrarouge.

Les déterminations cristallographiques (système cristallin et paramètres de maille) ont été conduites par les techniques du monocristal et sont rassemblées dans les tableaux 1–3. Certains composés n'ont pu être isolés sous forme de monocristaux. Il s'agit de $Li_2SO_3\beta$ (forme haute température), $LiRbSO_3$ et $LiCsSO_3$. Ils ont été caractérisés par leur diagramme de poudre.[1]

D'après la connaissance des paramètres cristallographiques, l'*isostructuralité des sulfites avec les sels d'anions tétraèdriques de symétrie T_d est très limitée*: seuls Rb_2SO_3 et Cs_2SO_3 d'une part, et $NaRb_3(SO_3)_2$ d'autre part sont respectivement de types structuraux $K_2SO_4\beta$ et glasérite (3): composé de formule $CaBa_3(SiO_4)_2$. Par contre l'*isostructuralité avec les composés à anion tétraèdrique de symétrie C_{3v} est plus riche*; ainsi nous avons respectivement les isostructuralités suivantes. Sels simples (*a*) Rb_2SO_3 et Cs_2SO_3 avec M_2PO_3F pour M = K, Rb, Cs; (*b*) $(NH_4)_2SO_3 \cdot H_2O$ et $(NH_4)_2PO_3F \cdot H_2O$ (1). Sels doubles: (*a*) $LiKSO_3 \cdot H_2O$ avec $LiKPO_3F \cdot H_2O$ (4); (*b*) $LiKSO_3\alpha$ et $LiNH_4SO_3$ avec $LiMPO_3F$ (5) pour

ρ_m(g/cm^3)	3.106(12)	
Z	1	1

M = K, Rb, Cs et NH_4; (*c*) $NaRb_3(SO_3)_2$ et $NaTl_3(SO_3)_2$ avec $NaM_3(PO_3F)_2$ (6) pour M = K et Rb.

Enfin les sels $LiKSO_3\beta$ (forme haute température), $LiRbSO_3$ et $LiCsSO_3$ (isotypes entre eux) ne sont pas isotypes des composés à anions tétraèdriques de symétrie T_d (SO_4^{2-} et BeF_4^{2-}) et de symétrie C_{3v} (PO_3F^{2-}).

Les températures de deshydratation de $Li_2SO_3\cdot H_2O$, $LiKSO_3\cdot H_2O$, $LiRbSO_3\cdot 2H_2O$ et $LiCsSO_3\cdot 2H_2O$ sont respectivement de 78, 53, 5 et 55°C. L'oxydation des sulfites alcalins se produit vers 330, 435, 475, 720 et 740°C respectivement pour Li_2SO_3, Na_2SO_3, K_2SO_3, Rb_2SO_3 et Cs_2SO_3; puis vers 260, 290 et 330°C pour $LiKSO_3$, $LiRbSO_3$ et $LiCsSO_3$. Les sels d'ammonium, $(NH_4)_2SO_3\cdot H_2O$ et $LiNH_4SO_3$ se décomposent dès 30°C.

Le sulfite double $LiKSO_3$ obtenu par déshydratation de $LiKSO_3\cdot H_2O$ à 53°C est isotype des monofluorophosphates $LiMPO_3F$ anhydres; il possède une deuxième variété allotropique: dès 212°C, il passe à la forme $LiKSO_3\beta$ (appelée forme haute température) isotype des sels doubles anhydres $LiRbSO_3$ et $LiCsSO_3$.

En conclusion, les anions SO_3^{2-} et PO_3F^{2-}, à symétrie C_{3v} induisent autour de leur environnement une assymétrie de charge responsable d'une plus grande isostructuralité entre les sels de ces anions qu'entre les sels d'anions à symétrie T_d. En effet dans la grande majorité des structures réalisées sur les monofluorophosphates (1, 4–6) le F n'est pas lié avec ses voisins; il en est de même de la paire libre du S dans les composés sulfites isotypes correspondants.

Etude structurale de $LiCsSO_3\cdot 2H_2O$

Après avoir montré les isostructuralités entre certaines de ces phases et les monofluorophosphates correspondants, il était intéressant de connaître l'arrangement structural dans l'une de ces phases non isotypes; notre choix s'est porté sur $LiCsSO_3\cdot 2H_2O$ isostructural de $LiRbSO_3\cdot 2H_2O$.

L'étude sur monocristal en chambre de Weissenberg indique que $LiCsSO_3\ 2H_2O$ cristallise dans le système monoclinique groupe spatial $C2/m$, $C2$ ou Cm avec les paramètres indiqués dans le tableau 2.

Un test sur poudre montre que $LiCsSO_3\cdot 2H_2O$ a une réponse en optique non linéaire de l'ordre de 30 fois le quartz ce qui permet de ne retenir que les groupes non centro-symétriques, soit Cm ou $C2$.

Les mesures d'intensités ont été réalisées à température ambiante sur un monocristal de dimensions $0.34 \times 0.20 \times 0.15$ mm^3 à l'aide d'un diffractomètre Enraf-Nonius type CAD 3 utilisant la radiation MoKα monochromatisée. Un balayage $\theta/2\theta$ a été utilisé et 776 réflections ont été mesurées jusqu'à un angle de Bragg $\theta = 35°$. Nous avons éliminé toutes les réflections pour lesquelles $\sigma(I)/I$ était supérieure à 0.30. Les 729 réflections indépendantes restantes ont été corrigées des effets de Lorentz polarisation mais non d'absorption (μMoKα = 6.39 cm^{-1}).

Résolution de la structure

La structure a été résolue à partir d'une synthèse de Patterson tridimentionnelle qui a permis de localiser l'atome de césium en position particulière 2(*a*) pour le groupe d'espace *Cm*. Cette synthèse de Patterson n'est pas exploitable dans le groupe *C*2. Une synthèse de Fourier tridimentionnelle utilisant la contribution de cet atome de césium, dont les coordonnées ont été bloquées afin de fixer l'origine, a permis de localiser l'atome de S également en position particulière 2(*a*). Après affinement, une nouvelle synthèse de Fourier nous a permis de localiser les atomes d'oxygène des groupements SO_3 ainsi que ceux des deux molécules d'eau. L'affinement des coordonées de ces atomes ainsi que de leurs facteurs de température isotrope converge vers une valeur du coefficient de reliabilité:

$$R = \sum|F_o - |F_c||/\sum F_o = 0.108$$

A ce niveau une synthèse différence de Fourier permet de localiser l'atome de lithium en site tétraèdrique, mais non les atomes d'hydrogène des molécules d'eau. Les liaisons hydrogène possibles permettent de déterminer les positions des atomes d'hydrogène H_{11} et H_{12} de la molécule d'eau W(1), mais ceux de W(2) ne peuvent pas être positionnés. Le problème a été résolu par un calcul de minimisation de l'énergie électrostatique du réseau à l'aide d'un programme écrit par Tordjman.[2] Les positions déterminées alors ont été introduites pour un calcul

[2]G. Tordjman. Communication privée.

TABLEAU 4. Paramètres de positions atomiques (les écarts types mis entre parenthèses portent sur la dernière décimale)

	x/a	*y/b*	3/*c*
Li	0.174(3)	1/2	0.622(7)
Cs	0	0	0
S	0.2582(5)	0	0.719(1)
O(1)	0.3927(10)	0	0.833(3)
O(2)	0.2211(8)	0.215(1)	0.860(2)
W(1)	0.504(2)	0	0.426(3)
W(2)	0.271(2)	1/2	0.352(5)
H(11)	0.465	0	0.573
H(12)	0.465	0	0.215
H(20)	0.268	0.348	0.257

d'affinement et après trois cycles d'affinement avec agitation thermique anisotrope pour les atomes de Li, Cs, S et O et isotrope pour les atomes H, le coefficient de reliabilité non pondéré se stabilise à $R = 0.046$. Ce résultat confirme le choix du groupe *Cm* choisi pour la structure. Les facteurs de diffusion utilisés sont ceux donnés par Doyle et Turner (8) pour Li^+, Cs, S, O et ceux donnés par Stewart *et al.* (9) pour les atomes d'hydrogène. Le tableau 4 rassemble les positions atomiques finales.

Description de la structure

La fig. 1 donne la projection de la structure sur le plan *xOz*. L'arrangement structural peut être décrit à partir de chaines parallèles à l'axe *Oy*. Ces chaines sont formées de pyramides SO_3 et de tétraèdres LiO_4 ayant un sommet commun O(2). Li et S sont situés au niveaux $y = 0$ et $y = \frac{1}{2}$. Les différentes chaines SO_3—LiO_4 sont reliées entre elles par deux réseaux de liaison hydrogène, d'une part un réseau parallèle au plan *xOz* (niveau $y = 0$ ou $y = \frac{1}{2}$) à partir de W(1), d'autre part un second réseau perpendiculaire à ce plan à partir de la molécule W(2) (fig. 2).

La pyramide SO_3 a une symétrie proche de la symétrie C_{3v} (3*m*). Les valeurs des distances S—O dans l'ion sulfite (tableau 5), correspondent bien à la valeur théorique suggérée par Gillespie et Robinson (10): 1.54 Å. Ces distances sont en accord avec les valeurs trouvées pour plusieurs sulfites (11–19). Dans ce type de composés les oxygènes sont liés soit à des hydrogènes, soit à des métaux. Ces valeurs sont nettement plus élevées que celles rencontrées dans le cas où les atomes d'oxygène du motif SO_3^{2-} sont peu liés aux proches voisins (20, 21).

Le lithium est environné par quatre atomes d'oxygène, deux atomes d'oxygène O(2) de deux groupements SO_3 différents appartenant à une même chaine et deux atomes d'oxygène de deux molécules d'eau W(1) et W(2) situés au même niveau que l'atome de lithium soit $y = 0$ ou $y = \frac{1}{2}$, tableau 5.

Le césium se dispose dans des canaux perpendiculaires au plan *xOz*. Son environnement est contsitué par six proches voisins: deux oxygènes O(1) à $y = 0$ et 1 pour Cs($\frac{1}{2}$, $\frac{1}{2}$, 1); deux oxygènes O(2) à $y = 0.715$ et 0.285 pour Cs($\frac{1}{2}$, $\frac{1}{2}$, 1); deux oxygènes de W(1) à $y = 0$ et 1 et $z = 1.426$ pour Cs($\frac{1}{2}$, $\frac{1}{2}$, 1); et quatre autres voisins à des distances supérieures à 3.5 Å: 2W(1) ($y = 0$ et 1, et $z = 0.426$) et 2W(2) ($y = 0$ et 1, et $z = 1.352$) pour Cs($\frac{1}{2}$, $\frac{1}{2}$, 1).

Le doublet du S^{IV} est sur l'axe ternaire du groupement SO_3^{2-}. Cet axe fait un angle de 27° avec la direction S...Cs (fig. 3). La distance S...Cs de 3.80 Å est de 18% inférieure à la distance S—O...Cs linéaire de 4.64 Å rencontrée dans la bibliographie pour Cs_2SO_4 (20).

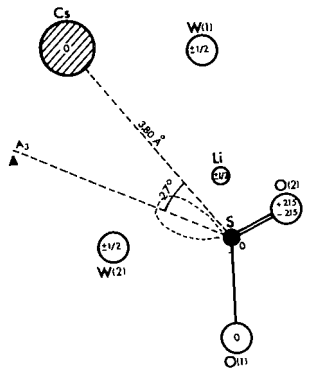

FIG. 3. Représentation du proche environnement du soufre dans la structure $LiCsSO_3 \cdot 2H_2O$.

Il a été signalé (1) une semblable diminution pour $(NH_4)_2PO_3F \cdot H_2O$ par rapport à $(NH_4)_2SO_3 \cdot H_2O$ puis Na_2PO_3F par rapport à Na_2SO_3. Il semble donc que l'activité stéréochimique de la paire électronique de S^{IV} (traduite par son encombrement) soit légèrement inférieure à celle du fluor.

