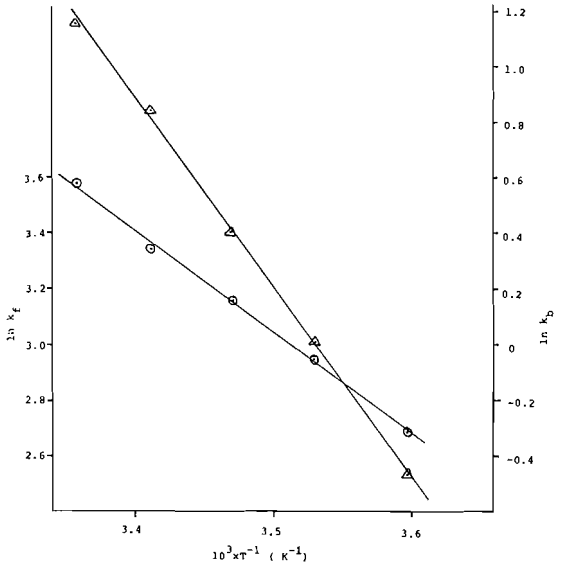

FIG. 1. Arrhenius plots for the reaction of salicylate ions with boric acid at pH 5.29: ⊙ forward reaction; △ backward reaction.

boric acid proceeds through the intermediate **4**, k_b and k_f will be complex functions of the rate constants k_1, k_{-1}, k_2, and k_{-2}. Hence, the Arrhenius plots for k_b and k_f might be appreciably curved. Figure 1 shows that this is not the case, so that any intermediate formed in the reaction must rapidly reach steady-state concentrations. If this is so, k_{obs} is given by [3]

$$[3] \quad k_{obs} = \frac{k_{-1}k_{-2}}{k_{-1} + k_2} + \frac{k_1 k_2}{k_{-1} + k_2}\,[H_3BO_3]$$

Hence, the equilibrium constant for the reaction is given by [4]

$$[4] \quad k_f/k_b = k_1k_2/k_{-1}k_{-2} = K_1K_2 = K_{HL^-}$$

This is consistent with the closely similar values of the rate ratios and equilibrium constants for most of the reactions summarised in Tables 1 and 2. The same correspondence of the kinetic and thermodynamic equilibrium constants would be observed if the reactions were one step processes. However, the k_f/k_b ratios and the values of K_{HL^-} are not the same for the reactions involving 5-sulfo- and 5-nitrosalicylate ions. Moreover, the values of k_{obs} vary slightly in the case of the sulfo compound (Table 3). These results suggest that, at least in some cases, kinetically significant intermediates such as **4** are formed during the course of the complexations.

The values of log k_b, log k_f, and log K_{HL^-} do not linearly correlate with any of the standard σ values. Since the carboxylate group is *meta* and the hydroxyl group is *para* to the substituent, this is perhaps not surprising. However, linear free energy correlations such as [5] were not significantly more successful in

correlating the data than the Hammett equation. It is interesting that the dissociation constants of the salicylic acids do not correlate particularly well with any combination of the various σ values (11). Not surprisingly, the best linear free energy relationship was obtained by plotting log K_{HL^-} or log k_f/k_b against pK_1. However, the separate values of log k_b and log k_f do not linearly correlate with pK_1. We interpret this to indicate that the rate constants are complex quantities, as required by Scheme 1.

$$[5] \qquad \log k = \sigma_m \rho_m + \sigma_p \rho_p$$

The activation parameters for the reaction of the unsubstituted salicylate ions with boric acid do not show any unusual features that would require the presence of an intermediate in the reaction. However, the results do not exclude the formation of such an intermediate but if one is formed it must reach steady-state concentration during the early stages of the reaction.

It was not expected that the entropy term would play such a large role in limiting the ease of complex formation. The transition state and the intermediate, if formed, must be very ordered compared to the reactants. This suggests strong solvation effects and the possibility of steric hindrance to the free rotation of the $B(OH)_3$ group.

Synthesis related to the octodiose in apramycin. Part III

HAROLD C. JARRELL AND WALTER A. SZAREK

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received July 31, 1978

HAROLD C. JARRELL and WALTER A. SZAREK. Can. J. Chem. **57**, 924 (1979).

A synthesis of methyl 2,3-di-*O*-benzyl-7,8-dideoxy-4-*O*-methylthiomethyl-D-*glycero*- and L-*glycero*-α-D-*gluco*-oct-7-enopyranoside (**11** and **12**) has been achieved by the reaction of methyl 2,3-di-*O*-benzyl-4-*O*-methylthiomethyl-α-D-*gluco*-hexodialdo-1,5-pyranoside (**9**) with vinylmagnesium bromide; the stereochemistry at C-6 was established by degradation of **12** to the enantiomer of a known heptose derivative. Olefin **12** was converted, in six steps, into a mixture of dialdose derivatives **18** and **19** from which methyl glycosides **21** and **20**, respectively, were prepared and shown to have the desired *trans*-decalin structure. The stereochemistry at C-7 in glycosides **20** and **21** was established by nmr spectroscopy.

An intramolecular reaction involving the methylthiomethyl function has been observed and shown to give rise to *O*-methylene derivatives.

HAROLD C. JARRELL et WALTER A. SZAREK. Can. J. Chem. **57**, 924 (1979).

On a réussi une synthèse des di-*O*-benzyl-2,3 didéoxy-7,8 *O*-méthylthiométhyl-4 D-glycéro- et L-glycéro-α-D-*gluco* octène-7 pyrannosides de méthyle (**11** et **12**) grâce à la réaction du di-*O*-benzyl-2,3 *O*-méthylthiométhyl-4 α-D-glucohexodialdo-1,5 pyrannoside de méthyle (**9**) avec le bromure de vinylmagnésium; on a déterminé la stéréochimie en C-6 par une déshydratation de **12** vers l'énantiomère de dérivé heptose connu. L'alcène **12** a pu être transformé, en six étapes, en un mélange de dérivés dialdoses **18** et **19** à partir desquels on a pu préparer les glycosides de méthyle **21** et **20** respectivement; ceci démontre qu'ils possèdent la structure décalinique *trans* désirée. On a démontré la stéréochimie en C-7 des glycosides **20** et **21** grâce à la spectroscopie rmn.

On a noté une réaction intramoléculaire impliquant le groupe méthylthiométhyle qui donne lieu à des dérivés *O*-méthylène.

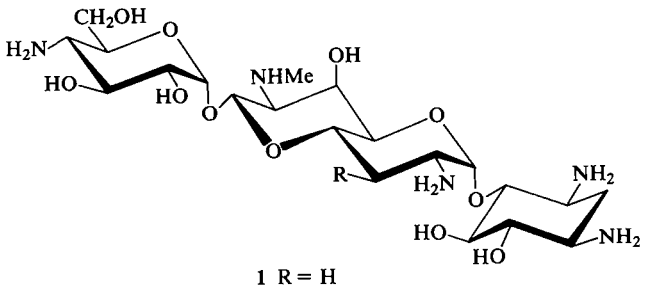
Introduction

Antibiotics have proven to be a rich source of higher-carbon amino sugars (1) which include the aminooctose in lincomycin (2) and in the ezomycins (3) as well as an 11-carbon amino sugar, namely, hikosamine, which is a component of the nucleoside antibiotic hikizomycin (4). Recently, apramycin (**1**) (5) and oxyapramycin (**2**) (6) have been shown to be components of the aminocyclitol antibiotic complex nebramycin (7). Structural studies have revealed that apramycin contains the unusual aminooctodiose **3** (8) whereas oxyapramycin contains **4** (6). In addition to its unique structural features, apramycin is of interest because it has been found to be a potent antibiotic relative to neamine (9*a*) and has been reported (10) to be inactivated by only one aminoglycoside-inactivating enzyme. Replacement of the terminal 4-amino-4-deoxy-D-glucose moiety in apramycin with a methyl group yields a cyclitol derivative which exhibits an antimicrobial spectrum similar to that of apramycin (9). In view of the latter result, this laboratory has been investigating the preparation of octodioses which are related to structures **3** and **4** and which may be useful in the synthesis of pseudodisaccharides containing these structures. An earlier report (11) from this laboratory described the synthesis of two octodioses which were not successfully converted into the desired *trans*-decalin structure. The present article describes in detail results, which have been outlined (12), of a synthesis of derivatives of two octodioses having a *trans*-decalin structure.

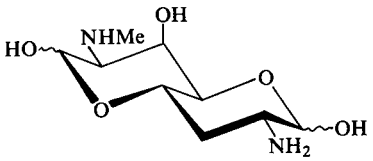
Results and Discussion

The synthesis utilizing a chain extension of the readily available derivative **9** is shown in Scheme 1. Methyl 2,3-di-*O*-benzyl-α-D-glucopyranoside (**5**) was selectively benzoylated with benzoyl chloride in pyridine to give methyl 6-*O*-benzoyl-2,3-di-*O*-benzyl-α-D-glucopyranoside (**6**) in good yield. In the ^{1}Hmr spectrum of **6** in dimethyl-d_6 sulfoxide, the hydroxyl proton gave a doublet at τ 4.48 ($J_{H,OH}$ = 6 Hz); this result established that acylation had occurred at O-6. Methylthiomethyl ether **7** was prepared by a modification of a procedure reported by Pojer and Angyal (13); **7** could not be isolated in a pure form. Crude **7** was *O*-debenzoylated to give crystalline **8** in 66% yield from **6**. Oxidation of **8** gave aldehyde **9** which was characterized by conversion into the crystalline 1,3-diphenylimidazolidine derivative **10**. Treatment

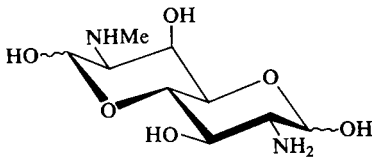
0008-4042/79/080924-09$01.00/0



1 R = H
2 R = OH



3

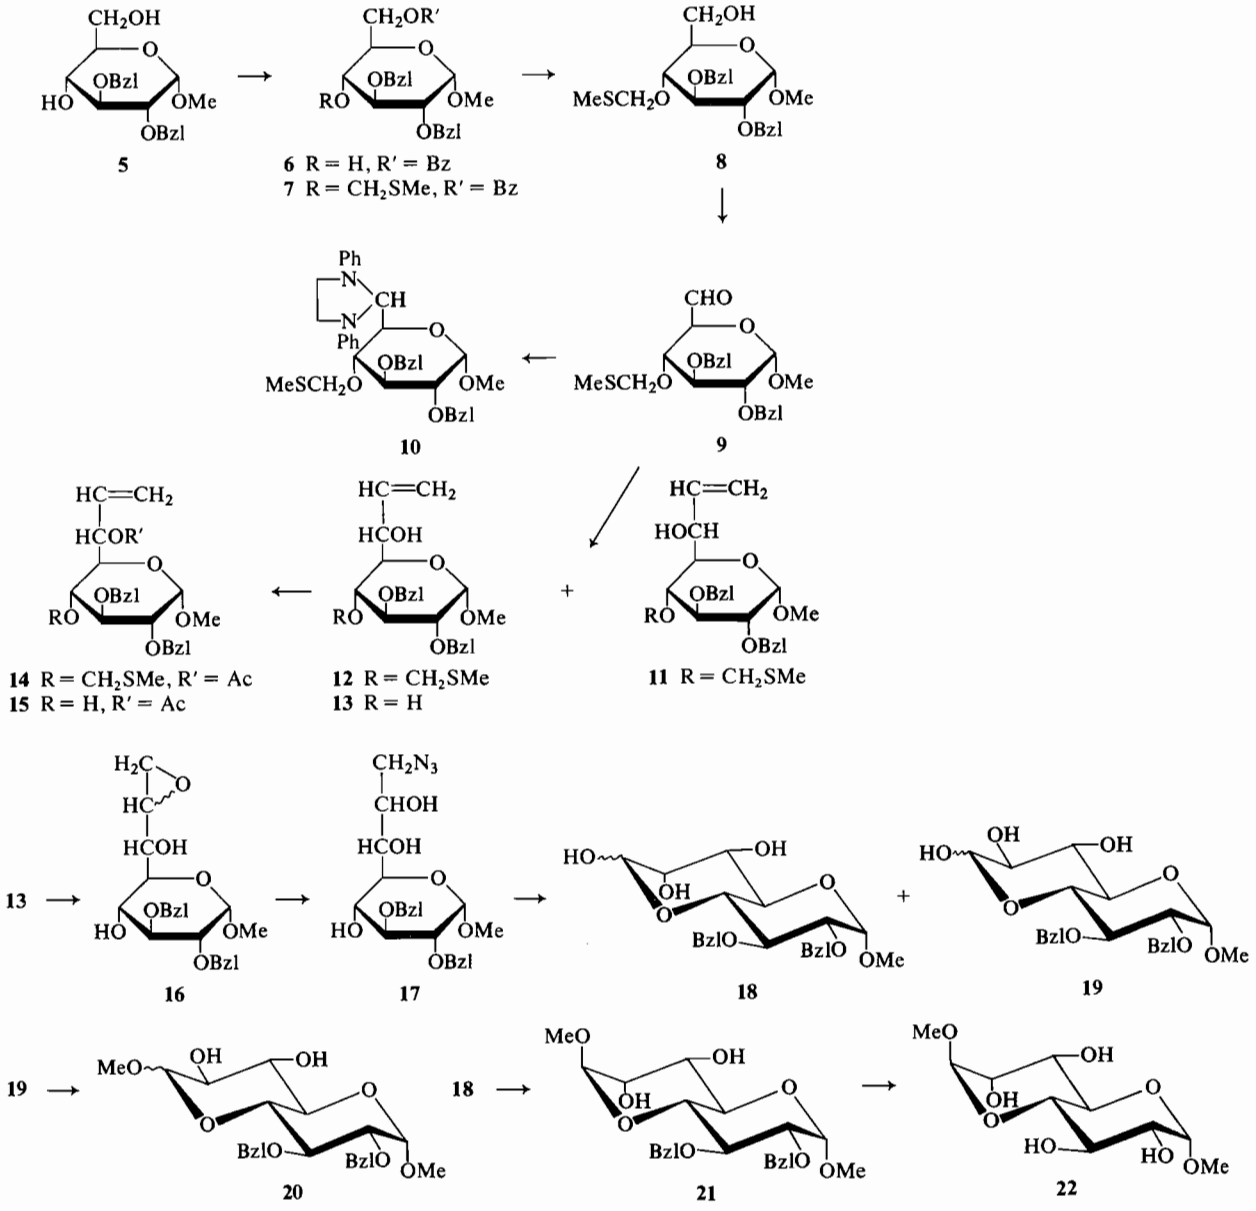


4

of compound **9** with vinylmagnesium bromide afforded the epimeric, dideoxy derivatives **11** and **12** in an approximately 1:5 ratio, respectively.

The stereochemistry at C-6 in compounds **11** and **12** was established by the route outlined in Scheme 2 (see below). Attempted removal of the methylthiomethyl group in **12** with methyl iodide (13) gave methyl 2,3-di-*O*-benzyl-7,8-dideoxy-L-*glycero*-α-D-*gluco*-oct-7-enopyranoside (**13**) and an equal quantity of a second product, namely, methyl 2,3-di-*O*-benzyl 7,8-dideoxy-4,6-*O*-methylene-L-*glycero*-α-D-*gluco*-oct-7-enopyranoside (**23**). Compound **23** presumably arises from attack of O-6 on the intermediate sulfonium ion resulting from *S*-methylation of the thioether function. The facility with which cyclization occurs is evidenced by the formation of **23** when an excess of water was present in the reaction mixture. Attempted removal of the methylthiomethyl function with silver nitrate and 2,6-lutidine (14) in aqueous tetrahydrofuran gave **13** and **23**. When the epimeric olefin **11** was treated with methyl iodide, methyl 2,3-di-*O*-benzyl-7,8-dideoxy-4,6-*O*-methylene-D-*glycero*-α-D-*gluco*-oct-7-enopyranoside (**24**) was formed as the major product. These results indicate that the intramolecular reaction occurred more readily in the case of compound **11** than in that of **12** and, therefore, reflect the stereochemistry of these derivatives at C-6. Structure **25** represents the projection along the C-5—C-6 bond of the rotamer of **12** which would be required for the cyclization of **12** to give **23**. Similarly, structure **26** represents the steric situation for the formation of compound **24** from **11**. Rotamer **26** might be expected to be more favored than rotamer **25**, and hence formation of **24** from **11** might be expected to be more facile than formation of **23** from **12**. In view of the preceding considerations, the major product from the Grignard reaction, namely **12**, may be assigned the L configuration and the minor product the D configuration at C-6, a conclusion which is supported by other results (see below). The problem experienced with the methylthiomethyl group may prove to be a general limitation on its usefulness in compounds in which an hydroxyl group is situated such that it can react at the methylthiomethyl group's methylene carbon during deprotection procedures.

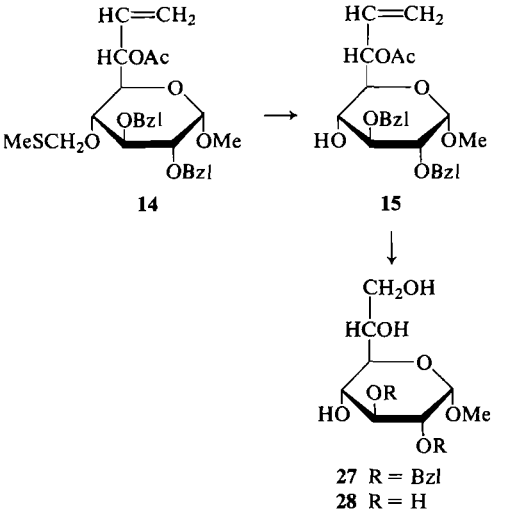
To establish unambiguously the configuration at C-6 in compounds **11** and **12**, compound **12** was degraded by the sequence of reactions shown in Scheme 2. Acetylation of **12** afforded **14** which reacted smoothly with methyl iodide to give **15** in 80% yield. Treatment of compound **15** with osmium tetroxide in the presence of sodium metaperiodate, followed by reduction of the resulting aldehyde with sodium borohydride, afforded methyl 2,3-di-*O*-benzyl-L-*glycero*-α-D-*gluco*-heptopyranoside (**27**). Re-



SCHEME 1

moval of the benzyl groups by hydrogenolysis over palladium-on-charcoal afforded methyl L-*glycero*-α-D-*gluco*-heptopyranoside (**28**) which had mp 163–165°C and $[\alpha]_D$ +137.8°. For methyl D-*glycero*-α-L-*gluco*-heptopyranoside, mp 167.5–169°C and $[\alpha]_D$ −142° have been reported (15). Thus, the major product of the Grignard reaction, namely **12**, has the L configuration and compound **11**, the minor product, has the D configuration at C-6.

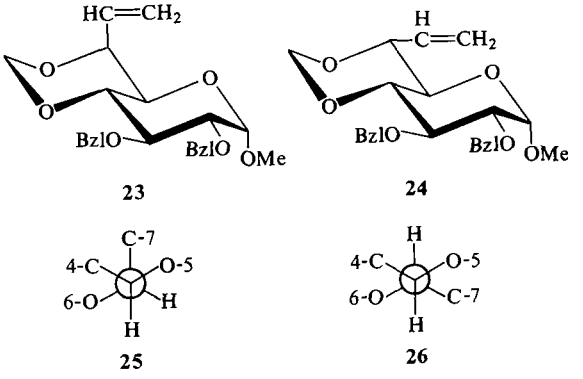
Treatment of compound **15** with aqueous methanol containing triethylamine afforded **13** in 80% yield. It was felt that an aldehyde function could be introduced most readily by the photolysis (16) of an azido derivative which was only partially protected; in this way the necessity of selectively protecting hydroxyl groups might be avoided. Epoxidation of compound **13** with *m*-chloroperbenzoic acid afforded the diastereomeric 7,8-anhydro derivatives **16** which migrated as a single spot in tlc. Treatment of the anhydro derivatives **16** with sodium azide in the presence of ammonium chloride (17) gave the epimeric, 8-azidooctose compounds **17** which were not separable by column chromatography on silica gel. Irradiation with uv light of azides **17** in benzene–



SCHEME 2

2-methoxyethanol afforded a mixture of dialdose derivatives **19** and **18** from which the former was isolated as a solid foam while the latter was obtained as crystals which showed no ir absorption attributable to an aldehyde group. ^{1}Hmr spectroscopy suggested that the products exist primarily as cyclic structures (*trans*-decalin) as evidenced by the absence of an aldehydic proton signal.

The reducing dialdose derivative **18** was treated with methanol in the presence of acidic, ion-exchange resin to give crystalline **21** in 49% yield. In the ^{1}Hmr spectrum (220 MHz) of compound **21** H-1 gives rise to a doublet at τ 5.42 ($J_{1,2}$ = 3.8 Hz) and H-8 appears as a doublet at 5.21 ($J_{7,8}$ = 1.8 Hz). Coxon (18) has reported that the H-1's of methyl 4,6-*O*-benzylidene-α-D-gluco- and -mannopyranoside resonate at τ 5.35 ($J_{1,2}$ = 3.5 Hz) and 5.35 ($J_{1,2}$ = 0.6 Hz), respectively. The values of the coupling constants $J_{1,2}$ and $J_{7,8}$ observed for H-1 and H-8, respectively, are also consistent with those observed for $J_{1,2}$ in the spectra of methyl α-D-gluco- and -mannopyranoside (19) as well as their derivatives



(18). Therefore, the product is assigned the L-*erythro*-D-*gluco* configuration as shown in structure **21**. Interestingly, the protons of the hydroxyl groups at C-6 and C-7 give rise to doublets; irradiation of the hydroxyl protons resulted in the partial collapsing of the multiplets arising from H-7 and H-6 at τ 6.01 and 6.11, respectively. Irradiation of H-6 and H-7 allowed the resonances at τ 7.31 ($J_{H,OH}$ = 3 Hz) and 7.34 ($J_{H,OH}$ = 4.5 Hz) to be assigned to HO-7 and HO-6, respectively.

Support for the stereochemical assignment of C-7 in compound **21** was obtained from ^{13}Cmr spectroscopy. In the ^{13}Cmr spectrum of **21** resonances at δ 101.0 and 99.0 can be assigned to C-8 and C-1, respectively. Gorin and Mazurek (20) have reported that for methyl α-D-gluco- and -mannopyranoside the anomeric carbons resonate at δ 100.3 and 101.9, respectively, whereas the corresponding 4,6-*O*-benzylidene derivatives have anomeric carbon resonances δ 99.9 and 101.7, respectively (21). The close agreement of the chemical shift observed for C-8 with the reported chemical shifts of C-1 of mannopyranosides supports the above assignment of the stereochemistry at C-7. Finally, only two resonances attributable to methyl groups were observed in both the ^{1}Hmr and ^{13}Cmr spectra of compound **21**, a result which establishes that in **21** there exists only one anomeric form at each of C-1 and C-8.

Removal of the benzyl groups in **21** by hydrogenolysis over palladium-on-charcoal afforded **22** which had mp 192–196°C (dec.) and $[\alpha]_D$ +56.3°. The ^{1}Hmr spectrum (220 MHz) of **22** showed doublets at τ 5.13 (J = 4.0 Hz) and 5.18 (J = 1.8 Hz) for H-1 and H-8, respectively. Irradiation of H-1 resulted in the H-2 signal's appearing as a doublet at τ 6.37 (J = 10 Hz). The observed splitting of H-8 (J = 1.8 Hz) is in agreement with the value (1.5 Hz) observed for $J_{1,2}$ in the spectrum of methyl α-D-mannopyranoside (19).

^{13}Cmr data for compound **22**, and for methyl α-D-gluco- and -mannopyranoside and their 4,6-*O*-benzylidene derivatives, are given in Table 1. The C-1 and C-2 resonances observed for **22** are in close agreement with the corresponding resonances reported for the D-glucose derivatives. The chemical shifts observed for C-8 and C-7 are in good agreement with those reported for C-1 and C-2, respectively, of the D-mannose derivatives. Thus, the ^{1}Hmr and ^{13}Cmr data establish that the product has the stereochemistry assigned in **22** and, therefore, corroborate the stereochemical conclusion which was reached for compound **21**.

Compound **19** was treated with methanol in a manner similar to that used for the preparation of **21**. Crystalline **20** was obtained, which was more dex-

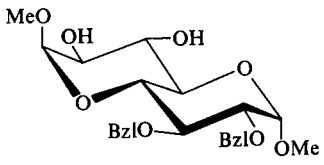
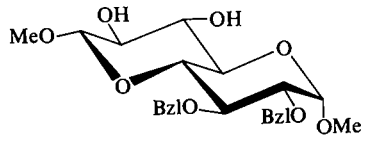
trorotatory than **21** and was shown to be a mixture of glycosides. In the ^{1}Hmr spectrum of the methanolysis product three signals attributable to methoxyl groups were observed at τ 6.42, 6.55, and 6.58, results which establish that the product was a mixture of anomers **29** and **30**. The stereochemistry of the octodiose derivatives **29** and **30** was assigned using the follow-



29



30

ing considerations. In the product's ^{1}Hmr spectrum (220 MHz) in chloroform-*d*, doublets at τ 5.19 (J = 3.3 Hz), 5.39 (J = 3.8 Hz), 5.41 (J = 3.8 Hz), and 5.75 (J = 7.5 Hz) have been assigned to H-8, H-1, H-1′, and H-8′, respectively, the nonprimed numbers referring to **29** and the primed numbers to **30**. The observed spacings of 3.8 Hz are consistent with that observed for H-1 (α anomer) in compound **21** and with the value of 3.6 Hz observed for $J_{1,2}$ in methyl α-D-glucopyranoside (19) and its derivatives (18). The assignment of the resonances at τ 5.39 and 5.41 to H-1 and H-1′ (assignments may be reversed) was based upon the observation that H-1 in **21** resonates at τ 5.42. The doublet for H-8′ has a spacing of 7.5 Hz, a value which is indicative of a *trans*-diaxial orientation of H-8′ and H-7′ and, therefore, of the β configuration in **30**.

The assignment of the signals for H-1, H-1′, H-8, and H-8′ were confirmed in the following way. The spectrum of the product mixture **20** in a mixture of chloroform-*d* and acetone-d_6 exhibited signals which were shifted relative to the corresponding signals observed in chloroform-*d*. Signals in the region of τ 6.20–6.60 were sequentially irradiated and positions were noted of signals which on irradiation caused the anomeric proton signals to collapse. This procedure

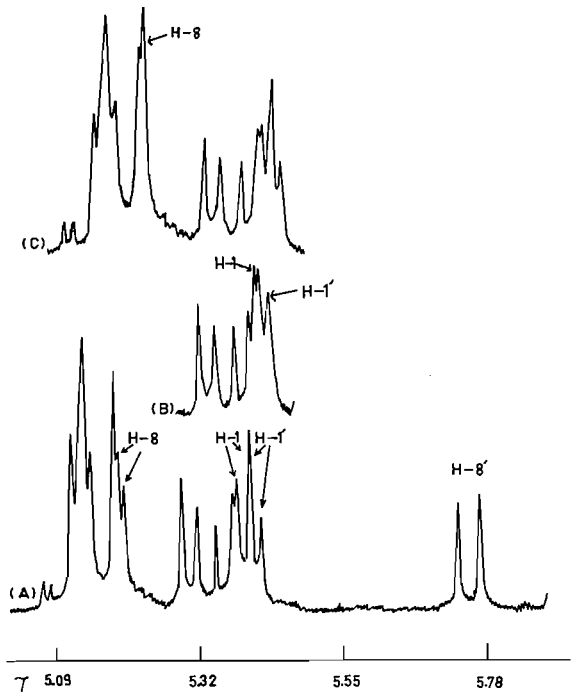


FIG. 1. (*A*) Partial ^{1}Hmr spectrum (chloroform-*d*) at 220 MHz of compounds **29** and **30**; (*B*) partial ^{1}Hmr spectrum (chloroform-*d*) at 220 MHz of compounds **29** and **30** with irradiation of H-2 and H-2′; (*C*) partial ^{1}Hmr spectrum (chloroform-*d*) at 220 MHz of compounds **29** and **30** with irradiation of H-7.

permitted the signals for H-2, H-2′, H-7 and H-7′ to be located. The corresponding signals in the spectrum in chloroform-*d* were then irradiated (see Fig. 1), a procedure which resulted in the signals for H-1, H-1′, and H-8 to be identified. Irradiation of the H-1's resulted in the multiplets, observed for H-2 and H-2′, to collapse to doublets with a spacing of 10 Hz, a value which is in agreement with that observed (18) for the coupling between *trans*-diaxial protons. The assignments of the signals for H-1, H-1′, H-8, and H-8′ were thus confirmed.

The observed values of 3.5 Hz and 7.5 Hz for the coupling constants $J_{7,8}$ and $J_{7',8'}$, respectively, are in agreement with the values of 3.0 and 7.5 Hz which have been reported (19) for $J_{1,2}$ in methyl α- and β-D-glucopyranoside, respectively. The ^{1}Hmr data establish that the product from the methanolysis of **19** is composed of a 1:1 mixture of anomeric glycosides (**29** and **30**) of D-*threo*-D-*gluco*-octodiose.

The present approach provides access to structures which are analogs of those found in **1** and **2**. To the authors' knowledge compounds **21**, **22**, **29**, and **30** represent the first synthetic examples of dialdoses which have the *trans*-decalin structure. Investigations into improvements in the synthesis of octodioses and the preparation of pseudodisaccharides containing these moieties are currently underway.

Experimental

Melting points were determined on a Fisher-Johns apparatus and are uncorrected. Optical rotations were measured with a Perkin-Elmer model 141 automatic polarimeter at 26 ± 3°C. Infrared spectra were recorded with a Unicam SP 1000 or a Perkin-Elmer 180 spectrophotometer. The ^{1}Hmr spectra were recorded at 60 MHz or with a Varian HR-220 spectrometer at 220 MHz in chloroform-*d* with tetramethylsilane (TMS) as the internal standard, unless otherwise stated. The ^{13}Cmr spectra were determined at 15.09 MHz on a Bruker HX-60 spectrometer equipped with an FT60M Fourier transform accessory; chemical shifts are given in parts per million downfield from TMS. Thin-layer chromatography (tlc) was performed with silica gel G, containing 1–3% of the indicator Lumilux Green ZS (Brinkmann), as the adsorbent in the following solvent systems (v/v): (*A*) 4:1 benzene – ethyl acetate; (*B*) 5:2 petroleum ether – ethyl acetate; (*C*) 1:1 benzene – ethyl acetate; (*D*) ethyl acetate; (*E*) 1:1 ethyl acetate – methanol. The term 'petroleum ether' refers to the fraction of bp 60–110°C. The developed plates were air dried and compounds located by heating the plates at 150°C after they had been sprayed with 10% aqueous sulfuric acid containing 1% cerium sulfate and 1.5% molybdic acid; benzyl ethers were detected by irradiation of the developed plates with short-wavelength uv light from a 2537 Å 'Mineralight.' Column chromatography was performed on Brinkmann silica gel (70–230 mesh).

Ultraviolet irradiations were performed with a 450-W Hanovia medium-pressure mercury-arc lamp (Cat. No. 679A-36) contained in a water-cooled, quartz immersion well. The whole assembly was mounted in a borosilicate glass reaction vessel.

Methyl 6-O-Benzoyl-2,3-di-O-benzyl-α-D-glucopyranoside (6)

To a cooled (0°C) solution of **5** (23) (3.7 g) in pyridine (50 mL), benzoyl chloride (1.25 mL) in pyridine (10 mL) was added dropwise with stirring. Thin-layer chromatography (solvent *A*) revealed that after 3 h compound **5** (trace), a major component (R_f 0.46), and a trace of a minor component (R_f 0.73) were present. The reaction mixture was poured into ice water and the resulting mixture was extracted with chloroform; the chloroform extract was washed successively with cold 2 *N* sulfuric acid, saturated aqueous sodium hydrogen carbonate, and water. Concentration of the dried ($MgSO_4$) chloroform solution afforded a syrup which was adsorbed onto silica gel and the column eluted (solvent *A*). Compound **6** was obtained as a colorless syrup (3.6 g, 76%) which solidified on standing. Recrystallization from petroleum ether afforded **6** as white needles having mp 75–77°C, $[\alpha]_D$ +22 ± 1° (*c* 1.4, $CHCl_3$); ν_{max} (KBr): ~3485 (OH) and 1695 cm^{-1} (OBz); ^{1}Hmr τ: 1.80–2.00 (2H, aromatic H's), 2.37–2.95 (12H, aromatic H's), 4.88–5.60 (7H, H-1—H-3, 2 CH_2—C_6H_5's), 5.90–6.65 (7H, H-4, H-5, H-6's, OMe), 3.30 (1H, OH, exchanged in D_2O); ^{1}Hmr (dimethyl-d_6 sulfoxide) τ: 4.48 (1H, d, $J_{H,OH}$ = 6 Hz, OH). *Anal.* calcd. for $C_{28}H_{30}O_7$: C 70.3, H 6.3; found: C 69.7, H 6.4.

Methyl 2,3-Di-O-benzyl-4-O-methylthiomethyl-α-D-glucopyranoside (8)

Glacial acetic acid (4 mL) and acetic anhydride (6.6 mL) were added to a solution of compound **6** (1.43 g) in dry dimethyl sulfoxide (10 mL), and the mixture was stirred at room temperature for 24 h. The reaction mixture was poured into cold, saturated sodium hydrogen carbonate. The neutral mixture was extracted with chloroform (3 × 20 mL); the extract was washed with water, dried ($MgSO_4$), and concentrated to a syrup (1.3 g) which was shown by tlc (solvent *B*) to be composed of two compounds having R_f 0.59 (major) and R_f 0.53 (minor). Column chromatography and an attempted distillation of the crude product failed to provide pure **7**.

Crude **7** (1.3 g) in methanol (30 mL) was treated for 4 h at 5°C with methanolic sodium methoxide (5 mL, ~1 *M*). Neutralization of the reaction mixture with Dry Ice followed by evaporation of the resulting mixture afforded a residue which was dissolved in chloroform. The chloroform extract was washed with water, dried ($MgSO_4$), and concentrated to a syrup. Crystallization from petroleum ether afforded **8** as white needles (690 mg, 53%) having mp 88.5–89.5°C, $[\alpha]_D$ +153.2 ± 2° (*c* 2.2, $CHCl_3$); ^{1}Hmr τ: 2.70 (10H, aromatic H's), 4.60–6.60 (14H, H-1—H-5, H-6's, 2 CH_2—C_6H_5's, SCH_2O, OH), 6.53 (3H, OMe), 7.85 (3H, s, SMe). *Anal.* calcd. for $C_{23}H_{30}O_6S$: C 63.6, H 7.0, S 7.4; found: C 63.3, H 6.8, S 7.5.

Methyl 2,3-Di-O-benzyl-4-O-methylthiomethyl-α-D-gluco-hexodialdo-1,5-pyranoside (9)

Methyl 2,3-di-*O*-benzyl-4-*O*-methylthiomethyl-α-D-glucopyranoside (**8**, 4.35 g) in dry dimethyl sulfoxide (75 mL) was treated with *N*,*N*′-dicyclohexylcarbodiimide (8.0 g), pyridine (0.4 mL), and trifluoroacetic acid (0.4 mL) for 18 h at room temperature to give a single product having R_f 0.7 (solvent *C*). The reaction mixture was diluted with ethyl acetate (50 mL) and a solution of oxalic acid dihydrate (3.75 g) in methanol (10 mL) was added to the mixture. After 30 min the mixture was poured into ice cold, saturated aqueous sodium chloride and the resulting mixture was filtered. The organic phase was separated and the aqueous solution was extracted with ethyl acetate (2 × 20 mL). The combined phase was washed with saturated aqueous sodium hydrogen carbonate and then with water. The aqueous washings were extracted with ethyl

acetate and the organic phases were combined, dried ($MgSO_4$), and concentrated to dryness. The syrupy residue was dissolved in warm acetone (20 mL) and the remaining *N,N'*-dicyclohexylurea was removed by filtration. The filtrate was concentrated to give **9** as an orange syrup which had ν_{max}(film) 1730 cm^{-1} (C=O) and which was used without further purification.

*1,3-Diphenyl-2-(methyl 2',3'-di-*O*-benzyl-4'-O-methylthiomethyl-α-*D*-gluco-pentopyranosid-5'-yl)imidazolidine (**10**)*

Compound **8** (870 mg) was oxidized as described above. After oxalic acid dihydrate (0.75 g) in methanol (5 mL) had been added to the reaction mixture, the mixture was filtered and *N,N'*-diphenylethylenediamine (400 mg) was added to the filtrate. After 24 h at room temperature the mixture was refrigerated to give **10** as colorless needles (800 mg). Recrystallization from ethanol gave **10** as colorless needles having mp 113–115.5°C, $[\alpha]_D$ −32.0 ± 0.9° (*c* 1.09, $CHCl_3$); ^{1}Hmr τ: 2.53–3.47 (20H, aromatic H's), 4.30 (1H, s, H-2), 4.85–5.67 (7H, H-1', OCH_2S, 2 CH_2—C_6H_5's), 5.75–6.77 (8H, H-4's, H-5's, H-2'—H-5'), 6.90 (3H, s, OMe), 7.83 (3H, s, SMe). *Anal.* calcd. for $C_{37}H_{42}N_2O_5S$: C 70.9, H 6.8, S 4.5; found: C 70.9, H 6.7, S 4.0.

*Methyl 2,3-Di-*O*-benzyl-7,8-dideoxy-4-*O*-methylthiomethyl-*D*-glycero- and -*L*-glycero-α-*D*-gluco-oct-7-enopyranoside (**11** and **12**)*

A solution of crude **9** (~4.35 g) in dry tetrahydrofuran (15 mL) was added dropwise with vigorous stirring to a tetrahydrofuran (10 mL) solution of vinylmagnesium bromide (prepared from vinyl bromide (3.9 mL) and magnesium turnings (1.37 g)). The reaction mixture was stirred at room temperature for 4 h after which time tlc (solvent *A*) revealed that all of the starting material had disappeared. Aqueous ammonium chloride (30 mL) was added dropwise to the cooled (0°C) reaction mixture. Ethyl acetate (30 mL) was added and the organic phase separated; the aqueous phase was extracted with ethyl acetate (2 × 30 mL). The combined organic solution was washed with saturated aqueous sodium chloride, dried ($MgSO_4$), and concentrated to a syrup. Column chromatography on silica gel (solvent *A*) gave methyl 2,3-di-*O*-benzyl-7,8-dideoxy-4-*O*-methylthiomethyl-*L*-*glycero*-α-*D*-*gluco*-oct-7-enopyranoside (**12**) as a colorless syrup (2.9 g, 62.9%) having R_f 0.67, $[\alpha]_D$ +109.7 ± 0.8° (*c* 1.29, $CHCl_3$); ν_{max} (film): 3500 (OH) and 1455 cm^{-1} (C=C); ^{1}Hmr τ: 2.65 (10H, aromatic H's), 3.65–4.30 (1H, m, vinyl H), 6.40–5.75 (10H, 2 vinyl H's, 2 CH_2—C_6H_5's, SCH_2O, H-1, H-2), 5.80–6.75 (7H, H-3—H-6, OMe), 7.03 and 7.15 (1H, OH, exchanged in D_2O), 7.80 (3H, SMe). *Anal.* calcd. for $C_{25}H_{32}O_6S$: C 65.2, H 7.0, S 7.0; found: C 65.4, H 6.9, S 6.8.

Methyl 2,3-di-*O*-benzyl-7,8-dideoxy-4-*O*-methylthiomethyl-*D*-*glycero*-α-*D*-*gluco*-oct-7-enopyranoside (**11**) was isolated as a homogeneous syrup (560 mg, 12.1%) which crystallized on standing. Recrystallization from hexane afforded **11** as white needles having R_f 0.39, mp 93–94°C, $[\alpha]_D$ +115.5 ± 0.5° (*c* 2.1, $CHCl_3$); ν_{max} (KBr): 3450 (OH) and 1450 cm^{-1} (C=C); ^{1}Hmr τ: 2.73 (10H, aromatic H's), 3.65–6.75 (18H, H-1—H-7, H-8's, 2 CH_2—C_6H_5's, SCH_2O, OMe), 7.05 (1H, bs, OH, exchanged in D_2O), 7.90 (3H, s, SMe). *Anal.* found: C 64.9, H 6.8, S 6.9.

*Treatment of Compound **12** with Methyl Iodide*

A mixture of **12** (660 mg), methyl iodide (0.75 mL) and sodium hydrogen carbonate (0.6 g) was refluxed for 12 h. Thin-layer chromatography (solvent *A*) revealed that all of **12** had reacted to give a mixture (1:1) of two components having R_f 0.70 and 0.16. Water (2.5 mL) was added to the reaction mixture and then the mixture was concentrated to dryness. The residue was partitioned between chloroform and water; the chloroform solution was washed with water, dried ($MgSO_4$), and evaporated to an orange syrup. The syrup was adsorbed onto a column of silica gel and fractions were eluted (solvent *A*). Methyl 2,3-di-*O*-benzyl-7,8-dideoxy-4,6-*O*-methylene-*L*-*glycero*-α-*D*-*gluco*-oct-7-enopyranoside (**23**) was isolated as a homogeneous syrup having R_f 0.70, $[\alpha]_D$ −25.1 ± 1° (*c* 0.88, $CHCl_3$); ν_{max} (film): 1460 cm^{-1} (C=C); no ir absorption attributable to OH; ^{1}Hmr τ: 2.67 (10H, aromatic H's), 3.45–5.60 (12H, 3 vinyl H's, H-1, H-2, H-6, OCH_2O, 2 CH_2—C_6H_5's), 5.70–6.80 (6H, H-3—H-5, OMe). *Anal.* calcd. for $C_{24}H_{28}O_6$: C 69.9, H 6.8; found: C 70.4, H 6.9.

Methyl 2,3-di-*O*-benzyl-7,8-dideoxy-*L*-*glycero*-α-*D*-*gluco*-oct-7-enopyranoside (**13**) was isolated as crystals which upon recrystallization from petroleum ether gave white needles having R_f 0.16, mp 109–110°C, $[\alpha]_D$ −1.6 ± 0.8°, $[\alpha]_{365}$ −29.4 ± 0.8° (*c* 1.2, $CHCl_3$); ^{1}Hmr τ: 2.65 (10H, aromatic H's), 3.70–4.35 (1H, m, vinyl H), 4.45–5.75 (8H, 2 vinyl H's, H-1, H-2, 2 CH_2—C_6H_5's), 6.00–6.70 (7H, H-3—H-6, OMe), 6.90–7.60 (2H, 2 OH's). *Anal.* calcd. for $C_{23}H_{28}O_6$: C 69.0, H 7.1; found: C 68.8, H 7.1.

The reaction was repeated using the same procedure as outlined above except that acetone was replaced by water–acetone (1:1 (v/v)) as the solvent. Thin-layer chromatography revealed that compounds **13** and **23** were produced in approximately equal proportions.

*Treatment of **12** with Silver Nitrate and 2,6-Lutidine*

Silver nitrate (288 mg) was added to **12** (157 mg) and 2,6-lutidine (107 mg) in tetrahydrofuran–water (0.8 mL, 4:1 (v/v)) and the mixture was stirred for 16 h at room temperature. Thin-layer chromatography (solvent *A*) showed that **12**, **13**, and **23** were present with **23** being the preponderant component.

*Treatment of Methyl 2,3-Di-*O*-benzyl-7,8-dideoxy-4-*O*-methylthiomethyl-*D*-glycero-α-*D*-gluco-oct-7-enopyranoside (**11**) with Methyl Iodide*

Compound **11** (560 mg) in acetone (5 mL) was treated with methyl iodide (0.75 mL) and sodium hydrogen carbonate (600 mg) as described for **12** (see above). Thin-layer chromatography (solvent *A*) showed that after 12 h the reaction mixture contained a major component (R_f 0.84) and a trace of a minor component (R_f 0.12) but no starting material. The major product was isolated by the procedure described for **23** to give, after column chromatography on silica gel (solvent *A*), methyl 2,3-di-*O*-benzyl-7,8-dideoxy-4,6-*O*-methylene-*D*-*glycero*-α-*D*-*gluco*-oct-7-enopyranoside (**24**) as an amorphous solid (70 mg) which could not be crystallized. The product had $[\alpha]_D$ +30.9 ± 0.8° (*c* 1.2, $CHCl_3$); ν_{max} (film): 1450 cm^{-1} (C=C); no ir absorption attributable to OH; ^{1}Hmr τ: 2.67 (10H, aromatic H's), 3.73–5.47 (10H, 3 vinyl H's, OCH_2O, 2 CH_2—C_6H_5, H-1), 5.65–6.75 (8H, H-2—H-6, OMe). *Anal.* calcd. for $C_{24}H_{28}O_6$: C 69.9, H 6.8; found: C 69.6, H 7.1.

*Methyl 6-O-Acetyl-2,3-di-O-benzyl-7,8-dideoxy-4-O-methylthiomethyl-L-glycero-α-D-gluco-oct-7-enopyranoside (**14**)*

Compound **12** (2.9 g) in pyridine (30 mL) was treated with acetic anhydride (3 mL) for 48 h at room temperature and then the mixture was poured with vigorous stirring into ice water (300 mL). The aqueous mixture was extracted with chloroform; the chloroform extract was washed successively with cold 2 *N* sulfuric acid, saturated aqueous sodium hydrogen carbonate, and water. Concentration of the dried ($MgSO_4$) chloroform solution afforded a syrupy residue which was fractionated on silica gel (solvent *A*) to give **14** as a homogeneous syrup (2.9 g, 92.7%) having R_f 0.78, $[\alpha]_D$ +82.3 ± 1.2° (*c* 0.85, $CHCl_3$); ν_{max} (film): 1745 cm^{-1} (OAc); no ir

absorption attributable to OH; ^{1}Hmr τ: 2.70 (10H, aromatic H's), 3.85–6.70 (15H, 3 vinyl H's, H-1—H-6, OCH_2S, 2 CH_2—C_6H_5's, OMe), 7.87 (6H, SMe, OAc). *Anal.* calcd. for $C_{27}H_{34}O_7S$: C 64.5, H 6.8, S 6.4; found: C 65.1, H 7.0, S 6.3.

*Methyl 6-*O*-Acetyl-2,3-di-*O*-benzyl-7,8-dideoxy-*L*-glycero-α-*D*-gluco-oct-7-enopyranoside (15)*

A mixture of compound **14** (2.9 g), methyl iodide (4.2 mL), and sodium hydrogen carbonate (3.6 g) in acetone (60 mL) was refluxed overnight to give a single component having R_f 0.44 (solvent *A*). The reaction mixture was processed in the usual way (see above) to give, after column chromatography on silica gel (solvent *A*), compound **15** as a colorless syrup (2.3 g, 80%) having $[\alpha]_D$ +2.9 ± 0.4°, $[\alpha]_{365}$ −17.2 ± 0.9° (*c* 1.05, $CHCl_3$); ν_{max} (film): 3520 (OH) and 1730 cm^{-1} (OAc); ^{1}Hmr τ: 2.65 (10H, aromatic H's), 3.70–5.40 (9H, 3 vinyl H's, H-1, H-2, 2 CH_2—C_6H_5), 5.70–6.70 (7H, H-3—H-6, OMe), 6.97–7.10 (1H, OH, exchanged in D_2O), 7.90 (3H, s, OAc). *Anal.* calcd. for $C_{25}H_{30}O_7$: C 67.9, H 6.8; found: C 67.9, H 6.8.

*Methyl 2,3-Di-*O*-benzyl-*L*-glycero-α-*D*-gluco-heptopyranoside (27)*

A mixture of compound **15** (2.3 g) and osmium tetroxide (10 mL of a 1% solution of osmium tetroxide in *tert*-butyl alcohol) in ethyl ether – water (50 mL, 1:1 (v/v)) was treated with sodium metaperiodate (5.5 g) and the mixture was vigorously stirred overnight at room temperature. Thin-layer chromatography (solvent *A*) revealed the absence of **15** (R_f 0.44) and the presence of one product (R_f 0.23). The ether solution was separated, and the aqueous phase was extracted with ethyl ether (2 × 50 mL); the combined ether solution was concentrated to a small volume to which methanol (100 mL) was added. Sodium borohydride (900 mg) was added to the methanol solution and the mixture was stirred overnight at room temperature. The reaction mixture was neutralized (pH 7) with concentrated hydrochloric acid and the neutral mixture was evaporated to a residue which was concentrated several times with methanol. Thin-layer chromatography (solvent *D*) showed that the syrupy residue contained a major component (R_f 0.25) and a trace of material which did not migrate. The residue was extracted with hot ethyl acetate (3 × 50 mL) and the extract was concentrated to a syrup which was fractionated on a column of silica gel (solvent *D*) to give **27** as a homogeneous syrup (1.4 g, 64%) having $[\alpha]_D$ +15.6 ± 0.5° (*c* 1.0, $CHCl_3$); ν_{max} (film): 3450 cm^{-1} (OH); no ir absorption attributable to acetyl or aldehyde functions; ^{1}Hmr τ: 2.69 (10H, aromatic H's), 4.90–5.60 (5H, H-1, 2 CH_2—C_6H_5), 5.70–6.85 (13H, H-2—H-6, H-7's, OMe, 3 OH's, 3 exchanged in D_2O). *Anal.* calcd. for $C_{22}H_{28}O_7$: C 65.3, H 7.0; found: C 64.9, H 7.4.

Methyl L-glycero-α-D-gluco-Heptopyranoside (28)

Compound **27** (500 mg) in ethanol (75 mL) was hydrogenated (60 psig) over 10% palladium-on-charcoal for 6 h to give one product (R_f 0.51, solvent *E*). The reaction mixture was filtered and the filtrate was concentrated to a solid residue which was recrystallized from ethanol to give **28** as white needles (220 mg, 80%) having mp 163–165°C and $[\alpha]_D$ +137.8 ± 0.5° (*c* 1.5, H_2O). For methyl D-*glycero*-α-L-*gluco*-heptopyranoside mp 167.5–169°C and $[\alpha]_D$ −142° have been reported (16). *Anal.* calcd. for $C_8H_{16}O_7$: C 42.9, H 7.2; found: C 43.2, H 7.5.

*Methyl 2,3-Di-*O*-benzyl-7,8-dideoxy-*L*-glycero-α-*D*-gluco-oct-7-enopyranoside (13)*

Methyl 6-*O*-acetyl-2,3-di-*O*-benzyl-L-*glycero*-α-D-*gluco*-oct-7-enopyranoside (**15**) (3.2 g) in a mixture of triethylamine (5 mL), water (5 mL), and methanol (10 mL) was left overnight at room temperature. The reaction mixture was concentrated to a residue which was partitioned between chloroform and water. The dried ($MgSO_4$) chloroform extract was concentrated to a solid which was recrystallized from petroleum ether to give **13** as needles (2.3 g, 80%) having mp 106–107°C; for another sample of **13** mp 109–110°C had been observed (see above). The product had the same mobility (tlc) as the other sample of **13** and the ^{1}Hmr spectra of the two samples were indistinguishable.

*Methyl 7,8-Anhydro-2,3-di-*O*-benzyl-*D*-threo- and -*L*-erythro-α-*D*-gluco-octopyranoside (16)*

m-Chloroperbenzoic acid (1.03 g) was added to a stirred solution of **13** (1.9 g) in dry dichloromethane (50 mL). After 48 h the reaction mixture was filtered and the filtrate was washed with aqueous sodium hydrogen carbonate. Concentration of the dried ($MgSO_4$) dichloromethane solution afforded a residue which was fractionated on a column of silica gel (solvent *C*). Compounds **16** were isolated as a mixture which was a white solid (1.55 g, 78.7%) having R_f 0.24, mp 118.5–120.5°C (softened at 111.5°C), $[\alpha]_D$ +9.0 ± 0.9° (*c* 1.22, $CHCl_3$); ^{1}Hmr τ: 2.67 (10H, aromatic H's), 4.90–5.55 (5H, H-1, 2 CH_2—C_6H_5's), 5.90–7.35 (13H, H-2—H-7, H-8's, 2 OH's, OMe). *Anal.* calcd. for $C_{23}H_{28}O_7$: C 66.3, H 6.8; found: C 66.0, H 7.1.

*Methyl 8-Azido-2,3-di-*O*-benzyl-8-deoxy-*D*-threo- and -*L*-erythro-α-*D*-gluco-octopyranoside (17)*

A mixture of sodium azide (1 g), ammonium chloride (500 mg), and anhydro derivatives **16** (1.55 g) in 2-methoxyethanol (25 mL) – water (2.5 mL) was refluxed for 1 h. The reaction mixture was partitioned between chloroform and water; the dried ($MgSO_4$) chloroform extract was concentrated to a solid which was purified by column chromatography on silica gel (solvent *C*). Azides **17** were obtained as an amorphous solid mixture (1.39 g, 82%) which had R_f 0.34 (solvent *C*), mp 122–128°C (softened at 110°C), $[\alpha]_D$ +9.9 ± 1° (*c* 1.01, $CHCl_3$); ν_{max} (KBr): 2095 (N_3) and 3380 cm^{-1} (OH); ^{1}Hmr τ: 2.65 (10H, aromatic H's), 4.90–5.60 (5H, H-1, 2 CH_2—C_6H_5's), 5.87–7.53 (14H, H-2—H-7, H-8's, OMe, 3 OH's, 3 exchanged in D_2O). *Anal.* calcd. for $C_{23}H_{29}N_3O_7$: C 60.1, H 6.4, N 9.1; found: C 59.7, H 6.3, N 9.0.

Photolysis of Compounds 17

A solution of azides **17** (1.6 g in benzene–2-methoxyethanol (100 mL, 9:1 (v/v)) under nitrogen was irradiated with uv light for 6 h after which time tlc (solvent *D*) showed that all of the starting material had reacted. The reaction mixture was concentrated to a syrup which was adsorbed onto silica gel; the column was eluted with solvent *D*. A mixture of two components (560 mg, 36.7%) having R_f 0.44 and 0.35 was obtained as a syrup which solidified on standing and which reduced Fehling's solution. Recrystallization from hexane – ethyl acetate gave compound **18** as a white powder (210 mg) having R_f 0.45 (solvent *D*), mp 88–89°C, $[\alpha]_D$ +20.6 ± 0.5° (*c* 2.13, $CHCl_3$); ν_{max} (KBr): 3400 cm^{-1} (OH); no ir absorption attributable to an aldehyde group; ^{1}Hmr τ: 2.50–2.90 (10H, aromatic H's), 4.87–5.65 (6H, H-1, H-8, 2 CH_2—C_6H_5), 5.70–7.45 (12H, H-2—H-7, OMe, 3 OH's, 3 exchanged in D_2O). Compound **18** reduced Fehling's solution. *Anal.* calcd. for $C_{23}H_{28}O_8$: C 63.9, H 6.5; found: C 63.9, H 6.5.

In a second experiment azides **17** (1.4 g) afforded **18** and **19** as a mixture (755 mg, 57.3%) from which **19** (R_f 0.35) was isolated as a solid foam (140 mg); the sample of **19** was revealed by tlc (solvent *D*) to be contaminated with compound **18** (≤10%). This material had $[\alpha]_D$ +14.8 ± 0.5°, $[\alpha]_{365}$ +27.3 ± 0.5° (*c* 1.76, $CHCl_3$); ^{1}Hmr τ: 2.40–2.91 (10H,

aromatic H's), 4.70–6.93 (18H, H-1—H-8, 2 CH_2—C_6H_5's, OMe, 3 OH's).

Methanolysis of Compound ***18***

Compound **18** (100 mg) in dry methanol (30 mL) was refluxed for 16 h in the presence of Dowex 50 ion-exchange resin (H^+) with the exclusion of moisture. The reaction mixture was filtered and the filtrate was concentrated to a crude product which was purified by column chromatography on silica gel (solvent *D*) to give **21** as white crystals (50 mg, 48.5%). Recrystallization from hexane – ethyl acetate gave **21** as white needles having R_f 0.59 (solvent *D*), mp 148.5–150°C, $[\alpha]_D$ $-11.6 \pm 0.9°$, $[\alpha]_{365}$ $-53.1 \pm 0.9°$ (*c* 1.20, $CHCl_3$); ^{1}Hmr (220 MHz) τ: 2.61–2.82 (10H, aromatic H's), 5.06, 5.15, 5.16, and 5.37 (4 1H d's, J_{vic} = 10.5 Hz, 2 CH_2—C_6H_5's), 5.21 (1H, d, $J_{7,8}$ = 1.8 Hz, H-8), 5.42 (1H, d, $J_{1,2}$ = 3.8 Hz, H-1), 6.01 (1H, m, H-6), 6.00, 6.20, and 6.49 (3 1H t's, J = 9.5 Hz, H-3, H-4, H-5), 6.52 (1H, m, $J_{2,3}$ = 10 Hz, H-2), 6.60 and 6.61 (2 3H s's, 2 OMe's), 7.31 (1H, d, $J_{7,OH}$ = 3.0 Hz, HO-7), 7.34 (1H, d, $J_{6,OH}$ = 4.5 Hz, HO-6); ^{13}Cmr data ($CDCl_3$) δ: 128.4, 128.3, 128.1, 127.9, and 127.5 (aromatic), 101.0 (C-8), 99.0 (C-1), 55.3 and 54.8 (2 OMe's). *Anal.* calcd. for $C_{24}H_{30}O_8$: C 64.6, H 6.8; found: C 64.5, H 6.7.

Methanolysis of Compound ***19***

Compound **19** (140 mg) was treated with dry methanol (30 mL) in a manner similar to that used with **18**. After a reaction time of 48 h, tlc (solvent *D*) revealed that the reaction mixture contained a trace of **19** (R_f 0.35) and a component having R_f 0.50. The product was isolated by the procedure which was used for **21** to give compound **20** as a white solid (70 mg). Recrystallization from hexane – ethyl acetate gave white crystals having mp 120–122°C, $[\alpha]_D$ $+15.2 \pm 0.6°$, $[\alpha]_{365}$ $+25.4 \pm 0.6°$ (*c* 1.58, $CHCl_3$); ^{1}Hmr (220 MHz) τ: 2.91–2.84 (10H, aromatic H's), 5.11–5.37 (4H, 2 CH_2—C_6H_5's), 5.19 (0.5H, d, $J_{7,8}$ = 3.5 Hz), 5.39 (0.5H, d, J = 3.8 Hz, H-1 or H-1′), 5.41 (0.5H, d, J = 3.8 Hz, H-1 or H-1′), 5.75 (0.5H, d, $J_{7',8'}$ = 7.5 Hz, H-8′), 5.98–7.48 (14H, H-2—H-7, 2 OH's, 2 OMe's). The protons of the methoxyl groups gave three singlets having chemical shift values of τ 6.42, 6.55, and 6.58. Double-resonance experiments are described in Results and Discussion. *Anal.* calcd. for $C_{24}H_{30}O_8$: C 64.6, H 6.8; found: C 64.7, H 6.9.

Preparation of Compound ***22***

Compound **21** (200 mg) in ethanol (50 mL) was hydrogenated (50 psig) over 10% palladium-on-charcoal to give a single product having R_f 0.60 (solvent *E*). The reaction mixture was concentrated to give **22** as a white solid (100 mg, 84%) having mp 192–196°C (dec.), $[\alpha]_D$ $+56.3 \pm 0.5°$, $[\alpha]_{365}$ $+168° \pm 1°$ (*c* 1.07, $CHCl_3$); ^{1}Hmr data (220 MHz, D_2O with sodium 2,2-dimethyl-2-silapentane-5-sulfonate as the internal standard) τ: 5.13 (1H, d, $J_{1,2}$ = 4.0 Hz, H-1), 5.18 (1H, d, $J_{7,8}$ = 1.8 Hz, H-8), 6.01 (1H, m, $J_{7,6}$ = 3.2 Hz, H-7), 6.05–6.11 (1H, m, H-6), 6.16 and 6.20 (2 1H t's, J = 10 Hz, 4-H, H-5), 6.37 (1H, $J_{2,3}$ = 10 Hz, H-2), 6.43–6.52 (1H, m, H-3), 6.55 and 6.57 (2 3H s's, 2 OMe's); ^{13}Cmr (D_2O) δ: 101.7 (C-8), 99.8 (C-1), 72.0, 70.9, 70.5, and 70.1 (C-2, C-3, C-6, C-7), 68.3 and 67.4 (C-4, C-5), 55.2 (OMe, α-*manno*), and 54.7 (OMe, α-*gluco*). *Anal.* calcd. for $C_{10}H_{18}O_8$: C 45.1, H 6.8; found: C 44.7, H 7.2.

Acknowledgements

The authors are grateful to the National Research Council of Canada for its generous financial support of this work in the form of a scholarship (to H.C.J.) and a grant (to W.A.S.). They also wish to acknowledge the encouragement and interest of the late Professor J.K.N. Jones, and to thank Dr. Arthur Grey for obtaining the 220-MHz ^{1}Hmr spectra.

Hydrogenation during ligand exchange reactions between ferrocene and pyrene

CHOI CHUCK LEE, KEN J. DEMCHUK, AND RONALD G. SUTHERLAND

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask. Canada S7N 0W0

Received November 1, 1978

CHOI CHUCK LEE, KEN J. DEMCHUK, and RONALD G. SUTHERLAND. Can. J. Chem. **57**, 933 (1979).

From ligand exchange reactions between ferrocene and pyrene, carried out in the presence of $AlCl_3$–Al, the η^6-pyrene-η^5-cyclopentadienyliron, η^6-4,5-dihydropyrene-η^5-cyclopentadienyliron, and η^6-4,5,9,10-tetrahydropyrene-η^5-cyclopentadienyliron monocations (**2**, **3**, and **4**, respectively) as well as the η^6-pyrene-*trans*-bis-η^5-cyclopentadienyliron and η^6-4,5,9,10-tetrahydropyrene-*trans*-bis-η^5-cyclopentadienyliron dications (**5** and **7**, respectively) were isolated and identified. A possible mechanism for the partial hydrogenation of the pyrene ligand is discussed.

CHOI CHUCK LEE, KEN J. DEMCHUK et RONALD G. SUTHERLAND. Can. J. Chem. **57**, 933 (1979).

A partir de réactions d'échange de ligands entre le ferrocène et le pyrène effectuées en présence de Al–$AlCl_3$ on a pu identifier et caractériser les monocations η^6-pyrène η^5-cyclopentadiénylfer, η^6-dihydro-4,5 pyrène η^5-cyclopentadiénylfer et η^6-tétrahydro-4,5,9,10 pyrène η^5-cyclopentadiénylfer (respectivement **2**, **3** et **4**) ainsi que les dications η^6-pyrène *trans*-bis-η^5-cyclopentadiénylfer et η^6-tétrahydro-4,5,9,10 pyrène *trans*-bis-η^5-cyclopentadiénylfer (respectivement **5** et **7**). On discute d'un mécanisme possible pour l'hydrogénation partielle du ligand pyrène.

[Traduit par le journal]

In 1975, the first observation of a partial hydrogenation of the aromatic ligand during the ligand exchange reaction between ferrocene and naphthalene or anthracene, carried out in the presence of $AlCl_3$-Al, was reported from this laboratory (1). Other polycyclic aromatic ligands have also been found to give similar hydrogenations (2), and it is of interest to note that in a recent communication on the synthesis of bis(η^6-naphthalene)chromium(0) (3), it was stated in a footnote that control experiments with naphthalene–$AlCl_3$–Al–$CrCl_3$ in C_6H_5Cl as solvent gave bis(η^6-tetralin)chromium(0) as the main product. On the basis of the observation of a stereospecific hydrogenation when 9,10-dimethylanthracene was the aromatic ligand, a mechanism for the hydrogenation process has also been proposed recently (4). As an extension of these studies, the present work was undertaken on the ligand exchange reaction between ferrocene and pyrene in order to ascertain the extent of hydrogenation that might occur during ligand exchange with this tetracyclic aromatic system.

In ligand exchange reactions between ferrocene and phenanthrene, effected in the presence of $AlCl_3$–Al, hydrogenation could take place at the C-9,10 positions giving rise to η^6-phenanthrene-η^5-cyclopentadienyliron and η^6-9,10-dihydrophenanthrene-η^5-cyclopentadienyliron monocations and η^6-phenanthrene-*trans*-bis-η^5-cyclopentadienyliron and η^6-9,10-dihydrophenanthrene-*trans*-bis-η^5-cyclopentadienyliron dications (5). In similar reactions with pyrene (**1**), if analogous partial hydrogenations occur at C-4,5 and C-9,10, monocations **2**, **3**, and **4**, and dications **5**, **6**, and **7**, might be obtained. In the present work, attempts were made to isolate and characterize these cations.

The extent of hydrogenation in ligand exchange reactions between ferrocene (FcH) and polycyclic arenes has been found to be highly dependent on reaction conditions such as the molar ratio of the reactants, the reaction temperature and the nature

*As the mono- or dihexafluorophosphate salt.

of the solvent. For example, in the formation of the tetralin complex from naphthalene, an increase in the relative amount of $AlCl_3$ or a decrease in the relative amount of FcH tended to increase the proportion of the hydrogenated product (2). Moreover, the use of *n*-alkanes as solvent instead of alicyclic hydrocarbons such as decalin tended to decrease the extent of hydrogenation (2, 5). Utilizing the usually employed molar ratio of 1:1:2:1 for arene–FcH–$AlCl_3$–Al, and an *n*-alkane as solvent to minimize hydrogenation, attempts were made to prepare nonhydrogenated products such as ion **2**. However, often mixtures of products were obtained. Thus reaction with a molar ratio of 1:1:2:1 for **1**–FcH–$AlCl_3$–Al in refluxing *n*-hexane (69°C) for 20 h or in refluxing *n*-heptane (98°C) for 16 h gave about 16% yields of a 3:1 mixture of the η^6-pyrene-η^5-cyclopentadienyliron cation (**2**) and the η^6-4,5-dihydropyrene-η^5-cyclopentadienyliron cation (**3**), and these products, as their hexafluorophosphate salts, were separated by passage through an alumina column. When the same reaction was carried out in refluxing *n*-decane (174°C) for 16 h, a 24% yield of **2** was obtained directly without chromatographic separation. At this higher temperature, besides a greater yield of **2**, any hydrogenated product such as **3** has apparently been decomposed. Using a molar ratio of 1:1:10:1 for **1**–FcH–$AlCl_3$–Al, reaction in decalin at 115°C for 16 h gave a 9% yield of the η^6-4,5,9,10-tetrahydropyrene-η^5-cyclopentadienyliron cation (**4**). When **2**, **3**, and **4**, as their hexafluorophosphate salts, were subjected to pyrolytic sublimation under reduced pressure (4), pyrene, 4,5-dihydropyrene, and 4,5,9,10-tetrahydropyrene, respectively, were recovered, thus confirming the nature of the arene ligands in ions **2**, **3**, and **4**.

From the work with naphthalene on the effect of varying the amount of $AlCl_3$ on the extent of hydrogenation, interpolation of the data suggested that a reaction carried out with a molar ratio of 1:1:5.6:1 for naphthalene–FcH–$AlCl_3$–Al at 140°C for 4 h in decalin would give a 1:1 mixture of the nonhydrogenated and hydrogenated naphthalene and tetralin complexes (2). Using these conditions with **1** instead of naphthalene, only a 6% yield of the η^6-4,5,9,10-tetrahydropyrene-*trans*-bis-η^5-cyclopentadienyliron dication (**7**) was obtained. Morrison *et al.* (6) have previously reported the preparation, from ligand exchange reactions, of a number of dications including the nonhydrogenated η^6-pyrene-*trans*-bis-η^5-cyclopentadienyliron dication (**5**). Using the conditions of Morrison *et al.* (molar ratio of 1:20:100:33 for **1**–FcH–$AlCl_3$–Al in refluxing cyclohexane (81°C) for 16 h), we have obtained, in 35% yield, only the tetrahydro dicationic product **7**. With a molar ratio of 1:2:2:1 for **1**–FcH–$AlCl_3$–Al, a reaction carried out in refluxing *n*-decane (174°C) for 16 h gave a mixture of products from which a 5% yield of the nonhydrogenated dication **5**, as its hexafluorophosphate salt, was recovered. In the present work, however, it has not been possible to obtain the η^6-4,5-dihydropyrene-*trans*-bis-η^5-cyclopentadienyliron dication (**6**).

The identification of the structures of ions **2**, **3**, **4**, **5**, and **7** was greatly facilitated by their ^{1}H and ^{13}C nmr spectra. These spectral data are summarized in Tables 1 and 2. When hydrogenation occurs at C-4,5 or at C-4,5, and C-9,10, these carbon positions become methylene groups and only in the hydrogenated ions **3**, **4**, and **7** do methylene absorptions in the aliphatic region appear in both the ^{1}H and ^{13}C spectra (Tables 1 and 2). For dications **5** and **7**, the symmetry of the structures greatly simplified both their ^{1}H and ^{13}C spectra. The two CpFe groups are assigned a *trans* geometry by analogy with similar assignments in dications formed from other poly-

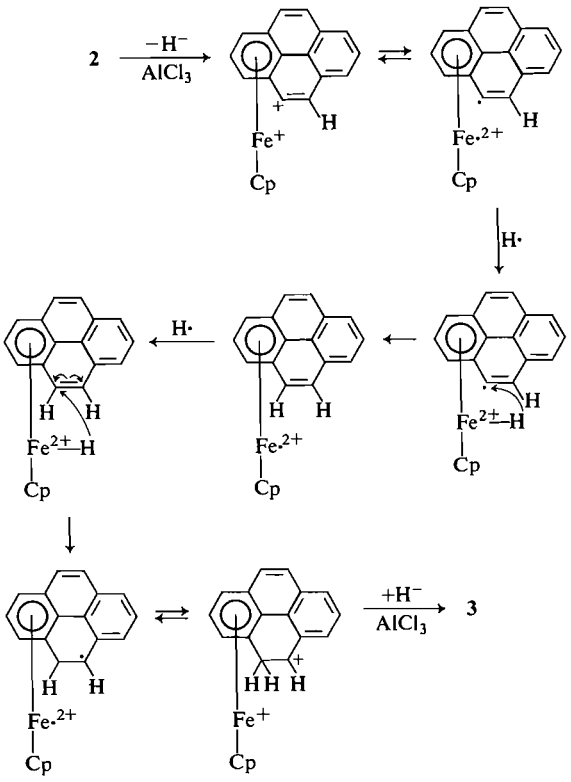
cyclic arenes (1, 4–7). Moreover, if the two CpFe groups were *cis*, in dication **7**, four of the C-4,5,9,10 protons would be on the same side (*endo*) and the other four would be on the opposite side (*exo*) relative to the two CpFe groups, and it would be unlikely for these protons to appear as a broad singlet in the ^1H spectrum as was observed (Table 1).



SCHEME 1

The partial hydrogenation of the pyrene ligand observed in the present work may be formulated via the ion–radical mechanism which has been proposed and discussed earlier (4). The formation of ion **3** from **2** is illustrated in Scheme 1. The hydrogenation is initiated by the hydride abstraction from C-4 of **2** by $AlCl_3$ to give a carbonium ion. An intramolecular oxidation–reduction would then take place through the transfer of an electron from Fe(II) to give Fe(III), while the carbonium ion center is reduced to a radical, and this is followed by reactions with H atoms as previously described (4). The process may be repeated starting with hydride abstraction from C-10 of **3**, eventually giving rise to the tetrahydro cation **4**. It may be noted that the carbonium ions derived from hydride abstraction from C-4 of **2** and C-10 of **3** should be of high stability and could be formed quite readily since they are structurally analogous to α-ferrocenyl substituted carbocations which have extraordinarily high stability (8, 9). Further hydrogenation of the uncomplexed aromatic ring of **4** is not feasible since hydride abstraction from this ring would not give a stable carbonium ion analogous to an α-ferrocenyl substituted carbocation.

Experimental

Ligand Exchange Reactions

Ligand exchange reactions between pyrene (**1**) and ferrocene (FcH), effected in the presence of $AlCl_3$–Al, were carried out using a general procedure as previously described (1), but with

*Isolated as the mono- or dihexafluorophosphate salt.
†Separated from a 3:1 mixture of **2** and **3** through an alumina column by elution with acetone.
‡Separated by passage through an alumina column with elution by nitromethane after all monocations were removed by elution with acetone.

the experimental conditions varied as summarized in Table 3 to give cations **2**, **3**, **4**, **5**, and **7**. The following is an illustration of a typical experiment.

A mixture of 5.1 g (25 mmol) of pyrene, 4.7 g (25 mmol) of ferrocene, 6.7 g (50 mmol) of $AlCl_3$, and 0.65 g (25 mmol) of Al powder in 50 mL of *n*-heptane was heated under N_2 and under reflux (98°C) for 16 h. After cooling to room temperature, 50 mL of H_2O was added and the mixture was filtered to remove all solid material. The aqueous layer was separated, washed with hexane, and then filtered into a concentrated solution of ammonium hexafluorophosphate (4.0 g, 25 mmol, in 10 mL of H_2O). The hexafluorophosphate salts that precipitated were collected by filtration, redissolved in acetone and passed through an alumina column (chromatographic activated alumina F-20, Sargent-Welch Scientific Co.). Elution with acetone gave 1.4 g (12%) of the hexafluorophosphate salt of η^6-pyrene-η^5-cyclopentadienyliron cation (**2**) and 0.5 g (4%) of the hexafluorophosphate salt of η^6-4,5-dihydropyrene-η^5-cyclopentadienyliron cation (**3**). These products, as well as the hexafluorophosphate salts of **4**, **5**, and **7**, were identified by their ^1H and ^{13}C nmr spectra (Tables 1 and 2). The data from the C and H analyses are given in Table 3.

Pyrolytic Sublimation of 2, 3, and 4

The hexafluorophosphate salt of monocation **2**, **3** or **4** was pyrolytically sublimed at 0.1 Torr and at 180°C in an oil bath as previously described (4) to give, respectively, pyrene, 4,5-dihydropyrene, or 4,5,9,10-tetrahydropyrene in yields of 85–90%. The pyrene so obtained, mp 150°C, was identical to a commercial sample. The 4,5-dihydropyrene and 4,5,9,10-tetrahydropyrene melted, respectively, at 132°C (lit. (10) mp 132°C) and 136°C (lit. (11) mp 134–136°C), and their mass spectra show parent ions at *m/e* 204 and 206, respectively, as expected.

Reçu le 1 août 1978

JEANINE LLINARES, JEAN-PIERRE GALY, ROBERT FAURE, EMILE-JEAN VINCENT et JOSÉ ELGUERO. Can. J. Chem. **57**, 937 (1979).

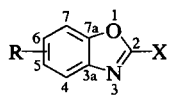
Les spectres de rmn du ^{13}C de 34 benzoxazoles, de l'oxazole et de 10 *o*-aminophénols ont été enregistrés. Tous les déplacements chimiques ont été attribués à partir des effets de substituant. Les structures des produits obtenus par nitration du benzoxazole ont été déterminées par rmn du ^{13}C. Les perturbations induites par une substitution en position 2 sont discutées en fonction d'un modèle empirique qui fait intervenir les paramètres structuraux *F*, *R* et *Q**. Nous discutons également de la tautomèrie azido–tétrazole (position 2 substituée par un groupement N_3) et de la tautomèrie prototropique (position 2 substituée par des groupements NH_2, OH et SH). Enfin, nous avons comparé les déplacements chimiques et les constantes de couplage de l'oxazole et du benzoxazole.

JEANINE LLINARES, JEAN-PIERRE GALY, ROBERT FAURE, EMILE-JEAN VINCENT, and JOSÉ ELGUERO. Can. J. Chem. **57**, 937 (1979).

Thirty-four benzoxazoles, oxazole, and 10 *o*-aminophenols have been studied by ^{13}C nmr spectroscopy. All the signals have been attributed from substituent effects. The structure of products obtained by nitration of benzoxazole have been determined by ^{13}C nmr. The shifts induced by substitution at the 2 position have been discussed as a function of an empirical model using the structural parameters *F*, *R*, and *Q**. Azido–tetrazole equilibria (N_3 in position 2) and prototropic tautomerism (NH_2, OH, and SH in position 2) have been also discussed. The chemical shifts and coupling constants of oxazole and unsubstituted benzoxazole have been compared.

Introduction

Dans le cadre d'études physicochimiques entreprises depuis plusieurs années sur les benzazoles (benzimidazole (1, 3, 8), indazole (1, 4, 5, 7, 8), benzotriazole (1, 8) et benzothiazole (2, 6, 9)), nous présentons dans ce mémoire les résultats de la résonance magnétique nucléaire du carbone-13 des dérivés benzoxazoliques du type **I**. Notre travail portera principalement sur les effets de la substitution en position 2, effets que nous comparerons avec ceux de la série benzothiazolique (9). Lors de la synthèse de dérivés nitrés, nécessaires pour attribuer les déplacements chimiques, certains problèmes nous ont conduits à étudier le mécanisme de la nitration en série benzoxazolique.



I

Partie expérimentale

Les spectres de carbone-13 ont été enregistrés sur un spectromètre Varian CFT-20. Les composés ont été étudiés à la température de 28 ± 2°C, en solution dans le diméthyl sulfoxyde hexadeutérié. Les déplacements chimiques, mesurés sur les spectres découplés par bruit par rapport à la raie centrale du solvant, sont rapportés au signal du TMS par la relation [1] (10), et sont donnés avec une précision supérieure à 0.1 ppm.

$$[1] \quad \delta_{TMS} = \delta_{DMSO\text{-}d_6} + 39.6 \text{ ppm } (\delta \text{ en ppm})$$

Les constantes de couplage sont mesurées sur les spectres couplés, avec une erreur absolue de 0.5 Hz.

La plupart des composés étudiés ont déjà été décrits dans la littérature (la première référence renvoie au mode de synthèse utilisé, la seconde à l'article où sont données les principales caractéristiques du produit; dans certains cas, ces deux références peuvent coincider): **1** (11, 12), **1***a* (13, 14), **1***b*,[2] **2** (11, 15), **3**,[2] **4** (16), **5** (11, 17), **6** (11), **7** (18), **8** (19), **9**,[2] **9***a* (20), **9***b*,[2] **10** (21, 22), **11**,[2] **11***a* (23, 24), **11***b* (23, 25), **12** (26), **13** (26, 27), **14** (28), **15** (22, 29), **16** (30), **17** (31), **18** (32), **19** (33), **20** (32, 33), **21** (33), **22** (34), **23**,[2] **24**,[2] **25**,[2] **26**,[2] **27** (23), **33** (35, 36), **34** (37), **35**,[2] **36** (38), **37** (39, 40), **38**[2], **39** (41, 42).

Par contre, les produits suivants n'étaient pas connus (tous les produits ont été recristallisés dans l'éthanol).

Le chloro-5 benzoxazole **11***c* est obtenu en chauffant le chloro-4 formamido-2 phénol vers 160–180°C sous une pression de 10^{-2} Torr, selon le procédé de Bamberger (23). Ce composé est un solide de couleur beige qui cristallise en paillettes, pf 36–37°C.

L'azido-2 benzoxazole **14** traité par l'acide nitrique fumant en présence d'acide sulfurique, selon la méthode décrite par Newberry et Phillips (20), donne l'azido-2 nitro-6 benzoxazole **14***a*. Ce dernier est un solide jaune-orangé, pf 207°C (déc.).

Les formanilides **28, 29** et **30** sont préparés par action de l'acide formique sur les aminophénols correspondants (43): (*i*) le formamido-2 nitro-4 phénol **28** a été étudié en uv par Passerini (25), mais n'a pas été décrit. C'est un solide rouge brique, pf 245°C (déc.); (*ii*) le formamido-2 nitro-5 phénol **29** est un solide jaune-vert, pf 235°C (déc.); (*iii*) le chloro-4 formamido-2 phénol **30** cristallise en paillettes marron foncé, pf 165°C.

Par action de l'acide nitrique fumant sur les dérivés mononitrés **28** et **29** (20), on obtient les dérivés dinitrés: (*i*) le dinitro-4,6 formamido-2 phénol **31**, solide jaune clair, pf 196°C (déc.); (*ii*) le dinitro-3,5 formamido-2 phénol **32**, solide jaune, pf 165°C (déc.).

Résultats

Attribution des déplacements chimiques

Lors de précédents travaux dans la série du benzothiazole (6, 9), nous avons présenté une méthode d'attribution des déplacements chimiques des carbones protonés de l'homocycle. Ce procédé, basé sur l'hypothèse que les perturbations sur le cycle hexagonal sont similaires en grandeur et en direction à celles observées en série benzénique (44), conduit à d'excellents résultats, même lorsque le domaine de résonance de ces atomes est peu étendu, comme dans le cas du benzothiazole (6, 9).

A notre avis, le substituant le plus adapté pour l'étude de ce genre de problème est le groupement nitro; les raisons de ce choix sont les suivantes: (*i*) d'une part les effets de ce substituant sont nettement différenciés selon la position considérée; ainsi, en série benzénique (44), les perturbations sont les suivantes: *ipso* = 19.6, *ortho* = −5.3, *meta* = 0.8 et *para* = 6.0 ppm; (*ii*) d'autre part, du moins en ce qui concerne la série benzothiazolique, la nitration est une réaction facile à mettre en oeuvre. Toutefois, un des aspects négatifs de ce choix est la faible solubilité des dérivés nitrés, ce qui nécessite un temps d'accumulation plus élevé.

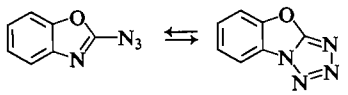
En série benzoxazolique, l'utilisation du substituant nitro entraine des complications supplémentaires. Comme nous le montrerons dans le cas du benzoxazole lui-même **11**, certains dérivés nitrés, moins stables que leurs homologues soufrés, s'ouvrent en milieu acide. En conséquence, l'obtention, dans cette série, de substrats nitrés est plus aléatoire. Par ailleurs, ces composés nitrés peuvent également s'hydrolyser durant l'étude spectroscopique; ainsi, dans le spectre rmn du ^{13}C du méthyl-2 nitro-6 benzoxazole **9***a* (solvant: DMSO-d_6), on note l'apparition progressive de nouvelles raies de résonance attribuables à un produit d'hydrolyse (il est bien connu que les solvants polaires aprotiques, comme le DMSO, accélérent l'attaque nucléophile de l'eau).

Néanmoins, comme le domaine de résonance des carbones protonés de l'homocycle des dérivés benzoxazoliques est relativement large, les effets d'autres substituants que le groupe nitro permettent également de réaliser une attribution complète des déplacements chimiques. La seule ambiguïté concerne les signaux des carbones C-5 et C-6, lorsque l'écart entre les déplacements de ces deux carbones est inférieur ou égal à 0.5 ppm; dans ces conditions, certaines des attributions du tableau 2 peuvent être inversées.

Dans le tableau 1 sont rassemblées les perturbations dues à une substitution sur l'homocycle (valeurs entre parenthèses), pour quelques dérivés benzoxazoliques substitués en position 2. Au cours de notre étude en série benzothiazolique (9), nous avons observé une légère dépendance entre la grandeur de la perturbation et la nature du substituant en position 2; cependant ceci ne rend pas notre approche inopérante. Les valeurs du tableau 1 montrent qu'il en est de même en série benzoxazolique, du moins dans le cas des substituants nitro et chloro, et que, de plus, cette dépendance semble plus importante qu'en série soufrée. Le manque de données ne nous permet pas d'effectuer une étude quantitative de ce phénomène.

Dans le tableau 2 sont présentées les valeurs des déplacements chimiques des divers benzoxazoles substitués en position 2. La plupart des attributions ont été faites par analogie avec les résultats précédents ou par analyse des spectres couplés (cas des chloro-2 et bromo-2 benzoxazoles, **16** et **17**). En ce qui concerne les benzoxazoles substitués par un groupement électron attracteur, nous avons considéré que le signal du carbone C-6 résonnait à une fréquence plus élevée que celui relatif à C-5, et ce pour les raisons suivantes: (*i*) d'une part on observe un comportement similaire en série benzothiazolique; (*ii*) d'autre part, une permutation des attributions conduit à de plus mauvaises corrélations avec les paramètres structuraux.

Enfin, signalons que l'azido-2 benzoxazole **14** peut présenter un phénomène de tautomèrie azido–tétrazole (A ⇄ T):



14A **14T**

Les résultats de la rmn du ^{13}C indiquent que seule

*Les déplacements chimiques sont exprimés en ppm par rapport au TMS; les valeurs entre parenthèses représentent les effets de substituant.
†Déplacements dont l'attribution peut être inversée.
‡Ces raies ne sont pas observables (voir texte).

la forme azide est présente en solution dans le DMSO-d_6, en accord avec nos résultats antérieurs sur ce type d'équilibre (45).

Etude de la réaction de nitration du benzoxazole

Certaines structures benzoxazoliques peuvent s'hydrolyser, plus ou moins rapidement, en milieu acide. Ainsi, dans le cas du benzoxazole **11**, l'hydrolyse acide conduit à l'*o*-formylamino phénol **27**.

Cette hydrolyse intervient durant la nitration de **11**, puisqu'au lieu des dérivés normalement attendus, **11***a* et **11***b*, on obtient les formylamino phénols mononitrés, **28** et **29** (25% de **28** et 75% de **29**); par chauffage sous pression réduite, le mélange conduit aux nitro-5 et nitro-6 benzoxazoles, **11***a* et **11***b* (schéma 1). En aucune façon, la réaction ayant été répétée plusieurs fois, nous n'avons observé de dérivés benzéniques dinitrés.

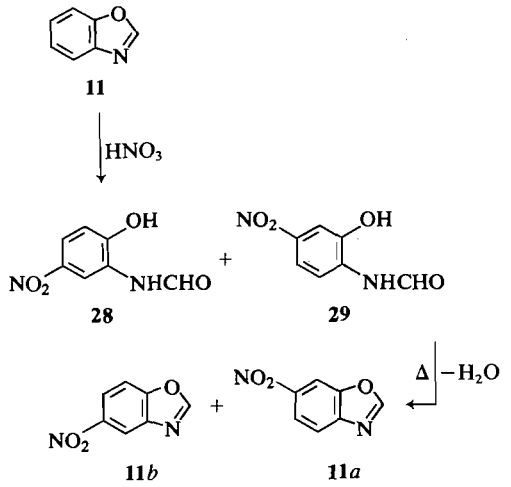

SCHÉMA 1.

Les structures des différents produits de la réaction de nitration du benzoxazole ont été déterminées par une étude comparative des déplacements chimiques du ^{13}C; à cet effet, nous avons synthétisé, et ce de façon univoque, chacun des produits représentés dans le schéma 1, selon la voie réactionnelle du schéma 2.

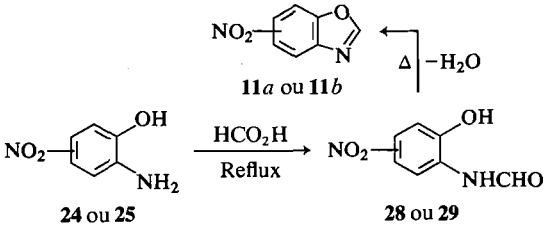

SCHÉMA 2.

L'hydrolyse du benzoxazole est donc une réaction parasite intervenant lors de la nitration de celui-ci. Le problème que l'on veut résoudre est la connaissance de l'ordre dans lequel ces deux réactions vont se réaliser. Dans cette intention, nous avons nitré l'*o*-formylamino phénol (produit d'hydrolyse du benzoxazole) **27**. Par une étude comparative des déplacements chimiques du ^{13}C et par des synthèses

SCHÉMA 3.

univoques (nitration de **28** et **29**), nous avons pu identifier les différents composés obtenus (schéma 3).

On obtient toujours deux dérivés dinitrés dont la proportion dépend de l'acidité du milieu réactionnel. Compte tenu du site de nitration, on peut admettre qu'en milieu fortement acide le substrat est une espèce protonée sur le groupe formamido.

Ces expériences (obtention des dérivés mononitrés **28** et **29** à partir du benzoxazole **11**, et obtention des dérivés dinitrés **31** et **32** à partir de l'*o*-formylamino phénol **27**) démontrent avec certitude que la nitration (formation de **11***a* et **11***b*) précède l'hydrolyse.

Les déplacements chimiques des différents phénols sont rassemblés dans le tableau 3; l'étude des dérivés **26** et **30** sert à confirmer les attributions.

Discussion

Corrélations empiriques entre déplacements chimiques du ^{13}C et paramètres structuraux

En série hétéroaromatique, la déficience des calculs de mécanique quantique à prédire correctement les valeurs des déplacements chimiques a conduit de nombreux auteurs à relier les résultats expérimentaux avec certains paramètres structuraux, caractéristiques de la nature du substituant (46, 47).

Comme dans le cas des dérivés benzothiazoliques (9), et dans l'intention de réaliser des corrélations avec les effets de substituant observés en série benzoxazolique, nous avons utilisé l'équation triparamétrique [2] proposée par Smith et Proulx (48, 49).

$$[2] \qquad \Delta\delta^{13}C = aF + bR + cQ^* + d$$

Dans cette équation, F et R sont les paramètres structuraux de Swain et Lupton (50); F représente une mesure des effets de champ et R une mesure des effets de résonance. Q^* est un paramètre semi-

†Cette publication, produit 33.

empirique défini par Schaefer et coll. (51) comme étant égal à P/Ir^3 (P représentant la polarisabilité de la liaison C—X, I le premier potentiel d'ionisation de l'élément X et r la distance C—X). Les auteurs de la référence (51) ont également suggéré que Q^* pouvait être une mesure empirique du terme paramagnétique σ_p^A de l'équation de Ramsey (52).

Dans le tableau 4 sont réunis les résultats de ces corrélations: coefficients de régréssion, écart type et coefficients de corrélation (r). Pour comparaison, dans le même tableau, nous donnons les résultats obtenus précédemment en série benzothiazolique (9).

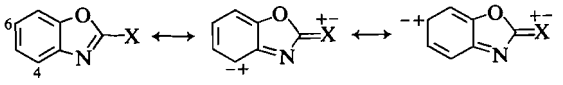
Un premier examen des résultats du tableau 4 montre qu'à l'exception du carbone C-2 les corrélations sont bien meilleures en série benzoxazolique, plus particulièrement en ce qui concerne les carbones de jonction. On peut critiquer, à juste titre, cette dernière affirmation, étant donné la non-similitude du nombre et de la nature des substituants dans les deux séries. Cependant, nous avons vérifié que l'omission des valeurs relatives aux groupements fluoro et nitro n'améliorent pas les corrélations en série benzothiazolique.

Dans la corrélation relative au carbone C-2, et comme en série benzothiazolique (9), nous avons exclu la valeur du groupement amino, car, pour ce substituant, l'écart entre la valeur expérimentale et la valeur calculée est trop élevé (~10 ppm). Cette déviation, qui ne semble pas due à la présence d'une certaine quantité de tautomère imino-2 benzoxazoline, pourrait plutôt être attribuée à l'existence d'importantes associations avec le solvant (53); en effet, les paramètres structuraux du groupement amino (et Q^* en particulier) ont été déterminés à partir d'études portant sur des dérivés de l'aniline (54), substrat dans lequel de telles associations n'interviennent pas.

Par ailleurs, contrairement à ce que l'on observe en série benzothiazolique (9), le déplacement du carbone C-2 dépend peu du paramètre Q^*. Si on

considère que ce paramètre structural représente une mesure grossière de l'effet stérique, on peut expliquer cette absence de relation par des interactions plus faibles entre le substituant et l'hétéroatome lorsque ce dernier est un oxygène. Par contre, l'effet inductif de cet atome se traduit par d'importantes modifications des valeurs des déplacements chimiques du substituant en position 2; on observe un effet de blindage par rapport au dérivé soufré. Ces résultats sont rassemblés dans le tableau 5.

Les déplacements des carbones, C-4 et C-6 sont surtout fonction des effets de résonance, ce que l'on peut expliquer par la prépondérance des structures canoniques dipolaires suivantes:



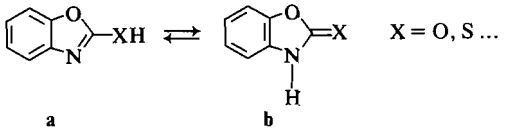
Le déplacement du carbone C-6 dépend également des effets de champ (paramètre F) et de Q^*. Il est intéressant de remarquer que les déplacements de C-6 sont les seuls à être fonction des trois paramètres F, R et Q^*, et que la position 6 de l'homocycle est la plus réactive vis-à-vis des réactions de substitution électrophile.

Dans le cas de C-4, C-5 et C-7 les coefficients de régréssion sont peu dépendants de la nature de l'hétéroatome (S ou O). Par contre, dans le cas de C-6, les coefficients, bien que de même signe, ont une valeur plus grande pour le dérivé oxygéné, ce qui traduit une relation plus importante avec le substituant en position 2.

Enfin, le fait que les carbones C-5 et C-6 dépendent également de Q, confirme que ce paramètre ne représente pas seulement la mesure des effets stériques.

Etude de la tautomérie prototropique

Certains benzoxazoles substitués en position 2 présentent un phénomène de tautomérie prototropique:



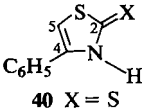
a **b**

Ce type d'équilibre a fait l'objet de nombreux travaux en série hétérocyclique aromatique (55). Au cours de précédentes études, nous avons montré les avantages et les inconvénients de l'utilisation de la rmn du ^{13}C pour de possibles analyses qualitatives et quantitatives de ce problème (9, 56). Sans revenir sur ces résultats, précisons néanmoins que, lorsque l'hétéroatome X représente un atome de soufre ou d'oxygène, l'équilibre est très fortement déplacé vers la forme **b**, et que l'influence de l'état physique (solide, solution ou phase vapeur) est très importante (57).[3]

Les déplacements chimiques des composés pouvant présenter ce phénomène de prototropie, ainsi que les valeurs de certains produits modèles (dans lesquels le proton pyrrolique a été remplacé par un groupement méthyle), sont rassemblés dans le tableau 6. Les effets du groupement nitro (composé **36**) permettent, comme nous l'avons précédemment expliqué, de réaliser une attribution complète des déplacements chimiques des carbones de l'homocycle du dérivé **35**. Compte tenu de la similitude des spectres, nous garderons la même attribution pour le composé **38**. En toute rigueur, l'utilisation des effets de substituant pour attribuer les signaux de structures prototropes est critiquable. En pratique, comme l'équilibre est fortement déplacé vers l'une des formes tautomères, l'introduction d'un substituant sur le noyau benzénique ne modifie pas, d'une manière appréciable par la méthode spectroscopique, la position de l'équilibre.

La comparaison des déplacements chimiques des carbones du cycle oxazolique des différents composés du tableau 5 montre que l'équilibre est très déplacé vers les structures de type **b**. De plus, comme nous l'avons signalé en série benzothiazolique (9), le carbone C-4 est plus blindé dans **b**. Cet effet est attribué à la variation de l'électronégativité de l'atome d'azote N_3. Les autres carbones de l'homocycle sont, quant à eux, peu influencés par le phénomène de tautomérie.

Récemment (58), dans le cas de la phényl-4 Δ-4-thiazolinethione-2 **40** et de son homologue oxygéné **41**, nous avons mis en évidence des couplages entre le proton pyrrolique et les carbones du cycle (en particulier avec C-2).



40 X = S
41 X = O

On n'observe pas ce type de couplage dans le cas du dérivé non substitué; on explique ce phénomène par un ralentissement de l'échange du proton pyrrolique avec le milieu environnant, lorsque le cycle est substitué par un groupement phényle.

La benzocondensation ne conduit pas à une observation similaire: dans le spectre couplé de **35**, le signal du carbone 2 représente un singulet; quant aux figures de couplage des carbones de jonction,

[3]L'existence en solution de structures associées (dimérisation ou association avec le solvant) a été mise en évidence pour ce type de composés (53). De plus, dans le cas du diméthylsulfoxyde, les constantes d'association sont relativement importantes.

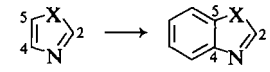
Effets de la benzocondensation et analyse des couplages $^nJ(C,H)$

Les perturbations créées par la condensation d'un noyau benzénique sur des hétérocycles pentagonaux-1,3 sont présentées dans le tableau 7.

Comme pour la série monohétéroatomique (59), l'effet de la benzocondensation sur le carbone en position 2 dépend, non pas de l'électronégativité de l'hétéroatome adjacent, mais de sa taille. En effet, on observe, pour ce carbone, l'ordre de variation suivant:

TABLEAU 7. Effets de la benzocondensation en série pentagonale-1,3



A *B*

X	ΔC-2*	ΔC-4*	ΔC-5*
O†	1.8	13.5_5	10.3

Nucleophilic reactions of zwitterionic species from deprotonation of η^6-arene-η^5-cyclopentadienyliron cations

CHOI CHUCK LEE, BARRY R. STEELE, KEN J. DEMCHUK, AND RONALD G. SUTHERLAND

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received December 18, 1978

CHOI CHUCK LEE, BARRY R. STEELE, KEN J. DEMCHUK, and RONALD G. SUTHERLAND. Can. J. Chem. **57**, 946 (1979).

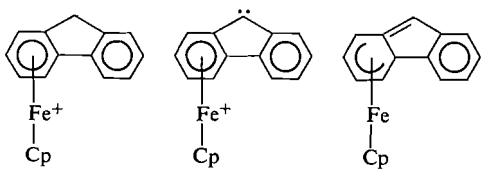
A variety of η^6-arene-η^5-cyclopentadienyliron cations in which the arene ligand has an α-carbon substituent containing one or more hydrogens can be deprotonated with base to give the corresponding neutral zwitterionic species. These zwitterions can react *in situ* as nucleophiles with different substrates, such as CH_3I, CO_2, and CS_2, to give a wide range of synthetic applications.

CHOI CHUCK LEE, BARRY R. STEELE, KEN J. DEMCHUK et RONALD G. SUTHERLAND. Can. J. Chem. **57**, 946 (1979).

Un grand nombre de cations η^6-arène η^5-cyclopentadiénylfer dans lesquels le ligand arène possède un carbone en α portant un ou plusieurs hydrogènes peuvent être déprotonés à l'aide de bases et donnent naissance aux espèces zwittérioniques neutres correspondantes. Ces zwittérions peuvent réagir *in situ* comme nucléophiles avec divers substrats, tels CH_3I, CO_2 et CS_2, donnant lieu à un large éventail d'applications en synthèse.

[Traduit par le journal]

Recently, Johnson and Treichel (1) reported that the deprotonation of the η^6-fluorene-η^5-cyclopentadienyliron cation (**1**) with *tert*-BuOK in C_6H_6 gave the neutral, zwitterionic η^6-fluorenyl-η^5-cyclopentadienyliron (**2**) which subsequently can react as a nucleophile with alkyl halides such as CH_3I. Similarly, Helling and Hendrickson (2) also obtained **2** from the reaction of **1** with sodium bis(trimethylsilyl)amide in benzene, as well as the analogous neutral complexes from the treatment, with $NaNH_2$ in NH_3, of η^6-arene-η^5-cyclopentadienyliron cations in which the aromatic ligands were triphenylmethane, diphenylamine, and carbazole. While the crystallographic studies of Johnson and Treichel (1) indicated that **2** may be formulated with the zwitterionic structure **2***a*, Helling and Hendrickson (2) also stressed the contribution from a π-cyclohexadienyliron complex with an exocyclic double bond (e.g., **2***b*), especially in the case where the original arene ligand was triphenylmethane.



1 **2***a* **2***b*

In conjunction with our studies on ligand exchange reactions between arene and ferrocene (3–5), we have also observed the formation of **2** from **1**, even under the relatively mild, basic conditions of K_2CO_3 in dimethylformamide (DMF). We wish to report that the deprotonation to give zwitterionic species is not restricted to systems such as **1** but can occur in a variety of η^6-arene-η^5-cyclopentadienyliron cations (**3**) in which the arene ligand possesses one or more saturated α-hydrogens. The zwitterion can then react *in situ* as a nucleophile to provide a wide range of synthetic possibilities.

The η^6-arene-η^5-cyclopentadienyliron cations (**3**) were prepared from ligand exchange reactions between the arene and ferrocene in the presence of $AlCl_3$–Al (4, 5). In a typical experiment, 2.0 mmol of **3**, as the hexafluorophosphate salt, was stirred in tetrahydrofuran (THF) at a given temperature. Upon addition of an equivalent or an excess of *tert*-BuOK, there was an immediate change in color to deep red or dark blue, indicative of the formation of the zwitterionic species.[1] The substrate such as CH_3I was added and the mixture was stirred for 30 min and then allowed to warm to room temperature.

[1]As sample cases, from cation **3** with mesitylene or triphenylmethane as the arene ligand, after the THF solution was concentrated, the zwitterion was isolated by chromatographic separation on silica gel and identified by mass spectroscopy.

[a]Reaction I involves deprotonation of 3 with 1 equiv. of *tert*-BuOK in THF followed by treatment with CH_3I, the whole process being carried out at room temperature or at the temperature indicated.
[b]Reaction II involves deprotonation of 3 with an excess of *tert*-BuOK in THF followed by treatment with CO_2 (IIA) or CS_2 (IIB) and then with $(CH_3)_2SO_4$, the whole process being carried out at room temperature or at the temperature indicated.
[c]Reaction III involves deprotonation of 3 with an excess of K_2CO_3 in DMF followed by treatment with the indicated RX, the whole process being carried out at room temperature.
[d]The initial product was the blue zwitterionic η^6-9-(2,4-dinitrophenyl)-9-fluorenyl-η^5-cyclopentadienyliron which upon treatment with HCl gave the 65% yield of the η^6-9-(2,4-dinitrophenyl)fluorene-η^5-cyclopentadienyliron cation.

During the reaction, the color also changed to yellow or orange. Upon quenching the reaction with H_2O containing NH_4PF_6, the product, η^6-substituted arene-η^5-cyclopentadienyliron cation (**4**), as the hexafluorophosphate salt, was extracted with CH_2Cl_2 and then precipitated from the dried extract by the addition of ether. When necessary, purification and separation of mixed products were effected by chromatography through an alumina column (4, 5). All the product ions (**4**) were identified by their ^1H and ^{13}C nmr spectra. The results are summarized in Table 1.

The variety of reactions given in Table 1 serves only to illustrate the wide range of synthetic applications. The ready formation of the zwitterions apparently arises from complexing the arene with the highly electron withdrawing $CpFe^+$ group. Similar activations of the α-carbon in nucleophilic reactions by carbonylchromium groups in systems such as methyl arylacetate – chromium tricarbonyl and related compounds have also been reported (6, 7).

We wish to communicate the present results in preliminary form since the method used is apparently of general applicability. It is likely that a variety of zwitterions besides those given in Table 1 may also be utilized in nucleophilic substitution reactions with many other substrates, thus providing a wide ranging possibility for the alkylation and functionalization of η^6-arene-η^5-cyclopentadienyliron cations. Since we have already shown that the aromatic ligand in cations such as **4** may be regenerated as the substituted arene itself either photolytically (4), or in better yields by pyrolytic sublimation under reduced pressure (5), the synthetic applications may be extended to include the preparation of substituted arenes. As an example, 9-methylxanthene was recovered in

85–90% yield from vacuum sublimation of the η^6-9-methylxanthene-η^5-cyclopentadienyliron cation (Table 1). Currently, we are extending our studies to include similar reactions with other heterocyclic ligands. Cations **3** with heterocyclic ligands other than xanthene (thioxanthene, 9,10-dihydroacridine, and phenothiazine) have been prepared and their deprotonation and subsequent nucleophilic substitution reactions are under investigation.

Temperature dependence of rate constants for reaction of oxygen atoms, O(^3P), with allene and 1,3-butadiene[1]

W. S. NIP,[2] D. L. SINGLETON, AND R. J. CVETANOVIĆ
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received December 11, 1978

W. S. NIP, D. L. SINGLETON, and R. J. CVETANOVIĆ. Can. J. Chem. **57**, 949 (1979).

Rate constants were determined for the reactions of O(^3P) atoms with allene and with 1,3-butadiene by a phase shift technique in which oxygen atoms were generated by modulated mercury photosensitized decomposition of nitrous oxide and monitored by the chemiluminescence from their reaction with NO. Over the temperature interval 297–574 K, the Arrhenius equation for the O(^3P) + allene reaction is $k_{1A} = (2.99 \pm 0.41) \times 10^{-11} \exp[(-941 \pm 54)/T]$ cm^3 molecule^{-1} s^{-1}, where the indicated uncertainties are 95% confidence limits. At 299 and 488 K, the rate constant for O(^3P) + 1,3-butadiene is essentially the same, within 10%, with an average value of 2.07×10^{-11} cm^3 molecule^{-1} s^{-1}.

W. S. NIP, D. L. SINGLETON et R. J. CVETANOVIĆ. Can. J. Chem. **57**, 949 (1979).

On a déterminé les constantes de vitesse des réactions des atomes O(^3P) avec l'allène et le butadiène-1,3 en faisant appel à la technique du déplacement de phase dans laquelle les atomes d'oxygène sont générés par une décomposition modulée photosensibilisée par le mercure de l'oxyde nitreux et contrôlée par la chimiluminescence de leur réaction avec NO. A des températures allant de 297 à 574 K, l'équation d'Arrhénius pour la réaction O(^3P) + allène est $k_{1A} = (2.99 \pm 0.41) \times 10^{-11} \exp[(-941 \pm 54)/T]$ cm^3 molécule^{-1} s^{-1} où les incertitudes indiquées sont à l'intérieur de limites de confiance de 95%. A 299 et 488 les constantes de vitesse pour la réaction de O(^3P) + butadiène-1,3 sont pratiquement les mêmes à ±10%, et la valeur moyenne est 2.07×10^{-11} cm^3 molécule^{-1} s^{-1}.

[Traduit par le journal]

Introduction

The reactions of ground state oxygen atoms with diolefins have not been studied as extensively as the reactions with olefins. Analyses of products at high (1–7) and low (8) pressures suggest that the general mechanism of the diolefin reactions is similar to that of the olefins, i.e. electrophilic addition of O(^3P) to the double bond.

The only determinations of absolute rate constants for reactions of atomic oxygen with diolefins have been for allene and 1,3-butadiene,

[1*A*] O(^3P) + allene → products

[1*B*] O(^3P) + 1,3-butadiene → products

The two absolute values at room temperature for k_{1A} (9, 10) differ from the relative values of Havel (4) by more than a factor of two. The relative (1, 11) and absolute (9) results for k_{1B} agree well at room temperature, but there is only one reported determination of the temperature dependence (9). In the present work the phase-shift technique is used to determine absolute values of k_{1A} and k_{1B}, and their temperature dependence.

Experimental

The apparatus has been described in detail elsewhere (12–14) and will be described only briefly here. O(^3P) atoms were produced by mercury photosensitized decomposition of nitrous oxide using a sinusoidally modulated low pressure mercury lamp. The concentration of O(^3P) was monitored by the chemiluminescence from NO_2* when NO was introduced into the flowing reaction mixture. The reaction sequence is

$$Hg6(^1S_0) + h\nu(253.7\,nm) \rightarrow Hg6(^3P_1) \quad \text{(fast)}$$

$$Hg6(^3P_1) + N_2O \rightarrow Hg6(^1S_0) + N_2 + O(^3P) \quad \text{(fast)}$$

[1] $$O(^3P) + \text{diolefin} \rightarrow \text{products}$$

[2] $$O(^3P) + NO + M \rightarrow NO_2^* + M$$

$$NO_2^* \rightarrow NO_2 + h\nu \quad \text{(fast)}$$

$$NO_2^* + M \rightarrow NO_2 + M \quad \text{(fast)}$$

The phase-shift, ϕ, between the incident 253.7 nm light and the NO_2^* chemiluminescence was measured with photomultipliers and a lock-in amplifier. The 253.7 nm light was isolated with an interference filter between the lamp and the reaction cell, and at the entrance to the photomultiplier tube which viewed the incident light. A Corning 3-70 filter was used with the photomultiplier viewing the chemiluminescence. Since the reactions labeled 'fast' do not contribute significantly to the phase shift, ϕ is related to the reaction rates according to

[3] $$2\pi\nu/\tan\phi = k_1[\text{diolefin}] + k_2[NO][M]$$

where ν is the modulation frequency (1600 or 5970 Hz). For constant [NO] and [M], a plot of $2\pi\nu/\tan\phi$ vs. [diolefin] gives a straight line with slope equal to k_1 and intercept, k_2[NO][M].

Reagents flowed into the reaction cell via calibrated flow meters. The temperature of the reaction cell was measured by a thermocouple and controlled to better than 1 K. Oxygen atoms were generated at the rate of 7×10^{12} s^{-1}. The flow rates were such that the maximum consumption of diolefin was less than 0.04%.

The purities of the gases were, according to the manufacturers: allene, $\geq$ 97%; 1,3-butadiene, 99.9%; N_2O, 98%; NO, 99.0%. The NO was passed through a molecular sieve trap to remove NO_2 and H_2O. The other gases were used without further purification.

Results

Typical plots of $2\pi\nu/\tan\phi$ vs. [diolefin] for allene and 1,3-butadiene are shown in Figs. 1 and 2. The linearity of these plots indicates the validity of eq. [3]. The rate constants determined from the slopes of these plots using a linear least-squares analysis are shown in Table 1. The rate constants for allene can be represented by the Arrhenius equation

$$k_{1A} = (2.99 \pm 0.41) \times 10^{-11} \times \exp[(-941 \pm 54)/T]\ \text{cm}^3\ \text{molecule}^{-1}\ \text{s}^{-1}$$

which is plotted in logarithmic form in Fig. 3. The indicated uncertainties are 95% confidence limits based on 5 degrees of freedom and a Student's t value of 2.571. The rate constants for the reaction with 1,3-butadiene are plotted also in Fig. 3. Although a slight negative Arrhenius activation energy is evident in the case of 1,3-butadiene, it is probably better, because data were obtained at only two temperatures, to consider the rate constants to be, within the experimental error, independent of temperature in this interval. The average of the two values of k_{1B} is 2.07×10^{-11} cm^3 molecule^{-1} s^{-1}.

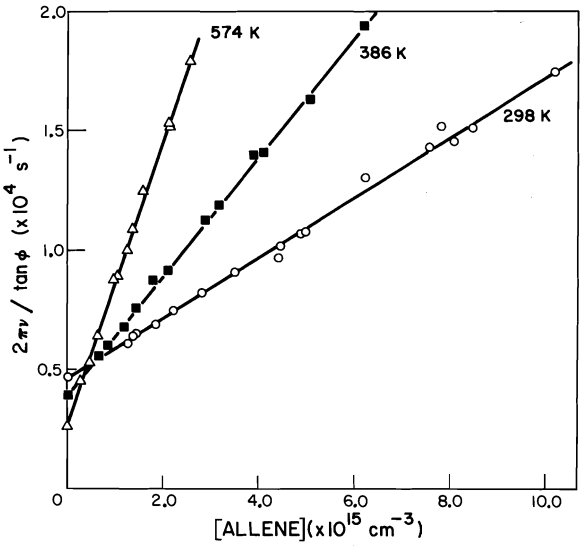

FIG. 1. Plots of $2\pi\nu/\tan\phi$ vs. concentration of allene at three different temperatures. The concentration of NO and the total pressure were constant at each temperature.

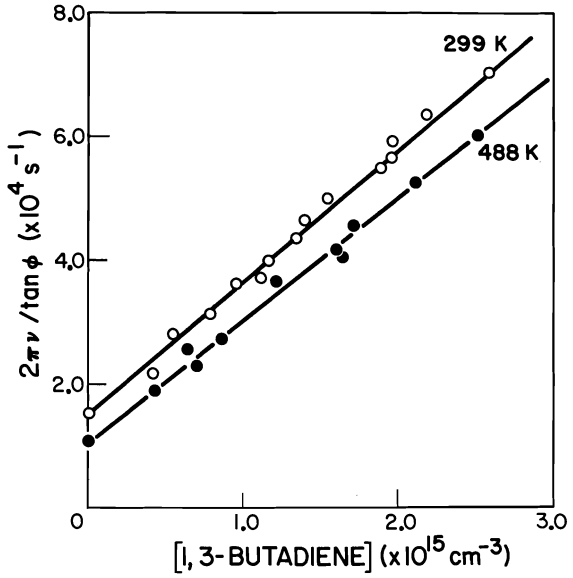

FIG. 2. Plots of $2\pi\nu/\tan\phi$ vs. concentration of 1,3-butadiene at two temperatures. The concentration of NO and the total pressure were constant at each temperature.

Any systematic error in k_{1A} and k_{1B} is probably less than 20%, based on estimated potential systematic errors in phase shift (14), flow rate, and pressure measurements.

Values of k_2 obtained from the intercepts of plots of $2\pi\nu/\tan\phi$ vs. [diolefin] are given in Table 1. They are slightly higher than the literature values (14–16). A possible explanation could be the presence of a small amount of NO_2 in the N_2O used in the present

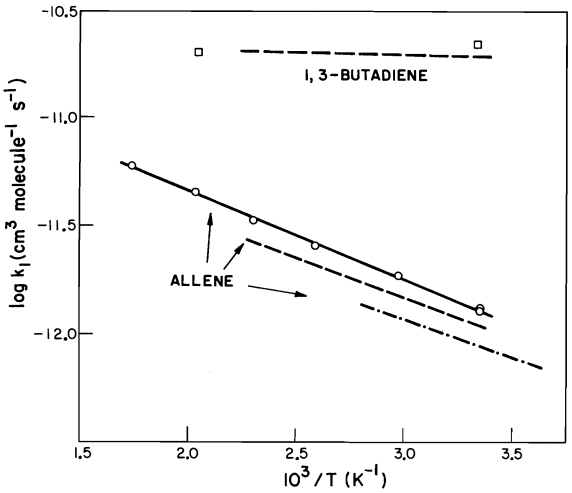

FIG. 3. Arrhenius plots of the rate constants of reaction of $O(^3P)$ with allene and with 1,3-butadiene. $k_{O+allene}$: ○ and solid line, this work; --- ref. 9, ·-·-· ref. 10. $k_{O+1,3\text{-butadiene}}$: □, this work; ---, ref. 9.

work. About 150 ppm of NO_2 would be required to account for the difference. The NO_2 content was found to vary dramatically among three different cylinders of N_2O that were analyzed. Concentrations of NO_2 between 2.6 and 0.01 ppm were found. Unfortunately, the cylinder of N_2O which was used for the rate constant determinations was depleted before the decision to analyze for NO_2 was made, so that it is uncertain whether the NO_2 content could have been as high as 150 ppm. It should be noted that this amount of NO_2 would not affect the values of k_1 obtained from the slopes of plots of $2\pi\nu/\tan\phi$ vs. [diolefin].

Discussion

The concentration of oxygen atoms in the present work is sufficiently small that secondary reactions of $O(^3P)$ with products of reaction [1*A*] or [1*B*] are negligible. Less than 0.9% and 0.2% of the oxygen atoms in reactions [1*A*] and [1*B*], respectively, are consumed by secondary reactions at room temperature, according to calculations based on a generalized mechanism previously outlined (13). The phase shift measurements showed no significant effect due to a factor of 10 reduction in the intensity of the incident 253.7 nm light (hence a factor of 10 change in the rate of production of $O(^3P)$).

The rate constants for $O(^3P)$ + allene, k_{1A}, obtained in the present work agree well (<20% difference) with the flash photolysis results of Atkinson and Pitts (9), who determined k_{1A} over a slightly smaller temperature range. The agreement with the discharge–flow results of Herbrechtsmeier and Wagner (10) is not as good, as seen in Fig. 3, but the difference is no more than 35%. Havel (4) determined k_{1A} relative to $k_{O+1\text{-butene}}$ and $k_{O+isobutene}$ at a total pressure of 610 Torr. With our recent values of $k_{O+1\text{-butene}}$ and $k_{O+isobutene}$ (17), Havel's value of k_{1A} is $\sim 3 \times 10^{-12}$ cm^3 molecule^{-1} s^{-1}, which is more than a factor of two higher than that from the present work. The reason for the discrepancy is not clear. Although it is possible that secondary reactions may have occurred in Havel's experiments because of the high conversions (~30%), the same results, within 6%, were obtained from relative disappearance of reactants and from relative appearance of products (4).

The trend in the values of k_{1A} reported in the literature may appear to suggest increasing values of the rate constant with increasing pressure. The reported values at room temperature vary from 0.87×10^{-12} at 5 Torr (10), to $\sim 1.2 \times 10^{-12}$ at 26–50 Torr (ref. 9, present work), to $\sim 3 \times 10^{-12}$ cm^3 molecule^{-1} s^{-1} at 610 Torr (4). However, in the present work there was no significant difference

between the rate constants determined at 29 and at 59 Torr. Also, the rate constants of the reactions of $O(^3P)$ with olefins are independent of pressure (17, 18). It would be desirable to have values of k_{1A} obtained by one technique over an extended range of pressures.

The present results for O + 1,3-butadiene are in excellent agreement with those reported by Atkinson and Pitts (9), and confirm that k_{1B} is essentially independent of temperature over the range 297–500 K, as seen in Fig. 3. Furthermore, the activation energy reported by Cvetanović (1) for O + 1,3-butadiene relative to O + 1-butene, when combined with our results for O + 1-butene (17), is 0.06 kcal mol^{-1}, consistent with the present results. The relative rate constants at 298 K of Cvetanović (2) and McClenny (11), taken relative to 1-butene, are 4.2 (1) and 5.4 (11), respectively, which can be put on an absolute scale using our value of $k_{O+1\text{-butene}}$ (17). The relative values of k_{1B} become 1.7×10^{-11} and 2.2×10^{-11}, respectively, again in good agreement with the present average value of 2.07×10^{-11} cm^3 $molecule^{-1}$ s^{-1}.

The low activation energies for the diolefin reactions are consistent with an addition mechanism proposed on the basis of product analyses (1–8), i.e., addition of the oxygen atom to the double bond followed by stabilization, rearrangement, or fragmentation of the adduct, as occurs for olefins. The room temperature rate constants for O + allene and O + 1,3-butadiene have been shown (9) to fit adequately into the correlation of $k_{O+olefin}$ vs. the ionization potential of the olefin. Also, the activation energies for reactions [1*A*] and [1*B*] are consistent with the correlation between activation energies for O + olefin reactions vs. ionization potential of the olefin (19). On the other hand, the pre-exponential factors for O + allene and O + 1,3-butadiene are somewhat larger ($2–3 \times 10^{-11}$) than those for most of the O + olefin reactions ($1–1.5 \times 10^{-11}$, except for tetramethylethylene, for which it is 2.1×10^{-11} cm^3 $molecule^{-1}$ s^{-1}) (17), reflecting, perhaps, the number of double bonds. However, because there is evidence of curvature in the Arrhenius plots for some O + olefin reactions (17, 18), trends in pre-exponential factors should be interpreted with caution.

Decomposition of vinyl chloride induced by multiphoton absorption of infrared radiation. I. Decomposition yields[1]

A. GANDINI, C. WILLIS, R. A. BACK, AND J. M. PARSONS

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received September 11, 1978

A. GANDINI, C. WILLIS, R. A. BACK, and J. M. PARSONS. Can. J. Chem. **57**, 953 (1979).

The infrared induced decomposition of vinyl chloride has been studied as a function of pressure and as a function of exciting wavelength with a pulsed CO_2 laser. The main reaction gives C_2H_2 and HCl

$$C_2H_3Cl \rightarrow C_2H_2 + HCl$$

but smaller amounts of C_2H_4 are observed. At pressures below 0.5 Torr, the yield of C_2H_4 shows apparent enhancement relative to C_2H_2. In an earlier publication it had been speculated that this was due to dissociation from higher vibrational levels attained in the multiphoton absorption process. Present data indicate this is not the case and suggest rather strongly that the enhanced C_2H_4 yield is derived from infrared induced decomposition of C_2H_3Cl on cell windows and walls.

The effective quantum yield of C_2H_2 increases approximately linearly with pressure in the range 0–2.5 Torr and C_2H_3Cl, H_2, and O_2 produce similar behaviour. This is interpreted in terms of collisional enhancement of photon absorption associated with depletion of specific rotational states by the laser radiation.

A. GANDINI, C. WILLIS, R. A. BACK et J. M. PARSONS. Can. J. Chem. **57**, 953 (1979).

Utilisant un laser à CO_2 on a étudié la décomposition, induite par l'infrarouge, du chlorure de vinyle en fonction de la pression et en fonction de la longueur d'onde servant à exciter. La réaction principale fournit du C_2H_2 et du HCl,

$$C_2H_3Cl \rightarrow C_2H_2 + HCl$$

mais on a observé la formation de quantités plus faibles de C_2H_4. A des pressions inférieures à 0.5 Torr, le rendement en C_2H_4 subit une augmentation par rapport à C_2H_2. Dans une publication antérieure, il avait été suggéré que ceci est dû à une dissociation provenant de niveaux vibrationnels supérieures obtenues dans un processus d'absorption multiphoton. Les données rapportées ici indiquent que ce n'est pas le cas et suggèrent plutôt fortement que l'augmentation du rendement en C_2H_4 provient de la décomposition induite par l'infrarouge du C_2H_3Cl sur les fenêtres et les parois de la cellule.

Le rendement quantique effectif de C_2H_2 augmente d'une façon approximativement linéaire avec la pression entre 0 et 2.5 Torr. Le C_2H_3Cl, H_2 et O_2 provoquent des comportements semblables. On interprète ces résultats en termes d'une augmentation collisionnelle de l'absorption des photons qui est associée avec une diminution des états rotationels spécifiques provoquée par la radiation laser.

Introduction

In a recent communication (1) on the isotopically selective infrared photolysis of vinyl chloride, C_2H_3Cl, we reported preliminary results which showed that below 1 Torr the isotopic selectivity of the decomposition decreased with decreasing pressure. It was suggested that this behaviour was due to enhanced amounts of C_2H_4 being produced at low pressures which led to non-selective disappearance of the substrate. On the basis of a few results we speculated that the ratio of molecular elimination (2), reaction [1], to bond scission (3), reaction [2],

[1] $C_2H_3Cl \rightarrow C_2H_2 + HCl \qquad E_A = 69$ kcal/mol

[2] $C_2H_3Cl \rightarrow C_2H_3 + Cl \qquad \Delta H = 90$ kcal/mol

$\downarrow$

C_2H_4 + products

was varying with pressure. This implied that a competition between multiphoton absorption, collisional deactivation, and decomposition determined the energy content of the decomposing molecules and thereby their mode of decomposition. If true, this interpretation is important to the understanding of the physical processes involved in multiphoton dissociation, and therefore we have investigated the phenomenon in greater detail. The present results suggest that the processes at low pressures leading

[1]NRCC No. 17262. Presented, in part, at International Quantum Electronics Conference held at Atlanta, May 1978.

predominantly to ethylene are unrelated to the gas-phase multiphoton decomposition, and that in the latter the ratio of molecular elimination to bond scission is pressure independent.

During the progress of the present studies a paper by Lussier and Steinfeld (4) covering some aspects of the infrared induced decomposition of vinyl chloride was published. Using 0.1–1.0 J pulses from a CO_2 TEA-laser focussed with a relatively long focal length lens into 10 Torr of C_2H_3Cl they report production of only C_2H_2 and HCl. In a few experiments using a much shorter focal length lens they observed break-down and report a new product absorption in the ir analysis which was tentatively assigned to diacetylene.

Experimental

Radiation from a line-tunable CO_2 TEA-laser (Lumonics Model 103: pulse duration ~250 ns, pulse energy 5–6 J, beam intensity ~1.3 J cm^{-2}) was focussed into a cylindrical Pyrex cell (40 mm id, 60 mm long) fitted with NaCl windows (Harshaw laser-grade) by a germanium lens ($f = 40$ mm) placed approximately 1 cm from the front window. The focal point coincided roughly with the centre of the cell. Samples were irradiated (normally for 15 min at 36 pulse/min) and the entire cell contents were transferred to an inlet tube of a gas chromatograph where the amounts of C_2H_2 and C_2H_4 formed were determined. Mass spectrometric analysis was used to identify other minor products. Experiments with vinyl chloride alone were restricted to pressures below ~2.5 Torr, above which break-down was observed. With added H_2 total pressures up to 20 Torr were possible without break-down.

Results

The absorption spectrum of vinyl chloride contains two main bands in the region accessible to CO_2-laser radiation, the CH_2 rocking mode (ν_7) centred around 1040 cm^{-1} and the twist mode (ν_{10}) around 950 cm^{-1}. We have investigated laser-induced decomposition in both regions. The yield per pulse is reported as an *effective reaction volume*, the amount of reagent decomposed expressed as a volume at the ambient reagent pressure and temperature. If in the focal region there is a sharp fluence threshold beyond which decomposition is virtually complete, the volume defined by this threshold will in fact equal the effective reaction volume. It is in any case a convenient way to present the data, whether or not such threshold behaviour pertains. It should be noted that this usage tacitly includes a first-order reagent pressure term, so that the effective reaction volume is proportional to a percent decomposition or a decomposition probability.

Effect of Pressure

Figure 1 shows the observed yields of products as a function of vinyl chloride pressure the P_{18} line of the 10.6 μm band. Figure 2 shows similar data for

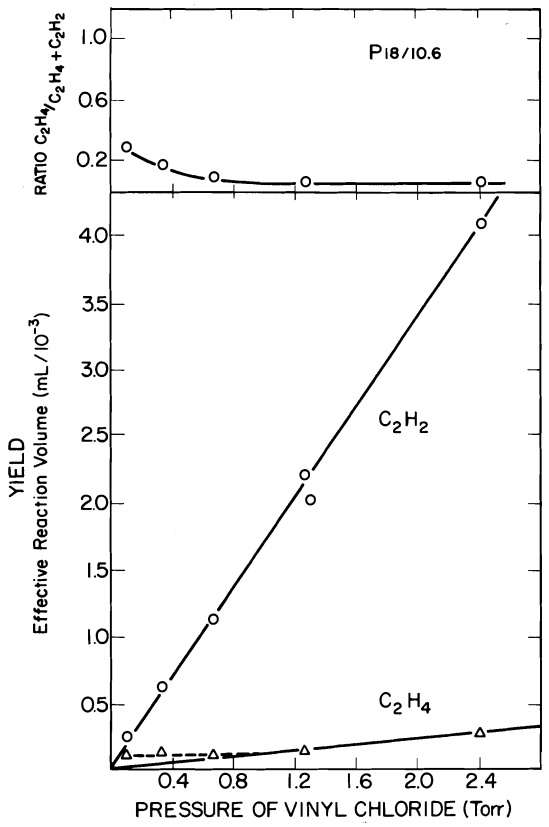

FIG. 1. Observed yields of C_2H_2 and C_2H_4 as a function of pressure of vinyl chloride for irradiation with P_{18} line of 10.6 μm band of CO_2 laser (6.7 J/pulse).

the P_{20} line of the 9.6 μm band. These data are typical of the experiments carried out in the two regions. The yield of C_2H_2 decreases linearly towards zero with decreasing pressure, whereas that of C_2H_4 is enhanced at low pressure. Irradiation in the ν_{10} band shows only a slight enhancement in the fraction of C_2H_4 in the products; irradiation in the ν_7 bands shows a much larger increase with C_2H_4 becoming the dominant product below 0.4 Torr.

Starting with 0.1 Torr vinyl chloride, addition of H_2 leads to a decrease in C_2H_4 yield but an increase in C_2H_2. Data for the variation of yields with pressure for irradiation with the P_{20}/10.6 μm line are collected in Table 1.

Effect of Irradiation Time

The amounts of C_2H_2 and C_2H_4 formed were linear with time for low conversions, shown for a series of experiments in Fig. 3. The invariance of yields per pulse suggests that both are primary products of photolysis, although secondary decomposition within a single pulse cannot be ruled out.

Effect of Wavelength

The yields of C_2H_4 and C_2H_2 for irradiation with

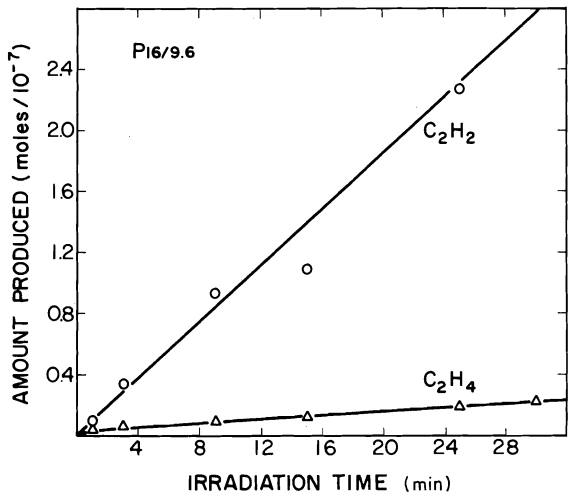

FIG. 3. Formation of C_2H_2 and C_2H_4 as a function of irradiation time: pulse rate, 36 pulses/min of P_{16} line of 9.6 μm band, 1.0 Torr C_2H_3Cl.

various laser lines are given in Table 2. All yields are normalized to the same pulse energy using the dependence to the power 2.3 (below) and were measured with 1.0 Torr vinyl chloride plus 5.0 Torr H_2. The H_2 was added in an attempt to minimize variations with pressure.

Effect of Varying Energy per Pulse

The yields of decomposition were measured at 2, 4, and 6 J/pulse with the P_{20} line at 9.6 μm. The amount of product formed for two pressures of vinyl chloride, 0.36 Torr and 2.00 Torr, fitted a simple expression giving a dependence of yield on pulse energy to the 2.3 ± 0.2 power.

Discussion

The main results to be discussed are the increase in C_2H_4 yield observed at low pressure and the variation of C_2H_2 yields with pressure. Only brief mention will be made of the variation of yields with wavelength of the laser radiation. As will be seen, such a spectral dependence will be a complex function of pressure, fluence, and probably flux. Moreover, recent work by Steinfeld and co-workers (5) has examined this aspect in some detail making further comment here redundant.

TABLE 2. Yields from irradiation with various CO_2 laser lines (15 min irradiation at 36 pulse/min; 1.0 Torr C_2H_3Cl, 5.0 Torr H_2)

Line	Energy per pulse (J)	Amount of product ($mol/10^{-9}$)		Effective reaction volume ($mL/10^{-3}$) (normalized to 6 J/pulse incident)

Formation of Ethylene at Low Pressure

A probable mechanism for formation of C_2H_4 in the multiphoton decomposition of C_2H_3Cl is through the vinyl radical,

$$[2] \qquad C_2H_3Cl \xrightarrow{nh\nu} C_2H_3 + Cl$$

$$[3] \qquad C_2H_3 + C_2H_3Cl \rightarrow C_2H_4 + \text{products}$$

This hypothesis was tested by photolysing C_2H_3Cl with added DBr or I_2 which should give characteristic products in reactions with vinyl radicals,

$$[4] \qquad C_2H_3D + Br \rightarrow C_2H_3D + Br$$

$$[5] \qquad C_2H_3 + I_2 \rightarrow C_2H_3I + I$$

Photolysis of 0.1 Torr C_2H_3Cl with the P_{20} line at 9.6 μm with either 1.0 Torr DBr or 0.3 Torr I_2 followed by mass spectrometric analysis showed no detectable C_2H_3D or C_2H_3I. Limits of detection corresponded to the interception of less than 1% of the vinyl radicals required to produce the observed yield of C_2H_4, a strong indication that C_2H_3 radicals were not involved in its formation.

In a series of experiments where photolysis of C_2H_3Cl was interspersed with experiments involving other compounds, it was noted that the 'enhanced' C_2H_4 yield was much less reproducible than the C_2H_2 yields and showed dependence on cell history. This led to the suspicion that adsorption of C_2H_3Cl on cell walls and windows was involved and further that C_2H_4 was being formed outside the focal region. The data given in Table 3 were taken to test this hypothesis. The three experiments at nominally zero pressure involved flushing the cell with vinyl chloride at a relatively high pressure and then pumping. As can be seen, significant yields of C_2H_4 were formed in all three cases: pumping overnight reduced the yield compared to that obtained with only 15 min pumping and focussing the beam in the 'empty' cell led to yields of C_2H_4 very similar to those obtained with 0.1 Torr C_2H_3Cl in the cell. The yields of C_2H_2 were very much smaller than those observed for the low-pressure photolysis of C_2H_3Cl. The other experiments for increasing pressures of C_2H_3Cl photolysed with the unfocussed beam all gave similar yields of C_2H_4, comparable to those obtained in the focussed beam experiments, but C_2H_2 yields which again were very much smaller.

Taken together, this evidence argues against significant formation of C_2H_4 in the collisionless multiphoton decomposition of C_2H_3Cl. Although

there is a distinct wavelength dependence and the behaviour is not observed to the same extent in other vinyl compounds we have studied (6), C_2H_4 formation is most likely associated with decomposition of C_2H_3Cl adsorbed on the cell walls and windows. The detailed mechanism of the induced decomposition on the cell walls is probably complex and more extensive study does not seem warranted at present.

Variation of Yields with Pressure

If small corrections are made for the amount of C_2H_2 apparently formed on the cell walls or windows, the C_2H_2 yield increases linearly both with pressure of vinyl chloride and with pressure of added gas up to about 2 Torr (Figs. 1 and 2, Table 1). This behaviour was not expected. Elsewhere (7) it has been shown that the product yields in some multiphoton decompositions with focussed beams follow the general expression

$$[6] \qquad \text{Yield} = a + bP$$

The first team corresponds to the yield arising from essentially collisionless decomposition. The second term, linear in substrate pressure, represents the product formed by a collisional energy pooling mechanism. It is not reasonable to explain the observed behaviour of C_2H_3Cl in this way. The pressure dependent term usually tends to become dominant only at much higher pressures than found with vinyl chloride (8) and more importantly, when collisional energy pooling makes a significant contribution, addition of a non-absorbing inert gas decreases rather than increases the yield (7, 9).

A much more reasonable explanation of the observed pressure dependence is that pressure affects the photon absorption process. The rotational envelopes of the absorption bands in vinyl compounds are very broad compared to the effective bandwidth of the exciting radiation, even when power broadening is taken into account. In the absence of rotational repopulation, only a small fraction of the molecules is accessible to the laser radiation.[2] The most obvious effects of pressure are simple pressure broadening, and an increase in the rate of rotational repopulation during the laser pulse, so that the effect of line bleaching is reduced and a larger fraction of molecules becomes accessible to excitation. Absorption studies on C_2H_3Cl strongly support this explanation (5).

The observed dependence of the amount of product formed on (pulse energy) 2.3 is larger than the 3/2-power dependence usually found with focussed beams. One could speculate that power broadening of the exciting radiation could lead to spectral overlap with more rotational levels as the energy per pulse is increased, resulting in higher-order dependence on pulse energy than would otherwise be expected. However, uncertainties in the variations of power density in the reaction zone make a quantitative assessment of this effect difficult.

Variation of Yields with Wavelength

The variation in the acetylene yields with wavelength shown in Table 2 follows approximately the low-intensity low-resolution absorption spectrum of vinyl chloride (4), except for the yield with the P_{32} line at 933 cm^{-1}, which lies in a more structured region of the absorption spectrum, and showed the highest yield both in the present and previous studies (4). In view of the probably complex effects of pressure, dynamic Stark modulation, and line bleaching on the absorption, already discussed in some detail by Steinfeld *et al.* (4, 5), and in view of the uncertain power gradients in the focussed beam, further discussion of the wavelength dependence is unwarranted here.

Conclusions

The enhanced yield of C_2H_4 observed in the low pressure decomposition of vinyl chloride is probably not formed in the gas phase multiphoton process, but rather on the vessel surface. The observed linear pressure dependence of the C_2H_4 yields is more significant. We have attributed this behaviour to collisional repopulation of J-states depleted by absorption, without which only a small fraction of the molecules are accessible to excitation. This type of behaviour may be general, especially in hydrogen-containing species, which tend to have broad rotational envelopes.

[2]This should not be true for irradiation on the Q-head ($\Delta J = 0$) which will allow a much higher fraction of molecules to be excited. In the bands involved in the present study there is not a well developed Q-head and the suggestion cannot be tested.

Phosphorus-31 nuclear magnetic resonance spectra of methylplatinum(II) and methylpalladium(II) cations containing 4-substituted pyridine ligands

HOWARD C. CLARK[1] AND CHARLES R. MILNE

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 3K7

Received September 12, 1978

HOWARD C. CLARK and CHARLES R. MILNE. Can. J. Chem. **57**, 958 (1979).

The ^{31}P nmr spectra of the compounds *cis*-[$M(CH_3)(L)$diphos]PF_6, where M = Pd, Pt; L = 4-C_5H_4NX; X = CH_3, H, NMe_2, COOMe, COMe, CN; diphos = 1,2-bisdiphenylphosphino ethane, have been recorded. The ^{31}P chemical shifts and ^{31}P–^{195}Pt coupling constants decrease regularly as the ρ values of the substituent on pyridine decrease. These trends are attributed to decreasing lone pair donation from phosphorus as the electron donating ability of the other ligands on the metal increases. The *trans* influence of the coordinated pyridine molecule, as measured by $J(^{195}Pt$–$^{31}P)$, is greater than its *cis* influence on the phosphorus atoms.

HOWARD C. CLARK et CHARLES R. MILNE. Can. J. Chem. **57**, 958 (1979).

On a déterminé les spectres rmn ^{31}P des composés *cis*-[$M(CH_3)(L)$diphos]PF_6 où M = Pd, Pt; L = X-4C_5H_4N; X = CH_3, H, NMe_2, CO_2Me, COMe, CN; diphos = bisdiphényl-phosphino-1,2 éthane. Les déplacements chimiques du ^{31}P et les constantes de couplage ^{31}P–^{195}Pt diminuent régulièrement avec une diminution des valeurs ρ des substituants de la pyridine. On attribue ces tendances à une diminution de la disponibilité de la paire libre du phosphore lorsque le caractère électrodonneur des autres ligands sur le métal augmente. L'influence *trans* de la molécule de pyridine coordonnée, telle que mesurée par $J(^{195}Pt$–$^{31}P)$, est plus grande que son influence *cis* sur les atomes de phosphores.

[Traduit par le journal]

Introduction

The factors contributing to the nature of ^{31}P chemical shifts and coupling constants are not particularly well defined. It has been suggested that the electronic and steric properties of the substituents on phosphorus determine ^{31}P chemical shifts and coupling constants by varying the amount of *s* character associated with the phosphorus lone pair (1–4). In addition, ^{31}P chemical shifts and coupling constants of coordinated tertiary phosphines are also affected by the properties of the other ligands at the metal centre. We are particularly interested in the latter contribution to ^{31}P chemical shifts and coupling constants.

Accordingly we have prepared and have obtained the ^{31}P nmr spectra of complexes of the type [$M(CH_3)$diphos(L)]PF_6 where L is a pyridine substituted in the 4 position, M = Pd or Pt and diphos = 1,2 bisdiphenylphosphino ethane. We hoped to be able to correlate ^{31}P chemical shifts, $J(^{31}P$–$^{31}P)$ and $J(^{31}P$–$^{195}Pt)$ values with the electronic properties of the substituted pyridines as measured by the Hammett substituent constant ρ (5). The use of the chelating diphosphine, diphos, allows the measurement and comparison of both *trans* and *cis* influences with the same molecule, while the study of analogous Pd and Pt complexes allows comparisons of trends between second and third row transition metals.

Results and Discussion

The ^{31}P chemical shifts and coupling constants of the new compounds are summarized in Table 1. We have not determined the relative signs of the coupling constants; thus their absolute values are presented.

The ^{1}H decoupled ^{31}P nmr spectra of the cations where M = Pd consist of two doublets with chemical shifts of about 60 and 40 ppm, having a mutual coupling constant of about 23 Hz. The ^{1}H decoupled spectra where M = Pt consist of two signals at around 57 and 37 ppm. Each signal is flanked by ^{195}Pt satellites of ca. one-fourth intensity. No ^{31}P–^{31}P coupling is observed.

The low field signals have a $J(^{31}P$–$^{195}Pt)$ of about 1720 Hz while the high field signals have a $J(^{31}P$–$^{195}Pt)$ of about 3700 Hz. Thus, the low field signal in each spectrum is assigned to the phosphorus atom *trans* to the methyl group, P^c, and the high field signal to the phosphorus atom *trans* to the substituted pyridine (6, 7) P^t.

The assignment of the resonances of the palladium cations is based on the argument that the chemical shifts of the phosphorus nuclei should be similar to those in a similar environment in the platinum compounds.

The ^{31}P resonances of P^t, the phosphorus atom *trans* to the pyridine, for both M = Pd and Pt, occur

around 37 ppm while those for P^c, the phosphorus atom *cis* to the pyridine, occur at around 59 for M = Pd and 50 ppm for M = Pt. The chemical shift values for P^t are obviously influenced by changing the pyridine 4-substituent but for M = Pt, unexpectedly, the changes show no relationship to ρ values. For M = Pd, the ^{31}P chemical shifts of P^t decrease in a regular way with decreasing σ values of the substituent (Fig. 1).

The values of the ^{31}P chemical shift for P^c, on changing the substituent on pyridine, decrease in an essentially linear fashion, for both M = Pd and Pt, with decreasing ρ value of the *para* substituent (Fig. 1), although the changes are smaller than for P^t.

These trends can be understood by considering the relation between the electron density at the metal and the amount of electron density on the phosphorus lone pair. On coordination to a transition metal, the ^{31}P chemical shift of a tertiary phosphine invariably moves to lower field from its free value (3). This downfield shift is due to removal of electron density from the phosphorus lone pair *via* donation to suitable metal orbitals. It would seem reasonable, therefore, that an increase in the electron density on the metal would lessen the availability of metal orbitals to accept electron density from the phosphorus. Thus, in this case increasing the electron density at the metal by increasing the donating ability of the pyri-

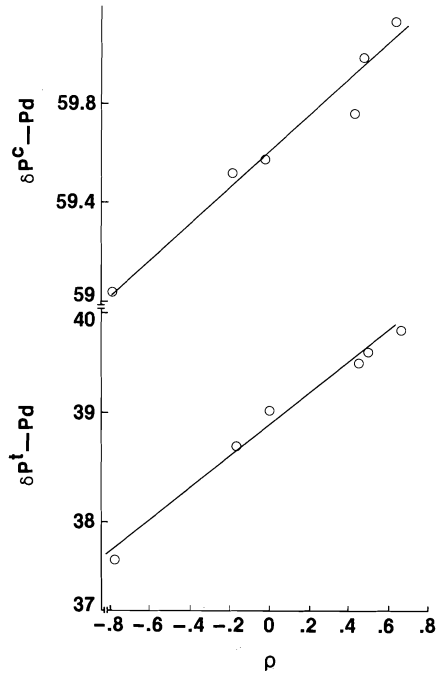

FIG. 1. Plot of $\delta(P^t\text{–}Pd)$ and $\delta(P^c\text{–}Pd)$ vs. ρ.

dine causes the observed decrease in ^{31}P chemical shifts for both the *trans* and *cis* phosphorus atoms.

The ^{31}P–^{195}Pt coupling constants for P^t increase in an essentially linear fashion from 3654 Hz ($X = NMe_2$, $\rho = -0.79$) to 3822 Hz ($X = CN$, $\rho = +0.66$) as ρ increases. The ^{31}P–^{195}Pt coupling constant for P^c also increases, although not so dramatically, in a steady manner from 1713 Hz to 1728 Hz as ρ increases from -0.79 to $+0.66$ (Fig. 2). Note that, in Fig. 2, different scales are used for P^c and P^t and that the effect on $J(Pt–P^t)$ is about 10 times greater than for $J(Pt–P^c)$.

The larger ranges for P^t than for P^c are a result of *trans* influence being larger than *cis* influence. It is widely believed that the Fermi contact term makes the major contribution to the magnitude of platinum–phosphorus coupling constants (8). Therefore, factors which allow the platinum 6*s* orbital to participate more fully in bonding to a phosphorus atom will increase the platinum–phosphorus coupling constant. In this case, decreasing the electron donation of the other ligands on the metal by increasing the ρ value of the 4-substituent on pyridine increases the availability of the Pt 6*s* orbital to the phosphorus atoms resulting in larger values for both $|J(P^c–Pt)|$ and $|J(P^t–Pt)|$.

Conclusions

It has been shown that ^{31}P chemical shifts and ^{31}P–^{195}Pt coupling constants of tertiary phosphine atoms bonded to Pd and Pt are sensitive to small changes in the electronic properties of the other ligands on the metal. Increasing the electron donating ability of these other ligands leads to regular decreases in both ^{31}P chemical shifts and ^{31}P–^{195}Pt coupling constants. Although both *cis* and *trans* phosphorus atoms are affected, the changes in $J(^{31}P–^{195}Pt)$ are greater for the *trans* phosphorus atom.

Experimental

Phosphorus-31 nmr spectra of the cations in dichloromethane solution were measured in 5 mm tubes with a 12 mm reference tube of 1% H_3PO_4. Chemical shifts *downfield* from this reference are in *positive* ppm. A Varian XL-100 spectrometer at 40.5 MHz was employed along with Fourier transform techniques.

The compounds Pd(Me)(Cl)diphos and Pt(Me)(Cl)diphos were prepared as described previously (9, 10). The cationic compounds [M(Me)(Py-X)diphos]PF_6 were all prepared in a similar manner; thus, only a representative preparation is described.

To a suspension of Pd(Me)(Cl)diphos (0.200 g) in tetrahydrofuran (10 mL) was added one equivalent of pyridine followed by a tetrahydrofuran solution of $AgPF_6$ (0.095 g). After an hour the solution was stripped to dryness and extracted with dichloromethane (10 mL). Passage of the dichloromethane solution through a 1/2 in. column of Florosil, concentration and subsequent addition of diethylether gave white crystals of Pd(Me)(py)diphosPF_6 in 80% yield. All of the compounds listed in Table 1 are analysed for the correct C, H, and N content.

Standard free energies (ΔG_t^0) and entropies (ΔS_t^0) of transfer of HX (X = Br and I) from water to glycerol–water mixtures containing 10, 30, 50, and 70 wt.% glycerol have been determined from emf measurements on the cell: Pt, H_2(g, 1 atm)/HX(*m*), solvent/AgX–Ag at seven equidistant temperatures ranging from 10–40°C. The observed ΔG_t^0–composition profiles of HBr, HI, and also of HCl obtained from the relevant literature data are essentially similar to those in aquo-alcoholic and aquo-glycolic systems. But the observed short maxima in $T\Delta S_t^0$(HX)–composition profiles with their relative order: HI > HBr > HCl in water-rich compositions and the reverse order at higher proportions of glycerol are indicative of the effect of small structure promoting propensity of glycerol. Comparison of $T\Delta S_t^0$(HI)–composition profiles of methanol, isopropanol, and *tert*-butyl alcohol on the one hand and that of methanol, ethylene glycol, and glycerol on the other, leads us to suggest that the structure promoting ability of hydrophobic —CH_3 group is significantly reduced due to 'specific site hydration' effect when its one H-atom is being replaced by one hydrophilic —OH group. Also, the compositions at which the characteristic maxima appear, either in the former cases or in the latter, are, as expected, the size effect of the co-solvents.

INDRA NARAYAN BASUMALLICK et KIRON K. KUNDU. Can. J. Chem. **57**, 961 (1979).

Les énergies libres (ΔG_t^0) et entropies (ΔS_t^0) standard de transfert de HX (X = Br et I) de l'eau vers des mélanges de glycérol–eau contenant 10, 30, 50 et 70% en poids de glycérol ont pu être déterminées à partir de mesures de fem sur la cellule: Pt, H_2(g, 1 atm)/HX(*m*), solvant AgX–Ag à sept températures équidistantes allant de 10 à 40°C. Les profils observés pour ΔG_t^0–composition pour HBr, HI et aussi pour HCl, obtenus à partir de données appropriées provenant de la littérature, sont presque semblables à ceux obtenus dans des systèmes aquo-alcoolique et aquo-glycolique. Toutefois les légers maxima observés dans les profils de $T\Delta S_t^0$(HX)–composition avec leur ordre relatif: HI > HBr > HCl à des compositions riches en eau et les ordres inverses à des proportions plus élevées de glycérol indiquent qu'il existe un léger effet favorisant la formation de structures dans le glycérol. Les profils de $T\Delta S_t^0$(HI)–composition du méthanol, de l'isopropanol et du *tert*-butanol d'une part et ceux du méthanol de l'éthylèneglycol et du glycérol d'autre part permettent de suggérer que la facilité avec laquelle le groupe hydrophobe —CH_3 favorise la formation de structures diminue d'une façon importante, à cause d'un effet "d'hydratation d'un site spécifique" lorsqu'on remplace un de ses hydrogènes par un groupe-OH hydrophile. De plus, les "compositions magiques" auxquelles les maxima caractéristiques apparaissent soit dans les premiers ou les derniers cas, sont, tels que prévus, dû à l'effet de grosseur des co-solvants.

Introduction

Denaturation of aqueous solutions of proteins by urea and their stabilization by glycerol and their possible genesis from the alteration of water structure are a subject of wide biochemical interest (1–4). Whilst the numerous studies made so far (1–3) have helped reveal the structuredness of urea–water mixtures to a large extent, the corresponding studies in glycerol–water mixtures are remarkably few and hence the effect of glycerol on water structures is yet a conflicting issue (4–9).

It is now increasingly recognized (10–16) that, like various direct and indirect techniques, the thermodynamic quantities, specifically the standard enthalpies and entropies of transfer, of various solutes serve as fairly useful probes for gaining structural information of aquo-organic solvents. Previously, as part of the studies of ion–solvent interactions as well as the structuredness of aquo-organic solvents, Kundu and co-workers (3) reported the free energies (ΔG_t^0) and entropies (ΔS_t^0) of transfer of hydrogen halides in urea–water mixtures and drew important reflections on the structuredness of the solvents. So, it should be of particular interest to extend such studies to glycerol–water mixtures as well. Moreover, glycerol being intermediate between mono-ols and mono-

saccharides, such studies are also expected to be amply useful in correlating structural effects of simple alcohols and simple sugars.

In glycerol–water mixtures transfer free energies of HCl or the related standard potentials (E^0) of the Ag–AgCl electrode are known at different temperatures (17–19) and those of HBr and HI or the E^0 values of Ag–AgBr and Ag–AgI electrodes are known (5*a*) at one temperature only. A recent study (15) has, however, emphasized that studies of transfer entropies of HCl, HBr, and HI side by side rather than any of the solutes alone provide an additional support to the effectiveness of ΔS_t^0(HX) as a probe for solvent structures. So, the chief object of the present paper is to report the ΔS_t^0 of HBr and HI in this solvent system as obtained by determining the E^0 values of the Ag–AgBr and Ag–AgI electrodes at seven equidistant temperatures ranging from 10–40°C and to examine the structuredness of the solvents. Cell [A]

[A] Pt, H_2(g, 1 atm)/HX(*m*), glycerol (Y) + water/AgX–Ag

where X = Br or I and Y = 10, 30, 50, and 70 wt.% glycerol, has been used for the determination of E^0 values.

Experimental

Glycerol (G.R., Merck) was purified by vacuum distillation with considerable rejection of head and tail fractions. Deionized water was distilled from alkaline $KMnO_4$ and redistilled before use. Purification of HBr and HI (Riedal de Haenag), preparation of solutions and electrodes, cell design, and the general experimental procedure were essentially the same as described before (3, 20). Electromotive force measurements were made with a precision potentiometer and a moving coil galvanometer (Cambridge Instrument Co.). The time taken to reach equilibrium was 3–4 h and the constancy ±0.1 mV for 1 h was taken to be the criterion of equilibrium. Final readings were occasionally checked with a freshly platinized Pt-electrode and were found to agree to within ±0.2 mV. Equilibrium values were recorded first at lowest temperature and then at successively higher temperatures. The equilibrium emf values when checked at a lower temperature were found to be reproducible to within ±0.2 mV.

Solvent densities (21), vapour pressure data (21) computed at each temperature as before (15) using Rault's law, and the dielectric constant values (ε_s) taken from Akerlof's data (22) are given elsewhere.[4]

Results

The standard potential E_m^0 (on the molal scale) of the Ag–AgX electrode at any temperature for any solvent was obtained by use of an extrapolation function $E^{0\prime}$ defined by [1] (20*a*)

[1] $$E^{0\prime} = E + 2k' \ln m - 2k'A_0B_0m^{1/2} \times (1 + a_0Bm^{1/2})^{-1} - 2k' \ln (1 + 0.002M_sm) = E_m^0 - 2k'\beta m$$

where the parameters have their usual significance (20*a*). The emf values (E) corrected to a hydrogen pressure of 1 atm against the molalities (m) of HX have been tabulated elsewhere.[4] The relevant parameters including Debye–Hückel constants A_0B_0 ($= 2.303 \times 1.824 \times 10^6 d_s^{1/2}(\varepsilon_s T)^{-3/2}$) and B_0 ($= 50.29 d_s^{1/2}(\varepsilon_s T)^{-1/2}$) are given in Table 1. Computed $E^{0\prime}$ values were fitted to a linear plot against m by a least-squares procedure, from which E_m^0 and the slope $2k'\beta$ values were determined. As earlier (20), the value of a_0 was taken as zero, since this gave a good linear plot in each case and reasonable variation of a_0 had no significant influence on E_m^0. Table 1 gives the values of E_m^0 and $2k'\beta$ for the Ag–AgX electrodes for the solvent mixtures at different temperatures. The average standard deviation in E_m^0 values is ±0.3 mV and average uncertainty in $2k'\beta$ values is ±0.004 V mol^{-1} kg.

As shown in Table 1, E_m^0 values for the Ag–AgBr electrode at 25°C compare fairly well with those of Khoo (5*a*); but the values for the Ag–AgI electrode increasingly differ and the divergence is as large as 4 mV at 50 wt.% glycerol. It should be noted that Khoo's data for the Ag–AgI electrode are based on cells comprising borate buffer and KI instead of pure HI as in cell [A]. But it is well known that boric acid forms borospiranic acid complex [B] with glycerol (23) imparting enchanced acidity to the solution.

[B] 
This is also evident from the pK_a data reported by Khoo (5*a*), which are found to decrease from 7.308 at 10 wt.% glycerol to 5.947 at 50 wt.% glycerol, in contrast to what are expected from the decreased dielectric constant of the solvents. Moreover, Khoo's values impart a hump in the related ΔG_t^0–composition profile, which seems rather unusual, as no such hump is exhibited either by the present set of data or by those for HCl and HBr reported by Khoo (5*a*) and others (17, 19) as obtained by use of cell [A] comprising of pure HX instead of borate buffers.

The E_m^0 values of the Ag–AgX electrodes at different temperatures for each solvent were fitted by the method of least-squares to [2]

[2] $$E_m^0 = a + b(t - 25) + c(t - 25)^2$$

where t is the temperature in deg Celsius. The co-efficients a, b, and c for the electrodes in different

[4]Complete set of the actual experimental data and the solvent constants required for computing $E^{0\prime}$ (eq. [1]) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

solvent mixtures are presented in Table 2. Those for the Ag–AgCl electrode computed from Knight *et al.*'s relevant data (18) for 10 and 30 wt.% glycerol and from Harned *et al.*'s data (17) for 50 wt.% glycerol are also included in Table 2.

The free energy changes (ΔG_t^0) accompanying the transfer of 1 mol of HX from the standard state in water to the standard state in each of the mixed solvents were evaluated on the mole fraction scale at 25°C using [3]

$$[3]\quad \Delta G_t^0(\mathrm{HX}) = -F\,[(E_m^0)_s^{\,25°C} - (E_m^0)_w^{\,25°C}] - 2 \times 298.15R \ln M_s/M_w$$

and the corresponding entropy changes (ΔS_t^0) by [4]

$$[4]\quad \Delta S_t^0(\mathrm{HX}) = F(b_s - b_w) + 2R \ln M_s/M_w$$

where the subscripts s and w refer to the solvent and water, respectively. As before (20), probable uncertainties in ΔG_t^0 and ΔS_t^0 are 21 J mol^{-1} and ±1 J K^{-1} mol^{-1} respectively, ΔG_t^0, ΔS_t^0, and $T\Delta S_t^0$ (T = 298.15 K) values for HBr, HI, and HCl are presented in Table 3.

Discussion

Free Energies of Transfer

ΔG_t^0(HX)–composition profiles for this solvent system (Fig. 1) resemble closely those in aqueous alcohols (15, 20), glycol (24), etc. and typical of systems having decreasing dielectric constant and

TABLE 3. Standard free energies (ΔG_t^0), entropies (ΔS_t^0), and related quantities $\Delta Y = T\Delta S_t^0(H^+) + T\Delta S_{t,ch}^0(X^-)$ of transfer of HX (X = Cl, Br, or I) from water to glycerol + water mixtures at 25°C

†Reference 5*a*.

more or less similar variation of chemical nature, including acidity, basicity, hydrogen-bonding capacity, and structural features. Thus, as the proportion of the co-solvent increases, the transfer of both HCl and HBr is found to be increasingly unfavourable and that of HI, though favourable at water-rich compositions, has a tendency to become unfavourable at co-solvent-rich compositions. Moreover, at any given composition, ΔG_t^0(HX) decreases in the order HCl, HBr, HI, as is expected if, as in aqueous alcohols, the effects of decreased dielectric constant and the acidity of the mixed solvents destabilize the anions (5, 15, 25).

When the electrostatic effects (26), $\Delta G_{t,el}^0$(HX), which arise from the difference in the dielectric constant of the solvents, are tentatively computed by the simple Born equation (27) using $r_{H_3O^+} = 2.76$ (28) and Pauling's crystallographic radius for X^- (29) and are subtracted from the respective ΔG_t^0(HX) values, the resulting 'non-electrostatic' or 'chemical' contributions, $\Delta G_{t,ch}^0$(HX), become increasingly negative, as shown in Fig. 1. As has been found to be the case in aqueous alcohols (15), if the solvation of these ions be assumed to be dictated chiefly by 'acid–base' type ion–solvent interactions (25), and the acid–base nature of the solvents be essentially similar (5*a*) to those of aqueous alcohols (15), the results would apparently suggest that in this solvent system as well H^+ is solvophilic and halide ions hydrophilic and that the solvophilicity of H^+ exceeds the hydrophilicity of the halide ions at least in the range of composition studied. This would then imply that these mixed solvents are more 'basic' but less 'acidic' than water. This 'basicity' and 'acidity' of course mean electron-pair donicity and acceptibility of the solvents respectively (25).

However, for a better understanding of the ion–solvent interactions the splitting of ΔG_t^0(HX) to individual ion contributions is in order. Till recently two sets (5*a*, 30) of $\Delta G_t^0(i)$ values have been reported for these ions. The data obtained by Khoo (5*a*) using Feakins-type extrapolation procedure (25), however,

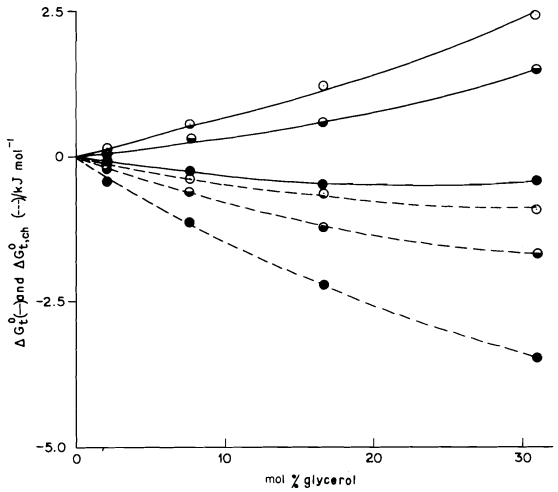

FIG. 1. Variation of ΔG_t^0(HX) and $\Delta G_{t,ch}^0$(HX) (broken lines) at 25°C with mol% glycerol: ○, HCl; ◒, HBr; ●, HI.

differ from those obtained by Wells' method (30) not only in magnitude but even in sign, as in the cases of H^+ and I^-. Consequently, the interpretation of the results and the nature of the ion–solvent interactions derived thereof are also different in the two cases. Under the circumstances, the attempt for elucidating the true picture of the solvation of these ions in these solvents should await till individual ion contributions are obtained by other suitable methods (31), particularly by reference electrolyte Ph_4AsBPh_4 (Ph = phenyl) method which has been very recently demonstrated (32) to be theoretically sound and hence more useful than others.

Entropies of Transfer

As in aquo-alcoholic systems (15), $T\Delta S_t^0$(HX)–composition profiles for this system (Fig. 2) exhibit 'characteristic' maxima at water-rich compositions followed by downward trends at higher co-solvent compositions. Also, the relative order of $T\Delta S_t^0$(HX) values in the region of maxima is a regular one: HI > HBr > HCl; but a reverse one at higher composition of glycerol. Moreover, when ΔS_t^0(HX)

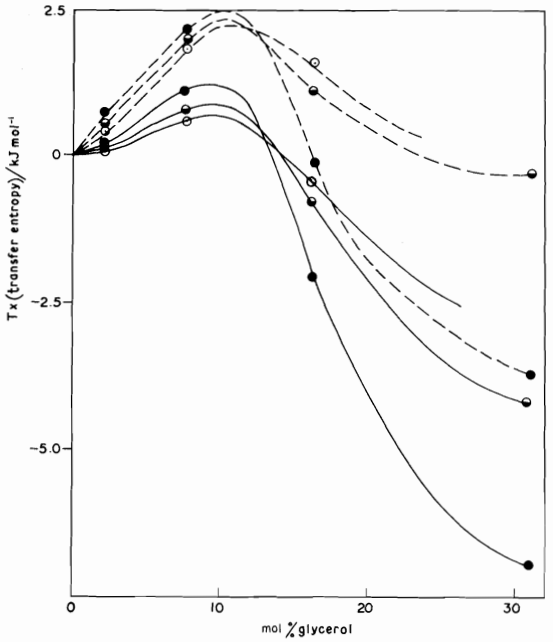

FIG. 2. Variation of $T\Delta S_t^0(HX)$ and $\Delta Y = T\Delta S_t^0(H^+) + T\Delta S_{t,ch}^0(X^-)$ (broken lines) with mol% glycerol: ○, HCl; ◒, HBr; ●, HI.

values are tentatively rationalized by subtracting the Born-type electrostatic contributions of the halide ions computed in a manner described earlier (27), one finds that as in aquo-alcoholic solvents (15) the quantities $\Delta Y = T\Delta S_t^0(H^+) + T\Delta S_{t,ch}^0(X^-)$ (Fig. 2) are shifted upwards, retaining the essential features of $T\Delta S_t^0(HX)$–composition profiles all the same.

The implications of the observed $T\Delta S_t^0(HX)$, or more preferably, ΔY–composition profiles for this system can be visualized in the light of our previously proposed semi-quantitative theory (15). This was essentially based on the Frank and Wen (33) model of ion-solvation and on our earlier views (3, 15, 20, 34) that the transfer of any of these ions from water to a mixed solvent consists of four successive steps: (*i*) dismantling of the hydration zones to give the bare ion and infinitely dilute gas of water molecules, (*ii*) condensation of the gas to give normally structured liquid water, (*iii*) evaporation of solvent molecules required for step (*iv*) from the bulk solvent to give dilute gas of solvent molecules, and (*iv*) solvation of the bare ion and its introduction into the solvent.

Taking into account the detailed entropy changes for the composite transfer process and assuming that for the solvents containing up to at least 50 wt.% co-solvent the primary solvation zone is composed wholly of water (31), it has been concluded (15) that

(*a*) when solvent structure > pure water structure

$$\Delta S_{t,ch}^0(HX) > 0 \text{ and } \Delta S_{t,ch}^0(HI) > \Delta S_{t,ch}^0(HBr) > \Delta S_{t,ch}^0(HCl)$$

(*b*) when solvent structure < pure water structure

$$\Delta S_{t,ch}^0(HX) < 0 \text{ and } \Delta S_{t,ch}^0(HI) < \Delta S_{t,ch}^0(HBr) < \Delta S_{t,ch}^0(HCl)$$

Moreover, since small amounts of monohydric alcohols by virtue of their hydrophobic moieties promote three-dimensional (3D) ice-like structures while larger amounts break up the same due to increased packing imbalance (35) and also the observed $\Delta S_{t,ch}^0(HX)$–composition profiles for these aqueous alcohols are in accord with the dictates of the above theory, it has been concluded that ΔY–composition profile should serve as a useful probe for the structuredness of other aquo-organic solvents.

In the light of the above observations the results of the present study could be taken to suggest that like the monodrydic alcohols small addition of glycerol also promotes water structure but larger amounts break up the same and that the maximum structure promotion occurs at about 9 mol% glycerol. Moreover, it may be observed from Fig. 3, where ΔY–composition profiles for a number of co-solvents are illustrated, that while the characteristic maxima of isopropanol and *tert*-butyl alcohol are significantly sharper, narrower, and higher compared to that of methanol, those of ethylene glycol and glycerol are somewhat flat and short as that of methanol. Since the monohydric alcohol containing larger hydrophobic group causes a more rapid and more extensive promotion followed by an equally rapid and complete collapse due to packing imbalance, the compositions at which the maximum in $T\Delta S_t^0$ or ΔY appears will be smaller for the larger hydrophobic moiety of the alcohol. Consequently, the flat maxima of nearly similar heights for methanol, ethylene glycol, and glycerol suggest that the structure promoting propensities of these co-solvents are more or less similar and much smaller compared to higher monohydric alcohols and that their observed compositions of maxima are also in accord with their respective sizes.

Again, the significant difference between the maxima in isopropanol + water and glycerol + water systems indicates that the effect of structure promoting propensities of hydrophobic $—CH_3$ groups in isopropanol is appreciably reduced when replaced by $—CH_2OH$ groups in glycerol. This is possibly due to the fact that the monomeric 'dense' water in equilibrium with 'bulky' 3D structure of water instead of being repelled due to hydrophobicity

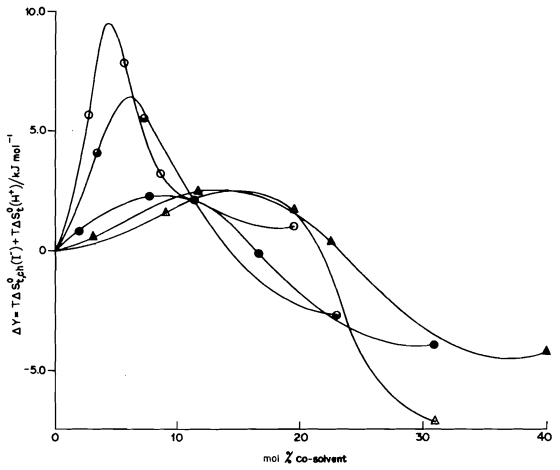

FIG. 3. Variation of $\Delta Y = T\Delta S_{t,ch}^{0}(I^-) + T\Delta S_t^0(H^+)$ with mol% co-solvents: ○, *tert*-butyl alcohol (20*a*); ◒, isopropanol (15); ●, glycerol (present work); ▲, ethylene glycol (24); and △, methanol (estimated from the data of ref. 41).

of $-CH_3$ groups and inducing 'ice-berg' formation (36) or 'hydrophobic hydration' (36) are likely to induce 'specific site hydration' (37) forming hydrogen bonds with hydrophilic —OH sites of $-CH_2OH$ groups and thus causes an appreciable reduction in structure promotion. This further explains why there is little difference in the heights and extensiveness of characteristic maxima in the cases of ethylene glycol and glycerol compared to that of methanol, as two of its H-atoms in methyl group are successively substituted by less hydrophobic and less structure-promoting $-CH_2OH$ groups. The observed shifting of maximum towards lower co-solvent compositions is also indicative of the result of an increased number of $-CH_2OH$ groups of the co-solvents. This seemingly suggests that the characteristic maxima of higher polyols would be shifted to so low co-solvent compositions that those polyols are likely to behave as effective structure breakers, as are evidenced from various studies (38) and also expected from the effect of 'specific site hydration' as well as the compatibility of polyol conformation with the solvent structure (37). In the cases of lower polyols like glycerol, however, the structure-promoting effects of hydrocarbon skeletons seem hardly augmented by the structure-breaking effects of 'specific site hydration' as these polyols are likely to assume conformations which are completely compatible (4, 39) with the water structure at least in water-rich compositions.

Notably, close similarity of the variations of Washburn number in glycerol–water mixtures with that in methanol–water mixtures also led Khoo (5*b*) to invoke the same type of structural variation as contended from the results of the present study. Moreover, the observed maxima in the β (cf. [1])–composition profiles for HCl and HBr in glycerol–water mixtures have also been attributed by Khoo (5*a*) to similar structural changes of the solvents. Variations of some physical properties such as water activities (6), viscosities (7), sound absorption (7, 8), and partial molar volumes (9), however, indirectly suggest that the incremental addition of glycerol simply affects a gradual breakdown of 3D structure of water. Moreover, a comparison (4) of apparent volumes and heat capacities of transfer of several ionic solutes from water to glycerol–water mixtures and literature data for the said transfer quantities to D_2O and to 3 *m* urea solutions suggests that as in urea–water mixtures there is less structural order in glycerol–water mixtures than in water. But present observations when compared with our earlier findings in urea–water mixtures (3) reflect some apparent differences in the structural behaviour of the two co-solvents. Thus, while increasing addition of urea (up to 3 *m*) shifts the equilibrium: water (dense) ↔ water (bulky) to the left glycerol like the simple mono-ols shifts the same to the right at least up to the composition of its characteristic maxima. As the conformation of urea (40) and glycerol (4, 39) are compatible with the water structure, the effect of 'specific site hydration' presumably induces urea to shift the equilibrium towards the left while the predominant effect of hydrophobic character over 'specific site hydration' induces glycerol to shift the same towards the right.

The preparation and crystal structure of pentaiodinium hexafluoroantimonate(V) containing I_{15}^{3+}

JACK PASSMORE, PETER TAYLOR, TOM WHIDDEN, AND PETER S. WHITE

Department of Chemistry, University of New Brunswick, P.O. Box 4400, Fredericton, N.B., Canada E3B 5A3

Received October 12, 1978

JACK PASSMORE, PETER TAYLOR, TOM WHIDDEN, and PETER S. WHITE. Can. J. Chem. **57**, 968 (1979).

Crystalline pentaiodinium hexafluoroantimonate was prepared by the reaction of I_2 and SbF_5 in AsF_3. The crystals were triclinic, $a = 8.295(4)$ Å, $b = 15.61(1)$ Å, $c = 8.390(4)$ Å, $\alpha = 81.49(4)°$, $\beta = 110.02(4)°$, $\gamma = 85.06(4)°$, $Z = 3$, space group $P\bar{1}$. The structure was solved by multiple-solution direct methods and Fourier syntheses and refined by full-matrix and blocked-matrix least-squares procedures to a final R of 0.062 and R_w of 0.090 for 2229 reflections with $I \geq 3\sigma(I)$. The two crystallographically independent planar, bent I_5^+ chains (one centrosymmetric, the other essentially centrosymmetric), each have two collinear central bonds of 2.899(2) Å (×2); 2.896(2), and 2.920(2) Å, bond angles 180° and 178.7(6)°, respectively, and two shorter terminal bonds of 2.680(3) Å (×2); 2.666(3) and 2.698(2) Å, with bond angles between central and terminal bonds of 94.53(6)° (×2); 93.86(7) and 93.17(7)°, respectively. Three I_5^+ units are joined by a weak (3.416(3) Å) interaction to form what may be regarded as an I_{15}^{3+} unit. The SbF_6^- anions are approximately octahedral.

JACK PASSMORE, PETER TAYLOR, TOM WHIDDEN et PETER S. WHITE. Can. J. Chem. **57**, 968 (1979).

On a préparé l'hexafluoroantimonate de pentaiodinium cristallin en faisant réagir du I_2 avec du SbF_5 dans le AsF_3. Les cristaux sont tricliniques, $a = 8.295(4)$ Å, $b = 15.61(1)$ Å, $c = 8.390(4)$ Å, $\alpha = 81.49(4)°$, $\beta = 110.02(4)°$, $\gamma = 85.06(4)°$, $Z = 3$, groupe d'espace $P\bar{1}$. On a résolu la structure par des méthodes directes de solutions multiples et des synthèses de Fourier et on l'a affinée par la méthode des moindres carrés (matrices complète et diagonale) jusqu'à une valeur finale de R de 0.062 et R_w de 0.090 pour 2229 réflexions avec $I \geq 3\sigma(I)$. Les deux chaînes de I_5^+ sont planes, recourbées et indépendantes du point de vue cristallographique; l'une est centrosymétrique et l'autre est essentiellement centrosymétrique et chacune possède des liaisons centrales mesurants 2.899(2) Å; 2.896(2) et 2.920(2) Å avec des angles de liaisons respectifs de 180° et 178.7(6)° et deux liaisons terminales plus courtes de 2.680(3) Å (×2); 2.666(3) et 2.698(2) Å avec des angles entre les liaisons centrales et terminales qui sont respectivement de 94.53(6)° (×2); 93.86(7) et 93.17(7)°. Il y a trois unités de I_5^+ qui sont réunies par une interaction faible (3.416(3) Å) formant ce qu'on peut considérer comme une unité de I_{15}^{3+}. Les anions de SbF_6^- sont approximativement octaédriques.

Introduction

A wide variety of halogen homopolyatomic anions have been well characterized for some time (1–3). More recently, polyatomic halogen cations have been prepared and identified (1, 4). The structure of Br_2^+ and I_2^+ in $Br_2Sb_3F_{16}$ (5) and $I_2Sb_2F_{11}$ (6) have been determined by X-ray crystallographic methods. Vibrational evidence (4) has been given in support of the bent Cl_3^+, Br_3^+, and I_3^+ cations. Evidence has recently been presented for salts of Br_5^+ (7) and Cl_2^+ (8). Of the iodine cations, I_3^+, I_5^+, and possibly I_7^+ have been observed in fluorosulphuric acid and 100% sulphuric acid solutions (4) but no structural data for the latter two ions were obtained. The following salts of polyatomic iodine cations have been prepared as solid compounds: $I_2M_2F_{11}$ (M = Sb, Ta) (9), I_3SO_3F and I_7SO_3F (10), I_3AsF_6 (11) and I_3SbF_6 (12), and I_3AlCl_4 and I_5AlCl_4 (13). Nuclear quadrupole resonance measurements (13) indicated that I_3^+ in I_3AlCl_4 has a bent structure with an angle of 97.1°. The compound I_5AlCl_4 was prepared in the same study but no structural data were reported.

In this work we have prepared I_5SbF_6 by the oxidation of I_2 with SbF_5 and have determined its structure by X-ray diffraction methods.

Experimental

Preparation of Pentaiodinium Hexafluoroantimonate(V)

Preparative techniques are described in ref. 11. In the reaction from which single crystals were obtained, iodine (5.89 g, 23.2 mmol) and SbF_5 (3.08 g, 14.2 mmol) were reacted in AsF_3 (7.09 g, 53.7 mmol) for 1 h at room temperature. The resulting dark brown solution was filtered through a sintered disk and the washing repeated until only a white solid remained. The AsF_3 and excess I_2 were condensed back onto this solid and allowed to stand overnight. Further reaction was found to occur, the solution becoming coloured. The entire

0008-4042/79/090968-06$01.00/0

process was repeated three times after which no further reaction was evident. Slow removal of the solvent produced a black, highly crystalline solid which was pumped to constant weight in order to remove trace amounts of iodine. The weight of soluble product (7.72 g) was not inconsistent with the formation of I_5SbF_6. Elemental analysis of the white insoluble solid (0.82 g) agrees with the stoichiometry SbF_3; however, the Raman spectrum is very different from that of SbF_3 but similar to $(SbF_3)_x{\cdot}(SbF_5)$, where x very approximately equals 5, this is the subject of further investigation.[1]

X-ray Crystallography of Pentaiodinium Hexafluoroantimonate(V)

The crystal chosen for study approximated to a right parallel-piped of dimensions ca. 0.033 × 0.027 × 0.014 cm, and included angle of approximately 125° between the two long edges. This was mounted in a rigorously dried glass capillary. Preliminary Weissenberg and precession photographs showed the crystal to be triclinic and yielded initial unit cell dimensions. Accurate cell parameters were obtained using a least-squares fit of cell dimensions and an orientation matrix to the diffractometer settings for 11 well-centered reflections ($30° \leq 2\theta \leq 40°$) distributed through the hemisphere in which data were collected. Crystal data for I_5SbF_6 are:

I_5SbF_6 fw = 870.3
Triclinic, $P\bar{1}$, a = 8.295(4) Å, b = 15.61(1) Å, c = 8.390(4) Å, α = 81.49(4)°, β = 110.02(4)°, γ = 85.06(4)°, V = 999 Å^3, Z = 3, ρ_c = 4.34 g cm^{-3}, $F(000)$ = 1110, $\mu(MoK_\alpha)$ = 138.4 cm^{-1} (λ = 0.71069 Å, 20(±2)°C).

The reduced cell is obtained by the transformation (100)/(00$\bar{1}$)/(010) and has parameters a = 8.295 Å, b = 8.390 Å, c = 15.612 Å; α = 81.489°, β = 85.055°, γ = 69.98°. This cell satisfies the conditions for the reduced cell stated by Buerger (14, 15).

Intensities were collected on a Picker FACS-I four-circle diffractometer using graphite crystal monochromated MoK_α radiation. An ω–2θ scan with a base width of 2° (2θ) corrected for dispersion of the K_α doublet, and a scan rate of 1° per min was employed. Background counts (20 s) were measured at each end of the scan. Data were collected for $2\theta \leq 45°$. Two reflections were measured as standards every thirty reflections. These varied less than 1.5σ from their mean throughout the data collection.

A total of 2593 independent reflections were measured in four octants. Of these, 2229 (86%) were initially classified as observed, being greater than 3$\sigma(I)$ where $\sigma(I)$ is estimated from counter statistics (16). Corrections for Lorentz and polarization factors were applied to the data. Application of an absorption correction (17) to the data was purposefully delayed until a reasonably low R value was obtained. This method was used to make certain that crystal definition was correct and the application of the correction improved the model. When applied, the correction reduced R from 0.126 to 0.090. Maximum and minimum transmission factors were 0.22 and 0.07, respectively.

Structure Determination

Data reduction and structure refinement utilized the X-RAY 76 program package (18). Atomic scattering factors for the neutral atoms were taken from Cromer and Mann (19) and the iodine and antimony scattering factors were corrected for anomalous dispersion (20). Statistical treatment of the normalized structure factors indicated a centric crystal system and the structure determination was therefore carried out in the space group $P\bar{1}$. Initial positional parameters were determined using the MULTAN system of direct methods programs (21). A total of 243 reflections with $E \geq 1.70$ were used as input to MULTAN. An E-map phased by the best solution from MULTAN gave the positions of 9 out of the 10 iodine and antimony atoms. An F_o synthesis using these parameters determined the position of the remaining heavier atom and two of the fluorines. With these atomic positions included in the calculation, two cycles of least-squares refinement reduced the R value to 0.134. The function minimized by the procedure was $\Sigma w(|F_o| - |F_c|)^2$ with $w = 1$. Another F_o synthesis at this point allowed the determination of the remaining fluorine positions. Including all atoms in the calculation with isotropic thermal parameters, refinement converged at R = 0.126. The absorption correction was then applied as noted above. When the thermal parameters of the iodine and antimony atoms were varied anisotropically R dropped to 0.081.

Weighting factors for the procedure were changed to $w = 1/\sigma(F)^2$ where $\sigma(F)$ is directly derived from $\sigma(I)$ (15). With the inclusion of the new weighting scheme the refinement converged to R = 0.062, R_w = 0.090 for 2229 reflections. Average shift/error for the final cycle was 0.049 with a maximum value of 0.294 associated with a fluorine atom. A ΔF synthesis at this point showed a maximum electron density of 2.13 e$^-$/Å^3 at (0.0908, 0.0410, −0.0113), 1.04 Å from Sb1, indicating essentially no misplaced or uncounted atoms. The high noise level due to the fluorescence in the sample may be the cause of this. A number of other peaks approaching this height are distributed throughout the unit cell. Final positional parameters appear in Table 1.[2]

An attempt was made to refine the structure in the space group $P1$. The atoms were displaced from their centric posi-

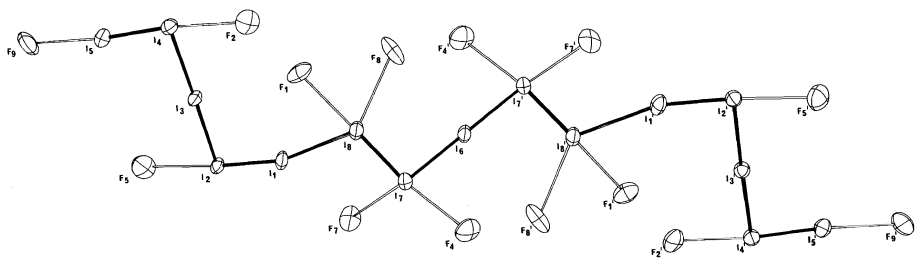

FIG. 2. The configuration of I_{15}^{3+} showing interionic contacts. Crystallographic centre of symmetry at I_6 (0, 1/2, 0).

tions and then refined by least-squares methods. It was found that the shifts generated by the least-squares refinement tended to return the atoms to the centric configuration. No improvement in the *R* value occurred with refinement converging at the significantly poorer *R* value of 0.111. This indicates that the space group had been correctly chosen as $P\bar{1}$.

Results and Discussion

The crystal packing is shown in Fig. 1 and the structure of the iodine cations and the interionic contacts are illustrated in Fig. 2. Appropriate bond lengths and angles are presented in Tables 2 and 3. There are no anion–cation contacts less than 2.98(1) Å (Table 2) suggesting that $I_5^+SbF_6^-$ is predominantly an ionic species. Shorter contacts (2.89(2) Å) have been observed (6) in $I_2^+Sb_2F_{11}^-$ for the more electrophilic I_2^+ ion.

The distance between I(1) and I(8) (3.416(3) Å, Table 2, Fig. 2) is comparable to bonds found between atoms in elemental I_2 (in-plane intermolecular I_2–I_2 distance = 3.496(6) Å, ref. 22) and in some iodine anions (central I—I bond in I_{16}^{4-} = 3.450(3) Å, ref. 23). These are significantly less than the sum of Van der Waals radii for iodine (3.92 Å, ref. 24) and have been considered as weak bonding interactions (22). The next closest iodine–iodine contact is between iodine cations and is essentially at Van der Waals distance (I(5)–I(5′) = 3.906(3) Å, Table 2). Therefore, the centrosymmetric I_{15}^{3+} grouping can be identified (Fig. 2) giving rise to an overall formulation of I_{15}^{3+}-$(SbF_6^-)_3$. This species may gain an extra measure of stability by delocalization of electrons over the larger chain. The two independent I_5^+ units are planar[3] and the angle between each plane and the next is 22.7°, small enough that the I_{15}^{3+} unit itself may be considered very roughly planar. The configuration of the I_5^+ units (and the I_{15}^{3+} as a whole) may reflect some type of π-bond delocalization and/or may minimize electrostatic repulsions.

The two crystallographically independent I_5^+ units, one required by crystal symmetry to be centrosymmetric, contain bond distances and angles that are similar (see Tables 2 and 3). The terminal I—I bonds are comparable with those found in I_2 (22, 25). They have bond distances of 2.666(3)–2.698(2) Å. The central collinear bonds have dis-

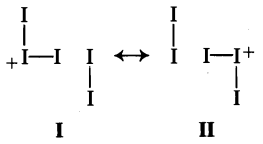
[3]Photocopies of table giving least-squares plane through I_5^+ cations may also be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

TABLE 2. Bond lengths (Å) with estimated standard deviations in parentheses

(*a*) Intramolecular		(*b*) Intermolecular[a]	
Bond	Distance	Bond	Distance
I(1) · · · I(5)		Inter-ionic	
I(5)—I(4)	2.666(3)	I(1)—I(8)	3.416(3)
I(4)—I(3)	2.920(2)	I(2)—I(2′)	3.907(3)
I(3)—I(2)	2.896(2)	I(5)—I(5′)	3.906(3)
I(2)—I(1)	2.698(2)	I(1) · · · I(5)	
I(8) · · · I(8′)		I(5)—F(9)	2.98(1)
I(8)—I(7)	2.680(3)	I(4)—F(2)	2.99(1)
I(7)—I(6)	2.899(2)	I(2)—F(5)	3.03(2)
SbF_6^-		I(8) · · · I(8′)	
Sb(1)—F(1)	1.89(2)	I(8)—F(1)	3.06(2)
—F(2)	1.88(2)	—F(8)	3.40(1)
—F(3)	1.86(1)	I(7)—F(4)	3.01(2)
Sb(2)—F(4)	1.85(2)	—F(7)	3.19(1)
—F(5)	1.83(2)		
—F(6)	1.88(2)		
—F(7)	1.84(2)		
—F(8)	1.87(2)		
—F(9)	1.86(1)		

[a]Included are I—I distances ≤ 4.00 Å, and all I—F distances ≤ 3.40 Å.

tances 2.896(2)–2.920(2) Å and are comparable with bond lengths observed for the symmetric linear I_3^- ion in $(C_6H_5)_4AsI_3$ (26) (2.920(2) Å). We note that the average I—I distance in various symmetric and asymmetric I_3^- ions remains very close to the same value (1). This appears to be true also of $I_5^+SbF_6^-$ (average central bond length I(1) · · · I(5) = 2.908(3) Å, I(8) · · · I(8′) = 2.899(2) Å; average terminal bond length I(1) · · · I(5) = 2.682(3) Å, I(8) · · · I(8′) = 2.680(3) Å). The variation in bond lengths in I_5^+ suggests that it may be described by valence bond structures **I** and **II**

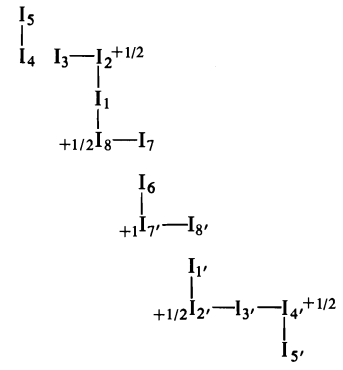


I **II**

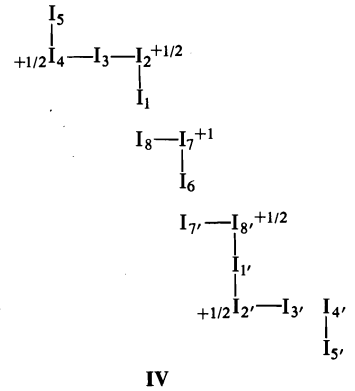
giving formal bond orders of 1.0 and 0.5 for terminal and central bonds, respectively. The observed bond angles, similar in both I_5^+ units (Table 3, Fig. 2) are consistent with this model. The angle at I(2), I(4), and I(7) (94 ± 1°) is somewhat smaller than that calculated for I_3^+ from nqr measurements (97.1°, ref. 13) and that observed in the isoelectronic Te_3^{2-} (113.1(2)°, ref. 27) presumably in part because of reduced bond–bond repulsions.

There is weak interaction between the iodines containing the formal positive charge and the fluorines in the anions (Table 2, Fig. 2), whereas the central bridging iodines in both crystallographically different I_5^+ units show no such interaction. However, there are other interactions which involve I_5^+ terminal atoms. (N.B. Resonance structures **III** and **IV** place some positive charge on I(8), see below.) The geometry about I(1) and I(8) would suggest that I(8) donates an electron pair to I(1) (angles of 90° have been found with halogens acting as donors in various adducts and 180° with acceptors (29)). This would lead to some positive charge on I(8). The stereochemistries about all iodine atoms (including I–F contacts less than 3.39 Å and I–I contacts less than 3.90 Å) are consistent with VSEPR theory (28).

Further support for an interpretation of the species as I_{15}^{3+} is found in the minor variations observed in formally similar bond lengths. The terminal I(4)—I(5) bond (2.666(3) Å) of the I_{15}^{3+} unit is significantly shorter than the related I(1)—I(2) and I(7)—I(8) bonds (Table 2). This may be a consequence of the interaction between I(1) and I(8) linking the I_5^+ units and subsequently lengthening the I(1)—I(2) (2.698(2) Å) and I(7)—I(8) (2.680(3) Å) bonds, thus causing them to approach the distance observed in solid I_2 (2.715(6) Å, ref. 22). The I(4)—I(5) bond, being more isolated, is closer to the length found for gaseous I_2 (2.666 Å, ref. 25). Subsequent polarisation may lead to the observed lengthening of I(4)—I(3) and shortening of I(3)—I(2) relative to I(7)—I(6). Perhaps valence bond structures such as **III** and **IV** make a small contribution to the bonding in I_{15}^{3+}.



III



IV

TABLE 3. Bond angles (deg) with estimated standard deviations in parentheses

Bond	Angle	Bond	Angle
SbF_6^-		$I(1)\cdots I(5)$	
F(1)—Sb(1)—F(2)	89.9(7)	I(1)—I(2)—I(3)	93.86(7)
—F(3)	89.9(7)	I(2)—I(3)—I(4)	178.7(6)
F(2)—Sb(1)—F(3)	90.5(7)	I(3)—I(4)—I(5)	93.17(7)
F(4)—Sb(2)—F(5)	178.6(8)	$I(8)\cdots I(8')$	
—F(6)	89.0(9)	I(8)—I(7)—I(6)	94.53(6)
—F(7)	89.1(9)	I(7)—I(6)—I(7′)	180
—F(8)	90.0(8)	Inter-ionic	
—F(9)	90.6(7)	I(2)—I(1)—I(8)	162.88(8)
F(5)—Sb(2)—F(6)	90.4(9)	I(7)—I(8)—I(1)	111.54(7)
—F(7)	91.4(8)	I(1)—I(2)—F(5)	173.5(4)
—F(8)	91.2(8)	I(3)—I(2)—F(5)	80.8(3)
—F(9)	88.1(7)	I(5)—I(4)—F(2)	173.6(4)
F(6)—Sb(2)—F(7)	177.9(9)	I(3)—I(4)—F(2)	80.5(3)
—F(8)	88.9(8)	I(4)—I(5)—F(9)	175.5(4)
—F(9)	89.9(8)	I(6)—I(7)—F(4)	76.4(3)
F(7)—Sb(2)—F(8)	90.2(8)	—F(7)	150.1(4)
—F(9)	91.0(8)	I(8)—I(7)—F(4)	170.4(3)
F(8)—Sb(2)—F(9)	178.6(1.0)	—F(7)	81.8(3)
		F(4)—I(7)—F(7)	107.5(5)
		I(7)—I(8)—F(1)	172.3(3)
		—F(8)	112.3(3)
		I(1)—I(8)—F(1)	70.9(2)
		—F(8)	129.9(3)
		F(1)—I(8)—F(8)	68.9(4)

These would lead to some bonding between I_5^+ units and provide an explanation of the slight lengthening of I(3)—I(4) and I(1)—I(2) and the small shortening of I(2)—I(3) and I(4)—I(5) with respect to the average bond lengths at their respective positions in the I_5^+ cation (see Table 2). Thus the bond distances in the central centrosymmetric I_5^+ unit are 'average', and the asymmetric bond distances are to be found in the outer I_5^+ cations.

We note that, from observation of the number and strength of the I–F contacts (Table 2), the more numerous cation–anion interactions present in the central I_5^+ unit suggest that it possesses more positive character than the terminal units. This would be in keeping with some contribution from valence bond structures **III** and **IV** which place a positive charge of 1.5 on the central I_5^+ cation and 0.75 on each terminal I_5^+ unit.

Both SbF_6^- anions are regular octahedra (average Sb—F distance 1.86 ± 0.02 Å, average F—Sb—F angle 90 ± 1°, Tables 2 and 3). Some variation in Sb—F distance is to be expected as a consequence of varying involvement in cation–anion interactions; however, within the limits of error, no obvious differences were detected.

EUGENE M. L. VALERIOTE, LLOYD D. GALLOP, and PEDRO J. ARAGON. Can. J. Chem. **57**, 974 (1979).

Measurements of the solubility of lead sulphate in 35% by weight sulphuric acid, pure water, and at two intermediate acid concentrations have been made over the temperature range 25°C to −50°C using differential pulse anodic stripping voltammetry.

Values of the standard enthalpy of solution, derived from the data and from that of other workers, have been found to be higher than those obtained from emf measurements. The extent of lead sulphate ion pairing is analyzed at 25°C and discussed. The slowness of equilibration of acid solutions supersaturated with lead sulphate was judged of importance in deciding the relevance of the use of thermodynamically calculated lead ion concentrations with respect to lead acid battery mechanisms.

EUGENE M. L. VALERIOTE, LLOYD D. GALLOP et PEDRO J. ARAGON. Can. J. Chem. **57**, 974 (1979).

Nous avons mesuré la solubilité du sulfate de plomb, à des températures variant de −50°C à 25°C, dans une solution d'acide sulfurique à 35%, dans de l'eau pure, et dans deux solutions intermédiaires par la méthode de voltammétrie de décapage anodique à pulsation différentielle.

Des valeurs de l'enthalpie standard de solution, derivées de nos données et de celles d'autres chercheurs, étaient plus hautes que celles obtenues par la mesure de forces électromotrices. Nous avons analysé et étudié le degré de formations de paires d'ions de sulfate de plomb à 25°C. On a jugé que la lenteur de mise à l'équilibre des solutions acides, sursaturées en sulfate de plomb, était importante pour décider de la pertinence de l'usage des concentrations de l'ion de plomb, calculées thermodynamiquement en regard du mécanisme de l'accumulateur de type plomb-acide.

Introduction

Information on the low temperature solubility of lead sulphate is of importance to the understanding of the reaction processes involved in the operation of lead acid batteries under conditions of severe cold. For reasons that are not yet established, the lead acid battery, at very low temperatures (≤ -30°C), is incapable of accepting recharge at acceptably rapid practical rates. It has been suggested that the electrochemical reactions of both the $PbSO_4/PbO_2$ positive electrode (1) and the $Pb/PbSO_4$ negative electrode (2) are related to the solution rate of lead sulphate and that the precipitation or dissolution of $PbSO_4$ is controlled by its solubility. Although the evidence is stronger for a dissolution–precipitation mechanism at the negative than at the positive electrode, both mechanisms appear to be very complicated (3–6), giving rise to a need for low temperature lead sulphate solubility and dissolution rate data.

Measurements of lead sulphate solubility do not appear to have been made at temperatures below 0°C, and particularly not at temperatures near the freezing points of concentrated H_2SO_4 solutions, although the need for such data is clear (7). Lead sulphate solubilities have been determined as a function of sulphuric acid concentrations in the temperature range of 0 to +50°C (8–14).

A method based on the reaction of dissolved lead with dithizone to form a coloured complex which could be detected photometrically (8, 9) gave good agreement with iodometric determination of lead, following evaporative concentration of dissolved lead chromate (10). Other methods (11–13) also agreed well, except for the lead chromate-colorimetric method of Crockford and Brawley (14), where

competition between chromate and sulphate ion pairing may be the cause of the low values in the range of 0.5–50% acid.

In order to understand the role of dissolved lead at very low temperatures, a knowledge of its concentration is required. This may be estimated by application of the van't Hoff equation, using values of ΔH obtained from solubility measurements at higher temperatures, as has been done in order to interpret the low temperature charging kinetics of anodic films on lead in sulphuric acid solutions (5). However, the validity of such an extrapolation remains to be demonstrated experimentally.

The previous methods cited were not sufficiently sensitive to determine lead quantitatively at concentrations much less than 1 ppm, whereas at −50°C, concentrations of the order of 40 ppb might be expected on the basis of extrapolation of the van't Hoff expression, using the Craig and Vinal data (8). However, measurement of such low concentrations of lead are well within the capability of modern analytical techniques such as atomic absorption spectroscopy (AA) and stripping voltammetry and both methods were assessed for the present work. Although AA was a suitably sensitive method for analysis of lead in pure (acidified) water, strong interference by sulphuric acid was observed at the two strongest lead absorption wavelengths (283.2 nm and 217.0 nm) and this technique was abandoned. However, it has been used successfully recently in a study (15) in which micro-aliquots of sulphuric acid were evaporated to dryness prior to atomization of the residual lead.

Of the various stripping voltammetry methods, differential pulse anodic stripping voltammetry with deposition at a hanging mercury drop electrode (HMDE) was chosen for reasons of required accuracy, minimal deposition time, and availability of equipment.

Experimental

The concentrations of lead sulphate in water and in aqueous sulphuric acid solutions, equilibrated at various temperatures, were determined using differential pulse anodic stripping voltammetry (DPASV) at a hanging mercury drop electrode, calibrated by determination of standard solutions containing known quantities of lead (16). The work was carried out cooperatively at the Defence Research Establishment Ottawa (DREO) and at the Cominco Product Research Centre (CPRC), using essentially the same methods but with some differences of detail as discussed below. At CPRC lead sulphate solubilities were determined in pure water and in three concentrations of sulphuric acid: 0.1, 1.0, and 4.4 *M* at temperatures from 25°C to near the freezing point of the solutions, or to −40°C for 4.4 *M* acid. At DREO measurements were also made for pure water and a more extensive study of 35% sulphuric acid was carried out covering a temperature range from +25°C to −50°C.

Apparatus and Instrumentation

A Princeton Applied Research Corporation polarograph (PARC Model 174A), with HMDE and polarographic cell, was used. At DREO the reference electrode was $Hg/Hg_2SO_4/35\%\ H_2SO_4$ and at CPRC a PARC saturated calomel electrode was used. The pulse (25 mV pp) was superimposed on a 2 mV/s potential scan. The current was sampled at the end of, and immediately before, the application of each pulse and the difference was recorded on a suitable *x–y* or *x–t* recorder.

Thermostatted ethanol–water baths (FTS Multicool, FTS Systems Inc., Stone Ridge, NY) were used to equilibrate solutions (±0.3°C). A magnetic stirrer, built into the bath, was used to stir the solution by means of a magnetic bar in the 1 L glass (DREO) or 500 mL polyethylene (CPRC) bottle. In later experimental work at DREO, this stirrer failed and periodic manual agitation was required during the lengthy equilibration periods. The same magnetic stirrer stirred both the solution and the bath fluid at CPRC, but at DREO, a paddle stirrer was used for the bath so that stirring of the solution and the bath fluid were independent.

Chemicals and Purity

Standard solutions of acidified lead nitrate were made up using high purity (<1 ppb Pb) nitric acid (Baker Ultrex®) and water which was prepared by multiple distillation, pyrodistillation (17), deionization, pre-electrolysis, or a combination of these. The standard solutions and the solvent were periodically checked by comparison of new standard solutions with older ones or by blank runs on solutions containing no added lead, using AA or DPASV. The lead concentrations of the solvent water were generally less than 2 ppb. Reagent or analytical grades of $PbSO_4$, $PbNO_3$, and sulphuric acid were normally used. For runs with added chloride or for blank determinations in sulphuric acid, Baker ULTREX® acids (<1 ppb Pb) were used. Care was taken to ensure that all solutions containing lead were acidic (pH < 2) at all times, whether they were in glass or polyethylene containers, to prevent significant lead adsorption on container surfaces (18).

At DREO, the polarographic cell and all glassware were soaked in 30% nitric acid for several hours and rinsed in lead-free (<1 ppb) distilled water before each use and the cell was dried in a vacuum oven following the final rinse. At CPRC, blank determinations were repeated for dilute nitric acid solutions following the rinse step until the DPASV lead peak reached a steady value characteristic of less than 3 to 4 ppb Pb before proceeding to the analysis of the unknown samples.

Mercury was triply distilled, with further prior purification steps at DREO such as passage through a pin-hole filter, agitation with an air stream under dilute nitric acid and a Hulett distillation procedure (19). Nitrogen for deoxygenation was scrubbed, by passage through vanadous chloride solutions (20) and water, before admission to the cell. Disposable Eppendorf pipettes were used for transfer (spiking) of standard solutions.

Analytical Procedures

At each temperature of the study, sulphuric acid solutions containing excess solid lead sulphate were equilibrated with continuous and intermittent stirring. From time to time, samples were withdrawn for analysis following a settling period during which the solutions were not stirred. At DREO 1 mL samples were withdrawn through a medium-porosity fritted disc after an overnight stand without stirring. At CPRC, to avoid excessive temperature excursions, due to the ganging of the two

stirring systems, settling times of only 5 to 10 min were allowed. For 35% acid, a relatively inefficient glass wool – filter paper – glass wool filtration system was used at CPRC but this was changed to a medium-porosity fritted disc and filter paper for the lower acid concentrations. For the 35% H_2SO_4 solutions it was found necessary to dilute the sample 10- to 20-fold in order to eliminate background noise and loss of reproducibility. Accordingly at DREO, the 1 mL samples were added to 20 mL of water in the polarographic cell. At CPRC for the lower concentrations of acid, 12 mL samples were withdrawn, the first being used to rinse the sampling system and the second being added to the cell or transferred to a polyethylene storage bottle containing 4 drops of concentrated ULTREX® nitric acid.

Dilution of the sample of 35% acid carried with it the disadvantage of necessitating a correction for the lead contributed by the dilution water, which was done in three ways. Firstly, in most of the early determinations, this correction (~1 ppb) was obtained for the dilution water, acidified with ULTREX® nitric acid directly. In the second method, two 1 mL aliquots of the unknown were added to the solution and determinations made after each addition. The difference in currents between the second and first aliquot could then be taken as due to the second aliquot only. The results using both methods agreed within experimental error.