$LiCsSO_3 \cdot 2H_2O$ présente un pouvoir de doublage de fréquence optique remarquablement élevé. L'étude de cette propriété sur monocristal est en cours de réalisation.

Cycloadditions and other chemistry of 4-oxygenated pyrazoles

PAUL J. FAGAN, ELI E. NEIDERT, MARTIN J. NYE,[1] MICHAEL J. O'HARE, AND WAH-PIU TANG

Guelph–Waterloo Centre for Graduate Work in Chemistry (Guelph Campus), Department of Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received August 11, 1978

PAUL J. FAGAN, ELI E. NEIDERT, MARTIN J. NYE, MICHAEL J. O'HARE, and WAH-PIU TANG. Can. J. Chem. **57**, 904 (1979).

Several synthetic routes to some new substituted pyrazol-4-ols and the reactions: methylation, acetylation, Michael addition, and oxidation are reported. Synthesis and cycloaddition reactions of the systems pyrazolium-4-olate and 3,4-diazacyclopentadienone are also reported. The former does not cycloadd, whereas the latter behaves as both a diene and a dienophile in various cycloadditions.

PAUL J. FAGAN, ELI E. NEIDERT, MARTIN J. NYE, MICHAEL J. O'HARE et WAH-PIU TANG. Can. J. Chem. **57**, 904 (1979).

On rapporte de nouvelles méthodes de synthèse de nouveaux pyrazolols-4 substitués et leurs réactions de méthylation, d'acétylation, d'additions de Michael et d'oxydation. On rapporte aussi la synthèse et des réactions de cycloaddition des systèmes pyrazolium-olate-4 et diaza-3,4 cyclopentadiènones. Les premières ne donnent pas de réaction de cycloaddition alors que les dernières se comportent à la fois comme des diènes et des diénophiles lors de diverses réactions de cycloaddition.

[Traduit par le journal]

Pyrazoles bearing an oxygen atom in the 4 position are of interest since one would expect some of the chemical reactions particularly cycloaddition to differ markedly from the 3- and 5-oxygenated analogues (1). Another point of interest is that the 4-oxygenated pyrazoles are in general less accessible synthetically and hence have received much less attention. This work was initiated from an interest in the possible cycloaddition reactions of the systems **1** and **2**. Compound **1** was found to cycloadd but compound **2** did not. This paper[2] includes these results and reports a number of new compounds synthesized incidently.

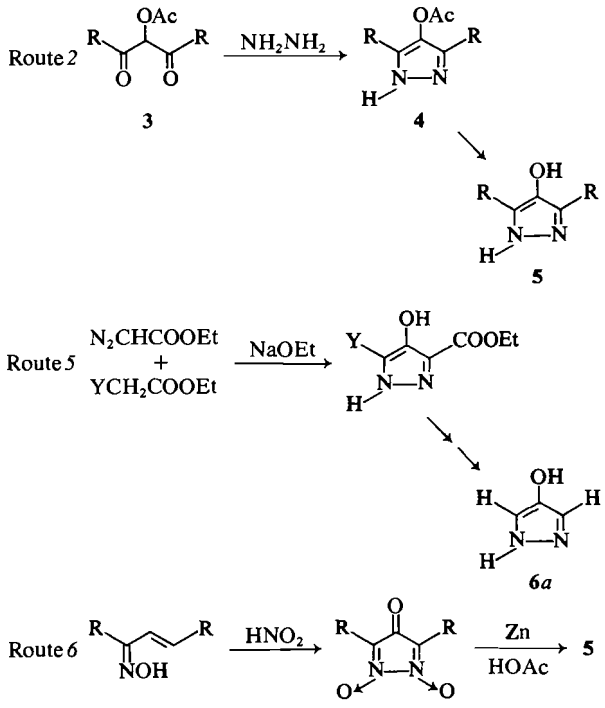
Results and Discussion

Ring Synthesis

Four general ways of synthesizing pyrazol-4-ols have already been reported (4). Of these the preferred route (route *2*) is shown in Scheme 1. The fifth and sixth methods first used by Bertho and Nüssel (5) and Freeman *et al.* (6), respectively, and used in this laboratory are also shown in Scheme 1.



(Y = COOEt or CN. When Y = COOEt, ***6a*** can be produced by hydrolysis and decarboxylation)

‖See Experimental.

6*l* several by-products were obtained and identified (Scheme 2). Under conditions of aqueous work-up the main products were the hydrazones **7**, **8**, and **9**, whereas under anhydrous conditions **6***l*, **10**, and **11** were the isolated products. Compound **10** was shown to be the precursor to **6***l* and **11**.

Synthesis of **6***m* and **6***n* from **6***k* by action of methanolic potassium hydroxide at room temperature and ammonium acetate at 130°C, respectively, are reported. It is curious in the latter case that none of the 3,5-dicarbamyl product could be isolated even when the temperature and duration of the reaction were increased.

Methylation

O-Methylated pyrazol-4-ols (**6***r* and **6***s*) may be synthesized in 60–70% yields by shaking a solution of the pyrazole in aqueous sodium hydroxide with dimethyl sulfate (presumably via an anion intermediate), whereas *N*-methyl derivatives (**6***i*, **6***s*, and

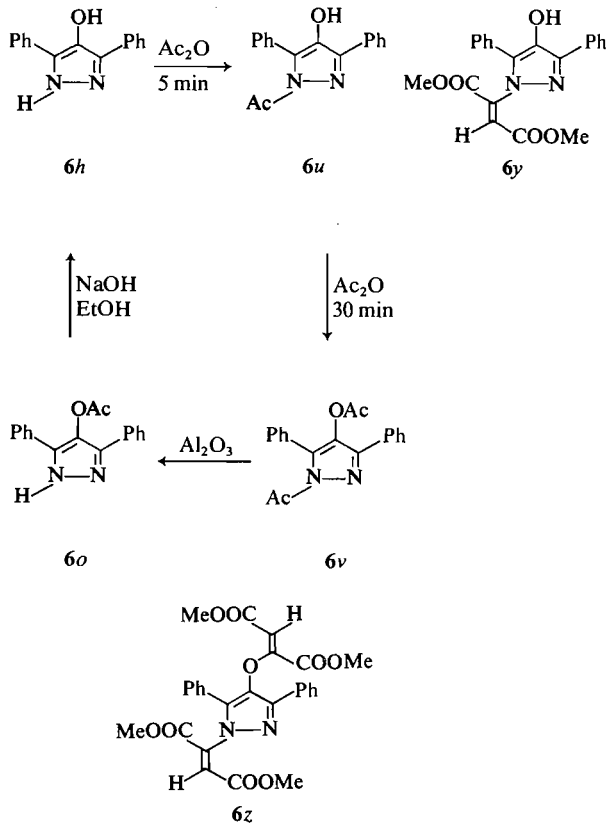
6*t*) may be prepared by direct heating with dimethyl sulfate (DMS) or methyl iodide. Similarly, *N,N'*-disubstituted pyrazolium compounds may be made directly from either an *N*-substituted or from an *N*-unsubstituted pyrazol-4-ol by heating it with excess dimethyl sulfate or methyl iodide to give the methosulfate or iodide salt which is then treated with alkali or passed down an ion exchange column to generate the zwitterion (**2***a–h*). The zwitterions **2***b* and **2***f* have also been prepared by treating 2-acetoxy-1,3-diphenyl-1,3-propanedione and 3-acetoxy-2,4-pentanedione (**12**) with *N,N'*-dimethylhydrazine. The analogous reactions of **12** with *N,N'*-diphenylhydrazine and *N*-methylhydroxylamine were unsuccessful. Table 2 summarizes the yields and melting points.

Acetylation

Acetylation of pyrazol-4-ols by refluxing with acetic anhydride occurs at both the N_1 and O positions but the rate of *N*-acetylation is faster. Hence depending on the time of reaction one can isolate either *N*-acetyl- or *N,O*-diacetylpyrazol-4-ols as the main products (see Scheme 3). Conveniently the *O*-acetylpyrazol-4-ols can be prepared by monodeacetylation of the diacetyl compounds by passing them down a column of neutral alumina. For example **6***o* is formed by deacetylation of **6***v* in 93% yield. The site of acetyl substituent is readily revealed by the carbonyl band in the ir spectrum



6*h* **6***u* **6***y*

6*o* **6***v*

6*z*

SCHEME 3

(*O*-acetyl ~ 1760 cm^{-1}, *N*-acetyl ~ 1740 cm^{-1}). An alternative route to *O*-acetyl compounds is via route *2* in Scheme 1.

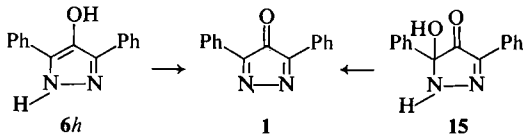
N-Benzoylation is effected on pyrazol-4-ols by heating them at 100°C with benzoyl chloride. Table 2 reports yields and melting points.

Michael Additions

Attempts at cycloadditions between 1,3-diphenylpyrazol-4-ol and dimethylacetylene dicarboxylate (DMAD) yielded the 1:1 and 1:2 Michael adducts **6***y* and **6***z* instead (Table 2).

Oxidation

1,3-Diphenylpyrazol-4-ol (**6***h*) is oxidized to 1,3-diphenyl-3,4-diazacyclopentadienone (**1**) by lead



dioxide in dry ether. It is a purple solid, deep red in acetonitrile solution and purple in concentrated sulfuric acid – acetonitrile mixtures, like tetraphenylcyclopentadienone (**13**) in all these respects. However, unlike **13**, **1** has a barely detectable ir carbonyl band (at 1740 cm^{-1}) in the solid state. Weak ir bands are known (10) to occur when the change in dipole moment during transition is close to zero and this could conceivably be the case for **1** as the polarity of the CO bond would be greatly reduced compared to normal ketones by the contribution from the five resonance structures represented by **14** which are stabilized by virtue of the aromatic sextet and also the presence of the electronegative nitrogen atoms. The charges calculated for **1** and cyclopentadienone by the HMO method, although imprecise, clearly show the expected trend (Fig. 1).

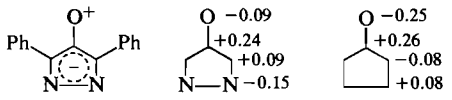


FIG. 1. Charges calculated for **1** and cyclopentadienone.

Conversion of **6***h* to **1**, observed by visible spectrophotometry, can also be effected in solution by thionyl chloride or by butyl nitrite both of which have been used for analogous reactions by Büchi and Lukas (11). Further confirmation of the structure of **1** is gained by its observed formation in solution from 5-hydroxy-3,5-diphenylpyrazolin-4-one (**15**) (prepared by reaction of diphenyltriketone with hydrazine (4)), by treatment with concentrated sulfuric acid.

Solutions of **1** are very unstable at room temperature even in the dark and within 30 min are practically completely decomposed. A crystalline product may be isolated from the solution and had previously been tentatively assigned (3) structure **16** from elemental analysis, uv, ir, and ^{1}Hmr spectra. This structure was later confirmed by Trost and Whitman (12) by mass and ^{13}C spectra.

Cycloadditions of the Diazacyclopentadienone (1)

Two questions were of great interest in connection with the cycloadditions of **1**. Firstly, does it react as a diene (13–15), as a dienophile (13, 16), or as a 1,3 dipole (13, 16)? Secondly, if **1** behaves as a diene, is it an example of the rare class of electron deficient dienes described by Sauer and Weist (17) which are highly reactive towards unactivated (electron rich) alkenes?

When **1** was treated with a wide variety of cycloaddition reagents with various conditions of solvent and temperature, it behaved either as a diene or a dienophile but not as a 1,3 dipole. As a dienophile it reacted with 2,3-dimethyl-1,3-butadiene to give **17** and with cyclopentadiene to give an analogous product. As a diene it reacted with [2.2.1]bicycloheptene to give **18**, presumably via **19** by loss of carbon monoxide and hydrogen. The latter steps have plenty of analogies (18). No products were isolated when **1** was treated with maleic anhydride, dimethylacetylene dicarboxylate, diphenylacetylene, dimethyl fumarate, carbon disulfide, isobutyl vinyl ether, cyclohexene, and cyclopentene.

Although the diene and dienophile reactivities of **1** were anticipated, the self condensation to give **16** is unusual. The first step, a simple Diels–Alder dimerization to give **20**, is presumed but one would then anticipate formation of **21** by loss of carbon monoxide as normally observed for cyclopentadiene dimers (18) and as occurs when **18** is formed from **19**. Instead nitrogen is lost. A possible explanation is that although carbon monoxide is lost by concerted reverse cycloaddition, nitrogen may be eliminated by a two-step free radical process (**10** → **22** → **23**). There is a precedent (15) for this mechanism in that **24** on heating (120°C) is converted to **25** and a diradical intermediate analogous to **23** was proposed. The factor which encourages the free radical mechanism for both **20** and **24** could be the presence of a stabilizing nitrogen substituent attached directly to the carbon radical generated in the initial bond breaking step. Note that this substituent is absent in **19** and hence the radical mechanism would be discouraged in favour of a concerted reverse cycloaddition. The final product **16** could then arise by two-step cycloaddition of **23** to another mole of **1**.

The above suggested mechanism has the advantage of avoiding symmetry problems associated with the simpler mechanism (**20** → **26** → **16**). If the latter mechanism is concerted, according to the Frontier Molecular Orbital (FMO) theory (19, 20), the overlapping lobes of the HOMO orbital of one reactant and the LUMO orbital of the other reactant should have the same phase. Figure 2 shows the eigenvector coefficients of the HOMO's and LUMO's of **1** and **26** as calculated by the Huckel π method and reveals a mismatch for suprafacial attack and therefore the reaction is disallowed. Similarly suprafacial extrusion of N_2 from **20** is disallowed. Hence a four-step radical mechanism for conversion of **20** to **16** is probable but a four-step heterolytic mechanism or a combination of both cannot be ruled out. Trost *et al.* (12) observed the formation of **16** from the bis-diazoketone **27** and proposed a mechanism in which **27** is converted to **1** and further **27** reacts with 2 moles of **1** with elimination of 2 moles of N_2. This mechanism may still be correct provided **27** is present but this current work reveals an alternative route which does not require reaction of **27** with **1**. The ability of **1** to react with [2.2.1]bicycloheptene but not maleic anhydride is intimately connected with its strong electron affinity and this property is further emphasized by the observation that it can oxidize hydrochloric acid to chlorine. When dry hydrogen chloride is passed through a solution of **1** in dry ether, chlorine gas is readily detected and a quantitative yield of 1,3-diphenylpyrazol-4-ol hydrochloride is produced. The low intensity carbonyl ir band of **1** is a manifestation of the comparable electron affinity of the heterocyclic ring relative to the exocyclic oxygen atom and this situation might also give rise to susceptibility of the oxygen of the carbonyl group towards nucleophilic attack. Indeed **1** reacts immediately with triphenylphosphine as does also the similarly electron-deficient 2,5-diphenyl-3,4-dicyanocyclopentadienone. In the latter case a crystalline adduct was obtained and characterized (21) but in the case of **1**, triphenylphosphine oxide and **6***h* were isolated which implies formation of **28** followed by hydrolysis in work-up.

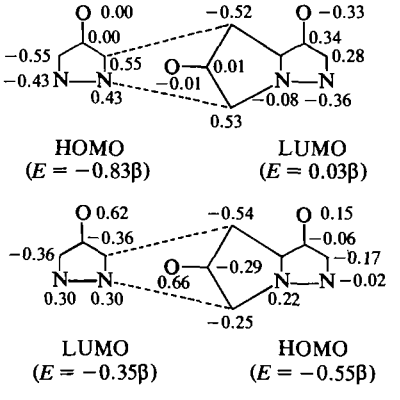

FIG. 2. Eigenvector coefficients and orbital energies of the HOMO's and LUMO's of **1** and **26**.

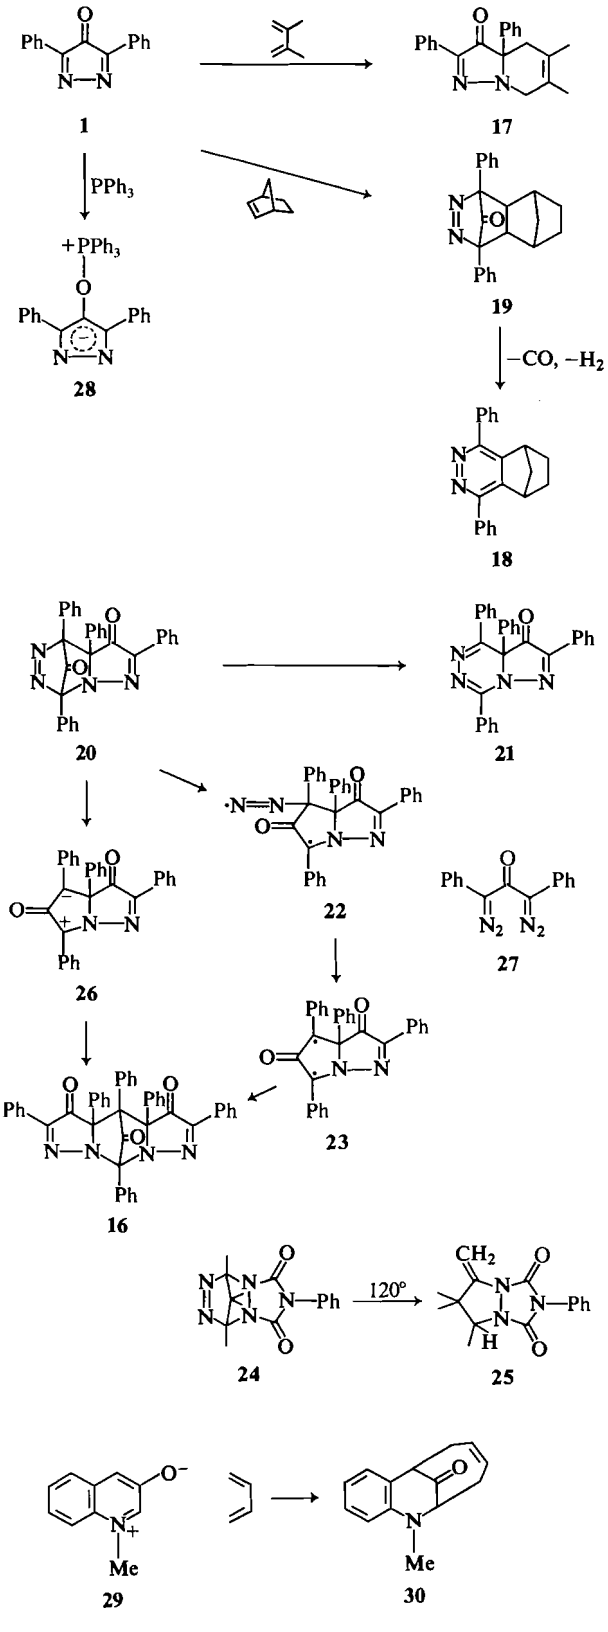
Cycloadditions of 4-Oxidopyrazolium (2)

In a previous paper (22) a first example of a heterocyclic zwitterion cycloadding to a diene was reported (**29** → **30**) and using FMO theory it was predicted that the 4-oxidopyrazolium system (**2**) should behave in a similar way (**2** → **31**). Figure 3 shows the eigenvector coefficients of the interacting lobes of the frontier orbitals. Since then exhaustive attempts to cycloadd **2** bearing methyls at the 1 and 2 positions and either H (**2***a*), phenyl (**2***f*), or ethoxycarbonyl (**2***h*) at the 3 and 5 positions with numerous dienes and activated alkenes and alkynes have failed. The most likely compound to succeed was thought to be **2***h* as it bears electron withdrawing activating groups but it suffered from instability problems. For example it is completely destroyed by heating it for 15 h at 100°C in bromoform. The nmr spectrum indicated conversion to 1-methyl-3,5-diphenyl-4-methoxypyrazole. This type of behaviour had been observed previously for derivatives of **2** bearing phenyl or methyl substituents (2, 23). In the presence of moisture the decomposition accelerates and 1-methylpyrazol-4-ol arises by hydrolysis and decarboxylation. For example acetonitrile containing 0.02% water decomposes **2***h* in 12 h at room temperature. So in the case of **2***h* any cycloaddition activity was masked by the highly competitive side reactions. For **2***a* and **2***f* the explanation of inactivity must be the fact that neither the HOMO nor LUMO lies close to zero and rates of cycloaddition are roughly inversely proportional to the energy difference between the interaction frontier orbitals (20).

Experimental

Infrared spectra were recorded on a Beckmann IR5A spectrophotometer as Nujol mulls unless otherwise stated and major peaks are reported in reciprocal centimeters. Nuclear magnetic resonance spectra were recorded on a Varian A-60A spectrometer using the internal standards DSS (sodium 2,2-dimethyl-2-silapentane-5-sulfonate) and TMS in $CDCl_3$ unless otherwise stated, and the data are presented in the order; chemical shift in ppm relative to the standard, multiplicity, number of protons, and assignment. Ultraviolet spectra were recorded on a Unicam SP-800 spectrophotometer in 95% ethanol unless otherwise stated and the data are presented in the following order: λ_{max} in nm, molar extinction coefficient (in parentheses). Mass spectra were run on a Varian MAT CH7 spectrometer. Symbols have the following meanings: b, broad; i, inflection; sh, shoulder; s, singlet; m, multiplet; d, doublet; t, triplet; q, quartet. Melting points were determined on a Mel-Temp apparatus and are uncorrected. Most of the



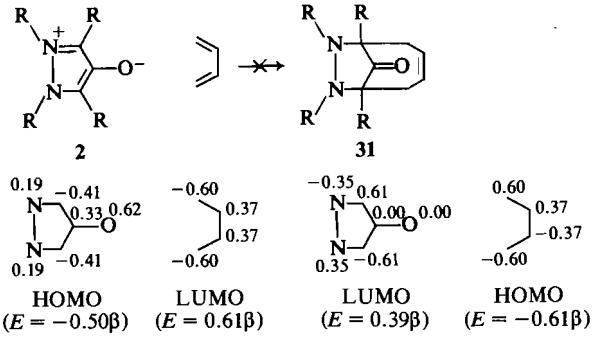


FIG. 3. Eigen-vector coefficients and orbital energies of the HOMO's and LUMO's of **2** and 1,3-butadiene.

elemental analyses (performed by A. B. Gygli, Microanalysis Laboratories Ltd., Toronto; C. Daesslé, Organic Microanalyses, Montreal; and H. S. McKinnon, Chemistry Department, University of Guelph) and ir spectra have been omitted for brevity and are available from the Depository of Unpublished Data.[3] All new compounds had satisfactory elemental analysis.

Route 2 (3 → 4 → 5)

The starting materials, 1,3-diphenyl-2-acetoxy-1,3-propanedione, 3-acetoxybenzoylacetone, and 3-acetoxypentane-2,4-dione, were prepared according to the methods of Neufville and Pechmann (24), Böhme and Schneider (8), and Auwers and Auffenberg (25), respectively. Typical procedures are given below for **6***j* and **6***q*, together with ^{1}Hmr and uv spectra for the products.

*3,5-Dimethylpyrazol-4-ol (**6**b)*—uv: 232 (5270); ^{1}Hmr (acetic-d_3 acid-d_1) 2.23 (s, 6H, CH_3).

*1,3,5-Trimethylpyrazol-4-ol (**6**c)*—^{1}Hmr: 2.13 (s, 6H, CH_3), 3.65 (s, 3H, N—CH_3).