Finally a third method of eliminating background and other dilution water contributions to the measured current was used for the last analyses of 35% H_2SO_4 at 25°C, 0°C, −20°C, and −40°C. This emerged as the method of preference. Twenty mL of 0.5 *M* ULTREX® hydrochloric acid solution was added to the polarographic cell and degassed for at least 45 min by nitrogen bubbling through the cell. The HCl was added to desorb organic contaminants which may have been adsorbing on the mercury drop and causing spurious results, due to variations of electroactive area, from run to run. It has been shown (21) that many organic molecules which are adsorbed from sulphate solutions at the potential of the lead peak are desorbed in chloride solutions.

One or two aliquots of standard solution were added to the supporting electrolyte before addition of 1 mL of the unknown, followed by at least three more standard additions. Without such prior additions of lead, sensitivity often appeared to change subsequent to addition of the unknown. After each addition, lead was deposited on the mercury drop at a uniform stirring rate and for a fixed selected potential and time. The differential pulse polarograms were then run at room temperature. Some typical results obtained for samples from solutions of 35% sulphuric acid equilibrated at −40°C are shown in Fig. 1. The differences between the peak current in the solutions containing the unknown plus the standard additions and the peak current immediately prior to the addition of the unknown are plotted against the lead added to the unknown as standard additions. The intercept at zero then gives the concentration of lead in the unknown, which must then be corrected for the dilution factor. Thus the concentrations shown are those in the polarographic cell; the concentration in the 1 mL sample of unknown before dilution was approximately 20 times larger than shown by the intercept.

The third procedure (described above) appeared to give the best reproducibility and most constant detection sensitivity during a series of lead additions (such as in Fig. 1). Furthermore it automatically corrected for any residual lead contributed by the dilution water. For these reasons it was found to be the preferred method, although it was only used for a limited part of the work (see Fig. 2).

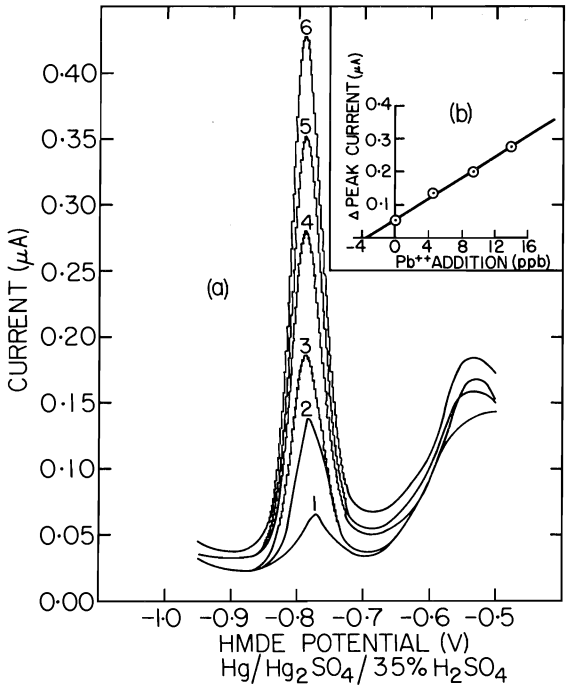

FIG. 1. (*a*) Plots of experimentally observed pulsed anodic stripping scans for 20 mL solutions of 0.5 *M* HCl supporting electrolyte, degassed for 45 min using N_2 passed through a vanadous chloride scrubber with no addition (*1*) and with additions of 10 μL of a $PbNO_3$ standard solution (0.0100 g/L lead), i.e. 1.00×10^{-7} g of lead (*2*); plus 1 mL of 35% sulphuric acid, saturated with $PbSO_4$ at −40°C (*3*); plus three more 10 μL additions of the standard lead nitrate solution (*4*, *5*, and *6*). (*b*) Plot of current peak heights for peaks *3* to *6* minus the peak height of peak *2*, from (*a*) vs. the increment by standard addition of concentration of lead to the 20 mL solution containing the unknown lead sulphate aliquot (i.e. peak *3* is plotted as zero added lead).

Results and Discussion

Treatment of Data

For the equilibrium

[1] $$PbSO_4(s) \rightleftharpoons Pb^{2+}(aq) + SO_4^{2-}(aq)$$

the solubility product at constant pressure can be shown (22) to vary with temperature according to a form of the van't Hoff isochore:

[2] $$[\mathrm{d} \ln K_{sp}/\mathrm{d}(1/T)]_P = -\Delta H^0/R$$

for ideal solutions where ΔH^0 is the standard enthalpy of solution.

This equation can be rewritten as:

[3] $$\left(\frac{\mathrm{d} \ln C_{Pb^{2+}(satn)}}{\mathrm{d}(1/T)}\right)_P + \left(\frac{\mathrm{d} \ln C_{SO_4^{2-}(satn)}}{\mathrm{d}(1/T)}\right)_P + \left(\frac{\mathrm{d} \ln \gamma_\pm^{\,2}}{\mathrm{d}(1/T)}\right)_P = -\frac{\Delta H^0}{R}$$

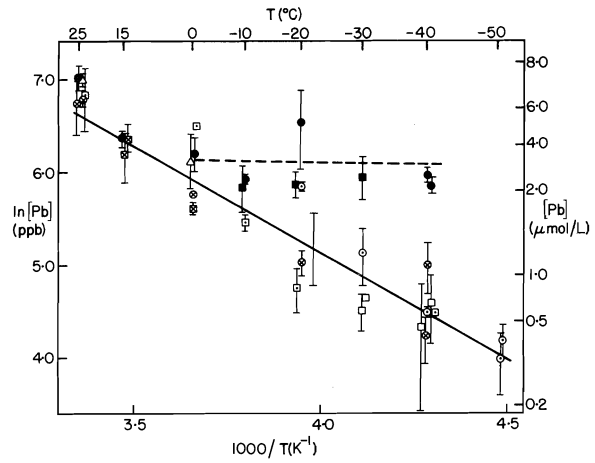

FIG. 2. Logarithm of experimentally determined values of saturation lead concentration in 35% sulphuric acid as a function of reciprocal equilibration temperature: data of Craig and Vinal (8), △; CPRC data for solutions previously equilibrated at a higher temperature, ●, or a lower temperature, ■; DREO data for solutions previously equilibrated at a higher temperature, ⊙, or at a lower temperature, ⊡, and containing no chloride; DREO data for solutions previously equilibrated at a higher temperature, ⊗ or at a lower temperature, ⊠, determined in 0.5 *M* HCl solutions. Right hand ordinate scale refers to volume at 25°C.

where $\gamma_{\pm}$ is the stoichiometric mean molal activity coefficient of $PbSO_4$.

If concentrations are expressed as molal quantities (or on any other weight basis) the analytical concentration of sulphate will be negligibly dependent on temperature in sulphuric acid which is sufficiently concentrated that the contribution to the total sulphate concentration due to lead sulphate dissociation is negligible. Then if the temperature coefficient of $\gamma_{\pm}$ can be neglected, the following approximation is obtained

$$[4] \qquad \left(\frac{\mathrm{d} \ln C_{Pb^{2+}(satn)}}{\mathrm{d}(1/T)}\right)_P \simeq -\frac{\Delta H^0}{R}$$

In pure water, the first two terms of eq. [3] contribute equally to ΔH^0 and the third term represents the variation of interionic forces with temperature, including ion-pairing effects. In sulphuric acid solutions, where the main source of sulphate ion is the acid, the third term will also include acid association effects.

From a plot of $\ln C_{Pb^{2+}(satn)}$ vs. $1/T$, ΔH^0 can be estimated from the slope according to eq. [4]. The value of the slope will be $-\Delta H^0/R$ in moderately concentrated acid solutions and $-\Delta H^0/2R$ (by comparison with eq. [3]) in pure water.

The analytical results obtained for 35% sulphuric acid solutions saturated with lead sulphate are given in Fig. 2. The points represent sets of experimental results grouped according to the supporting electrolyte (presence of chloride or quantity of sulphuric acid added), and modifications of experimental technique or chronology. The solid straight line was obtained from a linear regression analysis of 81 concentrations, experimentally determined at DREO. A correlation coefficient of -0.91 was obtained with a slope of $2.29 \pm 0.23R$ at the 95% confidence level, corresponding to a value of $\Delta H^0 = 4.56 \pm 0.46$ kcal mol^{-1}.[5] The standard error about the central point is indicated by the vertical bars. Where the point plotted represents an average of at least three experimental determinations, the standard deviation is indicated by vertical bars. Where no bars appear the point represents only two determinations.

Results obtained at CPRC and by Craig and Vinal, using a dithizone method (8), are also shown for comparison. At temperatures of 0 to -40°C (broken line) there is very little correlation (correlation coefficient $= -0.26$) between the solubilities (determined at CPRC) and temperature. The correlation improves but remains poor (-0.47) if the 15°C data are included. This is probably due to inadequate settling time (5–10 min) and inadequate filtration, resulting in the inclusion of suspended lead sulphate in the sample. As noted previously, the filtration system was changed for later CPRC work, for which $PbSO_4$ concentrations were much higher; inclusion of suspended lead did not appear to be a problem at the lower H_2SO_4 concentrations and at high temperatures. Reasonably close agreement with the dithizone method (8) was obtained at 0 and 25°C.

When the linear regression analysis was repeated, including the Craig and Vinal (8) and the CPRC data for 0–25°C, along with the 24 DREO points plotted in Fig. 2, a correlation coefficient of -0.95 was obtained giving a value of $\Delta H^0 = 4.74 \pm 0.61$ (95% confidence). Even at the 75% confidence level, where the estimated error term is one-half that given, these two samples are insignificantly different.

Results obtained for the three sulphuric acid concentrations and for pure water, in the temperature range of 0 to 25°C, are similarly plotted and compared with literature values in Fig. 3. Because of the limited number of points, the uncertainties in ΔH^0 given are at the 75% confidence level. There is no statistically significant dependence of ΔH^0 on concentration within the limits of experimental uncertainty. Thus a reasonable estimate of lead sulphate solubility at a sulphuric acid concentration in the

[5] 1 kcal = 4.1840 kJ.

range of 0 to 4.5 M and 0 to 25°C would be obtained by application of the van't Hoff isochore using $\Delta H^0 = 5.6 \pm 0.5$ kcal mol^{-1} and an experimental value of solubility for the same acid concentration at only one temperature. A somewhat more accurate estimate to include temperatures below 0°C, and for acids of battery strength, would be obtained from a value of $\Delta H^0 = 4.7 \pm 0.3$ kcal mol^{-1} (75% confidence).

Although the larger errors in the higher temperature data of Fig. 3 make it impossible to determine a concentration dependence of ΔH^0, the more precise data of Fig. 2 may correspond to a genuinely lower value of ΔH^0 in 4.5 M acid, compared to 1.0 M acid or less.

All of these values of ΔH^0 are appreciably higher than the value of 3.0 kcal mol^{-1} derived from emf (23) measurements or from standard heats of formation (24). Even for the case of lead sulphate in pure water, which one might expect to most closely obey the Debye–Hückel theory, and therefore give values of ΔH^0 most comparable to those from emf data, measurements of the temperature dependence of solubility in the range 0 to 25°C consistently yield values of ΔH^0 greater than those derived from emf measurements. From solubility determinations by five groups of workers, using gravimetric and conductivity methods, over the range 0 to 25°C (11), a value of $\Delta H^0 = 5.9$ kcal mol^{-1} can be calculated. Determinations by other groups using a lead chromate-iodometric method (10, 11, 14) yield values of $\Delta H^0 = 4.0$ kcal mol^{-1} over the range 0 to 35°C but 3.6 kcal mol^{-1} for 25 to 50°C.

This discrepancy cannot be explained as due to increasing non-ideality of solution as temperature decreases, which might have made neglect of the third term of eq. [3] unjustified. If $\gamma_\pm$ becomes smaller as the temperature decreases, due to increased ion pairing for example, or as predicted by Debye–Hückel theory, neglect of this term would yield values of ΔH^0 smaller than the true values, since the third term of eq. [3] would be negative. Nor can the discrepancy be explained as due to insufficient equilibration of solutions or uptake of suspended lead sulphate in the samples, since both these experimental problems would cause a reduced dependence of measured lead content on temperature and (again) a smaller derived value of ΔH^0 than the true value. Thus the discrepancy would become even larger if the temperature coefficient of $\gamma_\pm$ could not be neglected.

One possible reason for the discrepancy may be related to some unreliability of the temperature coefficient of the standard emf of the lead – lead sulphate electrode, on which the value of $\Delta H^0 = 3.0$ kcal mol^{-1} appears to be based. Harned and Hamer (25), whose work yields a value of 2.9 kcal mol^{-1}, formed an adverse opinion of the reliability of this electrode in acid solutions (26). This may be related to the formation of oxides or basic sulphates beneath the oxide layer (4, 6). Other emf measurements on the lead – lead sulphate electrode and the lead amalgam – lead sulphate electrode (26) yield values of ΔH^0 of 3.7 and 3.8 kcal mol^{-1}, respectively.

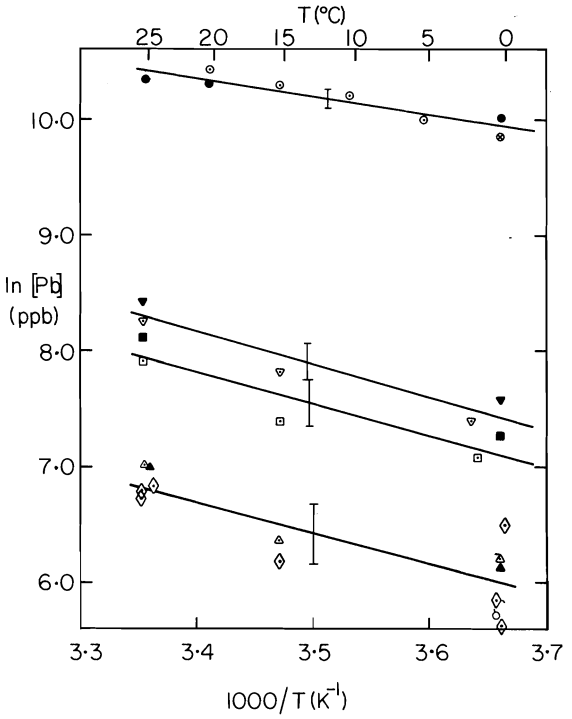

FIG. 3. Logarithm of lead concentration in water and in sulphuric acid solutions saturated with lead sulphate at various temperatures. Water: ●, from refs. 10, 14; ⊗, from ref. 12; ⊙, CPRC data; – slope × $2R = \Delta H^0 = 6.2 \pm 1.4$ kcal mol^{-1} for fitted least-squares line (75% confidence level). 0.1 M H_2SO_4: ■, from ref. 8; ⊡, CPRC data; – slope × $R = \Delta H^0 = 5.4 \pm 1.9$ kcal mol^{-1}. 1.0 M H_2SO_4: ▼, from ref. 8; ▽, CPRC data; – slope × $R = \Delta H^0 = 5.6 \pm 1.5$ kcal mol^{-1}. 35% (4.5 M) H_2SO_4: ▲, from ref. 8; △, CPRC data; ◇, DREO data; – slope × $R = \Delta H^0 = 5.2 \pm 1.2$ kcal mol^{-1}.

Since there appears to be good reason to believe that the value of $\Delta H^0 = 4.7 \pm 0.6$ kcal mol^{-1} (95% confidence level) obtained from Fig. 3 is not too high, some re-examination of the E^0 values may be in order to resolve the discrepancy.

Ion Pairing Effects

The probable effect of change of degree of ion pairing with temperature on the calculated values of ΔH^0 has already been indicated. In the experimental work described, the concentration of free unpaired

ions in the sulphuric acid solutions was measured using DPASV by means of calibration using lead nitrate standard additions for which the degree of ion pairing would be expected to be small. The 35% acid was diluted by a factor of at least 10 and normally 20 for DPASV analyses in order to reduce the concentration of ion pairs as much as possible, yet retain a sufficiently concentrated total lead content to permit precise analyses. Other researchers cited, complexed the lead as dithizone (8, 9), or precipitated the lead and determined it as lead chromate (10, 13, 14). In spite of the different methods used, generally good agreement between this work and that of other workers was obtained with the exception of the gravimetric study of Crockford and Brawley (14) for sulphuric acid solutions. (Their results for pure water, however, were obtained by iodometric titration of the chromate and were in good agreement with other determinations.)

In order to assess the extent and importance of ion pairing at 25°C, the overlapping and consistent experimental data of Craig and Vinal (8) and Purdum and Rutherford (10) for lead sulphate solubility as a function of sulphuric acid concentration were used. The latter data, obtained at 20°C, were corrected to 25°C using an equation of the form of eq. [4] for the correction. The values are given in Table 1 as a function of sulphuric acid concentration. These are also shown in Fig. 4, as a plot similar to that given by Craig and Vinal (8) although their temperature correction to the Purdum and Rutherford data was somewhat less theoretically based than that used here.

From the experimentally determined lead solubility, it is possible to calculate the apparent mean ionic activity coefficient $(f_\pm)_a$ from the solubility product,

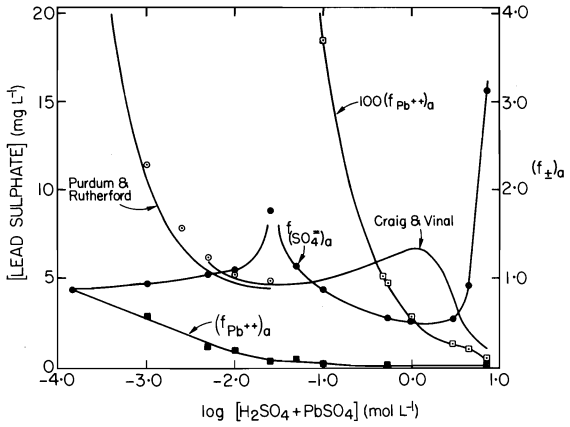

FIG. 4. Values of lead sulphate solubility as determined by Craig and Vinal (8) at 25°C (solid curve) and Purdum and Rutherford (10) at 20°C corrected to 25°C using a van't Hoff isochore for extrapolation (solid curve) or a linear extrapolation (8) (open circles). Values of calculated apparent ionic activity coefficients (see text) for sulphate ion (●), lead ion (■), and lead ion expanded 100 times (⊡).

using values of the sulphate ion concentration (27) determined by Raman spectroscopy (28–30).

$$[5]\quad K_{sp} = a_{Pb^{2+}}a_{SO_4^{2-}} = (f_\pm)_a^2 C_{Pb}[SO_4^{2-}] = 1.585 \times 10^{-8}\ \text{mol}^{-2}\ \text{L}^{-2}$$

The term $(f_\pm)_a$ is an apparent value as is the apparent concentration of lead ion C_{Pb}, which is the sum of the concentrations of free lead ions and of ion pairs in solution:

$$[6]\quad C_{Pb} = [Pb^{2+}] + [PbSO_4]_{aq}$$

Thus $(f_\pm)_a$ absorbs any errors due to a lack of knowledge of ion pairing by treating the electrolyte as if only unpaired ions existed. The values of $(f_\pm)_a$

so calculated are given in the third column of Table 1. From the stoichiometric mean molal activity coefficients for sulphuric acid solutions (31), a formal sulphate ion activity can be calculated, which can be combined with the solubility product to give a value of lead ion activity. From the spectroscopically determined sulphate ion concentrations and the measured lead solubilities, formal values of the apparent lead and sulphate mean ionic activity coefficients, respectively, can be calculated. These have been plotted in Fig. 4.

Ion pairing can be taken into account explicitly, and values of $f_\pm$ (for free ions) can be calculated, given a value for the association constant of lead sulphate

$$[7] \quad K_{assn} = [PbSO_4]_{aq}/(f_\pm)^2[Pb^{2+}][SO_4^{2-}]$$

for the equilibrium

$$\begin{matrix} & (1-\alpha)C_{Pb} & \alpha C_{Pb} & [SO_4^{2-}] \\ [8] & PbSO_4(aq) & \rightleftharpoons Pb^{2+}(aq) & + SO_4^{2-}(aq) \end{matrix}$$

where, for an ionization constant of the ion pair, α, the concentrations of each species are indicated above the equation. Then

$$[9] \quad K_{assn} = (1-\alpha)/\alpha(f_\pm)^2[SO_4^{2-}]$$

where

$$[10] \quad [SO_4^{2-}] = [SO_4^{2-}]_a + \alpha C_{Pb}$$

i.e. the sum of sulphate ion contributed from the sulphuric acid solution and that contributed by the dissociation of lead sulphate, and

$$[11] \quad K_{sp} = \alpha (f_\pm)^2 C_{Pb} [SO_4^{2-}]$$

Equations [9] to [11] can be solved directly to obtain values of $f_\pm$ and α:

$$[12] \quad \alpha = 1 - [K_{sp}K_{assn}/C_{Pb}]$$

$$[13] \quad f_\pm = (K_{sp}/\alpha C_{Pb}[SO_4^{2-}])^{1/2}$$

although at concentrations of H_2SO_4 between 0.000 and 0.001 M, where the terms on the right hand side of eq. [10] would be comparable to one another, an iterative process might be necessary to obtain values of $f_\pm$ and $[SO_4^{2-}]$. A value of the association constant, given by $\log K_{assn} = 2.4$ (32), is independently available from conductivity and radiochemical solubility measurements of $PbSO_4$ in water and Na_2SO_4 solutions (29). The values for $[SO_4^{2-}]$, $f_\pm$, and α, so obtained, are given in columns 4 to 6 of Table 1. In column 7, the concentration of unpaired lead is also given.

It is apparent from Table 1 that at concentrations of sulphuric acid greater than 0.1 M, more than 25% of the lead in solution is bound up in ion pairs and that in battery strength acid, more than half is so bound. The formation of these neutral complexes in solution has been found to be slow (29) in agreement with our observations that several days of continuous stirring or several weeks of intermittent stirring were necessary before obtaining time-invariant solubilities. For example the lowest solubility point at -40°C in Fig. 2 was an average for solutions previously at 25°C and equilibrated for 3 to 7 weeks at -40°C; during this time the measured solubilities decreased from 82 ppb after 22 days of equilibration to 56 ppb at 33 days and 51 ppb at 47 days. This would suggest that if the values of measured solubility at very low temperatures are in error, they are too high for solutions previously at higher temperatures and in such a case the value of ΔH^0 estimated is too low. The time required for equilibration following an increase in temperature or dilution of the sample seemed to be less. There was no apparent increase of the peak current with time for successive scans, following dilution of the 1 mL unknown sulphuric acid aliquot by the 20 mL of acidified water in the polarographic cell which one might expect if ion pair dissociation was a slow process.

The values of apparent ionic activity coefficient for sulphate ion, given in Fig. 4, are not altered if $f_\pm$ values are used instead of $(f_\pm)_a$. However, the values of $f_{Pb^{2+}}$ will be greater than those of $(f_{Pb^{2+}})_a$ according to the equation

$$[14] \quad f_{Pb^{2+}} = (f_{Pb^{2+}})_a/\alpha$$

The curve for the lead ionic activity coefficient in Fig. 4 would be increased somewhat at high concentrations of acid if $(f_{Pb^{2+}})_a$ were replaced by $f_{Pb^{2+}}$. However, this will not substantially alter the basic interpretation of the relationship between solubility and activity coefficients which can be drawn from the graph.

Thus the solubility minimum, near 0.025 M H_2SO_4, is due to a strong maximum in the sulphate ion activity, prior to which the common ion effect determines lead solubility. The lead solubility then increases up to an acid concentration of about 1 M because the decreasing sulphate ionic activity coefficient causes a decrease in sulphate activity despite its increasing concentration. There is a minimim in the sulphuric acid activity coefficient at about 1.7 M (30) however, so that sulphate activity increases once again at higher concentrations leading to a further decrease of lead solubility after the maximum.

Summary and Conclusions

The temperature dependence of lead sulphate solubility in 35% sulphuric acid has been determined down to -50°C and confirmed for other acid concentrations and for pure water. Solubility data deter-

mined using DPASV, as well as for those using other analytical methods, appear to give larger positive values of the standard enthalpy of solution, as obtained by application of the van't Hoff equation, than have been obtained from emf data. Values of saturation lead ion and lead sulphate ion pair concentrations at 25°C have been calculated. The data for 35% sulphuric acid are not sufficiently precise to state that ΔH^0 is completely independent of temperature over the temperature range of 25°C to −50°C studied. If subsequent work confirms the linearity of Fig. 4 with greater accuracy, however, the temperature-independent ΔH^0 value may suggest that the degree of ion pairing is independent of temperature since, due to the experimental technique, the measured lead is the sum of paired and unpaired lead in solution. Alternatively, increased ion pairing at lower temperatures may be compensated for by other factors such as shifts of hydration or bisulphate dissociation equilibria.

The lengthy equilibration time required to attain constant concentrations raises a question of the significance of using thermodynamic values of lead sulphate solubilities in trying to interpret lead acid battery behaviour. Based on the present observations, solutions in a battery might exist for days or weeks in a state of supersaturation with respect to lead sulphate, following a discharge or a reduction of temperature. However, the higher surface area (per unit electrolyte volume) of lead sulphate crystals in battery plates might provide more effective equilibration than observed in the solutions studied here. Only accurate measurements of lead sulphate solubility at various temperatures, and with samples from actual batteries, can resolve this question. In the meantime it must be assumed that the kinetics of lead sulphate dissolution and precipitation are of at least as much importance in discussing battery reactions as are the thermodynamics and that assumptions of thermodynamically calculated lead concentrations must be made with caution.

π-Complex equilibria between ethylene and $PdCl_4^{2-}$ in aqueous solution

RAJ N. PANDEY[1] AND PATRICK M. HENRY

Guelph–Waterloo Centre for Graduate Work in Chemistry, Guelph Campus, Department of Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received October 3, 1978

RAJ N. PANDEY and PATRICK M. HENRY. Can. J. Chem. **57**, 982 (1979).

The interaction of aqueous $PdCl_4^{2-}$ with ethylene to form π-complexes has been reinvestigated using a reactor with high efficiency gas–liquid mixing. This reactor permitted study of the equilibria at low $[H^+]$ and $[Cl^-]$, the conditions under which the oxidation of ethylene to acetaldehyde proceeds rapidly.

$$C_2H_4 + PdCl_4^{2-} + H_2O \rightarrow CH_3CHO + 2HCl + Pd(0) + 2Cl^-$$

Previously the π-complex formation had been determined at high $[H^+]$ and $[Cl^-]$ to retard the oxidation reaction which interfered with study of the non-oxidative equilibria.

Two equilibria reactions were reported where K_1 and K_2 have appreciable values.

$$PdCl_4^{2-} + C_2H_4 \underset{}{\overset{K_1}{\rightleftharpoons}} PdCl_3(C_2H_4)^- + Cl^-$$

$$H_2O + PdCl_3(C_2H_4)^- \overset{K_2}{\rightleftharpoons} PdCl_2(H_2O)(C_2H_4) + Cl^-$$

The present measurements give K_1 values close to those previously reported: $K_1 = 19.6$ at $\mu = 2\ M$ (adjusted with $NaClO_4$); 11.0 at $\mu = 3\ M$ (adjusted with $NaClO_4$); and 14.7 at $\mu = 3\ M$ (adjusted with $LiClO_4$). However, the K_2 values are much less than those reported earlier. Thus the maximum possible value of K_2 at $\mu = 3\ M$ ($LiClO_4$) consistent with the present data is less than 0.01 while the previously reported value was 0.22. Possible reasons for the differences between the two studies are discussed.

The values of the aquation constant K_h needed for treating the gas uptake data were determined spectrally

$$PdCl_4^{2-} + H_2O \overset{K_h}{\rightleftharpoons} PdCl_3(H_2O)^- + Cl^-$$

and found to be 0.012 at $\mu = 2\ M$ and 0.0060 at $\mu = 3\ M$ ($NaClO_4$). Spectra taken at high [Pd(II)] indicate dimeric species are *not* formed under these conditions.

RAJ N. PANDEY et PATRICK M. HENRY. Can. J. Chem. **57**, 982 (1979).

Faisant appel à un réacteur permettant un mélange gaz/liquide très rapide, on a réétudié l'interaction entre le $PdCl_4^{2-}$ aqueux avec l'éthylène formant des complexes π. Ce réacteur a permis d'étudier l'équilibre à de basses concentrations de H^+ et de Cl^-, les conditions permettant une oxydation rapide de l'éthylène en acétaldéhyde.

$$C_2H_4 + PdCl_4^{2-} + H_2O \rightarrow CH_3CHO + 2HCl + Pd(0) + 2Cl^-$$

Antérieurement, on avait déterminé la formation du complexe π à des concentrations élevées de H^+ et de Cl^- afin de retarder la réaction d'oxydation qui interfère avec l'étude de l'équilibre non-oxydant.

On avait rapporté l'existence de deux réactions d'équilibre possédant des valeurs de K_1 et de K_2 importantes.

$$PdCl_4^{2-} + C_2H_4 \underset{}{\overset{K_1}{\rightleftharpoons}} PdCl_3(C_2H_4)^- + Cl^-$$

$$H_2O + PdCl_3(C_2H_4)^- \overset{K_2}{\rightleftharpoons} PdCl_2(H_2O)(C_2H_4) + Cl^-$$

Les mesures effectuées dans le présent travail donnent des valeurs de K_1 semblables à celles rapportées antérieurement: $K_1 = 19.6$ à $\mu = 2\ M$ (ajusté avec du $NaClO_4$); 11.0 à $\mu = 3\ M$ (ajusté avec du $NaClO_4$); et 14.7 à $\mu = 3\ M$ (ajusté avec du $LiClO_4$). Toutefois les valeurs de K_2 sont beaucoup plus faibles que celles rapportées antérieurement. Ainsi la valeur maximale possible pour K_2 à $\mu = 3\ M$ ($LiClO_4$) et en accord avec les données actuelles est moins que 0.01 alors que la valeur rapportée antérieurement est 0.22. On discute des raisons qui permettraient d'expliquer les différences entre les deux études.

On a déterminé spectrométriquement les valeurs pour la constante, K_h, d'aquation nécessaire

---

[1]Present address: Guelph Chemical Laboratories, 500 York Road, Guelph, Ont., Canada N1E 3J4.

0008-4042/79/090982-08$01.00/0

pour le traitement des données d'assimilation des gaz et on a trouvé que cette constante est égale à 0.012 à $\mu = 2\ M$ et 0.0060 à $\mu = 3\ M$ ($NaClO_4$).

$$PdCl_4^{2-} + H_2O \underset{}{\overset{K_h}{\rightleftharpoons}} PdCl_3(H_2O)^- + Cl^-$$

Des spectres déterminés à des concentrations élevées de Pd(II) indiquent qu'il n'y a *pas* de formation d'espèces dimères dans ces conditions.

[Traduit par le journal]

Introduction

The basic reaction of the Wacker Process for acetaldehyde manufacture is the oxidation of ethylene by $PdCl_4^{2-}$ in aqueous solution to give acetaldehyde (1). The kinetics and mechanism of [2]

$$[1] \quad C_2H_4 + (1/2)O_2 \xrightarrow[\text{aq.HCl}]{\overset{PdCl_2}{CuCl_2}} CH_3CHO$$

$$[2] \quad PdCl_4^{2-} + C_2H_4 + H_2O \rightarrow CH_3CHO + Pd(0) + 2HCl + 2Cl^-$$

have been studied by several groups of researchers (1–10). There is general agreement that under a range of reaction conditions ($[Pd(II)] = 0.005$–$0.04\ M$; $[Cl^-] = 0.1$–$1.0\ M$; $[H^+] = 0.04$–$1.0\ M$), the rate expression is given by [3]. Analogous rate expressions have been found for other acyclic olefins (8, 11).

$$[3] \quad \frac{-d[C_2H_4]}{dt} = \frac{k_1[PdCl_4^{2-}][C_2H_4]}{[H^+][Cl^-]^2}$$

On the basis of the kinetic studies plus other evidence, the following general reaction sequence is accepted by most workers in the field.

$$[4] \quad PdCl_4^{2-} + C_2H_4 \underset{}{\overset{K_1}{\rightleftharpoons}} \underset{\mathbf{1}}{PdCl_3(C_2H_4)^-} + Cl^-$$

$$[5] \quad \mathbf{1} + H_2O \underset{}{\overset{K_2}{\rightleftharpoons}} \underset{\mathbf{2}}{PdCl_2(H_2O)(C_2H_4)} + Cl^-$$

$$[6] \quad \mathbf{2} + H_2O \xrightarrow{-H^+} \underset{\mathbf{3}}{PdCH_2CH_2OH}$$

$$[7] \quad \mathbf{3} \rightarrow CH_3CHO + Pd(0)$$

In spite of the effort expended in studying this oxidation there is still controversy concerning several aspects of the reaction pathway. For instance the form of the rate expression at low $[H^+]$ and $[Cl^-]$ (2), the mode of transformation of **2** to **3** (12) as well as the mode of decomposition of **3** to final products (2) have all been topics of discussion. Two controversial points, which are experimentally related, involve the form of the rate expression at high [Pd(II)] and the value of K_2 in [5].

Moiseev and co-workers, using a reactor which did not contain a gas phase, were able to fit their data to a two term rate expression (6–8):

$$[8] \quad \frac{-d[olefin]}{dt} = k_I \frac{[PdCl_4^{2-}][olefin]}{[H^+][Cl^-]^2} + k_{II} \frac{[PdCl_4^{2-}]^2[olefin]}{[H^+][Cl^-]^2}$$

One characteristic of the experimental technique of these workers is that the calculation of the rate constant from the experimental data is very sensitive to the values of K_1 and K_2 in [4] and [5], respectively. Unfortunately these values were not measured under conditions the oxidation kinetics were determined but rather at high $[Cl^-]$ and $[H^+]$ to prevent the oxidation reactions, [6] and [7], from interfering with the equilibrium measurements (13–16). Furthermore, although constant ionic strength was maintained with ClO_4^- as $[Cl^-]$ was varied, the variation in $[Cl^-]$ was in some cases as much as 75% of the total ionic strength. The principle of constant ionic strength would not be expected to hold with such changes in solution composition.

One of the authors used a high efficiency gas–liquid mixing reactor to measure the kinetics of the oxidation of ethylene and other acyclic olefins (9). This reactor, which contained a gas phase, was suitable for measuring values of K_1 and K_2 under the actual reaction conditions the kinetics were determined. At an ionic strength of 2, adjusted with ClO_4^-, the value of K_2 was found to be less than 10^{-2} from a rather limited set of data. At the same ionic strength Moiseev reported that a value of 0.14 for K_2 is most consistent with his experimental results (7, 16).

Later one of the authors measured the kinetics of the oxidation at high Pd(II) at $\mu = 2\ M$ and found no evidence for the second term (10). It was suggested that the second term may be an artifact arising from using inaccurate values of K_1 and K_2 in treating the kinetic data for the one phase reactor system. However, the very high efficiency gas–liquid reactor was not available for this study and it was later claimed that the second term was not detected because of diffusion limitations (7) of the reactor used.

Since the presence of a second term in the rate expression could have very interesting mechanistic implications in Pd(II) chemistry, it is worthwhile to examine both the π-complex equilibria under the reaction conditions as well as the kinetics at high Pd(II) using a high efficiency gas–liquid mixing reactor. This paper will describe a study of the first, the equilibria between $PdCl_4^{2-}$ and ethylene under the reaction conditions.

Finally it has been suggested (7) that one reason that equilibrium [5] was not detected in earlier studies (9) is that the aquation of $PdCl_4^{2-}$ under the reaction conditions was not taken into account.

$$[9] \qquad PdCl_4^{2-} + H_2O \underset{}{\overset{K_h}{\rightleftharpoons}} PdCl_3(H_2O)^- + Cl^-$$

Thermodynamic values of K_h range from 2–4 × 10^{-2} (17–22). The value of K_h at higher ionic strength might be expected to be lower since $PdCl_4^{2-}$ would be stabilised more than the simply charged ions. One determination of K_h at $\mu = 2\ M$ gave a value of 2.56×10^{-2} (22). This value of K_h would indicate aquation is only important at low $[Cl^-]$. In any case it seems worthwhile to check this value since it is higher than expected from the thermodynamic values. Another point that deserves checking is the possibility that monomer–dimer equilibrium exists at high [Pd(II)].

$$[10] \qquad 2PdCl_4^{2-} \underset{}{\overset{K_D}{\rightleftharpoons}} 2Pd_2Cl_6^{2-} + 2Cl^-$$

The presence of such an equilibrium could seriously affect the interpretation of kinetic data. A potentiometric study suggested that dimeric Pd(II) complexes do not exist under the conditions the oxidation reaction was studied (23). Confirmation of this important point by spectral studies is desirable.

Experimental

Materials

The palladous chloride was purchased from Engelhardt, Inc. All other chemicals were of reagent grade. Preparation of reaction mixtures has been described (10).

Spectral Studies

The spectra were recorded on a Cary 118 spectrophotometer at 25°C. The cells were of 10 mm or 0.5 mm pathlength depending on the palladium(II) concentration.

Ethylene Uptake Studies

The reactor, shown in Fig. 1, has a volume of ca. 500 mL. Near the bottom it has a sintered glass base, sealed to the sides of the reactor. During the course of a reaction the ethylene is continuously circulated through the reactor by means of a varistaltic pump (VP). As the gas passes through the glass frit it is broken into small bubbles. The reaction mixture is also stirred by means of a magnetic stirring bar. The amount of ethylene absorbed is measured using a gas buret. The mercury in the leveling bulb is constantly raised so the levels in the bulb and the gas buret are at the same height, thus maintaining atmospheric pressure. To minimize escape of gas by diffusion through vinyl tubing, glass tubing was used as much as possible to connect the varistaltic pump and gas buret to the reactor. Where flexible tubing was required thick walled vinyl tubing was used. The temperature was maintained by circulating thermostated water at 25.0 ± 0.1°C through the outer jackets of the reactor and gas buret.

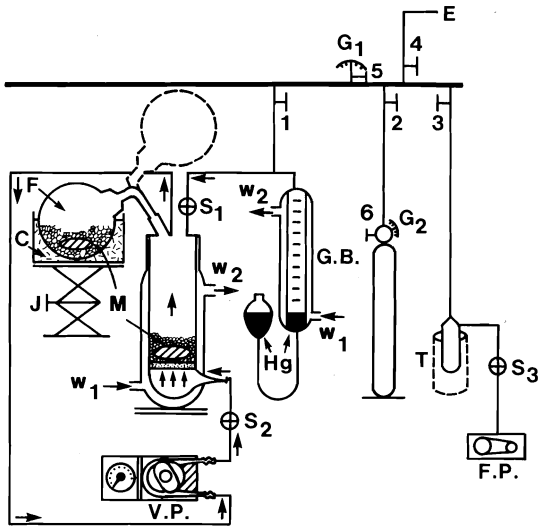

FIG. 1. Schematic diagram of reactor: C, constant temperature bath; J, adjustable jack; E, fume hood; 1–6, metal valves (vacuum tight); S_1–S_3, glass stopcocks; G_1, G_2, gauges; W_1, W_2, inlets and outlets of thermostated water; VP, varistaltic pump; FP, forepump; R, glass reactor; F, delivery flask; M, stirring magnets; G.B., gas buret.

To start a run 25 mL of the reaction solution is placed in the flask (F) which is placed in a constant temperature bath (C) at 25 ± 0.1°C. The bath is held on an adjustable jack (J). After the reaction mixture came to temperature the tube between the Hg leveling bulb and the gas buret was clamped to prevent Hg from flowing into the pump. The valves 1, 2, 3, and 5 and glass stopcocks S_1, S_2, and S_3 were opened and the forepump (FP) turned on to evacuate the system up to the ethylene cylinder. While the pump was on the magnetic stirrer in the flask F was turned on to aid in removing dissolved gases. After a couple of minutes the stirring bar was turned off and ethylene was added until slightly over 1 atm was attained. Then the clamp was removed from the tubing on the gas buret and gas was allowed to escape by means of the valve No. 4 to a fume hood (E). When 1 atm of gas was in the reactor as indicated by the equal mercury levels in leveling bulb and buret, valve No. 4 was closed and the varistaltic pump and magnetic stirring bar in the reactor activated. The reaction solution was then added to the reactor by revolving the flask F to the position indicated by the dotted line.

As it has been suggested that ethylene uptake prior to start of a run could be a source of error (7), the amount of gas uptake was measured by the solution in flask F before transfer to the reactor. For several minutes there is no appreciable gas uptake. Since in an actual run there is only a delay of seconds between charging with ethylene and start of a run, this cannot be a source of error.

Results

All equilibrium studies were carried out at 25°C. The π-complex equilibria studies were made at 1 atm ethylene pressure.

[a] K_h is for equilibrium given by [9]; $[HClO_4] = 0.31$ M for all runs.
[b] Total [Pd(II)] = 7.99×10^{-5} for these runs and 7.79×10^{-5} for the remainder.
[c] Value of K_h calculated from plot of [11] is 1.2×10^{-2} M with $\Delta\varepsilon = 1.62 \times 10^4$.
[d] Value of K_h calculated from plot of [11] is 0.60×10^{-2} M with $\Delta\varepsilon = 2.33 \times 10^4$.

Tetrachloropalladate(II) Aquation Equilibrium

The equilibrium given by [9] was studied at μ = 2 M adjusted with $NaClO_4$ and μ = 3 M adjusted with $LiClO_4$.

Ultraviolet spectra in the range 400–200 nm of solutions at fixed Pd(II) and with $[Cl^-]$ varying from 0.01 to 0.6 M give isosbestic points at 260 and 310 nm, suggesting that the two species are in equilibrium in this range. The changes in spectra indicate that one species is gradually being converted to a second species. At $[Cl^-] = 0.6$ M the conversion is complete and further increase in $[Cl^-]$ causes no change in spectra.

Assuming the equilibrium given by [9] is operative, a relationship between change in optical density and K_h can be derived. This relationship, which has been derived previously (24), is given by [11]

$$\frac{P_0}{\Delta D} = \frac{1}{\Delta\varepsilon l} + \frac{[Cl^-]}{\Delta\varepsilon l} \qquad [11]$$

where P_0 = total [Pd(II)]; $\Delta\varepsilon$ is the difference in extinction coefficients between the two species at a given wavelength, l = pathlength, and $\Delta D = D_\infty - D_i$ where D_i are the optical densities at various $[Cl^-]$ and D_∞ is obtained from the final spectrum above 0.6 M $[Cl^-]$. Plots of $P_0/\Delta D$ vs. $[Cl^-]$ at several [Pd(II)] and different wavelengths give straight lines from which $\Delta\varepsilon$ and K_h can be calculated. Some typical data are shown in Table 1. If the data are treated in a similar fashion assuming [10] is operative, the values of K_D do not remain constant but vary over a factor of about 4. Thus [10] cannot be the correct equilibrium at low [Pd(II)].

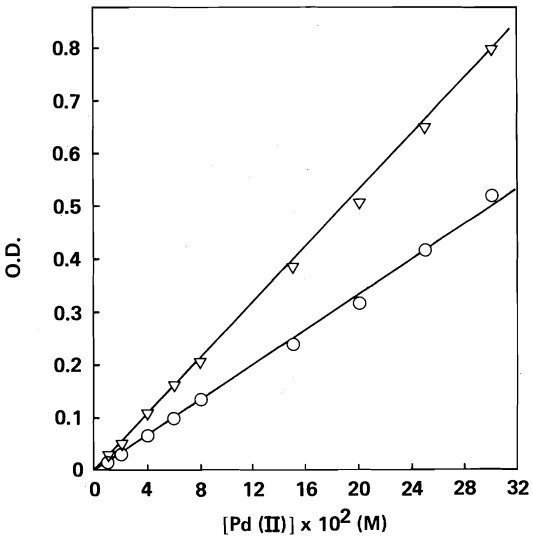

FIG. 2. Plots of O.D. vs. [Pd(II)] at μ = 2 M (adjusted with $NaClO_4$) and 25°C. $[HClO_4] = 0.20$ M, $[Cl^-] = 0.20$ M.

Spectra were also taken at high [Pd(II)] concentration to see if there was any evidence of equilibria such as [10] becoming important in this range. As shown in Fig. 2 there is a linear relationship between optical density and [Pd(II)] indicating that there is no polymeric species formed at high [Pd(II)].

π-Complex Formation

π-Complex formation was determined from initial ethylene uptake using the rapid gas–liquid mixing reactor shown in Fig. 1. The rate of gas absorption this reactor can achieve was determined by the measuring of CO_2 uptake by 0.2 *M* NaOH. The measured rate was 600 mL CO_2/min/25 mL. Since the maximum rate of ethylene uptake due to the oxidation was 10 mL/min/25 mL, the initial fast uptake of ethylene due to ethylene solution and π-complex formation would be complete before any appreciable oxidation occurs. In all runs this was the observed result and if a small correction for uptake due to oxidation was required, it was made by extrapolation to zero time. The amount of uptake due to solubility was determined by blank runs in which all reagents but the palladium(II) chloride were present.

In addition to the equilibrium given in [4] and [5] there is the possibility of the following two equilibria being operative:

$$[12] \quad PdCl_4^{2-} + 2C_2H_4 \overset{K'}{\rightleftharpoons} PdCl_2(C_2H_4)_2 + 2Cl^-$$

$$[13] \quad PdCl_2(C_2H_4)(H_2O) + H_2O \overset{K_3}{\rightleftharpoons} PdCl_2(C_2H_4)(OH)^- + H_3O^+$$

Moiseev found that [12] and [13] were inconsistent with his experimental results (8) and the present study confirms the fact they are not present. Thus values of K_1' calculated at various $[Cl^-]$ varied over a wide range and the amount of π-complex formed was independent of $[H^+]$ thus eliminating [13].

Assuming that the true equilibria are given by [4] and [5] the following equality can be written

$$[14] \quad [C_2H_4]_\varepsilon = [C_2H_4] + [PdCl_3(C_2H_4)^-] + [PdCl_2(C_2H_4)(H_2O)]$$

where $[C_2H_4]_\varepsilon$ represents the total ethylene absorbed and $[C_2H_4]$ is the ethylene solubility.

Dividing [14] by $[C_2H_4]$ and expressing the concentration ratios in terms of K_1, K_2, $[PdCl_4^{2-}]$, and $[Cl^-]$, [15] is readily derived where $\phi = [C_2H_4]_\varepsilon / [C_2H_4]$.

$$[15] \quad \frac{[\phi - 1][Cl^-]^2}{[PdCl_4^{2-}]} = K_1[Cl^-] + K_1K_2$$

Thus a plot of the left hand side of [15] vs. $[Cl^-]$ should give a plot with slope equal to K_1 and intercept equal to K_1K_2. In Fig. 3 is shown the plot of the data at $\mu = 2$ *M* adjusted with $NaClO_4$. Both the original data (9) as well as the present results are included. The data are corrected for the aquation reaction [9], using the value of 0.012 for K_h.

All points but the highest $[Cl^-]$ of the older data fall on a straight line. The least-squares fit excluding this point gives a value of K_1 of 19.6 ± 1.3 from the slope. The intercept is 0.063 which gives a value of 3.2×10^{-3} for K_2. The value calculated using the maximum positive variation of the intercept at the 95% confidence level is 0.33 which gives a maximum K_2 of 0.016. The arrow shows the intercept required to give a K_2 of 0.14, the previously reported value (16). The data used for the plot are listed in Table 2.

A similar plot for $\mu = 3$ *M* adjusted with $NaClO_4$ is shown in Fig. 4. In this case the data were corrected for [9] using $K_h = 0.0060$, the value found for the $LiClO_4$ system at the same ionic strength (see Table

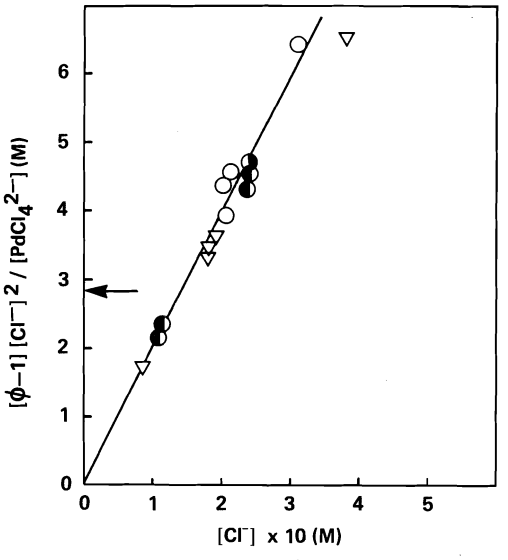

FIG. 3. Plots of $[\phi - 1][Cl^-]^2/[PdCl_4^{2-}]$ vs. $[Cl^-]$ at $\mu = 2$ *M* (adjusted with $NaClO_4$). Data from Table 2. Arrow indicates intercept of Levanda and Moiseev (ref. 16). $[HClO_4]$ = ○, 0.2 *M*; ◐, 0.8, 0.6 *M*; ◑, 0.25 *M*; ▽, corrected data of Henry (ref. 9).

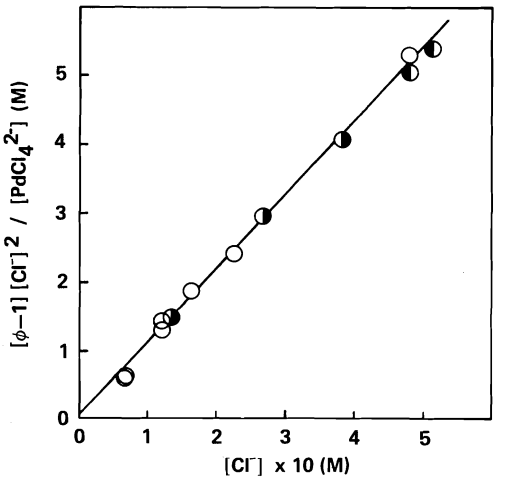

FIG. 4. Plots of $[\phi - 1][Cl^{-2}]/[PdCl_4^{2-}]$ vs. $[Cl^-]$ at $\mu = 3$ *M* (adjusted with $NaClO_4$). Data from Table 3; an average value has been plotted for identical runs. $[HClO_4]$ = ◑, 0.2 *M*; ○, 0.4 *M*; ◐, 0.8 *M*.

[a] K_1 and K_2 defined by [4] and [5], respectively. Ethylene solubility $= 3.27 \times 10^{-3}\ M$.
[b] Cl^- added as NaCl.
[c] Calculated using $K_h = 6.0 \times 10^{-3}$.
[d] These quantities defined by [14] and [15].

1). A value of 11.0 ± 0.3 is calculated from the slope with the intercept being -0.015. The maximum value of the intercept at the 95% confidence level is 0.076 which gives a value of 0.007 for K_2. Data are listed in Table 3. The plot for the $LiClO_4$ at $\mu = 3\ M$ is shown in Fig. 5. The value of 0.0060 for K_h is used to correct the data. The slope is 14.7 ± 1.7 and the intercept is 0.10 which gives a value of 0.007 for K_2. The arrow indicates the intercept which would give a K_2 of 0.22, the previously reported value (16).

Discussion

The most important result of this study is the demonstration that values of K_2 for the equilibrium

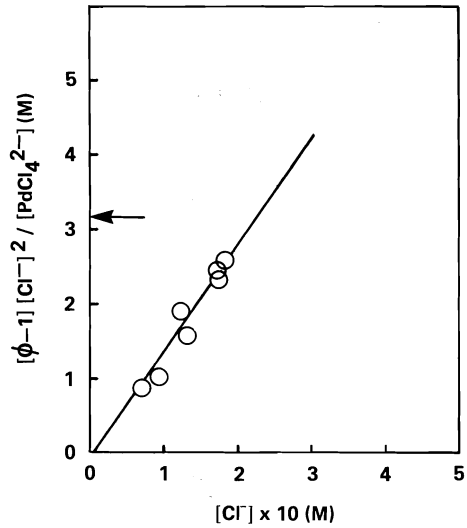

FIG. 5. Plots of $[\phi - 1][Cl^-]^2/[PdCl_4^{2-}]$ vs. $[Cl^-]$ at $\mu = 3\ M$ (adjusted with $LiClO_4$). Data from Table 4. Arrow indicates intercept of Levanda and Moiseev (ref. 16).

given by [5] are actually much less than those reported previously (7, 16) and, in fact, are too small to be accurately measured by the present techniques. Thus in both the $NaClO_4$ systems the intercept of the least-squares treatment of the data is actually negative while the corresponding intercept at $\mu = 2\ M$ gives a K_2 of 3.2×10^{-3} which is approximately 1/40 of the previously reported value of 0.14 ± 0.16. Even the maximum possible intercepts from the data are much below the previous values. This value is 0.016 for the $\mu = 2\ M$ systems and <0.01 for the $\mu = 3.0\ M$ systems with $LiClO_4$ as supporting electrolyte, the previous value was 0.22 (16).

The variation in values of K_2 obtained in the two studies must result from the difference in experimental techniques. In the earlier study the gas uptakes were measured at high $[Cl^-]$ and $[H^+]$ to prevent interference from the oxidation. It is true that a constant ionic strength was maintained with perchlorate ion but the fluctuations in solution composition were quite large. Thus chloride concentration was as high as 75% of the total ionic strength. Errors in this study could arise from two sources. First the extrapolation from the lowest $[Cl^-]$ used to $[Cl^-] = 0$ is quite large. Thus the lowest $[Cl^-]$ used was usually $>0.7\ M$. Extrapolation from this concentration to $[Cl^-] = 0$ must be considerably less accurate than extrapolations from $[Cl^-] \approx 0.1\ M$ as in the present study. Secondly, over the wide range of solution composition used the principle of constant ionic strength would not be expected to hold. A systematic variation in activity coefficients would give an erroneous slope. With such a large extrapolation even small errors in slope would cause large errors in the intercept. In the present study the highest $[Cl^-]$ is less than 20% of the total ionic strength so there should be little or no change in activity coefficients over the range of $[Cl^-]$ used.

As might be expected the differences in K_1 values in the two studies are much less than the K_2 values. This results from the fact that the slope is much less sensitive to the factors discussed above than is the intercept. The value of K_1 of 19.6 at $\mu = 2\ M$ is just a little higher than the average value of 17.4 previously found by one of the writers and the value of 15.0 reported by Levanda and Moiseev (16). At $\mu = 3\ M$ adjusted with $LiClO_4$ the present value of K_1 is 14.8 (16). The $NaClO_4$ system at $\mu = 3\ M$ has a little lower value of 11.0. This difference between the $LiClO_4$ and $NaClO_4$ systems might be expected since anionic species are mainly involved in the equilibrium given in [4] (Table 4).

The absolute values of K_1 and K_2 are of little direct importance to the mechanism of the oxidation of ethylene by aqueous $PdCl_4^{2-}$. It is true that a quantitative knowledge of the concentrations of **1** and **2** in [4] and [5], respectively, under various reaction conditions would allow the more accurate estimation of subsequent rate constants but this is only of basic importance in the demonstration that certain routes, such as [16], are impossible because of diffusion control (9).

$$[16] \qquad PdCl_2(C_2H_4)(H_2O) + OH^- \xrightarrow{\text{slow}} \mathbf{3}$$

However, this last calculation is valid even if K_2 has a value as high as 1.0.

Of more importance is the use of correct values of K_1 and K_2 in calculation of rate constants from experimental data. Errors of the order of those in the previous reported values would not affect the calculated values of the rate constants in the reactions with a gas phase but in the reactions without a gas phase the use of these incorrect values of K_1 and K_2 would cause considerable error in rate constants. Furthermore these errors in K_1 and K_2 will give systematic errors in the calculated rate constants which vary as $[Cl^-]$ and $[PdCl_4^{2-}]$ vary (10). The form of the rate expression at high $[PdCl_4^{2-}]$ as well as a discussion of the errors in K_1 and K_2 on the interpretation of the kinetic data of Moiseev and co-workers will be the topic of a later paper (25).

A few minor points deserve comment. First, the present work confirmed the conclusion of Levanda *et al.* (23) that dimeric species are not present in the reaction system and thus their involvement cannot be responsible for the two term rate expression given by [8].

The previous calculation of equilibrium constants by one of the authors (9) has been criticized because the aquation equilibrium, [9], was not taken into

account (7). This criticism is valid although at the time of the initial measurements the reported values of K_h (26) indicated the correction would be insignificant. In any case the correction is small and the recalculation of the original data (using a K_h of 0.0256) to give a K_2 of 0.05 (7) does not result from this correction but rather the fact the point of highest $[Cl^-]$ is inaccurate. This is obvious from Fig. 3.

The values of K_h determined in this work (0.012 M at $\mu = 3\ M$) are lower than Levanda's values of 0.0256 at $\mu = 2\ M$ and 0.017 at $\mu = 3\ M$ (22) but, as mentioned in the Introduction, his values seem high for the thermodynamic constants reported by a number of other workers.

Finally, several arguments advanced by Moiseev to justify his extrapolation over such a range of Cl^- and ClO_4^- solution compositions at constant μ rebut the suggestions of one of the authors (9) that his values of K_2 were in error because of changes in activity coefficients (8). The main thrust of these arguments is that a change in anion composition over the range used would change the activity coefficients relatively little (<10%). However a *systematic* error of this magnitude over the range of conditions used followed by a long extrapolation from the lowest chloride ion concentration would give a considerable error in the intercept. In actual practice the error would seem to be larger. Thus at $\mu = 2\ M$ the correct slope was found to be 19.6 while the value of Moiseev was 15.0.

Electrochemical synthesis of some 1,2-dimethyl 1,2-disubstituted ethylenes[1]

ROGER N. RENAUD AND PHILIPPE J. CHAMPAGNE

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received August 8, 1978

ROGER N. RENAUD and PHILIPPE J. CHAMPAGNE. Can. J. Chem. **57**, 990 (1979).

The anodic oxidation of sodium acetate in the presence of a series of 1,2-disubstituted ethylenes was performed in acetonitrile–water solution. Under low concentration of substrates, very good yields of the monomeric 1,2-dimethylated products were obtained. In the case of diethyl fumarate, an increase in concentration caused a decrease in the ratio of monomer to polymer when all other parameters were held constant.

The stereoisomers of the products were separated and their physical properties are reported.

ROGER N. RENAUD et PHILIPPE J. CHAMPAGNE. Can. J. Chem. **57**, 990 (1979).

L'oxydation de l'acétate de sodium en présence de molécules d'éthylène substituées en position 1 et 2 dans un mélange acétonitrile–eau fut étudiée. A basse concentration du substrat, de bons rendements en produits diméthylés furent obtenus. Il a été constaté dans le cas du fumarate d'éthyle que le rapport monomère/polymère diminue avec une augmentation de la concentration de l'ester.

Les stéréoisomères des produits furent séparés et leurs propriétés physiques sont rapportées.

The electrochemical oxidation of acetate anions in the presence of unsaturated substrates has been widely studied. Isolated double bonds usually give low yields of a mixture consisting of more than twelve compounds (1, 2). Important quantities of acetoxy and methoxy derivatives were obtained when the reaction was done in methanol. These results can be explained by a mechanism involving cationic intermediates which react with nucleophiles present in the medium. Ethylene has been reported to undergo either additive dimerization (3) or dimethylation (4) depending on the reaction conditions used. Butadiene as substrate also gave very low yields of adducts. The main products isolated in this case were dimers (5). Stilbene gave mainly diacetoxy derivatives which can be explained by a direct oxidation of the substrate (6). When the double bond is activated by one electron withdrawing group such as COMe, CHO, CO_2R, or CN, the radical formed by the addition of the methyl radical at the β-carbon is resonance-stabilized and, therefore, dimerizes in good yields (7). The reaction was represented as follows:

$$CH_3COO^- \xrightarrow{-e} CH_3^\bullet + CO_2$$

$$CH_3^\bullet + H_2C{=}CH{-}Y \longrightarrow CH_3CH_2{-}\dot{C}HY$$

$$2CH_3CH_2{-}\dot{C}HY \longrightarrow \begin{matrix} CH_3{-}CH_2{-}CHY \\ | \\ CH_3{-}CH_2{-}CHY \end{matrix}$$

The objectives of this present study were to determine the effect of two electron withdrawing groups on the methylation of double bonds and to develop a general synthetic procedure for the alkylation of activated double bonds. While our work was in progress a short communication appeared in the literature (8) concerning the methylation of dimethyl fumarate and dimethyl maleate. The authors claimed that the yields of dimethyl 1,2-dimethylsuccinate were nearly quantitative and that the maleate reacted faster than the fumarate. However, their results did not agree with our observations. Therefore, it was decided to complete our systematic study on a series of disubstituted ethylenic molecules.

Experimental

All starting materials were commercially available except for compound **4** which was prepared according to a method described in the literature (9). All melting points are uncorrected. The cell used in this study is illustrated in Fig. 1. Gas–liquid chromatographic analyses and separations were performed respectively on a Fisher/Victoreen Series 4400 and an Aerograph Autoprep model A-700 using a 20 ft × 3/8 in. column, 30% SE 30 on 45/60 chromosorb P. Proton magnetic resonance spectra were taken in deuteriochloroform on a Varian Associates spectrometer model E. M. 360 and are reported in the δ scale. The molecular weight determinations were carried out on a Hitachi Perkin-Elmer RMU-6D mass spectrometer.

Electrolysis of Sodium Acetate in the Presence of an Ethylenic Substrate (General Procedure)

The anodic solution consisted of a solution of the ethylenic substrate (Table 1) in a mixture of acetonitrile (170 mL) and water (70 mL). To this solution was added a solution of NaOH (6 g) in acetic acid (60 mL). The electrolysis was carried out at a current of 1.8 A (140 mA/cm²) at 20–25°C for 6 h or until 0.4 mol of electrons had been transferred. The anodic solution was then concentrated on a rotary vacuum evaporator and the low vapor pressure residue was poured into water (600 mL). The aqueous solution was extracted three to six times with 100

Purification and Physical Properties of the Products

(A) Diethyl 2,3-Dimethylsuccinate **6**

(*i*) From diethyl fumarate (**1**)

Distillation of the extracted oil at 75°C under a pressure of 0.01 Torr gave a colourless liquid which by vpc was mostly **6**, along with a small amount of starting material and traces of side reaction products. The monomeric product was further purified by preparative glc to give a colourless oil in 80% yield. This product, on vpc, showed two approximately equal peaks partly superimposed. This was taken to be a 1:1 mixture of the *meso* and *dl* isomers of **6**: nmr 4.2 (4H, q, J = 6.6 Hz, methylenes), 2.85 (2H, m, methines), 1.28 (6H, t, J = 6.6 Hz, methyls of ester groups), 1.24 (6H, d, J = 7.0 Hz, methyls at C-2 and C-3). *Anal.* calcd. for $C_{10}H_{18}O_4$: C 59.41, H 8.91; found: C 59.57, H 8.80.

Careful collection by preparative glc of the first of the superimposed peaks and the tailings of the second peak gave colourless oils with slightly different retention times on the analytical vpc and whose nmr's and elemental analyses were identical to that given above for the mixture. The slower moving fraction was hydrolyzed under acidic conditions to a diacid which melted at 124–127°C (literature (10) value for the *dl*-diacid is 127°C). The faster moving peak then corresponds to the *meso*-diester.

(*ii*) From diethyl maleate (**2**)

Distillation of the extracted oil as above gave a colourless oil which, by analytical vpc, contained **2** (70% of initial amount) and the same mixture of *meso*:*dl*-dimethylated monomer **6** as obtained above but in only 21% yield. No further attempts were made to separate these compounds.

(B) 2,3-Dimethylsuccinonitrile (7) from Fumaronitrile (3)

Distillation of the extracted solid and oil mixture at 140°C under a pressure of 0.01 Torr gave a colourless solid oil mixture which on repeated centrifuging in a 'Craig Tube' gave a dry, white solid melting at 45–46°C, and which showed two equal but well separated peaks on the vpc. These were shown to be the *meso*- and *dl*-isomers of **7**. The residual oil, by vpc analysis, also consisted mainly of the same two products plus a small amount of a slower moving product. This mixture was separated by column chromatography (silica gel column with 4:1 hexane/ethyl acetate as eluent). The column chromatography resulted in separation of the two solid products such that each showed only one peak on vpc. A sample of the solid which moved slower on the vpc, when treated with sodium methoxide in methanol, was converted to the same mixture of solids as obtained above.

Meso:*dl* isomeric mixture of **7**: mp 45–46°C (55% yield), nmr 2.73 (2H, m, methines), 1.29 (6H, d, J = 7.0 Hz, methyls); ms *m*/*e* 107 $(M - 1)^+$, 93 $(M - CH_3)^+$, 82 $(M - CN)^+$, 54 $(M/2)^+$. *Anal.* calcd. for $C_6H_8N_2$: C 66.64, H 7.46, N 25.91; found: C 66.34, H 7.42, N 25.79.

dl-Isomer of **7**: mp 57–59°C (assigned as the *dl*-isomer in ref. 10), nmr and ms as above. *Anal.* found for $C_6H_8N_2$: C 66.21, H 7.51, N 25.48.

Meso-isomer of **7**: mp 73.5–75°C (lit. (10) 46°C); nmr and ms as above. *Anal.* found for $C_6H_8N_2$: C 66.40, H 7.31, N 26.02.

(C) 2,3-Dimethyl-N-phenylsuccinimide **8** *from N-Phenylmaleimide* **4**

Extraction of the reaction mixture with CH_2Cl_2 yielded an oily solid product. Repeated extraction of the oil from this mixture with diethyl ether, in which the solid was relatively insoluble, gave a white solid which showed two separate and equal peaks on vpc analysis. This product was shown to be a 1:1 mixture of *cis*- and *trans*-isomers of **8** and corresponded to a yield of 80%. Melting point 124–126°C, nmr 7.40 (5H, m,

aromatic), 3.15 (1H, m, methine), 2.65 (1H, m, methine), 1.4 (6H, d of d's, methyls).

The chromatographic separation on silica gel column gave two different solids each of which had the same retention time on vpc as one or the other of the compounds in the original mixture of solids. These were shown, by comparison of melting points and nmr spectra with the literature values, to be the *cis*-**8** (melting at 127–129.5°C, lit. (11) 126°C) and *trans*-**8** (melting at 144–146°C, lit. 146°C). Treatment of the solid which moved slower on the vpc (*cis*-**8** or *meso*) with sodium methoxide in methanol resulted in its conversion to *trans*-**8** (*dl*) to the extent of about 95% conversion by vpc analysis.

*(D) 2,3-Dimethyl-*N*-ethylsuccinimide* **9** *from* N*-Ethylmaleimide* **5**

The mixture obtained from the extraction was fractionally distilled on a vacuum line. The low vapor pressure oil was collected in a stock trap and consisted of nearly pure *cis*- and *trans*-**9** (88% yield of 1:1 mixture). Pure **9** was obtained by a careful distillation in a Späth bulb at 0.01 Torr: nmr 1.28 (9H, m, methyls), 2.45 and 3.00 (2H, 2m, *cis*- and *trans*-methines), 3.58 (2H, q, methylene), ms *m/e* 155 $(M)^+$, 140 $(M - CH_3)^+$. *Anal.* calcd. for $C_8H_{13}NO_2$: C 61.94, H 8.39, N 9.03; found: C 61.76, H 8.27, N 9.08.

The *cis*- and *trans*-isomers were separated by preparative glc. The product corresponding to the second peak was converted to the product corresponding to the first peak in the presence of a methanolic solution of sodium methoxide. Therefore, assuming that the *trans*-isomer is thermodynamically more stable than the *cis*-isomer, as was found for **8**, the first peak should correspond to the *trans*-isomer and the second peak to the *cis*-isomer.

cis-**9**: nmr 3.56 (2H, q, $J = 7.4$ Hz, methylene), 2.95 (2H, m, methines), 1.2 (6H, d, $J = 7.0$ Hz, methyls at C-2 and C-3), 1.18 (3H, t, $J = 7.4$ Hz, methyl of the *N*-ethyl group). *Anal.* found: C 62.07, H 8.27, N 9.18.

trans-**9**: nmr 3.58 (2H, q, $J = 7.4$ Hz, methylene), 2.41 (2H, m, methines), 1.35 (6H, d, $J = 7.0$ Hz, methyls at C-2 and C-3), 1.18 (3H, t, $J = 7.4$ Hz, methyl of *N*-ethyl group). *Anal.* found: C 61.88, H 8.28, N, 8.99.

Results and Discussion

The electrochemical oxidation of sodium acetate in aqueous acetonitrile solution was carried out in the presence of five substrates (Table 1). Diethyl fumarate (**1**) and diethyl maleate (**2**) in 0.03 *M* solution gave diethyl 2,3-dimethylsuccinate (**6**) in 80% and 21% yields respectively. The use of methanol as solvent as described in ref. 8 did not improve the yields. The quantitative yields reported in ref. 8 were not obtained. Increasing the concentration of diethyl fumarate from 0.03 *M* to 1.00 *M* solution under the same experimental conditions caused a significant decrease in the monomer/polymer ratio. The amount of unreacted material also increased. Furthermore, a run was tried at a current density of 20 mA/cm^2 as reported in ref. 8 and no addition products were obtained. It was also mentioned in this reference that dimethyl maleate reacts faster with methyl radicals than dimethyl fumarate. It was observed by us that the fumarate reacted faster when equivalent amounts of dimethyl fumarate and diethyl maleate were used as substrates. The same observation was obtained for a mixture of diethyl fumarate and dimethyl maleate. Also, under the same experimental conditions, the diethyl fumarate was greater than 90% consumed during electrolysis while the diethyl maleate was only about 30% consumed.

The fumaronitrile (**3**) was methylated in acceptable yields. The melting point of the product was 46°C. Linstead and Whalley (10) reported melting points of 46 and 58°C for the *meso*- and the *dl*-2,3-dimethylsuccinonitrile respectively. Therefore, it seemed that the electrochemical dimethylation of fumaronitrile was stereospecific. However, we found by glc that the product melting at 46°C was an equal mixture of *meso*- and *dl*-stereoisomers. They were separated by column chromatography and one isomer melted at 58°C, corresponding to the *dl*-isomer found by Linstead, and the other at 73.5–76°C, corresponding to the *meso*-isomer. Linstead did not obtain a "clearcut" inversion of the isomers simply because the *meso*-isomer was in reality the *meso*:*dl* mixture. Each isomer could be converted into the same mixture of *meso*- and *dl*-isomers melting at 46°C in the presence of a base.

The methylation of *N*-ethylmaleimide **5** and *N*-phenylmaleimide **4** gave very good yields of dimethylated products, **9** and **8** respectively. The synthesis of *cis*- and *trans*-2,3-dimethyl *N*-phenylsuccinimide has been reported in the literature starting from the corresponding *erythro*- and *threo*-2,3-dimethylsuccinic acids (11). The products obtained by the electrolytic method was a mixture containing equal amounts of *cis*- and *trans*-stereoisomers. The *cis*-isomer was easily converted to the more stable *trans*-isomer in the presence of methoxide ion in methanol. The melting points, the mass spectra, and the nmr spectra agree well with the reported data for the *trans*- and the *cis*-isomers (11).

The unknown 2,3-dimethyl-*N*-ethylmaleimide was also obtained as a mixture of equal amounts of *cis*- and *trans*-stereoisomers. The more stable isomer was taken as the *trans*-isomer based on the fact that in the case of the *N*-phenyl derivative the *trans* is the more stable isomer.

It can be concluded that the methylation of ethylenic compounds substituted in the 1 and 2 positions with electron withdrawing groups, utilizing the electrochemical oxidation of acetate anion, results in high yields of the monomeric 1,2-dimethylated products. Practically no dimers or polymers were found under the described conditions. These products are readily isolated and purified and, except in the case of the fumarate and maleate, the stereoisomers are easily separated and characterized.

One observation which remains to be discussed is the great difference between the rates of methylation

of the fumarate and the maleate esters. The low reactivity of the maleate ester relative to the fumarate ester (and also the *N*-substituted maleimides) seems to indicate an effect of absorption and orientation of the substrate near the electrode. The orientation of the radical and the double bond relative to each other and to the electrode must be such that the rate of addition is fast compared to the rate of Kolbe product formation. The absorption of the maleate ester might be expected to be the same as that of the fumarate ester but the orientation of the double bonds may differ between the two. Such an effect is supported by another observation obtained in our laboratory[2]. Butadiene sulfone is absolutely inert toward methylation under the conditions of electrolysis described in the present work, even though other examples of methylation have been shown for unactivated double bonds such as ethylene (3, 4), butene-1 (2), and butene-2 (1). Therefore, the SO_2 group of the sulfone molecule may orient the double bond in such a way that the methylation is extremely slow relative to formation of the Kolbe product. Further studies on this subject are in progress.

Introduction

The chemistry of the divalent silicon species, silicon difluoride (SiF_2), has been extensively studied in recent years (1). Reactions with over seventy target molecules have been reported, and many of these reactions produce novel products. These commonly contain monomeric, dimeric, or trimeric SiF_2 units and result from addition and/or insertion on the reagent molecule. Relatively few reactions in which SiF_2 reacts with a non-metal hydride have been described, though it is likely that a variety of compounds could be formed by SiF_2 insertion with the non-metal hydride bond.

SiF_2 reacts with GeH_4 to form $H(SiF_2)_nGeH_3$ where $n = 1$–3 (2). There have been no reported reactions of SiF_2 with compounds containing Si—H bonds, though it is well known that other divalent silicon species such as $(CH_3)_2Si$ will react, for example, with $HSi(CH_3)_3$ (3).

The reaction with H_2S (4) produced the 1:1 insertion product $HSiF_2SH$ as well as rearrangement products $HSiF_2SSH$ and SiF_3SiF_2SSH. Reactions with H_2O (5), B_2H_6 (6), and NH_3 (7) have also been described. More recently PH_3 (8) was found to produce $HSiF_2PH_2$, SiF_3PH_2, $HSiF_2SiF_3$, and a number of other compounds which were too unstable thermally to characterize.

Our continuing investigations into the chemistry of silicon fluorides (9) have also led us to study the PH_3 reaction and the reaction of a number of other phosphorus derivatives including CH_3PH_2, $(CH_3)_2$-PH, and $(CH_3)_4P_2$. In addition, we report here the reactions of SiF_2 with $HSCH_3$ and $HSi(CH_3)_3$. Since our method of preparation of SiF_2 always results in a mixture of SiF_2 and SiF_4, we have studied separately the interaction of SiF_4 with these compounds. The polymerization of SiF_2, which always occurs during the reactions, presumably involves the formation of Si—Si bonds, which thus may offer further possible sites for reaction. We have therefore studied the interactions of Si_2F_6 as the simplest example of a silicon fluoride with a Si—Si bond, with this series of molecules.

Experimental

(*i*) SiF_2 was prepared by the method of Timms *et al.* (10). PH_3 (11), CH_3PH_2 (12), $(CH_3)_2PH$ (13), and $(CH_3)_4P_2$ (14) were prepared by standard methods. Si_2F_6 was prepared by fluorination of Si_2Cl_6 (15). $HSCH_3$ was obtained from Matheson and $HSi(CH_3)_3$ was obtained from Peninsular Chem. Research Inc.

(*ii*) Reactions with SiF_4 or Si_2F_6 were studied initially in sealed nmr tubes employing variable temperature ^1H and ^{19}F spectra from a Varian A56/60D spectrometer. Any reactions which seemed to offer some hope of isolation of useful products were then run on a larger scale on the vacuum line.

(*iii*) The hydrides were condensed with SiF_2 at −196°C. After warm-up the products were manipulated by conventional vacuum line techniques. In some cases a low temperature fractional distillation apparatus (16) was employed in an attempt to obtain purer compounds.

(*iv*) ^1H nmr spectra were obtained on Varian T60, A56/60D, and HA100 spectrometers. ^{19}F spectra were obtained on the Varian A56/60D machine while ^{31}P spectra were run in the FT mode on a Varian XL100 spectrometer. Mass spectra were obtained on a Dupont 21-490 mass spectrometer.

Results

(*i*) *Reactions with SiF_4 and Si_2F_6*

No reaction was observed between either SiF_4 or Si_2F_6 and PH_3 at low temperatures or on warm-up to room temperature. Si_2F_6 reacted with $(CH_3)_4P_2$ at −40°C in a complicated way. Si_2Cl_6 reacts with $(CH_3)_4P_2$ to give $SiCl_3P(CH_3)_2$ (17). Si_2F_6 has been reported to react with $(CH_3)_4P_2$ to produce $SiF_3P(CH_3)_2$ in 9% yield (18). In our reaction the

TABLE 1. Products of the reactions of silicon fluorides with non-metal hydrides*

Hydride	Reaction products with SiF_4	Si_2F_6	SiF_2
PH_3	NR	NR	$HSiF_3$, $HSiF_2SiF_3$, $HSiF_2PH_2$, SiF_3PH_2, $HSiF_2SiF_2PH_2$, Si_3F_8, involatile solid
CH_3PH_2	Yellow solid	Yellow solid	Si_2F_6, Si_3F_8, $HSiF_3$, $HSiF_2SiF_3$, involatile solid, no volatile Si—P compounds
$(CH_3)_2PH$	Yellow solid	Yellow solid	Si_2F_6, involatile solid, no volatile Si—P compounds
$(CH_3)_4P_2$	Yellow solid	$SiF_3P(CH_3)_2$ Yellow solid	$SiF_3P(CH_3)_2$, involatile solid
$HSCH_3$	NR	$HSiF_3$ SiF_3SCH_3	$HSiF_2SCH_3$, $HSiF_2SiF_2SCH_3$, SiF_3SCH_3, Si_2F_6, Si_3F_8, $HSiF_3$, $HSiF_2SiF_3$, $HSi(SiF_3)_2SCH_3$, $FSi(SiF_3)_2SCH_3$, $HSi(SiF_3)(SCH_3)_2$, $SiF_3Si(SCH_3)_3$, $HSiF_2Si(SCH_3)_3$, involatile solid
$HSi(CH_3)_3$	NR	NR	$FSi(CH_3)_3$, $SiF_3Si(CH_3)_3$, Si_3F_8, $HSiF_2Si(CH_3)_3$, $HSiF_2SiF_2Si(CH_3)_3$, involatile liquid

*NR = no reaction.

major product was an involatile yellow solid. A very small yield of $SiF_3P(CH_3)_2$ was produced. The compound was identified by nmr (data in Table 2).

CH_3PH_2 and $(CH_3)_2PH$ also produced unidentified yellow solids when reacted with Si_2F_6. Considerable broadening of both proton and fluorine nmr spectra was observed at −40°C when CH_3PH_2, $(CH_3)_2PH$, or $(CH_3)_4P_2$ were sealed with SiF_4 although only uncharacterized yellow solids were formed on warm-up. SiF_4 forms a 1:1 and a 2:1 adduct with $(CH_3)_3P$ at −78°C (19).

A 1:1 mixture of $HSCH_3$ and Si_2F_6 underwent little reaction at −40°C but after 1 h at room temperature only traces of starting materials remained and approximately equal quantities of $HSiF_3$ and SiF_3SCH_3 were produced. No reaction occurred between SiF_4 and $HSCH_3$.

$HSi(CH_3)_3$ did not react with Si_2F_6 or SiF_4.

(ii) Reactions with SiF_2

(a) General

Equal quantities of SiF_4 and hydride (0.07 mol) were taken for each reaction. Based on recovered SiF_4, the conversion to SiF_2 was around 50% for all reactions. The yield of total volatiles from the PH_3, $HSi(CH_3)_3$, and $HSCH_3$ reactions was about 10% based on condensed hydride. The relative yields of volatile products containing hydride moieties were similar in the three reactions. Yields from the other reactions were less than 1%. The ratio of hydride to SiF_2 in the involatile residues was not determined. These residues burn readily in air and are insoluble in organic solvents. All the residues were solid except that from $HSi(CH_3)_3$ which was a dense liquid. Nothing is yet known of the composition or structures of these residues.

When mixed in the gas phase SiF_4, SiF_2, and either $(CH_3)_2PH$ or $(CH_3)_4P_2$ reacted and deposited brown or purple solids on the walls of the apparatus prior to the co-condensation trap cooled to −196°C. No volatile products were obtained. However, by condensing alternate layers of reactants at −196°C, thereby avoiding mixing in the gas phase, small quantities of volatile product could be obtained, at least in the case of $(CH_3)_4P_2$.

Most of the volatile products from the PH_3, $HSCH_3$, and $HSi(CH_3)_3$ reactions which contained more than one SiF_2 or SiF_3 unit were thermally unstable, leaving solid residues in the vacuum line. This instability made attempts at purification by distillation or chromatography extremely difficult. Most of the identification is thus based on the low temperature nmr spectra of samples which had been subjected to minimum warming and which in many cases contained mixtures of compounds. The products identified from each reaction are shown in Table 1.

(b) PH_3 Reaction

We have identified the compounds (also found by Odom (8)) $HSiF_2PH_2$, SiF_3PH_2, and $HSiF_2SiF_3$. $HSiF_3$ was also recovered as a decomposition

TABLE 2. Summary of nmr data from the products of the reactions of SiF_2 with PH_3, CH_3PH_2, $(CH_3)_2PH$, $(CH_3)_4P_2$, $HSCH_3$, and $HSi(CH_3)_3$*

*Positive δ values are chemical shifts in ppm downfield relative to internal TMS for proton resonances, upfield relative to internal CCl_3F for fluorine resonances, and upfield relative to external H_3PO_4 for phosphorus resonances. All coupling constants are in Hz. s = singlet, d = doublet, t = triplet, q = quartet, sep = septet, m = multiplet.

product from the less volatile fractions but was not trapped out immediately after warm-up of the reaction mixture. The ^{19}F chemical shift of $HSiF_3$, which we have consistently found to be around 136 ppm (upfield relative to internal CCl_3F) from this and a number of other reactions, differs from the literature value of 109.5 ppm (20). We can find no reason for this discrepancy but suspect the literature value may be in error. The remaining chemical shifts and coupling constants agree with published values. SiF_3PH_2 has been prepared by a variety of routes not involving SiF_2 (21).

In addition to these compounds we have also been able to identify a new 2:1 compound $HSiF_2SiF_2PH_2$ which could be obtained by trap-to-trap distillation but which did not survive distillation in the low temperature column. This compound was fairly stable once dissolved in a TMS/CCl_3F solution. It was volatile at $-45°C$ and was trapped out at $-63°C$ together with some Si_2F_6, some unidentified compounds, and a large amount of Si_3F_8. The relatively high yield of Si_3F_8 prevented the isolation of a pure sample of $HSiF_2SiF_2PH_2$ since these compounds could not be separated on our distillation apparatus. Both ^{19}F resonances of Si_3F_8 are to low field of and are well separated from those of $HSiF_2SiF_2PH_2$. A large amount of yellow solid appeared in the nmr tube containing this mixture after 1 day at room temperature. The nmr data are given in Table 2, and the spectra of $HSiF_2SiF_2PH_2$ are shown in Fig. 1. No full analysis of the second order ^1H and ^{19}F spectra has yet been attempted.

Mass spectral evidence in the form of molecular ion peaks and reasonable fragment ions was also obtained. There was also evidence for $Si_2F_5PH_2$ and $Si_3F_7PH_2$ from the mass spectra of the unseparated reaction products.

(c) $(CH_3)_4P_2$ Reaction

By careful low temperature operation of the vacuum system $SiF_3P(CH_3)_2$ was recovered. This compound is also formed in the reaction with Si_2F_6 (18). Our nmr spectral parameters agree with the published values except for δF which we found at 130.2 ppm (literature value 109 ppm).

(d) CH_3PH_2 and $(CH_3)_2PH$ Reactions

No volatile Si—P compounds have been found that were sufficiently stable to permit identification. Si_2F_6, Si_3F_8, $HSiF_3$, and $HSiF_2SiF_3$ were recovered from the CH_3PH_2 reaction while only Si_2F_6 was found in the $(CH_3)_2PH$ reaction.

(e) $HSCH_3$ Reaction

A number of unexpected compounds were produced in this reaction in addition to the 1:1 product $HSiF_2SCH_3$ (largest yield), 2:1 product $HSiF_2SiF_2SCH_3$, SiF_3SCH_3, Si_2F_6, Si_3F_8, $HSiF_3$, and

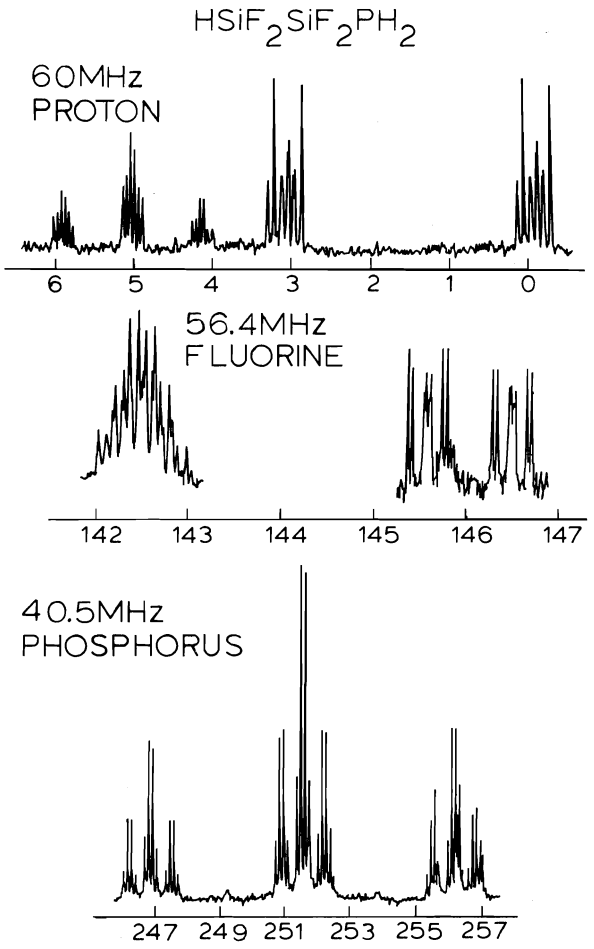

FIG. 1. Nuclear magnetic resonance spectra of $HSiF_2SiF_2PH_2$. Positive δ values are downfield from internal TMS for proton, upfield from internal CCl_3F for fluorine, and upfield from external H_3PO_4 for phosphorus.

$HSiF_2SiF_3$. The unexpected compounds contained varying numbers of SiF_3 and SCH_3 groups and included $HSi(SiF_3)_2SCH_3$, $FSi(SiF_3)_2SCH_3$, $HSi(SiF_3)(SCH_3)_2$, $SiF_3Si(SCH_3)_3$, and $HSiF_2Si(SCH_3)_3$. The nmr data which led to the identification of these compounds are given in Table 2. In some cases some of the ^{19}F and ^1H resonances were not observed. This was because the compounds were identified as mixtures in nmr tubes. Fractionation frequently changed the relative amounts of each compound but never separated them cleanly. The distribution of recovered products also varied from reaction to reaction. Thus these compounds were identified from a large number of nmr samples containing differing quantities of products. The diversity of the products in each tube resulted in a low concentration for each and frequent overlap of peaks in the ^1H spectra. These factors coupled with the low sensitivity of the available A56/60D spectrometer

relative to modern FT machines leave some doubt as to the identity of some of these compounds.

(f) $HSi(CH_3)_3$ Reaction

The product formed in highest yield was $FSi(CH_3)_3$. $SiF_3Si(CH_3)_3$ and Si_3F_8 were also produced. The 1:1 product $HSiF_2Si(CH_3)_3$ was formed in larger amounts than the 2:1 product $HSiF_2SiF_2Si(CH_3)_3$. Some unidentified volatile compounds were also produced. The involatile polymer was a clear viscous liquid. The nmr data are summarized in Table 2.

Discussion

The non-metal hydrides PH_3, $HSCH_3$, and $HSi(CH_3)_3$ all produced the 1:1 and 2:1 insertion product. Addition of methyl groups to P resulted in a loss of Si—P containing volatile products. It may be that the products were too unstable to isolate even though $SiF_3P(CH_3)_2$ was recovered from the $(CH_3)_4P_2$ reaction with SiF_2 and Si_2F_6. As mentioned above $(CH_3)_2PH$ reacts with SiF_2 at room temperature so that facile reaction occurs; but these products are not volatile, perhaps indicating that radical reactions and not simple insertion are dominant.

In the case of $HSCH_3$ more varied volatile products are produced than in the H_2S reaction. The 1:1 and 2:1 insertion products are formed as well as products from possible radical reactions. The sulphur radicals may be stabilized by the methyl group.

Similarly $HSi(CH_3)_3$ produces 1:1 and 2:1 insertion products as well as $FSi(CH_3)_3$ and $SiF_3Si(CH_3)_3$ and some unidentified unstable products.

The large amounts of $HSiF_3$, $HSiF_2SiF_3$, Si_2F_6, and Si_3F_8 might be products of the decomposition of thermally unstable products or might be formed by combination of radicals.

A spectrophotometric study of diphenylmethyllithium (DPM^-Li^+) and diphenylmethylpotassium (DPM^-K^+) in ethereal solvents has yielded information on ion pairing and solvation phenomena in these carbanion systems. Different spectral absorptions are observed, characteristic of two types of contact ion pairs (unsolvated and partially solvated) as well as the solvent separated ion pair species, on varying the cation and solvent. This contrasts with our previous observations with triphenylmethyl alkali metal salts where only contact and solvent separated ion pairs were observed. The effect of 18-crown-6 polyether and the effect of temperature changes on the ion pairing equilibria are evaluated. Thermodynamic parameters are obtained for equilibria pertaining to the DPM^-Li^+/THF and DPM^-Li^+/DME systems. The results are discussed in relation to literature reports on ion pairing in these systems as derived from nmr studies. Comparison with triphenylmethyl alkali metal salts yields information relating to delocalization and steric effects on ion pairing.

E. BUNCEL, B. C. MENON et J. P. COLPA. Can. J. Chem. **57**, 999 (1979).

Une étude spectrophotométrique du diphénylméthyllithium (DPM^-Li^+) et du diphénylméthylpotassium (DPM^-K^+) dans des solvants éthérés a fournit des informations concernant les paires d'ions et la solvatation dans ces systèmes carbanioniques. Lorsqu'on a fait varier le cation et le solvant, on a observé diverses absorbtions spectrales qui sont caractéristiques de deux types de paires d'ions de contact (non-solvaté et partiellement solvaté) de même que des paires d'ions séparés par le solvant. Ces résultats diffèrent de ceux obtenus au cours de nos travaux antérieurs avec les sels triphénylméthyles de métaux alcalins alors qu'on avait observé uniquement la présence de paires d'ions de contact ou séparés par le solvant. On a évalué l'effet de polyéther-6 couronne-18 et de changements de température sur les équilibres des paires d'ion. On a obtenu des paramètres thermodynamiques pour l'équilibre relatif aux systèmes DMP^-Li^+/THF et DMP^-Li^+/DME. On discute des résultats en fonction de rapports, parus dans la littérature, concernant les paires d'ions présentes dans ces systèmes qui sont basés sur des études rmn. Une comparaison avec des sels triphénylméthyles de métaux alcalins fournit des informations concernant les effets stériques et la délocalisation sur le pairage des ions.

[Traduit par le journal]

In our study of triphenylmethyllithium (TPM^-Li^+) and triphenylmethylpotassium (TPM^-K^+) in ethereal solvents by uv–visible spectroscopy, it was found that these carbanion alkali metal salts showed spectral behaviour characteristic of contact or solvent-separated ion pairs, depending on the nature of the solvent, cation, temperature, and complexing agents (1). The results could be compared with a parallel study of these carbanion systems by ^1H nmr spectroscopy (2).

In this paper we have extended the systematic study to investigation of diphenylmethyl carbanion alkali metal salts (3). It was anticipated that comparison with the triphenylmethide system would be informative regarding delocalization and steric effects on ion pairing. In addition, a recent ^{13}C nmr study (4) of diphenylmethyl carbanion alkali metal salts has given evidence on ion pairing and solvation effects, providing an independent measure for comparison of our results. The necessity of investigating ion-pairing phenomena by different experimental techniques has been emphasized (5). An earlier spectrophotometric study (6) of 1,1-diphenylhexyllithium in THF or di-*n*-propyl ether and benzene or hexane mixtures was interpreted in terms of formation of specific complexed species such as RLi·2THF and RLi·4THF. Study (7) of the 1,1,4,4-tetraphenylbutane dianion, $Ph_2\bar{C}CH_2CH_2\bar{C}Ph_2$, in THF at various temperatures gave evidence of formation of more than one type of ion pair, though overlap of the absorption bands did not permit the separate observation of each ion pair. Some related spectrophotometric studies of carbanions, including the fluorenyl (8, 9) and phenylallyl (10, 11) systems have been described. We have now found that, in contrast to our previous study with triphenylmethyl alkali metal salts, the results with the diphenylmethyl system point to the presence of three types of ion pair species differing in solvation state. Whereas contact and solvent separated ion pairs have been

[1]Carbanion mechanisms. Part 10. For Part 9, see ref. 1.

0008-4042/79/090999-07$01.00/0

well characterized spectrally, there have been only scant reports in the past of partially solvated contact ion pairs in the carbanion series.

Results and Discussion

Diphenylmethyllithium (DPM^-Li^+) in THF solution was readily prepared by reaction of diphenylmethane (DPM) with *n*-butyllithium (12). The reactions in DME and Et_2O, however, proceeded only to partial completion and solutions of DPM^-Li^+ in these solvents were obtained from the THF solution by removal of THF under vacuo and replacement by the desired solvent. Diphenylmethylpotassium (DPM^-K^+) was obtained by reaction of DPM with potassium amide in THF or DME (13). The Et_2O solution of DPM^-K^+ was prepared from the THF solution as in the case of DPM^-Li^+/Et_2O above.

Effect of Solvent on Spectral Characteristics and the Nature of Ion Pairing

The spectrum of DPM^-Li^+ in Et_2O and DME at room temperature exhibits a single absorption maximum at 407 and 448 nm, respectively, while in THF two broad peaks at ca. 418 and 448 are present (Fig. 1). By analogy with reasoning detailed previously (1), these observations would suggest that DPM^-Li^+ exists in Et_2O predominantly as the contact ion pair, in DME predominantly as the solvent separated ion pair, and in THF as a mixture of both species in comparable concentrations. The bathochromic shift on passing from contact to solvent separated ion pairs is a characteristic feature of carbanion alkali metal systems studied hitherto (14). The greater effective solvating capability of DME relative to THF is evident by the fact that in the former case an appreciably larger proportion of solvent separated ion pairs are present. As these two solvents have virtually identical dielectric constants, it is probable that the possibility of bidentate coordination towards the cation of DPM^-Li^+ by DME is responsible for this effect.

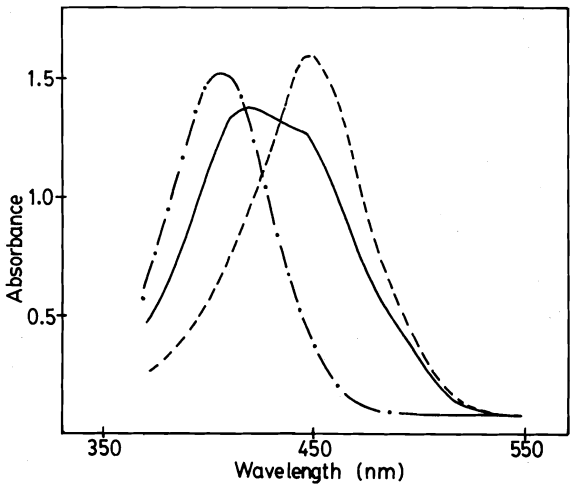

FIG. 1. Visible absorption spectra of diphenylmethyllithium in ether (·····), tetrahydrofuran (—), and dimethoxyethane (---) at room temperature.

However, the current results with diphenylmethyl carbanions (Table 1) differ from those obtained in our study of the triphenylmethyl system (Table 2). In the TPM^-Li^+ case the contact ion pair species, associated with the shorter wavelength absorption, were only observed in ether so that the results did not allow evaluation of the effect of solvent on the contact ion pair absorption. In the DPM^-Li^+ case, on the other hand, as is apparent from Fig. 1, the shorter wavelength absorption in THF is appreciably shifted with respect to Et_2O. By comparison, in studies of the fluorenyl anion system by uv–visible spectroscopy, from which we derive most of our current knowledge of the spectral characteristics of the different types of ion pairs, the F^-,Li^+ contact ion pair exhibited negligible shift (2 nm) in λ_{max} with change in solvent (9).

The present results bring forth the question whether in the DPM^-Li^+ system more than one type of contact ion pair is present, differing in solvation state. Corresponding evidence was presented (10) in the case of the 1,3-diphenylbutene anion (DPB^-) for formation of an externally solvated contact ion pair (DPB^-,M^+,S_n), in addition to the conventional (virtually unsolvated) contact ion pair (DPB^-,M^+), and the solvent separated ion pair ($DPB^-||M^+$) species. Thus the equilibria [1]–[3] were invoked on the basis of the following observations

$$[1] \qquad DPB^-,M^+ + nS \rightleftharpoons DPB^-,M^+,S_n$$

$$[2] \qquad DPB^-,M^+ + mS \rightleftharpoons DPB^-||M^+$$

$$[3] \qquad DPB^-,M^+,S_n + xS \rightleftharpoons DPB^-||M^+$$

and reasoning. (*a*) Equilibrium [1] involving formation of the externally solvated ion pair was indicated by the continuing shift in λ_{max} (467 → 502 nm) for DPB^-Li^+ in weakly solvating ethereal solvents such as Et_2O. (*b*) In media of intermediate solvating power such as tetrahydropyran absorption maxima were found to be present at 530 and 565 nm, in accord with equilibrium [3] being operative. (*c*) In dioxolane and *m*-dimethoxybenzene the two bands occurred at 500 and 565 nm, indicating that three species were present, apparently formed through combination of [1] and [2] or [1] and [3]. (*d*) In more powerful solvating media such as DME only the long wavelength (565 nm) absorption was found, characteristic of the solvent separated ion pair species.

TABLE 1. Contact (R^-,M^+), externally solvated contact (R^-,M^+,S_p), solvent separated ($R^-\|M^+$), and crown-ether complexed (R^-,X,M^+) ion pairs of diphenylmethyl carbanions

		λ_{max} (ε)[a,b]				
R^-M^+	Solvent	R^-M^+	R^-,M^+,S_p	$R^-\|M^+$	Fraction[c] of $R^-\|M^+$ at 25°C	λ_{max} R^-,X,M^+
DPM^-Li^+	Et_2O	407 (30 800)			0.0	445
	THF		418	448	0.4[d]	452
	DME			448 (37 000)	0.8[d]	448

	THF		440 (43 000)		0.0	448
	DME		441 (43 800)		0.0	445

[a]Extinction coefficient (L mol^{-1} cm^{-1}) at absorption maximum.
[b]The λ_{max} value refers to the predominant species in the given solvent.
[c]Reckoned as $[R^-\|M^+]/([R^-,M^+] + [R^-,M^+,S_n] + [R^-\|M^+])$.
[d]This fraction is estimated from $K = [SS]/[C_2]$ at 25°C, as calculated from absorbance changes at a single wavelength, i.e. λ_{max} for the solvent separated species (see text). The results are in qualitative agreement with a procedure based on the construction of the absorption spectra by means of the component curves due to the respective ion pairs.

TABLE 2. Contact (R^-,M^+) and solvent separated ($R^-\|M^+$) ion pairs of triphenylmethyl carbanions in ethereal solvents at room temperature: effect of solvent and counterion

		λ_{max}		
R^-M^+	Solvent	R^-,M^+	$R^-\|M^+$	Fraction of $R^-\|M^+$ at 25°C
TPM^-Li^+	Et_2O	446, 390 sh		0.15
	THF		500, 435 sh	0.95
	DME		496, 432 sh	1.00
TPM^-K^+	Et_2O	476, 414 sh		0.00
	THF		486, 420 sh	0.65
	DME		494, 430 sh	0.85

The results of our work can similarly be interpreted. Thus we propose that in the DPM^-Li^+ system the 407 nm absorption is associated with the unsolvated contact ion pair $DPM^-,Li^+(C_1)$, the 418 nm absorption with the externally solvated contact ion pair $DPM^-,Li^+,S_p(C_2)$, and the 448 nm absorption with the solvent separated ion pair $DPM^-\|Li^+(SS)$. Hence in Et_2O we have present predominantly C_1, possibly in equilibrium with a small proportion of C_2 (eq. [4]). In THF the equilibrium would involve mainly C_2 and SS (eq. [5]), the two species being present in comparable amounts. In DME equilibrium [5] would be substantially on the right hand side.

$$[4] \qquad DPM^-,Li^+ + pS \rightleftharpoons DPM^-,Li^+,S_p$$

$$[5] \qquad DPM^-,Li^+,S_p + qS \rightleftharpoons DPM^-\|Li^+$$

The ambient spectrum of DPM^-K^+ in Et_2O, THF, and DME exhibits single absorption maxima at 432, 440, and 441 nm, respectively (Fig. 2). By analogy with TPM^-K^+ in Et_2O (1) as well as other potassium salts of carbanions (11) one would expect DPM^-K^+ in Et_2O to exist as the contact ion pair (C_1). The bathochromic shift of 25 nm on going from DPM^-Li^+ to DPM^-K^+ in Et_2O would then correspond to the 30 nm shift observed for $TPM^-Li^+ \rightarrow TPM^-K^+$ (1). Bathochromic shifts of this order of magnitude are generally associated with increase in cationic radius for contact ion pairs and have been attributed (15) to a greater destabilization of the

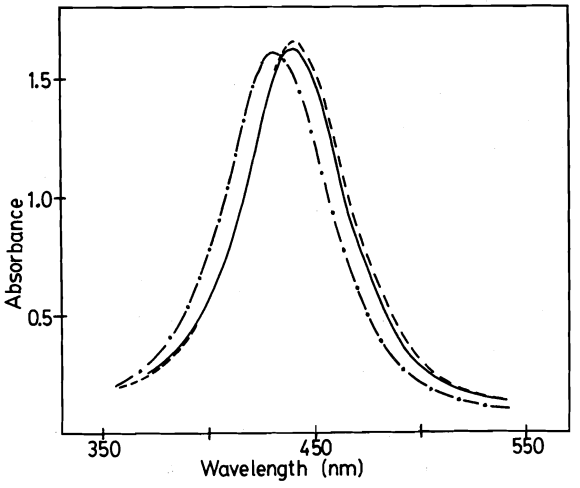

FIG. 2. Visible absorption spectra of diphenylmethylpotassium in ether (-·····-), tetrahydrofuran (—), and dimethoxyethane (---) at room temperature.

ground state than of the excited state with the larger cation. In the ground state the dipole is minimized by locating the cation close to the center of negative charge but on excitation there is a re-distribution of charge density, and hence an increased dipole, since the position of the cation is unaffected according to the Franck–Condon principle. This leads to a lower energy transition with the larger cation.

The λ_{max} value of DPM^-K^+ in THF or DME shows that in these media solvent separated ion pair species are present in negligible extent. The shift in λ_{max} from 432 nm in Et_2O to 440/441 nm in THF/DME can be ascribed to formation of the C_2 species by analogy with the above argument. We thus conclude that DPM^-K^+ in Et_2O exists predominantly as the C_1 species and in THF or DME predominantly as the C_2 species. In going from DPM^-Li^+ to DPM^-K^+ one would expect the degree of solvent separated ion pair formation to decrease, while contact/externally solvated contact ion pairs should increase, in a given solvent, in accord with the lesser solvation requirements of K^+ relative to Li^+. The results for THF and DME solvents (Table 1) bear out this expectation.

Externally solvated contact ion pairs are probably more commonly found than hitherto believed, though they may not always be spectrally resolvable. One can consider the solvent molecules in this type of ion pair to be peripherally coordinated to the cation, whereas in the solvent separated ion pair the cation is totally enveloped by the solvent molecules. Thus in the externally solvated contact ion pair charge delocalization takes place to a much lesser extent than in the solvent separated ion pair. This will be reflected in a smaller bathochromic shift for the former than for the latter, relative to the absorption maximum of the unsolvated contact ion pair.

Effect of 18-Crown-6 Ether

The addition of 18-crown-6 ether to DPM^-Li^+ in Et_2O or THF causes a shift in λ_{max} to 445 and 452 nm, respectively (Table 1), but for DME there is no noticeable change in the spectral absorption. Since crown ether complexed ion pairs have absorptions alike to the solvent separated ion pairs (1), this is further evidence that in the absence of crown DPM^-Li^+ in DME is present predominantly as the solvent separated ion pair. The shifts observed in the case of THF or Et_2O are in accord with our earlier conclusions that in the absence of crown DPM^-Li^+ exists in THF as a mixture of mainly the C_2 and SS species while in Et_2O predominantly C_1 is present. One would expect that crown ether should convert both types of contact ion pairs to the crown complexed species, as observed.

When 18-crown-6 ether was added to DPM^-K^+ in Et_2O, THF, and DME, there resulted in each case a shift in the absorption maxima, the final λ_{max} values being 444, 448, and 445 nm, respectively. These spectral characteristics correspond closely to crown ether complexed diphenylmethyllithium. Since change in cation generally has little effect on λ_{max} of solvent separated or complexed ion pairs (8–11), this corroborates our earlier conclusion that in the absence of crown ether DPM^-K^+ is present in these solvents as the two types of contact ion pairs. The small variation in λ_{max} of the crown ether complexed DPM^-K^+ ion pair with solvent change is quite comparable to corresponding observations with TPM^-K^+ (1).

Effect of Temperature

The absorption spectrum of solutions of DPM^-K^+ in Et_2O, THF, and DME remained unchanged over the temperature range 25 to −50°C. Thus there is no change in the type of ion pair present over this range.

Solutions of DPM^-Li^+ exhibited different spectral behaviour with change in temperature depending on the solvent. The effect of lowering the temperature below ambient was explored first. For DME or Et_2O the absorption spectrum remained unchanged on cooling to −50°C. In the former case this result is to be expected on the basis of the evidence that DPM^-Li^+ exists in DME predominantly as the solvent separated ion pair already at room temperature. Conversely it follows that in the latter case the contact ion pair is the predominant species present over the entire temperature range investigated.

The DPM^-Li^+/THF system has been found to exhibit large spectral changes on cooling to −60°C. Thus the absorption at 418 nm decreases while that at 448 nm increases in peak height (Fig. 3). The spectral changes are reversible, indicating that an equilibrium between two species is established. Since the DPM^-Li^+/THF system has been shown to contain the C_2 and SS species (see above), the spectral changes as a function of temperature correspond to a shift in the equilibrium [5] towards the right hand side, i.e. increased formation of solvent separated ion pairs at low temperatures.

Since in the DPM^-Li^+/DME system the ambient temperature spectrum suggested the predominance of SS species in the equilibrium [5], the effect of raising the temperature was examined on the expectation that a shift in position of the equilibrium would occur towards the C_2 species. A small effect was observed as anticipated on increasing the temperature 0 → 40°C, beyond which decomposition of the carbanion became important as shown by irreversibility of the spectral changes.

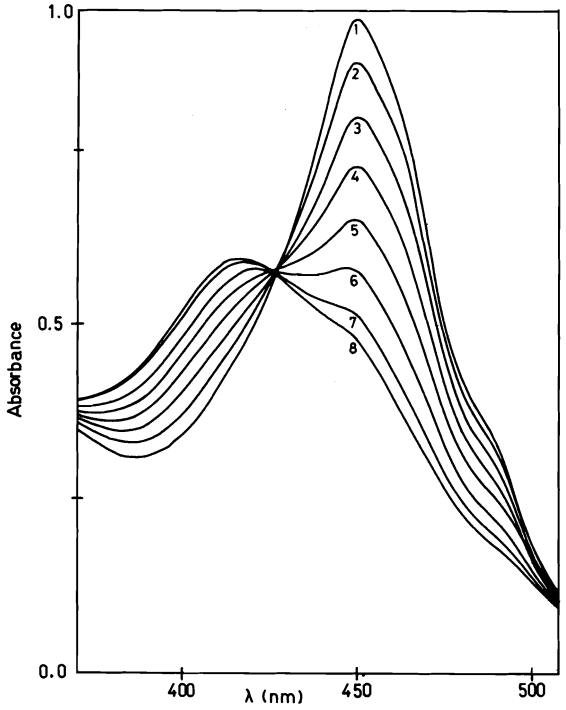

FIG. 3. Temperature variation of absorption spectra of diphenylmethyllithium in THF. Spectrum *1*, −58.0°C; *3*, −38.0°C; *5*, −14.5°C; *8*, +23°C.

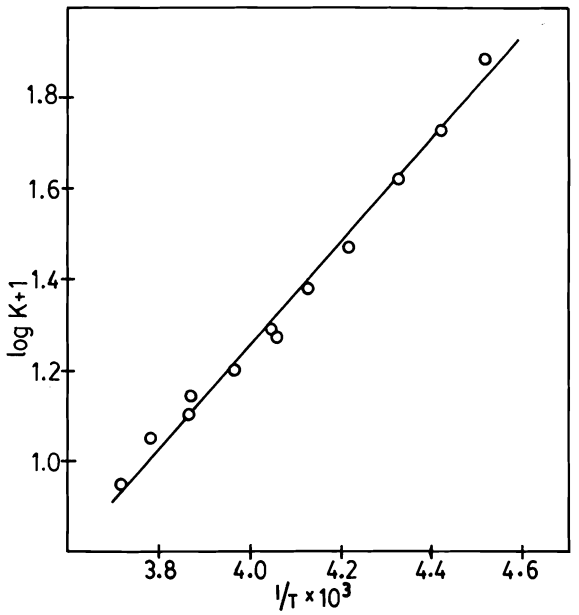

FIG. 4. log K vs. $1/T$ plot for diphenylmethyllithium in THF.

The spectral study as a function of temperature for the DPM^-Li^+/THF and DPM^-Li^+/DME systems allowed evaluation of the ΔH and ΔS parameters pertaining to equilibria [5]. The equilibrium constant at a given temperature was calculated from the expression

$$[6] \qquad K = [S]/[C] = (A - A_c)/(A_s - A)$$

where A is the observed (density corrected) absorbance value at 448 nm (λ_{max} corresponding to the SS species), while A_c, A_s are the absorbance values at 448 nm due to 100% C_2 and SS species, respectively. Since the spectrum of the C_2 species is not available, the absorption value at 448 nm due to 100% C_2 has been estimated from (*a*) the spectrum of DPM^-Li^+ in Et_2O (C_1), or (*b*) the spectrum of DPM^-Li^+ in THF at −64°C (SS), assuming that the extinction coefficients and shapes of the spectra of the C_1, C_2, and SS species are similar. From plots of log K vs. $1/T$ (e.g. Fig. 4 for DPM^-Li^+/THF) values of ΔH and ΔS were calculated. For DPM^-Li^+/THF one obtains $\Delta H = -5.4$ or -6.1 kcal/mol, $\Delta S = -20.2$ or -24.4 eu, respectively, when methods (*a*) or (*b*) were used to calculate the absorbance for 100% C_2 species at 448 nm. For DPM^-Li^+/DME, $\Delta H = -13.2$ kcal/mol, $\Delta S = -41$ eu. The error limit associated with these values is believed to be in the range 10–20%. Negative enthalpies and entropies have been characteristic of contact ⇌ solvent separated ion pair equilibria (14), and evidently the same principles apply in the formation of solvent separated ion pairs from the externally solvated contact ion pair species.

Comparison of Ultraviolet–Visible and Nuclear Magnetic Resonance Studies

Ion pairing in diphenylmethyl alkali metal salts was recently investigated by ^{13}C nmr spectroscopy (4) and the results are of interest in relation to the present work. The chemical shift changes observed for the α and *para* carbons as a function of solvent and temperature were interpreted in terms of contact and solvent separated ion pair formation. DPM^-Li^+ in DME at 25°C was found to be present almost exclusively as the solvent separated ion pair and in THF predominantly so, while DPM^-K^+ showed nmr evidence of only contact ion pairs in THF or DME.

The conclusions of the present work are in qualitative agreement with those derived from the ^{13}C nmr study, with the exception that the uv–visible study has allowed us to discern two types of contact ion pairs. Otherwise the degree of formation of solvent separated ion pairs is found to be of the same order of magnitude in both studies when the cation and solvent are varied. An important aspect of the nmr studies concerning which uv–visible spectroscopy yields no information is the sp^2 hybridized state of the central carbon in arylmethyl carbanions (16, 17), as expected on theoretical grounds (18).

Concluding Remarks

A significant finding of the present study is that the uv–visible spectral observations in the diphenylmethide system have allowed us to discern two types of contact ion pairs in addition to the solvent separated ion pairs, whereas the triphenylmethide system gave evidence of only one type of contact ion pair and the solvent separated ion pair (1).

Apart from the above finding, there is overall agreement between the conclusions of the present work and those derived from a ^{13}C nmr study of diphenylmethyl alkali metal salts (4). Previously substantial agreement had been found between our uv–visible study of triphenylmethyl alkali metal salts (1) and a corresponding ^{1}H nmr study (2) regarding the dependence of contact and solvent separated ion pair equilibria on the nature of the cation, solvent, and temperature.

A remarkable parallel of the TPM^- and DPM^- systems is the magnitude of the transition energy difference for the contact and the solvent separated (or crown ether complexed) ion pair absorptions. Thus for TPM^-Li^+, in Et_2O solvent, the transition energy difference on going from contact to complexed ion pairs is 6.3 kcal/mol, while for DPM^-Li^+ this takes the value 6.0 kcal/mol. The corresponding values for TPM^-K^+ and DPM^-K^+ are 1.9 and 1.8 kcal/mol, respectively. These parallel results are noteworthy in view of the different steric and delocalization characteristics of the two carbanions, a factor considered further below.

The tendency for solvent separated ion pair formation is greater for the Li^+ salt of both carbanions, in agreement with the greater solvation requirement of Li^+ versus K^+. However, on going from TPM^-Li^+ to DPM^-Li^+, or TPM^-K^+ to DPM^-K^+, the tendency for contact ion pair formation increases. This appears to arise in part due to delocalizability and in part to steric effects. The greater charge delocalization in TPM^- results in decreased electrostatic attraction for the cation, compared to DPM^- and its counterion. Concomitantly, the increased steric interaction between the cation and the anionic center in the "propeller" shaped trityl anion (18) will make contact ion pair formation more difficult, with the result that the solvent separated ion pair will be energetically preferred.

Finally we wish to draw attention to the conceptual difficulties involved in the clear definition of the various types of ion pairs. Thus in passing from contact to solvent separated ion pairs an intermediate state could be encountered with respect to the interaction between the charge separated solute species and the solvent molecules. This intermediate state has been termed as peripheral or external solvation, which should be of increased importance compared to the situation in contact ion pairs. Alternatively one could visualize the intermediate state as one in which the distance between the ions is larger than in the contact ion pair but not yet so large that a solvent molecule can be entirely placed between the two ions. The perturbation of the energy levels of the carbanion by the electric field of the cation will be influenced by this incipient solvation, with consequent effect on the spectral absorption. The present results have shown further that such intermediate states can have sufficient stability so as to be observable as separate species.

Experimental

Diphenylmethane (Eastman) was distilled under vacuo, bp 125°C (10 mm). *n*-Butyllithium in hexane (Aldrich or Ventron) was standardized by titration. The solvents employed were purified and dried as given previously (19). The reaction vessel used in the spectrophotometric method has been described (20). DPM^-Li^+ solutions in THF were prepared from DPM and *n*-BuLi as described previously for the case of TPM^-Li^+/THF (1). Solutions of DPM^-Li^+ in Et_2O or DME were prepared from the THF solution by removal of this solvent under vacuo and distillation of the desired solvent from a reservoir, under vacuo. This solvent replacement was performed at least twice in each case. The spectrophotometric measurements were performed as previously (1).

The spectra shown in Figs. 1 and 2 were taken in a 1 mm cell on a Unicam SP800B spectrophotometer. The carbanion concentrations were calculated from the weights of DPM and solvent employed. In Fig. 1 we have the $[DPM^-Li^+]$ values: Et_2O, 4.65×10^{-4} *M*; THF, 4.67×10^{-4} *M*; DME, 4.34×10^{-4} *M*. In Fig. 2 the $[DPM^-K^+]$ values are: Et_2O, 3.84×10^{-4} *M*; THF, 3.54×10^{-4} *M*; DME, 3.44×10^{-4} *M*.

The spectra given in Fig. 3 were taken on a Beckman Acta IV spectrophotometer using a 10 mm cuvette with $[DPM^-Li^+] = 3.18 \times 10^{-5}$ *M*.

OSAMU KIYOHARA, PATRICK J. D'ARCY, and GEORGE C. BENSON. Can. J. Chem. **57**, 1006 (1979).

Ultrasonic velocities and volumetric heat capacities at constant pressure were measured at 298.15 K for water + tetrahydrofuran mixtures over the whole concentration range using pulse–echo-overlap equipment and a flow microcalorimeter respectively. Isentropic and isothermal compressibilities and heat capacities at constant pressure and at constant volume were derived from the results in combination with the results of previous studies of thermal expansivities and excess volumes. The significance of the excess compressibilities and excess heat capacities is discussed in terms of molecular interactions.

OSAMU KIYOHARA, PATRICK J. D'ARCY et GEORGE C. BENSON. Can. J. Chem. **57**, 1006 (1979).

On a mesuré les vitesses ultrasoniques et les capacités calorifiques volumétriques à pression constante et à 298.15 K à toutes les concentrations de mélanges d'eau et de tétrahydrofuranne en faisant appel respectivement à un appareil de superposition d'écho pulsé et d'un microcalorimètre continu. On a déduit les compressibilités isentropes et isothermes ainsi que les capacités calorifiques à pression constante et à volume constant à partir des résultats examinés de concert avec des résultats d'études antérieures d'expansivités thermiques et de volumes en excès. On discute de la signification des compressibilités en excès et des capacités calorifiques en excès en termes d'interactions moléculaires.

[Traduit par le journal]

Introduction

Excess enthalpies, excess volumes, and thermal expansivities of water + tetrahydrofuran (THF) mixtures at 298.15 K have been reported previously (1, 2). The present paper describes the extension of our investigation of the thermodynamic properties of water + THF mixtures to include isobaric and isochoric heat capacities, and isentropic and isothermal compressibilities.

Experimental

Purification and handling of the THF and water were the same as in our previous work (1). The density of the THF used for the present measurements was 0.88197 g cm^{-3} at 298.15 K.

Ultrasonic velocities in water + THF mixtures were determined in a successive dilution mixing cell using a pulse–echo-overlap method (3, 4) with the rf generator operating at 3 MHz. The error of the velocities measured relative to water (1496.687 m s^{-1} at 298.15 K (5)) is believed to be less than 0.2 m s^{-1}; the error of the compositions of the mixtures is less than 0.02%.

The heat capacities of water + THF mixtures were studied in a Picker flow microcalorimeter. Details of this apparatus and its operation have been described previously (6, 7). A single reference procedure was used, in which the difference of the volumetric heat capacity $\Delta(C_p/V)$ of the mixture from that of water was determined. A value of 75.292 J K^{-1} mol^{-1} was adopted for the heat capacity of water at 298.15 K (8). The error of the molar heat capacity is estimated to be less than 0.1 J K^{-1} mol^{-1}. Mixtures were prepared by mass and the error in the mole fraction is less than 5×10^{-5}.

Results

Experimental values of the velocity of ultrasound u in water + THF mixtures are listed in Table 1, where x_1 is the mole fraction of water. The result for pure THF (1277.44 m s^{-1}) is somewhat lower than the value 1284.1 m s^{-1} interpolated from the measurements by Deshpande *et al.* (9) at 293 K and 308 K. There is a fairly sharp maximum of u at $x_1 = 0.938$. Our results are qualitatively similar to those of Baumgartner and Atkinson (10) which are available only in graphical form.

Isentropic compressibilities κ_S were calculated from the equation

$$[1] \qquad \kappa_S = (\rho u^2)^{-1}$$

where values of the density ρ were estimated from the densities of the pure components and the smoothing function for the excess volume of water + THF mixtures (1). The values obtained for κ_S are reported in Table 1.

Although absorption of ultrasound in the frequency range 10–60 MHz has been reported by Werblan *et al.* (11) for water + THF mixtures at 298 K, it appears that such absorption will not

significantly vitiate the interpretation of κ_S as the thermodynamic isentropic compressibility.

The results of the calorimetric measurements are summarized in Table 2, where the values of $\Delta(C_p/V)$ denote the deviation of the volumetric heat capacity of the mixture from that of pure water. Molar heat capacities C_p were derived from these values using densities estimated in the manner already described. The result for pure THF (123.56 J K^{-1} mol^{-1}) is in reasonable agreement with values in the recent literature (C_p/J K^{-1} mol^{-1} = 120 (12) and 123.9 (13)).

Isothermal compressibilities κ_T and isochoric heat

capacities C_V were calculated from the equations

$$[2] \qquad \kappa_T = \kappa_S + TV\alpha^2/C_p$$

and

$$[3] \qquad C_V = C_p\kappa_S/\kappa_T$$

where α is the thermal expansion coefficient and V is the volume at temperature T. Values of α for pure THF and water + THF mixtures at 298.15 K were taken from our previous work (2); $\alpha = 0.2572\ \mathrm{kK}^{-1}$ was used for water at 298.15 K (8).

Excess compressibilities and heat capacities of the mixtures were obtained from the general relation

$$[4] \qquad X^{\mathrm{E}} = X - X^{\mathrm{id}}$$

where X and X^{id} are the values of the particular property for the real mixture and the corresponding ideal mixture, respectively. The following formulas were used for the properties of the ideal mixture:

$$[5] \qquad \bar{V}^{\mathrm{id}} = \sum x_i \bar{V}_i^0$$

$$[6] \qquad \bar{C}_p^{\mathrm{id}} = \sum x_i \bar{C}_{pi}^0$$

$$[7] \qquad \kappa_T^{\mathrm{id}} = \sum \phi_i \kappa_{Ti}^0$$

$$[8] \qquad \alpha^{\mathrm{id}} = \sum \phi_i \alpha_i^0$$

and

$$[9] \qquad \kappa_S^{\mathrm{id}} = \kappa_T^{\mathrm{id}} - T\bar{V}^{\mathrm{id}}(\alpha^{\mathrm{id}})^2/\bar{C}_p^{\mathrm{id}}$$

where the superbar denotes a molar quantity and the superscript zero indicates a value for a pure component. In eqs. [7] and [8]

$$[10] \qquad \phi_i = x_i \bar{V}_i^0/\bar{V}^{\mathrm{id}}$$

is the volume fraction of component i. Results for κ_S^{E} and C_p^{E} are listed in Tables 1 and 2, respectively.

We were unable to find smoothing functions to represent the experimental results for κ_S^{E} and C_p^{E} accurately over the entire mole fraction range. Similar difficulties were experienced in our previous studies of other excess thermodynamic properties of water + THF mixtures (1, 2). The best representations were obtained with the functional form

$$[11] \qquad X^{\mathrm{E}} = z(1-z)\sum_{j=1}^{n} a_j(1-2z)^{j-1}$$

with z equal to the volume fraction in the case of κ_S^{E} and z equal to the mole fraction in the case of C_p^{E}. Values of the coefficients determined by the method of least squares with all points weighted equally are listed in Table 3, along with the standard deviations of the representations. These functions are suitable for interpolation over most of the mole fraction range, but are less reliable near the ends of the range, particularly for evaluating slopes near $x_1 = 1$.

*For κ_S^{E}, $z = \phi_1$; for C_p^{E}, $z = x_1$.

Plots of the experimental results for κ_S^{E} and C_p^{E} and of their representations by [11] are shown in Figs. 1 and 2. Also included in these figures are curves for κ_T^{E} and C_V^{E} calculated from the smoothed values of κ_S^{E} and C_p^{E}, and of $V^{\mathrm{E}}(1)$ and $\alpha^{\mathrm{E}}(2)$. Glew and Watts (14) reported excess enthalpies H^{E} for water + THF mixtures at 283 K and 298 K. Assuming that H^{E} varies linearly with temperature (i.e. C_p^{E} is independent of temperature) we estimated the values of $\partial H^{\mathrm{E}}/\partial T$ which are shown in Fig. 2. These

agree reasonably well with the results of our more direct calorimetric determinations.

Discussion

Previous studies of excess volumes, enthalpies, and thermal expansivities (1, 2) suggest that the THF molecule enhances water structure in dilute water + THF mixtures. Over the central mole fraction range, the mixture behaves like a pseudo two-phase system, and in THF-rich mixtures hydrogen bonding is the predominant interaction between water and THF molecules.

The excess isentropic and isothermal compressibilities in Fig. 1 are both negative over the whole mole fraction range with deep minima near $x_1 = 0.85$. The curves cross several times and the differences between them are relatively small. In Fig. 2 the excess heat capacities at constant pressure and at constant volume are positive. The maximum of C_p^E occurs at $x_1 = 0.78$, that of C_V^E at $x_1 = 0.91$. The C_V^E curve is relatively flat over the central mole fraction range.

The behavior of the excess compressibilities and of the excess heat capacities qualitatively support the view that strong hydrophobic hydration occurs in water + THF mixtures. To investigate this aspect further, partial molar excess compressibilities $K_{S,i}^E$ and $K_{T,i}^E$ and partial molar excess heat capacities $C_{p,i}^E$ and $C_{V,i}^E$ were calculated.[3] Over most of the mole fraction range, the smoothing equations for the excess properties κ_S^E, C_p^E, V^E, and α^E were used for this calculation. However, values for dilute THF mixtures were obtained by smoothing the experimental results with cubic splines. Curves of the partial molar excess compressibilities and heat capacities are plotted in Figs. 3 and 4. Values of $C_{p,2}^E$ from the literature (12) are included in Fig. 4 for comparison. At infinite dilution, the limiting value of $K_{S,2}^E$ is -71 cm^3 mol^{-1} GPa^{-1} and of C_p^E is 172 J K^{-1} mol^{-1}. These agree fairly well with values derived from the literature ($K_{S,2}^E$/cm^3 mol^{-1} GPa^{-1} $= -70.4$ (15); $C_{p,2}^E$/J K^{-1} mol^{-1} $= 160 \pm 11$ (16), 171 (17), 172 (12)).

The most interesting feature of the curves in Figs. 3 and 4 is the rapid change of the partial molar excess values for THF in the dilute THF region. Differences between the partial molar excess compressibilities at constant entropy and at constant temperature are relatively insignificant, and the variation of $K_{S,1}^E$ (and $K_{T,1}^E$) is nearly linear in x_1. The partial molar excess heat capacities for water are approximately

[3]By definition, $K_{S,i}^E$ and $K_{T,i}^E$ are the partial derivatives of the quantities $(V\kappa_S)^E$ and $(V\kappa_T)^E$ with respect to the moles of component i.

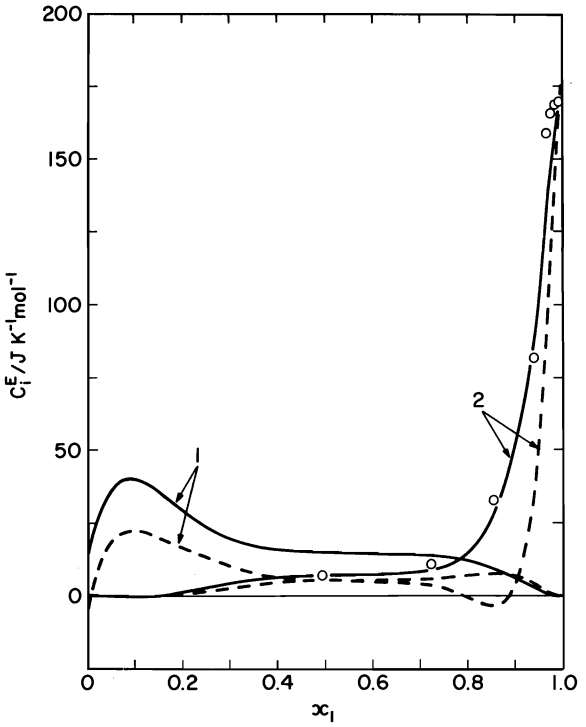

FIG. 4. Partial molar excess heat capacities of water (1) + THF (2) mixtures at 298.15 K. Curves: ——, $C_{p,i}{}^E$; ---, $C_{V,i}{}^E$. Labels denote component *i*. Points: ○, $C_{p,2}{}^E$ from ref. 12.

constant over the central mole fraction range and have small broad maxima near $x_1 = 0.1$. The general pattern of the curves in Fig. 4 is quite similar to that of the partial molar excess expansivities, apart from the sharp peak observed for the partial molar excess expansivity of THF at $x_1 = 0.94$ (2).

The positive slopes of $C_{p,1}{}^E$ and $C_{V,1}{}^E$ for $x_1 < 0.1$ are subject to rather large uncertainties because of the paucity of our measurements of C_p in this region. However, we believe that the elevated values of $C_{p,1}{}^E$ and $C_{V,1}{}^E$ for THF-rich mixtures are real and that they may be due to interactions between unlike species which promote association of water molecules. The subsequent flat behavior of these properties over the central mole fraction range supports the suggestion of a pseudo two-phase region consisting of clusters of water molecules and a random phase comprising water and THF molecules. Stabilization of the water clusters in the random molecular environment is reflected in the negative excess compressibilities and positive excess heat capacities. This picture is in accord with infrared studies (18) which show that the hydrogen bonding of water molecules is stronger in the range $x_1 = 0.15$–0.82 than in pure water, and also with nmr relaxation time measurements (19) which show an increase of water reorientation times in the water-rich region. However it should be noted that Dawber (20) has recently concluded from magneto-optical rotation studies that THF breaks the water structure over the whole mole fraction range. This contradiction appears to be largely semantic since the magneto-optical measurement is based on a comparison with pure water and formation of a clathrate cage is regarded as a disruption of the normal water structure (21).

Nucleophilic substitution in tris(pentafluorophenyl)phosphine

HANNA R. HANNA AND JACK M. MILLER[1]

Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received September 28, 1978

HANNA R. HANNA and JACK M. MILLER. Can. J. Chem. **57**, 1011 (1979).

Reaction of tris(pentafluorophenyl)phosphine with various nucleophiles (DMF, HMPA, HEPA, diethylformamide, hydrazine, UDMH, phenylhydrazine, formamide, and aniline) gave exclusively the replacement of all three *para* fluorines with the exception of aniline, phenylhydrazine, and formamide which gave mixtures of the mono- and bis-4-substituted phosphines. Sodium bisulphide and various alkoxides led mainly to C—P bond rupture though some alkoxides did under certain conditions give some of the expected substitution product. ^{19}F, ^{31}P, and ^{1}H nmr and mass spectral data are presented.

HANNA R. HANNA et JACK M. MILLER. Can. J. Chem. **57**, 1011 (1979).

La réaction de la tris(pentaphényl)phosphine avec divers nucléophiles (DMF, HMPA, HEPA, diéthylformamide, hydrazine, UDMH, phénylhydrazine, formamide et aniline) conduit uniquement à la substitution des trois fluors en *para* à l'exception de l'aniline, de la phénylhydrazine et de la formamide qui conduisent à des mélanges de phosphines mono- et bis-substituées. Le bisulfure et divers alcoolates de sodium conduisent à la rupture de la liaison C—P même si quelques alcoolates ont conduits, dans certains cas, à un peu du produit de substitution attendu. On présente des données de spectroscopie de masse et de rmn du ^{19}F, du ^{31}P et du ^{1}H.

[Traduit par le journal]

Introduction

As part of our continuing study of rearrangements in the mass spectra of perhaloaromatic compounds (1, 2) we wish to look at a series of substituted tetrafluorophenyl derivatives of phosphorus. Rather than preparing these by reaction of the corresponding fluoroaromatic lithium reagent with PX_3, etc., we investigated the possibility of their preparation by nucleophilic displacement of fluorine from tris(pentafluorophenyl)phosphine (**1**).

Reaction of hexafluorobenzene with nucleophiles such as NH_3 (3, 4), *N*-methylacetamide (5), amines (6–8), alkoxides (9–13), etc., is a well-known route for the production of pentafluorophenyl compounds. Studies of nucleophilic attack on pentafluorobenzene and its derivatives C_6F_5X (14–19) show that the fluorine *para* to the hydrogen or other substituent X is most readily substituted (e.g., X = H, Me, SMe, NMe_2) but *meta* substitution is possible (X = NH^-, O^-). Burdon (20) and Epiotis and Cherry (21) have explained these observations on both qualitative and on a MO basis.

There have been two previous reports of nucleophilic displacement of fluorine for pentafluorophenyl phosphorus compounds. Burdon *et al.* (22) have studied reactions of nucleophiles with pentafluorophenyldiphenylphosphine (**2**), its oxide (**3**), and sulphide (**4**). With NaOMe in MeOH, **2** gave the 4-methoxytetrafluorophenyl derivative, whereas with $MeNH_2$ in MeOH the 4-*N*-methylaminotetrafluorophenyl derivative was produced. In the case of **3** and in part **4**, methoxide resulted in cleavage of the C_6F_5 group from the phosphorus, though for **4** the 4-methoxy derivative was the main product (59%) along with some 21% of the 2,4-dimethoxytrifluorophenyl derivative. Methylamine with **3** or **4** resulted in mixtures of the *ortho*- and *para*-substituted tetrafluorophenyl compound when benzene was the solvent but exclusive *para* replacement was observed in ethanol as solvent. Magnelli *et al.* (11) report that the reactions of Me_2NH with $(C_6F_5)_2PCl$ gave a mixture of $(4\text{-}NMe_2C_6F_4)_2$ $PNMe_2$ or $[C_6F_3(NMe_2)_2]P(C_6F_5)(NMe_2)$.

In this work we have reacted **1** with a wide variety of nucleophiles with the results as noted below.

Results and Discussion

Tris[4-(N,N-dimethylamino)-2,3,5,6-tetrafluorophenyl]phosphine (5)

Pedersen *et al.* (24) showed that hexamethylphosphoric triamide (HMPA) is an excellent nucleophilic reagent for the introduction of a dimethylamino group into *para*-substituted nitrobenzenes, whereas high pressures were required for corresponding reactions of dimethylamine. The reaction was surprisingly fast, giving, after only 10 min, the trisubstituted *para* product (**5**) which was isolated in good yield. A small amount of the corresponding

0008-4042/79/091011-07$01.00/0

phosphine oxide was also detected as a by-product, presumably formed by air oxidation while the reaction mix was refluxing.

An analogous reaction using dimethylformamide (DMF) also yielded product **5** but in a very much slower reaction (51 h). This slow reaction permits the preparation of the mono- and bissubstituted derivatives as well as **5** since after 3 h only 14% of the starting material is consumed and the product at that point shows substitution in one of the rings. Substitution on the second ring begins after 7 h and substitution on all three rings begins to be detected after about 12 h. The yield in the DMF preparation is lower than when HMPA is used and more phosphine oxide impurity is produced by the longer reflux times.

The diethylamino derivatives (**6**) corresponding to **5** could be similarly prepared from diethylformamide (DEF) or hexaethylphosphoric triamide (HEPA); the latter reaction is much faster than the former, but requires 30 min for incomplete reaction compared with 10 min for the complete reaction with HMPA. This is consistent with the lower nucleophilicity of HEPA vs. HMPA (25, 26). The DEF route is preferred here on the basis of cost.

Another simple amine derivative was obtained from the reaction of aniline in ethanol with **1**, yielding the bis derivative after 71 h. With aniline as the solvent the same results were seen after only 6 h. Addition of KF to the aniline gave similar results in only 3 h, an example of enhanced nucleophilicity due to hydrogen bonding (27–32).

Reactions of $(C_6F_5)_3P$ with Hydrazines

Aqueous hydrazine in ethanol gave a good yield of tris(4-hydrazine-2,3,5,6-tetrafluorophenyl)phosphine (**7**). No oxidation of the phosphine was observed, possibly as a result of competing oxidation of the hydrazine. The reactions were solvent dependent, a good yield being obtained with a large excess of ethanol. Tetrafluorophenylhydrazine was the major product obtained at ethanol–water mixtures on the order of 2:1 or if aqueous hydrazine alone was used. In dioxane an exothermic reaction rapidly produced the phosphine oxide, $(C_6F_5)_3PO$.

N,N-Dimethylhydrazine reacted slowly with **1** under reflux conditions (40% after 7 h) but in the presence of finely divided anhydrous potassium fluoride a 71% yield was obtained in a shorter time (1½ h). This is due to the formation of a strongly hydrogen bonded solvate, with electron density donated by the fluoride ion via the hydrogen bond being able to improve the nucleophilicity of the $—NH_2$ group of the hydrazine. In addition the KF can convert HF produced to KHF_2. This improvement in yield is another example of strong hydrogen-bond-assisted reactions studied by Clark and Miller in a recent series of papers (27–32). Theoretical calculations of Emsley *et al.* (33) showed that the Mulliken charges on the hydroxy oxygen are greater in the acetic acid – fluoride system than in free acetate ion itself, consistent with the observed results.

Although the mass spectrum showed the expected molecular ion (*m/e* 652), proton and fluorine nmr spectra revealed a mixture of two isomeric compounds. Upon recrystallization, the major product obtained was tris[4-(*N,N*-dimethylhydrazine)-2,3,5,6-tetrafluorophenyl]phosphine (**8**) as shown by the nmr (^1H δ 2.6 ppm, sharp singlet, $(CH_3)_2N—$; δ 4.5 ppm, triplet due to coupling to 2 ring fluorines, —NH—: ^{19}F δ −156.9 ppm, multiplet 2 fluorines *ortho* to —NH— and δ −134.3 ppm, 2 fluorines *ortho* to phosphorus). The second product obtained from the mother liquor was the isomer with the hydrazine isomerized from unsymmetrical to symmetrical dimethylhydrazine, i.e., tris[4-(*N,N'*-dimethylhydrazine)-2,3,5,6-tetrafluorophenyl]phosphine (**9**), contaminated by a small amount of **8**. The ^1H nmr spectra show one methyl resonance at δ 2.6 and a second at 3.0 split into a triplet by the *ortho*-ring fluorines, the chemical shift being similar to that in compound **5**. Similarly, the ^{19}F nmr spectra has a new multiplet at δ −152.5 very similar to that observed for the two fluorines *ortho* to the $—NMe_2$ group in **5**. The other two fluorine resonances overlap those of **8**, such that their integrated intensity is equal to the two sets of fluorines *ortho* to nitrogen at δ −152.5 and −156.9. We are unable to account for this isomerization. On refluxing **1** with phenylhydrazine in THF a monosubstituted derivative was isolated, this being bispentafluorophenyl-(4-β-phenylhydrazine-2,3,5,6-tetrafluorophenyl)phosphine, ^1H and ^{19}F nmr confirming the structure.

Substitution by NH_2 Groups

Reaction of ammonium hydroxide with **1** in refluxing ethanol or THF with or without the presence of KF was unsuccessful but at elevated pressure in ethanol, mono- (**10**), di- (**11**), and tri- (**12**) substituted species were observed along with mixed species involving attack of both NH_2^- and ethoxide ion. In isopropanol the major product was the trisamino derivative (**12**). In hexane, a mixture of **11** and **12** was obtained. Ammonium hydroxide with no ethanol gave a mixture of **10**, **11**, and **12**, though anhydrous ammonia in ethanol did not react after 24 h. However, in THF at 130°C in the presence of anhydrous KF, anhydrous ammonia gave **11** as the sole product after 24 h or a mixture at a shorter time. This is another example of a hydrogen-bond-assisted reaction.

Refluxing **1** with commercial formamide gave a

mixture of **10**, **11**, and **12** plus a side product identified as $(NH_2C_6F_4)_2PC_6F_4NHCHO$ (**13**).

Other Nucleophiles

The reactions of **1** with different alkoxides in the corresponding alcohols lead mainly to C—P bond cleavage giving pentafluorobenzene and alkoxytetrafluorobenzene as the main products. When triphenylphosphine itself was subjected to similar conditions it was recovered unchanged. In pentafluorophenyldiphenylphosphine C—P bond cleavage did not occur but rather the fluorinated ring was substituted in the 4 position (22). It thus appears that on increasing fluorine substitution in the rings, the C—P bond becomes more susceptible to nucleophilic attack. However, with some of the higher alkoxides such as *tert*-butoxide, reaction at room temperature slowly gave a mono-substituted derivative. When methanol was replaced by ether as the solvent in the reaction of **1** with sodium methoxide, a 20% yield of tris(4-methoxy-2,3,5,6-tetrafluorophenyl)phosphine (**14**) was obtained as well as the usual cleavage products.

Somewhat similar behaviour was observed for tris(pentafluorophenyl)phosphine oxide (**15**), i.e.,

$$(C_6F_5)_3PO \xrightarrow[CH_3OH \text{ or hexane}]{NaOCH_3} (CH_3O)_2C_6F_3{-}\overset{\overset{O}{\parallel}}{P}{-}(OCH_3)_2$$

15 **16**

SH^- nucleophiles resulted only in cleavage products.

Nuclear Magnetic Resonance Studies

The ^1H, ^{19}F, and ^{31}P nmr spectra of the *para*-trissubstituted derivatives are summarized in Table 1. The proton nmr data are similar to that observed for the corresponding substituted benzene or pentafluorophenyl derivative, a fact which aided appreciably in the determination of substitution and isomerization in the case of the hydrazine derivatives.

In the ^{19}F spectra, $\delta_{2,6}$, the chemical shift of the fluorines *ortho* to phosphorus are only slightly affected, the range of shifts being from a low of -130.6 ppm for X = F to a maximum of -135.2 ppm for X = NH_2. Crudely, there is an electronegativity effect, on changing the substituting atom from F to O to N. All five nitrogen derivatives fall into the narrow range of -134.1 to -135.2 ppm. The range is only 0.7 ppm if —NH_2 is not considered.

The second ^{19}F shift, $\delta_{3,5}$, that of the fluorines *ortho* to the nucleophile and *meta* to the phosphorus show a much wider variation. The shift now ranges from -150.8 to -162.5 ppm in the following order of shifts upfield of $CFCl_3$: $NEt_2 < NMe_2 < NHNH_2 < NHNMe_2 < OCH_2 < F < NH_2$.

The F—F coupling constants show little variation, what there is usually being characteristic of the nucleophile X. For example, $J_{2,3}$ is in the narrow range of 19–21 Hz for nitrogen nucleophile vs. 16.7 for —OMe and 24.2 for F. None of the other F–F couplings of the AA′BB′X system show any systematic variation. Similarly, the P–F couplings show little variation on substitution of the fluorine at position 1 by various species, J_{P-F} falling into a narrow range of 35.8–37.8 Hz.

There was also very little variation in the ^{31}P chemical shifts. By far the greatest variation was noted when deuterioacetone rather than the $CDCl_3$ had to be used as the solvent.

Mass Spectra

The mass spectra of these compounds did not exhibit the dominant losses of PF_3, PF_2, and PF neutral species previously reported for **1** and related compounds (34, 35). Rather, the spectra appear to be dominated by fragmentation of the substituent. Only one compound, the amino derivative **12** showed metastable ion supported loss of PF_2 from the R_2P^+ ion (Scheme 1). This is contrasted with the fragmentation of the dimethylamine compound **5** shown in Scheme 2. Here the metastable ions show either loss of entire ligands or fragmentation of the ring substituent. The loss of HF is a common mode of fragmentation. The concentration of fragmentation modes involving the nitrogen or oxygen based nucleophiles suggests that the lone pairs on these atoms are the site of ionization, rather than the phosphorus lone pair suggested in the case of **1**.

For all the derivatives studied, the parent ions were of high intensity, being the base peak for compounds **1**, **5**, **12**, and **14**. For the remaining compounds the base peak is derived from losses of simple moieties from the nucleophile. All compounds showed loss of a first C_6F_4X group followed by a second, consistent with the behaviour of the parent compound $(C_6F_5)_3P$. Similar fragmentation of substituents is observed from the parent ion, R_3P^+, and the two products of the above cleavages, the R_2P^+ and RP^+ ions. For example, NMe_2 is lost from each in the case of **5**, C_2H_5 or CH_3 lost from each in the spectra of **6**, NH in the case of **7**, CH_3 from **8**, and OCH_3 or CH_3 in fragmentation of **14**. For almost all the derivatives studied, high mass ions carried the bulk of the positive ionization.

Experimental

Infrared spectra were recorded on PE 225 or 237B spectrometers using KBr disks. Nuclear magnetic resonance spectra were obtained on a Bruker WP-60 FT nmr spectrometer operating at 60 MHz (^1H, 90° pulse = 3.8 μs), 56.45 MHz (^{19}F, 90° pulse = 4.0 μs), and 24.288 MHz (^{31}P, 90° pulse = 11 μs). Spectra were normally run in $CDCl_3$ solution using deuterium lock, internal TMS reference (^1H), internal C_6F_6 reference (^{19}F reported relative to $CFCl_3$, negative numbers being upfield shifts) and external 85% H_3PO_4 (^{31}P). Some of

the spectra were obtained using quadrature detection after retrofit of this facility. Spectra were normally accumulated using a 30° flip angle in PAPS modes. Spectrometer operation was under the control of the Bruker FT nmr programs both disk and nondisk versions; 8K data blocks were collected giving 4K spectral blocks. Computed spectra and interactive fits of coupling constants were calculated on the WP-60 using the program NMRCAL + ITRCAL. The nmr data are summarized in Table 1.

Mass spectra were obtained on an AEI MS-30 double beam, double focussing mass spectrometer, operating at 70 eV ionizing energy, 4 kV acceleration voltage, 100 μA trap current, 1000 resolution, and a source temperature of 180°C. Solids were introduced into beam I via a solid probe and referenced to PFK in beam II inserted via a gas probe. Gas chromatographic – mass spectral analyses were carried out on a Pye 104 chromatograph interfaced to the MS-30 via both a glass frit and membrane separator, the former being preferable for these compounds. A 6 ft × ¼ in. glass column packed with 3% SE30 on Chromosorb W was used for all separations. Spectra are reported relative to the base peak equalling 100%.

Starting materials were prepared by literature methods for **1** (36) and **15** (23) with slight modifications to improve yields. Representative synthetic reactions are described below.

Reactions of 1 with HMPA and DMF

To a two-necked 100-mL flask fitted with a condenser and N_2 inlet, **1** (2.2 g, 4.0 mmol) was added along with hexamethylphosphoric triamide (15 mL) and stirred under reflux for 10 min at 230°C. On cooling, a pale yellow solid (2.2 g, 92%) was precipitated with 75 mL of sodium bicarbonate solution. The crude material recrystallized from ethanol and gave short white needles of tris[4-(*N*,*N*-dimethylamino)-2,3,5,-6-tetrafluorophenyl]phosphine (**5**) (1.8 g, 75% yield), melting at 110°C; ms *m/e* (relative intensity): 608(27), 607(M^+, 100), 606(11), 416(8), 415(32), 399(10), 223(22), 222(8), etc., ir ν_{max}: 2925(m), 2875(m), 2800(m), 1625(s), 1520(s), 1460(s), 1430(s), 1380(m), 1230(s), 1065(s), 960(m), 815(w) cm^{-1}; nmr, see Table 1. *Anal.* calcd. for $C_{24}H_{18}F_{12}N_3P$: C 47.45, H 2.97, N 6.92, F 37.56, P 5.11; found: C 47.0, H 2.85, N 7.14, F 37.43, P 5.09.

In an analogous reaction, **1** (1.5 g, 2.8 mmol) and DMF

(50 mL) were refluxed 51 h at 150°C. Work up as above gave **5** after recrystallization (1.2 g, 71% yield, mp 110°C), confirmed by spectral data and microanalysis. A similar reaction was monitored over a period of 23 h and the variations in the products are summarized below.

	Composition of product mix (%)*				
Product	3 h	7 h	9 h	13 h	23 h
$(C_6F_5)_2PC_6F_4NMe_2$	14	24	40	45	50

$(C_6F_5)_3P$	86	74	56	30	15

*Determined by ^1H and ^{19}F nmr.

*Reactions of **1** with DEF, HEPA, and Aniline*

Compound **1** (4 g, 7.6 mmol) was reacted for 71 h under reflux at 170°C with diethylformamide (50 mL). After cooling, the mixture was stirred for 1 h with a dilute solution of sodium bicarbonate. If no precipitate is obtained at this point, the mixture may be extracted with ether and the ethereal layer dried over $MgSO_4$ and evaporated to yield a brown liquid. This material, when chromatographed with toluene on a 60 cm silica gel column (50–200 mesh), gave a white solid, which, when recrystallized from ethanol, yielded white crystals of tris(4-*N*,*N*-diethylamino-2,3,5,6-tetrafluorophenyl)phosphine (**6**) (2.6 g, 50% yield), mp 135°C; ms *m/e* (relative intensity): 691(M^+ 81), 676(100), 662(5), 648(5), 632(16), 604(6), 574(5), 560(6), etc.; ir ν_{max}: 2965(m), 2925(w), 2865(w), 1625(s), 1455(s), 1367(d), 1340(w), 1195(s), 1085(s), 965(m), 815(m); nmr; see Table 1. *Anal.* calcd. for $C_{30}H_{30}N_3F_{12}P$: C 52.1, H 4.34, N 6.08, F 33.00, P 4.49; found: C 52.31, H 4.31, N 6.01, F 33.03, P 4.33.

In an analogous reaction, compound **1** (1 g, 2 mmol) was stirred under reflux with 10 mL of HEPA for 30 min. Reaction was not complete, with the disubstituted derivatives being observed. On the basis of cost this reaction was not pursued.

Reactions of **1** with aniline were tried under various conditions and the product identified spectroscopically. The mixture of mono-, di-, and trisubstituted product was not separated. A summary of these reactions is given below.

$(C_6F_5)_3P$ (g)	Aniline (mL)	C_2H_5OH (mL)	Reflux time (h), (temperature °C)	Substitution product (%) Mono	Di	Tri
1.1	35	35	2(86)	80	20	—
1.1	20	35	41(86)	70	25	5
1.1	20	35	48(86)	30	60	10
1.1	30	35	71(86)	10	80	10
1.1	30	—	6(180)	10	88	2
1.1	20	0.74 g KF added	3(180)	?	90	?

*Reactions of **1** with Hydrazine*

Compound **1** (3.2 g, 6.0 mmol) in absolute ethanol (105 mL) and 6.0 g of 64% aqueous hydrazine were stirred under reflux for 16.5 h. After cooling, the mixture was poured into 250 mL of water and a white solid (2.8 g) was collected by filtration. Recrystallization from aqueous ethanol gave white crystals of tris(4-hydrazino-2,3,5,6-tetrafluorophenyl)phosphine (**7**) (2.7 g, 79% yield), mp 145°C; ms *m/e* (relative intensity): 568(M^+, 93), 523(100), 508(95), 359(57), 344(45), 343(41), 342(48), 210(55), etc.; ir ν_{max}: 3300(s, br), 2580(w), 1640(s), 1464(s), 1376(m), 1296(m), 1272(s), 1184(m), 1152(s), 1112(m), 1088(m), 1048(w), 972(s), 916(m), 856(w), 832(w), 800(m) cm^{-1}; nmr, see Table 1. *Anal.* calcd. for $C_{18}H_9F_{12}N_6P$: C 38.03, H 1.58, N 14.79, F 40.14, P 5.46; found: C 37.95, H 1.55, N 14.90, F 40.23, P 5.46.

Compound **1** (2.1 g 4 mmol), *N*,*N*-dimethylhydrazine (UDMH, 99%, 6.0 g, 100 mmol), and potassium fluoride (2 g, 35 mmol) were stirred under reflux for 90 min and, after cooling, treated with a dilute sodium bicarbonate solution. The precipitate gave a white solid (2.1 g, 80.5%), mp 110°C. The nmr showed two isomers present (see Discussion). Recrystallization from ligroin (30–60°C) produced a white crystalline solid of tris(4-*N*,*N*-dimethylhydrazino-2,3,5,6-tetrafluorophenyl)phosphine (**8**) (1.8 g, 71% yield), mp 117°C; ms *m/e* (relative intensity): 652(M^+, 65), 608(43), 607(100), 565(35), 564(97), 238(85), 195(48), 69(41); ir ν_{max}: 3250(s), 2950(m), 2850(m), 2825(m), 2775(m), 2550(w), 1635(s), 1455 (s,br), 1375(s), 1270(s), 1625(w), 1210(w), 1110(s), 1015(w), 965(w), 875(m), 815(w), 725(s) cm^{-1}; nmr, see Table 1. *Anal.* calcd. for $C_{24}H_{21}N_6F_{12}P$: C 44.17, H 3.22, N 12.88, F 34.97, P 4.75; found: C 43.9, H 3.55, N 13.0, F 34.79, P 4.76.

The mother liquid yielded a material which showed the same mass spectra and an nmr spectrum indicative of a mixture of **8** and its SDMH isomer.

Compound **1** (1 g, 2 mmol), tetrahydrofuran (35 mL), and phenylhydrazine (2.0 g, 97.5%) were stirred under reflux for 8 h. After cooling and adding water, the product was extracted into ether, the ethereal extracts dried over $MgSO_4$, and evaporated giving a yellow solid. Recrystallization from aqueous ethanol gave yellow crystals of bispentafluorophenyl-(4-β-phenylhydrazino-2,3,5,6-tetrafluorophenyl)phosphine (0.4 g, 32%), mp 110°C; ms *m/e* (relative intensity): 620(M^+, 46), 529(46), 528(27), 362(35), 198(22), 105(27), 92(100), 77(81), 69(39), etc.; ^1H nmr δ: 5.87 (m, 1H), 613 (m, 1H), 6.99 ppm (m, 5H); ^{19}F nmr δ: −131.50 (m, 4F), −132.78 (m, 2F), −149.92 (m, 2F), −158.78 (m, 2F), −161.06 (m, 4F).

*Reactions of **1** with NH_4OH*

Compound **1** (1 g, 2 mmol), ammonium hydroxide (5 mL, 28–30% NH_3), potassium fluoride (3 g, 52 mmol), and THF (5 mL) were placed in a large glass test tube (16 × 3.6 cm) and placed in a 3000 psi Parr bomb (198-mL capacity). The bomb was cooled in liquid N_2 and the air evacuated. The sealed bomb was heated for 22 h at 130°C. On cooling the bomb was opened and its contents treated with dilute sodium bicarbonate solution, followed by extraction with ether. The ethereal extract gave a pale yellow solid (0.6 g) which was recrystallized from ligroin (30–60°) to give white crystals of tris(4-amino-2,3,5,6-tetrafluorophenyl)phosphine (0.5 g, 50%), mp 159°C; ms *m/e* (relative intensity): 541(21), 523(M^+, 100), 508(7.3), 360(8.3), 359(48), 290(9.6), 195(14.6), 79(33), etc.; ir ν_{max}: 3500(m), 3400(s), 2600(w), 1650(s), 1510(s), 1475(s), 1375(s), 1300(w), 1270(s), 1175(m), 1115(s), 290(m), 825(w), 750(w), 735 cm^{-1}; nmr, see Table 1. *Anal.* calcd. for $C_{18}H_6F_{12}N_3P$: C 41.30, H 1.15, F 43.59, N 8.03, P 5.93; found: C 41.31, H 1.03, N 8.18, F 43.52, P 5.80.

*Reaction of **1** with Sodium Methoxide*

To a solution of **1** (2.2 g, 4.0 mmol) in ether (200 mL) a solution made by dissolving sodium (0.276 g, 13 mmol) in dry methanol (15 mL) was added dropwise over 1 h. After 2 h at room temperature, the solution was treated with water and extracted with ether. Gas-chromatography – mass spectrometry showed the ethereal extract to contain four compounds with molecular ions of 168, 180, 140, and 568 corresponding to pentafluorobenzene, tetrafluoroanisole, trimethylphosphite, and tris(methoxytetrafluorophenyl)phosphine. Chromatography on silica using benzene as eluant gave a 20% yield of

a yellow liquid, tris(4-methoxy-2,3,5,6-tetrafluorophenyl)-phosphine; ms *m/e* (relative intensity): 569(30), 568(M^+, 100), 469(9), 389(38), 229(26), 210(50), 193(10), 167(10), etc.; ir ν_{max}: 2910(m), 2820(m), 1640(s), 1525(w), 1475(s), 1435(s), 1375(s), 1275(w), 1190(s), 1110(s), 980(m), 910(m), 813(m), 725(s) cm^{-1}; nmr, see Table 1.

The hydrolysis and ammonolysis of EDTA were studied in aqueous solution over a range of temperatures and at various pH values with the aid of nmr, gc, and gc – mass spectroscopic techniques. At high pH in the presence of ammonia, both ammonolysis and hydrolysis occur with the production of *N*-(2-aminoethyl)iminodiacetic acid (UEDDA), *N*-(2-hydroxyethyl)-iminodiacetic acid (HEIDA), and iminodiacetic acid (IDA) in molar ratios such that [IDA] = [UEDDA] + [HEIDA]. The first-order rate constant for the disappearance of EDTA at 175°C in dilute aqueous ammonia is 8.6×10^{-5} s^{-1} whereas in the absence of ammonia its hydrolysis constant is 4.2×10^{-5} s^{-1}. The value of ΔH^0 for this reaction is approximately 35 kcal/mol. When methylamine replaces ammonia, the UEDDA is replaced by *N*-(2-methyl-aminoethyl)iminodiacetic acid. The rate of hydrolysis is increased by the presence of a tertiary amine but the latter does not become incorporated into the reaction products. A reaction mechanism is proposed involving bimolecular S_N2 attack by base on a carbon atom of the ethylene bridge adjacent to a protonated nitrogen atom of EDTA with concomitant displacement of iminodiacetic acid.

RAMUNAS J. MOTEKAITIS, DAVID HAYES, ARTHUR E. MARTELL et WAYNE W. FRENIER. Can. J. Chem. **57**, 1018 (1979).

On a étudié l'hydrolyse et l'ammonolyse de l'AEDT dans des solutions aqueuses à diverses températures et divers pH en faisant appel à des techniques de rmn, de cpg et de spectroscopie de masse couplée à la cpg. A des pH élevés, en présence d'ammoniaque, il se produit une ammonolyse ainsi qu'une hydrolyse avec formation d'acides *N*-(amino-2 éthyl)iminodiacétique (AAEID), *N*-(hydroxy-2 éthyl)iminodiacétique (AHEID) et iminodiacétique (AID) dans les rapports molaires tels que [AID] = [AAEID] + [AHEID]. La constante de vitesse du premier ordre pour la disparition de l'AEDT à 175°C en solution dans l'ammoniaque dilué est égale à 8.6×10^{-5} s^{-1} alors qu'en l'absence d'ammoniac, la constante d'hydrolyse est égale à 4.2×10^{-5} s^{-1}. La valeur du ΔH^0 pour cette réaction est approximativement 35 kcal/mol. Si l'on remplace l'ammoniaque par de la méthylamine, il se forme de l'acide *N*-(méthylamino-2 éthyl)iminodiacétique au lieu de AAEID. La vitesse d'hydrolyse est accélérée par la présence d'une amine tertiaire; celle-ci n'est toutefois pas incorporée dans les produits de la réaction. On propose un mécanisme réactionnel impliquant une attaque S_N2 bimoléculaire par la base sur un atome de carbone du pont éthylène voisin de l'atome d'azote de ARDT protoné avec une substitution simultanée de l'acide iminodiacétique.

Introduction

Since important applications of EDTA involve its use in aqueous solution at high temperature and pressure and possibly in the presence of ammonia or other basic compounds, it seemed that a study of the kinetics and mechanism of such reactions would be of importance. Earlier studies of EDTA hydrolysis at elevated temperatures (1–6) resulted in conflicting reports. These experiments were carried out at relatively high temperatures, which precluded accurate determination of reaction rates. The present work describes hydrolytic measurements at more moderately elevated temperatures that allow the measurement of the rates of appearance of reaction products and the rates of disappearance of EDTA. The influence on reaction rate and product distribution resulting from the addition of basic substances such as ammonia and methylamine was also studied and was found to have mechanistic implications.

The pH was generally maintained at or near 9.3 by the addition of ammonia as a buffer as well as a reactant. The temperature range employed in this investigation, 145–175°C, was selected to provide a

[1]This work was carried out in the course of a contract between Dow Chemical Company and Coordination Chemistry Consultants.

0008-4042/79/091018-07$01.00/0

convenient range of reaction rates for experimental measurements.

Experimental

Materials

EDTA, methylamine, and triethylamine were obtained from Eastman Chemical Company. Hydroxyethyliminodiacetic acid (HEIDA) and iminodiacetic acid (IDA) were obtained from Aldrich Chemical Company. Reagent grade ammonia and gaseous hydrogen chloride for esterification were obtained from Matheson, Coleman and Bell. Methanol and potassium carbonate were obtained from Baker Chemical Company. The water employed was distilled from glass and the methanol was dried over Linde Molecular Sieves. The 50% NaOD/D_2O solution and 99.7% D_2O were obtained from Merck, Sharp and Dohme. Ethylenediamine-*N*,*N*-diacetic acid was synthesized by alkaline alkylation of *N*-acetylethylenediamine with bromoacetic acid, followed by alkaline hydrolysis of the amido group. *N*-Acetylethylenediamine was prepared by refluxing excess ethylenediamine with ethyl acetate for a 12-h period.

Instrumentation

The nmr spectra were recorded with a Varian T-60 nmr spectrometer which was found to be sufficiently accurate for quantitative determinations with the use of the sample preparation procedure described below. The gas chromatograms were obtained at 200°C on a Hewlett-Packard Model HP 5834a gas chromatograph equipped with a 12-ft, 3% OV-1 column and both FID and TC detectors. The gc mass spectrograms were measured with a Hewlett-Packard Model HP-5982-59-33, housed and operated by the Texas A&M Center for Trace Characterization, with the same chromatographic column but with linear temperature programming to shorten data collection time.

pH was measured at room temperature with a Beckman Research Model pH meter equipped with extension glass and calomel electrodes and was calibrated with standard strong acid and base to measure hydrogen ion concentration directly. The pH values cited in this paper were those measured at room temperature although the pH values at the high temperatures of the experimental runs may be estimated with known values of the heats of dissociation of water and heats of dissociation of the various bases used as buffers.

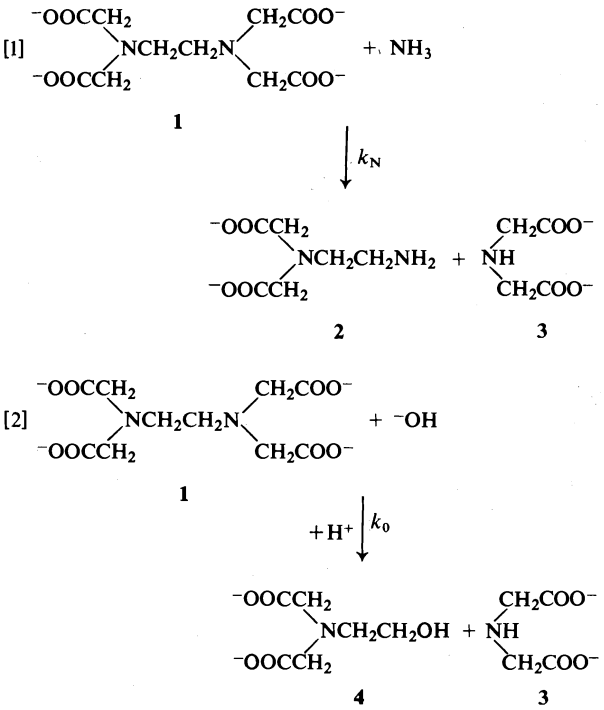
Procedure

Typical experimental runs were carried out as follows: a 2-L titanium glass-lined autoclave equipped with a titanium stirrer was charged with 1.50 L of 0.015–0.695 *M* EDTA, previously adjusted to the desired pH in the range 5.5–11, and was heated rapidly to the desired temperature in the range 145–175°C. Samples of the reaction solution were withdrawn at timed intervals and were analyzed either by nmr, gc, or gc – mass spectrometry. The nmr samples were prepared and measured in alkaline D_2O relative to TMS as an internal standard. The solvent was replaced by D_2O several times, followed by evaporation, and finally the solution was made up to 0.50 ml with 5% NaOD in D_2O. Precision nmr tubes were employed and calibrated by integration of a standard EDTA solution. Samples for gas chromatography were prepared through the use of a quantitative Fischer (7) methyl esterification procedure. Excess HCl was removed by vacuum evaporation followed by dilution to the desired concentration with dry methanol. Solid potassium carbonate was used to liberate the free esters from their hydrochloride salts immediately before injection in the gas chromatograph. Samples for gc – mass spectrometer analysis were prepared in the same manner.

Results and Discussion

Product Identification

EDTA (**1**) was found to decompose in dilute aqueous ammonia solution at 145–175°C by the nucleophilic attack of ammonia (eq. [1]) on **1** to produce *N*-(2-aminoethyl)iminodiacetic acid (**2**) and iminodiacetic acid (**3**) and by a similar hydroxyl attack (eq. [2]) to give *N*-(2-hydroxyethyl)iminodiacetic acid (**4**) in addition to **3**. The aminolysis reaction (eq. [1]) is new and had not been described previously, while the hydrolysis reaction (eq. [2]) is consistent with previous studies (1, 4, 5, 8) which had been made at much higher temperatures in ammonia-free systems.



Originally, tentative product identification was made through nmr spectral analysis. Although it had been reported earlier that the hydrolytic cleavage of EDTA produces **4** and **3**, the similarity in the values of the chemical shifts between the respective protons in acetate groups of compounds **2**, **3**, **4**, and even **1** precluded an unequivocal determination by the nmr method that **2** had indeed been formed. As is also shown in Table 1, a similar ambiguity arose which was caused by the proximity of the ethylene proton chemical shifts in the starting material **1** and the ammonia cleaved product **2**.

TABLE 1. Nuclear magnetic resonance spectra (60 MHz) of reference compounds measured in 0.15 *M* D_2O solutions containing 5% NaOD; chemical shifts are reported in Hz relative to trimethylsilylpropanesulfonate (TMS*)

Iminodiacetic acid (**3**)	186	
N-Hydroxyethyliminodiacetic acid (**4**)	191(2)	214(1)[b] 160(1)[b]
Glycine($NH_2CH_2COO^-$)	186	

[a]Relative integrated intensities in parentheses.
[b]Triplet.

A more direct confirmation of the new reaction product **2** was obtained through comparisons of the retention times shown in Table 2 from gas–liquid chromatograms of the methyl ester derivatives of the standard compounds with those obtained from the methyl esterified reaction mixture shown in Table 3. The gc technique also helped confirm the presence of the normal hydrolysis products, **3** and **4**, which had already been shown to form under the conditions of higher temperature even in the absence of ammonia. Table 2 contains a summary of the gc analytical data which were not only indispensable in fixing the reaction products but also provided evidence for the absence of any significant quantities of other side products. Thus, the reaction cleanly led only to the three products shown in [1] and [2].

To help appreciate the mechanism and the scope of these reactions, other reagents were substituted for dilute ammonia for adjusting pH, and representative samples of the results obtained are also presented in Table 3. All these reactions appear clean under a variety of reagent conditions as evidenced by the absence of gc peaks corresponding to the appearance of side products.

In the absence of ammonia, only the normal water-cleaved EDTA hydrolysis products were found. These experiments were carried out using NaOH, or TEA (triethylamine), or borax buffers. By contrast, ammonia was found to become incorporated into EDTA through the formation of UEDDA (**2**) and in an analogous way methylamine was found to react with EDTA according to [3] to give *N*-(2-methylaminoethyl)iminodiacetic acid (**5**) and the usual IDA (**3**). These assignments were made through the comparison of retention times listed in Table 3. In particular, the evidence for **5** was the appearance of a new single gc peak at 4.04 min replacing the 4.88 peak for UEDDA. The nmr spectrum (Fig. 1) of the product showed additional resonances at 2.26 and 2.92 ppm relative to TMS* (trimethylsilylpropionate), which are ascribable to

TABLE 2. Retention times and relative intensities/unit concentration of gas chromatographic peaks representing the methyl ester derivatives of compounds encountered in this study of EDTA in dilute ammonia solutions at 145–175°C and pH 5.5–11.0

No.	Compound	Retention time (min)	Relative sensitivity[a]
1	EDTA	21.05	1.00
2	UEDDA	4.88	0.39
3	IDA	1.05	0.55
4	HEIDA	2.73	0.34

[a]Values depend on both yield of derivative and on detector (FID) response.

TABLE 3. The gas chromatographic determinations of the esterified reaction products formed in the employment of various buffers to achieve an initial pH of 9.3 on EDTA solutions which were subsequently heated at 175°C[a]

Original composition	Derivative retention time (min)	Product assignment
EDTA + NaOH	1.03	IDA
	2.67	HEIDA
	21.53	EDTA
EDTA + NH_3	1.04	IDA
	2.69	HEIDA
	4.85	UEDDA
	21.55	EDTA

	2.85	HEIDA
	21.15	EDTA

[a]Unless stated otherwise.
[b]TEA = triethylamine.

[3] 
1 5 3

$N—CH_3$ and $N—CH_2CH_2—N$ type proton groupings. The 2.26/2.92 peak ratio is ~3:4.

The chemical shift assignments were confirmed by comparison with the chemical shifts observed for an 'analogous' N-methyl compound measured under identical conditions. Thus for *N,N'*-dimethylethylenediamine the resonance for $N—CH_3$ appears at 2.28 ppm and the remaining resonance for the dimethylene bridge protons is at 2.63 ppm from TMS*.

The degradation experiment under added oxygen was performed at 145°C and confirms that EDTA is stable toward oxidation by molecular oxygen. However, the presence of UEDDA was not detected at this temperature indicating a higher temperature reaction coefficient for ammonolysis as compared with the hydrolysis. For safety reasons, the reaction was not investigated under pressurized oxygen at higher temperatures.

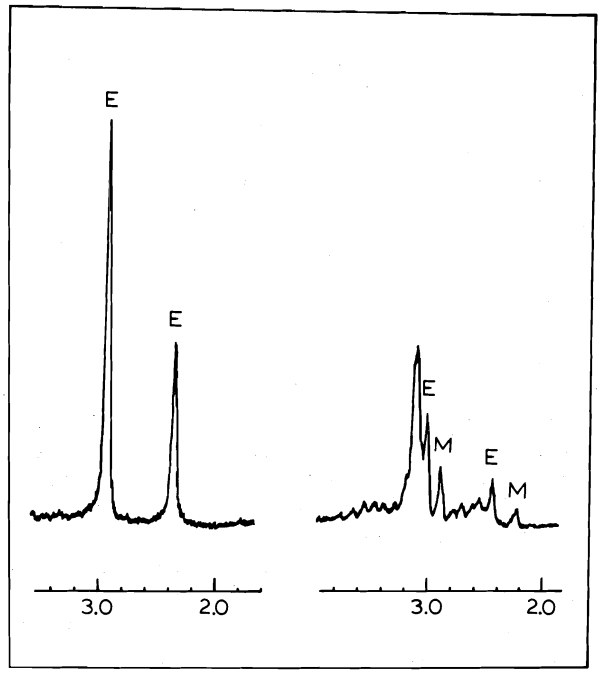

FIG. 1. Nuclear magnetic resonance spectra of two samples from the hydrolysis of EDTA at 175°C pH (25°C) 9.3 buffered with methylamine. Scale is in ppm relative to internal trimethylsilylpropionate: left, before heating; right, after 4.0 h of heating. Peaks marked M (see text) indicate the incorporation of methylamine through the formation of *N*-methylethylenediamine-*N'*,*N'*-diacetic acid; E represents EDTA peaks.

Ultimate identification of the reaction products shown in [1] and [2] was obtained through the comparison of gc – mass spectrometric data measured on the methyl esterified hydrolysis reaction products with those obtained on a set of methyl esterified known reference compounds. The mass patterns were identical in peak position, ratio, and number for corresponding pairs of compounds. The last four peaks and the strongest peaks are tabulated in Table 4.

An examination of the mass spectra indicates that EDTA and IDA esterify normally to yield the tetramethyl ester, 348 u, and the diester, 161 u, respectively, whereas UEDDA cyclizes during the acidic treatment with methanol to produce the monomethyl lactam, 172 u, while HEIDA forms a cyclic monomethyl lactone, 173 u. However, it is believed that under the experimental basic aqueous solution conditions, the actual products **2**, **3**, and **4** exist in their respective open forms.

Kinetics of EDTA Decomposition

For the chemical changes specified by [1] and [2], the overall rate of disappearance of EDTA through parallel solvolytic and ammonolysis paths was found to be proportional to the concentration of unreacted EDTA. Since the pH of the medium remained constant and a large excess of NH_3 was generally employed, first-order reaction conditions prevailed over a significant portion of the reaction time. Although the overlap in the nmr peak positions precluded the routine determination of the rates of formation of the three individual reaction products, the nmr method provided a very convenient means for following the rate of disappearance of EDTA itself.

The kinetic data listed in Table 5 were obtained from the slopes of plots of $\log_e I$ vs. t (I = integrated intensity of the $—CH_2CH_2—$ resonance) reflecting the observed first-order kinetic expression shown in [4]. These rate constants were measured at two

$$[4] \qquad -\mathrm{d[EDTA]}/\mathrm{d}t = k_{obs}\,[\mathrm{EDTA}]$$

concentrations and three temperatures as shown, yet appeared to be concentration independent within the scatter of the data. From a plot of $\log_e k_{obs}$ against reciprocal absolute temperature, the activation parameter $\Delta H_a^{\ddagger}$ was found to be 34.6 ($\sigma = 0.7$) kcal/mol.

With the fundamental rate law established for aqueous ammonia at pH 9.30 and 175°C and a firm

TABLE 4. Gas chromatographic – mass spectrometric data for EDTA-tetramethyl ester and esterified reaction products formed in ammoniacal solutions of EDTA at 145–175°C

No.	Compound	Mass (u)	Form	Last four peaks				Strongest peak
1	EDTA	348	Tetraester	317.1	348.2	349.2	350.2	174.1
2	UEDDA	172	Monoester lactam	157.1	163.0	172.1	173.0	113.1

TABLE 5. The pseudo-first-order rate constants for the disappearance of EDTA measured in aqueous NH_3 at pH 9.3 as a function of temperature and concentration

$[EDTA]_0$ (mol/L)	Time-averaged temperature	σ (°C)	k_{obs} (s^{-1})	σ (s^{-1})
0.015	174	4	7.8×10^{-5}	0.5×10^{-5}
0.065	175	1	8.8×10^{-5}	0.5×10^{-5}
0.015	162	1	2.5×10^{-5}	0.2×10^{-5}
0.065	163	1	2.8×10^{-5}	0.3×10^{-5}
0.015	149	1	7.5×10^{-6}	0.8×10^{-6}
0.065	149	1	8.1×10^{-6}	1.4×10^{-6}

proof of the reaction products formed, other reaction conditions were tried and the results of the variation in temperature, reagents, and pH are listed in Table 6. Thus, when ammonia is not present and NaOH is used to adjust the pH to 9.4, the value of the observed rate constant k_{obs} is reduced to about one-half of the original magnitude observed when NH_3 is present. Likewise, when pyridine was employed to effect 'neutralization' and just enough NH_3 was added to raise the pH, the value of the rate constant exceeded that of the NH_3-free run but was much lower than the NH_3-buffered solutions. Triethylamine in place of ammonia showed definite catalytic activity with a k_{obs} of $6.4\times10^{-5}\ s^{-1}$, yet only hydrolytic products were formed. Methylamine approached the reactivity of ammonia with a resulting k_{obs} of $7.8\times10^{-5}\ s^{-1}$ with the reaction progressing according to [4].

Variation in pH on the ammonia system showed that at pH 6.01, which corresponds to about half neutralization of EDTA, the rate constant was about the same as in the absence of ammonia at pH 9.3, with $k_{obs} = 3.6\times10^{-5}\ s^{-1}$. On the other hand, a very large excess of ammonia, pH 11.08, led to a pronounced increase of the rate with $k_{obs} = 1.1\times10^{-4}\ s^{-1}$.

The variation in k_{obs} measured under a variety of conditions indicates that the rate law may be a composite of both hydrolytic and ammonolysis terms with each term in turn depending on the degree of protonation of the EDTA anion itself. Therefore, in the most general case, the rate law may be expanded, as shown in [5], to include all the individual EDTA species present in the pH range over which the measurements have been made. The pseudo-first-order kinetic expression shown in [4] becomes identical with [5] only under three conditions: (*i*) the reactive species of EDTA predominates to the virtual exclusion of the other species in equilibrium with it; (*ii*) only one form of EDTA is reactive, irrespective of its concentration, while the remaining species are sufficiently less reactive to be neglected; (*iii*) the very remote possibility that the rate constants of the various forms are equivalent for reaction with NH_3, OH, OH_2 (i.e., $k_{NH_3}^{(1)} = k_{NH_3}^{(2)} = k_{NH_3}^{(3)}$, $k_{OH}^{(1)} = k_{OH}^{(2)} = k_{OH}^{(3)}$, and $k_{H_2O}^{(1)} = k_{H_2O}^{(2)} = k_{H_2O}^{(3)}$. This possibility may be discarded since reactivities of differently charged species cannot possibly be equivalent. The fact that first-order kinetics have indeed been observed under a variety of conditions provides preliminary evidence that mechanism *ii* is most likely.

$$[5]\quad -d[EDTA]/dt = \{k_{NH_3}^{(1)}[L^{4-}] + k_{NH_3}^{(2)}[HL^{3-}] + k_{NH_3}^{(3)}[H_2L^{2-}]\}[NH_3] + \{k_{OH}^{(1)}[L^{4-}] + k_{OH}^{(2)}[HL^{3-}] + k_{OH}^{(3)}[H_2L^{2-}]\}[OH^-] + \{k_{H_2O}^{(1)}[L^{4-}] + k_{H_2O}^{(2)}[HL^{3-}] + k_{H_2O}^{(3)}[H_2L^{2-}]\}$$

At this point, it is necessary to consider the detailed solution equilibria at 175°C, the temperature of the reaction. To accomplish this, the pK_a values for EDTA and NH_4^+ and K_W for water are needed at this elevated temperature. Although a direct measurement was not possible, an inverse temperature extrapolation technique was utilized to determine the ion product concentration constant for water and the proton association constants of EDTA at $\mu \simeq 0.100$ and $T = 175$°C. The values of $-\log K_W$ for water and $\log K_L^H$ for EDTA were measured at several elevated temperatures up to the boiling point of water and were then extrapolated to 175°C; $-\log K_W$ was found to be 10.72 while the successive log protonation constants for EDTA were determined to be 8.79, 5.62, 3.61, and 2.6. The pK_a for

[a]First three entries; subsequent entries are results of individual experiments.

NH_4^+ was taken from the literature (9, 10) and corrected for ionic strength while that for boric acid was calculated from the work of Mesmer *et al.* (11). The final values of log K^H used in the calculation of the initial species concentration at 175°C shown in Table 7 were 6.19 for NH_4^+ and 8.26 for H_3BO_3.

Table 7 illustrates some very important observations concerning the changes in species distributions upon elevating the temperature from 25 to 175°C. In all cases, the pH at 175°C is lower than the original to different extents, depending mainly on the principal buffer present. For example, Table 6 contains an entry which shows that the rate of hydrolysis promoted by NaOH at pH 9.4 and 25°C is characterized by a $k_{obs} = 4.28 \times 10^{-5}\ s^{-1}$. The use of material and electrobalance equations shows, in Table 7, that at 175°C, and pH 7.62, the hydroxide ion concentration rises some 20 times, while the predominating EDTA species, HL^{3-}, remains at ~93% of the total EDTA. Also the low pH solution dropped only ~0.8 pH units on heating while the free NH_3 concentration approached 10% of the total NH_3 added. The pK_a for NH_4^+ drops 2.94 log units in this temperature interval. In contrast, the borate buffered solution remained relatively alkaline, yet demonstrated a remarkably small k_{obs}. The remarkable catalytic effect of ammonia and the lack of catalysis by borate suggest an important role for low pH EDTA species in the hydrolysis reaction.

After calculation of high temperature initial distributions of the species under a variety of reaction conditions, the predominating species (*vide supra*, case *i*) model was tried both with and without k_{H_2O}. No satisfactory fit of the data could be obtained and the calculated results were inconsistent.

It was then assumed that only one protonated form of the EDTA was reactive while the remaining two were relatively unreactive. H_2L^{2-} was chosen as the reactive species because such a choice would be in conformity with several important observations. When HEIDA, or IDA, or NTA were subjected to the hydrolytic conditions described in this paper, no decomposition was observed over several half-lives of EDTA hydrolysis. The property which sets EDTA apart is that its structure possesses two basic nitrogen atoms on adjacent carbon atoms capable of facile protonation. The increased localization of positive charge resulting from diprotonation contributes to the affinity for negatively charged nucleophiles and lone pairs on amine bases, thus greatly increasing the reactivity and rate of initial nucleophilic attack. Presumably, the other EDTA species (i.e., HL^{3-} and L^{4-}) can also react with the same nucleophiles but require higher temperatures (i.e., their reaction rates are much lower).

With H_2Y^{2-} as the reactive species, [5] may be simplified considerably to give [6]. Since $[H_2L^{2-}]$ is

$$[6] \quad -d[EDTA]/dt = \{k^{(3)}[NH_3] + k^{(3)}[OH^-] + k^{(3)}\}[H_2L^{2-}]$$

only a part of the EDTA present in solution, at each pH (175°C) a concentration correction is necessary to equate terms in [4] to corresponding terms of [6]. Thus

$$[7] \quad k_{obs} = \frac{K_1^H K_2^H [H]^2 k_{obs}'}{1 + K_1^H[H^+] + K_1^H K_2^H [H^+]^2}$$

and

$$[8] \quad k_{obs}' = k_{NH_3}^{(3)}[NH_3] + k_{OH}^{(3)}[OH^-] + k_{H_2O}^{(3)}$$

Equation [8] was analyzed in two ways. First, a regression analysis was performed which in addition to giving a very poor overall fit, provided a very large $k_{H_2O}^{(3)}$ which rendered the contributions from hydroxide attack and ammonia attack relatively unimportant. The actual values obtained in this way also do not make chemical sense ($k_{OH}^{(3)} = 3.2 \times 10^{-3}\ M^{-1}\ s^{-1}$, $k_{NH_3}^{(3)} = 1.0 \times 10^{-2}\ M^{-1}\ s^{-1}$, and $k_{H_2O}^{(3)} = 3.9 \times 10^{-3}\ M^{-1}\ s^{-1}$ or $7.0 \times 10^{-5}\ M^{-1}\ s^{-1}$ for 55.5 *M* H_2O).

Another analysis of [8] was made assuming that $k_{H_2O}^{(3)}$ is relatively unimportant and as such can be

eliminated from [8]. A linear least-squares regression computation was made which gave $k_{NH_3}^{(3)} = 8.5 \times 10^{-3}\,M^{-1}\,s^{-1}$ and $k_{OH}^{(3)} = 5.1\,M^{-1}\,s^{-1}$ ($\sigma = 18\%$). This is a remarkable fit, which suggests that the kinetic model chosen is probably the correct one.

It appears then that the reaction pathways indicated by [1] and [2] may proceed by the attack of the respective nucleophiles (NH_3 or OH^-) on the diprotonated form of EDTA as shown in [9] and [10].

Enzymes in organic synthesis. 14.[1] Stereoselective horse liver alcohol dehydrogenase catalyzed oxidations of diols containing a prochiral centre and of related hemiacetals

J. Bryan Jones and Kar P. Lok

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received November 7, 1978

J. Bryan Jones and Kar P. Lok. Can. J. Chem. **57**, 1025 (1979).

The asymmetric synthetic potential of horse liver alcohol dehydrogenase catalyzed oxidations of variously 3-substituted pentane-1,5-diols has been further delineated. The oxidations proceed with enantiotopic selectivity to give the corresponding (3*S*)-3-substituted valerolactones of up to 78% ee. The reactions occur via initial oxidation of the pro-*S* hydroxyethyl group, with the initially-formed hydroxyaldehydes undergoing further *in situ* enzyme-catalyzed oxidation in their hemiacetal forms to give the (3*S*)-lactones directly. The hemiacetal oxidation step is also stereoselective, with oxidation of the (4*S*)-enantiomer being much preferred. The size of the substituent at C-3 in the diols (C-4 in the hemiacetals) affects both the enantiotopic and enantiomeric specificity of the enzyme. Both types of stereospecificity are highest when the substituents are smallest, such as methyl or ethyl, and diminish progressively for diol or hemiacetal substrates bearing large aliphatic or aromatic substituents. All reactions were carried out on a preparative (up to 2 g) scale.

J. Bryan Jones et Kar P. Lok. Can. J. Chem. **57**, 1025 (1979).

On a délimité d'une façon plus précise les possibilités en synthèse asymétrique d'oxydations catalysées par l'alcool déshydrogénase du foie de cheval de pentane-diols-1,5 varies. Les oxydations se produisent avec sélectivité énantiopique pour donner les 3*S* valérolactones correspondantes avec des èe allant jusqu'à 78%. Les réactions se produisent par l'intermédiaire d'une oxydation initiale du groupe hydroxyéthyle pro-*S*, avec une oxydation *in situ* catalysée par les enzymes, des hydroxyaldéhydes formés initialement et présents sous forme d'hémiacétals conduisant directement aux 3*S*-lactones. L'étape de l'oxydation de l'hémiacétal est aussi stéréosélective; l'oxydation de l'énantiomère 4*S* est de beaucoup favorisée. La taille des substituants en C-3 des diols (C-4 des hémiacétals) affecte la spécificité énantiotope et énantiomère de l'enzyme. La stéréospécificité de chaque type est à son maximum avec les substituants les moins volumineux tels un méthyle ou un éthyle et elle diminue progressivement lorsque les diols ou les hémiacétals portent des substituants aliphatiques ou aromatiques plus volumineux. On a effectué toutes les réactions au niveau préparatif (jusqu'à 2 g).

[Traduit par le journal]

Exploitation of the chiral catalytic properties of enzymes for asymmetric synthesis purposes is attracting increasing attention (2). HLADH,[2] a commercially available NAD^+-dependent alcohol dehydrogenase which catalyzes $CH(OH) \rightleftharpoons C{=}O$ oxidoreductions for a broad spectrum of substrates of organic chemical interest, is one of the most versatile of the enzymes of proven practical value (2). Of particular asymmetric synthesis value is its ability to effect enantiotopically selective transformations on substrates containing a prochiral centre. This was demonstrated previously (1*b*) with the diol substrates **1***a*, *d*, and *f*. The overall reactions observed are summarized in Scheme 1. For each of **1***a*, *d*, and *f*, enantiotopically selective oxidation of the pro-*S* hydroxyethyl group was the predominant reaction, with the initially-formed hydroxy aldehydes **2** undergoing subsequent HLADH-catalyzed oxidation in their hemiacetal forms **3** to give the lactones **4***a*, *d*, and *f* directly.

It is clear that two types of HLADH stereospecificity can influence the degree of enantiomeric enrichment observed in the product lactones **4**. These are enantiotopic selectivity in the **1** → **2** step and stereoselectivity during oxidation of the hemiacetal diastereomers **3**. The original study (1*b*) indicated that both types of stereospecificity could be important and that the extent of asymmetric synthesis was also affected by the nature of the R-group at C-3. However, no firm conclusions could be drawn from the limited data available.

We have now examined these important questions in more detail using the broadened structural range of diol substrates **1***a–h*. The stereospecificity of hemiacetal oxidation reaction has also been evaluated. The results show that the enantiotopic selectivity of HLADH in the **1** → **2** oxidation step

[1]For previous papers in this series, see ref. 1, and references therein.

[2]Abbreviations used: HLADH, horse liver alcohol dehydrogenase; NAD^+, nicotinamide adenine dinucleotide; FMN, flavin mononucleotide; ee, enantiomeric excess.

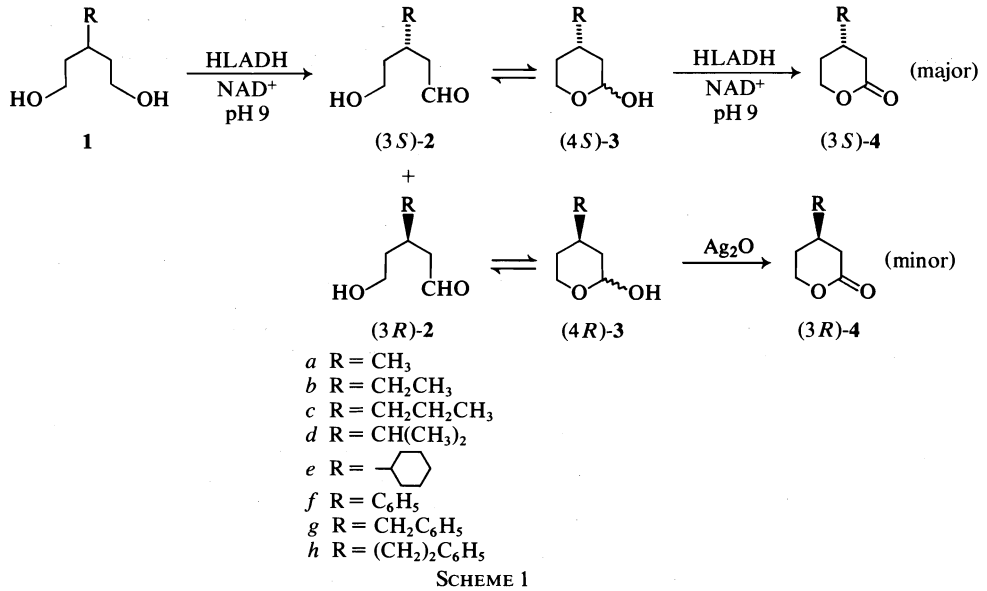

SCHEME 1

is the most important factor in determining the enantiomeric excess of the final lactone product **4** from diols **1** and that the stereospecificity of the enzyme diminishes for both **1** → **2** and **3** → **4** oxidations as the substituent R becomes larger.

Results

The diols **1***a–h* and the racemic lactones **4***a–h* were prepared by the methods used previously (1*a*, *b*) and diastereomeric mixtures of the hemiacetals **3***a–h* by reduction of (±)-**4***a–h* with diisobutylaluminum hydride (3).

Preparative-scale HLADH-catalyzed oxidations of the diols **1***a–h* and of the hemiacetals **3***a–h* were carried out at pH 9 using FMN recycling of catalytic amounts of the expensive NAD^+ coenzyme (1*d*). The reaction products contained the lactones (3*S*)-**4***a–h* and the hemiacetals (4*R*)-**3***a–h* of varying degrees of optical purity. The (4*R*)-enriched hemiacetals were oxidized to the corresponding (3*R*)-lactones with silver oxide, and the enantiomeric excesses and absolute configurations of each pair of lactones then determined. All enantiomeric excesses were determined directly (4). Absolute configurations were correlated by comparison with previously assigned (1*b*) lactones (**4***a*, *d*, and *f*) or by conversion to a 2-substituted succinic acid **7** or 3-substituted valeric acid **8** of known configuration using one of the Scheme 2 degradations. The results are summarized in Tables 1 and 2. A kinetic analysis of the hemiacetal substrate oxidations was also carried out. The data are recorded in Table 3.

[c]Based on 50% reaction.

Discussion

All of the enzyme-catalyzed reactions were carried out on synthetically significant (up to 2 g) amounts of the substrates. The hemiacetal oxidations were stopped after ~50% of reaction. (Enzyme-catalyzed resolutions of chiral substrates are traditionally terminated at this point since this is the stage at which optically pure products are obtained if the enzyme's stereospecificity is absolute). In contrast, with the symmetrical diol substrates **1**, the reactions were allowed to proceed to completion since enantiotopically selective transformations are true asymmetric inductions. Operating on symmetrical substrates thus has the great advantage that it avoids the inevitably lower (50% maximum) yields of a desired stereoisomer obtained when the substrate is a racemate. In the latter cases the unwanted enantiomers are generally wasted.

The experimental techniques used to carry out the enzyme-catalyzed oxidations were quite straightforward. The work-up procedure was also simple, consisting of continuous chloroform extraction, first at pH 3 to isolate the 3*S*-enriched lactones **4***a–h*, followed by a second continuous extraction at pH 12 to recover the 4*R*-enriched hemiacetals **3***a–h* present. The latter were all smoothly oxidized to the corresponding 3*R*-lactones with silver oxide. Good yields of the 3*S*-lactones were isolated in all cases. However, the amounts of 3*R*-enriched lactones obtained were somewhat reduced by mechanical losses during the hemiacetal extraction and subsequent oxidation stages. No attempt was made to optimize the yields in any reaction. The percentages listed in the Tables 1 and 2 can undoubtedly be improved significantly.

The optical purities of the 3*S*-lactones **4***a*, *g*, and *h* obtained previously (1*b*) were estimated from optical rotation data. Optical methods are, however, well recognized to be unreliable at times and all enantiomeric excesses reported in the present work were determined directly by gas chromatographic analysis of their (2*R*,3*R*)-butanediol orthoester derivatives (4). Care was taken during the absolute configuration correlations of Scheme 2 to ensure that no epimerization occurred at any stage.[3] Dehydrohalogenation of **5** to **6** using the diphenyldiselenide procedure (7) proved much superior to the 2,4,6-trimethylpyridine-mediated elimination used initially (1*b*).

The kinetic data (Table 3) on the hemiacetals **3***a–g* showed that each was a very good substrate of the enzyme, thereby confirming the earlier supposition (1*b*) that they were intermediates in the overall oxidation of **1** → **4**. With the exception of the

[3]The apparent discrepancies (1*b*, 6*a*) in the optical purity and absolute configuration assignments of the phenyl lactone **4***f* has now been resolved (6*b*). The (+)-enantiomer has the 3*S* absolute configuration (1*b*). A detailed investigation (6*b*) of the properties of **4***f* has shown that the erroneous 3*R* assignment (6*a*) was due to the unsuspected sensitivity of (+)-**4***f* to distillation. The other 3-substituted lactones are stable. The ee values for **4***f* based on optical rotation (1*b*, 6*b*) and the orthoester glc data of this paper are now in total agreement.

TABLE 3. Kinetic parameters for HLADH-catalyzed oxidations of the hemiacetals **3***a–h*[a]

Substrate	K_m(app) (mM)	V_{max}(s^{-1})
3*a*	2.9	1.67

[a]Determined at 25°C in 0.05 M glycine–NaOH buffer, pH 9 with [NAD^+] 5.0×10^{-4} M and [hemiacetal] $10^{-4} - 10^{-2}$ M.
[b]From ref. 5.
[c]From ref. 1*a*.

isopropyl compound **3***d*, each hemiacetal is oxidized at effectively the same maximum velocity. Furthermore, the V_{max} values are not significantly different from those of ethanol and cyclohexanol, for which NADH dissociation from the enzyme–NADH complex in the final step is rate determining (5, 8). NADH dissociation is thus the predominant rate determining step in the oxidation of the hemiacetals **3***a–c*, *e–f* also, just as it is for the diols **1***a–f* (1*a*). The much lower V_{max} value for **3***d* indicates that the hydride transfer step has become slow enough to be at least partly rate determining.

The results of the preparative-scale experiments summarized in Tables 1 and 2 are of considerable asymmetric synthesis interest. As Table 1 shows, HLADH always exhibits pro-*S* selectivity in its catalysis of the oxidation of the enantiotopic hydroxyethyl groups of the diols **1***a–h*. The degree of enantiotopic selectivity is strongly influenced by the size of the substituent at C-3. When it is small, e.g., methyl (**1***a*), the 3*S*-lactone isolated has a very high optical purity. The enantiomeric excess diminishes as the size of the R group is increased through ethyl (1*b*) to propyl (1*c*) but remains high as long as the steric bulk of the C-3 substituent remains below a critical threshold level. The isopropyl function has clearly begun to exceed the tolerance of the enzyme in this regard with the optical purity of (3*S*)-**4***d* being only 46%. Further increases in the size of the C-3 substituent lead to progressively diminishing enantiomeric excesses; for oxidation of the diols **1***e–h*, the optical purities of the lactone products are too low to be of asymmetric synthesis interest. The 3*S*-enriched lactones **4***a–h* are obtained in good yield and are the only major products. The amounts of the 3*R*-lactones obtained by chemical oxidation of the residual 3*R*-hemiacetals in the reaction mixtures were very low. Furthermore, their enantiomeric excess levels were unexciting, except for (3*R*)-**4***g*. In this case, the anomalously high optical purity of 68% is probably the result of an unusually powerful effect of substrate concentration on the relative rates of enzymic oxidation of the diastereomeric hemiacetal intermediates (1*a*).

From Table 2, it is seen that HLADH-mediated oxidation of the racemic hemiacetals (+)-**3***a–h* is routinely enantiomerically selective for the 4*S*-enantiomer.[4] The chemical yields of (3*S*)-**3***a–h* are very respectable, those of (3*R*)-**3***a–h* are low owing to the losses incurred during purification following chemical oxidation of their 4*R*-hemiacetal precursors. Again the enantiomeric excesses of the lactones are high when the C-4 group is small and diminish progressively as this substituent becomes larger. However, for the hemiacetal substrates, the stereoselectivity of the enzyme is far more sensitive to the size of the C-4 substituent than with the corresponding diol substrates. With the exception of **3***a*, the enantiomeric excesses of the lactones of Table 2 are not of practical asymmetric synthesis value.

As is usual in enzymic resolutions of racemates, the optical purities of the enantiomeric pairs of lactones **4***a–h* are effectively equal. This contrasts the situation in Table 1 where the optical purities of the enantiomeric lactones derived from the better diol substrates **1***a–c* are dramatically different. This fact, together with the disparities between the hemiacetal yields of the diol-derived 3*R*- and 3*S*-lactone pairs, proves conclusively that the enzyme is exhibiting true pro-*S* enantiotopic selectivity in its catalysis of the oxidation of the diols **1***a*, *b* to the initial hydroxyaldehyde products (3*S*)-**2***a–h*. Fortuitously, the second oxidation, **3** → **4**, also occurs with *S* stereoselectivity.

The enantiomeric excess levels of the 3*S*-lactones isolated from the diol precursors therefore reflect the combined effects of these enzyme specificity properties. From the data of Tables 1 and 2, it is seen that the enantiotopic selectivity factor is most important when the R substituent is smallest. Its influence diminishes as its bulk increases and becomes inconsequential when R is larger than isopropyl.

The results summarized in Tables 1 and 2 are all rationalizable in terms of the system of coordinates, termed the diamond lattice (2), whereby the preferred and allowed orientations of a substrate at the active site of the HLADH can be identified. The diol and hemiacetal analyses described previously (1*b*) apply without qualification.

[4]Oxidation of the hemiacetals is considered to take place with the C-2-hydroxyl group axially oriented in the ES complex (1*b*). Enantiomeric selectivity has also been observed in the HLADH-catalyzed oxidation of five-membered ring hemiacetals (1*c*).

The benzyl (**1***g*, **3***g*) and phenethyl (**1***h*, **3***h*) substrates were included in this study in order to ascertain whether or not the adverse interactions of the phenyl group of **1***f* and **3***f* with forbidden regions of the active site (1*b*) could be alleviated by progressive insertion of methylene groups. This is clearly not the case. Any large group in this region of the active site is evidently undesirable.

Experimental

Melting points were determined on a Fisher-Johns apparatus and are uncorrected. Infrared and nmr spectra were recorded for all compounds; in each case the spectra were unexceptional and selected spectral data only are reported. Optical rotations all refer to $CHCl_3$ (*c*, 1) solutions unless specified otherwise. Gas–liquid chromatographic analyses were performed using 1 m × 3 mm columns of 2% QF-1 on Chromosorb G with flame ionization detection. NAD^+ and FMN were purchased from Sigma. HLADH (EC 1.1.1.1) may be purchased from Worthington or Boehringer. It was assayed (8*c*) before use; the amounts of HLADH quoted represent milligrams of active enzyme.

Preparation of the 3-Substituted Pentanediols **1**a–h

The diols **1***a–d*, *f*, *g* were prepared as described previously (1*a*, *b*).

*3-Cyclohexylpentane-1,5-diol (***1***e)*

Diethyl cyclohexylmalonate (34 g, 0.14 mol, prepared as described by Hope and Perkin (9)) in dry tetrahydrofuran (200 mL) was added dropwise with stirring at 20°C to a suspension of lithium aluminum hydride (7.6 g, 0.2 mol) in dry tetrahydrofuran (400 mL). The mixture was heated on an oil bath at 60°C for 1 day and then cooled to 0°C. The reaction was quenched carefully with 3% aqueous sodium hydroxide (40 mL), filtered, and the dried ($MgSO_4$) filtrate evaporated. The residue was recrystallized from acetone to give *2-cyclohexylpropane-1,3-diol*, (16.5 g) mp 90–91°C.

Methanesulfonyl chloride (16.2 mL, 0.21 mol) was added dropwise to a solution of the above diol (15.8 g, 0.1 mol) in dry benzene (100 mL) and dry pyridine (50 mL) cooled to 5°C. The mixture was then stirred overnight at 20°C. The solid present was filtered off and washed with benzene and the combined organic filtrates washed with saturated aqueous sodium bicarbonate followed by saturated brine. The dried (Na_2SO_4) organic layer was evaporated to give *2-cyclohexylpropane-1,3-diol bismethanesulfonate* (30 g, 0.097 mol). This was dissolved in ethanol (150 mL) and potassium cyanide (13.7 g, 0.21 mol) in water (50 mL) added. The mixture was refluxed for 6 h, then 10 *N* aqueous sodium hydroxide (50 mL) was added and refluxing continued for a further 20 h. The resulting solution was concentrated to ~150 mL and washed with ether. The aqueous layer was decolourised with Norite, filtered, and the filtrate cooled in an ice bath and acidified with 6 *N* hydrochloric acid. The resulting solid was filtered off, dissolved in saturated aqueous sodium bicarbonate and then reprecipitated with 6 *N* hydrochloric acid to give, after drying, *3-cyclohexylglutaric acid* (8.28 g, 0.04 mol).