*1-Phenyl-3,5-dimethylpyrazol-4-ol (**6**d)*—uv: 225(i) (7890), 263 (11 550); ^{1}Hmr; 1.99 (s, 3H, CH_3), 2.04 (s, 3H, CH_3), ca. 6.80 (b, 1H, OH), 7.18 (s, 5H, aromatic).

*1,3-Dimethyl-5-phenylpyrazol-4-ol (70%) mixed with 1,5-dimethyl-3-phenylpyrazol-4-ol (30%) (**6**f)*—^{1}Hmr: 208 (s, 3H, CCH_3), 3.54 (s, 3 × 70% H, NCH_3), 3.59 (s, 3 × 30% H, NCH_3), 7.17–7.95 (m, 5H, aromatic).

*3-Methyl-1,5-diphenylpyrazol-4-ol or 5-methyl-1,3-diphenylpyrazol-4-ol (**6**g)*—^{1}Hmr: 2.13 (s, 3H, CH_3), 7.2 (m, 10H, aromatic).

*3,5-Diphenylpyrazol-4-ol (**6**h)*—uv: 252 (22 700), 276(sh) (17 100), 295(sh) (10 000); ^{1}Hmr (DMSO-d_6): 7.32–7.67 (m, 7H, aromatic + OH), 7.94–8.11 (m, 4H, aromatic), 8.40 (b, 1H, NH).

*1-Methyl-3,5-diphenylpyrazol-4-ol (**6**i)*—uv: 245 (21 500), 276(sh) (10 600); ^{1}Hmr: 3.80 (s, 3H, CH_3), 7.35–7.62 (m, 9H, aromatic + OH), 7.98–8.14 (m, 2H, aromatic).

*1,3,5-Triphenylpyrazol-4-ol (**6**j)*—phenylhydrazine (0.5 mL, 0.005 mol) was added to a warm solution of 1,3-diphenyl-2-acetoxy-1,3-propanedione (1.13 g, 0.004 mol) in 95% ethanol (10 mL). After refluxing the solution for 1.5 h orange crystals separated and were collected by filtration.

*4-Acetoxy-3,5-diphenylpyrazole (**6**o)*—uv: 251 (29 900); ^{1}Hmr: 2.26 (s, 3H, CH_3), 7.30–7.50 (m, 6H, aromatic), 7.60–7.77 (m, aromatic), 10.68 (bs, 1H, NH).

[3]Photocopies may be obtained, at a nominal charge, upon request from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

1-Methyl-4-acetoxy-3,5-diphenylpyrazole (6p)—uv: 247 (27 800); ^{1}Hmr: 2.13 (s, 3H, CH_3), 3.83 (s, 3H, NCH_3), 7.32–7.55 (m, 8H, aromatic), 7.75–7.92 (m, 2H, aromatic).

4-Acetoxy-1,3,5-triphenylpyrazole (6q)—phenylhydrazine (0.42 mL, 0.0042 mol) was added with stirring to a solution of 1,3-diphenyl-2-acetoxy-1,3-propanedione (1.13 g, 0.004 mol) in acetic acid (10 mL). The mixture was stirred for 1 h, left for 18 h, evaporated at reduced pressure, and the crude mass triturated with ether (5 mL) to yield 1.03 g (72%) crude product; uv: 248 (27 300), 271(i) (21 500), 283(i) (14 800); ^{1}Hmr: 2.15 (s, 3H, CH_3), 7.08–7.38 (m, 13H, aromatic), 7.66–7.83 (m, 2H, aromatic).

Route 5 (Preparation of 3-Carbethoxy-5-cyanopyrazol-4-ol (6l) and By-products 7–11)

A solution of 2.2 g (0.02 mol) of ethyl cyanoacetate, 2.2 g (0.02 mol) ethyl diazoacetate, and 20 mL of absolute ethanol was added to a solution of 1 g (0.04 mol) sodium in absolute ethanol. The solution was maintained at 0–5°C during the addition and for 3 h thereafter. After stirring at room temperature for an additional 14 h the solution was divided into two equal portions which were worked up, individually, as follows.

Anhydrous Work-up

Dry hydrogen chloride was bubbled into the solution followed by evaporation to dryness. The crude grey residue was triturated with 5 × 50 mL anhydrous ether. The ether was removed under reduced pressure leaving a viscous brown oil. Thin-layer chromatographic analysis showed that this oil consisted of one major component and several minor components. Purification by preparative tlc yielded 730 mg (33%) of a clear yellow oil identified as (*Z*)-ethyl ethoxycarbonylmethylhydrazonocyanoacetate (**10**) on the basis of the following spectral properties; ir (neat): 3210, 2980, 2230, 1740, 1720 (sh), 1690, 1220–1150, 1022, 785; ^{1}Hmr (CD_3CN): 1150 (b t), $J \simeq 5$ Hz, 1H, NH), 3.39 (d, $J = 5$ Hz, 2H, NCH_2), 4.30 (q, $J = 7$ Hz, 2H, CH_2CH_3), 4.20 (q, $J = 7$ Hz, 2H, CH_2CH_3), 1.34 (t, $J = 7$ Hz, 3H, CH_2CH_3), 1.25 (t, $J = 7$ Hz, 3H, CH_2CH_3), addition of D_2O causes NH to exchange and the NCH_2 peak to collapse to a singlet; ms: molecular ion at *m/e* 227; uv: 295.5 (1.5–1.8 × 10^4).

Aqueous Work-up

The remaining half of the solution was diluted with 4 volumes of water and extracted with 2 × 125 mL of ether. These ether layers were discarded. The remainder of the aqueous phase was acidified to pH 4–5 with dilute hydrochloric acid and extracted with 4 × 125 mL ether. The combined ether layers were washed with saturated sodium chloride solution and dried over anhydrous sodium sulfate. Upon removal of the ether under reduced pressure a viscous yellow oil consisting of two major components at R_f 5.1 and 4.2 (tlc) and several minor components was isolated. Purification by two successive collections from preparative tlc enabled the isolation of the two major components as white crystalline solids. The product having R_f 5.1 (360 mg, 19%) was identified as (*Z*)-ethoxycarbonylmethylhydrazonocyanoacetic acid (**9**), mp 104–106°C, on the basis of the following spectral properties; ir (KBr): 3500–2500(b, several bands), 2230, 1735, 1695, 1530, 1220–1170(strong), 1020, 776; ^{1}Hmr (CD_3CN): 8.80 (bs, 1H, NH), 7.32 (bs, 1H, COOH), 4.38 (d, $J = 5$ Hz, 2H, NCH_2), 4.32 (q, $J = 7$ Hz, 2H, CH_2CH_3), 1.32 (t, $J = 7$ Hz, 3H, CH_2CH_3), addition of D_2O causes NH and COOH to exchange and the NCH_2 peak to collapse to a singlet; ms: molecular ion at *m/e* 199; uv: 302.5 (1.48 × 10^4). *Anal.* calcd. for $C_7H_9N_3O_4$: C 42.21, H 4.56, N 21.09; found: C 42.37, H 4.66, N 21.16.

The material having R_f 4.2 (380 mg, 20%) was identified as a 2:1 mixture of (*Z*)-ethyl carboxymethylhydrazonocyanoacetate (**7**) and its (*E*)-isomer (**8**), respectively. It was not possible to separate these isomers by any simple techniques, thus the spectral data following is a superimposition of the spectral properties of **7** and **8**. From the ^{1}Hmr spectrum of the mixture it was possible to derive the spectra of **7** and **8** individually. These spectral properties were as follows; ir (KBr): 3500–2500(broad, several bands), 2200, 1730, 1690, 1235, 1180, 1160(sh), 767; ^{1}Hmr (**7**) (CD_3CN): 8.77 (bs, 1H, NH), 7.83 (bs, 1H, COOH), 4.46 (d, $J = 5$ Hz, 2H, NCH_2), 4.38 (q, $J = 7$ Hz, 2H, CH_2CH_3), 1.38 (t, $J = 7$ Hz, 3H, CH_2CH_3); ^{1}Hmr (**8**) (CD_3CN): 7.01 (bs, 1H, COOH), 4.29 (q, $J = 7$ Hz, 2H, CH_2CH_3), 3.29 (s, 2H, NCH_2), 1.27 (t, $J = 7$ Hz, 3H, CH_2CH_3); addition of D_2O causes NH and COOH protons to exchange immediately and the NCH_2 protons of **8** to exchange slowly (half-life 0.5 h), and the NCH_2 protons of **7** to collapse to a singlet; ms: molecular ion at *m/e* 199; uv: 298 (1.73 × 10^4). *Anal.* calcd. for $C_7H_9N_3O_4$: C 42.21, H 4.56, N 21.09; found: C 42.26, H 4.60, N 21.00.

A solution of 500 mg (2.2 mmol) of diester **10** was heated at reflux in 20 mL absolute ethanol containing 100 mg (4.35 mmol) of sodium for a period of 8 h. The solution became a very dark clear brown at the end of this time. Water (80 mL) was added to the solution followed by the addition of 6 *N* HCl until pH 8 was reached. The aqueous layer was extracted with 6 × 50 mL ether. The combined ether layers were washed with saturated sodium chloride solution and dried over anhydrous sodium sulfate. Removal of the ether under reduced pressure gave a viscous brown oil which crystallized slowly. Recrystallization from acetonitrile–chloroform yielded 40 mg (8%) of a white crystalline solid, mp 143–145°C (lit. (5) mp 144°C), identified as 3,5-dicarbethoxy-4-aminopyrazole (**11**) on the basis of the following spectral properties; ir (KBr): 3450, 3340, 3180(b), 2980, 1710, 1615, 1285, 1250, 1130, 788, 770; ^{1}Hmr (CD_3CN): ~12.9 (very broad elevation in base line, NH), 5.25 (bs, 2H, NH_2), 4.38 (q, $J = 7$ Hz, 4H, CH_2CH_3), 1.39 (t, $J = 7$ Hz, 6H, CH_2CH_3); ms: molecular ion at *m/e* 227; uv: 312 (8.27 × 10^3), (+0.1 *N* NaOH) 296 (6.24 × 10^3). *Anal.* calcd. for $C_9H_{12}N_3O_4$: C 47.57, H 5.77, N 18.49; found: C 47.50, H 5.52, N 18.75.

The remainder of the aqueous layer was acidified further to pH 5–6 and again extracted with 6 × 50 mL ether. After washing with saturated sodium chloride solution, the combined ether layers were dried over anhydrous sodium sulfate. The ether was removed under reduced pressure leaving a viscous brown oil consisting (tlc) of several components. The major component R_f 0.22 was collected by preparative tlc. Recrystallization from acetonitrile–chloroform yielded 20 mg (5%) of **6***l*, mp 228–229°C; ir (KBr): 3200(b), 2225, 1730, 1595, 1295, 1255, 1198, 1034, 782, 717; ^{1}Hmr (DMSO-d_6): ~5.1 (broad elevation in base line NH, OH), 4.19 (q, $J = 7$ Hz, 2H, CH_2CH_3), 1.26 (t, $J = 7$ Hz, 3H, CH_2CH_3); ms: molecular ion at *m/e* 181; uv: 283 (7.5 × 10^3), 329 (1.5 × 10^3), (+0.1 *N* NaOH) 329 (8.5 × 10^3).

3,5-Dicarbomethoxypyrazol-4-ol (6m)

A solution of 100 mg 3,5-dicarbethoxypyrazol-4-ol (**6***k*), 100 mg potassium hydroxide, and 10 mL methanol was stirred at room temperature for 12 h, 40 mL water was added, and the solution acidified with dilute hydrochloric acid to pH 6–7. This aqueous solution was extracted with 4 × 25 mL ether. The ether was removed under reduced pressure leaving a gray solid which was readily recrystallized from chloroform–hexane. Pure 3,5-dicarbomethoxypyrazol-4-ol (**6***m*) was isolated as a white solid, mp 240–242°C; ir (KBr): 3400, 3210, 1705, 1675, 1535, 1310, 1295, 1210, 1075, 1012, 887; ^{1}Hmr

(DMSO-d_6): 3.83 (s, 6H, OCH_3); uv: 275 (8×10^3), (+0.1 *N* NaOH) 319 ($7–8 \times 10^3$).