The cyclohexylglutaric acid (5.0 g, 24 mmol) in dry tetrahydrofuran (50 mL) was added dropwise with stirring at 20°C to lithium aluminum hydride (1.9 g, 50 mmol) in dry tetrahydrofuran (100 mL). The resulting suspension was refluxed for 8 h, then cooled to 0°C, and the reaction quenched by the careful addition of 2% aqueous sodium hydroxide (10 mL). The solid produced was filtered off, washed with tetrahydrofuran, and the combined filtrate and washings dried (Na_2SO_4) and concentrated. The residual oil was distilled to give 3-cyclohexylpentane-1,5-diol (**1***e*, 3.5 g) bp 131°C/0.05 Torr; ^1H nmr (C^2HCl_3) δ: 0.8–2.2 (16H, m) and 3.3–3.9 (6H, m) ppm. *Anal.* calcd. for $C_{11}H_{22}O_2$: C 70.92, H 11.90; found: C 70.77, H 11.78.

*3-Phenethylpentane-1,5-diol (***1***h)*

Sodium (11.5 g, 0.5 mol) was dissolved in ethanol (200 mL) and ethyl malonate (80 g, 0.5 mol) added. The mixture was maintained at 60°C during the slow addition of phenethyl bromide (92.5 g, 0.5 mol) and then refluxed for 20 h. The cooled (20°C) mixture was diluted with water (300 mL), the organic solution separated, and the aqueous layer extracted with ether. The combined organic solutions were dried ($MgSO_4$), evaporated, and the residue distilled to give diethyl phenethylmalonate (75 g), bp 168–170°C/2.5 Torr; ir (film): 1725 cm^{-1}; ^1H nmr (C^2HCl_3) δ: 1.3 (6H, t, J = 6 Hz), 2.0–2.9 (4H, m), 3.3 (1H, t, J = 7 Hz), 4.2 (4H, q, J = 6 Hz), and 7.2 (5H, s) ppm. *Anal.* calcd. for $C_{15}H_{15}O_4$: C 68.16, H 7.62; found: C 68.04, H 7.50.

The subsequent procedures were as described above for **1***e*. Reduction of the phenethylmalonate (74.5 g, 0.34 mol) gave *2-phenethylpropane-1,3-diol* as a crystalline product (40.3 g), mp 57°C; ^1H nmr (C^2HCl_3) δ: 1.3–2.0 (2H, m), 2.4–2.8 (3H, broad t), 3.4–4.0 (4H, m), and 7.2 (5H, s) ppm. *Anal.* calcd. for $C_{11}H_{16}O_2$: C 73.30, H 8.95; found: C 73.33, H 9.14. This diol (9 g, 50 mmol) was converted to *2-phenethylpropane-1,3-diol bismethanesulfonate* (16.7 g, 50 mmol) which was transformed directly into *3-phenethylglutaric acid* (3.6 g after recrystallization from water), mp 99–100°C; ^1H nmr (($C^2H_3)_2SO$) δ: 1.4–2.0 (2H, m), 2.1–2.9 (7H, m), and 7.1 (5H, s) ppm. Reduction of 3-phenethylglutaric acid[5] (11.8 g, 50 mmol) yielded *3-phenethylpropane-1,3-diol* (**1***h*, 8.53 g), bp 152–154°C/0.5 Torr; ^1H nmr (C^2HCl_3) δ: 1.3–1.9 (7H, m), 2.4–2.8 (2H, m), 3.3–4.1 (6H, m), and 7.2 (5H, s) ppm. *Anal.* calcd. for $C_{13}H_{20}O_2$: C 74.96, H 9.68; found: C 74.88, H 9.76.

Preparation of Hemiacetals **3**a–h

The 4-methylhemiacetal **3***a* was synthesized by the literature method (11). The remaining hemiacetals **3***b–h* were prepared by reduction of the corresponding lactone **4***b–h* with diisobutylaluminum hydride according to the procedure of Schmidlin and Wettstein (3). All of the hemiacetals were relatively unstable. These were used immediately following chromatographic purification.

*2-Hydroxy-4-ethyltetrahydropyran ((±)-***3***b)*

Diisobutylaluminum hydride (10 g, 70 mmol, 20% solution in *n*-hexane) was added dropwise with stirring under nitrogen at −78°C to 3-ethylvalerolactone ((±)-**4***b*, (1*a*), 3.9 g, 30 mmol) in dry toluene (300 mL). Stirring at −78°C was continued for a further 3 h and the reaction was then quenched by the slow addition of methanol until gas evolution ceased. The mixture was stirred for 30 min at 20°C, then diluted with ether (100 mL). Saturated brine (100 mL), followed by 6 *N* hydrochloric acid (50 mL) to destroy the resulting emulsion, were added and the organic layer separated. The aqueous solution was reextracted with ether and the combined ether solutions washed with saturated brine and then dried ($MgSO_4$). The solvent was rotary evaporated carefully at 20°C and the oil obtained chromatographed quickly on silica gel (50 cm × 2 cm column, ether – petroleum ether, bp 40–60°C (30:70) elution). Evaporation of the desired eluant fractions yielded 2-hydroxy-4-ethyltetrahydropyran ((±)-**3***b*, 2.9 g); ^1H nmr δ: 0.7–2.2 (10H, m) and 3.2–5.4 (4H, m) ppm.

[5]Subsequently prepared by the method of Koppang *et al.* (10).

This basic procedure was used to prepare each of the following hemiacetals (±)-**3***c–h*.

*2-Hydroxy-4-*n*-propyltetrahydropyran ((±)-**3***c*)*

This was obtained in 64% yield from 3-*n*-propylvalerolactone ((±)-**4***c* (1*a*), 5 g, 35 mmol); ^{1}H nmr (C^2HCl_3) δ: 0.8–2.2 (12H, m) and 3.2–5.4 (4H, m).

*2-Hydroxy-4-isopropyltetrahydropyran ((±)-**3**d)*

This was obtained in 76% yield from 3-isopropylvalerolactone ((±)-**4***d* (1*b*), 5 g, 35 mmol); ^{1}H nmr (C^2HCl_3) δ: 0.9 (6H, d, J = 6.4 Hz), 1.1–2.1 (6H, m), and 3.2–5.4 (4H, m) ppm.

*4-Cyclohexyl-2-hydroxytetrahydropyran ((±)-**3**e)*

3-Cyclohexylglutaric acid (8.28 g, 40 mmol, see preparation of **1***e*) was refluxed with acetic anhydride (50 mL) for 10 h. Excess acetic anhydride and acetic acid were removed by rotary evaporation and the residue distilled to give *3-cyclohexylglutaric anhydride* (6.3 g), bp 158°C/0.75 Torr; ir (film): 1750, 1820 cm^{-1}; ^{1}H nmr (C^2HCl_3) δ: 0.6–2.2 (12H, m) and 0.6–2.2 (4H, m) ppm. *Anal.* calcd. for $C_{11}H_{16}O_3$: C 67.32, H 8.22; found: C 67.21, H 8.18.

The anhydride (4.9 g, 25 mmol) in dry tetrahydrofuran (40 mL) was added at 0°C to sodium borohydride (0.95 g, 25 mmol) in dry tetrahydrofuran (10 mL). Stirring was continued for 10 h at 20°C, then 6 *N* hydrochloric acid (10 mL) was added cautiously and the mixture concentrated. Water (100 mL) was added and the solution extracted with ether (3 × 50 mL). The ether extract was dried (Na_2SO_4) and evaporated to give *3-cyclohexylvalerolactone* ((±)-**4***e*, 3.3 g), bp 120–121°C/0.2 Torr; ^{1}H nmr (C^2HCl_3) δ: 0.6–2.2 (14H, m), 2.2–2.7 (2H, m), and 4.0–4.6 (2H, m) ppm. *Anal.* calcd. for $C_{11}H_{18}O_2$: C 72.49, H 9.95; found: C 72.64, H 9.89.

Reduction of (±)-**4***e* by the Schmidlin and Wettstein (3) method gave 4-cyclohexyl-2-hydroxytetrahydropyran ((±)-**3***e*, 60% yield, acetone–hexane (1:3) elution) as a more-than-usually unstable hemiacetal.

*2-Hydroxy-4-phenyltetrahydropyran ((±)-**3**f)*

This was prepared from 3-phenylvalerolactone ((±)-**4***f* (12), 6.06 g, 35 mmol) in 55% yield (methanol – methylene chloride (1:20) elution); ^{1}H nmr (C^2HCl_3) δ: 0.8–4.2 (9H, m) and 7.2 (5H, s) ppm.

*4-Benzyl-2-hydroxytetrahydropyran ((±)-**3**g)*

This was obtained by reduction of 3-benzylvalerolactone ((±)-**4***g* (1*a*), 6.72 g, 35 mmol) in 61% yield; ^{1}H nmr (C^2HCl_3) δ: 0.9–4.3 (11H, m) and 7.3 (5H, s) ppm.

*2-Hydroxy-4-phenethyltetrahydropyran ((±)-**3**h)*

3-Phenethylglutaric acid (4.7 g, 20 mmol, see preparation of **1***h*) was converted to the anhydride as described above for (±)-**3***e*. *3-Phenethylglutaric anhydride* (2.78 g after recrystallization from ether – petroleum ether (bp 40–60°C)) had mp 69.5–70°C; ^{1}H nmr (C^2HCl_3) δ: 1.5–3.3 (9H, m) and 7.2 (5H, m). *Anal.* calcd. for $C_{13}H_{14}O_3$: C 71.54, H 6.47; found: C 71.47, H 6.54.

The above anhydride (10.9 g, 0.05 mol) in dry tetrahydrofuran (50 mL) was added at 0°C with stirring to sodium borohydride (2.0 g, 0.05 mol) in dry tetrahydrofuran (10 mL). Stirring was continued for 10 h at 20°C and 6 *N* hydrochloric acid (20 mL) then added cautiously. After concentrating, water (100 mL) was added to the mixture and it was extracted with ether (3 × 50 mL). The ether extract was dried (Na_2SO_4), evaporated, and the residual oil distilled to yield *3-phenethylvalerolactone* ((±)-**4***h*, 6.3 g) bp 153–154°C/0.25 Torr which subsequently solidified, mp 43–43.5°C; ^{1}H nmr (C^2HCl_3) δ: 1.3–3.0 (9H, m), 4.0–4.7 (2H, m), and 7.2 (5H, s) ppm. *Anal.* calcd. for $C_{13}H_{16}O_2$: C 76.44, H 7.89; found: C 76.52, H 7.84.

The lactone (±)-**4***h* (4.08 g, 0.02 mol) was reduced in the usual way to give 2-hydroxy-4-phenethyltetrahydropyran ((±)-**3***h*) in 75% yield (*n*-hexane–acetone (7:3) elution) as a colourless solid, mp 60–64°C; ^{1}H nmr (C^2HCl_3) δ: 0.8–2.8 (10H, m), 3.2–4.8 (3H, m), and 7.2 (5H, s) ppm.

*HLADH-Catalyzed Oxidation of the Diols **1**a–h*

The oxidations were effected on a 10 mmol of substrate scale using the previously described procedure (1*b*).[6] The enantiomeric excess of the product lactones (3*S*)- and (3*R*)-**4***a–h* were measured directly by glc examination of their orthoesters with (2*R*,3*R*)-butane-2,3-diol (4). The results are summarized in Table 1.

The physical properties of the lactones were as described previously (1*a*, *b*) or as given above for the racemates. The optical rotations observed are given below.

Compound	$[\alpha]_D^{25}$	% ee	Compound	$[\alpha]_D^{25}$	% ee
(3*S*)-**4***a*	−23.6°	78	(3*R*)-**4***a*	+4.7°	15
(3*S*)-**4***b*	−20.4°	74	(3*R*)-**4***b*	+5.8°	21
(3*S*)-**4***c*	−13.5°	67	(3*R*)-**4***c*	+2.0°	11
(3*S*)-**4***d*	−14.4°	46	(3*R*)-**4***d*	+11.5°	36
(3*S*)-**4***e*	+4.3°	18	(3*R*)-**4***e*	(−3.9°)[a]	26
(3*S*)-**4***f*	+0.8°	16	(3*R*)-**4***f*	−0.4°	6
(3*S*)-**4***g*	−19.1°	20	(3*R*)-**4***g*	(+24.2°)[a]	68
(3*S*)-**4***h*	−14.3°	18	(3*R*)-**4***h*	(+17.1°)[a]	36

[a]These compounds were obtained in very low yields (Table 1) and the quantities isolated were insufficient for accurate specific rotation measurements.

*HLADH-Catalyzed Oxidations of the Hemiacetals (±)-**3**a–h*

The enzyme-catalyzed oxidations of the hemiacetals (±)-**3***a–h* were each carried out on a 10 mmol of substrate scale. The physical properties of the product lactones **4***a–h* were as detailed previously (1*a*, *b*) or as given above for the racemates. Their ee's were determined directly by the orthoester glc analytical method (4). The overall results are summarized in Table 2.

The procedure for oxidation of the 4-methyl hemiacetal (±)-**3***a* is representative.

2-Hydroxy-4-methyltetrahydropyran (1.2 g, 10 mmol), NAD^+ (0.65 g, 1 mmol) and FMN (9.6 g, 20 mmol) were dissolved in 0.05 *M* pH 9 glycine – sodium hydroxide buffer (900 mL). The pH of the resulting solution was then readjusted to 9 with 10 *N* aqueous sodium hydroxide and HLADH (35 mg) added. The reaction mixture was kept in a stoppered flask for 12 h and the pH readjusted to 9 once again. After a further 7 h, glc analyses indicated the desired 50%-of-reaction point had been reached. The pH was then raised to 12 with 10 *N* aqueous sodium hydroxide and the mixture continuously extracted with chloroform for 2 days. (The aqueous solution was retained for further work-up, *vide infra*.) The dried ($MgSO_4$) chloroform extract was evaporated and the residual (4*R*)-hemiacetal **3***a* (514 mg) was oxidized with silver oxide (prepared by adding sodium hydroxide (2.4 g, 60 mmol) in water (10 mL) to silver nitrate (5 g, 30 mmol) in 60% aqueous ethanol (30 mL)). The mixture was stirred overnight and was then filtered and continuously extracted with chloroform for 1 day. The chloroform extract was discarded. The aqueous solution was acidified to pH 3 with 6 *N* aqueous hydrochloric acid and continuously extracted with chloroform for 36 h. After evaporation of the dried ($MgSO_4$) chloroform extract and molecular distillation of the residue, (3*R*)-3-methylvalerolactone ((3*R*)-**4***a*, 180 mg); $[\alpha]_D^{25}$ +20.0° (66% ee) was obtained.

The aqueous solution retained from the initial extraction

[6]Reactions were monitored by glc. The longest reaction period required was 6 days.

was brought to pH 3 with 6 *N* aqueous hydrochloric acid and then continuously extracted with chloroform for 2 days. Evaporation of the dried ($MgSO_4$) chloroform solution yielded, after molecular distillation, (3*S*)-3-methylvalerolactone ((3*S*)-**4***a*, 425 mg); $[\alpha]_D^{25}$ −21.5° (73% ee).

Oxidation of the remaining hemiacetals (±)-**4***b–h* in an exactly similar manner yielded lactones **4***b–h*, respectively.[6] The optical rotations observed are given below.

Compound	$[\alpha]_D^{25}$	% ee	Compound	$[\alpha]_D^{25}$	% ee
(3*S*)-**4***b*	−12.3°	44	(3*R*)-**4***b*	+12.9°	53
(3*S*)-**4***c*	−6.4°	29	(3*R*)-**4***c*	+5.2°	24
(3*S*)-**4***d*	−6.1°	20	(3*R*)-**4***d*	+7.0°	22
(3*S*)-**4***e*	+3.6°	12	(3*R*)-**4***e*	−1.5°	10
(3*S*)-**4***f*	+0.8°	13	(3*R*)-**4***f*	−0.7°	11
(3*S*)-**4***g*	−12.8°	12	(3*R*)-**4***g*	+6.8°	8
(3*S*)-**4***h*	−8.6°	14	(3*R*)-**4***h*	+4.2°	8

*Determination of Absolute Configurations of Lactones (3S)- and (3R)-**4**a–h*

The absolute configurations of (3*S*)- and (3*R*)-**4***a*, *d*, and *f* were known (1*b*).

*Correlation of (−)-(3S)-**4**b*

(−)-(3*S*)-Ethylvalerolactone (**4***b*, 1.28 g, 0.01 mol, $[\alpha]_D^{25}$ −20.4°) in absolute ethanol (20 mL) was treated with excess dry hydrogen bromide at 0°C. After being stirred overnight at 20°C, the solution was diluted with water (120 mL) and extracted with ether (3 × 50 mL). The ether extract was washed with saturated aqueous sodium bicarbonate, then with brine, dried ($MgSO_4$) and evaporated. Distillation of the residual oil gave (−)-*ethyl* (3R)-*5-bromo-3-ethylpentanoate* (2.16 g) bp 98–99°C/5 Torr, $[\alpha]_D^{25}$ −8.2°; ^{1}H nmr (C^2HCl_3) δ: 0.95 (3H, t, *J* = 6.0 Hz), 1.3 (3H, t, *J* = 7.0 Hz), 0.9–2.4 (7H, m), 3.45 (2H, t, *J* = 7.0 Hz), and 4.15 (2H, q, *J* = 7.0 Hz) ppm. *Anal.* calcd. (on racemate) for $C_9H_{17}O_2Br$: C 45.59, H 7.23; found: C 45.44, H 7.18.

The above ester (2.16 g, 9 mmol) was refluxed in 2,4,6-trimethylpyridine (10 mL) for 3 h. The cooled mixture was poured into saturated aqueous copper sulfate solution (200 mL) and extracted with ether. Evaporation of the dried ($MgSO_4$) ether solution followed by distillation yielded (−)-*ethyl* (3R)-*3-ethylpent-4-enoate* (280 mg), bp 70–71°C/15 Torr, $[\alpha]_D^{25}$ −4.6°; ^{1}H nmr (C^2HCl_3) δ: 0.9 (3H, t, *J* = 7.0 Hz), 1.2 (3H, t, *J* = 7.0 Hz), 1.4–1.9 (3H, m), 2.2–2.5 (2H, m), 4.1 (2H, q, *J* = 7.0 Hz), 4.8–5.0 (1H, m), 5.1 (1H, broad s), and 5.5–6.0 (1H, m) ppm. *Anal.* calcd. (on racemate) for $C_9H_{16}O$: C 69.20, H 10.32; found: C 68.61, H 10.69.

Hydrolysis of this olefinic ester (280 mg) was effected by refluxing in 5% ethanolic potassium hydroxide (20 mL) for 2 h. The cooled solution was then diluted with water (80 mL), acidified with 6 *N* hydrochloric acid, and continuously extracted with ether for 24 h. Evaporation of the dried ($MgSO_4$) ether extract afforded the free acid; this was dissolved immediately in methylene chloride and ozonized at −78°C for 45 min. After purging excess ozone with oxygen, the solution was concentrated to 15 mL and heated on a steam bath with formic acid (6 mL) in 30% hydrogen peroxide (60 mL) for 2 h.

The excess peroxide was decomposed with 10% Pd–C, and the mixture filtered and evaporated. Recrystallization of the solid obtained from ethyl acetate – petroleum ether (bp 40–60°C) gave (−)-(2*R*)-2-ethylsuccinic acid (65 mg) mp 93–94°C, $[\alpha]_D^{25}$ −8.7° (*c* 1, $(CH_3)_2CO$) (lit. (13) mp 96°C, $[\alpha]_D^{25}$ −15.4° ($(CH_3)_2CO$)).

*Correlation of (−)-(3S)-**4**c*

This was effected in an identical manner. (−)-(3*S*)-3-*n*-Propylvalerolactone (**4***c*, 1.14 g, 8 mmol) was treated with hydrogen bromide to give (−)-*ethyl-(3R)-5-bromo-3-n-propylpentanoate* (1.92 g), bp 107–109°C/4 Torr, $[\alpha]_D^{25}$ −5.8°, ^{1}H nmr (C^2HCl_3) δ: 0.95 (3H, t, *J* = 7.0 Hz), 1.25 (3H, t, *J* = 7.0 Hz), 0.9–2.4 (9H, m), 3.45 (2H, t, *J* = 7.0 Hz), and 4.5 (2H, q, *J* = 7.0 Hz). *Anal.* calcd. (on racemate) for $C_{10}H_{19}O_2Br$: C 47.82, H 7.63; found: C 47.90, H 7.53. On refluxing with 2,4,6-trimethyl pyridine, this ester (1.92 g) yielded (−)-*ethyl* (3R)-*3*-n-*propylpent-4-enoate* (153 mg), bp 77–78°C/15 Torr, $[\alpha]_D^{25}$ −3.6°; ^{1}H nmr (C^2HCl_3) δ: 0.9 (3H, t, *J* = 7.0 Hz), 1.2 (3H, t, *J* = 7.0 Hz), 1.4–1.9 (5H, m), 2.2–2.5 (2H, m), 4.1 (2H, q, *J* = 7.0 Hz), 4.8–5.0 (1H, m), 5.15 (1H, m), and 5.4–6.0 (1H, m) ppm. *Anal.* calcd. (on racemate) for $C_{10}H_{18}O_2$: C 70.55, H 10.66; found: C 70.42, H 10.54.

Subsequent hydrolysis followed by ozonolysis afforded (−)-(2*R*)-2-*n*-propylsuccinic acid (21 mg), mp 98–100°C (from benzene – petroleum ether (bp 40–60°C)), $[\alpha]_D^{25}$ −6.2° (*c* 1, $(CH_3)_2CO$) (lit. (13) mp 103–104°C, $[\alpha]_D$ −18°).

*Correlation of (−)-(3S)-**4**h*

Treatment of (−)-(3*S*)-3-phenethylvalerolactone (**4***h*, 1.3 g, 63 mmol, $[\alpha]_D^{25}$ −14.3°) with hydrogen bromide gave (−)-*ethyl* (3R-*5-bromo-3-phenethylpentanoate* (1.52 g), $[\alpha]_D^{25}$ −2.3°; ^{1}H nmr δ: 1.2 (3H, t, *J* = 6.0 Hz), 1.4–2.8 (9H, m), 3.4 (2H, t, *J* = 7.0 Hz), 4.1 (2H, q, *J* = 6.0 Hz), and 7.2 (5H, s) ppm. *Anal.* calcd. (on racemate) for $C_{15}H_{21}O_2Br$: C 57.51, H 6.75; found: C 57.32, H 6.88.

Sodium borohydride (0.104 g, 3 mmol) was added slowly with stirring at 0°C under nitrogen to a solution of diphenyl diselenide (0.78 g, 2.5 mmol) in dry ethanol (10 mL) until the yellow colour disappeared (7). The bromo ester (1.5 g, 4.5 mmol) was then added and the mixture refluxed overnight. The solution was cooled to 0°C and tetrahydrofuran (60 mL) added, followed by 30% hydrogen peroxide (7.6 mL, 8.4 mmol). $MgSO_4$ (2g) was added and the resulting slurry stirred at 20°C for 1 day. The mixture was then diluted with water and extracted with ether. The ether extract was washed with saturated aqueous sodium bicarbonate, dried (Na_2SO_4) and evaporated. Molecular distillation of the residual oil yielded (+)-*ethyl* (3R)-*3-phenethylpent-4-enoate* (372 mg), $[\alpha]_D^{25}$ +7.9° (*c* 1, C_6H_6); ^{1}H nmr δ: 1.3 (3H, t, *J* = 6.0 Hz), 1.5–2.0 (2H, m), 2.2–2.8 (5H, m), 4.1 (2H, q, *J* = 6.0 Hz), 4.8–6.1 (3H, m), and 7.2 (5H, s) ppm. *Anal.* calcd. (on racemate) for $C_{15}H_{20}O_2$: C 77.55, H 8.68; found: C 77.69, H 8.92. Hydrolysis of this olefinic ester (360 mg, 1.5 mmol) followed by ozonolysis gave (2*R*)-2-phenethylsuccinic acid (131 mg after recrystallization from ether – petroleum ether (bp 40–60°C)), mp 124–126°C, $[\alpha]_D^{25}$ +7.3° (*c* 0.5, EtOH) (lit. (14) mp 136–137°C, $[\alpha]_D^{25}$ +38.1°, EtOH).

*Correlation of (−)-(3S)-**4**g*

This was effected using the same procedures.[7] (−)-3*S*-3-Benzylvalerolactone (**4***g*, 1.5 g, 7.9 mmol, $[\alpha]_D^{25}$ −19.1°) was converted to (−)-ethyl (3*R*)-benzyl-5-bromopentanoate (1.7 g), bp 130°C/0.25 Torr, $[\alpha]_D^{25}$ −0.01° (*c* 1.8, EtOH), ^{1}H nmr δ: 1.2 (3H, t, *J* = 7.0 Hz), 1.7–2.8 (7H, m), 3.4 (2H, t, *J* = 7.0 Hz), 4.15 (2H, q, *J* = 7.0 Hz), and 7.2 (5H, m) ppm. The bromo ester (1.49 g, 5.2 mmol) was dehydrobrominated by the diphenyldiselenide – peroxide method to give (+)-*ethyl* (3R)-*3-benzylpent-4-enoate* (870 mg), $[\alpha]_D^{25}$ +6.6° (*c* 0.8, C_6H_6): ^{1}H nmr δ: 1.2 (3H, t, *J* = 7.0 Hz), 2.2–3.2 (5H, m), 4.1 (2H, q, *J* = 7.0 Hz), 4.85 (1H, m), 5.1 (1H, m), 5.5–6.05 (1H, m), and 7.25 (5H, m) ppm. *Anal.* calcd. (on racemate) for $C_{14}H_{18}O_2$: C 77.04, H 8.30; found: C 76.89, H 7.95. This

[7]Part of this work was done by Dr. H. B. Goodbrand.

unsaturated ester (870 mg, 4 mmol) was hydrolyzed and then ozonized to give, after chromatography on silica gel (ethyl acetate elution), (2*R*)-2-benzylsuccinic acid (620 mg), mp 159.5–160.5°C, $[\alpha]_D^{25}$ +5.4° (*c* 0.4, EtOAc) (lit. (15) for 2*S*-enantiomer, mp 160.5°C, $[\alpha]_D^{25}$ −27.0° (*c* 2.0, EtOAc).

Correlation of (+)-(3S)-4e

A solution of (+)-(3*S*)-3-cyclohexylvalerolactone (**4***e*, 1.45 g, 7.1 mmol, $[\alpha]_D^{25}$ +4.3°) in dry ethanol (15 mL) was saturated with dry hydrogen bromide at 0°C and then kept at 20°C overnight. Saturated brine (50 mL) was then added and the mixture extracted with ether (3 × 50 mL). Evaporation of the dried ($MgSO_4$) ether solution followed by molecular distillation yielded (−)-*ethyl* (3*S*)-*5-bromo-3-cyclohexylpentanoate* (1.48 g), $[\alpha]_D^{25}$ −1.8°. The bromo ester (1.0 g, 3.4 mmol) and tri-*n*-butyltin hydride (1.1 g, 3.8 mmol) in dry benzene (25 mL) was stirred under nitrogen at 20°C for 12 h and then refluxed for 4 h. The solvent was then evaporated and the oil obtained heated with 10% ethanolic potassium hydroxide (20 mL) at 100°C for 2 h. The mixture was cooled, diluted with water (50 mL), acidified with concentrated hydrochloric acid, and extracted with ether. Evaporation of the dried ($MgSO_4$) ether extract and then distillation afforded *3-cyclohexylvaleric acid* (500 mg), bp 172–174°C/20 Torr (lit. (15) bp 160–161°C/18 Torr). This acid was treated with ethereal diazomethane to give (+)-*methyl* (3S)-*3-cyclohexylvalerate* (410 mg), bp 120°C/20 Torr, $[\alpha]_D^{25}$ +1.2° (*c* 1, EtOH), (lit. (16) for 3*R*-enantiomer, $[\alpha]_D^{25}$ −7.2° (*c* 1, EtOH)).

Kinetic Studies

The rates of HLADH-catalyzed oxidations of (±)-**3***a–g* were determined as described previously (1*a*). The results are summarized in Table 3.

The reaction products of *N*-alkylquinoxalines with 7,7,8,8-tetracyanoquinodimethane

HEIMO JÜRGEN KELLER, DIETRICH NÖTHE, AND MANFRED WERNER

Anorganisch-Chemisches Institut der Universität Heidelberg, Im Neuenheimer Feld 270, 6900 Heidelberg 1, Federal Republic of Germany

Received October 27, 1978

HEIMO JÜRGEN KELLER, DIETRICH NÖTHE, and MANFRED WERNER. Can. J. Chem. **57**, 1033 (1979).

Simple (1:1) and complex (2:3) TCNQ salts of the *N*-ethylquinoxalinium (NEQ) and *N*-methylquinoxalinium (NMQ) cations were prepared and characterized. In contradiction to earlier claims it was found that the 1:1 NMQ–TCNQ compound is *not* highly conducting but is a semiconductor. The triclinic crystals with unit cell dimensions $a = 4.79$, $b = 10.46$, $c = 7.60$ Å, $\alpha = 93.49$, $\beta = 110.92$, $\gamma = 82.69°$ show triplet exciton lines in the epr spectra indicating the occurrence of dimerized radicals in this solid. The high dc conductivity of the *simple* salt as reported earlier can only be attributed to a complex salt.

HEIMO JÜRGEN KELLER, DIETRICH NÖTHE et MANFRED WERNER. Can. J. Chem. **57**, 1033 (1979).

On a préparé et caractérisé des sels TCNQ simples (1:1) et complexes (2:3) des cations *N*-éthylquinoxalinium (NEQ) et *N*-méthylquinoxalinium (NMQ). En opposition avec des prétentions antérieures, on a trouvé que le composé 1:1 NMQ–TCNQ *ne conduit pas bien* l'électricité mais est plutôt un semi-conducteur. Les dimensions de la maille des cristaux tricliniques sont $a = 4.79$, $b = 10.46$, $c = 7.60$ Å, $\alpha = 93.49$, $\beta = 110.92$, $\gamma = 82.69°$; ces cristaux présentent des raies d'exciton triplet dans leur spectre rpe ce qui indique la présence de radicaux dimères dans le solide. La conductivité cd élevée du sel *simple* rapportée plus tôt ne peut être attribuée qu'à un sel complexe.

[Traduit par le journal]

Introduction

Only a very few simple (1:1) TCNQ salts of *nitrogen-containing* donors (including organic amines and *N*-heterocyclic compounds) are reported to show high electrical conductivity (1, 2). One can therefore assume that these exceptional salts crystallize in regular segregated stacks. The most famous of these rare examples, the one-dimensional conductor NMP–TCNQ (3–6), seems to contain systematic crystal impurities (7, 8) which could favor this special arrangement of molecular radical ions in the solid. This supposition is supported by the fact that NMP–TCNQ shows increased dc conductivity after substitution of some part of NMP^+ by the neutral molecule phenazine (9).

It was our task to establish whether NMP–TCNQ and the three other 1:1 nitrogen donor compounds with comparatively high electrical conductivities (4-hydroxy-2,3,5,6-tetramethylanilinium–TCNQ (1), 5,8-dihydroxyquinolinium–TCNQ (1), and *N*-methylquinoxalinium–TCNQ (2)) are in fact outstanding exceptions to the general rule, i.e., that 1:1 salts of TCNQ with nitrogen donors normally do not crystallize in segregated uniform stacks, or whether there are any exceptions at all. Therefore, we reinvestigated one of the reported examples of 'highly conducting' 1:1 TCNQ–nitrogen-donor salts, *N*-methylquinoxalinium-7,7,8,8-tetracyanoquinodimethanide (NMQ–TCNQ) (2), its ethyl homologue and some other TCNQ derivatives. This paper summarizes some of the results concerning the chemistry and physics of these compounds.

Experimental

Preparation of Compounds

NMQ–TCNQ

This compound was prepared essentially as described by Melby (2). The procedure was altered because of the oxygen sensitivity of the solutions! To a boiling solution of 0.317 g (1.5 mmol) Li–TCNQ (which was prepared from LiI and TCNQ in CH_3CN) in 30 mL dry ethanol, was added *N*-methylquinoxaliniumiodide (NMQ–I) (0.408 g, 1.5 mmol) in 15 mL hot ethanol. The mixture was allowed to cool to room temperature. A microcrystalline *violet* product which was isolated after the filtration, was washed with a few millilitres of methanol and finally with ether. The yield was as described by Melby (2): 88%, mp 177°C (dec.). *Anal.* calcd. for NMQ–TCNQ, $C_{21}H_{13}N_6$: C 72.19, H 3.75, N 24.05; found: C 72.16, H 3.82, N 24.13.

For recrystallization (about 1 g in 100 mL acetonitrile) only absolutely oxygen- and moisture-free solvents could be used. All the procedures were carried out in a nitrogen atmosphere. After recrystallization and slow cooling in a Dewar flask, reddish-purple, shiny prisms up to an inch in size were obtained. All of them were *twinned* as shown by their X-ray and esr data.

$(NMQ)_2(TCNQ)_3$

TCNQ (0.204 g, 1 mmol) and NMQ–TCNQ (0.349 g, 1 mmol) were dissolved in 25 mL hot dry acetonitrile in a

0008-4042/79/091033-04$01.00/0

nitrogen atmosphere. The solution was filtered while hot and allowed to cool slowly to room temperature. Black needles with a metallic lustre separated and were filtered, washed with ether, and dried in a desiccator over $CaCl_2$. Recrystallization from acetonitrile and heatless drying in high vacuum did not change the properties of the isolated solid. The yield was 95%, mp 193°C (dec.). *Anal.* calcd. for NMQ(TCNQ)$_2$, $C_{33}H_{17}N_{10}$: C 71.60, H 3.10, N 25.30; calcd. for (NMQ)$_2$(TCNQ)$_3$·CH_3CN, $C_{56}H_{33}N_{17}$: C 71.25, H 3.52, N 25.22; calcd. for (NMQ)$_2$(TCNQ)$_3$, $C_{54}H_{30}N_{16}$: C 71.83, H 3.35, N 24.82; found: C 71.10, H 4.05, N 25.43; C 71.31, H 3.96, N 25.42;[1] C 72.09, H 3.54, N 24.61.[2]

N-*Ethylquinoxalinium–TCNQ (NEQ–TCNQ)*

A boiling solution of Li–TCNQ (0.317 g, 1.5 mmol) in 30 mL ethanol and a hot solution of NEQ iodide (0.429 g, 1.5 mmol, prepared as described previously (10)) in 15 mL ethanol were filtered under N_2 while hot, poured together, and *cooled rapidly*. The black lustrous, microcrystalline platelets which formed were filtered, washed with a few millilitres of methanol, and finally with ether, yield 63%, mp 139°C. *Anal.* calcd. for NEQ–TCNQ, $C_{22}H_{15}N_6$: C 72.71, H 4.16, N 23.13; found: C 72.52, H 4.40, N 23.03.

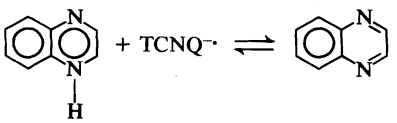
Slow cooling of the reaction mixture and recrystallization of the primary product yields only products containing appreciable amounts of the complex salt.

(NEQ)$_2$(TCNQ)$_3$

TCNQ (0.102 g, 0.5 mmol) and NEQ–TCNQ (0.182 g, 0.5 mmol) were dissolved together in 30 mL boiling acetonitrile (in an N_2 atmosphere!). The solution was filtered while hot and allowed to cool slowly to room temperature. The black crystals were washed with methanol and ether after filtration, yield 70%, mp 198–200°C. *Anal.* calcd. for: (NEQ)$_2$(TCNQ)$_3$·CH_3CN, $C_{58}H_{57}N_{17}$: C 71.67, H 3.84, N 24.50; (NEQ)(TCNQ)$_2$, $C_{34}H_{19}N_{10}$: C 71.97, H 3.35, N 24.68; (NEQ)$_2$(TCNQ)$_3$, $C_{56}H_{54}N_{16}$: C 72.24, H 3.68, N 24.07; found: C 71.72, H 3.48, N 24.52; C 71.78, H 3.47, N 24.45;[3] C 72.14, H 3.59, N 23.93.[4] These results show that on the basis of the analyses alone a clear decision cannot be made as to whether the composition of the complex salt is 1:2 or 2:3 (see Discussion).

Quinoxalinium–TCNQ (NHQ–TCNQ)

Attempts to synthesize a TCNQ salt of the protonated quinoxaline NHQ^+ were carried out on the basis of quinoxalinium iodide (NHQ–I) and perchlorate (NHQ–ClO_4) (obtained by direct reaction of quinoxaline dissolved in ethanol with an excess of the respective concentrated acid). Mixing the alcoholic solutions of these salts with alcoholic solutions of Li–TCNQ did not lead to the TCNQ salt. On the contrary, the deep green colour of the dissolved TCNQ anion disappeared immediately and, after a short period of time, greenish-yellow platelets precipitated. These platelets were identified as a mixture of TCNQ and H_2TCNQ. The experimental results suggest the following reaction



$$+ [HTCNQ^{\cdot}] \rightleftharpoons \tfrac{1}{2}H_2TCNQ + \tfrac{1}{2}TCNQ$$

which is similar to the reaction of $TCNQ^-$ with mineral acids (1). This result suggests that quinoxaline is too weak a base to form NHQ–TCNQ compounds in the usual way.

When the yellow solutions containing quinoxalinium salts and Li–TCNQ were cooled the color changed to green. This suggests that at lower temperatures the ionic forms are more stable. Accordingly, on quenching a solution of quinoxaline, TCNQ, and H_2TCNQ (2:1:1) in $CHCl_3$ in a liquid nitrogen bath a precipitate formed consisting of a mixture of greenish yellow crystals and a few violet crystals. The shiny violet platelets seem to be the 1:1 salt of NHQ–TCNQ.

Conductivity

The dc conductivity was measured on pressed pellets of about 0.3-mm thickness under a pressure of 1500 kPa. Resistivities of pressed powders frequently are about four orders of magnitude larger than values of single crystals measured along the radical chain direction.

Electron Paramagnetic Resonance Data

The epr spectra were taken on a Bruker B–ER 418 spectrometer with an nmr gaussmeter for field calibration and a DANA 320 D microwave frequency counter.

Discussion

The *N*-methyl- and *N*-ethylquinoxalinium ions form simple (1:1) and complex salts with TCNQ. Though the quinoxalinium salts are structurally similar to the *N*-alkylphenazinium ions, the chemistry is quite different predominantly owing to the reduced basicity of quinoxaline.

The experimental results clearly suggest that as already considered by Melby (2), a highly-conducting 1:1 NMQ–TCNQ adduct does not exist. The high conductivity reported for the 1:1 salts is possibly caused by an admixture of the complex salt in the 1:1 sample. The results prove that the 1:1 phase, which can be obtained in high purity by the usual (nevertheless more elaborate) methods, is a semiconductor (pressed pellet conductivity $4 \times 10^{-5}\ \Omega^{-1}\ cm^{-1}$) and has properties quite different from those reported by Melby (2). During the preparation of the 1:1 compound there was no evidence of another pure and conducting 1:1 phase. A *conducting* sample was then obtained by recrystallizing the pure NMQ–TCNQ in contact with the air. This sample had properties very similar to the ones mentioned by Melby (2). Whether this compound actually contains high amounts of the complex salt or only some neutral TCNQ 'impurities' in the stacks (which would give rise to partially charged TCNQ chains) was not investigated further. The formation of a sample contaminated with a complex salt can easily be explained in terms of the oxidation of $TCNQ^-$ anions to neutral TCNQ by air, which could result in the final precipitation of the complex salt. The latter compound is in fact a better conductor (pressed-pellet dc conductivity $4 \times 10^{-3}\ \Omega^{-1}\ cm^{-1}$ as compared to $4 \times 10^{-5}\ \Omega^{-1}\ cm^{-1}$ of the pure compound).

Typical epr spectra of NMQ–TCNQ at 230 K are

[1]Recrystallized from acetonitrile and dried in high vacuum.
[2]After heating the sample in high vacuum for 3 h to 120°C.
[3]Recrystallized from acetonitrile and dried under high vacuum.
[4]After heating the sample in high vacuum for 3 h to 120°C.

FIG. 1. Single crystal epr spectra of NMQ–TCNQ at 230 K. Spectra of three different crystal orientations (rotation of the crystal around an axis perpendicular to the field direction) which show the angular dependence of the triplet exciton splittings are drawn. The central peak corresponds to the 'impurity' peak.

shown in Fig. 1. Apart from the strong central line, sharp triplet exciton lines occur. The two different 'exciton' pairs are apparently due to the *twinning* of the crystal. The figure shows the spectra of three different crystal orientations, with the higher pair of peaks consecutively far apart from each other (*a*), closer together (*b*), and finally almost coinciding with the central $S = \frac{1}{2}$ peak (*c*).

This evidence of triplet excitons (which can be observed at room temperature too) proves that a kind of radical dimer exists in the lattice and can be thermally activated. Systems of this type cannot be expected to have high electrical conductivities.

As mentioned above, all the crystals obtained from NMQ–TCNQ were twinned. Therefore a full structure determination could not be carried out. Nevertheless we obtained the unit cell dimensions from single crystal X-ray data. The crystals are triclinic with $a = 4.79$, $b = 10.46$, $c = 7.60$ Å, $\alpha = 93.49$, $\beta = 110.92$, $\gamma = 82.69°$, and unit cell volume 352.7 Å.

The complex salt, which was obtained in very high yield by the usual methods, seems to be a 2:3 salt. The problems of varying stoichiometry and inclusion of solvent molecules for the complex TCNQ salts was recently discussed in connection with very similar donors (11, 12).

The pronounced differences in the behaviour of the semiconducting 1:1 and the highly conducting 2:3 compounds can easily be observed by comparing their ir spectra. The 1:1 compound shows highly resolved spectra with many typical and sharp peaks (most prominent the $\nu_{C\equiv N}$ at 2180 cm^{-1}) whereas the ir bands of the 2:3 compound are hidden under a broad and intense *electronic* absorption which is typical of all 'metallic' donor acceptor complexes (for a recent example see ref. 13; 16). The pressed pellet conductivity for this compound is 9×10^{-3} Ω^{-1} cm^{-1}, which fits well with previous reports on similar complexes (14).

The *N*-ethyl derivatives were investigated because of the special behaviour of *N*-ethylphenazinium–TCNQ (15). The chemical and physical behaviour of NEQ–TCNQ is very similar to that of NMQ–TCNQ.

The 1:1 adduct shows a pressed pellet conductivity of 4×10^{-5} Ω^{-1} cm^{-1}. The ir spectra with a $\nu_{C\equiv N}$ of 2180 cm^{-1} indicate, as seen above, no major electronic absorption in contrast to the 2:3 adduct which has a conductivity of 5×10^{-3} Ω^{-1} cm^{-1} and a very broad electronic absorption in the ir. The epr spectrum of the complex salt consists of a single line with a very anisotropic line width.

Received September 11, 1978

P. C. WONG and D. R. ARNOLD. Can. J. Chem. **57**, 1037 (1979).

Irradiation of the charge-transfer complex between 1,2,3-triphenylcyclopropene (**1**) and fumaronitrile (**7**) and maleonitrile (**8**) leads to formation of bicyclo[2.1.0]pentane cycloaddition products (**9, 10, 11**) and the photoene product (**12**). These products were also formed when the reaction was photosensitized (triplet–triplet transfer). The structure of the adducts was established by analysis of ^{13}C and ^{1}Hmr spectra. Nuclear Overhauser effect studies were also useful. The triplet energies of **7** and **8** (E_T ca. 50 kcal mol^{-1}) were determined by studying the photosensitized isomerization as a function of sensitizer triplet energy. The thermal stability of the new bicyclo[2.1.0]pentanes has been studied, particularly with regard to the isomerization resulting from cleavage of the central [0] bond in these strained systems. The mechanism of the photocycloaddition reactions is discussed.

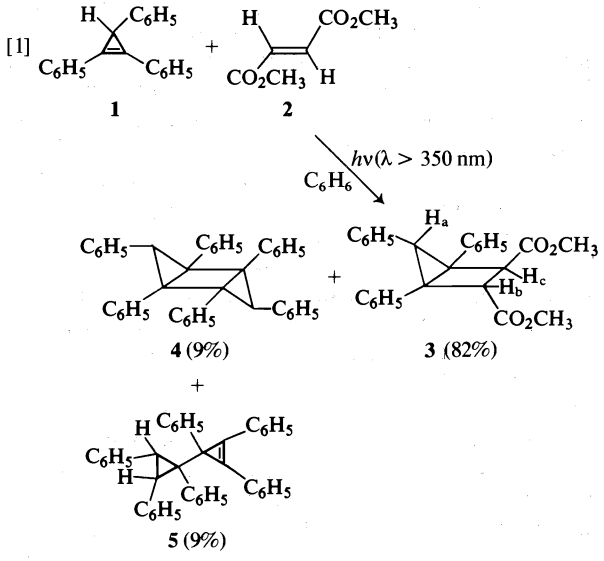
P. C. WONG et D. R. ARNOLD. Can. J. Chem. **57**, 1037 (1979).

L'irradiation du complexe de transfert de charge entre le triphényl-1,2,3 cyclopropène (**1**) et le fumaronitrile (**7**) et le maléonitrile (**8**) conduit à la formation de produits de cycloaddition bicyclo[2.1.0]pentane (**9, 10, 11**) et du produit (**12**) photoène. Ces produits se forment aussi lorsque la réaction est photosensibilisée (transfert triplet–triplet). On a déterminé la structure des adduits grâce à une analyse des spectres rmn ^{13}C et ^{1}H. Des études d'effet Overhauser nucléaire se sont aussi avérées utiles. On a déterminé les énergies triplet de **7** et de **8** (E_T ca. 50 kcal/mol) en étudiant l'isomérisation photosensibilisée en fonction de l'énergie du sensibilisateur triplet. On a étudié la stabilité thermique des nouveaux bicyclo[2.1.0]pentanes en particulier en ce qui a trait à l'isomérisation résultant du clivage de la liaison [0] centrale de ces systèmes tendus. On discute du mécanisme des réactions de photocycloaddition.

[Traduit par le journal]

Introduction

We have previously reported (1*b*,*c*) that the direct irradiation of the charge-transfer complex between 1,2,3-triphenylcyclopropene (**1**) and dimethyl fumarate (**2**) gives the bicyclo[2.1.0]pentane (**3**) (reaction [1]). Only one of the six possible stereoisomeric adducts was obtained as a primary product from this reaction, that having the ester groups *trans* and the phenyl at carbon-5 *exo*. This result could be taken as an indication that this type of cycloaddition reaction favours retention of the configuration of the olefin in the product. It was, however, impossible to test this hypothesis by using the isomeric olefin since no adduct was obtained when the weaker charge-transfer band of (**1**) and dimethyl maleate (**6**) was irradiated.[3] The possibility, therefore, remained that



the observed product stereochemistry was controlled by thermodynamic rather than kinetic factors. The determination of the factors which control the product stereochemistry is important not only from the practical standpoint of defining the synthetic utility, but also for an understanding of the mech-

[1]Contribution No. 192 from the Photochemistry Unit. This article is dedicated to Professor E. Havinga, on the occasion of his 70th birthday (May 7th, 1979). Part 6 of this series is ref. 1*a*.

[3]It is important to recall that the dimethyl maleate – dimethyl fumarate isomerization was not efficient under these conditions (1*c*).

0008-4042/79/091037-13$01.00/0

anism of this reaction. The proposed mechanism involved the cyclopropene triplet as the reactive species and thus a concerted cyclization would seem unlikely. Retention of stereochemistry could alternatively be explained as the result of rapid closure of a 1,4-diradical intermediate with a rate competitive with bond rotation.

Our search for a pair of isomeric olefins which would provide further examples of this type of reaction and allow a test of the stereospecificity led to fumaro- and maleonitrile (**7** and **8**). These dinitriles are more reactive dienophiles and 1,3-dipolarophiles than are the analogous diesters (2 and references cited therein). Furthermore, they have lower reduction potentials (3) so we expected they would form stronger charge-transfer complexes with **1**, complexes which would absorb at longer wavelengths and thus allow more efficient excitation.

In this paper, we report the results of a study of the photocycloaddition of **1** with the dinitriles **7** and **8**, brought about by irradiation of the charge-transfer band. We have characterized the bicyclo[2.1.0]pentane products and have also studied the thermal isomerization which results from cleavage of the [0] bond of these strained systems.

In contrast with the previous results with the isomeric diesters **2** and **6**, which were configurationally stable, the dinitriles **7** and **8** undergo comparatively rapid isomerization upon irradiation of the charge-transfer complex. In a search for an explanation for this difference in behaviour, we have studied the photosensitized (triplet–triplet transfer) isomerization of both the diesters and the dinitriles and conclude that the triplet energy of both of the dinitriles (E_T **7** and **8** ca. 50 kcal mol^{-1}) is considerably lower than that of the diesters (E_T **2** $\sim$ 61 kcal mol^{-1}, E_T **6** $>$ 72 kcal mol^{-1}) (4).

While this work was in progress, Farid and coworkers reported (5) a similar reaction involving the photocycloaddition of methyl 1,2-diphenylcyclopropene-3-carboxylate to dimethyl fumarate sensitized by triplet–triplet transfer. Their results and interpretation are in substantial agreement with ours. Furthermore, they were able to isolate and characterize the isomeric bicyclo[2.1.0]pentane, having the methyl ester groups *cis*, which gave an indication that reaction of the cyclopropene triplet did not occur with complete retention of the olefin configuration. Other pertinent results from their work will be mentioned in the Discussion.

Results

A benzene solution of **7** (0.3 *M*) and **1** (0.3 *M*) has long wavelength absorption not present in the spectrum of the individual components at the same concentration (Fig. 1). We assign this long wavelength absorption to the charge-transfer transition of the complex between **7** and **1**. Similar results were observed with **8** instead of **7**. The absorption spectra of both complexes tail about the same and extend to longer wavelength than do the complexes between either **2** or **6** and **1**.

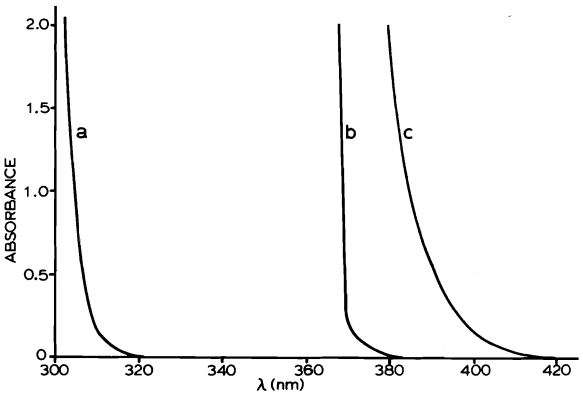

FIG. 1. Absorption curves for (*a*) **7** (0.3 *M*), (*b*) **1** (0.3 *M*), and (*c*) **7** and **1** (each 0.3 *M*) in benzene solution. Similar results were obtained using **8** instead of **7**.

Excitation of the charge-transfer band can be achieved by irradiation, with a medium pressure mercury vapour lamp, through a chemical solution filter (*A*) which absorbs light of wavelengths shorter than 350 nm.

A solution of **1** and **7** was irradiated through this filter solution and the progress of the reaction followed by proton nuclear magnetic resonance (^{1}Hmr) spectroscopy. After 24 h irradiation, all the cyclopropene had been consumed and the product mixture consisted of the tricyclohexane dimer of **1** (**4**), the bicyclo[2.1.0]pentane adducts **9**, **10**, and **11**, and the photoene product **12** (reaction [2]). Analysis of the ^{1}Hmr spectrum during the course of the reaction indicated that all of these products were primary products, although the ratio of products was not constant, and that the starting dinitrile **7** isomerized rather rapidly to a mixture of the isomers (**7**:**8**, 65:35).

When **1** and maleonitrile (**8**) were irradiated under these conditions, the same products resulted; however, the proportion of adducts **10** and **11**, having the cyano groups *cis*, was larger. Again, the starting dinitrile isomerized during the course of the irradiation until a photostationary state (**7**:**8**, 60:40) was obtained.

The cycloaddition reaction can be photosensitized (triplet–triplet transfer). For these experiments, a benzene solution of **1** (0.3 *M*), **7** (0.3 *M*), and thioxanthen-9-one (0.01 *M*, E_T = 65 kcal mol^{-1}) or fluoren-9-one (0.01 *M*, E_T = 53 kcal mol^{-1}) was

[2] 
irradiated through a chemical solution filter (*B*) which absorbs all wavelengths shorter than 358 nm. Under these conditions, the sensitizer absorbs most of the light. Using thioxanthen-9-one as sensitizer, after only 2-h irradiation, 89% of **1** was consumed, the same products (**8–12**) were obtained, only in a different ratio, and the dimer **5** was also formed. The ratio of the unreacted **7** and **8** was again 60:40.

The reaction mixtures from each of the above irradiations were separated by column chromatography to provide products for structural analysis. The yields of products, obtained under these varying conditions were accurately determined by quantitative ^{1}Hmr of the crude reaction mixtures and are summarized in Table 1. The isolated yields and material balance were generally good and are reported in the Experimental.

Some control experiments were carried out to confirm that these reactions were reactions of the excited state. Heating a sealed tube of a toluene solution of **1** (0.075 *M*) and **7** (0.15 *M*) at 120°C for 2 weeks gave a good yield (95%) of the dimer **5** and none of the other products. A benzene solution of **1** and **7** was refluxed, under nitrogen, and small portions of a free-radical chain initiator (azobisisobutyronitrile) were added over a 2-day period. The starting materials were largely recovered; the only product identified was the dimer **5** (~2%) present in amounts expected from the thermal (nonchain) reaction.

All three bicyclo[2.1.0]pentane adducts (**9**, **10**, and **11**) were thermally unstable. Heating adduct **9** in benzene solution at 65°C gave complete rearrangement to the corresponding phenyl-in isomer **13** (reaction [3]). The progress of this reaction was

[3] 
9 $t_{1/2}$ = 9.5 h at 65°C — **13**

followed by ^{1}Hmr and the half-life of **9** was 9.5 h under these conditions.

Adduct **10** is even more thermally labile. We were, in fact, unable to obtain **10** free from the corresponding phenyl-in isomer **14**. Heating a reaction mixture from the photosensitized (thioxanthen-9-one) irradiation of **1** and **7** for 1 h at 65°C gave rise to an equilibrium mixture of adducts **10** and **14** (ca. 1:3) among the other products. Adduct **14** is relatively stable in the crystalline form and since it is much less soluble than **10** in a mixture of chloroform–hexane, it can be obtained essentially pure upon crystallization from this solvent. Refluxing a benzene solution of **14** for 2 h gave an equilibrium mixture of **10** and **14** (23:77) (reaction [4]).

[4] 
10 (23%) — **14** (77%)

Adduct **11** was stable by comparison with **9** and **10**. Prolonged heating (24 h at 75°C) in benzene-d_6 resulted in decomposition of **11** to products which, from an analysis of the ^{1}Hmr spectra, did not include the isomeric bicyclo[2.1.0]pentane and which were not further characterized.

Proof of Structure of the Adducts

The structural assignments for the bicyclo[2.1.0]-pentane adducts (**9–11**, **13**, and **14**) was based largely upon an analysis of their nuclear magnetic resonance spectra, both ^{13}C and ^{1}H. This series represents all but one of the six possible stereoisomers, the missing member is the isomer having the 5-phenyl and both

cyano groups *endo*. Isomerization of **11** might have afforded this isomer; however, it was not detected and it seems reasonable that **11** is strongly favoured at equilibrium.

Details of the nmr spectra are reported in the Experimental. Only the salient features which distinguish each isomer will be discussed here. Consider first the isomeric pair **9** and **13**. The lack of symmetry in these isomers was obvious from both the ^{13}C and ^{1}Hmr spectra. Three features of the spectra allow the distinction between **9** and **13**. First, there is the long range 'w-coupling' observed between H_a and H_b for one of the isomers which is consistent with the geometry of **13**. Second, there is a 4% enhancement in the intensity of the signal assigned to H_a owing to the nuclear Overhauser effect (nOe) when H_b of the other isomer was double irradiated. This is an indication of the proximity of these nuclei and is consistent with **9**. The third observation is that the signals due to the protons in the aromatic region of the ^{1}Hmr spectrum of **9** appear as a series of multiplets over a broad region whereas the absorption in this region of **13** is a relatively narrow multiplet. This observation is reminiscent of the early report of the ^{1}Hmr of *cis*- and *trans*-1,2-diphenylcycloalkanes (6). The protons in the aromatic region of the *cis*-isomers appear as a multiplet whereas the *trans*-isomers have a relatively sharp singlet in this region. The multiplet was attributed to restricted rotation of the phenyl group in the more hindered (*cis*) isomers. This explanation is consistent with the relative stability of **9** and **13**; **9**, being the less stable isomer, has restricted rotation of the phenyl group and the multiplet absorption in the aromatic region. This correlation is also useful for assigning configurations of the other isomers, those having the phenyl on the apical carbon in the *exo* position (**10** and **11**) have a series of multiplets in the aromatic region while the corresponding (more stable) *endo*-phenyl isomer **14** has a relatively narrow multiplet.

The relatively simple ^{1}Hmr and ^{13}Cmr spectra of the other isomers are consistent with the more symmetric structures, **10**, **11**, and **14**. The assignment of structure **11**, that is, the isomer having both the phenyl in the 5-position and the cyano groups *exo* was made possible by the observation of a nuclear Overhauser effect. The intensity of the signal assigned to the proton on carbon-5 (H_a) increased (18%) when the protons on carbon 2 and 3 (H_b and H_c) were double irradiated.

The relationship between **10** and **14** was made apparent from the observation that they interconvert by inversion about the central [0] bond. In neither isomer is the proton on carbon-5 (H_a) significantly coupled to the protons H_b and H_c. The choice between them was made on the basis of the observed series of multiplets in the aromatic proton region of the ^{1}Hmr spectrum of **10**, while a relatively narrow multiplet is observed in this region of **14**. Furthermore, the relative stability of **10** and **14** is consistent with the assigned structures.

The structure of **12** was assigned on the basis of spectral (ir, mass, and ^{1}Hmr) characteristics. There is a close similarity of the ^{1}Hmr spectrum of **12** and that of phenylsuccinodinitrile (7). The structures of **4**

and **5** were established by direct comparison (^{1}Hmr, ir) with authentic samples (8).

For reasons which will be made clear below, estimates of the triplet energies of **7** and **8** were required. An attempt was made to observe direct $S_0 \rightarrow T$ absorption by utilizing the external heavy atom effect. The absorption spectra of the dinitriles (**7** and **8**) (0.3 *M*) were measured in ethyl iodide solution. Both solutions were visibly yellow but the spectra showed only structureless absorption tailing out beyond 450 nm (<63.5 kcal mol^{-1}). Since it is impossible to determine the onset of such tailing, no definite conclusions can be drawn from these spectra.

The triplet state energy of an alkene can sometimes be determined by observing the variation of the stationary state in the photosensitized *cis–trans* isomerization as a function of sensitizer triplet energy. This approach has been successfully applied to the closely related diethyl maleate – diethyl fumarate esters by Hammond and his co-workers (4). The photostationary states established upon irradiation of benzene solutions containing the dinitriles **7** and **8** and various sensitizers were measured and are recorded in Table 2. In every case, the stationary state was approached from both directions. With some sensitizers complications arose as the result of instability of the sensitizer and/or the formation of a light absorbing residue on the surface of the irradiation vessel. For instance, phenanthrenequinone was particularly unstable as a sensitizer and the formation of a residue was a serious problem in the case of 1,2-benzanthracene and acridine. To minimize these complications, mixtures of the dinitriles close to the stationary state were used instead of the pure isomers so that shorter irradiation times were required to reach the stationary state.

The efficiency of the isomerizations were qualitatively similar, comparable irradiation times were required to reach the stationary state, with the higher energy sensitizers; that is, with sensitizers having a triplet energy of 49 kcal mol^{-1} or greater.

Since the reported work (4) on the diesters used the ethyl derivatives and our studies have involved the methyl esters, we determined the photostationary states of **2** and **6** with a few sensitizers. In this case, the approach to stationary states became appreciably slower using sensitizers having a triplet energy below 61 kcal mol^{-1}. These results are also reported in Table 2.

Discussion

In our previous report, we proposed a mechanism for reaction [1] which involved initial excitation of the charge-transfer complex followed by an intersystem-crossing process which led to formation of the cyclopropene triplet. Product formation was attributed to the reactivity of the cyclopropene triplet. This mechanism is also applicable to reaction [2]; however, there are significant differences between the behaviour of the diesters and that of the dinitriles. Scheme 1, for reaction [2] starting with **1** and **7**, is abbreviated to illustrate only those steps which lead to products. The differences in behaviour between the diesters and the dinitriles can be explained in the

[d]No observed signal through scanning voltage from 0 to +2.2 V.

context of Scheme 1, as the result of the lower reduction potentials, the lower triplet energies, and the greater reactivity of the dinitriles in comparison to the diesters.

The reduction potentials of the diesters **2** and **6** and the dinitriles **7** and **8** are listed in Table 3. The dinitriles, since they have significantly lower reduction potentials than either of the diesters, should be better electron acceptors and the resulting charge-transfer complexes with **1** should absorb at longer wavelengths. The observations are consistent with these predictions. Charge-transfer complex formation between **6** and **1** is barely detectable in the long wavelength region of the absorption spectra of the mixture (1*b*). On the other hand, the charge-transfer complexes between both **7** and **8** and **1** are obvious from the extended absorption in this region (Fig. 1).

Step 1 $\quad \mathbf{1} + \mathbf{7} \rightleftharpoons [\mathbf{1}\text{–}\mathbf{7}]$

Charge-transfer complex formation

Step 2 $\quad [\mathbf{1}\text{–}\mathbf{7}] \xrightarrow{h\nu} [\mathbf{1}\text{–}\mathbf{7}]^*$

Excitation of the charge-transfer absorption band

Step 3*a* $\quad [\mathbf{1}\text{–}\mathbf{7}]^* \dashrightarrow \mathbf{1}^3 + \mathbf{7}$

Deactivation of the excited charge-transfer complex to give the cyclopropene triplet

Step 3*b* $\quad [\mathbf{1}\text{–}\mathbf{7}]^* \dashrightarrow \mathbf{1} + \mathbf{7}^3$

Deactivation of the excited charge-transfer complex to give the triplet of fumaronitrile

Step 4 $\quad \mathbf{1}^3 + \mathbf{7} \rightarrow [\dot{\mathbf{1}}\text{–}\dot{\mathbf{7}}]^3 \dashrightarrow \mathbf{9}\text{—}\mathbf{12}$

Reaction of the cyclopropene triplet, via 1,4-diradical intermediate(s) to yield adducts

Step 5 $\quad \mathbf{1}^3 + \mathbf{1} \rightarrow [\dot{\mathbf{1}}\text{–}\dot{\mathbf{1}}]^3 \dashrightarrow \mathbf{4} + \mathbf{5}$

Reaction of the cyclopropene triplet, via 1,4-diradical intermediate(s) to yield dimers

Step 6 $\quad \mathbf{7}^3 \rightarrow \alpha\mathbf{7} + (1 - \alpha)\mathbf{8}$

Isomerization of the fumaronitrile triplet

SCHEME 1

The use of filter solution *A*, which absorbs light of wavelength less than 350 nm, ensures that the excitation process involves predominantly, if not exclusively, the charge-transfer transition of the complex (step *2* in Scheme 1). The triphenylcyclopropene (**1**) does have absorption which tails out beyond 370 nm, so some direct excitation may occur; however, the cyclopropene alone is stable to direct irradiation (i.e., no dimers form) and the intersystem crossing process from the singlet of **1** has a quantum yield of less than 10^{-3} (8*a*). Furthermore, direct excitation of **1**, followed by complex formation between the singlet of **1** and **7** might give a species identical with that obtained by direct excitation of the charge-transfer complex (10).

Step *3* in Scheme 1 represents the deactivation pathway of the excited state of the charge-transfer complex which leads to formation of the triplet of one or both of the components of the complex. Most of the precedents for this process comes from photophysical studies where the triplet of one of the components of the charge-transfer complex or exciplex has been detected by flash spectroscopy or by phosphorescence (11). Surprisingly few examples of this potentially useful phenomena have been recognized in the area of preparative organic photochemistry (12).

In spite of the significant number of charge-transfer complexes studied by the photophysical techniques, it remains difficult to predict whether the triplet of a component of the complex will form upon irradiation. In the case of the complex between **1** and **2** it is clear that the irradiation gave only the triplet of **1**. This follows from the fact that the adduct **3** and the cyclopropene dimers **4** and **5** were obtained while isomerization of **2** was not observed. However, irradiation of the charge-transfer complex between **1** and **7** (or **8**) gives the triplet of both **1** (step 3*a*) and **7** (or **8**) (step 3*b*) since isomerization of the dinitrile was observed.

It seems likely that this difference can be attributed, at least in part, to the differences in triplet

TABLE 4. The application of the Weller equation to these systems

Reactants

[e]The Coulombic attraction terms are 0.056 and 0.90 eV for acetonitrile and benzene, respectively. The $\Delta\Delta F_{solv}$ is 1.91 eV from acetonitrile to benzene.

energy of **2** and **7** (and **8**). It may well be that while the excited state of the corresponding charge-transfer complexes can deactivate to give the triplet of **1** (E_T ca. 53 kcal mol^{-1}),[4] **7** (and **8**) (E_T ca. 50 kcal mol^{-1}), not enough energy is available to give the triplet of **2** (E_T = 61 kcal mol^{-1}). Since the large difference in triplet energy between the diesters and the dinitriles was unexpected, we will return to this point later.

There are several mechanisms which could apply to this intersystem crossing process; mixing of states which increase the probability of intersystem crossing, dipole–dipole or dispersion interactions, caged radical ion pair formation followed by back electron transfer, electron transfer between solvent-separated radical ions, etc. Although our results do not allow us to choose positively from among these possible explanations, we favour a mechanism involving the caged radical ion pair. It seems unlikely, in view of our use of nonpolar solvent, that solvent-separated radical ions are involved; yet, because of the large differences in oxidation and reduction potential of the components of the complex, it is reasonable to suggest considerable electron transfer in the complex and a radical–ion pair is not unlikely.

An estimate of the free-energy change associated with radical ion pair formation can be obtained by applying the concepts developed by Weller and his group (13). The Weller equation is shown in eq. [5].

$$[5]\quad \Delta G = ((E_{(D/D^+)} - E_{(A/A^-)} - (e_0^2/\varepsilon\alpha) + \Delta\Delta F_{solv})) - \Delta^1E_{0,0}$$

This empirical equation allows an estimate of the free-energy change (ΔG) for the electron transfer between a donor (D) and an acceptor (A) molecule within an encounter complex, based upon the oxidation potential of the donor and the reduction potential of the acceptor. The Coulombic attraction term takes into account the fact that the charges (e_0) remain within the encounter distance (α ca. 7 Å) in the solvent dielectric (ε). Since the oxidation and reduction potentials are measured in high dielectric solvents (e.g., acetonitrile, ε = 37) and the photochemical reaction is carried out in nonpolar solvents (benzene, ε = 2.28), a solvent correction term ($\Delta\Delta F_{solv}$) must be applied. The energy available ($\Delta^1E_{0,0}$) is the singlet energy.

The Weller equation is strictly applicable only to systems where no charge-transfer complex exists between the ground state molecules. Nevertheless, when the association constant for the charge-transfer complex is small (i.e., the binding energy between the components is weak), as it must be between **1** and **2**, **7** and **8**, the energy required for the electron transfer (the term in parentheses) is essentially the same and if the singlet energy of one of the components is used, the calculated free-energy change can be taken as a maximum (i.e., most favourable) value.

Table 4 lists the values which we have used in eq. [5] and the calculated ΔG values for the systems **1** and **2**, and **1** and **7** and **8**. Values have been calculated for both acetonitrile (where no solvent correction term is required) and benzene solution. The large negative values calculated when acetonitrile is the solvent leads to the prediction that radical–ion pair formation is favourable. Even for the benzene solutions, the calculated values are only slightly positive and we take this as an indication that radical–ion pair formation is possible in these systems as well.

There is a brief report in the literature which greatly influenced our thinking regarding the mechanism of step 3. Taylor[5] has studied the photo-

[4]Although **1** fluoresces strongly upon irradiation in rigid media at 77 K, we were unable to detect phosphorescence emission even when ethyl iodide was added to the solvent. This estimate was made by analogue with the reported triplet energy of methyl 1,2-diphenylcyclopropene-3-carboxylate which was determined by the Hammond–Herkstroeter method (5).

[5]G. N. Taylor. Private communication and unpublished results cited by Roth (16*a*).

chemically induced dynamic nuclear polarization (CIDNP) of the system naphthalene and **7** (16). Irradiation of a dilute solution of naphthalene and fumaronitrile (**7**) in acetonitrile-d_3 gave enhanced absorption of the protons on **7** and emission was observed for the protons of maleonitrile (**8**). This result was interpreted in terms of the radical–ion pair mechanism. The enhanced absorption of the protons on **7** results from back electron transfer within the singlet radical–ion pair, whereas the emission of the protons of **8** results from back electron transfer within the triplet radical–ion pair producing initially the triplet of **7** which can then isomerize to give **8**. Although it seems likely that a similar mechanism pertains during step 3, particularly in view of the similarities in the calculated free energy for the electron transfer processes (Table 4), we were unable to detect nuclear polarization upon irradiation of an acetonitrile-d_3 solution of **1** and **7**. Details of these attempts are given in the Experimental. It should also be mentioned that as a result of more recent advances in the theory of CIDNP, the mechanism originally proposed no longer uniquely explains the results.

Both of the isomeric dinitriles **7** and **8** react with the triplet of **1**. This is in contrast with the isomeric diesters **2** and **6** where the adduct is formed only with dimethyl fumarate (reaction [1]) (1*b*). The observed ratio of adducts to cyclopropene dimer (**4**) indicates that the reactivities of both **7** and **8** are comparable to that of **2**.

The ratio of one-to-one adducts (**9–12**) to cyclopropene dimers (**4** and **5**) was larger when the charge-transfer complex was irradiated than when the cyclopropene triplet was generated by photosensitization. This is consistent with previous results which were attributed to the cyclopropene triplet being formed next to the dinitrile upon irradiation of the charge-transfer complex and a rate of reaction of the cyclopropene triplet with the dinitrile which is competitive with diffusion (1*b*).

Although reaction [2] is not stereospecific with regard to the configuration of the vicinal cyano group, it is clear that there is some preference for retention of configuration (Table 1). These observations are in accord with the suggestion that the rate of ring closure of the intermediate 1,4-diradical which is formed initially in the triplet state (step 4 in Scheme 1), is competitive with the rate of bond rotation. There is adequate precedent for this behaviour (17).

The bicyclo[2.1.0]pentanes **9**, **10**, and **11** all have the phenyl on the apical carbon (carbon-5) in the *exo* position. This regiospecificity was also observed upon addition of **1** to **2** (reaction [1]) and to maleic anhydride (1*b*). Apparently, the phenyl on carbon-3 of the triplet of **1** hinders the formation of the initial bond on the same side even though the favoured configuration of the final product is the *endo*-phenyl isomer.

Reactions [3] and [4] provide additional examples of the isomerization of bicyclo[2.1.0]pentanes which illustrate the rate acceleration resulting from phenyl substitution at the bridge head. The half-life of **9**, 9.5 h at 65°C, is comparable to that of the analogous diester **3**, $t_{1/2} = 5$ h at 65°C (1*b*), which also rearranges to the phenyl-in isomer. The difference in thermodynamic stability between **9** and **13** favours **13** to such an extent that **9** was not detected at equilibrium. In contrast, the *cis*-dinitriles **10** and **14** are of similar stability with **14** only slightly favoured at equilibrium (reaction [4]). The isomer of **11** was not detected; this is perhaps not surprising since the apical phenyl and both nitriles would be forced *endo* in this isomer.

In addition to the bicyclo[2.1.0]pentane adduct, the adduct **12** was also obtained as a major product. A possible mechanism for formation of **12** involves hydrogen migration of the 1,4-diradical in competition with ring closure. The alternative concerted photoene process seems unlikely since this product was also obtained in the triplet sensitized reactions. Ring closure and hydrogen migration of 1,4-diradical intermediates has been proposed as the mechanism to account for the formation of the cyclopropene dimers **4** and **5** from the triplet of **1** (8). We have pointed out before that this explanation is not entirely satisfactory because the ratio of **4** to **5** is dependent upon the concentration of **1** (1*b*). Now, we find that **4**, but not **5**, is formed in reaction [2]. Clearly, different intermediates must be involved in the competitive formation of **4** and **5**. The reaction cannot simply be as shown in step 5 of Scheme 1.

It seemed possible that **5** and/or **12** could be products of a free-radical chain reaction; however, this was ruled out after control experiments indicated that neither **5** nor **12** was produced thermally in a chain initiated reaction. These control experiments also confirm that **5** does result from a thermal, non-chain, ene-reaction of **1** and that **7** does not compete with **1** via this mechanism. It should also be mentioned that the analogous ene-reaction product incorporating **2** was not observed from reaction [2]; however, Farid and co-workers (5), obtained this type of product from the triplet sensitized reaction of methyl 1,2-diphenylcyclopropene-3-carboxylate and **2**. Obviously, the factors which determine the ratio of these two types of products remains to be defined.

The Triplet Energy of Fumaro- and Maleonitrile

At the onset of this work, there was little indication in the literature as to what the triplet energy of fumaro- and maleonitrile might be. It was known that the triplets of butyrophenone (E_T = 72 kcal mol^{-1}), acetone (E_T = 78–80 kcal mol^{-1}), and benzophenone (E_T = 68 kcal mol^{-1}) were quenched at the diffusion controlled rate by fumaronitrile and so these results at least establish an upper limit for the triplet energy of this isomer (18, 19). It was also known that irradiation of ketones with a triplet energy that of biacetyl (E_T = 55 kcal mol^{-1}) and fluoren-9-one (E_T = 53 kcal mol^{-1}) could lead to some isomerization of fumaronitrile but the photostationary state was not reported and there was no mention of the efficiency of these isomerizations (18). The photo-CIDNP results mentioned earlier were the most informative in this regard, since they require that the triplet energy of both fumaro- and maleonitrile be less than that of naphthalene (E_T = 61 kcal mol^{-1}) (16).

In Table 2 are listed the photosensitized stationary state ratios of isomers **2**–**6** and **7**–**8** as a function of triplet energy of the sensitizer. The Saltiel plots of these data are shown in Fig. 2 (20).

Notice first that our results for the dimethyl esters are similar to those reported by Hammond and coworkers (4) for the diethyl esters. Energy transfer to dimethyl maleate (**6**) is apparently less than diffusion controlled when the triplet energy of the sensitizer is less than 70 kcal mol^{-1} and efficient energy transfer to dimethyl fumarate (**2**) requires a sensitizer having a triplet energy greater than 61 kcal mol^{-1}.

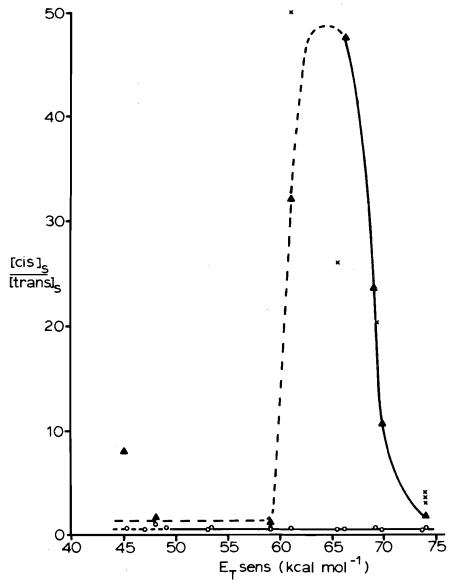

FIG. 2. Saltiel plots for ▲ dimethyl maleate and fumarate, × diethyl maleate and fumarate (4), and ⊙ maleonitrile and fumaronitrile.

No isomerization was induced when fluoren-9-one was the sensitizer and the isomerization observed when pyrene and acridine were used as sensitizers was relatively inefficient and of unknown mechanism. Rapid isomerization of **6** to **2** occurred when 9,10-dibromoanthracene was used as the sensitizer and the resulting mixture, i.e. >99% **2**, was identical to the thermodynamic equilibrium. Irradiation of this sensitizer is known to lead to carbon–bromine bond homolysis and the resulting bromine atoms could subsequently catalyze the thermal isomerization (21).

The behaviour of the isomeric dinitriles is obviously very different. The photosensitized stationary state is insensitive to variation in sensitizer triplet energy. Isomerization does, however, become relatively inefficient with sensitizers having a triplet energy less than 49 kcal mol^{-1} and no isomerization was observed with the sensitizer having triplet energy 44 kcal mol^{-1}. Our interpretation of these results is that the triplet energy of both **7** and **8** is approximately 50 kcal mol^{-1}.

Since it is known that sensitizers having a triplet energy between 68–78 kcal mol^{-1} are quenched at the diffusion-controlled rate by **7** and since the photostationary state is invariant over this range, it can be assumed that **8** also quenches these sensitizers at the diffusion limit. The fraction of triplets (**7**, **8**)[3] that decay to fumaronitrile (step 6 of Scheme 1) can be deduced from the photostationary state ratio established with these high energy triplet sensitizers: $\alpha = 0.61$.

Again in this case, isomerization was relatively rapid when 9,10-dibromoanthracene was the sensitizer. We believe the resulting mixture arises from a bromine atom catalyzed reaction and reflects the thermodynamic stability (33% **8** at 10°C; ΔG = 0.4 kcal mol^{-1}). The thermodynamic equilibrium has been established in a thermal reaction (180°C), catalyzed by iodine. The reported equilibrium value (33.8% **8**) (22) was based upon isolated yields and differs from the value we obtain (43.5% **8** at 180°C; ΔG = 0.2 kcal mol^{-1}) by vpc analysis of the crude reaction mixture. We believe it is fortuitous that the thermodynamic equilibrium is so similar to the photosensitized stationary state value.

No explanation was offered in the original work (4) for why diethyl maleate has such a high triplet energy relative to the fumarate. Since steric and electronic repulsions strongly (4.22 kcal mol^{-1}) (23) favour the *trans*-isomer in the ground state, the difference in the planar triplet state energies must be

proportionally larger; that is, the 'planar' triplet of diethyl maleate must be more than 16 kcal mol^{-1} above the 'planar' triplet of diethyl fumarate. To our knowledge the cause of this large difference has remained unexplained. Obviously, little or no difference exists between the triplet energy of **7** and **8**.

We were surprised that the triplet energies of the dinitriles were so much lower than that of the *trans*-diesters; we had assumed that **2**, **7**, and **8** would have similar triplet energies with the triplet of **6** being exceptionally high. This reasoning was based on the fact that both carbomethoxy and cyano substitution lowers the triplet energy of benzene by the same extent; methyl benzoate and cyanobenzene have essentially the same triplet energies (24). Baird (25) has proposed an empirical approach for estimating the energy of the 'twisted' π,π^* triplet of conjugated alkenes.[6] To use this approach to compare the relative triplet energies of two alkenes, one considers the relative stabilities of the pairs of radicals resulting from twisting each of the π bonds by 90°. From the reported heats of formation of the cyanomethyl radical (27) and fumaronitrile (28) the estimate of the 'twisted' triplet energy of fumaronitrile is 38.9 kcal mol^{-1}, similar to that of stilbene (37.8 kcal mol^{-1} (25)). The 'planar' triplet energy of *trans*-stilbene (49 kcal mol^{-1} (4)) is also close to that of the dinitriles. Unfortunately, the required thermodynamic data are not available for an estimate of 'twisted' triplet energy of the diesters.

An analysis based upon electron spin resonance hyperfine splitting, suggests that electron delocalization is much greater with the cyano than with the carbomethoxy substituted radicals (29).

It therefore seems likely that conjugation of the alkyl oxygen nonbonding pairs of electrons with the carboxyl carbonyl decreases the extent of conjugation of the carbonyl with the carbon–carbon double bond in the ground state and with the unpaired electrons in the triplet. This explanation gains some support from the relatively large reduction potential of the diesters (3), and the observation that rotation about the alkyl oxygen – carboxyl carbonyl carbon in the radical anion is relatively slow (30).

Experimental

General

Fumaronitrile (Aldrich Chemical Co.) was freshly sublimed under vacuum before use. Maleonitrile was prepared by thermal isomerization of fumaronitrile catalyzed with iodine (22), and was isolated by fractional distillation, column chromatography on neutral alumina (Woelm) eluting with a 1:1 mixture of benzene and hexane, followed by recrystallization from ether–pentane. 1,2,3-Triphenylcyclopropene was prepared using the method described by Breslow and Chang (31).

Dimethyl fumarate (Aldrich Chemical Co.) was recrystallized once from methanol.

Dimethyl maleate (Eastman Kodak Co.) was fractionally distilled twice before use.

The sensitizers thioxanten-9-one, 4,4′-dimethoxybenzophenone, 1,3,5-triacetylbenzene, 2-acetylfluorene, and phenazine (Aldrich Chemical Co.); benzophenone (Fisher Scientific Co.); benzil and 1,4-benzanthracene (BDH Chemical Co.); xanthen-9-one, 9,10-dibromoanthracene, fluoren-9-one 2-acetonaphthone, phenanthrene quinone, and pyrene (Eastman Kodak Co.); 4,4′-dicyanobenzophenone (32); were either repeatedly recrystallized or sublimed under vacuum until they gave a sharp melting point and showed a single spot on thin-layer chromatography using silica gel plates.

Thiophene-free benzene was obtained using the procedure employed by Wagner (19). The melting points were determined on a Thermolyne hot-stage microscope and were corrected. The combustion analyses were performed by Chemalytics Inc., Tempe, Arizona.

Mass spectra were obtained from a Varian Mat 311A mass spectrometer and are reported as *m/e* (relative intensity); only parent molecular-ion peak and the base peak are reported.

The infrared spectra were run in KBr disk on a PE-621 infrared spectrometer using the 1601 cm^{-1} absorption band of polystyrene for calibration. The ^{1}Hmr spectra were obtained either on a Varian T-60 or a Varian XL-100 spectrometer. The chemical shifts are taken as the centre of multiplets referring to tetramethylsilane and the coupling constants are the result of first-order analysis.

The ultraviolet absorption spectra were recorded on a Cary 118 spectrometer using 1.0-cm quartz cuvettes.

The ^{13}Cmr spectra were determined using a Varian XL-100-15 system operation at 25.2 MHz in the Fourier transform mode with 2000 Hz sweep widths, the peak positions were determined to ± 1 Hz reference to internal tetramethylsilane. Off-resonance decoupling was employed to confirm assignments for methylene, methine, and quarternary carbons.

All irradiations were performed using a General Electric Co. 1-kW medium pressure mercury vapour arc lamp with a quartz cooling jacket (Photochemical Research Associates). All solutions were placed in Pyrex irradiation vessels flushed with dry nitrogen and sealed with rubber septums. The irradiation vessels were immersed in a constant temperature bath maintained at 10°C.

Filter Solution A

$BiCl_3$ (200 mg) was dissolved in 10% HCl (150 mL) and this solution was placed in a container such that there was at least 1 cm of filter solution shielding the irradiation vessel. The long wavelength cut off is 350 nm. This filter solution was photolabile and was replaced after each 24-h irradiation.

Filter Solution B

Same as filter solution *A* except that a more concentrated solution of $BiCl_3$ was employed (1000 mg $BiCl_3$ in 150 mL 10% HCl). The long wavelength cut off is 358 nm.

Oxidation and Reduction Potential Measurements

Cyclic voltammetric data were obtained using a three-electrode cell with a Princeton Applied Research Electrochemistry System model 170. The working electrode was a platinum sphere sealed into glass and the counter electrode was a platinum wire. A $Ag/AgNO_3$ (0.1 *M*) electrode was used as a reference electrode and 0.1 *M* tetraethylammonium perchlorate as supporting electrolyte. The solvent was acetonitrile.

[6]Semiempirical molecular orbital calculations of the triplet energy ('planar') of both **7** and **8** range between 41.4 and 61.5 kcal mol^{-1} (26).

CIDNP Experiment

The light source was an Oriel Corporation 200-W HgXe lamp focused and passed down through a light pipe into the solution in a 5-mm nmr tube. The signals were detected by a Varian XL-100 ^{1}Hmr spectrometer. No CIDNP signal was found under the following conditions although we were able to reproduce Taylor's result (footnote 5 and ref. 16) under similar conditions: a CD_3CN (or C_6D_6) solution of **1** (18.6 m*M*) and **7** (13 m*M*) or a solution containing **1** (0.1 *M*) and **7** (0.1 *M*) in CD_3CN. Solutions were deaerated by purging thoroughly with dry nitrogen.

Irradiation of 1,2,3-Triphenylcyclopropene and Fumaronitrile

A solution containing 1,2,3-triphenylcyclopropene (3.0 g, 11.1 mmol) and fumaronitrile (0.9 g, 11.5 mmol) in 40 mL of benzene was irradiated through filter solution *A*. After 120-h irradiation, the ^{1}Hmr spectrum of the reaction mixture revealed that all the cyclopropene had been consumed. Remaining was a complex mixture of adducts, cyclopropene dimer, and the unreacted fumaronitrile together with maleonitrile.

Benzene was removed under vacuum and the residue was charged onto a column of silica gel (Woelm activity III) and eluted with hexane–benzene. The first component to be eluted was the hexaphenyltricyclohexane dimer **4** (546 mg, 18.2%), followed by the unreacted fumaronitrile, which sublimed readily as the solvent was being taken off. Adduct **9** (806 mg, 20.8%) was not stable under the column condition and had partially isomerized to the corresponding phenyl-in isomer **13**. Maleonitrile was next to be eluted and sublimed while the solvent was being evaporated. Adduct **10** isomerized to give an equilibrium mixture of **10** and **14** (202 mg, 5.2%). The photoene adduct **12** (431 mg, 13.9%) came next. The last component to be eluted was adduct **11** (100 mg, 2.6%). All of the above yields were isolated yields of pure compounds calculated on the bases of starting cyclopropene.

Since the adducts are labile to heat and/or silica gel, direct measurement of yields by ^{1}Hmr was conducted on the crude reaction mixture using cyclohexane as an internal standard. A benzene (0.5 mL) solution of 1,2,3-triphenylcyclopropene (0.3 *M*) and fumaronitrile (0.3 *M*) was irradiated for 24 h through filter solution *A*. The ^{1}Hmr spectra revealed that all the cyclopropene had been consumed. The calculated yields accounted for 89% of the cyclopropene consumed: dimer **4** (17.5%), adduct **9** (44.5%), adduct **10** (7.3%), adduct **11** (4.4%), the ene-product **12** (15.3%). The starting nitrile(s) was 75% consumed and the ratio of fumaronitrile to maleonitrile remaining was 65:35. Neither adduct **13** nor **14** was present in this reaction mixture.

Adduct **9** was purified by recrystallization from $CHCl_3$–hexane to give colourless rhombic crystals: mp 188–190°C; ir (KBr) ν: 3040, 2970, 2250 (m), 1600, 1495, 1442, 1160, 1080, 1030, 1000, 920, 850 cm^{-1}; ^{1}Hmr δ($CDCl_3$): 3.25 (H_a, s, 1H), 3.45 (H_b, d, 1H, J_{bc} = 4.5 Hz), 3.80 (H_c, d, 1H, J_{bc} = 4.5 Hz), 6.40–7.40 (m, 15H, the pattern of this multiplet was common to the phenyl-out adducts so far observed which divided into three groups of multiplets with the lowest field group being the largest); ^{1}Hmr δ(C_6D_6): 2.85 (H_a, s, 1H), 2.35 (H_b, d, 1H), 3.00 (H_c, d, 1H), 6.15–7.10 (m, 15H); no nOe effect was observed in $CDCl_3$ on H_a upon irradiating H_c, however, a 4% nOe enhancement of H_a was observed upon irradiating H_b in C_6H_6 while the intensity of H_c remained unchanged; ^{13}Cmr chemical shifts ($CDCl_3$): 43.6 (bridgehead carbons), 36.48 (methine carbons), 39.95 (apex carbon), 116.4 and 117.3 (cyanocarbons), 133.4 (one of the aryl carbons attached directly to the bicyclopentane nucleus), 126.6–132.0 (other aromatic carbons); ms (70 eV): 346 (95, M^+), 319 (100). *Anal.* calcd. for $C_{25}H_{18}N_2$: C 86.68, H 5.24; found: C 86.59, H 5.44. *Mol. Wt.* calcd. for $C_{25}H_{18}N_2$: 346.14699; found (mass spectroscopic): 346.14616.

Heating of adduct **9** in benzene at 65°C for 72 h gave complete rearrangement to the phenyl-in adduct **13** which, upon recrystallization from ether–hexane, gave colourless rhombic crystals: mp 141–143°C; ir (KBr) ν: 3030, 2965, 2255, 2245, 1600, 1500, 1445, 1320, 1190, 1125, 1075, 1030 cm^{-1}; ^{1}Hmr δ($CDCl_3$): 3.8 (H_b, d, 1H, J_{bc} = 5.35 Hz), 3.9 (H_a, broad s, 1H, J_{ac} = 1 Hz), 4.4 (H_c, q, J = 1 and 5.35 Hz), 7.4–7.9 (m, 15H). The same pattern was observed in C_6D_6 δ: 2.4 (d, 1H), 2.5 (broad s, 1H), 3.0 (q, 1H), 6.0–7.0 (m, 15H); since H_b and H_a overlapped, nOe was not attempted; ^{13}Cmr chemical shifts ($CDCl_3$): 40.3 and 42.2 (bridgehead carbons), 30.6 and 31.1 (methine carbons), 40.0 (apex carbon), 115.3 and 117.6 (cyanocarbons), 135.4 (one of the aryl carbons attached directly to bicyclopentane nucleus), 126.9–131.0 (other aromatic carbons); ms (70 eV): 346 (48, M^+), 319 (100). *Anal.* calcd. for $C_{25}H_{18}N_2$: C 86.68, H 5.24; found: C 86.41, H 5.49. *Mol. Wt.* calcd. for $C_{25}H_{18}N_2$: 346.14699; found (mass spectroscopy): 346.14633.

Adduct **10** was never isolated since isomerization occurred under mild conditions; on the other hand, the isomer, adduct **14**, readily crystallized from the mixture in $CHCl_3$–hexane: mp 215–217°C; ir (KBr) ν: 3065, 2248, 1600, 1500, 1450, 1280, 1085, 1032, 930, 830 cm^{-1}; ^{1}Hmr δ($CDCl_3$): 3.4 (s, 3H), 7.0–7.7 (m, 15H), the singlet at 3.4 was not split upon addition of a shift reagent Eu(fod)$_3$III; ^{1}Hmr δ(C_6D_6): 1.7 (s, 2H), 2.1 (s, 1H), 6.0–6.8 (m, 15H); ^{13}Cmr chemical shift ($CDCl_3$): 41.8 (bridgehead carbons), 31.8 (methine carbons), 40.2 (apex carbon), 116.3 (cyanocarbons), 133.5 and 131.0 (aryl carbons directly attached to bicyclopentane nucleus), 128.5–130.1 (other aromatic carbons); ms: 346 (81, M^+), 319 (100). *Anal.* calcd. for $C_{25}H_{18}N_2$: C 86.68, H 5.24; found: C 86.48, H 5.20.

Refluxing adduct **14** in benzene for 2 h gave an equilibrium mixture consisted of adduct **10** (23%) and adduct **14** (77%). The ir (KBr), ms, and tlc of this mixture was essentially the same as adduct **14** alone; however, ^{1}Hmr and ^{13}Cmr spectral assignments for adduct **10** can be obtained by subtracting the peaks due to adduct **14** from the spectra of the mixture: ^{1}Hmr δ($CDCl_3$): 3.55 (s, 1H), 3.8 (s, 2H), 6.4–7.8 (m, 15H, same pattern as adduct **3**); ^{1}Hmr δ(C_6D_6): 2.3 (s, 2H), 3.1 (s, 1H), 6.0–7.0 (m, 15H); ^{13}Cmr chemical shift ($CDCl_3$): 43.2 (bridgehead carbons), 35.0 (methine carbons), 38.4 (apex carbon), 115.0 (cyano carbons), 133.2 and 132.2 (aryl carbons attached directly to bicyclopentane nucleus), 126.0–130.3 (other aromatic carbons). Another piece of evidence supporting this thermodynamic equilibrium was the observation that, after crystals of **14** had been removed, the mother liquid which initially consisted of 72% of adduct **10** and 28% of adduct **14**, reverted to the equilibrium composition after 11 days at room temperature.

Adduct **11** was recrystallized from $CHCl_3$–EtOH to give shiny plates: mp 191–193°C (dec.); ir (KBr) ν: 3040, 2960, 2245, 1600, 1500, 1445, 1075, 1035, 925, 762, 700 cm^{-1}; ^{1}Hmr δ($CDCl_3$): 2.9 (H_a, s, 1H), 3.6 (H_b, s, 2H), 6.2–7.2 (m, 15H, same pattern as adduct **9**); ^{1}Hmr δ(C_6D_6): 1.6 (s, 1H), 2.0 (s, 2H), 5.6–6.8 (m, 15H); nOe ($CDCl_3$): irradiating H_a gave 7.3% enhancement of the methine protons and an 18% enhancement of H_a was observed when the methine protons were irradiated. ^{13}Cmr chemical shift ($CDCl_3$): 44.6 (bridgehead carbons), 36.8 (methine carbons), 41.8 (apex carbon), 115.9 (cyano carbons), 133.8 (one of the aryl carbons directly attached to bicyclopentane nucleus), 126.4–131.7 (other aromatic carbons); ms: 346 (75, M^+), 319 (100). *Anal.* calcd. for $C_{25}H_{18}N_2$: C 86.68, H 5.24; found: C 86.56, H 5.45. This adduct was also thermally unstable in solution. Upon heating

at 75°C in C_6D_6 for 24 h, the solution turned from colourless to red-brown, the ^{1}Hmr spectrum showed that **11** had been consumed, remaining was a singlet at $\delta(C_6D_6)$ 2.9 and a multiplet at 6.3–7.4 in the ratio ca. 1:10. No further attempt was made to characterize this product(s).

Compound **12** was colourless cubic crystals after recrystallization from $CHCl_3$–EtOH: mp 207–208°C; ir (KBr) ν: 3030, 2960, 2260, 2245, 1825, 1600, 1495, 1445, 1310, 1160, 1070, 1000, 960, 803 cm^{-1}; ^{1}Hmr $\delta(CDCl_3)$: 2.55 (d, 2H, J = 7 Hz), 4.3 (t, 1H, J = 7 Hz), 6.8–7.9 (m, 15H); ^{1}Hmr $\delta(C_6D_6)$: 1.2 (d, 2H), 2.9 (t, 1H), 6.2–7.4 (m, 15H); ms: 346 (9, M^+), 267 (100). *Anal.* calcd. for $C_{25}H_{18}N_2$: C 86.68, H 5.24; found: C 86.86, H 5.41. This compound was thermally stable and no change was observed upon heating at 75°C in C_6D_6 solution for 24 h.

Irradiation of 1,2,3-Triphenylcyclopropene and Maleonitrile

A solution containing 1,2,3-triphenylcyclopropene (80.4 mg, 0.3 mmol), maleonitrile (23.4 mg, 0.3 mmol) in benzene (1 mL) was irradiated through filter solution *A*. After irradiating for 47 h, analysis of the ^{1}Hmr spectrum revealed 94.4% of the cyclopropene had been consumed. The same products were found as in irradiation of the cyclopropene with fumaronitrile except the product ratios were different: adduct **9** (25.4%), adduct **10** (12.6%), adduct **11** (7.2%), compound **12** (18.2%), dimer **4** (19.5%). These yields are corrected for the unreacted cyclopropene and represent an 84% material balance. The ratio of the unreacted fumaronitrile and maleonitrile was 60:40.

Irradiation of 1,2,3-Triphenylcyclopropene and Fumaronitrile in the Presence of Thioxanthen-9-one

A solution of 1,2,3-triphenylcyclopropene (40.2 mg, 0.15 mmol), fumaronitrile (11.7 mg, 0.15 mmol), and thioxanthen-9-one (1 mg, 0.005 mmol) in benzene (0.5 mL) was irradiated through filter solution *B*. After 2 h, the ^{1}Hmr spectrum revealed that 89% of the cyclopropene had been consumed. The same products (and one additional) were obtained as upon direct irradiation: adduct **9** (17.9%), adduct **10** (14.0%), adduct **11** (4.7%), compound **12** (25.2%), dimer **4** (24.3%), and dimer **5** (11.8%). These yields were corrected for the cyclopropene unreacted and thus, 98% of the starting cyclopropene was accounted for. The ratio of the unreacted fumaronitrile and maleonitrile was 60:40. Essentially, the same results were obtained when fluoren-9-one was used as sensitizer.

Attempted Thermal Reactions of 1,2,3-Triphenylcyclopropene with Fumaronitrile

A solution of 1,2,3-triphenylcyclopropene (20 mg, 0.075 mmol), fumaronitrile (12 mg, 0.15 mmol) in toluene (1 mL) was sealed after three cycles of freeze–thaw and was then heated in an oil bath at 120°C. After heating for 450 h, most of the cyclopropene (>95%) was consumed while fumaronitrile remained unchanged. The sole product identified with ^{1}Hmr and tlc was dimer **5**.

A solution containing **1** (200 mg) and AIBN (10 mg) in benzene (5 mL) was refluxed under a nitrogen atmosphere. After 3 h, ^{1}Hmr and tlc showed small amount of **5** had been formed (half-life of AIBN at this temperature is ~1 h). Portions of AIBN (total 10 mg) were added after each 6 h. After 47 h of refluxing, ^{1}Hmr revealed ~2% of **5** as the sole product. A control experiment was performed in the absence of AIBN. After 48 h, approximately same amount of **5** was obtained.

Photostationary States of Photosensitized Isomerization of Fumaronitrile, Maleonitrile, Dimethyl Fumarate, and Dimethyl Maleate

Preliminary studies were conducted at higher concentration of fumaronitrile (0.3 *M*) and dimethyl fumarate (0.2 *M*) with the concentration of sensitizers being 0.05 *M* in benzene followed by ^{1}Hmr. Irradiations were done using a 0-51 Corning glass filter (cut off at 360 nm). The photostationary state was taken as the constant *cis–trans* ratio obtained upon prolonged irradiation.

To minimize possible complications, such as blocking of light due to polymer formation or sensitization other than triplet–triplet energy transfer from the lowest triplet excited state of the sensitizer, experiments were conducted at lower concentrations of quencher (0.05 *M*) and sensitizers (0.01 *M*). In these experiments, isomerization was followed by vapour phase chromatography (vpc) (PYE 140 vpc with a 5 ft 10% DEGS column at 175°C for the nitriles and 170°C for the esters). The response factors for the corresponding isomers were almost the same and the ratios were determined by weighing the peak areas. Also, 0.05 *M* of the synthetic mixtures close to the photostationary state were irradiated in the presence of 0.01 *M* sensitizer. In these experiments, no further change of the ratio of the *cis–trans* isomers occurred after a short period of irradiation. The results are listed in Table 2. In most of the cases, the two procedures gave the same (within experimental error) ratio of isomers.

The line width and spin–lattice relaxation rates of phosphorus and proton nuclei in PLP have been measured as a function of temperature in the presence of Mn(II) using pulsed nmr methods. The T_{1M} of ^{31}P in PLP–Mn(II) is very close to the T_{1M} values of β- and γ-phosphorus atoms in ATP–Mn(II) at ~40°C. The T_1 data of ^{31}P and ^1H have been interpreted in terms of the dipolar interaction between the electron and nuclear spins. With the assumption that the Mn(II) interacts directly with the phosphate of PLP the rotational correlation time τ_c at 38°C was calculated to be 7.6×10^{-10} s from phosphorus T_1 data. This τ_c value was subsequently used to calculate metal–proton distances from proton T_1 and T_2 data. The results lead to the conclusion that the phosphate-bound metal interacts directly with the aldehyde oxygen in a 1:1 PLP–Mn(II) complex. The linewidth of the ^{13}C resonances of PLP in the presence of Mn(II) supports this conclusion. The structure assigned for PLP–Mn(II) complex is in conformity with the structure for PLP–Co(II) complex.

TENKASI S. VISWANATHAN et TERRENCE J. SWIFT. Can. J. Chem. **57**, 1050 (1979).

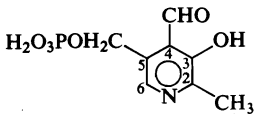
On a mesuré les largeurs des raies et les taux de relaxation spin–réseau des noyaux de phosphore et du proton du PLP en fonction de la température en présence de Mn(II) en faisant appel à des méthodes de rmn pulsée. Les valeurs de T_{1M} du ^{31}P dans le PLP–Mn(II) sont très près des valeurs de T_{1M} des atomes de phosphore β et γ dans l'ATP–Mn(II) à ~40°C. On a interprété les données de T_1 pour le ^{31}P et le ^1H en termes d'interactions dipolaires entre les spins électronique et nucléaire. En faisant l'hypothèse que le Mn(II) interagit directement avec le phosphate du PLP, on a calculé que le temps de corrélation rotationnelle, τ_c, à 38°C est égal à 7.6×10^{-10} s à partir des données de T_1, pour le phosphore. On a ultérieurement utilisé cette valeur de τ_c pour calculer les distances métal–proton à partir des données de T_1 et T_2 pour le proton. Les résultats conduisent à la conclusion que le métal lié au phosphore interagit directement avec l'oxygène de l'aldéhyde dans un complexe 1:1 PLP–Mn(II). Les largeurs des raies des résonances ^{13}C du PLP en présence de Mn(II) sont en accord avec ces conclusions. La structure attribuée au complexe PLP–Mn(II) est conforme à la structure du complexe PLP–Co(II).

[Traduit par le journal]

Introduction

The metal complexes of Schiff bases derived from pyridoxal phosphate (PLP) (**1**) have been well studied because of their importance as model systems for PLP-catalyzed enzymatic reactions such as transamination and deamination (1). Pyridoxal phosphate itself has considerable affinity for divalent metal ions and only a limited number of studies (2, 3) have been reported on these complexes. The recent report by Farago *et al.* (3) describes these complexes as insoluble and probably polymeric solids.

Nuclear magnetic resonance is one of the powerful techniques used in the determination of binding sites, when the ligand in question possesses more than one binding site. Paramagnetic metal ions, in particular, cause large changes in the chemical shifts and relaxation rates of the neighbouring nuclei making the metal ion an exceptionally good probe of its environment. We have used a combination of ^{31}P, ^1H, and ^{13}C nmr studies to find the nature of the divalent metal ion complexes of PLP. The results presented in this report are useful in assigning an unambiguous structure for the PLP–Mn(II) complex.



1 Pyridoxal phosphate

Experimental

Pyridoxal phosphate was purchased from Sigma Chemical Co. and it was found to be free of paramagnetic impurities. Measurements of proton line widths were done at 60 MHz at 37°C on a Varian A60A nmr spectrometer. Measurements of proton spin–lattice relaxation times and all the ^{13}C and ^{31}P nmr determinations were done on a Varian XL-100 in the

0008-4042/79/091050-06$01.00/0

pulsed FT mode. The temperature of the A60A and XL-100 probes were determined by inserting a calibrated thermometer inside the spectrometer cavity. The T_1 determinations were done by the inversion–recovery method. Usually 10 different τ values were taken with the largest τ value about three times the null point. The error in the T_1 values obtained in this study varied from 3 to 10%.

Internal tetramethylammonium (TMA) chloride was used as the reference for ^1H and ^{13}C nmr studies. The reference used for ^{31}P nmr was hexamethylphosphoramide (HMPA) contained in a coaxial tube. All nuclear resonances with frequency greater than the resonance frequency of the reference material were given positive sign for the chemical shift.

Theory

The effects on the nmr spectrum of a ligand molecule exchanging between the first coordination sphere of a paramagnetic metal ion and the free solution are described by the equations of Swift and Connick (4) and Luz and Meiboom (5). The contributions T_{1p}^{-1} and T_{2p}^{-1} by the metal ion to the observed relaxation rates are determined by the relaxation times of the resonances in the bound state, T_{1M} and T_{2M}, the fraction of the coordinated ligand, f, and the average residence time of the ligands in the bound form, τ_m:

$$[1] \qquad T_{1p}^{-1} = f/(T_{1M} + \tau_M)$$

$$[2] \qquad T_{2p}^{-1} = f/\tau_M\left[\frac{T_{2M}^{-1}(T_{2M}^{-1} + \tau_M^{-1}) + \Delta\omega_M^2}{(T_{2M}^{-1} + \tau_M^{-1})^2 + \Delta\omega_M^2}\right]$$

where $\Delta\omega_M$ is the shift between the resonances of free and bound ligand at the slow exchange limit (4).

Shulman *et al.* (6) modified the Solomon–Bloembergen equations (7, 8) to describe the relaxation of the ligand bound to the Mn(II) ion:

$$[3] \qquad T_{1M}^{-1} = \frac{2}{5}\left[\frac{S(S+1)g^2\beta^2\gamma_I^2}{r^6}\right]\tau_c$$

$$[4] \qquad T_{2M}^{-1} = \frac{7}{15}\left[\frac{S(S+1)g^2\beta^2\gamma_I^2}{r^6}\right]\tau_c + \frac{1}{3}\left[\frac{S(S+1)A^2}{\hbar^2}\right]\tau_e$$

where γ_I is the magnetogyric ratio, $A/\hbar$ is the scalar coupling constant between the nucleus and the electron, and r is the nuclear–electron distance. The dipolar correlation time τ_c and the scalar correlation time τ_e are given by:

$$[5] \qquad \tau_c^{-1} = \tau_s^{-1} + \tau_M^{-1} + \tau_r^{-1}$$

$$[6] \qquad \tau_e^{-1} = \tau_s^{-1} + \tau_M^{-1}$$

where τ_s is the electron spin relaxation time and τ_r is the rotational correlation time. In deriving [3] and [4] it has been assumed that $(\omega_s\tau_c)^2 \gg 1$ and $(\omega_s\tau_e)^2 \gg 1$, where ω_s is the resonance frequency of the electron.

Results and Discussion

Phosphorus Nuclear Magnetic Resonance Studies

The temperature dependence of the normalised paramagnetic contribution to the relaxation rates $(fT_{1p})^{-1}$ and $(fT_{2p})^{-1}$ of the phosphorus resonance of PLP–Mn(II) are shown in Fig. 1. The following features are noticeable in the curves. (*i*) As the temperature is raised $(fT_{2p})^{-1}$ passes through a maximum at 54°C and then decreases with further increase in temperature. (*ii*) The value of $(fT_{2p})^{-1}$ at its maximum is about 150 times larger than the value of $(fT_{1p})^{-1}$ at the same temperature. (*iii*) Increase in temperature causes decrease in the value of $(fT_{1p})^{-1}$ in the temperature range studied.

Since $T_{2p}^{-1} \gg T_{1p}^{-1}$ for the phosphorus resonance in PLP–Mn(II), it follows that $\tau_M^{-1} \gg T_{1M}^{-1}$ at the temperature of maximum $(fT_{2p})^{-1}$ or higher. At 54°C and above one would expect the value of T_{1p}^{-1} to reflect truly the weighted average longitudinal relaxation rate. Figure 2 shows the linear dependence of T_{1p}^{-1} and T_{2p}^{-1} of the phosphorus resonance of PLP on the concentration of added Mn(II) ion at 69°C. Little shifting of the phosphorus resonance was observed.

From the measured T_{1p}^{-1} values, it is possible to calculate the distance of the phosphorus atom from the Mn(II) ion using [3]. A knowledge of the magnitude of the dipolar correlation time τ_c is essential for the calculation of r. However, qualitative conclusions may be drawn by comparing the results for PLP–Mn(II) with results published for similar complexes

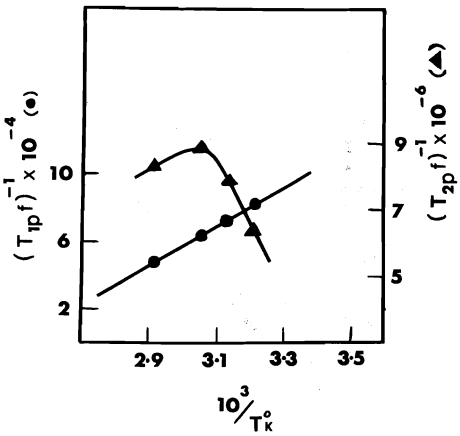

FIG. 1. The temperature dependence of $(fT_{2p})^{-1}$ and $(fT_{1p})^{-1}$ of the ^{31}P resonance of PLP–Mn(II) complex at 40.5 MHz. The pD of the solution was 7.0 and the concentration of PLP was 0.75 *M*. Mn(II) was added to yield a [Mn(II)] to [PLP] ratio of 1.33×10^{-5}.

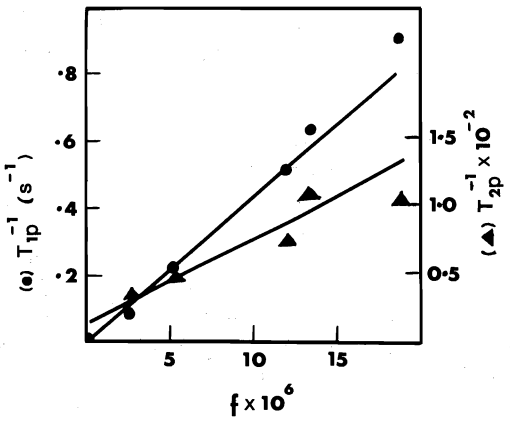

FIG. 2. The dependence of T_{1p}^{-1} and T_{2p}^{-1} of the ^{31}P resonance of PLP on the concentration of the added Mn(II) at 69°C.

such as ATP–Mn(II). The value of 0.8×10^5 s^{-1} for $(fT_{1p})^{-1}$ of phosphorus in PLP–Mn(II) is in excellent agreement with a value of 1×10^5 for the β- and γ-phosphorus resonances of ATP–Mn(II) at 40°C. Since ATP and PLP are similar in size, their rotational correlation times should have similar magnitude. With that assumption the conclusion is that the nature of the Mn–phosphate interaction is similar for Mn–ATP and Mn–PLP, namely, direct binding.

Since 'direct binding' of Mn(II) to the phosphate of PLP is a reasonable conclusion from our results, one can use the values of g, S (10, 11), and r (12) available in the literature for $LiMnPO_4$ to calculate the correlation time for PLP–Mn(II). For $g = 2.0$, $S = 5/2$, and $r = 3.3$ Å, the value of τ_c is 4.4×10^{-10} s at 69°C, 6×10^{-10} s at 54°C, and 7.6×10^{-10} s at 38°C.

Measurement of $(fT_{2p})^{-1}$ in the temperature range studied does not provide any binding structure information since $T_{2M}^{-1} \approx \tau_M^{-1}$ at temperatures as high as 69°C. Since in this slow exchange limit [2] reduces to $fT_{2p} = \tau_M$, the exchange rate may be calculated from the line width measurement. The average residence time of PLP molecules in the coordination sphere of Mn(II) at 38°C is 0.16 μs and τ_M has an activation energy of 5.6 kcal/mol.

Proton Nuclear Magnetic Resonance Studies

The addition of Mn(II) to a solution of PLP at pD 6.2 does not cause any significant shift of any of the proton resonances. However, selective broadening of the proton resonances does take place. The maximum broadening was observed for the formyl proton resonance. The line broadening of the 6-H proton was about half of that observed for the formyl proton whereas the 2-methyl proton broadening was only one-fifth of the broadening of the formyl proton. The dependence of the line width at half-height of these and the solvent (HDO) proton resonances on the concentration of the added Mn(II) at 37°C are shown in Fig. 3. The temperature dependences of the logarithm of the full line width at half-height of the 2-methyl, 6-H, and the solvent HDO resonances are shown in Fig. 4. This figure shows that at 37°C the observed line widths of all these protons are the weighted average values. The

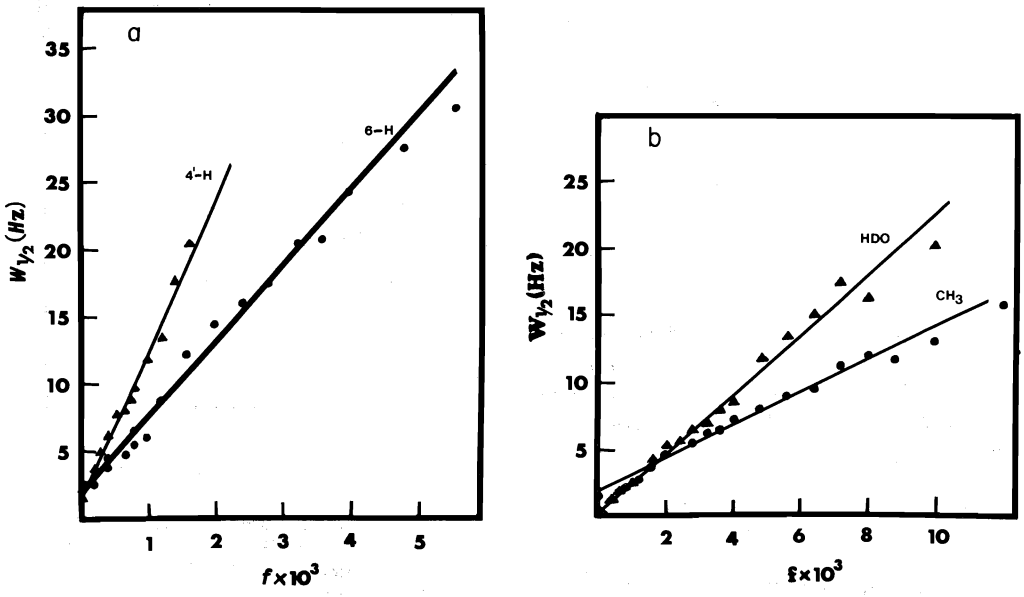

FIG. 3. The full line width at half-height of the proton resonances of PLP (0.25 M) at pD 6.2 and at 37°C as a function of the Mn(II) concentration: (*a*) 4-CHO and 6-H protons and (*b*) 2-methyl and solvent (HDO) protons.

TABLE 1. The transverse and longitudinal relaxation rates (s^{-1}) and metal–nuclei distances (Å) for the PLP–Mn(II) complex

Nuclei	$(fT_{2p})^{-1}$ at 60 MHz	r	$(fT_{1p})^{-1}$ at 100 MHz	r
4-CHO proton	1.7×10^4	6.0	9.6×10^3	6.4
5-CH_2 proton[a]	—	—	2.2×10^4	5.6
6-H proton	8.7×10^3	6.7	9.0×10^3	6.5
2-CH_3 proton[b]	1.9×10^3	8.6	—	—
Phosphorus	—	—	8×10^4	3.3[c]

[a]The measurement of line widths is complicated by the coupling of ^{31}P to the 5-CH_2 resonance.
[b]The T_1 value of the methyl resonance was not measured.
[c]Assumed for a direct binding of Mn(II) to phosphate.

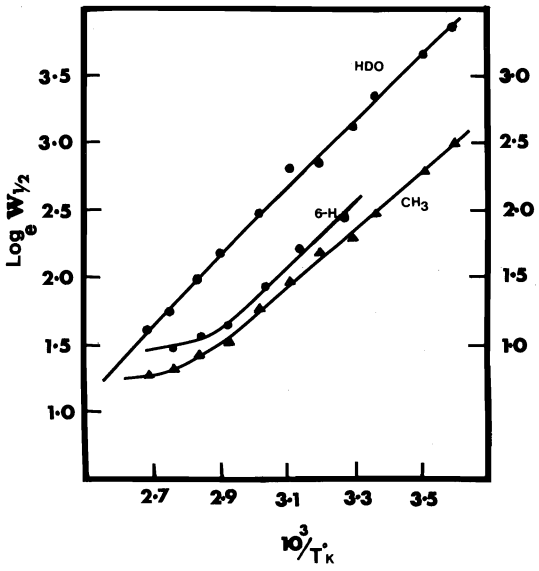

FIG. 4. The temperature dependence of the full line width at half-height of the solvent HDO (right scale) and the 6-H and 2-methyl (left scale) proton resonances of PLP–Mn(II) at pD 6.2. The [Mn(II)] to [PLP] ratio, f, was 1.4×10^{-3} for 6-H proton and 4×10^{-3} for 2-methyl and HDO protons. The concentration of PLP was 0.25 M.

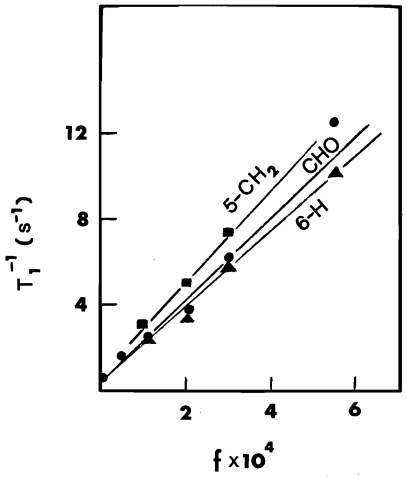

FIG. 5. The dependence of the observed T_1^{-1} of the 5-methylene, 4-CHO, and the 6-H proton resonances (100 MHz) of PLP (0.25 M) at 35°C on the ratio of [Mn(II)] to [PLP].

temperature dependence of $(fT_{2p})^{-1}$ of the formyl proton (not shown) exhibits a maximum at ~40°C. Consequently, the line width of the formyl proton may have some contributions from rate effects and it yields an upper limit for T_{2M}^{-1}.

The T_1 relaxation times of the 4-CHO, 6-H, and 5-CH_2 proton resonances were also measured at 37°C. However, these measurements were done at 100 MHz. The dependence of the observed T_1^{-1} for these protons on the concentration of the added Mn(II) is shown in Fig. 5. The large HDO peak at the center of the proton spectrum of PLP introduced some spectral phasing problems, especially when the T_1 run was in the complete control of the computer. Consequently, only peaks to the low field side of the HDO peak were plotted for T_1 determination. Thus, the T_1 values of the 2-methyl protons were not determined. The extrapolated T_2^{-1} and T_1^{-1} values at 60 and 100 MHz, respectively, of the proton resonances in the 1:1 PLP–Mn(II) complex are shown in Table 1. The $(fT_{2p})^{-1}$ for 6-H is slightly lower than the $(fT_{1p})^{-1}$ of this proton. This is spurious since $T_1^{-1} \leq T_2^{-1}$ for all systems without exception and may be the result of experimental uncertainties. However, the significant point is that the values of $(fT_{1p})^{-1}$ and $(fT_{2p})^{-1}$ are comparable indicating that the spin–lattice relaxation of the proton resonances in PLP–Mn(II) are controlled by the dipolar mechanism. Consequently, the expression for T_{2M}^{-1} of the protons in the PLP–Mn(II) complex is:

$$[7] \qquad T_{2M}^{-1} = 7/15[S(S+1)g^2\beta^2\gamma_I^2 r^{-6}\tau_c]$$

The expression for T_{1M}^{-1} is given by [3]. Thus, the ratio of T_{2M}^{-1} to T_{1M}^{-1} would be 7:6 or approximately unity.

The proton relaxation data could be used to calculate the metal–proton distances using [3] and [7] and from a knowledge of the rotational correlation time. It was shown by Sternlicht *et al.* (9) that the P—O—

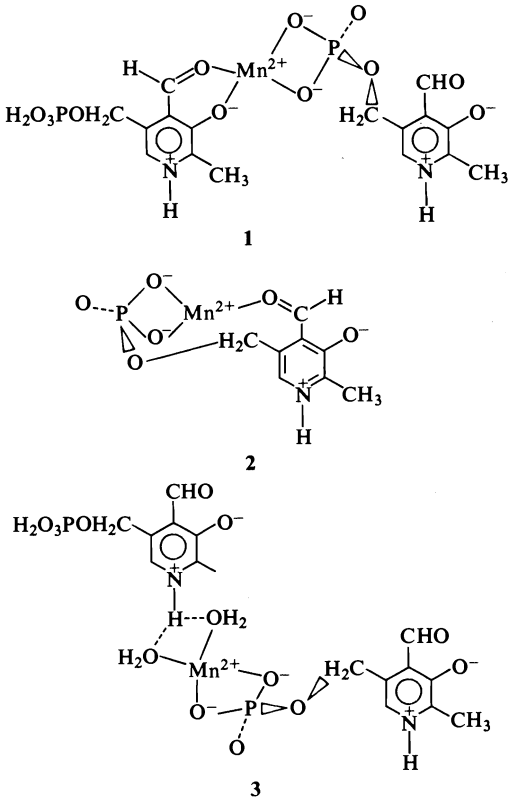

FIG. 6. Scheme of three possible PLP–Mn(II) complexes.

Mn—OH_2 chain is rigid relative to its axis and the fastest motion is a tumbling of that chain. The tumbling may be isotropic since the 1:1 PLP–Mn(II) complex lacks symmetry elements. Under these circumstances, the correlation time for all the PLP protons would be the same as the ^{31}P correlation time. The metal–proton distances calculated from [3] and [7] with a τ_c value of 7.6×10^{-10} s are tabulated in Table 1. Since the value of τ_c may be in error owing to certain assumptions made in its calculation, no significance could be given to the absolute magnitudes of these metal–proton distances.

The metal–proton distances tabulated in Table 1 are extremely valuable in arriving at a structure for the PLP–Mn(II) complex. The shortest distance from the metal is observed for 5-CH_2 protons, which strongly supports our conclusion that Mn(II) binds directly to the phosphate. There are three possibilities for the phosphate-bound metal to interact with the ring: (*i*) The metal may bind to both 4-CHO and 3-O^- functional groups of another PLP molecule in a 2:1 PLP–Mn(II) complex. (*ii*) The metal may interact only with the aldehyde oxygen in a 1:1 complex. (*iii*) The metal may interact with the heterocyclic nitrogen in a 2:1 or a 1:1 complex.

The third possibility is less likely since the nitrogen remains protonated at the pD employed (6.2) in our studies. Table 1 also reveals that the 2-methyl protons are more than 2 Å units farther away from the metal ion than the 4-CHO proton, which will be inconsistent with this model. The first possibility would place the methyl protons closer to the Mn(II) than the 6-H proton, which is inconsistent with the observed *r* values. The second model would place the metal closest to the methylene protons. The 6-H and 4-CHO protons would be nearly equidistant with the latter closer to the metal ion and the methyl protons would be quite far away from the metal ion. The average *r* values of 5.6, 6.4, 6.6, and 8.6 Å for 5-CH_2, 4-CHO, 6-H, and the 2-methyl protons observed in our results entirely supports this model. The next question would be whether complex **2** is a majority species? Potentiometric studies of Mn(II) and PLP at a total PLP concentration of 0.001 *M* indicate (14) that a 1:1 complex is formed and the stability constant of the complex indicates a definite interaction with the ring. However, it is possible that a sequential binding mechanism exists. The metal may be bound tightly to the phosphate all the time and this metal–phosphate complex exchange rapidly with complex **2**, which may account for less than 100% of Mn(II) in solution, a situation similar to the Mn–ATP complex in solution (13). Our evidence does not rule out this possibility.

Carbon Nuclear Magnetic Resonance Studies

The gradual addition of Mn(II) to a 0.75 *M* PLP solution at 35°C produces selective broadening of the carbon resonances of PLP. Figures 7*a* and 7*b* show the aromatic region of the ^{13}C nmr spectrum of PLP before and after Mn(II) was added to obtain a

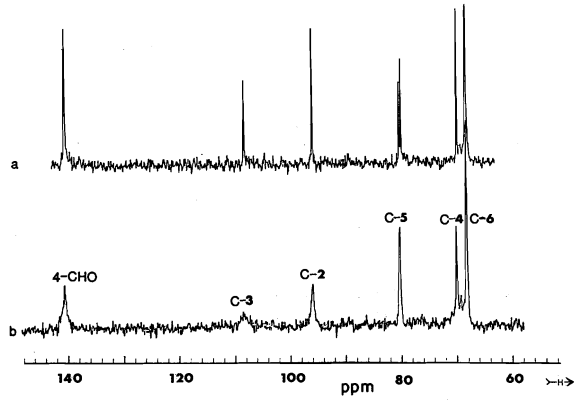

FIG. 7. The aromatic region of the ^{13}C nmr spectrum of 0.75 *M* PLP solution at pD 7.0: (*a*) metal-free solution and (*b*) after addition of Mn(II) to $f = 5.33 \times 10^{-4}$. The broadening of the side-chain carbon resonances, 5-methylene and 2-methyl, by Mn(II) present to this concentration was negligible.

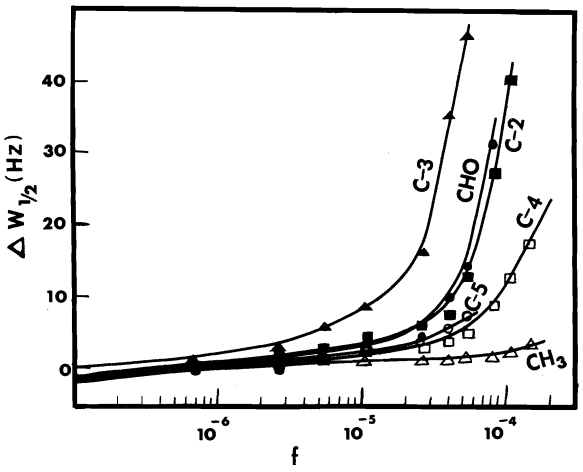

FIG. 8. The dependence of the full line width at half-height of the C-3, C-2, 4-CHO, C-4, C-5, and 2-methyl carbon resonances (25.16 MHz) of PLP (0.75 *M*) at pD 7.0 and at temperature 35°C on the logarithm of the [Mn(II)] to [PLP] ratio.

[Mn(II)] to [PLP] ratio of 5.33×10^{-4}. The C-3 carbon broadening is the largest, followed closely by the 4-CHO and C-2 broadenings. A plot of the full line width at half-height of the C-2, C-3, C-4, C-5, 2-CH_3, and 4-CHO resonances, caused by the addition of Mn(II) against log *f* is shown in Fig. 8. The C-5, C-6, and 5-CH_2 resonances have a small coupling to the ^{31}P making accurate measurement of their line widths difficult. However, rough measurements showed that the line broadening follows the order C-3 $\gg$ 4-CHO $\approx$ C-2 $\gg$ C-5 $\approx$ C-4 $\gg$ C-6 $\approx$ 5-CH_2 > 2-CH_3. Very little shifting was observed for any of the carbon resonances even for large amounts of added Mn(II). The temperature dependence of the ^{13}C line widths was not studied.

The ATP–Mn(II) complex was studied in detail with the use of ^{13}C nmr by Kuntz *et al.* (13). These authors showed that the transverse relaxation of the ^{13}C resonances of ATP–Mn(II) is dominated by the scalar mechanism. Hence, the Solomon–Bloembergen equation describing T_{2M}^{-1} for the carbon resonances reduces to:

$$[8] \qquad T_{2M}^{-1} = S(S+1)A^2\tau_e/3\hbar^2$$

Thus, relative values of T_{2M}^{-1} do not have any relationship to the metal–carbon distances. The T_{2M}^{-1} values rather indicate the extent of spin delocalisation to these carbon atoms. The large T_{2M}^{-1} observed for the C-3 may be the result of covalent binding of Mn(II) to the 4-CHO and subsequent spin transport by the resonance of the *o*-hydroxyaldehyde functional group. The value of $(fT_{2p})^{-1}$ for C-3 in PLP–Mn(II) is about 25 times larger than the $(fT_{2p})^{-1}$ for C-5 and C-8 resonances of ATP–Mn(II). In ATP the C-5 and C-8 carbons are α to the heterocyclic nitrogen to which Mn(II) was shown to form a covalent bond (13). Thus, the large values observed for T_{2p}^{-1} of the carbon resonances of PLP–Mn(II) probably indicate covalent binding of the metal ion to the ring.

In conclusion, the present ^{31}P, ^{1}H, and ^{13}C nmr study of the PLP–Mn(II) system indicates a structure for the metal–PLP complex in which the metal ion is simultaneously bound to the phosphate and the aldehyde oxygen. A similar structure has been proposed for the PLP–Co(II) complex (Swift and Viswanathan, to be published) and other divalent metal ion complexes of pyridoxal phosphate.

Synthesis of a thioanalogue of neamine. The reaction of nitrosochloroadducts of glycals with thiols

GERRY KAVADIAS,[1] ROBERT DROGHINI, YVON PÉPIN,[2] MARCEL MÉNARD, AND PHILIPPE LAPOINTE

Bristol Laboratories of Canada, 100 Industrial Boulevard, Candiac, P.Q., Canada J5R 1J1

Received October 20, 1978

GERRY KAVADIAS, ROBERT DROGHINI, YVON PÉPIN, MARCEL MÉNARD, and PHILIPPE LAPOINTE. Can. J. Chem. **57**, 1056 (1979).

The reaction of the dimeric 4-*O*-acetyl-6-azido-2,3,6-trideoxy-2-nitroso-α-D-*ribo*-hexopyranosyl chloride **2** with cyclohexanethiol and 2-propanethiol is stereospecific and produces the corresponding 2-hydroxyimino-1-thio-α-D-*erythro*-hexopyranosides **3***a* and **3***c* in high yields. Acetylation of the oxime **3***a* followed by reduction with borane, then by reduction with sodium borohydride and acetylation gave cyclohexyl 2,6-diacetamido-4-*O*-acetyl-2,3,6-trideoxy-1-thio-α-D-*ribo*-hexopyranoside (**4***b*). By a similar sequence of reactions, the oxime **3***c* was converted to isopropyl 2,6-dibenzamido-4-*O*-benzoyl-2,3,6-trideoxy-1-thio-α-D-*ribo*-hexopyranoside (**4***c*).

Condensation of the nitrosochloro adduct **2** with (1*S*,2*S*,4*R*,5*R*)-2,4-diethoxycarbonylamino-5-hydroxycyclohexanethiol (**5***c*) gave the α-D-thioglycoside **6***c* which, after acetylation followed by reduction and removal of the protective groups, yielded (1*S*,2*S*,4*R*,5*R*)-2,4-diamino-5-hydroxycyclohexyl 2,6-diamino-2,3,6-trideoxy-1-thio-α-D-*ribo*-hexopyranoside (**7***c*), a thioanalogue of neamine.

GERRY KAVADIAS, ROBERT DROGHINI, YVON PÉPIN, MARCEL MÉNARD et PHILIPPE LAPOINTE. Can. J. Chem. **57**, 1056 (1979).

La réaction du chlorure du *O*-acétyl-4 azido-6 tridéoxy-2,3,6 nitroso-2 α-D-*ribo*-hexopyrannosyle dimère **2** avec le cyclohexanethiol et le propanethiol-2 est stéréospécifique et conduit aux hydroxyimino-2 thio-1 α-D-*érythro*-hexopyrannosides **3***a* et **3***c* correspondants avec de bons rendements. L'acétylation de l'oxime **3***a*, suivie par une réduction avec le borane, puis par une réduction avec le borohydrure de sodium et une acétylation conduit au diacétamido-2,6 *O*-acétyl-4 tridéoxy-2,3,6 thio-1 α-D-*ribo*-hexopyrannoside de cyclohexyle (**4***b*). Utilisant les mêmes réactions, on peut transformer l'oxime **3***c* en dibenzamido-2,6 *O*-benzoyl-4 tridéoxy-2,3,6 thio-1 α-D-*ribo*-hexopyrannoside d'isopropyle (**4***c*).

La condensation de l'adduit chloro-nitroso **2** avec le (1*S*,2*S*,4*R*,5*R*) diéthoxycarbonylamino-2,4 hydroxy-5 cyclohexanethiol (**5***c*) conduit à l'α-D-thioglycoside **6***c* qui, après une acétylation suivie d'une réduction et de l'élimination des groupes protecteurs, fournit le diamino-2,6 tridéoxy-2,3,6 thio-1 α-D-*ribo*-hexopyrannoside de (1*S*,2*S*,4*R*,5*R*) diamino-2,4 hydroxy-5 cyclohexyle (**7***c*), un thioanalogue de la néamine.

[Traduit par le journal]

In continuation of our research program in the area of aminocyclitol antibiotics (1), we thought it desirable to explore the synthesis and biological properties of thio analogues of the clinically important antibiotics. The target structures were the kanamycins, gentamicins, tobramycin, etc., in which one or both of the glycosidic oxygens have been replaced by a sulfur atom(s). These novel structures have not been reported previously.

The present paper describes the synthesis of a thioanalogue of neamine, namely the (1*S*,2*S*,4*R*,5*R*)-2,4-diamino-5-hydroxycyclohexyl 2,6-diamino-2,3,6-trideoxy-1-thio-α-D-*ribo*-hexopyranoside (**7***c*).

Several problems are associated with the preparation of 1-thio-α-glycosides such as **7***c* and related compounds, the most important of which are: (*a*) a glycosidation process to yield selectively the α-glycosidic structure, (*b*) the availability of thio analogues of 2-deoxystreptamine as the aglycon components in the synthesis; and (*c*) the selection of protective groups which could easily be removed at the end of the synthesis in the presence of sulfur.

1-Thioglycosides (2) can be prepared by several methods, the most important of which are: (*i*) by reaction of an aldose with a thiol under strongly acidic conditions (3) yielding mixtures of 1,2-*cis*- and 1,2-*trans*-isomers; (*ii*) by the Helferich reaction (4) involving the reaction of a fully acetylated sugar with a thiol in the presence of a Lewis acid (5); (*iii*) from the reaction of *O*-acetylglycosyl halides with an alkali salt of a thiol (6); and (*iv*) by *S*-alkylation of 1-thio sugars with alkyl halides (7). None of the above procedures could be adopted for the synthesis of **7***c* for obvious reasons.

A promising potential route for the preparation of

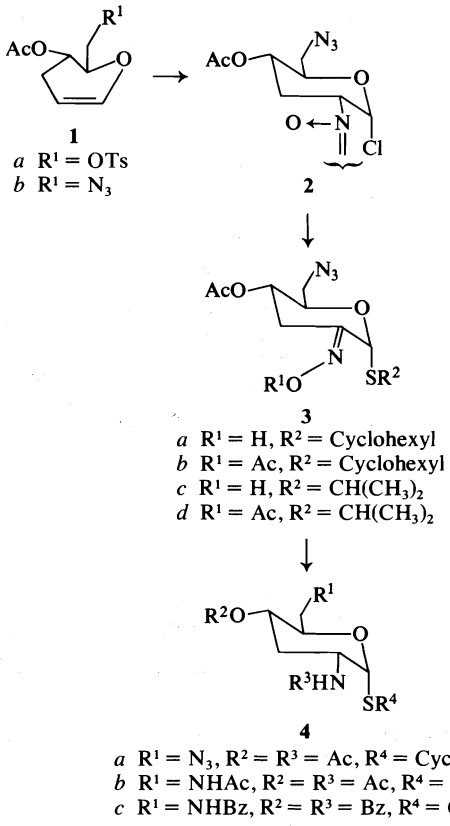
7*c* appeared to be the reaction of the nitrosochloro adduct **2** with the aminothiol **5**. It is well known that the reaction of nitrosochloro adducts of glycals with alcohols, also known as the Lemieux–Nagabhushan reaction (8–19), produces selectively the α-glycosides in most cases and can be used to prepare 2-amino- and 2-hydroxyglycosides. A similar reaction, however, of nitrosochloro adducts of glycals with thiols has not been described previously and in order to determine its utility for the synthesis of the 1-thio-α-D-glycoside **7***c*, the reaction of the nitrosochloro adduct **2** with cyclohexanethiol and 2-propanethiol were examined first.

4-*O*-Acetyl-3-deoxy-6-*O*-tosyl-D-glucal (**1***a*) was prepared by a literature procedure (20); on treatment with sodium azide in dimethylformamide (DMF) a 50% yield of 4-*O*-acetyl-6-azido-3,6-dideoxy-D-glucal (20) (**1***b*) was obtained. Treatment of the glucal **1***b* with nitrosyl chloride in methylene chloride gave the dimeric 4-*O*-acetyl-6-azido-2,3,6-trideoxy-2-nitroso-α-D-*ribo*-hexopyranosyl chloride (20) (**2**) in high yield.

Condensation of the nitrosochloro adduct **2** with cyclohexanethiol in DMF at 23°C in the presence of 2,2,6,6-tetramethylpiperidine (TMP) afforded cyclohexyl 4-*O*-acetyl-6-azido-2,3,6-trideoxy-2-hydroxyimino-1-thio-α-D-*erythro*-hexopyranoside (**3***a*) in high yield. The ^{1}Hmr spectrum of **3***a* showed two anomeric proton singlets at δ 5.8 and 6.51, in a ratio of 10:1, presumably due to *E*- and *Z*-oxime isomers, respectively. This assumption was based on a previous report (14) that the anomeric proton of the *E*-isomer of 2-hydroxyimino-α-glucopyranosides resonates at higher field than that of the *Z*-isomer. Acetylation of the oxime **3***a* produced the acetate **3***b* which on reduction with borane (16) in tetrahydrofuran followed by acetylation gave a mixture of cyclohexyl 2-acetamido-4-*O*-acetyl-6-azido-2,3,6-trideoxy-1-thio-α-D-*ribo*-hexopyranoside (**4***a*) and cyclohexyl-2,6-diacetamido-4-*O*-acetyl-2,3,6-trideoxy-1-thio-α-D-*ribo*-hexopyranoside (**4***b*). The reduction of **3***b* with borane had caused partial reduction of its azide function. For identification purposes the two products were separated by chromatography on a silica gel column. Reduction of the azido group in **4***a* with sodium borohydride in isopropanol (21) followed by acetylation provided **4***b*. The yield of **4***b* based on the oxime acetate **3***b* was 50%. These reactions are summarized in Scheme 1. Structural assignment to **4***a* as the α-D-*ribo*-isomer was based on ^{1}Hmr spectroscopy. The ^{1}Hmr spectrum of **4***a* (Fig. 1) showed a doublet at δ 5.39 ($J_{1,2}$ = 5 Hz) due to the anomeric proton. It also showed a double triplet at δ 2.16 ($J_{2,3_e} = J_{3_e,4}$ = 5 Hz, J_{vic} = 12 Hz) due



(Ac = $COCH_3$; Bz = COC_6H_5; Ts = $CH_3C_6H_4SO_2$)

SCHEME 1

to the equatorial H-3 indicating that this proton was coupled with two adjacent axial protons. It also exhibited an octet at δ 4.44 ($J_{1,2} = J_{2,3_e}$ = 5 Hz, $J_{2,3_a}$ = 13 Hz, $J_{2,NH}$ = 8 Hz) with band intensities ratio of 1:2:2:3:3:2:2:1, due to H-2, in good agreement with a theoretical first-order spectrum (Fig. 2) for this proton. These spectral data are in complete accord with the structure assigned to **4***a*. The ^{1}Hmr spectrum of **4***b* was also in agreement with that expected for the assigned structure.

Treatment of the nitrosochloro adduct **2** with 2-propanethiol in dimethylformamide in the presence of 2,2,6,6-tetramethylpiperidine produced isopropyl 4-*O*-acetyl-6-azido-2,3,6-trideoxy-2-hydroxyimino-1-thio-α-D-*erythro*-hexopyranoside (**3***c*). Acetylation of the oxime **3***c* gave the oxime acetate **3***d*. Reduction of **3***d* with borane in tetrahydrofuran (16) followed by reduction with sodium borohydride in isopropanol (21), to reduce the azide function, and benzoylation gave a 32% yield of isopropyl 2,6-dibenzamido-4-*O*-benzoyl-2,3,6-trideoxy-1-thio-α-D-*ribo*-hexopyranoside (**4***c*). The ^{1}Hmr spectrum of **4***c* was interpreted via extensive decoupling experiments (Fig. 3). It

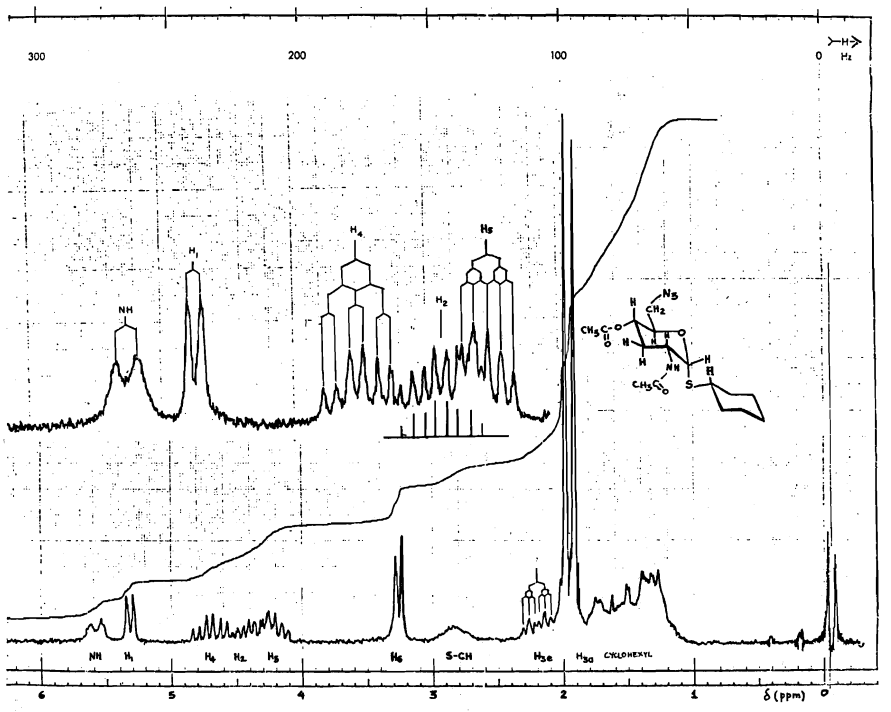


FIG. 1. The ^{1}Hmr spectrum at 100 MHz of cyclohexyl 2-acetamido-4-*O*-acetyl-6-azido-2,3,6-trideoxy-1-thio-α-D-*ribo*-hexopyranoside in deuteriochloroform.

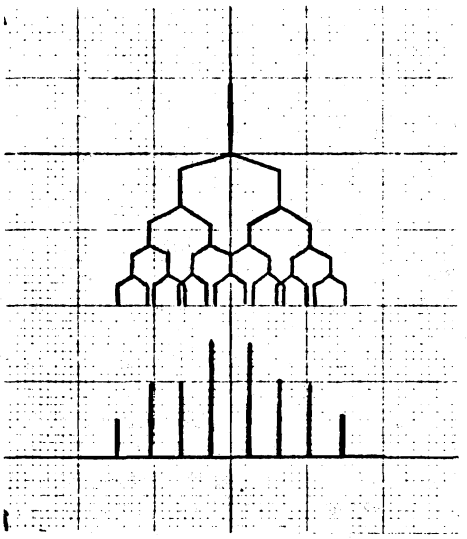

FIG. 2. Theoretical spectrum of H-2 in **4***a* calculated from the coupling constants $J_{2,3_a} = 13$, $J_{2,NH} = 8$, $J_{1,2} = 5$. $J_{2,3_e} = 5$ Hz.

exhibited a doublet at δ 5.51 ($J_{1,2}$ = 5 Hz) due to the anomeric proton, a double triplet at δ 1.81 (J_{vic} = 15 Hz, $J_{2,3_a} = J_{3_a,4}$ = 11 Hz) due to the axial H-3, and a double triplet at δ 2.52 (J_{vic} = 13 Hz, $J_{2,3_e} = J_{3_e,4}$ = 4.5 Hz) due to the equatorial H-3. The above data can only be consistent with the α-D-*ribo*-configuration for **4***c*. The preparation of the above model α-D-thioglycosides from the nitrosochloro adduct **2** demonstrated as anticipated that this process could successfully be applied to prepare thioanalogues of aminocyclitol antibiotics.

The preparation of **7***c* (Scheme 2) was then undertaken. The aminothiol **5***b* was prepared by our previously published method (22). Condensation of the nitrosochloro adduct **2** with the aminothiol **5***b* in dimethylformamide in the presence of 2,2,6,6-tetramethylpiperidine gave an 82% yield of the crystalline oxime **6***a*. The ^{1}Hmr spectrum of **6***a* showed a one-proton singlet at δ 5.85 due to the anomeric proton and, on the basis of precedents (14) discussed above, the *E*-configuration was assigned to this product. Acetylation of the oxime **6***a* afforded the acetate **6***b* which on reduction with borane in tetrahydrofuran gave a complex mixture of products due to the reduction of the oxime, of the azido and of the benzamido groups. The *N*-benzoyl protective group in **5***b* was then replaced with *N*-ethoxycarbonyl group.

Treatment of the nitrosochloro adduct **2** with **5***c* in dimethylformamide in the presence of 2,2,6,6-tetramethylpiperidine afforded an 80% yield of crystalline oxime **6***c*. Acetylation of **6***c* produced the acetate **6***d* which, on reduction with borane in tetrahydrofuran (16) followed by acetylation, gave a

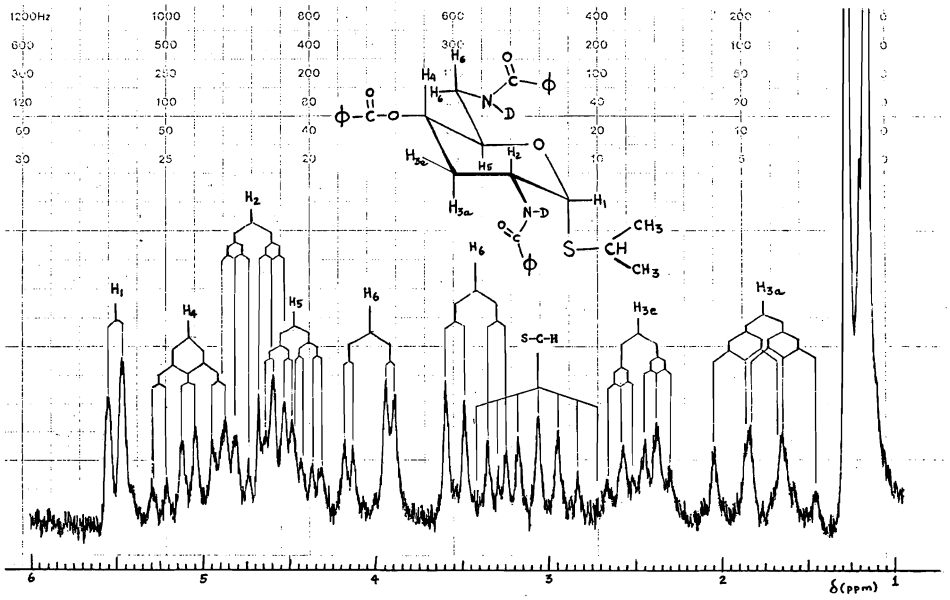

FIG. 3. The ^{1}Hmr spectrum at 60 MHz of isopropyl 2,6-dibenzamido-4-*O*-benzoyl-2,3,6-trideoxy-1-thio-α-D-*ribo*-hexopyranoside in deuteriochloroform. The amide protons have been exchanged with deuterium (D_2O, trifluoroacetic acid).

mixture of the 6-azido compound **7***a* and of the 6-acetamido product **7***b*. Hydrogenation of this mixture in methanol – acetic anhydride solvent mixture in the presence of platinum oxide catalyst afforded crystalline **7***b* in 30% yield based on the oxime **6***c*. The structure of **7***b* was established by chemical and spectroscopic means. Desulfurisation of **7***b* with Raney nickel in ethanol gave **8** thus establishing that **7***b* was a thioglycoside. The ^{1}Hmr spectrum of **7***b* contained a doublet at δ 5.43 due to

SCHEME 2

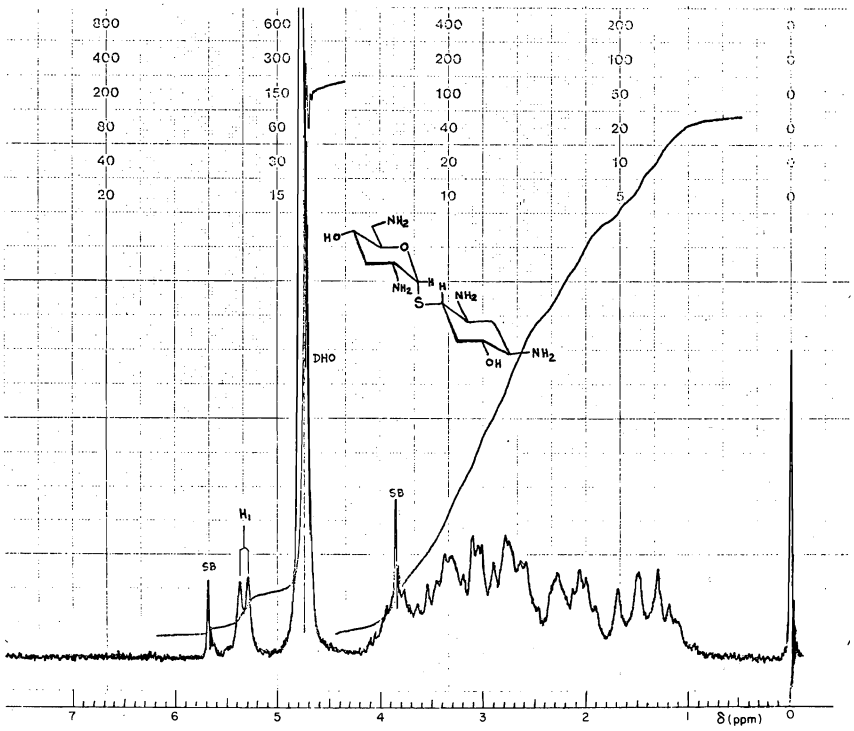

FIG. 4. The ^{1}Hmr spectrum of **7***c* at 60 MHz in D_2O.

the anomeric proton with a coupling constant of 5 Hz consistent with an α-D-*ribo*-configuration.

Removal of the protective groups in **7***b* by basic hydrolysis gave **7***c*. The ^{1}Hmr spectrum of **7***c* (Fig. 4) confirmed the assigned structure and exhibited a doublet at 5.35 (J = 5 Hz) due to the anomeric proton.

Compound **7***c* exhibited no significant antibiotic activity against 32 test organisms. At a concentration of 250 μg/mL compound **7***c* showed no inhibition in the growth of *Staphylococcus aureus*. The minimum inhibitory concentration (MIC) of neamine against this organism was 8 μg/mL.

Experimental

The melting points were determined on an Electrothermal melting point apparatus and are not corrected. The ir spectra were recorded on a Unicam SP-200G grating ir spectrometer. ^{1}Hmr spectra were obtained at 60 or 100 MHz with either a Varian EM-360A or an HA-100 spectrometer. Tetramethylsilane (for solutions other than deuterium oxide) and sodium 4,4-dimethyl-4-silapentane-1-sulfonate (for solution of deuterium oxide) were used as internal standards. Thin-layer chromatography (tlc) was carried out on microscope slides coated with silica gel and the spots were visualized with iodine or sulfuric acid. Optical rotations were measured with a Perkin-Elmer Model 141 polarimeter. The analyses were performed by Micro-Tech Laboratories, Skokie, IL.

*4-O-Acetyl-6-azido-3,6-dideoxy-D-glucal (**1**b)*

This product was prepared by a modified literature procedure (20) as follows. To a solution of 4-*O*-acetyl-3-deoxy-6-*O*-tosyl-D-glucal (**1***a*) (34.5 g, 0.11 mol) in dry dimethylformamide (400 mL) at 80°C, was added sodium azide (14 g, 0.22 mol) and the mixture stirred for 1 h maintaining the temperature between 75 and 80°C. The reaction mixture was poured into ice water (400 mL) and extracted with methylene chloride (3 × 150 mL). The combined extracts were washed successively with saturated sodium bicarbonate solution and water and dried (Na_2SO_4). Removal of the solvent by evaporation gave 19.7 g of a dark-colored syrup which on tlc (silica, 20% ethyl acetate in petroleum ether) showed three spots of R_f 0.48, 0.35 (major, **1***b*), and 0.25. The crude product was purified by column chromatography on silica gel (1 kg) using 20% ethyl acetate in petroleum ether as eluent to give 10.5 g (50%) of 4-*O*-acetyl-6-azido-3,6-dideoxy-D-glucal (**1***b*) as an oil; ir (neat): 2100, 1715, 1660 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 2.06 (s, 3H, OAc), 2.0–2.7 (m, 2H, H-3), 3.45 (d, 2H, H-6, J = 4.5 Hz), 4.00 (d of t, 1H, H-5, $J_1 = J_2 = 4.5$, $J_3 = 8$ Hz), 4.71 (d of d of d, 1H, H-2, $J_1 = 6$, $J_2 = 4.5$, $J_3 = 3$ Hz), 4.98 (d of t, 1H, H-4, $J_1 = J_2 = 8$, $J_3 = 6$ Hz), 6.39 (d of t, 1H, H-1, $J_1 = J_2 = 2$, $J_3 = 6$ Hz).

*4-O-Acetyl-6-azido-2,3,6-trideoxy-2-nitroso-α-D-ribo-hexopyranosyl Chloride (**2**)*

This product was prepared by a modified literature procedure (20) as follows. The glucal **1***b* (3.0 g, 15.2 mmol) was dissolved in dry methylene chloride (60 mL) in a 250 mL three-neck flask equipped with a low temperature thermometer and gas inlet and outlet tubes. Nitrogen was passed through the magnetically stirred solution while it was cooled to −70°C in a Dry Ice – acetone mixture. To this solution was added a cold solution of nitrosyl chloride (3.2 g, 49 mmol) in methylene chloride (20 mL) and the mixture was stirred for 1 h under nitrogen while the temperature was slowly increased to −20°C.

The reaction mixture was filtered to remove some solid impurities and evaporated to give 3.6 g (90%) of **2** as a gum; ^{1}Hmr ($CDCl_3$) δ: 2.10 (s, 3H, OAc), 6.75 (m, 1H, H-1).

This material, soon after its preparation, was used without further purification in the glycosidation reaction.

*Cyclohexyl 4-O-Acetyl-6-azido-2,3,6-trideoxy-2-hydroxyimino-1-thio-α-*D*-erythro-hexopyranoside (3a)*

A solution of 1.52 g (5.8 mmol) of **2**, 1.5 mL of 2,2,6,6-tetramethylpiperidine and 1.3 mL of cyclohexanethiol in 5 mL of dry DMF was stirred at 23°C for 3 h. The reaction mixture was evaporated and the residue was dissolved in ether (100 mL). The ether solution was washed with 10% hydrochloric acid (100 mL) and water and, after drying, was evaporated to give 1.95 g (99%) of the oxime **3*a*** as a syrup. A sample (1.0 g) was chromatographed on a silica gel column using chloroform as eluent. The *E*-isomer was eluted first giving 630 mg as an oil; $[\alpha]_D^{23}$ +105° (*c* 1.0, EtOH); ir (neat): 3330, 2090, 1730 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 2.09 (s, 3H, OAc), 5.80 (s, 1H, H-1).

The *Z*-isomer was eluted next, to give 70 mg of material as an oil; $[\alpha]_D^{23}$ +121° (*c* 0.5, EtOH); ir (neat): 3320, 2090, 1730 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 2.10 (s, 3H, OAc), 6.51 (s, 1H, H-1).

*Cyclohexyl 2-Acetoxyimino-4-O-acetyl-6-azido-2,3,6-trideoxy-1-thio-α-*D*-erythro-hexopyranoside (3b)*

A solution of 0.63 g (1.84 mmol) of the oxime **3*a*** (*E*-isomer) and 1.6 mL of acetic anhydride in 4 mL of anhydrous pyridine was left at 23°C for 20 h. The reaction mixture was diluted with ether and washed first with 10% sodium bicarbonate solution and then with water and dried. Removal of the solvent by evaporation left a syrup (0.68 g) which was chromatographed on silica gel with chloroform to give 0.58 g (82%) of the acetate **3*b*** as a syrup $[\alpha]_D^{23}$ +151° (*c* 0.7, EtOH); ir (neat): 2100, 1770, 1740 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 2.10 and 2.18 (2s, 6H, OAc), 5.94 (s, 1H, H-1).

*Cyclohexyl 2,6-Diacetamido-4-O-acetyl-2,3,6-trideoxy-1-thio-α-*D*-ribo-hexopyranoside (4b)*

To a solution of 0.26 g (0.68 mmol) of the oxime acetate **3*b*** in 5 mL of anhydrous THF at 0°C under nitrogen was added a 1 *M* solution of borane in THF (7 mL). After the addition of borane, the cooling bath was removed and the reaction mixture was stirred at room temperature for 3 h. The excess borane was decomposed by dropwise addition of methanol (10 mL) at 0°C, the reaction mixture was diluted with methylene chloride, and washed with water. After drying, the solvent was removed *in vacuo* to give 220 mg of a syrup. This product was dissolved in dry pyridine (4 mL), acetic anhydride (2 mL) was added and the solution let stand at 23°C for 3 h. The reaction mixture was diluted with methylene chloride and washed successively with 10% sodium bicarbonate solution and water. After drying, the solvent was removed *in vacuo* to give 280 mg of a syrup. Thin-layer chromatography (5% MeOH in $CHCl_3$) showed two spots of R_f 0.55 (**4*a***) and 0.4 (**4*b***). This material was chromatographed on silica gel using ether as eluent. The azido compound **4*a*** was eluted first; 80 mg, mp 148°C; $[\alpha]_D^{23}$ +151° (*c* 0.6, EtOH); ir (Nujol): 3320, 2090, 1730, 1650 cm^{-1}; ^{1}Hmr ($CDCl_3$) at 100 MHz δ: 1.2–1.8 (m, 11H, cyclohexyl and H-3$_a$), 1.90 (s, 3H, NHAc), 1.98 (s, 3H, OAc), 2.16 (d of t, 1H, H-3$_e$, J_{vic} = 12 Hz, $J_{2,3_e} = J_{3_e,4}$ = 5 Hz), 2.90 (m, 1H, S—C—H), 3.31 (d, 2H, H-6, *J* = 5 Hz), 4.26 (d of t, 1H, H-5, $J_1 = 10$, $J_2 = 5$, $J_3 = 5$ Hz), 4.44 (octet, 1H, H-2, $J_{1,2} = J_{2,3_e} = 5$, $J_{2,3_a} = 13$, $J_{2,NH} = 8$ Hz), 4.77 (d of t, 1H, H-4, $J_{3_a,4} = J_{4,5} = 10$, $J_{3_e,4} = 5$ Hz), 5.39 (d, 1H, H-1, $J_{1,2} = 5$ Hz), 5.64 (d, 1H, NH, *J* = 8 Hz).

The second product was the amide **4*b***, 60 mg, mp 229–230°C (MeOH); $[\alpha]_D^{23}$ +178° (*c* 0.5, EtOH); ir (Nujol) 3320, 3300, 1730, 1640 cm^{-1}; ^{1}Hmr ($CDCl_3$) at 100 MHz, δ: 1.0–2.0 (m, 11H, cyclohexyl and H-3$_a$), 2.0 (s, 6H, NAc), 2.05 (s, 3H, OAc), 2.29 (d of t, 1H, H-3$_e$, J_{vic} = 8, $J_{2,3_e} = J_{3_e,4}$ = 5 Hz), 2.82 (m, 1H, S—C—H), 3.43 (d, 2H, H-6, *J* = 4 Hz), 4.16 (d of t, 1H, H-5, $J_1 = J_2 = 10$, $J_3 = 4$ Hz), 4.35 (octet, 1H, H-2, $J_{1,2} = J_{2,3_e} = 5$, $J_{2,3_a} = 13$, $J_{2,NH} = 8$ Hz), 4.64 (d of t, 1–H, H-4, $J_{3_a,4} = J_{4,5} = 10$, $J_{3_e,4} = 5$ Hz), 5.30 (d, 1H, H-1, $J_{1,2} = 5$ Hz), 5.76 (m, 2H, NH). *Anal.* calcd. for $C_{18}H_{30}N_2O_5S$: C 55.62, H 7.71, N 7.40; found: C 56.00, H 7.83, N 7.25.

The azide **4*a*** (80 mg) and sodium borohydride (80 mg) were dissolved in dry isopropanol (4 mL) and the solution was heated under reflux for 18 h. The reaction mixture was diluted with water and extracted with methylene chloride. The organic extracts, after drying were evaporated to give a syrup (60 mg). This product was acetylated with acetic anhydride in pyridine to give 72 mg (86%) of **4*b***, mp 229–230°C, identical in all respects with the product described above. This material was combined with the one above to give a total of 132 mg of **4*b***, which corresponds to a 50% yield based on the oxime acetate **3*b***.

*Isopropyl 2,6-Dibenzamido-4-O-benzoyl-2,3,6-trideoxy-1-thio-α-*D*-ribo-hexopyranoside (4c)*

A solution of 2.6 g (10 mmol) of **2**, 2 mL (20 mmol) of 2-propanethiol and 3.3 mL of 2,2,6,6-tetramethylpiperidine in 40 mL of dry dimethylformamide was stirred at 23°C for 2 h. The reaction mixture was diluted with ether and washed successively with water, 1 *N* hydrochloric acid, and water and dried. Removal of the solvent by evaporation gave the oxime **3*c*** as a syrup. Thin-layer chromatography (ether) showed a major spot of R_f 0.73 and three minor ones with R_f 0.66, 0.51, and 0.42.

The above product and acetic anhydride (5 mL) were dissolved in pyridine (20 mL) and the solution let stand at 23°C for 16 h. The reaction mixture was diluted with methylene chloride and the solution washed with 10% sodium bicarbonate and water and dried. Removal of the solvent by evaporation gave 3.1 g (91% based on **2**) of the acetylated oxime **3*d***. Thin-layer chromatography (ether–hexane (4:1)) showed a major spot of R_f 0.48 (**3*d***) and a minor of R_f 0.34.

The above oxime acetate **3*d*** (3.1 g) was dissolved in dry THF (40 mL) and the solution, blanketed with nitrogen, was cooled to 0°C. A solution of 1 *M* borane in THF (60 mL) was added and the solution stirred at room temperature, under nitrogen, for 3 h. The excess borane reagent was decomposed with methanol and the reaction mixture was evaporated. The residue and sodium borohydride (1.5 g) were dissolved in dry isopropanol (40 mL) and the solution was heated under reflux for 18 h. After cooling to room temperature, Dowex 1-X8 resin (OH^- form) was added and the mixture stirred at 23°C for 2 h. The mixture was filtered and the filtrate evaporated to dryness. The residue was dissolved in pyridine (20 mL), benzoic anhydride was added, and the mixture stirred at 23°C for 18 h. The reaction mixture was poured into ice water and the solid precipitate collected. Recrystallization from methanol gave 1.7 g (32% based on **2**) of **4*c***, mp 212–217°C; ir (Nujol): 3320, 1730, 1720, 1640 cm^{-1}; ^{1}Hmr ($CDCl_3$) of the *N*-deuterated product, δ: 1.27 (d, 6H, CH_3, *J* = 7 Hz), 1.81 (d of t, 1H, H-3$_a$, J_{vic} = 13 Hz, $J_{2,3_a} = J_{3_a,4}$ = 11 Hz), 2.52 (d of t, 1H, H-3$_e$, J_{vic} = 13, $J_{2,3_e} = J_{3_e,4}$ = 4.5 Hz), 3.08 (m, 1H, S—C—H), 3.44 (d of d, 1H, H-6, J_1 = 14.5, J_2 = 6.5 Hz), 4.05 (d of d, 1H, H-6, J_1 = 14.5, J_2 = 3 Hz), 4.50 (octet, 1H, H-5, $J_1 = 10$, $J_2 = 6.5$, $J_3 = 3$ Hz), 5.09 (d of t, 1H, H-4, $J_{3_a,4} = J_{4,5} = 10.5$, $J_{3_e,4} = 4.5$ Hz), 5.51 (d, 1H, H-1, $J_{1,2} = 5$ Hz), 7.22–8.15 (m, 15H, ArH). *Anal.* calcd. for $C_{30}H_{32}N_2O_5S$: C 67.65, H 6.05, N 5.26; found: C 67.42, H 5.93, N 5.34.

(1S,2S,4R,5R)-2,4-Diethoxycarbonylamino-5-hydroxycyclohexanethiol (5c)

To a stirred solution of 3.05 g (13 mmol) of the hydrochloride salt of **5a** (22) in 30 mL water, under nitrogen atmosphere, was added 7.65 g (91 mmol) of sodium bicarbonate to liberate the free base. After gas evolution ceased, 10 mL methanol was added. To this mixture was added dropwise (10 min) a solution of 4.2 g (39 mmol) of ethyl chloroformate in 6.5 mL dry acetone and the reaction mixture was stirred at room temperature for 1.5 h. The solids which were formed were collected by filtration and dried to give 3.6 g of a mixture of **5c** and its *S*-carbethoxy derivative. This product was added to a 1 *N* solution of sodium hydroxide in 80% ethanol (25 mL) and the mixture stirred at room temperature for 30 min under nitrogen. The solution was diluted with ethanol (25 mL), neutralized with Dowex 50W-X8 cation exchange resin (12 g), and evaporated to give 2.3 g (58%) of **5c**, mp 200–202°C; $[\alpha]_D^{25}$ +16.5° (*c* 1.0, pyridine); ir (Nujol): 3300, 1700, 1550 cm^{-1}. *Anal.* calcd. for $C_{12}H_{22}N_2O_5S$: C 47.04, H 7.24, N 9.14, S 10.46; found: C 47.03, H 7.34, N 9.08, S 10.30.

(1S,2S,4R,5R)-2-Benzamido-4-ethoxycarbonylamino-5-hydroxycyclohexyl 4-O-Acetyl-6-azido-2,3,6-trideoxy-2-hydroxyimino-1-thio-α-D-erythro-hexopyranoside (6a)

A solution of 3.4 g (13 mmol) of freshly prepared **2**, 4.4 g (13 mmol) of **5b** (22) ($[\alpha]_D^{25}$ +33.4°) and 2.25 g (16 mmol) of 2,2,6,6-tetramethylpiperidine in 25 mL of dry dimethylformamide was stirred for 2 h at room temperature under a nitrogen atmosphere. Thin-layer chromatography on alumina plates with 10% ethanol in chloroform as eluent showed one spot of R_f 0.46 (**6a**). The reaction mixture was poured into ice water (200 mL) and the solids were collected by filtration, washed with water, and dried to give 6.0 g (82%) of **6a**. A sample (1.85 g) was recrystallized from ethanol to give 0.8 g of **6a**, mp 198–200°C (dec.); $[\alpha]_D^{25}$ +134° (*c* 0.7, DMF); ir (Nujol): 3450, 3300, 2100, 1750, 1680, 1640, 1540 cm^{-1}; ^{1}Hmr (DMSO-d_6) δ: 1.17 (t, 3H, CH_3, J = 7 Hz), 2.0 (s, 3H, OAc), 4.0 (q, 2H, CH_2 of CO_2Et, J = 7 Hz), 5.85 (s, 1H, H-1), 7.3–8.0 (m, 5H, ArH). *Anal.* calcd. for $C_{24}H_{32}N_6O_8S$: C 51.05, H 5.71, N 14.88, S 5.66; found: C 51.10, H 5.70, N 14.85, S 6.46.

Preparation of the Oxime Acetate (6b)

A solution of 4.36 g (7.7 mmol) of **6a** (mp 198–200°C) and 6.4 mL of acetic anhydride in 24 mL of dry pyridine was stirred at room temperature for 24 h. The mixture was poured into cold water (400 mL) and the solids collected by filtration, washed with water, and dried under vacuum (100°C, 2 h) to give 4.16 g (83%) of **6b**, mp 177–181°C; $[\alpha]_D^{25}$ +96.7° (*c* 1.0, $CHCl_3$); ir (Nujol): 3300, 2100, 1780, 1730, 1680, 1630, 1540 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.20 and 4.07 (t and q for CO_2Et), 2.0, 2.08 and 2.13 (3s, 9H, Ac), 5.97 (s, 1H, H-1), 7.2–8.0 (m, 5H, ArH). *Anal.* calcd. for $C_{28}H_{36}N_6O_{10}S$: C 51.84, H 5.59, N 12.96, S 4.94; found: C 51.72, H 5.54, N 13.02, S 4.96.

(1S,2S,4R,5R)-2,4-Diethoxycarbonylamino-5-hydroxycyclohexyl 4-O-Acetyl-6-azido-2,3,6-trideoxy-2-hydroxyimino-1-thio-α-D-erythro-hexopyranoside (6c)

A solution of 2.9 g (11 mmol) of freshly prepared **2**, 3.36 g (11 mmol) of **5c**, and 1.55 g (11 mmol) of 2,2,6,6-tetramethylpiperidine in 22 mL dry dimethylformamide was stirred for 2 h at room temperature under nitrogen atmosphere. The solution was diluted with water (150 mL) and stirred for 15 min. The crystalline product which was formed was collected by filtration, washed with water (3 × 30 mL), and dried *in vacuo* at 100°C to give 3.82 g (65%) of **6c**, mp 167–171°C. The combined filtrate and washings were extracted with chloroform (3 × 80 mL). The chloroform extracts were combined, washed with water (5 × 100 mL), dried, and evaporated. The syrupy residue, on trituration with ether (30 mL), solidified. The crystalline product was collected by filtration, washed with ether, and dried to give 0.86 g of **6c**. Both crops showed on tlc (alumina, 10% EtOH–CH_2Cl_2) a single spot of R_f 0.44. The two crops were combined to yield 4.68 g (80%) of **6c**; $[\alpha]_D^{25}$ +132° (*c* 0.9, DMF); ir (Nujol); 3450, 3300, 3200, 2100, 1750, 1695, 1540 cm^{-1}; ^{1}Hmr ($CDCl_3$–DMSO-d_6) δ: 1.27 (t, 6H, CH_3, J = 7 Hz), 2.08 (s, 3H, OAc), 4.13 (q, 4H, CH_2 of CO_2Et), 5.75 (s, 1H, H-1). *Anal.* calcd. for $C_{20}H_{32}N_6O_9S$: C 45.10, H 6.06, N 15.78, S 6.02; found: C 45.05; H 5.81, N 15.95, S 6.37.

(1S,2S,4R,5R)-2,4-Diethoxycarbonylamino-5-acetoxycyclohexyl 2,6-Diacetamido-4-O-acetyl-2,3,6-trideoxy-1-thio-α-D-ribo-hexopyranoside (7b)

A solution of 5.7 g (10.7 mmol) of the oxime **6c** and 8 mL of acetic anhydride in 35 mL dry pyridine was left at room temperature for 24 h. Water (5 mL) was added to decompose the excess of acetic anhydride. The reaction mixture was diluted with chloroform (200 mL) and washed with water (5 × 200 mL). The chloroform solution, after drying, was evaporated to give 6.3 g (95%) of the oxime acetate **6d** as a foam. Examination by tlc (10% ethanol in chloroform) showed a single spot of R_f 0.61; $[\alpha]_D^{25}$ +65.7° (*c* 1.0, $CHCl_3$); ^{1}Hmr ($CDCl_3$) δ: 1.23 and 1.29 (2t, 6H, $CO_2CH_2CH_3$), 2.08, 2.12, and 2.22 (3s, 9H, CH_3CO), 4.13 and 4.20 (2q, 4H, CO_2CH_2-CH_3), 5.9 (s, 1H, H-1).

The oxime acetate **6d** (6.3 g, 10.2 mmol) was dissolved in dry tetrahydrofuran (25 mL) and the solution, blanketed with nitrogen, was cooled to 0°C with stirring. A 1 *M* solution of borane in tetrahydrofuran (100 mL) was added gradually and after the addition was completed, the cooling bath was removed, and the reaction mixture was stirred at room temperature for 3 h. The excess of borane reagent was destroyed by dropwise addition of methanol (80 mL) at 0°C and the solution evaporated *in vacuo*. The residue was dissolved in methanol (50 mL), the solution evaporated, and the process repeated once more. The resultant syrupy product was dissolved in a methanol–water mixture (5:1, 120 mL), 20 g of Rexyn 201 (anion exchange resin, OH^- form) was added and the mixture was stirred at room temperature for 1.5 h to decompose the borane–amine complex. The resin was filtered off and washed with a hot solution of concentrated ammonium hydroxide (2 mL) in ethanol (100 mL). The filtrate and washings were combined and evaporated *in vacuo* to give 3.9 g of product as a foam. Examination of this product by tlc using NH_4OH–EtOH–$CHCl_3$ (1:5:5) as eluent showed two major spots of R_f 0.23 and 0.32 and two minor ones of R_f 0.59 and 0.81. The ir spectrum showed only a comparatively small azide band.

The above product (3.9 g) and acetic anhydride (10 mL) were dissolved in dry pyridine (30 mL) and the solution was stirred at room temperature for 20 h. The reaction mixture was diluted with chloroform (200 mL) and washed with water (3 × 200 mL). The chloroform solution, after drying, was evaporated *in vacuo* to give 3.7 g of product as a foam. Inspection by tlc (silica, 10% EtOH–$CHCl_3$) showed the substance to contain two major components (R_f 0.19 and 0.41) and three other minor components.

The above product (3.70 g) and acetic anhydride (40 mL) were dissolved in methanol (150 mL). To this solution was added platinum oxide catalyst (0.8 g) and the mixture was hydrogenated in a Paar apparatus at room temperature and an

initial pressure of 50 psi for 2 h. The reaction mixture was filtered through a bed of activated charcoal (2.5 cm × 4.5 cm id) and the cake was washed with ethanol (4 × 25 mL). The combined filtrate and washings were evaporated *in vacuo* to give 3.2 g of solid material. This product was mixed with ethyl acetate (30 mL) and the mixture was refluxed with stirring for 20 min then cooled to room temperature and the crystalline precipitate collected to give 1.98 g (30% based on the oxime **6***c*) of **7***b*. Thin-layer chromatography (10% EtOH–$CHCl_3$) showed one major spot of R_f 0.20 (**7***b*) and traces of another component with R_f 0.40. The analytical sample was prepared by recrystallization from ethanol – ethyl acetate, mp 266–267°C; $[\alpha]_D^{25}$ +106° (*c* 1.0, DMF); ir (Nujol): 3310, 1740, 1690, 1650, 1550 cm^{-1}; ^{1}Hmr (DMSO-d_6) δ: 1.15 and 1.20 (2t, 6H, CH_3 of CO_2Et), 1.80, 1.83, 1.97, and 2.0 (4s, 12H, Ac), 3.93 and 4.03 (2q, 4H, CH_2 of CO_2Et), 5.43 (d, 1H, H-1, $J_{1,2}$ = 5 Hz). *Anal.* calcd. for $C_{26}H_{42}N_4O_{11}S$: C 50.47, H 6.84, N 9.06, S 5.18; found: C 50.26, H 6.77, N 9.13, S 5.32.

*(1S,2S,4R,5R)-2,4-Diamino-5-hydroxycyclohexyl 2,6-Diamino-2,3,6-trideoxy-1-thio-*α*-*D*-ribo-hexopyranoside (7c)*

To a 2.4 *N* solution of sodium hydroxide in ethanol (10 mL) was added 0.5 g (0.8 mmol) of **7***b* and the mixture was heated under reflux under nitrogen with stirring for 19 h. Examination by tlc (silica, MeOH – concentrated NH_4OH – $CHCl_3$, 4:2:1) showed several spots indicating incomplete hydrolysis. The solvent was removed by evaporation, replaced with water (10 mL), and the solution was heated under reflux under nitrogen for 25 h. The reaction mixture was neutralized with an equivalent amount of hydrochloric acid (1 *N*, 24 mL) and filtered to remove some insoluble matter. The filtrate was evaporated *in vacuo* and the solid residue extracted twice with boiling ethanol (25 and 10 mL). The combined ethanol extracts were evaporated to give 0.5 g of a solid product. Thin-layer chromatography showed two spots of R_f 0.39 (**7***c*) and 0.65. This material was chromatographed on Rexyn 102 (NH_4^+, 13 g) and resin eluted successively with water (100 mL), 0.1 *N* ammonium hydroxide (400 mL), and 1 *N* ammonium hydroxide (400 mL). Fractions of 15 mL were collected in tubes. The fractions containing **7***c* (tubes 19–48) were combined and evaporated to give 150 mg of **7***c*. This product was further purified by chromatography on silica gel plates using MeOH – concentrated NH_4OH – $CHCl_3$ (4:2:1) as eluent to give **7***c* as an amorphous solid; ^{1}Hmr (D_2O) δ: 5.35 (d, 1H, anomeric, *J* = 5 Hz). *Anal.* calcd. for $C_{12}H_{26}N_4O_3S \cdot \frac{1}{2}H_2O$: C 47.04, H 8.55, N 18.28, S 10.46; found: C 45.90, H 8.52, N 17.18, S 9.80.

Desulfurization of 7b

To a solution of 100 mg of **7***b* in 10 mL ethanol was added Raney nickel catalyst (~0.5 g) and the mixture heated under reflux with stirring for 1.5 h. The reaction mixture was filtered and the catalyst was washed with boiling ethanol. The combined filtrate and washings were evaporated to give 90 mg of a solid product. Thin-layer chromatography (10% ethanol in chloroform) showed two major spots of R_f 0.57 (**8**) and 0.21, and three minor of R_f 0.35, 0.32, and 0.28. The product was chromatographed on silica gel plates (10% ethanol–chloroform as eluent) to give 30 mg of **8**, mp 110–112°C, resolidified and melted at 150–151°C; ^{1}Hmr ($CDCl_3$) δ: 1.27 and 4.13 (t and q for CO_2Et), 2.08 (s, 3H, OAc). *Anal.* calcd. for $C_{14}H_{24}N_2O_6$: C 53.15, H 7.65, N 8.85; found: C 53.26, H 7.63, N 8.79.

Received November 30, 1979

EDWARD PIERS, MICHAEL ZBOZNY, and DONALD C. WIGFIELD. Can. J. Chem. **57**, 1064 (1979).

The syntheses of 4a-(3-chloropropyl)- (**22**), 4a-(3-iodopropyl)- (**23**), and 4a-mesyloxymethyl-4,4a,5,6,7,8-hexahydro-2(3*H*)-naphthalenone (**24**) are described. The results obtained from the intramolecular alkylation of each of these compounds under a variety of experimental conditions are summarized in Tables 1 and 2. It was found that alkylative cyclization of compounds **22** and **23** gave varying amounts of two products, one (**34**) resulting from α′ alkylation and the other (**35**) being derived from α alkylation. In contrast, intramolecular alkylation of the enone **24** produced only the γ alkylation product **11**, or afforded a mixture of **11** and the α alkylation product **41**. The intramolecular alkylation results are discussed in terms of Scheme 5.

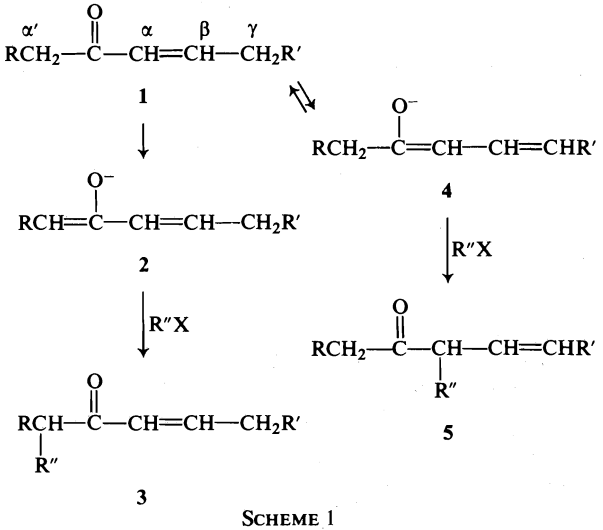
EDWARD PIERS, MICHAEL ZBOZNY et DONALD C. WIGFIELD. Can. J. Chem. **57**, 1064 (1979).

On décrit les synthèses des (chloro-3 propyl)-4a (**22**), (iodo-3 propyl)-4a (**23**) et mésyloxyméthyl-4a hexahydro-4,4a,5,6,7,8 (3*H*)-naphtalénones-2 (**24**). Les résultats obtenus lors de l'alkylation intramoléculaire de chacun de ces composés dans diverses conditions expérimentales sont résumés dans les Tableaux 1 et 2. On a trouvé que la cyclisation alkylante des composés **22** et **23** conduit à des quantités variables de deux produits, l'un, **34**, provenant d'une alkylation en α′ et l'autre, **35**, dû à une alkylation en α. Par ailleurs, l'alkylation intramoléculaire de l'énone **24** ne fournit que le produit **11**, correspondant à une alkylation en γ, ou à un mélange de **11** et du produit d'alkylation α, **41**. On discute des résultats d'alkylations intramoléculaires en termes du Schéma 5.

[Traduit par le journal]

Introduction

The intermolecular alkylation of α,β-unsaturated ketones has been, and continues to be, a very important reaction in the area of synthetic organic chemistry. It appears to be quite well established that, in general, treatment of an enone (e.g., **1**, see Scheme 1) with a strong, nonnucleophilic base (e.g., lithium diisopropylamide) under aprotic conditions, results in the kinetically controlled formation of the α′ enolate anion **2**. If alkylation of the latter is fast compared with enolate anion equilibration, it is possible to obtain the α′ alkylation product **3** in good yield.[2] On the other hand, if a compound such as **1** is treated with a base under conditions (e.g., in the presence of a protic solvent) which promote enolate anion equilibration (thermodynamic control), the more stable (compared with **2**) dienolate anion **4** is obtained. Alkylation of **4** occurs preferentially at the α carbon, affording **5** as the primary alkylation product.[3]



SCHEME 1

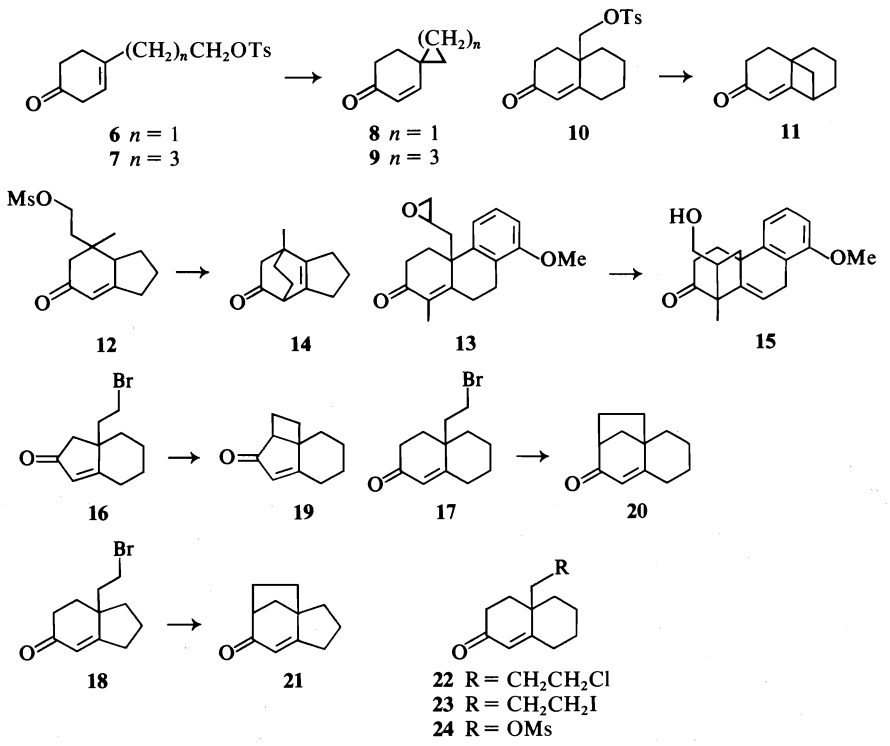
In contrast to the number of reported studies concerning the intermolecular alkylation of α,β-unsaturated ketones, the intramolecular variant of this type of reaction has received relatively little attention. Nevertheless, on the basis of the few examples which

[1]Author to whom correspondence should be addressed.

[2]For some examples, see ref. 1.

[3]For a general discussion regarding this type of reaction, see ref. 2.

0008-4042/79/091064-11$01.00/0



SCHEME 2

can be found scattered throughout the chemical literature, it is clear that every possible mode of cyclization has been observed. For example, treatment of the keto tosylates **6** and **7** (see Scheme 2) with sodium hydride in refluxing dioxan containing a small amount of *tert*-butyl alcohol gave, in fairly low yields, the γ alkylation products **8**[4] and **9**, respectively (3). In similar fashion, the substituted octalone **10**, upon treatment with potassium *tert*-butoxide in hot *tert*-butyl alcohol, gave the enone **11** as the only intramolecular alkylation product (5).[5] On the other hand, intramolecular alkylation of the substrates **12** (sodium hydride in hot dimethoxyethane containing a small amount of ethanol) (7) and **13** (potassium *tert*-butoxide in hot benzene) (8) afforded as the major products the α alkylated materials **14** and **15**, respectively. Finally, in what has been to date the most extensive single study of the intramolecular alkylation of enones, Cargill and Jackson (9) showed that treatment of the bromo ketones **16–18** with potassium *tert*-butoxide in *tert*-butyl alcohol resulted in the exclusive (or nearly exclusive) formation of the α′ alkylation products **19–21**, respectively.

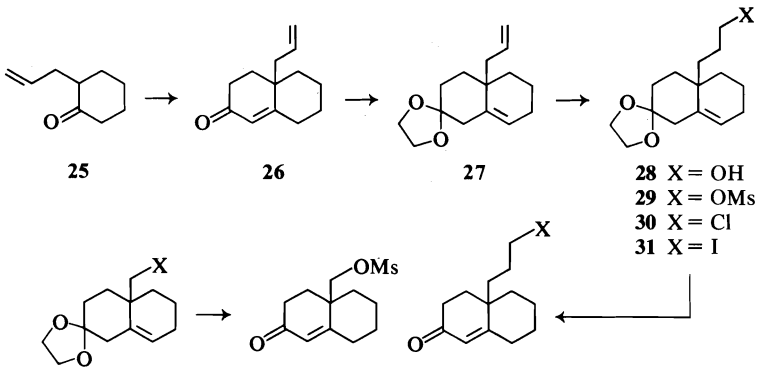
[4]For other examples of γ alkylation involving the closure of three-membered rings, see ref. 4.

[5]For similar γ alkylations of 19-mesyloxy-(or tosyloxy-)-Δ[4]-3-keto steroids, see ref. 6.

The examples cited above indicate that substrate structure has a marked effect on the site of intramolecular alkylation of α,β-unsaturated ketones. However, we were intrigued by the following question: is it possible to control the site of alkylation within a given substrate by varying reaction conditions and/or by varying the nature of the leaving group? Clearly, an affirmative answer to this question would have potentially useful repercussions in synthesis (particularly in the area of natural product synthesis), since alkylation at different positions would give rise to products with distinctly different carbon skeletons. To our knowledge, no study aimed at obtaining an answer to the above question has as yet been reported. In this paper, we describe the preparation and intramolecular alkylation of the substituted octalones **22–24**. The results obtained clearly show that, with these substrates at least, it is indeed possible to (partially) control the site of intramolecular alkylation by varying experimental conditions.

Preparation of 4a-(3-Chloropropyl)- (22), 4a-(3-Iodopropyl)- (23), and 4a-Mesyloxymethyl-4,4a,5,6,7,8-hexahydro-2(3*H*)-naphthalenone (24)

The two substituted octalones **22** and **23** were prepared from 2-allylcyclohexanone (**25**) (10) via a



SCHEME 3

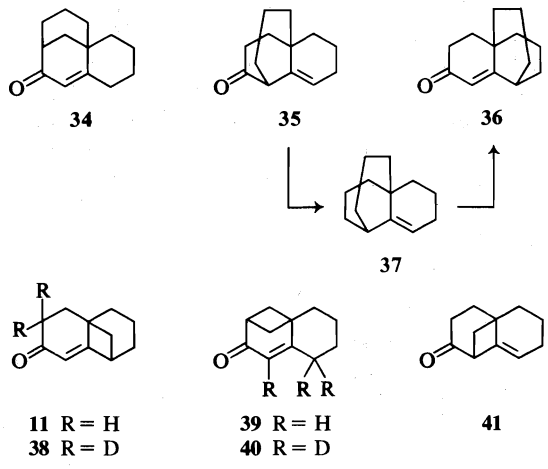
straightforward sequence of reactions as outlined in Scheme 3. Robinson annelation of **25** with methyl vinyl ketone by means of a procedure very similar to that reported by Marshall and Fanta (11) gave the octalone **26** which, upon subjection to standard ketalization conditions (ethylene glycol, *p*-toluenesulfonic acid, benzene), afforded the ketal diene **27**. Site-selective hydroboration of the latter with disiamylborane (12), followed by oxidation of the resultant trialkylborane intermediate with alkaline hydrogen peroxide, gave the olefinic alcohol **28**, which was converted (methanesulfonyl chloride, triethylamine, dichloromethane) into the corresponding mesylate **29**. Treatment of **29** with lithium chloride in refluxing acetone followed by hydrolysis (sulfuric acid in aqueous acetone) of the resultant ketal chloride **30** afforded the substituted octalone **22**. In similar fashion, the ketal mesylate **29** was also converted into the iodo compound **23**.

The known ketal alcohol **32** (13) served as a convenient starting material for the mesyloxymethyl octalone **24**. Thus, treatment of the former compound with methanesulfonyl chloride – triethylamine in dichloromethane gave the crystalline ketal mesylate **33** which, upon hydrolysis with sulfuric acid in aqueous acetone, afforded the desired octalone **24**.

Characterization of Intramolecular Alkylation Products

Before discussing the results obtained from the intramolecular alkylation of the octalones **22**–**24**, it is appropriate to make a few remarks regarding the characterization of the products of these reactions. Theoretically, three possible products could have been obtained from the alkylative cyclization of the octalones **22** and **23**: the enone **34** (derived from α′ alkylation), the β,γ-unsaturated ketone **35** (α alkylation), and the enone **36** (γ alkylation) (see Scheme 4). In fact, subjection of **22** and **23** to intramolecular alkylation under a variety of experimental conditions (*vide infra*) afforded only two different products. On the basis of spectral data obtained from pure samples of these products, it was clear that one of them was the β,γ-unsaturated ketone **35**, the product of α alkylation. However, although **35** could be distinguished readily from the other possible products **34** and **36**, a similar distinction between the latter two compounds (both α,β-unsaturated ketones) was not at all straightforward, since one would expect the spectral data obtained from these two substances to be very similar. This problem of determining the identity of the second alkylation product was solved by means of chemical transformations.

Subjection of the α alkylation product **35** to a modified Wolff–Kishner reduction procedure (14) gave the tricyclic olefin **37**. Allylic oxidation of the latter with chromium trioxide – dipyridine complex in dichloromethane (15) afforded the α,β-unsaturated ketone **36**, the compound which would have been derived from γ alkylation of the octalones **22** and **23**. Spectral data clearly showed that the oxidation product **36** was different from the α,β-unsatu-



SCHEME 4

rated ketone **34** which was obtained from the alkylation reactions.

When the mesyloxymethyl octalone **24** was subjected to intramolecular alkylation under a variety of experimental conditions (*vide infra*), the sole product obtained in most cases was the α,β-unsaturated ketone **11** (γ alkylation). This compound had been obtained and characterized previously by Mukharji and Ganguly (5). To further confirm the structural assignment, compound **11** was subjected to base-catalyzed deuteration. Mass spectral analysis of the product **38** showed that two deuterium atoms had been incorporated into the molecule. It is clear that if the original alkylation product had been that derived from α′ alkylation (the α,β-unsaturated ketone **39**), the deuteration experiment would have produced the trideuterio derivative **40**.

Intramolecular alkylation of **24** with potassium *tert*-butoxide in hexamethylphosphoramide (*vide infra*) gave a major product different from **11**. Spectral analysis of this material showed clearly that it was the β,γ-unsaturated ketone **41**, the product of α alkylation.

Intramolecular Alkylation Studies. Results and Discussion

The two halo enones **22** and **23** were subjected to intramolecular alkylation under a variety of experimental conditions and the results are summarized in Table 1. In similar fashion, the results obtained from alkylative cyclization of the mesyloxy enone **24** are tabulated in Table 2.

From the data summarized in Tables 1 and 2, it is clear that there was considerable variation in the relative amounts of α′, α, and γ alkylation, this variation depending on the nature of the substrate and on the experimental conditions used. On the one hand, it is of interest to try to understand the product ratio variation for each individual substrate as a function of reaction conditions. Even more intriguing, however, is the extraordinary contrast between the internal alkylations of compounds **22** and **23** as compared with those of the enone **24**. The former substrates yielded varying amounts of α and α′ alkylation but no γ alkylation, whereas the latter substance gave only α and γ alkylation products (no α′ alkylation).

The framework in which one must endeavor to understand these intramolecular alkylations is given in Scheme 5. The main features of this scheme may be summarized as follows. Deprotonation of the ketone **42** can, in principle, give rise either to the α′ enolate anion **43** or to the resonance delocalized dienolate anion **44**. It has been well established that kinetically controlled deprotonation takes place on the α′ position to give an anion of the type **43** (1) but that the thermodynamically more stable anion is that

of the type **44**, reached by subsequent proton transfer equilibration. Anion **43** would subsequently alkylate to give the α′ products (**34** or **39**) and anion **44** would alkylate to afford either or both of the α (**35**, **41**) and γ (**36**, **11**) alkylation products. It is clear, then, that the competition between rates of anion equilibration and of alkylation may represent a key point in understanding these reactions. Consideration of the various individual results follow.

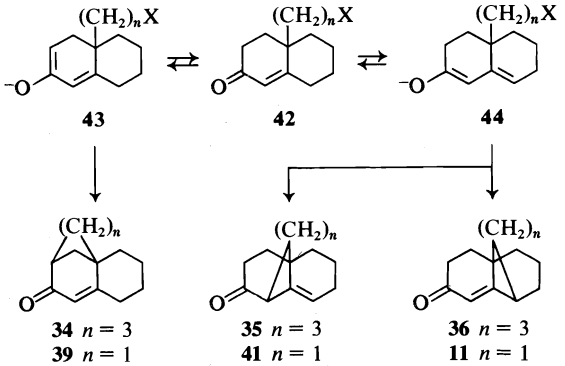
(a) Internal Alkylation of Compound 22

(i) Use of LDA–HMPA in THF (Table 1, Entry 7)

Under conditions where equilibration of the anion **43** does not occur, it is clear that the only possible internal alkylation product is the α′ product **34**. The title conditions are known to meet this criterion (1) and, indeed, the experimental results confirm exclusive formation of compound **34**.

(ii) Use of Me_3COK in Me_3COH (Table 1, Entry 1)

At the other end of the reaction condition spectrum, the conditions involving potassium *tert*-butoxide in the protic solvent *tert*-butyl alcohol are known to effect equilibration between ions of the type



SCHEME 5

43 and **44** (2). Equilibration of this sort does not, however, necessarily allow for an *a priori* prediction of which product (α′ or α,γ) would predominate. Even though ion **44** predominates, it would still be possible for α′ alkylation to be significant, or even predominate, if α′ alkylation happened to be a substantially lower energy barrier process (Curtin–Hammett principle (16)). As it happens, the experimentally obtained result was an 88:12 ratio in favor of α alkylation; two explanations are possible for the significant amount of α′ alkylation. On the one hand, anion equilibration might be complete and this product ratio might simply represent the alkylation of the equilibrium mixture as indicated above (Curtin–Hammett). On the other hand, the significant amount of α′ alkylation product might be derived from significant remaining amounts of α′ anion **43**, owing to incomplete anion equilibration. Although this one result obviously does not allow distinction between these possibilities, consideration of subsequent results favours the second explanation and the following results will be discussed in terms of the rate competition between anion equilibration and anion alkylation.

(iii) Use of Me_3COK in THF (Table 1, Entry 3)

The use of tetrahydrofuran as solvent (entry 3) in place of *tert*-butyl alcohol (entry 1) essentially reversed the α to α′ product ratio, giving an 85:15 ratio in favor of α′ alkylation. This result is clearly consistent with slower anion equilibration in the aprotic solvent and thus an increased alkylation to equilibration rate ratio of the initially formed anion (**43**).

(iv) Effect of Cation and of Cation-complexing Solvents and Reagents (Table 1, Entries 2, 4, 5, 6, 8)

Use of these reagents had a substantial and expected effect on the rate of reaction, as represented crudely by the time required for completion of the

alkylation (Tables 1 and 2). Use of cation complexing reagents either as additive (18-crown-6) or solvent (hexamethylphosphoramide) increased the activity of the anion and decreased the required reaction time to 15 min or less. In contrast, decreasing the activity of the anion by the greater coordination of Li^+ led to the necessity of a 6-h reflux to complete the alkylation reaction. Inspection of the results shows that the α to α′ product ratio is correlated with this experimentally variable anion activity. Proceeding from entry 1 to entry 2, it is seen that the effect of 18-crown-6 was to increase the α to α′ product ratio from a value of 88:12 to 95:5. Similarly, in aprotic solvents the relative amount of α alkylation product **35** increased from 15% (tetrahydrofuran, entry 3) to 35% (addition of 18-crown-6, entry 4) and up to 81% when hexamethylphosphoramide was used as total solvent (entry 5). In contrast, proceeding from entry 1 to entry 6, it is seen that the retarding effect of the lithium cation reduced the α to α′ product ratio from 88:12 to 57:39.

These results are characterized by greater anion activity being associated with an increased α to α′ product ratio and diminished anion activity being associated with a decreased α to α′ product ratio. The simplest rationalization of these results appears to be in terms of competition between the rate of equilibration of the anion **43** to anion **44** with the rate of alkylation. This is a classic case of competition between the anion acting as a base or as a nucleophile, respectively, and the results are consistent with the idea that increased anion activity accelerated both equilibration and alkylation, but that the rate of equilibration was affected to a greater extent than that of alkylation. Thus, for example, in circumstances where the anion activity was increased, this caused increased equilibration relative to alkylation and resulted in an increased α to α′ product ratio.

It should be emphasized that the above generalizations, although they appear to be the most reasonable rationalization of the experimental results, are based only on product ratios and approximate times for completion of reaction and should not be confused with a proven explanation. They do, however, at least provide a useful framework within which product ratios may be predicted and experimentally manipulated. Consideration of these generalizations, for example, leads to the use of the combination of experimental conditions and low temperature for increased selectivity, in order to achieve an alkylation in which α′ alkylation is entirely suppressed (Table 1, entry 8).

(b) Internal Alkylation of Compound ***23****. Effect of Leaving Group*

Continuing the consideration of these internal alkylations in terms of the rate competition between anion equilibration and alkylation, it is clear that the nature of the leaving group would have a more clear-cut and predictable effect. Although the variation of conditions mentioned above affected the rates of both equilibration *and* alkylation, the nature of the leaving group would, to a first approximation, affect only the rate of alkylation. The prediction of the effect of increasing the leaving group ability of X (cf. **42**) by the use of iodine in the place of chlorine (17), is that the rate of alkylation would be increased relative to that of equilibration, thus giving rise to increased α′ alkylation. The experimental results indicate a dramatic shift in this direction. Comparison of entry 9 with entry 1 (Table 1) shows that under identical experimental conditions, compound **23** (chloride as leaving group) gave 88% α alkylation while enone **23** (iodide as leaving group) produced only the α′ alkylation product. To explore the degree to which the latter result could be manipulated, conditions which caused increased α alkylation in the case of compound **22** were applied to **23** (entries 10, 11). Some α alkylation product was indeed obtained under these conditions but a maximum of only 22%.

(c) The Absence of γ Alkylation

Although the dienolate anion **44** could, in principle, alkylate both at the α and at the γ position,[6] no detectable amounts of γ alkylation product were formed in the internal alkylation of compounds **22** and **23**. One of us has previously found it useful to consider the *C*- vs. *O*-alkylation of ambident anions in terms of the nature of the transition state (18) and the same type of consideration seems appropriate also in this regioselectivity question. If the transition state of the alkylation process were essentially reactantlike, a dominating factor in determining the α to γ product ratio would be the electron density at these positions in the anion **44** and thus one would expect predominant formation of the α alkylation product **35**. If, on the other hand, the transition state were productlike, factors affecting product stability would also be felt in the transition state, and thus, for purely kinetic reasons, one would obtain the more stable product, in this case the conjugated ketone arising from γ alkylation (compound **36**).

In this framework, the experimental observation of exclusive α alkylation is unremarkable. The product-determining reaction involves the conversion of a reactive intermediate **44** into a stable product (**35** and/or **36**). Application of Hammond-postulate (19) reasoning to this situation leads to the expectation

[6]It is also conceivable that both anions **43** and **44** could undergo *O*-alkylation. However, these processes would result in the formation of compounds having a double bond at a bridgehead.

of a reactantlike transition state and, therefore, α alkylation.

(d) Internal Alkylation of Compound **24**

(i) Use of Me_3COK in Me_3COH (Table 2, Entry 1)

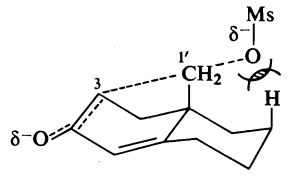
Intramolecular alkylation of the mesyloxy enone **24** under these conditions gave exclusively the γ alkylation product **11**. This result is in sharp contrast to the alkylative cyclization of compounds **22** and **23** under the same conditions (Table 1, entries 1, 9). In the case of compound **24**, not only was α′ alkylation completely suppressed but the product derived from the dienolate anion **44** ($n = 1$) was exclusively the γ alkylation product **11**, whereas with **44** ($n = 3$, derived from **22**) only α alkylation occurred.

(ii) Other Conditions

Use of other reaction conditions (Table 2, entries 2, 3, 4, 5), which had caused variation of the alkylation product ratio in the case of compound **22** caused no variation when applied to compound **24**. In each case the only detectable alkylation product was that of γ alkylation, compound **11**. Most noteworthy is the reaction employing lithium diisopropylamide as base, conditions which gave 100% α′ alkylation of compound **22** (Table 1, entry 7). These conditions gave no reaction with compound **24** at room temperature, and when forced, using a 2-day reflux, again gave exclusively γ alkylation (Table 2, entry 5).

(iii) Absence of α′ Alkylation

The absence of α′ alkylation in the case of compound **24**, a striking difference in comparison with the behaviour of the enones **22** and **23**, requires comment. The fact that using lithium diisopropylamide as base, conditions which normally give rapid and exclusive α′ alkylation, gave no reaction except under forcing conditions, clearly indicates a substantial barrier to internal α′ alkylation in the case of compound **24**. Molecular models indicate the probable origin of this barrier to be steric interaction between the leaving mesylate group and the axial hydrogen at C-6. (cf. **45**). The recent formulation of the Baldwin



45

rules (20) have highlighted the critical importance of maintaining the appropriate geometry in displacement reactions. In the case of α′ alkylation of compound **24** this is the angle C-3—C-1′—OMs, which must be 180° (cf. **45**). Since both C-3 and C-1′ are more or less fixed in space, the direction of leaving of the mesylate group is rigidly controlled and heads directly to within the van der Waals radius of the axial hydrogen at C-6. Postulation of this steric repulsion to leaving is clearly a rationalization similar to the suggestion of Brown and co-workers to the leaving of 2-*endo* substituents from norbornyl derivatives (21). It is noteworthy that although the angles of departure of the mesylate group in α and γ alkylation of compound **24** are also fixed, the line of departure does not encounter such steric interference. In addition, the flexibility of the three-carbon side chain in compounds **22** and **23** renders the steric hindrance factor irrelevant for these substances. Thus, the resistance to α′ alkylation is peculiar to compound **24**.

(iv) Predominant γ Alkylation

In the alkylative cyclization of compounds **22** and **23**, the competition between α and γ alkylation was totally in favor of the α pathway. We rationalized this observation in terms of a reactantlike transition state, based on a Hammond postulate analysis (see (c), above). Clearly in order to account for the fact that internal alkylation of **24** under conditions summarized in Table 2, entries 1–5, gave only γ alkylation product, this rationalization must be modified. For a reactantlike transition state, the ideal conditions are the reaction of a reactive intermediate, via a small barrier, to a stable product. Although these conditions are met in the internal alkylation of compounds **22** and **23**, there are two modifying factors which must be considered in the alkylation of compound **24**. Firstly, because of the formation of the strained four-membered ring, the energy barrier to reaction is increased and, secondly, for the same reason, the stability of the product is reduced. Thus, the reaction has a higher activation energy and is less exothermic, and the Hammond postulate prediction is that of a transition state that is less reactantlike. Evidently the transition state shift in going from compounds **22** and **23** to compound **24** was sufficiently large so that the product stability factor in the transition state predominated over the electron density factor.

(v) Formation of the α Alkylation Product

If the above transition state argument has any validity, then the way in which it might be possible to induce α alkylation of the mesyloxy enone **24** would be to use conditions in which the transition state would be more reactantlike. Two factors are significant here: the energy barrier to reaction and the exothermicity of the process. The former can be reduced and the latter increased simultaneously by using conditions which would generate a more reactive anion. This approach proved to be successful. When **24** was treated with potassium *tert*-butoxide

in hexamethylphosphoramide (Table 2, entry 6), the predominant process became that of α alkylation (ratio of **41**:**11** = 80:20). Addition of 18-crown-6 to render the anion even more 'free' further increased this ratio to 92:8 (Table 2, entry 7).

Conclusions

It was found that internal alkylation of compounds **22** and **23** involved a competition between α and α′ alkylation. This competition is most easily rationalized in terms of competition between the relative rates of anion equilibration and irreversible alkylation. Exclusive formation of α′ product required either a good leaving group (compound **23**) or conditions in which anion equilibration was suppressed (lithium diisopropylamide in aprotic solvent). Predominant formation of the α product required a poorer leaving group (compound **22**), and the maximum reactivity of the anion, since fortunately, increased anion reactivity (hexamethylphosphoramide, 18-crown-6) apparently increased the rate of anion equilibration more than it did the rate of alkylation. No γ alkylation of compounds **22** and **23** was observed; this can be rationalized in terms of a reactantlike transition state.

Internal alkylation of compound **24** was apparently governed by entirely different considerations. Steric requirements of the leaving group are considered to be responsible for the total lack of α′ alkylation. Furthermore, the strain induced by the formation of the four-membered ring is considered to give rise to a less reactantlike transition state, leading to the exclusive formation of the γ alkylation product under most conditions. Raising the anion reactivity (hexamethylphosphoramide, 18-crown-6) can, apparently, restore some of the reactantlike nature of the transition state, leading to α alkylation predominating to the extent of 92%.

It is clear from the results described in this paper that it is indeed possible to control, at least to some extent, the site of intramolecular alkylation of a specific α,β-unsaturated ketone. Since each different mode of internal alkylation produces a product possessing a distinctive carbon skeleton, it is also clear that this control has obvious synthetic implications.

Experimental

General

Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected. Infrared spectra were recorded on a Perkin-Elmer model 710 spectrophotometer. Proton magnetic resonance spectra were measured using Varian Associates spectrometers, models T-60 and/or HA-100 or XL-100. Signal positions are given in δ units, with tetramethylsilane as the internal standard; the multiplicity, integrated peak areas and proton assignments are indicated in parentheses. High resolution mass spectrometric measurements were recorded on an A.E.I. model MS-50 mass spectrometer. Gas–liquid chromatographic analyses were carried out with a Hewlett-Packard model 5832A gas chromatograph containing a 6 ft × 0.125 in. column (5% OV-17 on 80–100 mesh HP Chromosorb W). Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver, B.C.

Preparation of Substrates for Intramolecular Alkylation Studies

*4a-Allyl-4,4a,5,6,7,8-hexahydro-2(3*H*)-naphthalenone (26)*

To a cold (−10°C), efficiently stirred mixture of 3 *N* methanolic sodium methoxide (3 mL) and 2-allylcyclohexanone (**25**) (10) (100 g, 0.72 mol) were added, over a period of 2 h, 54 g (0.77 mol) of methyl vinyl ketone. The reaction mixture was stirred at −10°C for 24 h. The thick, creamy mixture was diluted with water and the resultant mixture was extracted thoroughly with ether. The combined ether extract was washed with brine and dried over anhydrous magnesium sulfate. Removal of the ether gave ~180 g of crude oil. This material was dissolved in 5% methanolic sodium methoxide and the resulting solution was refluxed for 2 h and then cooled. The base was neutralized by addition of glacial acetic acid and the solvent was removed under reduced pressure. The residue was dissolved in ether and the resultant solution was washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent gave a yellow oil. Distillation of the latter gave 50 g of 2-allylcyclohexanone, bp 100–105°C/19 Torr, and 46 g (67%, based on unrecovered starting material) of the octalone **26**, bp 110–115°C/0.4 Torr; ir (film): 1675, 1620, 910 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.95–2.88 (diffuse, 14H), 4.77–6.17 (diffuse, 4H). *Anal.* calcd. for $C_{13}H_{18}O$: C 82.06, H 9.53; found: C 81.90, H 9.77.

Preparation of the Ketal Diene 27

A solution of the octalone **26** (5 g, 26.3 mmol), ethylene glycol (4.6 ml, 75.0 mmol), and *p*-toluenesulfonic acid (100 mg) in 160 mL of benzene was refluxed under a Dean–Stark water separator for 18 h. The cooled solution was washed successively with aqueous sodium bicarbonate and brine, and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air bath temperature 135–145°C/0.5 Torr) of the residual oil, gave 5.5 g (92%) of the ketal diene **27**; ir (film): 1640, 1090, 905 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 3.92 (s, 4H, ketal protons), 4.76–6.10 (diffuse, 4H, olefinic protons). *Exact mass* calcd. for $C_{15}H_{22}O_2$: 234.1618; found: 234.1620.

Preparation of the Ketal Alcohol 28

To a cold (0°C), stirred solution of 2-methyl-2-butene (14.3 mL, 0.131 mol) in 100 mL of tetrahydrofuran under an atmosphere of nitrogen was added 6.72 mL (0.065 mol) of borane – dimethyl sulfide complex. After the solution had been allowed to stir at 0°C for 1 h, a solution of the ketal diene **27** (5.0 g, 0.021 mol) in 40 mL of tetrahydrofuran was added. The resulting reaction mixture was allowed to stir at room temperature for 2 h and was then cooled again to 0°C. To this cold solution was added, successively and dropwise, 85 mL of 3 *N* aqueous sodium hydroxide and 85 mL of 30% aqueous hydrogen peroxide. The resulting mixture was allowed to warm to room temperature and was stirred for 3 h. Most of the solvent was removed under reduced pressure and the residual material was diluted with water and then thoroughly extracted with ether. The combined ether extract was washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent gave an oil which was subjected to column chromatography on silica gel. Elution with mixtures of petroleum ether and ether produced 4.6 g (70%) of the ketal alcohol **28** as a colorless oil. An analytical sample of this material, obtained by preparative glc, exhibited ir (film): 3450, 1090 cm^{-1}; ^1H nmr

($CDCl_3$) δ: 3.60 (poorly resolved t, 2H, —CH_2OH), 3.98 (s, 4H, ketal protons), 5.46 (broad m, 1H, olefinic proton). *Exact mass* calcd. for $C_{15}H_{24}O_3$: 252.1726; found: 252.1726.

*Preparation of 4a-(3-Chloropropyl)-4,4a,5,6,7,8-hexahydro-2(3H)-naphthalenone (**22**)*

To an ice cold solution of the ketal alcohol **28** (3 g, 11.9 mmol) and methanesulfonyl chloride (1.5 g, 13 mmol) in 80 mL of dry dichloromethane was added, dropwise, 1.8 g of triethylamine. The solution was allowed to stir under an atmosphere of nitrogen for 1 h and then poured into ice water. The resultant mixture was extracted with dichloromethane. The combined extract was washed with water and dried over anhydrous magnesium sulfate. Removal of the solvent gave 3.8 g (97%) of the crude ketal mesylate **29** which exhibited ir (film): 1450, 1350, 1170, 1090 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 3.03 (s, 3H, —OSO_2CH_3), 3.98 (broad s, 4H, ketal protons), 4.28 (t, 2H, —CH_2—OMs, J = 7 Hz), 5.50 (broad m, 1H, olefinic proton). This material was not purified further.

A solution of the crude ketal mesylate **29** (3.8 g, 11.2 mmol) and anhydrous lithium chloride (2.5 g, 60 mmol) in dry acetone was refluxed for 18 h. Most of the solvent was removed under reduced pressure and the residual material was diluted with water and then thoroughly extracted with ether. The combined ether extract was washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent gave the crude ketal chloride **30** (2.8 g, 87% from the ketal alcohol **28**) as a slightly yellow oil. This material, which was not purified further, exhibited ir (film): 1450, 1090 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 3.50 (m, 2H, —CH_2Cl), 3.97 (s, 4H, ketal protons), 5.47 (m, 1H, olefinic proton).

To a solution of the crude ketal chloride **30** (2.8 g, 10.4 mmol) in 20% aqueous acetone was added 0.3 mL of sulfuric acid and the resulting solution was refluxed for 14 h. After the solution had been cooled, solid sodium bicarbonate was added and most of the solvent was removed under reduced pressure. The residual mixture was diluted with water and then thoroughly extracted with ether. The combined ether extract was washed with water and dried over anhydrous magnesium sulfate. Removal of the solvent gave a crude oil which was subjected to column chromatography on silica gel. Elution of the column with mixtures of petroleum ether and ether afforded 2.1 g (78% from the ketal alcohol **28**) of the chloro octalone **22**, which was further purified by distillation (air bath temperature 125–130°C/0.03 Torr). This material exhibited ir (film): 1660, 1620, 1450 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.07–2.60 (diffuse, 16 H), 3.57 (m, 2H, —CH_2Cl), 5.82 (broad s, 1H, olefinic proton). *Exact mass* calcd. for $C_{13}H_{19}{}^{35}ClO$: 226.1124; found: 226.1120.

*Preparation of 4a-(3-Iodopropyl)-4,4a,5,6,7,8-hexahydro-2(3H)-naphthalenone (**23**)*

A stirred solution of the crude ketal mesylate **29** (1.2 g, 3.6 mmol), sodium iodide (18 mmol), and sodium bicarbonate (4 mmol) in acetone was refluxed for 20 h. Most of the solvent was removed under reduced pressure. The residual material was diluted with water and then thoroughly extracted with ether. The combined ether extract was washed successively with water, brine, aqueous sodium thiosulfate, and water, and dried over anhydrous magnesium sulfate. Removal of the solvent afforded the crude ketal iodide **31**. This material was dissolved in 40 mL of 10% aqueous acetone and 0.15 mL of sulfuric acid was added to the resultant solution. The solution was refluxed for 18 h. After solid sodium bicarbonate had been added to the cooled solution, most of the solvent was removed under reduced pressure. The residual material was diluted with water and then extracted thoroughly with ether. The combined ether extract was washed with water and dried over anhydrous magnesium sulfate. Removal of the solvent afforded a white crystalline material which, upon recrystallization from a mixture of petroleum ether and ether, gave 350 mg (36%) of the iodo octalone **23** as white needles, mp 60–61°C; ir ($CHCl_3$): 1665, 1620 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.03–2.57 (diffuse, 16 H), 3.17 (m, 2H, —CH_2I), 5.73 (broad s, 1H, olefinic proton). *Exact mass* calcd. for $C_{13}H_{19}IO$: 318.0484; found: 318.0482.

*Preparation of 4a-Mesyloxymethyl-4,4a,5,6,7,8-hexahydro-2(3H)-naphthalenone (**24**)*

To a cold (0°C), stirred solution of the ketal alcohol **32** (13) (2.24 g, 10 mmol) and methanesulfonyl chloride (12 mmol) in 70 mL of dichloromethane under an atmosphere of nitrogen was added, dropwise, 18 mmol of triethylamine. After the solution had been allowed to stir at 0°C for 45 min, it was poured into ice water and the resulting mixture was extracted thoroughly with dichloromethane. The combined extract was dried over anhydrous magnesium sulfate. Removal of the solvent afforded a quantitative yield of the crude ketal mesylate **33** as an oily solid. An analytical sample of **33**, obtained by recrystallization of a small amount of this material from ether – petroleum ether, exhibited mp 102–102.5°C; ir ($CHCl_3$): 1350. 1170, 1090, 940 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 3.00 (s, 3H, —OSO_2CH_3), 3.84 (s, 4H, ketal protons), 4.20 (m, 2H, —CH_2OMs), 5.60 (m, 1H, olefinic proton). *Exact mass* calcd. for $C_{14}H_{22}O_5S$: 302.1188; found: 302.1173.

To a solution of the crude ketal mesylate **33** (obtained as described above) in 60 mL of 10% aqueous acetone was added, dropwise, 1 mL of sulfuric acid, and the resulting solution was refluxed for 24 h. Solid sodium bicarbonate was added to the cooled solution and most of the acetone was removed under reduced pressure. The residual material was diluted with water and extracted with ether. The combined extract was washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by recrystallization of the resulting crystalline material from carbon tetrachloride – hexane, gave 1.75 g (68% from the ketal alcohol **32**) of the mesyloxy octalone **24**, mp 98–99°C; ir ($CHCl_3$): 1670, 1620, 1350, 1170, 980, 940 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 3.00 (s, 3H, —OSO_2CH_3), 4.33 (s, 2H, —CH_2OMs), 5.80 (s, 1H, olefinic proton). *Exact mass* calcd. for $C_{12}H_{18}O_4S$: 258.0926; found: 258.0918.

Intramolecular Alkylation Experiments

Base: Potassium tert-*Butoxide; Solvent:* tert-*Butyl Alcohol (Table 1, Entries 1,2,9,10; Table 2, Entries 1, 2)*

To a solution of potassium *tert*-butoxide (2.0 mmol) and, where appropriate, 18-crown-6 (2.0 mmol) in dry *tert*-butyl alcohol (20 mL) under an atmosphere of nitrogen was added a solution of the appropriate octalone (**22**, **23**, or **24**) (1.0 mmol) in 20 mL of dry *tert*-butyl alcohol and the resulting solution was stirred at the desired temperature for the designated length of time. The solution was poured into ice cold 0.1 *N* hydrochloric acid and the resultant mixture was extracted thoroughly with ether. The combined extract was washed successively with water and brine and dried over anhydrous magnesium sulfate. Removal of the solvent afforded a crude oil which was subjected to glc analysis in order to determine the ratio of products. At this point, 1.0 mmol of a standard compound (10-methyl-$\Delta^{1(9)}$-octal-2,5-dione, Wieland–Miescher ketone (22))[7] was added to the crude product and the resultant mixture was analyzed by glc to determine the (glc) yield of the products.

[7]This compound was chosen as a standard because it was found to possess a glc molar response factor (thermal conductivity detector) essentially identical with those of the various alkylation products. Also, its retention time was different from that of each of the alkylation products.

Finally, the entire mixture was subjected to bulb-to-bulb distillation under reduced pressure and the isolated yield of the products was determined by subtracting the weight of the standard compound which had been added from the total weight of distilled material.[8]

Base: Potassium tert-*Butoxide; Solvent: Tetrahydrofuran (Table 1, Entries 3, 4; Table 2, Entry 3)*

A solution of potassium *tert*-butoxide (2.0 mmol) in 20 mL of *tert*-butyl alcohol was distilled, under an atmosphere of nitrogen, until most of the alcohol had been removed. The remaining solvent was removed by warming the flask under reduced pressure (vacuum pump). To the residual potassium *tert*-butoxide was added successively 20 mL of dry tetrahydrofuran, 18-crown-6 (2.0 mmol, when desired) and a solution of 1.0 mmol of the appropriate octalone (**22** or **24**) in 20 mL of tetrahydrofuran. After the resultant solution had been stirred at the desired temperature for the appropriate length of time, it was subjected to work-up and analysis procedures identical with those described above.

Base: Potassium tert-*Butoxide; Solvent: Hexamethylphosphoramide (Table 1, Entry 5; Table 2, Entries 6, 7)*

To 2.0 mmol of dry potassium *tert*-butoxide (prepared as described above) under an atmosphere of nitrogen was added successively 20 mL of dry hexamethylphosphoramide, 2.0 mmol of 18-crown-6 (when desired), and a solution of 1.0 mmol of the appropriate octalone (**22** or **24**) in 20 mL of dry hexamethylphosphoramide. After the resultant solution had been stirred at the desired temperature for the designated length of time, it was subjected to work-up and analysis procedures identical with those described above, except that product extraction was done with petroleum ether instead of with ether.

Base: Potassium tert-*Butoxide; Solvent:* tert-*Butyl Alcohol – Tetrahydrofuran (40:60) (Table 1, Entries 8, 11)*

To a cold (−78°C), stirred solution of potassium *tert*-butoxide (2.0 mmol) and, where appropriate, 18-crown-6 (2.0 mmol) in 32 mL of a 1:1 mixture of dry *tert*-butyl alcohol and dry tetrahydrofuran, under an atmosphere of nitrogen, was added slowly a solution of 1.0 mmol of the appropriate octalone (**22** or **23**) in 8 mL of dry tetrahydrofuran. After the resultant solution had been stirred at −78°C for 30 min, it was allowed to warm to room temperature and then stirred for an additional 15 min. Work-up and analysis procedures were identical with those described above.

Base: Lithium tert-*Butoxide; Solvent:* tert-*Butyl Alcohol (Table 1, Entry 6; Table 2, Entry 4)*

To 20 mL of dry *tert*-butyl alcohol, under an atmosphere of nitrogen, was added successively 2.0 mmol of *n*-butyllithium (hexane solution) and a solution of 1.0 mmol of the appropriate octalone (**22** or **24**) in 20 mL of dry *tert*-butyl alcohol. After the resultant solution had been refluxed for the designated length of time, it was cooled and subjected to work-up and analysis procedures identical with those described above.

Base: Lithium Diisopropylamide; Solvent: Tetrahydrofuran (Table 1, Entry 7; Table 2, Entry 5)

To a stirred solution of diisopropylamine (2.2 mmol) and hexamethylphosphoramide (2.0 mmol) in 20 mL of dry tetrahydrofuran, under an atmosphere of nitrogen, was added 2.0 mmol of *n*-butyllithium (hexane solution). A solution of 1.0 mmol of the appropriate octalone (**22** or **24**) in 20 mL of dry tetrahydrofuran was added and the resultant reaction mixture was kept at the required temperature for the designated period of time. The solution was cooled to 0°C and subjected to work-up and analysis procedures identical with those described above.

Isolation and Characterization of Intramolecular Alkylation Products

The α,β-Unsaturated Ketone ***34***

Distillation (air bath temperature 115–125°C/0.2 Torr) of the crude product obtained from an experiment as summarized in Table 1, entry 9, afforded (94%) the tricyclic α,β-unsaturated ketone **34** as a clear colorless oil which exhibited one peak on glc; ir (film): 1670, 1618 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.73–2.70 (diffuse, 17H), 6.02 (s, 1H, vinyl proton). *Exact mass* calcd. for $C_{13}H_{18}O$: 190.1357; found: 190.1363.

The β,γ-Unsaturated Ketone ***35***

The distilled product obtained from an experiment as summarized in Table 1, entry 2 (ratio of **34**:**35** ≈ 5:95) was subjected to column chromatography on silica gel. Elution of the column with ether – petroleum ether gave a pure sample of the tricyclic β,γ-unsaturated ketone **35**; ir (film): 1710 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.90–2.63 (diffuse, 16H), 2.87 (broad s, 1H), 5.56 (t, 1H, olefinic proton, J = 4.0 Hz). *Exact mass* calcd. for $C_{13}H_{18}O$: 190.1357; found: 190.1352.

Wolff–Kishner Reduction of the β,γ-Unsaturated Ketone ***35***

To 25 mL of anhydrous diethylene glycol, under an atmosphere of nitrogen, was added 0.84 g (36.5 mmol) of sodium metal and the mixture was stirred until all of the sodium had reacted. Anhydrous hydrazine (prepared by refluxing hydrazine hydrate over sodium hydroxide) was distilled directly into the resulting solution until the latter refluxed freely at 165°C. The solution was cooled and 470 mg (2.47 mmol) of the tricyclic ketone **35** was added. The mixture was refluxed for 12 h and excess hydrazine was distilled (the distillate was saved) from the mixture until the internal temperature of the latter reached 210°C. Refluxing was then continued for an additional 8 h. The mixture was cooled, combined with the distillate (see above), and then poured into water. The resulting mixture was extracted with petroleum ether. The combined extract was washed with water and dried over anhydrous magnesium sulfate. Removal of the solvent gave a colorless oil which upon distillation (air bath temperature 135–140°C/7.0 Torr) afforded 0.35 g (90%) of the tricyclic olefin **37**; ir (film): 1665 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.13–2.50 (diffuse, 19H), 5.30 (t, 1H, olefinic proton, J = 4.0 Hz). *Exact mass* calcd. for $C_{13}H_{20}$: 176.1565; found: 176.1572.

Preparation of the α,β-Unsaturated Ketone ***36***

To a solution of chromium trioxide – dipyridine complex (16.7 mmol) in 40 mL of dry dichloromethane, under an atmosphere of nitrogen, was added a solution of the tricyclic olefin **37** (0.195 g, 1.11 mmol) in 5 mL of dichloromethane. The resulting mixture was stirred at room temperature for 6 h, was filtered through Celite, and the filtrate was passed through a short column of activity III neutral alumina. The column was washed with additional volumes of dichloromethane. The combined eluant was washed successively with water, 3 *N* hydrochloric acid, and water and then dried over anhydrous magnesium sulfate. Removal of the solvent followed by distillation (air bath temperature 135°C/0.2 mm) of the residual oil gave 0.180 g (86%) of the tricyclic α,β-unsaturated ketone **36** as a colorless oil; ir (film): 1670, 1630 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.13–2.83 (diffuse, 17H), 5.78 (s, 1H, olefinic proton). *Exact mass* calcd. for $C_{13}H_{18}O$: 190.1357; found: 190.1357.

[8]The boiling point of the Wieland–Miescher ketone was very near to, although somewhat lower than, those of the various alkylation products.

The α,β-Unsaturated Ketone ***11***

The crude product obtained from an experiment as summarized in Table 2, entry 1, was distilled (hot box) under reduced pressure, affording, in 74% yield, the pure tricyclic α,β-unsaturated ketone **11** (5); ir (film): 1660 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 5.75 (s, 1H, olefinic proton). *Exact mass* calcd. for $C_{11}H_{14}O$: 162.1045; found: 162.1038.

The β,γ-Unsaturated Ketone ***41***

The crude product obtained from an experiment as summarized in Table 2, entry 7, was distilled (hot box) under reduced pressure, affording, in 75% yield, a clear oil which was shown (glc analysis) to consist of two components in a ratio of approximately 92:8. Subjection of this mixture to preparative glc gave a very small amount of the minor component (identical with the enone **11**) and a sample of the pure tricyclic β,γ-unsaturated ketone **41**; ir (film): 1720 cm^{-1}; ^1H nmr ($CDCl_3$) δ: ~2.5 (m, 2H, $-CH_2C(=O)-$), 3.55 (t, 1H, $-CH-C(=O)-$), 5.35 (t, 1H, olefinic proton). *Exact mass* calcd. for $C_{11}H_{14}O$: 162.1045; found: 162.1053.

Deuteration of the α,β-Unsaturated Ketone ***11***

To a solution of 40 mg of the α,β-unsaturated ketone **11** in 1.0 mL of 1,2-dimethoxyethane was added 0.5 mL of deuterium oxide and a catalytic amount of potassium hydroxide. The solution was stirred at room temperature for 3 days. A small amount of acetic acid was added and the resultant mixture was extracted with ether. The combined extract was washed successively with water, aqueous sodium bicarbonate and brine, and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (hot box, reduced pressure) of the residual oil gave 32 mg of the dideutero derivative **38**. *Exact mass* calcd. for $C_{11}H_{12}D_2O$: 164.1170; found: 164.1164.

A study of ^{14}N relaxation and nitrogen–proton spin coupling in Watson–Crick base pair models through Fourier transform measurements on NH proton spin–lattice relaxation in the rotating frame

MICHAEL E. MOSELEY AND PETER STILBS

Department of Physical Chemistry, Uppsala University, Box 532, S-751 21 Uppsala, Sweden

Received August 14, 1978

MICHAEL E. MOSELEY and PETER STILBS. Can. J. Chem. **57**, 1075 (1979).

Indirect measurements of nitrogen-14 nuclear spin–lattice relaxation times and direct proton coupling constants are presented together with carbon-13 T_1 data for a series of alkyl-substituted nucleic acid bases and mixtures thereof in DMSO-d_6. With the exception of the guanine NH nitrogen, which possibly experiences a decrease in the electric field gradient upon complexation with cytosine, no indications of significant changes in the electronic environment around the nitrogen nuclei were found for any combination of bases. Forsén–Hoffman spin saturation transfer experiments on the NH and NH_2 protons are also presented.

MICHAEL E. MOSELEY et PETER STILBS. Can. J. Chem. **57**, 1075 (1979).

On rapporte des mesures indirectes de temps de relaxation spin–nucléaire réseau de l'azote-14 et des mesures directes de constantes de couplage du proton ainsi que des données de T_1 pour le ^{13}C pour une série de bases d'acides nucléiques substitués par des groupes alkyles et de leurs mélanges dans le DMSO-d_6; aucune des combinaisons de bases ne semble conduire à des changements importants dans l'environnement électronique autour du noyau d'azote. On rapporte aussi des expériences de transferts de saturation de spin de Forsén–Hoffman sur des protons NH et NH_2.

[Traduit par le journal]

Introduction

Despite a great body of knowledge concerning the static structure of the inherent specific interaction between complementary nucleic acid bases, in which adenine specifically hydrogen bonds with thymine and cytosine with guanine, very little is known about the dynamic properties of the base pairs or of how the bonding influences the electronic character of the amino and imino moieties involved in the interaction. Although other factors than hydrogen bonding (stacking, hydrophobic forces, etc.) probably contribute to the specificity of interaction, it has been shown by Shoup *et al.* (1) and by Katz and Penman (2) that significant amino and imino ^1H downfield shifts occur in mixtures of complementary bases in solution but not for noncomplementary base pairs. Such downfield ^1H shifts are characteristic of hydrogen bonding and do reflect changes in the electronic environment of the NH groups involved. Since ^{14}N spin relaxation times and direct ^{14}N–^1H spin couplings also reflect such changes we have found it to be of interest also to investigate their behaviour under similar conditions.

The present paper therefore concerns measurements of ^{14}N relaxation times (T_{1N}) and direct proton–nitrogen spin coupling constants ($^1J_{^{14}N-H}$) made on the nucleic acid base derivatives 9-ethylguanine (henceforth denoted as G), 9-methyladenine (A), 1-methylcytosine (C), and 1-methylthymine (T) and mixtures thereof in water-free DMSO-d_6 solutions, employing the technique presented earlier (3) utilizing Fourier transform measurements of NH proton spin–lattice relaxation in the rotating frame (spin locking, $T_{1\rho}$).

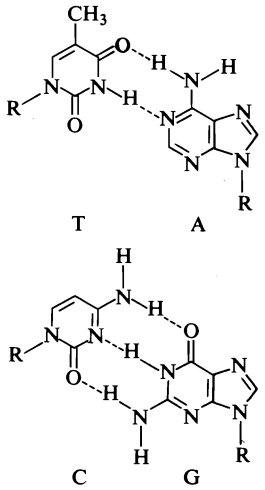

FIG. 1. The complementary base pairs G + C and A + T.

The $T_{1\rho}$ method for indirect determination of relaxation times and spin–spin couplings for quadrupolar nuclei embodies measurements of T_1 and $T_{1\rho}$ for (usually) directly bonded spin $\frac{1}{2}$ nuclei (see

0008-4042/79/091075-05$01.00/0

refs. 3–5). $T_{1\rho}$ is essentially T_1 measured at a very low field (B_1 instead of B_0), and thus becomes sensitive to the intensity of magnetic field fluctuations at an angular frequency of ω_1 ($=\gamma B_1$) instead of ω_0 ($=\gamma B_0$). Owing to common spectrometer design this will typically be in the kHz range. Sources of extraneous magnetic field fluctuations in this frequency range are, for example, (partially collapsed) spin couplings between the spin $\frac{1}{2}$ nuclei being studied and a rapidly relaxing (usually quadrupolar) nucleus. Assuming a spin coupling of J Hz, a quadrupolar relaxation time of T_{1q} s, and a spin of I makes $1/T_{1\rho}$ for the spin $\frac{1}{2}$ nucleus larger than its $1/T_1$ value by an amount shown in [1] (4, 5):

$$[1]\quad 1/T_{1\rho(sc)} = 1/T_{1\rho(obs)} - 1/T_1 = (\pi J)^2 \tfrac{4}{3}(I(I+1))\frac{T_{1q}}{1+(\omega_1 T_{1q})^2}$$

Here $1/T_{1\rho(sc)}$, the relaxation effect due to scalar coupling with the quadrupolar nucleus, is seen to depend on the strength of the B_1 field, provided that $\omega_1 T_{1q}$ is significant with regard to unity. Under these circumstances a study of the ω_1 dependence of $T_{1\rho}$ does give information about both T_{1q} and J. If $\omega_1 T_{1q}$ is close to zero, T_{1q} can still be evaluated, however, provided that J can be estimated independently.

Another possible source of magnetic field fluctuations in the kHz range is chemical exchange between nonequivalent sites and exchange rates and shift differences can be measured in a similar fashion (4–6). When both mechanisms are present simultaneously an analysis of the $T_{1\rho}$ data becomes uncertain and difficult, a factor which has been very troublesome in the present work (*vide infra*). Initial attempts to study the unsubstituted nucleosides were discontinued owing to disturbing proton exchange effects and it was also found necessary to prepare the samples under anhydrous conditions to eliminate possible proton exchange effects with water. Alternative approaches, which would eliminate this problem, are to study the $T_{1\rho}$ of ring carbon-13 nuclei or fluorine-19 in fluorinated analogues. However, in both cases more than one nitrogen will contribute to their $T_{1\rho}$ relaxation, making the analysis complicated and uncertain.

Experimental

The nucleoside base derivatives 1-methylcytosine (C) and 9-methyladenine (A) were obtained from Vega-Fox Biochemicals. 1-Methylthymine (T) was obtained from Pfaltz and Bauer Research Chemicals and 9-ethylguanine (G) was obtained from Sigma Chemical Co. Deuterated dimethyl sulphoxide (DMSO-d_6), purchased from Ciba-Geigy, was dried with 4 A molecular sieves and transferred to a vacuum line storage bulb through standard vacuum line techniques.

Samples were prepared by first degassing weighed amounts of the bases in 5-mm medium-wall tubes and then DMSO-d_6 was distilled over from the storage bulb to make the concentrations 0.1 M for each derivative. In addition, samples of T and G were prepared at 0.2 M as well (denoted 2T and 2G). 9-Ethyladenine (A) was only sparingly soluble in DMSO-d_6, to an estimated concentration of 0.07 M.

Chemical shifts were measured using the center of the DMSO-d_5 signal as an internal reference, and later adding the observed shift of DMSO-d_5 relative to TMS to these values.

Traces of water in the samples were found to be negligible and usually not observable in the proton spectra.

All measurements were made by Fourier transform methods on a JEOL FX-100 pulsed nmr spectrometer with double quadrature detection under control of the JEOL Autostacking program. The method of measurement, as well as the data analysis and error estimation were carried out as previously described (3, 6) noting that for each sample, $T_{1\rho}$ for each NH and NH_2 proton signal was measured from 15 spectra at each of six ω_1 values in the range 2600 to 18000 rad/s and that all quoted error limits correspond to a 90% confidence interval, encompassing only random error limits.

Forsén–Hoffman spin saturation transfer experiments (7) were carried out on all samples having two or more exchangeable proton types (NH, NH_2) and average proton lifetimes in each site were estimated.

Carbon-13 relaxation times for all ring methine carbons were measured for the same samples by the progressive saturation method. Each determination embodied the measurement of 11 spectra, each of 11 000 accumulations, at an observed temperature of 25°C.

Results and Discussion

Hydrogen-bond-induced Shifts and Proton Exchange Effects

The data in Table 1 present changes in amino and imino proton shifts for all combinations of bases, confirming earlier studies (1, 2). As previously pointed out (1, 2) the bases are already strongly hydrogen bonded in DMSO and the shift changes thus to reflect even more pronounced hydrogen bonding conditions. The pair interaction G + C is very significant whereas the A + T interaction is

TABLE 1. Interaction shifts upon base pairing

	δ				
Base	G-NH	G-NH_2	T-NH	A-NH_2	C-NH_2
G	(10.53)[a]	(6.43)[a]			
2G	0.02	0.01			
T			(11.17)[a]		
2T			0.02		
A				(7.16)[a]	
C					(6.93)[a]
G + C	0.98	0.46			0.34
G + A	0.00	0.00		0.01	
G + T	0.00	0.00	0.01		
A + T			0.00	0.01	
T + C			0.02		0.00
C + A				0.00	0.00

[a]The shift of this signal is taken as a reference and downfield shifts are denoted positive.

not. Although it may be possible to get more clear-cut results on solvents which do not form hydrogen bonds (2), this was not possible in the present study due to solubility reasons and to increased exchange rates for protons bonded to nitrogen.

Since the application of the present method relies on very slow exchange of the studied protons, an investigation of their lifetimes was carried out through Forsén–Hoffman spin saturation transfer experiments (7). Reliable data could be obtained for signals not too closely spaced and are summarized in Table 2. Proton exchange for G-NH protons is most severe with C-NH_2 protons and probably also with T-NH protons. Interestingly, exchange of G-NH_2 protons is invariably slow in all systems. Exchange between T-NH and G-NH_2 protons is very pronounced though considerably slower between T-NH protons and A-NH_2 protons.

A similar study on a few base combinations was recently presented by Iwahashi and Kyogoku (9) with much the same results. While information of this kind could have significant chemical implications, we must emphasize that it does not in any way prove that proton exchange occurs within a *base pair* as suggested in ref. 9. NH and NH_2 proton lifetimes at 25°C are of the order of a second although the lifetimes of the base pairs are probably less than a millisecond, since only averaged sets of ^1H nmr signals are observed.[1] Therefore, many other proton exchange pathways are possible, including exchange through trace impurities.

Nitrogen-14–Proton Spin Coupling Constants ($^1J_{^{14}N-H}$) and Nitrogen-14 Relaxation Times (T_{1N}) in Nucleic Acid Base Derivatives

In nucleic bases where the nitrogen-14 nucleus is directly linked to a proton the nuclei yield large direct spin couplings on the order of 65 Hz, characteristic of sp^2-type nitrogens (10, 11).[2] The measured coupling constants are given in Table 3 for each base or combination thereof. Nothing from the data seems to indicate any experimentally significant difference in the coupling constants between imino and amino groups in each base either alone in varying concentrations or upon admixture of bases, ruling out possible changes in nitrogen hybridization.

The data within parentheses in Tables 3 and 4 are *apparent* values, obtained from an analysis of proton T_1 and $T_{1\rho}$ data for signals shown (by the previously mentioned Forsén-Hoffman experiments) to be subject to significant proton exchange with no account for thereby induced effects on $T_{1\rho}$. The real significance of these data is unclear, since to our knowledge no theory presently exists for effects of slow exchange combined with averaging of N–H coupling on $T_{1\rho}$. All original T_1 and $T_{1\rho}$ data are given in the Appendix and can be used together with the data in Tables 1 and 2 to calculate more reliable data with the appearance of such a theory.[3]

TABLE 2. Estimated site lifetimes from Forsén-Hoffman measurements

	Lifetime (s)				
Base	G-NH	G-NH_2	T-NH	A-NH_2	C-NH_2
G	>7	>3[a]			
2G	>7	>3[a]			
G + C	≈0.02[b]	>3			0.13
G + A	>7	>3		>5	
G + T	[c]	>3	[c]		
A + T			1.1[d]	1.1[d]	
T + C			0.03		0.07
C + A				[e]	[e]

[a]This is the lower limit estimated from the observation of no significant saturation effect and a T_1 of 0.25 s. However, since the lifetime of a G-NH proton appears to be >7 s, the lower limit must be considerably higher, probably >15 s.
[b]Experimentally uncertain value. The G-NH_2 lifetime which can be more accurately determined, suggests a G-NH lifetime of the order of 0.06 s.
[c]Partial overlap prevented measurement. Signals were significantly broadened; significant proton exchange is suspected (<0.05 s).
[d]These apparently inconsistent values arise from the lower A concentration (cf. Experimental).
[e]Partial overlap. No significant signal broadening. Proton exchange is suspected to be slow (>5 s).

Changes in the electronic environment of the interacting nitrogen as well as changes in rotational behaviour affect nitrogen-14 relaxation times. The dominant relaxation mechanism is quadrupolar relaxation (8) and in the present mobility range relaxation rates are given by [2]:

$$[2]\quad \frac{1}{T_{1q}} = \frac{1}{T_1} = \frac{1}{T_2} = \frac{3}{8}\left(\frac{e^2qQ}{\hbar}\right)^2\left(1+\frac{\eta^2}{3}\right)\tau_c$$

Here eq is the electric field gradient at the nitrogen nucleus, η is the assymetry parameter of the field gradient, eQ is the electric quadrupole moment of ^{14}N, and τ_c is the rotational correlation time. Since changes in relaxation behaviour can be due to either changes in the electronic environment or changes in the rotational rate of the molecules, independent estimates of τ_c must be made in order to enable an interpretation of the data in Table 4. These estimates

[1]Compare with the results in Fig. 4 of ref. 2.

[2]The original relations given in refs. 10 and 11 concern ^{15}N nuclei for which the coupling constants are $(\gamma(^{15}N)/\gamma(^{14}N)) = 1.402$ times larger.

[3]The C-NH_2 data should also be corrected for $T_{1\rho}$ contributions from hindered internal rotation of the amino group (1, 12). However, since our DMSO solutions cannot be cooled much below 25°C and since a comparison between our spectra and those of Shoup *et al.* (1, 12) clearly indicates that $\delta\nu$ and (or) τ_c for this process are highly solvent dependent, this is not possible in the present study. It is clear, however, that this $T_{1\rho}$ contribution is much smaller in the present study than in the spectra at 25°C given in ref. 12.

TABLE 3. Nitrogen-14–proton spin–spin coupling constants in nucleic acid base derivatives[a]

	J^{14}_{N-H} (H_3)

have been made through interpretation of the carbon-13 T_1 measurements of the ring methine carbons which are summarized in Table 5.

Combining data of Tables 4 and 5 makes possible for example, the deduction that the 30% T_{1N} decrease of the G-NH_2 nitrogen in the G + C mixture is due to decreased molecular mobility. Although somewhat speculative, some comment can be made about the corresponding G-NH and C-NH_2 data. The $T_{1\rho}$ data for the ^1H signals are affected by the same proton exchange effect but still the apparent (*vide supra*) T_{1N} values show opposite trends.

The C-NH_2 T_{1N} decrease can be explained by decreased mobility but the G-NH increase might

possibly be due to a decreased electric field gradient upon complexation. No major T_{1N} or carbon-13 T_1 changes were observed upon admixture of any non-complementary base pairs and unfortunately no reliable T_{1N} data could be obtained for the A + T pair due to the mentioned proton exchange effects.

The data can similarly be used to estimate relative electric field gradients at the nitrogens by inserting τ_c data deduced from carbon-13 T_1 measurements in [2].[4] Information of this kind is not readily obtained from direct nitrogen-14 nmr and nqr studies owing to the low concentrations and the large number of nitrogens contributing to the spectra. It is seen that the T-NH nitrogen experiences a lower field gradient than does the G-NH nitrogen. The field gradient is also higher at the G-NH_2 nitrogen than either the A- or C-NH_2 nitrogens.

Reçu le 14 juillet 1978

JAMES BOUQUANT, ALAIN MAUJEAN et JOSSELIN CHUCHE. Can. J. Chem. **57**, 1080 (1979).

Une méthode de détermination des paramètres intrinsèques K et Δ de complexes réactif lanthanidique–substrat a été étendue aux molécules conformationnellement mobiles. Ces paramètres déterminés pour une série d'alcools cyclohexaniques secondaires (cyclohexanol et méthyl-2 cyclohexanol) et tertiaires (méthyl-1 cyclohexanol et éthyl-1 cyclohexanol) complexés par $Eu(DPM)_3$ et $Yb(DPM)_3$ ont permis de déterminer les constantes d'équilibre conformationnelles entre les espèces libres d'une part, et les espèces complexées d'autre part.

Les résultats obtenus pour les espèces libres sont en bon accord avec ceux obtenus par d'autres méthodes physico-chimiques. Pour les espèces complexées, un déplacement de l'équilibre conformationnel important est observé dans le cas des faibles valeurs des quotients d'association.

Pour la première fois, le groupement *tert*-butyle du réactif $Yb(DPM)_3$ a été utilisé comme sonde conformationnelle.

JAMES BOUQUANT, ALAIN MAUJEAN, and JOSSELIN CHUCHE. Can. J. Chem. **57**, 1080 (1979).

A method for the determination of the intrinsic parameters K and Δ for lanthanide–substrate complexes has been extended to conformationally mobile molecules. These parameters, determined for a series of secondary cyclohexane alcohols (cyclohexanol and 2-methylcyclohexanol) and for tertiary alcohols (1-methylcyclohexanol and 1-ethylcyclohexanol) complexed with $Eu(DPM)_3$ and $Yb(DPM)_3$ lead to the determination of the conformational equilibrium constants between the free species on one part and the complexed species on the other.

The results obtained for the free species are in good agreement with those obtained by other physicochemical methods. For the complexed species an appreciable shift of conformational equilibrium is noted for low values of the association constants.

For the first time, the *tert*-butyl group of $Yb(DPM)_3$ has been used as a conformational probe.

Introduction

Ces dernières années les réactifs de déplacement chimique ont été très utilisés pour déterminer la configuration de substrats conformationnellement homogènes (1, 2); par contre, les résultats relatifs à des systèmes conformationnellement mobiles sont beaucoup moins nombreux. Les études portent, en particulier, sur la rotation des amides (3–5) et des amino esters (6), systèmes pour lesquels la barrière énergétique entre les rotamères est assez élevée. Dans l'étude des équilibres conformationnels pour lesquels il existe un échange rapide, il est admis que les variations des déplacements chimiques avec la concentration du réactif paramagnétique sont à relier aux populations et aux déplacements chimiques intrinsèques des conformères; ces derniers sont ceux de composés modèles complexés (7–10) ou évalués (11–17) en utilisant l'équation de MacConnell–Robertson (18). Toutefois, on peut remarquer que ces méthodes supposent que l'aptitude à se complexer des différentes espèces en équilibre rapide est la même et que le chélate n'a pas d'effet sur cet équilibre. Cette hypothèse ne semble pas toujours vérifiée: en effet, un déplacement des équilibres rotationnels (3–6, 19) et conformationnels (7, 13 et références citées, 14, 20–23) a été mis en évidence en présence de réactif. En ce qui concerne les alcools cyclohexaniques, objets de ce travail, il a été montré (24, 25) que la valeur de la constante d'interaction dépend fortement de la position axiale ou équatoriale de l'hydroxyle. Dans une note précédente (26), nous avons décrit la première étude quantitative d'un équilibre conformationnel qui tient compte d'un éventuel déplacement de l'équilibre conformationnel par le réactif.

Nous nous proposons ici de compléter cette étude en montrant que la méthode de détermination des paramètres caractéristiques de l'interaction entre les réactifs lanthanidiques et les bases de Lewis, développée précédemment (27), peut s'appliquer aux molécules conformationnellement mobiles. Les paramètres apparents (K et Δ) ainsi obtenus, permet-

SCHÉMA 1

tent de calculer la constante d'équilibre conformationnel entre les espèces libres d'une part, et complexées d'autre part.

Le modèle proposé sera ensuite testé sur des alcools cyclohexaniques conformationnellement mobiles substitués ou non en positions 1 et 2 (Schéma 1).

Le choix de ces substrats se justifie dans la mesure où les constantes d'équilibre conformationnel sont connues ou peuvent être estimées. Leur connaissance nous permettra de dégager un certain nombre de critères pour apprécier la validité des valeurs obtenues. Nous montrerons, également, l'intérêt de changer de réactif ou de solvant dans une telle étude.

Modèle proposé

Le modèle proposé s'applique à un nombre quelconque de conformères, toutefois pour simplifier, nous considèrerons seulement le cas de deux conformères S_a et S_e pour le substrat S. Dans l'hypothèse de la formation de complexes de stoechiométrie 1:1 (25) en présence d'un réactif de déplacement chimique, on peut postuler l'existence des équilibres suivants:

$$\begin{array}{ccc} S_a + R & \overset{K_1}{\rightleftharpoons} & S_e + R \\ \Big\downarrow\uparrow K_a & & \Big\downarrow\uparrow K_e \\ S_aR & \overset{K_c}{\rightleftharpoons} & S_eR \end{array}$$

K_a, K_e d'une part, K_1 et K_c d'autre part, sont respectivement les constantes d'association de S_a et S_e avec R et d'équilibres conformationnels des formes libres et associées.

Désignons par C^0 et C les concentrations initiales et à l'équilibre, et par δ et δ_{RS} respectivement les déplacements chimiques mesurés en référence interne des conformères libres et complexes. Le déplacement chimique observé est alors donné par la relation [1]:

$$[1] \quad \delta_{obs} = \frac{C_{S_a}\delta_a + C_{S_e}\delta_e + C_{RS_a}\delta_{RS_a} + C_{RS_e}\delta_{RS_e}}{C_S^0}$$

Nous admettrons que δ_a et δ_e peuvent être assimilés au déplacement chimique du substrat libre ($\delta_a \simeq \delta_e \simeq \delta_0$) qui est la moyenne pondérée de ces deux valeurs.[2] Dans ces conditions, l'expression du déplacement chimique induit par le réactif s'écrit:

$$[2] \quad \delta_{ind} = \delta_{obs} - \delta_0 = \frac{C_{RS_a}\Delta_a + C_{RS_e}\Delta_e}{C_S^0}$$

Dans cette expression $\Delta_a = \delta_{RS_a} - \delta_0$ et $\Delta_e = \delta_{RS_e} - \delta_0$, sont les déplacements chimiques intrinsèques des noyaux engagés dans le complexe.

En outre, la loi d'action de masse permet de relier les concentrations entre elles:

$$[3] \quad K_a = \frac{C_{RS_a}}{C_{S_a}C_R}; \quad K_e = \frac{C_{RS_e}}{C_{S_e}C_R}$$
$$K_1 = \frac{C_{S_e}}{C_{S_a}}; \quad K_c = K_1\frac{K_e}{K_a}$$

Après combinaisons des éqs [2] et [3] nous obtenons:

$$[4] \quad \delta_{ind}(1 + K_1)(\Delta_a + K_c\Delta_e) = K_a(\Delta_a + K_c\Delta_e - \delta_{ind}(1 + K_c)) \times (C_R^0(\Delta_a + K_c\Delta_e) - \delta_{ind}C_S^0(1 + K_c))$$

Si les concentrations initiales en réactif et en substrat sont maintenues égales (27), l'éq. [4] s'écrit:

$$[5] \quad \delta_{ind} = -\left(\frac{(\Delta_a + K_c\Delta_e)(1 + K_1)}{K_a(1 + K_c)^2}\right)^{1/2}\left(\frac{\delta_{ind}}{C_S^0}\right)^{1/2} + \frac{\Delta_a + K_c\Delta_e}{1 + K_c}$$

Il apparaît que la courbe représentative de la fonction $\delta_{ind} = f(\delta_{ind}/C_S^0)^{1/2}$ est une droite de pente P_m et d'ordonnée à l'origine Δ_m

$$[6] \quad P_m = -\left(\frac{(\Delta_a + K_c\Delta_e)(1 + K_1)}{K_a(1 + K_c)^2}\right)^{1/2}$$

$$[7] \quad \Delta_m = \frac{\Delta_a + K_c\Delta_e}{1 + K_c}$$

Posons $K_m = \Delta_m/P_m{}^2$

$$[8] \quad K_m = \frac{K_a(1 + K_c)}{(1 + K_c)}$$

où K_m et Δ_m sont les paramètres intrinsèques apparents du complexe S–Eu(DPM)$_3$.

Après combinaisons des éqs [7] et [8], nous ob-

[2]La différence $\delta_a - \delta_e$ est de quelques hertz, alors que les déplacements chimiques induits sont comprise entre 10 et 20 ppm.

tenons les expressions suivantes:

$$[9] \qquad K_1 = \frac{K_a - K_m}{K_m - K_e}$$

$$[10] \qquad K_1 = \frac{K_a(\Delta_a - \Delta_m)}{K_e(\Delta_m - \Delta_e)}$$

$$[11] \qquad K_c = \frac{K_e}{K_a} K_1 = \frac{\Delta_a - \Delta_m}{\Delta_m - \Delta_e}$$

Ces équations sont formellement analogues à celles proposées par Stolow (28) et Eliel et Luckack (29) respectivement dans le cas de la protonation des amines et de mesures cinétiques de la solvolyse de tosylates de cyclohexyle.

Ces relations indiquent clairement que la connaissance des déplacements chimiques intrinsèques permet uniquement de calculer K_c. Les paramètres des conformères nécessaires à l'évaluation de K_1 peuvent être estimés à partir d'une étude de la complexation de composés modèles semblables.

Quelle que soit la méthode utilisée pour évaluer les paramètres intrinsèques, ceux-ci sont déterminés avec une incertitude fonction de la nature du substrat du réactif ou du solvant (25). Les constantes d'équilibre conformationnel K_1 ou K_c seront acceptables à la condition nécessaire que la variable X_a ou X_e (notée $X_{a/e}$) soit significativement différente de X_m (X désigne le quotient d'association ou le déplacement chimique intrinsèque). Les deux variables $X_{a/e}$ et X_m étant calculées dans deux échantillons indépendants, la condition précédente sera vérifiée (30) si la variable aléatoire:

$$X_d = \frac{X_{a/e} - X_m}{\sigma_{(X_{a/e} - X_m)}}$$

ne suit pas une loi de Student.

Dans l'expression ci-dessus, $\sigma_{X_{a/e} - X_m}$ représente l'écart type estimé de la différence $X_{a/e} - X_m$.

En d'autres termes, $X_{a/e} - X_m$ sera significativement différent de zéro si la condition $X_d > t_{\nu,\alpha}$ ou $z = X_d/t_{\nu,\alpha} > 1$ est vérifiée. La borne $t_{\nu,\alpha}$ donnée par la table de Student, est atteinte dans moins de $\alpha\%$ des cas pour ν degrés de liberté ($\nu = n_{a/e} + n_m - 4$: expression dans laquelle n représente le nombre de mesures de la variable $X_{a/e}$ ou X_m).

Determination des paramètres intrinsèques

Nous savons que la précision de mesure des paramètres intrinsèques est fonction de la grandeur des quotients d'association (27). Il était donc intéressant de comparer les complexations des cyclohexanols avec, d'une part $Eu(DPM)_3$[3] (association la plus forte), et d'autre part $Yb(DPM)_3$ (association la plus faible) (25).

[3](DPM)H = tétraméthyl-2,2,6,6 heptane dione-3,5.

Réactif de déplacement chimique Eu(DPM)$_3$

Les valeurs des quotients d'association et des déplacements chimiques intrinsèques des complexes $Eu(DPM)_3$–cyclohexanols conformationnellement mobiles (**1** à **5**) en solution dans le chloroforme deutérié sont reportées dans le tableau 1. Dans ce même tableau sont également rappelés les paramètres intrinsèques des *tert*-butyl-4 cyclohexanols homologues qui ont été étudiés (25) dans les mêmes conditions expérimentales. Ces alcools sont notés (tableau 1) avec un indice a ou e pour rappeler la position axiale ou équatoriale de la fonction alcool.

La comparaison des résultats fait apparaître que les valeurs des paramètres intrinsèques obtenues pour les alcools conformationnellement mobiles sont toujours comprises entre celles des dérivés tertiobutylés. En ce qui concerne l'alcool tertiobutylé $\mathbf{3}_a$, homologue de la conformation *trans* di-axiale de l'isomère **3**, il n'a pas pu être isolé; toutefois, pour l'alcool $\mathbf{3}_a$, le méthyle axial étant trans à l'hydroxyle, l'influence de ce méthyle sur la complexation doit être faible, voire nulle (25). De ce point de vue, il est à prévoir pour l'isomère $\mathbf{3}_a$ des valeurs des paramètres intrinsèques proches de celles du *tert*-butyl-4 cyclohexanol *cis* ($K = 323\ M^{-1}$ et $\Delta = 26.49$ ppm calculées (25) à partir de l'hydrogène en position 1). On peut d'ailleurs remarquer que les paramètres intrinsèques de **3** sont bien compris entre ceux de cet alcool et de l'alcool $\mathbf{3}_e$.

Réactif de déplacement chimique Yb(DPM)$_3$

Dans les conditions expérimentales utilisées ($C_R^0 = C_S^0$), ce réactif présente l'inconvénient de provoquer des élargissements de raies tels que nous perdons l'information relative à la multiplicité de ces raies. Cet élargissement explique pourquoi nous nous sommes limités à la détermination des déplacements chimiques des raies des radicaux méthyle et *tert*-butyle. En effet, seules ces raies peuvent être mesurées avec une précision acceptable.

En outre, les quotients d'association avec $Yb(DPM)_3$ étant plus faibles que ceux avec $Eu(DPM)_3$ (25), nous avons pu envisager l'étude d'une part des alcools **1**, **4** et **5** dans le tétrachlorure de carbone et d'autre part des alcools **1** et **5** dans le chloroforme deutérié.

La comparaison des valeurs des paramètres intrinsèques (K et Δ, tableau 2) à celles rapportées dans le tableau 1 fait apparaître clairement que les déplacements chimiques avec $Yb(DPM)_3$ sont environ 3.5 fois plus grands que ceux observés avec $Eu(DPM)_3$. Quant aux quotients d'association, ils restent inférieurs à ceux de $Eu(DPM)_3$ même lorsque le solvant est le tétrachlorure de carbone. Par contre, nous retrouvons des propriétés communes pour ces deux réactifs, à savoir: (*i*) le *tert*-butyl-4 cyclohexanol *cis*

interagit plus fortement que le *trans*; (*ii*) les valeurs des paramètres intrinsèques des alcools mobiles sont situées entre celles des alcools homologues conformationnellement homogènes, excepté pour le déplacement chimique du méthyle de l'alcool **4**.

Dans le tableau 2 sont également consignés des résultats originaux relatifs aux paramètres intrinsèques des *tert*-butyles du ligand DPM. Il avait été observé (31), qualitativement, que l'addition de substrat à $Eu(FOD)_3$ entraînait un déplacement de la résonance des *tert*-butyles du réactif vers les champs forts. Nous avons envisagé une étude quantitative de ce déplacement dans le but de trouver éventuellement une voie d'accès aux quotients d'association. En particulier, avec $Yb(DPM)_3$, la variation du déplacement chimique des *tert*-butyles est suffisante pour déterminer les paramètres intrinsèques correspondant à ce groupement. En examinant les résultats, on constate un excellent accord entre les quotients d'association déterminés à partir du réactif ou du substrat (tableau 2). Remarquons dès maintenant que cette concordance peut être intéressante d'un point de vue pratique pour l'étude de la complexation de substrats pour lesquels les noyaux ont une raie de résonance très large (mesure imprécise du déplacement chimique) ou pas de raie de résonance.

Les valeurs des déplacements chimiques intrinsèques des *tert*-butyles du réactif sont indépendantes du solvant mais, par contre, sont influencées par une interaction stérique entre le substrat et le réactif. En effet, pour un alcool de configuration donnée, le déplacement chimique intrinsèque est d'autant plus grand que le substituant porté par le carbone 1 est plus volumineux (comparer entre eux $\mathbf{1}_a$, $\mathbf{4}_a$ et $\mathbf{5}_a$ ou $\mathbf{1}_e$, $\mathbf{4}_e$ et $\mathbf{5}_e$). En outre, pour deux alcools épimères en 1, on observe entre les déplacements un écart qui croît avec l'encombrement stérique du substituant (comparer $\mathbf{1}_a$ et $\mathbf{1}_e$, puis $\mathbf{4}_a$ et $\mathbf{4}_e$, et enfin $\mathbf{5}_a$ et $\mathbf{5}_e$). Ce résultat peut être interprété comme un changement de géométrie du réactif complexé (31, 32). En l'absence de substrat, il existe une interaction réactif–solvant puisque le déplacement chimique des groupements *tert*-butyles, mesurés par rapport à une référence interne de cyclohexane, sont respectivement de -91 ± 0.3 Hz dans le tétrachlorure de carbone et de -107.5 ± 0.3 Hz dans le chloroforme deutérié.

Dans le cas de $Eu(DPM)_3$, l'écart $\Delta_a - \Delta_e$ des valeurs extrêmes des déplacements chimiques intrinsèques ($\Delta(\mathbf{1}_a) = 26 \pm 3$ Hz; $\Delta(\mathbf{1}_e) = 26 \pm 5$ Hz; $\Delta(\mathbf{4}_a) = 39 \pm 3$ Hz et $\Delta(\mathbf{4}_e) = 33 \pm 3$ Hz à 60 MHz) des groupements *tert*-butyles du réactif sont plus faibles que ceux déterminés avec $Yb(DPM)_3$; ce qui semble confirmer l'origine stérique plutôt qu'électronique de ces effets (rayon ionique de Eu^{3+} superieur à celui de Yb^{3+}. Ce faible écart exclut l'utilisation des groupements *tert*-butyles de $Eu(DPM)_3$ pour des études quantitatives.

Analyse conformationnelle

L'évaluation des paramètres X_a ou X_e intervenant dans les éqs [9] à [11] ne peut pas se déduire de l'étude à basse température du complexe $Eu(DPM)_3$–substrat conformationnellement mobile. En effet, on n'observe jamais qu'un seul signal très large à -120°C pour le cyclohexanol **1** complexé, élargissement de la raie de résonance attribué à un ralentissement de la relaxation électronique (3). Les valeurs de ces paramètres peuvent être déduites des dérivés *cis* et *trans tert*-butylés en 4 conformationnellement homogènes. Cette approximation est justifiée dans la mesure où la présence d'un groupement *tert*-butyle en position équatoriale a une influence négligeable sur les valeurs de ces paramètres intrinsèques. Nous avons constaté, en effet, que deux alcools de même configuration mais appartenant respectivement à la série stéroïdique et cyclohexanique ont des valeurs de K et Δ très voisines (25). En remplaçant dans les éqs [9] à [11] les différents paramètres par leurs valeurs extraites des tableaux 1 et 2, nous pouvons calculer les constantes d'équilibre conformationnel des alcools **1** à **5**. Nous en déduisons alors directement la différence d'enthalpie libre calculée par la relation classique:

$$\Delta G^0 = -RT \log K$$

Les résultats obtenus avec les alcools cyclohexaniques secondaires et tertiaires sont rassemblés respectivement dans les tableaux 3 et 4. Dans ces tableaux, nous avons éliminé les valeurs de ΔG^0 calculées à partir des paramètres pour lesquels z est inférieur à l'unité au seuil 5% (*vide supra*). On constate en effet que ces valeurs comparées à celles de la littérature sont aberrantes.

D'une manière générale, nous remarquons que les valeurs de $\Delta G_1{}^0$ calculées à partir des valeurs des quotients d'association sont en bon accord, alcool **1** excepté, avec celles relevées dans la littérature et rappelées dans les tableaux. Dans le cas du cyclohexanol, le $z_{K_a - K_m}$ inférieur à 1 est dû à la faible différence entre les valeurs des quotients d'association (tableaux 1 et 2) et à une grande incertitude sur leurs déterminations. En effet, nous avons montré (27) que les erreurs sur la détermination des K sont d'autant plus grandes que les valeurs de ceux-ci sont plus élevées. La diminution de ces paramètres par utilisation de $Yb(DPM)_3$ et du chloroforme deutérié entraîne une meilleure détermination de ΔG^0.

En ce qui concerne les alcools tertiaires, nous ne connaissons pas de valeurs de $\Delta G_1{}^0$ déterminées par d'autres méthodes dans des solvants "inertes" à une température voisine de 40°C. Cependant, on peut

s'attendre à ce que les différences d'énergie libre pour les molécules **5** et **6** soient comparables, car il est généralement admis que les énergies libres des groupes méthyles et éthyles sont équivalentes (35 et références citées). Nous observons effectivement que nous pouvons attribuer aux alcools tertiaires **4** et **5** une valeur moyenne, calculée à partir des quotients d'association, de ΔG_1^0 = 0.16 kcal/mol. Cette valeur indépendante du réactif ou du solvant est comparable à celles de 0.21 et 0.24 kcal/mol déterminées par équilibration de **4** en présence respectivement d'acide acétique (37) et d'acide perchlorique (38) en solution aqueuse. Par contre, elle est très inférieure à la valeur de 0.41 kcal/mol obtenue par intégration des raies de résonance magnétique nucléaire des deux conformères (34 et références citées) à basse température.

Quant aux valeurs de ΔG_1^0 calculées à partir des déplacements chimiques, l'accord entre les valeurs observées et attendues est beaucoup moins satisfaisant. On constate en général pour une même expérience que la valeur de $z_{\Delta_a/_e - \Delta_m}$ est alors inférieure à $z_{K_a/_e - K_m}$ à l'exception du méthyle de **5** (tableau 4). Dans ce dernier exemple, il est vraisemblable que la conformation de la chaine éthyle dans les conformères axiaux et équatoriaux diffère de celle des composés modèles complexés par le réactif, l'effet étant moins sensible pour le groupement méthylène du radical éthyle.

Des valeurs de ΔG^0 plus précises pourraient être

déterminées en considérant des groupements éloignés du site fonctionnel tels que H(2)*trans* ou H(3)*cis*. Cependant, en présence de $Eu(DPM)_3$ et $Yb(DPM)_3$, nous observons, à 60 MHz, un recouvrement des raies de ces hydrogènes cyclohexaniques, en particulier dans les isomères conformationnellement mobiles.

Dans les tableaux 3 et 4, nous avons uniquement rapporté les valeurs de ΔG_c^0 calculées à partir des valeurs des paramètres qui donnaient les valeurs de ΔG_1^0 les plus proches des valeurs attendues. En présence de réactif paramagnétique, nous observons toujours un déplacement de l'équilibre conformationnel qui s'accompagne d'une diminution de la différence d'enthalpie libre à l'exception du cyclohexanol. Compte tenu de [11], l'importance du déplacement croît avec le rapport K_e/K_a et nous constatons que le réactif le moins complexant $Yb(DPM)_3$ déplace davantage l'équilibre que $Eu(DPM)_3$. L'équilibre ne sera pas déplacé lorsque $K_e = K_a$, condition souvent admise implicitement mais rarement vérifiée.

Conclusion

La méthode de détermination des paramètres intrinsèques K et Δ des complexes réactif–substrat, développée précédemment (27) a été étendue à celle des molécules conformationnellement mobiles. Les paramètres déterminés dans le cas des cyclohexanols ont permis de calculer des différences d'enthalpie libre ΔG_1^0 comparables à celles atteintes par d'autres techniques physico-chimiques. Ces résultats obtenus par utilisation de réactifs de pouvoir complexant très différent nous autorisent à accorder un seuil de confiance élevé à la grandeur des paramètres intrinsèques.

Les valeurs les plus satisfaisantes de ΔG_1^0 ont été déterminées à partir des quotients d'association. D'un point de vue pratique, s'il y a discordance, pour un complexe donné, entre les valeurs de ΔG_1^0 obtenues à partir de K et de Δ, le choix doit s'effectuer par référence au test statistique. La validité de ce test sera renforcée en augmentant le nombre d'expériences indépendantes (minimisation des erreurs systématiques).

Pour la première fois, à notre connaissance, nous avons utilisé le groupement *tert*-butyle du réactif comme "sonde conformationnelle."

Enfin, nous avons constaté, dans tous les cas étudiés, un déplacement de l'équilibre conformationnel des molécules complexées, d'autant plus grand que le quotient d'association est plus faible. Aussi, toute étude structurale par résonance magnétique nucléaire de molécules conformationnellement mobiles en présence de réactif devra être précédée d'une connaissance approfondie de l'aptitude à se complexer des différentes espèces en équilibre.

Partie expérimentale

Synthèse et purification des cyclohexanols

La préparation des alcools, à l'exception du cyclohexanol qui est d'origine commerciale (Merck), a été décrite précédemment (39). Avant utilisation, les cyclohexanols ont été purifiés par chromatographie en phase vapeur (cpv) puis sublimés.

En ce qui concerne la séparation des stéréoisomères du méthyl-2 cyclohexanol-1, leur séparation a dû être envisagée à partir des éthers silylés correspondants, obtenus avec un rendement quantitatif selon le protocole décrit par Corey et Venkateswarlu (40). Ces éthers silylés sont séparés par cpv sur colonne Carbowax 20 M (15%, $\frac{3}{8}$) à 70°C. Chaque stéréoisomère authentique est ensuite soumis à une hydrolyse acétique selon le protocole décrit par Corey et Venkateswarlu (40).

Préparation des échantillons

La préparation des solutions et les conditions d'enregistrement des spectres de rmn sur Varian A 60 A sont analogues à celles décrites précédemment (27).

Isotope effects in nucleophilic substitution reactions. II. Secondary α-deuterium kinetic isotope effects: a criterion of mechanism?

KENNETH CHARLES WESTAWAY[1] AND SYED FASAHAT ALI

Department of Chemistry, Laurentian University, Sudbury, Ont., Canada P3E 2C6

Received August 1, 1978

KENNETH CHARLES WESTAWAY and SYED FASAHAT ALI. Can. J. Chem. **57**, 1089 (1979).

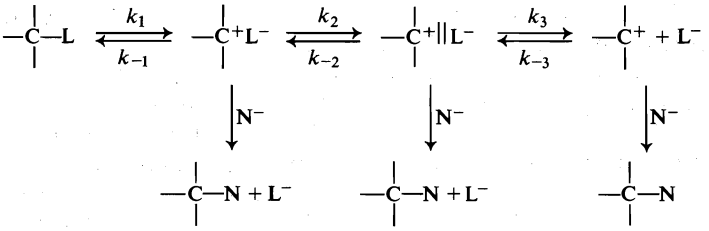
A very large secondary α-deuterium kinetic isotope effect of 1.179 ± 0.007 (1.086 ± 0.003 per α-deuterium) has been observed for the S_N2 reaction of thiophenoxide ion with benzyldimethylphenylammonium ion in DMF at 0°C. This large isotope effect which is far outside the range reported for S_N2 reactions, is attributed to the fact that the extraordinarily large steric crowding around the Cα—H bonds in the substrate is reduced in the S_N2 transition state. The structure of the transition state is shown to be consistent with this hypothesis.

KENNETH CHARLES WESTAWAY et SYED FASAHAT ALI. Can. J. Chem. **57**, 1089 (1979).

Dans la réaction S_N2 de l'ion thiophénolate avec l'ion benzyldiméthylphénylammonium dans le DMF à 0°C, on a observé un effet isotopique cinétique secondaire du deutérium en alpha qui est très grand 1.179 ± 0.007 (1.086 ± 0.003 par deutérium α). Cet effet isotopique important, qui est à l'extérieur des valeurs rapportées pour des réactions S_N2, peut être attribué au fait que l'encombrement stérique qui est particulièrement important au niveau des liaisons Cα—H dans le substrat est réduit dans l'état de transition S_N2. On démontre que la structure de l'état de transition est en accord avec cette hypothèse.

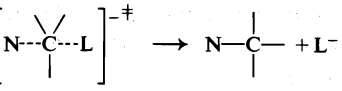
[Traduit par le journal]

The magnitude of secondary α-deuterium kinetic isotope effects has been widely accepted as a criterion for distinguishing between nucleophilic substitution reactions at saturated carbon which react by way of a carbonium ion mechanism, eq. [1],



[1]

and those reacting by the one-step S_N2 mechanism (1 and ref. 2, pp. 104–137), eq. [2]



[2]

The criterion simply stated, is that large secondary α-deuterium kinetic isotope effects, i.e. $(k_H/k_D)_\alpha$ of ≥ 1.07 per α-deuterium for a primary alkyl iodide, Table 1, identifies a carbonium ion mechanism whereas isotope effects of less than 1.04 per α-deuterium for a primary substrate (3) (including inverse isotope effects) indicate that the reaction proceeds by the S_N2 mechanism.

Unfortunately, the magnitude of these isotope effects does not remain constant for a particular substrate. For example, the magnitude of the isotope effect changes significantly when (*i*) the leaving group is changed (3, 4) and also (*ii*) with a shift in the rate-determining step of a carbonium ion reaction (ref. 2, p. 137). In fact, maximum secondary α-deuterium kinetic isotope effects are observed when the formation of the solvent-separated ion pair or the free carbonium ion, i.e. when the k_2 or the k_3 step in [1], is rate determining. Smaller isotope effects of about 75% of the maximum values are observed when formation of the intimate ion pair (the k_1 step) is rate determining (ref. 2, p. 137), Table 1. Finally, the magnitude of these isotope effects can be changed to a smaller extent (1–2% per α-deuterium) by a change in solvent (5, 6).

Although the magnitude of the secondary α-deuterium kinetic isotope effects for S_N2 reactions also

Br	1.125	1.09
I	1.09	1.07
NO_3	≥1.18	≥1.14

varies with the leaving group,[2] the variations are much smaller than those observed in carbonium ion reactions (ref. 2). This criterion of mechanism is successful in spite of these variations because the isotope effects for S_N2 reactions are significantly smaller (≤1.04 per α-deuterium) than those found for reactions involving carbonium ion intermediates.

Although many workers have measured secondary α-deuterium kinetic isotope effects for S_N reactions with the leaving groups shown in Table 1, only two isotope effects have been measured for S_N reactions of quaternary ammonium ions. Ko and Leffek (7) found very large secondary α-deuterium kinetic isotope effects (k_H/k_D) of 1.12 and 1.10 per α-deuterium at 30°C for the reaction between bromide ion and benzyldimethylphenylammonium ion in chloroform and acetone, respectively, eq. [3]. These isotope

$$3PhCH_2\overset{+}{N}(CH_3)_2PhBr^- \rightleftarrows \underset{\text{'A'}}{[(PhCH_2\overset{+}{N}(CH_3)_2Ph)_2Br^-]^+} + [PhCH_2\overset{+}{N}(CH_3)_2PhBr_2]^-$$

$$[3]\ \text{'A'} \xrightarrow{\text{slow}} \left[\begin{array}{c} PhCH_2 \quad (CH_3)_2NPh \\ Br^- \\ PhCH_2\overset{+}{N}(CH_3)_2Ph \end{array}\right]^+ \xrightarrow{\text{fast}} PhCH_2Br + (CH_3)_2NPh + PhCH_2\overset{+}{N}(CH_3)_2Ph$$

effects are considerably larger than those observed for S_N2 reactions and Leffek and Ko very reasonably concluded that these reactions must involve the formation of a carbonium ion intermediate in the slow step of the reaction. Based on this and other evidence (8, 9) these authors proposed that the reaction followed an 'ionic internal nucleophilic substitution' mechanism involving the triple ion 'A' shown in [3] (7, 10).

Although large secondary α-deuterium kinetic isotope effects should be observed for this mechanism, the formation of a benzyl carbonium ion seemed unlikely for several reasons. First, subsequent studies showed that quaternary ammonium salts could react in dipolar aprotic solvents by an S_N2 mechanism (11). Second, the reverse of these reactions, the Menshutkin reaction, occurs by an S_N2 process (12) and the principle of microscopic reversibility requires that the forward reaction also be an S_N2 process. Finally, all the experimental evidence except for the secondary α-deuterium kinetic isotope effects, is equally consistent with a mechanism where the substitution occurs in a one-step S_N2 reaction within the triple ion, 'A,' eq. [4].

$$[4]\ \text{'A'} \longrightarrow \left[\begin{array}{c} \quad Ph\ H \\ \delta^- \diagdown\ \diagup\ \delta^+ \\ Br\cdots C \cdots N(CH_3)_2Ph \\ \quad\ | \\ \quad H \\ PhCH_2\overset{+}{N}(CH_3)_2Ph \end{array}\right]^{\ddagger +} \downarrow \quad PhCH_2Br + (CH_3)_2NPh + PhCH_2\overset{+}{N}(CH_3)_2Ph$$

If the reaction occurs by the mechanism shown in [4], very large secondary α-deuterium kinetic isotope effects result when dimethylaniline is the leaving group and the criterion of mechanism based on the magnitude of these isotope effects fails.

It was important to measure a secondary α-deuterium kinetic isotope effect for an S_N2 reaction of a quaternary ammonium salt to learn if this criterion of mechanism applied to these reactions. Westaway and Poirier (11) have demonstrated that the reaction of benzyldimethylphenylammonium ion with thiophenoxide ion at 0°C in DMF is an S_N2 process, eq. [5].

$$[5]\ PhS^- + PhCH_2\overset{+}{N}(CH_3)_2Ph \longrightarrow \left[\begin{array}{c} \quad H\ Ph \\ \delta^- \diagdown\ \diagup\ \delta^+ \\ PhS\cdots C \cdots N(CH_3)_2Ph \\ \quad\ | \\ \quad H \end{array}\right]^{\ddagger} \downarrow \quad PhSCH_2Ph + (CH_3)_2NPh$$

The secondary α-deuterium kinetic isotope effect was determined for this reaction in order to test the hypothesis that an isotope effect of ≤1.04 per α-deuterium is observed for all S_N2 reactions.

[2]The magnitudes of secondary α-deuterium kinetic isotope effects for S_N2 reactions will also be affected by a change in the nucleophile.

Results and Discussion

The secondary α-deuterium kinetic isotope effect for the reaction shown in [5] was measured using the competitive technique (11, 13, 14). The isotope effect was calculated using [6].

$$[6] \qquad (k_H/k_D)_\alpha = \frac{\ln (1 - f)}{\ln \left(1 - \left(\frac{R_0}{R_f}\right) f\right)}$$

where f is the extent of reaction expressed as a fraction, R_0 is the ratio of the undeuterated to dideuterated quaternary ammonium salt in the reactant, and R_f is the ratio of the undeuterated to dideuterated benzyl phenyl sulfide in the product after small extents of reaction (15). The isotope effect per α-deuterium is the square root of the value obtained from [6]. The initial concentrations of the undeuterated and dideuterated quaternary ammonium salts in the reactant were determined from the weights of the undeuterated and deuterated quaternary salts and the deuterium content of the deuterated quaternary ammonium salt.[3] The ratio of undeuterated to dideuterated benzyl phenyl sulfide was determined in a mass spectrometric analysis of the product. The fraction of reaction was determined in a gas chromatographic analysis using the internal standard technique (11). The results are presented in Table 2.

The secondary α-deuterium kinetic isotope effect measured for small fractions of reaction for the S_N2 reaction of benzyldimethylphenylammonium ion with thiophenoxide ion at 0°C is 1.179 ± 0.007 or 1.086 per α-deuterium. The magnitude of this isotope effect is significantly larger than the maximum value of the isotope effect for S_N2 reactions, $k_H/k_D = 1.082$ or 1.04 per α-deuterium. The magnitude of this unexpectedly large isotope effect was confirmed by measuring the isotope effect at large fractions of reaction even though these isotope effects are less accurate. The isotope effects at high fractions of reaction are less accurate because (*i*) the differences between the isotopic ratios of the reactant and product are smaller (15) and thus the error in the R_0/R_f ratio, eq. [6], is larger and (*ii*) because the fraction of reaction cannot be determined as accurately at high extents of reaction. A Duncan's test (16) shows that the isotope effects measured at 36 and 63% of completion (Table 2) are not significantly different at the 96% confidence level from those measured for lower fractions of reaction. In addition, there is no trend in the isotope effects with fraction of reaction and this rules out a systematic error in the analyses. The constant value of this isotope effect over a wide range of fractions of reaction illustrates that the isotope effect for this reaction is $k_H/k_D = 1.179$ (1.086 per α-deuterium).

This secondary α-deuterium kinetic isotope effect is much larger than the upper limit of 1.04 per α-deuterium for S_N2 reactions and the criterion of mechanism based on the magnitude of this isotope effect fails, at least in the case where the leaving group is *N*,*N*-dimethylaniline. The very large isotope effect found in this study suggests that the maximum value of the isotope effect for S_N2 reactions will have to be carefully established when large, bulky leaving groups such as quaternary ammonium, sulfonium, or possibly even nitrate or arenesulfonate are involved in the reaction. Although the result of this study clearly illustrates that the magnitude of secondary α-deuterium isotope effects cannot be used as an absolute criterion of mechanism for S_N reactions, it does not totally destroy the usefulness of these isotope effects. The maximum value of 1.04 per α-deuterium is probably valid for most of the small or medium sized leaving groups in Table 1.

It is interesting to speculate on the reason for the very large isotope effect observed in the S_N2 reaction between benzyldimethylphenylammonium ion and thiophenoxide ion. The magnitude of secondary α-deuterium kinetic isotope effects is primarily determined by the changes that occur in the Cα—H out-of-plane bending vibration when the reactant is converted to the transition state (2, pp. 104–137, 17, 18). In an S_N reaction involving a carbonium ion intermediate, eq. [1], the Cα—H bonds are more sterically crowded in the tetrahedral substrate than in the transition state whether the formation of an ion pair or the free carbonium ion is rate determining. The Cα—H out-of-plane bending vibrations will be of lower frequency (energy) in the transition state of the rate-determining step and the zero point energy difference between the Cα—H and Cα—D out-of-plane bending vibrations will be smaller (19), Fig. 1*a*. A large normal isotope effect is observed for these reactions. For an S_N2 reaction, the opposite is true. Here the out-of-plane bending vibrations are usually of higher energy in the more sterically crowded trigonal bipyramidal transition state than in the tetrahedral reactant. The zero point energy difference is larger in the transition state and a small or inverse isotope effect is observed, Fig. 1*b*.

In the S_N2 reaction of the benzyldimethylphenylammonium ion the situation is again different. The bulky phenyl group and the extremely large leaving group (*N*,*N*-dimethylaniline, is even larger than a *tert*-butyl group) on the α-carbon place the Cα—H bonds in the reactant in an extremely crowded environment. Thus, the Cα—H out-of-plane bending vibrations in the substrate would be very high energy

[3]See Experimental for details.

[a]This mole ratio was calculated on the basis that 98.1% of the deuterated quaternary salt was dideuterated at the α-carbon (see Experimental).
[b]These values were obtained by correcting the observed fraction of reaction for the error in the recovery of the product.
[c]The error limits are the standard deviation.

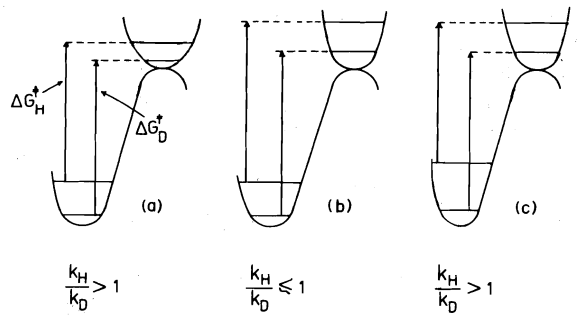

FIG. 1. The reaction coordinate diagram for (*a*) an S_N reaction with a carbonium ion intermediate, (*b*) an S_N2 reaction, and (*c*) an S_N2 reaction of a substrate that is very sterically crowded around the α-carbon.

and an unusually large zero point energy difference would be observed. In this circumstance, the zero point energy difference might be smaller in the transition state and a normal kinetic isotope effect would be found, Fig. 1*c*. This would be particularly likely if the $C\alpha\text{---}\overset{\delta-}{S}$ and the $C\alpha\text{---}\overset{\delta+}{N}$ bonds in the transition state were significantly longer than the normal $C\alpha\text{—}\overset{+}{N}$ and Cα—S bonds of the reactant and product respectively (20).[4]

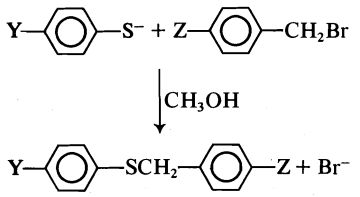
Finally, it is worth noting that the steric explanation of the very large isotope effect in this S_N2 reaction is supported by the work of Kaplan and Thornton (21). These investigators concluded that the secondary α-deuterium kinetic isotope effects in the closely related S_N2 reaction between *N*,*N*-dimethyl-d_6-aniline and methyl *p*-toluenesulfonate was caused by steric crowding in the transition state.

Structure of the Transition State

Nitrogen (leaving group) kinetic isotope effects and Hammett ρ values have been used to determine the lengths of the Cα---N and Cα---S bonds in this S_N2 transition state. In a previous study the nitrogen (leaving group) kinetic isotope effect was found to be 1.0200 ± 0.0007 (11). This isotope effect which is approximately half of the theoretical maximum nitrogen isotope effect, shows that the Cα—N bond is significantly weaker in the S_N2 transition state. Thus, the Cα---N bond is reasonably long in the transition state. This conclusion was supported by the magnitude of the Hammett ρ value for reactions with different *para* substituents on the phenyl ring of the leaving group, i.e., where the rates of reaction for *para*-substituted phenylbenzyldimethylammonium ion were used to prepare a Hammett plot (11). In fact, the ρ value of +2.04 is approximately half of the value obtained for an equilibrium protonation of *para*-substituted dimethylanilines (11). This also suggests a substantial weakening of the Cα—N bond in the transition state and it can be concluded that the Cα—N bond is substantially longer in the transition state than in the reactant.

An estimate of the length of the Cα—S bond in the transition state was obtained in the following manner. Hudson and Klopman (22) reported the rate constants for the S_N2 reactions of several *para*-substituted thiophenoxide ions with several different *para*-substituted benzyl bromides eq. [7].

[7]



Y = OCH_3, CH_3, H, Cl, Br, and OAc
Z = OCH_3, CH_3, H, Br, and NO_2

When the log k/k_0 values calculated for the reactions of several *para*-substituted thiophenoxide ions with a particular *para*-substituted benzyl bromide were plotted against the sigma value of the *para* substituent on the thiophenoxide ion, good Hammett plots were obtained. The correlation coefficients for the Hammett plots for the five different benzyl bromides of [7] averaged 0.97 with extreme values of 0.95 and 0.99 (23). A consideration of the ρ values obtained in these Hammett plots led to the idea that the magnitude of the ρ value is inversely related to the length of the S---Cα bond in the transition state. If the S---Cα bond is almost fully formed in the transition state, the sulfur atom will be almost neutral. This means there will be a large change in the charge on the sulfur in going to the transition state and a large ρ value would be observed. Conversely, a long S---Cα bond would lead to a small ρ value.

The rate constants for the S_N2 reaction of *para*-substituted thiophenoxide ions with benzyldimethylphenylammonium ion are given in Table 3. The Hammett ρ value is −1.70 ± 0.047[5] with a correlation coefficient of 0.990. This ρ value is approximately half the magnitude of the Hammett ρ value of 3.30 (correlation coefficient = 0.997) calculated from the ionization constants of *para*-substituted thiophenols (24), eq. [8]. The relatively small ρ value of −1.70 for the S_N2 reaction indicates that there is a

[4]Although this large normal secondary α-deuterium kinetic isotope effect could also be a result of a transition state that is much looser (has longer S---Cα and Cα---N bonds) than other S_N2 transition states, the above explanation is preferred because (*i*) there is no evidence to suggest that this transition state is looser than normal (in fact other information from studies in our lab indicate that this is not the case) and (*ii*) because the study by Kaplan and Thornton (21) indicates that steric crowding is present in closely related S_N2 reactions.

[5]Standard deviation.

TABLE 3. Rate constants for the reaction of *para*-substituted thiophenoxide ions with benzyldimethylphenylammonium ion at 0°C in DMF

Para substituent on the thiophenoxide ion	$k \times 10^2$ (L mol^{-1} s^{-1})
—OCH_3	4.62
—CH_3	2.43
—H	1.28
—Cl	0.613

relatively small change in charge on the sulfur atom in going to the transition state. This in turn, means that the S—Cα bond formation is far from complete, i.e., that the S---Cα bond is fairly long in the transition state of this S_N2 reaction.

[8] 
Combining the information about the S---Cα bond with that for the Cα---N bond leads to a complete (albeit qualitative) model of the transition state for the S_N2 reaction between benzyldimethylphenylammonium ion and thiophenoxide ion. In fact, both the S---Cα and Cα---N bonds are reasonably long in the transition state. Any increase in the length of the Cα—N bond moves the very bulky $(CH_3)_2NC_6H_5$ group away from the alpha carbon and reduces the steric crowding around the Cα—H bonds. The Cα---N bond is reasonably long in the transition state and thus the steric crowding around the Cα—H bonds will be markedly reduced from that in the substrate.[6,7] Normally, this reduction in steric crowding is balanced by an increase in steric crowding caused by the approach of a nucleophile. In this reaction, however, the S---Cα bond is also long in the transition state and the nucleophile will not increase the steric crowding around the Cα—H bonds significantly.[8] The net effect would be a much less crowded environment for the Cα—H bonds in the transition state. This means that the frequency of the Cα—H out-of-plane bending vibrations will be less in the transition state. The zero point energy difference for the Cα—H and Cα—D bonds will be lower than that in the reactant and a normal isotope effect should be observed. Thus, the hypothesis that this unusually large secondary α-deuterium kinetic isotope effect is caused by an inordinately large steric crowding around the α-carbon in the substrate which is relieved in going to the transition state, is supported by the structure of the transition state for this reaction.

Finally, it is worth noting that the secondary α-deuterium kinetic isotope effect of 1.179 measured in this study compares very well with the isotope effects of 1.20 in chloroform and 1.25 in acetone[9] measured by Leffek and Ko (7) for the reaction of the same substrate with bromide ion. The close agreement between the isotope effects for the bromide ion and the thiophenoxide ion reactions suggests that both of the reactions occur by the same mechanism, i.e., the one-step S_N2 mechanism. Thus, it is reasonable to conclude that the reaction with bromide ion in chloroform and acetone occurs by an internal S_N2 mechanism (an S_N2 reaction within the triple ion, eq. [4]) and not by the carbonium ion mechanism shown in [3].

The carbonium ion mechanism for the bromide ion reaction is unlikely for another reason. The smallest secondary α-deuterium kinetic isotope effect expected for a carbonium ion reaction is $k_H/k_D = 1.07$ per α-deuterium (Table 1). The isotope effects measured by Leffek and Ko for this reaction; $k_H/k_D =$ 1.10 and 1.12 per α-deuterium, are only slightly larger than the smallest possible value. In fact, a very large isotope effect (larger than most of the isotope effects in Table 1) would be expected if the benzyldimethylphenylammonium ion was converted into a benzyl carbonium ion during the reaction. This would occur for several reasons. First, calculations by Hartshorn and Shiner (26) have shown that the maximum secondary α-deuterium kinetic isotope effect for the reaction of a quaternary ammonium ion is large (approximately 1.19 per α-deuterium). Thus, an isotope effect of at least 1.14 per α-deuterium ($k_H/k_D = 1.30$) would be observed even if the ionization step were fully rate determining (2, p. 137). In fact, an even larger isotope effect than 1.14 per

[6]The Cα—H out-of-plane bending absorption occurs at 1487 cm^{-1} in the benzyldimethylphenylammonium ion. This is significantly higher energy than the corresponding absorptions in benzyl compounds with smaller leaving groups and hence less crowded environments at the α-carbon. For example, the Cα—H out-of-plane bending vibrations occur at 1440 cm^{-1} for benzyl chloride, 1448 cm^{-1} for benzyl bromide, 1460 cm^{-1} for benzyl formate, 1460–1490 cm^{-1} for benzyl-*tert*-butyl sulfone, 1485 cm^{-1} for benzyltrimethylammonium ion, and 1490 cm^{-1} for dibenzyldimethylammonium ion (25).

[7]For most S_N2 reactions the leaving group will be smaller than dimethylaniline and the reduction in the steric crowding around the Cα—H bonds will be smaller.

[8]This is the first transition state where the length of the nucleophile–α-carbon bond has been estimated. Comparisons with other systems are therefore impossible.

[9]The isotope effect for the reaction with thiophenoxide ion in DMF was measured at 0°C whereas the isotope effect for the reactions with bromide ion were measured at 30°C. The temperature effects on secondary alpha deuterium kinetic isotope effects are small (2, 7). The isotope effect for the reaction with thiophenoxide ion at 30°C would be approximately 1.17.

α-deuterium would be expected for a carbonium ion reaction because (*i*) the leaving group is extremely large and the initial state will be sterically crowded, (*ii*) the relief of steric crowding associated with the lengthening of the Cα—N bond of the very bulky leaving group is not replaced by an increased crowding from the approaching nucleophile (see Fig. 1), and (*iii*) because leaving group kinetic isotope effect studies have shown that the α-carbon leaving group bond is longer in the transition state of a carbonium ion reaction than in an S_N2 reaction (27, 28). Thus, the secondary α-deuterium kinetic isotope effects for the reaction are not large enough to be consistent with the formation of a benzyl carbonium ion intermediate.

In conclusion, this study has shown (*i*) that the magnitude of secondary α-deuterium kinetic isotope effects cannot be used as an absolute criterion of mechanism particularly for reactions of substrates with large, bulky leaving groups. (*ii*) The complete modelling of the S_N2 transition state for the reaction between benzyldimethylphenylammonium ion and thiophenoxide ion has shown that the structure of the transition state is consistent with the large normal isotope effect observed in this reaction. (*iii*) This study has also shown that the maximum value of secondary α-deuterium kinetic isotope effects for S_N2 reactions is more dependent on the leaving group than was previously suggested (2, pp. 104–137). This means that the maximum value of the isotope effect for S_N2 reactions will have to be established for each leaving group before the criterion of mechanism based on the magnitude of these isotope effects can be used with complete confidence. Finally, (*iv*) these results suggest that the reaction between benzyldimethylphenylammonium ion and bromide ion in chloroform and acetone also occurs by way of an S_N2 mechanism within the triple ion.

Experimental

Materials

The preparation of benzyldimethylphenylammonium nitrate, sodium thiophenoxide, and the solvent, *N*,*N*-dimethylformamide, are described elsewhere (11). The benzyl-1,1-d_2-dimethylphenylammonium nitrate was prepared from benzyl-1,1-d_2 bromide and *N*,*N*-dimethylaniline using the method described for the undeuterated compound (11). The benzyl-1,1-d_2 bromide was prepared in two steps. First, 25.5 g (0.177 mol) of ethyl benzoate was reduced with 4.0 g (0.095 mol) of lithium aluminum deuteride (Merck) in anhydrous ether to give 18.5 g (88%) of benzyl-1,1-d_2 alcohol (13). An nmr analysis indicated that the alcohol was 99% deuterated at the α-carbon. Next, anhydrous hydrogen bromide gas (Matheson) was bubbled through a solution containing 18.0 g (0.163 mol) of the alcohol in 50 mL of benzene for 3 h. The benzene layer was separated, washed with water and dried over anhydrous $CaCl_2$. The benzene was removed on the rotary evaporator and the product distilled to give 17.2 g (61%) of benzyl-1,1-d_2 bromide, bp 56°C (3 Torr), lit. (29) bp 56°C (3 Torr). An nmr analysis indicated the bromide was 99% deuterated. The 4.5 g (64% yield) of pure benzyl-1,1-d_2-dimethylphenylammonium nitrate, mp 157–157.5°C lit. (11) mp 157–158°C), produced from 4.0 g (0.023 mol) of benzyl-1,1-d_2 bromide and 3.1 g (0.026 mol) of *N*,*N*-dimethylaniline was also 99% deuterated. A mass spectrometric analysis showed that the quaternary ammonium salt was 98.1% dideuterated and 1.9% monodeuterated at the 1-position (*vide infra*).

The undeuterated benzyl phenyl sulfide standard required for the mass spectrographic analysis was prepared previously (11). The deuterated standard, benzyl-1,1-d_2 phenyl sulfide, was prepared by refluxing 2.3 g (0.013 mol) of the benzyl-1,1-d_2 bromide with sodium thiophenoxide in ethanol for 3 h. The sodium thiophenoxide was formed when 2.64 g (0.024 mol) of benzenethiol reacted with the sodium ethoxide produced from 0.58 g (0.025 mol) of sodium and 15 mL of degassed, anhydrous ethanol. Most of the ethanol was removed on the rotary evaporator and 100 mL of cold water was added. The solid that precipitated was filtered and recrystallized from ethanol. The purified yield was 1.10 g (41%), mp 42°C (lit. (30) mp 42°C). The amount of deuterium on the α-carbon was determined in a mass spectrometric analysis (*vide infra*).

The *para*-substituted sodium thiophenoxides used to determine the rate constants for the Hammett plot were prepared using the procedure described for sodium thiophenoxide (11). The yield of the sodium *p*-chlorothiophenoxide was significantly lower (60%) than that of the other salts.

Secondary α-Deuterium Kinetic Isotope Effect

This isotope effect was measured by the competitive technique (11, 13). The reactions were carried out using the procedure described in the section entitled 'Kinetic Measurements' in ref. 11 except that the reactant was a mixture of almost equal quantities of the deuterated and undeuterated benzyldimethylphenylammonium nitrate. The amounts of *dideuterated* and undeuterated quaternary ammonium salts in the starting material were calculated from the weights of the deuterated and undeuterated substrate and the percentage (98.1%) of the dideuterated compound in the deuterated benzyldimethylphenylammonium nitrate. The deuterium content of the deuterated quaternary ammonium salt was estimated by mass spectrometry (*vide infra*). The reactions were stopped after fractions of reaction ranging from 17 to 63% of completion by pouring the reaction mixture into 1400 mL of cold (0°C) pH 12 water. The product, a mixture of deuterated and undeuterated benzyl phenyl sulfide, was extracted from this mixture.[10] The fraction of reaction was estimated from the results of a gas chromatographic analysis of the sulfide (11). The volume of the ether solution used in the gas chromatographic analysis was reduced to approximately 0.25 mL by evaporating the ether in a stream of nitrogen and the ratio of the undeuterated to dideuterated benzyl phenyl sulfide determined by mass spectrometry (*vide infra*). The isotope effect was calculated using [6].

Mass Spectrometric Analyses

The amount of dideuterated quaternary ammonium salt in the deuterated substrate (required in the calculation of R_0 in [6]) was determined in a mass spectrometric analysis of the benzyl phenyl sulfide recovered (11) from reactions taken 100% to completion. The ratio of undeuterated to dideuterated

[10]Control experiments using synthetic mixtures showed that 93 ± 3% of the benzyl phenyl sulfide was recovered. This error in the recovery was taken into account in calculating the fraction of reaction.

benzyl phenyl sulfide in the product of reactions taken part way to completion (R_f in [6]) were also determined by a mass spectrometric analysis of benzyl phenyl sulfide. These analyses involved injecting 25 μL of the concentrated ether solutions containing the benzyl phenyl sulfide produced in the reaction (*vide supra*), into the liquid inlet system of a Dupont 21-491 double focussing mass spectrometer. The oven temperature was 140°C and the source temperature was 180°C. The ionizing voltage was 70 eV. The actual analyses were done by adjusting the sensitivity so that the largest of the *m/e* 200 and 202 peaks was expanded to nearly full scale on the galvanometric recorder (the concentration of benzyl phenyl sulfide was large enough so that a low sensitivity was used). The *m/e* 200–202 peaks were scanned 12 times using a scan speed of 200 s/decade and a chart speed of 0.5 in./s. The sample was pumped out and the background run at high sensitivity until there was no signal in the 200–202 mass range. The same sample was then reinjected and scanned 12 more times. The heights of the appropriate peaks were measured to the nearest hundredth of an inch and the ratio of the peaks calculated with the largest peak (either the *m/e* 200 or 202 peak) given a height of 100. The average ratio from all the scans for a particular sample was used in [9] and [10] to calculate the ratio of undeuterated to dideuterated benzyl phenyl sulfide in the sample.

$$[9] \qquad H_{200} = d_0 + \left(\frac{a}{100}\right)d_2$$

$$[10] \qquad H_{202} = \left(\frac{b}{100}\right)d_0 + d_2$$

H_{200} and H_{202} are the heights of the *m/e* 200 and 202 peaks, respectively, d_0 is the percentage of undeuterated sulfide, d_2 is the percentage of the dideuterated sulfide, a is the height of the *m/e* 200 peak from the deuterated benzyl phenyl sulfide, and b is the height of the *m/e* 202 peak for the undeuterated benzyl phenyl sulfide. The parameters a and b were determined by running samples of the deuterated and undeuterated benzyl phenyl sulfide at least twice during the analyses of the samples obtained from different experiments. It is worth noting that the monodeuterated substrate does not interfere in the analysis because it is converted to monodeuterated benzyl phenyl sulfide which gives a peak at *m/e* 201.

The amount of dideuterated substrate in the benzyl-1,1-d_2-dimethylphenylammonium nitrate was determined in two ways: (*i*) by determining the relative heights of the *m/e* 201 (monodeuterated) and 202 (dideuterated) peaks of the benzyl phenyl sulfide produced when a reaction of the deuterated quaternary ammonium salt was taken 100% to completion, and (*ii*) by determining the term c (eq. [11]) which makes the ratio of undeuterated to dideuterated benzyl phenyl sulfide obtained when a mixture of undeuterated and deuterated benzyldimethylphenylammonium nitrate was reacted 100% to completion, equal to the weight ratio of the undeuterated to deuterated substrate in the reactant.

$$[11] \qquad \frac{\text{wt. undeuterated reactant}}{\text{wt. deuterated reactant}} = c\left(\frac{\text{undeuterated product}}{\text{dideuterated product}}\right)$$

The term c is in fact, the fraction of dideuterated material in the deuterated quaternary ammonium salt. The results from five different reactions showed that the benzyl-1,1-$d_2$dimethylphenylammonium nitrate was 98.1 ± 0.7% dideuterated at the 1 position. This value was used to calculate the ratio of undeuterated to dideuterated quaternary ammonium salt (R_0) in the starting material of the isotope effect experiments. The percentage of the dideuterated benzyldimethylphenylammonium nitrate in the deuterated substrate was confirmed when it was found that the benzyl-1,1-d_2 phenyl sulfide produced from the benzyl-1,1-d_2 bromide used in the synthesis fo the deuterated quaternary ammonium salt, was also 98% dideuterated. In fact, the results from 11 different experiments using the two methods described above, indicated that the benzyl-1,1-d_2 phenyl sulfide was 97.7 ± 0.5% dideuterated.

The undeuterated to dideuterated ratio for the benzyl phenyl sulfide in the product from reactions taken part way to completion (R_f) was determined using the ether solution from the gas chromatographic analysis (*vide supra*).

Hammett ρ Value

The procedure used to measure the rate constants required for the Hammett plot has been described (11). The only difference was that the colour which developed at the end point in the titration of the substituted thiophenoxide ions varied from pink to blue. A purple colour is observed at the end point when sodium thiophenoxide is titrated.

Pseudo-first-order rate constants for the decarboxylation of 3-hydroxy- and 3-aminopicolinic acids in aqueous solution at 150°C were determined and plotted as a function of acidity. Each rate profile has a maximum at an acidity well above the isoelectric point and this is attributed to decarboxylation of an intermediate protonated at the 2-position, analogous to the intermediates involved in the decarboxylation of salicylic and anthranilic acids. There is also a shoulder on each rate profile at a lower acidity corresponding to the isoelectric point where the Hammick ylide mechanism has a rate maximum in most picolinic acid decarboxylations. It is concluded that 3-hydroxy- and 3-aminopicolinic acids decarboxylate by the ylide mechanism at low acidity and by the protonation mechanism at higher acidities. In agreement with this interpretation, the ^{13}C kinetic isotope effect in 3-hydroxypicolinic acid decarboxylation is 2.0% on the ylide part of the curve, 1.3% where decarboxylation of the protonated intermediate is rate determining, and drops to 0.4% in the intermediate region. Comparison of the rate constants for ylide decarboxylation with those for other 3-substituted picolinic acids shows that 3-hydroxy and 3-amino substituents facilitate decarboxylation, probably by their inductive and field effects on the developing negative charge at the 2-position of the transition state.

GERALD E. DUNN, HARALD F. THIMM et RAJANI K. MOHANTY. Can. J. Chem. **57**, 1098 (1979).

On a déterminé les constantes de vitesse de pseudo-premier ordre pour la décarboxylation des acides hydroxy-3 et amino-3 picoliniques en solution aqueuse à 150°C et on a tracé la courbe qui les relie à l'acidité. Pour chaque profil de vitesse, il existe un maximum à une acidité bien au dessus du point isoélectrique et on l'attribue à la décarboxylation d'un intermédiaire protoné en position 2, analogue aux intermédiaires impliqués dans la décarboxylation des acides salicyclique et anthranilique. On note aussi un épaulement sur chaque profil de vitesse, à une acidité plus basse que celle du point isoélectrique, où la vitesse pour le mécanisme ylide de Hammick est maximale pour les décarboxylations de la plupart des acides picoliniques. On en conclut que les acides hydroxy-3 et amino-3 picoliniques se décarboxylent par un mécanisme ylide à faible acidité et par un mécanisme de protonation à des acidités plus élevées. En accord avec cette interprétation, l'effet isotopique cinétique ^{13}C observé lors de la décarboxylation de l'acide hydroxy-3 picolinique est égal à 2% dans la portion ylide de la courbe, à 1.3% lorsque la décarboxylation implique un intermédiaire dans l'étape qui détermine la vitesse et tombe à 0.4% dans la région intermédiaire. Une comparaison des constantes de vitesse pour la décarboxylation par l'intermédiaire d'ylides avec celles d'autres acides picoliniques substitués en position 3 montre que les substituants hydroxy-3 et amino-3 facilitent la décarboxylation, probablement grâce à leurs effets inductifs et de champs sur la charge négative qui se développe en position 2 de l'état de transition.

[Traduit par le journal]

Introduction

The preceding papers in this series reported that the pH dependence of the first-order rate constants for decarboxylation of picolinic acid (1) and 3-benzoyl-, 3-carboxyl-, 3-bromo-, and 3-nitropicolinic acids (2) in aqueous solution fit the mechanism proposed by Dyson and Hammick (3) for decarboxylation of picolinic acid in nonaqueous solvents, as shown in reaction [1]. This mechanism requires that the first-order rate constant be a maximum at the isoelectric pH and that there be a ^{13}C kinetic

[2] 
isotope effect at all pH's, both of which criteria were satisfied (1, 2). However, the pH–rate profiles for 3-hydroxy- and 3-aminopicolinic acids do not have maxima at their isoelectric pH's, so they were assumed to proceed by some mechanism other than [1]. The present paper reports an investigation of the mechanism of decarboxylation of these two acids.

Results and Discussion

3-Hydroxypicolinic Acid

The successive ionization constants of 3-hydroxypicolinic acid are defined in eq. [2]. Dutt *et al.* (4) report $pK_2 = 5.17$ and $pK_3 = 10.76$ at 25°C and ionic strength $\mu = 0.10$. Potentiometrically, we find $pK_2 = 5.21$ and $pK_3 = 10.74$ at 25°C and $\mu = 1.0$. The concentration maximum for HA^- under these conditions is therefore at pH 8.0. The value of K_1 is not known but, since pK_1 for picolinic acid is 1.08 (5) and an *ortho* hydroxy group increases the ionization constant of benzoic acid by 1.2 pK units, one may estimate pK_1 for 3-hydroxypicolinic acid as probably in the vicinity of zero. This puts the concentration maximum for H_2A in the vicinity of pH 2.6. Consequently, if 3-hydroxy, like other picolinic acids, decarboxylates in zwitterionic form by the Hammick mechanism (1, 2), there should be rate maxima at pH 2.6, or 8, or both.

The decarboxylation of 3-hydroxypicolinic acid in buffered aqueous solution is found to be first order with respect to substrate and the pseudo-first-order rate constants are recorded in Table 1. It is seen that the maximum rate constant occurs, not at either concentration maximum, but near pH 0. The rate constants are plotted against acidity in Fig. 1, which shows that the rate profile is not symmetrical, as would be the case if only one species were decarboxylating, but has a distinct shoulder at approximately pH 2.5. This suggests that H_2A may be decarboxylating by the Hammick mechanism at the concentration maximum as expected but there is evidently an additional mechanism for decarboxylation which has its rate maximum at a pH lower than either of the concentration maxima. The rate maximum at high acidity is reminiscent of the decarboxylation of aminobenzoic acids, where the rate maximum occurs a few pH units below the isoelectric pH (6, 7). In these cases decarboxylation takes place from intermediates in which the carbon α to the carboxyl group is protonated before decarboxylation. The pH–rate profile for 3-hydroxypicolinic acid may then be accounted for by a Hammick-type decarboxylation of H_2A in the pH range 2–5, which is overwhelmed by electrophilic substitution by proton at higher acidities.

[a]Average of two runs ± maximum deviation. Constants with no deviation listed are from single runs.

The Hammick part of the decarboxylation may be represented by eq. [3].

[3] 

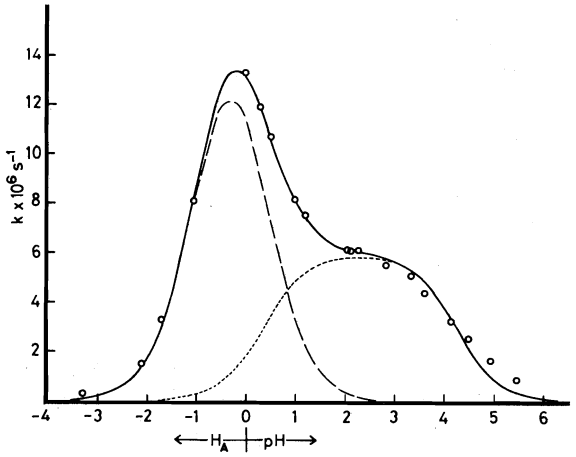

FIG. 1. Pseudo-first-order rate constants for the decarboxylation of 3-hydroxypicolinic acid in aqueous solution at 150°C. Circles represent experimental points. The solid line is generated by [12], the dashed line by [11], and the dotted line by [5].

The equilibrium concentration of H_2A is given by [4], in which [C] represents the total stoichiometric concentration of substrate.

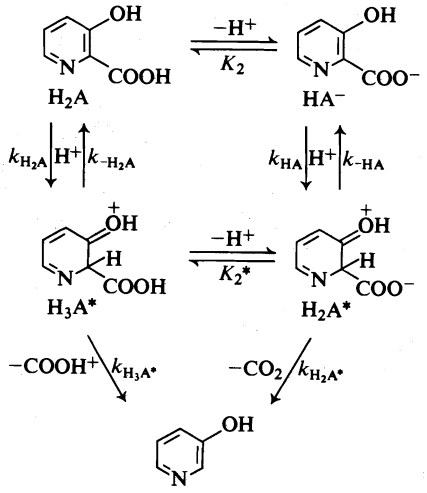
$$[4] \qquad [H_2A] = \frac{[C]}{\frac{[H^+]}{K_1} + 1 + \frac{K_2}{[H^+]}}$$

The pseudo-first-order rate constant for this part of the decarboxylation is therefore given by [5].

$$[5] \qquad k_{ylide} = \frac{k_H}{\frac{[H^+]}{K_1} + 1 + \frac{K_2}{[H^+]}}$$

The protonation mechanism analogous to that found for the amino- and hydroxybenzoic acids is given by [6]. Applying the steady-state approximation to ($[H_3A^*] + [H_2A^*]$) and recognizing that K_3 is negligible at pH < 5, one obtains [7] as the expression for the dependence of the pseudo-first-order rate constant for this part of the decarboxylation upon acidity.

[6]



$$[7] \qquad k_{prot} = \frac{k_{H_2A}[H^+] + k_{HA}K_2}{\frac{[H^+]}{K_1} + 1 + \frac{K_2}{[H^+]}} \times \frac{k_{H_3A^*}[H^+] + k_{H_2A^*}K_2^*}{(k_{-H_2A} + k_{H_3A^*})[H^+] + (k_{-HA} + k_{H_2A^*})K_2^*}$$

As in the aminobenzoic acid case (6, 7), the mechanism can be simplified with the aid of ^{13}C kinetic isotope effects. Table 2 shows the ^{13}C kinetic isotope effects in the decarboxylation of 3-hydroxypicolinic acid at various pH's. There is a distinct isotope effect in the pH range 2–5. This is as expected, since we postulate the Hammick mechanism (eq. [5]) to predominate in this region and its rate-determining step is C—C bond breaking. In the acidity range 0 to −3 where the protonation mechanism (eq. [7]) should predominate, the isotope effect is small at low acidity, probably zero when the effect from the overlapping Hammick mechanism is subtracted, and increases at high acidities. This is the pattern shown by aminobenzoic acids decarboxylating by the protonation mechanism, and can be interpreted in the same way.

With the observation that in mechanism [6] the only C—C bond-breaking steps (and therefore the only ones which can produce ^{13}C kinetic isotope effects) are $k_{H_2A^*}$ and $k_{H_3A^*}$, the interpretation is as follows. At low acidity [7] reduces to [8]

$$[8] \qquad k = \frac{k_{HA}k_{H_2A^*}[H^+]}{k_{-HA} + k_{H_2A^*}}$$

so that the observed rate constant increases with acidity, as observed. However, since the isotope effect is small in this region, k_{-HA} must be small compared to $k_{H_2A^*}$, indicating that H_2A^* decarboxylates faster than it deprotonates.

At high acidity [7] reduces to [9]

TABLE 2. ^{13}C kinetic isotope effects in the decarboxylation of 3-hydroxypicolinic acid in aqueous solution at 150°C

	% isotope effect	
pH or H_A (25°C)	Observed[a]	Calculated from [12]
4.35	2.03±0.04	2.00
2.32	1.96	2.00
0.15	0.50±0.01	0.42
−0.92	0.38	0.48
−1.95	0.62	0.90
−2.18	1.26	1.00

[a]Percentage isotope effect = $(k_{12}/k_{13} - 1)100$ ± average deviation of three runs. Where no deviations are listed, results are from a single run.

[9] $$k = \frac{k_{H_2A}K_1k_{H_3A^*}}{k_{-H_2A} + k_{H_3A^*}}$$

so that the observed rate constant should level off at high acidity. In fact, however, the rate constant decreases at high acidity. To account for this we postulate that, as in the aminobenzoic acid case, $k_{H_3A^*}[H^+] < k_{H_2A^*}K_2^*$; i.e. that the COOH group in H_3A^* ionizes to COO^- in H_2A^* before decarboxylating. With this assumption, [7] at high acidity becomes [10].

[10] $$k = \frac{k_{H_2A}K_1k_{H_2A^*}K_2^*}{(k_{-H_2A} + k_{H_3A^*})[H^+]}$$

Then, in order to account for the large ^{13}C kinetic isotope effect at high acidity, we postulate that $k_{-H_2A} > k_{H_3A^*}$. Putting these three assumptions ($k_{-HA} > k_{H_2A^*}$, $k_{H_3A^*}[H^+] < k_{H_2A^*}K_2^*$, $k_{H_3A^*} < k_{-H_2A}$) into [7] produces [11].

[11] $$k_{prot} = \frac{k_{H_2A}[H^+] + k_{HA}K_2}{\frac{[H^+]}{K_1} + 1 + \frac{K_2}{[H^+]}} \times \frac{1}{\frac{k_{-H_2A}}{k_{H_2A^*}K_2^*}[H^+] + 1}$$

The overall expression for the dependence of rate constant upon pH is then obtained by combining [5] and [11] to give [12].

[12] $$k = k_{ylide} + k_{prot} = \frac{\left(k_{H_2A} + \frac{k_Hk_{-H_2A}}{k_{H_2A}K_2^*}\right)[H^+] + k_{HA}K_2 + k_H}{\left(\frac{k_{-H_2A}}{k_{H_2A^*}K_2^*}[H^+] + 1\right)\left(\frac{[H^+]}{K_1} + 1 + \frac{K_2}{[H^+]}\right)}$$

To fit the data of Table 1 to eq. [12] it is necessary to assume some acidity function for protonation at acidities above pH 0, where [12] reduces to [13].

[13] $$\log k = \log\left(\frac{k_{H_2A}k_{H_2A^*}K_2^*}{k_{-H_2A}} + k_H\right)K_1 + pH$$

In this range the pH term must be replaced by an acidity function, but the proper function is not known. However, since most acidity functions are proportional to H_0 (8), pH may be replaced by nH_0. A plot of log k vs. H_0 for the high acidity points gives a straight line with $n = 0.46$. This slope is similar to that obtained for the decarboxylation of pyrimidinecarboxylic acids (9) and corresponds roughly to that for the acidity function H_A. Therefore, in Fig. 1 rate constants at high acidities are plotted against H_A.

Also using H_A at high acidities, the data of Table 1 were fitted to [12] by an iterative least-squares computer program (10) with the results shown in Table 3. The curve generated by [12] with the data of Table 3 is shown as the solid line in Fig. 1. It can be seen that the fit of the experimental points to the curve is reasonably good and that the values of pK_1 and pK_2 at 150°C obtained from the kinetic data are in reasonable agreement with the values at 25°C. As is the case with other picolinic acids (1), pK_1 is not much affected by the rise in temperature but pK_2 is decreased by about 1 pK unit. The tailing of the points at pH's above 4 suggests that the monoanion, HA^-, may also be decarboxylating, as is the case with picolinic acid itself (1), but the number of experimental points in this region is not sufficient to justify the additional complexity that inclusion of this mode of decarboxylation would produce in [12].

TABLE 3. Rate and equilibrium constants at 150°C calculated from [12] and the data of Tables 1 and 4

Parameter	3-Hydroxypicolinic acid	3-Aminopicolinic acid
$k_{H_2A} + \frac{k_Hk_{-H_2A}}{k_{H_2A^*}K_2^*}$	4.04×10^{-5}	4.26×10^{-6}
$k_{HA}K_2 + k_H$	5.92×10^{-6}	3.27×10^{-5}
K_1 (pK_1)	0.441 (0.36)	2.12×10^{2} (−2.33)
K_2 (pK_2)	5.62×10^{-5} (4.25)	3.09×10^{-2} (1.51)
$\frac{k_{-H_2A}}{k_{H_2A^*}K_2^*}$	9.74×10^{-2}	4.49×10^{-3}

It is apparent from the shape of the curve in Fig. 1 that at pH > 3 the ylide mechanism predominates over the protonation mechanism, so that the rate profile should be represented in this region by [5]. In this same region [12] reduces to [14], which means

[14] $$k = \frac{k_{HA}K_2 + k_H}{\frac{[H^+]}{K_1} + 1 + \frac{K_2}{[H^+]}}$$

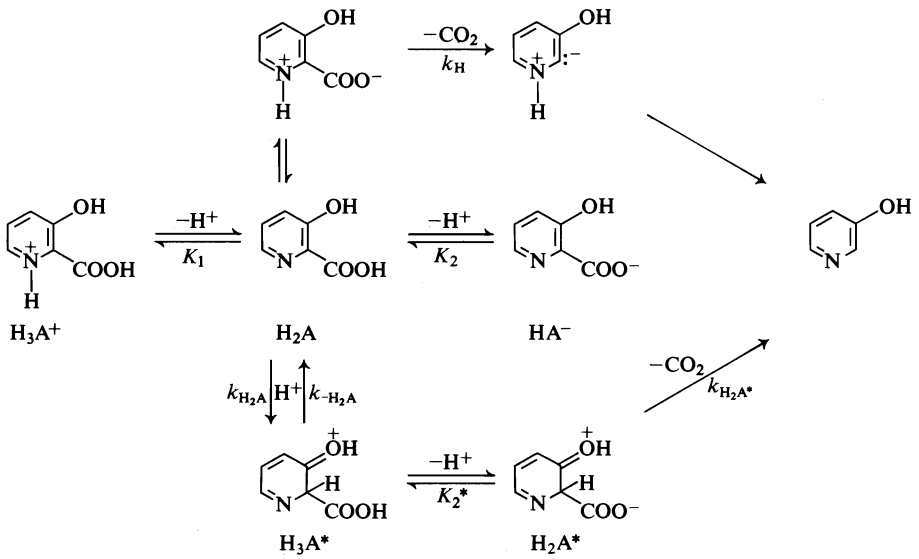
that $k_{HA}K_2$ must be negligible compared to k_H, or $k_H = 5.92 \times 10^{-6}\ s^{-1}$. This makes it possible to draw separate rate profiles of the ylide and protonation mechanisms, as shown by the dotted lines in Fig. 1.

Furthermore, multiplying the value of k_H by the value of the last parameter in Table 3 and comparing the result with the value of the first parameter in Table 3 shows that the second term in the first parameter is negligible. Equation [12] can therefore be reduced to [15]. The final mechanism, of which

[15] $$k = \frac{k_{H_2A}[H^+] + k_H}{\left(\frac{k_{-H_2A}}{k_{H_2A}K_2^*}[H^+] + 1\right)\left(\frac{[H^+]}{K_1} + 1 + \frac{K_2}{[H^+]}\right)}$$

[15] is the kinetic expression, is a combination and

[16]



simplification of reactions [2], [3], and [6] which may be represented by [16].

In the pH region 6 to 2.5 H_2A is decomposing by the ylide mechanism, k_H represents the rate-determining step with a ^{13}C isotope effect and k increases as $[H_2A]$ increases. As pH decreases from 2.5 to 0.5, $[H_2A]$ remains relatively constant but k continues to increase because H_2A is being protonated to H_3A^* which decarboxylates rapidly via H_2A^*; k_{H_2A} is the rate-determining step, so there is no ^{13}C isotope effect. From pH 0.5 to $H_A = -3$ the rate of protonation of H_2A to H_3A^* exceeds the rate of decarboxylation of H_2A^* so that the rate-determining step is $k_{H_2A^*}$ which has a ^{13}C kinetic isotope effect; k decreases as H_2A^* (which is now in tautomeric equilibrium with H_2A) is increasingly converted to H_3A^+ which does not decarboxylate.[2]

This mechanism, as represented by [12], can be used to predict changes in the ^{13}C kinetic isotope effect with pH. Assuming isotope effects of 2% in k_H and 1% in $k_{H_2A^*}$, one calculates the isotope effects shown in Table 2. The agreement between calculated and observed isotope effects at a particular pH is only fair but the trend is correct and the difference between observed and calculated values is probably not much outside the experimental error, particularly when the naive treatment of acidity functions is considered.

In summary, then, the proposed mechanism agrees satisfactorily with the rate vs. pH profile, the expected ionization constants at 150°C, and the variation of ^{13}C kinetic isotope effect with pH. Obviously these observations can not prove the mechanism to be correct, but they do show that it is consistent with the data, and it is consistent also with what is known about the mechanisms of decarboxylation of hydroxybenzoic and picolinic acids.

3-Aminopicolinic Acid

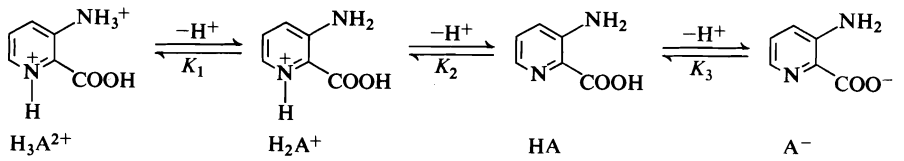
The protonation equilibria for 3-aminopicolinic acid are shown in [17], omitting the zwitterionic forms. Literature values for pK_2 and pK_3 are 1.22 and 7.20, respectively, without reference to ionic strength (11). Potentiometrically, in 1 *M* KCl we found $pK_2 = 1.53$ and $pK_3 = 7.09$. No doubt pK_1 would be considerably negative.

The pseudo-first-order rate constants for 3-aminopicolinic acid are shown in Table 4 and plotted against pH in Fig. 2. It is seen that the pH vs. rate profile has a similar shape to that for 3-hydroxypicolinic acid, except that the ring-protonation mechanism contributes relatively more to the total rate in the amino acid case. The data were fitted to [12] by the same procedure used for the hydroxy acid, with the results shown in Table 3.

As in the hydroxypicolinic acid case, the shape of the rate profile suggests that $k_{HA}K_2$ is negligible compared to k_H, so that the overall rate constants can be separated into their ylide and protonation

[2]A referee suggests that H_3A^+ is at all times in tautomeric equilibrium with H_3A^*, which decarboxylates directly by loss of $COOH^+$ without the intermediacy of H_2A^*. To account for the decreasing rate at high acidity he postulates that the equilibrium constant for the tautomerism between H_3A^+ and H_3A^* changes with the medium so as to decrease $[H_3A^*]$ as acidity increases. This is, of course, a possible interpretation but we prefer the one in the text because the referee's mechanism requires an unpredictable change in the tautomeric equilibrium constant, because it requires that protonation at a carbon site be always rapid and because 3-hydroxypicolinic acid is following the same pattern as anthranilic acid (6), for which the rate decrease occurs at much lower acidity (pH 1.5 to 0) where no such dramatic medium effect is possible.

[17]



components by means of eqs. [5] and [11] as shown by the dotted lines in Fig. 2.

Finally, it should be noted that the decarboxylation study of 3-hydroxy- and 3-aminopicolinic acids was originally undertaken as part of a study of the effect of 3-substituents on the rates of decarboxylation by the ylide mechanism (2) but that the 3-hydroxy and 3-amino acids had to be eliminated from the study because of the intrusion of the protonation mechanism. Now that rate constants for the ylide component of the decarboxylation of these acids are available, they are compared with those from other 3-substituted picolinic acids (2) in Table 5.

TABLE 4. Pseudo-first-order rate constants for decarboxylation of 3-aminopicolinic acid in aqueous solution at 150°C

pH or H_A (25°C)	Buffer	$k \times 10^6$ (s^{-1})[a]
4.18	NaH_2PO_4	1.41
3.91	HCl, NaH_2PO_4	1.60
3.43	HCl, NaH_2PO_4	1.74±0.02
3.13	HCl, NaH_2PO_4	3.83±0.04
1.70	HCl, KCl	10.7
1.00	HCl, KCl	26.7±0.1
0.66	HCl, KCl	30.3±0.2
0.30	HCl, KCl	33.6
0	HCl	38.0±0.2
−0.45	H_2SO_4	41.9
−1.05	H_2SO_4	61.4
−1.71	H_2SO_4	150
−2.23	H_2SO_4	253
−3.38	H_2SO_4	52.6

[a]Average of two runs ± maximum deviation. Constants with no deviation listed are from single runs.

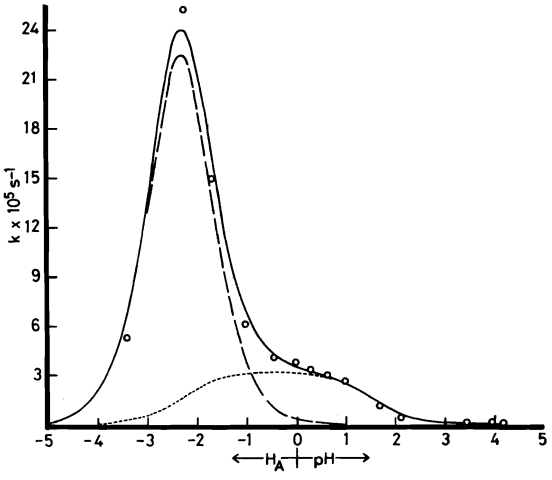


FIG. 2. Pseudo-first-order rate constants for the decarboxylation of 3-aminopicolinic acid in aqueous solution at 150°C. Circles represent experimental points. The solid line is generated by [12], the dashed line by [11], and the dotted line by [5].

TABLE 5. First-order rate constants for the decarboxylation of 3-substituted picolinic acids by the Hammick mechanism in aqueous solution at ionic strength 1.0

Substituent	Temperature (°C)	k_H (s^{-1})
Amino	150	3.2×10^{-5}
Hydroxy	150	5.9×10^{-6}
Methyl	150	4.0×10^{-6}
None	150	1.1×10^{-6}
Benzoyl	150	$\geq 4.5 \times 10^{-4}$
Carboxyl	150	$\geq 1.2 \times 10^{-3}$
	95	3.3×10^{-6}
Bromo	95	1.5×10^{-5}
Nitro	95	$\geq 1 \times 10^{-3}$

From the earlier set of rate constants (2) it was observed that all 3-substituents increase the rate of decarboxylation by the ylide mechanism and it was concluded that 3-substituents exert their influence largely by inductive or field effects tending to stabilize negative charge at the 2-position of the ylide. But, since 3-methyl also accelerates the decarboxylation, it was felt that steric interaction with the carboxyl group must favor decarboxylation. The new data for 3-hydroxy and 3-amino substituents confirm that the electronic component of the 3-substituent effect is largely inductive since they, like 3-carboxyl, 3-benzoyl, 3-bromo, and 3-nitro substituents accelerate decarboxylation. It is surprising that the 3-amino substituent should have a larger inductive effect than 3-hydroxy but it must be remembered that substituents also affect the zwitterionic distribution of protons within the various species and that it may well be the protonated amino group which has the large inductive effect.

Experimental

3-Hydroxypicolinic acid was a commercial product (Aldrich). The synthesis of 3-aminopicolinic acid has been described previously (2), as have the methods of measuring rates (2) and ^{13}C kinetic isotope effects (12). All pH's were measured with an Orion digital pH meter, Model 801. In the negative region H_A values (13) were calculated from density measurements of sulfuric acid solutions.

WILLIAM A. AYER, LOIS M. BROWNE, YUJI NAKAHARA, MOTOO TORI, and LOUIS T. J. DELBAERE. Can. J. Chem. **57**, 1105 (1979).

The structures of lucidine B, dihydrolycolucine, and lycolucine, representatives of a new type of *Lycopodium* alkaloid, have been determined, mainly on the basis of an X-ray crystallographic study of a derivative (*N,O*-di-*p*-bromobenzoyltetrahydrodeoxyoxolucidine B) of lucidine B. Dehydrogenation of lucidine B gives dihydrolycolucine which in turn has been prepared from lycolucine.

WILLIAM A. AYER, LOIS M. BROWNE, YUJI NAKAHARA, MOTOO TORI et LOUIS T. J. DELBAERE. Can. J. Chem. **57**, 1105 (1979).

On a déterminé les structures de la lucidine B, de la dihydrolycolucine et de la lycolucine, représentatifs d'un nouveau type d'alcaloïde du *Lycopodium*, en se basant principalement sur une étude de diffraction de rayons-X effectuée sur un dérivé (la *N,O*-di-*p*-bromobenzoyltétrahydrodésoxyoxolucidine B) de la lucidine B. La déshydrogénation de la lucidine B conduit à la dihydrolycolucine qui a pu être préparée à son tour à partir de la lycolucine.
[Traduit par le journal]

In 1963 we described the separation of the alkaloids of *Lycopodium lucidulum* into strong and weak bases (1). The strong bases have been the subject of two further reports (2, 3). In 1968 the separation of the weak bases, which constitute about 80% of the total alkaloids, was described in more detail and the structure of one of these bases, luciduline (**1**), was reported (4). Luciduline, however, is one of the minor components of the weak base fraction and considerable work in these (5, 6) and other (7) laboratories has been devoted to the separation and identification of the remaining alkaloids. We have succeeded in characterizing several different $C_{30}N_3$ alkaloids from this source (5, 6) and now wish to report the structures of three of these alkaloids, representatives of a distinctively new type of *Lycopodium* alkaloid.

Separation of the weak bases of *L. lucidulum* was accomplished by countercurrent distribution between chloroform (moving phase) and saturated aqueous potassium hydrogen tartrate (stationary phase) followed by extensive column and thin layer chromatography over alumina.[1] Two isomeric alkaloids $C_{30}H_{49}N_3O$, named lucidine A and lucidine B, were isolated, along with a compound $C_{30}H_{43}N_3O$ (lycolucine) and a compound $C_{30}H_{45}N_3O$ (dihydrolycolucine).[2]

Structure **2** is proposed for lucidine B on the basis of an X-ray crystallographic study of the derivative **3** (*N,O*-di-*p*-bromobenzoyltetrahydrodeoxyoxolucidine B) prepared from lucidine B as described below. The presence of the tertiary $\rangle N—COCH_3$ and $\rangle N—CH_3$ groups in lucidine B are readily established by spectroscopic methods (ir, ^{1}Hmr). The presence of the fully substituted imino group is revealed by the ease of $NaBH_4$ reduction to dihydrolucidine B which, unlike lucidine B, shows NH absorption in the ir, and by the presence of a C=N absorption band (1643 cm^{-1}) in desacetyllucidine B (**4**), prepared by acid catalyzed hydrolysis of lucidine B. When a chloroform solution of lucidine B is stirred in the presence of air, a more polar com-

[1]Details of the separation procedure will be provided in the full paper. They may also be found in refs. 5 and 6.

[2]Several other $C_{30}N_3$ alkaloids, not yet fully characterized, are also present. Copies of the infrared spectra of the four alkaloids mentioned are available from the Depository of Unpublished Data. Photocopies may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

pound $C_{30}H_{49}N_3O_2$ ('oxolucidine B'), **5**, is formed. Spectroscopic studies indicate the presence of a tertiary hydroxyl in oxolucidine B, and the X-ray structure reveals its position. Facile aerial oxidation of cyclic imines is well precedented (8). Treatment of **5** with lithium aluminum hydride in tetrahydrofuran brings about reduction of the imino group and the *N*-acetyl group and provides 'tetrahydrodeoxyoxolucidine B', **6**. Acylation of **6** with *p*-bromobenzoyl chloride in pyridine provided the first crystalline derivative in this series, *N*,*O*-di-*p*-bromobenzoyltetrahydrodeoxyoxolucidine B, **3**, mp 203–205°C (from ethyl acetate).[3] The complete structure of **3** was determined by an X-ray crystallographic study. Compound **3** crystallized in the monoclinic system with the following crystal data:

$C_{44}H_{59}N_3O_3Br_2$ fw = 837.8
$P2_1$, a = 11.340(1), b = 15.859(2), c = 12.922(3) Å, β = 115.5°, V = 2097.6 Å^3, Z = 2, ρ_o = 1.30 g/cm^3, ρ_c = 1.32 g/cm^3. Radiation Ni-filtered CuKα, λ = 1.5406 Å, temperature 22°C. Data collected: hkl, $\bar{h}kl$, $h\bar{k}l$, $\bar{h}\bar{k}l$ with $3° \leq 2\theta \leq 50°$ and hkl, $\bar{h}kl$ with $50° \leq 2\theta \leq 103°$. A total of 2435 reflections comprised the data set.

The solution of the structure involved examining the Patterson map to obtain the positions of the two bromine atoms of the molecule. Structure factors calculated for these bromine atoms produced an R index ($R = [\sum_{hkl}||F_o| - |F_c||]/[\sum_{hkl}|F_o|]$, where F_o and F_c are the observed and calculated structure factors, respectively) of 0.374. Twelve additional atoms, corresponding to two six-membered rings in chair conformations, were chosen from a subsequent difference Fourier map. The quantity minimized was $\sum_{hkl}\omega(|F_o| - k|F_c|)^2$, where ω is the weight and k is the scale factor relating to the observed and calculated structure amplitudes, in the CRYLSQ program of the X-RAY 70 system (9). The positions of the remaining nonhydrogen atoms were obtained by continually phasing on larger molecular fragments and calculating difference maps. After full matrix isotropic refinement of all of the 52 nonhydrogen atoms of the molecule, the R index was 0.186. Further blocked anisotropic refinement produced an R index of 0.097. Twelve hydrogen atoms were located on subsequent difference maps and were assigned isotropic temperature factors based on their peak heights. The hydrogen atom positional parameters (but not the temperature factors) were included in subsequent blocked refinement. Convergence was achieved at an R index of 0.087.

The choice of the enantiomorph was checked by converting the y/b values of these final atomic coordinates to $-y/b$ values; the corresponding structure factor calculation produced an R index of 0.131. Application of Hamilton's significance test

10

(10) shows that the original coordinates correspond to the correct enantiomorph of the molecule to a confidence level >99.5%.[4] A perspective drawing of **3** is shown in Fig. 1.

Dihydrolycolucine shows the properties of a 2,3,6-trisubstituted pyridine (λ_{max} 276 nm (ε 8500), $\lambda_{max}^{H^+}$ 279 nm (ε 13 400), AB quartet at δ 7.30 and δ 6.84 (J = 8 Hz)) and is assigned structure **7**. Dehydrogenation of lucidine B (**2**) with 5% Pd–C in refluxing isoquinoline gives, among other products, dihydrolycolucine (**7**), confirming the stereochemical features depicted for **7**.

Lycolucine, mp 198–200°C, on mild catalytic hydrogenation affords dihydrolycolucine (**7**). The uv spectrum (λ_{max} 261 nm (ε 8800), 272 nm (ε 7800), and 300 nm (ε 10 200)) indicates the extra unsaturation is conjugated to the pyridine ring and the ^{1}Hmr spectrum shows the presence of a single olefinic proton (δ 6.60, s). Treatment of lycolucine with cyanogen bromide in chloroform gives the *N*-cyanodiene **9** (λ_{max} 230, 282, 294, 309 nm), and establishes that the double bond in lycolucine (**8**) is located between C-10 and C-11, and not between C-10′ and C-11′.

It is interesting to note that the structures of these new alkaloids may be derived formally by attaching two (enantiomeric) $C_{11}N$ units (compare with **1**) to a piperidine ring as indicated by the broken lines in **10**. The fusion of a single $C_{11}N$ unit to a piperidine ring is found in the *Lycopodium* alkaloid phlegmarine (7).

Received October 12, 1978

PAULO C. ISOLANI, LEONARD W. REEVES, and J. ATILIO VANIN. Can. J. Chem. **57**, 1108 (1979).

Depolarized components of laser light scattering patterns have been investigated for type II lyotropic liquid crystals. These patterns are characterized by intensity maxima and minima with constant angular separation. By using the Bragg equation, a set of distances typical for lamellar arrays can be derived. Two possible models are proposed to explain the results: the first is that the distances are related to the average diameter of lyomesomorphic micelles not accessible to low angle X-ray studies and the second model is a repeating hyperstructure of micellar microdomains.

PAULO C. ISOLANI, LEONARD W. REEVES et J. ATILIO VANIN. Can. J. Chem. **57**, 1108 (1979).

On a étudié les composantes dipolarisées des modèles de diffusion de la lumière laser pour des cristaux liquides lyotropes de types II. Ces modèles sont caractérisés par des maxima et minima d'intensité entre lesquels on observe des séparations angulaires constantes. Faisant appel à l'équation de Bragg, on a pu dériver un ensemble des distances typiques pour des arrangements lamellaires. On propose deux modèles pour expliquer les résultats: pour le premier, on fait l'hypothèse que les distances sont reliées au diamètre moyen des micelles lyomesomorphiques qui ne sont pas accessibles aux études par rayons-X aux petits angles alors que le second modèle est une hyperstructure de microdomaines micellaires qui se répètent.
[Traduit par le journal]

Introduction

In the last few years, Reeves and co-workers have been studying magnetically aligned lyotropic liquid crystals by means of nmr spectroscopy (1–11). The structure of most of these mesophases is not known and a tentative classification based on magnetic properties was proposed by Reeves *et al.* (6). This work reports a new contribution to the study of lyomesophases, in the sense that an attempt is made to clarify how the organized micellar arrays behave in magnetic fields by means of light scattering studies.

Light scattering phenomena, showing interference due to particle size in micellar or macromolecular solutions, were extensively studied during the 1940 decade by protein chemists (12). Friberg *et al.* used light scattering to distinguish between normal and inverted micelles in amphiphilic micellar solutions (13). Light scattering in thermotropic nematic and cholesteric liquid crystals have also been studied (14–18). Recently, Ribota reviewed the results in thermotropic smectic mesophases (19).

We have investigated intensity measurements of depolarized scattered light by lyotropic type II liquid crystals (6) and its dependence on the angle of scattering and sample orientation in magnetic fields.

Experimental

Scattering Studies

Light scattering experiments were carried out in a home-made apparatus. A Spectra-Physics model 155 helium-neon laser was used as a light source. The laser beam passed through a polarizer before incidence on the sample, which was kept in a 5 mm diameter high quality nmr tube. Scattered light passed through a narrow pass-band interference filter for 6328 Å wavelength (Oriel Optics, 90 Å FWHM), a second polarizer crossed with respect to the first, and was detected by a photo-multiplier (RCA No. 4832) placed immediately behind a 10 μm slit.

Sample, interference filter, second polarizer, slit, and photo-multiplier were placed in a closed box mounted on a goniometer which allowed angular readings. Sample position coincided with the center of the goniometer and it could be kept immobile with respect to the laser beam as well as rotating with the detector.

A HP model 6516a DC power supply was used for the photo-multiplier. Optimum signal-to-noise ratios were attained at 800 V. Current was measured by a Keithley model 616 digital electrometer. Typical currents were in the range of 10^{-7} A. Scattering patterns were obtained by plotting the photo-multiplier current as function of the scattering angle.

Optical birefringence was measured by a Zeiss universal polarizing microscope.

Sample Preparation

Typical percent weight compositions of samples are the following: Sample A: 36% sodium decanoate, 6% KCl,

[1]Work partially presented at the 29th Annual Meeting of the Brazilian Society for the Advancement of Science (SBPC), São Paulo, July 1977.

[2]Visiting Professor since 1967, Universidade de São Paulo.

0008-4042/79/091108-03$01.00/0

4% decanol, and 64% water. Sample B: 37% sodium decylsulfate, 6% Na_2SO_4, 6% *n*-decanol, and 51% water. Sample C: 36% sodium dodecanoate, 6% KCl, and 68% water.

Sample alignment was achieved in the 23.5 kG magnet of a Varian XL-100-12 NMR spectrometer, with or without sample spinning of a high precision 5 mm nmr tube. It was observed that liquid crystalline samples of this kind, once oriented in a magnetic field, keep their alignment at room temperature for several months. Samples were removed from the magnet without shaking and placed in the light scattering apparatus. All the experiments were performed in an air-conditioned room with temperature 23 ± 1°C.

Results

Figure 1 shows a typical pattern of depolarized scattered light. This specific lyomesophase was sample A, oriented in the 23.5 kG magnet overnight with sample spinning, as for a conventional nmr experiment. Angular measurements show maxima and minima in light intensity separated by well defined angles.

The angular separations between those maxima showed no modifications by varying slightly (about 2%) the relative concentrations of the sample constituents, as far as it still was a type II lyotropic liquid crystal. There was also no change with the direction of polarization of incident light. These separations were shown to vary only with the nature of the detergent headgroup in the mesophase. It is important to emphasize that the intensity of depolarized scattered light was observed to be much lower with respect to scattered polarized light; thus, only by using a crossed second polaroid was it possible to observe the diffractogram.

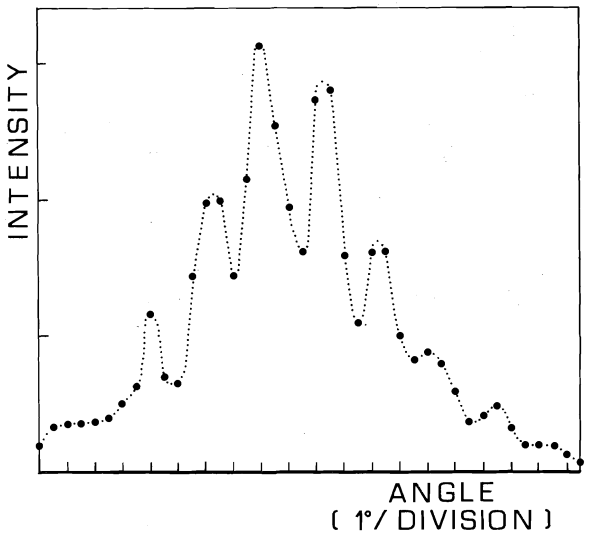

FIG. 1. Pattern of depolarized scattered light from sample A. Relative depolarized scattering intensity versus angle of diffracted laser light. Diffraction patterns have also been photographed in each case.

Measurements on sample A showed sharp maxima separated by 2° ± 15′ angle. By using the Bragg equation, $\lambda = 2d \sin \theta$, a set of *d* spacing values was obtained, with the relation 1:0.50:0.33:0.25:0.20, which are characteristic of lamellar arrays with 9.2 ± 1.2 μm periodicity. Sample C gave the same periodicity within experimental error. Lyomesophases of sodium decylsulfate (sample B) also gave sharp scattering maxima, but not as well defined as for sample A. For this mesophase, the scattering pattern shows an angular separation of 1° ± 15′. Using again the Bragg equation, these data can be fitted to a lamellar array of periodicity 19 ± 4 μm. The intensity of scattered light and the definition of intensity maxima were observed to be strongly dependent on the alignment of samples. Unoriented samples showed the same angular separation between maxima, though the observed pattern was very diffuse and sometimes not observable. All samples after stationary alignment in a magnetic field showed intense scattering and good maxima definition when the laser beam coincided with the direction of the steady magnetic field. Incidence in the perpendicular direction showed less sharp maxima and lower intensity of scattered light. Samples aligned by spinning in the magnetic field have shown the greatest light scattering intensity and the best maxima definition. All samples, when examined in a polarizing microscope, were characterized as optically monoaxial, showing negative birefringence.

Discussion

Extensive low-angle X-ray diffraction studies on samples of the same composition of sample B indicate that the structure of this kind of lyomesophase can be explained by a model consisting of arrays of disc-shaped lamellar micelles of about 38 Å thickness, corresponding to the length of two chains, with long range orientational but not positional order. The separation between micelles is in the range 54 to 92 Å and is filled with water. These distances are obtained directly from the low-angle X-ray diffractogram (20, 21).

The effect of the magnetic field is to align the normal to the disc surface (the so-called director) perpendicularly to the magnetic field force lines. Samples oriented in stationary magnetic fields have micellar directors in all directions perpendicular to the field. In the cylindrical tube of high quality, usually employed for nmr studies, the directions perpendicular to the liquid crystal/glass interface are favoured and therefore the distribution of the directors in the plane perpendicular to the magnetic field direction is not uniform. Samples which are aligned

by spinning the nmr tube perpendicular to the magnetic field have directors oriented perpendicularly to the force lines and parallel to the spinning axis. Obviously, unoriented samples have directors in all possible directions in space, but some cooperative effects between neighbour micelles or wall effects can induce local order over short ranges.

The pattern of scattered light can be explained by one of the following models: (*i*) The greatest dimension of the micelle or the average disc diameter, not accessible for investigation by low angle X-ray diffraction, might be responsible for the periodicity and give rise to the characteristic distance detected by visible light scattering. This hypothesis is supported by the fact that no X-ray scattering is observed in a direction perpendicular to the orienting magnetic field (20). In this respect also the analysis of the diffractogram widths in the low angle X-ray study (20, 21)[3] indicates a disc size greater than 1000 Å. (*ii*) The micelles may be packed in a super-superstructure, which could be called a hyperstructure or micellar microdomain. These hyperstructures could have a size corresponding to the distance obtained in this work and they might be disposed in a lamellar array.

Observations of samples in the polarizing microscope showed evidence of the micellar orientation between cover and slide. The observed optical monoaxial pattern suggested that in this thin layer of liquid crystal surface orientation makes the disc-shaped micelles stay in a position parallel (and, consequently, the directors perpendicular) to the glass surface. Further experiments in type I lyomesophases are in progress and the results will be reported briefly.

Absorption and magnetic circular dichroism spectra of metal-free phthalocyanine in ultraviolet-transparent solvents

KATHERINE A. MARTIN AND MARTIN J. STILLMAN[1]

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received October 30, 1978

KATHERINE A. MARTIN and MARTIN J. STILLMAN. Can. J. Chem. **57**, 1111 (1979).

Absorption and magnetic circular dichroism spectra of metal-free phthalocyanine (H_2Pc) have been recorded over the range 270–800 nm. The use of solvents transparent in the 270–400 nm region allows the observation for the first time of the B band spectral envelope of H_2Pc in solution. The mcd spectrum clearly indicates that the complex $(NH_4)_2Pc$ is formed when ammonia is bubbled through a solution of H_2Pc in dimethyl sulphoxide. The multi-transition nature of the B band region is identified as a property of the phthalocyanine π electron system rather than arising from charge transfer between the ring and a central metal cation.

KATHERINE A. MARTIN et MARTIN J. STILLMAN. Can. J. Chem. **57**, 1111 (1979).

On a enregistré, entre 270 et 800 nm, les spectres d'absorption et de dichroïsme circulaire magnétique de la phtalocyanine (H_2Pc) ne contenant pas de métal. Utilisant des solvants qui n'absorbent pas entre 270 et 400 nm, on a pu observer pour la première fois la bande B, enveloppe spectrale de H_2Pc en solution. Le spectre de dcm indique clairement qu'il y a formation du complexe $(NH_4)_2Pc$ lorsqu'on fait barbotter de l'ammoniac dans une solution de H_2Pc dans le diméthylsulfoxyde. On a identifié que la nature multitransitionnelle de la bande dans la région B est une propriété du système d'électrons π de la phtalocyanine et qu'elle n'est pas due à un transfert de charge entre le cycle et un cation métallique central.
[Traduit par le journal]

The numerous calculations reported in the literature describing the electronic states in the phthalocyanine molecule (1–4) contrast with the paucity of data of a systematic nature that can be used to check the accuracy of these theoretical predictions. In particular, two problems are evident from a survey of both the calculations and the available spectra. (*i*) The perturbation of the central metal cations' orbitals on the ring π orbitals results in considerable variation in the observed MPc spectra (5–7); (*ii*) even with the same metal cation at the centre of the phthalocyanine ring, the effect of solvent and axially coordinating ligand can cause dramatic changes to the intensities and band energies of the major features of a "typical" phthalocyanine spectrum (5–8).

The key to this problem appeared to us to be the measurement of the spectra of a wide range of phthalocyanine complexes in a single solvent in which axial ligation effects on the π spectrum could be studied. It is clear from the calculations that we must attempt to include $\pi \rightarrow \pi^*$ transitions to 250 nm (3). For unlike the analogous porphyrin spectra the 250–380 nm region in the phthalocyanines is characterized by a series of broad, overlapping bands in both solution (6, 7) and solid state spectra (9, 10). In addition, magnetic circular dichroism spectra (mcd) should be included to provide polarization and angular momentum data to aid in the assignment (7, 10, 11).

Clearly an important spectrum in this survey is that of metal-free phthalocyanine as this will allow identification of both metal and ligand effects. Phthalocyanines are notoriously insoluble, in most spectroscopically-useful solvents. We have shown previously that it is possible to obtain the spectra of a large range of MPc complexes in dimethyl sulphoxide (DMSO) (7), and these experiments have been extended by us and others (12, 13) to include dimethyl acetamide (DMA), and dimethyl formamide (DMF). No spectra of H_2Pc in such solvents have been reported to our knowledge.

Solid state spectra, both from crystals in the β phase (14), and sublimed thin films in the α phase (9, 10), are available, but ligand effects cannot be studied readily due to extensive broadening and Davydov splitting (10). While vapour phase absorption experiments (15) have yielded spectra in the uv region (down to 200 nm), it is unlikely that ligand binding studies would be successful at these elevated temperatures. Solution spectra of H_2Pc have been reported in α-chloronaphthalene (5), where the two-banded Q band in the 670–690 nm region characterizes the D_{2h} symmetry resulting from the substitution of the metal, M^{2+}, by two protons, unfortunately the uv region is almost totally obscured

0008-4042/79/091111-03$01.00/0

in this solvent. Whalley (16) reported that H_2Pc exhibited a D_{4h} spectrum in pyridine, but, yet again, the solvent absorption in uv region restricted the analysis. Our data do confirm her characterization of the chromphoric species as the pyridinium salt.

Absorption and mcd spectra of H_2Pc between 270 nm and 720 nm in DMSO and DMA have been obtained by two methods. Figure 1 shows the spectra recorded after the addition of very dilute HCl to a solution of Li_2Pc in DMA at room temperature. A similar absorption spectrum is produced by dissolving multiply-sublimed H_2Pc in DMSO at 150°C, in this case there is a red-shift of 2 nm compared with the acid-produced spectrum. The band centres in the absorption are 693, 660, 638 (sh), 633 (sh), 600, 360 (sh), 333, 305, and 285 nm (sh) for H_2Pc in DMSO. When ammonia gas is bubbled vigorously through a solution of H_2Pc in DMSO the absorption and mcd spectra shown in Fig. 2 are obtained, with new band centres at 669, 638 (sh), 603, 380 (sh), and 367 nm. This species is stable at room temperature for several hours. Spectra with a similar visible region band envelope are obtained when other nitrogen donor ligands are added to H_2Pc in either DMA or DMSO (13).

We suggest that the chromophoric species in each of these complexes is the Pc^{2-} ion, thus with ammonia we have $(NH_4^+)_2Pc^{2-}$. Bubbling nitrogen gas through the ammonia saturated solution for 30 min displaces the bound ammonia. The absorption spectrum now reverts to its original form, which is characterized by two bands in the Q region at 693 and 660 nm.

The mcd spectra clearly indicate the difference in the symmetry between the two phthalocyanine complexes (H_2Pc in DMSO and H_2Pc + NH_3(g) in DMSO), supporting our assignment of H_2Pc as the molecular species in Fig. 1 and Pc^{2-} as the species in Fig. 2. It is perhaps reasonable to suggest that the $(NH_4)_2Pc$ spectrum, with its D_{4h}, 18π electron ring unperturbed by the asymmetric protons of the H_2Pc species, will most closely resemble a 'pure' phthalocyanine spectrum.

If this is the case, then we have, for the first time, a clear indication of the complex nature of the B region at 340 nm. The mcd spectra support the view that these absorption bands are all centred on the ring, which implies that there are at least three distinct states in this region arising from the π molecular orbitals. Until now it has been impossible to separate unambiguously the ring $\pi \rightarrow \pi^*$ transitions, from charge transfer transitions between the ring, the metal cation and/or the axial ligands.

The presence of a multi-transition envelope in the B region has not been generally discussed in the literature. With the advent of mcd spectroscopy the details of this region have become much clearer.

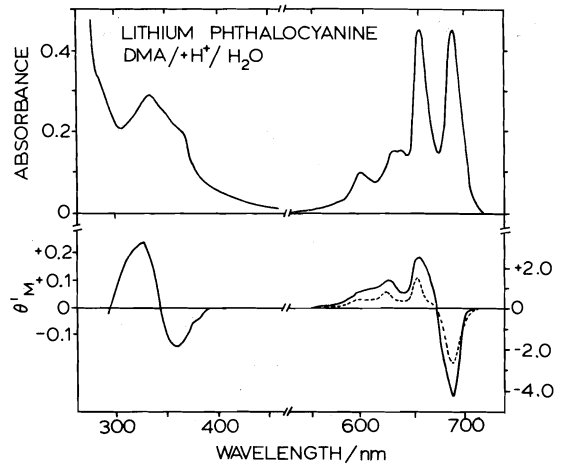

FIG. 1. Absorption and mcd of H_2Pc in DMA prepared by the addition of dilute acid to a solution of Li_2Pc. A magnetic field of 5.0 T was used for the mcd.

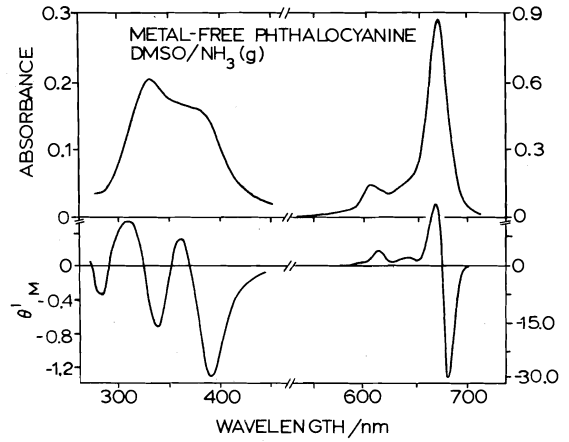

FIG. 2. Absorption and mcd of $(NH_4)_2Pc$ in DMSO prepared by bubbling NH_3(g) into a solution of H_2Pc. A magnetic field of 5.5 T was used for the mcd in the uv region and 1.4 T in the visible region.

Dale (6) used the ordering of states given by Weiss *et al.* (17) to assign the band envelope observed in this region in the spectrum of FePc complexes in DMSO. These data give a B band energy of between 25 000 cm^{-1} (400 nm) in $FePc(CN)_2$ and 29 000 cm^{-1} (345 nm) in FePc, and an N band energy close to 31 000 cm^{-1} (323 nm) for each species studied. These values are far from the energies observed in the vapour phase (15), however, the effect of the Fe^{2+} cation is still unknown. In our experiments we have extended the accessible wavelength range with DMSO to 260 nm, in doing so we have observed a band close to 270 nm for a wide range of complexes (7, 13). This transition, part of which is quite clear

in the mcd spectrum of $(NH_4)_2Pc$, Fig. 2, as a negative lobe at ca. 283 nm, lies close to the N band assigned by Edwards and Gouterman (15). We consider that the band envelope observed in the 330 nm region arises from at least two degenerate $\pi \rightarrow \pi^*$ transitions associated with the configurations that give rise to the B band.

On the interpretation of measured rotational and vibrational relaxation times. III. Failure of the mixture rule for non-dilute gases

HUW O. PRITCHARD, NABIL I. LABIB, AND ARUNACHALAM LAKSHMI
Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3

Received October 26, 1978

HUW O. PRITCHARD, NABIL I. LABIB, and ARUNACHALAM LAKSHMI. Can. J. Chem. **57**, 1115 (1979).

The rotation–vibration relaxation of a mixture of a diatomic gas (approximately simulating hydrogen) with an inert gas is studied both by direct integration, and by an approximate linearised normal-mode method. It is shown that although the linearised normal-mode approximation is a powerful aid to understanding these processes, its numerical accuracy is limited to high dilutions (e.g. 1% of X_2 in M) and to times shorter than the final relaxation time.

Direct numerical integration of the relaxation equations for various mixture ratios shows that the plot of vibrational relaxation rate constant vs. mole fraction x is non-linear, and that the slope of this plot near $x = 0$ can be correlated with the rates of the R–R processes, *not* the V–V processes as is normally assumed. A brief discussion is presented of the conditions under which the linear mixture rule for relaxation is rigorously obeyed: as is the case for chemical reaction, these conditions are impossibly stringent.

An appendix presents a comparison of the transition probabilities used in this series of papers with those recently obtained by Tarr and Rabitz for the relaxation of hydrogen in argon.

HUW O. PRITCHARD, NABIL I. LABIB et ARUNACHALAM LAKSHMI. Can. J. Chem. **57**, 1115 (1979).

On a étudié la relaxation rotation–vibration d'un mélange d'un gaz diatomique (simulant l'hydrogène) avec un gaz inerte par une intégration directe ainsi que par une méthode approximative du mode normal linéaire. On montre que même si l'approximation du mode normal linéaire est très utile pour comprendre ces processus, son exactitude numérique est limitée à hautes dilutions (environ 1% de X_2 dans M) et à des temps plus courts que le temps final de relaxation.

Une intégration numérique directe des équations de relaxation pour divers rapports de mélange montre que la courbe reliant la constante de vitesse de la vibration de relaxation et la fraction molaire (x) n'est pas linéaire et que la pente de cette courbe près de $x = 0$ peut être reliée aux taux des processus R–R et *non pas* aux processus V–V comme il est généralement supposé. On présente une brève discussion des conditions où la règle des mélanges linéaires pour la relaxation est suivie d'une façon rigoureuse: comme c'est le cas pour la réaction chimique, ces conditions sont très strictes.

Dans un appendice, on présente une comparaison des probabilités de transitions qui sont utilisés dans cette série de communications avec celles récemment obtenues par Tarr et Rabitz pour la relaxation de l'hydrogène dans l'argon.

[Traduit par le journal]

Introduction

The two preceding papers in this series (1, 2) have been devoted to the problem of understanding the nature of the rotation–vibration relaxation process for a system of diatomic molecules infinitely diluted in an inert-gas bath. In the absence of a detailed set of vibrational and rotational transition probabilities for any molecule, calculations were conducted using two hypothetical sets of transition probabilities, one termed the "standard" set which, it was hoped, would mimic the behaviour of H_2, and the other termed a "modified" set which was intended to

0008-4042/79/101115-07$01.00/0

mimic the behaviour of a typical diatomic molecule. As time passes, more information is becoming available concerning the required transition probabilities for H_2 itself and it would appear that, at 1500 K, our so-called "standard" set couples the rotational and vibrational relaxations a little too strongly: an analysis of this problem is presented in the Appendix.

However (anticipating the results presented below), because of the partial failure of the linearised normal-mode approach, most of the conclusions of this paper were derived from numerical integration of the relaxation equations; these equations are stiff and an increase in the separation of characteristic times for rotational and vibrational relaxation would automatically bring with it a corresponding increase in the computing time required to perform the necessary integrations. Consequently, this work continues to use the "standard" set of T–V, T–R, and T–VR transition probabilities used previously, essentially for three reasons: first to minimise computing costs, second to facilitate comparison with the earlier work, and third because at the low temperature of 500 K considered here, it does not obscure any of the essential features of the H_2/M relaxation process. The model used in this work, therefore, consists of this "standard" set of transition probabilities describing the relaxation of H_2 in M at infinite dilution, as summarized[1] in Table I(1), together with an additional non-linear term in each differential equation for the ith population n_i, viz.,

$$[1]\quad \frac{dn_i}{dt} = [M]Z\sum_k (P_{k\to i}n_k - P_{i\to k}n_i) + Z'\sum_{jkl}(P_{kl\to ij}n_k n_l - P_{ij\to kl}n_i n_j)$$

In eq. [1], [M] is the number density of the inert gas atoms, n_i is the number density of H_2 molecules in state i, Z and Z' are the collision numbers for M and H_2 and for H_2 and H_2 respectively, $P_{i\to k}$ is the transition probability per collision between M and H_2 of a transfer from state i to state k, and $P_{ij\to kl}$ is the probability of a simultaneous transfer in two colliding H_2 molecules from states i and j to states k and l.

The values chosen for the $P_{ij\to kl}$ transition probabilities at 500 K were taken from the calculations of Zarur and Rabitz (3), and, in order to generalise them to all required transitions in the system, were fitted to the empirical formula

$$[2]\quad P_{ij\to kl} = 0.006\exp[-(0.002|\Delta\varepsilon| + 2.5|\Delta J|)]$$

where $|\Delta\varepsilon|$ is the energy difference in cm^{-1} for any *exothermic* process and $|\Delta J|$ is the net change in J for the two partners; this parametrisation fits the results of Zarur and Rabitz reasonably closely. Endothermic and exothermic processes are of course related by the detailed balancing relationships

$$[3a]\quad \tilde{n}_i\tilde{n}_j P_{ij\to kl} = \tilde{n}_k\tilde{n}_l P_{kl\to ij}$$

$$[3b]\quad \tilde{n}_i P_{ij\to kj} = \tilde{n}_k P_{kj\to ij}$$

$$[3c]\quad \tilde{n}_i P_{i\to k} = \tilde{n}_k P_{k\to i}$$

where $\tilde{n}_i$ etc. represent the equilibrium number densities at the temperature of the heat bath.

In order to keep the size of the problem within reasonable bounds, the temperature for study was chosen to be 500 K so that truncation at 10 levels was permissible; also, because of the intrinsic interest of the $v = 1, J = 1$ level in laser-schlieren experiments, the calculations were again performed on the odd-J system, i.e. *ortho*-hydrogen. Likewise, because of the rapid decay of eq. [2] with $|\Delta\varepsilon|$, no values of $P_{ij\to kl}$ were calculated for $|\Delta\varepsilon| > 1000\ cm^{-1}$, which is acceptable at this temperature. Moreover, to facilitate some analysis of the results (since the linear mixture law does not necessarily hold for X_2 at infinite dilution in a mixture of two inert gases) it was assumed that as far as all T–V, T–R, and T–VR processes are concerned, H_2 and M have the same efficiencies, i.e.

$$[4]\quad ZP_{i\to k} = Z'P_{ij\to kj} \text{ for all } j$$

Linearised Normal Mode Results

Equation [1] can easily be put in normal-mode form by assuming that in the second term, n_j and n_l can be replaced by their equilibrium values $\tilde{n}_j$ and $\tilde{n}_l$, respectively, and by performing the appropriate summations: this transforms [1] into the form

$$[5]\quad \frac{dn_i}{dt} = (\mathbf{A} + x\bar{\mathbf{B}})n_i = \bar{\mathbf{C}}n_i$$

where x is the mole fraction of H_2 in the mixture. Note that in this representation, the matrix $\mathbf{A}$ contains all the T–VR processes for H_2–H_2 collisions: the matrix $\mathbf{A}$ really is

$$[6]\quad \mathbf{A} = (1 - x)\mathbf{A} + x\mathbf{A}'$$

since by eq. [4], $\mathbf{A} \equiv \mathbf{A}'$; thus the matrix $\bar{\mathbf{B}}$ contains only transition probabilities $P_{ij\to kl}$ for which k and l differ from i and j. One would expect this linearised form to be extremely accurate for small temperature changes, or for the final approach to equilibrium, especially so as $x \to 0$. Examination of the normal-mode diagrams generated from the solution of eq. [5] shows that, for $x = 0.01$ or 0.02, they are imperceptibly different (if the comparison is made

[1]Equations, figures, and tables located in Parts I and II (refs. 1 and 2) will henceforth be denoted by a Roman prefix indicating the Part number, followed by the number of the equation, etc., in parentheses.

visually) from each other, or from the normal-mode diagrams such as we have published previously (1, 2) for the infinitely dilute system; see, e.g., Fig. I(1). Moreover, in a given relaxation, e.g. a temperature step from 300 to 500 K, or from 499.5 to 500 K, the corresponding relaxation strengths ξ_i (as defined in eq. I(10)) are only slightly different for the three cases $x = 0$, 0.01, and 0.02. This is consistent with Shuler's observation almost 20 years ago (4) that the inclusion of these non-linearities does not alter the essential pattern of the relaxation.

Examination of the magnitudes of the eigenvalues themselves, however, yields an unexpected result which restricts the general usefulness of the linearised normal-mode technique. Apart from the zero eigenvalue, which is required by conservation, all the other eigenvalues move to a slightly more negative value, as required by the appropriate addition theorem. Most eigenvalues move by only a small amount, varying between 0.1 and 0.2%; however, the last eigenvalue (hereinafter designated simply as λ) representing the final vibrational part of the relaxation (see e.g. M_{14} of Fig. I(1)) is approximately doubled as x goes from 0 to 0.01, and is moved almost as much again when x goes from 0.01 to 0.02. This was not expected since the vibrational relaxation time of H_2 should not be grossly sensitive to the mole fraction x, and in fact it can easily be shown to be an artefact by direct numerical integration of eq. [1]. This integration gives the population evolution directly, and thus the evolution of the energy

$$[7] \qquad \Delta E(t) = E(t) - E_{\text{Boltzmann}}$$

of the system; the required relaxation time is then derived simply as the numerical derivative

$$[8] \qquad \tau_{\text{vib}}^{-1} \equiv -\lambda = \mathrm{d} \ln \Delta E(t)/\mathrm{d}t$$

For $x = 0.01$ and 0.02, the final relaxation times (τ_{vib}) are only very slightly different from the unperturbed value (i.e. for $x = 0$) as expected: the actual magnitudes of the differences will be discussed in detail later in this paper.

Comparison of the population and energy evolutions calculated from the linearised normal modes and by direct integration is quite interesting. Both calculations agree well (better than 1% in any particular value) right through almost to the end of the rotational part of the relaxation, but then they begin to differ because of the incorrect long-time behaviour of the linearised form, eq. [5]. If the temperature change is very small, e.g. 499.5 → 500 K, this deficiency can be patched up by artificially adjusting the last non-zero eigenvalue back to the proper value (given by eq. [8]) or else to the unperturbed value, since these two quantities differ by so little; however, for larger temperature jumps, this trick will not work since the eigenvectors and eigenvalues of $\bar{\mathbf{C}}$ are now no longer mutually consistent,[2] and some calculated populations go negative in the very early stages of the relaxation. In view of these limitations, we will not discuss this linearised form of the master equation any further in this paper, except in-so-far as it helps to throw light on the nature of the relaxation process; other than that, it would appear that its usefulness as a computational technique would be limited to exploring ultrasonic rotational relaxation measurements. The only discussions of which we are aware concerning the conditions for linearisation of vibrational relaxation equations are for the special case of mixtures of harmonic oscillators (4–6).

Some Simple Results Concerning Population Evolution at Early Times

There has been considerable interest over the years in the concept of canonical invariance in relaxation processes (5, 7, 8), but as more integration results become available, it becomes clear that canonical invariance is likely to be a rather unusual occurrence. It turns out to be a very common occurrence for some populations to set off in the wrong direction once the relaxation is allowed to commence, before turning around and approaching their final equilibrium values: alternatively, some populations overshoot and approach their final equilibrium values from the "wrong" direction; examples and explanations of these occurrences were given in Part II. In the non-dilute case, there are two additional sources for these "false starts" and overshoots, which can be understood relatively easily in algebraic terms. The dominant fluxes for X_2/X_2 collision processes are usually those of the kind

$$X_2(i) + X_2(i) \rightarrow X_2(i+1) + X_2(i-1)$$

where i denotes either a rotational or a vibrational quantum number. We can write the *initial* fluxes for these processes as

$$[9] \quad \delta_i \equiv F_{ii \rightarrow i+1,i-1} = P_{ii \rightarrow i+1,i-1} m_i^2 + P_{i+1,i-1 \rightarrow ii} m_{i+1} m_{i-1}$$

[2]It appears that this large shift of the vibrational relaxation eigenvalue is an interference effect. If we choose other non-physical sets of $P_{i \rightarrow k}$, e.g. the present ones truncated to tridiagonal form, the set corresponding to the tridiagonal sum rule (eq. [8] of ref. 19), or the full matrix of probabilities given by eq. [16*a*] of ref. 9 (cf. Fig. I(5)), the last non-zero eigenvalue is hardly changed on going from the matrix $\mathbf{A}$ to matrix $\bar{\mathbf{C}} = \mathbf{A} + 0.01\bar{\mathbf{B}}$ (cf. eq. [5]). None of these forms possesses a normal mode which is clearly recognisable as "vibrational", as is M_9 of Fig. I(1). However, when a more physically realistic set of transition probabilities is used, so that the slowest mode of relaxation is essentially vibrational, then there is interference between this and M_4' of $\bar{\mathbf{B}}$ in Fig. 2, resulting in a large shift in the combined eigenvalue.

where the m_i etc. represent the equilibrium number densities at the starting temperature; because of detailed balancing, eq. [3*a*], we then find that

$$[10]\quad \delta_i \equiv F_{ii\rightarrow i+1,i-1} = \text{constant } m_i^2\left(\frac{m_{i+1}m_{i-1}}{m_i^2}\frac{\tilde{n}_i^2}{\tilde{n}_{i+1}\tilde{n}_{i-1}} - 1\right)$$

We imagine a change to take place from T_i (with equilibrium populations m_{i-1}, m_i, and m_{i+1}) to T_f (with equilibrium populations $\tilde{n}_{i-1}$, $\tilde{n}_i$, $\tilde{n}_{i+1}$): then it is simple to show that for a harmonic oscillator, for all i (except the highest and the lowest in the system of levels) δ_i is zero, whereas for a Morse oscillator δ_i is always negative if $T_i > T_f$, and for a rigid rotor δ_i is always positive if $T_i > T_f$ (with the respective signs reversed if $T_i < T_f$).

Numerical Experiments for Non-dilute Relaxing Systems

Equation [1] was solved numerically for a series of hypothetical mixtures of M and X_2, X_2 being taken to have the same energy-level structure as *ortho*-H_2. In order to circumvent complications from the failure of the mixture rule for the relaxation of X_2 in a mixture of M and M′, M and X_2 (≡M′) were assumed to have identical T–VR transition rate constants for collisions with X_2, cf. eq. [4]; these were derived from eq. [16] of ref. 9, cf. Table I(1) for a selection of numerical values. For collisions between pairs of X_2 molecules, the transition probabilities were those appropriate to H_2/H_2 collisions, parametrised as eq. [2]. The initial distribution for each relaxation calculation, following our earlier work (2), was assumed to be one in which the population distribution was appropriate to the temperature of 500 K, except that the population of the $v = 1, J = 1$ state was increased by a factor of 100, to simulate a typical laser-schlieren relaxation experiment.

Figure 1 shows the results of these calculations, expressed as $-\lambda$, the rate constant for the final approach of the internal energy to the equilibrium value, found by using eq. [8]. It can be seen that the vibrational relaxation time, even for this idealised model, does not obey the mixture rule, and the plot is rather similar to those obtained by Glänzer (10) for nitric oxide – argon mixtures. In the special case of H_2 – inert-gas mixtures, there have been two sets of experiments: those of Dove and Teitelbaum (11) which show a linear relationship between $|\lambda|$ and x_{H_2} for $x_{H_2} > 0.35$ — very much as we find in Fig. 1; and those of Audibert, Joffrin, and Ducuing (12) which show a linear portion over most of the range of mole fraction, but a definite downward curvature as $x_{H_2} \rightarrow 0$. In the remainder of this section, we devote

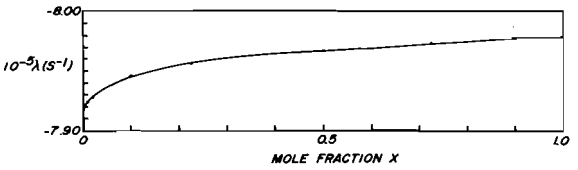

FIG. 1. Plot of $-\lambda = \tau_{vib}^{-1}$ for mixture of M and X_2, with a total number density of 3.5×10^{19} particles cm^{-3}. The T–VR transition rates are constrained to be identical for collisions of both M and X_2 with X_2, and are defined by the "standard" set of probabilities, eq. [16] of ref. 9. The TVR–TVR transition rates are defined by eq. [2].

our attention to the problem of deducing the physical meaning of the slope of this line, $d\lambda/dx$.

If the mixture rule is obeyed, then following the traditional arguments (13, 14) we would have

$$[11]\quad \lambda = (1-x)\lambda^{M/X_2(T-VR)} + x\lambda^{X_2/X_2(T-VR)} + x\lambda^{X_2/X_2(TVR-TVR)}$$

which, since we have taken identical transition rate matrices for the first two terms, reduces to

$$[12]\quad \lambda = \lambda^0 + x\lambda'$$

where λ^0 is the eigenvalue at infinite dilution and λ' is the $\lambda^{X_2/X_2(TVR-TVR)}$ of eq. [11]. Thus, the plot in Fig. 1 would be expected to be a straight line whose slope $d\lambda/dx$ would give the (so-called) V–V relaxation rate constant. Examination of the matrix of energy fluxes at a time $t = |\lambda^{-1}|$ reveals that by far the largest energy flux is due to the transitions $(v = 1, J = 1) \leftrightarrow (v = 0, J = 1)$ and $(v = 1, J = 3) \leftrightarrow (v = 0, J = 3)$ as expected; the energy fluxes for bimolecular collisions are dominated by two processes in the $v = 0$ manifold

$$[13]\quad J = 3 + J = 3 \leftrightarrow J = 1 + J = 5$$

$$[14]\quad J = 3 + J = 5 \leftrightarrow J = 1 + J = 7$$

The relative importance of these bimolecular processes varies with x (the ratio of [13]/[14] being about 1.15 at $x = 0.01$ and about 2.52 at $x = 1$), as also does their absolute importance, being about 0.2% of the total energy flux at $x = 0.01$ and 5% of it at $x = 1$.

Because of network-like effects, the final value of λ is very insensitive indeed to arbitrary variations in individual values of $P_{ij\rightarrow kl}$, and the only meaningful correlation we have been able to find is that if the values of $P_{ij\rightarrow kl}$ are doubled for *all* processes like [13] and [14] *having* a net $\Delta J = 0$, then the initial slope of the λ vs. x curve doubles from $-5.0_5 \times 10^4\ s^{-1}$ to $-1.0 \times 10^5\ s^{-1}$ at $x = 0$. Doubling of other subsets of the $P_{ij\rightarrow kl}$ has only insignificant effect on the initial slope of $d\lambda/dx$. This clearly identifies $|d\lambda/dx|_{x=0}$ as the mean rate constant for R–R processes of the

types [13], [14], etc. This identification is strongly confirmed by our normal-mode analysis. Figure 2 shows the form of the normal modes for the linearised perturbation matrix $\bar{\mathbf{B}}$ of eq. [5]. It can be seen that three of the "effective modes" are vibrational in character, i.e. M_2', M_3', and M_4', and that they are among the fastest modes; the remainder are all rotational in character, with the two slowest having time constants of -5.1×10^4 and $-3.6 \times 10^4\ s^{-1}$, respectively. If we now imagine a hypothetical relaxation in which only the matrix $\bar{\mathbf{B}}$ is operative (i.e. all the $P_{i\to k}$ and $P_{ij\to kj}$ are put equal to zero in eq. [1]) then 90% of the relaxation strength is carried by the mode M_8', and most of the rest by M_5' and M_6'. Since M_5' and M_6' both have time constants of the order of $-1 \times 10^6\ s^{-1}$, and since M_9' which involves $v = 0, J = 9$ is (therefore) not used, this hypothetical relaxation appears to have a time constant of $-5.1 \times 10^4\ s^{-1}$, virtually exactly the value derived from the initial slope of $d\lambda/dx$. This, in our view, conclusively identifies the quantity $|d\lambda/dx|_{x=0}$ as the rate constant for R–R relaxation,[3] and were it not for doubts about the validity of the mixture rule for two different monatomic gases, one might now be able to deduce an approximate R–R relaxation rate constant for H_2/H_2 collisions from the laser-schlieren data of Audibert *et al.* (12). For somewhat different reasons, that the rotational and vibrational relaxations are expected to be better separated, and that the temperature regime is very different from that considered here, we cannot identify at this stage the significance of the initial slope in Glänzer's nitric oxide – argon experiment (10) without undertaking further model calculations designed to reproduce the behaviour of such mixtures at 2500 K.

Having discerned the meaning of $|d\lambda/dx|_{x=0}$ in this model calculation, we have now to identify the meaning of the slope at other values of x. To this end, we examined the sensitivity of λ to variations in the $P_{ij\to kl}$ for $x = 0.75$ and $x = 1$. Doubling all of the probabilities of the J-conserving transitions (like [13] and [14]) raises the relaxation rate minutely, but has the same effect at both concentrations, so that $|d\lambda/dx|_{x\to 1}$ remains unchanged at $1.9 \times 10^3\ s^{-1}$. On the other hand, doubling all the transition probabilities for which $\Delta v = \pm 1$ does almost double the slope, to $3.2 \times 10^3\ s^{-1}$, suggesting that we are dealing here with an R–V property. However, there is no eigenvalue of the linearised relaxation matrix $\bar{\mathbf{B}}$ smaller than $-3 \times 10^4\ s^{-1}$ and, moreover, the vibrational components of this "effective" relaxation have time constants of the order of $-6 \times 10^5\ s^{-1}$ or faster: consequently, although $|d\lambda/dx|_{x\to 1}$ appears from our sensitivity tests to be the R–V relaxation rate constant, this conclusion is not corroborated by our (admittedly imperfect) normal-mode analysis.

The Linear Mixture Rule

The current state of theoretical knowledge concerning the linear mixture rule as it applies to chemical reaction was summarised recently by Boyd (15). He concluded that the conditions for rigid adherence to the mixture rule are impossibly stringent, and the problem remains as to how to predict the conditions under which experimentally observable deviations from the rule may be expected. As an eigenvalue problem, internal relaxation is really no different from chemical reaction, and so we may expect the same considerations to apply: perhaps a useful clue is that the linear mixture rule for reaction appears to hold to acceptable accuracy when the V–V transition rates are small compared with the T–V rates, but it fails badly when they are large (16). Experimental tests of the linear mixture rule in relaxation over large ranges of composition are few, and the results were summarised at the beginning of the preceding section.

Before we can take any particular experiment and try to interpret the meaning of $d\lambda/dx$, as we have been able to do for the limiting case $|d\lambda/dx|_{x=0}$ in this work, we have to know how much of the curvature in the λ vs. x plot is due to the simple failure of the linear mixture rule for the T–V or T–VR relaxations alone — in other words, if we exclude all non-linear terms, how curved will be the plot considering the relaxation as $[(1 - x)M + X_2] + [xM' + X_2]$? As Boyd showed for the reaction case, the conditions for zero curvature are impossibly stringent, and we have found only two.[4] The first is when *each* T–VR (or T–V) transition probability for X_2 in collision with M′ is the *same multiple* of the corresponding probability for X_2 with the other partner M; our simplifica-

[3]One might argue, on inspection of Fig. 2, that the truncation scheme has excluded some very important states, namely $v = 2, J = 1$ and 3, so that processes of the type $X_2(v = 0,J) + X_2(v = 2,J) \leftrightarrow 2X_2(v = 1,J)$ are missing. We have repeated a selection of these calculations with a different set of 10 levels, including these two but excluding $v = 0, J = 9$ and 11. The results are only insignificantly different from those already discussed, as would be expected since processes of this type are unimportant in H_2 at these temperatures. In our laser-schlieren simulation calculation, the energy flux for this reaction is about 10^{-7} of that for $M + X_2(v = 1,J) \leftrightarrow M + X_2(v = 0,J)$. This would not be the case for heavier molecules and/or higher temperatures.

[4]It is trivial to show that if the matrix A_M governing the relaxation of X_2 at infinite dilution in M *commutes* with the matrix $A_{M'}$ governing the relaxation of X_2 at infinite dilution in M′, then the mixture rule will hold for the relaxation of X_2 at infinite dilution in mixtures of M and M′ (the examples cited here both fall into this class); otherwise, the mixture rule cannot hold rigorously (15).

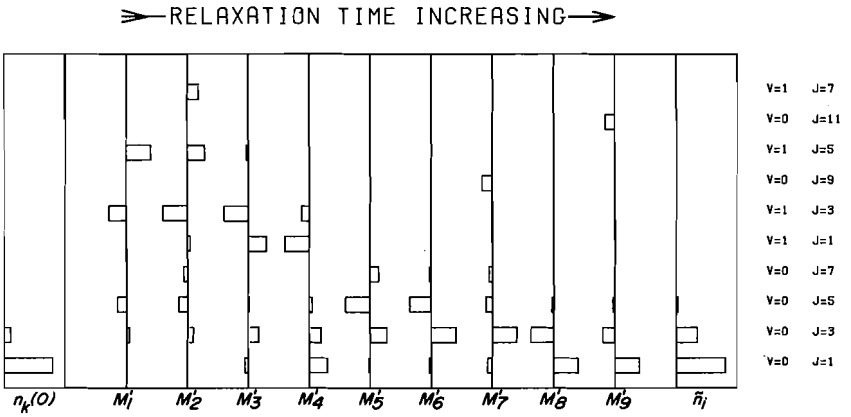

FIG. 2. Effective normal modes for the linearised TVR–TVR transition matrix $\bar{\mathbf{B}}$; for details of how to interpret these diagrams, see ref. 1.

tion, eq. [4], is a special case of this condition. The second occurs when *one set* of T–VR (or T–V) probabilities (say for M′) obeys the special form of the sum rule for which all the non-zero eigenvalues ($\lambda^{M'}$) are degenerate, i.e. eq. [42] of ref. 17. This happens because of a special feature, that no matter what the value of x is (provided that $x_{M'} \neq 1$), the eigenvectors of the combined relaxation matrix $\mathbf{A}$

$$[15] \qquad \mathbf{A} = (1 - x)\mathbf{A}_M + x\mathbf{A}_{M'}$$

are always the same as those of $\mathbf{A}_M$: this being the case, all the eigenvalues of $\mathbf{A}$ (except the one at zero) are shifted by the same amount, i.e.

$$[16] \quad \lambda_{n-1} = \lambda_{n-1}{}^{M} = \lambda_{n-1}{}^{M'} = 0,$$
$$\text{otherwise } \lambda_i = (1 - x)\lambda_i{}^{M} + x\lambda^{M'}$$

Clearly, a new program of calculations of a much more specific nature needs to be undertaken: in the first place, we must know under what conditions *observable* departures from the linear mixture rule *for* T–VR *relaxation only* will occur for systems of interest, specifically at the present time H_2 or NO admixed with inert gases. When this has been achieved, it will then be necessary to superimpose on these calculations the non-linear terms, and explore the relationships between the slope $d\lambda/dx$ and the R–R, V–V, or VR–VR relaxation rates, as may be appropriate, for the particular temperature and set of energy-level spacings in question.

Appendix

Recently, Tarr and Rabitz (18) have published details of calculations on T–V, T–R, and T–VR transitions amongst the first 27 states of *para*-H_2 for temperatures of 1000, 2000, and 2500 K. We have interpolated these probabilities to 1500 K in order to make a comparison of the best currently available

theoretical data with our assumed "standard" and "modified" sets of probabilities. The level structure for even J is somewhat different from that of odd J, with the first 20 levels ranging only up to ($v = 0, J = 14$), ($v = 1, J = 12$), and ($v = 2, J = 8$) instead of ($v = 0, J = 15$), ($v = 1, J = 11$), ($v = 2, J = 7$), and ($v = 3, J = 3$); however, with due allowance for the substitution of $v = 3$ levels for the topmost J-levels of $v = 1$ and $v = 2$, the normal-mode diagrams for our two sets of assumed probabilities with even J are exactly what one would expect by inspection of the already published odd-J diagrams, i.e. Figs. I(4) and II(3) respectively. The normal-mode diagram for the transition probabilities of Tarr and Rabitz is very similar indeed to that for our "modified" set: fifteen of the nineteen modes are clearly recognisable as being the same, and they come out in precisely the same order in both cases. The differences between the diagrams are two-fold. First, the modes for our "modified" set tend to couple non-adjacent J states a little too strongly — for example, referring to Fig. II(3), the $v = 2, J = 5$ component of M_1 would be at least a factor of two too large. Second, where the modes are not immediately recognisable as being the same, our "modified" set modes have a somewhat more complex structure: this is immaterial in practice since there is virtually no traffic carried by these modes (i.e. ξ_i is minute) in any practical relaxation; these very complex modes appear to be unphysical.

The net result is that the *qualitative* form of the normal modes used in the relaxation of H_2 at infinite dilution at 1500 K would be virtually indistinguishable whether our "modified" set of probabilities or those of Tarr and Rabitz were used. The relaxations would not be the same, however, since although the modes have the same ordering of time constants, the grouping of the time constants is rather different. The points of similarity and difference are best shown by comparing the contributions of the various modes to a practical relaxation, and this is done in Fig. 3 for all three sets of probabilities, for a sudden heating from 300–1500 K. It is clear that the probabilities of Tarr and Rabitz are intermediate between our "standard" set and our "modified" set[5] in respect of the uncoupling of the rotational and vibrational relaxations, and that in fact, to produce virtually indistinguishable relaxation behaviour at 1500 K, all

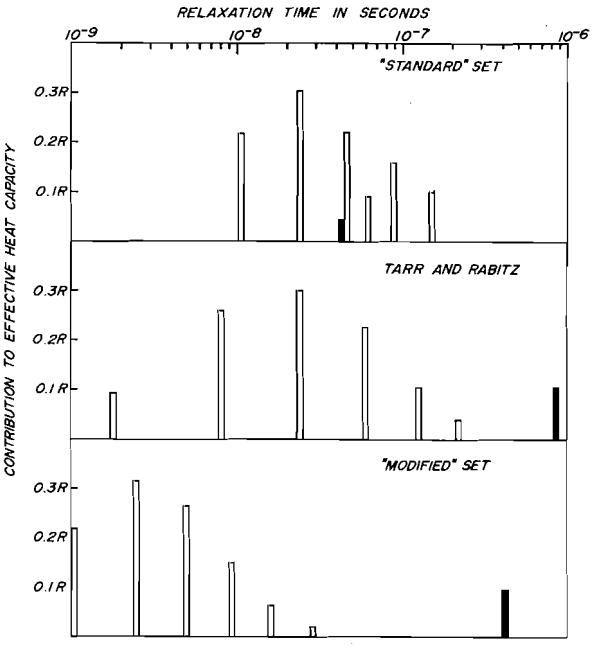

FIG. 3. Normal-mode analysis of a relaxation of *para*-H_2, at infinite dilution in M, from $T_i = 300$ K to $T_f = 1500$ K. From top to bottom, the transition probabilities are those of the "standard" set used throughout this series of papers (i.e. eq. [16] of ref. 9), those of Tarr and Rabitz (18) and those of our "modified" set (derived from the "standard" set by multiplying all T–R transition rates by 10 and dividing all other transition rates by 10). In all cases $\Sigma_i \eta_i = 1.136$ R, the mean heat capacity of *para*-H_2 between 300 and 1500 K; also, the component of the relaxation which is essentially vibrational in character is indicated by shading.

that would be necessary would be to take our "standard" set (i.e. eq. [16] of ref. 9), leave the rotational (i.e. T–R) probabilities unchanged, but multiply all probabilities for which v changes by a factor of about 0.05.

Returning to the problem of the present investigation where we have limited our calculations for the sake of feasibility to $T = 500$ K, we could simply take our "standard" set of transition probabilities and scale all the vibrational components by one-twentieth. However, because of step-length restrictions, this would make our integrations lengthier and costlier by a factor of at least 10. Moreover, it is unnecessary from the point of view of understanding the physics of the relaxation since at 500 K, even with our "standard" set of probabilities, the rotational and vibrational relaxations separate, and the final group of non-zero eigenvalues does correspond to the vibrational part of the relaxation, cf. Fig. I(1) and also the lengthy discussion of laser–schlieren experiments in Part II (2).

[5]In Fig. II(2), due to an accidental interchange of two cards in the computer program, the bottom two panels of the figure should be displaced to the left by a factor of 2.8 in t: this alters the details, although not the overall principle, of the discussion of this diagram in the first fifteen lines of p. 2377.

Etude chimique et spectroscopique du système $B(SCH_3)_3$–$B(NCS)_3$

Le triméthylthioborate $B(SMe)_3$ réagit à la température ordinaire avec le triisothiocyanatoborane $B(NCS)_3$ pour donner des mélanges contenant $B(SMe)_3$, les dérivés mixtes $B(NCS)(SMe)_2$ et $B(NCS)_2(SMe)$ en faible concentration et des dérivés d'association. Les composés précédents ne sont pas isolables par suite de l'existence d'équilibres chimiques. Les données de rmn, de spectrométrie ir et de spectrométrie de masse sont reportées. Des structures faisant intervenir des liaisons donneur–accepteur S–B entre les monomères sont proposées pour les dérivés d'association $\{B(NCS)_2(SMe)\}_2$, $\{B(NCS)_2(SMe)\}_2\{B(NCS)_3\}$ et $\{B(NCS)_2(SMe)\}_2\{B(NCS)_3\}_2$. La réaction de ces composés avec la triméthylamine conduit à la formation de $Me_3NB(NCS)_3$ et $Me_3NB(NCS)_2(SMe)$. La même réaction avec le diméthyl-sulfure est incomplète et ne conduit qu'à la formation de $Me_2SB(NCS)_3$. Les acidités décroissent dans l'ordre $B(NCS)_3 > B(NCS)_2(SMe) > B(NCS)(SMe)_2 > B(SMe)_3$. Cette décroissance explique la dimérisation de $B(NCS)_2(SMe)$ a lieu, contrairement à celle de $B(NCS)(SMe)_2$.

HABIB-RAMAN ATCHEKZAI, HENRI MONGEOT, JACQUES DAZORD, and JEAN-PIERRE TUCHAGUES. Can. J. Chem. **57**, 1122 (1979).

Reaction of trimethylthioborate, $B(SMe)_3$, with triisothiocyanatoborane, $B(NCS)_3$, at room temperature gives mixtures containing $B(SMe)_3$, the mixed compounds $B(NCS)(SMe)_2$ and $B(NCS)_2(SMe)$ in low concentration, and association compounds. The previous compounds cannot be isolated due to equilibria being set up. Mass spectrometry, infrared and nmr data are reported. Structures involving S–B donor–acceptor bonds between the monomers are proposed for the association compounds $\{B(NCS)_2(SMe)\}_2$, $\{B(NCS)_2(SMe)\}_2\{B(NCS)_3\}$, and $\{B(NCS)_2(SMe)\}_2\{B(NCS)_3\}_2$. Reaction of these compounds with trimethylamine yields $Me_3NB(NCS)_3$ and $Me_3NB(NCS)_2(SMe)$. The same reaction with dimethylsulphide is incomplete and yields only $Me_2SB(NCS)_3$. Acidity strength decreases in the order $B(NCS)_3 > B(NCS)_2(SMe) > B(NCS)(SMe)_2 > B(SMe)_3$. This trend explains why dimerization of $B(NCS)_2(SMe)$ occurs whereas $B(NCS)(SMe)_2$ is unassociated.

Introduction

Le pseudo-halogène NCS est bien connu pour présenter de nombreuses analogies avec les halogènes. Ses propriétés chimiques sont considérées comme intermédiaires entre celles de l'iode et du brome (1). Le triisothiocyanate de bore $B(NCS)_3$ a généralement un comportement voisin de celui des halogénures de bore autres que BF_3 avec lesquels il donne d'ailleurs des réactions de redistribution (2, 3). Le triméthylthioborate $B(SMe)_3$ conduit facilement à des redistributions, en particulier avec les halogénures de bore BX_3 (4, 5); il y a alors formation de $BX(SMe)_2$ et $BX_2(SMe)$ ainsi que du dimère $\{BX_2(SMe)\}_2$. La tendance à la dimérisation augmente de l'iode au chlore. Nous avons entrepris l'étude du système $B(SMe)_3$–$B(NCS)_3$ en vue de le comparer aux systèmes $B(SMe)_3$–BX_3.

Résultats

Le mélange à la température ordinaire de $B(NCS)_3$ et $B(SMe)_3$ en solution dans des solvants inertes (CS_2, CCl_4, ...) conduit à des redistributions immédiates; les systèmes ainsi obtenus contiennent les deux dérivés libres $B(NCS)_2(SMe)$ et $B(NCS)(SMe)_2$ mais ceux-ci, et en particulier le premier, sont toujours en concentration très faible par suite de la formation de dérivés d'association. Ces dérivés d'association se forment en quantité d'autant plus importante que le mélange contient une forte proportion d'isothiocyanate. A titre d'exemple, le mélange de $B(NCS)_3$ avec une faible quantité de $B(SMe)_3$ ne conduit pratiquement qu'à la formation de produits d'association alors qu'à l'opposé, on obtient des solutions diluées qui ne laissent apparaître en rmn ^{11}B que les composés $B(NCS)(SMe)_2$ et

0008-4042/79/101122-05$01.00/0

$B(SMe)_3$, le rapport $B(NCS)(SMe)_2/B(SMe)_3$ pouvant dépasser 9%. Dans ce dernier cas, ces mélanges sont obtenus soit par mélange de $B(NCS)_3$ et $B(SMe)_3$, soit, beaucoup plus lentement, par la réaction:

$$B(SMe)_3 + AgNCS \rightarrow B(NCS)(SMe)_2 + AgSMe$$

Les deux dérivés $B(NCS)(SMe)_2$ et $B(NCS)_2(SMe)$ ont été caractérisés par spectrométrie de masse à partir de leurs pics moléculaires, par rmn ^{11}B et ^1H (voir tableau 1) et par spectrométrie infrarouge (voir tableau 2). Ces dérivés, comme tous ceux dans lesquels le bore est lié au groupe NCS possèdent une structure *iso*. Signalons comme preuve le fait que leur spectre infrarouge s'apparente respectivement à celui de $BX_2(NCS)$ et de $BX(NCS)_2$. C'est ainsi que pour ces derniers les vibrations de valence CN apparaissent respectivement vers 2045 et 2010 cm^{-1} (3) et qu'un effet isotopique $^{10}B^{11}B$ d'environ 10 cm^{-1} est observé vers 800 cm^{-1} sur νC═S, aussi bien pour BCl_2NCS et BBr_2NCS[1] que pour $B(SMe)_2(NCS)$. Les valeurs des déplacements chimiques observées en rmn ^{11}B sont également en bon accord avec une structure du même type que dans $B(NCS)_3$.

TABLEAU 1. Déplacements chimiques[a] observés sur les composés non associés et leurs complexes (en ppm)

Composé	rmn ^{11}B	rmn ^1H	rmn ^{13}C

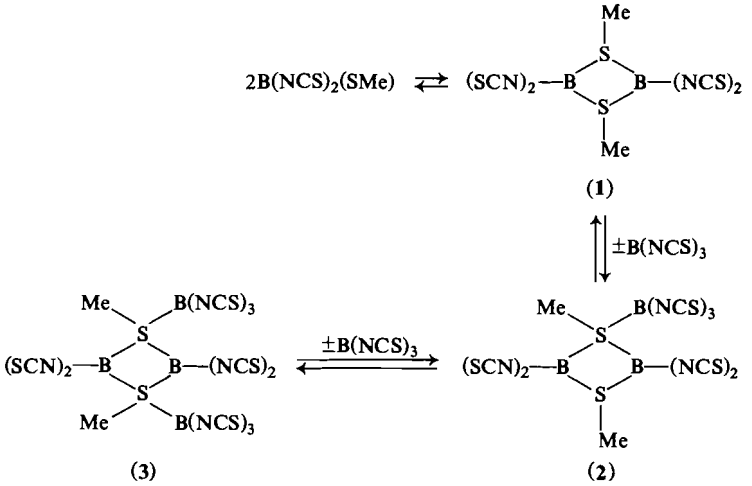
$Me_3NB(NCS)_3$	−28	—	—
$Me_2SB(NCS)_3$	−30.5		

[a]Les valeurs des déplacements chimiques sont comptées négativement quand les pics se situent vers les champs forts par rapport à l'étalon (rmn ^{11}B étalon externe $B(OMe)_3$, rmn ^1H et ^{13}C étalon interne $Si(CH_3)_4$).
[b]La valeur donnée dans la littérature est −43 ppm (9).
[c]Il s'agit de la valeur obtenue à partir de $B(NCS)_3$ pur en solution dans CS_2 (3).
[d]Valeur obtenue pour un mélange équimoléculaire de Me_3N et $B(SMe)_3$.

L'existence des produits d'association a été mise en évidence par rmn ^{11}B et ^1H et par des mesures de masse molaire au moyen de la tonométrie. Des tentatives de distillation n'ont pas permis d'isoler de produits purs. Toutes les réactions observées sont réversibles; nous avons pu rendre compte de la totalité des phénomènes observés à partir des équilibres suivants:

$$B(NCS)_3 + 2B(SMe)_3 \rightleftarrows 3B(NCS)(SMe)_2$$

$$2B(NCS)_3 + B(SMe)_3 \rightleftarrows 3B(NCS)_2(SMe)$$



Etude des dérivés d'association

Le composé $B(NCS)_2(SMe)$ se dimérise de la même façon que ses homologues halogénés $BX_2(SMe)$ (4, 5). Cependant les phénomènes observés ne se limitent pas à une simple dimérisation. En effet, l'étude des mélanges $B(NCS)_3$–$B(SMe)_3$ dans un rapport molaire $B(NCS)_3/B(SMe)_3$ compris entre 0 et 4 montre que le degré d'association moyen dans les composés d'association est compris entre 2 et 3.2 environ. D'autre part, le rapport NCS/SMe dans ces composés est supérieur à 2 ce qui suggère la possibilité de fixation d'une ou deux molécules

[1]Etude du champ de force des molécules BX_2NCS à publier.

TABLEAU 2. Fréquence des principales bandes infrarouge observées[c]

$B(NCS)_2(SMe)$[a]	$B(NCS)(SMe)_2$[a]	Produit d'association[b]	Attribution
2025 TF	2070 TF	2020 à 2060 TF	νCN
1302 TF			$\nu_a{}^{10}BN_2$
1275 f			$\nu_a{}^{11}BN_2$
	1238 f		$\nu^{10}BN$
	1212 m		$\nu^{11}BN$
		1070 à 1165 F	$\nu_s BN_2$
	800 f		νC═S (^{10}B)
	790 m		νC═S (^{11}B)
		730 à 760 F	νC═S

[a]Le faible nombre de bandes répertoriées pour $B(NCS)_2(SMe)$ et $B(NCS)(SMe)_2$ est dû à la faible concentration de ces produits dans les mélanges.
[b]Le produit d'association 1 donne une bande à 2060 cm^{-1}.
[c]Le spectre de $B(SMe)_3$ étant connu (8), il n'a pas été reporté ici. TF = très forte, F = forte, m = moyenne, f = faible, tf = très faible.

$B(NCS)_3$ sur ce dimère. La formation de ces dérivés est réversible; c'est ainsi qu'ils se dégradent très rapidement lorsqu'on les met en solution dans $B(SMe)_3$ pour redonner $B(NCS)(SMe)_2$. Les déterminations de masses molaires ne sont plus possibles pour des solutions riches en $B(NCS)_3$ par suite de la formation connue (3, 6) du polymère insoluble $\{B(NCS)_3\}_n$.

L'étude des spectres d'absorption infrarouge de ces dérivés nous montre que les vibrations de valence νCN se trouvent dans la région 2020–2070 cm^{-1}. Leur fréquence n'a donc subi qu'une élévation très faible par suite de l'association ce qui indique que les groupes NCS ne sont pas modifiés. De plus la très légère augmentation de fréquence observée suggère que le bore est passé de l'état tricoordiné à l'état tétracoordiné; nous avons en effet noté un phénomène analogue (7) dans l'étude des complexes $R_3NBX_n(NCS)_{3-n}$ avec $n = 0, 1, 2$.