3-Carbamyl-5-carbethoxyl-5-carbethoxypyrazol-4-ol (6n)

A mixture of 100 mg (0.44 mmol) 3,5-dicarbethoxypyrazol-4-ol (**6***l*) and 4 g (0.05 mol) ammonium acetate was heated at 130°C (mixture melts at 100–120°C) for 2 h and the crude fusion products completely dissolved by addition of water followed by dilute HCl to pH 5–6. The combined ether extract (3×50 mL portions) was dried over anhydrous sodium sulfate and concentrated. Thin-layer chromatographic analysis revealed the presence of three components one of which was starting material. The major component (bottom spot) was readily purified by recrystallization leaving 35 mg (41%) of 3-carbamyl-5-carbethoxypyrazole-4-ol (**6***n*) as a white crystalline solid, mp 261–263°C; ir (KBr): 3460, 3315, 3200, 1685, 1678, 1655, 1325, 1173, 1023, 820, 784, 750; ^{1}Hmr (DMSO-d_6): 4.28 (q, $J = 7$ Hz, 2H, CH_2CH_3), 1.27 (t, $J = 7$ Hz, 3H, CH_2CH_3); uv: 271 ($10–12 \times 10^3$).

Route 7 *(O-Methylation of Pyrazol-4-ols)*

Typical *O*-methylations are illustrated below.

4-Methoxy-3,5-diphenylpyrazole (6r)—A solution of **6***h* (1.18 g, 5 mmol) in 10% NaOH (60 mL) was heated to 60°C to dissolve and diluted to a volume of 90 mL with water; 2.5 mL of dimethyl sulfate was added and the two phases vigorously shaken. Solids were filtered and more methyl sulfate (2.5 mL) added to the filtrate to give a second crop of solid. The combined products were washed with water and dried; uv: 255 (28, 100), 291(sh) (6000); ^{1}Hmr: 3.63 (s, 3H, CH_3), 7.28–7.53 (m, 6H, aromatic), 7.83–8.00 (m, 4H, aromatic), 10.87 (s, 1H, NH).

1-Methyl-4-methoxy-3,5-diphenylpyrazole (6s)—uv: 251 (24 100); ^{1}Hmr: 3.55 (s, 3H, OCH_3), 3.83 (s, 3H, NCH_3), 7.33–7.86 (m, 8H, aromatic), 8.02–8.18 (m, 2H, aromatic).

Route 8 *(N-Methylation of pyrazol-4-ols)*

Typical examples are given below.

1,2-Dimethylpyrazolium-4-olate monohydrate (2a)—^{1}Hmr (DMSO-d_6): 7.02 (s, 2H, aromatic), 3.79 (s, 6H, CH_3); uv (H_2O): 285 (4000).

1,2,3,4-Tetramethylpyrazolium-4-olate monohydrate (2b)—uv (H_2O): 289 (7900); ^{1}Hmr (D_2O): 3.77 (s, 6H, NCH_3), 2.21 (s, 6H, CCH_3).

1,2,3-Trimethyl-5-phenylpyrazolium-4-olate monohydrate (2c)—uv (H_2O): 311 (9200); ^{1}Hmr (D_2O): 7.55 (s, 5H, aromatic), 3.87 (s, 3H, NCH_3), 3.69 (s, 3H, NCH_3), 2.32 (s, 3H, CCH_3).

1,3,5-Trimethyl-2-phenylpyrazolium-4-olate monohydrate (2d)— uv (H_2O): 297 (7500); ^{1}Hmr (D_2O): 7.84–7.38 (m, 5H, aromatic), 3.56 (s, 3H, NCH_3), 2.35 (s, 3H, CCH_3), 2.05 (s, 3H, CCH_3).

1,3-Dimethyl-2,5-diphenylpyrazolium-4-olate monohydrate or 1,5-dimethyl-2,3-diphenylpyrazolium-4-olate monohydrate (2e)—uv (H_2O): 322 (10 200); ^{1}Hmr (D_2O): 7.69–7.18 (m, 10H, aromatic), 3.55 (s, 3H, NCH_3), 2.45 (s, 3H, CCH_3).

1,2-Dimethyl-3,5-diphenylpyrazolium-4-olate (2f)—uv: 226 (14 200), 248(i) (6700), 325 (9700); ^{1}Hmr (D_2O): 8.61 (s, 10H, aromatic), 3.75 (s, 6H, CH_3).

1-Methyl-2,3,5-triphenylpyrazolium-4-olate (2g)—uv (H_2O): 341 (11 500); ^{1}Hmr: 8.02–7.16 (m, 15H, aromatic), 3.58 (s, 3H, aromatic).

1,2-Dimethyl-3,5-dicarbethoxypyrazolium-4-olate (2h)—A solution of 500 mg (2.2 mmol) 3,5-dicarbethoxypyrazol-4-ol (**6***k*) in 6 mL dimethyl sulfate was heated at 100°C for 2 h. After cooling to room temperature, dry ether was added dropwise until crystallization was initiated. The product was filtered and recrystallized from acetonitrile–ether to yield 600 mg (60%) of 3,5-dicarbethoxy-1,2-dimethylpyrazolium-4-ol methosulfate, mp 133–134°C; ^{1}Hmr (CD_3CN): 4.54 (q, $J = 7$ Hz, 4H, CH_2CH_3), 4.35 (s, 6H, N—CH_3), 3.48 (s, 3H, $MeSO_4$), 1.42 (t, $J = 7$ Hz, 6H, CH_2CH_3). A 100 mg (0.27 mmol) sample of the methosulfate was dissolved in a minimum amount of acetonitrile at room temperature. To this solution was added 1 equiv. of triethylamine and an immediate appearance of precipitate was noted (**2***h*). Maximum crystallization was achieved by adding carbon tetrachloride and cooling; uv: 278 (10 000 est.); ^{1}Hmr (D_2O): 4.28 (q, $J = 7$ Hz, 4H, CH_2CH_3), 4.08 (s, 6H, NCH_3), 1.22 (t, $J = 7$ Hz, 6H, CH_2CH_3), internal standard: acetone taken as 2.07.

1-Methyl-3,5-diphenylpyrazol-4-ol (6i)—A mixture of **6***h* (2.36 g, 0.01 mol) and dimethyl sulfate (4.8 mL, 0.05 mol) was heated in an oil bath (100–130°C) until dissolution and then for 10 min more. After cooling, 150 mL of water was added with stirring to dissolve excess dimethyl sulfate. A precipitate of **6***i* formed, and was filtered and washed with water.

Route 9

A typical example is given below.

1,2,3,5-Tetramethylpyrazolium-4-olate (2b)—A mixture of 1,2-dimethylhydrazine hydrochloride (1.40 g 10.5 mmol), 3-acetoxy-2,4-pentanedione (1.40 g, 10.4 mmol) and 80% aqueous ethanol (25 mL) was heated at reflux for 3 h. The solution was concentrated under vacuum to 20 mL and extracted with 3×20 mL of ether and the combined layers were washed with 2×10 mL portions of water. The water layers were concentrated to a viscous oil which crystallized on standing. Recrystallization was effected with acetone–acetonitrile mixture. This product, the hydrochloride of **2***b* was converted to **2***b* by ion exchange over Amberlite IR45 resin.

Route 10

Typical mono- and diacetylations are given below.

1-Acetyl-3,5-diphenylpyrazol-4-ol (6u)—A mixture of **6***h* (0.94 g, 4 mmol) and acetic anhydride (1.6 mL, 17 mmol) was heated at reflux for 5 min. After cooling, 15 mL of water was added and the precipitate (**6***u*) filtered; uv: 233(i) (20 500), 298 (18 900), 376 (784); ^{1}Hmr: 8.12–8.28 (m, 2H, aromatic), 7.42–7.65 (m, 8H, aromatic), 4.90 (s, 1H, OH), 2.70 (s, 3H, CH_3).

4-Acetoxy-1-acetyl-3,5-diphenylpyrazole (6v)—A mixture of **6***h* (0.94 g, 4 mmol) and acetic anhydride (5 mL, 52 mmol) was heated at reflux for 30 min. Cooling and addition of water caused **6***v* to precipitate; uv: 232 (20 400), 273 (20 300); ^{1}Hmr: 7.87–8.03 (m, 2H, aromatic), 7.42–7.65 (m, 8H, aromatic), 2.77 (s, 3H, $NCOCH_3$), 2.11 (s, 3H, $OCOCH_3$).

1-Acetyl-4-methoxy-3,5-diphenylpyrazole (6w)—uv: 233 (19 600), 287 (19 800); ^{1}Hmr: 8.14–8.31 (m, 2H, aromatic), 7.44–7.66 (m, 8H, aromatic), 3.55 (s, 3H, OCH_3), 2.73 (s, 3H, $OCOCH_3$).

1-Benzoyl-3,5-diphenylpyrazole (6x)—^{1}Hmr: 7.20–7.65 (m, 11H, aromatic), 7.93–8.20 (m, 4H, aromatic).

Deacetylation

A typical selective deacetylation was the conversion of **6***v* to **6***o* which was effected by passing a warm solution of **6***v* (640 mg) in minimum benzene through a column packed with neutral alumina (200 mesh) (20 g); **6***o* was eluted with benzene–acetone mixture (6:1).

Route 11

1:1 and 1:2 Adducts (6y and 6z)

A mixture of **6***h* (1.18 g, 5 mmol) and dimethylacetylene dicarboxylate (DMAD) (2.13 g, 15 mmol) in 60 mL of acetonitrile was heated at reflux for 3 h. The solvent was removed under vacuum, the residue dissolved in benzene, and chroma-

tographed on a neutral alumina column. Using benzene, acetone, and methanol as eluting solvents, the order of elution was DMAD, **6***z*, and **6***y*; **6***y*: uv: 239 (23 000), 275(sh) (13 500), 335 (4200); ^{1}Hmr: 8.07–8.23 (m, 2H, aromatic), 7.38–7.63 (m, 9H, aromatic + OH exchangeable with D_2O), 6.93 (s, 1H, C═CH), 3.63 (s, 3H, CH_3), 3.55 (s, 3H, CH_3); **6***z*: uv: 238 (24 100), 323 (17 000); ^{1}Hmr: 7.93–8.10 (m, 2H, aromatic), 7.37–7.55 (m, 8H, aromatic), 6.05 (s, 1H, C═CH), 5.90 (s, 1H, C═CH), 3.68 (s, 3H, CH_3), 3.67 (s, 3H, CH_3), 3.58 (s, 3H, CH_3), 3.57 (s, 3H, CH_3).

2,5-Diphenyl-3,4-diazacyclopentadienone (1)

Compound **6***h* (1.0 g, 4.3 mmol), lead dioxide powder (20 g, 84 mmol), and 1500 mL of anhydrous ether were stirred vigorously for 10 min. The lead dioxide was filtered and the red solution evaporated under vacuum as quickly as possible. The purple solid was washed with carbon tetrachloride; yield: 0.9 g (85%), mp 110°C (dec.); ir: 3150, 1565, 1535, 1255, 982, 885; uv (ether): 253 (13 000), 433 (900). *Anal.* calcd. for $C_{13}H_{10}N_2O$: C 77.95, H 5.12, N 7.91; found: C 77.71, H 5.47, N 8.02.

1,4,6,7,8,10-Hexaphenyl-2,3,11,12-tetraazatetracyclo-[5.5.1.0^{2,6}0^{8,12}]trideca-3,10-diene-5,9,13-trione (16)

Compound **6***h* (1.0 g, 4.3 mmol), lead dioxide powder (20 g, 84 mmol), and 1500 mL of anhydrous ether were stirred vigorously for 1 h. The lead dioxide was filtered and the yellow solution reduced to 20 mL by vacuum distillation; yield 0.5 g (50%), mp 205–207°C (dec.) (lit. (12) mp 206–208°C).