L'évolution des spectres de rmn ^{11}B du système $B(SMe)_3$–$B(NCS)_3$ est représentée sur la fig. 1. Quand on ajoute progressivement $B(NCS)_3$ à $B(SMe)_3$, il apparait successivement dans la partie du spectre située vers les champs forts par rapport à $B(OMe)_3$ des pics larges pour $\delta = -27$, -23.5, -19 et -14.6 ppm. Le premier pic est attribué au composé **1**, la dimérisation de $B(NCS)_2(SMe)$ se traduisant par un fort déplacement vers les champs forts. Le pic situé à -23.5 ppm est attribué aux deux atomes de bore appartenant au cycle du composé **2**. Le fait qu'un atome de soufre du cycle devienne tétravalent entrainant un léger déblindage du bore. Le pic observé à -19 ppm est attribué aux deux atomes cycliques du composé **3**, les deux atomes de soufre du cycle étant cette fois tétravalents. Enfin, le pic situé à -14.6 ppm appartient à $B(NCS)_3$ libre, le déplacement chimique observé est en effet très voisin de celui déterminé pour $B(NCS)_3$ seul; de plus,

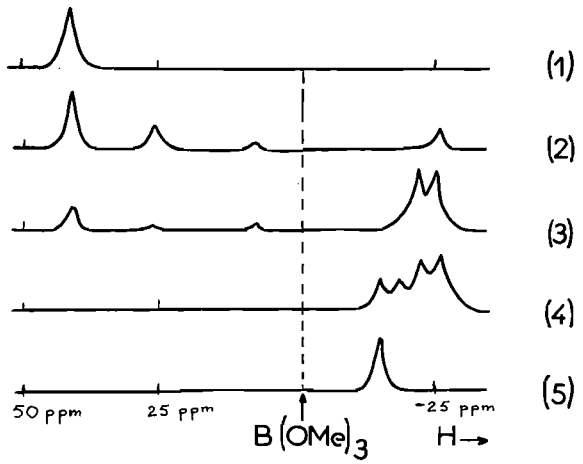


FIG. 1. Evolution des spectres de rmn ^{11}B du système $B(SMe)_3$–$B(NCS)_3$ en solution dans CS_2: (*1*) $B(SMe)_3$ pur, (*2*) $\{B(NCS)_3\}/\{B(SMe)_3\} = 0.28$, (*3*) $\{B(NCS)_3\}/\{B(SMe)_3\} = 2$, (*4*) $\{B(NCS)_3\}/\{B(SMe)_3\} = 5$, (*5*) $B(NCS)_3$ pur.

l'étude des spectres infrarouge a permis d'établir avec certitude que l'existence de ce composé dans les mélanges est liée à la présence du pic situé à -14.6 ppm. Nous pensons par ailleurs que les atomes de bore de $B(NCS)_3$ liés aux atomes de soufre cycliques dans les composés **1** et **2** sont peu différents les uns des autres, et donnent lieu à des déplacements chimiques voisins de -27 ppm. Cette valeur est en effet peu différente de celle obtenue avec les complexes $Me_3NB(NCS)_3$ et $Me_2SB(NCS)_3$ (voir tableau 1). De plus on observe un léger élargissement du pic situé à -27 ppm quand on ajoute des quantités croissantes de $B(NCS)_3$ à un mélange.

En rmn du proton, les spectres des produits d'association évoluent également en fonction de la composition du mélange. Quand on ajoute progressivement $B(NCS)_3$ à une solution de $B(SMe)_3$ il apparait d'abord un massif centré vers $+2.74$ ppm

puis progressivement un second massif vers +3 ppm alors que les pics du premier massif diminuent d'intensité pour devenir très faibles. Nous attribuons le premier massif aux groupes CH_3 liés à un soufre tricoordiné, et le second à ceux liés à un soufre tétracoordiné. La multiplicité des pics trouve sa justification dans le fait que chaque composé peut exister sous deux formes isomères. Il est à noter que Siebert et coll. (5) observent pour $BI_2(SMe)$ et son dimère des pics à +2.73 et +3.12 ppm. Nous obtenons un écart identique (0.39 ppm) entre la position du pic de $B(SMe)(NCS)_2$ (+2.25 ppm) et celle de son dimère (+2.74 ppm).

Réactions de complexation avec Me_3N et Me_2S

Dans le but d'avoir des indications complémentaires sur le système $B(SMe)_3$–$B(NCS)_3$, nous avons étudié les réactions de Me_3N et Me_2S avec $B(SMe)_3$, $B(NCS)_3$ ainsi que les produits formés en les mélangeant. $B(SMe)_3$ conduit avec Me_3N à un complexe instable, qui est facilement détruit par élimination de l'amine en portant simplement le produit sous vide à la température ordinaire. Par suite d'une réaction d'échange rapide, on n'observe qu'un seul pic en rmn ^{11}B quand on mélange Me_3N avec $B(SMe)_3$ en excès. La position de ce pic est intermédiaire entre celle de $B(SMe)_3$ libre et celle observée avec un mélange équimolaire de deux réactifs (voir tableau 1). Nous avons également observé un phénomène d'échange rapide en rmn du proton.

Dans les mêmes conditions $B(NCS)_3$ donne un complexe stable; celui-ci réagit d'ailleurs dans une faible proportion avec $B(SMe)_3$ suivant:

$$Me_3NB(NCS)_3 + B(SMe)_3 \rightarrow Me_3NB(NCS)_2(SMe) + B(NCS)(SMe)_2$$

ce qui montre que le complexe $Me_3NB(NCS)_2(SMe)$ est plus stable que $Me_3NB(NCS)(SMe)_2$. Il est à noter que la complexation d'un mélange s'accompagne d'une redistribution des groupes NCS et SMe. C'est ainsi que la complexation des produits résultant du mélange de $B(NCS)_3$ et $B(SMe)_3$ dans un rapport 2 (voir fig 1, spectre *3*) conduit presque exclusivement à $Me_3NB(NCS)(SMe)_2$.

Les mêmes réactions de complexation effectuées à partir de Me_2S n'ont permis de montrer que l'existence de $Me_2SB(NCS)_3$. Contrairement à Me_3N qui dissocie presque complètement les dérivés d'association, Me_2S qui est une base plus faible ne réagit que partiellement sur les produits d'association pour donner $Me_2SB(NCS)_3$. Le produit 1 subsiste dans ces conditions.

L'étude de ces réactions de complexation montre que le pouvoir accepteur du bore dans les composés $B(NCS)_n(SMe)_{3-n}$ augmente avec n. Ceci explique que seul $B(NCS)_2(SMe)$ se dimérise avec formation du cycle B_2S_2. Ce cycle renferme deux liaisons donneur–accepteur S–B que l'on rencontre également dans Me_2S–$B(NCS)_3$.

Discussion

D'après les structures que nous avons proposées pour les composés **1**, **2** et **3**, la formation des produits d'association résulte de liaisons donneur–accepteur. Le fait que leur formation soit concurrencée par des réactions de complexation avec une base de Lewis justifie bien l'existence de ce type de liaison. Les déplacements chimiques observés en rmn ^{11}B rendent également bien compte du fait que le bore joue un rôle d'accepteur. Par contre, il peut paraître surprenant que seul le soufre lié au groupe méthyl intervienne en tant que donneur, alors que, ni l'azote, ni le soufre des groupes NCS ne sont concernés. Cette hypothèse repose sur les considérations suivantes: en premier lieu l'étude des spectres infrarouge ne révèle aucune modification des groupes NCS. D'autre part, l'étude des spectres de rmn ^1H permet de classer les groupes CH_3 en deux types; il est logique de penser que c'est l'environnement du soufre auquel ils sont liés qui en est responsable plutôt que celui des groupes NCS beaucoup plus éloignés. Enfin, ceci est conforme au fait que $B(NCS)_3$ en solution est exclusivement sous forme de monomère.

Au sujet de $B(NCS)_3$, nous avons signalé qu'il avait tendance à former des polymères solides, mais il s'agit de composés très stables qu'il n'est plus possible de dissocier par l'action d'une amine. Il semble d'ailleurs que les molécules de $B(NCS)_3$ soient liées entre elles par des liaisons C—N, ce qui expliquerait la présence dans leur spectre infrarouge d'une bande forte et large entre 1550 et 1600 cm^{-1}. Or les spectres des produits d'association dont il est question ici ne renferment aucune bande de ce type.

Le système étudié diffère des systèmes BX_3–$B(SMe)_3$ par la formation des composés **2** et **3**. Si on fait abstraction de ce phénomène, il est assez voisin du système BBr_3–$B(SMe)_3$, en particulier en ce qui concerne les proportions relatives de produits libres et associés.

Partie expérimentale

$B(NCS)_3$ préparé par réaction de BBr_3 sur AgNCS (3) a été caractérisé à partir de ses spectres de rmn ^{11}B et infrarouge ainsi que par des mesures de masse molaire. $B(SMe)_3$ a été obtenu par action de MeSH sur BCl_3 en présence de Et_3N en solution dans l'éther (10). Il a été caractérisé à partir de son spectre de rmn ^{11}B (9), de son spectre infrarouge (8) et de mesures de masse molaire.

Les complexations par Me_3N ont été réalisées à basse température. L'amine (produit commercial contenu dans une bouteille métallique) est introduite par petites fractions à l'aide d'une rampe à vide dans une ampoule contenant les produits à complexer. Au cours de l'introduction, l'ampoule est à la température de l'air liquide, on la laisse ensuite revenir à la température ambiante tout en agitant le mélange. Cette opération est répétée jusqu'à ce qu'on se trouve en présence d'un excès d'amine. Les complexations, portant sur des quantités de produit allant de 1 g à 10 g, ont lieu indifféremment en présence ou non de solvant (CH_2Cl_2 ou CS_2). Dans le cas de la complexation par Me_2S, la réaction n'est pas violente et on ajoute lentement à la température ordinaire le sulfure liquide à une solution du produit à complexer maintenue sous agitation.

Les produits étudiés étant hydrolysables, toutes les manipulations sont été effectuées à l'abri de l'air.

Détermination des masses molaires

Le solvant utilisé a été dans tous les cas CS_2. Sa tension de vapeur a été déterminée à 0°C et 25°C par mesure directe à l'aide d'un manomètre à mercure. Aucune variation notable du degré d'association n'a été décelée entre ces deux températures.

Spectrométrie de masse

Les spectres ont été enregistrés à l'aide d'un appareil A.E.I. MS 902 à double focalisation avec une énergie d'ionisation de 70 eV. Nous avons introduit les produits par ballon chauffé tout en verre (all glass heated inlet system) à des températures allant de 25°C à 90°C. La température doit être d'autant plus élevée que le mélange est riche en $B(NCS)_3$. La source était dans tous les cas maintenue à 70°C. En plus des pics moléculaires de $B(SMe)_3$, $B(NCS)(SMe)_2$, $B(NCS)_2(SMe)$ et $B(NCS)_3$, des fragments dûs à $B(SMe)_3$ (11) on note la présence des ions $\{SB(NCS)(SCH)_3\}^+$, $\{NB(SCH_3)_2\}^+$ et $\{B(NCS)(SCH_3)\}^+$ qui proviennent de la fragmentation de $B(NCS)(SMe)_2$.

Spectrométrie infrarouge

Les spectres ont été enregistrés à l'aide d'un spectromètre Perkin-Elmer modèle 457, les cellules à liquide utilisées étaient munies de fenêtres en CsI.

Résonance magnétique nucléaire

Les spectres ont été enregistrés à l'aide d'un appareil Varian X.L.100 avec une fréquence de 32.1 MHz pour les noyaux ^{11}B et ^{13}C, et avec un appareil Varian A60A à la fréquence de 60 MHz pour les noyaux ^1H.

Détermination de la composition d'un mélange

Pour déterminer la composition d'un mélange à l'équilibre, nous avons tenu compte des quantités de $B(NCS)_3$ et $B(SMe)_3$ introduites au départ (celles-ci sont déterminées par pesée), des mesures de masse molaire, et des courbes intégrales en rmn ^{11}B. A titre d'exemple, nous reportons ci-dessous les résultats obtenus pour un mélange dont le spectre est représenté fig. 1, spectre *3*. Pour une composition de départ en millimoles de: $B(SMe)_3$: 10, $B(NCS)_3$: 20.49, CS_2: 844.54, les surfaces de pics de rmn ^{11}B sont à l'équilibre: $B(SMe)_3$: 6.29, $B(NCS)(SMe)_2$: 4.19, $B(NCS)_2(SMe)$: 5.59, produits d'association: 83.91. Compte-tenu de la présence de monomères, on obtient pour les produits d'association la formule empirique $B(NCS)_{2.22}(SMe)_{0.78}$. En admettant que ceux-ci sont constitués des composés **1**, **2** et **3**, le rapport NCS/SMe précédent correspond à un degré d'association de 2.6 ou encore à la formule empirique $\{B(NCS)_2(SMe)\}_2\{B(NCS)_3\}_{0.6}$. Les mesures de masse molaire effectuées sur la même solution ont permis de déterminer un degré d'association de 2.5, ce qui, comptetenu de la présence de 16% environ de molécules non associées conduit pour les produits d'association à un degré d'association de 2.8. Etant données l'instabilité des solutions de $B(NCS)_3$ et l'imprécision dans les dosages par rmn ^{11}B, ces résultats peuvent être considérés comme compatibles.

Remerciements

Nous remercions Monsieur Simeon, Service du Professeur Delmau, Université Lyon I, d'avoir enregistré la plupart de nos spectres de rmn.

Nous remercions également Monsieur Desruaz, Maître-Assistant du Laboratoire de Chimie Analytique de la Faculté de Pharmacie de Lyon, d'avoir enregistré nos spectres de masse.

JEAN-YVES GAL, CHRISTINE LAVILLE, FRANÇOISE PERSIN, MICHEL PERSIN, JEAN-CLAUDE BOLLINGER et THÉOPHILE YVERNAULT. Can. J. Chem. **57**, 1127 (1979).

On a mesuré la conductibilité électrique de 19 électrolytes 1-1 MX (M = alcalin, ammonium quaternaire; X = halogénure perchlorate, nitrate) dans les mélanges eau–hexaméthylphosphotriamide à 25°C. A l'aide de l'hypothèse de l'équimobilité des ions dans Bu_4NBPh_4, on a déduit les conductibilités individuelles pour 17 ions monovalents dans ces mélanges. Après une critique des méthodes traditionnellement utilisées, nous montrons que seule la théorie de Zwanzig permet, à partir de ces résultats, d'aborder objectivement le problème des interactions ion–solvant. Cependant, cette théorie ne permet pas, dans l'état actuel de son développement, d'élucider la totalité des problèmes puisque Zwanzig considère le déplacement de l'ion nu mais elle permet de bien distinguer, selon la mobilité d'un ion, la nature des interactions entre celui-ci et le solvant.

JEAN-YVES GAL, CHRISTINE LAVILLE, FRANÇOISE PERSIN, MICHEL PERSIN, JEAN-CLAUDE BOLLINGER, and THÉOPHILE YVERNAULT. Can. J. Chem. **57**, 1127 (1979).

The electrical conductibilities of 19 1-1 MX electrolytes (M = alkaline, quaternary ammonium; X = perchlorate, halide, nitrate) in water–hexamethylphosphotriamide mixtures at 25°C has been measured. The individual conductibilities of 17 monovalent ions in these mixtures were calculated using the hypothesis of ion equimobility in Bu_4NBPh_4. Following a critical review of the traditionally used methods, it has been shown that, from these results, Zwanzig's theory alone allows the objective assessment of ion–solvent interactions. However, this theory at its present state of development cannot be used to elucidate all the problems (because Zwanzig considers the displacement of the free ion) but it does distinguish the nature of the interactions between an ion and the solvent, depending on the mobility of that ion.

Introduction

Les mélanges eau–hexaméthylphosphotriamide (HMPT) sont caractérisés par de fortes interactions entre les deux solvants. La variation importante de la viscosité en fonction de la composition du mélange nous a conduits à poursuivre dans ces milieux, l'étude des mobilités ioniques que nous avions entreprise dans le HMPT pur dans une étude précédente (1). Nous avons alors abordé le problème de la solvatation des ions dans les mélanges eau–HMPT en utilisant l'ensemble de nos résultats. En raison de l'incapacité des méthodes routinières à donner un ensemble cohérent de conclusions sur la sphère de solvatation des ions, nous nous sommes proposés d'appliquer la théorie de Zwanzig (2, 3) pour étudier le comportement des ions à partir de leur conductivité équivalente limite.

Partie expérimentale

L'origine et la purification des sels et du solvant ont été indiquées précédemment (1). Nous avons aussi indiqué notre façon d'opérer et les réserves en ce qui concerne la rusticité de notre appareillage.

Les mélanges eau–HMPT sont obtenus par pesée. Les solutions mères ont été contrôlées par dosage (méthodes électrochimiques variées ou spectrophotométrie de flamme selon les cas).

Les résultats publiés pour chaque mélange sont déduits, pour chaque sel, de 3 à 6 séries de 15 mesures sur des solutions de concentration $C = 4 \times 10^{-4}$ à 10^{-2} mol L^{-1}. Nous avons tracé pour chaque sel des graphes $\Lambda_0 = f(X_{HMPT})$ où Λ_0 est la conductibilité limite équivalente et X_{HMPT} la fraction molaire en HMPT. Les valeurs retenues sont issues du lissage de ces courbes, nous ne pouvons donc fournir les tableaux de mesures des conductivités en fonction des concentrations.

On estime pour les Λ_0 une incertitude de ± 0.05 Ω^{-1} cm^2 mol^{-1}.

Propriétés physiques des mélanges eau–HMPT

L'évolution des propriétés physiques des mélanges eau–HMPT avec leur composition a été récemment discutée (4–10). Il apparaît clairement que les deux solvants ont une grande affinité l'un pour l'autre, les variations d'enthalpie, d'enthalpie libre et d'entropie d'excès étant toujours négatives

[1]Auteur à qui toute correspondance doit être adressée.

0008-4042/79/101127-09$01.00/0

(4, 7), cette dernière permettant de supposer une organisation plus grande dans les mélanges que dans les solvants purs.

On peut calculer l'enthalpie de solvatation de l'eau dans le HMPT pur (8). La valeur trouvée ($\Delta H = -52.7$ kJ mol^{-1}) semble indiquer de la part du HMPT un pouvoir accepteur du proton encore supérieur à celui du DMSO (11). Par des mesures de temps de relaxation des protons Kessler et coll. (6, 10) confirment la stabilisation de la structure des mélanges eau–HMPT, essentiellement dans les milieux riches en eau, le maximum étant situé pour une fraction molaire en HMPT de l'ordre de 0.15. La variation de la viscosité (6–8) nous a semblé en tous points remarquable. Sur la fig. 1, on peut observer une très forte augmentation de la viscosité des mélanges par rapport aux solvants purs.

Ce phénomène est atténué lorsqu'on élève la température mais il reste néanmoins bien plus important que celui observé pour les mélanges d'eau et de solvants courants (fig. 1). La viscosité est maximale pour une fraction molaire en HMPT de l'ordre de 0.2, ce qui semble confirmer une stabilité maximum des mélanges dans ce domaine.

En fait, le comportement général des mélanges eau–HMPT est compatible avec le modèle proposé par Franks et Ives (14) pour les mélanges eau–éthanol et repris depuis par de nombreux auteurs pour d'autres mélanges eau–solvant (15–20). Aux fortes teneurs en eau, les interactions entre les molécules d'eau se trouveraient renforcées par la présence du HMPT, les structures tétraédriques seraient stabilisées. La faible variation du facteur de Kirkwood dans les milieux riches en eau (8) indique que la structure de l'eau n'est pas défaite par les premiers apports en HMPT, ce qui est confirmé par Saumagne et coll. (21) dans l'infrarouge. Dans le cas du HMPT, ce maximum de structuration de l'eau résulterait d'une part de l'influence hydrophobe des groupements méthyle et d'autre part de la forte polarité de cette molécule et de son encombrement stérique. Les molécules de HMPT seraient emprisonnées dans le réseau des molécules d'eau qu'elles auraient renforcé. Ce modèle explique bien l'augmentation constante du volume molaire partiel du HMPT (8) quand X_{HMPT} augmente (phénomène que l'on n'observe pas avec les solvants donnant eux-mêmes des liaisons hydrogènes (11, 22, 23)). Dans ce domaine, les propriétés solvatantes du HMPT devraient être faibles et l'on pourrait s'attendre à une solvatation préférentielle des ions par l'eau.

Lorsque X_{HMPT} augmente, les agrégats d'eau sont progressivement remplacés par des agrégats mixtes de composition dépendant de la teneur en HMPT.

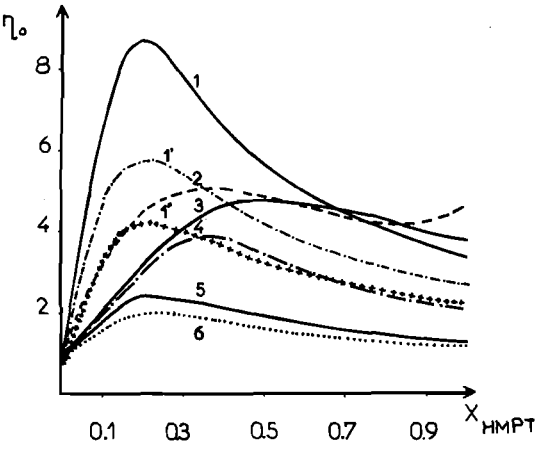

FIG. 1. Viscosité en centipoises de différents mélanges en fonction de X fraction molaire en composé organique. (*1*) Eau–HMPT à 25°C; (*1'*) eau–HMPT à 35°C; (*1''*) eau–HMPT à 45°C; (*2*) eau–terbutanol à 25°C (15); (*3*) eau–NMA à 30°C (12); (*4*) eau–DMSO à 25°C (13); (*5*) eau–éthanol à 25°C (16); (*6*) eau–dioxane à 25°C (15, 16).

Si on retient pour rayon de sphère rigide la molécule d'eau 1.37 Å (24) et 3.36 Å pour celui de la molécule de HMPT (25), il est clair que ϕ_{HMPT} la fraction volumique de HMPT augmente beaucoup pour de faibles augmentations de X_{HMPT} et le milieu doit rapidement se comporter peu différemment du HMPT lui-même. On peut mettre alors en évidence dans l'infrarouge des complexes $H_2O(HMPT)_2$ et $H_2O(HMPT)$ (21) et également $\{H^+(HMPT)_4\}OH^-$ qui a été confirmé par conductométrie et rmn de ^1H et ^{31}P (9). L'étude des variations de la constante diélectrique (4, 5, 10, 26) en fonction des X_{HMPT} n'a pas révélé une quelconque singularité des mélanges eau–HMPT. Par contre, le calcul à partir de ces résultats de la constante diélectrique d'excès (7, 8) met bien en évidence une augmentation de l'orientation des dipoles de l'eau dans le domaine riche en eau (fig. 2).

Il nous a semblé intéressant d'effectuer des mesures de mobilités ioniques dans les mélanges eau–HMPT essentiellement en raison des fortes variations de la viscosité en fonction de la teneur en HMPT. Nous verrons lors de l'interprétation de nos résultats selon la théorie de Zwanzig combien le comportement diélectrique d'un mélange de solvants est important et combien il est nécessaire d'en tenir compte lorsque l'on veut relier les valeurs des mobilités des ions à leur état de solvatation.

Etude des mobilités ioniques dans les mélanges eau–HMPT à 25°C

Nous avons indiqué dans notre précédent mémoire (1) comment nous déterminons la conductivité

TABLEAU 1. Valeurs des constantes physiques et des constantes α, β, E_1, E_2 (27) pour les différents mélanges étudiés à 25°C

	0.05	0.1	0.2	0.3	0.4	0.6	1

équivalente limite des sels en utilisant l'équation de Fuoss–Onsager (27). Nous résumons dans le tableau 1 les constantes correspondant aux mélanges étudiés et dans le tableau 2 les valeurs de conductivités équivalentes limites obtenues pour l'ensemble des sels étudiés.

La fig. 3 montre bien que l'addition de HMPT à l'eau diminue considérablement la conductivité des sels, ce qui est compatible avec la forte augmentation de la viscosité. Lorsque celle-ci diminue, la conductivité n'augmente pas dans les mêmes proportions, ce qui montre bien déjà que la viscosité n'est pas le seul facteur important.

Pour atteindre les valeurs des conductivités équivalentes limites ioniques, nous avions dans notre premier mémoire (1), considéré que dans le HMPT pur:

$$\tfrac{1}{2}\Lambda_0(Bu_4NBBu_4) = \lambda_0(Bu_4N^+) = \lambda_0(Bu_4B^-)$$

En fait, le tétrabutylborate de tétrabutylammonium est trop peu soluble dans les milieux riches en eau pour pouvoir servir de référence. Nous avons dû avoir recours à une autre hypothèse de travail en utilisant le tétraphénylborate de tétrabutylammonium, soit:

$$\Lambda_0(Bu_4NBPh_4) = \Lambda_0(Bu_4NX) + \Lambda_0(NaBPh_4) - \Lambda_0(NaX)$$

$$\tfrac{1}{2}\Lambda_0(Bu_4NBPh_4) = \lambda_0(Bu_4N^+) = \lambda_0(Ph_4B^-)$$

où X est I, Br et ClO_4.

Cette méthode conduit à augmenter encore l'incertitude absolue sur $\lambda_0(Bu_4N^+)$. Nous avons dans le tableau 3 comparé les résultats tirés de ces deux hypothèses de travail. Il apparaît dans les milieux riches en HMPT où la première méthode est applicable, que les résultats obtenus à l'aide de la seconde peuvent être considérés comme satisfaisants dans le cadre de notre étude. Nous rapportons dans le tableau 4, l'ensemble des valeurs de conductivités ioniques équivalentes limites trouvées pour les différents mélanges eau–HMPT étudiés. Il semblerait que la mobilité des anions dépende plus de la viscosité du milieu. Par ailleurs, pour l'ensemble des ions, au-delà d'une fraction molaire en HMPT de l'ordre de 0.3, on peut remarquer que la mobilité varie peu et qu'elle est très nettement inférieure aux valeurs correspondant à l'eau pure. Les mélanges eau–HMPT ne permettent donc pas d'obtenir des milieux très conducteurs du courant électrique.

Interprétation des résultats, étude de la solvatation des ions

L'utilisation de valeurs de mobilités ioniques pour aborder l'étude des interactions ion–solvant conduit à classer les méthodes de travail en deux catégories.

1. Méthodes conventionnelles

Elles reposent sur l'hypothèse que l'ion est sphérique et qu'il est entouré d'une sphère de solvatation qu'il entraîne dans son déplacement. La composition de la sphère de solvatation dépend de la nature de l'ion et des proportions des deux cosolvants. Dans une première étape, le mélange de solvant est assimilé à un milieu continu. Selon la composition de la sphère de solvatation les λ_0 seront différents et de ce fait les mesures de conductivités

ioniques constituent une approche de l'étude de la solvatation des ions par les mélanges de solvants.

Ces méthodes ont été largement utilisées et toutes conduisent à des contradictions que les auteurs ont levées en ajoutant des hypothèses supplémentaires. Le milieu ambiant ne serait plus un continuum, mais sa structure au voisinage d'un ion dépendrait de la nature de cet ion. En définitive, ces méthodes permettent bien de retrouver ce que l'on cherche à obtenir a priori: les cations sont plus solvatés par les solvants polaires, les anions sont plus solvatés par les solvants protiques, les gros anions polarisables peuvent être solvatés par les solvants polaires aprotiques.

On peut citer les études qui consistent: à tracer les variations de λ_0 en fonction de la viscosité, en négligeant les phénomènes diélectriques (12, 20, 34–36); à étudier les variations du produit de Walden $\lambda_0\eta_0$ en fonction de la fraction molaire (14, 15, 18, 37–39); à calculer le volume de solvatation des ions selon la méthode de Robinson et Stokes que nous avons exposée dans notre précédent mémoire (1, 14, 15, 18, 37–39).

Nous avons utilisé ces différentes méthodes dans les mélanges eau–HMPT (40). Nos résultats sont bien cohérents avec ce qui a été publié dans d'autres mélanges, mais nous ne pensons pas qu'ils permettent de faire avancer le problème, c'est pourquoi nous

préférons exposer l'interprétation de nos mesures de mobilités ioniques en se référant à la théorie de Zwanzig (2, 3).

2. Méthode basée sur l'exploitation de la théorie de Zwanzig

Nous avons récemment rappelé cette théorie dans le cadre de son application dans le HMPT pur (25).

La loi de Stokes (41) ne traduisant pas parfaitement le comportement hydrodynamique des ions (36), une correction à cette loi a été proposée par Fuoss (42) et évaluée quantitativement par Boyd (43) et Zwanzig (2). Ils ont calculé une force diélectrique de friction en supposant que le déplacement relatif entre l'ion et un élément de volume de solvant était constant. Cette force de friction provient de l'énergie produite par l'ion orientant les dipoles de solvant qu'il rencontre lors de son déplacement. Ce calcul tient compte du retard dû à la relaxation des dipoles autour de l'ion en mouvement.

Quelques années plus tard, la vitesse relative d'un ion et d'un solvant dépendant de la distance entre l'ion et un élément de volume du solvant, Zwanzig (3) a revu sa théorie. Il vient à distinguer le cas où les molécules de solvant n'adhèrent pratiquement pas à la surface de l'ion (slipping = glissement parfait) et le cas où les dipoles de solvant proches de l'ion sont retenus plus ou moins longtemps près de l'ion (sticking = adhésion).

L'équation résultante du produit de Walden devient alors:

$$\lambda_0\eta_0 = \frac{ZeF}{AR_c + (B/R_c^3)}$$

où $A = A_v\pi$ représente les forces de freinage hydrodynamique dues au milieu. Et

$$B = A_D \frac{(Ze)^2(\varepsilon_0 - \varepsilon_\infty)\tau}{\varepsilon_0(2\varepsilon_0 + 1)\eta_0}$$

les forces de friction diélectrique. Z étant la charge de l'ion, F le Faraday, R_c le rayon cristallin de l'ion, ε_0 la constante diélectrique du solvant, ε_∞ la constante diélectrique à fréquence infinie, η_0 la viscosité du solvant, τ le temps de relaxation diélectrique, A_v et A_D des constantes respectivement égales à 6 et 3/8 dans le cas du "sticking" et 4 et 3/4 dans le cas du "slipping".

Il est important de bien remarquer qu'à ce jour la théorie de Zwanzig suppose que l'ion, positif ou négatif, se déplace dans un milieu continu et que le rayon pris en compte par Zwanzig est le rayon cristallin. Cela veut dire que, sans nier les phénomènes de solvatation, l'auteur suppose que les ions ne se déplacent pas en entraînant avec eux leur "sphère" de solvatation mais qu'ils la reconstituent de proche en proche.

Dans le cas du glissement parfait, l'échange ion–solvant est infiniment rapide, l'adhésion correspond au cas où la vitesse de déplacement de l'ion dépend de la cinétique de cet échange.

L'analyse sommaire de l'équation de Zwanzig

montre que pour les gros ions, le terme en R_c sera prépondérant et que ce sera le terme $1/R_c^3$ pour les petits ions. Cela conduit à prévoir un maximum pour les courbes $\lambda_0\eta_0 = f(1/R_c)$. Ce maximum a bien été observé sur les courbes expérimentales (44–47). Lorsque le terme en R_c est prépondérant on retrouve l'expression de la loi de Stokes. Le déplacement des ions est alors limité principalement par les forces de friction hydrodynamique.

Dans le cas des petits ions, ces dernières deviennent progressivement négligeables devant les forces dues aux interactions diélectriques.

L'application de la théorie de Zwanzig pour les cations a été effectuée dans l'eau, le méthanol, l'éthanol et l'acétonitrile par Kay et Evans (48) en 1966. Plus récemment Fernandez-Prini et Atkinson (47) en 1971 se sont intéressés à cette théorie dans l'eau et d'autres solvants polaires et dipolaires aprotiques.

Ces auteurs ont constaté que le maximum des mobilités calculé d'après la théorie correspondait au maximum expérimental pour les solvants dipolaires aprotiques à condition de considérer le cas du "glissement parfait". Pour les solvants polaires la théorie prévoit la position du maximum sauf dans le formamide.

Ils concluent également que dans les solvants aprotiques dipolaires, les mobilités des ions ammoniums quaternaires sont en accord avec la théorie de Zwanzig et celle de la loi de Stokes. Ils admettent donc que le déplacement de ces ions est essentiellement contrôlé par des forcés de friction hydrodynamique.

Pour les cations alcalins ces auteurs ont constaté que les courbes expérimentales se situaient toujours au-dessus des courbes théoriques quels que soient les solvants. La théorie prévoit donc un freinage plus important que les résultats expérimentaux ne le font apparaître. L'écart d'autre part est plus important pour les courbes obtenues dans les solvants protiques et particulièrement dans l'eau. Ces auteurs montrent également que l'excès de mobilité observé est d'autant plus grand que l'ion est plus petit, la théorie de Zwanzig donnerait alors trop d'importance au terme relatif à la force de friction diélectrique.

Nous avons représenté sur les figs 4 et 5 les courbes $\lambda_0\eta_0 = f(1/R_c)$ relatives aux différents cations et anions que nous avons étudiés dans les mélanges eau–HMPT. Nous constatons qu'elles présentent toutes un maximum comme le prévoit la théorie de Zwanzig, que les courbes obtenues pour les mélanges de fraction molaire $X_{HMPT} < 0.15$ sont situées au-dessus de celles de l'eau, que pour les mélanges de fraction molaire $X_{HMPT} > 0.15$ plus le mélange est

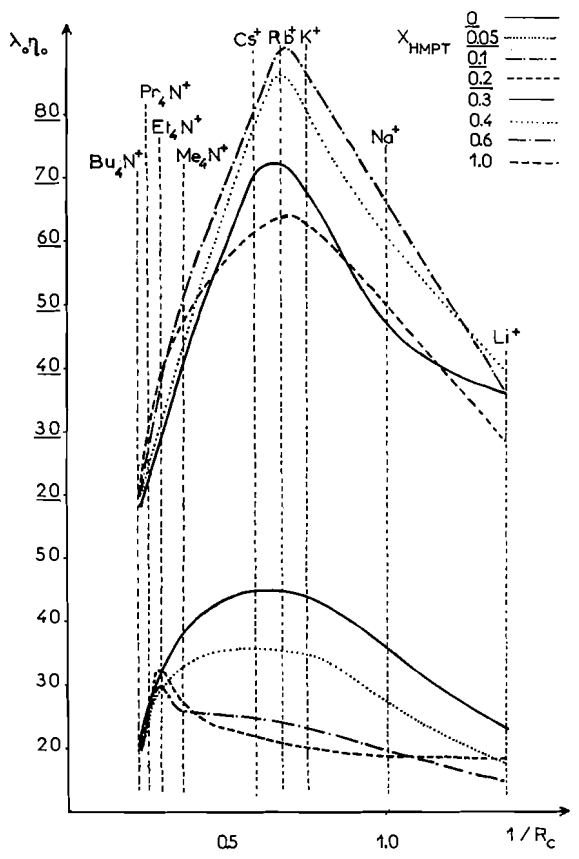

FIG. 4. Variation du produit $\lambda_0\eta_0$ (Ω^{-1} cm^2 equiv.$^{-1}$ cP) des cations en fonction de $1/R_c$.

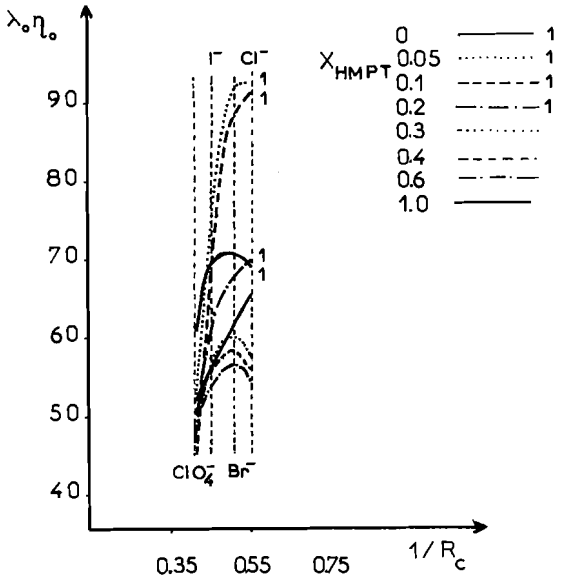

FIG. 5. Variation des produits $\lambda_0\eta_0$ (Ω^{-1} cm^2 equiv.$^{-1}$ cP) des anions en fonction de $1/R_c$.

riche en HMPT, plus la courbe $\lambda_0\eta_0 = f(1/R_c)$ s'aplatit.

On peut d'après ces constatations considérer que l'ion est moins freiné dans les mélanges riches en eau que dans l'eau ou les autres mélanges eau–HMPT. On peut concevoir que cet excès des mobilités des ions dans ces mélanges par rapport à l'eau serait dû à une diminution des interactions diélectriques ion–solvant par suite des propriétés physiques particulières des mélanges dans ce domaine. On a vu en effet que ces milieux étaient plus structurés que l'eau par suite d'interactions dipole–dipole importantes entre la molécule d'eau et la molécule de HMPT (8–10). L'on peut donc peut-être envisager que les forces de friction diélectrique qui s'exercent entre les molécules de solvant et l'ion seraient plus faibles que si les molécules de solvant n'interagissaient pas. Dans les milieux riches en HMPT, le ralentissement plus important des ions peut provenir d'une augmentation des forces de freinage aussi bien hydrodynamique que diélectrique étant donné la polarité du HMPT et l'encombrement stérique de sa molécule.

L'analyse des courbes $\lambda_0\eta_0 = f(1/R_c)$ montre que les ions Cs^+, Rb^+, K^+ situés aux environs du maximum, c'est-à-dire à la limite des zones de prédominance, subissent l'influence plus ou moins importante des forces de friction hydrodynamique ou diélectrique selon le mélange.

Dans les mélanges de fraction molaire $X_{HMPT} = 0.05$, 0.1 et 0.2, le plus gros cation alcalin Cs^+, de par sa position, semble obéir plutôt à la loi de Stokes. Il subirait davantage l'influence de la viscosité que dans les autres milieux. Dans les milieux riches en HMPT, les gros ions alcalins sont situés bien à droite du maximum. Si l'on considère que le HMPT est un composé très polaire, dans les milieux où il sera en excès par rapport à l'eau on peut envisager que les forces de friction diélectrique entre l'ion et le solvant deviennent de plus en plus importantes au fur et à mesure que la teneur en HMPT du milieu augmente. On constate que même l'ion Me_4N^+ dans ces milieux très riches en HMPT est à droite du maximum. Cet ion semble donc subir principalement des interactions diélectriques dans ces milieux.

Dans cette zone intermédiaire où la viscosité et la constante diélectrique influent plus ou moins selon la composition du solvant et selon l'ion se trouvent également situés les anions.

Il convient d'ajouter que les anions ne se placent pas sur la même courbe que les cations, ce qui est contraire à la théorie. Ce résultat n'est pas propre aux mélanges eau–HMPT, Kay et coll. rapportent que cela a été observé dans tous les solvants (44). Wolynes (49) a récemment noté que seule une théorie moléculaire pourrait tenir compte de l'influence de la charge de l'ion. Dans les mélanges eau–HMPT étant donnée l'allure des courbes, il semble que dans les mélanges riches en eau ($X_{HMPT} < 0.2$) la viscosité joue un rôle plus important que la constante diélectrique sur le déplacement des anions ClO_4^-, I^-, Br^-. Par contre, dans les mélanges à plus forte teneur en HMPT, les forces de friction diélectrique augmentant, les plus petits anions, Cl^- et Br^- subiraient plus leur influence.

En définitive, la théorie de Zwanzig ne peut donner dans son expression actuelle des informations sur la sphère de solvatation des ions.

Par contre, la distinction entre les forces de freinage hydrodynamique et les forces de freinage de nature diélectrique permet de bien mettre en évidence les différences d'interactions entre les ions et les mélanges selon la nature de ces ions et leur rayon cristallographique et selon les proportions relatives des deux cosolvants. Les contradictions apparentes relevées lors de l'exploitation conventionnelle des résultats peuvent être expliquées si l'on se réfère à la théorie de Zwanzig.

3. Retour sur les méthodes conventionnelles

Nous avons reporté sur la fig. 6 les courbes $\lambda_0 = f(\eta_0)$ des différents ions étudiés. Ces courbes présentent deux parties, la partie supérieure correspondant

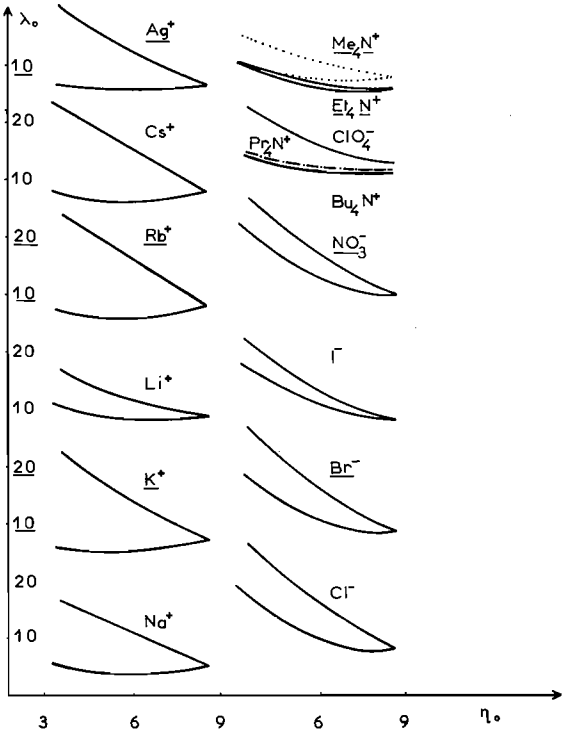

FIG. 6. Courbes $\lambda = f(\eta)$ de différents ions.

aux milieux riches en eau. Pour les gros cations ammoniums quaternaires, l'angle des deux parties des courbes est nul ce qui conduit à conclure que la viscosité est le facteur prédominant. C'est bien ce que l'on retrouve avec la théorie de Zwanzig, mais ici sans faire l'hypothèse que les ions ammoniums quaternaires ne sont pas solvatés. Cela est beaucoup plus conforme aux travaux récents où l'on envisage une solvatation de ces ions pour expliquer certaines de leurs propriétés aux interfaces (50, 51). Pour les cations alcalins on constate une croissance de l'angle avec la taille du cation que l'on ne saurait expliquer par une augmentation de la solvatation des gros ions par le HMPT.

En fait, cette croissance est due à une élévation de la branche de courbe relative aux milieux riches en eau. Il semblerait que si l'importance des forces diélectriques est sensiblement la même pour tous ces cations dans les milieux riches en HMPT, elle serait plus faible pour les plus gros cations dans les mélanges riches en eau, c'est bien ce que nous avons vu.

Pour les anions, plus l'anion est gros et plus l'angle est petit et c'est la courbe relative aux milieux riches en HMPT qui varie le plus.

Les gros anions ClO_4^- et I^-, plus proches de la zone où la viscosité a un effet prédominant sur le déplacement des ions, sembleraient influencés davantage par ce facteur que les petits anions Br^-, Cl^-. Par contre, ces derniers ions subiraient en plus un effet supplémentaire dû aux forces de friction diélectrique. Ces forces de freinage supplémentaires pourraient expliquer que la mobilité des plus petits anions dans les mélanges riches en HMPT soit inférieure à celle qu'ils possèdent dans les milieux plus riches en eau.

Ainsi la théorie de Zwanzig permet semble-t-il d'apporter une explication simple aux problèmes que nous posaient l'interprétation des courbes $\lambda_0 = f(\eta_0)$.

Il peut être également intéressant d'étudier l'évolution du produit de Walden en fonction de la fraction molaire en HMPT en tenant compte de l'analyse des résultats selon la théorie de Zwanzig.

Pour les cations alcalins et les petits anions au voisinage de $X_{HMPT} = 0.2$, les courbes $\lambda_0\eta_0 = f(X_{HMPT})$ présentent un maximum comme c'est le cas dans tous les autres mélanges eau–solvant (fig. 7).

Il semble qu'il ne soit pas indispensable d'invoquer une désolvatation spéciale des ions dans le domaine du voisinage du maximum du produit de Walden ni une destructuration du milieu. En effet, dans la zone riche en eau, nous avons envisagé une diminution des interactions diélectriques entre l'ion et le solvant. Cette baisse des forces de friction diélectrique vis-à-vis des petits ions pourrait par conséquence entraîner une croissance de leur mobilité, celle-ci dépendant en effet beaucoup de ces forces. Vers les milieux plus riches en HMPT, l'addition de ce composé induirait un effet inverse par suite de la polarité élevée du HMPT.

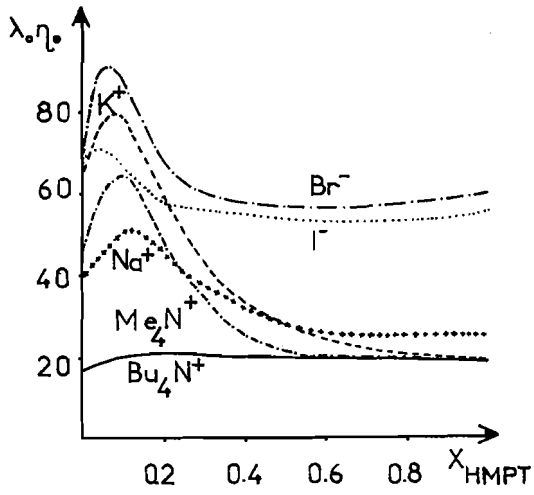

FIG. 7. Variation de $\lambda_0\eta_0$ (Ω^{-1} cm^2 equiv.$^{-1}$ cP) de quelques ions en fonction de X_{HMPT}.

Pour les anions ClO_4^-, I^- et le cation Bu_4N^+, l'absence de maximum marqué des courbes $\lambda_0\eta_0 = f(X_{HMPT})$ est en accord avec le fait que le déplacement de ces ions dépendrait davantage des forces hydrodynamiques et dans ce cas la théorie de Zwanzig prévoit aussi une invariance du produit de Walden.

Conclusion

Il ressort de notre travail que les mesures de mobilités ioniques effectuées dans les mélanges eau–HMPT ne permettent pas d'élucider les problèmes de la solvatation des ions mais que l'application de la théorie de Zwanzig permet de rendre compte de la répartition des influences de la viscosité et de la constante diélectrique d'un solvant sur ces mobilités.

De nombreux auteurs et récemment Kay et coll. (44) considèrent que les méthodes conductométriques ne peuvent apporter des informations sur la solvatation que par la détermination des constantes de dissociation des sels. Il n'est pas toujours possible d'atteindre ces constantes par des mesures de conductivité, d'autres méthodes électrochimiques peuvent être utilisées (40), nous en rendrons compte dans un prochain mémoire. Mais il convient bien de relever que les mesures de mobilités ioniques sont des données cinétiques alors que les constantes thermodynamiques sont déterminées à l'équilibre. Une corrélation des résultats ne peut être envisagée de façon systématique.

Studies on the adsorption and the association of cytidine sulphate at the dropping mercury electrode with phase-sensitive ac-polarography

YASSEIN M. TEMERK

Chemistry Department, Faculty of Science, Assiut University, Assiut, Egypt

Received June 5, 1978

YASSEIN M. TEMERK. Can. J. Chem. 57, 1136 (1979).

The adsorption and association of cytidine sulphate have been studied by using phase-sensitive ac-polarography in acidic buffer solution (pH 3.24) at the dropping mercury electrode. At low bulk concentrations, adsorbed molecules of cytidine sulphate at maximal adsorption potential (−0.7 V) are orientated in 'dilute' adsorption layer planar to the electrode surface where the interaction of π-electrons with interface favours adsorption. At bulk concentrations above a threshold value (6.6×10^{-3} *M*), the stacking interactions between vertically oriented molecules lead to association and formation of a compact layer; and a pit is observed. The concentration dependence of the ac-capacity current at a maximal adsorption potential (−0.7 V) shows a two-step Frumkin isotherm due to association of the adsorbed molecules. The adsorption parameters are computed and discussed.

YASSEIN M. TEMERK. Can. J. Chem. 57, 1136 (1979).

On a étudié l'adsorbtion et l'association du sulfate de cytidine en faisant appel à la polarographie-ca sensible aux phases, en solution acide tamponnée à un pH de 3.24 au niveau de l'électrode à goutte de mercure. A des concentrations globales faibles, les molécules de sulfate de cytidine adsorbées, au potentiel d'adsorbtion maximal (−0.7 V), sont orientées dans des couches d'adsorbtion "diluées" qui sont dans le plan de la surface de l'électrode où l'interaction des électrons π avec l'interface favorise l'adsorbtion. A des concentrations globales supérieures à une valeur de seuil (6.6×10^{-3} *M*), les interactions d'entassement entre les molécules orientées verticalement conduisent à une association et à la formation d'une couche compacte; on observe un creux. L'influence de la concentration sur le courant de capacité ca à un potentiel d'adsorbtion maximal (−0.7 V) suggère l'existence d'une isotherme de Frumkin en deux étapes qui est due aux molécules adsorbées. On a évalué les paramètres d'adsorbtion et on les discute.

[Traduit par le journal]

Introduction

The nucleic acids are substances of paramount biological and physiological significance. In the living cell, nucleic acids come into contact with various types of boundaries such as the surface of ribosomes and nuclear membranes. Interactions of nucleic acid with charge biological interfaces involve several specific processes with adsorption being the initial stage (1). Since both the charged interfaces found in biological systems, such as cell surfaces, and nucleic acid are very complex macromolecular assemblies (2, 3), it seems prudent to study the adsorption and interfacial orientations of the bases occurring in nucleic acids and derivatives of analogous structure. The surface of a cell has been compared to a liquid–solid interface like an electrode (4).

The adsorption properties of some bases, nucleosides and mononucleotides, present in the nucleic acid have been studied at the mercury electrode (5–17). Previous investigations have been made by Vetterl and co-workers (5–9) on pyrimidine and purine bases and nucleotides and by Elving and co-workers (10–13) on adenine and cytosine mono- and oligonucleotides using measurement of the changes of the double layer capacity with the impedance bridge or by means of total ac-polarography. Recently Nürnberg and co-workers (14–16) and Kinoshita *et al.* (17) have determined the adsorption parameters of cytosine, adenine, and deoxyadenine mononucleotides by out-of-phase ac-polarography and single sweep voltametry.

In the present paper the adsorption stages and the association of cytidine sulphate at charged interfaces have been investigated by using phase-sensitive ac-polarography. This investigation is focussed on the interfacial behaviour of adsorbed molecules of cytidine sulphate when the surface is covered by a rather 'dilute' coverage in contrast to the properties of the film stage resulting at higher bulk concentrations. No work on this salt of cytidine from the present standpoint has been published.

Experimental

(a) Chemicals and Solutions

Cytidine sulphate was a commercial sample from Serva, Heidelberg, FRG. A McIlvaine buffer brought to constant ionic strength of 0.5 *M* by addition of KCl was used as a sup-

0008-4042/79/101136-05$01.00/0

FIG. 1. porting electrolyte. The pH was measured with an Orion digital pH meter, Model 701. All chemicals were reagent grade, KCl was Merck "Suprapur". Triply distilled water was used for preparing all solutions. The cytidine sulphate content of the polarographed sample was determined with a Unicam SP 800 Spectrophotometer at 279 nm.

(b) Apparatus and Method

The ac-polarographic measurements were carried out with a PAR Analyzer, Model 170, in a thermostated Metrohm cell with a three electrode system. Phase-sensitive ac-polarograms corresponding to the out-of-phase component of the total ac response were recorded at 90°, amplitude 5 mV (peak-to-peak), scan rate of dc ramp 2 mV s^{-1}, and a fixed medium frequency of 330 Hz.

The electrocapillary maximum potential was measured with a streaming type capillary electrometer similar to that used originally by Grahame (18).

The dropping mercury electrode used had the following characteristics: mercury flow rate $m = 0.229$ mg s^{-1}, natural drop time $t = 22.2$ s at open circuit in 1 *M* KCl and at a height of the mercury reservoir $h = 82.5$ cm. The drop time was controlled by mechanical detachment of the drop. The reference electrode was an Ingold saturated calomel electrode, and a platinum coil served as auxiliary electrode. All measurements were performed at 5°C.

Results and Discussion

Phase-sensitive ac-polarograms of cytidine sulphate in acidic buffer solution (pH 3.24) at the dropping mercury electrode are shown in Fig. 1. The recorded out-of-phase ac-component (90° phase angle) reflects, due to its strict proportionality to the differential double layer capacity (19), in potential ranges where no faradaic response occurs.

For relatively low bulk concentrations of cytidine sulphate (4 × 10^{-5} *M* – 4 × 10^{-3} *M*), the ac-polarograms indicate a progressive decrease of the capacitive ac signal around electrocapillary zero charge E_{ecm} (−0.54 V (sce) for the supporting electrolyte), corresponding to progressive coverage of the electrode surface by the 'dilute' adsorption layer. However, at cytidine sulphate concentrations at or above the threshold value (6.6 × 10^{-3} *M*), a sudden sharp decrease in an ac-capacity current is observed at a maximal adsorption potential .−0.7 V giving a very sharply defined pit. With increasing bulk concentration the pit grows in depth up to a saturation value and also in extension with respect to more positive and more negative potentials. The conclusions of Vetterl and co-workers (5–9) and Nürnberg and co-workers (14–16) suggest that the pit reflects the association of the oriented molecules on the electrode surface by intermolecular attraction forces and

formation of a compact layer. The broad peak following at more negative potentials (−1.1 V) is caused by a re-orientation of the adsorbed cytidine sulphate. This ac-peak which is also observed with cytidine (16), adenine mono-nucleotides (14, 15), denatured (20) and native DNA and related biosynthetic polynucleotides (21), is due to a structural rearrangement of the adsorbed species. It was established that in DNA this peak is specifically connected with a rearrangement of cytosine and adenine moieties of the adsorbed biopolymer. Closer inspection of this peak shows that the height of the peak measured (Δi_{ac}) varies linearly with frequency (up to 420 Hz) of the superimposed alternating voltage and presents a constant phase angle of 90°. These characteristics correspond to a peak of a nonfaradaic nature and the phenomenon is purely capacitive. After the re-orientation peak at more negative potential (around −1.35 V), an extended minimum capacitance is observed indicating a lateral adsorption of cytidine sulphate on the cathodic area. The rise of the response at more negative potentials (−1.4 V) is caused by a faradaic response due to cytidine sulphate reduction in an adsorbed state.

Further quantitative studies on the adsorption and the association of cytidine sulphate could be elucidated by plotting Δi_{ac}, the decrease of the capacitive ac-current with respect to the i_{ac} value of the blank supporting electrolyte for a given bulk concentration, as a function of bulk concentration of cytidine sulphate (C). The plot of Δi_{ac} vs. C at the maximal adsorption potential −0.7 V indicates a two-step isotherm (curve *a*, Fig. 2), corresponding to two adsorption stages of cytidine sulphate on the electrode surface. The first stage, which gives rise to the inflexion point at bulk concentration 2.0×10^{-4} M, reflects the 'dilute' adsorption layer for relative low bulk concentrations of cytidine sulphate. Above the threshold concentration value 6.6×10^{-3} M, one obtains the second stage, which is due to strong lateral interactions and high interaction coefficients between the adsorbed molecules giving rise to a compact layer of the adsorbed cytidine sulphate on the electrode surface. It is concluded that at maximal adsorption potential (−0.7 V) cytidine sulphate is oriented in a dilute adsorption layer planar to the electrode surface where the interaction of π-electron with the interface favours the adsorption. With the increase of the bulk concentration above the threshold value, the stacking interactions between vertically oriented molecules lead to association and formation of a compact layer in the pit region. The ratio at full coverage for the first and second step of isotherm indicates that the number of adsorbed molecules for the dilute layer is increased by a factor

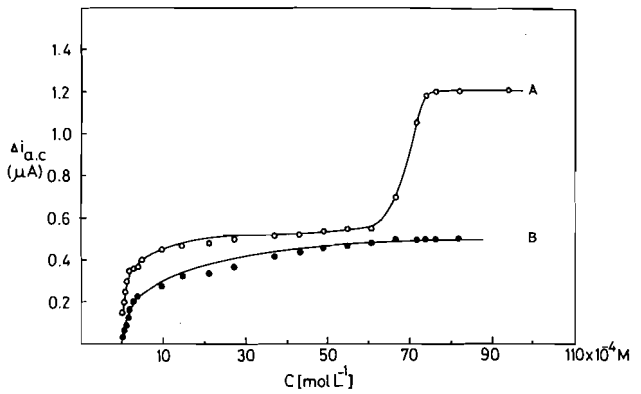

FIG. 2. Dependence of the capacity current decrease Δi_{ac} on the bulk concentration of cytidine sulphate, 0.5 McIlvaine buffer, pH 3.24, curve (*a*), adsorption potential −0.7 V; curve (*b*), adsorption potential −1.35 V, other conditions as in Fig. 1.

of 2.4 for the compact layer. This is in good agreement with the conclusions of Parsons (22) and Damaskin *et al.* (23) that the number of water molecules displaced from the surface by adsorption of a hydrophobic species is doubled for a change in adsorption orientation from the planar to the vertical position.

The concentration dependence of the ac-capacity current Δi_{ac} has the form of a one-step isotherm for the extended cathodic capacitance minimum at −1.35 V (curve *b*, Fig. 2). This indicates that the association of the adsorbed molecules of cytidine sulphate takes place only at potentials more positive than the re-orientation peak where the pit occurs. On the other hand, at potentials more negative than −1.2 V the adsorbed molecules of cytidine sulphate are more accessible to reduction via the cytosine moiety than to association on the electrode surface.

The dependence of the ac-capacity current per unit area of the dropping mercury electrode on the drop time (t) is of considerable interest. The curves are obtained at a maximal adsorption potential −0.7 V (Fig. 3). The horizontal curves *1* and *2* indicate the independence of ac-capacity current on the drop time for rather low bulk concentrations. This reflects the adsorption equilibrium of cytidine sulphate on the electrode surface for dilute adsorption layer. However, for concentrations larger than the threshold value where the pit occurs on ac-polarograms, a decrease of the ac-capacity current is observed (curve *3*, Fig. 3), indicating a slow adsorption process due to re-arrangement of the surface layer from a dilute state to a compact state. At very large bulk concentrations a compact layer is already formed and the adsorption equilibrium is attained more rapidly

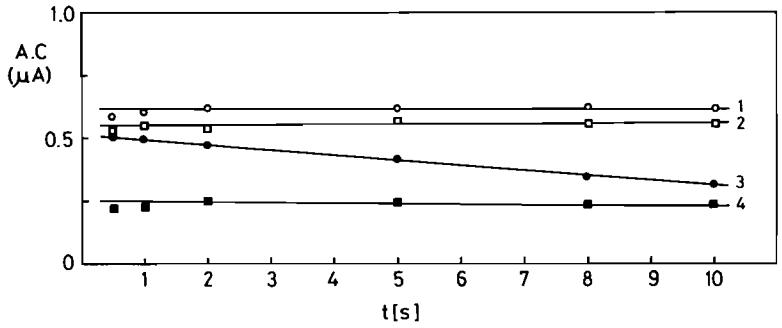

FIG. 3. Time dependence of the out-of-phase component of ac-current. pH 3.24, adsorption potential $E_s = -0.7$ V, concentration of cytidine sulphate: (*1*), 4.0×10^{-5} *M*; (*2*), 3.5×10^{-4} *M*; (*3*), 7.0×10^{-3} *M*; (*4*), 2.2×10^{-2} *M* cytidine sulphate, other conditions as in Fig. 1.

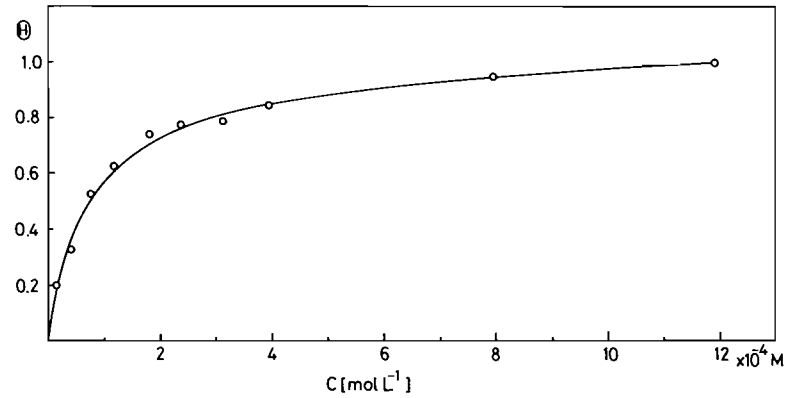

FIG. 4. Dependence of surface coverage Θ on the bulk concentration of cytidine sulphate for dilute layer, pH 3.24, adsorption potential $E_s = -0.7$ V, Θ is calculated from the results of out-of-phase ac-polarography. Other conditions as in Fig. 1.

(curve *4*, Fig. 3). A similar phenomenon has been observed previously for the formation of a compact layer of cytidine at the HDME (16). The result shown in Fig. 3 indicates that the ac-readings corresponding to 'dilute' adsorption layer are well equilibrium values. Accordingly, the following adsorption parameters are computed for the 'dilute' adsorption layer.

In order to calculate the adsorption parameters for the dilute adsorption layer at maximal adsorption −0.7 V, the equilibrium values of the ac-capacity current at a given bulk concentration were measured and the degree of coverage Θ was calculated using the relation

$$[1] \quad \Theta = (C_0 - C)/(C_0 - C_m) = \Delta i_{ac}/(\Delta i_{ac})_m$$

where *C*'s are the differential capacities in the supporting electrolyte (C_0), at a given bulk concentration of cytidine sulphate (C), and at bulk concentrations corresponding to full coverage (C_m), Δi_{ac} is the decrease of the capacitive ac-current (with respect to the i_{ac}-value of the blank supporting electrolyte) for a given bulk concentration and $(\Delta i_{ac})_m$ is the maximal decrease corresponding to full coverage. The concentration dependence of the surface coverage for the 'dilute' adsorption layer is shown in Fig. 4. It has been found that the experimental data fit well a Frumkin adsorption isotherm given by eq. [2].

$$[2] \quad BC = [\Theta/(1 - \Theta)] \exp(-2a\Theta)$$

where Θ is the degree of coverage, a the interaction coefficient, b the adsorption coefficient, and C the bulk concentration of cytidine sulphate.

The interaction coefficient a was determined from the slope of the logarithmic plot of the Frumkin isotherm and the adsorption coefficient B from the values at half coverage (Θ = 0.5). The free energy of adsorption ($-\Delta\bar{G}^0$) was then calculated from the adsorption coefficient B (Θ = 0.5) according to eq. [3].

$$[3] \quad B = \frac{1}{55.5} \exp\left(\frac{-\Delta\bar{G}^0}{RT}\right)$$

The calculated values of the adsorption parameters of cytidine sulphate for the 'dilute' adsorption layer at pH 3.24 are: adsorption coefficient, 8.7 ×

10^3 L/mol; interaction coefficient, 0.48; free energy of adsorption, 7.27 kcal/mol; bulk concentration at half coverage ($C_{\Theta=0.5}$), 7×10^{-5} M; pit potential, -0.70 V, orientation potential, -1.1 V. The moderately high positive interaction coefficient a for the 'dilute' layer indicates moderate lateral attractive interaction of adsorbed molecules. The rather large adsorption coefficient of cytidine sulphate is quite common behaviour for heterocyclic compounds as has been shown previously (24) for pyridine derivatives. The low value of adsorption energy $-\Delta\bar{G}^0$ indicates that the deviation from adsorption equilibrium is minimized and that equilibrium is established at relatively low bulk concentration of cytidine sulphate.

Characterization of autohydrolysis aspen (*P. tremuloides*) lignins. Part 1. Composition and molecular weight distribution of extracted autohydrolysis lignin

MIRANDA G. S. CHUA AND MORRIS WAYMAN

Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A4

Received November 2, 1978

MIRANDA G. S. CHUA and MORRIS WAYMAN. Can. J. Chem. 57, 1141 (1979).

Extractive-free aspen wood meal was subjected to autohydrolysis at 195°C for 5 min to 2 h, and the lignin extracted with 90% dioxane. Extracted autohydrolysis lignin was found to be higher in carbon but lower in hydrogen and oxygen content than aspen milled wood lignin. The methoxyl content was also lower than the reference lignin. These differences have been attributed to condensation and incorporation into the lignin of non-lignin components. A lignin extractability curve with a maximum delignification at autohydrolysis time of 30–40 min was found. From molecular weight distribution studies the ratio of high molecular weight to low molecular weight materials varied for the different extracted lignins and reached a maximum at autohydrolysis time of 40 min. A mechanism of depolymerization/repolymerization of the lignin via carbonium ions has been proposed. *p*-Hydroxybenzoic acid is postulated as contributing to the extractability of aspen lignin by acting as a blocking agent.

MIRANDA G. S. CHUA et MORRIS WAYMAN. Can. J. Chem. 57, 1141 (1979).

On a soumis de la sciure de bois de tremble (ne contenant plus de produits pouvant être extraits) à une autohydrolyse à 195°C pour des temps allant de 5 min à 2 h puis on en a extrait la lignine par du dioxanne à 90%. On a trouvé que la lignine extraite de l'autohydrolyse contient plus de carbone et moins d'hydrogène et d'oxygène que la lignine provenant de bois de tremble broyé. La quantité de méthoxyle qui y est contenue est aussi plus faible que celle contenue dans la lignine de référence. On a attribué ces différences à la condensation et à l'incorporation dans la lignine de composants qui ne sont pas des lignines. On a déterminé une courbe permettant d'évaluer la facilité d'extraction de la lignine; elle présente un maximum de délignification à des temps d'autohydrolyse de 30 à 40 min. En se basant sur des études de distribution de masses moléculaires, on a déterminé que le rapport des produits de masses moléculaires élevées/produits de masses moléculaires plus faibles varie suivant les différentes lignines extraites et qu'il atteint un maximum à un temps d'autohydrolyse de 40 min. On propose un mécanisme de dépolymérisation/repolymérisation de la lignine par l'intermédiaire de carbocations. On croit que l'acide *p*-hydroxybenzoïque facilite l'extraction de la lignine de tremble en agissant comme agent bloqueur.

Introduction

Autohydrolysis (1, 2) of wood with water or steam at elevated temperature and pressure is catalysed by the organic acids formed from the wood components during the hydrolysis. The chemical changes which take place during autohydrolysis in the three main constituents of wood (hemicelluloses, cellulose, and lignin) are very much dependent on the temperature and the time at temperature. The hemicelluloses are hydrolysed to soluble sugars by the organic acids, mainly acetic acid derived from the acetylated polysaccharides present in wood. However, under more drastic conditions secondary reactions occur which result in the formation of furfural, hydroxymethyl furfural, and their precursors by the dehydration of pentoses and hexoses (3–5). The reactive precursor besides undergoing self-polymerization can participate in condensation reactions with lignin (refs. 5–10, ref. 11, pp. 287–295, 395–399).

Lignin degradation and modification during autohydrolysis has been reported by various investigators. In their studies of prehydrolysis kraft pulping, Traynard and Eymery (12) and Richter (13, 14) observed that the treatment of wood with water at high temperatures in prehydrolysis affected the lignin and its subsequent behaviour in kraft pulping. Work in this laboratory has shown that the solubility of lignin in 90% dioxane after autohydrolysis is a maximum over a narrow time range at each temperature between 165°C and 215°C. Goldschmid (15) and Stanek (16) found and identified monomeric lignin degradation products present in autohydrolysis liquor. Modification of the lignin remaining in the wood after autohydrolysis is indicated by its subsequent extractability by various organic solvents (12, 17) and dilute alkali as was found in this laboratory. It has also been observed that softwood lignins are much more affected by prehydrolysis treatment than hardwood lignins (14).

Studies on the steaming of wood have centred

0008-4042/79/101141-09$01.00/0

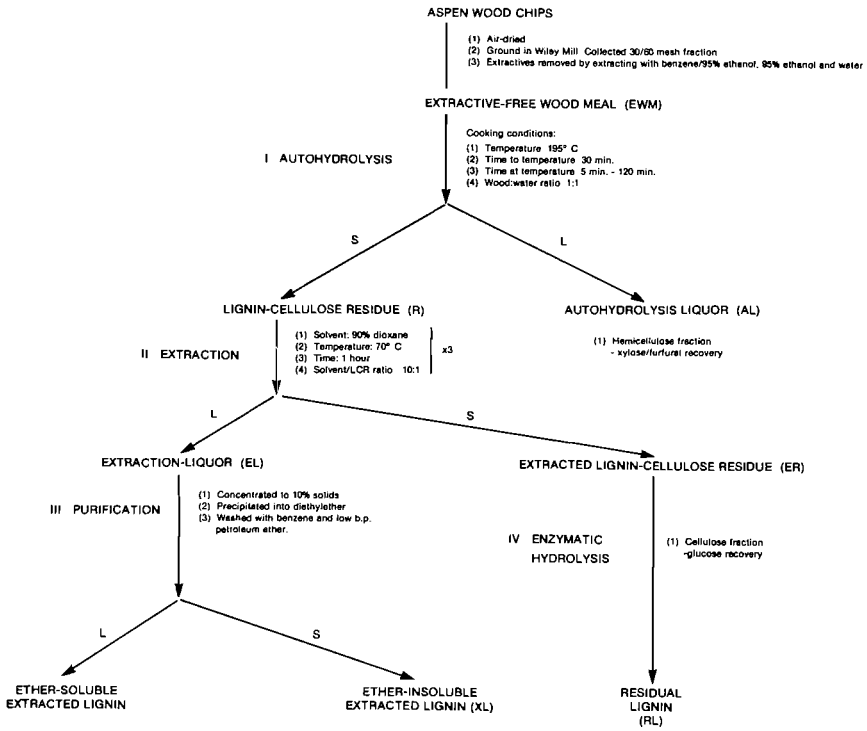

FIG. 1. Flow-chart of overall process involving the following four stages: I, autohydrolysis; II, extraction; III, purification; IV, enzymatic hydrolysis.

mainly on the hemicellulose fraction, for example, in the production of furfural (ref. 11, pp. 272–331) and on the cellulose fraction, as in the case of prehydrolysis pulping (14) and lately as a possible pretreatment before enzyme saccharification of the cellulose in wood (18). Thus far there has been very little comprehensive work with regard to the effect of steaming on the lignin component.

The purpose of this present work was to characterize the lignin obtained on autohydrolysis with a view to elucidating the mechanism involved in lignin depolymerization and repolymerization. In addition, it is hoped that such characterization would further the utilization of the autohydrolysis lignin which represents a potential source of renewable phenolic compounds, as well as medically interesting compounds (46).

The overall process used to obtain the extracted autohydrolysis lignin (XL) and the residual autohydrolysis lignin (RL) involved the four stages of autohydrolysis, extraction, purification, and enzyme hydrolysis as outlined in Fig. 1. The present paper deals with the chemical composition and the physical characterization of the extracted autohydrolysis lignin.

Results

Extractives

The percentage of extractives in aspen wood meal on extracting with benzene/95% ethanol (2:1), 95% ethanol, and water was 2.7% based on dry aspen wood meal. It was necessary to work with extractive-free wood meal (EWM) to avoid difficulties in interpreting results as lignans and polyphenolic extractives have similar chemical properties to lignin.

Autohydrolysis (Fig. 1)

The pH of the autohydrolysis liquors from the different cooking times at 195°C was between 3.2–3.4, and xylose contents ranged from 0.3–6.2% based on EWM for the longest to the shortest cook, representing less than 40% of the xylose potentially obtainable from aspen. This indicated that 195°C may not be the optimum temperature for hemicellulose recovery since the bulk of the hemicellulose is degraded. The lignocellulosic residue (R) yields were between 69 and 73%.

Extraction of R with 90% dioxane resulted in isolating the extractable lignin (XL) portion leaving behind the insoluble lignin fraction termed residual lignin (RL). Yields of extracted lignocellulosic resi-

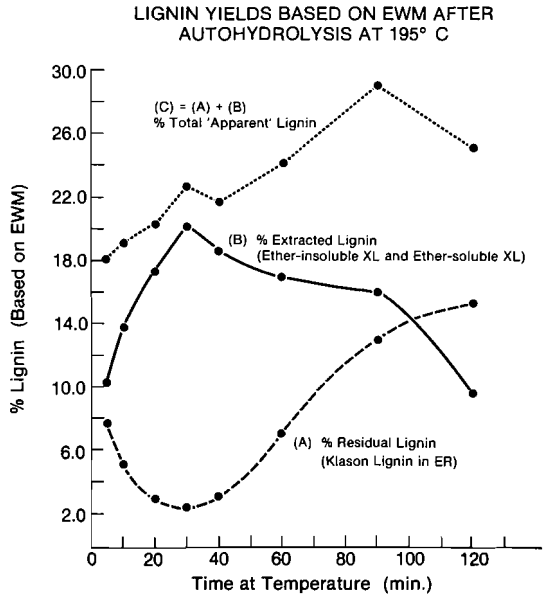

FIG. 2. Lignin yields based on EWM after autohydrolysis at 195°C.

due (ER) were between 50–61% based on EWM, and pH of the extraction liquor varied from 4.0–5.2.

A characteristic delignification trend as indicated by curve *A* in Fig. 2[1] was obtained, with maximum lignin extactability represented by minimum Klason lignin left in ER in the 30-min cook. Curve *A* suggests that during autohydrolysis two types of reactions are occurring. Initially the faster reaction, depolymerization of the native lignin by acidic hydrolysis, predominates, accounting for the solubility of the lignin in the solvent. However, as heating continues, condensation/repolymerization reactions take over, resulting in increasing amounts of insoluble residual lignin.

Curve *B* in Fig. 2 represents the total lignin recovered after extraction and purification by precipitation into ether. It represents both the ether-soluble and ether-insoluble (the bulk of the material) extracted lignin. Curve *C* is the sum of curves *A* and *B* and has been termed total 'apparent' lignin because it contains another component which is not lignin. This is substantiated by the fact that the Klason lignin content in the original aspen wood meal is 17.6%, but as shown in Fig. 2 the amount of 'apparent' lignin ranges from 18.1% upwards to 29.0%. The data support Klemola's (3) postulate that reactive hemicellulose degradation products, such as furfural and its precursors, can react with the lignin during autohydrolysis, thereby accounting for the apparent increase in lignin content. This also explains the low yield of xylose obtained in the autohydrolysis liquor mentioned earlier.

Elemental Analyses of Extracted Autohydrolysis Lignin (XL) (Table 1)

Using aspen milled wood lignin (MWL) purified according to the method of Lundquist *et al.* (19) as the reference lignin, two trends were observed. First the C-content of the extracted lignins is higher than the reference lignin whereas the H and O contents are consistently lower. These changes in C, H, and O can result from (*a*) condensation reactions which involve the elimination of water; and/or (*b*) they can also be associated with incorporation into the lignin of entities having higher C to H/O ratios during autohydrolysis; and/or (*c*) the initial preferential removal of syringyl to guaiacyl units at the shorter autohydrolysis times.

The second significant observation is that the methoxyl content per C_9 unit decreases gradually with increasing cooking time. This could be attributed to demethoxylation of the lignin during autohydrolysis, as is indicated by the presence of methanol (0.5–0.6% based on EWM or 2.5–3.0% based on lignin) found in the autohydrolysis liquor (20). Also, Klemola identified six catechol derivatives among the low-molecular degradation products, suggesting demethylation during the course of steam hydrolysis as catechols have not been identified in wood protolignins (21). Another explanation would point again to the inclusion of so-called non-lignin components, in all probability carbohydrate degradation products, which would also contribute to the decreasing percentage of methoxyl content observed. Pepper and Siddiqueullah (22) in their work with acidolysis lignins encountered similar C, H, O changes and lowering of methoxyl content with increasing acidolysis time. They attributed the differences to either non-homogeneity of protolignin or to inclusions of non-lignin (carbohydrate) residues. Finally, a variation of the proportion of syringyl to guaiacyl units in the extracted lignins would again account for the observed methoxyl content trend. All this implies that the extracted lignins are modified lignins, different from milled wood lignin, which has been widely accepted as representative of protolignin.

The rate of change in C% and OCH_3% in the first 30–40 min of autohydrolysis is 7–8 times greater than for the next 80 min. It is interesting to note that the transition point is the same as in delignification (Fig. 2) and molecular weight distribution (Fig. 4).

[1]Data in support of Fig. 2 are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

*Aspen milled wood lignin purified according to the method by Lundquist (19) was prepared by Mr. J. H. Lora.

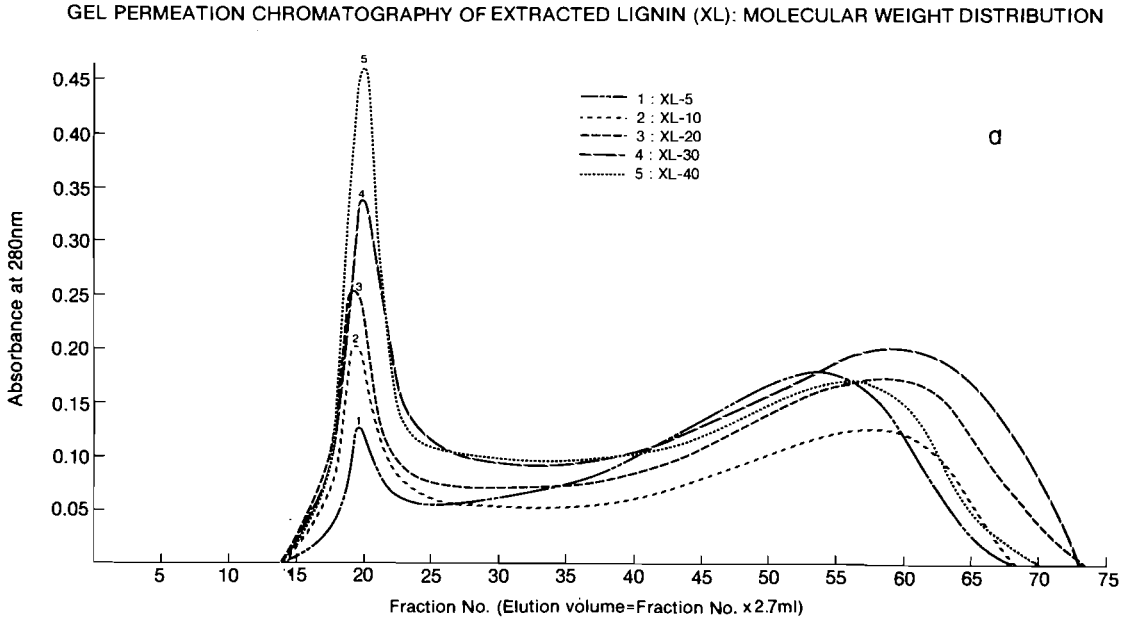
Molecular Weight Distribution (MD) of XL by Gel Permeation Chromatography (Fig. 3)

Gel permeation chromatography has proved to be a fast and effective method of fractionating polymers according to molecular size. In applying gel permeation chromatography to the study of MD of extracted lignins, the analytical system used by Obiaga and Wayman (23, 24) employing Sephadex G-100 (a dextran gel) swollen in dimethyl sulphoxide (DMSO) was again used. DMSO, a good lignin solvent, swells Sephadex G-100 to a greater extent than water (25), and adsorption effects of the lignin on the gel are absent. The hydrodynamic volume of lignin in DMSO is different from globular protein or dextran in aqueous buffer, and conventional calibration standards are of little use. To calibrate the column, lignin samples of known molecular weight have been used. However, in using one column of a single pore size for fractionating a polydisperse polymer like lignin, molecular weights and polydispersities obtained from the chromatograms are only approximate, because separation is incomplete. In spite of this inherent limitation, substantial information can be derived by comparing the XL chromatograms.

A prominent and common feature to all the XL chromatograms shown in Fig. 3 is the distinct dual-peaked character of the elution pattern, which clearly indicates that the XL are highly polydisperse. Broadly speaking the chromatograms can be divided into two fractions, namely, a high molecular weight at fraction number 20 and a low molecular weight portion at fraction number between 50–65, termed HML and LML respectively. The different XL have different amounts of HML and LML materials. Especially interesting is the observed increase in HML material from autohydrolysis time of 5 min to 40 min, with subsequent decrease of the peak thereafter.

It was found that although the quantity of XL injected was the same for all samples, the areas obtained for the chromatograms were slightly different. This can probably be attributed to different absorptivities for the different samples and for individual fractions. The absorptivities increased from 17.5 L g^{-1} cm^{-1} for XL-5 to 24.9 L g^{-1} cm^{-1} for XL-120, compared to 13.6 L g^{-1} cm^{-1} for MWL. The absorptivities for HML and LML were 16.9 and 23.8 L g^{-1} cm^{-1}, respectively. Due to this, analyses have been made based on the comparison of areas and on ratios of HML:LML which will enable one to follow the solubilization, degradation, and repolymerization processes taking place during autohydrolysis. Figure 4 illustrates the increase of the HML to LML materials in the extracted lignin with autohydrolysis time, reaching a maximum HML:LML ratio of 0.6 at 30–40 min, which is also the region of maximum lignin extractability. In order to compare the amounts of HML to LML generated based on original wood, the areas under the HML and LML peaks were multiplied by factors proportional to the yield of purified extracted lignin at each autohydrolysis time. The soluble HML material was found to increase, again reaching a maximum at the region of maximum delignification, followed by a decrease corresponding to an increase in the amount of insoluble residual lignin. This suggests that soluble HML is recondensing to form insoluble lignin. The LML fraction has two maxima, one at autohydrolysis time of 30 min and the other at 90 min. The first maximum is related to the initial extraction of low molecular weight material and the second, at longer autohydrolysis time, to degradation of HML under the more drastic conditions.

Acidolysis lignins of known molecular weights and polydispersities were used to calibrate the Sephadex G-100 column as is shown in Fig. 5. However, it was not possible to obtain a complete calibration curve of molecular weight vs. retention volume for the system, because the HML ($\overline{M}_w$ = 196 000) is above the exclusion limit of the gel used. In comparing the



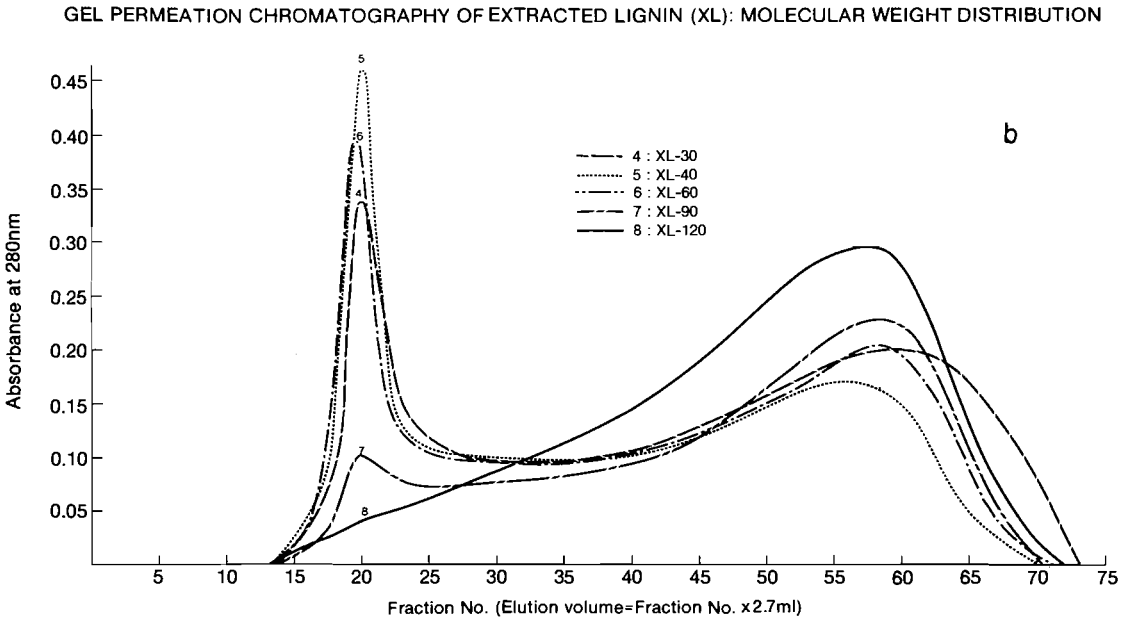


FIG. 3. Gel permeation chromatography of extracted lignin (XL): molecular weight distribution.

chromatograms of MWL and XL-40, it would appear that autohydrolysis resulted in the formation of more HML material. This has been substantiated by work in this laboratory with MWL under autohydrolysis conditions, which showed initial building-up of HML material followed by a decrease.

Table 2 contains the molecular weight determinations and polydispersities for XL's and MWL. The weight average molecular weight, $\overline{M}_w$, was determined for samples XL-40, XL-120, HML, and MWL. Using the $\overline{M}_w$ obtained for XL-40 and XL-120 together with the intrinsic viscosity measurements for all XL, and applying the Mark–Houwink equation, $\overline{M}_w$ was calculated for the other XL. Although reservations with regard to the absolute value of the numbers based on two measurements

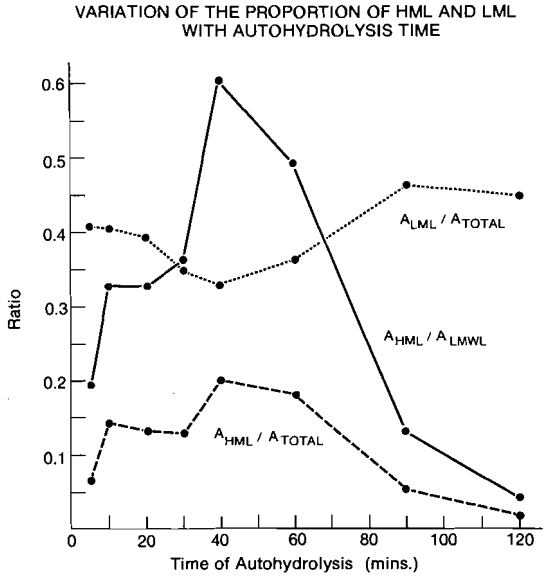

FIG. 4. Variation of the proportion of HML and LML with autohydrolysis time.

and the assumption that the Mark–Houwink relationship applies for XL, the values of $\bar{M}_w$ and the polydispersities so generated do not contradict, but supplement the trends observed for the MWD patterns obtained from gel permeation chromatography studies as shown in Figs. 3 and 5. The $\bar{M}_n$, $\bar{M}_w$ and the polydispersities increase for the first 30–40 min of autohydrolysis and decrease thereafter.

These molecular weight numbers and polydispersities are higher than observed for kraft lignins (24, 26) but more similar to the values obtained for lignosulphonates (27). This is indicative of the difference in mechanisms between alkaline pulping and acid pulping resulting in cleavage of different bonds in lignin and therefore varying molecular weight. Gierer (28) in his review of the reactions of lignin during pulping discussed in detail the mechanisms of alkaline and acid pulping.

It is interesting to note that the HML material has a $\bar{M}_w$ of 196 000. On the other hand, the XL-40 (which has the highest proportion of HML:LML material) has an average $\bar{M}_w$ of only 16 000. This means that the actual number of HML molecules in each of the XL is quite small.

In using the Mark–Houwink equation, $[\eta] = KM^a$, the value of a was found to be about 1.6, whereas alkali lignin and lignosulphonates believed to have spherical conformations had values of 0.1–0.5. In addition, linear and branched polymers like cellulose and xylan had a values of between 0.75 to 1.15 (29). The high value of a obtained suggests that the extracted lignin has a linear rather than a spherical conformation.

Discussion

From MD studies, it has been shown that increasing amounts of soluble HML material are being extracted with increasing autohydrolysis time up to the region of maximum lignin extractability. This phenomenon of successively extracting more higher molecular weight material as the cook proceeds is a common observation for both alkaline and acid delignification processes (30–32) and oxidized lignin (33). However, different interpretations have been placed on such MD patterns from chemically prepared lignin. The presence of a maximum over the time range considered suggests that the depolymerization/repolymerization reactions of lignin during autohydrolysis are taking place via a consecutive series of reactions, with the existence of an intermediate species which can be maximized. Alkaline nitrobenzene oxidation studies have also shown that XL increases in degree of condensation with autohydrolysis time. This implies that the soluble HML, although still extractable, is highly condensed, formed probably from the condensation of low molecular weight depolymerized lignin. This is related to the disappearance of the initial LML peak, which is associated with the appearance of the maximum of the HML peak. It is thus seen that repolymerization of lignin can be regarded as a succession of condensations leading eventually to the formation of insoluble residual lignin. Thus, soluble HML is postulated to be the intermediate species in the formation of insoluble residual lignin from depolymerized lignin. Scheme 1 illustrates the postulated pathway of depolymerization/repolymerization reactions of lignin during autohydrolysis.

As has been established by various authors (34–37), cleavage of lignin bonds under acidic conditions involves the formation of resonance-stabilised carbonium ions. In addition, carbonium ions are also strong electrophiles with the ability to participate in substitution forming carbon–carbon bonds with the aromatic C-1 or C-6 atom. Lignin depolymerization and condensation can be viewed as proceeding via a carbonium ion mechanism resulting in the observed extractability and repolymerization.

In autohydrolysis studies (1), aspen lignin has been found to be the most readily extractable compared with lignin of other hardwoods and softwoods studied. Aspen lignin is almost unique in that it contains large amounts of *p*-hydroxybenzoate groups, up to about 10% by weight (38–40). The ease of extractability of aspen lignin may thus be related to the presence of these *p*-hydroxybenzoate groups. *p*-Hydroxybenzoic acid, from hydrolysis of the *p*-hydroxybenzoate groups, can act as a blocking agent, preventing the self-condensation of lignin carbonium ions to-

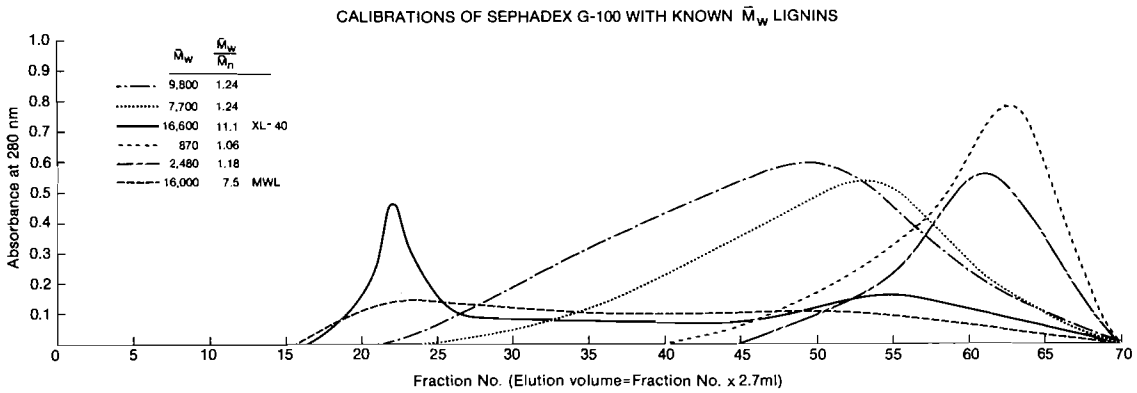

FIG. 5. Calibrations of Sephadex G-100 with known $\overline{M}_w$ lignins.

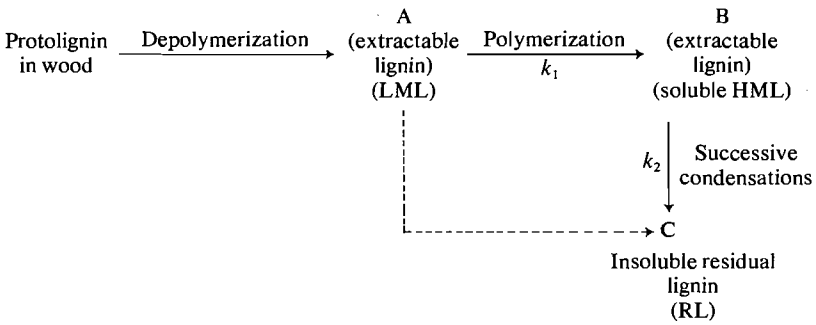
TABLE 2. Intrinsic viscosity η, $\overline{M}_n$, $\overline{M}_w$, and polydispersity of milled wood lignin (MWL) and extracted lignin (XL)

Sample no.	η dL/g (in DMF)	No. average molecular weight $\overline{M}_n$	Weight average molecular weight $\overline{M}_w$	Polydispersity $\overline{M}_w/\overline{M}_n$
MWL	—	2 120	16 000*	7.5
XL-5	0.082	1 320	10 900	8.3
XL-10	0.109	1 370	13 100	9.6
XL-20	0.133	1 480	14 800	10.0
XL-30	0.162	1 560	16 800	10.8
XL-40	0.159	1 490	16 600*	11.1
XL-60	0.124	1 390	14 200	10.2
XL-90	0.072	1 090	10 000	9.2
XL-120	0.050	970	8 000*	8.2

*$\overline{M}_w$ for MWL, HML, XL-40, and XL-120 were determined by Mr. W. Q. Yean on the Beckman Spinco Model E Ultracentrifuge. $\overline{M}_w$ for HML was 196 000. The other $\overline{M}_w$ were calculated from the Mark–Houwink equation $[\eta] = KM^a$, using K and a values derived by solving the simultaneous equations for samples XL-40 and XL-120.



SCHEME 1. Representation of depolymerization/repolymerization reactions of lignin. The soluble HML passes through a maximum. LML = low molecular weight lignin, $\overline{M}_w < 8\,000$; soluble HML = soluble high molecular weight lignin, $\overline{M}_w \sim 196\,000$.

wards the formation of insoluble residual lignin, thereby allowing the lignin to be extractable. Wayman and Lora (2) have shown that during autohydrolysis, some aromatic additives acting as blocking agents are effective in preventing self-condensation to insoluble lignin and enhance the extractability of the lignin.

Experimental

(a) Preparation of Extracted Autohydrolysis Lignin

The wood used in these experiments was aspen. Extractive-free wood meal (EWM) was prepared according to TAPPI standard T12 m-59. Autohydrolysis of 30 g of EWM for each run (with a wood:water ratio 1:1) was carried out in 300 mL pressure vessels equipped with pressure gauge, thermocouple and safety valve. The pressure vessel was heated in a silicone

oil bath maintained at 195°C. Preheating time as indicated by the thermocouple and pressure gauge was 30 min. After heating for a further 5 min to 2 h, the pressure vessel was cooled by immersing in ice–water, the contents removed, washed with boiling water, and filtered. Washing was repeated 3 times to ensure complete removal of hemicellulose and its degradation products.

The lignocellulosic residue (R) was air-dried and batch extracted with 10 times its weight of 90% dioxane at 70°C for 1 h. After three extractions, the residue was thoroughly washed with boiling water, air-dried, and its Klason lignin content determined. This value represented the residual lignin left in the pulp after autohydrolysis. The three extracts, containing the extracted lignin, were combined and concentrated in a Buchi Rotovapor-R vacuum evaporator to approximately 1/10 its original volume. To displace the initial water present in the solvent system, pure dioxane was added and the solution concentrated further until a final solution of approximately 10% lignin in dioxane was obtained.

Purification was carried out by precipitating the above solution dropwise into anhydrous diethyl ether, stirring vigorously. The precipitation was done in stages. To 200 mL of ether 5–6 mL of solution was added, the solution centrifuged at 1500 rpm for 5 min, the supernatant decanted, 200 mL of fresh ether added, and a further 5–6 mL of solution added. The procedure was repeated until all the solution was precipitated. The precipitate was washed twice with fresh ether, twice with pure benzene, and twice with low-boiling petroleum ether. The lignin, in the form of a brown powdery material, was air-dried to remove traces of petroleum ether and stored in a vacuum desiccator. The supernatant ether was collected and vacuum evaporated to recover the low molecular weight lignin components. The yields of both products were determined.

(b) Elemental Analyses, Methoxyl Determination of Extracted Lignin, and % Carbohydrate in the Extracted Lignin

Lignin samples were analysed for C, H, and methoxyl content by Schwarzkopf Microanalytical Laboratory, Inc., New York.

The % carbohydrate in the extracted lignin was determined by measuring the amount of sugar present in the final hydrolysis liquor after Klason analysis. Two methods of sugar analysis were used: (*i*) dinitrosalicyclic acid (41) and (*ii*) phenol – sulphuric acid method (42).

(c) Analytical Gel Permeation Chromatography

The column used for molecular weight distribution (MD) analysis consisted of Sephadex G-100 swollen in dimethyl sulphoxide, packed in a Pharmacia solvent resistant glass column SR 25/45 with two polytetrafluoroethylene (PTFE) flow adaptors attached to the column ends. A Marriotte flask served as solvent reservoir as well as maintaining the elution rate through the column at 18 mL/h by adjusting its height. Sample injection was via a Sarle sample applicator valve assembly with a sample loop of 0.3 mL. The concentration of the sample injected was 3.5 mg/mL. The column was run on upward flow. The column effluent was continuously monitored at 280 nm with an ISCO UA-5 Absorbance Monitor (Instrumentation Specialties Co.) equipped with a micro-flowcell of capacity 10 μL and 5 mm light path length. The fractions were collected in a 2.7 mL siphon which had a manometer electrode assembly which triggered an event marker producing a spike of the chromatogram each time the siphon was filled and the contents dumped into a fraction collector. A complete chromatogram giving the MD pattern was obtained after 11 h.

(d) Preparative Gel Permeation Chromatography

For preparation of narrow molecular weight fractions a Pharmacia K50/100 column with two PTFE flow adaptors, packed with Bio-Gel A 0.5 m 50–100 mesh was used. The Bio-Gel A was obtained pre-swollen in 0.001 *M* Tris-EDTA buffer. The buffer was displaced in stages by 25%, 50%, and finally 75% dioxane. The preparative column was run with 75% dioxane as eluant for convenience of recovery of the lignin after fractionation. The flow and monitoring scheme was essentially the same as for the analytical column, except that the injection was via a Pharmacia SA-5 sample applicator and a 10 mL siphon was used.

Samples of approximately 100–120 mg of XL-40 in 1.5 mL of 75% dioxane were run through the column until sufficient material was collected for the high molecular weight peak (fractions 19–21). Flow rate was maintained at 58 mL/h and total elution time was 7 h. The collected fraction labelled high molecular weight lignin (HML) was concentrated in a vacuum evaporator and recovered as in (*a*) for lignin purification. The sample was used for weight average molecular weight determination.

(e) Beckman Spinco Model E Analytical Equilibrium Ultracentrifuge, $\overline{M}_w$

The weight average molecular weight of samples MWL, XL-40, XL-120, and HML were determined using the short-column sedimentation equilibrium technique on a Beckman Spinco Model E analytical ultracentrifuge. The determinations were carried out by Mr. W. Q. Yean at McGill University, using a reported procedure (43, 44).

(f) Ultraviolet Absorptivity at 280 nm

A Unicam SP 1700 spectrophotometer was used to determine the extinction coefficients of milled wood lignin (MWL) and XL at 280 nm. The samples were dissolved in DMSO and the spectra obtained relative to the solvent.

(g) Determination of Number Average Molecular Weight, M_n and Intrinsic Viscosity, η

The number average molecular weight of MWL and XL were determined using a Hewlett-Packard Model 302B vapor pressure osmometer. Samples in the concentration range 8–60 g/L in dimethyl formamide were run and the average of triplicate determinations at each concentration was taken. The dimethyl formamide was dried over anhydrous sodium sulphate and distilled before use. The instrument was calibrated using benzil (MW 210). An experimental value of 354 for curcumin was obtained giving a 4% error. The working temperature was 80°C and steady state was reached after 6 min. The molar concentration constant for the system was 12.35.

The intrinsic viscosities of the extracted lignin were determined using an automatic recording capillary viscometer (45). Measurements were made in dimethyl formamide at 25°C with solutions of about 0.1 g/dL concentration.

Acknowledgments

The authors wish to thank the National Research Council of Canada for both the award of an NRCC postgraduate scholarship to one of them (M.G.S.C.) and for a research grant which supported this investigation. The authors also wish to thank Mr. J. H. Lora for the sample of milled wood lignin used in this work, and for helpful discussion of the results.

Spin trapping of the $\cdot CO_2^-$ radical in aqueous medium

JOHN R. HARBOUR AND MICHAEL L. HAIR

Xerox Research Centre of Canada Limited, 2480 Dunwin Drive, Mississauga, Ont., Canada L5L 1J9

Received November 6, 1978

JOHN R. HARBOUR and MICHAEL L. HAIR. Can. J. Chem. 57, 1150 (1979).

The $\cdot CO_2^-$ radical has been generated by photolysis of a solution of sodium peroxydisulfate containing sodium formate and by hydrogen abstraction using $TiCl_3$ and H_2O_2 in the presence of sodium formate. In both cases, the inclusion of DMPO resulted in the formation of a spin adduct with $a^N = 15.8$ G, $a_\beta^H = 19.1$ G, and $g = 2.0058$ which is assigned to the $\cdot CO_2^-$ adduct. In addition the DMPO adduct of $SO_4^{-\cdot}$ is presented. Finally, it is shown that DMPO can react with anionic radicals and that the resultant spin adducts are themselves highly dissociated.

JOHN R. HARBOUR et MICHAEL L. HAIR. Can. J. Chem. 57, 1150 (1979).

On a pu généré le radical $\cdot CO_2^-$ en photolysant une solution de peroxydisulfate de sodium contenant du formate de sodium et par enlèvement d'hydrogène faisant appel à du $TiCl_3$ et du H_2O_2 en présence de formate de sodium. Dans chacun des cas, l'inclusion de DMPO conduit à la formation d'un adduit de spin avec $a^N = 15.8$ G, $a_\beta^H = 19.1$ G et $g = 2.0058$ que l'on attribue à l'adduit du $\cdot CO_2^-$. De plus on présente l'adduit du $SO_4^{-\cdot}$ avec le DMPO. Finalement on montre que le DMPO peut réagir avec des radicaux anioniques et que les adduits de spin qui en résultent sont eux-mêmes très dissociés.

Introduction

The use of spin trapping has been steadily increasing during the past few years. The technique has found application in biological systems (1–3), pigment dispersions (4, 5), polymer systems (6), and studies of chemical reaction mechanisms (7). One particular spin trap, 5,5′-dimethyl-1-pyrroline-1-oxide (DMPO) which was introduced by Janzen and Liu (8) in 1973, has been found to be particularly useful since the hyperfine splitting constants of the adducts depend strongly on the nature of the radical trapped and exhibit sufficient variation to make identification of different radicals relatively easy. In addition this trap is extensively soluble in water (as well as other solvents) and is uncharged.

The utility of the trapping technique depends to a large extent on the number of radical adducts which have been characterized in terms of the hyperfine splitting constants. Janzen and Liu (8) have compiled a list of various radical adducts of DMPO in benzene. However, in relation to the biological applications of spin trapping, it is important to consider the aqueous environment and the types of radicals which may exist in and derive from water. The initial effort in this area identified the formation of the hydroxyl ($\cdot OH$) and superoxide (O_2^-) radical adducts of DMPO (9). This was followed by the utilization of these results in a photochemical study of chlorophyll in micelles (2) and of both chloroplasts (1) and chromatophores (2). We have now extended this list to include the $\cdot CO_2^-$ radical which derives from the biologically important carbon dioxide (CO_2). This radical was generated by two independent means and trapped with DMPO in aqueous medium.

Experimental

The electron spin resonance (esr) and photochemical equipment have been previously described (9). DMPO was synthesized and purified prior to use by vacuum distillation. Sodium persulfate ($Na_2S_2O_8$), sodium formate, hydrogen peroxide, and titanium trichloride (15% w/v) were used as received from BDH Chemicals Ltd. The water was double distilled from an all glass apparatus.

Results and Discussion

Chawla and Fessenden (10) have shown that photolysis of an aqueous peroxydisulfate ($S_2O_8^{2-}$) solution in the presence of sodium formate results in the generation of the $\cdot CO_2^-$ radical. The $SO_4^{-\cdot}$ radical anion is initially formed according to reaction [1].

$$[1] \qquad S_2O_8^{2-} \xrightarrow{h\nu} 2SO_4^{-\cdot}$$

This radical is a good one-electron-transfer oxidizing agent. Hence it reacts with formate ion according to reaction [2].

$$[2] \qquad SO_4^{-\cdot} + HCO_2^- \rightarrow HSO_4^- + \cdot CO_2^-$$

This photochemical system can therefore serve as a generator of $\cdot CO_2^-$ radicals.

When DMPO was added to a solution of $S_2O_8^{2-}$ and the system photolyzed, an esr signal was observed which presumably results from the trapping of the $SO_4^{-\cdot}$ radical (see Fig. 1). Large signal intensities ($\sim 10^{-4}$ *M*) could be generated within several

0008-4042/79/101150-03$01.00/0

FIG. 1. The esr spectrum resulting from photolysis of an aqueous $Na_2S_2O_8$ (3×10^{-3} *M*) solution containing DMPO (~1 *M*). The $^{\bullet}OH$ adduct (1:2:2:1) is superimposed upon the $SO_4^{-\bullet}$ spectrum (see text).

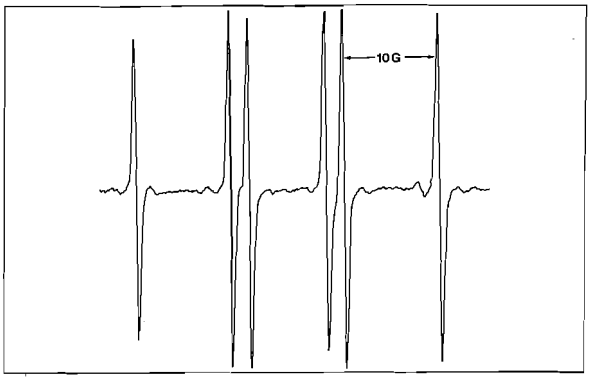

FIG. 2. The esr spectrum of the $^{\bullet}CO_2^-$ adduct of DMPO generated by $TiCl_3$ and H_2O_2.

seconds of photolysis and this observation can be contrasted to the absence of any signal under similar photolysis of a DMPO blank. This signal has $a^N = 13.9$ G, $a_\beta^H = 10.1$ G, $a_{\gamma_1}^H = 1.3$ G, $a_{\gamma_2}^H = 0.9$ G, and $g = 2.0062$. This radical is rather unstable decaying under these conditions with a decay time, τ, (time to 1/e of the initial value) of ~20 s.

As can be seen from Fig. 1, a small amount of $^{\bullet}OH$ radical adduct could also be detected. This radical has also been observed by Chawla and Fessenden (10) when $S_2O_8^{2-}$ was irradiated in the presence of the fumarate spin trap. They argued that $^{\bullet}OH$ results from the reaction

[3] $$SO_4^{-\bullet} + OH^- \rightarrow SO_4^{2-} + {}^{\bullet}OH$$

The hydroxyl radical adduct of DMPO is quite stable under these conditions as contrasted to the $SO_4^{-\bullet}$ adduct. Hence the apparent equal production of both adducts seen in Fig. 1 only reflects the fact that much of the $SO_4^{-\bullet}$ adduct has decayed away.

Addition of sodium formate to the solution yields a new esr signal upon irradiation (Fig. 2). This signal has $a^N = 15.8$ G, $a_\beta^H = 19.1$ G, and $g = 2.0058$ and is assigned to the $^{\bullet}CO_2^-$ adduct which is formed according to reaction [2]. The $SO_4^{-\bullet}$ adduct signal is much diminished under these conditions and can be reduced further by additional formate. This demonstrates that the $^{\bullet}CO_2^-$ results from a reaction with $SO_4^{-\bullet}$ and in fact competes with the DMPO for the available $SO_4^{-\bullet}$ radicals.

A second method for production of $^{\bullet}CO_2^-$ exists and has been used to confirm the assignment. The system Ti^{3+}–H_2O_2 is known (11) to oxidize formate in both acidic and basic media. The hydroxyl radical is first produced

[4] $$Ti^{3+} + H_2O_2 \rightarrow 2{}^{\bullet}OH$$

and this subsequently reacts with the formate

[5] $$^{\bullet}OH + HCO_2^- \rightarrow H_2O + {}^{\bullet}CO_2^-$$

In acidic solutions the $^{\bullet}CO_2H$ radical is formed whereas in neutral or basic solutions the $^{\bullet}CO_2^-$ radical is generated.

Addition of Ti^{3+} into a solution of H_2O_2 containing DMPO results in a strong $^{\bullet}OH$ radical adduct signal. However, when formate is initially present, an esr signal is generated which is identical to that shown in Fig. 2. Hence, as expected from reaction [4], this system produces the $^{\bullet}CO_2^-$ adduct.

Both of these independent methods of generation of the $^{\bullet}CO_2^-$ radical lead to the same signal in the presence of DMPO. This strongly suggests that the radical being observed is the adduct of the $^{\bullet}CO_2^-$ radical. Chawla and Fessenden (10) have demonstrated that the $^{\bullet}CO_2^-$ radical is a carbon-centered radical with $g = 2.00045$ and $\Delta H_{pp} \sim 2.3$ G. The signal we assign to the $^{\bullet}CO_2^-$ adduct reflects that the radical trapped was indeed a carbon-centered radical. This can be deduced from the facts that a_β^H is quite large, no a_γ^H is observed and $g = 2.0058$.

It is worth noting that the spin trap DMPO is reacting with ionic radicals in this work. The pK of $^{\bullet}CO_2H$ is less than 2 which implies that essentially all of the radical is present in the ionized form ($^{\bullet}CO_2^-$). Similarly the $SO_4^{-\bullet}$ radical is an anion. The present study therefore demonstrates that anionic radicals can be trapped with DMPO. This may also have been the case with O_2^- in water (4) but the fact that it has a pK of 4.6 leads to uncertainty as to which species was actually being trapped. Finally, once these adducts are formed, a new equilibrium is established. For example, the spin adduct of CO_2^- is a carboxylic acid. Since this acid derives from a salt, the spin adduct is present as the salt of a weak acid. Assuming a dissociation constant of $\sim 1 \times 10^{-5}$ and a concen-

tration of $\sim 1 \times 10^{-4}$ M, the spin adduct will be predominantly (>99%) in the ionized state.

Formation of aminals from amines via Pummerer rearrangement

SUMAN RAKHIT, MICHAEL GEORGES, AND JEHAN F. BAGLI
Chemistry Department, Ayerst Laboratories, Montreal, P.Q., Canada H3C 3J1

Received November 27, 1978

SUMAN RAKHIT, MICHAEL GEORGES, and JEHAN F. BAGLI. Can. J. Chem. **57**, 1153 (1979).

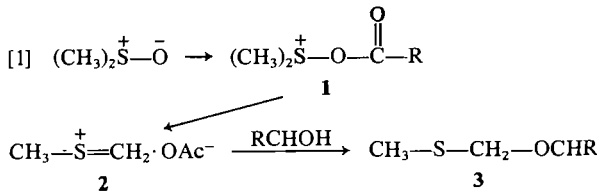
Reaction of 2-amino-3-nitropyridine with acid chlorides in the presence of dimethyl sulfoxide and a tertiary base, such as pyridine, unexpectedly yielded the aminal *N,N'*-bis(3-nitro-2-pyridinylimino)methylene **5**. A similar aminal **6** formed when 2-amino-5-nitropyridine was treated under the same conditions. However, simple aminopyridines such as 2-aminopyridine or 2-amino-6-methylpyridine gave only the 2-*N*-methylenethiomethyl derivatives. It was proved that the aminals are formed by the attack of a suitable base on the *N*-methylenethiomethyl intermediates with expulsion of methyl mercaptan. The formation of these unusual aminals may be explained to be taking place via a Pummerer type rearrangement.

SUMAN RAKHIT, MICHAEL GEORGES et JEHAN F. BAGLI. Can. J. Chem. **57**, 1153 (1979).

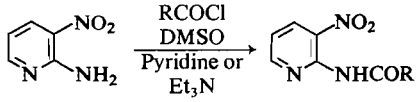
La réaction de l'amino-2 nitro-3 pyridine avec des chlorures d'acide en présence de DMSO et d'une base tertiaire comme la pyridine conduit d'une façon surprenante à l'aminal, *N,N'*-bis(nitro-3 pyridinyl-2 imino)méthylène (**5**). Il y a formation d'un aminal semblable (**6**) lorsqu'on fait réagir l'amino-2 nitro-5 pyridine dans les mêmes conditions. Toutefois des aminopyridines simples comme l'amino-2 pyridine ou l'amino-2 méthyl-6 pyridine ne conduisent qu'à des dérivés *N*-méthylènethiométhyles-2. On a prouvé que les aminals se forment par une attaque d'une base appropriée sur des intermédiaires *N*-méthylènethiométhyles avec l'expulsion de méthylmercaptan. La formation de ces aminals surprenants peut être expliquée par une transposition du type Pummerer.

[Traduit par le journal]

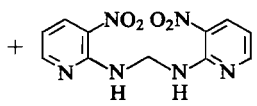
Activation of DMSO (dimethyl sulfoxide) by a variety of electrophiles such as acetic anhydride and related compounds is well documented (1). The intermediate complex **1** is known to decompose via a Pummerer rearrangement to yield an acyloxsulfonium salt of type **2**. These intermediates readily react with nucleophile generated from alcohols leading to thiomethyl ethers (2). Analogous reaction of the reactive intermediate **2** in the presence of an amine would be expected to yield hemithiomethyl aminals. However, such compounds have hitherto not been reported.



In a synthetic programme involving acylation of aminopyridines, 2-amino-3-nitropyridine was reacted with ethyl oxalyl chloride in pyridine at room temperature in the presence of DMSO as a cosolvent. Surprisingly, the desired oxamate represented only the minor component of the reaction mixture. The major product obtained from this reaction was crystallized from acetone (mp 198–200°C; $C_{11}H_{10}N_6O_4$, *m/e*: 290 (M^+)). The nmr spectrum in DMSO-d_6 showed six aromatic protons at δ 6.8–8.3 and two methylene protons of an aminal at δ 5.4 (t, J = 5.5 Hz) that collapsed to a singlet after D_2O exchange. The ir spectrum showed no carbonyl absorption. The above spectral data could be best accommodated by the structure **5**. This structure was further confirmed by X-ray crystallographic studies[1] and is represented as in Fig. 1*a*.



minor
4



major
5

To test the scope of this unusual reaction, several 2-aminopyridines were allowed to react under the same conditions. 2-Amino-5-nitropyridine gave the aminal **6** (mp 267–268°C; $C_{11}H_{10}N_6O_4$, *m/e* 290 (M^+)). In contrast, 2-aminopyridine and 2-amino-6-methylpyridine yielded the hemithiomethyl aminal derivatives **7** (mp 61–63°C; $C_7H_{10}N_2S$, *m/e* 154 (M^+))

[1]The structure was determined by three dimensional X-ray crystallography by Drs. A. W. Hanson and C. Huber of the National Research Council of Canada, Ottawa. Details will be published elsewhere. Further information is obtainable from A. W. Hanson.

0008-4042/79/101153-04$01.00/0

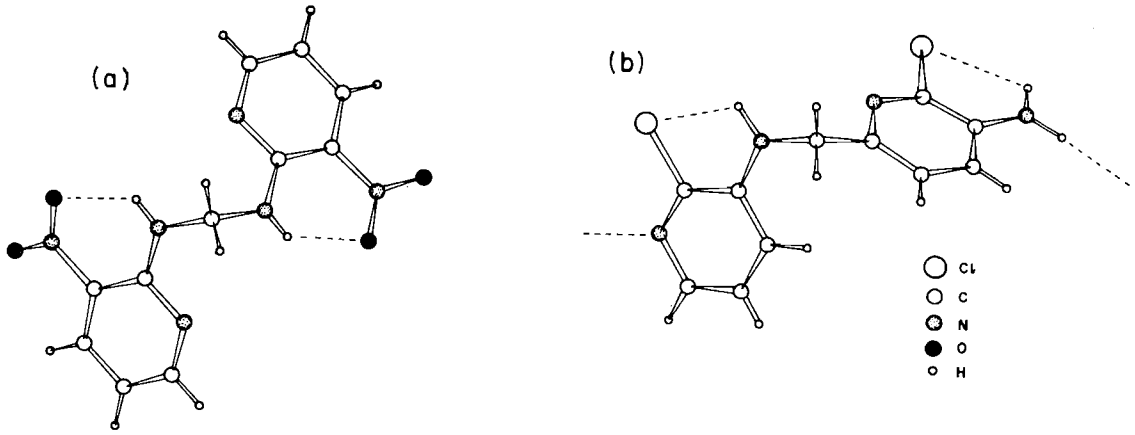


FIG. 1. Perspective view of (*a*) compound **5** and (*b*) compound **15**.

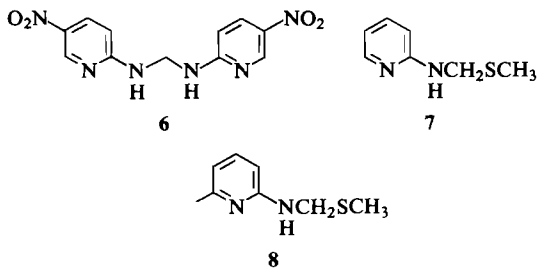
and **8** (oil; $C_8H_{12}N_2S$, *m/e* 168 (M^+)) respectively, along with some acylated products.

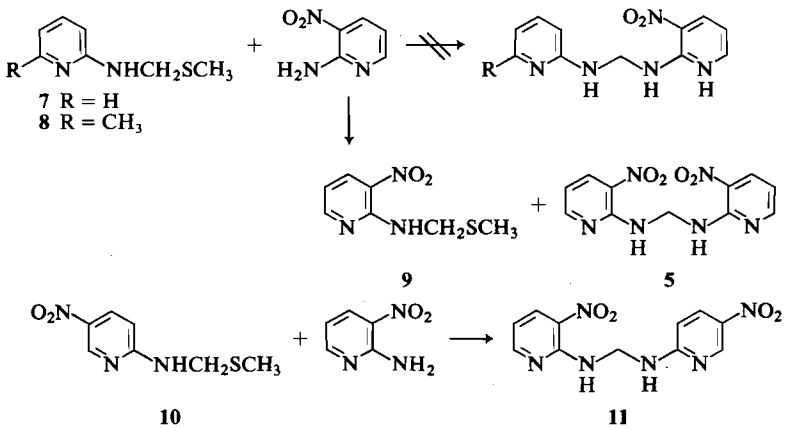
The absence of the aminal in the reaction of DMSO – acid chloride with 2-aminopyridine or 2-amino-6-methylpyridine suggested that the hemithiomethyl aminals were the progenitors in the formation of the aminal. When a time course study was performed of the reaction of 2-amino-3-nitropyridine and DMSO – ethoxalyl chloride in either DMSO or CH_2Cl_2 in the presence of Et_3N, and the reaction quenched at half-time, it was possible to isolate the corresponding hemithiomethyl aminal derivative **9** (mp 90–92°C; $C_7H_9N_3O_2S$, *m/e* 199 (M^+); nmr DMSO-d_6 δ: 2.15 (s, —SCH_3), 4.65 (d, N—CH_2—S, J = 7 Hz collapsing to a singlet after exchange with D_2O). This intermediate disappeared in time with the corresponding increase in the yield of the aminal at the end of the reaction. Also, when the isolated hemithiomethyl aminal **9** was heated at 80°C with 2-amino-3-nitropyridine in DMSO, the aminal **5** was obtained in quantitative yield.



6 **7** **8**

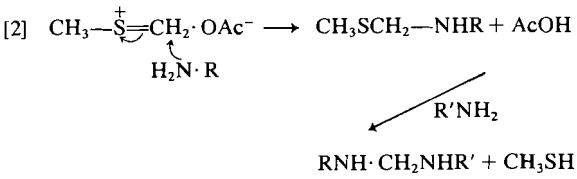
The establishment of the precursor of aminal formation in this reaction suggested its potential utility for the synthesis of mixed aminals using various combinations of hemithiomethyl aminal derivatives and amines. When compounds **7** or **8** were treated with 2-amino-3-nitropyridine in DMSO or CH_2Cl_2 in the presence or absence of Et_3N at 80°C, no mixed aminal was formed. The products were identified as **9** and **5**. However, when the *N*-methylenethiomethyl derivative **10** was allowed to react with 2-amino-3-nitropyridine under the conditions described above, the corresponding mixed aminal **11** (mp 212–214°C; $C_{11}H_{10}N_6O_4$, *m/e* 290 (M^+)) was obtained in 30% yield.

Formation of the hemithiomethyl aminal **9** and

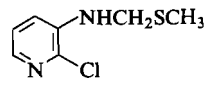


10 **11**

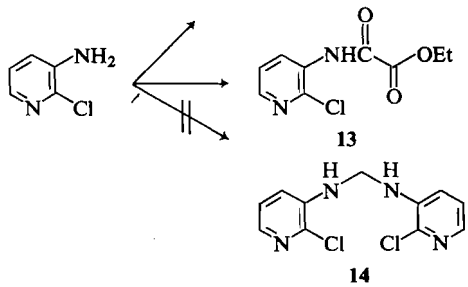
aminal **5** in the above reaction must follow a pathway similar to that reported for the formation of methylenethiomethyl ethers **3**. Thus the intermediate **2**, must be quenched by a molecule of amine to generate the hemithiomethyl aminal. The thiomethyl compound must then react with amine to lead to aminal and methyl mercaptan. The second step appears to be dependent on the base strength of the attacking and leaving nucleophile as demonstrated by the reaction of **7** to **9**.



On the other hand, when 2-chloro-3-aminopyridine was treated with DMSO – ethoxalyl chloride in DMSO containing Et_3N, it produced the methylenethiomethyl derivative **12**, the acylated product **13**, and a small amount of a compound (mp 217–219°C; $C_{11}H_{10}N_4Cl_2$, *m/e*: 268, 270, 272 (M^+, $M^+ + 2$, $M^+ + 4$)). The nmr spectrum showed only five aromatic protons, one of them being a quartet at 7.56 ($J_1 = 4.5$ and $J_2 = 1.5$ Hz). This precludes the structure **14**, the expected product formed similar to **5**. It also showed three (2 + 1) exchangeable protons



12

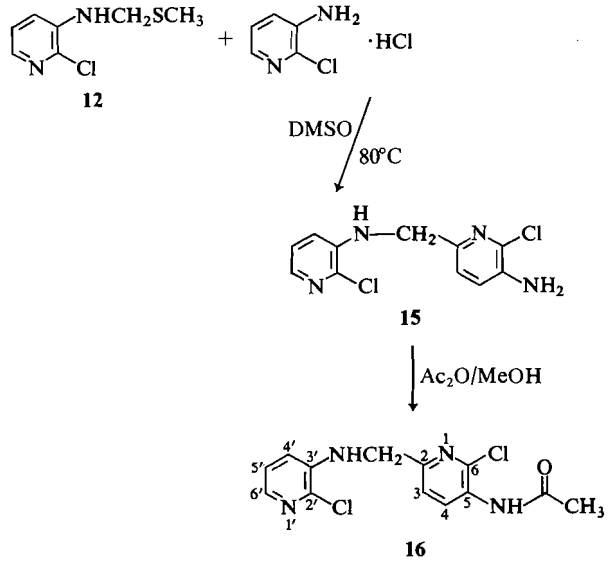


13

14

attributable to NH protons and a two proton doublets for CH_2NH (δ 4.41 (2H, d, $J = 6$ Hz)) collapsing to a singlet after D_2O exchange; ir ($CHCl_3$) ν: 3495, 3439, and 3400 cm^{-1}. These data strongly suggested structure **15** for the new compound. This product could be obtained in better yield (30%) by heating the methylenethiomethyl derivative **12** with the hydrochloride salt of the base in DMSO at 80°C for 10 min. The structure of **15** was finally established by X-ray crystallography[1] and is represented in Fig. 1*b*.

Acylation of **15** by acetic anhydride in methanol yielded the monoacetate **16** (mp 169–171°C; $C_{13}H_{12}N_4OCl_2$, *m/e*: 310, 312, 314 (M^+, $M^+ + 2$, $M^+ + 4$)).



16

The nmr spectrum of **16** was very informative: it showed three proton singlets at δ 2.12 (—CH_3CO), a two-proton doublet at δ 4.41 for CH_2NH, collapsing to a singlet after D_2O exchange. The five aromatic protons could be assigned as follows according to their splitting patterns. Two *ortho*-coupled protons at δ 7.25 (H3) and 8.03 (H4) ($J = 8.5$ Hz), one proton (H5′) as doublet of a doublet at δ 7.10 ($J_{5'6'} = 4.5$, $J_{5'4'} = 8$ Hz) one proton (H6′) as two doublets (*ortho* and *meta* coupled) at 7.56 ($J_{5'6'} = 4.5$, $J_{4'6'} = 1.5$ Hz). These data are clearly indicative of structure **16**, and hence the structure of **15** follows from them.

Experimental

Melting points were determined in a Thomas Hoover-Unimelt apparatus and are uncorrected. Infrared (ir) spectra were recorded on a Perkin Elmer model 225 spectrophotometer in chloroform solution or as a mull. The proton magnetic spectra (^{1}Hmr) were measured on a Varian CFT-20 spectrometer using tetramethylsilane as internal standard. Mass spectra (ms) were determined on a LKB 9000-S spectrometer.

N,N′-Bis(3-nitro-2-pyridinyl)methanediamine (5)

Ethoxalyl chloride 1.37 g (0.01 mol) was added slowly to cold dimethyl sulfoxide (10 mL). This mixture was then added to a solution of 2-amino-3-nitropyridine 1.36 g (0.01 mol) in dimethyl sulfoxide (10 mL). The reaction mixture was allowed to stir at room temperature for a period of 18 h, when tlc showed disappearance of the starting material. The mixture was poured into ice water and the resulting precipitate was collected, washed with water and air dried to give 1.4 g of the desired product (98% yield). A portion was crystallized from acetone, mp 198–200°C; ^{1}Hmr (DMSO) δ: 5.4 (t, 2H, $J = 5.5$ Hz, $HNCH_2NH$, collapsing to singlet after exchange), 6.8–8.3 (m, 6H, aromatic); ir (mull) ν_{max}: 3420 (NH), 1505, and 1350 cm^{-1} (NO_2); ms (170°C) *m/e* 290 (M^+). *Anal.* calcd. for $C_{11}H_{10}N_6O_4$: C 45.52, H 3.45, N 28.97; found: C 45.49, H 3.37, N 29.25.

N-[(Methylthio)methyl]-2-pyridineamine (7)

Ethoxalyl chloride (6.8 g) was added to cold dimethyl

sulfoxide (4.0 g). The resulting mixture was then added to a solution of 2-aminopyridine (4.7 g) in 200 mL of benzene containing triethylamine (5 g). The mixture was heated under reflux for a period of 3 h. It was cooled and washed successively with cold 2 *N* HCl and water, dried over anhydrous sodium sulfate, and filtered. Removal of solvent *in vacuo* yielded an oil that was purified by chromatography over silica gel using 5% acetone, methylene chloride as eluant. The appropriate fractions were mixed to yield 2.5 g of desired product; mp 61–63°C; ^{1}Hmr ($CDCl_3$) δ: 2.05 (s, SCH_3), 4.4 (d, J = 6.5 Hz, $NHCH_2$ collapsing to singlet after D_2O exchange), 6.2–7.9 (m, 4H, aromatic); ms *m/e* 154 (M^+). *Anal.* calcd. for $C_7H_{10}N_2O_2S$: C 54.54, H 6.54, N 18.17; found: C 54.53, H 6.70, N 17.99.

*5-Nitro-*N*-[(methylthio)methyl]-2-pyridinamine (10)*

Ethoxalyl chloride (4.08 g) was added to cold dimethyl sulfoxide (2.5 mL). This mixture was added to a solution of 2-amino-5-nitropyridine (4.17 g) in benzene (50 mL) containing triethylamine (4 mL). The mixture was refluxed for a period of 6 h, after which it was washed with water and dried over anhydrous sodium sulfate and filtered. Removal of solvent yielded a mixture of solids that was chromatographed over silica gel using 3% ethyl acetate in methylene chloride as eluant. Appropriate fractions were collected to yield 1.8 g (30% yield) of the desired product; mp > 250°C; ^{1}Hmr (DMSO) δ: 2.15 (s, 3H, SCH_3), 4.45 (d, 2H, J = 7 Hz, NH—CH_2 collapsing to singlet after D_2O exchange), 6.5 (d, 1H, J = 8 Hz, aromatic), 7.9 (dd, 1H, J_1 = 2 Hz, J_2 = 8 Hz), 8.6 (d, 1H, J = 2 Hz, aromatic); ir (mull) ν_{max}: 3420 (NH), 1505, and 1350 cm^{-1} (NO_2); ms *m/e* 199 (M^+). *Anal.* calcd. for $C_7H_9N_3O_2S$: C 42.21, H 4.55, N 21.10; found: C 42.10, H 4.39, N 20.92.

N,N′-*Bis(5-nitro-2-pyridinyl)methane Diamine (6)*

This product was synthesized exactly in the same manner as described for **5** excepting that the reaction mixture was refluxed for 18 h. After the reaction was over, the solution was cooled and poured into ice. The resulting precipitate was collected, washed thoroughly with water and dried. It was further purified by chromatography over silica gel using 5% ethyl acetate – methylene chloride as eluant. The appropriate fractions were mixed to give the desired product in a yield of 70%. It was crystallized from methylene chloride – acetone; mp 267–268°C; ^{1}Hmr (DMSO) δ: 5.4 (t, 2H, J = 5.5 Hz, $NHCH_2NH$, collapsing to singlet after D_2O exchange); ir (mull) ν_{max}: 3420 (NH), 1505, and 1350 cm^{-1} (NO_2); ms *m/e* 290 (M^+). *Anal.* calcd. for $C_{11}H_{10}N_6O_4$: C 45.52, H 3.45, N 28.97; found: C 45.70, H 3.45, N 29.30.

N-*(3-Nitro-2-pyridinyl)*-N′-*(5-nitro-2-pyridinyl)methane Diamine (11)*

A mixture of 2-amino-3-nitropyridine (1.39 g) and 2-*N*-methylenethiomethyl-5-nitropyridine (2.0 g) in 10 mL dimethyl sulfoxide was refluxed for a period of 6 h. After this, the reaction mixture was cooled and poured into ice water. The resulting precipitate was collected, washed thoroughly with water, and air dried. The mixture was chromatographed over silica gel using methylene chloride as solvent. Identical fractions were mixed together to give three products. The first fraction (0.1 g) was identified as 2-*N*-methylenethiomethyl-3-nitropyridine **9**; mp 90–92°C; ^{1}Hmr ($CDCl_3$) δ: 2.1 (s, 3H, SCH_3), 4.3 (d, 2H, $NHCH_2$), 6.5–7.2 (m, 2H, aromatic), 7.9 (dd, 1H, J_1 = 2, J_2 = 8 Hz, aromatic); ms *m/e* 199 (M^+). *Anal.* calcd. for $C_7H_9N_3O_2S$: C 42.21, H 4.55, N 21.10; found: C 42.46, H 4.55, N 21.44.

The second fraction (0.2 g) was identified as the *N,N′*-bis(3-nitro-2-pyridinyl)methane diamine **5**; mp 198–200°C (identical nmr and ir spectra and no depression in melting point on admixture with the authentic sample).

The third fraction (1.1 g) was identified as the desired product; mp 212–214°C; ^{1}Hmr (DMSO) δ: 5.4 (t, 2H, J = 5.5 Hz, $NHCH_2NH$), 6.7–7 (m, 4H, aromatic), 8.2 (dd, 2H, J_1 = 2, J_2 = 9 Hz, aromatic); ms *m/e* 290 (M^+). *Anal.* calcd. for $C_{11}H_{10}N_6O_4$: C 45.52, H 3.45, N 28.97; found: C 45.27, H 3.42, N 28.87.

*2-Chloro-*N*-[(methylthio)methyl]-3-pyridinamine (12)*

To a cooled mixture of dimethyl sulfoxide (5.5 g) and dry tetrahydrofuran (75 mL), acetyl chloride (5.5 g) was added. To this solution triethylamine (14.1 g) and 3-amino-2-chloropyridine (6.4 g) were added successively. The reaction mixture was refluxed for 18 h, after which the solvent was removed under reduced pressure. The residual oil was purified by chromatography over silica gel using 20% ethyl acetate – methylene chloride as eluant, thus giving 8.8 g of the desired product as an oil (yield 93%); ^{1}Hmr ($CDCl_3$) δ: 2.12 (s, 3H, SCH_3), 4.36 (d, 2H, J = 6.6 Hz, $NHCH_2$), 7.06 (m, 2H, aromatic), 7.25 (dd, 1H, J_1 = 4, J_2 = 1.5 Hz, aromatic); ms *m/e* 188 (M^+). *Anal.* calcd. for $C_7H_9N_2SCl$: C 44.56, H 4.77, N 14.85; found: C 45.27, H 4.84, N 14.36.

*5-Amino-*N*-(2-chloro-3-pyridinyl)-6-chloropyridine-2-methanamine (15)*

A solution of 2-chloro-3-*N*-methylenethiomethylpyridine **12** (3.8 g) and 2-chloro-3-aminopyridine hydrochloride (3.3 g) in dimethyl sulfoxide (5 mL) was heated at 80°C for a period of 15 min. The cooled reaction mixture was poured into ether. The ether layer was decanted off and discarded. The resulting oil was washed several times with ether. The residue was chromatographed over silica gel using 20% ethyl acetate in methylene chloride as eluant. Appropriate fractions were mixed together to give 1.7 g of the desired product (30% yield); mp 127–129°C (methylene chloride – hexane); ^{1}Hmr ($CDCl_3$) δ: 4.45 (d, 2H, J = 6 Hz, NH—CH_2), 6.75–7.15 (m, 4H, aromatic), 7.7 (dd, 1H, J_1 = 4.5, J_2 = 1.5 Hz, aromatic); ms *m/e*: 268, 272, 274 (M^+, $M^+ + 2$, $M^+ + 4$). *Anal.* calcd. for $C_{11}H_{10}N_4Cl_2$: C 49.25, H 3.73, N 20.90; found: C 48.93, H 3.73, N 20.90.

*5-Acetamido-*N*-(2-chloro-3-pyridinyl)-6-chloropyridine-2-methanamine (16)*

A solution of **15** (200 mg) in pyridine (5 mL) and acetic anhydride (1.5 mL) was stored at room temperature for a period of 18 h. Excess of anhydride was decomposed by adding methanol under cooling and the mixture was poured into ice water. The resulting precipitate was collected, washed with water, and air dried to give a brown powder that was purified by chromatography over silica gel using 20% ethyl acetate – methylene chloride as eluant. Thus 150 mg of the desired product was obtained (65% yield); mp 169–171°C (methylene chloride – hexane); ^{1}Hmr (DMSO) δ: 2.12 (s, 3H, CH_3CO), 4.41 (d, 2H, J = 6 Hz, $NHCH_2$), 6.85 (dd, 1H, J_1 = 8, J_2 = 1.5 Hz), 7.10 (dd, 1H, J_1 = 8, J_2 = 4.5 Hz), 7.25 (d, 1H, J = 8.5 Hz), 7.56 (dd, 1H, J_1 = 4.5, J_2 = 1.5 Hz), 8.03 (d, 1H, J = 8.5 Hz); ms *m/e*: 310, 312, 314 (M^+, $M^+ + 2$, $M^+ + 4$). *Anal.* calcd. for $C_{13}H_{12}N_4OCl_2$: C 50.32, H 3.87, N 18.06; found: C 50.08, H 3.69, N 18.13.

Received September 21, 1978

B. P. GIRI, G. PRASAD, and K. N. MEHROTRA. Can. J. Chem. **57**, 1157 (1979).

Several diimines have been synthesised from the reaction of substituted imines with sodium in dry ether followed by bubbling in oxygen and subsequent protonation. A probable mechanistic route for the formation of products through the dimerisation of initially formed anion radicals is presented and an alternative route, through the dimerisation of radicals formed by hydrogen abstraction from starting imine, has been excluded by substituent labelling experiments. Ketone hydrazones on treatment with sodium in ether and subsequent air oxidation gave substituted diazomethanes in excellent yields (88–95%).

B. P. GIRI, G. PRASAD et K. N. MEHROTRA. Can. J. Chem. **57**, 1157 (1979).

On a synthétisé plusieurs diimines en faisant d'abord réagir des imines substituées avec du sodium dans l'éther anhydre puis en y faisant barbotter de l'oxygène et finalement en protonant. On a présenté un mécanisme probable pour la formation de produits par l'intermédiaire de la dimérisation des radicaux anions qui se forment initialement; on a exclu un autre mécanisme possible impliquant une dimérisation des radicaux formés par l'enlèvement d'hydrogène de l'imine de départ en se basant sur des études impliquant le marquage des substituants. Si l'on traite des hydrazones de cétones par du sodium dans l'éther, puis qu'on oxyde le tout par de l'air, on obtient des diazométhanes substitués avec d'excellents rendements (88–95%).

[Traduit par le journal]

The reductive dimerisation of substituted anils either by the reaction of active metals (Li, Na, and K) in nonaqueous solvents (1) or of aluminium in moist ether (2) has been reported. This procedure has been extended to *N*-substituted imines (3). It was considered necessary to observe the effect of added oxygen before protonation of the sodium salt in the reaction of several substituted imines with sodium in dry ether. In the present paper we describe this modified procedure which leads to a new and more convenient synthetic route to substituted diimines. This one-step method has a distinct superiority over the conventional method, the condensation of 1,2-ethanediamines and carbonyl compounds, as the preparation of 1,2-ethanediamines alone would involve several steps. Similar treatment of ketone hydrazones leads to the formation of substituted diazomethanes in excellent yields.

Results and Discussion

The product mixture obtained with benzaldehyde *N*-benzylimine (**1***a*; Ar = Ar′ = C_6H_5, R = H) was separated by repeated (4–5) fractional crystallisation from ethanol; it consisted of *meso*- and *dl*-*N*,*N*′-dibenzylidene-1,2-diphenylethylenediamine (**2***a*; 17% each). Authentic samples of *meso*- and *dl*-**2***a* were prepared according to the method reported (4) and were identical to the products (ir, nmr, and mp). Catalytic hydrogenation of *meso*- and *dl*-**2***a* gave *meso*- and *dl*-*N*,*N*′-dibenzyl-1,2-diphenyl-1,2-diaminoethane (5), respectively (ir, nmr, and also mp in case of *meso* product, Table 1).

The probable reaction sequence for the formation of *meso*- and *dl*-diimines can be as shown in Scheme 1.

The radical anion formed by an electron transfer from sodium to imine **1***a* dimerises. The dianion may exist in equilibrium with the dicarbanion which may take up 2 molecules of oxygen; loss of hydroperoxide ions would lead to the diimines **2***a*. A similar equilibrium between the amide ion, obtained from aminoalkylsilanes in the presence of traces of *n*-butyllithium, and the isomeric carbanion has been proposed (6). The elimination of hydroperoxide ions has been suggested in the formation of diazomethanes from the reaction of ketone hydrazones with methyl lithium (7).

An alternative route for the formation of diimines (**2***a*) could be through the dimerisation of the intermediate radical formed by a possible hydrogen abstraction from the imine as shown in Scheme 2. This mechanistic route could be tested by labelling experiments.

Benzaldehyde *N*-(*p*)-methylbenzylimine (**1***b*; Ar = C_6H_5, Ar′ = $pCH_3C_6H_4$, and R = H) when simi-

larly treated as **1***a* gave two products which were separated by repeated fractional crystallisation and characterised as *meso*- and *dl*-*N*,*N*′-di-*p*-methylbenzylidene-1,2-diphenylethylenediamine (**2***b*; 11% each) on the basis of analytical and spectral (uv, ir, and nmr) data. The structure of *meso*-**2***b* was confirmed by comparison (ir and undepressed mixture melting point) with an authentic sample obtained from the condensation of *meso*-1,2-diphenyl-1,2-diaminoethane (4) with *p*-methylbenzaldehyde. This excludes the mechanistic route for the formation of diimines given in Scheme 2.

Similar treatment of benzaldehyde and *p*-methoxybenzaldehyde *N*-benzhydrylimines (**1***c* and *d*) gave *dl*-*N*,*N*′-dibenzhydrylidene-1,2-diphenylethylenediamine (**2***c*) and *dl*-*N*,*N*′-dibenzhydrylidene-1,2-di-*p*-methoxyphenylethylenediamine (**2***d*), respectively, whereas the *p*-chlorobenzaldehyde *N*-benzhydrylimine (**1***e*) afforded both *meso*- and *dl*-*N*,*N*′-dibenzhydrylidene-1,2-di-*p*-chlorophenylethylenediamine (**2***e*) The *dl*-isomers of **2***c*, *d*, and *e* show a common feature in their nmr spectra (Table 2). Four aromatic protons in each appeared at higher field (between δ 6.47–6.62) as compared with the chemical shifts of

remaining aromatic protons (δ 7.25–7.33). On catalytic hydrogenation the *dl*-diimines (**2***c* and *d*) in separate experiments gave *dl*-dihydrodimers of imines (ir and mmp) (5). The formation of diimines with benzaldehyde N-substituted imines can be as shown in Scheme 3.

Ketone hydrazones (**3***a–f*) on similar treatment, as described for imines, gave substituted diazomethanes (**4***a–f*) in 88–95% yield. The structural assignment of the products **4***a–f* was made on the basis of similarity of ir spectra (9, 10) and melting points (Table 3) and also by conversion to their respective azines **5***a–f*

SCHEME 3

which were characterised on the basis of spectral data (Table 4). The formation of diazomethanes can be as shown in Scheme 4.

Electron transfer from sodium to hydrazones **3***a–f* and loss of sodium hydride may lead to the anion *m*. When oxygen or air was not bubbled through the reaction mixture, protonolysis of *m* gave the starting ketone hydrazones (**3***a–f*). Addition of oxygen to *m* and loss of hydroperoxide ion would lead to the substituted diazomethanes (**4***a–f*). A similar mechanism has been proposed in the oxidation of benzophenone hydrazone anion formed by the reaction of methyl lithium in tetrahydrofuran (7). The above method provides a useful and convenient method for synthesising substituted diazomethanes in better yields in comparison with the earlier methods (7 and 8).

Experimental

Melting points were obtained on a Büchi apparatus (capillary method) and have been uncorrected. Infrared spectra were recorded on a Perkin-Elmer 720 spectrometer. Ultraviolet spectra were obtained in 95% ethanol on a Cary-14 spectrophotometer. Proton nuclear magnetic resonance data were obtained on a Varian A-60D spectrometer using TMS as internal standard.

Preparation of Imines

The starting imines were prepared by the condensation of an equimolar mixture of carbonyl compound and aliphatic amine as reported in the literature (11, 12) and characterised on the basis of ir, uv, and nmr data.

Preparation of Ketone Hydrazones

The ketone hydrazones were prepared by the condensation of ketone (2.0 g) with hydrazine hydrate (2.0 g) in 1 mL of *n*-butanol (13) and characterised by ir, uv, and nmr data.

General Procedure for Preparation of Diimines 2

Pieces of sodium (1.0 g, 0.044 g at.) were slowly added to dry ether (40 mL) with stirring under a nitrogen atmosphere. Stirring was continued and the contents were heated under reflux for 2 h. A solution of the imine (1.0 g) in dry ether (40 mL) was added dropwise. The reaction mixture was stirred and heated under reflux for 3–12 h. Oxygen gas was passed through for 15 min and the mixture was allowed to cool. Unreacted pieces of sodium were removed by filtration. The ethereal suspension was treated with 10% aqueous ammonium chloride and the organic layer was washed twice with water and dried over sodium sulfate. The solvent was removed on a rotary evaporator and the residual material was crystallised from methanol. The products were separated by repeated

fractional crystallisation from ethanol. The analytical results are given in Table 1 and the spectral data of the products in Table 2.

*General Procedure for Preparation of Diazomethanes **4** and Azines **5***

In this procedure a solution of the hydrazone (2.0 g) in dry ether (75 mL) was used in place of imine. The red-violet product obtained was dissolved in *n*-hexane (25 mL) and filtered to remove any unreacted hydrazones. The solid products were crystallised from *n*-hexane. When air or oxygen was not bubbled into the reaction mixture and the sodium salt was washed with aqueous ammonium chloride, the starting hydrazones were recovered almost quantitatively.

The benzene solution of diaryldiazomethanes **4***a–f* was heated at reflux temperature till complete disappearance of red-violet coloration. The solvent was removed on a rotary evaporator and the residue was crystallised from ethanol to give the azines.

JOHN E. DRAKE, BORIS M. GLAVINČEVSKI, H. ERNEST HENDERSON, and CLARA WONG. Can. J. Chem. **57**, 1162 (1979).

The mass spectral fragmentation patterns of bis(trimethylsilyl)- and bis(trimethylgermyl)carbodiimides are compared. Metastable confirmed transitions involve elimination of neutral fragments apparently containing Si=N and/or Si=C bonds. The fragmentation pathways are similar for the germyl analogue but no proof of a fragment containing a Ge=C bond was observed.

JOHN E. DRAKE, BORIS M. GLAVINČEVSKI, H. ERNEST HENDERSON et CLARA WONG. Can. J. Chem. **57**, 1162 (1979).

On compare les types de fragmentation en spectrométrie de masse des bis(triméthylsilyl) et bis(triméthylgermyle) carbodiimides. Des transitions confirmées par des ions métastables impliquent l'élimination de fragments neutres contenant apparemment des liaisons Si=N et/ou Si=C. Les voies de fragmentation sont semblables dans le cas des analogues germylés; toutefois on n'a obtenu aucune preuve permettant de confirmer la présence d'un fragment contenant une liaison Ge=C.

[Traduit par le journal]

In a recent publication, we reported the synthesis, characterisation, and reactivity of various silyl- and germylcarbodiimides (1). Of these, only $(H_3GeN:)_2C$ has been analysed by mass spectrometry and from the observed ion fragments the existence of several rearrangement ions was deduced (2). The existence of both positively charged and neutral fragments containing an Si=C bond has been postulated in mass spectroscopic studies of organosilicon compounds (3, 4), as has the formation of species containing the Si=N bond in the spectra of silazanes (5). The two trimethyl derivatives $Me_3SiNCNSiMe_3$ and $Me_3GeNCNGeMe_3$ were selected for a comparative study of their fragmentation pathways to avoid problems of interpretation that might arise from 'hydrogen stripping' in the hydrido analogues. The carbodiimide skeleton could provide a basis for interesting rearrangements and also for the formation of intermediates involving double bonds to silicon or germanium.

Experimental

The mass spectra were obtained using a Varian MAT CH5 double focusing spectrometer, of reversed geometry, equipped with an INCOS 2000 computer system. The spectra were recorded at 70 eV. The metastable transitions were observed in the field free region by scanning the accelerating voltage (1–3 kV) at constant electric sector voltage (285 kV) and magnetic strength. The *m/e* value of the daughter ion is known to the nearest mass unit. It was possible, under special conditions, in the normal electron-impact spectrum, to record the silicon compound under high resolution to 0.001 eV. A linear least-squares iterative computer program (SMASABD)[1] was used to fit theoretical polyisotopic patterns of our compounds to the experimental data, and another program (MASPEC)[1] was used to calculate the theoretical polyisotopic clusters of each ion fragment. In 'clusters' involving silicon, the presence of M, M − 1, or M − 2 peaks could be readily discerned; typical average deviations obtained from the SMASABD program were ca. 1.0 for silicon species but closer to ca. 5.0 for germanium clusters.

$Me_3SiNCNSiMe_3$ and $Me_3GeNCNGeMe_3$ were prepared as described previously and their purity checked by their vibrational and ^1H nmr spectra (1). Carbodiimides are readily hydrolysed to the oxides, so great care must be taken to avoid any contact with moisture when the mass spectra are recorded.

Results and Discussion

The major features of the fragmentation patterns of $Me_3SiNCNSiMe_3$ and $Me_3GeNCNGeMe_3$ are very similar and surprisingly simple. If only those peaks with an ion count greater than 5% of the base peak are considered, then the main ions present are

$$Me_3SiNCNSiMe_3^+ \rightarrow Me_3SiNCNSiMe_2^+ \rightarrow Me_3Si^+$$

for the silane and

$$Me_3GeNCNGeMe_3^+ \rightarrow Me_3GeNCNGeMe_2^+ \rightarrow Me_3Ge^+ \rightarrow MeGe^+$$

for the germane. Table 1 includes all those peaks which have an ion count greater than 1% of the base peak and which are clearly part of a silicon- or germanium-containing ion.

In the course of investigating the metastable-supported fragmentation pathways for $Me_3SiNCNSiMe_3$ (Table 2) it becomes apparent that the loss of neutral species containing Si=C or Si=N bonds can readily account for the majority of features in Scheme 1. The

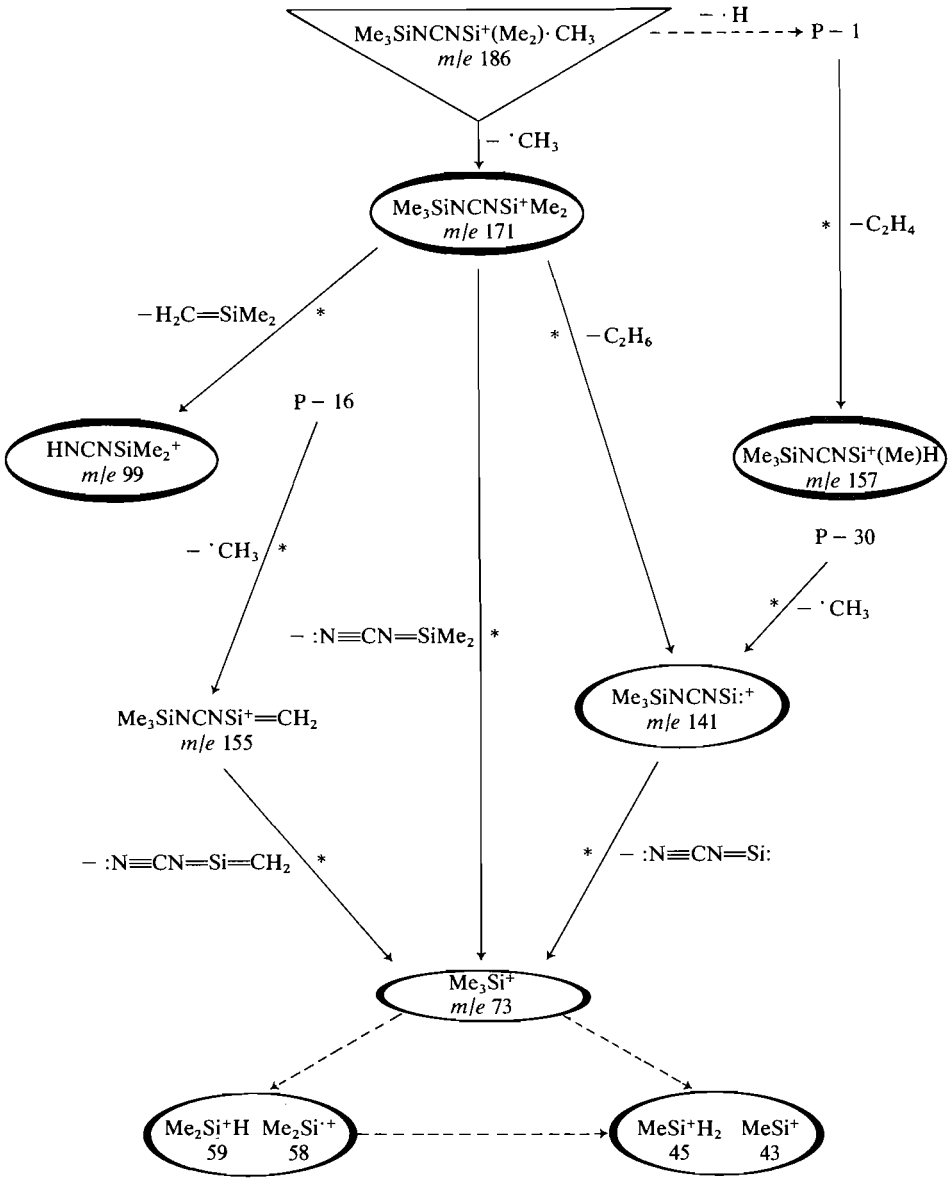

SCHEME 1. Fragmentation pattern for bis(trimethylsilyl)carbodiimide

formation of Me_3Si^+ arises from the loss of neutral fragments that apparently contain a Si=N bond and for which similar and reasonable electronic structures can be proposed. The transfer of charge to the 'other end' of the molecule should be a relatively simple mechanism given the delocalized nature of the π-bonding system in the SiNCNSi skeleton. Unfortunately, we were unable to get accurate determination of the parents of the ion below Me_3Si^+. Clusters containing one and two methyl groups attached to silicon are mixtures. The relative peak intensities suggest that the ions Me_2SiH^+ (*m/e* 59.024; calcd. 59.0317) and Me_2Si^+ can be detected in a ratio of ca. 3:1 as are the ions $MeSiH_2^+$ (*m/e* 44.98; calcd. 45.0161) and $MeSi^+$ (*m/e* 42.96; calcd. 43.0004). The genesis of the intermediates at *m/e* 157, 155, and 141 leads to metastable-confirmed transitions which apparently arise from 'parents' that have one hydrogen atom less than an ion that is seen in the main spectrum. These parents at *m/e* 185, 170, and 156 show insignificant abundances in the normal running mode and the origins of the latter two are unknown. The signal corresponding to *m/e* 99 is seen at 99.0219 under higher resolution which indicates

the presence of $Me_2SiNCNH^+$ (*m/e* calcd. 99.0378) rather than Me_3SiNC^+ (*m/e* calcd. 99.0504). The former ion requires the loss of the neutral fragment $CH_2{=}SiMe_2$, whereas the latter requires the formation of two odd-electron scission products. It is difficult to assign unambiguously the species of *m/e* 100. The peak is of low intensity, making metastable and high resolution work less reliable. The metastable studies show an array of poorly characterised parent ions (Table 2) and in high resolution spectra there is

*Peaks of good intensity are marked with an asterisk.

an indication of peaks of even lower intensity at *m/e* 100.03 and possibly at 99.96 in addition to the main one at 99.9954. Thus it seems clear that more than one species is present, one of which could be $Me_2Si_2N^+$ (*m/e* calcd. 100.0039) resulting from the loss of HCN (from *m/e* 127) and MeCN (from *m/e* 147). The formation of rearrangement ions of this type was suggested in the mass spectrum of $H_3GeNCNGeH_3$ (2) but there was no indication of the corresponding species, $Me_2Ge_2N^+$, in the spectrum of $Me_3GeNCNGeMe_3$.

The polyisotopic nature of germanium results in the mass spectrum of $Me_3GeNCNGeMe_3$ being potentially more complex than that of the silicon analogue. This not only leads to difficulty in assessing the degree of 'hydrogen-loss' in simple species such as Me_2Ge^+ compared with Me_2GeH^+, but also makes metastable work more difficult, because relatively few *m/e* values have significantly high intensities. Nevertheless, we can establish some metastable-confirmed transitions and suggest a probable pattern (Scheme 2) based on a comparison with the silicon analogue. The principal route is again the loss of methyl group to give the P − 15 ion followed by loss of a large neutral fragment to give Me_3Ge^+. This neutral fragment can be written as with the silicon analogue, as involving a double bond from the group IV element to nitrogen. Equally well, it may be written in a Zwitterion form which avoids the necessity of involving a π-bond to germanium, namely as $^-$:N=C=N—Ge^+Me_2 rather than as :N≡C—N=$GeMe_2$. This is also true of the fragment :N≡C—N=Ge: which can be written as :$^-$N=C=N—Ge^+:. It is interesting to note that there is no indication, either in the main spectrum or the metastable studies, of the intermediate $Me_3GeNCNGe{=}CH_2^+$ (*m/e* 245 for ^{74}Ge) which would contain a double bond between germanium and carbon, even though the corresponding pathway certainly exists in the silane. The presence of $HNCNGeMe_2^+$ and/or Me_3GeNC^+ (*m/e* 145 for ^{74}Ge) cannot be ruled out completely because very weak peaks were detected in the region of *m/e* 141 to 145 but they did not correspond to a typical germanium cluster. The elimination of C_2H_6 from $Me_3GeNCNGeMe_2^+$ is similar to that noted from Me_2GeCl^+ in the spectrum of Me_3GeCl (6) and the corresponding transition in the silicon analogue is metastable-confirmed. The elimination of C_2H_4 from Me_3Ge^+ is a well established pathway (6, 7).

Bound complex and triple collision mechanisms for diatom dissociation and recombination

NEIL SNIDER
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6
Received November 22, 1978

NEIL SNIDER. Can. J. Chem. **57**, 1167 (1979).

A method was devised for estimating relative contributions to atom recombination from the bound complex and triple collision mechanisms. The method is based on three assumptions: a collinear model is valid, recrossings of a suitably chosen transition state surface equally affect both contributions to the recombination rate, and the two contributions correspond to crossings of parts of the transition state surface which differ only in total energy. Ratios of the rate constants for recombination by the two mechanisms were calculated for a classical model of Br and I atom recombination in rare gases. The ratios had already been obtained for the model from three-dimensional trajectory calculations. The results disagreed by as much as a factor of ten for helium as the third body, but they were within 50% or better for xenon. It was argued that the discrepancies are largely due to a breakdown of the second of the foregoing assumptions. The formula for the rate constant for recombination by both mechanisms together was extended to three dimensions at the expense of introducing an adjustable parameter. The extended formula was found to give results in agreement with the trajectory calculation to within 30% or better.

NEIL SNIDER. Can. J. Chem. **57**, 1167 (1979).

On a developpé une méthode qui permet d'évaluer les contributions relatives à la recombinaison d'un atome par des mécanismes de liaison complexe et de collision triple. La méthode est basée sur trois hypothèses: un modèle colinéaire est valable, les recoupements d'une surface d'état de transition choisie judicieusement affecte d'une façon égale les deux contributions à la vitesse de recombinaison et les deux contributions correspondent à des recoupements de portions de la surface de l'état de transition qui ne diffèrent que dans leur énergie totale. On a calculé les rapports des constantes de vitesse pour la recombinaison par les deux mécanismes pour un modèle classique de recombinaison d'atomes de Br et de I dans des gaz rares. On a déjà obtenu les rapports pour le modèle à partir de calculs de trajectoires tridimensionnelles. Les résultats diffèrent par des facteurs pouvant atteindre 10 lorsque l'hélium est le troisième corps; dans le cas du xénon les résultats ne diffèrent que par 50% ou moins. Il est proposé que ces différences sont dues en grande partie à l'insuffisance de la deuxième hypothèse. On a étendu la formule de la constante de vitesse pour la recombinaison par les deux mécanismes aux trois dimensions en faisant intervenir un paramètre ajustable. On a trouvé que la formule étendue conduit à des résultats en accord à 30% ou mieux avec les calculs de trajectoire.

[Traduit par le journal]

Introduction

The simplest mechanism for gas phase recombination of two atoms A in the presence of an inert diluent M is a termolecular process

[1] $$2A + M \rightarrow A_2 + M$$

However, in practice, diluent gases are never completely inert, and the formation of bound species AM is always a possibility. Theories of the rate of recombination have been formulated (1, 2) wherein AM plays a central role,

[2] $$A + 2M \leftrightharpoons AM + M \quad \text{rapid equilibrium}$$
$$AM + A \rightarrow A_2 + M$$

Reaction [1] has come to be known as the "triple collision" mechanism for recombination, and reactions [2] as the "bound complex" mechanism (3).

In the reverse process, dissociation of A_2, the final step in the collisional excitation of A_2 to the dissociated state may be either the break-up of A_2,

[3] $$A_2 + M \rightarrow 2A + M$$

or exchange,

[4] $$A_2 + M \rightarrow AM + A$$

Reaction [3] is the reverse of [1], and [4] is the reverse of the second step of [2]. By detailed balancing the ratio of rates of [1] and [3] is equal to the ratio of rates of [2] and [4]. It follows that the recombination rate via the triple collision mechanism relative to the recombination rate via the bound complex mechanism is equal to the branching ratio for the possible reactions of M with A_2.

If M is one of the rare gases, the A—M bond is generally weak, and AM is not easy to detect experimentally. Thus, it is that there are no experimental data concerning the relative rates of [1] and [2] in this case. What are available are results of trajectory

0008-4042/79/101167-10$01.00/0

calculations for Br atoms and I atoms recombining in the presence of He, Ar, and Xe (3, 4). These studies indicate that for M = Ar, Xe the bound complex mechanism predominates at low temperatures, the triple collision mechanism at high temperatures whereas for M = He the triple collision mechanism predominates at all temperatures of interest.

The primary objective of the present work is to develop and test a method for estimating the relative rates of dissociation and recombination via the two aforementioned mechanisms. Three approximations are introduced over and above those of the trajectory studies. First, the problem is reduced to one dimension. Second, the dynamics are simplified as per transition state theory (5). Third, the contributions to the rate from the two mechanisms are identified with fluxes across parts of the transition state surface which differ only in total energy. The potential energy surfaces are assumed to be the same as those used in the above cited trajectory studies (6), and comparisons are made with the ratios of triple collision and bound complex contributions to the equilibrium rate of recombination k_r^{eq} from these studies. One thereby eliminates uncertainties due to lack of knowledge of the potential energy surfaces, to the need to correct for non-equilibrium effects, and to the need to correct for quantum effects. Discrepancies between the estimated values of the branching ratios and those calculated from trajectories can be due only to the three approximations mentioned previously.

A secondary objective of this work is to test a simple method for extending collinear results for k_r to three dimensions (7). The extended results can be compared directly to the values of k_r^{eq} obtained from trajectories. This comparison will provide some indication of the amount of inaccuracy which results from simplification of the dynamics.

Formulation of the Theory

Transition State Theory

The following derivation makes reference to reactions [3] and [4]. Extension to reactions [1] and [2] is effected by a straightforward application of the principle of detailed balancing. Semiclassical transition state theory has recently been formulated in one dimension (8) for the reaction scheme represented by [3] and [4]. The theory expresses the rate constant for the overall disappearance of A_2 by reactions [3] and [4] in terms of a phase space function $\mathcal{O}$. This function is a unit step function, and its discontinuity occurs at the surface in phase space which has been chosen to be the transition state.

In the just mentioned theory, the classical limiting expression for the sum of rate constants for reactions [3] and [4] is obtained by combining eqs. [13] and [15] of ref. 8,

$$[5]\quad k_3 + k_4 = \mathcal{I}_{Int}^{-1}(\beta/2\pi\mu)^{1/2} \times \int \{\mathcal{O}, H\}\theta(-\{\mathcal{O}, H\}) \exp(-\beta H)\, dpdq$$

where $\mathcal{I}_{Int}$ is the phase integral for the vibrational degree of freedom of A_2, β is the reciprocal of Boltzmann's constant times temperature, μ is the reduced mass of the A_2–M pair, H is the Hamiltonian for the system with the center of mass taken to be at rest, $\{\ \}$ denotes Poisson bracket, θ is the unit step function, and p and q are the momenta and coordinates for the two degrees of freedom of the collinear, three-atom system with fixed center of mass. It is to be noted that the integral on the right of [5] is essentially a surface integral since the Poisson bracket of $\mathcal{O}$ contains as a factor a Dirac delta function which is non-zero only at the transition state. Provided only that the transition state surface entirely separates the A_2 + M region from the rest of the phase space, eq. [5] gives an upper bound to the exact classical $k_3 + k_4$ for the same model (5).

The transition state surface to be assumed in the present work resembles the one employed in the original version of the variational theory of three-body recombination (9). This surface is defined differently in different regions of phase space. In the region for which a function $f(q)$ is negative, i.e. the region which by definition of f includes reactant-like configurations, it is the surface along which H_{Int}, the Hamiltonian for the vibrational degree of freedom of isolated A_2, is equal to D, the dissociation energy. In the region for which H_{Int} is less than D, it is the surface along which f is zero. The function $\mathcal{O}$ is then given by

$$[6]\qquad \mathcal{O} = \theta(D - H_{Int})\theta(-f)$$

In the present work the explicit form of f to be assumed differs from that of ref. 9 although, as in ref. 9, it is made to depend on a variational parameter. The explicit form of f used in the present work will be discussed later along with the rationale underlying its choice.

Partitioning of the Surface

The desired branching ratio Γ is given by

$$\Gamma = k_3/k_4$$

Equation [5] cannot provide this ratio. The transition state surface can be divided into a part through which pass trajectories which contribute to [3] and another part through which pass trajectories which contribute to [4]. However, one does not know how to effect this partitioning of the surface without actually computing the trajectories. Lacking trajectories, one must resort to a reasonable assumption.

Before discussing the partitioning which was here

assumed, it is to be noted that the law of conservation of energy imposes limits on that portion of the surface through which reactive trajectories may pass and also on the portion through which dissociative trajectories may pass. Let ε_∞ be the binding energy of isolated AM. Then for H less than $D - \varepsilon_\infty$ no reaction can take place, and for H between $D - \varepsilon_\infty$ and D only reaction [4] can occur. Thus the integration in [5] is restricted to that part of the surface for which H is greater than $D - \varepsilon_\infty$, and the integral over the part for which H lies between $D - \varepsilon_\infty$ and D may contribute only to k_4.

The simplest assumption one can make is that trajectories which pass through that part of the surface for which H is greater than D contribute *entirely* to [3]. This assumption is the one which was finally adopted in the present work. It leads to an upper bound to k_3 because all trajectories which contribute to [3] *must* pass through that part of the surface for which H is greater than D. The assumption seems physically reasonable in those cases for which A–M attractive forces are weak. In such a case it seems unlikely that many trajectories for which H is greater than D would contribute to reaction [4]. If the A–M attractive forces are strong, however, the assumption probably breaks down because many trajectories which cross the transition state surface are likely to be deflected into the AM + A region and to have their excess energy channeled into relative AM − A translation. Nevertheless, in those cases for which calculations are reported here, the A–M attractive forces are weak.

Formula for the Branching Ratio

The branching ratio is thus assumed to be a ratio of integrals over portions of the transition state surface which differ only in total energy. As the first step in the evaluation of these integrals, explicit coordinates are chosen. These are R, the distance from M to the center of mass of A_2 and r, the A–A distance, both conveniently mass weighted,

$$[7] \quad r = (2b)^{1/2} r_{AA} \qquad R = (2b)^{-1/2}(r_{AM} + \tfrac{1}{2} r_{AA})$$

In [7], r_{AA} is the A–A distance, r_{AM} is the distance between M and the nearest A, and b is given by

$$[8] \quad b = (1 + 2m_A/m_M)^{1/2}$$

where m_A and m_M are the masses of the designated atoms. In terms of these coordinates the Hamiltonian for the vibration of isolated A_2 is given by

$$[9] \quad H_{Int} = p_r^2/2\bar{\mu} + V_0(r)$$

and the total Hamiltonian is given by

$$[10] \quad H = (p_R^2 + p_r^2)/2\bar{\mu} + V_0(r) + V_1(R, r)$$

where $\bar{\mu}$ is given by

$$[11] \quad \bar{\mu} = \tfrac{1}{2} b\mu = m_A/b$$

and p_R, p_r are the momenta conjugate to the designated coordinates.

With $\mathcal{O}$ given by [6] and coordinates given by [7], the Poisson bracket in the integrand of [5] becomes

$$[12] \quad \{\mathcal{O},H\} = -\bar{\mu}^{-1}\left[p_r \frac{\partial V_1}{\partial r} \delta(D - H_{Int})\theta(-f) + \left(\frac{\partial f}{\partial r} p_r + \frac{\partial f}{\partial R} p_R\right)\delta(-f)\theta(D - H_{Int})\right]$$

where δ denotes the Dirac delta function. Substituting [12] into [5] and applying the assumption of the previous section concerning the parts of the integral which contribute to k_3 and k_4, one obtains

$$[13] \quad k_3 = (\beta\mathcal{I}_{Int})^{-1}(b/2)^{1/2} \int (F_3 + G_3)dR$$
$$k_4 = (\beta\mathcal{I}_{Int})^{-1}(b/2)^{1/2} \int (F_4 + G_4)dR$$

where F_3 and G_3 are given by

$$[14a] \quad F_3(R) = (2\pi)^{-1/2}(\beta/\bar{\mu})^{3/2} \int dr\, \delta(-f) \int dp_R dp_r \left(\frac{\partial f}{\partial r} p_r + \frac{\partial f}{\partial R} p_R\right)\theta\left(\frac{\partial f}{\partial r} p_r + \frac{\partial f}{\partial R} p_R\right) \times \theta(D - H_{Int})\theta(H - D)\exp(-\beta H)$$

$$[14b] \quad G_3(R) = (2\pi)^{-1/2}(\beta/\bar{\mu})^{3/2} \int dr\, \theta(-f) \int dp_R dp_r\, p_r \frac{\partial V_1}{\partial r}\theta\left(p_r \frac{\partial V_1}{\partial r}\right)\delta(D - H_{Int})\theta(H - D)\exp(-\beta H)$$

The functions F_4 and G_4 differ from F_3 and G_3 in that $\theta(H - D)$ in [14] is replaced by $\theta(H - D + \varepsilon_\infty)\theta \times (D - H)$. The branching ratio is given by

$$[15] \quad \Gamma = [\int (F_3 + G_3)dR]/[\int (F_4 + G_4)dR]$$

It is to be noted that the F's and G's are dimensionless. Since $\beta\mathcal{I}_{Int}$ has the units of time, it is clear from [13] that k_3 and k_4 have the units of velocity, as they should.

Integrations over r, p_R, and p_r in [14] require no special skill, only a certain amount of care. The mathematical manipulations involved are described in the Appendix. The zero of energy is taken to be the energy of the three atoms at infinite separation and at rest. Hence, D is set to zero. For F_3 and F_4 one obtains

$$[16a]\quad F_3(R) = (\{Z[\beta V_0(r_+)\csc^2\phi_+] - Z[\beta V(R,r_+)]\}\sec\phi_+ \exp[-\beta V_0(r_+)] - \{Z[\beta V_0(r_+)\operatorname{ctn}^2\phi_+] - Z[\beta V_1(R,r_+)]\} + 2(-\beta V_0(r_+)/\pi)^{1/2}\tan|\phi_+|\exp[\beta V_0(r_+) \times \operatorname{ctn}^2\phi_+])\exp[-\beta V_1(R,r_+)] \quad \text{for} \quad V_1(R,r_+) \geq V_0(r_+)\operatorname{ctn}^2\phi_+$$

$$= 2(-\beta V_0(r_+)/\pi)^{1/2}\tan|\phi_+| \quad \text{for} \quad V_1(R,r_+) < V_0(r_+)\operatorname{ctn}^2\phi_+$$

$$[16b]\quad F_4(R) = (\{Z[\beta V(R,r_+)] - Z[\beta V_c(R,r_+)]\}\sec\phi_+\exp[-\beta V_0(r_+)] - Z[\beta V_1(R,r_+)]) \times \exp[-\beta V_1(R,r_+)] \quad \text{for} \quad V_1(R,r_+) \geq V_0(r_+)\operatorname{ctn}^2\phi_+$$

$$= (\{Z[\beta V_0(r_+)\csc^2\phi_+] - Z[\beta V_c(R,r_+)]\}\sec\phi_+\exp[-\beta V_0(r_+)] - Z[\beta V_0(r_+)\operatorname{ctn}^2\phi_+] + 2(-\beta V_0(r_+)/\pi)^{1/2}\tan|\phi_+|\,\theta[-V_0(r_+)]\{\exp[\beta V_1(R,r_+)] - \exp[\beta V_0(r_+)\csc^2\phi_+]\})\exp[\beta V_1(R,r_+)] \quad \text{for} \quad V_1(R,r_+) < V_0(r_+)\operatorname{ctn}^2\phi_+$$

The function Z is defined by

$$[17]\qquad Z(\chi) = 2\pi^{-(1/2)}\,\theta(-\chi)\gamma(3/2, -\chi)$$

where γ denotes the incomplete gamma function. The function $r_+(R)$ is obtained by solving the equation

$$f(R,r) = 0$$

for r. The angle ϕ_+ is given by

$$[18]\qquad \tan\phi_+ = \mathrm{d}r_+/\mathrm{d}R$$

The potential functions V and V_c are given by

$$V = V_0 + V_1 \quad V_c = V + \varepsilon_\infty$$

For G_3 and G_4 one obtains

$$[19a]\quad G_3(R) = \pm\{1 - Z[\beta V_1(R,r_-)]\}\exp[-\beta V_1(R,r_-)] + 2\sum_m \pm\{1 - Z[\beta V_1(R,r_m)]\} \times \exp[-\beta V_1(R,r_m)] \pm \{1 - Z[\beta V_1(R,r_+)]\}\exp[-\beta V_1(R,r_+)]$$

$$[19b]\quad G_4(R) = \pm Z[\beta V_1(R,r_-)]\exp[-\beta V_1(R,r_-)] + 2\sum_m \pm Z[\beta V_1(R,r_m)]\exp[-\beta V_1(R,r_m)] \pm Z[\beta V_1(R,r_+)]\exp[-\beta V_1(R,r_+)]$$

where r_- is the value of r for which V_0 changes sign and is understood to be less than r_+. The r_m's are values of r between r_- and r_+ at which V_1 has maxima or minima. The plus signs in [19] apply at values of r for which V_1 is a minimum; the minus signs apply at maxima.

To proceed further, one needs explicit expressions for V_0, V_1, and f. In general these expressions will be such that the R-integration must be done numerically.

Extension to Three Dimensions

In the present work it is assumed that the one-dimensional k_3 and k_4 differ from their three-dimensional analogs by factors which are the same for both. It follows from this assumption that [15] may be used to estimate branching ratios for the corresponding three-dimensional system. Such is not the case for the rate constants themselves.

A fairly simple method for generalizing one-dimensional values of the recombination rate constant to three dimensions has been proposed (7). The result is given by eq. [14] of the just mentioned reference,

$$[20]\quad k_r = \frac{R_g\sigma h^3 X^*}{n\pi^2 m_A k\theta_r}\left(1 + \frac{2m_A}{m_M}\right)^{1/2}\tilde{T}^{1/n-1} \times \gamma(n^{-1}, \beta\varepsilon_c)r\sum_i P_{N+1,i}\exp(-\beta\varepsilon_i)$$

where R_g is the ratio of electronic degeneracies for the ground states of A_2 and 2A, σ is a hard sphere collision cross section, k is Boltzmann's constant, θ_r is the characteristic rotational temperature of A_2,

and $\tilde{T}$ is $(\beta D_e)^{-1}$. The parameters X^*, n, and ε_c characterize the angular momentum dependence of the height of the centrifugal barrier for a rotating Morse oscillator of well depth D_e. The way in which X^*, n, and ε_c are calculated is described in ref. 7. At low temperatures one can safely make the approximation

$$[21] \qquad n^{-1}\gamma(n^{-1},\beta\varepsilon_c) = \Gamma(1 + n^{-1})$$

where (in this section only) Γ denotes gamma function. The factor r is the non-equilibrium correction, which is set equal to one if k_r is assumed to be k_r^{eq}. The sum in [20] is related to the rate constant for the total disappearance of A_2,

$$[22] \quad \sum_i P_{N+1,i} \exp(-\beta\varepsilon_i) = \bar{u}^{-1} Q_{Int}(k_3 + k_4)$$

where Q_{Int} is the partition function for the vibrational degree of freedom of A_2, and $\bar{u}$ is the mean relative velocity of A_2–M pairs.

In the classical limit Q_{Int} is $h^{-1}\mathscr{I}_{Int}$. Hence, from [13] and [22] one obtains

$$[23] \quad \sum_i P_{N+1,i} \exp(-\beta\varepsilon_i) = (\pi b\mu/\beta)^{1/2}h^{-1} \times \int (F_3 + F_4 + G_3 + G_4)\,dR = (2\pi m_A \tilde{T} D_e/b)^{1/2}h^{-1}\mathscr{I}$$

In the second line of [23], [11] has been used, and $\mathscr{I}$ denotes the integral in the foregoing line. Combining [8], [20], [21], and [23] and using the standard formula (10) for θ_r of a diatomic molecule in terms of m_A and the internuclear distance r_e, one obtains

$$[24] \quad k_r^{eq} = 4\pi R_g X^* \Gamma(1 + n^{-1}) r_0^2 r_e^2 \times (2\pi D_e/m_A)^{1/2} \tilde{T}^{(1/n - 1/2)} b^{1/2} \mathscr{I}$$

where r_0 is the hard sphere collision diameter. The parameters n and X^* are fixed for given Morse parameters r_e and α. The only adjustable parameter in [24] is therefore r_0. Equation [24] gives the rate constant for recombination in three dimensions by reactions [1] and [2] together. In its derivation the tacit assumption has been made that k_3 and k_4 in three dimensions both differ from their one-dimensional analogs by the same factor. In this respect the derivation is consistent with the derivation of the branching ratio in the preceding section.

Explicit Formula for r_+

The function $r_+(R)$ is obtained by solving the equation

$$f(R,r) = 0$$

for r. Hence, the choice of a specific functional form for r_+ implies a choice of f. The graph of r_+ in the r–R plane represents that portion of the transition state surface which is most easily visualized.

The explicit form of r_+ to be used in the present study was motivated by several considerations. The first is that it must represent a curve which completely separates the A_2 + M region of configuration space from the AM + A region. Another is that it should be simple. A third is that it should depend on a parameter in order to allow some flexibility of choice. The potential energy surfaces assumed in the present work either have no saddle point or, at most, a saddle point of negligible height with respect to the AM + A valley. Hence, in the present study one cannot be guided in the standard way in one's choice of the transition state. The final, somewhat arbitrary condition on r_+ is that for some value of the parameter it should represent the transition state for a symmetric potential surface with a saddle point.

The above considerations led to the choice

$$r_+ = \tfrac{1}{3} bR + a\,\sigma_\infty/R$$

where a is the parameter, and σ_∞ is the equilibrium internuclear distance for isolated AM. In the present study a was chosen such as to minimize $k_3 + k_4$. Hence, it is not an adjustable parameter.

Numerical Results

Numerical evaluation of the integrals on the right of [13] was carried out using a subroutine based on Simpson's rule. All of the a-dependence of the rate constants is in these integrals. In a typical case, evaluation of $\mathscr{I}$ at five to ten values of a was sufficient to locate the minimum. As can be seen from eq. [19], the computation of G_3 and G_4 entails the location of relative maxima and minima in V_1. These extrema were found using a slightly modified version of Harwell Subroutine VD02A. The calculations reported here were done on a B6700, but it was found that calculations of this type can be performed satisfactorily on a PDP1103.

Thirty cases, six A_2–M combinations at each of five temperatures, were studied. They are the same as those reported in ref. 4. The potential function assumed is potential B of ref. 6. Morse functions with the standard Br_2 and I_2 parameters were used for V_0. For the sake of ready reference, these parameters are included in Table 1. Also for the sake of ready reference, the additional parameters which enter into V_1 are presented in Table 2. These parameters are the same as those used in ref. 4, thus making the results of this study and that one strictly comparable. The potential energy surface for Br_2 + Ar is depicted in Fig. 1. The potential surfaces for the other five A_2 + M combinations are qualitatively much the same.

	Xe	0.4100	0.390	1.84	2.9

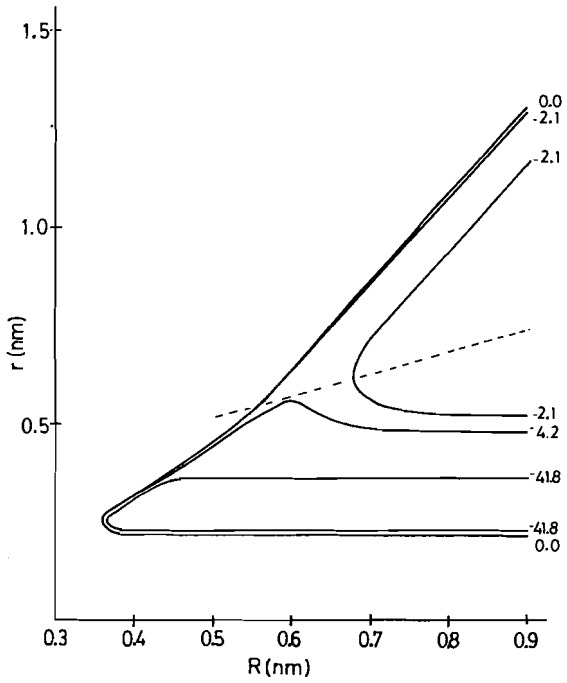

FIG. 1. Assumed potential energy surface for Br_2–Ar collisions. Note that the contours are not equally spaced in energy. The dashed line indicates the $r_+(R)$ curve for T = 1500 K.

In Table 3 the branching ratios calculated in the present study are presented along with those calculated in ref. 4. Agreement is seen to be fair for M = Xe and for M = Ar but poor for M = He. Also shown in Table 3 are the values of a, denoted a_m, for which the sum $k_3 + k_4$ is minimized. The resulting curve of $r_+(R)$ for Br_2 + Ar at 1500 K is shown in Fig. 1. In all cases a_m decreases somewhat with increasing temperature, but the resulting shift in $r_+(R)$ is never great.

The data of Table 3 are shown graphically in Fig. 2 as a plot of $\log_{10} \Gamma$ vs. $\log_{10} \beta\varepsilon_\infty$. The results of ref. 4 for M = Xe, Ar and the results of the present study all lie close to a straight line of slope $-3/2$. Interestingly, a $(\beta\varepsilon_\infty)^{-3/2}$ dependence of Γ was also found in three-dimensional trajectory studies of N_2 + Ar and Cl_2 + Ar (11). Finally, it can be seen from the scatter in the results from ref. 4 that some of the discrepancy between those results and the present ones is due to random numerical errors in the trajectory calculations.

Table 4 shows values of k_r^{eq} given by eq. [24] along with corresponding values from ref. 4. Also shown are the values of r_0, these having been obtained from a least-squares fit of the k_r^{eq}'s of ref. 4 to eq. [24]. Agreement of the k_r^{eq}'s is generally better than agreement of the Γ's, but it still must be regarded as only fair since an adjustable parameter has been used. Again, random errors in the trajectory calculations seem to be causing part of the disagreement. The best fit values of r_0 are smaller than the corresponding σ_0's of Table 2. This would be expected since transition state theory gives an upper bound. It is also to be noted that the r_0's do not increase in the same order as do the σ_0's, the values for M = He being most notably out of line.

Discussion

The results of the present study are in fair agreement with the results of a three-dimensional trajectory study of the same model (4) for the cases M = Xe, Ar. Agreement is poor for M = He. The discrepancies may be due to one or more of the three simplifying assumptions adopted in the present study. It will here be argued that the largest discrepancies between the results of this work and those of ref. 4, i.e. the discrepancies in the Γ's for M = He,

are due to a breakdown of the fundamental assumption of classical transition state theory.

From Table 4 one sees that the k_r^{eq}'s calculated in the present study agree fairly well with those calculated in ref. 4. The method of calculation used in the present study is based on a simple extension of one-dimensional results to three dimensions. This extension changes both k_3 and k_4 by the same factor. The implication is that a one-dimensional calculation should suffice to determine Γ. One therefore has evidence (albeit inconclusive) for the validity of using the analogous collinear model in calculations of Γ. Another bit of evidence is the $\beta\varepsilon_\infty$-dependence of Γ as shown in Fig. 2. It seems reasonable to suppose that the displacement of the trajectory values for M = He from a straight line is due to dynamical effects. It is less likely that the phase integrals of three-dimensional transition state theory differ in such an essential way from those of the one-dimensional theory that the resulting values

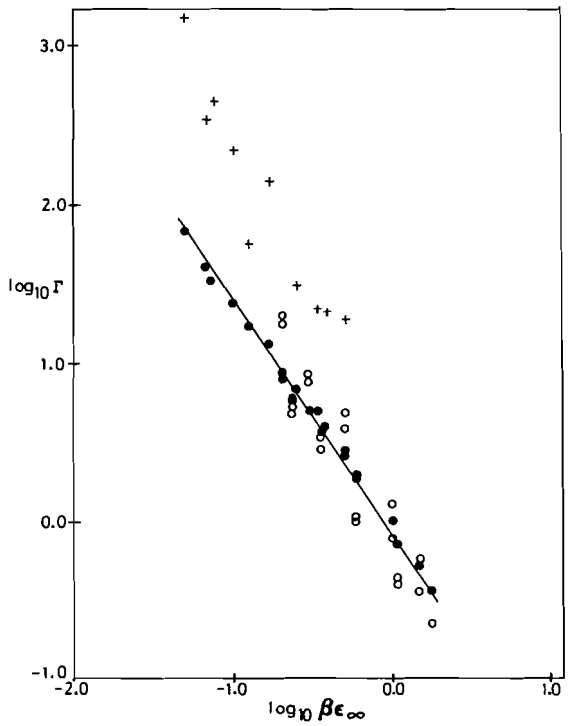

FIG. 2. log–log plot of the branching ratios from ref. 4 and from the present work. Filled circles represent results of the present work; open circles, results from ref. 4 for M = Xe, Ar; crosses, results from ref. 4 for M = He.

of log Γ as a function of log $\beta\varepsilon_\infty$ lie close to a straight line in the one case but not in the other. Thus the reduction to a collinear model does not appear to cause the large discrepancies between the Γ's calculated in the present work and those calculated in ref. 4.

As already mentioned, the assumed partitioning of the transition state surface is such as to give an upper bound to k_3 but not k_4. Since Γ is defined as k_3/k_4, it follows that this assumption as to the partitioning of the surface is more likely to overestimate Γ than to underestimate it. However, in the cases of worst disagreement the present calculations grossly underestimate Γ. One is therefore not inclined to ascribe these discrepancies to a breakdown of the assumption as to the partitioning of the surface.

One is left with the fundamental assumption of classical transition state theory, and at this point one should recall the physical significance of this assumption (5). The assumption is entirely valid provided that all trajectories which cross the transition state surface cross it only once. The more recrossings of the surface there are, the larger is the amount by which the transition state theory approximation overestimates the rate constant.

TABLE 4. Comparison of calculations of equilibrium rate constants for a model of halogen recombination in inert gases

				k_r^{eq} (10^9 L^2/mol^2 s)

			1000	0.96	0.86
			1500	0.85	0.67

It is reasonable to suppose that multiple crossings are most likely through that portion of the transition state surface which has been associated with the bound complex mechanism (11). There the total energy is lower, and hence, the effect of the A–M attractive forces is larger. This effect very likely manifests itself in more complicated trajectories which make more crossings of the transition state surface.

It may be noted in passing that one can now advance a plausible explanation for the relatively large values of r_0 obtained for M = He. As mentioned in the previous section, the ratio of r_0 to σ_0 is a rough indication of the amount by which the trajectory value of k_r^{eq} is reduced relative to the transition state theory value, said reduction being due to recrossings. In the case of M = He the contribution to the overall rate from reaction [4] is relatively small. Since this is the contribution expected to be most reduced by recrossings, the overall reduction due to recrossings is expected to be smaller in this case.

The very large values of Γ for M = He are an indication that the relative contributions from reaction [4] which are already smallest at the level of transition state theory are also most greatly diminished due to recrossings. However, the cause is probably different in the two cases. At the level of transition state theory a small contribution from [4] is most likely due to a small value of ε_∞, as is indicated by Fig. 2. The further reduction due to recrossing is more likely due to the small mass of He. One may ascribe at least some of the complexity of the recrossing trajectories to incipient vibration of AM. The frequency of this vibration increases as the reduced mass of AM decreases. Hence, it seems reasonable that the smaller mass of He should cause more recrossing of that part of the transition state surface which has been associated with the bound complex mechanism.

It should be emphasized that the foregoing arguments are no more than plausible. Only a thoroughgoing analysis of the trajectories for the model would rigorously account for the discrepancies between the results of the present work and those of ref. 4.

The method described herein provides fairly reliable values of relative rates for recombination by reactions [1] and [2] in cases where AM is weakly bound and the masses of A and M are large. Although the method requires considerably less computation than do the trajectories, the amount of computation which it does entail still seems excessive in view of the simplicity of the final results, as indicated by Fig. 2. A search for further simplifications therefore seems in order, and the results reported here are mainly of interest in that they illustrate the discrepancies which arise as a consequence of more fundamental approximations.

Acknowledgments

This work was supported by a grant from the National Research Council of Canada. A discussion of the preliminary results with Professor George Burns was quite helpful. Assistance with the computations was provided by Mr. John Aitkens, Mr. Robert MacPherson, Mr. Derek Cheung, and Mr. Kevan Kristjanson.

Appendix

The object of this section is to show how eqs. [16] and [19] follow from [14]. Derivation of [19] is simpler and will be considered first. Substitution in [14*b*] of [10] for H, replacement of p_r by H_{Int} via [9], and integration over H_{Int} gives

$$G_3 = (\beta/2\pi\bar{\mu})^{1/2} \int dr\, \theta(-f)\theta(-V_0)|\partial\beta V_1/\partial r| \exp(-\beta V_1) \int dp_R\, \theta(p_R^2/2\bar{\mu} + V_1) \exp(-\beta p_R^2/2\bar{\mu})$$

The equation for G_4 is the same except in that $\theta(p_R^2/2\bar{\mu} + V_1)$ is replaced by $\theta(p_R^2/2\bar{\mu} + V_1 + \varepsilon_\infty) \times \theta(-p_R^2/2\bar{\mu} - V_1)$. The first of the foregoing factors is practically redundant since V_1 almost always exceeds $-\varepsilon_\infty$. Substitution of t^2 for $\beta p_R^2/2\bar{\mu}$ gives

$$G_3 = \pi^{-1/2} \int dr\, \theta(-f)\theta(-V_0)|\partial\beta V_1/\partial r| \exp(-\beta V_1) \int dt\, \theta(t^2 + \beta V_1) \exp(-t^2)$$

When V_1 is negative, the interval $-(-\beta V_1)^{1/2} \leq t \leq (-\beta V_1)^{1/2}$ is excluded from the range of t-integration by the unit step function. Hence, one obtains

[A1] $$G_3 = \int dr\, \theta(-f)\theta(-V_0)|\partial\beta V_1/\partial r| \exp(-\beta V_1)\,[1 - \operatorname{erf}(-\beta V_1)^{1/2}\,\theta(-\beta V_1)]$$

and similarly for G_4

[A2] $$G_4 = \int dr\, \theta(-f)\theta(-V_0)|\partial\beta V_1/\partial r| \exp(-\beta V_1) \operatorname{erf}(-\beta V_1)^{1/2}\,\theta(-\beta V_1)$$

where erf denotes error function.

Recalling the definitions of r_+ and r_-, one sees that the step function $\theta(-V_0)\theta(-f)$ implies limits of r_+ and r_- for the r-integration. Replacing r by βV_1 as the variable of integration, one obtains a sum of integrals each with a maximum in βV_1 as upper limit and an adjacent minimum in βV_1 as lower limit. Equation [17] and two integrations by parts give

[A3] $$\int_0^{-\chi\theta(-\chi)} \operatorname{erf}(-t)^{1/2}\, e^{-t}\, dt = 4\pi^{-1/2}\, e^{-\chi} \int^{(-\chi)^{1/2}\theta(-\chi)} \exp(-u^2)\, du = Z(\chi)\, e^{-\chi}$$

Thus eqs. [A1]–[A3] yield eq. [19].

Preparatory to evaluation of the integral in [14*b*], define ϕ by the relation

$$\tan\phi = (\partial r/\partial R)_f$$

from which follow

[A4] $$\frac{\partial f}{\partial R} = -\left[\left(\frac{\partial f}{\partial R}\right)^2 + \left(\frac{\partial f}{\partial r}\right)^2\right]^{1/2} \sin\phi$$

$$\frac{\partial f}{\partial r} = \left[\left(\frac{\partial f}{\partial R}\right)^2 + \left(\frac{\partial f}{\partial r}\right)^2\right]^{1/2} \cos\phi$$

Furthermore, from eq. [18] one obtains

[A5] $$\tan\phi_+ = \left(\frac{\partial r}{\partial R}\right)_{f=0}$$

From eqs. [A4] and the definition of r_+ follows the relation

[A6] $$\bar{\mu}^{-1}\left(\frac{\partial f}{\partial r}p_r + \frac{\partial f}{\partial R}p_R\right)\delta(-f) = \bar{\mu}^{-1}(p_r\cos\phi - p_R\sin\phi)\sec\phi\,\delta(r - r_+)$$

Next let s and α be given by

[A7]
$$s^2 = \bar{\mu}^{-2}(p_R^2 + p_r^2)$$
$$\cos\alpha = (\bar{\mu}s)^{-1}(p_r\cos\phi - p_R\sin\phi)$$

Insertion of [9], [10], [A6], and [A7] into [14*b*] gives

[A8]
$$F_3 = (\beta\bar{\mu})^{3/2}(2\pi)^{-1/2}\int dr\,\delta(r - r_+)\sec\phi\,\exp(-\beta V)\int ds\,s^2\theta(\tfrac{1}{2}\bar{\mu}s^2 + V)\exp(-\tfrac{1}{2}\beta\bar{\mu}s^2) \times \int_{-\pi/2}^{\pi/2} d\alpha\cos\alpha\,\theta[-\tfrac{1}{2}\bar{\mu}s^2\cos^2(\phi - \alpha) - V_0]$$

In the corresponding equation for F_4, $\theta(\frac{1}{2}\bar{\mu}s^2 + V)$ is replaced by $\theta(\frac{1}{2}\bar{\mu}s^2 + V_c)\theta(-\frac{1}{2}\bar{\mu}s^2 - V)$ where V and V_c are defined in the text.

The limits for the α-integration in [A8] are $-\pi/2$ and $\pi/2$ for V_0 less than $-\frac{1}{2}\bar{\mu}s^2$. For V_0 between $-\frac{1}{2}\bar{\mu}s^2$ and $-\frac{1}{2}\bar{\mu}s^2\sin^2\phi$ the limits become $\phi + \arccos z$, $\pi + \phi - \arccos z$ for ϕ less than zero and $\phi - \pi + \arccos z$, $\phi - \arccos z$ for ϕ greater than zero where z is given by

$$z = (-2V_0/\bar{\mu}s^2)^{1/2}$$

For V_0 between $-\frac{1}{2}\bar{\mu}s^2\sin^2\phi$ and zero the integral breaks into two parts, one with limits $-\pi/2$, $\phi - \arccos z$ and the other with limits $\phi + \arccos z$, $\pi/2$. For V_0 greater than zero the integral is zero. Hence, on integration over α and substitution of t^2 for $\frac{1}{2}\beta\bar{\mu}s^2$, eq. [A8] becomes

$$F_3 = 4\pi^{-1/2}\int dr\,\delta(r - r_+)\theta(-V_0)\sec\phi\,\exp(-\beta V)\Big[\int_0^{(-\beta V_0\csc^2\phi)^{1/2}} t^2\theta(t^2 + \beta V)\exp(-t^2)\,dt - \cos\phi\int_{(-\beta V_0)^{1/2}}^{(-\beta V_0\csc^2\phi)^{1/2}} t(t^2 + \beta V_0)^{1/2}\,\theta(t^2 + \beta V)\exp(-t^2)\,dt + (-\beta V_0)^{1/2}\sin|\phi| \times \int_{(-\beta V_0\csc^2\phi)^{1/2}}^{\infty} t\theta(t^2 + \beta V)\exp(-t^2)\,dt\Big]$$

The first integral in brackets can be evaluated using [A3] as can the second after substituting

$$u^2 = t^2 + \beta V_0$$

The last integral is trivial as is the integral over r. The final result is seen to be eq. [16*a*].

For F_4 one obtains after integration over α

[A9]
$$F_4 = 4\pi^{-1/2}\int dr\,\delta(r - r_+)\theta(-V_0)\sec\phi\,\exp(-\beta V)\Big[\int_0^{(-\beta V_0\csc^2\phi)^{1/2}} t^2\theta(t^2 + \beta V_c) \times \theta(-t^2 - \beta V)\exp(-t^2)\,dt - \cos\phi\exp(\beta V_0)\int_0^{(-\beta V_0\operatorname{ctn}^2\phi)^{1/2}} u^2\theta[u^2 + \beta(V_1 + \varepsilon_\infty)] \times \theta(-u^2 - \beta V_1)\exp(-u^2)\,du + \tfrac{1}{2}\sqrt{-\beta V_0}\sin|\phi|\int_{(-\beta V_0\csc^2\phi)^{1/2}}^{\infty}\theta(w + \beta V_c) \times \theta(-w - \beta V)\,e^{-w}\,dw\Big]$$

Recalling that V_1 can be assumed to be always greater than $-\varepsilon_\infty$ and using [A3] and [A5], one readily reduces [A9] to [16*b*].

The enol content of simple carbonyl compounds: an approach based upon pK_a estimation

Rate constants for oxygen-base-catalyzed enolization of di- and tricarbonyl compounds can be correlated by a Marcus equation, with hydroxide requiring a slightly different curve from other oxyanions. Data for monocarbonyl compounds fall on a slightly different, but similar, set of curves. The equilibrium constants for enolization for a set of monocarbonyl compounds were derived from recent work in this laboratory. These correlations permit estimation of pK_a^{Keto} for a number of other monocarbonyl compounds from kinetics data in the literature. Elaboration of methods previously developed permits estimation of pK_a^{Enol}. From the values of pK_a^{Enol} and pK_a^{Keto}, pK_{Enol} can be derived. It is pointed out that pK_a^{Keto} for acetone and acetophenone can be determined from the kinetics of the reaction with hypochlorite in base; the values so derived are in good agreement with those used in this work. pK_{Enol} values are reported for: 1,3-dichloroacetone, 2.0; 1,1-dichloroacetone, 4.9; ethyl pyruvate, 4.2; bromoacetone, 3.5; chloroacetone, 3.7; 1-phenyl-2-propanone, 4.5 (CH_2); 7.2 (CH_3); *p*-nitroacetophenone, 7.1; ethyl levulinate, 5.6; methoxyacetone, 6.9 (CH_2); 7.6 (CH_3); benzalacetone, 7.6; *p*-methoxyacetophenone, 7.8; 3-methyl-2-butanone, 8.0 (CH); 2,4-dimethyl-3-pentanone, 9.4.

J. PETER GUTHRIE. Can. J. Chem. 57, 1177 (1979).

Les constantes de vitesse de l'énolisation catalysée par des bases oxygénées de composés di- et tricarbonylés peuvent être reliées par une équation de Marcus dans laquelle l'hydroxyde demande une courbe légèrement différente de celle des autres oxyanions. Les données pour les composés monocarbonylés tombent sur un ensemble de courbes légèrement différentes mais semblables. On a déduit les constantes d'équilibre pour l'énolisation d'un ensemble de composés monocarbonylés, à partir d'un travail récent de notre laboratoire. Ces corrélations permettent d'évaluer le $pK_a^{Céto}$ d'un certain nombre d'autres composés monocarbonylés à partir des données cinétiques que l'on peut trouver dans la littérature. Une élaboration des méthodes développées antérieurement permet d'évaluer le pK_a^{Enol}. A partir des valeurs de pK_a^{Enol} et $pK_a^{Céto}$, on peut obtenir le pK_{Enol}. On met en évidence que les $pK_a^{Céto}$ de l'acétone et de l'acétophénone peuvent être déterminés à partir de la cinétique de la réaction de l'hypochlorite en milieu basique; les valeurs ainsi obtenues sont en bon accord avec celles utilisées dans ce travail. On rapporte des valeurs de pK_{Enol} pour le: dichloro-1,3 acétone, 2.0; dichloro-1,1 acétone, 4.9; pyruvate d'éthyle, 4.2; bromoacétone, 3.5; chloroacétone, 3.7; phényl-1 propanone-2, 4.5 (CH_2); 7.2 (CH_3); *p*-nitroacétophénone, 7.1; lévulinate d'éthyle, 5.6; méthoxyacétone, 6.9 (CH_2); 7.6 (CH_3); benzalacétone, 7.6; *p*-méthoxyacétophénone, 7.8; méthyl-3 butanone-2, 8.0 (CH); diméthyl-2,4 pentanone-3, 9.4.

Introduction

The problem of determining the enol content of simple carbonyl compounds has proven to be difficult and intractable. Early attempts to measure the enol content of such compounds as acetone (1, 2) have been shown to be subject to serious systematic errors (3, 4). Even the most modern variations on the halogen titration method (4) lead to results which are sometimes in conflict with the conclusions of other less direct measurements (5–7). Only very recently has it been possible to determine the enol content of some simple ketones by an indirect kinetic approach (8, 9) and this method requires specialized apparatus and considerable labor. We have presented in recent papers (7, 10) two general methods for evaluating the enol content of carbonyl compounds. This paper presents a third method which permits a great many further equilibrium constants to be evaluated from data in the literature.

It has been common practice for many years, following a suggestion of Bell (11), to estimate the pK_a for the keto form of carbonyl compounds from the rate of proton abstraction, using some form of rate equilibrium correlation. We have refined this procedure and have found that it is not permissible to use the correlation line for di- and tricarbonyl compounds for monocarbonyl compounds as has been done in the past (11, 12). By taking advantage of the work described in the earlier papers (7, 10), we can generate a correlation between rate and equilib-

rium constants for monocarbonyl compounds, and use this to estimate pK_a values for the keto tautomers of numerous additional compounds.

Procedures for estimating the pK_a values of alcohols on the basis of substitutent effects have been developed and widely used (13). We have extended this approach to give estimates of the pK_a of enols. If the pK_a for both the keto and the enol tautomer are known, then the equilibrium constant for enolization, K_{Enol}, is also known, since by definition:

$$K_{Enol} = K_a^{Keto}/K_a^{Enol}$$

This procedure does not lead to precise estimates of the enol content but it does give answers of useful accuracy and has the advantage of being extremely simple.

Results and Discussion

In Table 1 are collected data for oxygen base catalyzed enolizations of carbonyl compounds for which the pK_a is measurable by titration. To apply rate equilibrium correlations, it is important to have sets of reactions with transition states identical as to atoms undergoing changes in bonding, and charge type of reactants and products; accordingly, the data are divided into reactions catalyzed by oxyanions other than hydroxide, reactions catalyzed by hydroxide, and uncatalyzed (or water-catalyzed) reactions. There are also some data for amine-catalyzed reactions but since these only refer to simple enolization for tertiary amines and the set of data for tertiary-amine-catalyzed reactions was comparatively small, these catalysts were not considered in this initial examination of the method.

All of the rate and equilibrium constants were corrected for the number of enolizable hydrogens. The data were fitted to the simplest of the equations derived by Cohen and Marcus (14) to correlate rate and equilibrium constants:

$$[1] \qquad \log k = 10 - b[1 - (\log K/4b)]^2$$

This equation assumes that reaction involves diffusion together of catalyst and substrate (with a rate constant of $10^{10}\ M^{-1}\ s^{-1}$ (15)) reaction within the encounter complex, and diffusion apart of the products. The parameter b, the 'intrinsic barrier,' is defined as the barrier to reaction when $\log K = 0$; in the treatment used here the intrinsic barrier includes both the free energy of activation required to achieve proton transfer and also the free energy cost of forming the, presumably very weak, hydrogen bond between catalyst and substrate. More elaborate equations derived by Marcus (14) include a 'work term' which allows for this latter contribution; however, inclusion of a work term necessarily increased the number of parameters. As will be seen below the available data are satisfactorily described by the simple equation used, and show no systematic deviations which would justify the inclusion of an additional parameter.

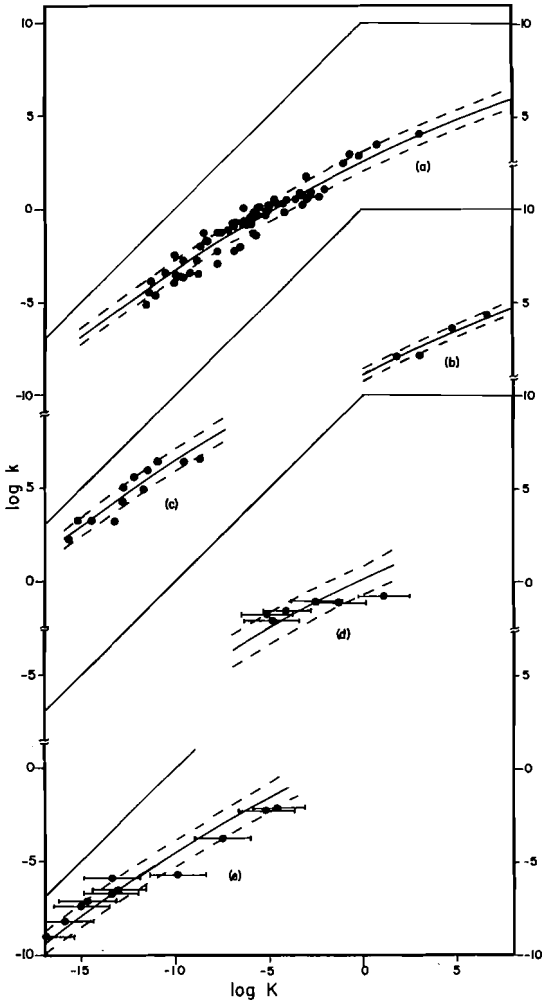

FIG. 1. Marcus plots for base-catalyzed enolization; for each curve the line corresponding to the best value of b (solid lines) and b plus or minus one standard deviation (dashed lines) are shown. Scales are offset by increments of 5–10 log units as indicated in order to avoid overlap. (*a*) Oxyanions other than hydroxide with di- or tricarbonyl compounds; (*b*) hydroxide with di- or tricarbonyl compounds; (*c*) water with di- or tricarbonyl compounds; (*d*) hydroxide with monocarbonyl compounds; (*e*) oxyanions other than hydroxide with monocarbonyl compounds.

The data for oxyanion bases other than hydroxide are found in Table 1*a*; Fig. 1 shows that these data are satisfactorily described by [1] with a b value of 7.50 ± 0.56. (A value of b was calculated for each point and all of the b values were averaged.) For any single substrate the scatter would be less.

In Table 1*b* are collected data for hydroxide-cata-

[o]A value of 8.02 (0.9) can be calculated from data in refs. 8 and 9.

lyzed enolizations. Figure 1 shows that these data are satisfactorily described by a b value of 8.89 ± 0.38. Unfortunately there are relatively few data for this process; this is a consequence of the very rapid reactions involved, so that only the limited number of laboratories equipped for fast kinetics can measure the rate constants. It is common to find that hydroxide ion does not fit Brønsted plots for oxyanion catalysts and this is borne out by the distinctive b value observed. One is tempted to speculate that the larger b value for hydroxide may represent the greater cost in lost solvation energy on forming the very weak hydrogen bond between hydroxide and substrate relative to the other oxyanions.

In Table 1*c* are collected data for water catalyzed enolizations. These reactions were assumed to represent general base catalyzed reaction. Figure 1 shows that the data are satisfactorily described by a b value of 7.74 ± 0.69. Although this is in fact indistinguishable from the value observed for oxyanions, it seems unwise to average them or to assume that this identity of b values is a general phenomenon, since the charge types of the reactions are so different: neutral plus neutral to anion plus cation, as opposed to anion plus neutral to neutral plus anion.

Earlier papers in this series (7, 10) reported evaluation by two independent methods of equilibrium constants for enolization of a number of simple carbonyl compounds. For these compounds equilibrium constants can now be correlated. The data employed are found in Table 2. Table 2*a* reports the available data for hydroxide-catalyzed enolization; Fig. 1 shows that these data are described by a b value of 9.90 ± 0.85. It is apparent that these equilibrium constants are significantly less precise than the titrimetric values used for polycarbonyl compounds and that the fit is distinctly poorer. On

TABLE 4. pK enol values for simple carbonyl compounds, predicted by estimating pK_a^{Keto} and pK_a^{Enol}

the other hand the available data do appear to conform to [1].[2] The b values for mono- and for polycarbonyl compounds are not demonstrably different, although it appears likely that with more and better data they would be shown to differ; in particular the low values of b for the monocarbonyl compounds are found for the equilibrium constants which are least reliable, namely those for methyl ethyl ketone and diethyl ketone, where free energies of formation of the enol ethers were either estimated or derived by indirect means. Furthermore the set of data for polycarbonyl compounds is very small.

Table 2*b* reports the available data for oxyanion catalyzed enolization; Fig. 1 shows that these data are described by a b value of 8.86 ± 0.78. This value seems to be clearly different from that observed for the polycarbonyl compounds[3] and lends support to the belief that the b values for hydroxide-catalyzed reactions will also turn out to be different.

The advantage of having performed these correlations is that they can now be used to calculate unknown equilibrium constants for enolate formation from rate constants for enolization. This is not particularly useful for polycarbonyl compounds where direct measurement is normally possible but is of great potential value for simple monocarbonyl compounds where the enol content is not readily determined.

The procedure employed is to calculate equilibrium constants for all enolizations for which rate constants are available, using the b values for monocarbonyl

[2]A referee has pointed out that the trend of the data for monocarbonyl compounds is in the direction expected if the 'work term' in the Marcus equation is larger than for diffusion alone; although we agree, we feel that the data are too few and of too low precision to justify inclusion of an additional parameter; caution in the use of these correlations for extrapolation is indicated and it would clearly be very desirable to have more data for reactive monocarbonyl compounds.

[3]The mean values are different at the 99% confidence level by the t-test (51).

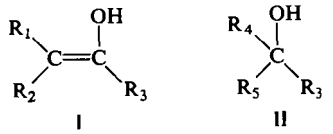
[h]Reference 41; corrected for hydration as described in ref. 42.
[i]Reference 43; corrected for hydration as described in ref. 44.
[j]Calculated from the rate constant for detritiation (ref. 36) assuming that k_H/k_T is the same as for pNO_2—C_6H_6—$COCH_3$, i.e. 18.2 (ref. 37).
[k]Reference 37.
[l]Reference 45.
[m]Reference 46; the rate constants were corrected for the temperature change from 35 to 25°C by assuming that the entropy of activation is the same as for the reactions of hydroxide with acetone (ref. 47) and for the primary deuterium isotope effect by using a value for this effect estimated from the rate constant using the correlation reported by Kresge *et al.* (35).
[n]Calculated from the rate constants for detritiation (ref. 36) assuming that k_H/k_T is the same as for *p*-chloroacetophenone, i.e. 14.8 (ref. 37).
[o]Calculated from the rate constant for detritiation (ref. 36) assuming that k_H/k_T is the same as for *m*-methylacetophenone, i.e. 15.8 (ref. 37).
[p]Calculated from the rate constant for detritiation (ref. 36) assuming that k_H/k_T is the same as for *p*-methylacetophenone, i.e. 14.8 (ref. 37).
[q]Calculated from the rate constant for detritiation (ref. 36) assuming that k_H/k_T is the same as for acetophenone, i.e. 15.1 (ref. 37).
[r]Reference 48; the data were corrected from 41.85 to 25°C, assuming that relative rates would be the same at both temperatures, using acetone as a standard; the rate constant for acetone was taken from ref. 38.
[s]Reference 49; the rate constants reported in this paper were measured in 2:1 dioxane–water at 32°C; it was assumed that relative rates would be the same in water at 25°C; acetone was used as a standard (ref. 38).
[t]Calculated from the rate constant for detritiation (ref. 36) assuming that k_H/k_T is the same as for acetone, i.e. 13.1. (Calculated using k_H from ref. 38 and k_T from ref. 47.)

compounds; then from the known pK_a values for the catalysts, the pK_a^{Keto} values can be calculated. These are averaged for each compound, using data for all bases which have been studied. There are in some cases serious discrepancies, amounting to 1 or 2 pK_a units; however, since error analysis suggests that the pK_a^{Keto} values cannot be better than ±2 pK_a units, given the nature of the correlations and the data, this is not a basis for rejecting the method but simply an illustration of its imperfections.

The scatter of the estimated pK_a^{Keto} values is indicated by the standard deviations calculated for the average pK_a^{Keto} values; in all cases this is less than the 2 pK unit uncertainty expected for each value. The final values of pK_{Enol} are assumed to be uncertain by about 2 pK units; this error arises mainly from the uncertainty in the enol content of the monocarbonyl compounds used to determine b and can only be reduced by more precise determination of these enol contents. Rate equilibrium correlations cannot be precise when the structural variation is close to the reaction site, as in the present case. On the other hand, such correlations are not of much utility unless they apply over a wide range of reactivity; there is thus a sort of uncertainty principle which dictates that one can have precise correlations over such a narrow range of structural types as to have little predictive utility, or one can have approximate correlations over wide ranges of structural types which are of considerable predictive utility. The present correlation falls in the latter category; by analogy with the behaviour shown by the polycarbonyl compounds, which obey [1] over a range of 15 powers of 10 in equilibrium constant, we expect that the correlation of monocarbonyl compounds, which is closely similar, will be of similar wide applicability, although the data presently available are over a narrower range of equilibrium constants than is desirable.

To calculate pK_{Enol} from pK_a^{Keto} it is necessary to estimate pK_a^{Enol}. In a recent paper (7) methods were developed to do this, making use of the analogies of

alcohol and phenol pK_a values for which well accepted linear free energy relations linking pK_a and σ^* or σ are available. For an enol **I**, the effects of



I II

substituents R_1 and R_2 upon the enol pK_a are assumed to be the same as the effects of the same substituents in the *ortho* position of a phenol upon the pK_a of the phenol. For R_1 the analogy is obviously very close; for R_2 it is less so and the assumption that the effects are the same must introduce an error. However, since the largest ΔpK_a for a substituent (chloro) is 1.4, and the difference in ΔpK_a between *cis*- and *trans*-chloro seems unlikely to be a large fraction of this, the error will not be prohibitively large. For R_3 the effect on the enol pK_a is assumed to be the same as for the effect upon the alcohol pK_a in **II**, which is estimated using the correlation with σ^* of Takahashi *et al.* (13). The ΔpK_a values and related data are contained in Table 3 which has been deposited within the Depository of Unpublished Data.[4] The starting point for the estimations is the pK_a of the enol of acetophenone, which have been recently evaluated by Novak and Loudon (16) as 11.0. Since the zero point for σ^* is methyl and not phenyl, a more convenient reference point for calculations is the enol of acetone, which can be estimated to have pK_a of 11.8 from the difference in σ^* for methyl and phenyl. The pK_a^{Enol} values so estimated are found in Table 4, as are the pK_{Enol} values we calculate.

In this connection it is of interest that there is a check upon the pK_a^{Keto} values deduced for acetone and acetophenone. Dubois and Toullec (8, 9) have demonstrated that the reaction of the enol of acetone with halogens is diffusion controlled, since the rate constants for the reaction of the enol with chlorine, bromine, or iodine are identical. It is reasonable to anticipate that the rate constant for the reaction of the enolate would be even faster and that even for a slightly less reactive halogenating agent such as hypochlorous acid the reaction of the enolate would be diffusion controlled. Many years ago, in a study which has not received the attention it deserves, Bartlett and co-worker (17, 18) investigated the base catalyzed chlorination of ketones and demonstrated a change in kinetic form from zero order in halogen to first order in halogen with increasing concentration of hydroxide ion. Furthermore the kinetics for the pseudo-second-order reaction of ketone and halogen required both a water catalyzed and a hydroxide catalyzed path; i.e.,

$$v = k_{obs}\,[\text{halogen}]\,[\text{ketone}] \qquad k_{obs} = a + b[OH^-]$$

In alkaline aqueous solutions of chlorine the major species is ClO^-. The kinetic term proportional to hydroxide concentration is clearly due to the reaction of enolate ion with hypochlorite; this reaction between two anions would be expected to be fast but not diffusion controlled. The hydroxide independent term is most reasonably ascribed to reaction of enolate with hypochlorous acid; the kinetically equivalent reaction of enol with hypochlorite should be much slower than the reaction of the enolate but the two terms in the rate law are of similar magnitude in 0.1 *N* NaOH.

If we assume the above interpretation of the rate law and that the reaction of enolate with hypochlorous acid is diffusion controlled, then the rate constant for this reaction is given by:

$$k_{obs} = k_{diff}K_a^{Keto}/K_a^{HOCl}$$

and

$$K_a^{Keto} = k_{obs}K_a^{HOCl}/k_{diff}$$

Bartlett's (17, 18) kinetics were performed at 35°C; K_a^{HOCl} at 35°C was calculated from the thermodynamic parameters tabulated by Larson and Hepler (19); k_{diff} was taken as $10^{10}\ M^{-1}\ s^{-1}$ (15). Then from the rate constants for the hydroxide independent contribution to the reaction rate the pK_a^{Keto} values for acetone and acetophenone can be calculated as 19.1 and 18.0 (at 35°C) in remarkably good agreement with the values deduced from the values for pK_a^{Enol} and pK_{Enol} given in a recent paper (7), namely 19.0 and 17.7, respectively (at 25°C). It appears that the hypochlorite method should be a very powerful tool for determining pK_a^{Keto} in aqueous solution.

The results in Table 2 for pK_a^{Keto} are relatively unsurprising and show the sorts of effects which one would have intuitively expected. The values predicted for pK_{Enol}, on the other hand are frequently quite surprising. It is to be hoped that independent means can be found to check some of these values to test the validity of our method. In particular, the contrast between 1,1- and 1,3-dichloroacetone is quite striking, since one would not have expected that having the second chlorine *not* attached to the enol double bond would favor enolization more than having it attached. This can be rationalized in terms of the beneficial effects of avoiding steric congestion which is imposed on the 1,1-isomer. Steric effects appear in both pK_a^{Enol} and pK_a^{Keto} but are automatically allowed for by our empirical method for

[4]Copies of material on deposit may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

evaluating pK_a^{Keto}; there should be little or no steric effect upon pK_a^{Enol}. Although the methods which we have used to estimate pK_a^{Enol} are admittedly crude, it seems highly unreasonable that they can be grievously in error.

The principal reason why an approach such as the present one has not been proposed before is probably that there has been, until very recently, no unambiguous independent value for the pK_a for any simple enol which could be used as a starting point for estimating pK_a values for other enols. Now that one such value has been reported by Novak and Loudon (16), it is possible to estimate such pK_a values with considerable confidence that they are at least approximately correct, because of the considerable body of knowledge concerning the effects of substituents on the pK_a values of various classes of compounds.

Conclusions

By the methods outlined in this paper, it is possible to estimate the pK_{Enol} for any carbonyl compound for which kinetic data for oxyanion catalyzed enolization are available at 25°C in water.

Low temperature (−70°C) irradiation of 3,3,4,5-tetramethyl-3*H*-pyrazole (**2***a*) leads to the formation of the 1,2-diazabicyclo[2.1.0]pent-2-ene (**3***a*), as has been reported previously. Irradiation of 3,3-dimethyl-4,5-diphenyl-3*H*-pyrazole (**2***b*) under identical conditions did not result in formation of the analogous product but lead instead to formation of the cyclopropene via decomposition of the vinyl diazo compound. The thermal rearrangements of **2***a* and a series of 5-aryl-3,3-dimethyl-4-phenyl-3*H*-pyrazoles (**2***b–d*) lead to formation of the 4*H*-pyrazoles **6***a–d* and the *N*-methylpyrazoles **5***a–d*, resulting from competitive methyl migrations to carbon and nitrogen. The Arrhenius parameters for the rearrangement of **2***b* were determined. Decomposition of the methiodides derived from the 4*H*-pyrazoles **6***a–d* leads to formation of the *N*-methylpyrazoles **5***a–d*; the mechanism of this decomposition was examined by high temperature ^{1}Hmr spectroscopy. The *N*-methylpyrazoles were synthesized by independent routes and the structures were assigned with the aid of lanthanide shift reagents, ^{1}Hmr solvent shift studies, and ^{13}Cmr spectroscopy. The thermodynamic equilibria of the isomeric *N*-methylpyrazoles were determined and found to be influenced by a small substituent effect. The photochemical and thermal behaviour of 3*H*-pyrazoles is discussed and compared to that of 1-pyrazolines.

WILLIAM J. LEIGH et DONALD R. ARNOLD. Can. J. Chem. **57**, 1186 (1979).

L'irradiation à basse température (−70°C) du tétraméthyl-3,3,4,5 3*H*-pyrazole (**2***a*) conduit à la formation du diaza-1,2 bicyclo[2.1.0] pentène-2 (**3***a*) comme il a été rapporté antérieurement. L'irradiation du diméthyl-3,3 diphényl-4,5 3*H*-pyrazole (**2***b*) dans des conditions semblables ne conduit pas à la formation du produit analogue mais plutôt à la formation d'un cyclopropène par l'intermédiaire de la décomposition du composé vinyldiazo. Les transpositions thermiques de **2***a* et d'une série d'aryl-5 diméthyl-3,3 phényl-4 3*H*-pyrazoles (**2***b–d*) conduisent à la formation des 4*H*-pyrazoles (**6***a–d*) et des *N*-méthylpyrazoles (**5***a–d*) provenant de migrations compétitives de méthyles vers le carbone ou l'azote. On a déterminé les paramètres d'Arrhénius pour la transposition de **2***b*. La décomposition des méthiodures des 4*H*-pyrazoles **6***a–d* conduit à la formation des *N*-méthylpyrazoles **5***a–d*; on a étudié le mécanisme de cette décomposition par spectroscopie rmn ^{1}H à haute température. On a synthétisé les *N*-méthylpyrazoles par d'autres méthodes et on a attribué leurs structures grâce aux déplacements induits par les lanthanides, à des études de déplacements chimiques induits par les solvants et par spectroscopie rmn ^{13}C. On a déterminé les équilibres thermodynamiques des *N*-méthylpyrazoles isomères et on a trouvé qu'ils sont influencés par des petits effets de substituants. On discute des comportements photochimique et thermique des 3*H*-pyrazoles et on les compare à ceux des pyrazolines-1.

[Traduit par le journal]

Introduction

The photochemical and thermal reactions of 1-pyrazolines (**1**) have been extensively studied. Although some questions may still remain regarding the details of the mechanism(s), the overall course of the reaction is, predictably, extrusion of nitrogen followed by formation of the cyclopropane and/or propylene for both modes of activation (reaction [1]) (1). The photochemical and thermal behaviour of the analogous 3*H*-pyrazoles (**2**) is much less well understood and is clearly not yet fully predictable. Four types of reactions have been described for derivatives of this system. The two modes of activation invariably lead to different types of products in each case. Reactions [2] and [3] have been observed upon photochemical excitation and reactions [4] and [5] are typical thermal reactions.

Reaction [2], formally a photochemically allowed 4π*e* disrotatory electrocyclic ring closure (2), has been observed only upon irradiation at low temperature (< −40°C), presumably because the 1,2-diazabicyclo[2.1.0]pent-2-ene product (**3**) is thermally unstable and reverts to the starting material at higher temperatures. The only reported examples of this reaction involve fully alkylated 3*H*-pyrazoles (3). The more common photochemical reaction is formation of the vinyl diazo compound (reaction [3]) (4 and references cited therein). This reaction can be

[1] 
viewed as a 6e electrocyclic ring opening. Photochemical decomposition of the vinyl diazo compound (**4**) then leads to the cyclopropene, whereas thermal activation can lead to decomposition to give the cyclopropene (4) and/or to a concerted recyclization back to the 3*H*-pyrazole (5, 6). In those cases studied in detail, there was little or no direct loss of nitrogen from the 3*H*-pyrazole; that is, without the intermediacy of the vinyl diazo compound (4). Similarly, to our knowledge, there is no report of a photochemical sigmatropic rearrangement of a 3*H*-pyrazole.

Reactions [4] and [5] can be thermally allowed suprafacial [1,5]-sigmatropic rearrangements, although other mechanisms may be involved under some conditions (6). There are now numerous reports of these reactions in the literature (7–9). Usually, one of the possible products (**5** or **6**) predominates to the exclusion of the other, although

[4] 
[5] 
there have been two recent reports of competitive rearrangements (9, 10). In view of the facile thermal loss of nitrogen from the 1-pyrazolines, it is surprising that this reaction is not an important thermal reaction of 3*H*-pyrazoles. We know of only two, rather special, examples (5*b*, 9).

In this paper, we report the results of a study of the photochemical and thermal reactions of the 3*H*-pyrazoles, **2***a–d*. Results from the series **2***b–d* allow an assessment of the importance of electronic factors on reactions [4] and [5]. The kinetic parameters for the competitive [1,5]-sigmatropic rearrangements of **2***b* have been measured and the competition between these rearrangements and loss of nitrogen is discussed in light of these results.

Results

The 3*H*-pyrazoles **2***a–d* were known compounds, prepared as part of our earlier study, by the reaction of hydrazine and the corresponding α,β-unsaturated ketones followed by oxidation of the 2-pyrazolines (4).

The irradiation of **2***a*, at low temperature, has been studied previously (**3***a*, *b*) and our results agree with those reported. The proton magnetic resonance spectra (^{1}Hmr) of the irradiated solution, kept at low temperature, indicates the 1,2-diazabicyclo[2.1.0]pent-2-ene, **3***a* (R_1–R_4 = CH_3) was formed in high yield. When this solution was allowed to warm to room temperature, the ^{1}Hmr spectrum indicated almost quantitative reversion to starting material; there was a small amount (<5%) of tetramethylcyclopropene also detected. When **2***b* was irradiated under comparable low temperature conditions, no diazabicyclopentene was detected; 3,3-dimethyl-1,2-diphenylcyclopropene was observed (^{1}Hmr). When the irradiation of the 3*H*-pyrazoles **2***a–d* was carried out at 10°C, first the vinyl diazo compounds (**4***a–d*) and subsequently the cyclopropenes were produced in high yield (4). We found no evidence in any case for formation of a rearrangement product.

The thermal rearrangement studies were carried

out in degassed, sealed tubes with diphenyl ether as solvent. Progress of the reaction was followed by ^{1}Hmr spectroscopy. When **2***a* was heated at 182°C, reaction was essentially complete after 11 h and *N*-methylpyrazole, **5***a* (R_1–R_4 = CH_3, 36%), and 4*H*-pyrazole, **6***a* (R_1–R_4 = CH_3, 64%), were produced. Continued heating (ca. 50 h) of this mixture resulted in complete conversion of **6***a* to **5***a*. The rate of disappearance of **2***a*, determined from the integrated ^{1}Hmr spectra, followed first-order kinetics (Table 1). The rate constant and product ratio were the same, within experimental error, when diphenyl ether – pyridine (10:1) was the solvent. The products (**6***a* and **5***a*) were identified by comparison of their spectra (ir, ^{1}Hmr) with those of authentic samples of the known compounds.

The thermal (194°C, 6 h) rearrangement of **2***b–d* also leads to the formation of two products, **5***b–d* and **6***b–d*. The other possible *N*-methylpyrazoles (**5***e–g*) were *not* detected in these reaction mixtures. In these cases, both of the products, **5***b–d* and **6***b–d*, were stable to further heating at this temperature so the product ratios reflect the relative rates of formation. The rate of disappearance of the 3*H*-pyrazoles and the product ratios were determined by integrating the ^{1}Hmr spectra. The rate of reaction of **2***b* was also studied as a function of temperature. These results are summarized in Table 1.

The products from these thermal rearrangements were isolated by column chromatography; they are all new compounds. The structure assigned to the 4*H*-pyrazoles **6***b–d* was first suggested by a comparison of their spectra (ir, ^{1}Hmr, and uv) with those of similar known compounds; these data are summarized in the Experimental. Treatment of **6***a–d* with methyl iodide leads to formation of the 4*H*-pyrazolium iodides **7***a–d*, which were also fully characterized. When compounds **7***b–d* were heated to their melting points under vacuum, methyl iodide was lost and the *N*-methylpyrazoles **5***b–d* were obtained in essentially quantitative yield. When **7***a* was subjected to the same conditions, **5***a* was obtained along with an appreciable quantity of its methiodide **9***a*. The position of the *N*-methyl substituent in compounds **7***b–d* was assigned partially from the fact that thermal decomposition gives only the analogous *N*-methylpyrazoles **5***b–d*. Furthermore, the ^{1}Hmr spectra of the series **7***a–d* show the expected small coupling of the *N*-methyl protons with the adjacent methyl group which is shifted significantly downfield.

We wondered if the *N*-methyl substituent in **7***a–d* could equilibrate between the nitrogens before the thermal decomposition, although the isomeric salts were never detected. This possibility was tested by studying the ^{1}Hmr spectrum of **7***a* at high temperature (80–150°C). The shape and position of the two singlets due to the methyls at carbons 3 and 5 remained unchanged even at 150°C. Furthermore, double irradiation of either the C-3 or C-5 methyl signals had no measurable effect on the integrated intensity of the other at this temperature. We conclude that any exchange of the methyl group between nitrogen-1 and -2 must be slow relative to the proton nuclear spin relaxation process. The formation of the *N*-methylpyrazole, methyl iodide, and 1,2,3,4,5-pentamethylpyrazolium iodide and the concomitant disappearance of **7***a* was clearly evident during the time required to carry out this ^{1}Hmr study at these temperatures.

The isolation of the *N*-methylpyrazoles **5***b–d* from reaction [7] effectively rules out the occurrence of any unsuspected rearrangement during the course of reactions [5], [6], or [7].

The gross structures of the *N*-methylpyrazoles **5***b–d* were established by comparison of their spectra (ir, ^{1}Hmr) with those of the products from an alternative synthesis. Condensation of methyl hydrazine with the 1,2-diaryl-1,3-butanediones (**8***b*, *d*, and *h*)

gave the *N*-methylpyrazoles **5***b*, *d*, *e*, *g*, *h*, and *i* (reaction [8]). We were unable to synthesize the *para*-cyano diketone (see Experimental), so the *para*-cyano pyrazoles **5***c* and *f* were obtained by treatment of the *para*-bromo derivatives (**5***h* and *i*) with cuprous cyanide (reaction [9]). The isomeric pairs were separated by column chromatography.

The assignment of structure of the isomers was made largely on the basis of nuclear magnetic resonance studies; both ^{13}Cmr and ^{1}Hmr spectra were used. There are distinct differences in the spectra which allow the isomers to be divided into the two series **5***b–d* and **5***e–g*. Solvent and shift reagent studies on the ^{1}Hmr spectra of the isomeric pair **5***b* and **5***e* were then particularly useful for distinguishing the two series.

The spectra of **5***b* and **5***e* in the presence of varying amounts of the lanthanide shift reagents, Eu(fod)$_3$ and Pr(fod)$_3$, are summarized in Figs. 1 and 2. The *N*-methyl protons in **5***b* are shifted ca. 1.3 ppm by Eu(fod)$_3$ and 2.7 ppm by Pr(fod)$_3$,[3] while the *C*-methyl protons are shifted to a considerably lesser extent (0.6 and 0.7 ppm by Eu(fod)$_3$ and Pr(fod)$_3$, respectively). Two of the aromatic protons, presumably the *ortho*-protons of the 3-phenyl group, undergo shifts of ca. 1.0 ppm by Eu(fod)$_3$ and 4.6 ppm by Pr(fod)$_3$. On the other hand, the *N*-methyl and *C*-methyl protons in **5***e* are *both* shifted ca. 6.8 ppm by Eu(fod)$_3$ and 6.6 ppm by Pr(fod)$_3$, while the aromatic protons are relatively unaffected.

Elguero and co-workers obtained similar results in a study of the effect of the dipivalomethides of Co^{II}, Ni^{II}, Eu^{III}, and Pr^{III} on the ^{1}Hmr spectra of 1,3-dimethyl-, 1,5-dimethyl-, and 1,3,5-trimethylpyrazole, all of which have been well characterized (11*a*). Their results are consistent with complexation of the shift reagent at the unsubstituted nitrogen atom of the pyrazole ring; methyls in the 1- and 3-positions are shifted roughly equally and to a much greater extent than is a 5-methyl substituent. They also observed a shift in the position of the *ortho*-phenyl protons in 1-phenylpyrazole.

The magnitude of the pseudocontact shifts effected by the addition of a lanthanide shift reagent are due both to the relative distances between the substrate protons and the paramagnetic centre in the shift reagent – substrate complex and the degree of association of the substrate and shift reagent in solution (11*b*). Although the former is more important for our purposes, it can be seen from the data in Figs. 1 and 2 that the degree of association of **5***b* with both Eu(fod)$_3$ and Pr(fod)$_3$ is smaller than that of **5***e* with the two shift reagents. This may indicate that **5***e* exhibits a somewhat greater degree of Lewis basicity than does **5***b*, although we have no other evidence to support this conclusion. Further, it appears that Pr(fod)$_3$ is a somewhat better complexing agent with **5***b* than is Eu(fod)$_3$.

Further support for the identities of pyrazoles **5***b–i* comes from the solvent shift studies. Elguero and Jacquier observed remarkable consistencies in the ^{1}Hmr spectra of a number of 1,3- and 1,5-dimethylated pyrazole derivatives as a function of solvent (11*c*). In deuteriochloroform, they observed a small difference in chemical shift between 3-methyl

[3]Extrapolated to equimolar concentrations of pyrazole and shift reagent Pr(fod)$_3$, tris(6,6,7,7,8,8,8,-heptafluoro-2,2-dimethyl-3,5-octanedionato)praseodymium (see Figs. 1 and 2).

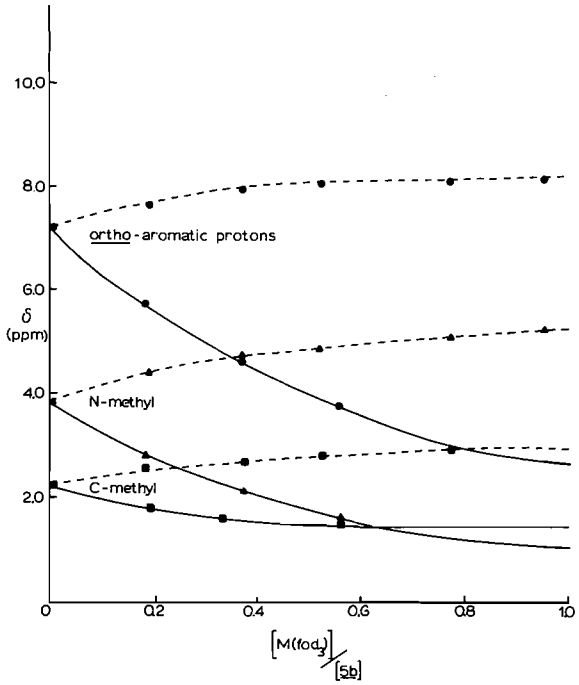

FIG. 1. ^{1}Hmr shift reagent study of **5***b* using Pr(fod)$_3$ (—) and Eu(fod)$_3$ (----).

and 5-methyl protons, with the 5-methyl protons occurring at higher field than 3-methyl protons. The differences in chemical shift in benzene solution are even more distinct; they found 3-methyl protons at 2.15–2.25 ppm and 5-methyl protons at 1.4–1.7 ppm. Although the methyl proton chemical shifts of **5***b–i* in deuteriochloroform are entirely consistent with their generalizations, the spectra in deuteriobenzene are far more illuminating owing to the greater differences observed. As can be seen in Table 2, the ^{1}Hmr spectra of **5***b*, *c*, *d*, and *h* all show methyl singlets in the range 1.62–1.71 ppm, while the corresponding signals in the spectra of **5***e*, *f*, *g*, and *i* occur in the range 2.35–2.46 ppm.

^{13}Cmr spectroscopy has also been shown to be useful for distinguishing isomeric pyrazoles of this type (11*d*). Table 2 lists the positions of the *C*- and *N*-methyl carbons in the 25.2 MHz ^{13}Cmr spectra of **5***b–i* in deuteriochloroform solution; certain generalizations are again apparent. It can be seen that 3-methyl carbons occur in the range 12.4–12.6 ppm, while 5-methyl carbons fall in the 9.7–10.0 ppm range. The *N*-methyl carbon shieldings cannot be placed in such characteristic frequency ranges, although it can be seen that within each isomer pair the *N*-methyl carbon in the 1,5-dimethyl isomer occurs at higher field than that of the 1,3-dimethyl isomer by 0.2–0.4 ppm.

The difference in thermodynamic stability between

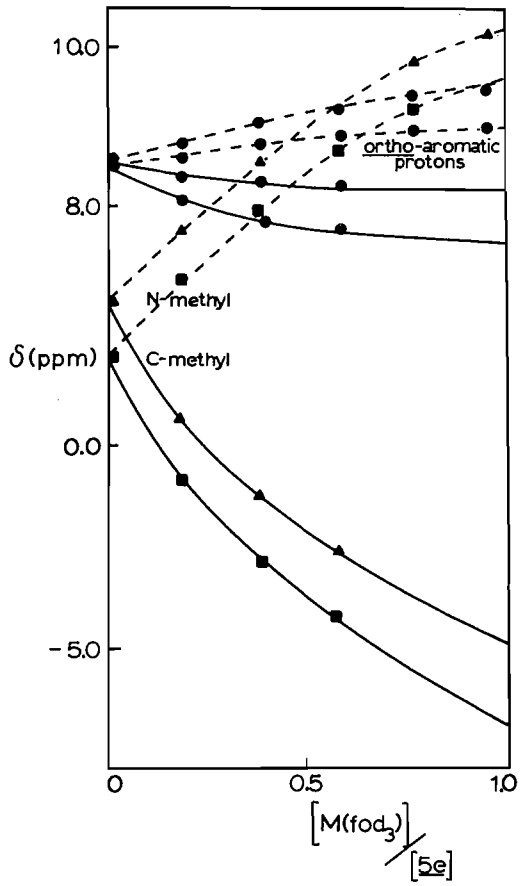

FIG. 2. ^{1}Hmr shift reagent study of **5***e* using Pr(fod)$_3$ (—) and Eu(fod)$_3$ (----).

the isomeric *N*-methylpyrazoles was determined. Equilibrium was established when the individual isomers were heated in diphenyl ether solution with methyl iodide added as a catalyst (reaction [10]). The consistency of the relative stability of the isomeric pairs, i.e., **5***b–d* more stable than **5***e–g*, constitutes additional evidence for the proposed structural assignments.

Discussion

The photochemical electrocyclic reactions of compounds having the 1,2-diaza-1,3-diene chromophore have not received much attention. There are, however, enough examples reported to indicate that this is an interesting and potentially fruitful research area; reactions [11] (3*a*, *b*), [12] (12), and [13] (13) illustrate this point. Reactions [2], [11], and [13] can be viewed as 4πe electrocyclic ring closures, while reaction [12] is a 6e electrocyclic process. Analogous reactions in the carbocyclic series are, of course, well known (14).

To our knowledge, there are no examples of direct

loss of nitrogen upon irradiation of this chromophore. It is not suprising that neither concerted loss of nitrogen nor cleavage to give the vinyl and diazenyl radicals occurs; the central carbon–nitrogen bond must be rather strong in the ground state and even more bonding in the excited state. On the other hand, photochemically-induced homolytic cleavage to give the α,β-unsaturated diazenyl and alkyl radicals is not unlikely and may in fact account for the formation of **4** in reaction [3].

It seems likely that, in the case of **2***a*, reaction [2] is competing with reaction [3] and, at 10°C, the occurrence of the thermal reversion of **3***a* to **2***a* accounts for the ultimate high yield of cyclopropene upon irradiation at this temperature. We were unable to detect **3***b* from the irradiation of **2***b* at −77°C but cannot rule out the possibility that **3***b* would revert back to **2***b* at a rate fast enough to preclude its detection at this temperature. It is also pertinent to recall

[11] 
10 11

12 13 14

[13] 
15 16

that reaction [3] occurs with **2***b–d* at ca. 10 K (4), although no attempt was made to detect **3***b–d* at this temperature. Clearly, the factors which influence the competition between reactions [2] and [3] have yet to be determined.

Reactions [4] and [5] are best described as thermally-allowed competitive suprafacial [1,5]-sigmatropic rearrangements. The evidence supporting this mechanism is, briefly: (*i*) the rate of rearrangement of **2***a,b* is not affected by the addition of base; (*ii*) the major products (**6***a–d*) are the result of kinetic, not thermodynamic, control; (*iii*) the rates of reactions [4] and [5] are relatively insensitive to substituent effects throughout the series **2***a–d*; (*iv*) the kinetic analysis of the rearrangement of **2***b* is consistent with a concerted reaction; and (*v*) these reactions are similar to those of the carbocyclic analog 5,5-dimethylcyclopenta-1,3-diene, whose rearrangement has been shown to occur by a concerted mechanism (reaction [14]) (15).

[14] 
R = H, CH_3

The relative rates of reactions [4] and [5] of **2***a–d* favour reaction [5] in every case. The substituents on **2***b–d* have little influence on this ratio; however, the formation of the 4*H*-pyrazole is particularly favoured in the case of **2***a*. This is in spite of the fact that the *N*-methylpyrazoles are much more thermodynamically stable than the 4,4-disubstituted isomers. The resonance energy of pyrazole itself has been calculated to be ca. 10 kcal mol^{-1} (16). Obviously then, the transition state for reaction [4] must resemble the starting material and not the final product. There are several factors which may influence the relative rates of these two reactions. Perhaps the most important consideration is the fact that suprafacial migration from carbon-3 to nitrogen-2 renders the nitrogen tetrahedral; conformational and electronic reorganization must take place before the aromatic stabilization can develop. If this is so, it seems likely that, *in the absence of aromatic stabilization*, the bonding arrangement in **6**, with two relatively strong carbon–nitrogen double bonds, is more stable than that in **5**. Furthermore, the steric repulsion of the vicinal groups R_3 and R_4 in **2** is decreased when migration occurs toward carbon-4.

The observation that only one of the two isomeric *N*-methylpyrazoles **5***b–d* is formed during reaction [4] is consistent with a concerted [1,5]-sigmatropic rearrangement. This is particularly meaningful since the relative thermodynamic stability of the two isomers is only slightly in favour of **5***b–d*; product formation is therefore controlled by kinetic factors.

There is a consistent substituent effect on the absolute rate of reaction within the limited series **2***b–d*. Expressed in terms of the usual Hammett relationship, a plot of the rate of disappearance of **2***b–d* as a function of the substituent constant σ_p gives a straight line with slope $\rho = +0.33$ (correlation coefficient 0.998). This substituent effect is also reflected on the rate of appearance of the corresponding 4*H*-pyrazoles. The small magnitude of the effect and the accuracy of the experimental data do not allow an evaluation of the variation in rate of the minor reaction [4]. This small positive ρ is consistent with a concerted reaction.

Figure 3 is an Arrhenius plot of the rate of rearrangement of **2***b* to **5***b* and **6***b* as a function of temperature. The kinetic parameters from this data are summarized in Table 3. Included in the table are the Arrhenius parameters for the thermal rearrangement of the analogous carbocyclic systems, 5,5-dimethylcyclopentadiene (15) and 1,5,5-trimethylcyclopentadiene (reaction [14]) (17, 18).

We are now in a position to comment upon the competition between thermal loss of nitrogen and

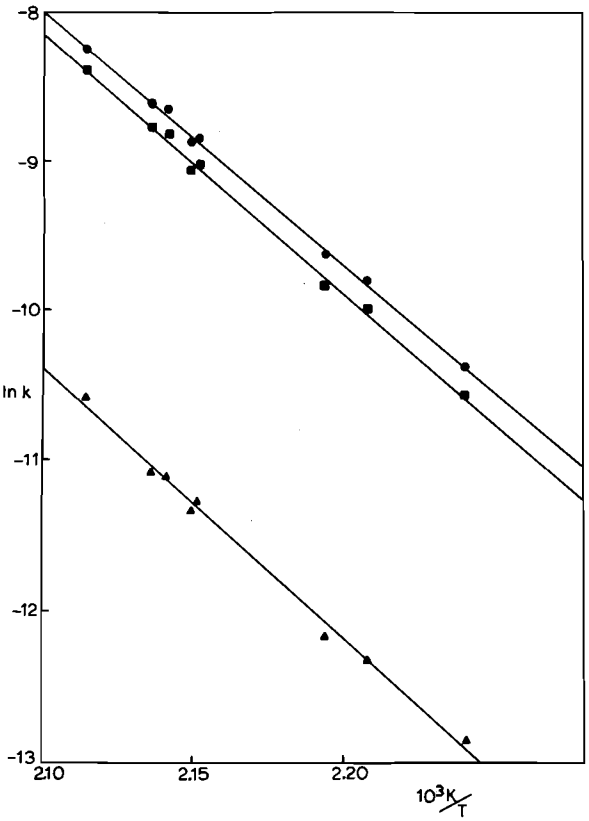

FIG. 3. Arrhenius plot for the thermal rearrangement of **2***b* in diphenyl ether: ●, disappearance of **2***b*; ■, appearance of **6***b*; ▲, appearance of **5***b*.

TABLE 3. Arrhenius parameters for the thermal rearrangement of **2***b*

Reaction	E_a(kcal mol^{-1})[a]	$\Delta S^{\ddagger}$ (eu)[a]	Correlation coefficient
[4][b]	35.6±1.1	−7.0±2.3	0.9973
[5]	34.2±0.7	−5.6±1.6	0.9987
[4] + [5]	33.4±0.5[c]	−6.7±1.0[c]	0.9993
	(34.3±1.0)[d]		
[14] R = H	43.3±2.4	3.0±3	—
[14] R = Me	40.3 (16)	−4 (16)	—
	(43.8) (17)	(0.7) (17)	

[a]It has been pointed out (20) that for the temperature range studied and the error inherent in nmr measurements (5%), the error in $\Delta S^{\ddagger}$ is ca. 3 eu and in E_a, ca. 1.2 kcal mol^{-1}. The errors listed are those estimated from least squares analysis of our data.

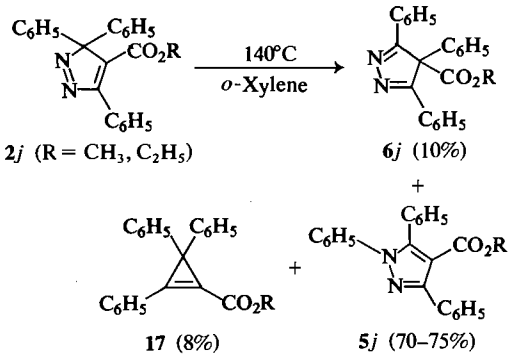
[b]The rate constants for reaction [4] were calculated from the measured rate constants for reaction [5] and the product ratios (6:5 = k_5/k_4).

[c]Determined from the rate constants for disappearance of **2***b* ($k_{dec} = k_4 + k_5$).

[d]Calculated from $E_{a,4+5} = (k_4E_{a,4} + k_5E_{a,5})/(k_4 + k_5)$; the value given is the mean of eight calculations.

[1,5]-sigmatropic rearrangement of 3*H*-pyrazoles. We know of only two reported examples of the thermal loss of nitrogen from a 3*H*-pyrazole (**5***b*, 9). Russian workers have reported (9) that the thermal decomposition of methyl and ethyl 3,3,5-triphenyl-3*H*-pyrazole-4-carboxylate (**2***j*) in *o*-xylene gave the products of [1,5]-sigmatropic rearrangement to both nitrogen (**5***j*) and carbon (**6***j*), as well as the cyclopropene **17**, (reaction [15]) (9). The closely related dimethyl 3,3-diphenyl-3*H*-pyrazole-4,5-dicarboxylate (**2***k*) has also been studied (7*b*); however, no mention was made of the cyclopropene in this case. This apparent dichotomy may simply be the result of differences in experimental conditions. The formation of the cyclopropene **17** from **2***j* was observed upon heating in *o*-xylene, reaction being complete after 40 min at 140°C. When this reaction was carried out using acetic acid as solvent (80–90°C, 3 h), **17** was

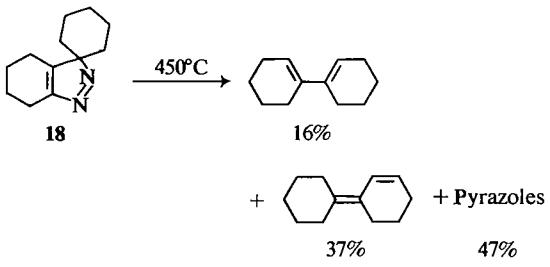
[15]



not reported among the products. Acetic acid (118°C) was also used in the study of the rearrangement of **2***k*. It seems likely that either in acetic acid the cyclopropene is formed but is unstable (the material balance was poor) or the rearrangement is catalyzed by acetic acid and at the lower temperatures used the loss of nitrogen simply does not compete. Both acid-catalyzed ring opening of cyclopropenes and acid-catalyzed rearrangement of 3*H*-pyrazoles are well documented (7, 19). In fact, the first reported example of the rearrangement of a 3*H*-pyrazole used acetic acid as solvent (7*a*); perhaps for this reason, acetic acid has usually been used. It may be that cyclopropenes would have been recognized as minor products had the rearrangements been examined in other solvents.

The other reported example of the loss of nitrogen

[16]



from a 3*H*-pyrazole is the flash vacuum pyrolysis (450°C) of **18**, reaction [16] (5*b*). These high temperature conditions may very well increase the relative importance of the higher activation energy process.

In the thermal decomposition of 1-pyrazolines (reaction [1]), the bulk of the evidence indicates that both carbon–nitrogen bonds are breaking at the transition state (21). This appears to be the case even when the two incipient radical sites differ considerably in stability. Simultaneous cleavage of both carbon–nitrogen bonds in 3*H*-pyrazoles seems highly unlikely. As mentioned previously, the difference between the two carbon–nitrogen bond dissociation energies must be very large in this case. In the analogous alkyl phenyl azo compounds, there is good evidence that only one carbon–nitrogen bond cleaves (reversibly) to give the alkyl and phenyl diazenyl radicals thermally (22). Therefore, it seems likely that the transition state for thermal ring opening in 3*H*-pyrazoles would involve predominantly the breaking of only the carbon-3–nitrogen-2 bond. Notice that the initially formed carbon-centred radical from **2***a–d* would be a tertiary alkyl radical, not allylic until bond rotation becomes possible. On the other hand, in the case of **2***j* where cyclopropene is a significant thermal decomposition product, the initially formed carbon-centred radical is 'bisbenzylic.' With these concepts in mind, we can now compare the reported kinetic parameters for the thermal decomposition of 3,3-dimethyl-1-pyrazoline (**1***a*; R_1–R_4 = H, R_5 = R_6 = CH_3) (1*a*) with those we have measured for **2***b*.

The activation energy for the decomposition of **1***a* (reaction [1]), E_a = 40 kcal mol^{-1}, and the entropy change, ΔS = 10.8 eu, are to be compared with E_a = 33.4 kcal mol^{-1} and ΔS = −6.7 eu for the rearrangement (reactions [4] and [5]) of **2***b*. Even though the activation energy for the decomposition of **1***a* via reaction [1] is considerably higher than that for rearrangement of **2***b*, the rate of decomposition is significantly faster; $k_{\text{dec } 1a}$ = 2.04 × 10^{-3} s^{-1} [4] vs. $k_{\text{dec } 2b}$ = 2.62 × 10^{-4} s^{-1} at 200°C. This is of course the result of the very much larger increase in entropy upon decomposition of **1***a*. The large positive value of ΔS for reaction [1] of **1***a* is consistent with simultaneous cleavage of both carbon–nitrogen bonds at the transition state. Since the transition state for the thermal loss of nitrogen from 3*H*-pyrazoles would involve cleavage of only the one carbon–nitrogen bond, a considerably smaller ΔS value would be involved. If we take 40 kcal mol^{-1} as a reasonable value of the activation energy for carbon–nitrogen bond cleavage in **2***b*,[5] we can calculate what the frequency factor would have to be for this reaction to occur at a rate approximately 3% (the limit of detection by ^{1}Hmr) of that of the rearrangement at the same temperature; log A is calculated to be 13.5. This corresponds to $\Delta S^{195°C} \sim 0.3$, which is again a reasonable value for a reaction of this type. At higher temperatures, the cleavage reaction would then increase in importance; in fact, at 450°C, the temperature at which the flash vacuum pyrolysis of **18** was carried out (reaction [16]), the ratio of the rate constants for rearrangement versus cleavage of **2***b* would be $k_{\text{rearr}}/k_{\text{cleav}} \sim 2.8$. The combination of a high activation energy and a small positive ΔS for the cleavage process allows the [1,5]-sigmatropic rearrangement(s) to compete with loss of nitrogen at lower temperatures.

Tautomeric equilibria in heterocycles has received a great deal of attention in the literature; a number of techniques have been applied to the determination of tautomeric composition in the N—H pyrazole series (23). Most of these methods involve comparison of physical and/or spectral properties of an N—H pyrazole with those of the 1- and 2-methylated derivatives, yet the isomeric equilibria in *N*-alkyl pyrazoles has received little attention.

In the course of our study of the thermal rearrangement of **2***b–d*, we found it necessary to determine the thermodynamic equilibrium constants; we found a small but significant substituent effect on the equilibrium constants for the 1,5- and 1,3-dimethylpyrazole pairs **5***b,c*; *c,f*; *d,g*. The usual Hammett plot of equilibrium constant (K = [1,5-isomer]/[1,3-isomer]) as a function of σ_p for the substituents (H, OMe, CN) on the 3(5)-aryl group reveals a linear relationship with slope ρ = +0.78 (correlation coefficient 0.996).

Elguero *et al.* (23) have pointed out the lack of any dependable criteria for the prediction of tautomeric composition in N—H pyrazoles. They were, however, able to make a qualitative correlation between the tendency of a substituent to occur in the 3- or 5-position and the sign of the Hammett σ_m for that substituent. Electron-donating groups appear to prefer the 5-position, whereas electron-withdrawing groups prefer the 3-position. The situation is complicated by the fact that hydrogen bonding (forming dimeric species) can contribute significantly to the relative tautomeric stability, particularly in nonpolar solvents. Our results with the *N*-methyl derivatives **5***b–g* agree with this qualitative correlation; the

[4]Calculated from reported Arrhenius parameters.

[5]Since the initially formed radical is *not* allylic, and inductive effects are known to have little effect on bond dissociation energies, the energetics of this process can be reasonably approximated by those found for the decomposition of **1***a*.

1,5-dimethyl isomers are favoured in all cases, presumably owing to the fact that all three aryl substituents are electron-withdrawing inductively. It is the *relative* position of the equilibria that is instructive in our case, and it can be seen that the presence of an electron-withdrawing aryl substituent favours the 1,5-dimethyl isomer more than does an electron-donating aryl substituent.

Conclusions

3*H*-Pyrazoles undergo two types of photochemical reaction, a 4πe electrocyclic ring closure and cleavage to give the vinyl diazo compounds. Since the former has been observed only with fully alkylated 3*H*-pyrazoles, the factors governing the relative importance of the two reactions are not well understood.

3*H*-Pyrazoles undergo three types of thermal reactions; two competitive [1,5]-sigmatropic rearrangements, and cleavage followed by loss of nitrogen. Cleavage of the N-1—C-5 bond becomes more important when radical stabilizing groups are present at C-5 or at high temperatures.

Isomeric (tautomeric) equilibria in *N*-methyl (N—H) pyrazoles are partially governed by the electronic characteristics of substituents in the 3- and 5-positions; electron-withdrawing substituents prefer the 3-position.

^{1}Hmr shift reagent studies, solvent shift studies, and ^{13}Cmr spectroscopy are all useful techniques for the differentiation of isomeric 1,3- and 1,5-dimethylpyrazoles.

Experimental

All melting points are corrected. ^{1}Hmr spectra were recorded on either a Varian HA-100 or Varian XL-100 spectrometer and are reported in parts per million downfield from TMS. ^{13}Cmr and ^{19}Fmr spectra were recorded on a Varian XL-100 nmr spectrometer and are reported in parts per million downfield from TMS and parts per million upfield from $CFCl_3$, respectively. Infrared spectra were recorded on a Perkin-Elmer 621 grating infrared spectrometer and are reported in wavenumbers, calibrated against the 1601.8 cm^{-1} polystyrene absorption. Ultraviolet–visible absorption spectra were recorded on a Cary 118 spectrometer and are reported in nanometers. A Fisher Proportional Temperature Control Unit with an insulated silicon oil (Dow Corning 210-H) bath was used in the kinetic studies. Temperatures were recorded using a copper–constantan thermocouple.

The 3*H*-pyrazoles **2***b–d* were prepared by an adaptation of the method of Williams and Dolbier (4, 24).

3,3,4,5-Tetramethyl-3*H*-pyrazole (**2***a*) was prepared by the method of Closs and Heyn (25). Yield from the pyrazoline was 52% (bp 40°C/2.6 Torr). The compound discolours when stored at −25°C and it was therefore redistilled before use.

Low Temperature Irradiation of 2a

A freshly distilled sample of **2***a* (0.05 g, 4.4×10^{-4} mol) was dissolved in methylene chloride (Fisher Spectrograde, 1.0 mL) in a Pyrex nmr tube and placed in a quartz Dewar containing Dry-Ice and acetone. The sample was irradiated with a 450-W medium pressure mercury vapour lamp (Hanovia) for 45 min. The ^{1}Hmr spectrum, taken at room temperature, indicated the formation of the 1,2-diazabicyclo-[2.1.0]pent-2-ene (> 60% yield) (**3***a, b*). The ir spectrum, also at room temperature, had the C=N stretching band at 1604 cm^{-1}. Allowing the solution to sit at room temperature regenerated the 3*H*-pyrazole (^{1}Hmr, ir).

Low Temperature Irradiation of 2b

3,3-Dimethyl-4,5-diphenyl-3*H*-pyrazole (**2***b*, 0.02 g, 9.7×10^{-5} mol) was dissolved in methylene chloride and irradiated as above for 1 h. The tube was transferred without warming to the precooled probe (−70°C) of the XL-100 nmr spectrometer. The ^{1}Hmr spectrum was that of 1,1-dimethyl-2,3-diphenylcyclopropene; no other products were detected.

Thermal Rearrangement of 2a

Freshly distilled **2***a* (0.03 g, 2.4×10^{-4} mol) was dissolved in diphenyl ether (distilled, 0.6 mL), degassed (four freeze–pump–thaw cycles), and sealed in an nmr tube. The tube was heated at 182°C for 11 h; progress of the reaction was monitored by ^{1}Hmr. Concentration vs. time data were obtained by normalizing the integrated intensity of the 3-methyl singlet of **2***a* against the total integrated intensity of the 1–4 ppm region. After 11 h, the reaction mixture consisted of **5***a* and **6***a* in the ratio 1:2, accounting for at least 75% of the material present; **2***a* had completely disappeared at this point. Continued heating for another 40 h resulted in the complete disappearance of **6***a*; the ^{1}Hmr spectrum showed the presence of **5***a*. Chromatography on a silica gel column yielded **5***a* as a colourless oil (0.02 g, 60%) which was identified by spectral comparisons with literature data (26). 4*H*-Pyrazole **6***a* was identified by heating a degassed, sealed tube of **2***a* (0.12 g) in benzene (0.3 mL) at 192°C for 4.5 h; the ^{1}Hmr spectrum at this point revealed the mixture consisted of 11% **2***a* and 85% **6***a* and **5***a* in the ratio 36:1. The tube was opened and the solvent evaporated to a brown oil (0.12 g); the major peaks in the ir spectrum matched the ir spectrum of an authentic sample of **6***a*.

A third sample of **2***a* (0.030 g) in diphenyl ether – pyridine (10:1, 0.6 mL) was degassed, sealed, and heated at 182°C as above. The rate of rearrangement of **2***a* in this case was the same as above (10.4×10^{-5} s^{-1}), within experimental error.

The 3*H*-pyrazoles **2***b–d* were purified by column chromatography (alumina) followed by three recrystallizations from hexane. Kinetic parameters were obtained by heating 0.5 mL portions of a solution of the 3*H*-pyrazole (3.8×10^{-3} mol) and mesitylene (0.13 g, 1.1×10^{-3} mol) in diphenyl ether (10 mL), which were degassed (four freeze–pump–thaw cycles) and sealed in nmr tubes. The mesitylene was used as an internal standard and was shown to be unreactive under these experimental conditions. Concentration vs. time data were obtained by recording the ^{1}Hmr spectra over at least 20 time intervals and measuring the intensity of the 3*H*-pyrazole methyl peak normalized against the mesitylene integral. The resultant plots of ln [I] vs. t in all cases yielded a straight line through at least four half-lives. The Arrhenius parameters for the rearrangement of **2***b* were obtained from a least-squares analysis of the first-order rate constants for disappearance of starting material as a function of temperature.

The possibility of an acid-catalyzed rearrangement was discounted by conducting the rearrangement in the presence of hexamethylenediamine at 192°C. Neither the rate of rearrangement nor the product distribution differed from the rearrangement in the absence of base at this temperature.

Preparative-scale Thermolyses: 2b–d

Thermal Rearrangement of 2b

A solution of **2***b* (0.10 g, 4.1×10^{-4} mol) in benzene (0.5 mL) was degassed and sealed in an nmr tube. The tube was

heated at 200°C for 16 h; progress of the reaction was followed by ^{1}Hmr and was essentially complete after 4 h. The crude reaction mixture was chromatographed on a silica gel (10 g) column with hexane–benzene and benzene–ether mixtures (starting with pure hexanes and increasing the proportion of benzene by 10% every 500 mL eluted). Pyrazole **5***b* (0.010 g, 10%) was eluted with pure benzene and identified by comparison with an authentic sample (*vide infra*). 4*H*-Pyrazole **6***b* (0.083 g, 81%) was eluted with ether (10%) – benzene and recrystallized twice from ether–hexane, mp 122–123.5°C; ir (KBr): 3070(m), 2985(m), 1579(m), 1520(s), 1498(m), 1446(m), 755(s), 763(s), 692(s, br); uv λ_{max} (ethanol): 277 (14 100); λ_{max} (hexane): 274 (12 000); ^{1}Hmr ($CDCl_3$) δ: 1.66 (s, 3H), 1.98 (s, 3H), 7.32 (m, 10H); *Anal.* calcd. for $C_{17}H_{16}N_2$: C 82.22, H 6.50, N 11.28; found: C 82.26, H 6.68, N 11.09.

Thermal Rearrangement of **2**c

A solution of **2***c* (0.048 g, 1.76×10^{-4} mol) in benzene (0.3 mL) was degassed and sealed in an nmr tube. The tube was heated at 200°C as above for 16 h. The crude reaction mixture was chromatographed on a silica gel (5 g) column with benzene–ether mixtures. Pyrazole **5***c* (0.005 g, 10%) was eluted with ether (2%) and **6***c* (0.036 g, 75%) with pure ether. Pyrazole **5***c* was identified by comparison with an authentic sample (*vide infra*). 4*H*-Pyrazole **6***c* was further purified by sublimation (120°C/0.1 Torr) and one recrystallization from absolute alcohol, mp 162–162.5°C; ir (KBr): 3070(w), 2230(s), 1568(m), 1496(m), 1380(w), 1270(w), 860(s), 848(s), 759(s), 700(s), 559(s); uv λ_{max} (ethanol): 284 (15 000); λ_{max} (hexane): 285 (16 500); ^{1}Hmr ($CDCl_3$) δ: 1.69 (s, 3H), 2.03 (s, 3H), 7.08 (m, 2H), 7.37 (m, 3H), 7.59 (d, 2H), 7.78 (d, 2H). *Anal.* calcd. for $C_{18}H_{15}N_3$: C 79.09, H 5.53; found: C 79.13, H 5.79.

Thermal Rearrangement of **2**d

A solution of **2***d* (0.050 g, 2.8×10^{-4} mol) in benzene (0.3 mL) was degassed, sealed, and heated as above for 16 h. Chromatography on silica gel (5 g) with hexane–benzene and benzene–ether mixtures afforded **5***d* (0.008 g, 16%), which was eluted with ether (2%) – benzene and identified by comparison with an authentic sample (*vide infra*). Pyrazole **6***d* (0.041 g, 82%) was eluted with ether (15%) – benzene and recrystallized three times from hexanes, mp 119–119.5°C; ir (KBr): 2840(w), 1604(s), 1578(m), 1503(s), 1418(s), 1309(s), 1248(s), 1172(s), 1033(s), 832(s), 763(m), 697(s); uv λ_{max} (ethanol): 307 (20 400); λ_{max} (hexane): 296 (19 100); ^{1}Hmr ($CDCl_3$) δ: 1.69 (s, 3H), 2.00 (s, 3H), 3.83 (s, 3H), 6.96 (d, 2H), 7.28 (m, 2H), 7.55 (m, 3H), 7.82 (d, 2H). *Anal.* calcd. for $C_{18}H_{18}N_2O$: C 77.67, H 6.52, N 10.07; found: C 77.78, H 6.46, N 9.79.

4*H*-Pyrazoles **6***b–d* were identified by comparison of their spectral properties with those of **6***a* and 3-phenyl-4,4,5-trimethyl-4*H*-pyrazole. Particularly diagnostic is the medium intensity C=N stretching band at 1570–1580 cm^{-1} in the ir spectra. The uv spectrum of **6***b* in hexane is almost identical to that of 3-phenyl-4,4,5-trimethyl-4*H*-pyrazole (λ_{max} (hexane): 271 (14 100)).

Preparation of 4H-*Pyrazolium Iodides (*7a–d*)*

*1,3,4,4,5-Pentamethyl-*4H*-pyrazolium Iodide (*7a*)*

A solution of **6***a* (0.18 g, 1.42×10^{-3} mol) in methyl iodide (4 mL) was refluxed on the steam bath for 15 min, resulting in the formation of a colourless precipitate. Anhydrous ether (3 mL) was added, and the mixture was filtered. The precipitate was washed with ether (2 × 0.5 mL) and dried, yielding the product as colourless crystals (0.36 g, 1.4×10^{-3} mol, 97%) which were recrystallized twice from absolute alcohol, mp 180–183°C (dec); ir (KBr): 2975(w), 1640(m), 1595(s), 1469(m), 1441(m), 1391(m), 1297(m), 790(m), 692(m); uv λ_{max} (ethanol): 222 nm (14 000); ^{1}Hmr ($CDCl_3$) δ: 1.63 (s, 6H), 2.32 (s, 3H), 2.99 (m, 3H), 4.16 (m, 3H).

Heating the salt (0.14 g, 5.4×10^{-4} mol) to its melting point under vacuum for 5 min resulted in the formation of an orange oil which bubbled vigorously, and a colourless oil which condensed on the walls of the flask. The orange oil crystallized on cooling. The ^{1}Hmr spectrum ($CDCl_3$) of this mixture showed it to contain 1,3,4,5-tetramethylpyrazole (δ: 1.85 (s, 3H), 2.10 (br s, 6H), 3.65 (s, 3H)) and 1,2,3,4,5-pentamethylpyrazolium iodide (δ: 4.10 (br s, 6H), 2.37 (br s, 6H), 1.98 (s, 3H)) (27) in the ratio 1:2. The material balance was poor (0.09 g), probably owing to loss of the 1,3,4,5-tetramethylpyrazole by vaporization.

*1,4,5-Trimethyl-3,4-diphenyl-*4H*-pyrazolium Iodide (*7b*)*

A solution of **6***b* (0.10 g, 4.0×10^{-4} mol) in methyl iodide (3 mL) was refluxed for 2 h, during which time a yellow precipitate formed. Anhydrous ether (3 mL) was added and the mixture was filtered. The yellow precipitate was washed with ether (2 × 0.5 mL) and dried (0.14 g, 3.5×10^{-4} mol, 87%). The material was further purified by three recrystallizations from chloroform–ether alternated with three recrystallizations from absolute alcohol to yield yellow crystals of **7***b*, mp 154.5–155°C (dec.); ir (KBr): 1637(m), 1547(s), 1495(m), 1444(s), 1157(w), 1076(w), 774(s), 698(s), 636(m); uv λ_{max} (ethanol): 219 (22 800), 299 (9700); ^{1}Hmr ($CDCl_3$) δ: 2.20 (s, 3H), 2.78 (br s, 3H), 4.42 (br s, 3H), 7.26 (m, 10H). *Anal.* calcd. for $C_{18}H_{19}N_2I$: C 55.40, H 4.91, N 7.18; found: C 54.77, H 5.01, N 7.35.

Heating the methiodide (0.05 g, 1.3×10^{-4} mol) to its melting point under vacuum resulted in the vigorous release of methyl iodide and formation of **5***b* (0.03 g, 1.2×10^{-4} mol, 91%).

*3-(4-Cyanophenyl)-4-phenyl-1,4,5-trimethyl-*4H*-Pyrazolium Iodide (*7c*)*

A solution of **6***c* (0.10 g, 3.7×10^{-4} mol) in methyl iodide (3 mL) was refluxed on the steam bath for 2 h, which resulted in the formation of a yellow precipitate. Work-up as above yielded the product as yellow crystals (0.11 g, 2.6×10^{-4} mol, 71%) which were further purified by five recrystallizations from absolute alcohol – anhydrous ether, mp 142.5–143°C (dec.); ir (KBr): 2229(s), 1626(s), 1575(m), 1535(s), 1498(m), 1442(m), 859(s), 702(s), 597(s); uv λ_{max} (ethanol): 217 (sh, 28 400), 250 (sh, 11 100), 355(sh, 11 000), 390 (12 600); ^{1}Hmr ($CDCl_3$) δ: 2.28 (s, 3H), 2.79 (br s, 3H), 4.42 (br s, 3H), 7.25 (m, 4H), 7.59 (s, 5H). *Anal.* calcd. for $C_{19}H_{18}N_3I$: C 54.95, H 4.37, N 10.12; found: C 54.84, H 4.50, N 10.31.

Heating the methiodide (0.06 g, 1.5×10^{-4} mol) to its melting point under vacuum resulted in vigorous release of methyl iodide and the formation of **5***c* (0.03 g, 1.1×10^{-4} mol, 75%).

*3-(4-Methoxyphenyl)-4-phenyl-1,4,5-Trimethyl-*4H*-pyrazolium Iodide (*7d*)*

A solution of **6***d* (0.09 g, 3.4×10^{-4} mol) in methyl iodide (2.5 mL) was refluxed for 1 h, during which time a bright yellow precipitate was formed. Addition of anhydrous ether, filtration, washing (anhydrous ether), and drying yielded the product as bright yellow crystals (0.11 g, 2.5×10^{-4} mol, 75%). The material was further purified by one recrystallization from absolute ethanol and three recrystallizations from chloroform–ether, mp 181.5–182°C (dec.); ir (KBr): 2930(w), 1608(s), 1529(s), 1510(s), 1427(m), 1263(s), 1176(s), 842(m), 790(m); uv λ_{max} (ethanol): 215 (sh, 24 300), 245 (sh, 6400), 340 (12 200). ^{1}Hmr ($CDCl_3$) δ: 2.20 (s, 3H), 2.77 (br s, 3H), 3.77 (s, 3H), 4.32 (br s, 3H), 6.73 (d, 2H), 7.21 (m, 5H), 7.45

(d, 2H). *Anal.* calcd. for $C_{19}H_{21}N_2OI$: C 54.30, H 5.04, N 6.67; found: C 53.86, H 5.07, N 6.96.

Heating the methiodide (0.02 g, 5.2×10^{-5} mol) to its melting point under vacuum resulted in vigorous release of methyl iodide and formation of **5***d* (0.01 g, 4.7×10^{-5} mol, 89%) which contained less than 8% of the other isomer.

*Preparation of 4,5-Diphenyl-1,2,3-trimethylpyrazolium Iodide (***9***b)*

Pyrazole **5***b* (0.05 g, 2.0×10^{-4} mol) was dissolved in methyl iodide (0.5 mL), placed in an nmr tube, degassed (four freeze–pump–thaw cycles) and the tube was sealed. The mixture was heated at 100°C for 4 h. Evaporation of the excess methyl iodide yielded the product as yellow crystals (0.07 g, 1.9×10^{-4} mol, 96%) which were recrystallized twice from chloroform–ether affording colourless plates of **9***b*, mp 224–225°C (dec.); ir (KBr): 1550(m), 1460(s), 1441(m), 1424(m), 1400(s), 1346(s), 791(s), 766(s), 708(s); uv λ_{max} (ethanol): 215 (15 000), 255 (sh, 4000); ^{1}Hmr ($CDCl_3$) δ: 2.49 (br s, 3H), 4.19 (br s, 3H), 4.39 (br s, 3H), 7.18 (m, 5H), 7.38 (s, 5H). *Anal.* calcd. for $C_{18}H_{19}N_2I$: C 55.40, H 4.91, N 7.18; found: C 55.57, H 4.83, N 6.83.

Compound **9***b* was also synthesized in 97% yield from **5***e* as above.

Thermolysis of **9***b* (0.05 g, 1.3×10^{-4} mol) at its melting point under vacuum resulted in vigorous bubbling and the formation of a colourless oil (0.03 g, 1.2×10^{-4} mol, 95%). The nmr spectrum showed the oil to be a 4:1 mixture of **5***b* and **5***e*.

High Temperature ^{1}H Nuclear Magnetic Resonance Spectrum of **7**a

The ^{1}Hmr spectrum of **7***a* in DMF-d_6 was examined at five temperatures between 80–150°C by heating a sealed tube in the probe of the XL-100 nmr spectrometer. No broadening or coalescence of any of the signals was observed at these temperatures. No decrease in intensity of the C-3 or C-5 methyl singlets was observed upon double irradiation of the C-5 or C-3 methyl singlets. The spectrum was complicated by the steady decomposition of **7***a* to give **5***a*, methyl iodide, and 1,2,3,4,5-pentamethylpyrazolium iodide.

Preparation of **5**b–i

Desoxybenzoin Enol Acetate

The procedure is that of Barnes *et al.* (28). A mixture of desoxybenzoin (15.0 g, 0.08 mol) and potassium acetate (30 g, 0.31 mol) in acetic anhydride (300 mL) was refluxed for 1 h in a 500-ml round-bottom flask equipped with magnetic stirrer, condenser, and drying tube. The resultant dark brown liquid was allowed to cool slightly, poured into water (1.4 L), and then stirred at room temperature for 0.5 h. The resulting brown crystalline suspension was extracted with ether (3 × 200 mL). The combined ether extracts were washed repeatedly with a saturated aqueous solution of sodium bicarbonate until CO_2 evolution had ceased, followed by one wash with water (100 mL). The dark brown solution was then dried over anhydrous magnesium sulphate and filtered. Evaporation of solvent afforded a dark brown oil (16.3 g) which crystallized upon addition of methanol. The crystals were filtered, washed with methanol, and dried. Reduction of the mother liquors afforded an additional quantity of product. A second recrystallization from methanol afforded the product as slightly brown crystals (12.4 g, 0.05 mol, 68%, mp 102–103°C (lit. (28) mp 101°C).

4-Methoxydesoxybenzoin Enol Acetate

This was prepared by refluxing 4-methoxydesoxybenzoin (10.1 g, 0.045 mol) and potassium acetate (20 g, 0.20 mol) in acetic anhydride (140 mL) for 18 h. Following work-up (as above), the product was recrystallized once from ethanol to afford brown crystals (5.89 g, 0.022 mol, 49%, mp 82–87°C, lit. (28) mp 88°C).

4-Bromodesoxybenzoin Enol Acetate

This was prepared by refluxing 4-bromodesoxybenzoin (10.1 g, 0.04 mol) and potassium acetate (20 g, 0.20 mol) in acetic anhydride (140 mL) for 20 h. Work-up and subsequent recrystallization from ethanol–water afforded the product as brown crystals (6.1 g, 0.02 mol, 61%, mp 104–106°C). Chromatography on a silica gel column with 1:1 benzene – petroleum ether followed by two recrystallizations from ethanol afforded the compound as colourless crystals (mp 107–108°C); ir (KBr): 1751(s), 1489(m), 1395(m), 1373(m), 1227(s), 1215(s), 1070(s), 1040(s), 1010(s), 939(m), 858(m), 851(m), 817(s), 754(s), 704(s), 573(m); uv λ_{max} (ethanol): 294 (25 000), 225 (10 100); λ_{max} (hexane): 292 (27 400), 223 (12 100); ^{1}Hmr ($CDCl_3$) δ: 2.28 (s, 3H), 6.67 (s, 1H), 7.42 (m, 9H). *Anal.* calcd. for $C_{16}H_{13}O_2Br$: C 60.59, H 4.13; found: C 60.87, H 4.20.

4-Cyanodesoxybenzoin Enol Acetate

This was prepared by refluxing 4-cyanodesoxybenzoin (8.14 g, 0.037 mol), and potassium acetate (10 g, 0.10 mol) in acetic anhydride (150 mL) for 1 h. Work-up and recrystallization from ethanol afforded the product as yellow crystals (6.94 g, 0.026 mol, 70%, mp 107–109°C). Column chromatography of a portion of the product on silica gel with benzene yielded the enol acetate as colourless crystals which were recrystallized twice from ethanol (mp 110–111°C); ir (KBr): 3028(w), 2223(s), 1752(s), 1601(s), 1371(s), 1211(s, br), 1178(s), 1040(s), 821(s), 745(m), 691(s); uv λ_{max} (ethanol): 230 (11 800), 308 (27 400); λ_{max} (hexane): 227 (11 100), 302 (25 000); ^{1}Hmr ($CDCl_3$) δ: 2.33 (s, 3H), 6.81 (s, 1H), 7.48 (m, 5H), 7.66 (s, 4H). *Anal.* calcd. for $C_{17}H_{13}NO_2$: C 77.55, H 4.98; found: C 77.67, H 4.97.

Synthesis of 1-Aryl-2-phenyl-1,3-butanediones (29)

1,2-Diphenyl-1,3-butanedione

Desoxybenzoin enol acetate (10.0 g, 0.04 mol) and acetyl chloride (1.5 mL, 0.02 mol) were dissolved in 1,2-dichloroethane (25 mL) in a 250 mL three-necked round-bottom flask fitted with overhead stirrer, gas inlet tube, and reflux condenser with drying tube ($CaCl_2$). The solution was cooled to 0°C in an ice bath and BF_3 (purified by bubbling through concentrated H_2SO_4) was let into the flask at such a rate so as to keep the mixture below the reflux temperature.

The BF_3 was absorbed rapidly for the first 15 min, at which time the brown mixture solidified; an additional quantity of dichloroethane (25 mL) was added. The reaction mixture was stirred at 0°C under a BF_3 atmosphere for 3 h.

A solution of sodium acetate (7.0 g, 0.09 mol) in water (25 mL) was added and the dichloroethane was distilled off on the steam bath. The aqueous mixture was refluxed for another 0.5 h, during which time a yellow oil formed. The mixture was cooled and extracted with ether (3 × 50 mL). The combined organic fractions were washed once with saturated aqueous bicarbonate (20 mL), once with water (20 mL), dried over anhydrous sodium sulphate, and filtered. Evaporation of solvent yielded a light yellow liquid (11.4 g); methanol (25 mL) was added and the subsequent solution was cooled. The product was isolated as slightly yellow crystals (enol form, 7.4 g, mp 86–89°C (lit. (30) mp 88–89°C)). Reduction of the mother liquors afforded slightly yellow plates (diketo form, 1.6 g, mp 76–80°C (lit. (29, 30) mp 76–77°C)). Total yield was 90%.

1-(4-Methoxyphenyl)-2-phenyl-1,3-butanedione

This was prepared as above from 4-methoxydesoxybenzoin enol acetate (0.39 g, 1.4×10^{-3} mol) and acetyl chloride (0.01 mL) in 1,2-dichloroethane (1 mL). Following sodium acetate hydrolysis, the product was extracted with benzene. Evaporation of solvent afforded brown crystals (0.39 g) which were shown by ^{1}Hmr to consist of the difluoroborate ether of the diketone (major), the diketone (two tautomeric forms), and 4-methoxydesoxybenzoin. The mixture was chromatographed on a silica gel (30 g) column with hexanes (10%) – benzene. First isolated from the column were yellow crystals of the difluoroborate ether (0.22 g, 6.8×10^{-4} mL, 47%), which were recrystallized once from ether–benzene and once from ethanol (mp 141–144°C); ir (KBr): 2848(w), 1600(s), 1580(s), 1550(s), 1463(br, s), 1439(m), 1342(s), 1265(s), 1179(s), 1059(br, s), 1022(s), 846(m), 775(m), 704(m), 558(m); uv λ_{max} (ethanol): 364 (16 000), 240 (5600); λ_{max} (hexane): 358 (26 400), 240 (7500); ^{1}Hmr ($CDCl_3$) δ: 2.17 (s, 3H), 3.80 (s, 3H), 6.71 (d, 2H), 7.33 (m, 7H); ^{19}Fmr ($CDCl_3$–$CFCl_3$): −140.1 ppm from $CFCl_3$. *Mass ion* calcd.: 316.1078; found: 316.1080. *Anal.* calcd. for $C_{17}H_{15}BF_2O_3$: C 64.59, H 4.78; found: C 64.72, H 4.61.

Next was isolated 4-methoxydesoxybenzoin (0.04 g) and finally a yellow oil (0.08 g); spectral data (^{1}Hmr, ir) identified it as a 1:2 mixture of the β-diketone and one of its enol forms; ir (KBr): 2920(w), 2840(w), 1720(m), 1670(m), 1602(s), 1510(m), 1422(w), 1264(s), 1173(s), 1030(m); uv λ_{max} (ethanol): 335 (sh, 1700), 286 (11 000), 235 (sh, 10 500); λ_{max} (hexane): 330 (sh, 1800), 277 (11 700), 220 (sh, 12 000); ^{1}Hmr ($CDCl_3$) β-diketone δ: 2.14 (s, 3H), 3.73 (s, 3H), 5.45 (s, 1H), 6.70 (d, 2H), 7.73 (d, 2H), 7.20 (m, 5H); enol δ: 1.94 (s, 3H), 3.65 (s, 3H), 6.45 (d, 2H), 7.18 (m, 7H), 18.9 (s, 1H).

Refluxing the difluoroborate ether (0.035 g, 1.1×10^{-4} mol) in methanol (4 mL) for 2.5 h, followed by evaporation of solvent, yielded a yellow oil (0.034 g). The ^{1}Hmr spectrum showed it to be a roughly equal mixture of the β-diketone and enol, plus a small amount of unreacted starting material. Chromatography on a silica gel column with benzene gave 0.010 g of the β-diketone–enol mixture as a yellow oil whose ir spectrum (KBr) matched that given above.

1-(4-Bromophenyl)-2-phenyl-1,3-butanedione

This was prepared as above from 4-bromodesoxybenzoin enol acetate (5.133 g, 0.016 mol) and 4 drops acetyl chloride in 1,2-dichloroethane (13 mL). A longer hydrolysis time was required in this case (1.5 h) since after 0.5 h a considerable amount of a black solid, insoluble in organic solvents, remained. Extraction with benzene–ether (1:1) and subsequent work-up yielded a brown-red solid (5.55 g); the ^{1}Hmr spectrum showed it to consist of the β-diketone and 4-bromodesoxybenzoin in the ratio 2:1. Repeated washings of the solid with anhydrous ether was effective in removing the desoxybenzoin, leaving impure crystals of 1-(4-bromophenyl)-2-phenyl-1,3-butanedione (2.76 g, 8.7×10^{-3} mol, 54%) which was used without further purification for the preparation of the pyrazoles.

The combined ether filtrates were evaporated and the residue was dissolved in hot ethanol and then cooled. The resulting crystals were filtered, washed, and dried, and identified as 4-bromodesoxybenzoin (1.52 g). The evaporated mother liquors were then chromatographed on a silica gel column, eluting with 10% hexanes in benzene. Initial fractions contained the desoxybenzoin; subsequent fractions containing the diketone were combined and recrystallized five times from 95% ethanol to yield light yellow needles of 1-(4-bromophenyl)-2-phenyl-1,3-butanedione (enol form), mp 83.5–84.5°C; ir (KBr): 3061(w), 3035(w), 1712(br, w), 1676(br, m), 1583(br, s), 1482(m), 1395(m), 1070(s), 1010(s), 834(m), 702(s); uv λ_{max} (ethanol) 316 (11 500), 258 (11 900); λ_{max} (hexane): 316 (12 700), 242 (8800); ^{1}Hmr ($CDCl_3$) δ: 2.05 (s, 3H), 7.21 (m, 9H), 17.31 (s, 1H). *Anal.* calcd. for $C_{16}H_{13}O_2Br$: C 60.59, H 4.13; found: C 60.37, H 4.20.

Several attempts to synthesize 1-(4-cyanophenyl)-2-phenyl-1,3-butanedione from 4-cyanodesoxybenzoin enol acetate by the above method and variations thereof were unsuccessful; the starting material and/or 4-cyanodesoxybenzoin were recovered in every case.

Preparation of **5**b, d, e, g, h, i

The pyrazoles were prepared by refluxing the β-diketone with a 4–5 molar excess of anhydrous methyl hydrazine in benzene for 8–12 h. The ^{1}Hmr and ^{13}Cmr spectra of these compounds are summarized in Table 2.

For example, 1,2-diphenyl-1,3-butanedione (2.00 g, 8.8×10^{-3} mol) and methyl hydrazine (1.93 g, 0.042 mol) were dissolved in benzene (40 mL) in a 100-mL round-bottom flask equipped with condenser and magnetic stirrer. Reflux for 8 h gave a light yellow solution which was removed from the heat, dried (magnesium sulphate), and filtered. The solvent and excess methylhydrazine were removed on the rotary evaporator to yield a yellow oil (2.02 g, 92%). The ^{1}Hmr spectrum showed the mixture consisted of **5***b* and **5***e* in the ratio 2:3. The isomers were separated by chromatography on an alumina (150 g) column with hexane–ether mixtures (ether concentration was increased by 3% for every 1000 mL of solvent eluted until a 12% ether solution was reached). The first compound to be eluted was **5***e*, which was recrystallized twice from ether and identified as 1,3-dimethyl-4,5-diphenylpyrazole (*vide infra*), mp 134–134.5°C; ir (KBr): 3061(w), 2929(w), 1603(s), 1513(s), 1488(m), 1439(m), 1363(m), 1019(s), 994(s), 769(s), 593(s); uv λ_{max} (ethanol): 233 (14 500); λ_{max} (hexane): 239 (16 000). *Anal.* calcd. for $C_{17}H_{16}N_2$: C 82.22, H 6.50, N 11.28; found: C 82.39, H 6.71, N 11.08.

Mixtures of **5***b*, *e* were eluted next and finally **5***b* was eluted. The mixtures were combined and rechromatographed; **5***b* was recrystallized twice from ether and identified as 1,5-dimethyl-3,4-diphenylpyrazole (*vide infra*), mp 121–122°C; ir (KBr): 3047(w), 2952(w), 1603(sh), 1547(m), 1495(m), 1436(m), 1367(m), 1076(s), 967(s), 768(s), 705(s); uv λ_{max} (ethanol): 231 (16 200); λ_{max} (hexane): 237 (17 100). *Anal.* calcd. for $C_{17}H_{16}N_2$: C 82.22, H 6.50, N 11.28; found: C 82.22, H 6.59, N 11.40.

Preparation of **5**d *and* g

The difluoroborate ether of 1-(4-methoxyphenyl)-2-phenyl-1,3-butanedione (1.381 g, 4.4×10^{-3} mol) and methyl hydrazine (1.93 g, 0.042 mol) were dissolved in benzene (50 mL) and refluxed as above for 16 h. Work-up yielded slightly yellow crystals (1.13 g, 4.05×10^{-3} mol, 93%). The ^{1}Hmr spectrum of the crude product showed it to consist of **5***d* and *g* in the ratio 1:12. This mixture was chromatographed on an alumina (65 g) column with an ether (1%) – benzene solution. The first fractions eluted contained **5***g* (0.77 g), which was recrystallized twice from hexane to give colourless crystals which were identified as 1,3-dimethyl-5-(4-methoxyphenyl)-4-phenylpyrazole, mp 122.5–123°C; ir (KBr): 3023(w), 2969(w), 2828(w), 1612(m), 1517(s), 1493(m), 1460(m), 1375(m), 1022(s), 850(m), 764(s), 593(m); uv λ_{max} (ethanol): 239 (21 500), 255 (sh, 11 500); λ_{max} (hexane): 243 (19 600), 260 (sh, 13 300). *Anal.* calcd. for $C_{18}H_{18}N_2O$: C 77.67, H 6.52, N 10.07; found: C 77.65, H 6.60, N 10.19.

The remaining fractions from the column consisted of mixtures of **5***d* and *g* (0.34 g). This mixture was dissolved in hot hexane and cooled; **5***g* crystallized (0.17 g).

Pure **5***d* was isolated by heating **5***g* (0.20 g, 7.0×10^{-4} mol) and methyl iodide (0.04 mL, 7.0×10^{-4} mol) in benzene (2 mL) in a Carius tube (which had been degassed and sealed) at 220°C

for 1 h. Evaporation of the benzene and excess methyl iodide yielded the equilibrium mixture of **5***d* and *g* (0.20 g, 100%). Fractional recrystallization from hexane–ether, followed by sublimation (105°C, 2 Torr) and three recrystallizations from hexane–ether afforded **5***d* as colourless crystals (mp 96.5–97°C) which were identified as 1,5-dimethyl-3-(4-methoxyphenyl)-4-phenylpyrazole; ir (KBr): 2994(w), 2839(w), 1608(m), 1527(s), 1434(s), 1386(m), 1036(s), 843(s), 761(s), 589(m); uv λ_{max} (ethanol): 242 (14 500), 255 (sh, 13 100); λ_{max} (hexane): 245 (19 400), 257 (sh, 17 800). *Anal.* calcd. for $C_{18}H_{18}N_2O$: C 77.67, H 6.52; found: C 77.69, H 6.64.

Preparation of **5**h, i

1-(4-Bromophenyl)-2-phenyl-1,3-butanedione (2.73 g, 8.52 $\times 10^{-3}$ mol) and methyl hydrazine (3.27 g, 0.071 mol) were dissolved in benzene (50 mL) and refluxed as above for 18 h. Work-up yielded a red oil (2.78 g) which consisted of **5***h* and *i* (approximate ratio 1:12) and 4-bromodesoxybenzoin. The mixture was chromatographed on a silica gel column with benzene–hexane mixtures, which resulted in the isolation of 4-bromodesoxybenzoin (0.34 g). Elution with ether (1%) – benzene gave pure **5***h* (0.16 g, 4.86×10^{-4} mol, 6%) which was recrystallized twice from hexanes, yielding colourless crystals of 3-(4-bromophenyl)-1,5-dimethyl-4-phenylpyrazole, mp 122–123°C; ir (KBr): 3073(w), 2934(w, br), 1603(w), 1491(m), 1434(s), 1066(s), 1013(s), 964(s), 838(s), 696(s); uv λ_{max} (ethanol): 240 (17 100), 261 (sh, 14 000); λ_{max} (hexane): 243 (18 900), 263 (sh, 17 300). *Anal.* calcd. for $C_{17}H_{15}N_2Br$: C 62.40, H 4.62, N 8.56; found: C 62.38, H 4.45, N 8.48.

Continued elution with ether (1%) – benzene gave **5***i* (1.85 g, 5.62×10^{-3} mol, 66%) which was recrystallized twice from hexanes, affording colourless crystals of 5-(4-bromophenyl)-1,3-dimethyl-4-phenylpyrazole, mp 105–106°C; ir (KBr): 3068(w), 2935(w), 1601(m), 1487(m), 1370(m), 1074(m), 1015(s), 855(s), 765(s), 699(s); uv λ_{max} (ethanol): 230 (sh, 18 100), 237 (17 800); λ_{max} (hexane) 228 (16 200), 244 (16 100). *Anal.* calcd. for $C_{17}H_{15}N_2Br$: C 62.40, H 4.62, N 8.56; found: C 62.46, H 4.89, N 8.74.

Preparation of **5**c *(31)*

A dry DMF (2 mL) solution of **5***b* (0.18 g, 5.5×10^{-4} mol; contained ~20% **5***i*) and cuprous cyanide (0.11 g, 1.2×10^{-3} mol) in a 10-ml round-bottom flask fitted with air condenser, magnetic stirrer, and drying tube was refluxed for 11 h.

The brown reaction mixture was poured into hot aqueous 10% sodium cyanide and heated on the steam bath for 1 h, during which time a yellow-brown oil formed. After cooling, the oil was extracted with benzene (3 × 15 mL). The combined benzene fractions were washed with water (3 × 10 mL), dried over magnesium sulphate, and filtered. Evaporation of the solvent yielded a yellow oil (0.13 g, 4.7×10^{-4} mol, 85%) which was then chromatographed on a silica gel column with benzene (70%) – hexane. First to be eluted was **5***c*, which was recrystallized once from hexanes, affording colourless crystals of 3-(4-cyanophenyl)-1,5-dimethyl-4-phenylpyrazole, mp 143–144°C; ir (KBr): 2224(s), 1606(s), 1492(m), 1379(m), 1282(m), 1119(m), 853(s), 692(s), 551(s); uv λ_{max} (ethanol): 232 (sh, 17 000), 285 (16 000); λ_{max} (hexane): 227 (sh, 12 400), 244 (sh, 11 500), 282 (15 000). *Anal.* calcd. for $C_{18}H_{15}N_3$: C 79.09, H 5.53; found: C 78.89, H 5.76.

Preparation of **5**f

A dry DMF (3 mL) solution of **5***i* (0.75 g, 2.0×10^{-3} mol) and cuprous cyanide (0.23 g, 2.6×10^{-3} mol) was refluxed (11 h) in a 10-mL round-bottom flask fitted with air condenser, drying tube, and magnetic stirrer.

The slightly brown mixture was then poured into hot aqueous 10% sodium cyanide (25 mL) and heated on the steam bath for 1 h, during which time a white precipitate appeared and gradually redissolved, followed by the appearance of a yellow oil. The mixture was cooled and the oil was extracted with benzene (3 × 15 mL). The combined organic fractions were washed with water (3 × 10 mL), dried over magnesium sulphate, and filtered. Evaporation of solvent yielded a yellow oil (0.69 g) which was chromatographed on an alumina column with hexane–benzene mixtures and finally ether (1%) – benzene. A total of 0.39 g of the pyrazole was collected (1.44×10^{-3} mol, 72%) and was recrystallized twice from ether–hexane to afford colourless needles of 5-(4-cyanophenyl)-1,3-dimethyl-4-phenylpyrazole, mp 128–128.5°C; ir (KBr): 2230(s), 1612(s), 1602(s), 1519(m), 1376(m), 1020(m), 966(m), 826(s), 699(s), 596(s); uv λ_{max} (ethanol): 231 (15 400), 285 (sh, 6800); λ_{max} (hexane): 229 (17 400), 280 (8200). *Anal.* calcd. for $C_{18}H_{15}N_3$: C 79.09, H 5.53; found: C 78.87, H 5.31.

Catalyzed Thermal Equilibration of Isomeric N*-Methylpyrazoles*

Equilibria were established by heating degassed solutions of the pyrazoles **5***b–g* with methyl iodide (equimolar) in phenyl ether in sealed tubes for 6 days at 210°C. In the case of **5***b* and *e*, a small amount of **9** was used as catalyst instead of methyl iodide. The tubes were checked daily (^{1}Hmr), and at no time could the methiodides **9** be detected. The equilibrium ratios were estimated by ^{1}Hmr and are summarized in [10].

Milieux hyperbasiques: Recherches sur les amides et lactames ω-halogénés. Essais de cyclisation

THÉRÈSE CUVIGNY, PIERRE HULLOT, PATRICK MULOT, MARC LARCHEVEQUE ET HENRI NORMANT

Laboratoire de Synthèse Organique associé au C.N.R.S., Université Pierre et Marie Curie, tour 44–45, 4, place Jussieu 75230, Paris, France

Reçu 14 août 1978

THÉRÈSE CUVIGNY, PIERRE HULLOT, PATRICK MULOT, MARC LARCHEVEQUE et HENRI NORMANT. Can. J. Chem. **57**, 1201 (1979).

Les amides ω-halogénés *N,N*-disubstitués linéaires conduisent aux amides cycliques avec de bons rendements sous l'action des dialkylamidures de lithium "activés." Cependant, la même réaction avec les amides ramifiés donne principalement des amides ω-éthyléniques.

Les γ-et δ-lactames *N*-substitués, porteurs en α d'une chaîne ω-halogénée, fournissent dans les mêmes conditions des spirolactames tandis que les ε-lactames conduisent à un mélange de lactames spiraniques et éthyléniques.

THÉRÈSE CUVIGNY, PIERRE HULLOT, PATRICK MULOT, MARC LARCHEVEQUE, and HENRI NORMANT. Can. J. Chem. **57**, 1201 (1979).

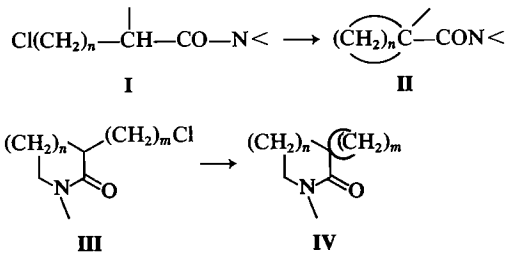
Linear halogenated *N,N*-disubstituted amides afford cyclic amides in good yields by reaction with 'activated' lithium dialkylamides. However, the same reaction with substituted amides gives mainly ω-ethylenic amides.

In the same way, *N*-substituted γ- and δ-lactams with an ω-halogenated chain in the α position afford pure spirolactams whereas the reaction of ε-lactams furnishes a mixture of spiro and ethylenic compounds.

Les *N,N*-dialkyl cyclanecarboxamides (**II**) sont en général isolés à partir des acides cyclanecarboxyliques ou des nitriles correspondants qu'il faut d'abord synthétiser (1). Une autre méthode emploie les sels de cycloalkyl amidinium formés à l'aide d'ène-diamines et de dihalogénures d'alkyle (2). Cependant, les *N,N*-dialkyl cyclobutanecarboxamides ne peuvent être obtenus par ce procédé.

Nous avons récemment décrit une synthèse directe de *N,N*-dialkylamides ω-chlorés (**I**) à partir d'amides tertiaires commerciaux (3). Une cyclisation intramoléculaire de ces composés pouvait conduire directement aux cycloalcane amides tertiaires (**II**) produits intéressants par leurs propriétés pharmacologiques (4) (inhibiteurs des effets psychotomimétiques du LSD entre autres).

D'autre part, les lactames chlorés **III**, également accessibles par notre méthode à partir des lactames commerciaux, pouvaient mener aux spirolactames **IV**:



I **II**

III **IV**

Amides et lactames ω-halogénés

Ces amides et lactames ont été préparés selon la méthode que nous avons mise au point (3). La plupart sont décrits (3, 5), cependant nous avons été amenés à synthétiser quelques nouveaux amides et lactames ω-halogénés (tableau 1). Ils ont été obtenus par condensation des produits commerciaux avec des halogénures ω,ω′-chlorobromés. Quelques essais effectués avec le dichloro-1,4 butane ont fourni des rendements moyens (40–50%) en lactames chlorés. Le lactame *13* a été obtenu à l'aide du dibromo-1,4 butane, le lactame *14* à partir du lactame chloré correspondant par échange (iodure de sodium).

Essais de cyclisation des amides ω-chlorés

L'action d'une base forte, telle les dialkylamidures de lithium "activés" (3) préparés directement à partir du métal et de l'amine en milieu benzène–HMPT, sur les amides chlorés **A** pouvait conduire soit à un amide ω-éthylénique **B** par élimination d'une molécule d'hydracide, soit à l'amide cyclanique recherché **C** par cyclisation intramoléculaire, ces deux réactions étant compétitives. La présence du HMPT dans le milieu permettait d'envisager la cyclisation avec un halogénure aussi peu actif que le chloré.

Les essais ont été réalisés par action du diéthyl amidure de lithium "activé" sur l'amide ω-chloré maintenu aux températures indiquées dans le tableau II. A la fin de l'addition on laisse revenir le milieu à la température ambiante (essais *6*, *9*, *10* exceptés).

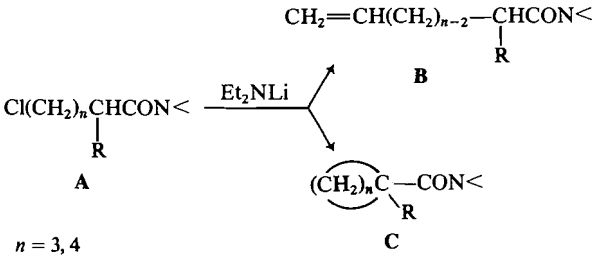
14	I	4	$(CH_2)_4$		Me	80

*Les réactions sont effectuées avec $ClCH_2{-}CH(CH_3){-}CH_2Br$.
†Rendement faible dû à la formation de 65% de lactame éthylénique.



Amides linéaires ω-chlorés A (R = H)

Dans ce cas, la réaction majoritaire est la cyclisation et on atteint avec un rendement satisfaisant les amides cyclobutaniques et cyclopentaniques attendus (tableau 2, essais *1*, *2* et *3*). Les substituants portés par l'azote n'influent pas sur le cours de la réaction.

Amides ramifiés ω-chlorés A (R ≠ H)

Une ramification en α de la fonction amide modifie les résultats profondément. On isole dans la plupart des cas un mélange d'amide ω-éthylénique **B** et d'amide cyclanique **C** mais la réaction d'élimination l'emporte et nous n'avons pas réussi à augmenter la proportion d'amides cyclaniques quel que soit *n* (3 ou 4). On peut penser que l'empêchement stérique au niveau du carbone en α de la fonction est responsable de cette évolution différente de la réaction. Nous avons alors isolé des amides ω-éthyléniques purs (essais *4*, *7*, *10*, *11*). Là encore, les substituants portés par l'azote ne changent pas le cours de la réaction. Si la ramification se trouve en γ de la fonction amide et en β de l'halogène on obtient aussi un mélange d'amides éthylénique et cyclanique:

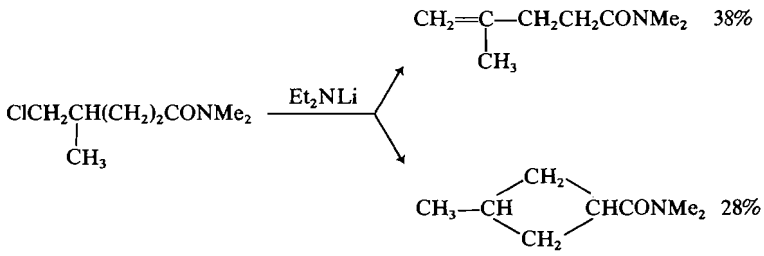


TABLEAU 2. Action du diéthyl amidure de lithium "activé" sur les amides ω-halogénés **A** → **B** + **C**

Essai	Amide initial	Température		Rendement (%)	
		Addition	Hydrolyse	**B**	**C**

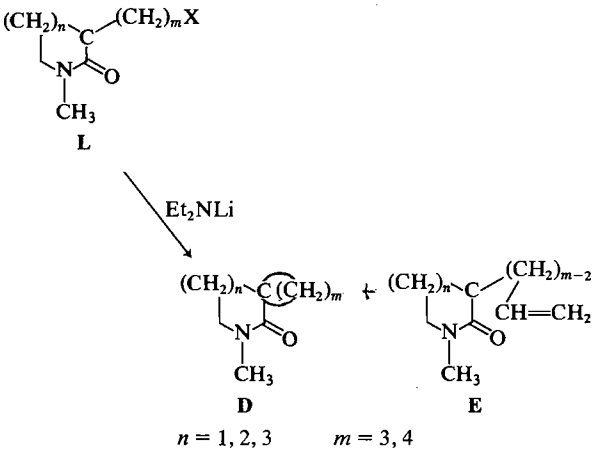
Essais de cyclisation des lactames halogénés en spirolactames

Nous avons étudié les γ, δ- et ε-lactames halogénés *N*-substitués:



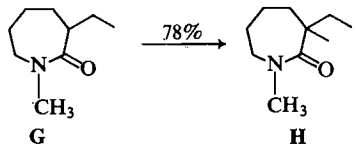
$n = 1, 2, 3$ $m = 3, 4$

Lors de tous les essais, nous avons additionné la base au lactame halogéné aux températures indiquées dans le tableau 3. La réaction de cyclisation intramoléculaire conduira à **D**, l'élimination d'une molécule d'hydracide à **E**. Les γ-lactames chlorés **L** ($n = 1$, $m = 3$ et 4) et les δ-lactames chlorés **L** ($n = 2$, $m = 3$ et 4) conduisent avec d'excellents rendements aux spirolactames **D**. Même le cycle cyclobutanique se forme aisément. Par contre, les ε-lactames **L** ($n = 3$, $m = 3$ et 4) ont fourni un mélange de **D** et de lactame éthylénique **E** si X = Cl, mais si X = Br ou I, la réaction d'élimination est totale.

Nous avons cependant constaté que, malgré une première substitution, la formation du carbanion en α du CO était aisée ainsi que l'alkylation ultérieure. Le lactame monosubstitué **G**, traité par un équivalent d'amidure activé, puis par l'iodure de méthyle a conduit au lactame dialkylé **H** avec un très bon rendement. Il est donc permis de penser que le demi échec rencontré lors de ces essais de cyclisation est dû, au moins en partie, à la conformation des ε-lactames.

TABLEAU 3. Action du diéthylamidure de lithium "activé" sur les lactames halogénés **L** → **D** + **E**

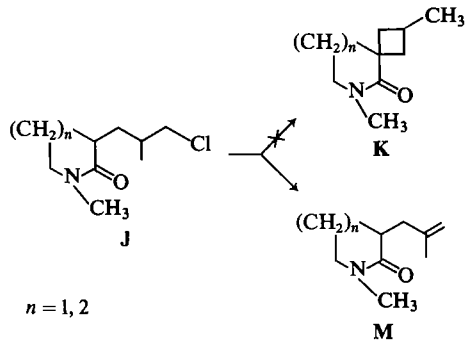
Essai	**L**			% **D**	% **E**
	n	*m*	X		
1	1	3	Cl	92	0
2	1	4	Cl	92	0
3	2	3	Cl	76	0
4	2	4	Cl	97	0
5	3	3	Cl	49	44
6	3	4	Cl	44	50
7	3	4	Br	0	85
8	3	4	I	0	83



D'autre part, nous avons tenté la cyclisation des γ- et des δ-lactames chlorés **J** présentant une ramification en β du chlore, ce qui aurait permis d'atteindre les spirolactames substitués **K**. Seule la réaction d'élimination a lieu; on isole alors le composé vinylique **M** avec un rendement de 76%.

Conclusion

Ces essais de cyclisation des amides et lactames chlorés **I** et **III** ont permis la mise au point d'une synthèse directe d'amides tertiaires cyclobutaniques



et cyclopentaniques et de γ- et δ-spirolactames dans d'excellentes conditions.

Partie expérimentale

La structure des différents produits a été confirmée par spectrographie infrarouge et rmn. Les spectres infrarouges ont été effectués avec un spectrophotomètre Perkin Elmer 457 sous forme de film. Les spectres rmn ont été enregistrés avec un appareil Perkin Elmer R 24 à 60 MHz sur des échantillons en solution dans le tétrachlorure de carbone et en utilisant le tétraméthyl silane comme référence interne. La pureté des produits a été contrôlée par cpv (colonne SE 30 de 2.5 m). Les analyses centésimales sont correctes à ±0.30% pour l'hydrogène et le carbone.

Amides ω-chlorés

Sauf indication contraire, suivre le mode opératoire décrit pour les amides linéaires, ramifiés ou cycliques (réf. 3).

A series of γ-sulfone sulfonyl chlorides undergo a novel reduction upon reaction with lithium aluminum hydride to furnish the corresponding ethyl sulfones. The reactions appear to proceed in an S_N2 fashion with the chlorosulfonyl moiety functioning as the leaving group. In general sulfonyl chlorides furnish mercaptans as hydride reduction products.

A novel two-phase hydrolysis is shown to convert a thiol ester to a symmetric sulfide which involves hydrolysis and an S_N2 displacement in the aqueous phase.

HARVEY OWEN FONG, WILLIAM RAYNE HARDSTAFF, DENIS GEORGE KAY, RICHARD FRANCIS LANGLER, RICHARD HERMAN MORSE et DEIG-NEVY SANDOVAL. Can. J. Chem. **57**, 1206 (1979).

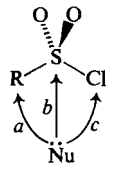
Une série de chlorures de γ-sulfone-sulfonyles subit une nouvelle réduction par réaction avec de l'hydrure de lithium et d'aluminium pour fournir les sulfones éthylées correspondantes. Les réactions semblent se produire par un mécanisme S_N2 dans lequel le groupe chlorosulfonyle agit comme nucléofuge. En général, les chlorures de sulfonyles conduisent aux mercaptans si on les soumets à une réduction par les hydrures.

On montre qu'une nouvelle hydrolyse en deux étapes permet de transformer un thioester en sulfure symétrique; la réaction implique une hydrolyse et une substitution S_N2 dans la phase aqueuse.

[Traduit par le journal]

Introduction

For some time, we have had an interest in the preparation and chemistry of sulfonyl chlorides (1–10). In principle, sulfonyl chlorides offer three potential sites for reactions with nucleophiles as shown below.



Pathway *c* involves sulfinate anion formation and has been suggested previously (5). Pathway *b* is an established pathway for the reaction of sulfonyl chlorides and represents the normal site of nucleophilic attack in sulfonate ester formation, when sulfenes do not intervene (11). To our knowledge, pathway *a* has not been observed or proposed previously.

Pathway *a* may be inferred as a possibility by analogy to other isomeric sulfur functional groups which can behave in the same way independently of the atoms by which the functional group is held in place. For example the following pair of cheletropic reactions are known (12, 13).

[1]  $\xrightarrow{\Delta}$ $R_1R_2C{=}CR_3R_4 + SO_2\uparrow$

[2]  $\xrightarrow{\Delta}$ $R_1R_2C{=}CR_3R_4 + SO_2\uparrow$

Thus the extrusion of SO_2 proceeds in a facile way whether the second point of attachment is sulfur or oxygen. The chlorosulfonyl group is well known to be a good leaving group when attached by oxygen (14, 15) as shown below.

[3] 
$\longrightarrow$ $Nu{-}R + SO_2 + Cl^-$

Hence, the possibility that the chlorosulfonyl moiety may function as a leaving group, whether it is attached by sulfur or oxygen, may be adduced. This possibility may have some immediate application in rationalizing the difficulties experienced in attempts to prepare sulfonyl chlorides, where the R group forms a particularly stable cation (16, 17). For

[1]To whom all correspondence should be addressed.

0008-4042/79/101206-08$01.00/0

example, we ourselves[2] have observed that 1-mercaptomethylnaphthalene forms 1-chloromethylnaphthalene upon chlorine–water oxidation under conditions which are known to furnish sulfonyl chlorides (6).

Results and Discussion

In connection with our ongoing studies of sulfide chlorinations (18), we wished to prepare some mercaptosulfones of the type: $RSO_2CH_2CH_2SH$. Our first attempt to prepare such a system utilized thiourea in standard fashion.

[4] $PhSO_2CH_2CH_2Cl \xrightarrow[(ii)\ ^-OH/H_2O]{(i)\ (NH_2)_2CS/EtOH} \times\!\!\rightarrow PhSO_2CH_2CH_2SH$

Since it is known that some sulfonyl chlorides can be converted into the corresponding mercaptans with lithium aluminum hydride (19, 20) we began the synthesis of the appropriate sulfone sulfonyl chlorides anticipating that they could be transformed into the desired mercaptosulfones with $LiAlH_4$. The general synthetic approach is outlined in Scheme 1.

Reaction of the sulfone sulfonyl chlorides **1***e*–**4***e* with lithium aluminum hydride furnished the corresponding ethyl sulfones as shown in [5].

[5] $RSO_2CH_2CH_2SO_2Cl \xrightarrow[THF]{LiAlH_4} RSO_2CH_2CH_3 + Li_2S$

1*e* R = Ph— **1***f*-**4***f*

2*e* R = CH_3CH_2—

3*e* R = CH_3—

4*e* R = $PhCH_2$—

Upon acidification of the reaction mixtures, H_2S was evolved.

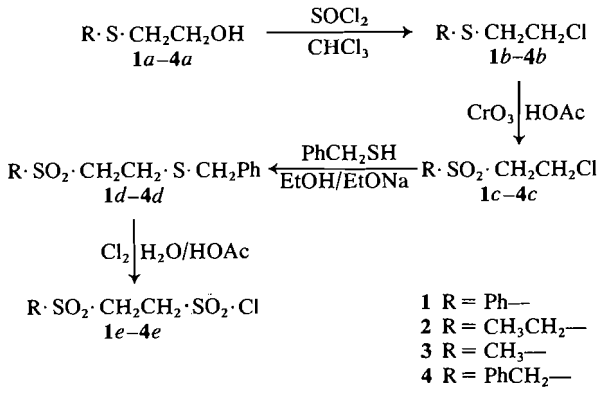
The first problem raised by these results is that of the scope of the reaction. Mercaptans are the products observed upon reduction of aromatic sulfonyl chlorides (ref. 20, p. 124), which would be resistant to nucleophilic attack on the carbon to which the chlorosulfonyl group is attached. However, it seemed possible that chlorosulfonyl groups attached to sp^3 carbon might normally give complete reduction to the corresponding alkyl group upon treatment with lithium aluminum hydride. Such a possibility was readily discarded by the results from the reduction of 2,2-diphenylethanesulfonyl chloride, which furnished the mercaptan as the exclusive product.

[6] $Ph_2CHCH_2SO_2Cl \xrightarrow[THF]{LiAlH_4} Ph_2CHCH_2SH$

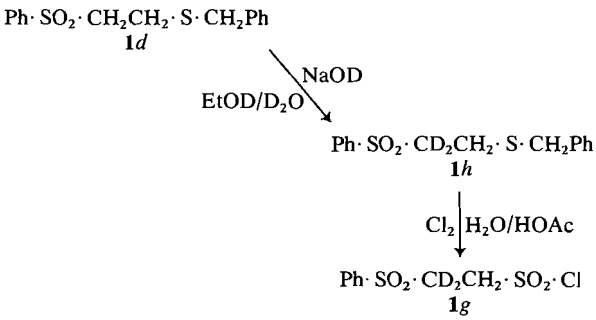
Consequently, the results observed for the hydride reductions of **1***e*–**4***e* are novel and not general whether or not the carbon bearing the chlorosulfonyl group is sp^3 hybridized.

We then began an examination of the mechanism of the reductions of **1***e*–**4***e*. Two reasonable possibilities were discernible, viz. (*i*) hydride induced elimination (E2 or $E1_{cb}$) followed by Michael-type addition of hydride to the intermediate vinyl sulfone or (*ii*) S_N2 displacement of the sulfur atom.

Our first attempt to distinguish between the two mechanistic schemes required the preparation of the dideuterated sulfone sulfonyl chloride **1***g* as shown in Scheme 2. Both mass spectrometry and nmr indicated that the sulfone sulfide **1***h* had incorporated ca. 94% deuterium at the carbon α to the sulfonyl group. Unfortunately, the mass spectrum of the sulfone sulfonyl chloride **1***g* did not show ions containing the methylene α to the sulfone sulfonyl group. However, the nmr of **1***g* indicated that no back-exchange had occurred during its preparation. Lithium aluminum hydride reduction of the dideuterated sulfone sulfonyl chloride **1***g* furnished phenyl ethyl sulfone which retained ca. 80% deuterium at the carbon α to the sulfonyl group. Work-up of this reaction involves the addition of water, so that there was a second opportunity for back-exchange before analysis of the product could be undertaken. In spite of these



SCHEME 1



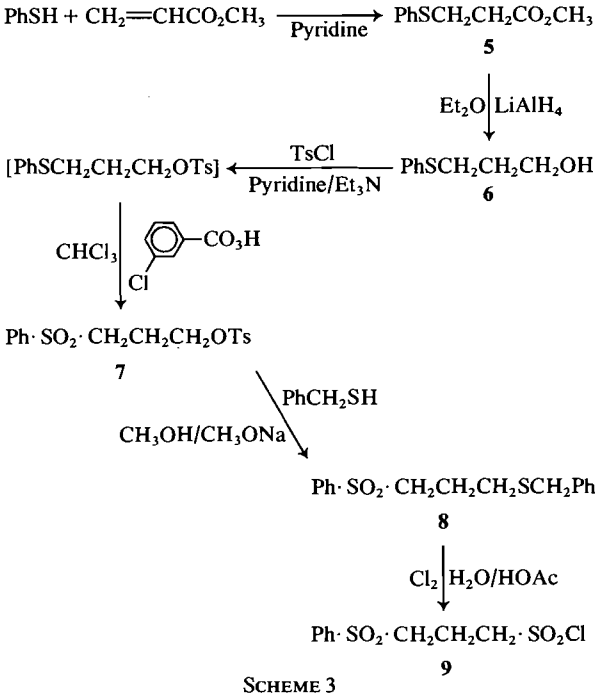
SCHEME 2

[2]H. O. Fong, R. F. Langler, and J. A. Pincock. Unpublished results.

difficulties, the labelling results indicate that somewhat more than half of the product formed without loss of label and that therefore the major pathway by which phenyl ethyl sulfone formed is an S_N2 displacement.

In our second approach, we have prepared phenyl vinyl sulfone and subjected it to standard hydride reduction conditions.[3] The product obtained was composed of oligomeric polysulfones which were separated on preparative tlc plates into three groups. The major band showed a very weak signal near δ 3.0 in its nmr, which could be attributed to a minor amount of phenyl ethyl sulfone (< 10% overall). The other bands showed no indication of phenyl ethyl sulfone by nmr or tlc. Consequently, it is now clear that an S_N2 displacement of sulfur is the near exclusive mode of formation of the ethyl sulfones.

The next point which we wished to clarify was the possible role of the sulfone sulfonyl groups in the reductions of **1***e*–**4***e*. To examine this question we have synthesized the sulfone sulfonyl chloride **9** which interposes another methylene between the sulfonyl groups. The complete synthesis of **9** is depicted in Scheme 3.



SCHEME 3

Treatment of the sulfone sulfonyl chloride **9** with lithium aluminum hydride furnished the mercaptosulfone **10**.

[3]Some vinyl sulfones may be satisfactorily reduced to the saturated sulfones with $LiAlH_4$ (21, 22).

[7] $PhSO_2CH_2CH_2CH_2SO_2Cl \xrightarrow[THF]{LiAlH_4}$ **9**

$PhSO_2CH_2CH_2CH_2SH \xrightarrow[MeOH/MeONa]{PhCH_2Cl}$ **8**

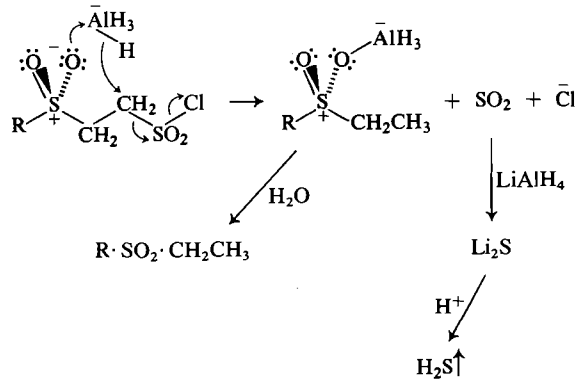
10

As expected **10** was readily converted into **8** under standard conditions.

The final problem remaining is that of the oxidation state of the sulfur atom when the carbon–sulfur bond is broken. By this time we had tentatively concluded that the chlorosulfonyl group was itself the leaving group displaced by hydride and that no preliminary reduction, for example to sulfinate anion, was necessary. Should this be the case, then another leaving group would be displaceable. Ideally a test case would involve a leaving group which was not capable of reduction before displacement, thereby removing the necessity of assuming that the chlorosulfonyl groups of **1***e*–**4***e* require conversion to another form before displacement can occur. We have chosen a chlorine atom as the leaving group.

[8] $PhSO_2CH_2CH_2Cl \xrightarrow[THF]{LiAlH_4} PhSO_2CH_2CH_3$

Consequently we have reached the view that these substitutions involve S_N2 displacements of the chlorosulfonyl group itself and that there must be some interaction between the reagent and the sulfone sulfonyl group. The most likely role for the sulfone sulfonyl group would be as an electron donor to the aluminum atom of the lithium aluminum hydride. This role would correspond to that of the carbonyl oxygen atom during a ketone reduction, viz. "$H:^-$ attacks carbon as the oxygen is complexing with released AlH_3" (23). Moreover aluminum hydrides generally form donor adducts with remarkable facility (24). The origin of the difference in behaviour of **1***e*–**4***e* and **9** would then lie with the fact that **1***e*–**4***e* would be able to form favorable six-membered transition states (as shown in Scheme 4) but **9** would



SCHEME 4

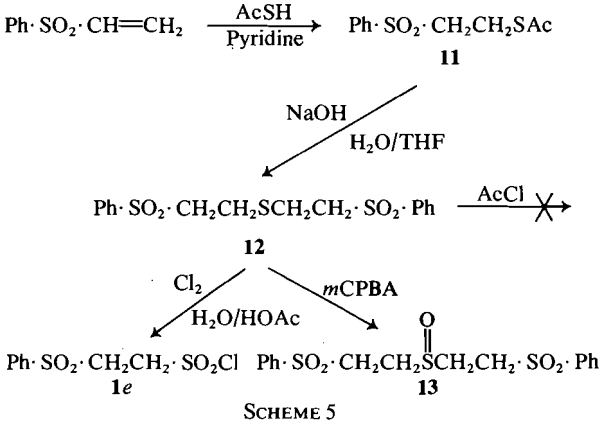
require an unfavourable seven-membered transition state and therefore reverts to typical behaviour, i.e., reduces to the mercaptan.

Scheme 5 depicts our final effort to establish a method for the preparation of the desired mercaptosulfones. We have prepared and hydrolyzed thiolacetate (**11**) in an attempt to obtain the mercaptosulfone corresponding to **1***e*.

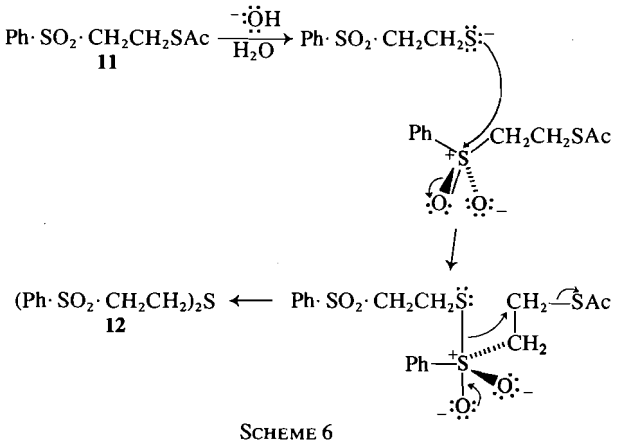
Treatment of the hydrolysis product **12** with acetyl chloride failed to afford **11**, although the conditions employed are known to convert thiols to thiol acetates (25). A priori the isolation of a nonmercaptan from thiolacetate hydrolysis suggested that **12** was a disulfide since thiols are well known to be sensitive to air oxidation (26). However, (*i*) chlorine–water oxidation of the disulfide would have furnished 2 equiv. of the sulfone sulfonyl chloride **1***e*, whereas **12** actually furnished **1***e* in 60% yield on a 1:1 basis and (*ii*) peroxidation of **12** furnished the corresponding disulfone sulfoxide **13** and not the disulfone thiolsulfinate required if **12** were a disulfide.

Under the experimental conditions used for the hydrolysis of **11**, the organic phase (THF) was not miscible with the aqueous phase. When an hydrophobic thiol ester, benzyl thiol acetate, was subjected to the same reaction conditions, it was recovered unchanged. This result suggests that hydrolysis occurs in the aqueous phase and not in the 'wet' THF layer. Hydrolysis of **11** with an equivalent of benzyl chloride present in the THF layer furnished the disulfone sulfide **12** and unchanged benzyl chloride. Finally, as expected, substitution of methanol for THF, which provides an homogeneous reaction mixture, failed to divert the formation of **12** from **11**. These latter results indicate that the S_N2 displacement proceeds in the same phase as the hydrolysis step, and that the displacement proceeds faster than the hydrolysis.

Since thiol esters normally hydrolyze smoothly to furnish thiols and not sulfides, the relatively rapid



SCHEME 5



SCHEME 6

S_N2 displacement, in this case, must be subject to an unusual acceleration in rate. A role for the thiol ester sulfonyl group in accelerating the substitution reaction is shown in Scheme 6.

In conclusion, then, we have observed a novel sulfonyl chloride reduction reaction which appears to be the first reported case in which a chlorosulfonyl group, attached to carbon by sulfur, functions as a leaving group. We have also furnished details for the novel hydrolytic conversion of a thiol ester into a symmetric sulfide.

Experimental

General

The ir spectra were recorded on a Perkin-Elmer 237B grating spectrophotometer. The nmr spectra were obtained on a Varian T-60 instrument using TMS as the internal standard. The mass spectra were recorded on a Dupont-CEC model 21-104 mass spectrometer. The samples were directly introduced using an allglass probe and the spectra run at 30 eV with a source temperature of 150°C. Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected.

Chlorinations

The appropriate amount of sulfide was suspended in glacial acetic acid (25 mL) and water (3 mL) added. Cl_2 (ca. 200 mL/min) was bubbled into the reaction mixture for 0.5 h. Water (100 mL) was added and the resultant mixture washed with chloroform (five 100-mL aliquots). The combined organic layers were washed with 2.5% w/v NaOH (two 50-mL aliquots). After drying and concentration a crude residue was obtained.

Standard Work-up

A volume of water equal to the total volume of the reaction mixture was added to the reaction. Methylene chloride (three 100-mL portions) was used to extract the aqueous mixture. The combined organic layers were dried and concentrated affording crude product.

Preparation of Sulfide Alcohols ***1***a–***4***a

(i) ***1***a *and* ***2***a

Sodium metal (1 equiv.) was dissolved in absolute ethanol (150 mL) and the appropriate mercaptan (10 g) was added. The reaction mixture was cooled and 2-chloroethanol (1

equiv.) in absolute ethanol (50 mL) was added dropwise over 15 min. The reaction mixture was refluxed for 1 h and subjected to standard work-up.

$PhSCH_2CH_2OH$ (**1***a*) was rectified (10.48 g, bp 140°C/5 Torr); ir ($CHCl_3$): 3460 cm^{-1}; nmr ($CDCl_3$) δ: 7.40 (5H, s), 3.76 (2H, t), and 3.10 (3H, m); ms *m/e*: 154 (M^+, 100%), 123 (90%), 109 (36.5%) and 45 (85%).

$CH_3CH_2SCH_2CH_2OH$ (**2***a*) was rectified (13.06 g, bp 90°C/25 Torr); ir ($CHCl_3$): 3455 cm^{-1}; nmr ($CDCl_3$) δ: 3.60 (3H, m), 2.73 (2H, t), 2.40 (2H, q), and 1.16 (3H, t).

(ii) 3a and 4a

Sodium metal (1 equiv.) was dissolved in absolute ethanol (150 mL) and 2-mercaptoethanol (10 g) was added. The reaction mixture was cooled and methyl iodide or benzyl chloride (1 equiv.) in absolute ethanol (50 mL) was added dropwise over 15 min. The reaction mixture was stirred at ambient temperature overnight. Standard work-up afforded crude sulfide alcohol.

$CH_3SCH_2CH_2OH$ (**3***a*) was rectified (6.84 g, bp 81°C/37 Torr); ir ($CHCl_3$): 3460 cm^{-1}; nmr ($CDCl_3$) δ: 3.70 (3H,m), 2.66 (2H, m), and 2.03 (3H, s).

$PhCH_2SCH_2CH_2OH$ (**4***a*) was rectified (17.86 g, bp 161°C 4.2 Torr); ir ($CHCl_3$): 3465 cm^{-1}; nmr ($CDCl_3$) δ: 7.23 (5H, s), 3.70 (2H, s), 3.60 (2H, t), 2.96 (1H, s), and 2.56 (2H, t); ms *m/e*: 168 (M^+ 16.7%) and 91 (100%).

Preparation of Chlorosulfides **1**b–**4**b

The sulfide alcohol (15 g) was dissolved in chloroform (30 mL) and the solution brought to reflux. Thionyl chloride (1 equiv.) in chloroform (20 mL) was added dropwise over a period of 15 min. Upon completion of the addition the reaction mixture was refluxed for 3 h and the solvent evaporated.

$PhSCH_2CH_2Cl$ (**1***b*) was rectified (14.279 g, bp 111°C/5 Torr); nmr ($CDCl_3$) δ: 7.50 (5H, m), 3.75 (2H, m), and 3.30 (2H, m); ms *m/e*: 174 (18.6%) 172 (M^+, 56%) 123 (100%), and 109 (35%).

$CH_3CH_2SCH_2CH_2Cl$ (**2***b*) was rectified (14.95 g, bp 71°C/30 Torr); nmr ($CDCl_3$) δ: 3.63 (2H, t), 2.90 (2H, t), 2.63 (2H, q), and 1.30 (3H, t).

$CH_3SCH_2CH_2Cl$ (**3***b*) was rectified (14.340 g, bp 48°C/20 Torr); nmr ($CDCl_3$) δ: 3.63 (2H, t), 2.80 (2H, t), and 2.18 (3H, s).

$PhCH_2SCH_2CH_2Cl$ (**4***b*) was rectified (12.393 g, bp 138°C/220 Torr); nmr ($CDCl_3$) δ: 7.23 (5H, s), 3.70 (2H, s), 3.50 (2H, t), and 2.70 (2H, t); ms *m/e*: 188 (10%), 186 (M^+, 30%), and 91 (100%).

Preparation of Chlorosulfones **1**c–**4**c

A mixture of chromium trioxide (2.5 equiv.) and glacial acetic acid (100 mL) was vigorously stirred. A solution of the chlorosulfide (5 g) in glacial acetic acid (10 mL) was added over 5 min and the reaction maintained at 90–100°C for 0.5 h. Standard work-up afforded a mixture of crude chlorosulfone and acetic acid.

$PhSO_2CH_2CH_2Cl$ (**1***c*) was obtained by dissolving the crude concentrate in chloroform (200 mL) and washing the organic solution with 5% NaOH (100-mL aliquots) until the aqueous pH remained basic. The organic layer was dried ($MgSO_4$), filtered, and concentrated. The residue was recrystallized from 95% ethanol (4.930 g, mp 51–53°C); ir ($CHCl_3$): 1325 and 1150 cm^{-1}; nmr ($CDCl_3$) δ: 7.75 (5H, m) and 3.60 (4H, m); ms *m/e*: 206 (4.3%), 204 (M^+, 13.0%), 141 (50%), and 77 (100%).

$CH_3CH_2SO_2CH_2CH_2Cl$ (**2***c*) was rectified (5.018 g, bp 141°C/5 Torr); ir ($CHCl_3$): 1320 and 1125 cm^{-1}; nmr ($CDCl_3$) δ: 3.90 (2H, t), 3.40 (2H, t), 3.13 (2H, q), and 1.33 (3H, t); ms *m/e*: 130 (5.4%), 128 (16.8%), 65 (18.9%), 63 (52.6%), and 29 (100%).

$CH_3SO_2CH_2CH_2Cl$ (**3***c*) was rectified (2.763 g, bp 150°C/12 Torr); ir ($CHCl_3$): 1325 and 1150 cm^{-1}; nmr ($CDCl_3$) δ: 4.00 (2H, t), 3.50 (2H, t), and 3.18 (3H, s); ms *m/e*: 65 (33%) and 63 (100%).

$PhCH_2SO_2CH_2CH_2Cl$ (**4***c*) was obtained in the manner described above for **1***c*. The chlorosulfone was recrystallized from 95% ethanol (4.296 g, mp 90–91°C); ir ($CHCl_3$): 1320 and 1120 cm^{-1}; nmr ($CDCl_3$) δ: 7.46 (5H, s), 4.33 (2H, s), 3.83 (2H, t), and 3.30 (2H, t); ms *m/e*: 92 (8.8%) and 91 (100%).

Preparation of $PhSCH_2CH_2CO_2CH_3$ *(5)*

Benzenethiol (15.620 g) was dissolved in dry pyridine (100 mL) and methyl acrylate (19.8 g) added dropwise over 20 min. The reaction mixture was stirred at ambient temperature for 1.5 h. Chloroform (100 mL) was added and the resultant solution washed with 10% HCl (four 100-mL aliquots). The organic phase was dried ($MgSO_4$), filtered, and the solvent evaporated. The residue was distilled at reduced pressure (22.47 g, bp 113–115°C/2 Torr); ir ($CHCl_3$): 1740 cm^{-1}; nmr ($CDCl_3$) δ: 7.40 (5H, s), 3.70 (3H, s) 3.20 (2H, t), and 2.66 (2H, t); ms *m/e*: 196 (M^+, 100%), 136 (48.3%), 123 (86.5%), and 109 (52.8%).

Preparation of $PhSCH_2CH_2CH_2OH$ *(6)*

Lithium aluminum hydride (0.639 g) was covered with diethyl ether (20 mL) and the mixture refluxed for 0.5 h. The mixture was cooled to ambient temperature and a solution of the sulfide ester (**5**, 3.300 g) in diethyl ether (100 mL) added dropwise over 15 min. The reaction mixture was refluxed for 1 h and cooled to ambient temperature. Ethyl acetate (5 mL) was added dropwise, followed by 1% HCl (20 mL) added dropwise. Water (100 mL) was added and the layers separated. The aqueous layer was washed with methylene chloride (four 100-mL aliquots). The organic layers were dried and concentrated. The crude sulfide alcohol was rectified at reduced pressure, affording clean **6** (1.808 g, bp 130°C/2 Torr); ir ($CHCl_3$) 3650 and 3460 cm^{-1}; nmr ($CDCl_3$) δ: 7.40 (5H, s), 3.80 (2H, t), 3.06 (2H, t), and 1.90 (3H, m); ms *m/e*: 168 (M^+, 63%), 123 (22.2%), and 110 (100%).

Preparation of $PhSO_2CH_2CH_2CH_2OTs$ *(7)*

The sulfide alcohol (**6**) (11.054 g) was dissolved in a solution of dry pyridine (150 mL) and triethyl amine (6.645 g) and the reaction mixture cooled with an ice–water bath. *p*-Toluenesulfonyl chloride (12.544 g) was added in small portions over 5 min and the reaction mixture stirred at room temperature for 1 h. Methylene chloride (300 mL) was added and the solution washed with 10% HCl (100-mL aliquots) until the aqueous pH remained acidic. The organic layer was dried and concentrated affording crude sulfide tosylate as an oil.

The total crude sulfide tosylate was dissolved in chloroform (475 mL) and the solution cooled with an ice–salt–water bath. *m*-Chloroperbenzoic acid (85%, 26.580 g) was added in small portions over a 10-min period. The ice was allowed to melt and the reaction reached ambient temperature with overnight stirring. The reaction mixture was washed with 2.5% NaOH (100-mL aliquots) until the aqueous pH remained basic. The organic layer was dried and concentrated. Crude sulfone tosylate was recrystallized from 95% EtOH affording clean **7** (17.308 g, mp 82–84°C); ir ($CHCl_3$): 1370, 1320, 1175, and 1150 cm^{-1}; nmr ($CDCl_3$) δ: 7.76 (9H, m), 4.20 (2H, t), 3.26 (2H, t), 2.46 (3H, s), and 2.10 (2H, m); ms *m/e*: 354 (M^+, 14.2%), 183 (100%), 155 (53%), 143 (75%), and 91 (60%).

Preparation of the Sulfone Sulfides **1**d–**4**d

Sodium metal (2 equiv.) was dissolved in absolute ethanol (100 mL) and the appropriate chlorosulfone **1***c*–**4***c* (5 g) was added. The reaction mixture was stirred at room temperature

for 15 min and phenylmethanethiol (1 equiv.) was added. The reaction mixture was refluxed for 1 h, cooled, and subjected to standard work-up.

$PhSO_2CH_2CH_2SCH_2Ph$ (**1***d*) was recrystallized from 95% ethanol (5.849 g, mp 68–71°C); ir ($CHCl_3$): 1325 and 1150 cm^{-1}; nmr ($CDCl_3$) δ: 7.86 (5H, m), 7.33 (5H, s), 3.70 (2H, s), 3.26 (2H, m), and 2.73 (2H, m); ms *m/e*: 292 (M^+, 6.3), 150 (59%), 123 (34%), and 91 (100%). *Anal.* calcd. for $C_{15}H_{16}O_2S_2$: C 61.61, H 5.51; found: C 61.23, H 5.67.

$CH_3CH_2SO_2CH_2CH_2SCH_2Ph$ (**2***d*) was recrystallized from 95% ethanol (5.970 g, mp 42–45°C); ir ($CHCl_3$): 1320 and 1125 cm^{-1}; nmr ($CDCl_3$) δ; 7.33 (5H, s), 3.76 (2H, s), 2.96 (6H, m), and 1.33 (3H, t); ms *m/e*: 244 (M^+, 5%), 150 (21%), 123 (21%), and 91 (100%). *Anal.* calcd. for $C_{11}H_{16}O_2S_2$: C 54.06, H 6.59; found: C 54.21, H 6.65.

$CH_3SO_2CH_2CH_2SCH_2Ph$ (**3***d*) was recrystallized from 95% ethanol (5.636 g, mp 56–58°C); ir ($CHCl_3$): 1320 and 1140 cm^{-1}; nmr ($CDCl_3$) δ: 7.26 (5H, s), 3.70 (2H, s), and 3.00 (7H, m); ms *m/e*: 230 (M^+, 8.3%), 150 (26%), 123 (27%), and 91 (100%). *Anal.* calcd. for $C_{10}H_{14}O_2S_2$: C 52.14, H 6.12; found: C 51.94, H 5.87.

$PhCH_2SO_2CH_2CH_2SCH_2Ph$ (**4***d*) was recrystallized from 95% ethanol (4.325 g, mp 152–153°C); ir ($CHCl_3$): 1325 and 1120 cm^{-1}; nmr ($CDCl_3$) δ: 7.33 (5H, s), 7.20 (5H, s), 4.10 (2H, s), 3.63 (2H, s), and 2.80 (4H, m); ms *m/e* 306: (M^+, 2%), 150 (20%), 123 (11%), and 91 (100%). *Anal.* calcd. for $C_{16}H_{18}O_2S_2$: C 62.71, H 5.92; found: C 62.98, H 5.83.

*Preparation of $PhSO_2CH_2CH_2CH_2SCH_2Ph$ (**8**)*

Sodium metal (0.130 g) was dissolved in methanol (25 mL) and phenylmethanethiol (0.7 mL) added. The sulfone tosylate (**7**) (2.000 g) was added and the reaction mixture stirred at room temperature overnight. Standard work-up furnished crude **8** which was recrystallized from 95% ethanol (1.120 g, mp 53–55°C); ir ($CHCl_3$): 1320 and 1145 cm^{-1}; nmr ($CDCl_3$) δ: 7.86 (5H, m), 7.37 (5H, s), 3.70 (2H, s), 3.23 (2H, t), 2.53 (2H, t), and 2.03 (2H, m); ms *m/e*: 306 (M^+, 2.9%), 143 (16.7%), 123 (13.1%), and 91 (100%). *Anal.* calcd. for $C_{16}H_{18}O_2S_2$: C 62.71, H 5.92; found: C 62.90, H 5.87.

Preparation of $Ph_2CHCH_2SCH_2Ph$

Sodium metal (0.321 g) was dissolved in absolute ethanol (100 mL) and phenylmethanethiol (1.7 mL) added. The tosylate of 2,2-diphenylethanol (4.69 g) was added and the reaction mixture refluxed for 48 h. Standard work-up afforded crude sulfide. The crude material was chromatographed on silica gel (450 g) employing carbon tetrachloride elution (100-mL fractions). Fractions 34–63 were combined and concentrated affording clean sulfide (1.509 g) as an oil; nmr ($CDCl_3$) δ: 7.33 (15H, m), 4.13 (1H, t), 3.66 (2H, s), and 3.13 (2H, d); ms *m/e*: 304 (M^+, 48%), 167 (100%), and 91 (98%).

*Preparation of the Sulfonyl Chlorides **1**e → **4**e, **9**, and $Ph_2CHCH_2SO_2Cl$*

The following benzylic sulfides were chlorinated following the procedure outlined under Chlorinations.

The benzylic sulfide (**1***d*) (4.999 g) furnished $PhSO_2CH_2CH_2SO_2Cl$ (**1***e*) (3.285 g, mp 179–181°C) after recrystallization from chloroform; ir ($CHCl_3$): 1390, 1330, 1170, and 1150 cm^{-1}; nmr (CD_3COCD_3) δ: 7.90 (5H, m), 4.37 (2H, m), and 3.90 (2H, m); ms *m/e*: 141 (60.4%), 125 (18.6%), and 77 (100%). *Anal.* calcd. for $C_8H_9ClO_4S_2$: C 35.75, H 3.37; found: C 35.48, H 3.51.

The benzylic sulfide (**2***d*) (5.343 g) furnished $CH_3CH_2SO_2CH_2CH_2SO_2Cl$ (**2***e*) (1.612 g, mp 104–106°C) after recrystallization from carbon tetrachloride; ir ($CHCl_3$): 1390, 1330, 1170, and 1140 cm^{-1}; nmr ($CDCl_3$) δ: 4.20 (2H, m), 3.66 (2H, m), 3.16 (2H, q), and 1.43 (3H, t); ms *m/e*: 222 (20.3%), 220 (M^+, 61%), 185 (96.2%), and 156 (100%). *Anal.* calcd. for $C_4H_9ClO_4S_2$: C 21.77, H 4.11; found: C 21.86, H 4.04.

The benzylic sulfide (**3***d*) (5.006 g) furnished $CH_3SO_2CH_2CH_2SO_2Cl$ (**3***e*) (2.684 g, mp 126–127°C) after recrystallization from chloroform; ir (KBr): 1375, 1325, 1160, and 1145 cm^{-1}; nmr (CD_3COCD_3) δ: 4.63 (2H, m), 3.90 (2H, m) and 3.23 (3H, s); ms *m/e* 143 (15%), 107 (12%), and 79 (100%). *Anal.* calcd. for $C_3H_7ClO_4S_2$: C 17.43, H 3.41; found: C 17.52, H 3.35.

The benzylic sulfide (**4***d*) (4.980 g) furnished $PhCH_2SO_2CH_2CH_2SO_2Cl$ (**4***e*) (3.524 g, mp 191–192°C) after recrystallization from chloroform, ir (KBr): 1375, 1325, 1160, and 1145 cm^{-1}; nmr (CD_3CN) δ: 7.50 (5H, s), 4.50 (2H, s), 4.10 (2H, m), and 3.70 (2H, m); ms *m/e*: 91 (100%), 65 (12.2%) and 48 (4.5%). *Anal.* calcd. for $C_9H_{11}ClO_4S_2$: C 38.22, H 3.92; found: C 38.08, H 3.90.

The benzylic sulfide (**8**) (6.229 g) furnished $PhSO_2CH_2CH_2CH_2SO_2Cl$ (**9**) (3.951 g, mp 117–119°C) after recrystallization from chloroform; ir ($CHCl_3$): 1335, 1320, 1170, and 1155 cm^{-1}; nmr (CD_3COCD_3) δ: 7.86 (5H, m), 4.23 (2H, t), 3.57 (2H, t), and 2.43 (2H, m); ms *m/e*: 284 (2.3%), 282 (M^+, 7.1%), 141 (100%), and 77 (88%). *Anal.* calcd. for $C_9H_{11}ClO_4S_2$: C 38.22, H 3.92; found: C 38.41, H 3.81.

$Ph_2CHCH_2SCH_2Ph$ (1.504 g) furnished crude 2,2-diphenylethanesulfonyl chloride. The crude sulfonyl chloride was chromatographed on silica gel (150 g) employing carbon tetrachloride elution (100-mL fractions). Fractions 12–20 were concentrated and combined affording clean sulfonyl chloride (0.786 g); ir (CCl_4): 1340 and 1175 cm^{-1}; nmr ($CDCl_3$) δ: 7.40 (10H, s), 4.90 (1H, t), and 4.50 (2H, d); ms *m/e*: 282 (2.3%), 280 (M^+, 7.3%), 180 (94%), 139 (100%), and 77 (91%).

Lithium Aluminum Hydride Reductions

The reductions of **1***e*–**4***e*, phenyl ω-chloroethyl sulfone and 2,2-diphenylethanesulfonyl chloride were all carried out in the same manner as illustrated below by the procedure for the reduction of **2***e*.

Lithium aluminum hydride (0.576 g) was added to dry THF (10 mL) and the mixture refluxed for 0.5 h. The mixture was cooled to ambient temperature and a solution of $CH_3CH_2SO_2CH_2CH_2SO_2Cl$ (**2***e*) (1.031 g) in THF (40 mL) was added dropwise over 10 min. The resultant solution was refluxed for 1 h. Upon cooling to room temperature ethyl acetate (5 mL) was added dropwise, followed by 1% HCl (20 mL) added dropwise. Standard work-up afforded clean diethyl sulfone (0.550 g) which was identical to authentic material by nmr, ir, and ms.

Results for these experiments are shown in Table 1.

*Reduction of $PhSO_2CH_2CH_2CH_2SO_2Cl$ (**9**)*

The sulfone sulfonyl chloride (**9**) (0.9976 g) was reduced with lithium aluminum hydride (0.448 g) as described above. The product was the mercaptosulfone **10** (0.491 g) obtained as an oil; ir (CCl_4): 1325 and 1150 cm^{-1}; nmr ($CDCl_3$) δ: 7.86 (5H, m), 3.37 (2H, t), 2.63 (2H, m), 2.00 (2H, m), and 1.46 (1H, t); ms *m/e*: 216 (M^+, 2.5%), 152 (94.8%), 143 (100%), 77 (65.5%), and 74 (52.5%).

*Reaction of $PhSO_2CH_2CH_2CH_2SH$ (**10**) and Benzyl Chloride*

Sodium metal (0.043 g) was dissolved in methanol (25 mL) and $PhSO_2CH_2CH_2CH_2SH$ (0.400 g) added. Benzyl chloride (0.236 g) was added and the reaction mixture stirred at ambient temperature for 24 h. Standard work-up furnished crude sulfone sulfide which was chromatographed on silica gel (50 g) employing chloroform elution (50-mL fractions). Fractions 3–5 were concentrated and combined affording clean sulfone sulfide (**8**) (0.128 g) which was identical to authentic material by nmr, ir, and tlc.

TABLE 1. Yields for $LiAlH_4$ reductions of sulfonyl substrates

Substrate	Product	Yield (%)
$PhSO_2CH_2CH_2SO_2Cl$ (**1***e*)	$PhSO_2CH_2CH_3$	79.0
$CH_3CH_2SO_2CH_2CH_2SO_2Cl$ (**2***e*)	$(CH_3CH_2)_2SO_2$	96.1
$CH_3SO_2CH_2CH_2SO_2Cl$ (**3***e*)	$CH_3SO_2CH_2CH_3$	94.4
$PhCH_2SO_2CH_2CH_2SO_2Cl$ (**4***e*)	$PhCH_2SO_2CH_2CH_3$	71.7
$Ph_2CHCH_2SO_2Cl$	Ph_2CHCH_2SH	51.5
$PhSO_2CH_2CH_2Cl$	$PhSO_2CH_2CH_3$	79.5

Preparation of $PhSO_2CD_2CH_2SCH_2Ph$ (1h)

Sodium metal (0.037 g) was dissolved in 95% CH_3CH_2OD–D_2O (35 mL) and the sulfone sulfide (**1***d*) (3.557 g) added. The reaction mixture was refluxed for 24 h. The bulk of the solvent (30 mL) was distilled off and the residue cooled. The dideuterated sulfone sulfide (3.331 g) was filtered off and shown to be identical to undeuterated material by ir, mp, and mixture mp; nmr ($CDCl_3$) δ: 7.86 (5H, m), 7.33 (5H, s), 3.70 (2H, s), and 2.73 (2H, s). Deuterium incorporation was determined by mass spectrometry on the cluster of ions at *m/e* 150 → 155 which indicated $\%d_0 = 0, d_1 = 10.5, d_2 = 81.9, d_3 = 6.6$.

Preparation and Reduction of $PhSO_2CD_2CH_2SO_2Cl$ (1g)

$PhSO_2CD_2CH_2SCH_2Ph$ (3.006 g) was converted into $PhSO_2CD_2CH_2SO_2Cl$ (2.417 g) as described for the nondeuterated sulfide (**1***d*). The dideuterated sulfone sulfonyl chloride was shown to be identical with nondeuterated material by ir, mp, and mixture mp. The nmr showed the absence of the signal at δ 3.90 which is present in the nmr of **1***e*.

$PhSO_2CD_2CH_2SO_2Cl$ (1.001 g) was reduced with lithium aluminum hydride (0.472 g) as described previously for **1***e*. The dideuterated phenyl ethyl sulfone obtained showed a weak multiplet at ca. δ 3.0 for nondeuterated and monodeuterated phenyl ethyl sulfone. The mass spectrum indicated a deuterium incorporation of $\%d_0 = 7.9, d_1 = 39.0, d_2 = 52.0, d_3 = 0.9$.

Reaction of Phenyl Vinyl Sulfone with $LiAlH_4$

Phenyl vinyl sulfone (1.003 g) was treated with lithium aluminum hydride (0.741 g) as described above for the sulfonyl compounds of Table 1. The crude product (0.709 g) showed three spots R_f, 0.08, 0.22, and 0.52 when developed (2×) on silica gel tlc plates with chloroform. A portion of the crude product (0.600 g) was chromatographed on preparative tlc plates and the bands scraped. All three bands showed SO_2 stretching in the ir spectra indicating that the products were sulfones. Each band was homogeneous on tlc and showed abundant ions in the mass spectrum with *m/e* > 170. The nmr showed the absence of the methylene signal near δ 3.0 from phenyl ethyl sulfone for the bands at R_f 0.08 and 0.22. The material at R_f 0.52 (0.217 g) showed a weak signal near δ 3.0 which if attributed to phenyl ethyl sulfone would mean that less than 25% of the sample was phenyl ethyl sulfone and that therefore less than 10% of the starting phenyl vinyl sulfone had been converted into phenyl ethyl sulfone

Preparation of $PhSO_2CH_2CH_2SAc$ (11)

Phenyl vinyl sulfone (1.006 g) and thioacetic *S*-acid (0.502 g) were added to dry pyridine (25 mL) and the reaction mixture stirred at ambient temperature for 1 h. Chloroform (100 mL) was added and the resultant solution washed with 10% HCl (50-mL aliquots) until the aqueous pH remained acidic. The organic layer was dried and concentrated affording crude **11**. The crude thiol ester was chromatographed on silica gel (100 g) employing chloroform elution (100-mL fractions). Fractions 5–8 were combined and concentrated affording the thiol ester as an oil (1.435 g); ir ($CHCl_3$) 1695, 1320, and 1150 cm^{-1}; nmr ($CDCl_3$) δ: 7.93 (5H, m), 3.40 (4H, m), and 2.33 (3H, s); ms *m/e*: 125 (22.6%), 77 (27.1%) and 45 (100%).

Hydrolysis of Thiol Ester 11

The thiol ester **11** (0.999 g) was added to a mixture of THF (80 mL) and sodium hydroxide (0.259 g) in water (16 mL). The reaction mixture was stirred at ambient temperature and worked up as described above for the preparation of phenyl vinyl sulfone. The residue was recrystallized from 95% ethanol (40 mL) affording clean disulfone sulfide (**12**) (0.637 g, mp 116–118°C); ir ($CHCl_3$): 1325 and 1150 cm^{-1}; nmr ($CDCl_3$) δ: 7.90 (10H, m), 3.33 (4H, m), and 2.90 (4H, m); ms *m/e*: 230 (31%), 229 (30%), 201 (18.2%), 87 (57.3%), 86 (100%), and 77 (58.9%). *Anal.* calcd. for $C_{16}H_{18}O_4S_3$: C 51.86, H 4.89; found: C 51.89, H 4.71.

Chlorinolysis of 12

The disulfone sulfide **12** (1.004 g) was suspended in glacial acetic acid (25 mL) and water (3 mL). Cl_2 (ca. 200 mL/min) was bubbled into the solution for 0.5 h. The reaction mixture was worked-up as described for the preparation of sulfonyl chlorides **1***e*–**4***e*. The crude residue furnished two crops of crystalline sulfone sulfonyl chloride **1***e* (0.431 g) which was identical to previously obtained **1***e* by ir, nmr, mp, mixture mp, and tlc. The mother liquor contained only traces of **1***e* as indicated by tlc.

Preparation of Disulfone Sulfoxide 13

A solution of the disulfone sulfide **12** (0.506 g) in chloroform (25 mL) was cooled with an ice–water bath and *m*-chloroperbenzoic acid (85%, 0.272 g) was added in small portions over 5 min. The ice was allowed to melt and the reaction to reach room temperature while stirring overnight. Methylene chloride (200 mL) was added and the resultant solution washed with 1% NaOH (50 mL). The organic phase was dried and concentrated. The residue was recrystallized from 95% ethanol (100 mL) affording clean disulfone sulfoxide (0.469 g, mp 179–181°C; ir (KBr): 1320, 1150, and 1055 cm^{-1}; nmr (DMSO-d_6) δ: 7.57 (10H, m), 3.30 (4H, m), and 2.86 (4H, m); Cmr (DMSO-d_6) δ: 43.12 (t), 47.87 (t) 127.79 (d), 129.51 (d), 134.14 (d), 138.46 (s); ms *m/e*: 141 (42.5%), 125 (37%), 109 (13%), and 77 (100%). *Anal.* calcd. for $C_{16}H_{18}O_5S_3$: C 49.72, H 4.69; found: C 49.51, H 4.73.

Acknowledgements

The authors are indebted to Mr. W. S. Mantle for some technical assistance during the initial stages of this work. We thank Dr. J. H. Kim for running the mass spectra. We are grateful to Dalhousie University for financial support in the form of a grant from the Research Development Fund.

ISHWARI P. SARASWAT, SURESH K. SRIVASTAVA, and ASHOK K. SHARMA. Can. J. Chem. **57**, 1214 (1979).

The parameters effective diffusion coefficients, activation energies, and entropies of activation are reported for the exchange of the ammine-complex cations of cobalt, viz. $[Co(NH_3)_6]^{3+}$ and $[Co(en)_3]^{3+}$ (en = enthylenediamine) on chromium ferrocyanide gel in the H form. The values of these constants throw significant light on the possible structural changes in the exchanger framework caused by the introduction of these large size complex cations. Kinetic measurements have been made as the function of particle size of the exchanger, temperature, and solution concentration of the exchanging ions. The slow step governing the rate of exchange is diffusion of ions through the exchanger particles.

ISHWARI P. SARASWAT, SURESH K. SRIVASTAVA et ASHOK K. SHARMA. Can. J. Chem. **57**, 1214 (1979).

On rapporte les paramètres suivants: coefficients effectifs de diffusion, énergies d'activation et entropies d'activation pour l'échange des cobaltiamines du type $[Co(NH_3)_6]^{3+}$ et $[Co(en)_3]^{3+}$ (en = éthylènediamine) sur des gels de ferrocyanure de chrome sous forme H. Les valeurs de ces constantes jettent de la lumière sur les changements structuraux possibles dans le squelette de l'échangeur qui sont causés par l'introduction de ces cations complexes volumineux. On a effectué des mesures cinétiques en fonction de la grosseur des particules d'échangeur, de la température et de la concentration de la solution des ions qui s'échangent. L'étape lente déterminant la vitesse de l'échange est la diffusion des ions à travers les particules d'échangeurs.

[Traduit par le journal]

Introduction

The rate factor in ion-exchange adsorption is of recognized importance for the economic and industrial employment of ion-exchangers. The ion-exchange kinetics of simple metal cations, particularly of alkali and alkaline earth metal ions, on various minerals, inorganic exchangers, and organic resins have been studied by a number of workers (1–7). However, little attention seems to have been paid to the kinetics and mechanism of exchange of large cations or complex cations on inorganic exchangers. In continuation of our studies on the exchange behaviour of some simple cations with chromium ferrocyanide gel [CFC] reported earlier (8), the present article deals with the kinetic measurements for the exchange of some ammine complex cations of cobalt(III), viz., $[Co(NH_3)_6]^{3+}$ and $[Co(en)_3]^{3+}$ on the same substrate. To understand the mechanism and other theoretical aspects of the exchange process some kinetic and thermodynamic parameters like effective diffusion coefficients, activation energies, and entropies of activation are reported.

Experimental

All the chemicals used were of analytical grade and the solutions were prepared in double distilled water. Bausch and Lomb Spectronic-20 and Unicam-500 were used for spectrophotometric measurements.

Preparation and Analysis

Chromium ferrocyanide with exchange capacity 3.65 mequiv./g was prepared as reported earlier (9). The synthesized sample was subjected to chemical analysis, thermogravimetric analysis, ir, and X-ray measurements and the data agreed with the data reported for the compound (9) $K_6Cr_2[Fe(CN)_6]_3 \cdot 16H_2O$. The above exchanger of appropriate particle size was converted to H^+ form by the treatment with 1 *M* HCl solution for 48 h.

The hexammine cobalt(III) chloride and trisethylenediamine cobalt(III) chloride were prepared (10) by the standard methods. The purity of the samples was checked by ir spectra and by the gravimetric estimation of cobalt (11).

Particle Size

The exchanger was passed through different sieves and the fractions (100–170), (170–200), and (200–300) B.S.S. mesh sizes were collected. For each fraction, slides having about one hundred particles each were prepared and mounted on projector, Agfa Diamator m (Germany), to get fifty times magnification. The diameter of each magnified image was measured in two perpendicular directions and the mean particle radius was evaluated. No change in the radius of the particles was observed when kept in the water for 48 h.

Rate Measurements

The modified limited bath technique (5) was employed for kinetic measurements. A number of stoppered boiling test tubes each containing 20 mL of the solutions were thermostated at the desired temperatures. The weighed samples of exchanger (0.05 g and 0.10 g for $[Co(NH_3)_6]^{3+}$ and $[Co(en)_3]^{3+}$, respectively) were introduced into each tube. In all cases, the total amount of the exchanging ions in solution was more than

[1]Present address: Indian Co-operation Mission, Kathmandu, Nepal.

0008-4042/79/101214-04$01.00/0

the ion-exchange capacity of the exchanger sample. During the experiments the solutions were mechanically shaken. At predecided intervals of times, the tubes were taken out from the thermostat and exchange process was checked by immediate filtration. The experiments were carried out with three different particle sizes, at different solution concentrations, and at four or five different temperatures with the accuracy of ± 0.1°C.

Results and Discussion

The extent of exchange F, at time t, has been determined as:

$$[1] \qquad F = \frac{Q_t}{Q_\infty} = 1 - \frac{6}{\pi^2} \sum_{n=1}^{\infty} \frac{\exp -n^2 Bt}{n^2}$$

Here, Q_t and Q_∞ are the amounts exchanged at time t and ∞ or at equilibrium, respectively. B is the time co-ordinate of Boyd's equation (1) and is expressed in terms of the effective diffusion coefficient D_i and particle radius r as:

$$[2] \qquad B = \pi^2 D_i / r^2$$

For the observed values of F, corresponding Bt values as derived from eq. [1] are obtained from Reichenberg's table (2).

The plots of Bt vs. t (Figs. 1, 2, 3), above a definite solution concentration, are straight lines passing through the origin. In the present system of investigation, this shows the validity of Boyd's equation (1) and Reichenberg's test (2) developed for the particle diffusion-controlled kinetics. The increase in the slopes of the straight line plots, and hence in the rate of exchange, with the decrease in the particle radius (Fig. 2) and increase in the temperature (Fig. 3) further suggests that the rate of exchange is governed by the diffusion of exchanging ions within the exchanger particles.

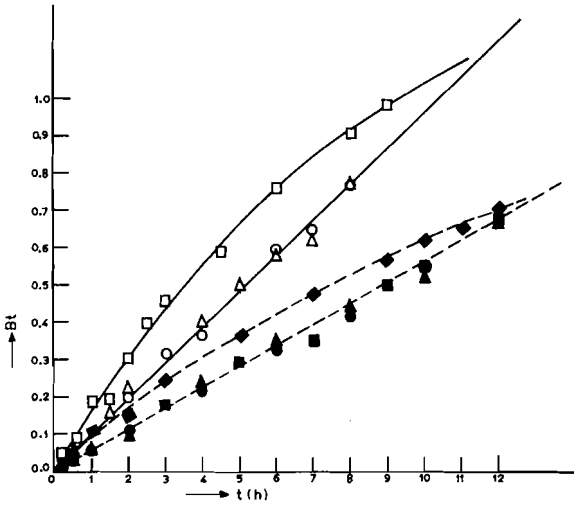

FIG. 1. Plots of Bt vs. t for $[Co(NH_3)_6]^{3+}$, solid lines, and $[Co(en)_3]^{3+}$, broken lines, using different solution concentration at 37.5°C on CFC ($r = 3.44 \times 10^{-3}$ cm): (△, ▲) 0.02 M; (○, ●) 0.01 M; (□, ■) 0.005 M; (◆) 0.0025 M.

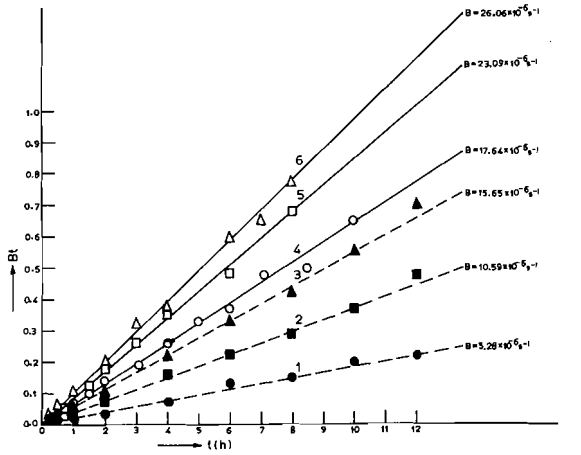

FIG. 2. Plots of Bt vs. t for $[Co(NH_3)_6]^{3+}$, solid lines, and $[Co(en)_3]^{3+}$, broken lines, using different particle sizes of CFC at 37.5°C: (1,4) $r = 6.79 \times 10^{-3}$ cm; (2,5) $r = 4.61 \times 10^{-3}$ cm; (3,6) $r = 3.44 \times 10^{-3}$ cm.

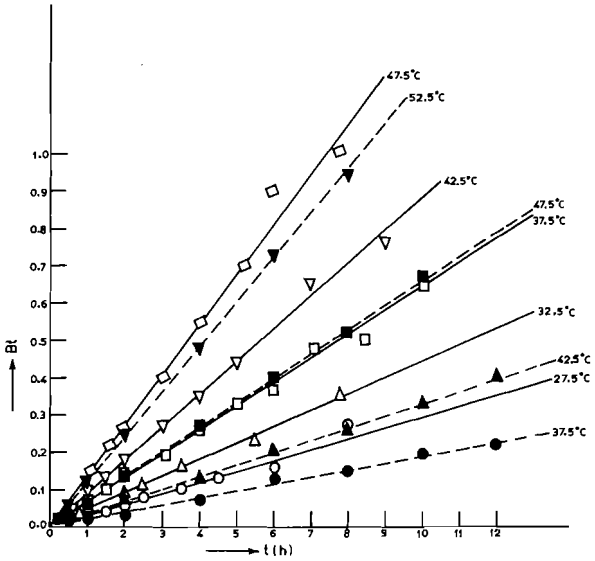

FIG. 3. Plots of Bt vs. t for $[Co(NH_3)_6]^{3+}$, solid lines, and $[Co(en)_3]^{3+}$, broken lines, at different temperatures using CFC ($r = 6.79 \times 10^{-3}$ cm).

It is clear from Fig. 1 that 0.01 M $[Co(NH_3)_6]^{3+}$ and 0.005 M $[Co(en)_3]^{3+}$ are the solution concentrations at and above which the Bt vs. t plots are straight lines and also the exchange rates are not concentration-dependent. This suggests that the particle-diffusion is the rate-controlling factor only at and above these concentrations. Although these concentrations are comparable with those required

for the particle-diffusion controlled kinetics of big ions on zirconium phosphate and oxide (12, 13) they are much lower than those observed for the simple cations on other exchangers (4, 7). In the present case, probably, the larger ionic sizes of complex cations and their slow rate of exchange decrease the possibility of the formation of a liquid film having significant concentration gradient around the exchanger-particles. Thus, even at lower solution concentrations, the prospects of film diffusion as the rate determining step are considerably minimized.

Figures 3 and 4 show an increase in the exchange rate with rise in temperature due to the increase in the mobility of the diffusing cations. The shape of the *F–t* curves (Fig. 4) indicates that the rate is initially rapid but slows down as the time passes. This behaviour is analogous to that observed by Heitner *et al.* (5) and Rawat *et al.* (7) for the exchange of simple cations on the H^+ form of chelating resin Bio-chelex-100 and Tantalum-arsenate respectively. However, the observations of Turse and Rieman (6) for the chemical-exchange of bivalent metal ions on Dowex A-1 are different.

The values of the time co-ordinate B are determined as the slopes of the straight line plots using the method of least-squares. The effective diffusion coefficient D_i at different temperatures calculated from B and exchanger radius (eq. [2]) are given in Table 1. Plots (Fig. 5) of the logarithm of D_i against $1/T(K^{-1})$ are straight lines indicating the validity of the Arrhenius equation:

$$[3] \qquad D_i = D_0 \exp(-E_a/RT)$$

From the slopes and intercepts, the energies of activation E_a and the D_0 respectively have been calculated using the method of least-squares.

The pre-exponential constant D_0 gives the entropy of activation $\Delta S^{\neq}$ (7, 14)

$$[4] \qquad D_0 = 2.72d^2 \frac{KT}{h} \exp\left(\frac{\Delta S^{\neq}}{R}\right)$$

where K and h are Boltzmann and Planck's constants, respectively, R (= 1.98 cal deg^{-1} mol^{-1}) is the gas constant, d (= 5 Å) is taken as the distance between the adjacent exchanging sites in the exchanger (7), and T is 273 K. The values of D_0, E_a, and $\Delta S^{\neq}$ are also recorded in Table 1.

The D_i values obtained for the exchange of $[Co(NH_3)_6]^{3+}$ are higher than that for the exchange of $[Co(en)_3]^{3+}$ (Table 1). It is because of the larger bulk of $[Co(en)_3]^{3+}$ ion that causes more hindrance to its entry into the solid phase and also retards its

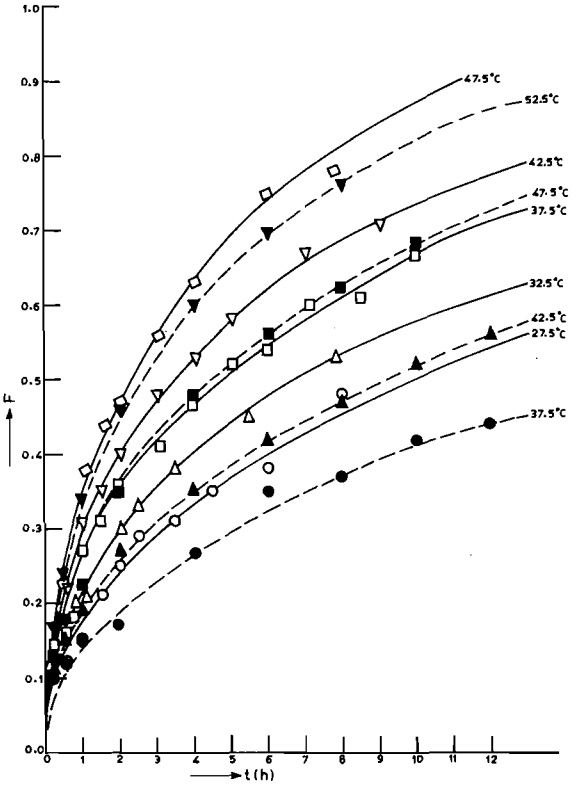

FIG. 4. Rate of exchange of $[Co(NH_3)_6]^{3+}$, solid curves, and $[Co(en)_3]^{3+}$, broken curves, at different temperatures using CFC ($r = 6.79 \times 10^{-3}$ cm).

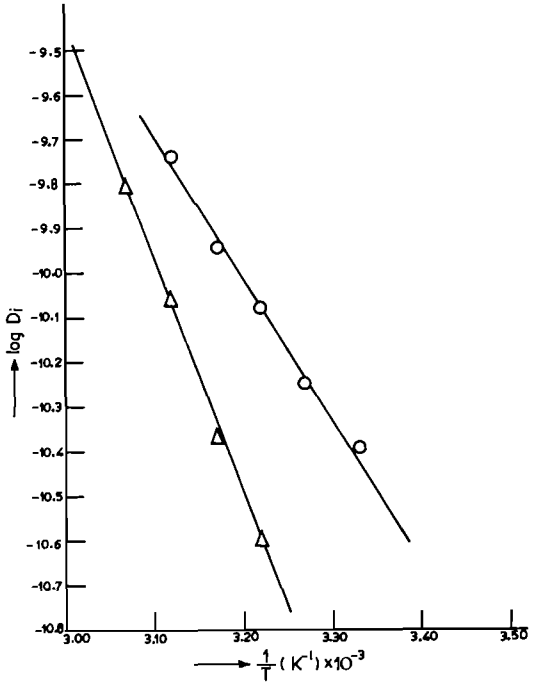

FIG. 5. Plots of log D_i vs. $1/T$; (○) for $[Co(NH_3)_6]^{3+}$ and (△) for $[Co(en)_3]^{3+}$.

TABLE 1. Parameters for the exchange on chromium ferrocyanide gel (radius of the exchanger particle $r = 6.79 \times 10^{-3}$ cm)

Exchanging system	Effective diffusion coefficient (D_i) $cm^2 s^{-1}$						D_0 ($cm^2 s^{-1}$)	Energy of activation (E_a) (kcal mol^{-1})	Entropy of activation ΔS^* (cal deg^{-1} mol^{-1})
	27.5 °C	32.5 °C	37.5 °C	42.5 °C	47.5 °C	52.5 °C			
$[Co(NH_3)_6]^{3+}/H^+$	41.06×10^{-12}	56.07×10^{-12}	82.48×10^{-12}	113.39×10^{-12}	181.20×10^{-12}	—	64.92×10^{-2}	14.05	+5.60
$[Co(en)_3]^{3+}/H^+$	—	—	24.69×10^{-12}	42.56×10^{-12}	87.07×10^{-12}	154.79×10^{-12}	$95.02 \times 10^{+5}$	25.00	+38.39

mobility within the pores of the exchanger particles. Here, it is to be noted that instead of 10^7 times higher value of D_0 for $[Co(en)_3]^{3+}$ as compared with D_0 value for $[Co(NH_3)_6]^{3+}$, the effective diffusion coefficient D_i is less for the former ion. It is due to the difference in the activation energy values of the two cations (Table 1).

In order to maintain the electroneutrality inside the exchanger, one complex cation must replace three mobile hydrogen ions from three exchanging sites. Thus, one complex cation inside the exchanger will reside between three neighbouring and relatively separated negative sites and will experience the coulombic force of attraction. This force of attraction will be greater for the more polarizable $[Co(en)_3]^{3+}$ ion than for the less polarizable $[Co(NH_3)_6]^{3+}$ ion (15). Thus the electrostatic contribution to the energy of activation will be higher in case of $[Co(en)_3]^{3+}$ ion. This explains higher value of activation energy for the $[Co(en)_3]^{3+}/H^+$ exchanging system. Moreover, these electrostatic forces may cause bending or coiling of the matrix that may be more in case of more polarizable cation $[Co(en)_3]^{3+}$. This deformation in the shape of the matrix will be associated with an increase in the total entropy of the system; and hence ΔS^* will be positive. This is what we observed.

The adsorption of tri-*n*-butylphosphate at the *n*-dodecane–water interface[1,2]

NORMAN H. SAGERT, WOON LEE, AND MICHAEL J. QUINN

Research Chemistry Branch, Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Man., Canada R0E 1L0

Received November 7, 1978

NORMAN H. SAGERT, WOON LEE, and MICHAEL J. QUINN. Can. J. Chem. **57**, 1218 (1979).

The adsorption of tri-*n*-butylphosphate (TBP) from *n*-dodecane to the *n*-dodecane–water interface has been studied as a function of TBP mole fraction up to 2.7×10^{-4} in the *n*-dodecane, and as a function of temperature from 293.15 K to 308.15 K. Free energies of adsorption were calculated from the results at low TBP mole fractions, where the surface pressures were linear with mole fraction. They were in the range −36.1 to −35.6 kJ/mol. The enthalpy of adsorption, determined from the variation of the free energies of adsorption with temperature, was −45.4 kJ/mol.

Several equations of state based on two-dimensional gas laws were applied to the results. The Schofield–Rideal equation described the results adequately but the simpler Volmer equation was inadequate especially at lower temperatures. Deviations from the Volmer equation were in the direction of higher surface pressure. A simple version of the two-dimensional solution model equation of state was not helpful.

NORMAN H. SAGERT, WOON LEE et MICHAEL J. QUINN. Can. J. Chem. **57**, 1218 (1979).

On a étudié l'adsorption du tri-*n*-butylphosphate (TBP) en solution dans le dodécane par des interfaces *n*-dodécane–eau; ces études ont été réalisées à des fractions molaires de TNP allant jusqu'à 2.7×10^{-4} dans le *n*-dodécane et à des températures allant de 293.15 à 308.15 K. On a calculé les énergies libres d'adsorption à partir des résultats obtenus aux faibles fractions molaires de TNP alors que les pressions superficielles sont linéaires avec la fraction molaire. Ces valeurs s'étalent de −36.1 à −35.6 kJ/mol. On a déterminé l'enthalpie d'adsorption, −45.4 kJ/mol, à partir de la variation des énergies libres d'adsorption en fonction de la température.

On a appliqué à nos résultats plusieurs équations d'état basées sur des lois des gaz bidimensionnelles. L'équation de Schofield–Rideal décrit les résultats d'une façon adéquate; toutefois l'équation plus simple de Volmer est inadéquate spécialement aux températures inférieures. Les déviations de l'équation de Volmer sont en direction d'une pression superficielle plus élevée. Une version plus simple d'une solution modèle bidimensionnelle de l'équation d'état ne s'est pas avérée utile.

Introduction

This work on the adsorption of tri-*n*-butylphosphate (TBP) at the *n*-dodecane–water interface forms part of a program to study interfacial properties relevant to solvent extraction systems, especially those systems useful for separating the components of irradiated nuclear fuel. The interfacial properties have not been studied as intensively as the equilibrium distributions (1). TBP was selected as a solute since it is frequently used as an extractant and, since it is often used with a diluent such as kerosene, *n*-dodecane was chosen as the organic phase.

The adsorption of nonionic surfactants at hydrocarbon–water interfaces has received considerable attention in recent years (2). Most of the work has involved adsorption of *n*-alcohols at the *n*-alkane–water interface (3–5). Some adsorption studies using esters and diesters as solutes have also been reported (6). The adsorption of nonionic phosphates at hydrocarbon–water interfaces has received relatively little attention, although some studies of the adsorption of TBP at the benzene–water interface have been reported (7–9).

To calculate the thermodynamic properties of adsorption, we have investigated the adsorption of TBP at the *n*-dodecane–water interface at low TBP mole fractions and at a number of temperatures. These thermodynamic properties are essentially a measure of solute–subphase interactions (3). We have also investigated adsorption at higher TBP mole fractions to study the applicability of various equations of state to the adsorbed layer. These isotherms are useful in describing the nature of the interface itself. We examined equations of state, such as the Schofield–Rideal equation (10), which are derived by considering the adsorbed layer to have the properties of a two-dimensional gas, and examined a simple equa-

[2]Presented in part at the 61st Chemical Conference of the Chemical Institute of Canada, Winnipeg, Man. June 1978.

0008-4042/79/101218-06$01.00/0

tion of state based on a two-dimensional solution model for the adsorbed layer (5, 11).

Experimental

Interfacial tensions were measured by the drop–volume method. Drops were formed on a stainless steel tip of 3.166 ± 0.001 mm radius and were aged at least 5 min. Volumes were measured with a 2500-mm³ Gilmont precision micrometer syringe fitted with a thermostatted barrel. The tip was located in a Ramé Hart closed thermostatted environmental chamber. Temperature control was to ±0.02 K and temperatures were known to ±0.05 K. This chamber was fitted with plane windows which allowed visual and photographic verification that the tip radius was the radius wetted by the liquid. Interfacial tensions were calculated using the Harkins and Brown correction curve (12). Interfacial tensions were reproducible to ±50 μN/m.

The *n*-dodecane was Phillips research grade. Before use it was passed through an alumina column. Its purity was better than 99.99 mol% as checked by gas chromatography. The water was triple distilled from Pyrex and had a final conductivity of 190 μS/m. No attempt was made to exclude CO_2. The TBP was Fisher purified grade, further purified by the method of Alcock *et al.* (13). This procedure involves shaking the TBP with dilute caustic solution and then distilling off some of the mixture to remove volatiles. Acidic impurities go into the aqueous phase. The TBP was then washed repeatedly with water, dried with a heat lamp, and stored over activated 12-mesh molecular sieve 4A.

A stock solution of TBP in *n*-dodecane was prepared. Appropriate amounts of stock solution were added to 5×10^{-5} m³ of *n*-dodecane plus 5×10^{-5} m³ of water in the environmental chamber to make up the required mole fraction in the *n*-dodecane. The system was then equilibrated by light shaking for 16 h. Since the distribution coefficient of TBP between *n*-dodecane and water is ~300 in favor of the *n*-dodecane (14), no correction was made for TBP dissolved in the water.

Densities were measured to within ±200 g/m³ using a 2.5×10^{-5} m³ pycnometer flask.

Results

n-*Dodecane–Water Interfacial Tensions*

Interfacial tensions of pure *n*-dodecane against water are shown in Fig. 1 as a function of temperature. Also shown are results of Aveyard and Haydon (15). Our results, while somewhat lower than those of Aveyard and Haydon, agree with theirs to within 150 μN/m. The temperature coefficient for our data is 85 ± 5 μN/(m K), based on a Students *t* distribution at the 95% confidence limit, compared with that of Aveyard and Haydon of 88 ± 9 μN/(m K) on the same basis. Thus our techniques gave results comparable with literature values.

Interfacial Adsorption of TBP

The adsorption of TBP at the *n*-dodecane–water interface was studied at 293.15, 298.15, 303.15, and 308.15 K for mole fractions of TBP in *n*-dodecane up to 2.74×10^{-4}, by measuring interfacial tensions. At these mole fractions, no significant changes in *n*-dodecane density were detected on adding TBP.

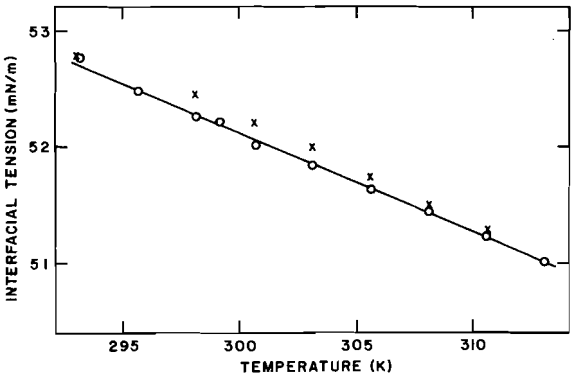

FIG. 1. Interfacial tensions at the *n*-dodecane–water interface as a function of temperature. The circles (○) represent our results and the crosses (×) represent those from ref. 15.

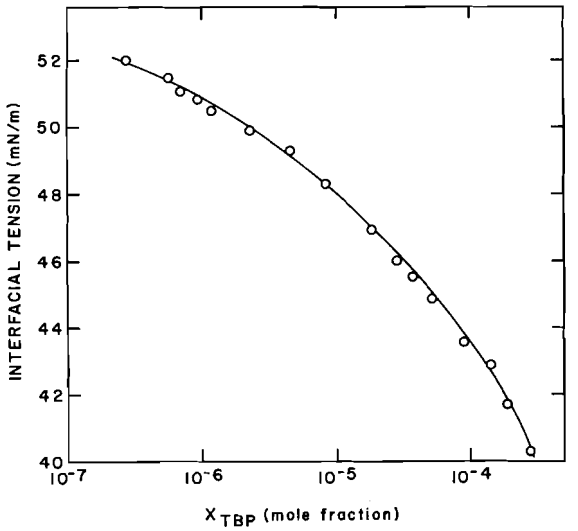

FIG. 2. Interfacial tensions at the *n*-dodecane–water interface on adding TBP to the *n*-dodecane. $T = 298.15$ K.

Results obtained at 298.15 K are shown in Fig. 2. The data at the four temperatures are expressed by eq. [1].

$$[1] \qquad \gamma = C_1 + C_2 \ln X + C_3 (\ln X)^2$$

where γ is the interfacial tension in mN/m and X is the mole fraction of TBP in the *n*-dodecane. The values of the constants, C_i, as determined by a second order least-squares fit are given in Table 1. These constants lead to fits of the data[3] which are within 0.2 mN/m. Additional measurements were made at 295.65, 300.65, and 305.65 K at TBP mole fractions up to 1.2×10^{-6}. The results in the region

[3]All the measured interfacial tensions are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

TABLE 1. Coefficients in eq. [1] for adsorption of TBP at *n*-dodecane–water interface

T(K)	$10^3\ C_1$	$10^3\ C_2$	$10^4\ C_3$
293.15	6.681986	−5.422585	−2.771724
298.15	6.024138	−5.636496	−1.963373
303.15	5.623144	−5.812889	−1.597319
308.15	5.917435	−5.898650	−1.915968

of TBP mole fraction up to 1.2×10^{-6} are shown in Fig. 3, omitting the intermediate temperatures for clarity. Here, the interfacial pressure π, which is the interfacial tension in the absence of TBP less that in its presence, is plotted against the mole fraction of TBP.

Calculation of Molecular Areas

For moderately surface-active solutes adsorbed from dilute solutions, Aveyard and Briscoe (4) have shown that the simple form of the Gibbs adsorption equation (eq. [2]) may be used to calculate the area per molecule available at the interface.

$$[2] \qquad A = -kT(\partial\gamma/\partial \ln fX)^{-1}$$

In eq. [2] A is the area per molecule, k, the Boltzmann constant, and f, the activity coefficient for TBP in *n*-dodecane. This mole fraction activity coefficient approaches unity for dilute solutions.

Activity coefficients for dilute solutions of TBP in organic diluents have not been measured directly, to the best of our knowledge. However, activity coefficients measured from the distribution coefficients of TBP between water and kerosene (14, 16) indicate that the activity coefficients approach unity at the dilutions used here. Siekierski (17) has used an expression to correlate much TBP activity coefficient data which predicts an activity coefficient of 0.987 (present definition) at a mole fraction of 2.3×10^{-3} in *n*-dodecane. Although trialkylphosphates are known to associate through a system of dipole–dipole bonds, dimerization constants are small (2.9×10^{-3} m^3/mol for TBP in *n*-hexane (18)). Current knowledge on association in trialkylphosphate systems has been described recently by Kertes and Tsimering (19). In this work we will consider the activity coefficients as unity.

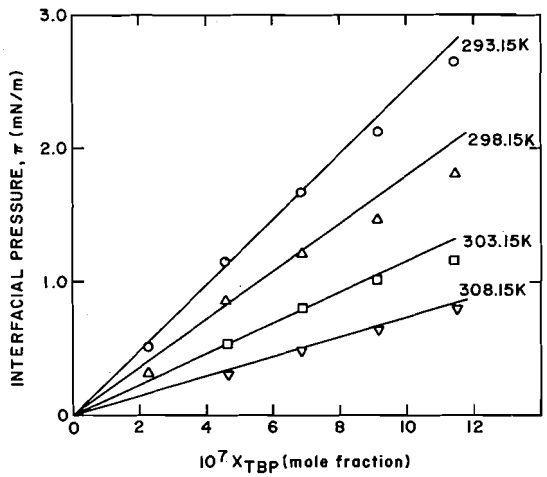

FIG. 3. Interfacial pressures as a function of mole fraction TBP in *n*-dodecane.

Using eqs. [1] and [2], the area per molecule may be calculated by eq. [3].

$$[3] \qquad A = -kT(C_2 + 2C_3 \ln X)^{-1}$$

Values of A were calculated at the experimentally used mole fractions, omitting the highest and lowest mole fraction of each set.

Discussion

Free Energies and Enthalpies of Adsorption

Standard free energies of adsorption, $\Delta_a\mu^\theta$ were calculated from eq. [4]

$$[4] \qquad \Delta_a\mu^\theta = -RT \ln (\pi/X)_0$$

where $(\pi/X)_0$ is the initial slope of the surface pressure curve when plotted against mole fraction of TBP in the *n*-dodecane (Fig. 3). The standard states were those of Aveyard and Briscoe (4). For the surface standard state they used a surface pressure of 1 mN/m. For the bulk standard state they used a hypothetical state, where the mole fraction of TBP was unity and the activity coefficient for TBP in *n*-dodecane was also unity. The free energies of adsorption, given in Table 2, range from −35.6 to −36.2 kJ/mol.

These free energies of adsorption are quite large and negative. For example, over the same temperature range, free energies of adsorption of octanol at the *n*-dodecane–water interface are in the range of −23.4 to −22.9 kJ/mol using the same standard states (4). It is thought (4, 5) that, at the oil–water interface, hydrocarbon chains are dissolved completely in the oil. The strong adsorption of *n*-alcohols has been attributed to polar group interactions as the

TABLE 2. Standard free energies of adsorption of TBP at the *n*-dodecane–water interface

T(K)	$-\Delta_a\mu^\theta$ (kJ/mol)

308.15	35.58

OH group is transferred from the oil to water. Our free energies for the adsorption of TBP from *n*-dodecane to the *n*-dodecane–water interface are about 12.7 kJ/mol more negative than those for adsorbing *n*-octanol from *n*-dodecane to the same interface. From this it might be inferred that the phosphate group of TBP has a greater tendency to interact with water than does the OH group of alcohols. Interactions between polar and self-associated liquids such as water and TBP are undoubtedly complex (19). Hydrogen bonding must be one of the major interactions between these species, especially in dilute solutions where a hydrogen-bonded equimolar hydrate is probably the major species (19–21). However, in dilute solution, hydrophobic stabilization of the water structure, the so-called "hydrophobic bonding" (22) has been shown to be very important in accounting for enthalpies of solution of trialkylphosphates in water (19). In more concentrated systems, which probably exist in the adsorbed phase, dipole–dipole interactions are likely important, because of the large dipole moment of TBP (23). Dimerization of TBP in more concentrated TBP–water systems is thought to occur through dipole–dipole interactions (18, 19, 21).

Although no exact tabular data are given, the work of Chifu, Andrei, and Tomoaia (7, 8) indicates that the free energy of adsorption of TBP from benzene to the benzene–water interface is much less negative than the values we have obtained for adsorption to the *n*-dodecane–water interface. This is in accord with evidence that there is some complexing between TBP and benzene (24). On the other hand, in their work, TBP mole fractions were high and activity coefficient corrections were not made.

Standard enthalpies of adsorption, $\Delta_a h^\theta$ were obtained from the temperature variation of the free energies (eq. [5]).

$$[5] \qquad \Delta_a h^\theta = \mathrm{d}(\Delta_a \mu^\theta/T)/\mathrm{d}(1/T)$$

The standard free energies of adsorption are shown in Fig. 4, plotted in the form suggested by eq. [5]. From Fig. 4, $\Delta_a h^\theta$ seems reasonably constant at -45.4 kJ/mol over this temperature interval.

It is interesting to compare this enthalpy for TBP adsorption from *n*-dodecane to the *n*-dodecane–water interface with the enthalpy of transfer of TBP from *n*-dodecane to water. The enthalpy of transfer of TBP from *n*-dodecane to water can only be estimated at the present time. By definition, this enthalpy is the enthalpy of solution of TBP in water minus the enthalpy of solution of TBP in *n*-dodecane. The latter enthalpy has been measured recently as $+7.4$ kJ/mol (25). However, the former enthalpy is not known. Recently, Kertes and Tsimering (19) measured the enthalpies of solution of trimethylphosphate (TMP)

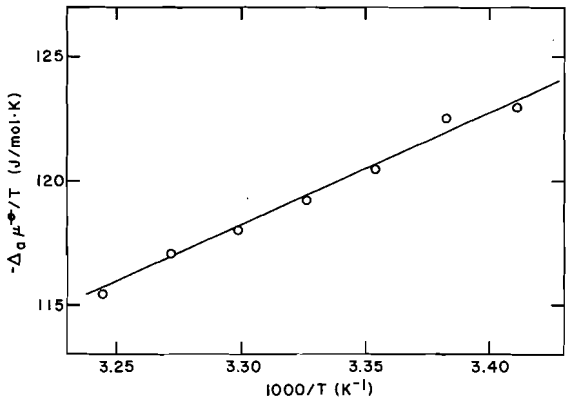

FIG. 4. Variation with temperature of the standard free energy of adsorption, $\Delta_a\mu^\theta$.

and triethylphosphate (TEP) in water and found large exothermic heats of solution with TEP giving the largest (most negative) enthalpy of solution. At infinite dilution, their values were -21.2 kJ/mol for TMP and -25.9 kJ/mol for TEP. Although they did not obtain an accurate value for the enthalpy of solution of tri-*n*-propylphosphate, they reported that it was larger (more negative) than that of TEP.

On the basis of a linear extrapolation of the TMP and TEP values, we estimated an enthalpy of solution for TBP of -35.5 kJ/mol. This is an absolute maximum (in the negative sense) since, as the hydrocarbon chains become very long, the enthalpy of solution will become less negative with increasing chain length (26). Therefore -42.9 kJ/mol may be taken as the absolute (negative) maximum for the enthalpy of transfer. Our observed enthalpy of adsorption of -45.4 kJ/mol for TBP with *n*-dodecane is of the order of, and somewhat larger than, this maximum enthalpy of transfer. Therefore the greater portion of the enthalpy of transfer seems accounted for when the TBP molecule reaches an equilibrium position in the interface, with, presumably, the phosphate group in the water. This situation is quite similar to that where *n*-octanol is the solute. In that case, the enthalpy of adsorption is -31.1 kJ/mol (4) and the enthalpy of transfer is about -26 kJ/mol, as determined from results of Aveyard and Mitchell (27) extrapolated to higher carbon chain lengths.

For the alcohols, the largest part of the enthalpy of transfer consists of an endothermic enthalpy of solution in *n*-dodecane with some contribution from a numerically smaller exothermic enthalpy of solution in water. Thus, it is relatively easy to rationalize the rough equivalence of the enthalpies of adsorption and transfer. However, with TBP, a large portion of the enthalpy of transfer comes from the exothermic enthalpy of solution in water, with a smaller contri-

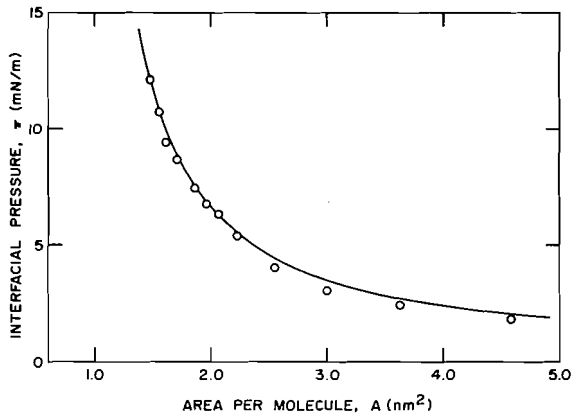

FIG. 5. Fit of surface pressure (π), area (A) data at 298.15 K to Schofield–Rideal equation using constants of Table 3.

bution from the endothermic enthalpy of solution in *n*-dodecane. This large enthalpy of solution in water has been ascribed (28) to "hydrophobic bonding" (22) where water structure is enhanced by the interaction of alkyl groups with the water. This hydration cage may involve about 30 water molecules (28). It would appear from this work that much of this structure is formed when the TBP molecule reaches its equilibrium position in the oil–water interface.

Surface Equations of State

The measured values of π and A can be fitted to two-dimensional equations of state which are analogous to the normal three-dimensional equations of state. The Schofield–Rideal equation (10) is frequently used.

$$[6] \qquad \pi(A - A_0) = ikT$$

Both A_0 and i are constants. The values obtained are given in Table 3 and a fit of the experimental data at 298.15 K is given in Fig. 5. The experimental data were not fitted by the usual $1/\pi$ vs. A plot, but rather, a non-linear, least-squares fitting routine (Chalk River Nuclear Laboratories CDC 6600 Fortran program LSQQ) based on Marquardt's method was used with eqs. [3] and [6] and the coefficients from Table 1 to reproduce the interfacial tension data. The errors given in Table 3 correspond to one standard deviation.

The values for A_0 of ≈ 0.9 nm^2 are similar to those at the benzene–water interface (0.97 and 1.14 nm^2) obtained by Tomoaia *et al.* (7) without and with added copper nitrate. Although A_0 is only a fitting constant, there is much evidence, for straight chain alcohols (5), at least, that it represents the static geometric area of the molecule at the interface. From molecular models, the area of the TBP molecule is ~ 1.0 nm^2, the exact area depending on the folding of the butyl groups.

TABLE 3. Constants of Schofield–Rideal equation

T (K)	A_0 (nm^2)	i
293.15	0.88±0.02	1.84±0.05
298.15	0.85±0.02	1.84±0.05
303.15	0.93±0.03	1.51±0.07
308.15	0.97±0.04	1.39±0.08

If the i in eq. [6] is 1.0 then the resulting equation is called the Volmer equation, and generally, our results do not fit the Volmer equation. The deviations observed (Table 3) may suggest extra repulsions in the monolayer rather than increased cohesion. Some of this repulsion could result from dipole–dipole interaction (29) if the adsorption forces are great enough to keep the dipoles aligned. Deviations from the Volmer equation could also arise from variation of A_0 with coverage, possibly due to changing orientation of TBP molecules in the interface. TBP molecules are more symmetric than the usual surfactant molecules making such changes possibly easier. On the other hand, the two-dimensional gas picture, which underlies the Volmer equation, may not be adequate for a solute such as TBP which is capable of restructuring the water phase (28).

Attempts were made to use a solution model for the surface (11). Generally, the simplifying assumption has to be made that the solute is located entirely in the *n*-dodecane. This assumption is clearly not a good one for TBP. If the *n*-dodecane – solute pair forms an ideal two-dimensional solution, then eq. [7] should hold (5). A similar equation has been used with some success by Fowkes (30).

$$[7] \qquad \pi = -\frac{kT}{\sigma_1} \ln\left(\frac{A - \sigma_2 + \sigma_1}{A - \sigma_2}\right)$$

In eq. [7] σ_1 and σ_2 are the surface areas of the solvent and solute, respectively. It would be expected that σ_1 and σ_2 would be quite different in this system. Unfortunately, it was not possible to fit our data using eq. [7]. When the data were plotted in the rearranged form suggested by Aveyard and Briscoe (5) and shown as eq. [8],

$$[8] \qquad [\exp(\pi\sigma_1/kT) - 1]^{-1} = A/\sigma_1 - \sigma_2/\sigma_1$$

all reasonable values of σ_1 gave ratios of σ_2/σ_1 between 2 and 3, but the slopes were always less than $1/\sigma_1$. The failure of the solution model may well result from the involvement of the water phase, if significant water restructuring takes place (28).

Anisotropic motion in 1-substituted adamantanes from ^{13}Cmr relaxation time data

HELMUT BEIERBECK, ROBERT MARTINO,[1] AND JOHN K. SAUNDERS
Département de Chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received August 31, 1978

HELMUT BEIERBECK, ROBERT MARTINO, and JOHN K. SAUNDERS. Can. J. Chem. **57**, 1224 (1979).

The carbon-13 relaxation time data and the calculated diffusion constants for several 1-substituted adamantane derivatives in various solvents are presented. The ratio of the diffusion constants for rotation about the principal axis relative to that about the two mutually perpendicular axes is found to vary significantly with substituent and to a lesser extent with solvent. The order for this ratio is $CO_2H > OH > NH_2 \approx Br$, which is interpreted in terms of the degree of association, either solute–solute or solute–solvent, and also the ease of rotation about the carbon–substituent bond.

HELMUT BEIERBECK, ROBERT MARTINO et JOHN K. SAUNDERS. Can. J. Chem. **57**, 1224 (1979).

Le temps de relaxation du carbone-13 de plusieurs dérivés d'adamantane substitués en position-1 a permis de calculer les constantes de diffusion pour la rotation autour de l'axe principal et autour des deux axes perpendiculaires à ce dernier. Le rapport de ces deux constantes de diffusion varie plus avec le substituent qu'avec le solvant. Ce rapport décroît dans l'ordre $CO_2H > OH > NH_2 \approx Br$, ce qui est interprété en termes d'association soit soluté–soluté soit soluté–solvant et aussi en termes de barrière de rotation autour de la liaison C—X.

^{13}C spin lattice relaxation times (T_1) have proven useful in the study of molecular dynamics of organic molecules in solution (1–4). The analysis of the T_1's for individual carbons leads to information on the overall molecular motion such as anisotropic behaviour (5–8) and thus on intermolecular interactions of the solute.

The dominant relaxation pathway for ^{13}C nuclei in the compounds studied is the dipole–dipole interaction between carbon and hydrogen. The relaxation rate thus depends principally on the number of attached hydrogens, and the modulation of the C—H bond vectors by molecular motion. If a C—H bond is situated parallel to a preferred axis of rotation, rotation about this axis does not modulate the C—H bond and the relaxation process for such a carbon is more efficient. This effect was observed in monosubstituted benzene derivatives (5). The T_1 value for the *para* carbon is shorter than for the *ortho* and *meta* since the *para* C—H bond is parallel to the C_2 axis. The 1-substituted adamantanes exhibit similar behaviour. The C—H *endo* bond of the δ carbons is parallel to the C_3 axis of rotation whereas the other C—H bonds are at angles of 60° or 90° to this axis. From the ^{13}C T_1 data, rotational diffusion constants may be derived by application of Woessner's equations (9) for axially symmetric ellipsoids.

We have determined relaxation times for a number of 1-substituted adamantanes in various solvents in order to study the effect of heterosubstituents on the anisotropy of the molecular motion and the interactions between solvents and heterosubstituents. The relaxation times are transformed into rotational diffusion constants which are compared with the macroscopic viscosity. For a molecule undergoing isotropic motion, the Stokes–Einstein expression (10) as modified by Gierer and Wirty (11) linking the diffusion constant with viscosity (η) is

$$\tau_c = (6R)^{-1} = 4\pi r^3 n f(r)/3kT$$

where τ_c is the effective rotational correlation time, R is the diffusion constant, r the molecular radius, and $f(r)$ is a correction factor, denoting the microviscosity factor which is defined (11) as

$$f(r) = [6(r_1/r) + (1 + r/r_1)^{-3}]^{-1}$$

where r_1 is the radius of solvent molecules. The correction factor was introduced to account for the observation that the Stokes–Einstein equation overestimates the magnitude of the rotational friction constant. In neat liquids, the above expression gives a value of approximately 1/6 for $f(r)$ whereas for a large number of associated and nonassociated liquids a value of 1/12 is found to be more compatible with experimental data (12). In solution, the situation is still more complex. In the ensuing discussion, we will compare the diffusion constant data, which gives insight into local fluid conditions, with the macroscopic viscosity which is averaged over the whole system and discuss qualitatively any marked discrepancies.

Results and Discussion

The T_1 data recorded as a function of solvent and viscosity are given in Table 1 as are the calculated rotational diffusion constants, R_1 and R_2. R_1 describes the rotation about the preferred axis, i.e. the C_3 axis. The T_1 values for the γ-carbons are always less than $2 \times T_1$ (β-carbons), due in part to the protons on the adjacent carbons contributing to the relaxation of the methine carbons to a greater extent than the β-carbons (13). This fact must be taken into account when calculating diffusion constants.

For the bromo derivative, the ratio of the diffusion constants, σ, varies between 1 and 2.95 whereas the ratio of the moments of inertia is 2.95. A plot of $(R_1)^{-1}$ versus viscosity is a straight line as illustrated in Fig. 1. Extrapolation to zero viscosity yields a value for R_1 of 1.2×10^{11} s^{-1} which differs significantly from the free rotation value of 1.7×10^{12} s^{-1} calculated using the moments of inertia and the equation derived by Bartoli and Litovitz (14), namely,

$$R_{free} = (9/2\pi)\,(kT/I)^{1/2}$$

This discrepancy, together with the σ values and the correlation of R_1 with viscosity, infer that molecular reorientation is diffusional in nature and that the inertial character is very small (15). The diffusion constant R_2, with one exception, decreases as the viscosity increases. The rate of rotation should be faster in $CDCl_3$ than in benzene according to viscosity whereas experimentally the reverse is observed. The value of R_2 will be dependent upon the solvation of the bromine relative to the hydrocarbon portion of the molecule as well as on viscosity. The small values of σ imply that there is no significant specific solvation of the bromine relative to the hydrocarbon moiety and that, with the exception of acetone, the principal reason for the anisotropic motion is a volume effect. In acetone the motion is essentially isotropic indicating that in this solvent, it is the hydrocarbon portion of the molecule which is the more strongly solvated.

For adamantan-1-ol, the molecular motion is quite anisotropic and σ varies from 3.3 in acetone to 9.5 in CD_3OD. There is no obvious correlation between viscosity and R_1 as can be seen in Fig. 1. The lack of correlation between R_2 and viscosity is to be expected since the OH group will be involved to a greater or lesser extent in hydrogen bonding either with other solute molecules or with the solvent. With the exception of acetone, the variation of σ as a function of solvent is reasonably small. In CCl_4, and to a lesser extent in $CDCl_3$, the molecule will exist in dimeric or polymeric forms due to intermolecular solute–solute hydrogen bonding, whereas in DMSO and CD_3OD the solute will exist essentially as solvated monomers. Due to the bulkiness of the adamantanyl moiety the associated species will most likely be the dimer with only limited access for the solvent to solvate the OH groups. The principal axis of rotation for the dimer will be almost parallel to the C_3 axis of rotation of the monomer with the center of gravity being between the two oxygens. The ratio of the volume[2] traced out by rotation about the major axis relative to the minor axis is approximately 1:2.5. Thus, based on volume considerations,[2] the value of σ should be about 2.5. However, rotation about the principal axis can occur via two mechanisms: rotation of the dimer as an entity or rotation about the C—O bond of the adamantanyl moiety. The experimental values of 6.5 and 7.2 infer that rotation about the C—O bond as well as the overall motion is important.