1,9-Diaza-3,4-dimethyl-6,8-diphenylbicyclo[4.3.0]-3,8-nonadien-7-one (17)

An ether solution of **1** was prepared as above and immediately after filtering the lead dioxide, 2,3-dimethyl-1,3-butadiene (1.0 g, 0.012 mol) was added. The red solution turned yellow after 10 min and the ether was removed under vacuum. The gummy residue was extracted with chloroform leaving the by-product **6***h* behind. Petroleum ether (bp 80–100°C) was added to the extract to give a slightly cloudy solution which was allowed to crystallize open to the air to yield 500 mg (37%) of **17**, which was recrystallized three times from carbon tetrachloride, mp 159–160°C; ir: 3040, 1680, 1188, 990, 830; uv: 270 (17 500), 392 (8200); ^{1}Hmr: 8.20 (m, 2H, aromatic), 7.40 (m, 8H, aromatic), 4.36 (m, 2H, NCH_2), 2.70 (q, J = 17 Hz, 2H, CH_2), 1.63 (m, 6H, CH_3). *Anal.* calcd. for $C_{21}H_{20}N_2O$: C 79.75, H 6.33, N 8.86; found: C 79.05, H 6.44, N 8.77.

4,5-Diaza-3,6-diphenyltricyclo[6.2.1.0^{2,7}]-2,4,6-undecatriene (18)

An ether solution of **1** was prepared as above and immediately after filtering the lead dioxide, [2.2.1]bicycloheptene (1.0 g, 0.011 mol) was added. After 4 h the red solution had turned yellow and the ether was evaporated under vacuum. The product (**18**) was crystallized twice from carbon tetrachloride to give 150 mg (13%) of flaky crystals, mp 230.5–231.5°C; ir: 3070, 1550, 1370, 1132, 767, 694, 667; uv: 265 (22 500); ^{1}Hmr: 8.20–7.45 (m, 10H, aromatic), 3.73 (m, 2H, CH), 2.14 (m, 2H, bridge CH_2), 1.63 (m, 4H, CH_2CH_2). *Anal.* calcd. for $C_{21}H_{20}N_2$: C 84.60, H 6.04, N 9.39; found: C 84.66, H 6.22, N 8.83.

Reçu le 13 juin 1978

FRANÇOIS BERTIN et JEAN DEROUAULT. Can. J. Chem. **57**, 913 (1979).

Les auteurs ont étudié, la nature du composé qui se forme lors de l'hydratation directe du chlorure de béryllium. On a analysé le composé par voie chimique, par spectroscopie infrarouge et Raman et par comparaison de ses spectres avec ceux du sulfate tétrahydraté. Les résultats sont en accord avec la formule $[Be(OH)(H_2O)_2{}^+Cl^-]_n$.

On fait l'hypothèse que le composé est un trimère cyclique et on a effectué une analyse simplifiée des coordonnées en vue de trouver un appui pour ces attributions.

FRANÇOIS BERTIN and JEAN DEROUAULT. Can. J. Chem. **57**, 913 (1979).

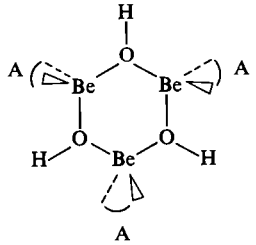
The authors have investigated the nature of the compound which is formed by direct hydration of beryllium chloride. The compound is analysed by chemical means, by infrared and Raman spectroscopy, and by comparison with the spectra of tetrahydrated sulphate. The results are consistent with the formula $(Be(OH)(H_2O)_2{}^+ Cl^-)_n$.

A cyclic trimeric compound is assumed and a simplified coordinate analysis is performed in order to support these assignments.

[Journal translation]

L'affinité particulière du béryllium pour les groupements oxygénés donneurs d'électrons permet d'obtenir de nombreux complexes stables (1). Cette stabilité est d'ailleurs renforcée lorsque des composés de coordination formés sont du type chélate comportant des liaisons Π plus ou moins conjuguées.

Certains de ces complexes sont dits polynucléaires hydroxydés lorsqu'ils renferment plusieurs ions métalliques séparés par des ponts hydroxo; par exemple, l'anion bicoordinateur (2) pyridine carboxylate-2 conduit au composé neutre dont la structure, établie par radiocristallographie (3), est schématisée ci-dessous.



A

En solution, les techniques basées sur les lois de la thermodynamique: potentiométrie, cryométrie, permettent de déterminer le degré de condensation des complexes du béryllium; ainsi on a pu mettre en évidence en milieu aqueux l'espèce trinucléaire hydroxydée $(Be_3(OH)_3(H_2O)_6)^{3+}$ (4, 5). De même, on peut suivre la substitution progressive des molécules d'eau de cette espèce par des bicoordinats tels que l'acide pyridine-carboxylique-2, les diacides carboxyliques, le sulfosalicylaldéhyde et certains amino-acides (1, 6). Il est à noter que peu de coordinats donnent des complexes contenant un seul atome de béryllium. Toutefois les techniques précédentes ne permettent pas une observation directe des espèces formées ce qui limite la validité des modèles proposés; par contre l'utilisation de la spectrométrie moléculaire (ir, Raman, rmn) peut donner des informations sur la structure des composés obtenus.

Lors d'un travail préliminaire (7) nous avons discuté les spectres ir et Raman des solutions aqueuses de chlorure de béryllium à concentration et pH variables; cette étude nous a permis de confirmer les résultats antérieurs obtenus par potentiométrie (5) à savoir l'existence de l'équilibre:

$$3Be(H_2O)_4{}^{2+} + 3OH^- \rightleftarrows (Be_3(OH)_3(H_2O)_6)^{3+} + 6H_2O$$

Dans une série d'articles concernant divers sels de béryllium, Grigor'ev et coll. (8) indiquent quelques fréquences infrarouges et Raman d'un composé solide présenté comme étant $BeCl_2 \cdot 4H_2O$ et les interprètent par la formation du cation $(Be(H_2O)_4)^{2+}$.

Nous avons cherché à compléter l'étude entreprise

0008-4042/79/080913-07$01.00/0

par Grigor'ev et à déterminer s'il est possible d'isoler une espèce autre que le complexe $(Be(H_2O)_4)^{2+}\cdot 2Cl^-$.

Nous avons cristallisé, par différentes méthodes, un hydrate solide du chlorure de béryllium et son homologue deutérié et nous avons enregistré leurs spectres ir et Raman; il apparaît que cette espèce est différente de celle étudiée par Grigor'ev. Afin de disposer d'éléments de comparaison, nous avons analysé les spectres du sulfate de béryllium tétrahydraté également étudié par cet auteur. Par un calcul de vibration simplifié, nous vérifions que la structure proposée pour le composé hydraté, que nous avons isolé à partir du chlorure de béryllium, est plausible.

Etude expérimentale

Préparation des produits solides

Sulfate

Le sulfate de béryllium tétrahydraté est un produit Prolabo. On le recristallise plusieurs fois dans l'eau pour disposer d'échantillons convenables pour les mesures Raman. L'analyse thermogravimétrique est compatible avec la formule $BeSO_4\cdot 4H_2O$: à 200°C le produit de départ a perdu quatre molécules d'eau et la calcination complète à 1000°C laisse l'oxyde BeO comme résidu.

Le composé $BeSO_4\cdot 4D_2O$ est obtenu directement en dissolvant le sulfate anhydre dans un grand excès d'eau lourde. Le produit obtenu par évaporation est redissous et précipité deux fois dans D_2O; sa cristallisation est difficile. Après séchage par P_2O_5 l'analyse thermogravimétrique confirme que le composé obtenu contient bien quatre molécules de D_2O par molécule de $BeSO_4$. Toutes les manipulations sont effectuées dans une boîte à gants.

Chlorures

Différents modes de préparation ont été essayés. Dans tous les cas, on part de $BeCl_2$ anhydre Merck. L'hydratation et la deutériohydratation sont réalisées façon identique.

(*a*) *L'hydratation lente*: elle est effectuée dans une boîte à gants en introduisant dans un récipient hermétiquement fermé, quelques cristaux de $BeCl_2$ anhydre d'une part, et d'autre part, un excès d'eau légère ou d'eau lourde. On s'arrange pour qu'il n'y ait pas de contact direct entre les cristaux et le liquide. Après quelques heures, les cristaux sont devenus pâteux puis sirupeux.

(*b*) *La dissolution brutale en milieu neutre*: la dissolution directe dans l'eau est une réaction violemment exothermique qui rompt les ponts Be—Cl et s'accompagne d'un dégagement de gaz chlorhydrique. On parvient à faire cristalliser un produit évidemment différent du composé $BeCl_2\cdot 4H_2O$ mentionné par Grigor'ev et coll. (8).

(*c*) *La dissolution brutale en milieu acide chlorhydrique*: $BeCl_2$ anhydre est mélangé à une solution plus ou moins concentrée de HCl (jusqu'à 10 *N*) dans un récipient totalement clos.

Les préparations obtenues suivant les modes *a*, *b* ou *c* sont désséchées par P_2O_5. Dans tous les cas il apparaît après quelques jours, une masse blanche que l'on broie, à l'abri de l'air, avant de terminer le séchage sous vide. Le départ de l'eau excédentaire est contrôlé périodiquement par l'enregistrement du spectre infrarouge de prises d'essais de ces composés. Comme les spectres des produits finaux sont tous identiques, il semble que, quel que soit le mode de préparation, on parvienne à un composé unique.

L'analyse élémentaire de ce composé a été effectuée (tableau 1): dosage de la teneur en chlore: précipitation de AgCl par addition de nitrate d'argent en excès; dosage de la teneur en métal: calcination à 1000°C pour transformer le produit en BeO.

Les pourcentages obtenus ne correspondent pas du tout au composé $BeCl_2\cdot 4H_2O$; ils se rapprochent davantage d'une composition du type $(BeCl(OH)(H_2O)_2)_n$: la teneur un peu élevée en chlore peut provenir d'une élimination incomplète de HCl, mais il est à noter que le rapport stoechiométrique en métal/chlore est très voisin de l'unité.

Enregistrement des spectres

Les spectres infrarouges sont obtenus au moyen d'un spectromètre Perkin-Elmer PE 457, à partir de pastilles dans KBr et avec des conditions normales d'enregistrement.

Les spectres Raman sont enregistrés sur un spectromètre Coderg PH ϕ avec la raie excitatrice à 488 nm d'un laser Spectra-Physics SP 165. Les conditions moyennes d'enregistrement des spectres sont les suivantes: puissance du laser 400 mW, tension d'alimentation du photomultiplicateur 850 V, largeur spectrale de fente 3 cm^{-1}, vitesse d'enregistrement 50 cm^{-1} par minute. Pour $BeSO_4\cdot 4H_2O$ on dispose un cristal sur un support; pour le dérivé deutérié on enferme les cristaux dans un tube conique en verre, scellé afin d'éviter l'échange entre D_2O et H_2O de l'atmosphère. Nous avons enregistré les spectres des chlorures en tube scellé également, mais les bandes observées ont une intensité très faible.

Description des spectres et interprétation

Sulfates

La fig. 1 présente les spectres ir et Raman de $BeSO_4,4H_2O$ et de son homologue deutérié enregistrés dans un domaine de fréquence inférieur à 1700 cm^{-1}.

En accord avec la littérature (9), nous retenons comme hypothèse de structure la juxtaposition d'ions tétraèdriques $Be(H_2O)_4^{2+}$ et SO_4^{2-} plus ou moins déformés. Nous présentons donc (tableau 2) une répartition des bandes observées par ir et Raman, entre les groupes BeO_4 et SO_4 et les molécules d'eau de coordination et une attribution de ces bandes aux modes normaux des groupes de symétrie respectifs. La présence de certaines bandes Raman peut s'expliquer par l'existence d'effets de corrélation qui entraînent des éclatements ou rendent actifs des modes interdits dans un motif isolé.

Nous comparons ces résultats à ceux de Grigor'ev et coll. (8) et nous soulignons les principaux points de désaccord. Par exemple, il ne nous paraît pas possible d'attribuer la bande ir à 975 cm^{-1} au mode $\nu_1(A_1)$ de SO_4^{2-}, en raison de l'écart de fréquence avec la bande Raman correspondante (17 cm^{-1}) et de l'intensité qui paraît trop importante pour un mode normalement interdit en ir, même si l'on admet une distorsion importante de l'ion SO_4^{2-} dans le cristal de l'hydrate, qui se traduit par des éclatements des modes fondamentaux de cet ion (à l'exception de ν_1). D'ailleurs cette bande disparaît complètement par deutériation pour être remplacée par une bande intense à 860 cm^{-1}. Grigor'ev observe,

TABLEAU 1. Analyse élémentaire du chlorure de béryllium hydraté

% pondéraux	Résultats expérimentaux	Hypothèse $BeCl_2 \cdot 4H_2O$	Hypothèse $(BeCl(OH)(H_2O)_2)_n$
Cl	39.7	46.7	36.4
Be	9.6	5.9	9.3

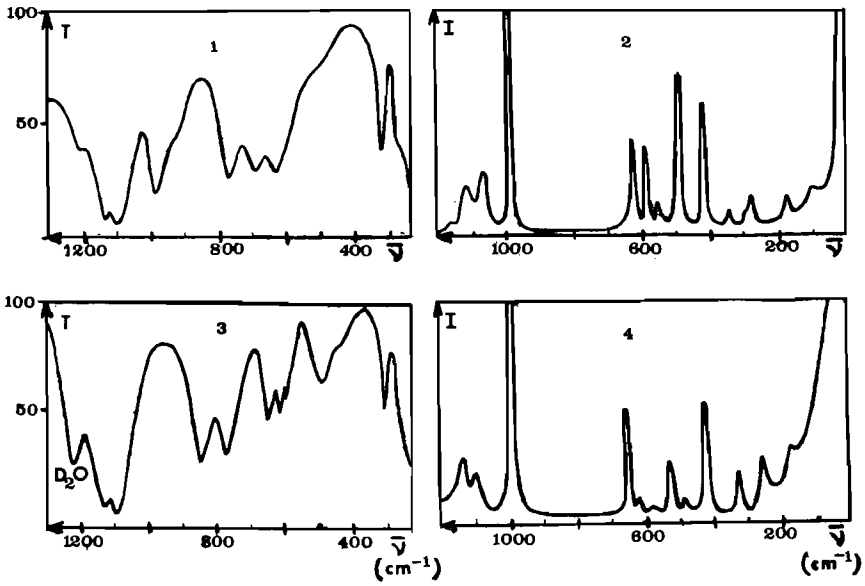


FIG. 1. Spectres infrarouges et Raman des sulfates de béryllium cristallisés. $BeSO_4 \cdot 4H_2O$: *1*, infrarouge; *2*, Raman. $BeSO_4 \cdot 4D_2O$: *3*, infrarouge; *4*, Raman.

lui aussi, une bande à 859 cm^{-1} sur $BeSO_4 \cdot 4H_2O$ et à 850 cm^{-1} sur $BeSO_4 \cdot 4D_2O$; il l'attribue à une composante du mode $\nu_3(F_2)$ de BeO_4. Cependant nous n'avons jamais observé de bande dans cette région pour l'hydrate, de plus l'éclatement proposé par Grigor'ev pour le mode $\nu_3(F_2)$: 690–859 cm^{-1} pour $Be(H_2O)_4^{2+}$ et 660–850 cm^{-1} pour $Be(D_2O)_4^{2+}$ nous paraît trop important; en conséquence, nous attribuons les bandes à 980 cm^{-1} (H_2O) et 860 cm^{-1} (D_2O) à un mouvement de rocking ou de wagging des molécules d'eau de coordination des ions Be^{2+}, en accord avec le rapport isotopique observé: 1.14.

Ces résultats concordent avec ceux obtenus par Gardiner et coll. (10) et Chang (11) sur le nitrate $Be(NO_3)_2 \cdot 4H_2O$ et avec nos propres résultats concernant les solutions acides de $BeCl_2$ (7) ou l'espèce $Be(H_2O)_4^{2+}$ est prépondérante (tableau 2).

Chlorures solides

Bien que l'enregistrement des spectres Raman soit très délicat, nous avons observé une bande vers 510 cm^{-1} déplacée par deutériation à 490 cm^{-1}, et il semble qu'il existe une bande à 415 cm^{-1}.

Les spectres infrarouges (fig. 2) présentent les caractéristiques communes suivantes: Une bande étroite, intense, située à 1120 cm^{-1} déplacée à 920 cm^{-1} par deutériation. Sa fréquence augmente lorsque le séchage est insuffisant et tend à rejoindre la fréquence observée sur les solutions (7). Un massif avec deux maxima à 860 et 890 cm^{-1} (H_2O) ou à 820 et 880 cm^{-1} (D_2O); l'observation est souvent rendue difficile par la présence d'une bande large, intense, à 950 cm^{-1} (H_2O) ou à 780 cm^{-1} (D_2O) due à l'eau d'hygroscopie de composés insuffisamment desséchés. Une bande à 690 cm^{-1}, déplacée à 550 cm^{-1} par deutériation; de plus il apparaît une bande de faible intensité située vers 540 cm^{-1} sur les spectres des produits hydratés et vers 400 cm^{-1} sur ceux des produits deutériés.

Ces résultats n'ont aucun point commun ni avec ceux de Grigor'ev qui suppose la formation d'une espèce $BeCl_2 \cdot 4H_2O$ à l'état solide, ni avec nos propres observations concernant les solutions acides de $BeCl_2$ (tableau 2). En particulier, l'absence d'une bande intense dans la région 300–350 cm^{-1}, observée sur tous les tétrahydrates cristallisés: sulfate, nitrate, perchlorate, ..., aussi bien en infrarouge qu'en

TABLEAU 2. Proposition d'attribution des bandes ir et Raman observées sur $BeSO_4 \cdot 4H_2O$ et son homologue deutérié; comparaison avec les attributions de Grigor'ev et coll (8); rappel des attributions proposées pour $BeCl_2 \cdot 4H_2O$ en solution aqueuse (7) (fréquences données en cm^{-1})

(*a*) $BeSO_4 \cdot 4H_2O$

[a]La notation correspondant à la symétrie T_d est conservée pour le groupe BeO_4 malgré la symétrie différente dans $Be(H_2O)_4^{2+}$; dans l'hypothèse de la symétrie T_d, le dénombrement est $\Gamma = 1A_1(\nu_1), 1E(\nu_2), 2F_2(\nu_3,\nu_4)$.

[b]Mouvements de déformation des molécules d'eau de coordination de l'ion Be^{2+}, δ: scissoring, ρ: rocking, w: wagging.

[c]Attribution incertaine (attribuable aussi au mode ν_3 de BeO_4).

[d]Vibration active non observée sur nos spectres.

[e]Vibration inactive.

[f]P: bande polarisée; DP dépolarisée.

REMARQUES: Les fréquences en italiques correspondent aux principaux points de désaccord entre nos résultats et ceux de Grigor'ev (le signe — représente les valeurs non indiquées par cet auteur; aucun résultat n'est reporté pour $BeSO_4$, $4D_2O$). Le doublet 412–507, attribué par Grigor'ev à la $\nu_2(E)$ de SO_4^{2-} pour le spectre ir de $BeSO_4 \cdot 4D_2O$, nous a paru plutôt correspondre aux mouvements des molécules d'eau, par analogie avec le spectre de $BeSO_4,4H_2O$ pour lequel ce même doublet n'est pas repéré en ir; cependant les spectres Raman de ces deux composés (fig. 1) présentent des différences importantes qui suggèrent qu'un changement de symétrie s'est produit dans le cristal au cours de la deutériation.

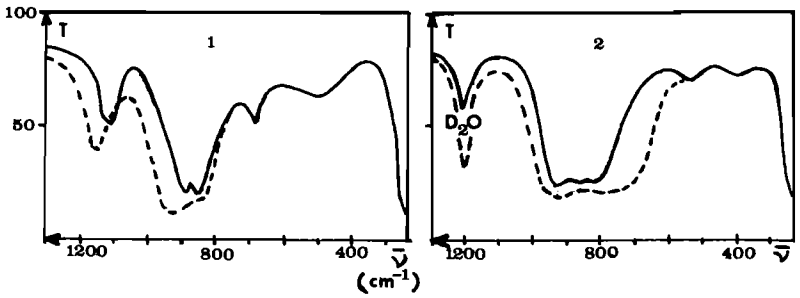

FIG. 2. Spectres infrarouges des chlorures de béryllium cristallisés. *1*, A l'état hydraté; *2*, à l'état deutériohydraté; *en pointillé*: l'allure du spectre lorsque le produit est insuffisamment sec.

Raman, exclut la présence de tétraèdres $Be(H_2O)_4^{2+}$. Par contre ces résultats correspondent assez bien à ceux que nous avons reportés pour les solutions neutres de $BeCl_2$ (7). Ainsi, l'existence d'une bande intense à 1100–1150 cm^{-1} voisine de celle que nous observons en solution nous conduit à admettre la formation d'un composé possédant des ponts hydroxo-, probablement polynucléaires, du type $((H_2O)_2Be(OH))_n^{n+} \cdot nCl^-$. Dans cette région en effet, une bande infrarouge a été observée par Scargill (12) sur les composés hydroxydés de l'étain et attribuée par cet auteur à la vibration de déformation du groupement SnOH. Les autres bandes que nous avons observées sont dues, soit à des vibrations symétriques ou asymétriques des liaisons métal–oxygène (515 cm^{-1} et 860–890 cm^{-1}), soit à des mouvements γ, hors du plan, des enchaînements Be—O—H (690 cm^{-1}) si l'on suppose que l'espèce formée est cyclique, ce que l'on ne peut affirmer avec certitude.

Nous remarquons que l'hypothèse de la formation de cette espèce est en bon accord avec les résultats de l'analyse élémentaire (tableau 1).

Le caractère hygroscopique particulièrement marqué de ce composé ne nous a pas permis de faire une étude radiocristallographique et d'établir avec certitude sa structure, mais l'hypothèse d'un trimère cyclique, déjà observé avec de nombreux composés du béryllium (1, 3 à 6) peut être envisagée.

Calcul des modes de vibrations de modèles simplifiés pour les cations $Be(H_2O)_4^{2+}$ et $(BeOH(H_2O)_2)_3^{3+}$

Le but de ce calcul de vibration n'est pas de déterminer des champs de forces précis, mais seulement de vérifier si les propriétés mécaniques d'un composé cyclique sont compatibles avec l'analyse des spectres proposée ci-dessus. Afin de disposer de constantes de forces de valeur raisonnable, nous avons déterminé en premier lieu le champ de forces d'un tétraèdre régulier BeO_4, comme modèle du cation $Be(H_2O)_4^{2+}$. Ensuite nous avons transféré les résultats au modèle cyclique $(BeOH(H_2O)_2)_3$. Nous tiendrons compte de l'existence des groupes hydroxo- mais nous négligerons les atomes d'hydrogène des molécules d'eau coordinées.

Ces calculs ont été effectués selon la méthode de Wilson et coll. (13), à l'aide de programmes écrits au laboratoire (14).