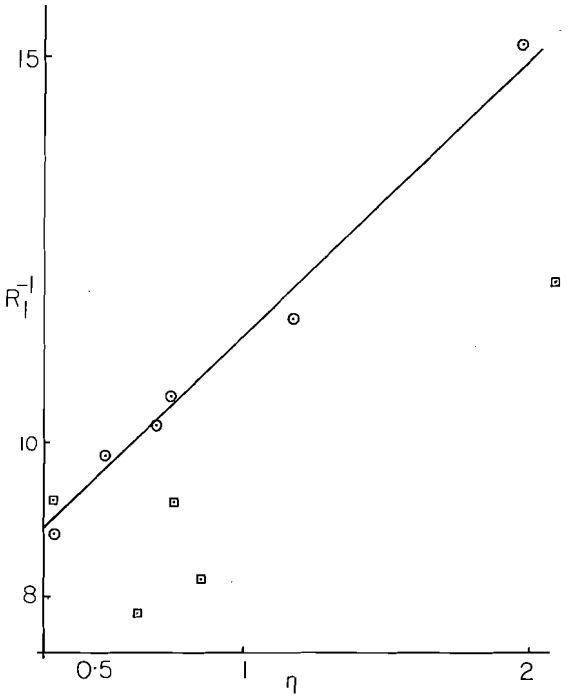

FIG. 1. Plot of $R_1^{-1} \times 10^{12}$ (s) versus viscosity, η (cP), for 1-bromoadamantane ○ and adamantan-1-ol □.

In order to have movement of the OH group in the more strongly solvating solvents, either the hydrogen bonds between the solvent and the OH group must be broken or the solvent molecules must rotate with the OH group. If the latter occurs, the

[2]Volumes were estimated from molecular models since the molecular volume so obtained correlated reasonably well with the experimental apparent molar volume.

centre of gravity of the molecular framework will approach the oxygen atom and the relative motion will be similar to that observed for solvents where the solute is involved in solute–solute interactions. Experimentally, the values of σ are 9.5 in CD_3OD and 6.7 in DMSO whereas in acetone it is only 3.3. This infers that the solute molecules are more strongly solvated in the former two solvents than in the latter. The value for acetone is an indication that the hydrogen bond formed between OH and the carbonyl group is significantly weaker than in either CD_3OD or DMSO, or that the solvent–solvent interactions are relatively weak. Similar results were obtained for phenol in acetone relative to other solvents (5).

The acid shows striking anisotropic behaviour with values of σ between 25 and 29. There is no correlation with viscosity, obviously due to extensive association in $CDCl_3$ and benzene. The amine exhibits quite different behaviour in that the motion is only slightly anisotropic. There is no correlation with viscosity since both R_1 and R_2 are largest in the most viscous solvent, CCl_4, and smallest in the least viscous solvent, CD_3OD.

In any discussion of the effect of association, whether by solvent or solute molecules, on the diffusion constants it is evident that R must be greater than k_{diss} (k_{diss} = rate constant for dissociation of the associated species) in order for evidence of association to be observed by T_1 measurements. As already mentioned, it appears that for the OH group, $R > k_{diss}$ for CD_3OD, DMSO, CCl_4, and $CDCl_3$ as solvents whereas in acetone the value of σ inferred that R and k_{diss} are of the same order of magnitude. For the amine in CCl_4, σ is very small and the rotation rates are faster than in the other solvents. This is a good indication that $k_{diss} > R$ for the dissociation of a solute–solute pair, that specific solvation of the NH_2 group by CCl_4 is minimal and that the T_1 values are essentially determined by the tumbling of a monomer. In other words, any solute–solute or solute–solvent pairs which are formed are too short-lived to be measured by this technique.

For 1-substituted adamantanes in which the substituents are engaged in strong intermolecular interactions, the value of σ will be large only if the barrier to rotation about the C—X bond is small. We have already discussed the case of X = OH where rapid rotation about the C—OH bond was suggested to explain the observed values. Although the barriers to rotation about the C—X bonds have not been determined for the compounds studied here, they are known in similar compounds (16). The barriers about C—CO_2H and C—OH are both relatively small, of the order of 2 and 4 kJ/mol, respectively (17, 18), whereas that for a C—NH_2 is significantly higher, namely 10 kJ/mol (18). Thus, for the acid, rotation about the C_3 axis of the molecule appears very rapid, due to the very low barrier to rotation about the C—CO_2H bond, even though the CO_2H group is 'fixed'. By contrast the amine exhibits smaller values of σ since the barrier is sufficiently high to restrict rotation about the C—NH_2 bond. Levy and Terpstra (19) studied benzoic acid as a 1 *M* solution in $C_2D_4Cl_2$ and found a tumbling ratio of 4.5, whereas in the adamantane derivative the value in $CDCl_3$ is 25.5. The R_2 values for the two compounds are within 20%. The tumbling ratios differ because the barrier to rotation in Ar—CO_2H is significantly higher than in the aliphatic compound due to overlap between the π electrons of the aromatic ring and the acid group. Comparison of each of the adamantane derivatives presented here with the corresponding aromatic compounds (5) shows that the degree of anisotropy is less in the latter since each of the heterosubstituents studied have either *p* or π electrons which overlap with the π electron system of the aromatic ring and increase the barrier.

For a spherical molecule, tumbling is characterized by the isotropic correlation time τ_c which represents the average of the overall molecular motion. For a nonspherical molecule undergoing anisotropic motion overall molecular motion is characterized by τ_{eff} (9), the trace of the tensor of the correlation times about the three mutually perpendicular axes. Values of τ_{eff} can be calculated using

$$1/\tau_{eff} = (1/3)(1/\tau_a + 1/\tau_b + 1/\tau_c)$$

where $\tau_a = (6R_2)^{-1}$, $\tau_b = (5R_2 + R_1)^{-1}$, and $\tau_c = (2R_2 + 4R_1)^{-1}$. The calculated τ_{eff} values for each molecule are also included in Table 1 with a plot of τ_{eff} versus viscosity being illustrated in Fig. 2 for the bromo and hydroxy derivatives. For the bromo compound, the points lead to a reasonably straight line with the exception of acetone. For the OH group, a straight line is also obtained, but in this case it is CD_3OD which appears to be the exception. The value in CD_3OD is just outside the limits of experimental error. In a study of the T_1 values of the CH_3 carbons of *tert*-butyl alcohol as function of solvent, it was found (20) that $1/T_1$ gave an excellent correlation with viscosity for nonhydroxylated solvents whereas the points for H_2O, D_2O, CD_3OD, and $(CH_3)_3C$—OH were above the line with the deviation being more pronounced for H_2O and D_2O. This deviation was interpreted in terms of changes in solvent structure upon introduction of the *tert*-butyl alcohol molecules.

It may have been expected that R_1 would be

independent of the attached group, provided the barrier to rotation about the C—X bond is small, since the rotation being measured is that of the adamantanyl moiety. Inspection of the data shows that neither the value of R_1 nor R_2 is independent of X. If we examine CD_3OD as example, the values of R_2 (at the same viscosity) are 3.2, 1.2, and 0.6 × 10^{10} s^{-1} for Br, OH, and CO_2H, respectively, whereas the corresponding values for R_1 are 7.0, 11.4, and 17.3 × 10^{10} s^{-1}, i.e. when the diffusion constant about the non-principal axis is decreased there is a concomitant increase about the principal axis. The values of τ_{eff}/η are also given in Table 1. Inspection of these data with respect to solvent shows that (*a*) in CD_3OD, the values for Br, OH, and CO_2H have the same value within experimental error whereas that for NH_2 is significantly different; (*b*) in $CDCl_3$ the values for OH and Br are similar whereas those for NH_2 and CO_2H vary significantly; (*c*) in CCl_4 the values do not differ significantly; (*d*) in DMSO the values are within experimental error of one another whereas for benzene and acetone large deviations are observed. The difference in CD_3OD and $CDCl_3$ of the amine is due to the restriction of rotation about the C—NH_2 bond. The acid even in CD_3OD exists almost exclusively as the dimer (19). In $CDCl_3$ and benzene, the value of σ is the same as that obtained in CD_3OD whereas both R_1 and R_2 are smaller. These results suggest that the degree of association for the acid is significantly greater in the relatively non-polar solvents than in CD_3OD, i.e., the acid forms aggregates in non-polar solvents whose overall motion is less than the dimer.

The last entry in Table 1 differs from those described previously in that the C—X bond is no longer coincident with the principal axis of the molecule. The value of σ is 2.7 (cf. 6.5 for the 1-OH) and both R_1 and R_2 have decreased with the most dramatic decrease being that for R_1. The decrease in σ does not indicate that solvation or dimerization of the CH_2OH group relative to the OH group is less but rather that in the associated form, rotation about the C—O bond is significantly restricted. The molecules probably exist as dimers and if we consider the dimer as an ellipse then the relative rates based on volume would be predicted to be about 3:1 which is similar to the observed σ value of 2.7.

Experimental

All compounds used were obtained commercially and were studied without further purification. The T_1 data were obtained using a Bruker HX-90 spectrometer equipped with a Nicolet 1083 computer using the inversion recovery method as described previously (21). At least 15 t values were obtained for each carbon as well as a minimum of 4 S_∞ values. The T_1 values were then obtained using the standard least-squares plot of ln $(S(\infty) - S(t))$ versus time. The error limits are estimated at $\pm 10\%$, although the values were found to be reproducible to $\pm 5\%$. Recently Grant and co-workers (22) have shown that cross correlation terms can be important in the relaxation processes for CH_2 and CH_3 carbons and thus, treatment of the relaxation time data as a monoexponential can lead to errors in the calculated T_1 values. The consequences of this effect in the presented data should be a minimum in that our main interest is in the comparison of values and that all T_1 values were obtained from the same range of t values ($0.2T_1$ to $1.4T_1$). The T_1 data were then analysed by use of a computer program based on the equations of Woessner (9) for an axially symmetric ellipse. The program takes into account the relaxation contributions of all protons. Viscosities were measured using a Ubbelohde viscosimeter as described by Tuan and Fuoss (23).

Received October 10, 1978

MARSHA T. J. GLIONNA and HUW O. PRITCHARD. Can. J. Chem. **57**, 1229 (1979).

An exploratory study has been made of the gas-phase reactions of methylene radicals, generated by the photolysis of ketene near 3000 Å, with methyl, ethyl, and allyl isocyanides at room temperature.

With methyl isocyanide, the principal product at low pressure is ethyl cyanide, together with a few percent of methyl cyanide; ethyl isocyanide is also formed, increasingly so as the total pressure is increased. Reaction appears to take place through a vibrationally excited ethyl isocyanide intermediate, and approximate rate constants for each reaction pathway are derived. Isotopic studies suggest that the methylene radicals insert in the H_3C—NC bond of the methyl isocyanide.

MARSHA T. J. GLIONNA et HUW O. PRITCHARD. Can. J. Chem. **57**, 1229 (1979).

On a effectué une étude préliminaire des réactions en phase gazeuse des radicaux méthylènes, produits par photolyse d'un cétène près de 3000 Å, avec des isocyanures de méthyle, d'éthyle ou d'allyle à température ambiante.

Avec l'isocyanure de méthyle, à basse pression, le produit principal est le cyanure d'éthyle avec un faible pourcentage de cyanure de méthyle; il se forme aussi de l'isocyanure d'éthyle dont la quantité augmente avec l'augmentation de la pression. Il semble que la réaction se produise grâce à un intermédiaire vibrationnellement excité de l'isocyanure d'éthyle; on a évalué les constantes de vitesse approximatives de chacune des voies de réaction. Des études isotopiques suggèrent que les radicaux méthylènes s'insèrent dans la liaison H_3C—NC de l'isocyanure de méthyle.

[Traduit par le journal]

Introduction

In a recent series of chemical activation studies, Rabinovitch and co-workers (1–3) have generated vibrationally excited molecules in which there are two (almost isoenergetic) pathways for decomposition, in competition with collisional stabilisation. It would be interesting to extend this kind of approach to the study of a vibrationally excited molecule which could decompose by two reaction paths having *very* different critical energies. For example, vibrationally excited cyclopropyl isocyanide could isomerise to allyl isocyanide at excitation energies greater than about 60 kcal mol^{-1} and to cyclopropyl cyanide at excitation energies greater than about 40 kcal mol^{-1}; isomerisation of both functional groups is also possible. Unfortunately, the production of vibrationally excited cyclopropyl isocyanide molecules by addition of methylene radicals to vinyl isocyanide is not feasible because vinyl isocyanide is rather unstable, both to visible light and with respect to spontaneous polymerisation (4). Consequently, despite the fact that more isomerisation pathways exist, we undertook to explore the homologous reaction, methylene radicals plus allyl isocyanide, in search of the same kind of information. However, although the expected range of mass 81 cyanides and isocyanides was observed, and their relative proportions varied with the total pressure, detailed identification of each product was not pursued because, unexpectedly, the major product of the reaction was allyl cyanide. Since allyl cyanide was not formed photochemically from allyl isocyanide under our conditions, we undertook the study reported below to try to elucidate the nature of this catalysed isomerisation. In view of the tentative conclusion reached, that the principal reaction of methylene radicals with saturated isocyanide molecules is to insert in the R—NC bond, the proposed study of methylene radicals with allyl isocyanide appears to be rather intractable because some of the same reaction products may arise both from the addition to the double bond and from the insertion into the allyl—NC bond. We now proceed to present evidence for this insertion of methylene radicals into the R—NC bond, where R is methyl, and also some circumstantial evidence for the same process when R is ethyl.

Experimental

Methyl, ethyl, *n*-propyl, *s*-propyl, and allyl isocyanides were prepared from the appropriate *N*-alkyl formamide by the method of Casanova, Schuster, and Werner (5); except in the case of *N*-methyl formamide which was obtained commercially, the other *N*-alkyl formamides were prepared from ethyl formate and the corresponding amine by standard methods

0008-4042/79/101229-04$01.00/0

(6). Each isocyanide was purified by vapour-phase chromatography.

Methyl, ethyl, *n*-propyl, *s*-propyl, and allyl cyanides, used for identification and calibration purposes, were obtained commercially.

Ketene was prepared by the pyrolysis of acetic anhydride vapour at 400°C (7), and after separation by trap-to-trap distillation, was stored at liquid nitrogen temperature; the liquid was degassed each time before use. Dideuterioketene (CD_2CO) was prepared in an analogous manner from 99% acetic anhydride-d_6, obtained from Merck, Sharp and Dohme.

Photolysis experiments were conducted at room temperature in a 500 mL Pyrex glass vessel, using the unfiltered light from a 100 W high-pressure mercury lamp; during the filling of the reaction vessel and the analysis of the products, it was necessary to avoid condensing isocyanide and ketene together in liquid nitrogen, as they react immediately under these conditions. Products were identified by gas chromatography (using a Pennwalt 223 column at 70°C) coupled with mass spectrometry.

Results and Discussion

Our initial supposition was that methylene radicals, which commonly insert into C—H bonds in organic molecules (8), would react with methyl isocyanide to form a vibrationally hot ethyl isocyanide molecule.

[1] $$CH_2 + CH_3NC \rightarrow [C_2H_5NC]^*$$

This excited molecule would then isomerise to ethyl cyanide

[2] $$[C_2H_5NC]^* \xrightarrow{k_1} C_2H_5CN$$

at a rate which can be estimated according to unimolecular reaction theory (9), or be stabilised collisionally

[3] $$[C_2H_5NC]^* + M \xrightarrow{k_2} C_2H_5NC + M$$

Thus, the relative rates of formation of cyanide and isocyanide should obey the simple form

[4] $$R_{EtCN}\,[M]/R_{EtNC} = k_1/k_2 = \text{constant}.$$

At low pressures (5–10 Torr of methyl isocyanide, 1–5 Torr of ketene), the reaction product was almost exclusively ethyl cyanide, with small amounts of methyl cyanide and hydrogen cyanide amounting, respectively, to about 10% and 1% of the total product. Increasing the total pressure of the system by addition of up to 600 Torr of argon or nitrogen led to small but increasing yields of ethyl isocyanide; qualitatively, at least, this is consistent with the reaction scheme proposed above.

Likewise, the reaction of methylene radicals with ethyl isocyanide gives significant quantities of *n*-propyl cyanide and *n*-propyl isocyanide, but only minute traces of *s*-propyl cyanide and *s*-propyl isocyanide. Neither methyl cyanide nor ethyl cyanide reacts with methylene radicals, nor are any of the cyanides or isocyanides affected by the photolysis lamp in the absence of ketene (cf. also refs. 10 and 11 for more extensive information on the photochemical reactions of methyl isocyanide).

Returning to the reaction of methylene radicals with methyl isocyanide, the relative variations of the yields of ethyl cyanide and ethyl isocyanide can be shown to be consistent with the reaction scheme [1]–[3], at least semiquantitatively. Because of the need to avoid condensing reactant or product mixtures in liquid nitrogen, and because of the relatively high pressures of argon required to produce significant quantities of ethyl isocyanide, we chose simply to study the variation of product yields with varying ketene pressure at fixed isocyanide pressure, realising that this procedure is somewhat unconventional and very inefficient in the use of methylene radicals. Table 1 gives a summary of the results of four experiments carried out at different ketene pressures, but otherwise performed under the same conditions. It is clear that, in the penultimate column of this table, the relationship [4] holds quite well. If we assume collision diameters of 4.5 and 5.5 Å respectively for CH_2CO and $[C_2H_5NC]^*$, the appropriate collision number $Z = 4 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} at room temperature. We may also assume (9) that the rate constant for deactivation of vibrationally excited ethyl isocyanide, i.e. k_2, is 0.1 times the collision rate constant Z, whence the data in Table 1 give k_1 as approximately $2.2_5 \times 10^{10}$ s^{-1}.

By using the following thermochemical data (all relating to the gas phase at room temperature)

$$\Delta H_f(CH_3NC) \simeq 41 \text{ kcal mol}^{-1} \quad (12)$$

$$\Delta H_f(CH_2) \simeq 92 \text{ kcal mol}^{-1} \quad (13)$$

$$\Delta H_f(C_2H_5CN) \simeq 12 \text{ kcal mol}^{-1} \quad (14)$$

the overall reaction

[5] $$CH_3NC + CH_2 \rightarrow C_2H_5CN$$

is approximately 121 kcal mol^{-1} exothermic, and since the ΔH for isomerisation of ethyl isocyanide is about -22 kcal mol^{-1} (12, 15), this indicates that the newly formed ethyl isocyanide molecule in reaction [1] contains about 99 kcal mol^{-1} of internal energy. We may then estimate the rate constant k_1 for the isomerisation of such an excited molecule (16), treated as a collection of Morse oscillators[1] and rigid rotors with kinetic and spectroscopic properties as tabulated in ref. 9, to be approximately 4.1×10^{10} s^{-1}. We conclude that in view of both the uncertainties in the theoretical model and in the experimental method, the proximity of this figure to

[1]Alternatively, in the harmonic-oscillator rigid-rotor approximation, the estimated value would be about 6×10^{10} s^{-1} (16).

TABLE 1. Relative rates of formation of products in the reaction of methylene radicals with methyl isocyanide at room temperature

P_{CH_2CO} (Torr)	P_{total} (Torr)	R_{EtCN}/R_{EtNC} ($\equiv R$)	R_{MeCN}/R_{EtNC} ($\equiv R'$)	$P_{total} \times R$ ($\times 10^{-3}$)	$P_{total} \times R'$ ($\times 10^{-3}$)
590	595	28.8	(0.5)	17.2	—
305	310	54.9	(1.7)	17.1	—
152	157	124	7.9	19.5	1.2
80	85	192	16.0	16.3	1.4

our experimentally derived value of about 2×10^{10} s^{-1} lends support to our interpretation of the experimental process.

The last column in Table 1 may suggest that the ratio $R_{MeCN}[M]/R_{EtNC}$ is also constant, if one acknowledges the fact that at high pressures, the yield of methyl cyanide is too small to be measured accurately on the tail of the methyl isocyanide peak: thus, it appears that at these energies, there could be another reaction channel available

$$[6] \qquad [C_2H_5NC]^* \xrightarrow{k_3} CH_3CN + CH_2$$

with $k_3 \sim 1.7 \times 10^9$ s^{-1}. This would imply that at very high temperatures, the thermal decomposition of ethyl isocyanide should yield small amounts of methyl cyanide, as well as the normal product ethyl cyanide; methyl isocyanide would also be formed by the reverse of reaction [1], but would not live long enough to be detected by conventional kinetic techniques.[2] At the same time, at these high temperatures, one would expect the formation of large quantities of hydrogen cyanide, since this is a major product in the conventional pyrolysis of ethyl cyanide (17, 18); however, in our reaction, the yield of hydrogen cyanide was only of the order of 10–20% of that of the methyl cyanide, and we were unable to estimate a rate constant for the postulated third channel

$$[7] \qquad [C_2H_5NC]^* \rightarrow HCN + C_2H_4$$

The observations described so far are not inconsistent with the proposed reaction scheme [1]–[3], but they do not shed any light on the nature of the addition process [1], neither in respect of the site of attack nor in respect of the degree of excitation of the methylene radical involved. The addition of small quantities of air or oxygen to our reaction mixtures, commonly used (1, 2) to ensure that only singlet methylene radicals undergo reaction, suppressed the formation of all the products noted above. However, in view of the high reactivity of isocyanides in general (19) and the incipient free-radical nature of the proposed adduct $[C_2H_5NC]^*$, we do not feel that this observation is decisive, one way or the other. Thus, although we have been unable to demonstrate conclusively that we observed the reactions of *singlet* methylene radicals, the high pressures used in Table 1 would tend to support that assumption. However, from the mass-spectroscopic evidence we now describe, it appears to be reasonably certain that the overall addition process [1] may be regarded as an insertion into the R—NC bond rather than an insertion into a C—H bond, as is usually observed (8).

Using dideuterioketene as the source of radicals, samples of ethyl cyanide and methyl cyanide taken from low-pressure runs, and a sample of ethyl isocyanide taken from a high-pressure run, were subjected to mass-spectroscopic examination. These experiments show that (*i*) the ethyl cyanide and ethyl isocyanide formed both contain two D atoms as expected; (*ii*) the cracking patterns of these molecules show fairly unambiguously that the CD_2 radical inserts into the H_3C—NC bond: in the first place, mass peaks are present at $m/e = 42$ (CD_2CN^+) and 40 ($CDCN^+$ or CH_2CN^+), but there is no peak at $m/e = 41$ ($CHDCN^+$); moreover, there is a strong peak at $m/e = 15$ (CH_3^+), but nothing above background at mass values of 16 (CH_2D^+) or 17 (CD_2H^+). This conclusion is also supported by the absence of *s*-propyl products in the reaction of methylene radicals with ethyl isocyanide, as noted above; (*iii*) the methyl cyanide formed in the CD_2-labelled reaction [6] contains no deuterium atoms.

[2]In this respect, it is interesting to note that the simple photolysis, under our conditions, of an unpurified commercial sample of ethyl cyanide gave small amounts of methyl cyanide, methyl isocyanide, and ethyl isocyanide, presumably through photosensitisation by an unknown impurity to form a hot ethyl cyanide molecule.

The rate of first-order hydrogen-ion independent chromium isotope exchange between benzylchromium(III) and chromium(II) ions is $1.2 \times 10^{-2}\ M^{-1}\ s^{-1}$ at 0°C in a 70% methanol–water solvent, $\Delta S^{\ddagger} = -28.5$ eu, $\Delta H^{\ddagger} = 10.3$ kcal M^{-1}. For the corresponding exchange between benzylchromium(III) and *p*-chlorobenzylchromium(III) ions, these figures are $1.2 \times 10^{-3}\ M^{-1}\ s^{-1}$, −32.2 eu, and 10.9 kcal M^{-1}.

M. PARRIS et A. W. ASHBROOK. Can. J. Chem. **57**, 1233 (1979).

La vitesse du premier ordre de l'échange isotopique du chrome, indépendante des ions hydrogène, du benzylchrome(III) et du chrome(II) est égale à $1.2 \times 10^{-2}\ M^{-1}\ s^{-1}$ à 0°C dans un solvant à 70% méthanol/eau; le $\Delta S^{\ddagger} = 28.5$ ue et le $\Delta H^{\ddagger} = 10.3$ kcal M^{-1}. Pour l'échange correspondant entre les ions benzylchrome(III) et *p*-chlorobenzylchrome(III), ces valeurs sont respectivement $1.2 \times 10^{-3}\ M^{-1}\ s^{-1}$, −32.2 ue et 10.9 kcal M^{-1}.

[Traduit par le journal]

It has been suggested (1) that the mixed coupling upon reduction of mixed organic halides by chromous ion results from an inner sphere exchange,

[1] Benzyl Cr^{2+} + *benzyl halide

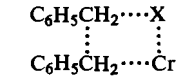
$$\rightleftharpoons \text{Benzyl halide} + \text{*benzyl } Cr^{2+}$$

occurring simultaneously with a coupling sequence,

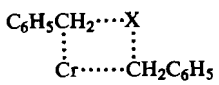
[2] Benzyl Cr^{2+} + *benzyl halide

$$\rightleftharpoons \text{Benzyl *benzyl} + \text{halo } Cr^{2+}$$

The extent to which these two reactions occur together leads to the postulate that similar intermediates are involved in both reactions (2), in particular a four-centred transition state for the coupling reaction,



kinetically indistinguishable from that for the exchange,

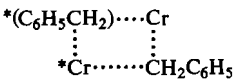


Evidence for the former transition state was apparently obtained when an optically-active *threo*-2,3-diphenylbutane resulted from the reduction of the α-phenethylchloride (2). It was of interest to determine the extent of exchange between two different benzylchromium(III) species: the more symmetric analogue of reactions [1] and [2],

[3] *Benzyl Cr^{2+} + benzyl *Cr^{2+} ⇌

$$\text{*Benzyl *}Cr^{2+} + \text{benzyl } Cr^{2+}$$

in order to assess the more symmetric four-centred transition state,



Experimental Section

Materials

Chromium(III) perchlorate stock solution was prepared from potassium dichromate, perchloric acid solutions by reduction with either ethanol or formic acid, and used to prepare chromium(II) solutions by reduction with zinc amalgam. The chromous solutions were always prepared immediately prior to their use, and always contained at least half as many gram-ions of Zn(II) as Cr(II).

^{51}Cr tracer was obtained from Atomic Energy of Canada Ltd. as a solution of sodium chromate. The tracer was added to an aliquot of the potassium dichromate and fumed with perchloric acid to remove any chloride.

1,1-Dimethyl-2-phenethylethanol (Eastman) was distilled, bp 62–64°C (1.5 mm), benzyl bromide (Eastman), 1,1-dimethyl-2-(*p*-chlorophenyl)ethanol, *p*-bromobenzyl bromide, *p*-methylbenzyl bromide, and *p*-methoxybenzyl bromide (Aldrich) were used without further purification.

Ion-exchange resin, Dowex 50-X2 and 50-X8, 100–200 mesh (Baker) was pretreated as follows: after removal of the fine material the remaining resin was warmed with a dilute alkaline solution of hydrogen peroxide, washed with dilute hydrochloric acid and then with water, and stored under 1 *m* perchloric acid.

*1,1-Dimethyl-2-(*p*-chlorophenyl)ethyl Hydroperoxide*

This was prepared by an adaptation of the method for 1,1-dimethyl-2-phenylethyl hydroperoxide (1). ***The preparation is***

0008-4042/79/101233-05$01.00/0

hazardous. Recrystallization from petroleum ether gave white needles, mp 51–52°C, yield 28%. Analysis by ceric titration showed greater than 99.5% hydroperoxide.

Apparatus

Ion-exchange columns were jacketted at 0°C. A well-type NaI crystal (1 × 1.5 in.) was used as a scintillation detector. Provision was made for continuous monitoring of the column eluate, fraction collection, and counting of individual samples. A Beckman model B spectrophotometer was used for chromium analyses on the column eluate.

Analysis

Chromium(II) concentrations were determined by ferric oxidation and ceric back-titration. Free acid was determined, after oxidation of any chromium(II) present, by passing an aliquot through an ion exchange column in the hydrogen ion form. Total chromium was determined spectrophotometrically at 372 nm, as chromate (3) after alkaline oxidation with hydrogen peroxide (4). The main chromium species (see Fig. 1*A*) separated from an exchange between benzylchromium(III) and chromium(II) ions, quenched by ferric ammonium sulphate, was found to be a sulphatochromium(III) ion plus a small (< 5%) amount of a disulphatochromium(III) ion, in addition to the hexaaquochromium(III) ion initially present. The sulphato complexes were identified by spectra (6) and by $CrSO_4$ analyses on the separated fractions. No ligated ethanol was found even when the benzylchromium(III) ion had been prepared originally in 90 vol.% ethanol–water at 0°C. Visually, oxidation of chromium(II) ion by ferric ammonium sulphate did not appear to be slower than by ferric perchlorate for which $k = 2 \times 10^3\ M^{-1}\ s^{-1}$ at 25°C, and the lack of ligated ethanol must reflect discrimination by chromium(II) ion against ethanol. Ethanol, bound and unbound, associated with chromic species was determined by the method of Kemp and King (5).

Determination of Rate Constants

1. Oxidation of Cr(II), Spectrophotometric Method

Solvent was measured into the capped, thermostatted cell and the appropriate reagent introduced by means of a hypodermic syringe.

2. Isotope Exchange Reactions

The general procedure used was as follows.

Exchange between Benzylchromium(III) Ion and Chromium(II) Ion

1,1-Dimethyl-2-phenethyl hydroperoxide or benzyl halide and solvent were nitrogen-flushed in a capped vessel. A stoichiometric quantity of chromium(II) perchlorate solution was added to produce the benzylchromium(III) ion. A known amount of labelled chromium(II) perchlorate solution was added and after a time the exchange was quenched by addition of a slight excess (2%) of oxygen-free ferric solution before injection of an aliquot into the ion-exchange column. The eluate activity was continuously monitored and Fig. 1 shows typical records obtained. In experiments in which ferric ammonium sulphate was used as the quenching reagent, the column was eluted initially with 1 *m* perchloric acid for the chromic sulphate species and then with 2 *m* perchloric acid for, first, the hexaquochromium(III) and, later, the benzylchromium(III) ion. In the case of ferric perchlorate quenching, 2 *m* perchloric acid was used throughout.

Exchange between Benzylchromium(III) Ion and p-Chlorobenzylchromium(III) Ion

Unsubstituted benzylchromium(III) ion was prepared from labelled chromium(II) ion and an aliquot of the unlabelled species injected into the labelled solution. After the required exchange time, an aliquot of the mixture was treated as before.

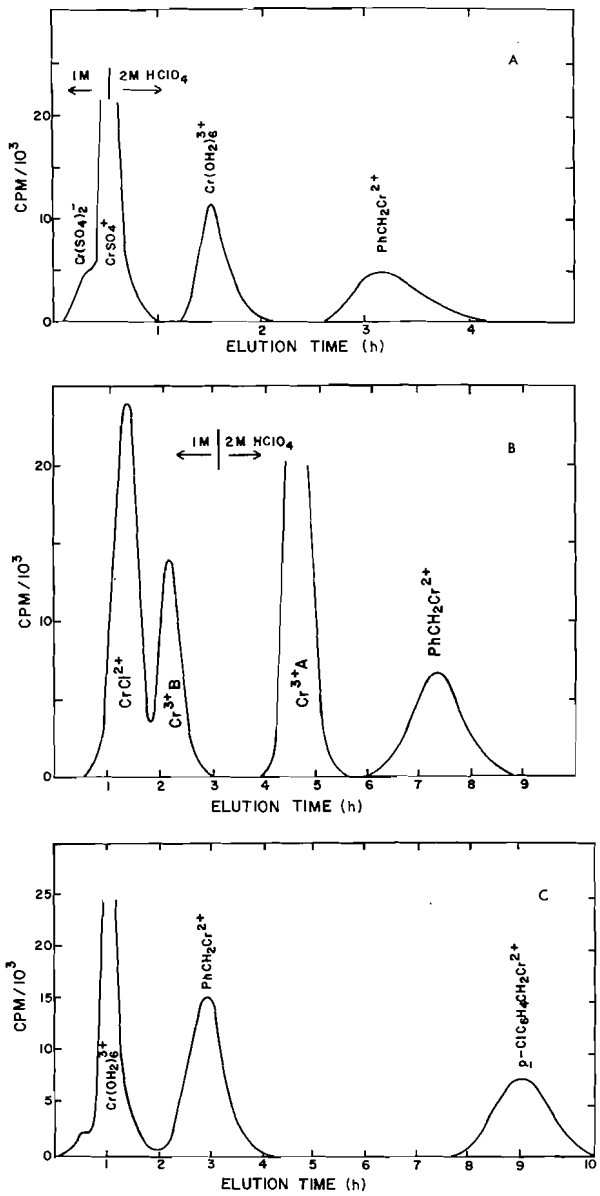


FIG. 1. (*A*) Elution of ^{51}Cr-containing species in the exchange between benzylchromium(III) and chromium(II) ions. (*B*) Elution of ^{51}Cr-containing species in the reaction between benzylchromium(III) ion and benzylchloride. (*C*) Elution of ^{51}Cr-containing species in the exchange between benzylchromium(III) and *p*-chlorobenzylchromium(III) ions.

Exchange between Benzylchromium(III) Ion and Hexaquochromium(III) Ion

The same general procedure was used, the labelled species being hexaaquochromium(III) ion.

3. Oxidation of Cr(II), Ion-exchange Method

In many cases it proved convenient to use an adaptation of the isotope exchange method in order to study the reaction

between benzylchromium(III) ion and the benzyl halides. Labelled benzylchromium(III) ion was prepared from 1,1-dimethyl-2-phenylethyl hydroperoxide and labelled Cr(II), mixed with the benzyl halide, and used in ion-exchange chromatography as before.

Results and Discussion

Exchange Reactions

The rate R at which a chromium(III) species exchanges with chromium(II) follows the McKay exponential function

$$R = -\frac{[Cr(III)][Cr(II)]}{[Cr(III)] + [Cr(II)]} \frac{\ln(1 - F)}{t}$$

F is the extent to which distribution of the label between chromium species approaches the equilibrium value of 1 and, where the Cr(III) is originally inactive, is given by

$$F = \frac{S_{Cr(III)}{}^t}{S_{Cr(III)}{}^\infty} = \frac{S_{Cr(II)}{}^0 - S_{Cr(II)}{}^t}{S_{Cr(II)}{}^0 - S_{Cr(II)}{}^\infty}$$

$S_x{}^t$ being the specific activity of species x at time t.

For a second-order exchange rate

$$R = k\,[Cr(III)][Cr(II)]$$

Table 1 contains data for the exchange between benzylchromium(III), $B_zCr(III)_{aq}{}^{2+}$, and chromium(II), $Cr_{aq}{}^{2+}$, ions at various temperatures, acid and salt concentrations.

The exchange

[4] $B_zCr(III)_{aq}{}^{2+} + {}^*Cr(II)_{aq}{}^{2+} \rightleftharpoons B_z{}^*Cr(III)_{aq}{}^{2+} + Cr(II)_{aq}{}^{2+}$

could perhaps result from the successive reactions

[5] $Cr(III)_{aq}{}^{3+} + {}^*Cr(II)_{aq}{}^{2+} \rightleftharpoons {}^*Cr(III)_{aq}{}^{3+} + Cr(II)_{aq}{}^{2+}$

[6] $B_zCr(III)_{aq}{}^{2+} + {}^*Cr(III)_{aq}{}^{3+} \rightleftharpoons B_z{}^*Cr(III)_{aq}{}^{2+} + Cr(III)_{aq}{}^{3+}$

since hexaaquochromium(III) ion, $Cr(III)_{aq}{}^{3+}$, is present, formed coincidentally with the benzylchromium(III) species. However, the rate constant for reaction [5] is $\leq 2 \times 10^{-5}\ M^{-1}\ s^{-1}$. For reaction [6] the exchange rate in 70 vol.% methanol – water at 0°C, $[B_zCr(III)^{2+}] = 2.0 \times 10^{-2}\ m$, $[Cr(III)_{aq}{}^{3+}] = 5.0 \times 10^{-2}\ m$ was found to be very slow; after 1.5 h practically no exchange had occurred and an upper limit for the rate constant is calculable,

$\leq 3 \times 10^{-5}\ M^{-1}\ s^{-1}$. The average rate constant for reaction [4] at 0°C is $1.2_2 \times 10^{-2}\ M^{-1}\ s^{-1}$, $\Delta S^{\ddagger} = -28.5 \pm 1.1$ eu, and $\Delta H^{\ddagger} = 10.3 \pm 0.3$ kcal mol^{-1}.

Figure 1*B* illustrates how two apparently distinct chromium(III) species (Cr_A^{3+} and Cr_B^{3+}) are produced in the reaction between benzylchromium(III) ion and various benzyl halides. The rate of increase of $[Cr_B^{3+}]$ followed the rate of increase of $[CrX^{2+}]$, the initial product of reduction of the benzyl halide, $C_6H_5CH_2X$, by the chromous ion. When the reaction was allowed to proceed after complete decomposition of the benzylchromium(III) ion, $[Cr_B^{3+}]$ increased, $[CrX^{2+}]$ decreased, and $[Cr_A^{3+}]$ remained virtually unchanged. It is concluded that Cr_B^{3+} results from aquation of CrX^{2+} and Cr_A^{3+} from the original oxidation of chromium(II) ion by 1,1-dimethyl-2-phenylethyl hydroperoxide. The Cr_A^{3+} was identified as $Cr(III)(H_2O)_6^{3+}$ by its absorption spectrum, λ_{max} 407 and 573 nm (5). Determination of bound ethanol in the Cr_B^{3+} species on the other hand showed 0.5 to 0.8 mol ethanol per atom Cr.

Rate constants for exchange between two different benzylchromium species (see Fig. 1*C* and eq. [3], *benzyl = *p*-chlorobenzyl)

[7] $(B_z)Cr(III)_{aq}^{2+} + (p\text{-}ClB_z)^*Cr(III)_{aq}^{2+} \rightleftharpoons (B_z)^*Cr(III)_{aq}^{2+} + (p\text{-}ClB_z)Cr(III)_{aq}^{2+}$

were found to vary significantly with the ion elution-rate owing to that reaction which had occurred after injection into the ion-exchange column yet prior to separation thereon. There is no obvious way to arrest this exchange; however, at constant elution-rate the log $(1 - F)$ plots are linear with a $t = 0$ intercept less than 1. The unit intercept is restored by shifting the plot ca. 1/2 h, indicative of a reasonably constant separation time. At 0°C the half-time for exchange was typically ca. 4 h and the rate constant for reaction [7] was found to be $1.2 \times 10^{-3}\ M^{-1}\ s^{-1}$, $\Delta S^{\ddagger} = -32.2 \pm 1.6$ eu and $\Delta H^{\ddagger} = 10.9 \pm 0.3$ kcal mol^{-1}.

The reactions between benzylchromium and benzyl halides were studied at temperatures between 0 and 25°C, Table 2, and the rate of disappearance of benzylchromium monitored spectrophotometrically at 360 nm. For example

[8] $PhCH_2Cr_{aq}^{2+} + PhCH_2Br \rightarrow$ Products

[8*A*] $PhCH_2Cr_{aq}^{2+} + PhCH_2Cl \rightarrow$ Products

[9] $PhCH_2Cr_{aq}^{2+} + p\text{-}BrC_6H_4CH_2Br \rightarrow$ Products

Reaction [8] implies and includes the sequence:

[10] $PhCH_2C(CH_3)_2OOH + 2Cr_{aq}^{2+} \xrightarrow{k_1} PhCH_2Cr_{aq}^{2+} + (CH_3)_2CO + Cr_A^{3+}$

[d] From *p*-MeObenzylbromide.
[e] Data from Table 1.

[11] $PhCH_2Cr_{aq}^{2+} + H_3O^+ \xrightarrow{k_2} PhCH_3 + Cr_A^{3+}$

[12] $PhCH_2Cr_{aq}^{2+} + PhCH_2Br \xrightarrow{k_3} PhCH_2CH_2Ph + CrBr_{aq}^{2+}$

[13] $CrBr_{aq}^{2+} \xrightarrow{k_4} Cr_B^{3+} + Br^-$

Reaction [9] implies and includes in addition the sequence:

[14] $PhCH_2Cr_{aq}^{2+} + p\text{-}BrC_6H_4CH_2Br \xrightarrow{k_5} p\text{-}BrC_6H_4CH_2CH_2Ph + CrBr_{aq}^{2+}$

[15] $PhCH_2Cr_{aq}^{2+} + p\text{-}BrC_6H_4CH_2Br \xrightarrow{k_6} PhCH_2Br + p\text{-}BrC_6H_4CH_2Cr_{aq}^{2+}$

[16] $p\text{-}BrC_6H_4CH_2Cr_{aq}^{2+} + PhCH_2Br \xrightarrow{k_7} p\text{-}BrC_6H_4CH_2CH_2Ph + CrBr_{aq}^{2+}$

[17] $p\text{-}BrC_6H_4CH_2Cr_{aq}^{2+} + p\text{-}BrC_6H_4CH_2Br \xrightarrow{k_8} p,p'\text{-}(BrC_6H_4CH_2)_2 + CrBr_{aq}^{2+}$

[18] $p\text{-}BrC_6H_4CH_2Cr_{aq}^{2+} + H_3O^+ \xrightarrow{k_9} p\text{-}BrC_6H_4CH_3 + Cr_A^{3+}$

The differential equations associated with these reaction schemes cannot be solved in closed form. Using known or estimated values for the rate constants k_1–k_9, a numerical integration by the Runge–Kutta method (8) confirmed that the observed spectrophotometric and concentration data are in agreement. The rate constants used were obtained as follows:

k_1: $10^3\ M^{-1}\ s^{-1}$ (1, 9);

k_2: calculated from experimental data for both the decrease in benzylchromium and the increase in Cr_A^{3+}, $2.3 \times 10^{-6}\ s^{-1}$ (2);

k_3, k_5, k_6, k_7, k_8: calculated from the initial rate of disappearance of the appropriate benzylchromium. These initial rates were practically the same for reactions [8] and [9]. Furthermore, organic product

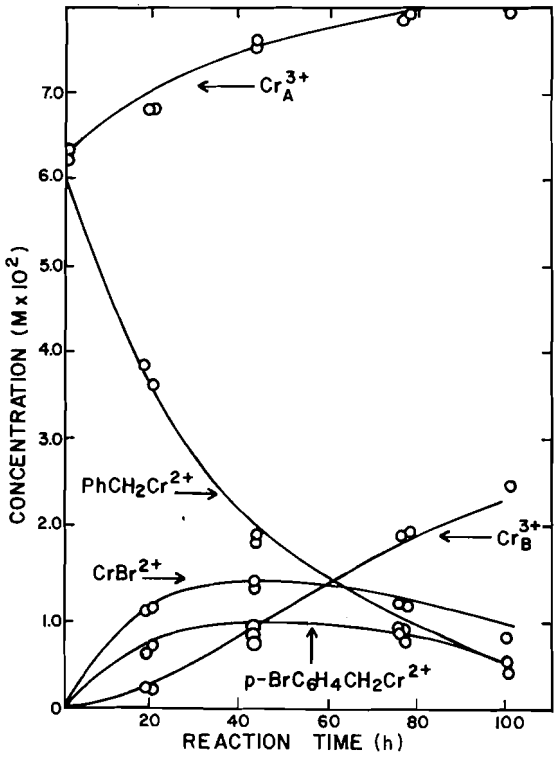

FIG. 2. Experimental (○) and calculated (—) concentrations for the reaction between benzylchromium(III) and *p*-bromobenzyl bromide at 0°C in 70 vol% methanol/water, $\mu = 0.5$, $[H^+] = 0.05$.

proportions from reactions between benzylchromium and several substituted benzyl halides were similar, indicating that reaction proportions, and so rates, are essentially the same. For the benzyl bromides, the rate constants used (at 0°C) were all $5.0 \times 10^{-5}\ M^{-1}\ s^{-1}$. For the chlorides the value of 1.0×10^{-7} was used.

k_4: aquation rate constants were calculated from available data. For chloropentaaquochromium(III) at 0°C, $[H^+] = 0.5$, a value $1.0 \times 10^{-8}\ s^{-1}$ was used (7) and for the bromo species, $2.0 \times 10^{-6}\ s^{-1}$ (10);

k_9: this was determined in the same way as k_2, $1.0 \times 10^{-6}\ s^{-1}$. The values for k_2 and k_9 used here, 2.3×10^{-6} and $1 \times 10^{-6}\ s^{-1}$, are comparable in ratio to the values at 28°C, 1.0×10^{-2} and $4.6 \times 10^{-3}\ s^{-1}$ from ref. 2. Figure 2 shows the experimental concentrations of reactants, intermediates and products for the reaction between benzylchromium(III) ion and *p*-bromobenzylbromide at 0°C, together with values calculated using these rate constants.

A gas chromatographic detector based on the quenching of luminescence from a P_4/O_2 cold flame

WALTER A. AUE AND ZBIGNIEW M. MIELNICZUK[1]

5637 Life Sciences Centre, Dalhousie University, Halifax, N.S., Canada B3H 4J1

Received October 3, 1978

WALTER A. AUE and ZBIGNIEW M. MIELNICZUK. Can. J. Chem. **57**, 1238 (1979).

Gas chromatographic effluents were detected by their quenching effect on the luminescence of a steady 'cold flame', as provided by the gas-phase reaction of phosphorus vapor and oxygen. The response of organic compounds correlated with their 'ease of oxidation' in accordance with the literature, suggesting that such compounds act as oxygen atom scavengers in the branched-chain P_4/O_2 reaction.

Most substances showed linear response over one to two orders of magnitude, and minimum detectable amounts ranged from 2×10^{-9}g (benzaldehyde) to 2×10^{-4}g (dichloromethane). The detector temperature could be varied to (*a*) alter response ratios, i.e. selectivity, among some types of compounds; and (*b*) produce easily-obtained Arrhenius plots. However, the response (luminescence quenching) of most compounds was independent of temperature over a considerable range.

WALTER A. AUE et ZBIGNIEW M. MIELNICZUK. Can. J. Chem. **57**, 1238 (1979).

On a détecté des gaz qui s'écoulent d'un chromatographe grâce à leur effet d'amortissement sur la luminescence d'une "flamme froide" stationnaire fournie par une réaction en phase gazeuse de vapeurs de phosphore et d'oxygène. Le taux de composés organiques peut être relié à leur facilité d'oxydation; cette observation est en accord avec les suggestions faites dans la littérature à l'effet que de tels composés peuvent agir comme pièges pour des atomes d'oxygène dans la réaction de P_4 chaîne ramifiée/O_2.

La plupart des substances répondent d'une façon linéaire selon un ou deux ordres de grandeur; les quantités minimales que l'on peut détecter vont de 2×10^{-9}g (benzaldéhyde) jusqu'à 2×10^{-4}g (dichlorométhane). On peut faire varier la température du détecteur afin de (*a*) faire varier les rapports de réponse, soit la sélectivité entre quelques types de composés; et (*b*) produire des courbes d'Arrhénius qui peuvent être obtenues facilement. Toutefois, la réponse (l'amortissement de luminescence) de la plupart des composés est indépendante de la température sur une grande étendue.

[Traduit par le journal]

Introduction

The chemiluminescent oxidation of white phosphorus has been known for a few centuries. The origin of its glow or 'cold flame' has intrigued and challenged many a scientist, and the literature on the subject has become voluminous (1). Yet, this complex phenomenon is still not understood in all of its aspects.

Semenoff characterized the luminescent oxidation of phosphorus as an isothermal, branched-chain radical reaction (2). This interpretation fitted well the easily-observed, sharp upper and lower limiting pressures of oxygen, outside of which there occurs little if any luminescence. The light-emitting species is unknown (3), but kinetic investigations have established reasonable models based on the correlation of these limits to various experimental parameters.

The gas-phase oxidation of white phosphorus, according to Dainton and Kimberley (4), proceeds as follows:

[1] $P_4 + O_2 \rightarrow P_4O + O$ initiation

[2] $P_4 + O + M \rightarrow P_4O + M$ propagation

[3] $P_4O_n + O_2 \rightarrow P_4O_{n+1} + O$ branching, where $n = 1$–9

[4] $O + O_2 + M \rightarrow O_3 + M$ termination

[5] $O +$ inhibitor $\rightarrow$ termination

[6] $O +$ wall $\rightarrow$ termination

Reaction [2] is strongly exothermic and has no energy of activation; but $E_{(4)} = 4.3$ kcal (4).

The reaction of primary interest in the context of this paper is the gas-phase termination step [5]. It competes with the chain propagating reaction [2] for oxygen atoms, thereby lowering, in the experiments by Dainton and Kimberley, the upper limit of oxygen pressure.

The reasonable use of reaction [5] in a gas chromatographic detector cannot rely on the measurement of a limit, i.e. a glow/no glow criterion. Rather, the reactions have to proceed well within limits to obtain

[1]Present address: Institute of Food and Nutrition, Warsaw, Poland.

0008-4042/79/101238-06$01.00/0

linear response to the inhibitor (the gas chromatographic effluent). Since reactions [2] and [5] compete for oxygen atoms, the inhibitor should decrease the (intrinsic) luminescence of a steady P_4/O_2 cold flame.

Under reasonable gc detector conditions, a cold flame is best produced from an excess of P_4 vapor and extremely small (sub-ppm) levels of O_2. Thus reaction [4] is of minor importance. Furthermore, the cold flame is small and sharply defined under these circumstances much like the flame of an FID. Thus, reaction [6] does not occur.

Since P_4/O_2 chemiluminescence consists mainly of a continuum (3), spectral discrimination cannot be usefully employed. But without spectral discrimination, any luminescence arising from the reaction of gc effluents with O or O_3, will in effect oppose the quenching effect on P_4/O_2 chemiluminescence. It could, indeed, lead to a net increase in light emitted. Thus 'positive' gc peaks could be observed under these circumstances in contrast to the usual 'negative' ones.

Many luminescent reactions involving O and O_3 are known (5), and have given rise to various air pollution monitors and even a gc detector (6). Judging from these data, as well as from two of our own studies (7, 8), there should exist particular cases where the magnitude of such responses becomes large enough to be noticed. These should not, however, seriously impair the over-all performance of the proposed detector.

It is understood that the effect of inhibitors on the P_4/O_2 reaction, and the reaction rates of such substances with oxygen atoms produced by other means (9), correlate to what one may vaguely describe as their 'ease of oxidation'. This term should be understood in the traditional context of organic synthesis; indicating, for instance, that benzaldehyde is much easier oxidized than toluene. Translated to detector response, then, the former should yield a much larger signal than the latter. On this basis, an approximate prediction of response can be had for many compounds. Conversely, the detector could serve to compare and quantify, in an easy manner, the oxidation behavior of many organic structures.

This reciprocity, in our view, is important. It helps to justify further investigation of the effects of gas chromatographic effluents on the luminescence yield of the P_4/O_2 reaction. Thus we would expect this study to be of interest in the following three contexts.

First, the context of oxygen atom chemistry. Many studies have been concerned with this topic (9) but, mostly owing to technical difficulties, much remains to be learned. The P_4/O_2 system, in the clean, flow-through configuration of a gc detector, appears to offer a cheap and convenient source of oxygen atoms with luminescence as built-in indicator. Gas chromatographic measurements are rapid and easily performed over a wide temperature range, besides contributing the inherent advantage of a highly purified test compound.

Second, the context of biochemical oxidation. It seems reasonable to speculate that a detector based on the reaction of oxygen atoms with analyte molecules, could parallel in some of its responses biochemical reactivity.

Many anthropogenic substances depend on microsomal oxidation for activation, detoxification, etc. Their chemical 'ease of oxidation' has been more than once correlated with biological activity; especially for anticholinesterases and carcinogens (10).

To invoke such speculations may seem far-fetched. However, their realization would not lack precedent. Most of the substances that respond well in the electron capture detector (ECD) are of considerable biological activity (pesticides, steroids, etc.), and a causal relationship has been suggested (11).

If so, then a strong response from the ECD can pin-point an 'important' substance in screening experiments. It may lead, as it has done on several occasions in the past, to the discovery of potentially harmful trace components in complex environmental or biological extracts. Possibly the P_4/O_2 detector can play a similar role.

Third, and of primary importance for this paper, is the analytical context. It concerns the prospect of developing a gas chromatographic detector for some analytically difficult types of compounds; compounds for which a truly selective gc detector does not now exist. In technical terms, this task appeared but a logical extension of our recent experience with phosphorus vapor for the determination of molecular oxygen in gas streams (7).

Experimental

Three photometric detector prototypes, designated OD1, 2 and 3, were used in this study. The first, OD1, served initially in the detection of oxygen (hence the abbreviation OD) down to the 20 pg level (7). The P_4/O_2 chemiluminescence was monitored by a low-noise PM tube through a light guide in non-dispersive mode. The construction of the technically improved models OD2 and 3, which are better suited to the monitoring of organic analytes via quenching of the P_4/O_2 chemiluminescence, has been described in detail (8). The three detectors differ in mechanical and operational detail (ease of cleaning, temperature control, etc.) but not in basic design or function. This paper, in contrast to refs. 7 and 8, deals not with detector construction but with the characterization and possible interpretation of its responses.

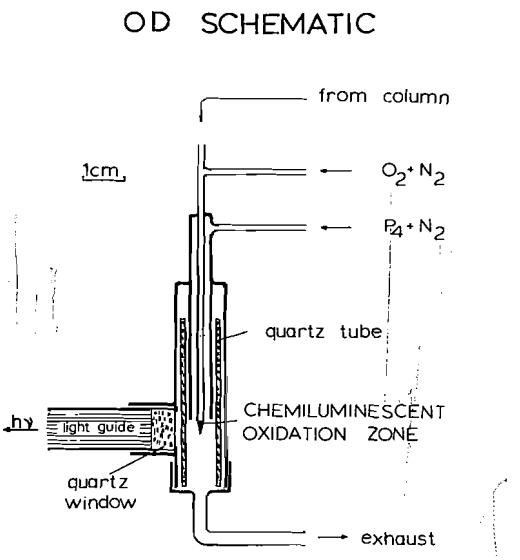

FIG. 1. Schematic detector cross section.

However, to allow facile orientation, the mostly used OD3 is shown in schematic representation in Fig. 1. P_4 vapor was supplied in a 20 mL/min stream of nitrogen, which had passed over liquid white phosphorus at 50°C. Oxygen was supplied by a minute stream of 'high purity' grade nitrogen (~14 ppm O_2), adjusted to produce a constant light level throughout the experiments. This level was established by prior signal/noise maximization.

Gas chromatographic conditions were essentially routine. A 150 × 0.2 cm id glass column packed with 3% OV-101 on Carbowax 20M-deactivated Chromosorb W, 100/120 mesh, was used with a 25 mL/min nitrogen flow. Test compounds were taken mostly from Chemical Standard Kits (Polyscience Corp. and Chem. Service) and used without further purification, provided not too many impurity peaks were noticed.

For calibration graphs, single compounds were injected at isothermal conditions. The temperature was chosen to produce approximately the same retention time for all compounds. For temperature dependence curves, typical solutes selected from preliminary runs were combined in one mixture, and chromatographed at four different dilutions with a standard temperature program. This was done to ensure that the values for the Arrhenius plot would be taken from within linear range.

On occasion, the column effluent was split to supply OD3 and a conventional FID simultaneously, or the FID exclusively. For comparison, OD3 was also operated with ozone as a reagent gas, or with a steady SiH_4/O_2 cold flame. The former served as tie-in to the work of Bruening and Concha (6), the latter provided a chemically different light source that was also quenched by column effluents (8). All other conditions were as indicated in the legends.

Results and Discussion

Most tested compounds produced response as expected, i.e. a decrease in the level of light reaching the photomultiplier tube (negative peaks). Positive peaks were observed occasionally, depending on the nature and concentration of the solute, and on detector conditions. Oxygen had to be present in the system for positive peaks to occur. Although interesting in their own right, these were not further evaluated in the context of this study. Also, no efforts were made to define any spectral features associated with the passage of peaks.

Table 1 lists most of the compounds that were used to test detector reponse. Values for molar response and linear range are deliberately given in one-digit

TABLE 1. Response and linear range

Compound	Response in mm peak height per mol injected (noise = 1 mm)	Linear range (g measured)
Benzaldehyde	2×10^{11}	$2\times10^{-9}-5\times10^{-8}$
Tetraethyllead	1×10^{11}	$5\times10^{-9}-4\times10^{-8}$
Piazselenole	1×10^{11}	$4\times10^{-9}-6\times10^{-8}$
p-Benzoquinone	1×10^{11}	$3\times10^{-9}-1\times10^{-7}$
Tetravinyltin	6×10^{10}	$1\times10^{-8}-1\times10^{-7}$
t-Butyldisulfide	5×10^{10}	$1\times10^{-8}-2\times10^{-7}$
Crotonaldehyde	4×10^{10}*	$1\times10^{-8}-5\times10^{-8}$
i-Butanol	4×10^{10}	$8\times10^{-9}-1\times10^{-7}$
l-Butanol	3×10^{10}	$1\times10^{-8}-1\times10^{-7}$
Dimethylsulfoxide	2×10^{10}	$1\times10^{-8}-2\times10^{-7}$
l-Pentanol	2×10^{10}	$1\times10^{-8}-1\times10^{-7}$
l-Hexanol	2×10^{10}	$1\times10^{-8}-2\times10^{-7}$
sec-Butanol	1×10^{10}	$3\times10^{-8}-2\times10^{-7}$
Mercaptoethanol	1×10^{10}	$3\times10^{-8}-9\times10^{-7}$
l-Octanethiol	7×10^{9}	$7\times10^{-8}-6\times10^{-7}$
Butyraldehyde	6×10^{9}	$9\times10^{-8}-3\times10^{-7}$
Valeraldehyde	6×10^{9}	$1\times10^{-7}-6\times10^{-7}$
Benzenethiol	5×10^{9}	$5\times10^{-8}-5\times10^{-7}$
t-Butanol	4×10^{9}	$4\times10^{-7}-6\times10^{-7}$
α-Pinene	4×10^{9}	$6\times10^{-8}-4\times10^{-6}$
t-Amyl alcohol	2×10^{9}	$1\times10^{-7}-8\times10^{-7}$
l-Octene	2×10^{9}	$1\times10^{-7}-1\times10^{-6}$
Phenol	1×10^{9}	$4\times10^{-7}-3\times10^{-6}$
2-Octanone	1×10^{9}	$2\times10^{-7}-9\times10^{-7}$
Fluorobenzene	6×10^{8}	$3\times10^{-7}-2\times10^{-6}$
Thiophene	3×10^{8}	$6\times10^{-7}-4\times10^{-5}$
n-Octane	2×10^{8}	$1\times10^{-6}-1\times10^{-5}$
Toluene	1×10^{8}	$3\times10^{-6}-9\times10^{-6}$
Benzene	3×10^{7}	$9\times10^{-6}-3\times10^{-4}$
Chlorobenzene	2×10^{7}	$2\times10^{-5}-2\times10^{-4}$
Bromobenzene	2×10^{7}	$2\times10^{-5}-8\times10^{-5}$
Dichloromethane	4×10^{6}	$3\times10^{-4}-8\times10^{-4}$

Compound	Response in mm peak height per mol injected	Comment
Diethylmercury	2×10^{10}	One point
Tetrahydrothiophene	1×10^{10}	Non-linear
Hexamethylditin	8×10^{9}	One point
Tetraethyltin	4×10^{9}	One point
Aniline	2×10^{9}	Non-linear
Anthracene	2×10^{9}	One point
Ferrocene	2×10^{9}	One point
Tetrabutylgermane	1×10^{9}	One point
α-Camphene	1×10^{9}	Non-linear
Phenanthrene	4×10^{8}	One point
Naphthalene	2×10^{8}	One point

*From linear range. Upper part of calibration curve non-linear, maximum response 7×10^{10}.

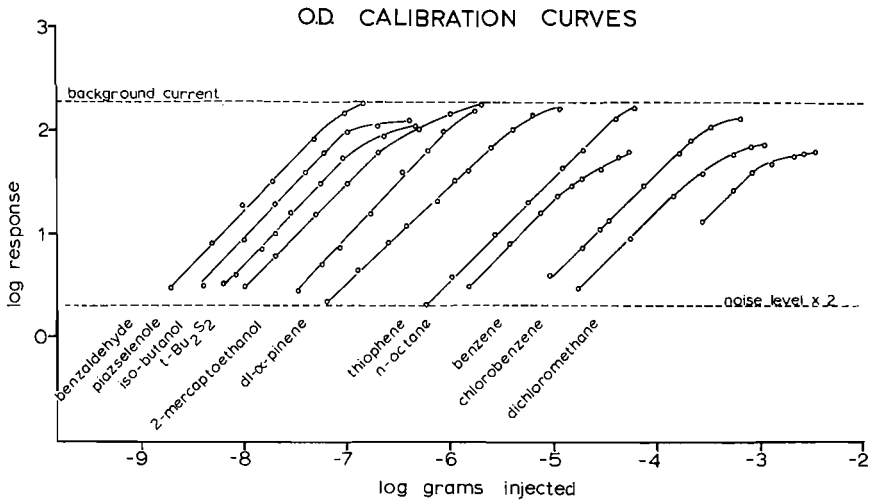

FIG. 2. Calibration curves for selected organic solutes quenching P_4/O_2 luminescence.

numbers, even though the short term reproducibility of peak heights was comparable to that obtained from other gc detectors. The sole purpose of Table 1 is to provide an approximate, general survey of the response obtained from various organic structures. While some approximate comparisons are thus reasonable to make, these data should not be used in a strictly quantitative context. It is easy enough to procure accurate comparisons with this detector on a peak area basis, (and it may, in fact, be very desirable to do so for studies of organic reactivity) but the necessary general precautions to ensure sample purity, guard against premature solute decomposition, etc. become extremely time-consuming when a large number of compounds is involved.

Hence, it has become common practice to forego such precautions in gc studies. While its limitations are obvious, that approach was clearly called for for an exploratory study such as this one.

Even with these limitations in mind, however, it is obvious from Table 1 that OD response relates to chemical structure, and that the 'ease of oxidation' criterion mentioned earlier plays a dominant role. Aldehydes and alcohols are among the best responding compounds; halogenated materials among the worst.

The first part of Table 1 lists a greater number of compounds for which full calibration curves have been established. The second part contains some more compounds that (*a*) did not show linear response or (*b*) were measured only at one concentration. In the former case, the numbers given for peak height per mole injected refer to the highest one measured. The three clearly non-linearly responding compounds, aniline, tetrahydrothiophene, and α-camphene showed slopes (in a log/log plot where slope 1 = linear) of 0.63, 0.84, and 2.0, respectively.

The linear range is given only as far as actually measured; extrapolation to $S/N = 2$ would have given slightly larger values in most cases. (This was done because a few compounds, notably dichloromethane, failed to show up at lower concentrations even though extrapolation of their calibration curves would have suggested otherwise). As can be seen from the few, typical examples shown in Fig. 2 and the numbers quoted in Table 1, compounds do differ in linear range. Furthermore, since the level of available light and the noise level are only two orders of magnitude apart, the linear ranges are of necessity very short.

It is interesting to compare, however approximate, the molar responses obtained for various types of compounds. For instance the series primary:secondary:tertiary butyl alcohols, with relative molar responses of 1:0.3:0.1 or anthracene:phenanthrene:naphthalene:toluene:benzene with relative responses of 1:0.2:0.1:0.05:0.02. These orders follow the general 'ease of oxidation', and various other examples can be found. Not surprisingly, results did deviate in a few cases from those expected. Little is known about the mechanism(s) involved, and there is always the possibility that oxidation of the analyte produces enough luminescence to reduce the observed P_4/O_2 flame quenching.

In general, the selectivity displayed towards alcohols, aldehydes, etc. should be helpful to the analyses of certain natural products, biofluids, and environmental samples. Most calibration curves, as judged by a few typical ones shown in Fig. 2, follow similar patterns.

There are exceptions, though-non-linear ones and those that flatten out relatively early. It ought to come as little surprise, however, that among the many compounds tested, some variation in mechanism should occur.

A similar statement can be made about the temperature dependence of response, shown in Fig. 3 as an Arrhenius plot for a few selected compounds. More than those shown were run and, as expected, similar structures did exhibit similar behavior.

From an analytical viewpoint, the relative response of a few compounds, say 2,4,4-trimethylpentene-2 and 1-hexanol, can be influenced by a judicious choice of detector temperature. Other compounds show little difference. Above a temperature around 140°C, response generally increases.

From a kinetic viewpoint, a different reaction mechanism would appear to take over above these temperatures. If we assume that the crucial step in quenching luminescence is the competition for oxygen atoms between reactions [5] and [2], then the slope of the lines in Fig. 3 should equal $-(E_A[5] - E_A[2])/2.3R$; provided the baseline current stays the same. If $E_A[2] = 0(4)$ and no other reaction interferes, the slope should be characteristic of the analyte reaction with oxygen atoms. Obviously this could not be applicable to the olefin, and would mean zero activation energy for (among other compounds not shown) benzaldehyde, and for octane and benzene in the lower temperature range. Thus, a difference in rates of some four orders of magnitude would have to be accounted for by the pre-exponential factor.

This seems quite unlikely. Maybe the simple, initial assumptions are incorrect; or perhaps the oxygen atoms are epithermal. Even though it is the quenching of the luminescence, and not the luminescence itself, that is being recorded, it follows the same trend as many chemiluminescent reactions, i.e. to exhibit little if any temperature dependence (12). The question of mechanism(s) remains unresolved.

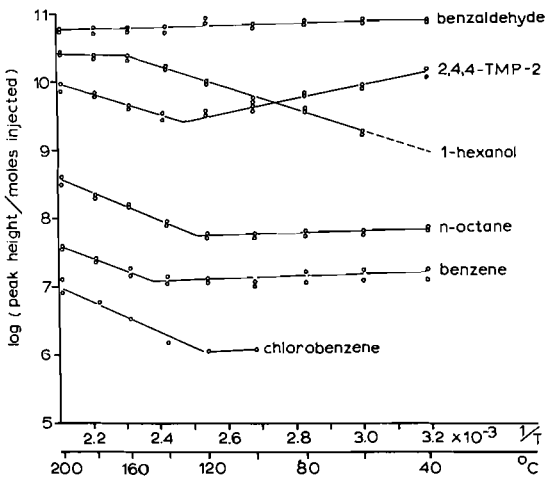

FIG. 3. Arrhenius plot for selected compounds.

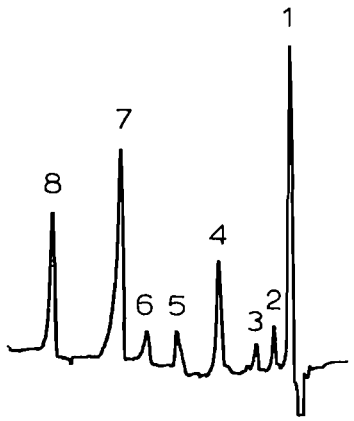

FIG. 4. Temperature programmed gc of selected analytes near their minimum detectable amounts. *1*: ~3 mg dichloromethane (solvent); *2*: 26 μg benzene; *3*: 150 ng 2,4,4-trimethylpentene (2); *4*: 13 μg *n*-octane; *5*: 50 μg chlorobenzene; *6*: unknown; *7*: 140 ng 1-hexanol; *8*: 26 ng benzaldehyde.

It may be added, however, that this exploratory study could not reasonably attempt, nor was it designed to provide, a definite answer to this question. Rather, the question was brought up to draw attention to an interesting problem, and to the relative ease with which a gc detector can provide relevant data.

Figure 4 shows a temperature programmed chromatogram of the six compounds used in the Arrhenius plot, at concentration levels not too far from minimum detectable limits. The figure demonstrates well the sensitivities and selectivities characteristic of the method.

A further demonstration of selectivity is provided in Fig. 5. The same mixture of compounds was detected by the OD operating in three different modes: the P_4/O_2 quenching mode discussed in this paper, an SiH_4/O_2 quenching mode (8), and an O_3-induced chemiluminescence mode (6, 8). Conventional FID detection was also included. In order to use the same mixture in all four cases and still detect all peaks in the FID, some compounds (e.g. *p*-quinone, piazselenole) had to exceed linear range in the OD, as may be noticed by the distorted peak shapes. The large differences among the four detection modes are readily apparent.

At present, the sensitivity of the OD for the best-responding analytes is close to that of the FID. More important, however, its selectivity favors easily oxidized compounds.

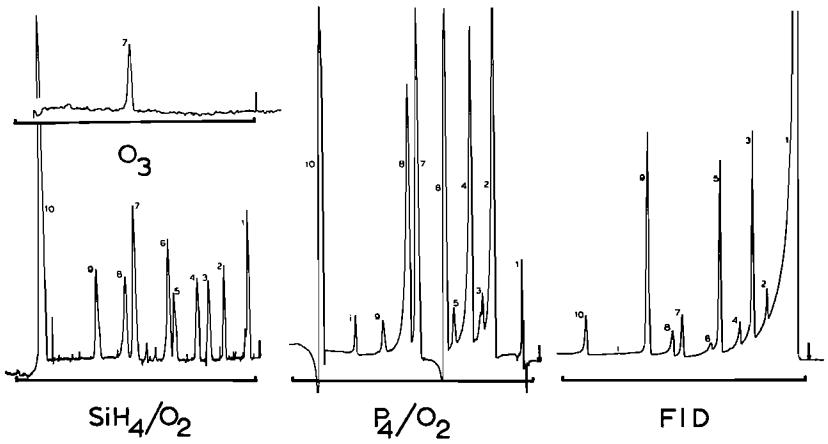

FIG. 5. Temperature programmed gas chromatography of selected compounds in the microgram range with four different detection modes. Injected for FID, P_4/O_2 quenching and SiH_4/O_2 quenching modes: *1*: 1 μL dichloromethane (solvent); *2*: 1.8 μg 1-pentanol; *3*: 4.3 μg *n*-nonane; *4*: 1.9 μg 1-hexanol; *5*: 3.8 μg *n*-decane; *6*: 3.5 μg *p*-quinone; *7*: 2.1 μg *tert*-butyldisulfide; *8*: 1.8 μg 1-octanol; *9*: 4.2 μg *n*-dodecane; *10*: 3.6 μg piazselenole; *i*: impurity. Fourfold amounts injected for O_3 luminescence mode. Recorder traces for the two quenching modes are inverted.

This property suggests its use on samples where the presence of such compounds is important, but is often obscured in the chromatogram by larger amounts of uninteresting co-eluates. One can speculate that aldehydes in air pollution samples, or in headspace from a variety of foods and beverages, may provide a case-in-point. It should also be interesting to examine volatiles in physiological fluids or breath in this manner.

Another possible use of the OD is operation in parallel with an FID. The OD/FID peak height ratio for a particular compound (normalized by means of an appropriate standard to account for day-to-day variation in the two detectors) should provide a very selective test of peak identity. To wit, this ratio should be fairly characteristic of a compound's nature, since such ratios can vary by more than four orders of magnitude (cf. Table 1), but could likely be determined with only a few percent relative standard deviation. The coincidence, within error limits, of the OD/FID ratios for an authentic standard and an analyte peak of the same retention, would greatly strengthen the assumption that the two compounds are indeed identical.

The azidonitration of tri-*O*-acetyl-D-galactal[1]

R. U. LEMIEUX AND R. M. RATCLIFFE[2]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received December 22, 1978

R. U. LEMIEUX and R. M. RATCLIFFE. Can. J. Chem. **57**, 1244 (1979).

Reaction of 3,4,6-tri-*O*-acetyl-D-galactal with excess ceric ammonium nitrate and sodium azide in acetonitrile produced 2-azido-1-nitrate addition products (53% β-*galacto*, 22% α-*galacto*, and 8% α-*talo*) and *N*-acetyl-3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-α-D-galactopyranosylamine was formed, on hydrolysis, in 10% yield. The reaction product provides a convenient source of D-galactosamine and 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-α-D-galactopyranosyl halides. The crystalline β-chloride is also reported. The use of these glycosyl halides as reactants for the preparation of 2-azido-2-deoxy-α- and -β-D-galactopyranosides under conditions promoted by both mercuric cyanide and silver salts are reported.

R. U. LEMIEUX et R. M. RATCLIFFE. Can. J. Chem. **57**, 1244 (1979).

La réaction du tri-*O*-acétyl-3,4,6 D-galactal avec du nitrate d'ammonium cérique en excès et de l'azoture de sodium dans l'acétonitrile conduit aux produits d'addition azido-2 nitrate-1 (53% β-*galacto*, 22% α-*galacto* et 8% α-*talo*); par hydrolyse, il y a formation de la *N*-acétyltri-*O*-acétyl-3,4,6 azido-2 désoxy-2 α-D galactopyrannosylamine avec un rendement de 10%. Le produit de la réaction s'avère une source convenable de la D-galactosamine et des halogénures du tri-*O*-acétyl-3,4,6 azido-2 désoxy-2 α-D-galactopyrannosyle. On rapporte aussi la formation du chlorure β cristallin. On rapporte l'utilisation de ces halogénures de glycosyle comme réactifs dans la préparation des azido-2 désoxy-2 α- et β-D-galactopyrannosides dans des conditions favorisées par des sels de cyanure mercurique et d'argent.

[Traduit par le journal]

Introduction

The occurrence of building units derived from 2-acetamido-2-deoxy-α-D-galactopyranose, which are *O*-linked to either serine or threonine, in a wide variety of glycoproteins (1, 2) including glycophorin A (3), epiglycanin (4), antifreeze glycoproteins (5), and the human blood specific glycoproteins (6) is well documented. Both α- and β-glycosidic units derived from *N*-acetyl-D-galactosamine occur in the oligosaccharidic antigenic determinants of a number of glycosphingolipids (7). Thus, there has developed widespread interest in achieving chemical syntheses of oligosaccharides containing these groupings both for immunochemical and enzymological studies (8). However, the lack of a readily accessible supply of either D-galactosamine or of suitable progenitors has curtailed research in this biologically important area. This work was initiated primarily to achieve the syntheses of oligosaccharides related to the A blood determinants (9) but has been extended to the synthesis of the T, T_N (10), and other important human cell-surface antigenic determinants.

The major source of D-galactosamine is by way of the acid hydrolysis of chondroitin sulfate (11). Numerous synthetic methods have been described including the chain extension of D-lyxose (12, 13), inversion of C-4 of D-glucosamine (14), the addition of ammonia to 1,6;2,3-dianhydro-β-D-talopyranose (15) and by reduction of oximes obtained by way of the addition of nitrosyl chloride to tri-*O*-acetyl-D-galactal (16).

The preparation of α-D-galactosaminides by way of 2-oximo-α-D-*lyxo*-hexopyranosides (17) provided the first synthesis of an *N*-acetyl-α-D-galactosaminidic disaccharide (18). However, to date, this method is handicapped by the fact that reduction of the intermediate oxime to the *galacto* configuration cannot be achieved with a high degree of stereoselectivity. More recently, Paulsen and co-workers (19–22), utilized 6-*O*-acetyl-2-azido-3,4-di-*O*-benzyl-2-deoxy-β-D-galactopyranosyl chloride to synthesize the terminal trisaccharide of the Forssman antigenic determinant and a partial structure of the A human blood group determinant. Thus, the utility of the azide group as a nonparticipating 2-substituent in glycosyl halides to be engaged in Koenigs–Knorr type glycosidation reactions was established but, to become attractive, a more ready access to 2-azido-2-deoxyglycosyl halides was needed than is provided by the 10-stage process used by Paulsen and co-workers. The main purpose of this communication is to report a relatively simple five-stage process from D-galactose to obtain 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-D-galacto-

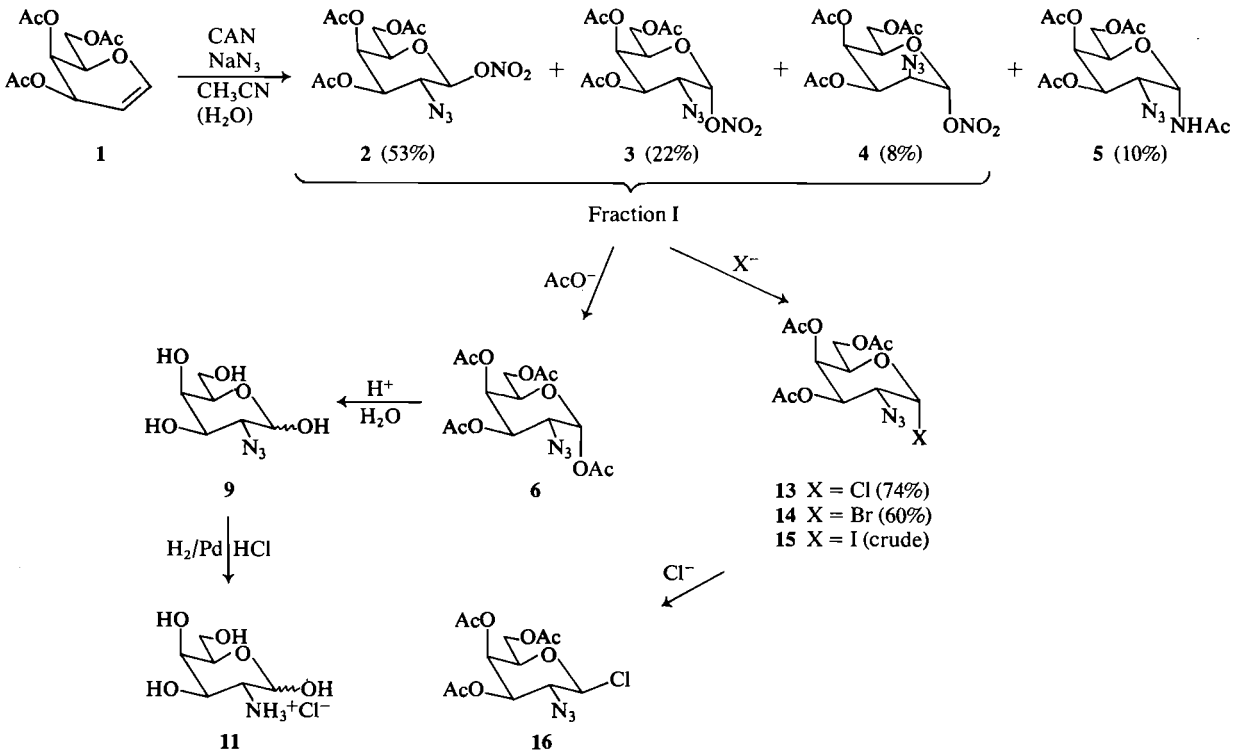


SCHEME 1. Azidonitration of D-galactal triacetate and some of the products derived therefrom.

pyranosyl halides. However, the method also provides ready access to D-galactosamine. The method appears generally applicable to *O*-protected glycals and is expected to find widespread application for the preparation of 2-azido-2-deoxyaldoses and their glycosides.

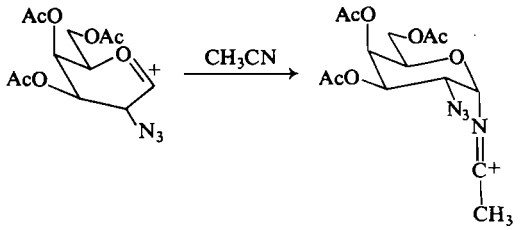
In 1971, Trahanovsky and co-workers (23, 24) reported the formation of α-azido-β-nitratoalkanes on treating alkenes with sodium azide and ceric ammonium nitrate in moist acetonitrile. The matter of central importance to the present application of this reaction was that the products obtained were consistent with the reaction being initiated by addition of an azide radical (23). Several mechanisms have been proposed (25) to rationalize the fate of the proposed azidoalkane radical intermediate. Although no reference could be found to the application of this 'azidonitration' reaction to vinyl ethers, it could be anticipated that a radical induced addition would follow the anti-Markovnikov route and, therefore, when applied to *O*-protected glycals would provide 2-azido-2-deoxyglycosyl nitrates. It may be mentioned that our attempts to induce free-radical addition of either ClN_3 or BrN_3 to *O*-acetylated glycals failed and only 1-azido-1-deoxy-2-halogeno-2-deoxy sugars were obtained. Further work in this regard was abandoned when a reaction involving chloroazide and with sulfuryl chloride as the radical initiator detonated with violence.

The more important aspects of this paper are outlined in Scheme 1. It is seen that, in the azidonitration of 3,4,6-tri-*O*-acetyl-D-galactal (**1**), 93% of the reaction products were identified and all of these products, as expected, contain the azide group at the 2-position with 85% of these products containing this group in the equatorial orientation (the *galacto* configuration). The similar azidonitration of other glycals will be reported separately (26). However, it is noteworthy at this point that the above-mentioned stereoselectivity appears related to the quasiaxial orientation of the 4-acetoxy group of **1** since the azidonitration of the acetates of D-xylal, D-glucal, and lactal all provided substantially lower yields of C-2 equatorial azide; namely, ratios of equatorial to axial isomer of 2, 1, and 3, respectively. This is in contrast to the ratio of 11 in the case of D-galactal triacetate. Thus, the development of a *syn*-diaxial interaction with an acetoxy group during the establishment of the azido group is more prohibitive than is the development of a *syn*-clinal interaction with a neighboring acetoxy group. It is not considered definite that the reaction is initiated by the attack of

the double bond by an azide radical rather than by a ceric–azide complex (23). The steric bulk of the latter could help to explain the stereochemical route of reaction. It is to be noted that it was necessary to use an excess of both CAN and sodium azide since some of these reagents are lost in the ceric oxidation of azide to nitrogen gas. The rate of this competing reaction appeared dependent on the concentration of the azide in solution. When *N*,*N*-dimethylacetamide was used as solvent, a solvent which rapidly provided a homogeneous reaction mixture, this competing reaction consumed all of the oxidant. It is possible that the reaction of CAN with azide ion to a ceric–azide species is rapid and that the azidonitration reaction is promoted relative to oxidation of the azide to nitrogen by a low concentration of azide ion.

Since the formation of the 1-acetamido product **5** requires water and the azidonitration was performed under strictly anhydrous conditions, this product must form during the isolation. Indeed, rapid tlc examination of the supernatant liquid of the reaction mixture provided no evidence of **5** in the reaction mixture. However, if this solution was worked up, **5** appeared in the product but the amount appeared less than that present when the solids were worked up separately. It is apparent, therefore, that the precursor of **5** is a relatively insoluble product. Azidonitration reactions in 10% aqueous acetonitrile (23) provided relatively poor yields of the azidonitrates in more complex reaction product mixtures. The 1-acetamido product **5** was readily separated from the azidonitrates **2**, **3**, and **4** by column chromatography using silica gel. The mixture of azidonitrates obtained in this way proved useful for the preparation of the 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-α-D-galactosyl halides (**13**, **14**, **15**). This mixture is referred to as the azidonitration reaction product fraction I.

One of the mechanisms suggested by Trahanovsky and Robbins (23) is that the initially formed azidoalkyl radical is oxidized to a carbonium ion which, in turn, accepts nitrate to form the azidonitrate. The formation of **5** would appear to be in line with this mechanistic pathway since the attack of the α-side of a carbonium ion (A) by nucleophilic acetonitrile to form a nitrilium ion (B) which in turn provides the precursor to **5** could be accounted for in this way. It seems evident, however, that any consideration of the mechanism for the azidonitration will need to take into account the tendency for the overall addition to provide *trans*-products of addition. Thus, the 1,2-*trans*-β-azidonitrate to 1,2-*cis*-α-azidonitrate ratios were 1.5, 2, 2, and 10 on azidonitration of the acetates of D-galactal, D-glucal, D-lactal, and D-xylal, respectively (26). These results do not appear likely to arise from attack by nitrate ion on intermediate



A B

glycosyl carbonium ions of type A (27). Furthermore, a reaction pathway involving a carbonium ion intermediate might be expected to give rise to appreciable yields of 2-azido-2-deoxyglycosyl azides but these were not detected in our reaction products.

Acetolysis of the crude β-azidonitrate **2**, obtained by removal of the α-nitrates **3** and **4** from fraction I by crystallization from ether, provided crystalline 1,3,4,6-tetra-*O*-acetyl-2-azido-2-deoxy-α-D-galactopyranose (**6**) which was readily recrystallized to high purity. As expected, hydrogenation of this compound led to migration of the 1-*O*-acetyl group to the developed amino group to form 2-acetamido-3,4,6-tri-*O*-acetyl-α-D-galactopyranose. It is considered interesting to note that an attempt to avoid this migration by performing the hydrogenation in the presence of acetic anhydride led to the formation of 2-(*N*-acetylacetamido-1,3,4,6-tetra-*O*-acetyl-2-deoxy-α-D-galactopyranose (**8**) in 30% yield. Di-*N*-acetylation of an amine is not expected to arise when using acetic anhydride in ethanol and therefore the formation of **8** must involve some intermediate which formed in the course of the hydrogenation. Deacetylation of **6** provided 2-azido-2-deoxy-D-galactose from which pure D-galactosamine hydrochloride was readily prepared. A process aimed at preparing this latter compound would appear to best proceed by way of anomerization of the crude reaction product using lithium nitrate in acetonitrile followed by crystallization of the α-azidonitrate **3**. However, since the product of the acetolysis of **3** (the β-anomer of **6**) resisted crystallization, this route was not explored in detail.

The main purpose of this investigation was to achieve syntheses of 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-D-galactopyranosyl halides (**13**, **14**, and **16**) to be used as reagents in the preparation of 2-azido- and 2-amino-2-deoxy-α- and -β-D-galactopyranosides. The α-chloride **13** and the α-bromide **14** were readily prepared in crystalline condition by replacement of the nitrate group of compounds **2** and **3** using an appropriate soluble halide salt and starting with fraction I. Lemieux and Hayami (28) reported the preparation of 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl chloride in good yield by kinetic control of the reaction of 2,3,4,6-tetra-*O*-acetyl-α-D-gluco-

pyranosyl bromide with tetraethylammonium chloride. Paulsen *et al.* (22) used this method to prepare protected 2-azido-2-deoxy-β-D-galacto- and -glucopyranosyl chlorides. Reaction of the 2-azido-2-deoxy-α-bromide **14** with tetraethylammonium chloride provided the β-chloride **16** but observation of the progress of the reaction by ^{1}Hmr showed that the α-chloride **13** was forming to an appreciable extent prior to the disappearance of **14**. It was therefore decided to investigate the use of the more reactive 2-azido-2-deoxy-α-iodide **15** as starting material. This compound was most conveniently prepared as a crude syrup starting from fraction I and used directly in a very brief (2.5 min) reaction to form the β-chloride **16** which proved readily isolable by crystallization. The yield from 3,4,6-tri-*O*-acetyl-D-galactal (**1**) was 31%.

To assess the behavior of the glycosyl halides **13**, **14**, and **16** in glycosidation reactions, reactions were conducted under two set conditions using *tert*-butyl alcohol as a representative of a hindered alcohol and benzyl alcohol as a representative of a more reactive alcohol. The alcohols were also chosen, in part, to facilitate a study of the reaction products by ^{1}Hmr. Two of the most widely used conditions for glycosidation were examined; namely, reactions promoted by mercuric cyanide and using benzene–nitromethane as solvent (29) and by silver carbonate in conjunction with a soluble silver salt (30) which provides a labile glycosyl intermediate and using methylene chloride as solvent. Although silver perchlorate is often used, silver trifluoromethanesulfonate (31) was used in the present experiments. Although the α-bromide **14** provided a Koenigs–Knorr condensation in the presence of silver carbonate alone, the α- and β-chlorides **13** and **16** were too unreactive.

Under the Helferich conditions, the α-chloride **13** underwent extremely slow reaction with both alcohols since less than 10% glycoside formation was observed in the reaction time allowed (48 h at 50°C). However, reaction was complete in the case of the α-bromide but the stereoselectivity was poor with a ratio of near 1 for the α- and β-glycosides formed. The yield of both the α- and β-glycosides was excellent (92%) in the case of the reaction with benzyl alcohol but only 51% in the case of the more hindered *tert*-butyl alcohol. The lack of stereoselectivity very likely arose from anomerization of the α-bromide to the β-anomer which would be expected to provide α-glycoside (27). Certainly, the β-chloride **16** was anomerized to the α-chloride **13** when the β-chloride was used as starting material. In this case, reaction effectively ceased with the disappearance of the β-chloride. The reaction with benzyl alcohol provided a 70% yield of glycoside with an α/β ratio of 5, with 30% of the starting material being converted to the α-chloride. In the case of the reaction using *tert*-butyl alcohol, the product contained the α-chloride in 50% yield. The yield of glycoside was only 21% but the α/β ratio was greater than 10. It is thus evident that under the Helferich conditions, reactions of the β-chloride proceed with a high degree of inversion of the anomeric center but that anomerization catalyzed by liberated chloride ion can very adversely affect the yield, especially with hindered alcohols.

The glycosidation reactions promoted by silver salts proceeded to complete reaction of the glycosyl halide. The reactions of the α-halides provided poor stereoselectivity. The yields of β-glycoside were higher starting with the α-chloride (α/β ratio = 0.6) than with the α-bromide (α/β ratio = 1.1). Also, the yields of glycosides were higher starting with the α-chloride (97% and 80% with the benzyl and *tert*-butyl alcohols, respectively) than with the α-bromide (72% and 58% with the benzyl and *tert*-butyl alcohols, respectively). The total yields of glycoside were virtually the same starting with the β-chloride as those obtained starting with the α-chloride. However, the α/β ratios (near 1.7 in each case) were, as expected, more in favor of α-glycoside formation. It is expected that the rather low degree of stereoselectivity exhibited in all of these silver salt promoted glycosidation reactions is related to an important pathway of the reaction occurring by way of a dissociation of the glycosyl halide with silver ion assistance to an oxocarbonium ion which is not coordinated to alcohol.

Experimental

The general procedures and analytical methods used were the same as previously described (27).

Azidonitrations

Although the azidonitrations were examined under a wide variety of conditions, all those reported herein were performed at −15°C and in a dry nitrogen atmosphere by adding a 0.2 *M* solution of the *O*-acylated glycal in dry acetonitrile to a dry mixture of sodium azide and ceric ammonium nitrate (CAN) with relative molar amounts of these reagents at 1:1.5:3, respectively. As soon as the addition was completed, strong stirring was begun and continued until the presence of the glycal could no longer be detected by the examination of the supernatant. The reaction was performed behind a barrier under a wide range of conditions including changes in temperature, solvent and relative amounts of reactants. Although such changes caused appreciable changes in yield and the coloration of the product, no lack of control was experienced. Nevertheless, it must be realized that hazardous conditions may be encountered and all azidonitrations should be conducted with due caution. Furthermore, the use and disposal of sodium azide must be carefully controlled.

*Azidonitration of 3,4,6-Tri-*O*-acetyl-D-galactal (1)*

Compound **1** (21.1 g, 0.077 mol) in acetonitrile (420 mL)

was added to a mixture of sodium azide (7.50 g, 0.115 mol) and CAN (126.5 g, 0.281 mol). The resulting suspension was vigorously stirred with cooling until analysis by tlc (Skellysolve B – ethyl acetate (6:4), silica gel) of the supernatant liquid phase no longer showed the presence of compound **1**. At this time, normally after an 8- to 10-h reaction period, cold diethyl ether (500 mL) and water (500 mL) were added. The organic layer was separated and washed with ice-cold water (3 × 500 mL) prior to drying over anhydrous sodium sulfate. Evaporation of the solvent left a yellow syrup (21.0 g).

The ^{1}Hmr spectrum of this product showed doublet signals at 5.68, 6.35, and 6.21 ppm which were assigned to the anomeric protons of the following reaction products; 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-β-D-galactopyranosyl nitrate (**2**), 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-α-D-galactopyranosyl nitrate (**3**), and 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-α-D-talopyranosyl nitrate (**4**). This latter compound was not isolated and the assignment of the α-configuration is made on the basis that a solution of the reaction product in acetonitrile-*N,N*-dimethylformamide (4:1) which contained lithium nitrate (as described in detail below for the anomerization of **2** to **3**) caused no detectable change in the amount of the component responsible for the signal at 6.21 ppm which is assigned to **4**. The total intensity for the above-mentioned signals for anomeric hydrogens relative to the total signals attributable to *O*-acetyl groups required compounds **2**, **3**, and **4** to comprise near 75% of the reaction product and to be present in the ratios near 1:0.67:0.15, respectively. It will be seen below that *N*-acetyl-3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-α-D-galactopyranosylamine (**5**) was also a major reaction product (10% yield) but its presence in the crude reaction product could not be detected by ^{1}Hmr.

To remove the acetamido compound **5** from the reaction product, the syrup (117 g) was dissolved in Skellysolve B – ethyl acetate (6:4) (300 mL) and immediately applied to a column (20 × 10 cm diameter) packed with solvent-wetted silica gel (400 g) and the chromatogram was developed with this same solvent system. The initial fractions (15 mL each) of the eluate which contained reaction products consisted of mixtures of the nitrates **2**, **3**, and **4**. The acetamido compound **5** was detected (tlc) after 30 such fractions had been collected and these initial fractions when combined and evaporated provided a mixture (68 g) of the nitrates **2**, **3**, and **4** which will be referred to hereafter as reaction product fraction I. The ratio of α-nitrate **3** to β-nitrate **2** in this product was normally close to 0.8, suggesting that some anomerization had occurred during the chromatographic separation. However, it is possible that the more reactive β-nitrate **2** underwent hydrolysis to a greater extent than did its α-anomer.

*3,4,6-Tri-*O*-acetyl-2-azido-2-deoxy-*β*-D-galactopyranosyl Nitrate (2)*

Trituration either of the above-described product from the azidonitration of tri-*O*-acetyl-D-galactal or of fraction I with diethyl ether caused a copious precipitation of a crystalline product which was removed by filtration. Evaporation of the ether left a syrup (12.6 g, 44% yield in the case of the crude product) which resisted crystallization although examination by tlc and ^{1}Hmr required this product to be about 80% pure title compound with the α-anomer (**3**) being the main contaminant; ir (film) ν_{max}: 2120 (N_3), 1650 (ONO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 5.60 (d, 1H, $J_{1,2}$ = 9.0 Hz, H-1), 5.42 (q, 1H, H-4), 5.08 (q, 1H, $J_{3,4}$ = 3.2 Hz, H-3), 3.82 (q, 1H, $J_{2,3}$ = 10.8 Hz, H-2), 2.18, 2.10, 2.03 (3s, 9H, $3CH_3$).

*3,4,6-Tri-*O*-acetyl-2-azido-2-deoxy-*α*-D-galactopyranosyl Nitrate (3)*

The crystalline product (8.3 g, 29% yield) which formed in the above-described treatment of the product from the azidonitration with ether was found to be the title compound mixed with the *talo*-isomer (**4**). This latter product proved difficult to remove by recrystallization. The pure title compound was best obtained by anomerization of **2**. The syrupy β-D-nitrate **2** (9.50 g, 25.5 mmol) was dissolved in a 4:1 (v/v) mixture (35 mL) of acetonitrile and *N,N*-dimethylformamide which contained anhydrous lithium nitrate (3.50 g, 50.1 mmol). After standing at room temperature for 41 h, the solution was diluted with dichloromethane (250 mL) before treatment with ice-cold water (3 × 125 mL). The organic layer was dried over sodium sulfate prior to evaporation to a syrup (9.0 g). This product crystallized from diethyl ether and was recrystallized to afford pure title compound **3**; mp 103–104°C, $[\alpha]_D^{25}$ +125° (*c* 1.0, $CHCl_3$); ir (film) ν_{max}: 2120 (N_3), 1650 (ONO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 6.35 (d, 1H, $J_{1,2}$ = 4.0 Hz, H-1), 5.49 (q, 1H, $J_{4,5}$ = 1.8 Hz, H-4), 5.24 (q, 1H, $J_{3,4}$ = 3.25 Hz, H-3), 4.12 (q, 1H, $J_{2,3}$ = 11.5 Hz, H-2), 2.18, 2.07, 2.02 (3s, 9H, $3CH_3$). *Anal.* calcd. for $C_{12}H_{16}N_4O_{10}$: C 38.30, H 4.29, N 14.89; found: C 38.52, H 4.32, N 14.69.

*N-Acetyl-3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-*α*-D-galactopyranosylamine (5)*

The reaction product from the azidonitration was chromatographed on a silica gel column using Skellysolve B – ethyl acetate (6:4 v/v) as solvent. The nitrates **2**, **3**, and **4** appeared first in the eluate but were not separated. Further development of the column provided a fraction in 10% overall yield which crystallized readily from diethyl ether. Recrystallization provided pure title compound (**5**); mp 142–143.5°C, $[\alpha]_D^{25}$ +68.0° (*c* 1, $CHCl_3$); ir (Nujol) ν_{max}: 3380 (NH), 2120 (N_3) cm^{-1}; ^{1}Hmr (DMSO-d_6) δ: 8.84 (d, 1H, $J_{NH,1}$ = 10.0 Hz, NH), 5.78 (q, 1H, $J_{1,2}$ = 5.5 Hz, H-1), 5.47 (q, 1H, $J_{3,4}$ = 3.5 Hz, H-3), 5.24 (d, 1H, H-4), 4.21 (q, 1H, $J_{2,3}$ = 11.5 Hz, H-2), 2.11, 1.98, 1.96, 1.91 (4s, 12H, $4CH_3$). *Anal.* calcd. for $C_{14}H_{20}N_4O_8$: C 45.16, H 5.41, N 15.05; found: C 44.92, H 5.50, N 14.93.

As described below, acid hydrolysis provided 2-azido-2-deoxy-D-galactose. The α-configuration was assigned on the basis of the optical rotation relative to that for the 1-acetoxy analog (**6**) and the strong deshielding observed for H-3 (assigned by spin-decoupling experiments).

*1,3,4,6-Tetra-*O*-acetyl-2-azido-2-deoxy-*α*-D-galactopyranose (6)*

A suspension of the crude syrupy β-D-nitrate **2** (8.0 g, 0.021 mol) and anhydrous sodium acetate (3.44 g) in glacial acetic acid (50 mL) was heated to 100°C for 1 h (tlc showed no remaining starting material). The reaction mixture was diluted with dichloromethane (250 mL) and this mixture was successively treated with ice-cold water (200 mL), saturated aqueous sodium bicarbonate (2 × 100 mL), and water (125 mL). Drying and evaporation of the organic layer left a yellow solid (7.5 g, 94%). Recrystallization from diethyl ether provided pure title compound (**6**) (6.9 g, 85%); mp 114–115°C, $[\alpha]_D^{25}$ +91.7° (*c* 1.05, $CHCl_3$) (lit. (22) mp 117°C, $[\alpha]_D^{20}$ +109° ($CHCl_3$)); ir (film) ν_{max}: 2120 (N_3) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 6.39 (d, 1H, $J_{1,2}$ = 3.6 Hz, H-1), 4.04 (q, 1, $J_{2,3}$ = 10.0 Hz H-2), 2.19, 2.09, 2.06 (3s, 12, $4CH_3$). *Anal.* calcd. for $C_{14}H_{19}N_3O_9$: C 45.04, H 5.13, N 11.26; found: C 44.88, H 5.11, N 11.15.

*2-Acetamido-1,3,4,6-tetra-*O*-acetyl-2-deoxy-*α*-D-galactopyranose (7) and its N-Acetyl Derivative (8)*

A solution of compound **6** (200 mg) in ethyl acetate (1 mL) was added to a suspension of 5% palladium-on-charcoal (80 mg) in ethanol containing acetic anhydride (0.25 mL). This mixture was hydrogenated at 1 atm and room tempera-

ture for 1 h. Examination by tlc using benzene – ethyl acetate – ethanol (5:5:1) showed the presence of two products. Removal of the catalyst and dilution with dichloromethane (5 mL) provided a solution which was washed with water (5 mL) before evaporation to a white solid (206 mg). The two components were separated by chromatography on a silica gel (20 g) column (20 × 2 cm) eluted with the above solvent system.

The first product to appear in the eluate was 2-*N*-acetylacetamido-1,3,4,6-tetra-*O*-acetyl-2-deoxy-α-D-galactopyranose (**8**) (68 mg, 30%); ^{1}Hmr ($CDCl_3$) δ: 6.32 (d, 1H, $J_{1,2}$ = 3.8 Hz, H-1), 5.72 (q, 1H, $J_{2,3}$ = 11.0 Hz, H-3), 5.53 (q, 1, $J_{3,4}$ = 3.5 Hz, H-4), 4.27 (q, 1, H-2), 2.36 (1s, 6, 2NAc), 2.16, 2.14, 2.04, 1.95 (4s, 12, $4CH_3$). These parameters are in good agreement with those reported for this compound by Pravdic and Fletcher (32).

The second fraction (100 mg, 43% yield) crystallized from ether; mp 177–178°C, $[\alpha]_D^{25}$ +99° (*c* 1, $CHCl_3$) (lit. (33) mp 178°C, $[\alpha]_D^{20}$ +102°). The ^{1}Hmr was in agreement with that reported by Tarasiejska and Jeanloz (34) for 2-acetamido-1,3,4,6-tetra-*O*-acetyl-2-deoxy-α-D-galactopyranose (**7**).

When the hydrogenation was performed under the same conditions except that the acetic anhydride was added after the reduction of the azide was complete, the product did not contain the *N*,*N*-diacetylamino compound (**8**) but was mainly 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-D-galactose.

*2-Azido-2-deoxy-*β-D-*galactose (**9**)*

A mixture of 1,3,4,6-tetra-*O*-acetyl-2-azido-2-deoxy-α-D-galactopyranose (**6**) (4.59 g) with 4 *N* aqueous hydrochloric acid (50 mL) was warmed until solution was complete and then left at room temperature for 15 h. After decolorization with charcoal, an equal volume of *n*-butanol was added and the solution was evaporated at 40°C to a yellow solid. Recrystallization from ethanol provided 2-azido-2-deoxy-β-D-galactose (**9**) (1.40 g, 56%): mp 161.5–163°C (dec.), $[\alpha]_D^{25}$ +76.9° (final) (*c* 0.98, H_2O); ir (Nujol) ν_{max}: 2130 (N_3) cm^{-1}; ^{1}Hmr (DMSO-d_6) δ: 4.30 (d, 1H, $J_{1,2}$ = 7.75 Hz, H-1); ^{13}Cmr (DMSO-d_6) δ: 95.5 (C-1). *Anal.* calcd. for $C_6H_{11}O_5N_3$: C 35.12, H 5.41, N 20.48; found: C 35.08, H 5.40, N 20.50.

Treatment of *N*-acetyl-3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-α-D-galactopyranosylamine (**5**) (1.0 g) in the same manner also provided recrystallized title compound (**9**) (0.324 g, 58%).

*2-Acetamido-2-deoxy-*D-*galactose (**10**)*

2-Azido-2-deoxy-D-galactopyranose (**9**) (1.0 g) was dissolved in methanol (20 mL) containing acetic anhydride (1.5 mL) and hydrogenated at room temperature and 1 atm in the presence of 5% palladium-on-charcoal (0.25 g). After 8 h, examination by tlc indicated the formation of only one product which was isolated in the usual manner and crystallized from ethanol to provide the title compound (**10**) as an anomeric mixture, mp 108–110°C, $[\alpha]_D^{25}$ +79° (final), (*c* 1, H_2O) (lit. (33) for the α-anomer mp 120–122°C, $[\alpha]_D$ +115 → 80° (water)); ^{1}Hmr (D_2O) δ: 5.44 (d, $J_{1,2}$ = 3.50 Hz, H-1α), 4.86 (d, $J_{1,2}$ = 7.25 Hz, H-1β), 2.24 (s, $COCH_3$).

D-*Galactosamine Hydrochloride (**11**)*

2-Azido-2-deoxy-D-galactopyranose (**9**) (100 mg) was dissolved in aqueous 90% methanol (5 mL) which contained 1.5 equiv. of hydrochloric acid. Low pressure hydrogenation in the presence of 5% palladium-on-charcoal (25 mg) followed by the usual work-up provided a residue (100 mg) which examination by tlc developed with isopropanol – ammonium hydroxide – water (7:1:2) gave evidence for only one substance with the same mobility as that of an authentic sample of the title compound (**11**). Crystallization from ethanol–methanol gave pure D-galactosamine hydrochloride (**11**) (50 mg, 48%): mp 182–200°C (dec.), $[\alpha]_D^{25}$ +89.5° (*c* 1, water) (lit. (12) mp 178–190°C, $[\alpha]_D^{25}$ +91.5° (final)); ^{1}Hmr (D_2O) δ: 5.66 (d, $J_{1,2}$ = 3.50 Hz, H-1α), 5.07 (d, $J_{1,2}$ = 8.50 Hz, H-1β).

*2-Acetamido-*N*-acetyl-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-galactosamine (**12**)*

N-Acetyl-3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-α-D-galactopyranosylamine (**5**) (1.135 g) was dissolved in acetic acid (10 mL) for low pressure hydrogenation in the presence of 5% palladium-on-charcoal (0.30 g). After 12 h, acetic anhydride (1 mL) was added. Catalyst removal and evaporation provided a solid (1.05 g) which crystallized on trituration with diethyl ether. Recrystallization from ethyl acetate – diethyl ether provided the title compound (**12**) (0.990 g, 85%); mp 192–193°C, $[\alpha]_D^{25}$ +104.4° (*c* 1, $CHCl_3$); ^{1}Hmr (DMSO-d_6) δ: 8.44 (d, 1H, $J_{NH,1}$ = 10.0 Hz, NH), 7.80 (d, 1H, $J_{NH,2}$ = 8.4 Hz, NH), 5.60 (q, 1H, $J_{1,2}$ = 5.0 Hz, H-1), 2.12, 2.01, 1.94, 1.80 (4s, 15H, $5CH_3$); ^{13}Cmr ($CDCl_3$–DMSO-d_6 (7:3) v/v)) δ: 75.5 (C-1); *Anal.* calcd. for $C_{16}H_{24}O_9N_2$: C 49.48, H 6.22, N 7.21; found: C 49.67, H 6.12, N 6.94.

*2-Azido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-galactopyranosyl Chloride (**13**)*

The syrupy azidonitration product (fraction I) (0.377 g) was dissolved in acetonitrile (12 mL) which contained tetraethylammonium chloride (0.754 g). After 5 h, the ^{1}Hmr was constant and the solution was diluted with dichloromethane (25 mL) before treatment with water (2 × 10 mL). Solvent removal left a syrup (0.325 g), which was applied to a column (1 × 10 cm) of silica gel (3.5 g) for chromatographic separation using Skellysolve B – ethyl acetate (6:4). The α-D-chloride (**13**) (0.260 g, 74%) crystallized from diethyl ether – pentane; mp 86–88°C, $[\alpha]_D^{25}$ +145° (*c* 1, $CHCl_3$); ^{1}Hmr ($CDCl_3$) δ: 6.20 (d, 1H, $J_{1,2}$ = 3.9 Hz, H-1), 5.52 (q, 1H, $J_{4,5}$ = 1.4 Hz, H-4), 5.38 (q, 1H, $J_{3,4}$ = 3.2 Hz, H-3). *Anal.* calcd. for $C_{12}H_{16}N_3O_7Cl$: C 41.21, H 4.61, N 12.01, Cl 10.14; found: C 40.91, H 4.52, N 12.60, Cl 10.34.

The title compound **13** (3.0 g, 75%) was readily obtained by anomerization of 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-β-D-galactopyranosyl chloride (**16**) (4.0 g) in acetonitrile (80 mL) with tetraethylammonium chloride (13.2 g) at room temperature for 16 h. Passage through a short column of silica gel was again used to obtain the crystalline product.

The difference between the optical rotation for **13** reported above and that, $[\alpha]_D^{20}$ +39.1° (CH_3CN), recorded by Paulsen *et al.* (22) should be noted.

*3,4,6-Tri-*O*-acetyl-2-azido-2-deoxy-α-D-galactopyranosyl Bromide (**14**)*

Treatment of the product of the azidonitration (14.24 g) with a suspension of lithium bromide (16.53 g) in acetonitrile (140 mL) at room temperature for 3 h followed by product isolation as described for the preparation of **13**, provided a syrup (13.0 g). Chromatography on a column (4 × 48 cm) of silica gel which was developed with benzene (100 mL) and finally benzene – diethyl ether (1:1) gave 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-α-D-galactopyranosyl bromide (**14**) (8.98 g, 60% yield) which was recrystallized from diethyl ether – pentane; mp 97–98°C, $[\alpha]_D^{25}$ +188.6° (*c* 1.95, $CHCl_3$), $[\alpha]_D^{25}$ +172.6° (*c* 1, CH_3CN) (lit. (22) mp 90°C, $[\alpha]_D^{20}$ +104° (*c* 1.2, CH_3CN)); ^{1}Hmr ($CDCl_3$) δ: 6.47 (d, 1H, $J_{1,2}$ = 4.0 Hz, H-1), 5.49 (q, 1H, $J_{4,5}$ = 2.7 Hz, H-4), 5.33 (q, 1H, $J_{3,4}$ = 3.25 Hz, H-3), 4.48 (m, 1H, H-5), 3.96 (q, 1H, $J_{2,3}$ = 10.5 Hz, H-2), 2.14, 2.04, 2.02 (3s, 9H, $3CH_3$). *Anal.* calcd. for $C_{12}H_{16}N_3O_7Br$: C 36.56, H 4.09, N 10.66, Br 20.27; found: C 36.73, H 4.39, N 10.57, Br 20.27.

3,4,6-Tri-O-acetyl-2-azido-2-deoxy-β-D-galactopyranosyl Chloride (16)

A solution of lithium iodide (62.5 g) in acetonitrile (250 mL) was added in the dark to the product of the azidonitration (25.0 g). After 20 min at room temperature, dichloromethane (500 mL) and cold saturated aqueous sodium thiosulfate (500 mL) were added. The organic phase was separated and washed with ice-cold water (2 × 500 mL), dried over sodium sulfate, and evaporated *in vacuo* to a yellow foam. The ^{1}Hmr spectrum of a sample of this product indicated that it consisted of about 75% of 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-α-D-galactopyranosyl iodide (**15**); ^{1}Hmr ($CDCl_3$) δ: 6.87 (d, 1H, $J_{1,2}$ = 4.0 Hz, H-1), 5.18 (q, 1H, $J_{3,4}$ = 3.7 Hz, H-3), 3.34 (q, 1H, $J_{2,3}$ = 10.5 Hz, H-2). No attempt was made to purify this product.

Instead, it was treated immediately with a solution of tetraethylammonium chloride (11.0 g) in acetonitrile (57 mL). After vigorous shaking for 2.5 min at room temperature, the turbid mixture was diluted first with dichloromethane (150 mL) and then with 10% aqueous sodium thiosulfate (100 mL). The organic phase was then washed with water (100 mL), dried, and rapidly evaporated *in vacuo* to a syrup which was promptly triturated with diethyl ether. Crystalline 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-β-D-galactopyranosyl chloride (**16**) (11.3 g, mp 102–104°C) was deposited. The overall yield from the tri-*O*-acetyl-D-galactal used in the azidonitration was 31%; $[\alpha]_D^{25}$ −16.5° (*c* 1, $CHCl_3$): ir (Nujol) ν_{max}: 2120 (N_3) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 5.37 (d, 1H, $J_{3,4}$ = 3.25 Hz, H-4), 5.13 (d, 1H, $J_{1,2}$ = 9.0 Hz, H-1), 4.84 (q, 1H, $J_{2,3}$ = 10.5 Hz, H-3), 3.82 (q, 1H, H-2), 2.15, 2.05, 2.03 (3s, 9H, $3CH_3$). *Anal.* calcd. for $C_{12}H_{16}N_3O_7Cl$: C 41.21, H 4.61, N 12.01, Cl 10.14; found: C 41.04, H 4.60, N 12.10, Cl 9.89.

The ^{1}Hmr data are in good accord with those reported by Paulsen *et al.* (22) for a syrupy product which was not further analyzed.

Glycosidation Reactions

In every case, a 10% molar excess of the alcohol (either benzyl alcohol or *tert*-butyl alcohol) over the glycosyl halide (1 mmol) was used and the reactions were conducted in the presence of Drierite (0.50 g). The reactions promoted by silver carbonate (3 mmol) and silver trifluoromethanesulfonate (0.05 mmol) employed dichloromethane (8 mL) as solvent and were conducted for 24 h at 5°C. The reactions promoted by mercuric cyanide (1.1 mmol) employed a 1:1 mixture of benzene and nitromethane (9 mL) as solvent and were conducted for 48 h at 50°C. The analyses of the reaction mixtures were made by isolation of the products in the usual manner using dichloromethane as the extracting solvent and then subjecting these syrupy products to examination by both ^{1}Hmr and ^{13}Cmr. The following signals were assigned: for the benzyl 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-D-galactopyranosides: ^{1}Hmr δ: 4.48 (d, $J_{1,2}$ = 8.2 Hz, H-1β), 5.20 (d, $J_{1,2}$ = 3.5 Hz, H-1α); ^{13}Cmr δ: 100.6 (C-1β), 97.1 (C-1α); and for the *tert*-butyl 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-D-galactopyranosides: ^{1}Hmr δ: 4.57 (d, $J_{1,2}$ = 8.0 Hz, H-1β) (H-1α signal was obscured); ^{13}Cmr δ: 97.3 (C-1β), 93.1 (C-1α). In the reactions involving the α-chloride **13** and promoted by mercuric cyanide, unreacted **13** remained and the amount of this material was estimated from the intensities of ^{1}Hmr doublet for H-1 ($J_{1,2}$ = 3.9 Hz) at 6.20 ppm and the ^{13}Cmr signal for C-1 at 92.8 ppm. This compound **13** also occurred in the reaction products from the mercuric cyanide promoted reactions of the β-chloride **16** (undoubtedly a product of anomerization of **16** by released chloride ion) and its formation effectively quenched the reaction. It was found that the relative intensities of the H-1 signals provided a ratio for the amounts of the α- and β-glycosides in good agreement with the ratio obtained by comparing the intensities of the signals for C-1. In the case of the *tert*-butyl glycosides the α/β ratio could also be estimated by comparison of the intensities for the signals of the *tert*-butyl groups at δ 1.30 (α-anomer) and 1.32 (β-anomer) ppm. The total yield of glycoside was estimated by comparison of the intensities of the signals present for the acetyl groups with those for the phenyl groups in the case of the benzyl glycosides and with those for the *tert*-butyl groups in the case of the *tert*-butyl glycosides.

Salts of the anion $Re(C_5H_7O_2)Cl_2^-$ have been made by the reduction of both *cis*- and *trans*-$Re(C_5H_7O_2)Cl_2$ with a number of different reducing agents. The salts have been examined and characterized by physical methods. An improved preparation for $Re(C_5H_7O_2)_3$ is reported.

C. J. L. Lock, C. N. Murphy et M. L. Turner. Can. J. Chem. 57, 1252 (1979).

On a préparé des sels de l'anion $Re(C_5H_7O_2)Cl_2^-$ par réduction des $Re(C_5H_7O_2)Cl_2$ *cis* ainsi que *trans* par un certain nombre d'agents réducteurs. On a étudié les sels et on les a caractérisés par des méthodes physiques. On rapporte une méthode améliorée de préparation du $Re(C_5H_7O_2)_3$.

[Traduit par le journal]

Introduction

When attempting to reduce *trans*-$Re(C_5H_7O_2)_2Cl_2$, **A**, with either halide abstracting agents such as a zinc–methanol mixture or thallium acetylacetonate, Courrier (1) obtained blue-green solutions, which were air-unstable and from which no solid products were isolated. Subsequent work by us showed that the same colour could be produced in organic solvents by the action of a variety of reducing agents on **A** but again no solid products were isolated. The identity of the blue-green material was first indicated when a green solid was isolated by the reduction of **A** in benzene with sodium borohydride. The material dissolved in water giving a green solution which rapidly decolorized, with the precipitation of an orange solid, later shown to be **A**. It appeared as if the blue-green colour was a simple one-electron reduction product of **A**. This suggested alternate and more efficient methods of preparing salts of the $[Re(C_5H_7O_2)_2Cl_2]^-$ anion. We describe this work here.

Experimental

Analyses were performed by A. B. Gygli, Toronto, Ont. The infrared spectra in the region 4000–250 cm^{-1} were recorded on a Perkin Elmer #283 grating spectrophotometer. The samples were mixed with KBr and pressed into thin discs. In the region 250–100 cm^{-1}, the spectra were obtained using a Nicolet Model 7199 Fourier transform infrared spectrophotometer. A Mylar beam splitter was used. The optical path was flushed with dry N_2 and 100 interferrograms were recorded for each sample. The samples were ground into a mull with Nujol and sealed in a polyethylene bag under N_2. A Cary 14 spectrophotometer was used to record the electronic spectra of aqueous or CH_3CN solutions in the region 50 000–6000 cm^{-1}. Diffuse reflectance spectra in the region 36 000–4000 cm^{-1} were recorded on a Beckman DK2A recording spectrophotometer. Magnesium oxide was used as a reference. Measurements of the magnetic susceptibilities of powdered, solid samples were made by the Faraday method at three different field strengths. Calibration of the magnetic apparatus was accomplished using mercury tetrathiocyanatocobaltate(II) obtained from Eastman Organic Chemicals, Rochester, New York, and cupric sulfate pentahydrate (Baker Analyzed Reagent). Diamagnetic corrections were taken from Earnshaw (2). Mass spectra[2] were recorded on a Consolidated Electrodynamic Corporation mass spectrometer Model 21-110B. The samples were injected at 200°C. The electrical resistances of aqueous solutions of $K[Re(C_5H_7O_2)_2Cl_2]$ were measured in a N_2 atmosphere. This resistance was measured between two platinum electrodes about 1 cm apart. Reduction potentials were measured on a Princeton Applied Research Polarographic Analyzer, Model 174 operating in a DC mode. The potential was scanned from +0.5 to −1.0 V with respect to a saturated calomel electrode using two techniques (cathodic stripping voltammetry and single sweep voltammetry). The accuracy was checked by measuring the reduction potential for the reaction

$$Hg_2X_2 + 2e \rightarrow 2Hg + 2X^-$$

These were found to be 0.28 V (X = Cl) and 0.19 V (X = Br) compared with literature values (3) of +0.27 and 0.14 V, respectively.

The complexes $Re(C_5H_7O_2)_2X_2$ (X = Cl, Br) were prepared as described previously (4). Subsequent reactions were executed in a glove box under a nitrogen atmosphere. All solvents and reagents used were reagent grade. The solvents were deoxygenated by bubbling dry N_2 through them.

Thallium trans-*Dichlorobis(pentane-2-4-dionato)rhenate(III), Tl[Re(C₅H₇O₂)₂Cl₂]*

This complex was prepared by refluxing 1 mmol (0.45 g) of $Re(C_5H_7O_2)_2Cl_2$ with an equimolar amount of $Tl(C_5H_7O_2)$ (0.30 g) in ether for several hours. The resulting green solid was collected by filtration and dried *in vacuo*, yield 30%. *Anal.*

calcd. (by hydrolysis and gravimetric determination as thallous chromate (5) and as $Re(C_5H_7O_2)_2Cl_2$, **A**): Tl 31.0, $Re(C_5H_7O_2)_2Cl_2$ 69.0; found: Tl 31 ± 1, $Re(C_5H_7O_2)_2Cl_2$ 69 ± 1. *Anal.* calcd. for precipitated A (M 455): C 26.4, H 3.1, Cl 15.6; found (M 420): C 26.2, H 3.6, Cl 17.5.

Sodium trans-*Dichlorobis(pentane-2,4-dionato)rhenate(III)*, *Na[Re(C₅H₇O₂)₂Cl₂]*

Several small shavings of sodium were added to a suspension of $Re(C_5H_7O_2)_2Cl_2$ (ca. 1 mmol) in acetonitrile (ca. 8 mL). The resulting deep green solution was separated from the unreacted rhenium(IV) complex by centrifuging and decanting. More solvent and sodium shavings were added to the unreacted complex and the process was repeated until additional shavings no longer resulted in the characteristic green color of the product. The product was then precipitated from solution by addition of ether and recrystallized from CH_3CN with ether, yield ~35%. *Anal.* calcd. for $C_{10}H_{14}Cl_2NaO_4Re$: C 25.1, H 3.0, Cl 14.8; found: C 24.9, H 3.1, Cl 14.7.

Potassium trans-*Dihalobis(pentane-2,4-dionato)rhenium(III)*, *K[Re(C₅H₇O₂)₂X₂] (X = Cl, Br)*

These green complexes were prepared in a manner identical to the preparation of $Na(Re(C_5H_7O_2)_2Cl_2]$ by using potassium shavings, yield ~30%. *Anal.* calcd. for $C_{10}H_{14}Cl_2KO_4Re$: C 24.3, H 2.9, Cl 14.3; found: C 24.3, H 3.0, Cl 14.2. *Anal.* calcd. for $C_{10}H_{14}Br_2KO_4Re$: C 20.6, H 2.4; found: C 20.9, H 2.7.

Tetraphenylarsonium trans-*Dichlorobis(pentane-2,4-dionato)-rhenate(III)*, *[(C₆H₅)₄As][Re(C₅H₇O₂)₂Cl₂]*

An aqueous solution of $K[Re(C_5H_7O_2)_2Cl_2]$ (ca. 1 mmol in 10 mL) was reacted with an aqueous solution of $[(C_6H_5)_4As]Cl$ (ca. 1 mmol in 10 mL). The product precipitated immediately. The product was purified by dissolving in dichloromethane followed by precipitation with diethylether. The product was analyzed by single crystal X-ray diffraction (6).

Preparation of Trispentane-2,4-dionatorhenium(III), *Re(C₅H₇O₂)₃*

(*a*) Dichlorobispentane-2,4-dionatorhenium(IV) (1 mmol, 0.45 g) and powdered zinc (1 mmol, 0.07 g) were stored in acetylacetone (~10 mL) under constant nitrogen flow. The solution rapidly turned bright green, then brown, and finally, after several minutes, to the deep maroon colour of $Re(C_5H_7O_2)_3$.

Ether (~20 mL) was added to the solution, which was then filtered through a fine sintered glass funnel on the vacuum line. The filtrate contained $Re(C_5H_7O_2)_3$ while unreacted $Re(C_5H_7O_2)_2Cl_2$, zinc, and zinc by-products were removed on the filter. $Re(C_5H_7O_2)_3$ was recovered from the solution by evaporation of the solvents under vacuum (yield ~50%).

(*b*) Dichlorobispentane-2,4-dionatorhenium(IV), (1 mmol, 0.45 g) in benzene solution was refluxed under nitrogen with zinc amalgam (~5 mL). In a few minutes a green solid was formed. After refluxing for several hours, the green solid redissolved giving a maroon solution of $Re(C_5H_7O_2)_3$. The purple solution was decanted from the amalgam and filtered to remove unreacted $Re(C_5H_2O_2)_2Cl_2$, zinc by-products, and rhenium metal. $Re(C_5H_7O_2)_3$ was recovered from solution by evaporation of benzene under vacuum (yield ~25%). *Anal.* calcd. for $C_{15}H_{21}O_6Re$: C 37.4, H 4.4; found (*a*): C 37.1, H 4.5; (*b*): C 37.0, H 4.4.

Results and Discussion

Addition of an alkali metal to *trans*-$Re(C_5H_7O_2)_2X_2$ (X = Cl, Br) in acetonitrile results in a one-electron reduction of the rhenium complex to give $M[Re(C_5H_7O_2)_2X_2]$ (M = Na or K). The reaction of $Tl(C_5H_7O_2)$ with $Re(C_5H_7O_2)_2Cl_2$ gives $Tl[Re(C_5H_7O_2)_2Cl_2]$. The reaction of $Re(C_5H_7O_2)_2X_2$ (X = Cl, Br, or I) with reducing agents to give similar salts appears to be more general than this, however. Although it was not possible to characterize the materials adequately, similar green products were obtained when using Zn, Zn amalgam, alkali metals, $NaBH_4$, or $LiAlH_4$ reacting with solutions of the Re(IV) complex in benzene or an ether. These complexes were all soluble in polar solvents such as acetonitrile, water, alcohol, or dimethyl sulphoxide and the aqueous solutions in air rapidly gave back $Re(C_5H_2O_2)_2X_2$. Where metals are the reductant the reduction involves a simple electron transfer but the reduction with the thallous salt must involve the concommitant formation of Tl(III). The reduction with the hydrides was more complex but likely involved hydrogen production.

Interestingly, the infrared spectra and X-ray diffraction patterns indicate that both *cis* and *trans* isomers of the Re(IV) complex give the same isomer of the Re(III) product. The thallium salt oxidized in the presence of air to give *trans*-$Re(C_5H_7O_2)_2Cl_2$ after several days. It is most likely, then, that the thallium salt is also the *trans* isomer and indeed the tetraphenylarsonium analogue has been shown to have this structure (6). The solid alkali metal salts of the chloro and bromo complexes also oxidize in the atmosphere to give $Re(C_5H_7O_2)_2X_2$ after several days. The solid Re(III) complexes are all stable indefinitely in the absence of oxygen. In aqueous medium, the reduction

$$Re(C_5H_7O_2)_2X_2 + e^- \rightarrow [Re(C_5H_7O_2)_2X_2]^-$$

occurs at virtually the same potential for both the chloro and bromo species (−0.28 and −0.29 V, respectively).

The alkali metal salts are soluble in water with $K[Re(C_5H_7O_2)_2Cl_2]$ behaving as a strong 1:1 electrolyte (Λ_0 = 106 cm² equiv^{-1} Ω^{-1}, infinite dilution; cf. NaCl Λ_0 126.5 cm² equiv^{-1} Ω^{-1}) (Fig. 1). This is consistent with a potassium cation and a $[Re(C_5H_7O_2)_2Cl_2]^-$ anion. The mass spectrum of $Tl[Re(C_5H_7O_2)_2Cl_2]$ (Table 1) does not show a parent ion peak; the highest peak occurs at *m/e* 455. This indicates a two-electron oxidation of the anion to give $[Re(C_5H_7O_2)_2Cl_2]^+$. The subsequent fragmentation of this ion is independent of its origin so that the mass spectrum of the thallium salt is very similar to that of the rhenium(IV) complex. The thallium salt has two additional peaks at *m/e* 205 and 203. The relative

intensities of these peaks are the same as the abundance of the two stable isotopes of thallium.

The infrared spectra of $M[Re(C_5H_7O_2)_2X_2]$ are listed in Table 2 for M = Na, X = Cl and M = K, X = Cl, Br. Also, some of the bands have been assigned empirically (see ref. 4). Assuming local C_{2h} symmetry, of the four Re—O stretching vibrations (A_g, B_{1g}, B_{2u}, and B_{3u}), only the vibrations of B_{2u} and B_{3u} symmetry will be ir active. It has previously been suggested (4) that bands observed around 463 and 250 cm^{-1} in $Re(C_5H_7O_2)_2X_2$ (X = Cl, Br) contain a large contribution from these modes. Similar bands observed around 450 and 250 cm^{-1} in each of the reduced species no doubt also contain a large contribution from these modes. It is noteworthy that the energies of these bands are similar for both the Re(IV) and the Re(III) complexes. It is likely then that the extra electron density in the reduced species is not associated with the ReO_4 moiety.

The Re—X stretching mode of B_{1u} symmetry is ir active and can be assigned to bands observed at 309 and 208 cm^{-1} in $Re(C_5H_7O_2)_2X_2$ (X = Cl and Br, respectively). In the reduced species these bands are found at 300 and 200 cm^{-1}, respectively. It is noted that for both the Re(IV) and the Re(III) complexes $\nu_{Cl}/\nu_{Br} \sim 1.5:1$. For a simple harmonic oscillator of a diatomic with the assumption that the force constant is the same for both Re—Cl and Re—Br the ratio of the frequencies is estimated (7) to be $\nu_{Cl}/\nu_{Br} \simeq 1.4$. The fairly close agreement between the observed and calculated ratios indicates that the Re—X stretching vibrations are fairly pure in both the Re(III) and Re(IV) complexes. If these Re—X vibrations are pure then their relative energies in the Re(IV) and Re(III) complexes should be indicative of the relative strengths of the Re—X bonds. Since the Re—X vibrations occur at slightly lower energy in the reduced species than in the Re(IV) complexes one would predict that the Re—X bond would be weaker and longer in the anions, as is observed (6).

The electronic spectra of the reduced species are summarized in Table 3. The numerous bands observed can be grouped into three regions. Region I contains bands of very high energy (greater than 35 000 cm^{-1}) and high extinction coefficients ($\sim$10 000 L mol^{-1} cm^{-1}). Region II contains bands of moderate energy (15 000–30 000 cm^{-1}) and moderately high extinction coefficients (2000–9000 L mol^{-1} cm^{-1}). Region III contains bands of relatively low energy (less than 15 000 cm^{-1}) and low extinction coefficients (100–400 L mol^{-1} cm^{-1}). A band observed around 30 000–36 000 cm^{-1} ($\varepsilon \sim$ 30 000 L mol^{-1} cm^{-1}) in many β-diketone complexes has been assigned (8) to transitions between π molecular orbitals of the β-diketone ligand. The complicated set of bands in region I is probably caused, at least in part, by this kind of ligand transition. The bands in

*ε is in L mol^{-1} cm^{-1}.

region II have extinction coefficients which are typical of metal → ligand or ligand → metal[3] charge transfer transitions (9). The strong band around 15 000 cm^{-1} results in the characteristic blue-green colour of the reduced species. The bands in region III are probably *d–d* transitions. The very low energy band ($\sim$4000 cm^{-1}) was too weak to be observed in solutions and its origin is unclear.

The reduced dichlorocomplexes exhibit room temperature magnetic susceptibilities which are typical of Re(III) in an octahedral environment (10) (1950×10^{-6} cgsu for M = Na and 2020 cgsu for M = K). Similarly, $K[Re(C_5H_7O_2)_2Br_2]$ has a room temperature magnetic susceptibility of 1370×10^{-6} cgsu.

The reduction of *trans*-$Re(C_5H_7O_2)_2Cl_2$ with zinc amalgam in aqueous medium results in a blue solution whose electronic spectrum is identical with that of an aqueous solution of $M[Re(C_5H_7O_2)_2Cl_2]$ (M = Na, K). This blue solution no doubt contains the $[Re(C_5H_6O_2)_2Cl_2]^-$ anion. In CH_3CN, however, this anion is formed only as an intermediate, the final product being $Re(C_5H_7O_2)_3$. The Zn(II) ions appear, then, to be catalyzing the formation of this latter complex. In aqueous solutions, the Zn(II) ion would be hydrated, thus poisoning the catalytic activity.

[3]The bands are probably ligand → metal charge transfer bands as they increase in energy as the formal oxidation state of the metal decreases.

Reçu le 31 juillet 1978

MAURICE MONNIER et JEAN-PIERRE AYCARD. Can. J. Chem. 57, 1257 (1979).

L'étude de la réaction de chlorodécarboxylation par le tetracetate de plomb en présence de LiCl (réaction de Kochi) d'une série d'acides cyclohexaniques et cyclohexéniques montre que celle-ci s'accompagne d'une acétoxydécarboxylation. La proportion d'acétate formé augmente avec l'encombrement stérique du groupement R vicinal du centre radicalaire. La différence de stéréosélectivité de la formation des acétates et des chlorures est expliquée en considérant une évolution partielle à partir des conformères les moins stables.

MAURICE MONNIER and JEAN-PIERRE AYCARD. Can. J. Chem. 57, 1257 (1979).

The chlorodecarboxylation reaction (Kochi reaction) of a series of cyclohexane and cyclohexene carboxylic acids was investigated. Competitive acetoxy decarboxylation occurs, and the proportion of acetates is shown to increase with steric hindrance due to the R-substituent relative to the radical center. A partial evolution involving high energy conformers is suggested to explain the difference of stereoselectivities in the formation of acetates and chlorides.

Introduction

Sous l'action du tétracétate de plomb et d'un chlorure alcalin, un acide carboxylique est facilement décarboxylé et le radical ainsi formé évolue vers le chlorure d'alkyle ou vers l'acétate correspondant. Mise au point par Kochi (2), cette réaction a été particulièrement bien étudiée tant au point de vue de la synthèse que du mécanisme, mais seuls des travaux limités ont abordé l'aspect stéréochimique de cette réaction (3–5). Ce mémoire est une contribution à cet aspect de la réaction de Kochi.

Pour approfondir ces problèmes, il est indispensable d'utiliser des substrats cyclohexaniques étant donné les possibilités de comparaison avec d'autres réactions radicalaires induisant des faces diastéréotopiques (6–8) et en particulier l'excellente analyse de Gruselle et Lefort (9).

Avec ces substrats, il est également possible d'étudier l'influence des effets stériques sur la stéréosélectivité et en passant aux homologues cyclohexéniques nous sommes en mesure de faire varier ces effets stériques.

Résultats

Ils sont rapportés dans le Tableau 1. La première observation est l'identité de stéréosélectivité quelle que soit la stéréochimie des acides de départ. Ceci est tout à fait conforme avec l'hypothèse du passage par un même radical intermédiaire. La seconde constatation est celle de l'importance de l'évolution vers les acétates lorsque l'encombrement stérique augmente à proximité du site radicalaire; cette caractéristique de la réaction de Kochi n'avait pas encore été mise en évidence.

En série cyclohexanique, pour la réaction normale de formation des chlorures, les stéréosélectivités observées sont en faveur de l'isomère thermodynamiquement le moins stable, même pour le radical *tert*-butyl-2 cyclohexyle pour lequel le pourcentage de chlorure *trans* obtenu est très légèrement supérieur au pourcentage de chlorure *cis*. En effet, il a été montré que pour ces structures l'existence d'une interaction gauche *tert*-butyle-X déstabilise fortement l'isomère *trans* (0.3 kcal pour X = OH (10), 1.5 kcal pour X = CN (11)) par rapport à l'isomère *cis*.

En série cyclohexénique, pour le radical méthyl-3 cyclohexényle, le chlorure *trans*, vraisemblablement le plus stable (11), est formé préférentiellement; par contre, pour le radical *tert*-butyl-3 cyclohexényle nous obtenons le résultat inverse.

Pour la réaction "anormale" de formation des acétates, les stéréosélectivités sont en faveur de l'isomère thermodynamiquement le plus stable dans trois cas sur quatre; l'exception étant celle de la structure *tert*-butyl-2 cyclohexyle.

Enfin, avec la réaction de chlorodécarboxylation de l'acide cyclohexène-3 carboxylique optiquement actif (12), nous avons confirmé que le chlorure et les deux acétates formés ont perdu toute activité optique, ce qui est en accord avec le passage par un radical en interconversion rapide.

Discussion

La structure *tert*-butyl-4 cyclohexyle constitue une référence pour comparer les diverses réactions; la stéréosélectivité obtenue (27%) résulte d'une attaque axiale préférentielle et est tout à fait analogue à celles (30 à 40%) de la majorité des réactions qui conduisent au chlorure d'alkyle en passant par le radical *tert*-butyl-4 cyclohexyle (4, 9, 13); une stéréosélectivité plus marquée (60%) a toutefois été observée par Gruselle et coll. (9) lors de la décomposition thermique de peracides qui conduit aux alcools correspondants. Il est évident qu'au delà de ces petites différences qui résultent des comportements spécifiques des espèces chimiques opposées au radical, dans l'étape qui détermine les proportions des produits, la stéréosélectivité est essentiellement déterminée par la structure du radical. L'interprétation est fondée sur les hypothèses d'états de transition précoces et d'une prédominance des interactions d'éclipsage (attaque équatoriale) sur les interactions stériques (attaque axiale) c'est-à-dire, d'un modèle tout à fait similaire à celui de Cherest et Felkin (14). La première hypothèse est tout à fait satisfaisante compte tenu de la forte exothermicité de l'étape qui conduit du radical au chlorure d'alkyle. Dans cette série cyclohexanique la présence d'un groupement méthyle équatorial vicinal du centre radicalaire ne modifie que légèrement la stéréosélectivité; ce groupement méthyle équatorial a donc des contingences stériques pratiquement identiques vis-à-vis des deux types d'attaques (axiale et équatoriale).

La chlorodécarboxylation de l'acide méthyl-2 cyclohexane carboxylique présente une stéréosélectivité plus faible (20%), la diminution correspondante pouvant être attribuée à une évolution partielle à partir du conformère à méthyl axial du radical. A partir de cette hypothèse, et en considérant l'enthalpie libre conformationnelle du groupement méthyle égale à 1.6 kcal mol^{-1} dans le radical méthyl-2 cyclohexyle (par analogie avec l'équilibre conformationnel de la méthyl-2 cyclohexanone (15)); nous pouvons calculer (cf. partie expérimentale) les différences d'enthalpie libre entre les différents états de transition soit (en kcal mol^{-1}):

$$[1] \quad \begin{aligned} (G^{\ddagger})_E{}^e - (G^{\ddagger})_E{}^a &\simeq +0.5 \\ (G^{\ddagger})_A{}^e - (G^{\ddagger})_E{}^a &\simeq +1.5 \\ (G^{\ddagger})_A{}^a - (G^{\ddagger})_E{}^a &\simeq -0.5 \end{aligned}$$

Compte tenu des approximations, les valeurs obtenues ne constituent que des ordres de grandeurs. L'inégalité $\Delta G^{\ddagger}{}_A{}^a < \Delta G^{\ddagger}{}_A{}^e$ montre une réactivité importante du conformère à méthyl axial. Dans ces conditions, la formation du chlorure *trans* s'effectue essentiellement à partir du conformère thermodynamiquement le moins stable, alors que du fait de la relation $\Delta G^{\ddagger}{}_E{}^a \simeq \Delta G^{\ddagger}{}_A{}^e$ le chlorure *cis* peut être obtenu à partir des deux conformations (16).

Ces résultats peuvent être expliqués de la façon suivante. Un groupement méthyle équatorial vicinal du centre radicalaire désactive au même degré et l'attaque axiale et l'attaque équatoriale de sorte qu'il ne modifie pratiquement pas la stéréosélectivité, alors qu'un méthyl axial désactive l'attaque équatoriale.

Avec le radical *tert*-butyl-2 cyclohexyle, la réaction de formation des chlorures d'alkyle s'effectue avec une stéréosélectivité quasi nulle (1%); d'autre part, la proportion d'acétates concurrents est nettement augmentée, ce qui suggère une diminution des vitesses de la réaction de formation des chlorures.

$$[2] \quad R^{\cdot} \rightarrow RCl$$

Le premier de ces faits expérimentaux résulte soit d'une influence spécifique du groupement *tert*-butyle sur la vitesse d'attaque axiale sur le conformère équatorial, dont la diminution serait due à un encombrement stérique plus marqué, soit à une contribution d'un autre conformère. N'ayant aucun moyen de contrôler la validité de la première hypothèse, nous pouvons au moins montrer que la seconde est raisonnable. En effet, par analogie avec les données relatives à la *tert*-butyl-2 cyclohexanone, nous pouvons considérer que le radical *tert*-butyl-2 cyclohexyle présente un équilibre entre un conformère à groupement *tert*-butyle équatorial et un conformère twist 1–4 (cf. Fig. 1).

La structure du deuxième conformère n'a pas été prouvée mais elle est très raisonnable compte tenu des données récentes (17). Un calcul analogue au précédent permet d'accéder aux différences d'enthalpie libre entre états de transition.

$$[3] \qquad (G^{\neq})_E{}^e - (G^{\neq})_E{}^a \simeq +0.4$$
$$(G^{\neq})_T{}^e - (G^{\neq})_E{}^a \simeq -1.2 \text{ kcal mol}^{-1}$$

La stéréosélectivité du conformère twist (T) est considérée comme totale car l'évolution vers le chlorure *trans* n'implique pas d'interaction *syn*-1,3 avec l'un des méthyl du *tert*-butyle (cf. Fig. 1); il est alors logique que l'énergie d'activation correspondante soit très nettement inférieure à celle de la réaction du conformère équatorial.

La formation des acétates pourrait être due à une réaction de type S_N2, catalysée par le tetracétate de plomb, sur les chlorures formés. Différents essais de substitution dans les conditions de la réaction de Kochi nous ont permis d'écarter cette éventualité.

Ce problème pouvait aussi être abordé dans le cadre de l'hypothèse d'une évolution du radical vers le carbocation correspondant (2, 5). Des essais d'acétoxydécarboxylation en milieu ionique (18) ne nous ayant pas conduit à des résultats analogues à ceux de la réaction de Kochi, nous resterons dans le cadre d'une évolution directe à partir des radicaux pour tenter de dégager une interprétation cohérente des résultats.

La première remarque concerne une différence de comportements de radicaux *cis*-méthyl-2 *tert*-butyl-4 cyclohexyle et méthyl-2 cyclohexyle, le premier conduisant exclusivement aux chlorures, alors que le second conduit à 16.3% d'acétates. L'explication la plus simple est que ces acétates résultent essentiellement de l'évolution à partir du conformère à méthyl axial; cela expliquerait également la stéréosélectivité (42%) en faveur de l'acétate *trans* (attaque axiale sur le conformère à méthyl axial). Cette interprétation implique que la réaction de formation des acétates est plus sensible aux effets stériques que celle qui conduit aux chlorures, ce qui est en accord avec le renforcement de la stéréosélectivité (67%) quand c'est le radical *tert*-butyl-2 cyclohexyle qui évolue vers les acétates correspondants. Ce renforcement de stéréosélectivité nous permet également d'éliminer l'hypothèse d'un état de transition plus tardif pour la réaction conduisant aux acétates; en effet, pour les *tert*-butyl-2 acétoxycyclohexane c'est l'isomère *cis* qui est thermodynamiquement le plus stable (10).

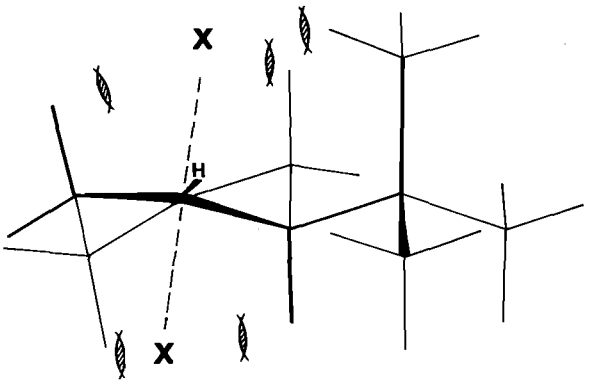

FIG. 1. Conformère twist du radical *tert*-butyl-2 cyclohexyle.

Enfin, pour l'évolution des radicaux cyclohexényles vers les chlorures les résultats sont a priori contradictoires; pour l'homologue *tert*-butylé, la stéréosélectivité (72%) est fortement en faveur du chlorure *cis* thermodynamiquement le moins stable (11), c'est-à-dire un comportement analogue à celui observé dans la série cyclohexanique. Au contraire le radical méthyl-3 cyclohexényle évolue vers le chlorure *trans* thermodynamiquement le plus stable; ce dernier résultat s'explique si l'on admet que l'équilibre conformationnel de ce radical est en faveur du conformère à méthyl pseudo-axial. Cette hypothèse ne semble pas déraisonnable; elle nous conduira à développer une analyse conformationnelle de ce type de structure.

Conclusion

La chlorodécarboxylation de Kochi est donc accompagnée d'une réaction parasite qui est une acétoxydécarboxylation et qui devient relativement importante lorsque les radicaux intermédiaires disposent d'un groupement encombrant au voisinage du site radicalaire. Les deux réactions sont examinées du point de vue de leur stéréosélectivité; elles sont généralement opposées mais peuvent être interprétées simplement en considérant une évolution partielle à partir des conformères les moins stables.

Partie expérimentale

Les spectres ir et rmn ont été enregistrés sur des appareils Perkin-Elmer modèle 377 et Varian EM 360 respectivement. Les analyses chromatographiques ont été effectuées sur des appareils Girdel 3000 ou Aérograph 90P.

Identification des composés

Les différents produits de réaction sont séparés par cppv et identifiés par spectroscopie infrarouge et par rmn (largeur de bande du proton *gem* du groupement fonctionnel). Le chloro-4 cyclohexène a été identifié à l'aide des spectres ir (19) et rmn déjà décrits. L'identification des acétoxy-3 et -4 cyclohexènes a été effectuée par comparaison avec des échantillons authentiques obtenus par estérification des cyclohexène-2,ol et cyclohexène-3,ol.

Les *tert*-butyl-3 X-4 cyclohexènes ont été identifiés par analyse des spectres rmn des composés trideutériés en position 3,6,6.

L'examen des constantes de couplage montre que les dérivés *cis* sont conformationnellement homogènes alors que les dérivés *trans* présentent un équilibre conformationnel.

L'identification des dérivés cyclohexéniques a d'autre part été confirmée par la comparaison de leurs produits d'hydrogénation avec les dérivés cyclohexaniques précédemment obtenus.

Paramètres des composés synthétisés

tert-*Butyl-2 chlorocyclohexanes*

Cis: ^{1}Hmr ($CDCl_3$) δ: 1 (s, 9H, C-2—t*Bu*), 1.0–2.2 (m, 9H, ring), 4.7–4.5 (m, 1H, *H*—C-1—Cl).

Trans: ^{1}Hmr ($CDCl_3$) δ: 1.05 (s, 9H, C-2—t*Bu*), 1.05–2.6 (m, 9H, ring), 4.2–3.6 (m, 1H, *H*—C-1—Cl).

tert-*Butyl-2 acétoxy cyclohexanes*

Cis: ^{1}Hmr ($CDCl_3$) δ: 0.9 (s, 9H, C-2—t*Bu*), 0.9–2.2 (m, 9H, ring), 2.07 (s, 3H, O—CO—*CH*$_3$), 5.03–5.23 (m, 1H, *H*—C-1—O—CO—CH_3).

Obtention des composés

Les acides de départ ont été obtenus par saponification des esters correspondants (11).

L'hydrogénation catalytique a été effectuée sur Pd/C 5% Fluka dans l'éthanol sous 1 atm.

La réaction de chlorodécarboxylation a été effectuée suivant le mode opératoire décrit par Kochi (2). Les rendements (acétates + chlorures) après séparation par cppv sont de 50% pour les dérivés méthylés et de 70% pour les dérivés *tert*-butylés.

Le tétracétate de plomb a été obtenu suivant la méthode de Vogel (21).

Séparation des composés

Les R-3 X-4 cyclohexènes (R = CH_3, $C(CH_3)_3$; X = Cl, OAc) ont été séparés sur une colonne de Carbowax 6000 de 2.5 m, diamètre 9.6 mm/colonne 115°C/débit 150 mL/min.

Les R-2 X-1 cyclohexanes (X = Cl, OAc; R = CH_3, $C(CH_3)_3$) ont été séparés sur une colonne de Réoplex 400 de 2.5 m, diamètre 9.6 mm/colonne 120°C/débit 120 mL/min.

Les acétoxy-1 *tert*-butyl-4 cyclohexane et chloro-1 *tert*-butyl-4 cyclohexane ont été séparés sur une colonne de tricresyl phosphate de 2.5 m, diamètre 9.6 mm/colonne 90°C/débit 120 mL/min.

Les chromatographies analytiques ont été effectuées sur des colonnes analogues.

Calcul des énergies libres des états de transition

Soient k_E^e et k_E^a les constantes de vitesse pour l'attaque sur le radical à groupement R équatorial et k_A^e et k_A^a celles pour l'attaque sur le radical à groupement R axial (cf. Schéma 2). La lettre minuscule désigne la face d'entrée, la majuscule la position du groupement.

La différence des différences d'énergie libre de l'état de transition suivant les attaques est pour chaque conformère

$$[4] \qquad \Delta\Delta G^{\ddagger}_E = \Delta G^{\ddagger}{}_E{}^e - \Delta G^{\ddagger}{}_E{}^a$$

$$[5] \qquad = -RT \ln (k_E{}^e/k_E{}^a)$$

$$[6] \qquad \Delta\Delta G^{\ddagger}_A = \Delta G^{\ddagger}{}_A{}^a - \Delta G^{\ddagger}{}_A{}^e$$

$$[7] \qquad = -RT \ln (k_A{}^a/k_A{}^e)$$

La réaction ayant un contrôle cinétique, le rapport des

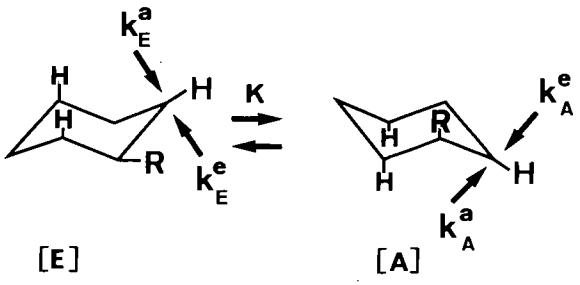

SCHÉMA 2

produits formés est égal au rapport de leurs vitesses de formation:

$$[8]\qquad \frac{[cis]}{[trans]}=\frac{\mathrm{d}[cis]/\mathrm{d}t}{\mathrm{d}[trans]/\mathrm{d}t}=\frac{k_E^a[E]+k_A^e[A]}{k_E^e[E]+k_A^a[A]}$$

$$=\frac{k_E^a+k_A^eK}{k_E^e+k_A^aK}\quad\text{avec}\quad K=[A]/[E]$$

La détermination de K à partir de la différence d'enthalpie libre ΔG^0 du radical permet de déterminer les différences d'énergie libre dans les états de transitions des différents conformères.

$$[9]\qquad \Delta\Delta G^{\ddagger}_{cis}=\Delta G^{\ddagger}_{E^a}-\Delta G^{\ddagger}_{A^e}=-RT\ln a\quad a=k_E^a/k_A^e$$

$$[10]\qquad \Delta\Delta G^{\ddagger}_{trans}=\Delta G^{\ddagger}_{E^e}-\Delta G^{\ddagger}_{A^a}=-RT\ln b$$

$$b=k_E^e/k_A^a$$

Pour le calcul des différences d'énergie libre: pour R = CH_3 le rapport k_E^e/k_E^a est tiré de nos résultats alors que le rapport k_A^a/k_A^e a été tiré des travaux de Cruselle et Lefort (8) sur la décomposition thermique de peracides cyclohexaniques. Pour R = $(CH_3)_3$—C nous avons considéré $k_A^e = 0$.

Complexation of cadmium(II) with water- and soil-derived fulvic acids: effect of pH and fulvic acid concentration

ROBERT A. SAAR AND JAMES H. WEBER[1]

Department of Chemistry, Parsons Hall, University of New Hampshire, Durham, NH 03824, U.S.A.

Received November 21, 1978

ROBERT A. SAAR and JAMES H. WEBER. Can. J. Chem. **57**, 1263 (1979).

We studied the conditional stability constants of cadmium(II) bound to fulvic acid derived from water and soil, and found that (1) stability constants increased with increasing pH, and (2) stability constants decreased as we increased the fulvic acid concentration toward 70 mg/L. The second effect does not occur for the copper(II)–fulvate system. Conformational changes that occur when a fulvic acid solution becomes more concentrated apparently weaken sites that are otherwise more accessible to weak-binding cadmium. From pH 4 to 8, the overall conditional stability constant increases from 1.4 to 12 × 10^3 for water-derived fulvic acid and from 1.7 to 43 × 10^3 for soil-derived fulvic acid. Increases in fulvic acid concentration from 20 mg/L to 70 mg/L halve the conditional stability constant at a given pH.

ROBERT A. SAAR et JAMES H. WEBER. Can. J. Chem. **57**, 1263 (1979).

Nous avons étudié les constantes de stabilité conditionnelles du cadmium(II) lié à de l'acide fulvique provenant d'eau et de sel et nous avons trouvé que (1) les constantes de stabilité augmentent avec le pH et (2) les constantes de stabilité diminuent lorsque nous augmentons la concentration de l'acide fulvique vers 70 mg/L. On ne note pas le second effet avec le système cuivre(II)/fulvate. Les changements conformationnels qui se produisent lorsqu'une solution d'acide fulvique devient plus concentrée semblent affaiblir les sites qui sont autrement plus accessibles au cadmium qui se lie faiblement. Du pH = 4 à 8, la constante de stabilité conditionnelle globale augmente de 1.4 à 12 × 10^3 pour l'acide fulvique provenant d'eau et de 1.7 à 43 × 10^3 pour l'acide fulvique provenant du sol. Lorsqu'on porte la concentration de l'acide fulvique de 20 mg/L à 70 mg/L à un pH donné, on réduit la constante de stabilité conditionnelle de moitié.

[Traduit par le journal]

Introduction

Fulvic acid (FA) is the fraction of naturally occurring humic matter that remains in solution at low pH. Its properties, particularly its ability to bind heavy metals, have been studied, but most fulvic acid for these studies has been extracted from soils (1–7). Work on humic materials extracted from natural waters is usually done on the total dissolved humic matter (fulvic and humic acids), not just on aquatic fulvic acid (6, 8–11).

Our group has isolated fulvic acids from river water (WFA) and from a podzol soil (SFA), and has carefully characterized them chemically and spectroscopically (12–14). This study describes the complexation of Cd^{2+} to these well-characterized samples. Many workers have noted that complexation of heavy metals to fulvic acid increases as the pH of the solution rises (3, 5, 6). The literature also shows decreased heavy-metal binding by fulvic acid as the ionic strength of the solution increases (10).

A third variable, largely overlooked, is the fulvic acid concentration itself. Fulvic acid is characterized as a polyelectrolyte (7), a class of molecules that changes conformation at different concentrations (15). Measurements by Reuter (16) on aquatic humic substances show a rapid increase in reduced viscosity (specific viscosity per unit concentration) as the humic material was diluted below about 100 mg/L

[1]To whom all correspondence should be addressed.

0008-4042/79/111263-06$01.00/0

at pH 7. He attributes the reduced-viscosity increase at low concentration to uncoiling of the humic structure. This uncoiling, or increase in apparent size of an average humic or fulvic acid molecule, may make sites more available for heavy-metal binding. As shown in gel permeation chromatographic studies (17), raising the pH or lowering the ionic strength also increases the apparent molecular size.

We designed our study to measure the effect of pH and fulvic acid concentration on the binding of Cd^{2+} (a highly toxic metal ion) to our WFA and SFA. Previous work in our group shows that copper(II) – fulvic acid binding is pH dependent (18). However, we had not observed that fulvic acid concentration affected the binding of Cu^{2+}. We employed Cd^{2+}, hoping it would be more sensitive than Cu^{2+} to conformational changes made by varying the polyelectrolyte (fulvic acid) concentration.

We analyzed free-metal concentration with ion-selective electrodes (ISE), an *in situ* method, because of difficulties with other techniques. Since our FA samples have average molecular weights below 700 amu (13), dialysis tubing we tried could not fully separate free and bound metal for analysis by atomic absorption spectrophotometry. Ultrafiltration with an Amicon UM05 membrane separates well enough, but requires too much time and fulvic acid.

Gel filtration chromatography is used for binding studies (19), but the aromaticity of our fulvic acids may interact non-ideally with the chromatographic resins (20). The surface activity of fulvic acid makes many voltammetric techniques difficult (21, 22), although aqueous humic matter apparently does not adsorb on the membranes of ion-selective electrodes (9).

Experimental

Materials

Fulvic acid. An earlier paper (12) describes the isolation and characterization of our soil- and water-derived fulvic acids.

Cadmium(II) solutions. Fisher SO-C-118 certified atomic absorption standard (1000 ppm) diluted with potassium nitrate electrolyte.

Copper(II) solutions. Orion copper(II) nitrate (0.1000 ± 0.005 *M*) standard, diluted with electrolyte.

Electrolyte. Mallinckrodt purified granular potassium nitrate crystals, dissolved in double deionized water.

KOH. Baker reagent grade 45% KOH, diluted with double deionized water or electrolyte, whichever gave the ionic strength closest to the experiment.

Apparatus

We measured the Cd^{2+} and Cu^{2+} concentrations with Orion model 94-48 and 94-29 solid-state ion-selective electrodes. The reference portion of a Corning model 476050 combination electrode was the reference for the ion-selective electrodes; a second Corning combination electrode monitored pH. Two Orion model 701A pH/mV meters recorded simultaneously free-metal concentration and pH.

We titrated into a Princeton Applied Research (Princeton, NJ, U.S.A.) model 9301 water jacketed cell. A P.M. Tamson circulating water bath maintained the temperature for all experiments at 25.0 ± 0.2°C. A magnetic stirring bar and stirrer maintained solution homogeneity.

Procedures

We titrated with either a cadmium-ion solution or a fulvic acid solution. For those experiments where metal-ion solution was the titrant, we placed 25.0 mL of the pH-adjusted fulvic acid solution, prepared daily in 0.1 *M* KNO_3, in the jacketed cell. We then added aliquots of the Cd^{2+} solution, also prepared that day from the concentrated metal-ion standards, with Gilson Pipetman variable pipets. To maintain pH within ± 0.03 pH units, we added small volumes of KOH solutions. We calibrated the ion-selective electrodes by adding standard metal-ion solutions to the electrolyte before and after each titration. Because the cadmium ion ISE has a small pH dependence, we calibrated that electrode at the pH of the day's work by adding KOH as needed.

For experiments where fulvic acid was titrant, we placed 25.0 mL of 0.1 *M* KNO_3 in the jacketed cell and added several aliquots of standard metal-ion solution to form a calibration curve. After adding the last metal aliquot, we began the titration with fulvic acid without changing the solution in the cell. Again, we adjusted the pH as necessary. We list the conditions for both types of experiment in Table 1.

ISE response flattens below about 10^{-6} *M* free metal so we computer fitted a polynomial of the form

$$\log [M^{2+}] = \sum_{i=0}^{n} a_i(mv)^i$$

to the calibration curves. $[M^{2+}]$ is the free metal ion concentration, *mv* is the millivolt reading from the ISE, a_i are the polynomial regression coefficients, and *n* is the order of the polynomial.

Calculations

We first tried to divide the binding sites on the fulvic acid into classes (such as strong, weak, and very weak) by the Scatchard method of analysis (23). Although we found 1.0 ± 0.3 sites per average fulvic acid molecule, the sites did not fall into well-defined classes with a given equilibrium constant for each. We observed a continuous variation in site strengths with respect to Cd^{2+}, which would explain the lack of clear breaks in our Scatchard plots.

Gamble and co-workers have demonstrated that fulvic acids contain acid functional groups with similar, but not identical pK_a values (7). The acid strength of these groups decreases as the degree of ionization increases. Work by several groups has shown that salicylic acid-type structures are the sites of copper chelation (24–26). We assume that such sites are available for cadmium(II) binding as well.

We expect that the extent of binding, and hence the stability constant for the cadmium–fulvate system will depend on pH and degree of association of metal and fulvic acid. The salicylic-type sites are similar but not identical, so the overall stability constant is a weighted average of the stability constants for each increment of chelating sites. The reaction at the *i*th

[a]Series of experiments where pH was the variable.
[b]Series of experiments where fulvic acid concentration was the variable.

type of chelating site is

$$[1] \qquad HFA_i^- + Cd^{2+} \rightarrow Cd\text{–}FA_i + H^+$$

Here, HFA_i^- is the *i*th type of fulvic acid binding site without metal, Cd^{2+} represents the free cadmium ion and Cd–FA_i is the *i*th type of cadmium–fulvate 1:1 complex. We define the incremental conditional stability constant K_i:

$$[2] \qquad K_i = [Cd\text{–}FA_i]/[HFA_i^-][Cd^{2+}]$$

The overall conditional stability constant K is

$$[3] \qquad K = \sum_{i=1}^{k} [HFA_i^-]K_i \Big/ \sum_{i=1}^{k} [HFA_i^-]$$

The weighting factors $[HFA_i^-]$ will change with pH and possibly with concentration of fulvic acid. Further, the overall conditional stability constant K will vary depending on the proportion of sites occupied by metal. With cadmium ions occupying the strongest sites at low metal-to-fulvic-acid ratios, each added increment of Cd^{2+} will go to successively weaker chelation sites so that K will drop. We calculated the overall stability constant K for various levels of cadmium loading, that is, for various values of $[Cd\text{–}FA]/C_{FA}$, where C_{FA}, the total fulvic acid concentration, equals $[HFA^-] + [Cd\text{–}FA]$. Our Scratchard analysis showed approximately one site per fulvic acid molecule, so we assumed that 1:1 complexes predominate. We used the expression

$$[4] \qquad K = [Cd\text{–}FA]/[HFA^-][Cd^{2+}]$$

for the conditional stability constant. Since total cadmium concentration, C_{Cd}, is

$$[5] \qquad C_{Cd} = [Cd\text{–}FA] + [Cd^{2+}]$$

$$[6] \qquad K = [Cd\text{–}FA]/(C_{FA} - [Cd\text{–}FA])[Cd^{2+}]$$

Results and Discussion

Tables 2 and 3 show the effect of pH and fulvic acid concentration on K for our water- and soil-derived fulvic acids. These K values are taken from the high $[Cd\text{–}FA]/C_{FA}$ part of those titrations where cadmium-ion solution is the titrant. $[Cd\text{–}FA]/C_{FA}$ represents the average number of cadmium ions bound per fulvic acid molecule. Figures 1–4 show that much higher stability constants exist early in the titration (at low $[Cd\text{–}FA]/C_{FA}$), due to the few strongest fulvic acid sites to which the cadmium ions from the first few titration aliquots bind.

TABLE 2. Effect of pH on cadmium – fulvic acid conditional stability constants*

	$K\times10^{-3}$	
pH	WFA	SFA
4.0	1.4	1.7
5.0	3.0	6.3

[a]Titrations done at pH 7.0 in 0.1 *M* KNO_3.
[b]Titrations done at pH 6.0 in 0.1 *M* KNO_3.

Much useful information appears in our log K vs. [Cd–FA]/C_{FA} graphs. The high [Cd–FA]/C_{FA} values represent an average of all the sites involved during titration and indicate the type of fulvic acid sample and experimental conditions. The somewhat lower log K values for WFA compared to SFA may be explained by its lower phenol OH content: 5.2 meq/g for SFA and 4.3 meq/g for WFA (12). This confirms the assumption that salicylic acid functional groups are the sites of binding (24–26).

It is clear from Figs. 1 and 2 that fulvic acid isolated from either water or soil binds Cd^{2+} more strongly as the pH is raised. There is a roughly two-fold increase in the binding constant, K, for each pH unit increase. These two figures also show that for lower pH values, the stability constant K becomes constant at lower levels of metal loading, that is, at lower [Cd–FA]/C_{FA}.

Figures 3 and 4 show the effect of fulvic acid concentration on its ability to complex metal ions. For both types of fulvic acids, we see higher conditional stability constants in the more dilute solutions. The dependence of stability constant on concentration occurs for solutions below about 1×10^{-4} M (about

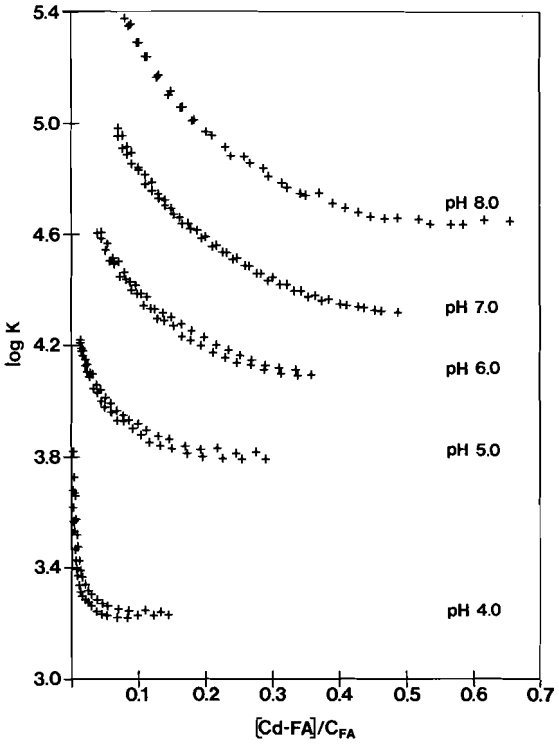

FIG. 2. Conditional stability constants for soil-derived fulvic acid as a function of pH. Data represent replicate titrations at each pH.

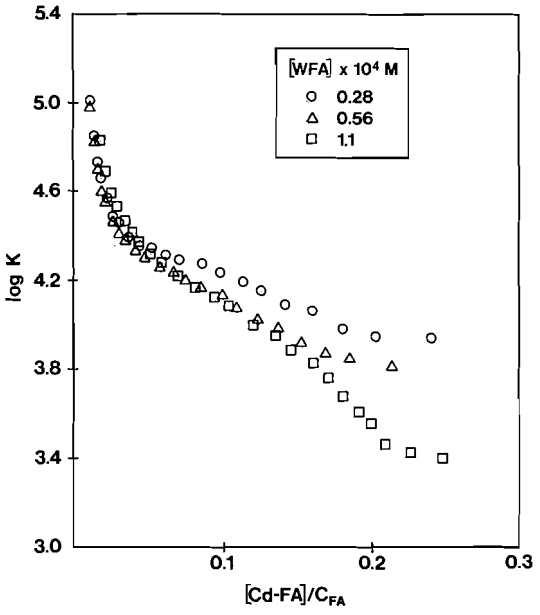

FIG. 3: Conditional stability constants at pH 7.0 for water-derived fulvic acid (WFA) at three different WFA concentrations.

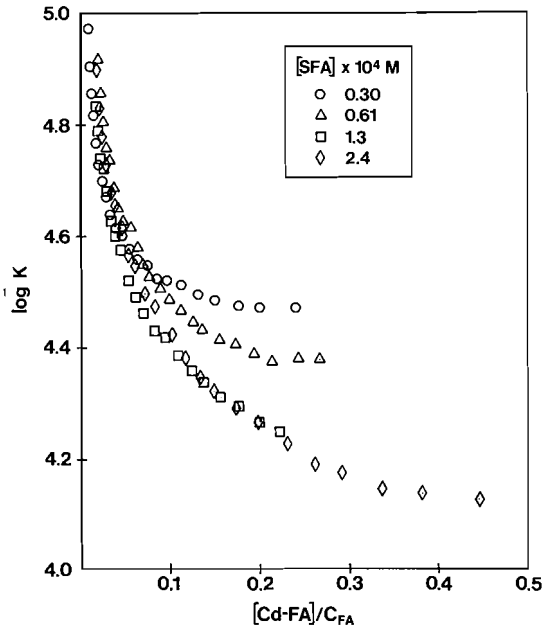

FIG. 4. Conditional stability constants at pH 6.0 for soil-derived fulvic acid (SFA) at four different SFA concentrations.

60–70 mg/L) using the molecular weights of 644 amu for SFA and 626 amu for WFA (13). This concentration corresponds well to the concentration range where Reuter found that reduced viscosities of aquatic humus change with concentration (16), that is, below about 100 mg/L. The higher reduced viscosity of dilute solutions may imply that the humus molecules are uncoiled or in an 'open' conformation.

Studies in our group (18) and the work of others (1–3, 5, 10, 27, 28) show that Cu^{2+} binds more strongly to fulvic and humic acids than Cd^{2+} does. We surmise that the conformational changes (decrease in apparent molecular size) that result from increasing the concentration of fulvic acids are forceful enough to block some potential Cd^{2+} binding sites. However, the stability of Cu^{2+} with the fulvate binding sites is great enough to overcome this relatively weak conformational blocking. We conclude that the intramolecular attractions (forces) involved here are stronger than those in Cd–FA complexation, but weaker than those in Cu–FA complexation. We expect that metal ions like Pb^{2+} that bind to simple organic ligands much as Cu^{2+} does (29) would not have stability constants that depend on fulvic acid concentration. Similarly, we anticipate that weak binding metals like Zn^{2+} would have concentration-dependent K values.

The data from reverse titrations (those where a fulvic acid solution is the titrant) confirm the concentration effect for cadmium. Early in such a titration, the stability constant drops after each addition of FA, but then levels off and begins to increase again toward the end of the titration (data represented by triangles in Fig. 5). This confirms that fulvic acid binding to cadmium is strongest when FA is most dilute (early in this type of titration). As we add more aliquots of FA titrant, its concentration in the cell increases and the K value drops. However, as we add more FA, the ratio of FA to Cd^{2+} increases, so that Cd^{2+} ions have an ever widening choice of sites on the fulvic acid for binding. The metal ions will bind preferentially to the strongest sites, so as we add more fulvic acid, the average K value increases.

The result is that the selection of titrant (FA or Cd^{2+}) makes a significant difference in the shape of the binding curve for cadmium due to the fulvic acid concentration effect. Figure 5 shows the two curve shapes for WFA at pH 6.0. Curve shapes for the SFA–cadmium system also depend on the titrant chosen and are very similar to those for WFA shown in Fig. 5. In contrast, we observed no FA concentration effect for the copper–fulvate system and our curves for both types of titration have the same shape, that is, K always increases when adding FA or K always decreases when titrating with Cu^{2+}.

We believe that fulvic acid concentration should be considered as an important variable when investi-

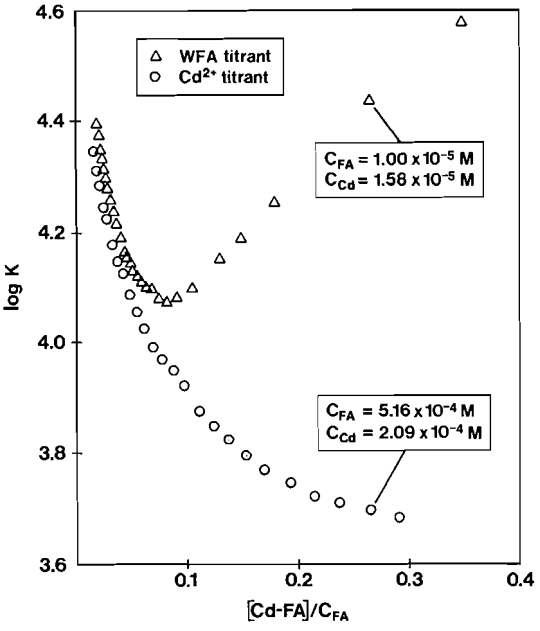

FIG. 5. Two pH 6.0 titrations, one each with WFA and Cd^{2+} as titrant. Reagent concentrations are shown for an experimental point in each titration with approximately equal $[Cd\text{–}FA]/C_{FA}$.

gating the transport of weakly bound metals like cadmium in natural systems. We have demonstrated that on a per-mole basis, fulvic acid binds cadmium most strongly when FA is in low concentration. Graphs such as those in Figs. 1–4 help to calculate the proportion of free and bound metal ion (cadmium ion in this case) for a given pH, for a range of fulvic acid concentrations and at different [Cd–FA]/C_{FA} values. If we assume that U.S. average river water has 10–13 mg/L of dissolved humic substances (30) and about 1 μg/L of Cd^{2+} (31), the low [Cd–FA]/C_{FA} parts of our figures would be most suitable. However, areas with much heavy-metal pollution might be best represented by the high [Cd–FA]/C_{FA} portions of these graphs. We observe finally that fulvic acids extracted from water and soils behave very similarly with respect to Cd^{2+} complexation.

The reactions of atomic oxygen with 1-propanol and 2-propanol

A. L. AYUB AND JOHN M. ROSCOE[1]

Department of Chemistry, Acadia University, Wolfville, N.S., Canada B0P 1X0

Received August 16, 1978

A. L. AYUB and JOHN M. ROSCOE. Can. J. Chem. 57, 1269 (1979).

The reactions of $O(^3P)$ with *n*-propanol and isopropanol were studied as a function of temperature. The absolute rate constants for these reactions, in the units M^{-1} s^{-1}, obey the following relations.

$$O + n\text{-propanol: } \ln k = 20.49 \pm 0.09 - (1.5 \pm 11\%) \times 10^3/T$$

$$O + \text{isopropanol: } \ln k = 19.58 \pm 0.07 - (1.1 \pm 13\%) \times 10^3/T$$

The activation energies of these reactions are similar to those of the corresponding reactions of methanol and ethanol, although some dependence on the strength of the α-C—H bond is discernible. The nearly constant pre-exponential factors for the reactions of methanol, ethanol, *n*-propanol, and isopropanol suggest that no special steric effects are present in the reactions of these compounds with $O(^3P)$. Mechanisms are discussed for the reactions of *n*-propanol and isopropanol with $O(^3P)$.

A. L. AYUB et JOHN M. ROSCOE. Can. J. Chem. 57, 1269 (1979).

On a étudié les réactions de $O(^3P)$ avec les *n*- et isopropanols en fonction de la température. Les constantes absolues de vitesse de ces réactions, en M^{-1} s^{-1}, obéissent aux relations suivantes:

$$O + n\text{-propanol: } \ln k = 20.49 \pm 0.09 - (1.5 \pm 11\%) \times 10^3/T$$

$$O + \text{isopropanol: } \ln k = 19.58 \pm 0.07 - (1.1 \pm 13\%) \times 10^3/T$$

Les énergies d'activation de ces réactions sont semblables à celles des réactions correspondantes du méthanol et de l'éthanol même si l'on peut discerner une relation avec la force de la liaison α-C—H. Le fait que les facteurs pré-exponentiels sont presque constants pour les réactions du méthanol, éthanol, *n*-propanol et isopropanol suggère qu'il n'existe pas d'effets stériques spéciaux lors de la réaction de ces composés avec $O(^3P)$. On discute des mécanismes de réaction des *n*- et isopropanols avec $O(^3P)$.

[Traduit par le journal]

Earlier work on the reactions of $O(^3P)$ with alcohols has established the importance of attack by the O atom on the hydrogens at the α-carbon atom of the alcohol (1–5). However, absolute rate constants over a range of temperatures are available only for the reactions of $O(^3P)$ with methanol and ethanol (4, 5). Kinetic data are also available for the reaction of 2-propanol with $O(^3P)$ at 298 K (3). The work presented here was undertaken to compare the Arrhenius parameters for abstraction of a hydrogen atom from the α-carbon atom of a primary and a secondary alcohol, and to investigate the possibility of steric effects in the reactions of $O(^3P)$ with alcohols.

Experimental

The experimental methods used in this work have been described in detail elsewhere (5). Briefly, the reactions were studied in a conventional fast flow system. The $O(^3P)$ was produced by adding NO to $N(^4S)$ atoms formed in a microwave discharge through N_2. The $O(^3P)$ concentrations were measured by determining the intensity of emission from excited NO_2 produced by a small amount of NO in excess of that required to completely consume the $N(^4S)$. The purification procedures for the NO and N_2 are described in detail elsewhere (5). The rate constants and product analyses were independent of the amount of excess NO.

Both *n*-propanol and isopropanol were refluxed with magnesium turnings in the presence of a small amount of I_2 to remove water. The alcohols were then purified further by fractional distillation until no impurities could be detected by gas chromatography. Their purity was estimated to be better than 99.999%.

Reaction products were analysed both by gas chromatography and by mass spectrometry. In the gas chromatographic analyses, the condensable products were collected in traps cooled in liquid nitrogen. They were then analysed on an 8-foot column of 10% Carbowax on Chromosorb W and on an 8-foot column packed with Porapak Q, using an F and M model 700 gas chromatograph with a flame ionization detector.

The mass spectrometric analyses were made by sampling through a molecular leak located in the reaction vessel. The mass spectra were obtained with a CEC model 21-104 single focussing mass spectrometer which was operated at sufficiently low ionizing voltages that interference due to fragmentation was minimal. Corrections for the small amount of residual fragmentation could easily be made.

Computer simulation of the reactions was done on a DEC-10 computer using a Fortran program described by Stabler and Chesick (6). This program was found to give

reliable results when tested on several mechanisms which are generally regarded as being accurate and for which extensive experimental data are available.

Results and Discussion

Kinetics

The absolute rate constants[2] for the reactions of $O(^3P)$ with *n*-propanol and isopropanol are given in Table 1 and the temperature dependence of these rate constants is shown in Fig. 1. The stoichiometric coefficients in Table 2 were not used in calculating the absolute rate constants. Since $\Delta[O]/\Delta[ROH]$ is much less than unity, and in view of the calculated effects of possible secondary reactions which are discussed later, it may be concluded that secondary reactions do not result in significant loss of $O(^3P)$. Thus, the measured rate constants are, in fact, the absolute rate constants.

The activation energy for the reaction of $O(^3P)$ with isopropanol is slightly less than that for the corresponding reaction of *n*-propanol. This might be expected since the α-C—H bond energy in isopropanol should be less than the α-C—H bond energy in *n*-propanol.

The Arrhenius preexponential factors for the reactions of $O(^3P)$ with *n*-propanol and isopropanol are similar. They are also similar to those reported earlier for the reactions of $O(^3P)$ with methanol (4, 5) and ethanol (5). This suggests that there is no significant 'steric effect' on the rate constant for the reactions of $O(^3P)$ with alcohols having up to three carbon atoms. This insensitivity to structure has been reported for reactions of $O(^3P)$ with other organic compounds containing oxygen (7). The relatively small preexponential factors for these reactions have been interpreted as indicating that $O(^3P)$ preferentially attacks the O-atom in the molecule. This electrophilic attack would result in relatively few collisions having the correct geometry for abstraction of the α-H atom from the alcohols studied here. There is considerable evidence that such abstraction is the initial step in the reactions of $O(^3P)$ with alcohols (2–5) and the electrophilic nature of $O(^3P)$ has been discussed elsewhere (7, 8).

Reaction Mechanism

The analytical data for the reactions of $O(^3P)$ with *n*-propanol and isopropanol are given in Table 2. Water and pinacol were also found in the products of the reaction of isopropanol with $O(^3P)$, but their yields were not measured. Based on these data and earlier work (2–5), the following reactions serve as the nucleus for describing the reactions of $O(^3P)$ with these alcohols.

[1] $O + C_3H_7OH \rightarrow C_3H_6OH + OH$

[2] $OH + C_3H_7OH \rightarrow C_3H_6OH + H_2O$

[3] $2C_3H_6OH \rightarrow C_3H_7OH + C_3H_6O$

[4] $2C_3H_6OH \rightarrow$ glycol

[2]Tables of the kinetic data from which these rate constants were calculated are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, The National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

While no glycol could be detected in the products of the reaction of $O(^3P)$ with *n*-propanol, and only a small amount of pinacol was recovered in the corresponding reaction of isopropanol, these products could easily have been lost on the walls of the apparatus.

The possibility of $O(^3P)$ consumption by the carbonyl product, C_3H_6O, and by OH was examined for each reaction by numerical integration of the appropriate rate equations. The additional reactions required for this analysis are

[5] $$O + C_3H_6O \rightarrow C_3H_5O + OH$$

[6] $$C_3H_5O + C_3H_7OH \rightarrow C_3H_6OH + C_3H_6O$$

[7] $$O + OH \rightarrow O_2 + H$$

Rate constants for reactions [2], [5], and [7] were taken from the literature (7, 9–11). Our value of k_1 was used and all other rate constants were made at least ten times as large as k_2. The ratio k_3/k_4 was adjusted to give the observed yield of the carbonyl compound. The calculations were then repeated with k_5 and k_6 set to zero, and then with k_7 set to zero as well. In the reaction of $O(^3P)$ with *n*-propanol, the inclusion of reaction [7] increased the overall rate constant by 5% and inclusion of reactions [5] and [6] altered the overall rate constant by 10%. In the reaction of $O(^3P)$ with isopropanol, the corresponding values were 0.3% and 1%. These calculations were made with a 50-fold excess of alcohol over $O(^3P)$, which is typical of our experimental conditions. Such estimates are likely to represent an upper limit on the effects of secondary reactions since the reactions of OH with the carbonyl compounds are also likely to be fast but were neglected for lack of kinetic data. It should therefore be safe to assume that reactions [5] to [7] played a negligible role in our experiments, within the uncertainties evident in Table 1. At least partial confirmation of this was found in a few experiments in which the ratio of $O(^3P)$ to alcohol was varied from 5 to 100. The calculated rate constant at 298 K was dependent on alcohol concentration until about a 15-fold excess of alcohol was used. Beyond this point, the rate constant was independent of alcohol concentration within experimental error. As expected, the smaller alcohol concentrations gave a substantially larger rate constant than was obtained with 20- to 100-fold excess of alcohol. Consumption of $O(^3P)$ by the α-alkanol radicals could not be estimated by the above method because of the lack of kinetic data. However, such reactions are unlikely to have been important since they would have made the yield of the carbonyl compound and relative consumption of $O(^3P)$ greater than the observed values. Participation by such reactions would have made the measured rate constants too large, and may have been responsible for the downward curvature of some of the pseudo first order plots which extended to relatively long reaction times.

Comparison of the Reactions of $O(^3P)$ with Alcohols

The reactions of $O(^3P)$ with C_1 to C_3 alcohols seem to follow the same general mechanism, although under the conditions in which we studied the reaction of $O(^3P)$ with methanol the reaction of $O(^3P)$ with OH seemed to be important (5). This is presumably

TABLE 3. Comparison of available kinetic data for reactions of $O(^3P)$ with alcohols*

*The uncertainties indicated represent one standard deviation.
†The results have been corrected as explained in the text.

due to the relatively small rate constant for the competing reaction of OH with methanol (9) and to the experimental limitations on the concentration of methanol relative to $O(^3P)$.

If the general mechanism proposed by Kato and Cvetanović (2, 3) and outlined here applies to the reaction of $O(^3P)$ with ethanol, the stoichiometric coefficient used to convert the measured rate constants for that reaction to absolute values (5) must be corrected for regeneration of ethanol by the disproportionation of the α-alkanol radical. When this is done, all the absolute rate constants reported in our earlier work on this reaction (5) must be multiplied by a factor of 1.6. This makes our absolute rate constant at 298 K in better agreement with that reported by Kato and Cvetanović (2) (Table 3). The revised temperature dependence of this rate constant is then given by $\ln k = 20.3 \pm 0.2 - (760 \pm 27\%)/T$.

The discrepancy between our results for the reaction of isopropanol with $O(^3P)$ and those of Kato and Cvetanović (3) is more serious and more difficult to understand. Although their experiments were made with a much larger excess of alcohol than was possible in our work, the effects of secondary reactions under our conditions were estimated to be negligible. Moreover, any such secondary reactions would have made our rate constants too large, while they are actually about an order of magnitude smaller than the value reported by Kato and Cvetanović based on competitive measurements using 1-butene. We are unable to detect any systematic errors in either our experiments or our calculations which could have caused this discrepancy. The kinetic measurements were made on two different flow systems by two persons working independently. The results obtained were in good agreement. The stoichiometry measurements were also made by two persons on two different flow systems, one equipped with a gas chromatograph and the other with a mass spectrometer. Again, the results obtained on the two systems were in good agreement. Clearly, further independent work is needed to resolve this question.

While the preexponential factors for the reactions of the alcohols are similar, a small but systematic dependence on the number of α-C—H bonds is discernible. When the preexponential factors are divided by the number of α-C—H bonds, the variation among the resulting values is random and is within experimental error. From this, it appears that apart from a statistical effect, there are no special steric influences in the reactions of $O(^3P)$ with the alcohols. No conclusions can be drawn from the activation energies for these reactions because their combined uncertainties are greater than the small differences among them. It seems, however, that the reported activation energy for the reaction of $O(^3P)$ with ethanol (5) may be somewhat too small since one would expect a value comparable to that for the corresponding reaction with n-propanol and larger than that for the reaction of $O(^3P)$ with isopropanol.

Received October 20, 1978

RODERICK E. WASYLISHEN and BRIAN A. PETTITT. Can. J. Chem. **57**, 1274 (1979).

Spin–lattice relaxation times are reported for the cyano, methylene, and ring carbons in liquid benzyl cyanide at selected temperatures between 215 and 406 K. The rotation of the molecule is modelled on the diffusion of a prolate spheroid and the following features are deduced: (*1*) rotation of the aromatic ring about the long axis of the molecule is about 3 times faster than rotation of this axis, (*2*) rotation of the —CH_2CN group about the long axis is about 1.5 times faster than the aromatic ring, and (*3*) activation energies associated with the temperature dependence of the $^{13}C—^1H$ dipolar relaxation rates agree with the hydrodynamical prediction of 3.6 kcal/mol associated with the temperature dependence of the ratio shear viscosity – temperature.

Linewidths of the cyano carbon resonance are shown to result from scalar coupling with ^{14}N.

Spin–spin coupling constants involving the cyano and methylene carbons are reported and compared with those calculated at the INDO level of molecular orbital theory.

RODERICK E. WASYLISHEN et BRIAN A. PETTITT. Can. J. Chem. **57**, 1274 (1979).

On rapporte les temps de relaxation spin–réseau des carbones du cyano, du méthylène et du cycle du cyanure de benzyle liquide à des températures déterminées entre 215 et 406 K. On peut imaginer le modèle pour la rotation de la molécule sur la base d'une diffusion d'une sphéroïde allongée et l'on a pu déduire les caractéristiques suivantes: (*1*) la rotation du cycle aromatique autour de son axe le plus long est environ 3 fois plus rapide que la rotation de cet axe, (*2*) la rotation du groupe —CH_2CN autour de son axe le plus long est environ 1.5 fois plus rapide que celle du noyau aromatique et (*3*) les énergies d'activation associées avec le fait que les taux de relaxation dipolaire $^{13}C—^1H$ dépendent de la température sont en bon accord avec la prédiction hydrodynamique de 3.6 kcal/mol qui est associée avec la relation entre la température et le rapport viscosité de cisaillement – température.

L'élargissement des raies de résonance du carbone du cyano provient d'un couplage scalaire avec le ^{14}N.

On rapporte les constantes de couplage spin–spin impliquant les carbones cyano et méthylène et on les compare avec celles calculées au niveau INDO de la théorie des orbitales moléculaires.

[Traduit par le journal]

Introduction

The rotational modes of a molecule usually constitute the 'lattice' that gives rise to the time dependence of the relaxation terms in the nuclear spin Hamiltonian; hence the widespread use of T_1 experiments in the study of liquid state rotational dynamics. The complexities of the liquid state rarely permit the interpretation of such experiments in any other than the crude terms of the rotational diffusion model, in which molecular rotations are regarded as the result of unspecified intermolecular torques fluctuating on a very short timescale. The model is generally accepted as a satisfactory framework within which the rates of rotation in the various modes of 'large' molecules can be compared. For example, the ^{14}N, ^{13}C, and ^2H resonances of acetonitrile, CH_3CN, have been thoroughly studied (1–7). At room temperature, CD_3CN rotates approximately 9 times faster about its C_3 axis than about axes perpendicular to this symmetry axis; and the two types of motion are characterized by activation energies (E_a's) of 0.8 kcal/mol and 1.7 kcal/mol, respectively (2). The present paper is concerned with the ^{13}C spin–lattice relaxation times of benzyl cyanide (C_6H_5—CH_2CN, Fig. 1), a derivative of acetonitrile, which exists as a liquid over a broad temperature range (249 to 507 K at atmospheric pressure). In addition $^{13}C,^{13}C$ coupling constants involving the methylene and cyano carbons are reported and compared with those calculated using the INDO semiempirical molecular orbital theory.

Previous nmr work on benzyl cyanide includes a variable temperature study of the ^{14}N linewidths by Wallach (8), and measurements of the temperature and pressure dependences of ^2H relaxation times of benzyl-4-d_1 cyanide and α,α-dideuterobenzyl cyanide by Jonas and co-workers (9–11). In their analyses, they emphasized the internal rotation of the —CH_2CN group (E_a = 2.9 kcal/mol), assuming this to be superimposed on isotropic overall rotation

0008-4042/79/111274-05$01.00/0

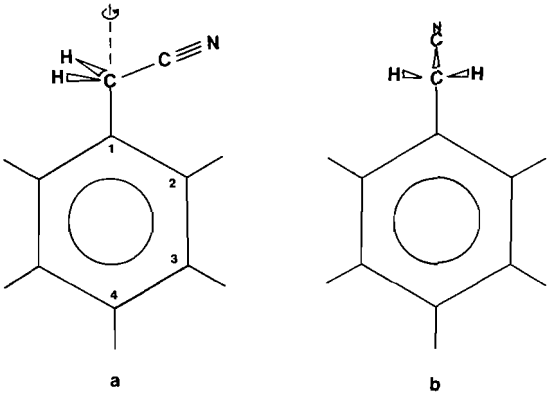

FIG. 1. Benzyl cyanide conformations.

(E_a = 3.3 kcal/mol). In a recent study, Schaefer *et al.* (12) measured the six-bond coupling constant between the methylene and *para* protons of 3,5-dichlorobenzyl cyanide and the analogous $^1H,^{19}F$ coupling constant in *p*-fluorobenzyl cyanide, from which they inferred a barrier height of approximately 0.35 kcal/mol for the twofold intramolecular potential of the $—CH_2CN$ group, the more stable conformation having the cyano group out of the aromatic plane (Fig. 1*b*). They also used the *ab initio* (STO-3G) molecular orbital scheme with partial geometry optimization to show that this quantity is less than 1 kcal/mol.

In the present paper, recognition of the grossly stochastic nature of the rotational diffusion model and the relatively weak interaction between the $C_6H_5—$ and $—CH_2CN$ fragments leads us to emphasize the anisotropy of the rotation and to regard any systematic effects that may result from the intramolecular potential as outside the scope of this picture, lost in the fluctuations of the number, momentum, and energy densities of the fluid.

Experimental

Benzyl cyanide (>98% purity) was obtained from the Aldrich Chemical Company and benzyl cyanide-*8*-^{13}C (i.e. ^{13}CN) and benzyl cyanide-*7*-^{13}C (i.e. $^{13}CH_2$) were obtained from Petrochem. The ^{13}C enriched samples were diluted with ordinary benzyl cyanide, 5% by volume cyclohexane-d_{12} was added to provide an internal lock, and the samples were degassed by the freeze–pump–thaw technique under vacuum and sealed.

Proton-decoupled ^{13}C spectra were obtained on a Varian CFT-20 spectrometer equipped with an 8 mm variable temperature probe. The spin–lattice relaxation times were measured using the inversion–recovery pulse sequence (d – 180° – t – 90°), where d is a delay time ($d > 5T_1$) and t is a variable time. T_1's of the methylene and aromatic carbons were measured independently using a sweep width of 125 Hz. Typically, 50 transients were accumulated for the methylene carbon (unenriched) and 16 to 25 transients for the ring carbons. Free induction signals were weighted slightly by an exponential weighting factor before being Fourier transformed. The 90° pulse width was 17 μs.

Nuclear Overhauser enhancement factors (nOe's) were measured using the gated proton decoupler with $d > 10T_1$ (^{13}C).

$^{13}C,^{13}C$ spin–spin coupling constants were measured using acquisition times > 10 s and are accurate to ±0.1 Hz.

Results and Discussion

^{13}C Spin–Lattice Relaxation Times and Rotational Diffusion Coefficients

Aromatic and Methylene Carbons

The dipolar part of the ^{13}C spin–lattice relaxation rate due to N identical, directly bonded protons is related to a reorientational correlation time, τ_2, in the extreme narrowing approximation by (13*a*)

$$[1] \qquad \frac{1}{T_1} = N\left(\frac{\gamma_C\gamma_H\hbar}{r^3}\right)^2 \tau_2$$

where γ_C and γ_H are the gyromagnetic ratios of ^{13}C and the proton, $2\pi\hbar$ is Planck's constant, and r is the C—H bond length. The rotational dynamics of the molecule are assumed to be adequately represented by the diffusion of a prolate spheroid with major axis passing through the $C_6H_5—CH_2CN$ bond. The rotation of this axis is characterized by a rotational diffusion coefficient, $D_\perp$, and the $C_6H_5—$ and $—CH_2CN$ groups are treated as rigid fragments in relative rotation about this axis, characterized by diffusion coefficients $D_\parallel$ and $D_\parallel'$, respectively. Woessner (14) has shown that the two coefficients are related to the correlation time by

$$[2] \quad \tau_2 = \frac{A}{6D_\perp} + \frac{B}{D_\parallel + 5D_\perp} + \frac{C}{4D_\parallel + 2D_\perp}$$

where $A = \frac{1}{4}(3\cos^2\theta - 1)^2$, $B = 3\sin^2\theta\cos^2\theta$, and $C = 3/4\sin^4\theta$, θ being the angle between the C—H vector and the major axis of the spheroid. Equation [2] explicitly refers to the $C_6H_5—$ group, and replacement of $D_\parallel$ by $D_\parallel'$ makes it applicable to the $—CH_2CN$ group. Because $\theta = 0$ for the *para* carbon (C_4), $\tau_2(C_4) = 1/6D_\perp$, such that the T_1 of this carbon is sufficient to determine $D_\perp$. The *ortho* (C_2) and *meta* (C_3) carbons both have $\theta = 60°$, so this model requires that their T_1's be equal. Standard geometries are assumed: the methylene carbon (C_m) is assigned the tetrahedral angle and r = 1.09 Å, and the aromatic r = 1.08 Å.

Table 1 displays the measured T_1's and the diffusion coefficients derived from them. The important features of this table can be summarized as follows: (*a*) $T_1(C_2) = T_1(C_3)$ within experimental error, (*b*) over 125 *K* temperature range, the T_1's and diffusion

coefficients change by an order of magnitude, (*c*) the aromatic ring rotates about the major axis of the molecule approximately 3 times faster than the axis itself, and (*d*) the —CH_2CN group rotates about the major axis approximately 1.5 times faster than the aromatic ring. The constancy of $D_\parallel/D_\perp$ is in accordance with simple hydrodynamical theory (15), which predicts that this ratio is determined by the molecular geometry. The value for benzyl cyanide is similar to those of *tert*-butylbenzene, phenylacetylene, and biphenyl (13*b*).

Plots of $1/T_1$ on a logarithmic scale versus reciprocal temperature for the aromatic and methylene carbons all give activation energies of 3.5 ± 0.3 kcal/mol. Simple hydrodynamical theory predicts that this quantity can be equated to the activation energy associated with the ratio η/T, where η is the shear viscosity (15). This prediction is upheld by published viscosity data for benzyl cyanide (16), which, when plotted as $\ln(\eta/T)$ versus $1/T$, gives a good straight line with a slope corresponding to an E_a = 3.6 kcal/mol.

The quantity $D_\parallel' - D_\parallel$ ($\simeq \frac{1}{2}D_\parallel$ in this case) is the rate of diffusive rotation of the —CH_2CN group with respect to the aromatic ring (17). In general, this quantity is probably determined by a complicated interplay of inter- and intramolecular effects; but some investigators have attempted to equate the activation energy associated with its temperature dependence to the barrier to internal rotation (18). The data in Table 1 is not accurate enough for such treatment, but in any case we regard the procedure as inadequate. The relationships between transport coefficients and more fundamental molecular properties are very elaborate (19), and features as complicated as the geometric variation of the total energy of a polyatomic molecule require techniques of a precision as yet unattempted by the most ambitious kinetic theorists.

Cyano Carbon

Spin–lattice relaxation times were measured for the cyano carbon, and the components due to dipolar coupling with protons, T_1^d, were extracted with the corresponding nOe factors (13*a*), giving the results in Table 2. T_1' is a relaxation time associated with the total rate of relaxation due to mechanisms other than ^{13}C—^1H dipolar coupling. Ln $(1/T_1^d)$ and ln $(1/T_1')$ are plotted versus reciprocal temperature in Fig. 2, from which it was determined that the former has E_a = 3.6 kcal/mol. T_1^d has contributions from the *ortho* and methylene protons, and studies of acetonitrile (5) and cyanoacetylene (20) suggest that protons on adjacent molecules may also contribute.

T_1' represents the combined effects of spin–rotation coupling, ^{13}C—^{14}N dipolar coupling, scalar coupling (of the second kind), chemical shift anisotropy, and possibly traces of paramagnetic species such as O_2 (13). Rough calculations show that ^{13}C—^{14}N dipolar coupling and chemical shift anisotropy, which have the same temperature dependence as the ^{13}C—^1H dipolar coupling, are expected to contribute, whereas the scalar mechanism can be discounted. The high temperature behaviour of T_1' is consistent with the spin–rotation mechanism, but this effect is difficult to quantify for a nucleus in an unsymmetrical environment.

Although it makes no contribution to T_1, the

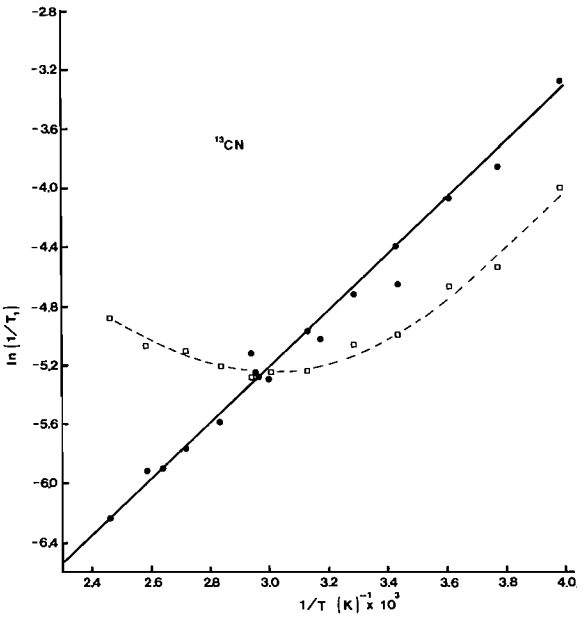

FIG. 2. The temperature dependence of the observed relaxation rates for the cyano ^{13}C in benzyl cyanide: the circles and solid line represent the ^{13}C—^{1}H dipolar component, and the squares and broken line represent the component due to other mechanisms.

scalar mechanism is very effective in the relaxation of the transverse component of the cyano ^{13}C magnetization. In this case, the spin–spin relaxation time, T_2^{sc}, is related to the ^{14}N spin–lattice relaxation time, $T_1(^{14}N)$, by (13*a*)

$$[3] \qquad \frac{1}{T_2^{sc}} = \frac{1}{T_1^{sc}} + \frac{8}{3}\pi^2 J^2 T_1(^{14}N)$$

where T_1^{sc} is very large and J is the ^{13}C—^{14}N spin–spin coupling constant. Since $\nu_{1/2} = (\pi T_2)^{-1}$ and it can be assumed that $T_1(^{14}N) = T_2(^{14}N)$ for rapid relaxation of the nitrogen, [3] can be approximated as

$$[4] \qquad \nu_{1/2}(^{13}C) \simeq \frac{8}{3}\frac{J^2(^{13}C—^{14}N)}{\nu_{1/2}(^{14}N)}$$

in terms of half-height linewidths. $J(^{13}$C—^{15}N) is -17.5 Hz in acetonitrile and -16.4 Hz in propionitrile (21), so we have estimated $J(^{13}$C—^{14}N) in benzyl cyanide as $\simeq -16\gamma(^{14}N)/\gamma(^{15}N) = 11.4$ Hz. Estimating ^{14}N linewidths from a graph in ref. 8 and using [4] we have calculated cyano ^{13}C linewidths which are in good agreement with experiment. For example, at 303, 378, 423, and 443 K the calculated (observed) values in Hz are 0.9 (1.2), 1.7 (1.7), 2.6 (2.3), and 3.0 (2.9), respectively.[1]

A few reservations about the analysis presented here should be stated. It is not completely certain that multispin effects (22) are absent in decoupled ^{13}C spectra, but we have made the usual assumption that single exponential recovery of the magnetization (as observed) is due to the mechanisms discussed above. More importantly, the choice of axes for the diagonalized rotational diffusion tensor was made heuristically, and the inertial and dipolar properties of the molecule due to the —CN group are thereby oversimplified. Also, it has been shown (23) that $D_{\parallel,\perp}$ is quite sensitive to small changes in molecular geometry. With these limitations in mind, we believe that the observed anisotropy, relative motion of the C_6H_5— and —CH_2CN groups, and hydrodynamically determined temperature dependence are significant features of the rotational dynamics.

$^{13}C,^{13}C$ Spin–Spin Coupling Constants

Cyano Carbon

Observed and calculated ^{13}C,^{13}C coupling constants involving the cyano carbon are listed in Table 3. The calculated values are Fermi contact contributions at the INDO–MO–FPT level of approximation (24–26) for the conformation in which the C≡N bond is in the plane of the benzene ring (Fig. 1*a*) and the conformation derived from this by rotation through 90° about the C_6H_5—CH_2CN bond (Fig. 1*b*). Standard geometries were used in all calculations (26).

The value 57.2 Hz observed for $^1J(CH_2,CN)$ in benzyl cyanide is similar to the value 56.6 Hz observed in acetonitrile (7), and the calculated values are substantially larger than those observed for both molecules (27, 28). Agreement might be improved if the orbital-dipolar (OD) and spin-dipolar (SD) contributions were included, but Blizzard and Santry (28) have estimated these terms to be only -2.56 and 0.57 Hz respectively in acetonitrile.

The value of $^2J(CN,C)$ in benzyl cyanide is only 3.53 Hz, in contrast to a value of 33.0 Hz reported for propionitrile (7). The INDO–MO–FPT procedure

TABLE 3. Observed and INDO–FPT calculated values of $^nJ(^{13}CN,^{13}C)$ in benzyl cyanide

Coupling constant	Observed values[a] (Hz)	Calculated values (Hz)	
		a	*b*
$^1J(CN,CH_2)$	57.2	76.30	74.96
$^2J(CN,C_1)$	3.53	−8.34	−9.39
$^3J(CN,C_2)$	3.37	3.35	3.60
$^3J(CN,C_6)$	3.37	5.65	3.60
$^4J(CN,C_3)$	≤0.3	−0.32	−2.51
$^4J(CN,C_5)$	≤0.3	0.00	−2.51
$^5J(CN,C_4)$	≃0.3	0.23	2.73

[a]Estimated error is ±0.1 Hz.

[1]Observed linewidths have been corrected for magnetic field inhomogeneity, estimated error ±0.3 Hz.

TABLE 4. Observed and INDO–FPT calculated values of $^nJ(^{13}CH_2,^{13}C)$ in benzyl cyanide

Coupling constant	Observed values[a] (Hz)	Calculated values (Hz)	
		a	*b*
$^1J(CH_2,C_1)$	44.25	48.29	48.09
$^2J(CH_2,C_2)$	4.05	−4.72	−4.89
$^2J(CH_2,C_6)$	4.05	−4.82	−4.89
$^3J(CH_2,C_3)$	3.61	5.15	4.80
$^3J(CH_2,C_5)$	3.61	5.10	4.80
$^4J(CH_2,C_4)$	≤0.6	−2.10	−1.78

[a]Estimated error ±0.1 Hz.

predicts −8.9 Hz in propionitrile, similar to the value for benzyl cyanide. If this large difference between the two molecules is real, then it appears that the combined OD and SD contributions to ^2J(C,C) are very different.