Tétraèdres BeO_4

Les paramètres géométriques du groupe BeO_4 sont ceux d'un tétraèdre régulier, avec distance BeO prise égale à 1.58 Å, en accord avec la littérature (3, 8). Pour tenir compte approximativement de la deutériation, nous avons affecté l'oxygène de masses égales à 18 ou 20. La détermination des constantes de forces des modes de symétrie A et E est sans ambiguité car il n'y a qu'un seul mode par espèce de symétrie, et donc pas de constante d'interaction. Les modes de symétrie F_2 étant au nombre de deux, il existe une constante d'interaction et le système est indéterminé. Selon la méthode de Torkington (15), la résolution de l'équation séculaire conduit à deux fonctions reliant une constante principale et la constante d'interaction dont les termes dépendent de la géométrie, des masses et des fréquences de vibration de la molécule. Les courbes obtenues $F_{11}^{F_2} = f_1(F_{12})$ et $F_{22}^{F_2} = f_2(F_{12})$ sont des ellipses. On trouve ainsi une infinité de champs de forces conduisant aux fréquences exactes, mais correspondant à des séparations d'énergie potentielle différentes. En l'absence des fréquences de dérivés isotopiques, le choix d'une solution est arbitraire; celle qui correspond à la constante de force de déformation minimum est souvent préférée (16) car les valeurs de la constante de force de valence obtenues ainsi sont en général les plus satisfaisantes. Les résultats que nous avons obtenus en appliquant la méthode ci-dessus aux tétraèdres BeO_4 (O = 18 et O = 20) conduisent aux valeurs moyennes mentionnées dans le tableau 3. Bien que la précision des effets isotopiques calculés paraisse bonne, cela ne signifie pas forcément que dans le cation réel $Be(H_2O)_4^{2+}$ les interactions entre les modes du groupe BeO_4 et les mouvements de l'eau soient négligeables, mais que celles-ci demeurent presque inchangées après deutériation.

TABLEAU 3. Champ de forces et fréquences calculées pour les modèles BeO_4

Constantes de forces		Modes	BeO_4 O = 18 ν_{calc} (cm^{-1})	BeO_4 O = 18 ν_{exp} (cm^{-1})	BeO_4 O = 20 ν_{calc} (cm^{-1})	BeO_4 O = 20 ν_{exp} (cm^{-1})

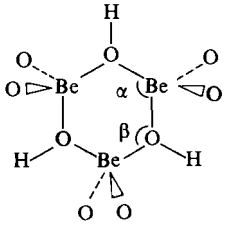
Cycle $(BeOH(O_2))_3$

D'après l'équilibre de cyclisation vu précédemment, il nous a paru logique de prendre comme modèle pour ce dérivé cyclique l'édifice atomique obtenu en joignant trois tétraèdres BeO_4 par leurs sommets, avec mise en commun des atomes d'oxygène.

La distance BeO a été gardée égale à 1.58 Å et les angles autour du béryllium ont été maintenus à 109° 28′. Nous avons fait l'hypothèse d'un cycle plan, ce qui conduit à un angle Be—O—Be égal à 130° 31′.



Comme ci-dessus, l'effet isotopique dû aux molécules d'eau a été simulé en affectant des masses de 18 ou 20 aux atomes d'oxygène correspondants. Cependant en raison de l'importance de la bande attribuée aux mouvements δOH au cours de l'analyse des spectres, nous avons tenu compte des hydroxydes OH réels et non des masses ponctuelles. La distance OH a été posée égale à 0.97 Å et les angles BeOH pris tous égaux.

Pour un tel modèle, de symétrie D_{3h}, les 39 modes se répartissent comme suit: $\Gamma = 5A_1' + 3A_2' + 8E' + 1A_1'' + 4A_2'' + 5E''$. Seuls les modes de type A_1', E' et E'' sont actifs en Raman alors qu'en infrarouge on ne peut observer que les modes A_2'' et E'.

Les coordonnées de vibration ont été écrites à partir de celles des tétraèdres, en distinguant toutefois les liaisons du cycle et les liaisons hors du cycle. Les déformations des angles Be—O—Be et Be—OH, ainsi que les déformations hors du plan γOH et τBeO ont été prises en compte. Les coordonnées surabondantes propres au cycle ont été éliminées au cours du calcul numérique, tandis que celles qui correspondent aux angles entourant les atomes de béryllium

ou d'oxygène (OH) ont été éliminées directement afin de pouvoir transférer les constantes de forces provenant du calcul précédent de BeO_4.

Un premier calcul a été effectué avec le champ de forces CF_1 (tableau 4). Dans ce champ de forces, les constantes transférées depuis BeO_4 ont conservé leur valeur d'origine et seules les constantes principales indispensables ont été définies pour le cycle (δBe—O—Be, τBeO) et les groupements hydroxydes (νOH, δOH et γOH). Le tableau 4 présente également les fréquences calculées pour les modes susceptibles de correspondre aux bandes observées. On voit que les fréquences de cycle sont trop faibles et l'effet isotopique sur δOH est trop transmis aux valences; de même le mouvement γOH a un effet isotopique trop faible. Le champ de forces CF_2, dans lequel la constante de force des liaisons BeO du cycle a été augmentée et quelques interactions introduites pour remédier aux défauts ci-dessus, conduit à des résultats assez satisfaisants (tableau 4).

Le nombre de constantes de forces calculées paraît élevé mais un grand nombre d'entre elles ont été transférées directement de BeO_4 sans modification.

En conclusion, ces calculs montrent que les propriétés mécaniques du modèle cyclique sont compatibles avec notre interprétation des résultats spectroscopiques. De plus, avec les réserves nécessaires dues aux approximations, il est possible de préciser l'attribution des bandes observées.

The kinetics of the reactions of boric acid with 5-substituted salicylate ions

ALAN QUEEN, LORNE DAVIES, AND ANDREW CON

Parker Chemical Laboratory, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received August 24, 1978

ALAN QUEEN, LORNE DAVIES, and ANDREW CON. Can. J. Chem. **57**, 920 (1979).

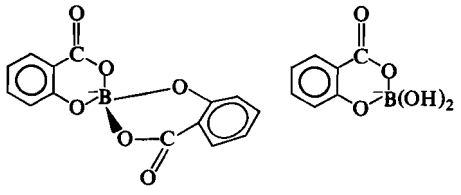
Salicylate ions form 1:1 complexes with boric acid. The kinetics of these reactions have been studied by the stopped-flow method and stability constants have been calculated from absorption measurements on the solutions at equilibrium. Temperature studies of the rates of reaction of boric acid and unsubstituted salicylate ions at pH 5.29 have been carried out. The data correlate well with the Arrhenius equation.

ALAN QUEEN, LORNE DAVIES et ANDREW CON. Can. J. Chem. **57**, 920 (1979).

Les ions salicylates forment des complexes 1:1 avec l'acide borique. On a étudié la cinétique de ces réactions par la technique des flux stoppés et on a calculé les constantes de stabilité à partir de mesures d'absorption de solution à l'équilibre. On a effectué des études sur la variation des vitesses de réaction de l'acide borique avec des ions salicylates non-substitués à un pH de 5.29 en fonction de la température. Les données sont en bon accord avec l'équation d'Arrhénius.
[Traduit par le journal]

Introduction

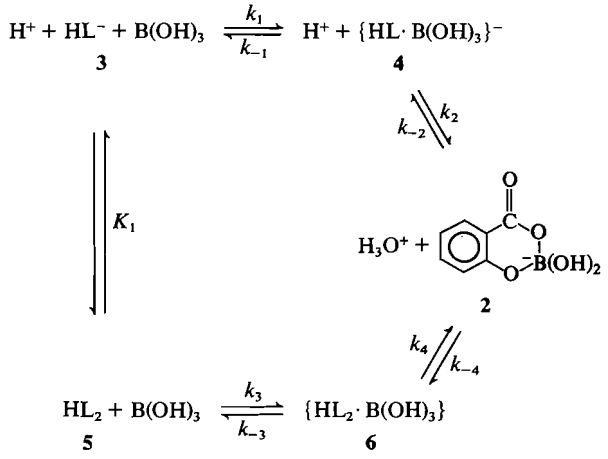
α-Hydroxyacids form 1:1 and 1:2 complexes with boric acid. At low hydroxy acid concentrations only the 1:1 complexes are important (1–5). Although the 1:1 complexes have not been isolated, the 1:2 complex formed from salicylate ions and boric acid has been shown (5) to have the spiro structure **1**. These results suggest that the 1:1 complex has the cyclic structure **2**. Further support for this view is provided by the observation (6) that borate ions specifically catalyse the hydrolysis of phenyl salicylate but not the corresponding reaction of phenyl *o*-methoxybenzoate. Moreover, we have found that boric acid causes large changes in the uv spectra of 5-substituted salicylate ions and *o*-hydroxybenzyl alcohol but has no effect on the spectra of methyl salicylate, *o*-methoxybenzoate ions, *p*-hydroxybenzoate ions, or *p*-hydroxybenzyl alcohol.



1 **2**

The rates of complexation of boric acid with salicylate ions may be readily measured by the stopped-flow method. A previous study (7) has shown that, at pH 5.29, the first-order rate constants are independent of the wavelength used to monitor the reaction. However, at pH 3.45, wavelength-dependent rate constants are observed. These results suggest that the reactions proceed through the intermediates **4** and **6** (Scheme 1).

It was thought that further information about the mechanism of the reaction might be obtained by studying the effects of temperature on the rate constants and by measuring the effects of substituents on the rate and equilibrium constants for complex formation. The results of these studies are reported.



SCHEME 1

Experimental

The 5-substituted salicylic acids were commercial samples which were recrystallised from water or aqueous ethanol to constant melting point. Boric acid was Fisher Certified Reagent. All materials were dried *in vacuo* over phosphorus pentoxide.

Temperatures were measured with a platinum resistance thermometer and were constant to within ±0.01°C. The kinetic data were obtained from measurements of the changes in transmitted light at 320 nm using a standard Canterbury

0008-4042/79/080920-04$01.00/0

stopped-flow apparatus (8). Rate constants were calculated by an on-line method that has been described (9) and were accurately first order over at least three half-lives. Each rate constant was measured 10 times in separate kinetic runs.

The equilibrium constants were calculated from spectroscopic data recorded at 320 nm, using the method of Rose and Drago (10) as previously described (7).

pH measurements were carried out at 25°C using a Radiometer pH meter calibrated at pH 4.00 ± 0.02 and pH 6.00 ± 0.02.

Results

Under the conditions used in the stopped-flow experiments, concentration changes are too small to be measured at low pH values where the salicylic acids are undissociated (7). For this reason, the present studies have been carried out at pH > 5, where the only reactants present in significant amounts are boric acid and salicylate ions.

The pseudo-first-order rate constants fit eq. [2], in all cases. Rate data for the salicylate ion reaction at pH 5.29 are listed in Table 1 for five different temperatures.

$$[2] \qquad k_{obs} = k_b + k_f[H_3BO_3]$$

The results at 24.76°C are only in fair agreement with our previous values for this reaction at 25°C and pH 5.29. These earlier data were obtained by fluorescence stopped-flow experiments using exciting light at 335 nm. However, measurements were also made at other wavelengths and with transmission measurements and no dependence of the rate constants on wavelength was observed. We are unable to explain the differences in the two sets of results but it is possible that an error was made in recording the pH value. The differences would be explained by a lower pH value for the earlier experiments. In any case, the conclusions drawn in the earlier paper are not changed and, importantly, the value of the ratio k_f/k_b is not greatly altered.

Plots of ln k_b and ln k_f against T^{-1} are shown in Fig. 1. Both plots are linear within the experimental error. The enthalpies and entropies of activation for the forward and backward reactions are given at the bottom of the table. The values of the ratio k_f/k_b are compared with those of the formation constant, K_{HL^-}, at 5, 15, and 25°C.

The rate constants for the reactions of 5-substituted salicylate ions with boric acid at pH 5.48 are summarised in Table 2. The equilibrium constants for complex formation, K_{HL^-}, are also shown in the same table together with the first dissociation constants, K_1, of the substituted salicylic acids (11).

Discussion

If the reaction between the salicylate ions and