The general behaviour of ^3J(C,C) as a function of dihedral angle has been investigated (29–33) and shown to be quite different for saturated systems than for systems with π character in the coupling path. That this quantity is not very useful in conformational analysis (30) is reflected in the similarity of its values for *a* and *b* (Fig. 1).

The values of ^4J(C,C) and ^5J(C,C) suggest that *a* contributes more than *b* to the averages, but the more accurate STO-3G calculations (12) of the energy of the free molecule do not support this. Long range H,H couplings are reasonably well reproduced by INDO–MO–FPT calculations (34), but the absence of good model compounds make such an assessment for C,C difficult.

Methylene Carbon

Values of $^nJ(CH_2,C)$ observed for benzyl cyanide are given in Table 4 along with those calculated by the INDO–MO–FPT method. The observed values are similar to those of toluene, benzyl alcohol, and benzyl chloride (35). The calculated values are not very sensitive to the orientation of the methylene group. The large values calculated for $^4J(CH_2,C)$ may indicate the importance of the OD and SD terms, but are more likely to result from limitations in the INDO approximation.

D. COLBOURNE, D. C. FROST, C. A. MCDOWELL, and N. P. C. WESTWOOD. Can. J. Chem. 57, 1279 (1979).

HeI photoelectron spectra are reported for pure gas-phase samples of the unstable methylbromamines, CH_3NHBr, CH_3NBr_2, and $(CH_3)_2NBr$. Results are also presented for the unsubstituted bromamines NH_2Br and $NHBr_2$ obtained as products from a gas-phase mixing of NH_3 and Br_2. The spectra are compared with those of the corresponding chloramines.

D. COLBOURNE, D. C. FROST, C. A. MCDOWELL et N. P. C. WESTWOOD. Can. J. Chem. 57, 1279 (1979).

On rapporte les spectres photoélectroniques, HeI, d'échantillons gazeux purs des méthylbromamines instables, CH_3NHBr, CH_3NBr_2 et $(CH_3)_2NBr$. On présente aussi des résultats pour les bromamines non-substituées NH_2Br et $NHBr_2$ que l'on a obtenues comme produits par mélange en phase gazeuse de NH_3 et Br_2. On compare les spectres avec ceux des chloramines correspondantes.

[Traduit par le journal]

Introduction

The simple unsubstituted bromamines, $NH_{3-n}Br_n$, are known to be rather unstable molecules (4–6), and for this reason have not been as extensively studied as the analogous chloramines (5, 6). Monobromamine (NH_2Br) has been prepared in ether solution by reaction of ammonia and bromine at 0°C (7) or −60°C (8), and dibromamine ($NHBr_2$) results from a modification of the same procedure (9, 10). The absorption spectra of ether solutions of these compounds indicates that there exists an equilibrium between bromamine, ammonia, and dibromamine (11). The preparation of both species in aqueous solution has been claimed (12, 13), identification being based on ultraviolet absorption spectrometry. These claims were later substantiated (14), and the presence of nitrogen tribromide (NBr_3) was also postulated. Only monobromamine has been prepared in the gas phase (15), following reaction of a large excess of ammonia with bromine diluted with nitrogen.

N-Bromoalkylamines are considerably more stable (16); the methylbromamines, although not isolated, have previously been prepared in aqueous solution (17), and as such have been studied by infrared (17) and ultraviolet (11, 17) absorption spectrometry. Similar studies, conducted in ether solution (11) indicate that an equilibrium between CH_3NHBr, CH_3NBr_2, and free amine occurs. Dimethylbromamine, $(CH_3)_2NBr$, is the only methylbromamine that has previously been prepared in the gas phase (15), albeit from a mixture of gaseous dimethylamine and bromine, where one of the components is always in excess. In summary, therefore, all of the unsubstituted and methylated bromamines are unstable, and have never been characterized in the gas phase. Methylation increases the stability.

We previously studied the HeI and NeI photoelectron (PE) spectra of the unsubstituted chloramines (NH_2Cl, $NHCl_2$, and NCl_3) and the methyl substituted chloramines (CH_3NHCl, CH_3NCl_2, and $(CH_3)_2NCl$) (2, 3), and now wish to extend this to the PE spectra of the bromo analogues. Our purpose is twofold: first, to obtain information on the electronic structures of these bromamines and relate them to those of the chloramines, and secondly, to illustrate how relatively pure samples of these molecules may be produced for gas-phase investigation. Thus following our earlier work on the chloramines (2, 3), the methylbromamines are prepared as volatile components of a solution reaction, and the unsubstituted monobromamine is prepared via a gas phase mixing reaction. Evidence for the formation and detection of dibromamine is presented. During the course of this work a paper was published on the PE spectrum of NH_2Br (18*a*) and subsequent to the completion of this manuscript, a paper on CH_3NHBr and CH_3NBr_2 also appeared in the literature (18*b*). All three species were obtained as constituents of Br_2/NH_3 (or CH_3NH_2) mixtures in the gas-phase, and the resultant "clean" spectra were obtained by spectrum stripping procedures. Here we present the PE spectra of *pure* gas-phase samples.

[1]Part III of a series. For parts I and II, see refs. 2 and 3. Part IV is ref. 1.

Experimental

(a) Methylbromamines

These were prepared in aqueous solution by mixing a solution of sodium hypobromite, NaOBr, with the appropriate amine solution. The temperature was maintained at 0°C. The methylbromamine thus formed was sufficiently volatile *in vacuo* to be led directly into the ionization chamber of the PE spectrometer (19) via a $CaCl_2$ trap to remove excess water.

(*i*) Preparation of the NaOBr solution: Br_2 was added slowly to a 20% NaOH solution at room temperature until there was an excess of halogen. This solution was kept in the dark at −10°C until required.

(*ii*) CH_3NHBr: an excess of 40% methylamine solution was added quickly to the hypobromite solution. As we have previously observed for CH_3NHCl (3), the ratio of amine:hypohalite for optimum yields was found to be critical, since insufficient amine results in the formation of CH_3NBr_2. Best yields were obtained at a pH of about 9.

(*iii*) CH_3NBr_2: 40% methylamine solution was added dropwise with stirring to the hypobromite solution. The dibromo-substituted species was formed under these conditions when the amine was not in excess (pH ~ 7).

(*iv*) $(CH_3)_2NBr$: 40% dimethylamine solution was added to the hypobromite solution until alkaline (pH ~ 10).

(*v*) Sampling: a similar technique to that used for the chloramines (2, 3) was found to be appropriate here; the volatile component from the solution was led directly into the PE spectrometer (19) via a $CaCl_2$ U-trap maintained at −37°C. Spectra were calibrated using the known ionization potentials (IP's) of CH_3I, H_2O, N_2, and Ar.

(b) Monobromamine (and Dibromamine)

Extensive experiments to prepare and sample the unsubstituted bromamines from aqueous solution were unsuccessful. Rapid decomposition in solution prevented the observation of any gas-phase bromamine. Nitrogen was observed in abundance. Similar results were obtained using a variety of solvents. Thus a direct gas-phase synthesis was devised, based on the generator used previously for the monochloramine synthesis (2, 20) which involved mixing of Br_2 and NH_3. NH_2Br is easily produced by this method (see later, and refs. 15 and 18*a*). The NH_3:Br_2 ratio, the flow rate, and temperature were all extensively varied in an attempt to improve the yield of gas-phase dibromamine, since the previous work (2, 3) indicated that substantial amounts of di- and even tri-chloramine are produced by this method.

Results

The HeI PE spectra of CH_3NHBr, CH_3NBr_2, and $(CH_3)_2NBr$ are shown in Fig. 1 *a*, *b*, and *c*, respectively. The spectra are relatively clean, the only contaminant being a trace of water evidenced by the sharp peak at 12.62 eV. Certain bands in each of the spectra show resolvable vibrational structure (listed in Table 1).

Spectra of NH_2Br in the presence of excess Br_2 (21) and excess NH_3 (22) are shown in Fig. 2 *a* and *b*, respectively, with expansions of the first region under the same conditions shown in Fig. 3 *a* and *b*. The first band of NH_2Br shows resolvable fine structure (Fig. 4).

All IP's and associated vibrational structure are given in Table 1 for the methylbromamines and Table 2 for the unsubstituted bromamines. The weak

Franck–Condon factors for the adiabatic transition of the first band may mean that the quoted adiabatic IP's are in error by one vibrational quantum. Error limits are given in Tables 1 and 2 together with the proposed assignments.

Assignments

(a) Methylbromamines

The assignments for the methylbromamines are based partly on the expected shifts for bromination of an amine, and partly on the previous results for the analogous methylchloramines (3). Since there appear to be no changes in the sequence of orbital energies (assuming Koopmans' theorem (23)) for

these methylbromamines, we prefer not to discuss them in detail, except to point out any unusual features. A comparison of Fig. 1 with Fig. 3 of ref. 3 will illustrate the direct correspondence of the IP's. The numerical values are summarized in the correlation diagram, Fig. 5. The results are in good agreement with the recent spectra obtained by spectrum stripping from mixtures (18*b*) (apart from an interchange of the closely spaced 7*a*′ and 4*a*″ orbitals).

Certain features of the spectra and the numerical values are worth considering. First, as expected, all IP's of the methylbromamines are lower than those of the corresponding methylchloramines. The effect is more pronounced for those bands involving considerable Br 4*p* character, i.e. the halogen lone pairs, and the *n*N + *n*X combinations. Secondly, all bands in the methylbromamines are more spread out than the corresponding bands in the methylchloramines. The individual IP's become more apparent, especially in the CH_3 region (>12.5 eV), where the location and assignment of individual IP's were more difficult in the case of the methylchloramines. We also note that the third and fourth bands of CH_3NBr_2 are now completely separated, whereas in $NHCl_2$ they are essentially degenerate, and only slighly separated in CH_3NCl_2. Thirdly, there are some slight variations in the vibrational fine structure observed on the sharp second bands of CH_3NHBr and $(CH_3)_2NBr$ compared to the corresponding structure on the methylchloramines. This structure was not observed in the recently published work (18*b*). Specifically, the observed structure on the second band of CH_3NHBr is 830 ± 50 cm^{-1}, and cannot therefore correspond to an N—Br stretching frequency, since the value for CH_3NHCl^+ is 750 ± 50 cm^{-1} (3). We prefer to assign this mode in both cases to an N—C stretching frequency (895, 875 cm^{-1} in the molecular ground state of CH_3NHCl (24)). On the second band of $(CH_3)_2NBr$, two progressions are resolvable, one of 320 ± 50 cm^{-1} not previously seen on the corresponding band of $(CH_3)_2NCl$, and the other of 1040 ± 50 cm^{-1}, corresponding to the excitation of

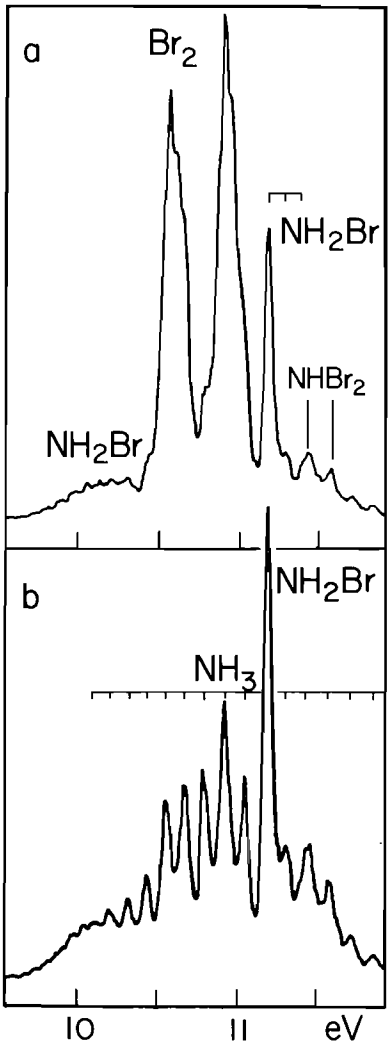

FIG. 3. Expansion of the 10–12 eV region in the gas-phase reaction of NH_3 and Br_2. (*a*) Excess Br_2 and (*b*) excess NH_3.

960 ± 50 cm^{-1} in $(CH_3)_2NCl^+$. The latter is either a reduced CH_3 deformation (1200–1150 cm^{-1} in molecular $(CH_3)_2NBr$ (25)) or an NC_2 stretching frequency (900 cm^{-1} in molecular $(CH_3)_2NBr$). The value of 320 cm^{-1} could be a reduced N—Br stretching frequency (525 cm^{-1} in $(CH_3)_2NBr$), although this seems unlikely in view of the non-bonding nature of this transition. The more plausible alternative is an NC_2 deformation (390 cm^{-1} for molecular $(CH_3)_2NCl$ (25)).

As mentioned above, the third and fourth bands of CH_3NBr_2 are now well separated, and the third band now shows some vibrational structure, 300 ± 50 cm^{-1}, the assignment of which is probably similar to that of $(CH_3)_2NBr$. Such structure was not observed on the corresponding bands of $NHCl_2$ or CH_3NCl_2 due to the overlapping of the peaks.

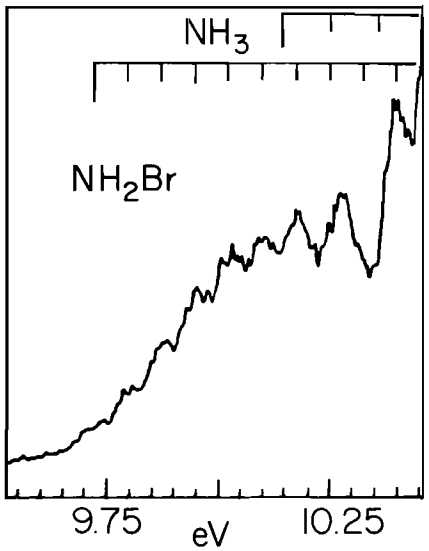

FIG. 4. Detail of the first band in the PE spectrum of NH_2Br.

(b) Monobromamine and Dibromamine

The PE spectrum of monobromamine should show five bands, directly analogous to those of monochloramine (2, 3). The spectra which are obtained from a gas-phase reaction of Br_2 and NH_3 always involve the presence of one of these components (e.g. Fig. 2*a*, excess Br_2, Fig. 2*b*, excess NH_3), and so values for only the first four IP's can be given with any certainty since the remaining band is of low intensity (see NH_2Cl (2)) and obscured by the broad ^2E state of NH_3^+ (15–18 eV) (22).

The first band (Fig. 4) with adiabatic and vertical IP's of 9.74 and 10.18 eV corresponds to an N—Br antibonding combination decreased by 0.34 eV from the corresponding band of NH_2Cl, and ~0.70 eV from the corresponding band of NH_3. It retains the broad envelope of a nitrogen lone pair, but the downward shift implies considerable Br 4*p* involvement. As with the first band of NH_2Cl there is a distinct vibrational progression, a mean value of 650 ± 50 cm^{-1} being observed (compare NH_2Cl, 760 ± 40 cm^{-1}) (2). The only vibrational data available for NH_2Br are those involving νN—Br (540 cm^{-1}) (6) and this is certainly a possible excitation since the orbital is N—Br antibonding. The other alternative which we considered for NH_2Cl (2) is a reduced value of the H_2N—Br bending frequency (estimated to be ~800 cm^{-1} in the molecular ground state).

The second band (Fig. 3) with coincident adiabatic and vertical IP's (11.19 eV) is sharp and intense, analogous to the corresponding bands in NH_2Cl (2) and the methylbromamines, CH_3NHBr and $(CH_3)_2NBr$ (Fig. 1). It retains the non-bonding character and is shifted from the corresponding band in NH_2Cl by −0.73 eV. From a careful study of

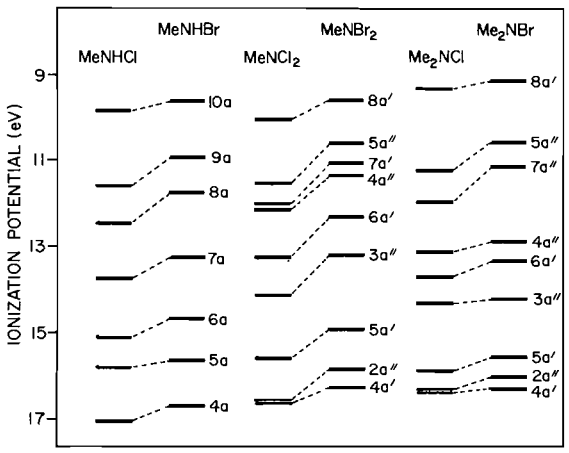

FIG. 5. Correlation diagram for the complete series of methylchloramines and methylbromamines. Valence level numbering.

many spectra under varying Br_2:NH_3 ratios, it is apparent that there are three other much weaker peaks in this region which are not associated with either Br_2 or NH_3. One (at 11.29 eV) is definitely associated with this intense second band and is assigned to a vibrational component at 840 ± 50 cm^{-1}, probably corresponding to the H_2N—Br bending frequency. From intensity changes, the other two peaks at 11.43 and 11.57 eV are not associated with this ionization event, and are therefore tentatively assigned to bands belonging to the third and fourth IP's of dibromamine, $NHBr_2$. Our rationale for this is twofold: these two bands increase in intensity with excess Br_2, and as we have previously observed (2), the reaction of excess gaseous Cl_2 with NH_3 leads to the formation of the dichloro- species. Finally, the observed values of 11.43 and 11.57 eV are very close to the predicted values for the third and fourth bands of $NHBr_2$ (see below). NBr_3 can be excluded on these grounds.

The third band of NH_2Br, the N—Br bonding combination, retains the same band envelope as the corresponding band of NH_2Cl, and is shifted by -0.81 eV to give a vertical IP of 12.69 eV. The spectrum shown in Fig. 2 shows a slight trace of residual Br_2 ($^2\Pi_{1/2\,u}$) (21) on the high energy side of this band.

The fourth IP is located at the onset of the band due to the ^2E state of NH_3^+ (22) and partially overlaps the $^2\Sigma_g^+$ state of Br_2^+ (21). We can, however, estimate a vertical IP of 15.0 ± 0.1 eV, the corresponding band of NH_2Cl occurring at 15.72 eV with a similar weak, broad Franck–Condon profile. The weaker fifth band, which occurs in NH_2Cl at 17.50 eV, is not observed here, since it occurs directly under the broad second band of NH_3. Previous work (18), also involving a gas-phase reaction of NH_3 and Br_2, gives a spectrum very similar to that reported here. The IP's are in relatively good agreement, a spectrum stripping procedure also locating the fifth IP at 16.93 eV. There is a slight discrepancy in the absolute position of the sharp second band, and the magnitude of the associated vibrational frequency. The latter is particularly confused by the presence of the bands due to $NHBr_2$.

Discussion

As mentioned above, and as illustrated in Fig. 5, the PE spectra of all the methylbromamines follow directly from those of the corresponding methylchloramines after incurring the usual shift due to replacement of Cl by Br. The mixing between orbitals is considerable for these low symmetry molecules, and thus all IP's show appropriate shifts dependent upon the extent of Br $4p$ involvement. The increased separation of most of the bands allows individual IP's beyond 12.5 eV to be assigned with more certainty although the deepest lying levels in CH_3NBr_2 and $(CH_3)_2NBr$ are still not completely separated. The proposed assignments are given in Table 1.

The unsubstituted bromamines are considerably more unstable than the methylated derivatives, and so PE spectra could not be obtained completely free of precursors. All attempts to prepare NH_2Br from solution resulted in spontaneous formation of solid

NH_4Br and the evolution of nitrogen. Even in the gas-phase reaction of NH_3 and Br_2 it was noted that high yields of NH_2Br resulted in increased formation of nitrogen. However, NH_2Br shows four IP's in the PE spectrum, similar in appearance and expected position to those of NH_2Cl (2). In addition, under certain conditions with excess Br_2 we were able to produce small amounts (estimated to be $<5\%$) of a new species (peaks at 11.43 and 11.57 eV) which we believe to be $NHBr_2$. By scaling the IP values for $NHCl_2$ by the ratio of the shifts for CH_3NCl_2 and CH_3NBr_2 we can predict a PE spectrum for $NHBr_2$, which should be close to the experimental spectrum. The numerical values are given in Table 2, together with the observed values; the agreement is remarkably good, and the correlation diagram (Fig. 6) shows the anticipated spacings between the first five bands. Also included in this correlation diagram, to complete the series of *N*-dihalamines, is difluoramine, NHF_2, the PE spectrum of which we have recently obtained (1).

The effect of Br and CH_3 substitution upon the absolute position (vertical IP) of the first band of NH_3 is summarized in Fig. 7. Here horizontal and vertical arrows refer to replacement of H by CH_3 or Br respectively. The diagonal arrows correspond to replacement of Br by CH_3. As we have previously noted for the chloramines (3), the first IP of NH_3 is substantially destabilized by the antibonding halogen interaction. However, from the observed shifts of Fig. 7, we may estimate vertical IP's for $NHBr_2$ and NBr_3, the former result being in good agreement with that estimate by the scaling method (Fig. 6 and Table 2). Again, the diagonal relationships are the most consistent, the replacement of any Br atom by a

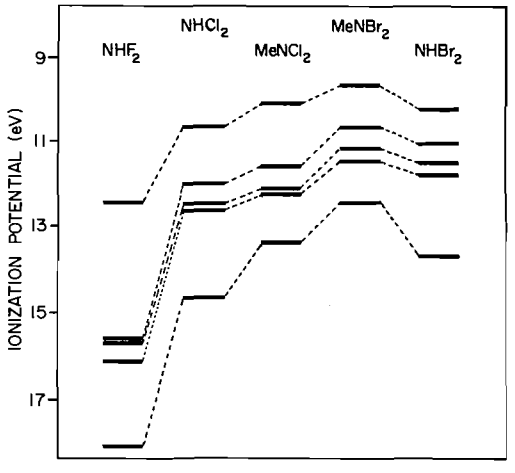

FIG. 6. Correlation diagram for the dihalamines, NHX_2 (X = F, Cl, and Br), and the methyldihalamines, CH_3NX_2 (X = Cl and Br).

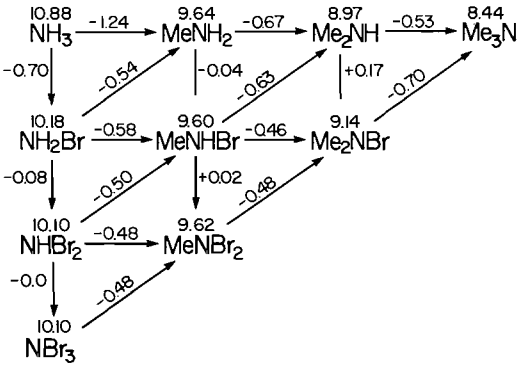

FIG. 7. Effect of Me and Br substitution upon the first IP's of substituted ammonias. Horizontal arrows, replacement of H by Me; vertical arrows, replacement of H by Br; diagonal arrows, replacement of Br by Me. Estimated values for $NHBr_2$ and NBr_3.

CH_3 group decreasing the first IP by a factor of 0.56 ± 0.14 eV (compare 0.78 ± 0.1 eV for the chloramines (3)).

From this work it seems unlikely that a pure sample of $NHBr_2$ for gas-phase investigation may ever be prepared, although it is possible that a spectrum stripping procedure similar to that used for NH_2Br (18) may be feasible in order to obtain a "clean" PE spectrum. $NHCl_2$ itself is prone to decompose when pure, although we have succeeded in obtaining impurity free spectra of this species (3). Addition of methyl groups does however confer substantial stability as we have seen for the methylbromamines. In the light of our recent work on the PE spectra of several halo and methyl substituted ammonias, we offer here an estimate of the gas-phase stability of these molecules based on their rates of decomposition, viz., $(CH_3)_2NCl > CH_3NCl_2 \sim (CH_3)_2NBr > CH_3NHCl > CH_3NBr_2 > CH_3NHBr > NH_2Cl > NCl_3 > NHCl_2 \gg NH_2Br > NHBr_2$. This is somewhat subjective, but hopefully useful to those wishing to investigate further these interesting compounds.

T. CHIVERS and J. PROCTOR. Can. J. Chem. **57**, 1286 (1979).

Pentasulfur hexanitride, S_5N_6, has been prepared in good yield by the reaction of $[n\text{-}Bu_4N^+][S_4N_5^-]$ with bromine (or iodine) in methylene chloride at 0°C. In contrast, the tetrasulfur pentanitride(−1) ion reacts smoothly with chlorine to give S_4N_5Cl, while the reaction with sulfuryl chloride produces S_4N_5Cl *and* S_5N_6 and the reaction with thionyl chloride produces a mixture of S_3N_2O, $S_3N_2O_2$, S_4N_4, and S_5N_6. Pentasulfur hexanitride is an air-sensitive, explosive, yellow-orange solid which sublimes at ca. 45°C/10^{-2} Torr without significant decomposition. It has been characterised by infrared, Raman, uv–visible, and mass spectra and by a single crystal X-ray structure determination. The crystals are monoclinic and belong to the space group $C2/c$, $a = 8.787(2)$, $b = 11.190(2)$, $c = 7.427(2)$ Å, $\beta = 106.46(2)°$, $V = 700.3(5)$ Å^3, $Z = 4$, $D_c = 2.317$ g cm^{-3}. The refined structure ($R_w = 0.040$) has twofold symmetry and resembles a basket in which an —N=S=N— unit (d(S—N) = 1.54 Å) is the handle which bridges an S_4N_4 cradle via S—N single bonds (d(S—N) = 1.70 Å). The introduction of this bridge widens one of the S---S transannular separations in S_4N_4 to 3.94 Å while the other is shortened to 2.43 Å. Thus, the S_4N_4 cradle can be viewed as two five-membered rings fused at the S—S bond.

T. CHIVERS et J. PROCTOR. Can. J. Chem. **57**, 1286 (1979).

On a préparé l'hexanitrure de pentasoufre, S_5N_6, avec de bons rendements par réaction du $[n\text{-}Bu_4N]^+[S_4N_5^-]$ avec du brome (ou de l'iode) dans le chlorure de méthylène à 0°C. Par ailleurs, l'ion pentanitrure de tétrasoufre (−1) réagit facilement avec le chlore pour donner le S_4N_5Cl alors que la réaction du chlorure de sulfuryle fournit du S_4N_5Cl *et* du S_5N_6 et que la réaction du chlorure de thionyle conduit à un mélange de S_3N_2O, $S_3N_2O_2$, S_4N_4 et S_5N_6. L'hexanitrure de pentasoufre est un solide jaune orange, sensible à l'air et explosif qui se sublime à environ 45°C/10^{-2} Torr sans se décomposer d'une façon importante. On l'a caractérisé grâce à ses spectres infrarouge, Raman, uv–visible et de masse et par une détermination de structure sur un cristal unique. Les cristaux sont monocliniques, groupe d'espace $C2/c$, $a = 8.787(2)$, $b = 11.190(2)$, $c = 7.427(2)$ Å, $\beta = 106.46(2)°$, $V = 700.3(5)$ Å^3, $Z = 4$, $D_c = 2.317$ g cm^{-3}. La structure affinée ($R_w = 0.040$) présente un axe de symétrie binaire et ressemble à un panier dans lequel une unité —N=S=N— (d(S—N) = 1.54 Å) est l'anse qui relie un S_4N_4 en cale par l'intermédiaire de liaisons simples S—N (d(S—N) = 1.70 Å). L'introduction de ce pont élargit une des séparations transannulaires S---S dans le S_4N_4 jusqu'à une valeur de 3.94 Å alors que l'autre est raccourci à 2.43 Å. On peut donc visualiser le S_4N_4 en cale sous la forme de deux cycles à cinq chainons reliés par une liaison S—S.

[Traduit par le journal]

Introduction

Although a number of sulfur nitrides have been known for many years (1), the development of their chemistry has, until recently, been slow and unsystematic. The central molecule of this chemistry is the tetramer, S_4N_4, which was first discovered in 1835 (2) but was not structurally characterised until 1963 (3). Thiazyl monomer, SN, is a radical with only a transient existence in the gaseous phase (1). The reactive, square planar dimer, S_2N_2, can be obtained by passing S_4N_4 vapor over silver wool and is an important precursor for the synthesis of polythiazyl, $(SN)_x$ (4, 5). This fascinating polymer and its halogenated derivatives have been the focus of attention of many of the recent studies of S—N compounds due to their metallic properties and superconducting behaviour (6, 7). The only other *unsaturated*[1] sulfur nitride known is S_4N_2, for which a structure with nitrogen atoms in the 1,3 positions of a six-membered ring has been established by a variety of physical techniques (8). However, the suggestion that the ring has a planar conformation awaits confirmation by X-ray crystallography (9).

In addition to these neutral molecules a rapidly growing number of binary S—N ions have been structurally characterised. The cations $S_3N_2^+$ (10), $S_4N_3^+$ (11), $S_4N_4^{2+}$ (12), $S_4N_5^+$ (13), and $S_5N_5^+$ (14) and the anions $S_3N_3^-$ (15) and $S_4N_5^-$ (16) belong to this group. As part of a study of the redox chemistry

[1]"Unsaturated" refers to sulfur nitrides in which the nitrogen atoms are two coordinate.

0008-4042/79/111286-08$01.00/0

of S_4N_5 cage species, we have investigated the oxidation of the $S_4N_5^-$ ion by halogens and certain halogen-containing reagents. We expected the formation of some novel halogenated sulfur nitrides. Instead, we found that pentasulfur hexanitride, S_5N_6, is a frequent product of these reactions. In this paper we describe the full details of various syntheses, the spectroscopic characterization and X-ray crystal structure determination of this new sulfur nitride (for a preliminary communication, see ref. 17).

Experimental

General Procedures

Acetonitrile, carbon tetrachloride, and methylene chloride were dried over phosphorus pentoxide and freshly distilled before use. All distillations of solvents and reagents and all reactions were carried out under nitrogen (99.99%; passed through Ridox and phosphorus pentoxide) or under vacuum. All glassware was flame-dried before use.

Chlorine (Matheson, 99.5%) and iodine (Fisher, resublimed grade) were used as received. Bromine (Baker) was stored over phosphorus pentoxide and potassium bromide before use. Thionyl chloride (Baker, bp 75–77°C) was purified by refluxing with linseed oil (10% by volume) for 2 h and was distilled prior to use. Sulfuryl chloride (Alfa, 99%) was distilled (large forerun discarded) and pumped under vacuum at room temperature until colorless before use. Sulfur dichloride (Matheson, Coleman and Bell, Technical) was doubly distilled under a static vacuum in a glass vacuum line from a vessel at 20°C to a receiver at −78°C. Sulfur monochloride (Alfa) was purified by distillation (large forerun discarded).

$Na^+S_4N_5^-$ was prepared from S_4N_4 and sodium azide in ethanol, and converted to n-$Bu_4N^+S_4N_5^-$ by treatment with tetra-*n*-butylammonium hydroxide (Eastman, 1 *M* in methanol) (18).

Instrumentation

Infrared spectra were recorded as Nujol mulls, using CsI windows (4000–250 cm^{-1}) or polythene discs (650–40 cm^{-1}),on a Perkin Elmer 467 spectrophotometer or a Digilab FTS 16 instrument, respectively. Raman spectra were obtained on samples sealed in glass capillaries under nitrogen using Argon (514.5 nm) and He/Ne (632.8 nm) lasers with a Jarrell-Ash spectrophotometer. Mass spectra were recorded on a Varian CH5 instrument operating at 70 eV. Ultraviolet–visible spectra were recorded for solutions made up in a Vacuum Atmospheres dry-box on a Cary 15 spectrophotometer. Elemental analyses were performed by Analytische Laboratorium, Engelskirchen, W. Germany. The X-ray crystal structure determination of S_5N_6 was carried out by Dr. Jan Troup of the Molecular Structure Corporation, TX.

The Synthesis of Pentasulfur Hexanitride, S_5N_6

(a) From the reaction of n-$Bu_4N^+S_4N_5^-$ *with Bromine*

Bromine (0.065 g, 0.404 mmol) in methylene chloride (30 mL) was added dropwise (20 min) with rapid stirring to a solution of n-$Bu_4N^+S_4N_5^-$ (0.284 g, 0.645 mmol) in methylene chloride (20 mL) at 0°C. After 5.5 h a *trace* of white precipitate was filtered off and shown to be an ammonium salt by its infrared spectrum. Partial removal of the solvent from the filtrate under vacuum produced an orange-yellow precipitate. The orange supernatant solution was decanted by pipette and the product was washed with cold (−20°C) methylene chloride. The product was recrystallised from methylene chloride at −78°C to give pentasulfur hexanitride (0.092 g, 0.376 mmol, 73% based on S). *Anal.* calcd. for N_6S_5: N 34.39, S 65.61; found: N 34.65, S 65.29.

CAUTION: It is strongly recommended that samples of S_5N_6 be handled in small quantities and with great care since the material will explode if subjected to friction, e.g., in the preparation of infrared mulls.

The infrared spectrum of S_5N_6 (Nujol) showed bands at 1306vw, 1193vw, 1088sh, 1066s, 1030s, 968w, 938s, 852s, 835w, 807vw, 694m, 648s, 621w, 573s, 554m, 500s, 463w, 433m, 418w, 388s, 327vw cm^{-1}. The Raman spectrum, obtained with either 514.5 or 632.8 nm excitation, showed bands at 1028s, 927w, 770w, 675s, 535m, 494w, 423s, 388w, 354w, 312w, 269vs, 225s, 160vs, and 130m cm^{-1}. Removal of solvent from the decanted orange solution yielded a red oil which became a dry yellow-orange powder after pumping in vacuo for 48 h at 23°C. This powder was identified as n-$Bu_4N^+Br_3^-$ by mp 69–70°C (lit: 72.5–74°C) and comparison of the infrared and Raman spectra with those of an authentic sample prepared by the literature method (19). The Raman spectra of both the product and the authentic sample of n-$Bu_4N^+Br_3^-$ in acetonitrile showed a strong band at 160 cm^{-1} corresponding to the ν_1 vibration of Br_3^- (cf. 162 cm^{-1} in $C_6H_5NO_2$ and 163 cm^{-1} in $CHCl_3$) (20). The far infrared spectrum showed a strong band at 194 cm^{-1} ($\nu_3(Br_3^-)$) cf. lit.: 193 cm^{-1} (20).

(b) From the Reaction of n-$Bu_4N^+S_4N_5^-$ *with Iodine*

Excess solid iodine (0.219 g, 0.842 mmol) was added to a stirred solution of n-$Bu_4N^+S_4N_5^-$ (0.098 g, 0.223 mmol) in methylene chloride (50 mL) at 23°C. After 4 h the solution was still dark purple. Slow removal of solvent *in vacuo* caused the precipitation of an orange solid as the solution cooled down. The supernatant solution was decanted by pipette and the product was washed with cold methylene chloride (3 mL), dried *in vacuo* for several hours and identified as pure S_5N_6 by comparison of its infrared and Raman spectra with those of an authentic sample. Removal of solvent and excess iodine *in vacuo* from the decanted solution yielded blue-black crystals identified as $Bu_4N^+I_3^-$ by mp 67.5–68°C (lit: 70–70.5°C) (21) and by comparison of its infrared and Raman spectra with those of an authentic sample prepared according to the literature (21). The Raman spectra of solutions in acetonitrile showed a strong band at 110 cm^{-1}, corresponding to the ν_1 vibration of I_3^- (cf. 104–108 cm^{-1} for other $R_4N^+I_3^-$ salts (R = Me, Et, *n*-Pr)) (22). The far infrared spectrum showed a strong band at 135 cm^{-1} ($\nu_3(I_3^-)$) cf. 132–138 cm^{-1} for other $R_4N^+I_3^-$ salts (22).

Reaction of $Na^+S_4N_5^-$ with Chlorine

Chlorine gas (0.041 g, 1.16 mmol) was condensed into a glass vessel containing $Na^+S_4N_5^-$ (0.125 g, 0.566 mmol) as a slurry in methylene chloride (25 mL). The reaction mixture was stirred at −78°C for 20 min. The white precipitate was filtered off and identified as sodium chloride containing a trace of unreacted $Na^+S_4N_5^-$. Solvent was removed from the filtrate and the greenish-yellow solid residue was pumped *in vacuo* for 10 h and then identified as pure S_4N_5Cl (0.060 g, 0.257 mmol) by comparison of its infrared spectrum with that of an authentic sample (13).

Reaction of $Na^+S_4N_5^-$ with Thionyl Chloride

Thionyl chloride (0.313 g, 2.64 mmol) in methylene chloride (25 mL) was added dropwise over 20 min to a slurry of $Na^+S_4N_5^-$ (0.569 g, 2.52 mmol) in methylene chloride (25 mL). The color of the solution became blood red im-

mediately. After completion of the addition, the solution was stirred for 30 min and the insoluble white solid, presumably sodium chloride, was filtered off. The volume of the filtrate was reduced to 5 mL *in vacuo*, and then the supernatant solution was decanted from the orange solid which precipitated as the solution cooled down. This product was washed with cold methylene chloride (3 × 2 mL) and, after drying at 35°C/10^{-2} Torr for 12 h, it was identified as pure S_5N_6 by its infrared spectrum.

Complete removal of solvent from the decanted filtrate produced a black residue containing yellow crystals. Sublimation of this residue at 25–30°C/10^{-2} Torr *for 1 h* gave bright yellow crystals of $S_3N_2O_2$ which had mp 95–96°C (lit: 100–101°C) (23) and an infrared spectrum, which showed bands at 1184vs, 1040s, 1017w, 998m, 685s, 658m, 507m, and 363s cm^{-1}, identical to that of a sample prepared by the method described by Brauer (24). Further sublimation at 30–40°C/10^{-2} Torr for several hours yielded S_4N_4, identified by its characteristic infrared spectrum.

After removal of S_5N_6 by crystallisation, the two products, $S_3N_2O_2$ and S_4N_4, are readily separated by the sublimation procedure described above if the $SOCl_2/Na^+S_4N_5^-$ molar ratio is slightly greater than one. However, when this ratio falls below one a fourth product, a red oil, is also formed. This oil sublimes readily at 20°C/10^{-2} Torr and was identified as S_3N_2O by comparison of its infrared spectrum with that of an authentic sample prepared by the method of Roesky and coworkers (25). The spectrum showed bands at 1180m, 1123m, 1107s, 1040sh, 972s, 749sh, 719s, 700sh, 660s, 580m, 557m, 495s, 387s, 377s, 321m cm^{-1}.

The *trace* of black residue which remains after removal of the other products by sublimation could not be identified. It consistently decomposed to S_4N_4 within 1–2 days on storage in a nitrogen atmosphere at room temperature.

Reaction of $Na^+S_4N_5^-$ with Sulfuryl Chloride

Sulfuryl chloride (0.092 g, 0.680 mmol) in methylene chloride (30 mL) was added dropwise over 15 min to a stirred slurry of $Na^+S_4N_5^-$ (0.151 g, 0.681 mmol) at 0°C. The colour of the solution became orange during the addition. After 2.5 h of stirring, the solution was filtered and solvent was removed from the filtrate to give a bright yellow powder shown by its infrared spectrum to be a mixture of S_5N_6 and S_4N_5Cl. Slow sublimation at 45–50°C/10^{-2} Torr gave S_5N_6, contaminated with a trace of black material, as the sublimate. The residue was S_4N_5Cl (infrared spectrum) (13).

X-ray Crystal Structure Determination

Crystal Preparation

A sample of S_5N_6, recrystallised from methylene chloride, was dissolved in carbon disulfide. Slow removal of solvent from this solution *in vacuo* yielded yellow prisms as the solution cooled down. The dimensions of the crystal used in this study were 0.15 × 0.15 × 0.20 mm. All manipulations were carried out under an atmosphere of dry nitrogen due to the sensitivity of S_5N_6 to oxidation by air.

Crystal Data

S_5N_6, $M = 244.36$, monoclinic. For calculation of cell constants, 25 reflections were computer-centered and the setting angles were refined by least-squares. The following systematic absences were observed: $h0l$, $l \neq 2n$. The cell constants are $a = 8.787(2)$, $b = 11.190(2)$, $c = 7.427(2)$ Å, $\beta = 106.46(2)°$, $V = 700.3(5)$ Å^3, $Z = 4$, $D_c = 2.317$ g cm^{-3}. The space group was $C2/c$, confirmed by refinement.

X-ray Measurements

The goniometer was mounted on an Enraf-Nonius CAD4 automated diffractometer under the control of a PDP 11/45 computer. Intensity data were collected at 23 ± 1°C using graphite monochromated MoK_α radiation ($\lambda = 0.71073$ Å) and a θ–2θ scan rate varying from 3 to 20°/min, depending on the intensity of the reflection. The scan range was from 2θ ($MoK_{\alpha 1}$) − 0.6° to 2θ ($MoK_{\alpha 2}$) + 0.6°. A counter aperture width of 2.0 mm, a crystal-to-detector distance of 21 cm, and an incident-beam collimator diameter of 2.0 mm were used in this study. Stationary-crystal stationary-counter background counts were taken at each end of the scan range. The ratio R of scan time to background counting time was 2.0. Of the 800 reflections collected in the range $0° < 2\theta(MoK_\alpha) < 60°$, 781 unique reflections with $I > 3\sigma(I)$ were retained as observed and corrected for Lorentz and polarization effects. Three representative reflections were measured periodically to check crystal and electronic stability, but no significant change in intensity was observed. The linear absorption coefficient of this compound is 15.24 cm^{-1} for MoK_α radiation and corrections for absorption, extinction, or changes in the intensity of the standard reflections were unnecessary.

Solution and Refinement of the Structure

The structure was solved by direct methods. Using 110 reflections ($E_{min} = 1.40$) and 1927 phase relationships, a total of 8 phase sets were produced. From an E-map prepared from the phase set showing the best probability statistics a total of 5 atoms were located. These atoms were included in least-squares refinement, resulting in agreement factors (defined below) of $R_1 = 0.26$ and $R_2 = 0.33$. The remaining atoms were located in succeeding difference Fourier syntheses. The structure was solved in space group Cc and later was determined to have two-fold symmetry so that it could be refined in the centrosymmetric space group $C2/c$.

In full-matrix least-squares refinement the function minimized was $\Sigma w(|F_o| - |F_c|)^2$ where the weight w is defined as $4F_o^2/\sigma^2(F_o^2)$. Scattering factors were taken from Cromer and Waber (26). Anomalous dispersion effects were included in F_c; the values of $\Delta f'$ and $\Delta f''$ were those of Cromer and Lieberman (27). Only the 630 reflections having $F_o^2 > 3\sigma(F_o^2)$ were used in the refinement. The following values pertain to the final cycle of least-squares refinement:

$$R_1 = \Sigma ||F_o| - |F_c|| / \Sigma F_o = 0.033$$

$$R_2 = [\Sigma w(|F_o| - |F_c|)^2 / \Sigma w F_o^2]^{1/2} = 0.040$$

For the six atoms studied, the number of variable parameters considered was 51. The esd of an observation of unit weight was then 1.102, while the maximum parameter shift was 0.03 times its esd.

The final difference Fourier map showed no significant residual electron density. Plots of $\Sigma w(|F_o| - |F_c|)^2$ versus F_o and $\lambda^{-1} \sin\theta$ showed no unusual trends. The final positional parameters and anisotropic thermal parameters are shown in Table 1. A list of observed and calculated structure factor amplitudes and a complete list of bond angles are available in the supplementary material.[2]

Results and Discussion

Preparation of Pentasulfur Hexanitride

The reaction of an excess of iodine with *n*-$Bu_4N^+S_4N_5^-$ in methylene chloride proceeds slowly at 23°C to give S_5N_6 and *n*-$Bu_4N^+I_3^-$. When bromine is used as the oxidizing agent, however, the

reaction takes place even at 0°C to yield S_5N_6 and n-$Bu_4N^+Br_3^-$. Both these synthetic routes produce pure S_5N_6 in good yield, but the reaction with bromine is preferred since it proceeds more quickly and the course of the reaction can be followed by observing the change in color of the solution from dark red to pale orange. It should be noted that small amounts of ammonium salts, identified by their infrared spectra, are also formed if the solvents are not scrupulously dry (cf. ref. 28).

In contrast, the reaction of a slurry of $Na^+S_4N_5^-$ in methylene chloride with chlorine at −78°C occurs rapidly to give S_4N_5Cl, which contains the cation $S_4N_5^+$ (13), and sodium chloride. Wolmershäuser and Street have recently pointed out (28) that bromination of S_4N_4 occurs in a different, and more complicated, manner from chlorination. The products depend markedly on the reaction conditions and either linear polymers of the type $(SNBr_y)_x$ (7, 29) or the cyclic compound $S_4N_3Br_3$ can be obtained (28). Both the linear and cyclic products contain the Br_3^- ion (28). It is apparent that the formation of the linear polymer involves an irreversible ring-opening of S_4N_4 (29), and in the reaction of S_4N_4 with *excess* bromine some evidence for the formation of the volatile monomer NSBr has been presented (28). In the present work, the conversion of $S_4N_5^-$ to $S_4N_5^+$ by chlorine can be viewed as a two electron oxidation which is manifested in the opening up of the unbridged S---S bond (2.71 Å) in the anion (16) to a non-bonding distance (ca. 4 Å) in the cation (13). It is possible that the reactions of $S_4N_5^-$ with the milder oxidizing agents, Br_2 and I_2, occur via a one electron oxidation to give the radical, $S_4N_5^{\bullet}$, but we have no evidence for this intermediate. Since a substantial rearrangement of the skeletal atoms occurs in the conversion of $S_4N_5^-$ to S_5N_6 further speculation on the reaction mechanism will be deferred until information of the dynamic behaviour of S—N cages in solutions is available from ^{15}N nmr studies.

The reaction of $Na^+S_4N_5^-$ with thionyl chloride at 0°C in methylene chloride was complex. In addition to sodium chloride, four products S_4N_4, S_5N_6, $S_3N_2O_2$, and S_3N_2O were separated and identified when the molar ratio $SOCl_2/Na^+S_4N_5^-$ was less than one. When this ratio exceeded one, S_3N_2O was not detected among the products possibly due to its conversion to $S_3N_2O_2$ by thionyl chloride, a reaction which was shown to occur in a separate experiment. Banister and Padley have reported that S_4N_4 reacts with thionyl chloride to give $S_3N_2O_2$ and S_4N_3Cl (30), but this cannot be the source of $S_3N_2O_2$ in the $S_4N_5^-/SOCl_2$ reaction since S_4N_3Cl was not identified among the products.

The reaction of sulfuryl chloride with $Na^+S_4N_5^-$ proceeded slowly to give a mixture of S_5N_6 and S_4N_5Cl, separable by sublimation. Presumably SO_2 was evolved during the reaction, since no sulfur–nitrogen oxides were obtained.

Physical Properties and Crystal Structure of Pentasulfur Hexanitride

Pure S_5N_6 ranges in color from yellow for powdered samples to orange for crystals. *The solid is explosive and great care should be taken to avoid friction or sudden heating when handling samples.* S_5N_6 can be sublimed without significant decomposition at 45–50°C/10^{-2} Torr, but the sublimate

[a]A complete list of bond angles is available as supplementary material (see footnote 2).

is accompanied by a trace of unidentified black material. A sample heated in a sealed capillary tube under nitrogen decomposed over the range 130–165°C. Analytically pure samples of S_5N_6 can be obtained by recrystallization from methylene chloride or carbon disulfide below 0°C, but decomposition of such solutions at 23°C is indicated by noticeable darkening during 12 h and exposure to air results in the immediate precipitation of a white ammonium salt (infrared spectrum). Solid samples of S_5N_6 can be stored for months in an inert atmosphere without significant decomposition but turn black within 2–3 min in air.

The structure of S_5N_6, determined by X-ray crystallography, is shown in Fig. 1. The important interatomic distances are shown in Table 2 and some selected bond angles have been included in Table 3. The structure resembles a basket in which an —N=S=N— unit (S(1)—N(1) = 1.54 Å) bridges two sulfur atoms of an S_4N_4 cradle via S—N single bonds (S(2)—N(1) = 1.70 Å). Within the cradle neither the variation of S—N distances (1.606–1.623 Å) nor the average S—N distance are significantly different from those found for S_4N_4 (1.619–1.633 Å) (31). The introduction of the bridge does, however, have a marked influence on the transannular S---S interactions of S_4N_4. One of the S—S distances (S(2)—S(2)′) is forced to open out to 3.93 Å while the other one becomes significantly shorter (S(3)—S(3)′ = 2.43 Å) than it is in S_4N_4 (2.58 Å (3), 2.59 Å (31)). As a result, the S_4N_4 cradle can be viewed as two fused five-membered rings, a structure

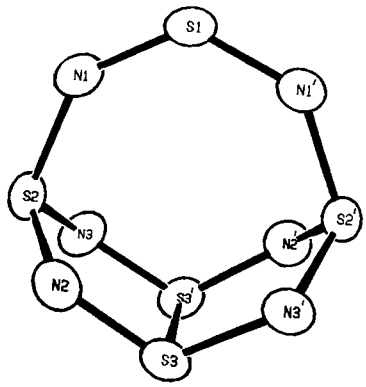

FIG. 1. X-ray structure of S_5N_6 showing symmetry related atoms labeled with primes.

which has been considered for $S_4N_4^{2+}$ (32) but has not been found in practice. It is now well established that a variety of derivatives of the five-membered S_3N_2 ring (33, 34), are obtained from the reactions of S_4N_4 with various oxidizing agents. Moreover, the mechanism proposed for the formation of $S_3N_2^+$ by the oxidation of S_4N_4 with arsenic pentafluoride invokes the formation of S_3N_2 rings after the loss of one electron by S_4N_4 (10). Thus, the incipient formation of five-membered rings in S_5N_6 is particularly significant.

Table 4 summarizes the least-squares planes and the dihedral angles between various planes in S_5N_6. From this data it can be seen that the almost planar group of atoms S(2)N(1)S(1)N(1)′S(2)′ is at 87–88° to the planes containing N(2)S(3)S(3)′N(3) and

N(2)′S(3)′S(3)N(3)′. The sulfur atoms S(2) and S(2)′ are a significant distance (0.36 and 0.39 Å, respectively) out of the latter two planes.

It is obvious from Fig. 1 that certain atoms in S_5N_6 are related by a C_2 symmetry axis which passes through S(1) and bisects S(3)—S(3)′. An alternative view of S_5N_6 is to consider S(2) and S(2)′ as the apical atoms of a distorted trigonal bipyramid (tbp) of sulfur atoms. Thus, the equatorial atoms would be S(1), S(3), and S(3)′. The six edges of the tbp joining axial and equatorial sulfur atoms are bridged by nitrogen atoms, while the three edges connecting equatorial sulfur atoms are unbridged. It is clear from inspection of a model that three equivalent configurations of S_5N_6, in which the atomic groups N(1)S(1)N(1)′ or N(2)S(3)N(3)′ or N(3)S(3)′N(2)′ alternately occupy the bridge position, could exist. Thus, *in solution* this S—N cage could exhibit fluxional behaviour with these three configurations as the interconverting forms. ^{15}N nmr studies would be

extremely useful in providing information on this point.

Bonding in Pentasulfur Hexanitride

Different approaches to a description of the bonding in electron-rich S—N cages have been reported in the literature. Banister has suggested that the bonding in S_4N_4 can be satisfactorily rationalized in terms of localized two centre bonds (35). Thus, the 44 valence electrons of S_4N_4 are allocated to lone pairs on each of the sulfur and nitrogen atoms, a bond pair to each S—N linkage and the remaining six electron pairs to the six S—S bonds of the S_4 tetrahedron. In preliminary communications (13, 17) we have adopted this approach to rationalize the structures of $S_4N_5^-$, $S_4N_5^+$, and S_5N_6. In contrast, molecular orbital calculations (36) allow only two transannular S—S bonds in S_4N_4 and assign the additional four electron pairs to non-bonding electron pairs on the nitrogen atoms (36*b*). Very recent *ab initio* Hartree Fock Slater SCF calculations on S_4N_4 support the view of only two S—S bonds in S_4N_4, the presence of only one S—S bond in $S_4N_5^-$, and no S—S bonds in $S_4N_5^+$ (37). A full account of these calculations is in preparation.

Spectroscopic Characterization of Pentasulfur Hexanitride

The uv–visible spectrum of S_5N_6 (in CH_2Cl_2) shows two smooth absorption bands at λ_{max} 375 (ε ca. 5×10^3 L mol^{-1} cm^{-1}) and 250 nm (ε ca. 6×10^4 L mol^{-1} cm^{-1}). The mass spectrum obtained at an ionizing voltage of 70 eV and probe temperature of 70°C showed no parent ion peak. Strong peaks at *m/e* 92 ($S_2N_2^+$), 78 (S_2N^+), 64 (S_2^+), and 46 (SN^+), in addition to a medium intensity peak at 138 ($S_3N_3^+$; cf. S_4N_4 (38)) and very weak peaks at 184 ($S_4N_4^+$) and 198 ($S_4N_5^+$) were observed. The infrared and Raman spectra of S_5N_6 are summarized in the Experimental section. Certain structural features of S_5N_6 should give rise to characteristic bands in the vibrational spectra. For example, the short bonds of the —N=S=N— bridge should give rise to infrared bands at relatively high frequencies. Thus, the strong bands at 1066 and 1030 cm^{-1} can probably be assigned to the asymmetric and symmetric stretching vibrations, respectively, of the —N=S=N— unit. The latter band shows a coincidence in the Raman spectrum (1028s cm^{-1}) as expected for a symmetric vibration. The S—S bond, S(3)—S(3)′, should exhibit a very strong band in the Raman spectrum and a frequency of <300 cm^{-1} can be predicted from the bond length of 2.43 Å (39). Thus, the band at 269 cm^{-1} is tentatively assigned to ν(S—S) (cf. 213 cm^{-1} for ν(S—S) in S_4N_4) (40).

Conclusions

Pentasulfur nitride is readily obtained in good yield by the oxidation of the $S_4N_5^-$ ion with Br_2 or I_2. This novel sulfur nitride has a structure in which an —N=S=N— unit bridges two sulfur atoms of an S_4N_4 cradle. The unexpected discovery of S_5N_6 provides an alternative starting point for the attempted synthesis of hitherto unsuspected sulfur–nitrogen cage species or linear polymers.

Acknowledgements

We are grateful to the National Research Council of Canada for financial support and, in particular, to Dr. Jan Troup of the Molecular Structure Corp., who carried out the X-ray crystal structure determination of S_5N_6. We also wish to thank Drs. R. Kydd and C. Lau for assistance in obtaining the Raman spectra and Mr. T. Smithson for recording the far infrared spectra.

Received June 26, 1978

MOHAMED M. GHONEIM and MOHAMED A. A. ASHY. Can. J. Chem. **57**, 1294 (1979).

The polarographic reduction of phenolphthalein, cresolphthalein, thymolphthalein, and α-naphtholphthalein has been studied in ethanolic Britton–Robinson buffer series (pH 2–12), non-aqueous ethanolic medium, and water–ethanol mixtures. The compounds are reduced through a single $2e^-$ wave in non-aqueous medium and aqueous buffered solutions of pH < 9 or $1e^-$ steps for pH > 9. The nature of the waves, mechanism of the electrode reaction, and kinetic parameters has been considered.

MOHAMED M. GHONEIM et MOHAMED A. A. ASHY. Can. J. Chem. **57**, 1294 (1979).

On a étudié la réduction polarographique de la phénolphtaléine, de la crésolphtaléine de la thymolphtaléine et de l'α-naphtolphtaléine dans une série de tampons éthanoliques de Britton–Robinson (pH 2 à 12), dans un milieu éthanolique non-aqueux et dans des mélanges eau–éthanol. La réduction des composés, dans les milieux non-aqueux et dans des solutions aqueuses tamponnées à des pH < 9, se produit au cours d'une vague unique impliquant $2e^-$ ou par des étapes de $1e^-$ pour des pH > 9. On a considéré la nature des vagues, le mécanisme de la réaction à l'électrode et les paramètres cinétiques.

[Traduit par le journal]

Introduction

Phenolphthalein and related compounds in solution were considered by Kolthoff (1) to exist in different hydration and ionic forms in equilibrium. It was concluded that the lactone form of phenolphthalein (2) is not reducible at the dropping mercury electrode, at least not at potentials less negative than that at which the wave of the supporting electrolyte appeared. The hydrated forms are reduced along a single two-electron reduction wave. The reduction of the red form, however, occurred in two one-electron steps. No thorough investigation of polarographic work on the phenolphthalein derivatives is available, also the exact mechanism of the polarographic reduction of phenolphthalein is not completely understood. The main reason is that the nature of the species present in aqueous solutions of different pH values is not known, and that there is no hard evidence for the existence of the forms participating in its colour change. A comprehensive study on the kinetics and mechanism of electroreduction of phenolphthalein or its derivatives is lacking in literature.

In the present study, we report the current–voltage curves of four phenolphthaleins in aqueous and nonaqueous ethanolic solutions as well as an attempt made to clarify the nature of the waves and to evaluate the kinetics of the electrode process.

Experimental

Stock solutions (10^{-2} mol L^{-1}) of phenolphthalein, cresolphthalein, thymolphthalein, or α-naphtholphthalein were prepared by dissolving the compounds (AR grade) in purified ethanol. The polarographic behaviour of these compounds was studied (*a*) in Britton–Robinson (3) buffer series of pH 2–12 containing different percentages of ethanol (25–35 vol%); (*b*) in non-aqueous ethanolic solution, and (*c*) in water–ethanol mixtures. In the media (*b*) and (*c*), 0.1 *M* LiCl was used as a supporting electrolyte. Ethanolic solutions of benzoic acid and sodium hydroxide, respectively, were used as proton-donor and as a base in the case of non-aqueous medium (*b*).

The prepared depolarizer solution (1.25 mL) was placed in a 25 mL calibrated flask and brought to the mark by adding solutions (*a*), (*b*), or (*c*) so that the final solution had 5×10^{-4} *M* of the depolarizer. The test solution was then transferred to the polarographic cell then deaerated with pure argon. An inert atmosphere was maintained over the solution during the reduction.

The polarograms were recorded with a pen recording Radiometer Polarograph (Polariter PO4 g). The electrode assembly E64 with a SCE (K 505) as anode and the dropping mercury electrode as cathode was used. The capillary characteristic in 0.1 *M* KCl (open circuit) were: $t = 3.54$ s drop^{-1} and $m = 2.575$ mg s^{-1} at a mercury height of 50 cm. A Corning research pH-meter, Model 12 accurate to ±0.01 pH unit, was used. All the potentials are referred to SCE at 25°C.

Owing to the limiting solubility of these compounds in aqueous buffered solutions, the measurements were carried out in solutions containing at least 25 vol% of ethanol to keep the compounds in solutions.

Results and Discussion

(*A*) *Behaviour in Aqueous Buffered Solutions*

Considering the number of waves observed at various pH values (2–12) and the variation of the

0008-4042/79/111294-05$01.00/0

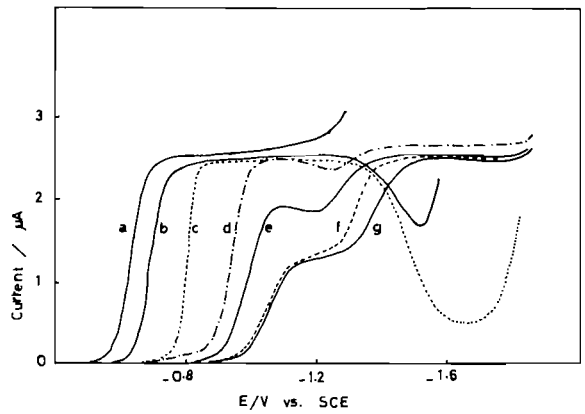

FIG. 1. Polarograms of 5×10^{-4} *M* cresolphthalein in 25 vol% ethanolic aqueous buffered solutions of pH: (*a*) 2.89; (*b*) 4.5; (*c*) 7.02; (*d*) 9.79; (*e*) 10.3; (*f*) 11.0; and (*g*) 11.51.

limiting current with pH, three polarographic trends are observed (cf. Fig. 1).

(*a*) In solutions of pH values < 8.5, a single $2e^-$ wave is observed, its height being pH-independent (e.g. Fig. 1, curves *a–c*). At pH values 3.5 to 8.5, the limiting current decreased to a minimum value in the potential range of about -1.6 to -1.7 V. However, before the flat minimum is attained, the wave of the supporting electrolyte appeared (2). The $E_{1/2}$–pH dependence of the single wave denotes that the H^+ ions are involved in the electrode reaction.

(*b*) In solutions of pH 8.5 to 10.5, two reduction waves of unequal heights are observed (e.g. Fig. 1, curves *d* and *e*). The height of the second wave gradually increases at the expense of the first one with increasing pH until both attain equal heights at pH values $\geq$ 10.5. The plots of i_1 as a function of pH for both waves yield typical dissociation and association curves. This behaviour indicates that the electrode reaction is governed by the rate of proton transfer which becomes slower at higher pH values. The descending or ascending parts of the i_1–pH curves shift to lower pH values in the presence of an increasing amount of ethanol (25–35%). This means that the rate of proton transfer becomes slower as the polarity of the medium is lowered.

(*c*) In media of pH values above 10.5, two $1e^-$ waves of equal height are obtained. The $E_{1/2}$ of the second wave is pH-dependent whereas that of the first wave is not (Fig. 1, curves *f* and *g*).

(*B*) *Behaviour in Non-aqueous Ethanolic Medium or Water–Ethanol Mixtures*

In 99.7% ethanolic solutions, phenolphthalein and its derivatives are reduced through a single two-electron wave (Fig. 2*A*, curve *a*); its height equalling that of the wave obtained in aqueous buffered

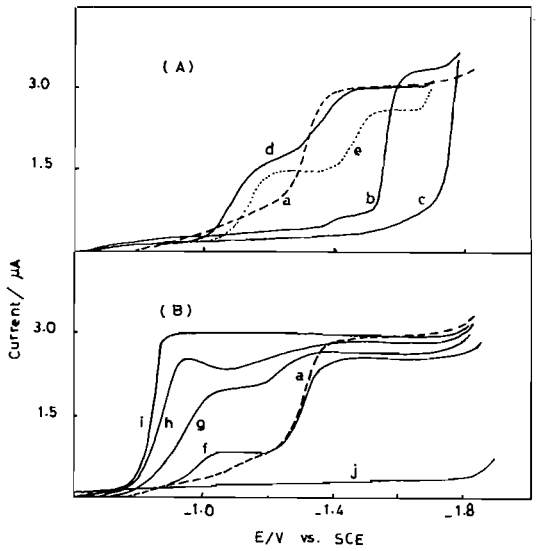

FIG. 2. Polarographic wave of 5×10^{-4} *M* phenolphthalein in non-aqueous ethanolic solution (curve *a*). (*A*) Effect of benzoic acid and sodium hydroxide on wave (*a*): (*b*) 10^{-4}, (*c*) 4×10^{-4} *M* benzoic acid; and (*d*) 10^{-3}, (*e*) 1.1×10^{-2} *M* NaOH. (*B*) Effect of increasing proportion of water in the ethanolic medium on wave (*a*): (*f*) 48; (*g*) 68; (*h*) 75; (*i*) 87 vol% water, and (*j*) residual current (non-aqueous).

solutions of pH < 8.5. The $E_{1/2}$ of this wave lies at more negative potential (-1.31 V) due to decreased availability of protons in non-aqueous ethanolic medium. The height of the wave is also proportional to the concentration of the depolarizer in solution.

The addition of benzoic acid, as a proton-donor, to ethanolic solution of phenolphthalein or its derivatives causes retardation, then complete elimination of the reduction wave (Fig. 2*A*, curves *b* and *c*). On the other hand, addition of sodium hydroxide turned the solution red and gave rise to polarograms of two one-electron waves similar to those obtained in aqueous buffered media of pH > 9 (Fig. 2*A*, curves *d* and *e*). This behaviour indicates that the presence of acid or base, respectively, leads to the formation of the non-reducible lactone form (I) or the electroactive red forms (V and VIII) through an acid–base equilibrium.

In water–ethanol mixtures, the polarograms (Fig. 2*B*) show the development of a prewave, at more positive potentials, on increasing the water percentage (Fig. 2*B*, curves *f–i*). This prewave attains the full height of the original polarogram when the media contain at least 80 vol% of water. This wave is preceded by a maximum, but this is easily eliminated when the solution is made 10^{-4}% with respect to Triton X-100. Enhancement of the reduction on increasing the water content in the medium is due to

[a] $S_1 = \Delta E_{d,e}/\Delta \log i/(i_d - i)$; $S_2 = \Delta E_{1/2}/\Delta pH$.

the increased availability of protons (from water) in a medium which is still more or less neutral. Also the addition of water facilitates the transformation of depolarizer molecules from the non-reducible lactone form (I) to the reducible hydrated form (II*a*).

These results support the idea (2) that the lactone form (I) is not reducible at the dropping mercury electrode at least at potentials more positive than that at which the wave of the supporting electrolyte appears.

Nature of the Waves

The effect of pressure at mercury head on the limiting current showed that the reduction process of the four depolarizers is mainly diffusion-controlled with a small kinetic contribution. The value of the exponent x in the relation i_l = constant $\times$ h^x amounts to 0.45–0.5.

Analysis of the waves applying the fundamental equation for polarographic waves (4) indicated that the reduction process proceeds in an irreversible manner. The values of transfer coefficient (α) and αn_a are determined from the slopes (S_1) of E_{de} vs. log $i/(i_d - i)$ plots at different pH values (Table 1). The most probable α-values are obtained for $n_a = 2$ at pH < 8.5 and $n_a = 1$ for the pH range above 10.5.

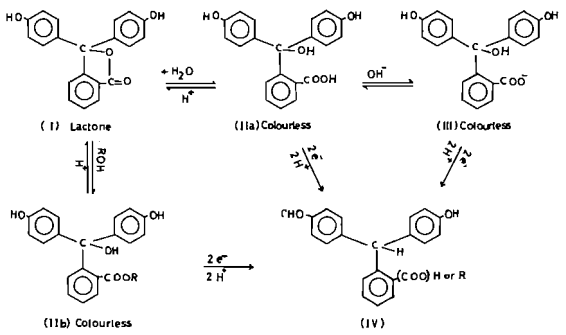
The $E_{1/2}$–pH plots of the first and second waves for the different depolarizers consist of three or two segments, respectively (Fig. 3). The breaks in these plots lie at pH values of ~8.5 and ~10.5 which correspond to those at which the reduction behaviour is changed. The number of protons (Z_{H^+}) participating in the rate-determining step is determined by using the relation:

$$Z_{H^+} = (\Delta E_{1/2}/\Delta pH)\,(\alpha n_a/0.059) = S_2/S_1$$

and is found to be, approximately, one (Table 1). Accordingly, the rate-determining step of the electrode process would involve one proton and two electrons (pH < 8.5) or one proton and one electron (pH ≥ 10.5). For intermediate pH values (8.5–10.5) both sequences are contributing in varying proportions.

According to the foregoing results, the reduction of any of the depolarizers under study at the electrode surface can be explained by the following schemes:

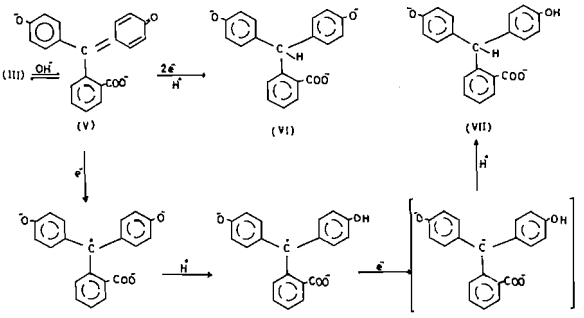
(*a*) In aqueous solutions of pH < 8.5 and non-aqueous media (Scheme 1)



SCHEME 1

The dominant species within these media is II*a* and III (aqueous) or II*b* (non-aqueous) forms (5); each one can be reduced through a two-electron step.

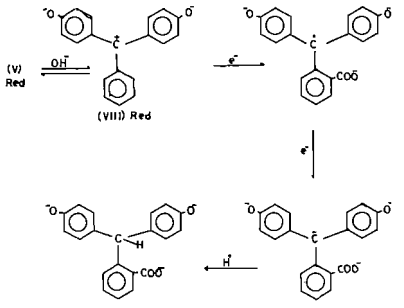
(*b*) In solutions of pH values 8.5–10.5 (Scheme 2)



SCHEME 2

The number of protons participating in the electrode process is, approximately, one (first wave); the second small wave is slightly pH-dependent. The processes according to Scheme 2 are considered to compete within this pH range.

(*c*) In solutions of pH values > 10.5 (Scheme 3)



SCHEME 3

The $E_{1/2}$ of the first step is independent of pH while that of the second step is pH-dependent. The mechanism is shown in Scheme 3.

The Electrode Reaction

The polarographic behaviour of the depolarizers in buffer solutions indicates that they belong to the category of organic compounds where $E_{1/2}$ and i_l are pH-dependent. The change of the reduction current with the pH of the medium leading to the splitting of the reduction wave was explained by Zuman (6). The main factors considered to govern the current changes are:

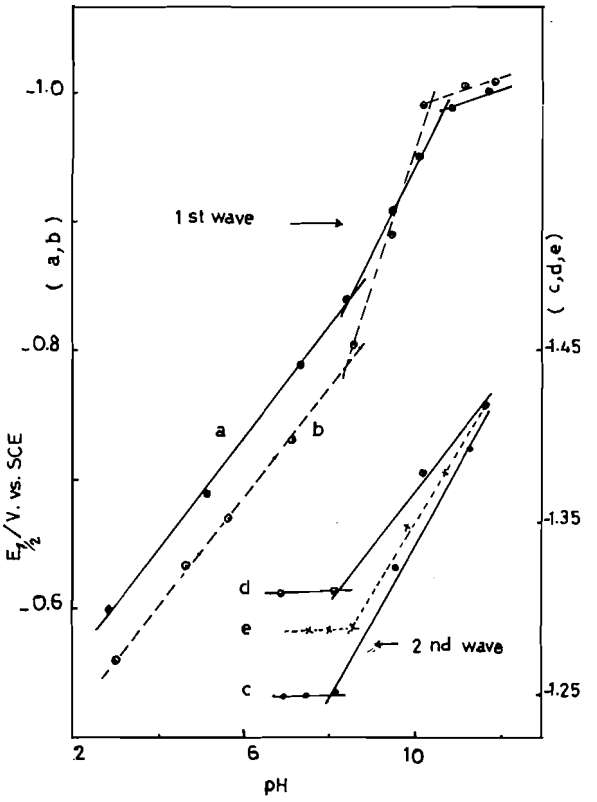


FIG. 3. $E_{1/2}$–pH curves of phenolphthalein (*a* and *c*); α-naphthalphthalein (*b* and *d*) and cresolphthalein (*e*). Curves *c*, *d*, and *e* are shifted three pH units to the right side of the scale.

(*i*) The existence of an acid–base equilibrium:

$$BH^- \underset{k_r}{\overset{k_d}{\rightleftharpoons}} B^{2-} + H^+$$

for which the variation of the current with pH is governed by the relation (7):

$$[1] \quad pH = \log 0.886\left(\frac{k_r t_1}{K}\right)^{1/2} + \log\left(\frac{i_l - i_{HB^-}}{i_{HB^-}}\right)$$

which is a modified form of the Koutecky equation (8).

(*ii*) Change of current due to chemical transformation. The probable chemical transformation with increasing pH in analogy to the case of fluorescein (9) is the formation of triphenyl carbonium ion

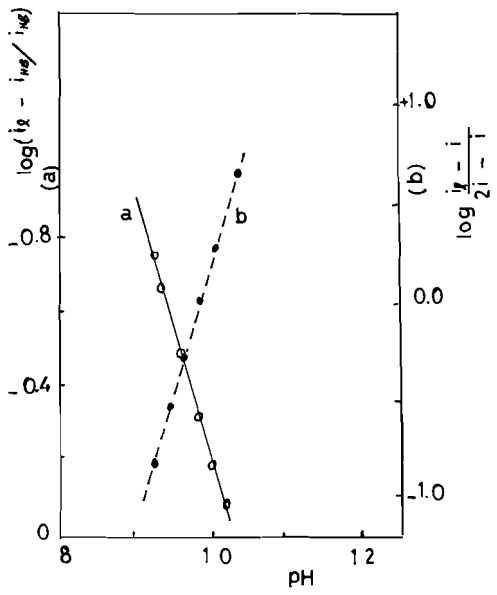

FIG. 4. Application of eqs. [1] and [2] for phenolphthalein.

(V $\rightleftharpoons$ VIII), the reduction of which proceeds to a free radical through one electron, whereas the overall reduction process corresponds to two electrons.

(*iii*) The existence of two electroactive forms which differ in the number of electrons consumed in the electrode reaction. In this case, the change of current with pH should follow the relation (6, 7):

$$[2] \quad \mathrm{pH} = \log 0.886\left(\frac{k_r t_1}{K}\right)^{1/2} - \log\left(\frac{i_1 - i}{2i - i_1}\right)$$

The plots of log $[(i_1 - i_{HB^-})/i_{HB^-}]$ or log $[(i_1 - i)/(2i - i_1)]$ vs. pH yield straight lines (e.g. Fig. 4), indicating the validity of eqs. [1] and [2].

Accordingly it may be concluded that the change in the reduction current of the depolarizers under investigation would depend on the three mentioned factors, which recalls the case of fluorescein (7).

According to the above findings, the electrode sequence for the reduction of the compounds under investigation in buffered solutions can be given as follows:

$$[3a] \quad (\mathrm{P})_{ox}^{-} + e^{-} \xrightarrow{E_1} P_1^{-2}$$

$$[3b] \quad P_1^{-2} + H^{+} \overset{K_1}{\rightleftharpoons} P_1H^{-} \text{ (pH-dependent)}$$

$$[4a] \quad P_1H^{-} + e^{-} \xrightarrow{E_2} P_2^{-2}$$

$$[4b] \quad P_2^{-2} + H^{+} \overset{K_2}{\rightleftharpoons} \text{Reduction product (pH-dependent)}$$

Processes [3*a*]–[4*b*] occur at lower pH values (<8.5) through one two-electron step. As the pH increases the protonation step [3*b*] slows down and the second reduction step [4*a*] is attained at higher potential, leading to separation of the two steps ($E_1 \neq E_2$). The lowering of i_1 at the first wave is due to slowed rate of protonation of the intermediate radical anion (P_1^{2-}).

Values of kinetic parameters ($k_{f,h}^0$, ΔG^*, αn_a, and α) of the electrode reaction were calculated as explained previously (10–12). The values of rate constant ($k_{f,h}^0$) are smaller than 3×10^{-5} cm/s denoting an irreversible process. On increasing pH of the medium $k_{f,h}^0$ decreases and energy of activation (ΔG^*) increases (Table 1), denoting a more difficult electron transfer and consequently a more difficult reduction process.

The oxidation of various diazirines by *m*-chloroperoxybenzoic acid as well as the activation parameters for these reactions have been investigated. The oxidation products and the information derived from kinetic studies indicate that the oxidation does not take place on the diazirine ring as expected but rather on the decomposition products of the diazirines. The oxidation products obtained are shown to be characteristic of the diazirine decomposition by carbenic and diazo pathways and thus the measurement of the oxidation products provides a measure of the partitioning of the two reaction pathways for diazirine decomposition.

MICHAEL T. H. LIU et IWAO YAMAMOTO. Can. J. Chem. 57, 1299 (1979).

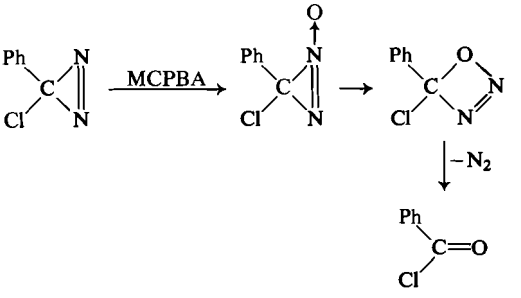
On a étudié l'oxydation de diverses diazirines par l'acide *m*-chloroperbenzoïque de même que les paramètres d'activation de ces réactions. Les produits d'oxydation et l'information que l'on tire des études cinétiques indiquent que l'oxydation ne se produit pas sur le cycle diazirine tel qu'attendu mais plutôt sur les produits de décomposition des diazirines. On montre que les produits d'oxydation obtenus sont caractéristiques de la décomposition de la diazirine par des voies carbéniques et diazo et la mesure des produits d'oxydation fournit donc une mesure de la repartition entre les deux voies réactionnelles pour la décomposition de la diazirine.

[Traduit par le journal]

Introduction

The chemistry of diazirines has been characterized by the facile thermal decomposition which generates carbenes (1–4), and generally low reactivity when compared with the linear isomers (5). Schmitz (4, 5), Lau (6), and more recently Bradley, Evans, and Stevens (7) have shown diazirines to be insensitive towards a wide range of compounds. The direct oxidation of the nitrogen–nitrogen double bond of the diazirine system is not known but the ozonisation of methyl-vinyldiazirine has been reported (8). The product of this oxidation process was an etherhydroperoxide which contained the original three member ring. It was hoped that in the present experiments the unknown azoxy analog could be made so that a new class of compounds would be available; the kinetic and mechanistic implications would be obvious. As well, extensive *ab initio* SCF-MO calculations with a double-zeta basis set of Gaussian type orbitals have been carried out for diazirine and diazirine *N*-oxide (9).

The present paper is an extension of previously reported work (10) in which the oxidation of chlorophenyldiazirine by *m*-chloroperoxybenzoic acid (MCPBA) gave benzoyl chloride. The results suggested that the *N*-oxide of the diazirine may be generated but that it decomposes under the conditions of the reaction. The formation of benzoyl chloride in the chlorophenyldiazirine oxidation was rationalized by the following mechanism:



It is to be noted that an intermediate, 1,2,3-oxadiazete, is formed prior to the formation of benzoyl chloride. This mechanism receives some support from the work of Snyder *et al.* (11) on the oxidation of diazobasketene with MCPBA to give the *N*-oxide which rearranged readily in boron trifluoride etherate. In view of the considerable interest in this area of chemistry, we decided to investigate the oxidation of several diazirines by various oxidants and in particular by MCPBA. Kinetic studies on the oxidation of phenyl-*n*-butyldiazirine and chlorophenyldiazirine by MCPBA in various solvents were also conducted.

Results and Discussion

The reactivity of diazirine towards a range of

[1]On sabbatical leave (1977–1978) from Department of Chemistry, Shinshu University at Ueda, Nagano 386, Japan.

0008-4042/79/111299-05$01.00/0

oxidants has been examined. Chlorophenyldiazirine is recovered almost unchanged after treatment with basic hydrogen peroxide and peracetic acid. The negative results with the above oxidants may at first appear to result from the milder reaction temperature as compared with the positive results with MCPBA. It will be shown later in this discussion that the negative results are really due to the inertness of the diazirine ring and not at all due to the effect of temperature. As well the relative degree of the oxidizing powers of the reagents used has no effect. The thermal decomposition of phenyl-*n*-butyldiazirine (**1**) in DMSO solvent has been investigated in detail by us and the intermediate formation of the diazo compound, 1-phenyl-1-diazopentane has been detected and the intermediate has been isolated. The decomposition of **1** and the subsequent decomposition of its product, 1-phenyl-1-diazopentane to give *cis* and *trans* 1-phenyl-1-pentenes (ratio *cis*:*trans* = 1:5) provide an interesting illustration of consecutive reactions (12).

In the oxidation of **1** by MCPBA in chlorobenzene and in 1,2-dichloroethane solvents, the products were *cis* and *trans* 1-phenyl-1-pentene oxides and valerophenone. In the oxidation reaction it was noted that the color of the solution was yellowish throughout the experiment and the characteristic red-color due to the formation of the diazo intermediate was not observed. As we could see no red color, we were led to believe that the oxidation was indeed taking place on the diazirine ring. If this were the case, the formation of the four-atom ring, 1,2,3-oxadiazete would be inevitable. This particular four-atom ring has been postulated in the decomposition of nitrosoimines (13) but has not been isolated. In view of its similarity to the 1,2-dioxetane system (14, 15), we were hoping that the 1,2,3-oxadiazete ring would produce excited carbonyl molecules (excited valerophenone in this case) which would luminesce. However, since the photo product acetophenone from valerophenone (resulting from a Norrish type II reaction) was not found in the above oxidation experiment, it was decided that the proposed mechanism would have to be examined more carefully.

Up to this point, we could not provide sufficient evidence to propose an unequivocal mechanism for the oxidation of diazirines. We have extended our investigation to determine the activation parameters for the oxidation of **1** by MCPBA in chlorobenzene and in 1,2-dichloroethane. In all kinetic experiments the concentrations of diazirine and MCPBA were both 0.05 *M* in chlorobenzene and in 1,2-dichloroethane, respectively. The results for the oxidation of **1** in chlorobenzene by MCPBA show that the reaction is not second-order as expected but rather the reaction is first-order. In fact, the first-order plot gave an excellent straight line even up to 80% reaction. Similar results were obtained for the reaction of **1** and MCPBA in 1,2-dichloroethane. Also, the first-order rate constants determined by N_2 evolution and separately by a uv spectrophotometric method agreed within 4%. The first-order rate constants for these reactions are tabulated in Table 1 and the oxidation products in various solvents are given in Table 2. The first-order rate constant at 99.8°C for the reaction of equimolar concentration of **1** and MCPBA in chlorobenzene was 6.31×10^{-4} s^{-1}. Additional experiments at the same temperature with a four-fold increase in MCPBA gave 6.50×10^{-4} s^{-1}. It is evident that the rate of reaction is not a function of MCPBA concentration. From the least-squares analysis of the rate constants in Table 1, the following activation parameters for **1** were obtained: in chlorobenzene, $\Delta H^{\ddagger} = 27.0$ kcal mol^{-1}, $\Delta S^{\ddagger} = -1.2$ cal deg^{-1} mol^{-1} and in 1,2-dichloroethane, $\Delta H^{\ddagger} = 27.6$ kcal mol^{-1}, $\Delta S^{\ddagger} = 0.74$ cal deg^{-1} mol^{-1}. Examination of these parameters reveals that they are merely the parameters for the decomposition of phenyl-*n*-butyldiazirine, the values of which have been reported already (12). When further kinetic studies were carried out using chlorophenyldiazirine and MCPBA in 1,2-dichloroethane, good first-order plots were obtained over the temperature range of 50–70°C. The following activation parameters for chlorophenyldiazirine were derived: $\Delta H^{\ddagger} = 25.8$ kcal mol^{-1} and $\Delta S^{\ddagger} = 1.7$ cal deg^{-1}

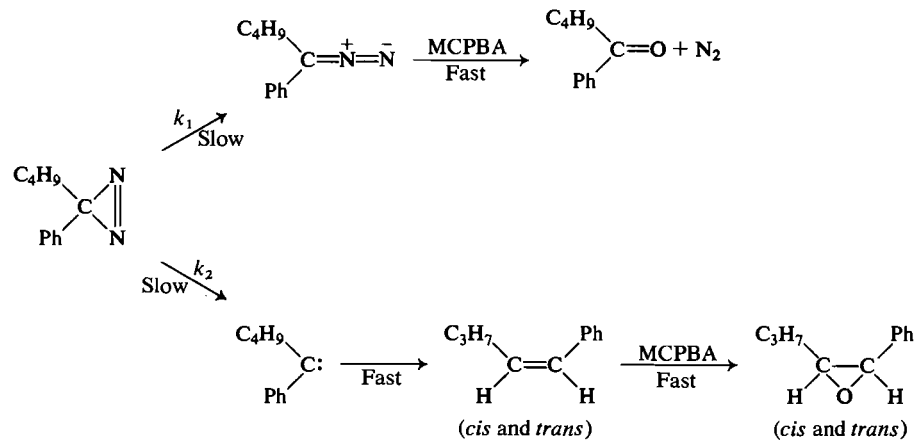
*Diazirine/MCPBA = 1/4.

mol^{-1}, in agreement with our earlier finding (16). These various kinetic results suggest that the oxidation by MCPBA does not take place on the ring but rather on the products of the decomposition. If the diazirine *N*-oxide were to be made, it would probably require a new synthetic route.

In order to account for the products of the reaction the following mechanism is postulated:



In pathway [1], the diazirine is isomerized to diazomethane which is rapidly consumed by MCPBA to give the corresponding ketone. In a control experiment, we have synthesized 1-phenyl-1-diazopentane independently and reacted it with MCPBA in chlorobenzene at room temperature, the distinct red-color of the diazo compound was completely removed in a few seconds with vigorous evolution of nitrogen. This result shows that the reaction requires little or no activation energy.[2] Analysis showed that valerophenone was the only product and therefore, 1-phenyl-1-diazopentane does not react with MCPBA to yield 1-phenyl-1-pentene or 1-phenyl-1-pentene oxide.

In pathway [2], the diazirine decomposes directly to give a carbene intermediate which rearranges to *cis* and *trans* 1-phenyl-1-pentenes which in turn are further oxidized to *cis* and *trans* 1-phenyl-1-pentene oxides by MCPBA. In a separate experiment conducted by heating a mixture of *cis* and *trans* 1-phenyl-1-pentenes (*cis*:*trans* = 1:10.8) and MCPBA in chlorobenzene at 100°C for 40 min, the products were *cis* and *trans* 1-phenyl-1-pentene oxides (*cis*:*trans* = 1:11.3). This indicates that all the *cis*-olefin is converted to the *cis*-epoxide and *trans*-olefin

[2]This conclusion is substantiated by the reaction of peroxybenzoic acid (in 1,2-dichloroethane) with diazodiphenylmethanes (ref. 17) for which the activation parameters were found to be $\Delta H^{\ddagger} = 5.8$ kcal mol^{-1}, $\Delta S^{\ddagger} = -40.0$ cal deg^{-1} mol^{-1}.

to *trans*-epoxide. This conclusion was again supported by the epoxidation of *trans*-stilbene with MCPBA which was shown to be a fast reaction even at room temperature (18). Thus the yields of the epoxides and of the ketones provide a measure of the partitioning of the two reaction paths. Our experiments show that in the decomposition of phenyl-*n*-butyldiazirine in chlorobenzene, MCPBA can be used as a trapping agent for the intermediate formation of olefin and for the diazo compound. The yields of the epoxides and of the valerophenone are approximately 50% each. This is to say that the decomposition of **1** in chlorobenzene is 50% carbenic and 50% via the diazo process. The percentage by each pathway does not appear to be very sensitive to temperature since the product ratio of ketone to epoxides is approximately the same at all temperatures (somewhat large values occur at the lowest temperatures). It was found that the ketone to epoxides ratio did not vary, even for a 4-fold increase in MCPBA concentration. In another non-polar solvent such as 1,2-dichloroethane, the ratio of ketone to epoxides is found to be very similar to the ratio when chlorobenzene was the solvent. However, in a more polar solvent, such as nitrobenzene, the decomposition of **1** occurs 75% by the diazo pathway and 25% by the carbenic pathway. In an even more polar solvent, DMSO, the pathway leading to 1-phenyl-1-diazopentane accounts for as much as 90% of the products (12). The concerted decomposition of **1** to give phenyl-*n*-butylcarbene is only of minor importance in this case (12). It is likely that the 1-phenyl-1-diazopentane is stabilized in the presence of polar solvent molecules. The solvent dependence of the decomposition pathways in the diazirine system is not well understood because there has been no method which could provide a good measure for the partitioning of the two reaction pathways. If the decomposition pathways in diazirine are indeed solvent dependent as it would appear to be in the present case, then a comparison of the decomposition pathways in diazo compound would be very interesting. In the decomposition of diethyl diazosuccinate (19), it was found that the diazo compound decomposes via a carbenic pathway in non-polar solvent, a diazonium pathway in protic solvent and a carbenoid pathway in acetic acid solvent. However, the participation of dual pathways in a given solvent is also possible in the thermal decomposition of a diethyl diazosuccinate (19).

If one examines the activation parameters for the decomposition of **1** in chlorobenzene ($\Delta H^{\ddagger} = 27.0$ kcal mol^{-1} and $\Delta S^{\ddagger} = -1.2$ cal deg^{-1} mol^{-1} where the decomposition of **1** is 50% diazo – 50% carbenic) and in DMSO ($\Delta H^{\ddagger} = 27.3$ kcal mol^{-1} and $\Delta S^{\ddagger} = -0.32$ cal deg^{-1} mol^{-1} where the decomposition of **1** is 90% diazo – 10% carbenic (12)), one observes that the enthalpies of activation in both solvents are very similar. This would imply that the $\Delta H^{\ddagger}$ values for

[*a*] 
and for

[*b*] 
are very similar in these two competitive processes. The results could also be interpreted to suggest that the $\Delta H^{\ddagger}$ value for process [*b*] is very large in DMSO solvent. However, in view of the solvent studies carried out in the thermal decomposition of chloroethyldiazirine (20), where the activation energies were found to be similar in a variety of solvents, this latter hypothesis does not seem to hold. Despite the fact that process [*a*] involves the breaking of one C—N bond and process [*b*] involves the breaking of two C—N bonds, the entropy of activation is nearly identical for the two elementary processes. This implies that the activated complex must be very much alike for both pathways. The element of single vs. double bond breaking must occur after the transition state and the transition state must resemble the diazirine in structure. This is substantiated by the fact that the $\Delta S^{\ddagger}$ values are very small; this indicates that no additional free rotations are developed in the transition state.

In conclusion, the pathway for the thermal decomposition of diazirine appears to be dependent on (*1*) the nature of the substituents on the diazirine ring, (*2*) the stability of the intermediate diazo compound, and (*3*) the ability of the solvent molecules to stabilize the intermediate (carbene or diazo compound) formed in the decomposition.

Experimental

The ir, nmr, and uv spectra were obtained with Perkin-Elmer Model 137, Varian T-60, and Unicam SP800 respectively. The vpc analyses were carried out using a Perkin-Elmer model F-11 equipped with a hydrogen flame detector.

Since the oxidation products for all the diazirines were common compounds, they were identified by comparing their ir and nmr spectra with authentic samples.

The chlorophenyldiazirine and phenyl-*n*-butyldiazirine were prepared according to methods described previously (12, 21).

The rates of reaction of various diazirines (0.05 *M*) with *m*-chloroperoxybenzoic acid (0.05 *M*) in 1,2-dichloroethane were determined by measuring the disappearance of diazirine according to standard spectrophotometric techniques (16) and by measuring the nitrogen evolution as a function of time. For the spectrophotometric experiments, the first-order rate constants were determined graphically from the plot of log $(D_t - D_\infty)$ vs. time, where D_t is the optical density at the

wavelength of observation (369 nm for phenyl-*n*-butyldiazirine and 390 nm for chlorophenyldiazirine) and D_∞ corresponds to that of complete reaction. For the nitrogen evolution experiments the first-order rate constants were determined graphically from the plot of log $(V_\infty - V_t)$ vs. time, where V_∞ is the volume of nitrogen measured at infinite time and V_t is that at time t. The first-order plots obtained in both methods were linear to at least 80% reaction.

Purification of m-*Chloroperoxybenzoic Acid (18)*

Peracid (3.5 g) (Aldrich 85%) was suspended in 91.1 mL of phosphate buffer solution (pH 7.5) and stirred for 2 h. The product, a white powder, was filtered, washed with distilled water (3 × 100 mL), and the powder was dried under reduced pressure for 2 days. The purity of MCPBA was determined by iodometric titration, which showed 99 ± 1% assay.

Preparation of 1-Diazo-1-phenyl-pentane

Valerophenone-*p*-toluene sulfonylhydrazone (6.6 g, 0.02 mol) was dissolved in 20 mL of distilled pyridine in a 100 mL round bottom flask equipped with a condenser and NaOH drying tube. Sodium methoxide (1.08 g, 0.02 mol) was added to this solution and the mixture was stirred at 75–80°C for 20 min. The contents were poured into 200 mL of ice–water and extracted with pentane (2 × 100 mL). The combined organic fractions were washed with water, dried, and concentrated *in vacuo* to give 2.15 g of dark red oil. The ir of this material showed an intense band at 2040 cm^{-1} (diazo $>C=N_2$).

Several diazirine oxidation experiments were carried out but only the oxidation with *m*-chloroperoxybenzoic acid gave positive results.

1. Basic Hydrogen Peroxide

Chlorophenyldiazirine (1.0 g), 30 mL of 50% hydrogen peroxide, and 4.0 g KOH were stirred at 40°C for 10 h. The resulting mixture was extracted with ether and almost all of the diazirine was recovered. A small amount of diazirine will decompose under these experimental conditions.

2. Peracetic Acid

A solution of 1.0 g chlorophenyldiazirine in 15 mL glacial acetic acid and 5 mL of 30% H_2O_2 was stirred at 40°C for 5 h. The solution was cooled, neutralized with NaOH, and extracted with CH_2Cl_2. Most of the diazirine was recovered.

3. m-*Chloroperoxybenzoic Acid*

(*a*) The reaction was carried out by refluxing 1.55 g of chlorophenyldiazirine and 2.06 g *m*-chloroperoxybenzoic acid in $CHCl_3$ for 5 h. The resulting solution was worked up quickly under basic conditions. Chromatographic analysis of the products indicated the presence of benzoyl chloride (45–50%), benzaldehyde (40%) and a trace amount of benzoic acid. The components were identified by comparing their ir and tlc with those of authentic samples. Benzoyl chloride was converted to benzamide, mp 130°C and benzaldehyde to its 2,4-dinitrophenylhydrazone, mp 237°C. The formation of benzaldehyde was attributed to the decomposition of unreacted starting material during aqueous work-up.

(*b*) Phenyl-*n*-butyldiazirine (200 mg) and 200 mg of *m*-chloroperoxybenzoic acid in 20 mL chlorobenzene were mixed and heated to reflux for 20 h. The color of the solution was yellowish throughout the experiment. The solution was washed with 2 × 20 mL saturated $NaHCO_3$, followed by 2 × 50 mL H_2O. After drying and evaporation in vacuo, 200 mg of yellow oil remained. Vapour phase chromatographic analysis on a 12 ft, 20% Carbowax column at 150°C showed that the products were valerophenone and *cis* and *trans* 1-phenyl-1-pentene oxides. ^1H nmr ($CDCl_3$) δ: 1.00 (t, 3, J = 6 Hz, CH_3), 1.20–1.80 (m, 4, methylenes), 6.92 (bm, 1, H—C—C_3H_7), 3.60 (d, 1, J = 2 Hz, H—C—C_6H_5), 7.35 (s, 5, aromatics). ms (70 eV) *m/e* (relative intensity): 162.122 (70, M^+, $C_{11}H_{14}O$), 133 (90, M—CHO), 119 (38, M—C_3H_7), 105 (85), 91 (100, M—C_4H_7O).

ARTHUR SMITH and STEPHEN FLETCHER. Can. J. Chem. **57**, 1304 (1979).

The fundamental processes underlying phase changes at electrode surfaces are often described in terms of the Kolmogoroff–Avrami theorem.

Some aspects of the 'fine structure' of this theorem are considered. Particular attention is paid to the case of two-dimensional nucleation and growth under the influence of an applied electrode potential (equivalent to supersaturation). A probabilistic analysis is presented for circularly-symmetric nuclei which obviates the need for concepts such as 'overlap' between emergent nuclei. The concept of a 'collision front' is introduced which is defined as the line of contact along which neighbouring nuclei collide. It is shown that for instantaneous nucleation (potentiostatic double step method) the extended set of collision fronts constitutes a net composed of irregular convex polygons. The properties of this net are investigated in some detail. In particular, the extent of applicability of the Kolmogoroff–Avrami equation is delineated, the distribution of collisional polygons is calculated, and an approximate treatment for the variance of the surface coverage function is presented. The general approach exposes clearly the relationship between the single nucleus and the multinuclear situations.

ARTHUR SMITH et STEPHEN FLETCHER. Can. J. Chem. **57**, 1304 (1979).

On considère quelques aspects de la structure fine de ce théorème. On attache une attention particulière au cas de la nucléation bi-dimensionnelle et à la croissance sous l'influence d'un potentiel d'électrode appliqué (équivalent à la sursaturation). On présente une analyse, basée sur le calcul des probabilités, pour des noyaux circulairement symétriques; ceci permet d'obvier à la nécessité de concepts comme celui du recouvrement entre des noyaux qui émergent. On introduit le concept d'un "front de collision" qui est défini comme la ligne de contact le long de laquelle des noyaux voisins entrent en collision. On montre que, dans le cas de la nucléation instantanée (méthode du double saut potentiostatique), l'ensemble étendu des ponts de collision constitue un filet composé de polygones convexes irréguliers. On a étudié, en détail, les propriétés de ce filet. En particulier, on a délimité la portée d'application de l'équation Kolmogoroff–Avrami, on a calculé la distribution des polygones collisionnels et on présente un traitement approximatif de la variation de la fonction exprimant la surface couverte. L'approche générale expose clairement la relation entre le noyau unique et les situations multinoyaux.

General Introduction

Although a great deal of experimental data relating to electrolytic crystal growth has been accumulated over the years, the fundamental processes underlying phase changes at electrode surfaces are not completely understood in detail. However, the general picture is clear and involves a number of well-established concepts. In particular, when an overpotential ($\eta = E - E_0$) is applied to a given electrode surface then the adunit concentration at that surface rapidly increases. These adunits arise following an electron-transfer process between the electrode surface and a suitably labile species; this will usually be a metal ion in the case of metal deposition and will be surface atoms themselves in the case of anodic film formations. The result of such an increase in the adunit concentration is that the adunits begin to form clusters with a distribution of sizes and stabilities (1). The larger clusters (nuclei) tend to grow while the smaller clusters (embryos) tend to diminish in size. The clusters with an equal probability of both growing and diminishing are of particular interest and are called critical nuclei. The steady-state properties of critical nuclei are usually derived from thermodynamic (2) or atomistic (3) considerations. On the other hand, nuclei larger than the critical size are the subject of kinetic investigations.

The emergence and subsequent growth of nuclei is a complex problem, for which two rather different lines of approach may be discerned in the literature. One of these approaches is the macroscopic mod-

0008-4042/79/111304-15$01.00/0

elling of polynuclear nucleation, which has proved useful in the interpretation of electrochemical experiments (4). The other theoretical approach has been to conduct (microscopic) Monte-Carlo simulations of events occurring at the atomic level (5), and these may be compared with crystal growth from the gas phase. Both approaches have met with success in their particular areas of applicability, but nevertheless a number of theoretical disparities exists between them. These disparities arise because of the different assumptions inherent in the two models. These assumptions, in turn, are necessary because of considerations of mathematical tractability in the macroscopic case, and because of limited computer resources in the Monte-Carlo case. Because of the assumptions made, discrepancies also exist between the individual models and actual experimental data.

In the case of Monte-Carlo simulations only small elements of surface may be considered in a given computer experiment, so that it is necessary to employ cyclical boundary conditions (5). The use of such boundary conditions necessarily precludes the observation of the simultaneous collision of large numbers of nuclei. However, this is the very state of affairs with which the macroscopic models concern themselves. Their strategy for dealing with such multi-centre collisions is to invoke the Avrami theorem (6), with the result that the 'fine structure' of events on the electrode surface is lost and even the probabilistic aspect of nucleation (so evident in Monte-Carlo simulations) is to some extent obscured.

The purpose of the present work is to investigate some microscopic consequences of the assumption of a macroscopic model of polynuclear nucleation. We do this for the case of two-dimensional nucleation, in which N_0 nuclei are effectively nucleated at $t = 0$ and thereafter grow uniformly across the electrode surface (4). Both exact solutions and computer-simulated data are calculated and compared. In particular, the 'fine structure' of the two-dimensional nucleation and growth model is investigated in detail to see how far geometrical properties of individual nuclei may be recovered. It is hoped that the results obtained will lead to more complete modelling of real situations, for example, the extension of present theory to polycrystalline substrates. Also a clearer comparison of macroscopic (geometric) and microscopic (Monte-Carlo) models may ultimately evolve via considerations of this sort. Because of the probabilistic nature of the present work, some of the results presented will also be relevant to such varied problems as the effect of electrode boundaries on nucleation and growth phenomena, the measurement of noise on microelectrodes, and the elucidation of the exact extent of applicability of the Avrami theorem to crystal growth kinetics.

Before considering the problem in detail, some fundamental aspects of two-dimensional nucleation are briefly considered which are pertinent to both microscopic and macroscopic models. The geometrical 'fine structure' of the macroscopic model is then calculated from first principles.

The Nucleation Rate

Nucleation consists in the formation of nuclei of critical size from a distribution of sub-critical clusters. As clusters larger than the critical size grow out, so the distribution re-adjusts towards its original condition, thus perpetuating the nucleation process. Clusters can grow via two possible processes. The first is the addition of individual adunits (atoms, ions) at the periphery of clusters. The second process is the addition of smaller clusters to larger clusters. Because the critical nucleus size is usually small, however, this latter route is statistically improbable, because the distances between subcritical nuclei are usually large compared to their diameters. Therefore it is considered that growth occurs only via the addition of individual growth units (7). Now, suppose an overpotential is applied to an electrode surface. The adunit concentration increases rapidly to a new value characteristic of that overpotential, and if the overpotential is large enough then critical nuclei emerge which become experimentally observable as a finite rate of nucleation. Thus, provided the nucleation process occurs isothermally, we may write for the steady-state of nucleation (7)

$$[1] \quad \langle A \rangle = \langle A_n \rangle = \langle A_{n+1} \rangle = \ldots \qquad n = 1, 2, 3, \ldots$$

$$[2] \quad \langle A \rangle = \omega_n{}^{+}\langle C_n \rangle - \omega_{n+1}{}^{-}\langle C_{n+1} \rangle$$

where A is the steady-state rate of nucleation, n is the number of adunits per cluster, C_n are the concentrations of clusters containing n adunits, and $\omega_n{}^{+}$ and $\omega_n{}^{-}$ are the (suitably averaged) probabilities that single adunits are added or subtracted from a cluster containing n adunits. Equation [2] may be solved for $\langle A \rangle$ provided the probabilities $\omega_n{}^{+}$ and $\omega_{n+1}{}^{-}$ are specified. In the most general case, on a thermodynamic view (2)

$$[3] \quad \frac{\omega_n{}^{+}}{\omega_{n+1}{}^{-}} = \exp\left[\frac{\Delta G_n}{kT} - \frac{\Delta G_{n+1}}{kT}\right]$$

in which ΔG_n is the increase in Gibbs free energy of the system when n adunits from the bulk phase form a cluster of n adunits on the electrode surface. By substituting [3] in [2] and using the boundary con-

dition $\langle C_\infty \rangle = 0$ one obtains

$$[4] \quad \frac{\langle C_1 \rangle}{\langle A \rangle} = \sum_{n=1}^{\infty} \left[\omega_n^+ \exp\left(\frac{-\Delta G_n}{kT}\right) \right]^{-1}$$

ΔG_n is a maximum for the cluster of critical size, and it is usually assumed that this maximum is sharp as a function of n. In this case, calling the number of adunits in the critical nucleus $\bar{n}$, the $\bar{n}$th term provides the major contribution to the sum of eq. [4]. Combining all other contributions in a single term Z, the Zeldovich factor (2), simple rearrangement gives

$$[5] \quad \langle A \rangle = Z\omega_{\bar{n}}^+ \langle C_1 \rangle \exp\left(\frac{-\Delta G_{\bar{n}}}{kT}\right)$$

This equation therefore relates the expectation value of the steady-state nucleation rate to three potential-dependent parameters; Z, $\omega_{\bar{n}}^+$ and $\Delta G_{\bar{n}}$. To evaluate the exact potential-dependence of $\langle A \rangle$, however, is not simple because Z and $\Delta G_{\bar{n}}$ are strongly dependent on the model chosen for the clusters. Also $\omega_{\bar{n}}^+$ is only an average quantity, in reality depending on the configuration and types of sites available at the peripheries of the critical nuclei. Monte-Carlo simulations aside, one method for circumventing these difficulties is to suppose that $\bar{n}$ is large (>50 adunits, say) so that $\Delta G_{\bar{n}}$ has a simple, macroscopic, thermodynamic significance. Upon further assuming a circular, two dimensional nucleus (2) then

$$[6] \quad Z^2 = \frac{\Delta G_{\bar{n}}}{4\pi(\bar{n})^2 kT}$$

so that [5] becomes

$$[7] \quad \langle A \rangle = \left(\frac{\Delta G_{\bar{n}}}{4\pi(\bar{n})^2 kT}\right)^{1/2} \omega_{\bar{n}}^+ \langle C_1 \rangle \exp\left(\frac{-\Delta G_{\bar{n}}}{kT}\right)$$

For the case of the deposition of a metal ion onto a substrate of the same metal, Budevski (8) has estimated $\langle A \rangle$ from eq. [7] with the result that

$$[8] \quad \langle A \rangle = K' \exp\left[\frac{(1-\alpha)zF\eta}{RT}\right]\sqrt{\eta} \times \exp\left[\frac{-b\Omega\bar{\varepsilon}^2}{zekT} \cdot \frac{1}{\eta}\right]$$

where K' is a constant, e is the electronic charge, α is the transfer co-efficient, z is the number of electrons transferred, R is the gas constant, T is the absolute temperature, k is the Boltzmann constant, ε is the mean value of the specific periphery energy of the edge of a cluster, Ω is the area occupied by an adunit on the surface of the cluster, b is a geometrical constant, and η is the overpotential. This equation is expected to hold at low overpotentials in the absence of surface diffusion. An alternative expression, valid at high overpotentials, has been calculated by Milchev *et al.* (9) using atomistic, rather than thermodynamic, arguments. This approach yields

$$[9] \quad \langle A \rangle = K'' \exp\left\{\frac{(\bar{n}+1-\alpha)ze}{kT}\eta\right\}$$

where K'' is approximately constant. Comparable expressions may also be obtained for the formation of anodic films by taking the surface free energy terms of the emergent crystalline phase into account in the evaluation of $\Delta G_{\bar{n}}$.

The essential features of eqs. [8] and [9] are that a given expectation value of the steady-state rate of nucleation is associated with a given overpotential, and that the dependence of $\langle A \rangle$ on η is likely to be very strong. These facts mean that experimental and theoretical analyses of electrochemical nucleation will necessarily be complex unless performed at constant overpotential. Also the number of nuclei will, in general, vary as a function of time.

If the nuclei arise independently of each other, then we may assume the nucleation process to be Poissonian, so that the probability of forming one nucleus in time dt is

$$[10] \quad P = \lambda \exp(-\lambda t)\, dt$$

where λ is a constant equal to $\langle A \rangle S'$, S' being the area of the electrode surface. If the number density of nuclei is sufficiently large, then stochastic variations will be unimportant and the overall process may be regarded as deterministic. That is, $A = \langle A \rangle$.

The Growth of Two-dimensional Nuclei

Following Fleischmann and Thirsk (4), we shall assume that any given nucleus has circular symmetry and is of fixed height h. Also, it is supposed that the critical nucleus size is small so that radial growth begins at $r = 0$ when $t = 0$, where r is the radius of the growing nucleus. When the slow step in the overall growth process is at the edge of the nucleus, the observed current density, following a potential step from a potential of no-growth to one of growth, may be expressed as (4)

$$[11] \quad i = nFh\left(\frac{\rho}{M}\right)\frac{ds}{dt} = \pi nFh\left(\frac{M}{\rho}\right)Ak^2t^2$$

Here s is the fractional surface coverage of the electrode, M is the gram-formula weight of the species composing the nuclei, ρ is the density of the nuclei, and k is a suitably averaged rate describing the radial growth. Experimental observation of growth of this type may be simplified in practice by the use of the double potential step method (10). In this case a large overpotential step is applied to the electrode for a short period of time, followed by a

second step to a lower overpotential. The first step serves to nucleate and grow a large number of supercritical nuclei which continue to grow at the lower overpotential (provided the first step was of sufficient duration for the nuclei to achieve a size which is stable at the lower overpotential). The advantage of this technique is that so many nuclei are nucleated at the first overpotential that their number is effectively constant at the second overpotential. In this case, eq. [11] becomes

$$[12] \quad i = nFh\left(\frac{\rho}{M}\right)\frac{ds}{dt} = 2\pi nFh\left(\frac{M}{\rho}\right)Nk^2t$$

where N is the number of nuclei nucleated at the higher overpotential. N obviously depends in this case on the overpotential of the first step, and on the time spent at that overpotential. Equation [12] is usually referred to as describing 'instantaneous' nucleation because the nucleation takes place effectively at $t = 0$. Also, it should be noted that eq. [11] is derived on the basis that nuclei do not mutually interfere as they grow, i.e., the boundaries of adjacent nuclei are far apart. However, as the nuclei become large the probability of collisions increases drastically, so that some sort of interference becomes inevitable. Usually, it is assumed that at points at which the periphery of one nucleus impinges on another, then growth ceases.[1] The particular advantage of this 'impinge-and-stop' hypothesis is that it allows the calculation of the $i(t)$ response to a potential step even when nuclei collide, provided the remaining periphery of a collided nucleus continues to grow in the same way after the collision as before it. This assumption allows the application of a geometrical, probabilistic, theorem to the electrode surface in order to modify eq. [12]. This theorem is due to Kolmogoroff (11) and Avrami (6). It states that for a locally random distribution of nuclei,

$$[13] \quad \langle S\rangle = 1 - \exp(-S_{ex})$$

Here S is the (fractional) surface coverage of the plane by the collided nuclei, and S_{ex} is the (fractional) surface coverage that would have been observed had the nuclei not collided. Note that as $S_{ex} \to 0$, $\langle S\rangle/S_{ex} \to 1$ and that as $S_{ex} \to \infty$, $\langle S\rangle \to 1$. Now, from [12] and [13] we see

$$[14] \quad i = nFh\left(\frac{\rho}{M}\right)\frac{dS}{dt} = nFh\left(\frac{\rho}{M}\right)\frac{dS_{ex}}{dt}\exp(-S_{ex})$$

which shows

$$[15] \quad i = 2\pi nFhN\left(\frac{M}{\rho}\right)k^2t\exp\left[-\pi\left(\frac{M}{\rho}\right)^2Nk^2t^2\right]$$

This useful solution, first obtained by Fleischmann and Thirsk (4), is therefore the amended version of eq. [12] so that the collision of nuclei has been taken into account. Naturally, eq. [15] has limitations, particularly those introduced via the Kolmogoroff–Avrami theorem, and it is of interest to determine precisely what these are. Therefore, we shall now consider the effect of both a finite number of nuclei and the effect of a finite growth region on the validity of eqs. [13] and [15].

The Kolmogoroff–Avrami Theorem

Equation [13] is central to the macroscopic (geometrical) treatment of nucleation and subsequent growth of 2-D phases, and therefore its range of validity should be examined. (In fact, eq. [13] may be generalized in n-dimensional space (6), but for convenience we shall restrict ourselves to the two-dimensional problem.) In a forthcoming paper (12), we shall prove that the Kolmogoroff–Avrami theorem may, under rather specific circumstances, overestimate $\langle S\rangle$ for certain growth rates and geometries of nuclei. However, suffice it to say for the present that for the instantaneous (and progressive) nucleation and growth of geometrically regular nuclei (circles, squares, etc.), which have identical spatial orientations and conserve their geometry as they grow, then the Avrami theorem applies within the mathematical limitations of eq. [13].

In the present work, we are concerned with the mathematical limitations of eq. [13] for two-dimensional instantaneous nucleation, in a situation where the number of nuclei (N) is finite and these nuclei are confined to a finite region A' of an area A in the two-dimensional plane. We shall regard N and A as 'large' in order to perform statistical operations, but not so large that the probability that S differs from its mean $\langle S\rangle$ by any appreciable amount is almost zero. In particular, we suppose that N centres are deposited in a convex region A' at time $t = 0$, each centre having a uniform probability $d\sigma/A$ of being in an element $d\sigma$ of area within A'.

Suppose now that each centre grows as a circular nucleus of radius r at time t, and that all the nuclei grow until they meet an edge of A' or another nucleus, at which stage growth in that direction stops, but growth in other directions is unaffected. Then S is a random variable and in theory, given the distribution of the centres, the probability distribu-

[1]Although this is probably reasonable for many cases of electrochemical crystal growth, it should be pointed out that other situations are, in fact, possible. For instance, coalescence may occur in the deposition of liquids such as mercury. Also, nuclei may 'bounce off' each other when they are deposited on liquid substrates (such as amalgams), or local competition for adatoms might slow growth in regions where centres interact.

tion function of S at time t could be calculated. This task is daunting to say the least, so we shall be content to check how valid [13] is as a measure of $\langle S \rangle$ and work towards the calculation of the variance of S.

In the outlined model there is the odd fact that S is totally deterministic for both small and large t, since $S = N\pi r^2/A$ for r small enough, since there is no overlap, and $S = 1$ for r large enough, since even a single nucleus would eventually cover A'.

Now, eq. [13] applies strictly to the limiting case $N \to \infty$, $A \to \infty$, $N/A = \rho$ where ρ is the uniform density of centres, so that in fact

$$S_{ex} = \lim \sum_{i=1}^{N} S_i/A$$

the limit being in the above sense, and where S_i is the area of the ith nucleus. For the geometry of nuclei described above, we may assign the probability that a point P in A' chosen at random will be in S_i'. This probability is clearly $\hat{S}_i/A$ where $\hat{S}_i$ is the area of $S_i' \cap A'$. Thus the probability that P belongs to at least one of the S_i' is

$$[16] \qquad q = 1 - \prod_{i=1}^{N} (1 - \hat{S}_i/A)$$

Evidently $q = \langle S \rangle$, so we now examine to what extent eq. [13] is a reasonable approximation to eq. [16].

Suppose that $\sum_{i=1}^{N} \hat{S}_i^2/A^2$ is small, so that the approximation $1 - \hat{S}_i/A = \exp(-\hat{S}_i/A)$ is valid, and that $\sum_{i=1}^{N} (S_i - \hat{S}_i)/A$ is also small so that overlap of the S_i' with A' is negligible. Then from [16]

$$\langle S \rangle = 1 - \prod_{i=1}^{N} (1 - \hat{S}_i/A) \simeq 1 - \exp\left(\sum_{i=1}^{N} -\hat{S}_i/A\right)$$

$$\simeq 1 - \exp\left(\sum_{i=1}^{N} -S_i/A\right) = 1 - \exp(-S_{ex})$$

Now if $\sum_{i=1}^{N} \hat{S}_i/A$ is as large as 3, although the relative error in approximating [16] by [13] is large, this is unimportant since both formulae predict a surface coverage of more than 95%. Hence we may assume $\sum_{i=1}^{N} \hat{S}_i/A \simeq 1$. In this general scheme there exists the possibility that some $\hat{S}_i$ are of the order of A_i which would make [16] deviate strongly from [13]. We therefore further assume that the $\hat{S}_i$ are of comparable magnitude (as in the case of circular nuclei each of radius r) and hence that $\hat{S}_i = O(A/N)$. Then

$$\sum_{i=1}^{N} \hat{S}_i^2/A^2 = O\left(\frac{1}{N}\right)$$

which is small for large N. For $\sum(S_i - \hat{S}_i)/A$ to be small it is necessary that $S_i = \hat{S}_i$ for a sufficiently large number of i. *Thus if the centres are uniformly distributed we expect only* $O(\sqrt{N})$ *of the* S_i' *to have parts outside* A'. This conjecture is dealt with in more detail later. Given the conjecture it follows that the error due to edge effects is $O(1/\sqrt{N})$ and so is generally bigger than the effect due the finiteness of N. Note that these two effects *tend to mask each other* in the sense that

$$1 - \exp\left(\sum_{i=1}^{N} -\hat{S}_i/A\right) < 1 - \exp\left(\sum_{i=1}^{N} -S_i/A\right)$$

while

$$1 - \prod_{i=1}^{N} (1 - \hat{S}_i/A) > 1 - \exp\left(\sum_{i=1}^{N} -\hat{S}_i/A\right)$$

It is important to know just how small N can be and still apply the simpler equation [13] instead of [16]. As an example suppose $S_i = A/N$ and $\hat{S}_i = A/2N$. Equation [13] gives $\langle S \rangle = 1 - e^{-1} = 0.63$ while [16] gives

$$\langle S \rangle = 1 - \left(1 - \frac{1}{N}\right)^{N - \sqrt{N}} \left(1 - \frac{1}{2N}\right)^{\sqrt{N}}$$

which has the values 0.57, 0.58, 0.59, 0.60, 0.61, for $N = 4, 9, 16, 25, 36, 49$, respectively.

In this section we note finally the case of N and A infinite, but ρ finite. This can be dealt with directly in terms of "nearest neighbour" theory (13), at least when the S_i' are circular and of the same radius r. Thus the probability that a point P is covered is simply the probability that at least one centre is within r of P, and this is $1 - \exp(-\pi\rho r^2)$. Since $\pi\rho r^2 = S_{ex}$, we recover [13].

Collision Fronts

Let us further consider the case when each S_i' is a circle of radius r. The radius is a function of time t, and is zero at $t = 0$. Suppose there is a set T of N centres. Each centre P becomes a circular nucleus which grows into a definite region R_p', determined uniquely by A' and the set T, until the region R_p' is completely filled. Thus A' is divided into precisely N regions (see Fig. 1).

Evidently a knowledge of the region R_p' will help towards the ultimate goal of describing the probability distribution function of the fractional surface coverage.

Firstly note R_p' may be described mathematically as

$$[17] \qquad R_p' = S_p' \cap A'$$

where

$$[18] \qquad S_p' = \bigcap_{\substack{Q \in T \\ Q \neq P}} H_{pq}$$

and where H_{pq} is the half plane containing the point

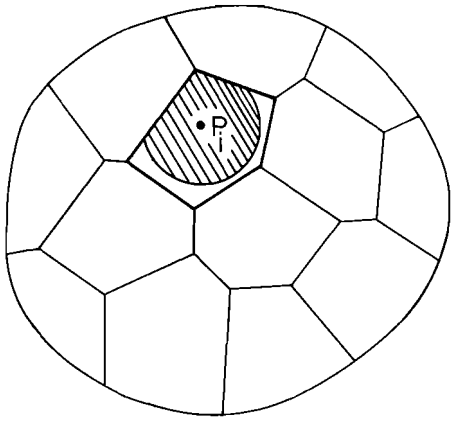

FIG. 1. Typical collision-front geometry illustrating the net of irregular convex m-gons. The nucleus centre P_i expands until the polygon surrounding P_i is filled.

P of T and whose edge is the perpendicular bisector of the line joining P to another point Q of T. *From* [17] *we see* R_p' *is a convex region (being the intersection of convex regions) and further* S_p' *is bounded by a polygon so that* R_p' *is also bounded by a polygon if* $S_p' \subset A'$.

The above regions are bounded by *collision fronts*, i.e. lines of contact of nuclei growing into each other. Even in the limiting case $N \to \infty, A' \to \infty, A/N = \rho$, any particular region R_p' remains finite in size, since with a uniform distribution of centres in the plane, the probability that a finite region of area B is devoid of points of T is $e^{-\rho B}$. Hence the probability of an infinite area devoid of points of T is zero, though arbitrarily large areas can occur.

Although the region R_p' is described in terms of all the members of T it is clear that only a finite subset T_p of T contributes to R_p', in the sense that some points of T could be removed without altering R_p'.

The characterization of T_p will be discussed in the next section, but first we turn to the problem of finding the distribution of the number of sides of a typical R_p'. This in itself is difficult, but to obtain the mean number of sides is not so difficult and oddly enough depends rather weakly on the actual distribution of T and is essentially a topological property of dividing the region A' in a certain way.

Consider again Fig. 1. It represents N regions, a number E of edges, and a number V of vertices where edges meet. It is easy to prove by an inductive argument that $(N + V - E)$ is topologically invariant and has value 1. (In Fig. 1, $N = 13$, $V = 24$, $E = 36$.) *The region* A′ *is divided in a special way since exactly three edges emanate from each vertex.* This statement holds with probability 1 since if four or more edges emerged from a vertex then at least four of the randomly distributed set of points T would lie on a circle. Therefore, since any edge connects two vertices, it follows directly that $V = 2E/3$ and so

$$E = 3(N - 1) \qquad [19]$$

Thus the total number of edges of all the regions R_p' is $2E - A(N)$, where $A(N)$ is the number of edges on the boundary of A'. Hence the mean number of sides M of a region R_p' is

$$M = 6(1 - 1/N) - A(N)/N \qquad [20]$$

This shows that $M < 6$ and

$$\lim_{N \to \infty} M = 6 \qquad [21]$$

provided only that $A(N) = o(N)$ as $N \to \infty$; so the dependence of this result on the distribution of T is indeed weak.

We now prove $A(N) = O(\sqrt{N})$ which yields [21] and completes the discussion of the effect of boundaries on the validity of the Kolmogoroff–Avrami theorem. The general approach is to imagine travelling out from a point P of T, and then deciding whether we first hit a collision front l_Q (associated with another point Q of T) or the boundary of A'.

Let P be a point of T, and let $l(\theta)$ be a straight line emanating from P in the direction θ relative to some fixed direction. *There will be no edge of* R_p' *encountered between* P *and* X (*where* X *is a point of* $1(\theta)$ *a distance* x *from* P) *provided the circle centre* X *radius* x *contains no point of* T *in its interior.* This is proved in the next section on the characterization of T_p. The probability that such a circle exists is $\exp(-\pi\rho x^2)$. Thus if $f(\theta)$ is the distance of P to the boundary of A', then the probability that l meets the boundary before meeting l_Q for some Q is $\exp(-\pi\rho f^2(\theta))$. Hence the probability of at least one of the lines $l(\theta)$ meeting the boundary of A' first is

$$\frac{1}{2\pi}\int_0^{2\pi} \exp[-\pi\rho f^2(\theta)]\,d\theta \leq \exp(-\pi\rho r_p^2)$$

where r_p is the closest distance of P to the boundary.

Let O be any fixed point of A' and R its closest distance to the boundary of A'. Assume that $R \to \infty$ as $A \to \infty$. Then $A \geq \pi R^2$. The proportion of points of T a distance s to $s + ds$ from O is $2\pi\rho s ds$. Hence the proportion of points which 'see' the boundary of A' along some line is $\leq 2\pi\rho s ds \times \exp[-\pi\rho(R - s)^2]$. Thus the expected number of points of T which see a boundary is

$$\leq \int_0^R 2\pi\rho s \exp[-\pi\rho(R - S)^2]\,dS$$

$$\leq 2\pi\rho R\int_0^\infty \exp(-\pi\rho s^2)\,dS = \pi R\sqrt{\rho}$$

$$\leq (A\pi\rho)^{1/2} = (\pi N)^{1/2}$$

As $A \rightarrow \infty$ the probability that a point of R_p' sees more than one boundary edge $\rightarrow 0$. Thus we have proved that $A(N) = O(\sqrt{N})$ as $N \rightarrow \infty$. Hence as $N \rightarrow \infty$ [20] becomes.

$$M = 6 + O(1/\sqrt{N}) \quad [22]$$

where the error is always negative. In a necessarily finite computer simulation, the difference between M and 6 would be an indicator of the magnitude of the boundary effect. However, the limiting version of [22] may be arrived at in an entirely different way, as we shall show after a discussion of the set T_p.

The Set T_p

Consider the case when A is large so that edge effects may be neglected. Under these circumstances, the set T_p of contributors to R_p' is determined uniquely by the following theorem: *The point* W *of* T *is a member of* T_p *if and only if there is a circle* C *with no points of* T *in its interior but with* P *and* W *on its circumference.*

First suppose such a circle C exists (see Fig. 2). Its centre X is on the perpendicular bisector L of PW. We need to show some part of L is a side of R_p', and to do this it is sufficient to show the point X must be on the boundary. Recalling the definition of R_p' in terms of intersections of half planes (eq. [18]), and noting that C is the locus of all possible contributors Y to R_p' such that X is on an edge of H_{py}, it follows that X is a point of the half plane M_{pu} of any contributor U which lies outside C. Thus X is contained in the intersection of all such half planes H_{pu}. Hence X is a point of R_p' and lies necessarily on the boundary.

Given that W is a contributor, the circle C may be constructed as follows. Some part of L is on the boundary of R_p' and in particular contributes a vertex Z of R_p'. Now define C as the circle centre Z radius ZP (which passes through W). Then C contains no contributors in its interior, since if it did, Z would cease to be a vertex.

An immediate corollary of the above theorem, illustrated in Fig. 3, is that the nearest neighbour A to P belongs to T_p. For we may take C as the circle with AP as diameter, which is contained in the circle centre P radius AP, which by definition does not contain points of T in its interior. Figure 4 illustrates the fact that even the second nearest neighbour to P may not be a member of T_p.

Knowing one member of T_p allows us to construct the whole set T_p by the following algorithm. Consider A to be vertically above P and draw the perpendicular bisector of AP. Starting at the point of intersection of AP with this bisector and proceeding to the right draw the largest circle with centre

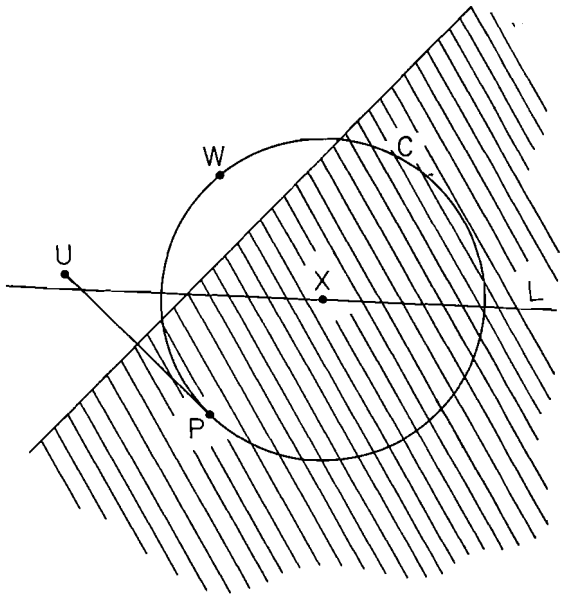

FIG. 2. Illustrating the fact that point W of T is a member of T_p if and only if there is a circle C with no points of T in its interior but with P and W on its circumference.

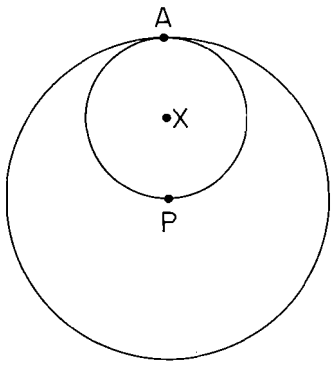

FIG. 3. Illustrating the fact that the nearest neighbour A to P belongs to T_p.

on the bisector which contains no point of T in its interior but does contain A, P, and a different point B of T on its circumference. Then B is a member of T_p (Fig. 5).

Replacing A by B, B by C in the above statement we obtain a third member C of T_p. Proceeding in a clockwise fashion the process ends when an apparently new point of T_p turns out to be A. The above construction is unique with probability 1.

The union of all construction circles above defines a unique region Q_p' whose boundary contains all the members of T_p and whose interior contains no member of T except P.

It is easy to see that $Q_p > 4R_p$ where Q_p is the area of Q_p'. However, the ratio Q_p/R_p can be

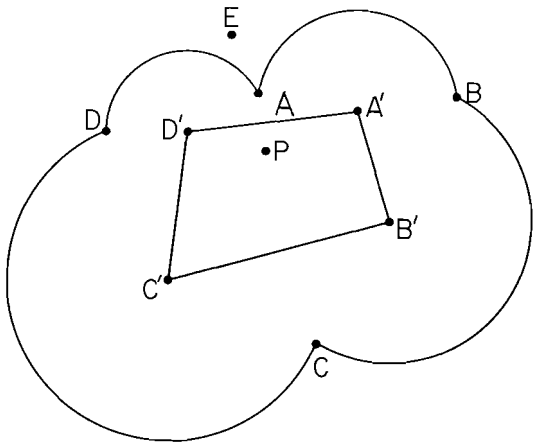

FIG. 4. The nearest neighbour A to P necessarily belongs to T_p and hence is always a contributor to the polygon. But the second nearest neighbour (in this case E) is not necessarily a contributor.

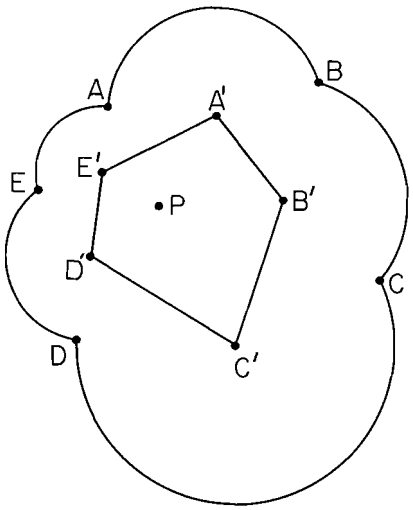

FIG. 5. Given P, the set $T_p\{A,B,C,D,E\}$ determines both R' (i.e. the polygon $A'B'C'D'E'$) and the region Q' (i.e. the union of circles, centres the vertices of R', passing through P).

arbitrarily large when R_p' is highly asymmetric (see Fig. 6). The quantity Q_p must figure in any exact calculation of the probability P_n that R_p' has precisely n sides.

The Distribution of Contributors

Suppose we are given P and another point W of T a distance $2d$ from P, we now seek the probability that W is a member of T_p. This information is useful for two reasons. Firstly, since we expect the probability to decay with d, a knowledge of the actual law of decay would allow the partition of the plane into essentially independent parts (in the sense that within some specified distance of P the probability is

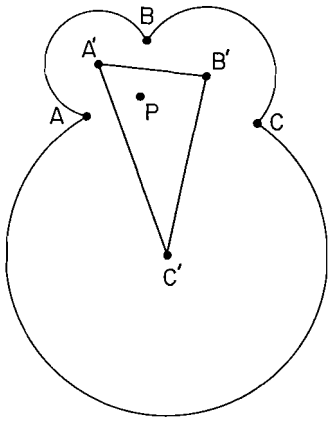

FIG. 6. The ratio Q/R is always >4. But if R' has an elongated shape then this ratio can be much larger, thus rendering the shape less likely to occur than a centrally symmetric shape.

very small of a member of T_p being further from P than that specified distance). Secondly, knowledge of the probability would yield the density of contributors at any point.

To find the probability it is necessary to use the criterion for W to be a member of T_p. Now W will not be a member of T_p if every circle with P, W on its circumference contains a point of T. Let $Q(x,y)$ be the probability that all circles passing through P and W with centres a distance $\leq y$ to the right of PW and all circles passing through P and W with centres a distance $\leq x$ to the left of PW contain a point of T.

Referring to Fig. 7 consider the two circles $PAWB$ (centre X) and $PCWD$ (centre Y), the distance of whose centres from PW are y and $y + dy$ respectively.

Let $E(x,y)$ be the event of which $Q(x,y)$ is the probability. *Then* E(x,y) *occurs if and only if either* E(x,y+dy) *occurs or if circle* PCWD *is devoid of points of* T *while the area* PAWC *contains a point of* T.

To prove this observe that if $E(x,y+dy)$ occurs then $E(x,y)$ occurs by definition. If, however, $PCWD$ contains no point of T (so $E(x,y+dy)$ fails to occur) and $PAWC$ contains a point of T, then this point is

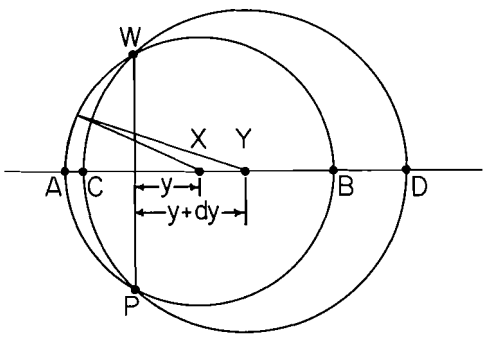

FIG. 7. Construction used in determining the probability that, given P, another point W is a member of T_p.

common to all circles passing through P and W with centres $\leq y$ from PW, to the right of PW. This point is also common to all circles passing through P and W with centres to the left of PW. Thus the event $E(x,y)$ occurs.

Further, if $E(x,y)$ occurs then either $E(x,y+\mathrm{d}y)$ occurs or if it does not there must be a point of T in area $PAWC$.

We have thus proved that

$$Q(x,y) = Q(x,y+\mathrm{d}y) + (\text{probability no point of } T \text{ is in } PCWD) \times (\text{probability a point of } T \text{ is in } PAWC)$$

Let the area of $PAWC$ be $f(y)\mathrm{d}y$. The radius of the circle $PCWD$ is $\{(y+\mathrm{d}y)^2 + d^2\}^{1/2}$. Hence the probability there is no point of T in $PCWD$ is $\exp\{-\rho\pi[(y+\mathrm{d}y)^2 + d^2]\}$ and so

$$Q(x,y) = Q(x,y+\mathrm{d}y) + \rho \exp\{-\rho\pi[(y+\mathrm{d}y)^2 + d^2]\} f(y)\mathrm{d}y$$

Dividing by $\mathrm{d}y$ and letting $\mathrm{d}y \to 0$ we obtain the differential equation

$$[23] \quad \partial Q/\partial y = -\rho f(y) \exp[-\pi\rho(y^2 + d^2)]$$

Solving [23] gives

$$[24] \quad Q(x,y) = Q(x,0) - \rho \exp(-\pi\rho d^2) \times \int_0^y \exp(-\pi\rho v^2) f(v)\,\mathrm{d}v$$

By symmetry we also have

$$[25] \quad Q(x,y) = Q(0,y) - \rho \exp(-\pi\rho d^2) \times \int_0^x \exp(-\pi\rho v^2) f(v)\,\mathrm{d}v$$

Putting $y = 0$ in [25] and substituting for $Q(x,0)$ in [24] gives

$$[26] \quad Q(x,y) = Q(0,0) - \rho \exp(-\pi\rho d^2) \times \left\{ \int_0^x \exp(-\pi\rho v^2) f(v)\,\mathrm{d}v + \int_0^y \exp(-\pi\rho v^2) f(v)\,\mathrm{d}v \right\}$$

Now $Q(0,0)$ is the probability that the circle diameter PW contains a point of T and thus

$$[27] \quad Q(0,0) = 1 - \exp(-\pi\rho d^2)$$

Hence from eqs. [26], [27]

$$[28] \quad Q(\infty,\infty) = 1 - \exp(-\pi\rho d^2) - 2\rho \exp(-\pi\rho d^2) \int_0^\infty \exp(-\pi\rho v^2) f(v)\,\mathrm{d}v$$

It is straightforward to calculate $f(y)$ and we obtain

$$[29] \quad f(y) = 2(d - y \tan^{-1} d/y)$$

Hence if $g(d)$ is the probability that a member of T a distance $2d$ from P is a member of T_p then $g(d) = 1 - Q(\infty,\infty)$, so from eqs. [28], [29]

$$[30] \quad g(d) = \exp(-\pi\rho d^2) + 4\rho \exp(-\pi\rho d^2) \times \int_0^\infty (d - x \tan^{-1} d/x) \exp(-\pi\rho x^2)\,\mathrm{d}x$$

Equation [30] may be expressed in either of the two forms

$$[31] \quad g(d) = 2d\sqrt{\rho} \exp(-\pi\rho d^2) + \operatorname{erfc}(d\sqrt{\pi\rho})$$

$$[32] \quad g(d) = 1 - 4\pi\rho^{3/2} \int_0^d t^2 \exp(-\pi\rho t^2)\,\mathrm{d}t$$

The form [31] shows $g(d)$ decreases steadily from 1 to 0 as d increases from 0 to ∞.

From [30] we may calculate the density of contributors a distance r to $r + \mathrm{d}r$ from P as $2\pi\rho r g \times (r/2)\mathrm{d}r$. Then the expected number of contributors to R_p' is

$$[33] \quad M = 2\pi\rho \int_0^\infty r \exp(-\pi\rho r^2/4)\,\mathrm{d}r + 8\pi\rho^2 \times \int_0^\infty \int_0^\infty r\left(\frac{r}{2} - x \tan^{-1}\frac{r}{2x}\right) \times \exp\left[-\pi\rho\left(x^2 + \frac{r^2}{4}\right)\right] \mathrm{d}x\mathrm{d}r$$

The transformation $x = R\cos\theta$, $r = 2R\sin\theta$ allows the evaluation of the second integral to be made while the first integral has value 4. Hence

$$[34] \quad M = 4 + 32\pi\rho^2 \int_0^\infty R^3 \exp(-\pi\rho R^2)\,\mathrm{d}r \times \int_0^{\pi/2} \sin\theta(\sin\theta - \theta\cos\theta)\,\mathrm{d}\theta$$

The expected result $M = 6$ follows using integration by parts. This result was obtained before by topological arguments (eq. [21]).

We can then regard $f(r) = (\pi\rho/3)rg(r/2)$ as the probability density of contributors at a distance r from P. The mean distance of a contributor to R_p' from P is

$$\int_0^\infty r f(r)\,\mathrm{d}r = \rho^{-1/2}\left(\frac{1}{2} + \frac{8}{9\pi}\right)$$

as is easily verified. This compares with the mean distance of the nearest neighbour to P, viz.

$$\int_0^\infty r[2\pi\rho r \exp(-\pi\rho r^2)]\,dr = \tfrac{1}{2}\rho^{-1/2}$$

(ref. 13). Thus the mean distance of a contributor is only about one and a half times that of the nearest neighbour, showing that although the shape of a region R_p' depends on the whole distribution of centres, the influence of centres outside a few units of $\rho^{-1/2}$ from P on R_p' is weak in the probabilistic sense.

The Distribution of Polygons

It would also be of interest to obtain both the probability P_m that a given region R_p' is a polygon with m sides (an m-gon) and the distribution of the sizes of m-gons for a given m, since these quantities are required for any detailed study of the distribution function for the surface coverage.

So far we have the result

$$[35] \qquad \sum_{m=3}^{\infty} mP_m = 6$$

Consider now a vertex of any polygon. By symmetry it can be seen that the mean value of an external angle of a polygon is $\pi/3$, which indicates that hexagons will predominate. Although this turns out to be true, the computer simulation described later indicates that approximately 25% m-gons are pentagons as compared to only 29% hexagons, so the predominance is not striking. (Geometrically, hexagons, pentagons, and heptagons will tend to have m-gons of a similar type as neighbours, simply because the sum of the interior angles of an m-gon depends on m.)

Suppose a polygon is chosen at random. One way to determine the number of sides is to proceed round the polygon counting the sum of the external angles. If after m such steps the sum is less than 2π, it is certain the polygon has at least $m + 1$ sides. If this experiment is repeated a large number of times, the probability Q_m that a polygon chosen at random has at least m sides is determined. Then $P_m = Q_{m-1} - Q_m$, $m = 3, 4, \ldots$.

Because the external angles of a polygon are not independent, P_m cannot be determined from the knowledge of the distribution of a single external angle taken at random.

However, suppose we let $\tau(\varphi)d\varphi$ be the probability that an external angle of a polygon taken at random has a value in the range $\varphi \to \varphi + d\varphi$. Let $P_n(\theta)d\theta$ be the probability that the sum of n such angles, regarded as independent, is in the range θ to $\theta + d\theta$. Then put

$$[36] \qquad Q_n = \int_0^{2\pi} P_n(\theta)\,d\theta$$

Thus Q_n is actually the probability that the sum of n random variables with given distribution $\tau(\theta)$ has a value $<2\pi$. This will be different from the probability actually required, namely the probability (Q_n') that a polygon has at least n sides. But a knowledge of Q_n gives us a measure of the interdependence of polygons and, as it turns out, the asymptotic behaviour of P_n for large n.

Now $P_n(\theta)$ is obtained by a convolution; which, using Fourier transforms, yields

$$[37] \quad P_n(\theta) = \frac{1}{2\pi}\int_{-\infty}^{\infty} e^{ik\theta}\left(\int_0^{\pi} \tau(\varphi)\, e^{-ik\varphi}\,d\varphi\right)^n dk$$

where it is noted that $\tau(\varphi) = 0$ for $\varphi < 0$ and $\varphi > \pi$. To obtain $\tau(\varphi)$ consider how a vertex O of a polygon is constructed. Let P_1, P_2, P_3 be three points of the set T, each of which contributes to the polygons belonging to the other two. Also, the vertex (O) is common to the three polygons. Referring to Fig. 8, the external angle φ of the polygon belonging to P_1 is the angle between OQ_2 and Q_3O. Since $OQ_2P_1Q_3$ is a cyclic quadrilateral $\varphi = \angle Q_2P_1Q_3 = \angle P_3P_1P_2 = \frac{1}{2}\angle P_2OP_3$. Thus if $\varphi_1 = \angle P_1OP_2$ and $\varphi_2 = \angle P_1OP_3$, then $\varphi = \frac{1}{2}|\varphi_1 - \varphi_2|$. Let us make the reasonable assumption that φ_1 and φ_2 are uniformly distributed in $[0,2\pi]$. Then

$$\tau(\varphi) = \left(\frac{1}{2\pi}\right)^2 \frac{d}{d\varphi}R(\varphi)$$

where $R(\varphi)$ is the region in the $\varphi_1\varphi_2$ plane determined by $0 \le \varphi_1 \le 2\pi$, $0 \le \varphi_2 \le 2\pi$, $|\varphi_2 - \varphi_1| \le 2\varphi$. This gives

$$R(\varphi) = 0,\ \varphi \le 0$$

$$R(\varphi) = 4\pi^2 - (2\pi - 2\varphi)^2,\ 0 \le \varphi \le \pi$$

$$R(\varphi) = 4\pi^2,\ \varphi \ge \pi$$

and hence

$$[38] \qquad \tau(\varphi) = (2/\pi^2)(\pi - \varphi),\ 0 \le \varphi \le \pi$$

Substituting [38] into [37] gives

$$[39] \quad P_n(\theta) = \left(\frac{2}{\pi^2}\right)^n \frac{1}{2\pi}\int_{-\infty}^{+\infty} \frac{e^{ik\theta}}{k^{2n}} \times (1 - ik\pi - e^{-ik\pi})^n\,dk$$

Let $f(k) = e^{ik\theta}(1 - ik\pi - e^{-ik\pi})^n$. Note $f(k)/k^{2n}$ has a removable singularity at $k = 0$, as does

$$f(-k)/k^{2n} \equiv f^*(k)/k^{2n}$$

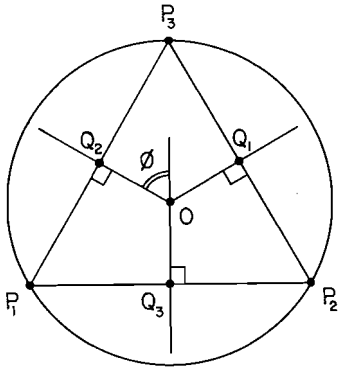

FIG. 8. Geometry of the vertex (O) of a polygon. The points P_1,P_2,P_3 are the centres of nuclei belonging to a set T, each of which contributes to the polygons belonging to the other two.

Also, expanding $\{(1 - ik\pi) - e^{-ik\pi}\}^n$ by the binomial theorem shows that

$$f(k) = e^{ik\theta}(1 - ik\pi)^n + g_1(k,\theta)$$

where for $\theta < \pi$, $g_1^*(k,\theta)$ decays exponentially as $k \to \infty$ in the upper half of the complex plane. Then

$$[40] \qquad P_n(\theta) = \left(\frac{2}{\pi^2}\right)^n \frac{1}{2\pi} \int_{-\infty}^{+\infty} \frac{h(k)}{k^{2n}} dk$$

where $h(k) = e^{ik\theta}(1 - ik\pi)^n + g_1^*(k,\theta)$ and the expression [40] is a Cauchy principal value integral. For $0 < \theta < \pi$, [40] may be evaluated by contour integration giving

$$[41] \quad P_n(\theta) = \left(\frac{2}{\pi^2}\right)^n \frac{1}{2\pi} \pi i \operatorname{res} \left\{\frac{h(k)}{k^{2n}}\right\}_{k=0}$$

$$= \left(\frac{2}{\pi^2}\right)^n \frac{i}{2} \operatorname{res} \left\{\frac{h(k) - f^*(k)}{k^{2n}}\right\}$$

$$= \left(\frac{2}{\pi^2}\right)^n \frac{i}{2} \times \operatorname{res} \left\{\frac{(1 - ik\pi)^n e^{ik\theta} - (1 + ik\pi)^n e^{-ik\theta}}{k^{2n}}\right\}_{k=0}$$

$$= -\left(\frac{2}{\pi^2}\right)^n \frac{1}{(2n-1)!} \times \mathcal{I}\{(D + i\theta)^{2n-1}(1 - ik\pi)^n\}|_{k=0}$$

where $\mathcal{I}$ denotes 'imaginary part of' and $D = d/dk$.

Equation [41] may be written in the real form

$$[42] \quad P_n(\theta) = \left(\frac{2}{\pi^2}\right)^n \frac{1}{(2n-1)!} \times (D + \theta)^{2n-1}(k\pi - 1)^n|_{k=0}$$

For $\pi < \theta < 2\pi$ the above procedure is modified slightly and we write

$$f(k) = e^{ik\theta}(1 - ik\pi)^n - n(1 - ik\pi)^{n-1} e^{ik(\theta-\pi)} + g_2(k,\theta)$$

where $g_2^*(k,\theta)$ decays exponentially in the upper half plane.

Corresponding to [42], the formula

$$[43] \quad P_n(\theta) = \left(\frac{2}{\pi^2}\right)^n \frac{1}{(2n-1)!} \times \{(D + \theta)^{2n-1}(k\pi - 1)^n + n(D + \theta - \pi)^{2n-1}(k\pi - 1)^{n-1}\}_{k=0}$$

is obtained. Thus

$$[44] \quad Q_n = \left(\frac{2}{\pi^2}\right)^n \frac{1}{(2n-1)!} \left\{\int_0^{2\pi} (D + \theta)^{2n-1} \times (k\pi - 1)^n|_{k=0} d\theta + n \int_\pi^{2\pi} (D + \theta - \pi)^{2n-1} \times (k\pi - 1)^{n-1}\right\}_{k=0} d\theta = \frac{2^n}{(2n)!} \times \{(D + 2)^{2n} z^n + n(D + 1)^{2n} z^{n-1}\}_{z=-1}$$

where now $D = d/dz$.

Finally, [44] gives

$$[45] \qquad Q_n = 2^n n! \sum_{r=0}^{n} \frac{(2^{n+r} - r)(-1)^r}{r!(n-r)!(n+r)!}$$

The first few values of Q_n are easy to obtain; $Q_2 = 1$, $Q_3 = 89/90$, $Q_4 = 115/126$, $Q_5 = 9329/12600$, etc. This then gives $P_3 = 1/90$, $P_4 = 8/105$, etc.

The graph of P_n versus n is illustrated in Fig. 9, where it is compared with a similar graph obtained by simulation. It is evident that the calculated values of P_n differ from the simulation values on two main counts. Firstly no account is taken in the above calculation of the fact that m-gons with $m = 5, 6, 7$ tend to occur in clusters, which makes these polygons occur more frequently than is calculated on the basis of independent polygons. Secondly no account is taken of the fact, discovered by the simulation experiment, that the mean size of an m-gon ($\bar{A}_m$) tends to increase linearly with m, an approximation being $(m-2)/4\rho$. This effect reduces the frequency of occurrence of polygons with m large as compared with the above calculations, because large deviations from the local density ρ are required as well as large deviations from the mean ($\pi/3$) of the external angle for such m-gons.

This latter observation gives us an upper bound on the decay with m of the actual probability of the occurrence of an m-gon.

We need only calculate the asymptotic form of

$Q_n - Q_{n+1}$. To do this we return to the integral form of Q_n rather than [45]. Now from [36] and [39] we have

$$[46] \quad Q_n = \left(\frac{2}{\pi^2}\right)^n \frac{1}{2\pi} \int_{-\infty}^{+\infty} \left(\frac{e^{2\pi ik} - 1}{ik}\right) \times \left(\frac{1 - ik\pi - e^{-ik\pi}}{k^2}\right)^n dk$$

For n large, only contributions to the integral near $k = 0$ are significant. We may therefore expand the second factor about $k = 0$, and re-express it in exponential form giving

$$[47] \quad Q_n - Q_{n+1} \sim \frac{1}{2\pi} \int_{-\infty}^{+\infty} \left(\frac{e^{2\pi ik} - 1}{ik}\right) \times \left[1 - \frac{2}{\pi^2 k^2}(1 - ik\pi - e^{-ik\pi})\right] \times (e^{-nik\pi/3 - nk^2\pi^2/12})\, dk$$

$$\sim \frac{1}{2\pi} \int_{-\infty}^{+\infty} (2\pi)\left(\frac{ik\pi}{3}\right) \times \exp(-nik\pi/3 - nk^2\pi^2/12)\, dk$$

$$= \frac{i\pi}{3} e^{-n/3} \int_{-\infty}^{+\infty} k \exp\left[\frac{-n\pi^2}{12}\left(k + \frac{2i}{\pi}\right)^2\right] dk$$

$$= \frac{2}{3} e^{-n/3} \int_{-\infty}^{+\infty} \exp\left[\frac{-n\pi^2}{12}\left(k + \frac{2i}{\pi}\right)^2\right] dk$$

$$= \frac{4}{(3\pi n)^{1/2}} e^{-n/3}$$

Thus P_n decays at least exponentially with n.

The Variance of S

It is evident from the preceding considerations that an analytical solution to the problem of finding the probability distribution function for nuclei growing at random in a large but finite region is well nigh impossible. Approximations can however be made.

In Fig. 10 a typical region R_i' is depicted in the case when all nuclei would be circles of radius r at time t if allowed to grow unimpeded. Let G_i' with area G_i be the area of the intersection of R_p' with the circle centre P_i radius r.

Now

$$[48] \quad S = \frac{1}{A} \sum_{i=1}^{N} G_i$$

which is exact. From [48] and the discussion of the Kolmogoroff–Avrami theorem

$$[49] \quad \langle S \rangle = \frac{N}{A} \langle G_i \rangle + O(1/\sqrt{N})$$

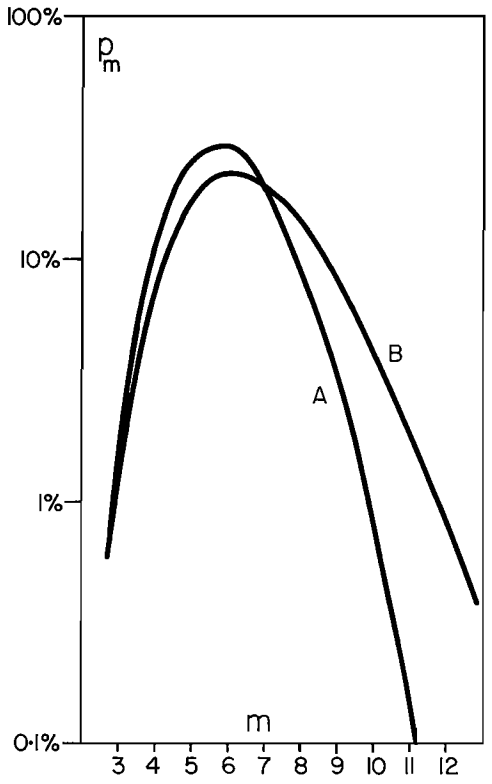

FIG. 9. The distribution of the number of sides of random m-gons (logarithmic scale). (A) Computer-simulated net, (B) according to eq. [45].

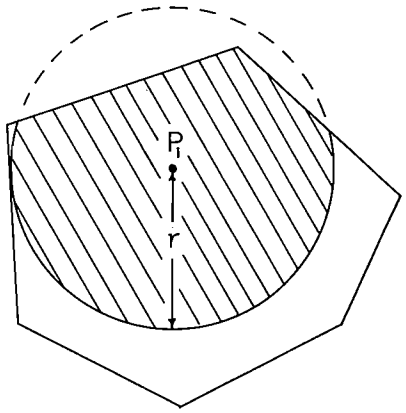

FIG. 10. The shape of a typical nucleus and its collision fronts.

Thus for N large enough, from [49] and [13] specialised to the case of circular nuclei

$$[50] \quad \langle G_i \rangle = \frac{1}{\rho}[1 - \exp(-\pi\rho r^2)]$$

Now

$$A = \sum_{i=1}^{N} R_i$$

so to order $1/\sqrt{N}$

$$[51] \qquad \langle R_i \rangle = 1/\rho$$

Thus $\langle G_i \rangle$ behaves as expected. For r small enough $G_i = \pi r^2$ and for r large enough $G_i = R_{p_i}$. For intermediate values of r all the geometric details of R_{p_i}' need to be considered.

Obviously the mean shape of R_{p_i}' is a circle. If it were a circle of radius x, and P_i were in the centre of this circle, then G_i would be πr^2 for $r \leq x$ and πx^2 for $r \geq x$. Thus a good model of the growth of a circular nucleus into a typical region R_i' would be one where x was a random variable such that $\langle G_i \rangle$ is given by [50] and $\langle R_i \rangle$ by [51]. For the moment let x be the distance between a centre P and a point Q on a collision front in an arbitrary direction. The circle centre Q radius QP necessarily has no point of T in its interior. Hence the probability that $x \leq y$ is $1 - \exp(-\pi\rho y^2)$. This suggests that we replace R_i' by a circle of radius x and probability distribution function $F_x(y) = 1 - \exp(-\pi\rho y^2)$, $y \geq 0$. Then

$$[52] \quad \langle R_i \rangle = \langle \pi x^2 \rangle = \int_0^\infty (2\pi\rho x)\pi x^2 \exp(-\pi\rho x^2)\, dx = 1/\rho$$

and

$$\langle G_i \rangle = \int_0^r (2\pi\rho x)(\pi x^2) \exp(-\pi\rho x^2)\, dx + \int_r^\infty (2\pi\rho x)(\pi x^2) \exp(-\pi\rho x^2)\, dx = \frac{1}{\rho}[1 - \exp(-\pi\rho r^2)]$$

Thus the replacement of R_i' by a circle with a radius with the above probability distribution does not alter $\langle G_i \rangle$ nor $\langle R_i \rangle$.

If we were to regard the circles R_i' as independent we get immediately that

$$\langle S \rangle = \rho\langle G_i \rangle = 1 - \exp(-\pi\rho r^2)$$

and

$$[53] \quad \langle (S - \langle S \rangle)^2 \rangle = (\rho^2/N)\langle (G_i - \langle G_i \rangle)^2 \rangle = (1/N)[1 - 2\pi\rho r^2 \exp(-\pi\rho r^2) - \exp(-2\pi\rho r^2)]$$

It is easy to see that the right hand side of [53] increases with r to value $1/N$. In the truly finite case, of course, the limiting value of the variance σ^2 is zero. The difference is accounted for when we realise that

$$A = \sum_{i=1}^{N} R_i$$

is a fixed quantity, and if we regard the R_i as random variables, A becomes a random variable. In spite of this difference, the way in which σ^2 varies with r at least for $\pi r^2 \ll A$ should follow the law [53]. A direct computer simulation of the distribution of the random variable S seems required to clear up to what extent [53] is valid.

Computer Simulation

For a random distribution of instantaneously-nucleated circular nuclei in a plane, the complete set of extended collision fronts constitutes a 'net' composed of irregular convex m-gons. Each m-gon represents the complete collision-front encountered by a single nucleus. The properties of the set of m-gons will obviously determine the shape of the i–t transient observed experimentally, and consequently is of fundamental importance. Also, investigation of the properties of such m-gons will provide insight into the limitations of the Avrami theorem as encountered, say, in measurement of electrochemical noise.

The simulation was built as follows. On the interval $[-1,+1]$ in both the x and y directions in the plane, 10^3 nuclei were distributed at co-ordinates determined by a random number generator. The area of the plane was thus 4 square units. The density of nuclei in any random element of the plane was such that it approached the expectation density of the complete plane. That is, the distribution was uniform.

Next, a second interval was defined $[-0.7,+0.7]$ in both the x and y directions in the plane which bounded a square box of 2 square units. Only nuclei inside this inner box were used as centres for calculations, but nuclei outside the box could be used for the calculation of collision fronts. This precaution was teleologically necessary to prevent m-gons 'spilling' outside $[-1,+1]$. On the rare occasions that a given nucleus spilled over anyway, the program recognised the m-gon and rejected it.

Since the area considered was half the total area, then approximately 500 nuclei could be examined per run. For each nucleus it was necessary to order its nearest neighbours in terms of their distances in polar co-ordinates, and then compute collision fronts individually until the complete m-gon had been calculated. Various properties of the resultant m-gons could then be established as desired. Note that the resultant density was $>2/500$ because some m-gons necessarily spilled over the inner box. The overall weighted average density, ρ, was 4.2×10^{-3}.

The first property of the m-gons investigated was the distribution of the number of sides. This is expressed as a percentage of all m-gons (P_m) in Fig. 9. The m-gons with more than a 5% probability of occurrence are those having 4, 5, 6, 7, and 8 sides. The expected number of sides, calculated earlier (eqs. [21] and [33]) was found to be 6. The overall weighted average number of sides, calculated for 24 000 nuclei, was found to be 5.999.

The average area of individual m-gons was also calculated. The result is shown in Fig. 11 which plots the average area as a function of m. An approximately linear relationship is found in accordance with

$$[54] \qquad \bar{A}_m \simeq (m - 2)/4\rho, \; m \geq 3$$

where ρ is the average density and $\bar{A}_m$ is the average area of an m-gon. This result explains, at least partially, the rapid diminution of P_m in Fig. 10 for $m > 8$. Obviously the probability of a single nucleus existing in a large 'open space' (i.e. $\bar{A}_m$ large) diminishes rapidly as m increases, because the overall distribution of other nuclei is uniform. Not a single 15-gon was recorded in 24 000 nuclei.

The area distribution of all nuclei was also calculated. In this case, 6000 nuclei were considered. The number of nuclei having areas between intervals of 4×10^{-4} area units were counted, and the results plotted versus the interval number (Fig. 12). A smooth distribution is found which rises rapidly to a maximum (at $A \simeq 4 \times 10^{-3}$ area units) and then exhibits a tailing region. The tailing region becomes statistically insignificant for the chosen number of nuclei (6000) above $A \simeq 1.2 \times 10^{-2}$ area units.

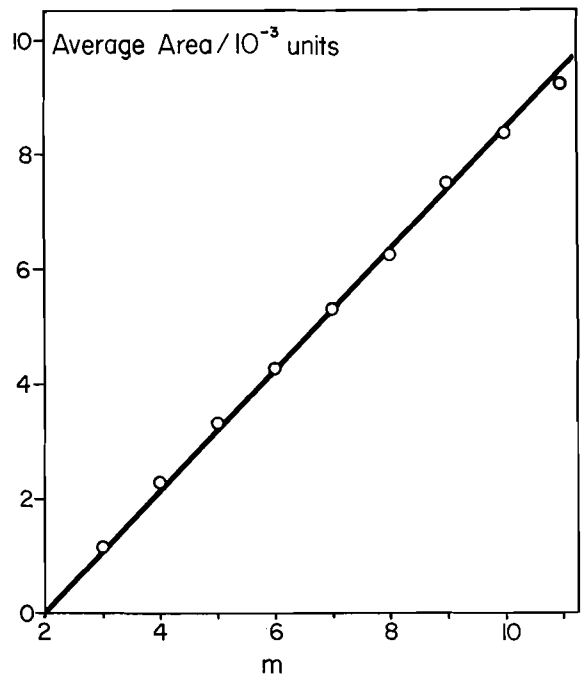

FIG. 11. The average area of individual m-gons. Points are computer simulated data. The solid line is from eq. [54].

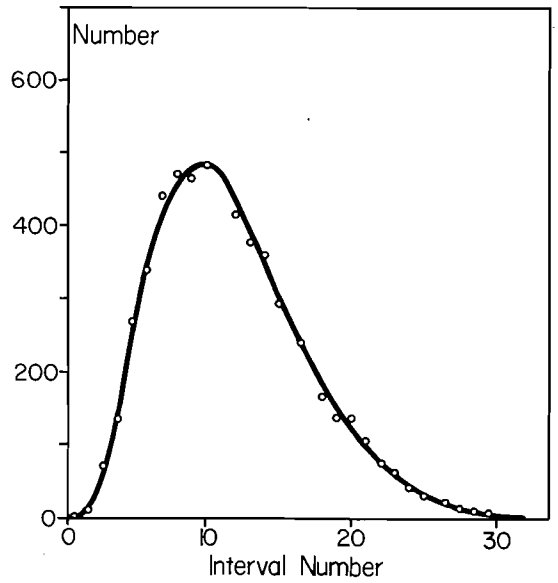

FIG. 12. The area distribution of m-gons (from computer simulation).

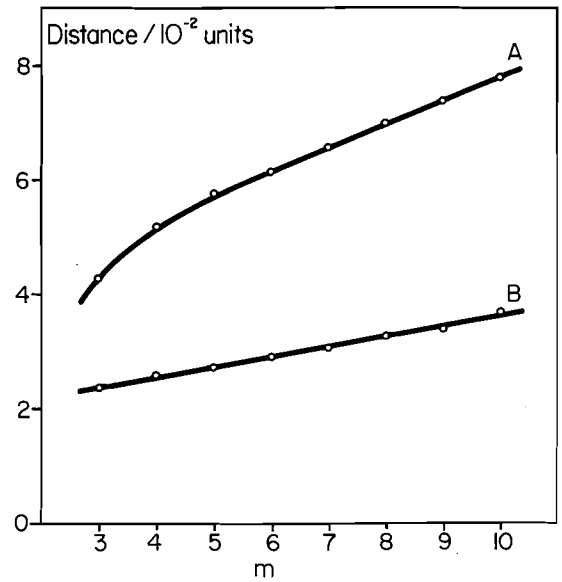

FIG. 13. The average distance from the centre P of a nucleus to (A) furthest vertex of a polygon and (B) nearest vertex of a polygon.

The properties of vertices of the m-gons were also examined. In particular, the average distances of nearest and furthest vertices from centre P were calculated for $n < 10$ from a sample of 6000 n-gons. The result is shown in Fig. 13. The average distance

of the nearest vertex of an m-gon varies linearly with m, while the average distance of the furthest vertex shows a more complex dependence. This dependence is probably $O(m^{1/2})$, meaning that m-gons containing a large number of sides would tend towards the circular.

Conclusions

A particularly useful area in which theories of two-dimensional nucleation and growth may be confronted with experimental data is in the study of electrocrystallization phenomena. However, a complication lies in elucidating the effects of electrode potential on the various nucleation parameters (the nucleation rate, the probability of addition or subtraction of adunits to a nucleus, etc.). It is well-known that these difficulties can be circumvented to some extent by the judicious application of the (potentiostatic) double potential step method. The theory of this method was briefly reviewed. It was then shown that for circularly symmetric nuclei the fine structure of events at the electrode surface could be quantified in some detail. In particular both stochastic and geometric properties of nuclei were calculated. These properties were then compared to the predictions of the Kolmogoroff–Avrami theorem, which is widely used in macroscopic theories of 2-D nucleation and growth to describe the mutual collision of randomly-distributed nuclei.

It was found that the Kolmogoroff–Avrami theorem broke down when either the number of nuclei was finite, or nuclei were confined within a finite area with fixed boundaries. The magnitude of the errors arising from the use of the Kolmogoroff–Avrami theorem in these circumstances was calculated. (Another possibility, namely that the Kolmogoroff–Avrami theorem may break down for certain geometries and growth rates of nuclei, other than circular, will be considered in a future publication.)

In the present work the concept of a *collision front* was also introduced, this being defined as the line of contact along which nuclei collide. This concept was used throughout to replace the older idea of 'overlap' between growing nuclei (6). It was shown that for a random distribution of instantaneously nucleated circular nuclei in a plane, the complete set of extended collision fronts constituted a 'net' composed of irregular convex m-gons. Each m-gon then represented the complete collision-front encountered by a single nucleus.

The properties of a set of m-gons in a given plane were then described, and it was shown that the average number of sides approached 6 as the number of nuclei approached infinity. The magnitude of the 'edge effect', due to boundaries of the plane, was shown to be $O(\sqrt{N})$.

A set T_p was then defined, which was composed of those nuclei which impinged on a given nucleus in such a way that the collision fronts constituted the unique m-gon into which the given neuclus grew. Some properties of this set were described, and in particular the distribution of contributors to T_p was calculated. The mean distance of contributors to the m-gon of a given nucleus was also calculated, and was compared with the mean distance of the nearest neighbour.

The distribution of m-gons was then investigated, with some interesting results. First of all, the distribution of 'random' m-gons was calculated and an explicit formula given. Comparison of this result with a computer-simulated 'net' of m-gons then showed that a clustering phenomenon occurred in the real situation, such that 5, 6, and 7-gons tended to be surrounded by other 5, 6, and 7-gons. Nevertheless the departure from 'ideal randomness' was not too great (Fig. 9). At large values of n (>13, say), the probability of observing a given m-gon was shown to decay at least exponentially with m.

An approximate treatment was then given for the variance of S, i.e. the surface coverage of the plane at some time t for a given growth law. The general approach here was to replace the real situation of circular nuclei growing into a set of m-gons with a hypothetical situation of circular nuclei growing into circular regions having a certain probability distribution function. The probability distribution function used was a natural choice and preserved the mean value properties of the real situation.

Finally, some computer-simulated data were reported which verified the concepts used in the body of the text. An additional fact which emerged from the computed data was that the average size of m-gons varied approximately linearly with m.

Vapour pressure and calorimetric data for the solution of sulfur dioxide in aprotic solvents

ROBERT L. BENOIT AND ETELA MILANOVA

Département de Chimie, Université de Montréal, C.P. 6210, Succ. A, Montréal (Qué.), Canada H3C 3V1

Received December 15, 1978

ROBERT L. BENOIT and ETELA MILANOVA. Can. J. Chem. 57, 1319 (1979).

Vapour–liquid equilibrium data for dilute sulfur dioxide solutions in sixteen solvents were derived from total vapour pressure measurements at 25°C. The SO_2 enthalpies of solution at infinite dilution ΔH^0 were determined at 25°C by direct calorimetry. The solvents used belong to the aprotic class. The ΔH^0 values (kcal mol^{-1}) are for the non-polar solvents, isooctane (−3.5), cyclohexane (−3.5), *n*-heptane (−3.8), benzene (−5.8), and for the polar solvents, 1,2-dichloroethane (−5.5), nitromethane (−6.2), nitrobenzene (−6.3), acetonitrile (−6.7), ethyl acetate (−7.1), sulfolane (−7.3), propylene carbonate (−7.5), trimethyl phosphate (−8.9), tetrahydrofuran (−9.4), dimethylformamide (−10.9), pyridine (−11.6), dimethylsulfoxide (−13.0). Out of three correlation methods which we tested to account for our data in non-polar solvents, the Hildebrand solubility parameter treatment gives the best results. The SO_2 enthalpies of solution, ΔH^0, in the polar solvents are discussed in terms of solvent basicity. There is a good correlation between the ΔH^0 values, which relate to the basicity of the bulk solvent, and the solvent 'donor number' which is a molecular basicity parameter.

ROBERT L. BENOIT et ETELA MILANOVA. Can. J. Chem. 57, 1319 (1979).

On a déduit de mesures de pression de vapeur totale à 25°C des données sur l'équilibre vapeur–liquide de solutions diluées d'anhydride sulfureux dans seize solvants. Les enthalpies de solution de SO_2 à dilution infinie ΔH^0 ont été déterminées à 25°C par calorimétrie directe. Les solvants étudiés font partie de la classe aprotonique. Les valeurs de ΔH^0 (kcal mol^{-1}) sont pour les solvants non-polaires, isooctane (−3.5), cyclohexane (−3.5), *n*-heptane (−3.8), benzene (−5.8) et pour les solvants polaires, 1,2-dichloroéthane (−5.5), nitrométhane (−6.2), nitrobenzène (−6.3), acétonitrile (−6.7), acétate d'éthyle (−7.1), sulfolane (−7.3), carbonate de propylène (−7.5), phosphate de triméthyle (−8.9), tétrahydrofuranne (−9.4), diméthylformamide (−10.9), pyridine (−11.6), diméthylsulfoxyde (−13.0). Des trois méthodes de corrélation que nous avons considérées pour rendre compte de nos données avec les solvants non-polaires, celle utilisant les paramètres de solubilité d'Hildebrand donne le meilleur résultat. Les enthalpies de solution de SO_2, ΔH^0, dans les solvants polaires sont reliées à la basicité des solvants. On observe une bonne corrélation entre les valeurs de ΔH^0 qui sont reliées à la basicité du liquide, et le "nombre donneur" des solvants qui caractérise la basicité moléculaire.

The recovery and concentration of dilute sulfur dioxide from gaseous effluents produced by stationary sources are an environmental and industrial problem of increasing importance (1). Some of the wet chemical processes being developed to remove SO_2 use non-aqueous absorbents (2). This lends interest to the establishment of data on the free energy and enthalpy changes for the absorption of gaseous SO_2 in solvents. Such thermodynamic data for the solvents which belong to the aprotic class have further value, because in these media SO_2 is cleanly and easily reduced, chemically or electrochemically, to the radical ion $SO_2^{-\cdot}$ and its dimer the dithionite ion. This reduction reaction is used to advantage in the preparation of industrially important alkali dithionites (3) and in the operation of the Li–SO_2 high density energy battery (4). Finally, additional data on the solution of SO_2, a polar gas, should be valuable to test the applicability of various theories and correlations which are being developed to account for the properties of solutions of gases in liquids (ref. 5 and references cited therein).

Available literature data on vapour–liquid equilibria of SO_2–solvent systems are fairly extensive but scattered (6). Results are often reported for SO_2 in the form of Henry's constants or infinite dilution activity coefficients as determined by gas–liquid chromatography (7, 8). SO_2 solubilities are also given (9, 10). Extensive total vapour pressure measurements have been used to calculate the excess Gibbs function G^E (11) for some solvents. Less recent data are found in Frank's review (12). The enthalpies of solution of SO_2 have been determined for only a few solvents and, except for dimethylaniline (13), from the temperature dependence, often within a limited range, of vapour pressure or solubility.

This paper reports vapour–liquid equilibrium data derived from total vapour pressure measurements at 25°C on sixteen SO_2–solvent systems at low SO_2 concentrations. The SO_2 enthalpies of solution at

0008-4042/79/111319-05$01.00/0

infinite dilution were also determined at 25°C by direct calorimetry. The solvents used for this study belong to the aprotic class and were selected to cover a wide range of basicity (14) so that the effect of this solvent property could be assessed.

Experimental

Apparatus and Procedure

Solution vapour pressures at 25°C were measured with a precision quartz spiral gauge (Texas Instruments). The experimental set-up has been described before (15). The SO_2 partial pressures were obtained from the total equilibrium vapour pressures by subtracting the solvent vapour pressure calculated according to Raoult's law. The SO_2 mole fractions of the solutions were below 0.1 and the SO_2 partial pressures below 150 mm Hg.

The gas calorimeter and procedure used have been given previously (15). The calculated enthalpies of solution per mole of SO_2 at 25°C were within experimental errors independent of the SO_2 concentration (0.03–0.18 M). The enthalpies of solution reported, which are averages of usually 3–4 determinations, are assumed to be equivalent to the SO_2 enthalpies of solution at infinite dilution ΔH^0. Reproducibility was 0.1–0.2 kcal mol^{-1}; however, with dimethylsulfoxide the standard deviation was unexplicably high: 0.91 kcal mol^{-1} for seven determinations.

For both types of measurements the SO_2 concentrations in the solvents were determined iodometrically after flooding with water immediately after each experiment. Methanol was used when required to insure miscibility. In the case of pyridine, an addition of acid preceded that of iodine.

Materials

The solvents were reagent grade, or distilled before use, and dried over 4A activated molecular sieves. Anhydrous sulfur dioxide from Canadian Liquid Air was 99.98% pure.

Results and Discussion

The partial pressures P_{SO_2} (mm Hg) at 25°C are plotted in Fig. 1 as a function of the SO_2 molar concentration C_{SO_2} for 13 solvents. The curves are linear at low C_{SO_2}, usually below 0.5 M, and the corresponding proportionality constants are expressed as $H = P_{SO_2}/X_{SO_2}$, where P_{SO_2} is in atm and X_{SO_2} is the SO_2 mole fraction calculated from C_{SO_2} and the density of the solvent. Since the fugacity corrections are less than 0.3%, in view of the low pressures used for extrapolation, H is simply Henry's law constant. Our average deviations in H vary according to the volatility and basicity of the solvents. For basic pyridine where the solvent vapour pressure P_S is near 20 mm Hg and P_{SO_2} varies up to 7 mm Hg, the average deviation is 11%, but for basic dimethylsulfoxide with $P_S \sim 0.60$ mm Hg and $P_{SO_2} \leq 8$ mm Hg the deviation is lower, 6.4%. For weakly basic nitrobenzene, $P_S \sim 0.3$ mm Hg and $P_{SO_2} \leq 110$ mm Hg, the deviation is 0.7% but for acetonitrile, $P_S \sim 85$ mm Hg and $P_{SO_2} \leq 100$ mm Hg, the deviation is higher, 1.8%. Values of H are reported in Table 1 together with literature data for

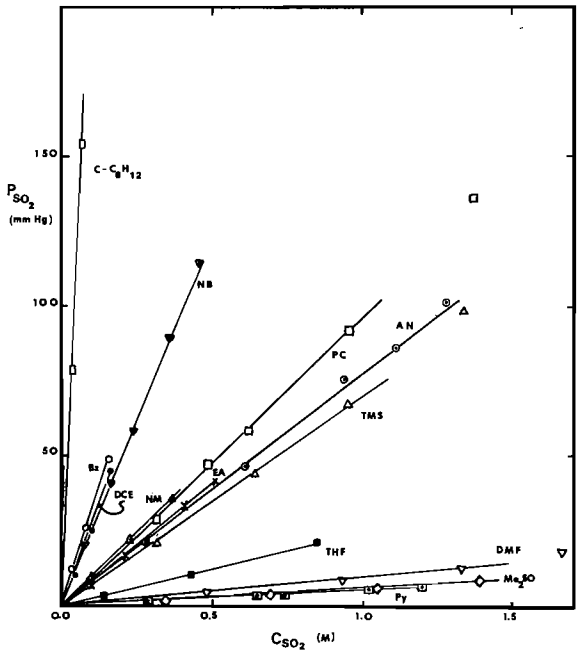

FIG. 1. SO_2 partial pressure for SO_2 solutions in aprotic solvents as a function of SO_2 molar concentration at 25°C. Pyridine (⊡, Py), dimethylsulfoxide (◇, Me_2SO), dimethylformamide (▽, DMF), tetrahydrofuran (■, THF), sulfolane at 30°C (△, TMS), acetonitrile (⊙, AN), ethyl acetate (×, EA), propylene carbonate (□, PC), nitromethane (◬, NM), nitrobenzene (▽, NB), 1,2-dichloroethane (●, DCE), benzene (○, Bz), cyclohexane (□, *c*-C_6H_{12}).

the solvents studied here and other solvents of interest. Our value for Me_2SO compares well with a previous value (7). Our value for nitrobenzene compares well with one out of three previous values (7, 8, 17). We believe that our static vapour pressure method leads to more reliable values of H; at any rate the chromatographic method appears to give widely different results where a comparison is possible such as for $C_6H_5NO_2$ (7, 8, 17).

In order to calculate the thermodynamic functions for the solution of SO_2, we take as standard states, for gaseous SO_2 that state in which SO_2 has unit atmosphere pressure, and for SO_2 as solute, that hypothetical state in which SO_2 has unit mole fraction. Then assuming ideal behaviour of the gas, the free energy of solution of SO_2 is given by:

$$\Delta G^0 = RT \ln H$$

Table 2 contains the values of ΔG^0 thus obtained, as well as ΔG^0 values calculated from reported SO_2 solubility data (10). These latter values are more positive than ours when the solubility of SO_2 is large, as is apparent when we compare data for nitromethane and acetonitrile. These differences arise because the SO_2–solvent systems studied

exhibit a positive deviation from Henry's law for increasing values of X_{SO_2}.

Our values for ΔH^0, the SO_2 enthalpy of solution, are listed in Table 2. In order to ascertain the validity of our direct calorimetric measurements, we also determined ΔH^0, for the solvent acetonitrile, from the dependence of Henry's law constant, H, on temperature. The values of H (atm) for 4–6 SO_2 concentrations ($0.2 < C_{SO_2} < 1.3\ M$) and three temperatures were as follows: 15.00°C, $H = 1.31$; 25.00°C, $H = 1.94$; 35.00°C, $H = 2.83$. ΔH^0 thus calculated, -6.8 kcal mol^{-1}, compares satisfactorily with the calorimetric values -7.1 ± 0.2 kcal mol^{-1} (five determinations). Furthermore, our calorimetric value -3.8 kcal mol^{-1} for the solvent *n*-heptane is identical with that calculated by Christian *et al.* (18) from their vapour pressure measurements at 10, 20, and 30°C. As expected, the ΔH^0 values deduced from the temperature coefficient of the SO_2 solubility are in rather poor agreement with our calorimetric ΔH^0 values. For example, we obtained for MeCN and benzene as solvents -7.1 and -5.8 kcal mol^{-1}, respectively, to be contrasted with -9.9 (10) and -6.7 kcal mol^{-1} (12) calculated from solubility. Our -7.1 kcal mol^{-1} value for ethyl acetate also suggests that $\Delta H^0 = -4.1$ kcal mol^{-1} for methyl acetate (12) is probably in error. Plotting our values of ΔH^0 against ΔG^0 both of which were independently determined, rather than plotting ΔS^0 vs. ΔG^0 or ΔH^0 vs. ΔS^0, in order to test for a simple "enthalpy–entropy relationship" (19), the slope of the correlation line is 2.91 and the correlation coefficient is only 0.973. However, the points do appear to follow a smooth (although non-linear) curve which could be used to estimate one thermodynamic parameter if the other one were known.

¶Calculated from solubility data and previous workers' conductivity data in ref. 25.

Turning to the results in Table 2, for the free energy of solution of SO_2 in the aprotic solvents, it is of interest to compare these ΔG^0 values in terms of deviations from Raoult's law. Taking $P^0 = 3.77$ atm for the vapour pressure of pure SO_2 at 25°C (8) and correcting for the non-ideality of the gas, the free energy of solution of SO_2 is calculated as $+0.79$ kcal mol^{-1} for an ideal system. Then, the systems involving the non-polar solvents, cyclohexane, *n*-heptane, isooctane, *n*-hexadecane, decahydronaphthalene, carbon tetrachloride, exhibit positive deviations

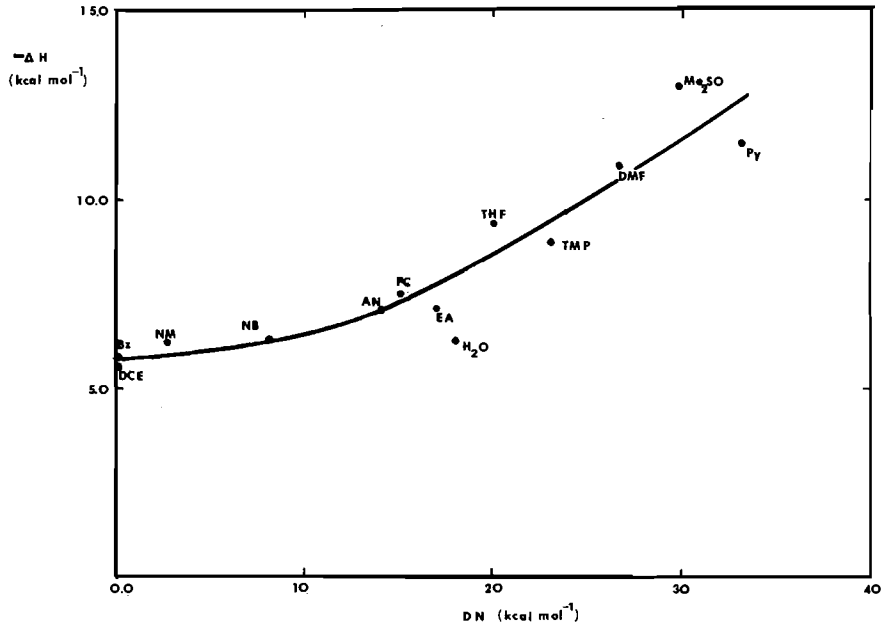

FIG. 2. Correlation between the enthalpy of solution of SO_2 in aprotic solvents and the donor number of the solvents.

from Raoult's law. Benzene, chlorobenzene, 1,2-dichloroethane, and nitrobenzene show only small deviations while all other polar aprotic solvents exhibit negative deviations from Raoult's law. These latter deviations can be attributed in the main to strong chemical interactions[1] between solute SO_2 and the basic solvent molecules.

Attempts were made to determine to what extent three correlation methods relating the solubility behaviour of gases in liquids (ref. 20 and references cited therein) to molecular parameters could account for our results with at least the three simpler non-polar solvents cyclohexane, *n*-heptane, and benzene. In both the free volume theory (20) and Pierotti's scaled particle theory, the calculated ΔG^0 and ΔH^0 values were found to be very sensitive to the solute and solvent molecular parameters whose values appear to differ widely according to the method used for their determination. Furthermore, both theories could not account for the observed higher SO_2 solubility in benzene. Hildebrand's solubility parameter method (ref. 21 and references cited therein) leads to better agreement between calculated and experimental values though the corresponding H values still differ by an average factor of 2. There again, uncertain values of molecular parameters, V_2^L, the partial molar volume of solute SO_2, as well as δ_2, the SO_2 solubility parameter, introduce a large uncertainty on calculated values of H.

Turning now to interactions of a chemical nature between solute SO_2 and solvent, it is of interest to try to account for such interactions in terms of acid–base reactions between SO_2, a Lewis acid, and basic solvent molecules. With this purpose in mind, we have plotted in Fig. 2 our values of ΔH^0, the SO_2 enthalpy of solution against an enthalpy parameter characterizing the basicity of the solvent molecules (14). We have taken as basicity parameter the widely used Gutman's donor number (DN) (22) which is minus the enthalpy of adduct formation between $SbCl_5$, a Lewis acid, and basic molecules as determined in dilute solution in 1,2-dichloroethane. The correlation between ΔH^0 and DN is good considering first that ΔH^0 relates to the basicity of the bulk solvent while DN relates to the basicity of isolated solvent molecules (14) and second that SO_2 is a "borderline" acid while $SbCl_5$ is a hard acid in Pearson's classification. The value $\Delta H^0 = -5.5$ kcal mol^{-1} for DN = 0 (1,2-dichloroethane) is remarkably close to the heat of condensation of SO_2 at 25°C, -5.4 kcal mol^{-1}. Then, if the enthalpy change for the solution of gaseous SO_2 in a solvent at 25°C is viewed as a two-step process, first condensation of SO_2 then followed by mixing of liquid SO_2 with the solvent, the previous observation indicates a very small heat of mixing of liquid SO_2 with 1,2-dichloroethane. This is somewhat unexpected considering the polar nature of both solute and solvent molecules. On the other hand, the ΔH^0 values (Table 2) for the non-polar solvents *n*-hexadecane, isooctane, cyclohexane, and *n*-heptane, all presumably with DN = 0, are all near -3.5 kcal mol^{-1}, so that this time the contribution of the heat of mixing is large and near

[1]No correlation was found between the ΔH^0 values and the dipole moment of the solvent molecules.

+2 kcal mol^{-1}. However, the calculation of this heat of mixing from the solubility parameters δ_1, δ_2, and V_2^L gives values which, although depending on the values selected for the parameters δ_2 and V_2^L, are respectively lower than +1.0 kcal mol^{-1} for isooctane, +0.7 for *n*-heptane, and +0.5 for cyclohexane. It thus appears that we cannot account simply for the heat of solution of SO_2 in these inert non-polar solvents.

In view of the preceding it is perhaps not surprising that in the correlation between ΔH^0 and DN some representative points are off the line by as much as 1.0 kcal mol^{-1} because of the effect of non-chemical interactions between SO_2 and solvent molecules. The position of the correlation line for DN $\geq$ 30 is in doubt because of the opposing values of ΔH^0 and DN for Me_2SO and pyridine, the solution enthalpy of SO_2 being more negative (although the margin of error is uncomfortably high) in Me_2SO than in pyridine, while the opposite is true for the enthalpy of reaction with $SbCl_5$. Reasons for this reversal may be that SO_2 and $SbCl_5$ do not interact with the same basic site in either the Me_2SO or pyridine molecules. DN (pyridine) could also be too large if the reaction between $SbCl_5$ and pyridine involved additional complex ionization of $SbCl_5$ or of the adduct. Among the solvents listed in Table 2, it is dimethylaniline which has the highest $-\Delta H^0$ value, 15.0 kcal mol^{-1}, as well as the lowest Henry constant. It is noteworthy that dimethylaniline is the non-aqueous absorbant used industrially to recover SO_2 from waste smelter gases (ref. 2 and references cited therein). It is apparent from Fig. 2 that the spread in the $-\Delta H^0$ values for the different solvents is some five times smaller than for the DN values. This is largely due to the fact that SO_2 is a much weaker Lewis acid than $SbCl_5$, in this respect SO_2 ranks even slightly weaker than I_2 (23). $SbCl_5$ is thus a better discriminating Lewis acid to differentiate bases in inert media such as 1,2-dichloroethane, but SO_2 has the advantage that it can be used to assess the basicity of bulk solvents because it does not give any complex ionization reaction with the more basic solvents as $SbCl_5$ does (14). That the representative point for the protic solvent H_2O (DN = 16.4 (24)) falls off the line in Fig. 2 is not unexpected and using for H_2O the value DN = 33, which is supposed to characterize the basicity of bulk water (22), makes matters even worse. This emphasizes the difficulty in relating bulk basicity to molecular basicity for protic solvents (14). However, assuming that water basicity plays a major part in determining the heat of solution of SO_2 in water,[2] our ΔH^0 data suggest that the basicity of bulk water is low and near that of nitrobenzene; interestingly, the same result holds for I_2, another non H-bonding molecular acid, since the heats of solution of solid I_2 are, respectively, +5.2 kcal mol^{-1} (H_2O) and +4.7 kcal mol^{-1} ($C_6H_5NO_2$).

[2]The major species in aqueous solution is SO_2 (ref. 26 and references therein).

Pyrolysis of cyclopentane behind reflected shock waves

BANSI L. KALRA,[1] STUART A. FEINSTEIN,[2] AND DAVID K. LEWIS[3]

Department of Chemistry, Colgate University, Hamilton, NY 13346, U.S.A.

Received May 23, 1978

BANSI L. KALRA, STUART A. FEINSTEIN, and DAVID K. LEWIS. Can. J. Chem. 57, 1324 (1979).

Gas samples containing either 0.20% or 1.0% cyclopentane plus 0.25% *tert*-butyl alcohol in argon have been heated to 1185–1257 K in a single pulse shock tube. The previously studied dehydration of the alcohol was used as an internal standard reaction for temperature measurement. Pyrolysis of the cyclopentane yielded a broad spectrum of C_1–C_5 hydrocarbon products; however, the products and their concentration ratios were in good agreement with those recently reported by Tsang, in a comparative rate study of cyclopentane pyrolysis vs. cyclohexene decyclization. Thus strong support is offered for Tsang's proposed complex mechanism involving (*a*) molecular isomerization to 1-pentene and subsequent degradation of that product, (*b*) molecular decomposition to cyclopropane and ethene, followed by isomerization of cyclopropane to propene, and (*c*) induced decomposition to a variety of C_1–C_5 hydrocarbons plus H_2 via hydrogen atom abstraction from cyclopentane by various radicals generated from 1-pentene. The only significant disagreement with Tsang's study is a ~40° temperature discrepancy; possible sources of this are discussed.

BANSI L. KALRA, STUART A. FEINSTEIN et DAVID K. LEWIS. Can. J. Chem. 57, 1324 (1979).

On a chauffé des échantillons gazeux contenant soit 0.20% ou 1.0% de cyclopentane plus 0.25% d'alcool *tert*-butylique dans l'argon à des températures allant de 1185 à 1257 K dans un tube de chocs à pulsation unique. On a utilisé la déshydratation étudiée antérieurement comme réaction de référence interne pour la mesure de la température. La pyrolyse du cyclopentane fournit une grand nombre d'hydrocarbures de C_1 à C_5; toutefois la nature des produits et les rapports de leurs concentrations sont en bon accord avec ceux rapportés par Tsang dans une étude comparée des vitesses de pyrolyse du cyclopentane vs la décyclisation du cyclohexène. Nos résultats militent donc fortement en faveur du mécanisme complexe proposé par Tsang qui implique (*a*) une isomérisation moléculaire fournissant du pentène-1 et une dégradation subséquente de ce produit, (*b*) une décomposition moléculaire en cyclopropane et en éthène et (*c*) une décomposition induite en une variété d'hydrocarbures de C_1 à C_5 plus du H_2 par l'intermédiaire d'enlèvements d'atomes d'hydrogène du cyclopentane par divers radicaux formés à partir du pentène-1. La seule différence importante avec l'étude de Tsang a trait à une différence d'environ ~40°; on discute des sources possibles de cette différence.

Introduction

Kinetic and thermodynamic parameters for thermal decompositions of hydrocarbon molecules are of interest on theoretical grounds (1), and because of the eventual usefulness of such information for numerical modeling of cracking and combustion reactions. We have been studying a number of small cyclic alkanes and alkenes at high temperatures in chemical shock tubes (2–4). This series included a brief unpublished study of cyclopentane at ~1200–1250 K via the comparative rate single-pulse technique, using *tert*-butyl alcohol as the internal standard.

Recently, Tsang (5) reported the results of an extensive and careful comparative single-pulse shock tube study of cyclopentane pyrolysis at 1050–1250 K, in which he used the decomposition of cyclohexene to ethene and 1,3-butadiene as the internal standard. He proposed a complex radical mechanism which provided a very satisfactory fit to his data. Arrhenius parameters determined for various steps in the overall process are in reasonable agreement with earlier studies of those specific reactions and/or with thermochemical predictions.

Tsang chose his experimental conditions so as to minimize the effects of interaction between the cyclopentane pyrolysis and the reference or possible impurity reactions; and there is nothing in his data or results to suggest that his efforts were unsuccessful. Nevertheless, our existing data, we feel, provide a further opportunity to confirm the probable reliability of Tsang's results, since they are derived from a different apparatus and standard reaction. The

purpose of this report is to compare our measured product yields with those reported by Tsang, and to draw attention to areas of agreement or disagreement and comment on their significance.

Experimental Section

The 2.54 cm id Pyrex single-pulse shock tube used for our comparative rate experiments has been previously described (6). Reaction products were analyzed on Varian Aerograph Model 1440-20 and Model 90-P gas chromatographs. The previously characterized reaction *tert*-butyl alcohol → isobutene + water (7) was used as the reference reaction. Both the cyclopentane (K and K Laboratories) and the *tert*-butyl alcohol (Brothers Chemical Co.) were subjected to an extensive pre-purification process consisting of a series of degassings at 77 K and distillations from slush baths. Gas chromatographic analysis for hydrocarbon impurities indicated probable final purity of > 99.99% for each reactant. Reaction mixtures were prepared in stainless steel tanks at $p > 1$ atm, with Ultra-High Purity grade argon (Matheson) diluent, at least three days before use.

Reactant sample compositions and experimental conditions are summarized in Table 1.

TABLE 1. Summary of experimental conditions

*Pressures in shock tube sample section before heating.
†Temperatures behind reflected shocks, deduced from isobutene yields, measured reaction times τ, and the previously measured rate constants for *tert*-butyl alcohol → isobutene + H_2O: $\log (k, s^{-1}) = 14.6 - 66\,200/4.576T$ (ref. 7).

Results

The following gases were found in product samples: hydrogen, methane, ethane, ethene, propene, allene, isobutene, *tert*-butyl alcohol, 1,3-butadiene, 1-pentene, cyclopentane, cyclopentene, and cyclopentadiene. Earlier studies of *tert*-butyl alcohol pyrolysis (7, 8) and a few runs on cyclopentane plus argon mixtures in the present study indicated that the isobutene was produced solely from the alcohol and that the 1,3-butadiene and C_5 products came only from the cyclopentane. The C_1, C_2, and C_3 products were produced primarily from cyclopentane, but with minor contributions from *tert*-butyl alcohol and its primary decomposition product, isobutene.

Graphs have been drawn of $\log_{10}$ $\{([\text{product}]_t/[⬠]_0) \times 100\}$ vs. $1/T$ (K) for each cyclopentane product. Examples for ethene, propene, allene, and butadiene appear in Fig. 1. Here, $[\text{product}]_t$ represents concentration of the product in the post-shock sample, and $[⬠]_0$ represents initial cyclopentane concentration for that run. The quantity within the { } is the percent product relative to initial reactant. This presentation is similar to a first-order rate plot; coincidence of the data representing different percentage mixtures would indicate first-order dependence on cyclopentane for production of a particular product. The lines through the groups of data in Fig. 1 were determined by linear least-squares analysis, with all variance assigned to the *y*-axis variable.

Also shown in Fig. 1 are least-squares lines through the product yields reported by Tsang (5) for comparable reaction times. The symbol on each line represents the upper limit of the temperature range covered by Tsang with the respective sample mixture. Extension of the line to the left of the symbol assumes that Tsang's results can be reliably extrapolated upward by 50–100 K as required. Since Tsang used cyclohexene decyclization as his comparative rate standard and deduced reaction temperatures from 1,3-butadiene yields, he was not able to determine production rates for that product from cyclopentane. And since Tsang's cyclopentane/cyclohexene reactant ratio was 100/1, we were concerned that the contribution of 1,3-butadiene from the subject molecule might be comparable to that from the standard, resulting in calculated temperatures higher than actual reaction temperatures. To assess this possibility, we have shown in Fig. 1*d* the expected percentage of 1,3-butadiene from cyclohexene, relative to initial cyclopentane concentration, as a function of temperature under the conditions of Tsang's experiments. The calculated values were based on the Arrhenius parameters for cyclohexene decyclization previously reported by Tsang (9). As can be seen, cyclohexene was probably the only significant source of butadiene at $T < 1200$ K.

Discussion

A comparison of the results of the two independent studies indicates good agreement in terms of products produced and their concentration ratios. Tsang did report small amounts of cyclopropane, which we did not observe; however, it is probable that this material was produced in our study but not recognized since its retention time and that of allene on our column were identical. Overall, it appears that the cyclopentane pyrolysis was proceeding via essentially the same mechanism in both studies, with no overwhelming effect from the comparative rate standard, from impurities, or from other experimental artifacts.

Considering both sets of data, there appears to be a trend toward decreasing reaction order at lower reactant percentages. Tsang's data from mixtures containing 0.4 to 5% cyclopentane show apparent

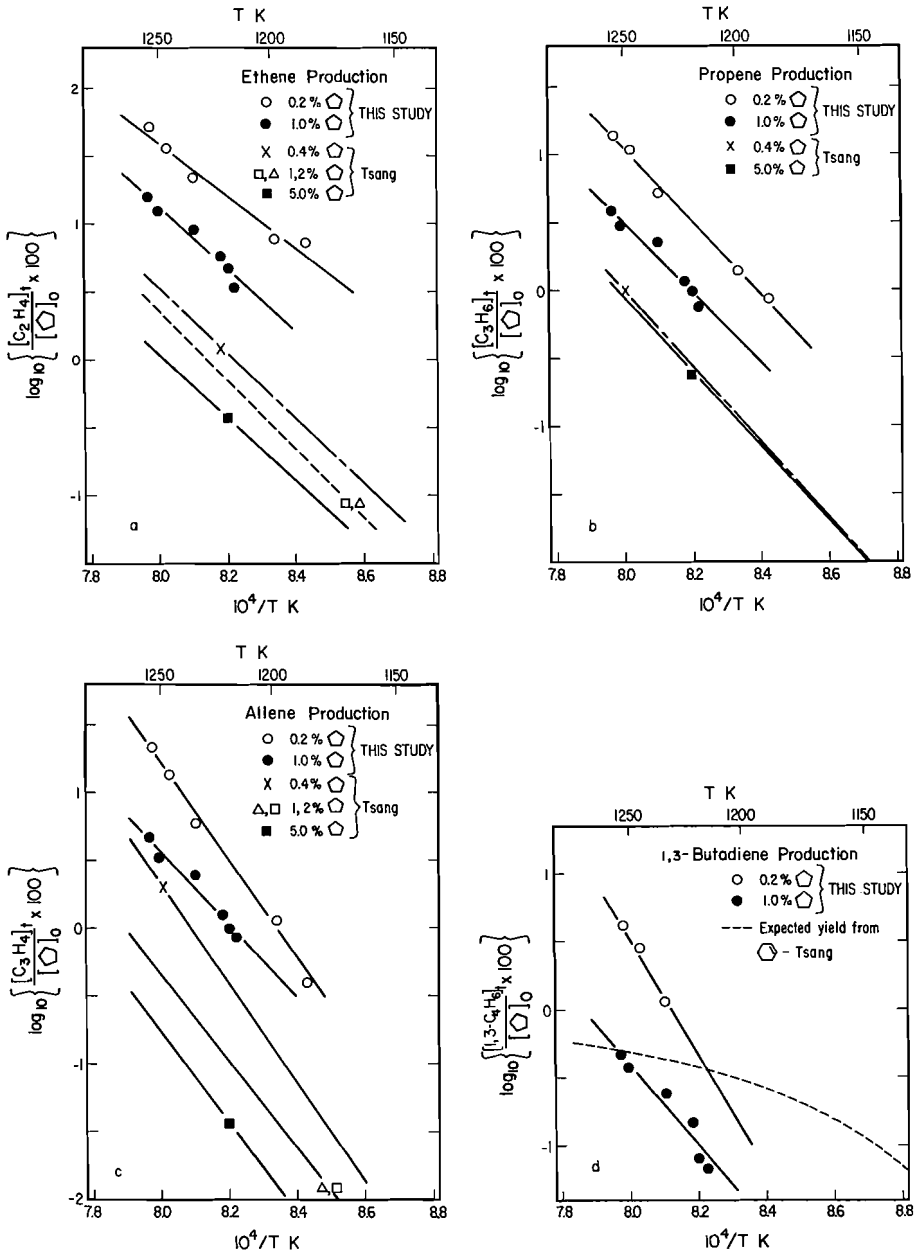

FIG. 1. (*a*) log (% C_2H_4) produced relative to initial concentration of cyclopentane as a function of $1/T$; (*b*) log (% C_3H_6) produced relative to initial concentration of cyclopentane as a function of $1/T$; (*c*) log (% C_3H_4) produced relative to initial concentration of cyclopentane as a function of $1/T$; (*d*) log (% 1,3-C_4H_6) produced relative to initial concentration of cyclopentane as a function of $1/T$.

reaction orders for production of most products between 0 and 1. Our data, from 0.2 to 1% mixtures give approximately zero order dependence on reactant for all C_1–C_4 products. This overall behavior is consistent with the speculation that the bulk of C_1–C_4 products are the result of induced decomposition of cyclopentane and subsequent reactions caused by relatively invariant quantities of impurities present in the comparative rate standard or diluent gas, or introduced into sample mixtures during the gas handling process.

A third area for comparison is the apparent extent of reaction in comparable percentage (1%) mixtures, at comparable reaction times and temperatures. Product % vs. inverse temperature plots (Fig. 1) for ethene, propene, and allene show a

40 ± 10 K discrepancy between the two studies. The larger than average difference (50° vs. 40°) for allene is consistent with our expectation that there was a small cyclopropane contribution to the allene analysis in our work, and the smaller than average (30° vs. 40°) difference for propene suggests that Tsang's propene production data from 1% mixtures may be slightly high. Lowering that line slightly would give about the same reaction order for propene production that we observed.

The ~40° difference may be attributed to (*a*) differences in impurity levels or other unknown factors, which differently affect the rates of cyclopentane pyrolysis in the two shock tubes, or (*b*) errors in temperature calculations on one or both shock tubes resulting from the choice of different comparative rate standard reactions or from non-ideal shock tube behavior. As described above, it seems unlikely that (*a*) is the dominant cause for the observed difference in rates. Possibility (*b*) will now be considered.

Tsang has previously studied the cyclohexene decyclization in comparative rate shock tube experiments against three other unimolecular reactions (9–11). The cleanliness of the reaction up to 1200 K and the close agreement among the three studies suggests that there can be very little error in Tsang's cyclopentane study temperature calculations attributable to incorrect Arrhenius parameters. However, a possible source of error in Tsang's study is induced decomposition of the standard molecule by radicals that must have been present. Tsang has measured rates of fragmentation of cyclohexyl radical generated from *tert*-butyl cyclohexane (12) and from induced decomposition of cyclohexane (13), but there is inadequate information available to estimate the extent of induced decomposition of cyclohexene relative to that of cyclopentane, in a mixture of the two. If the same relative percentages of each reactant suffered induced decomposition, which seems a reasonable assumption, then a small but not negligible fraction of the cyclohexene loss could be attributed to the induced channel.

Since the Arrhenius parameters for *tert*-butyl alcohol pyrolysis used for temperature calculations in the present work were determined from a study of *tert*-butyl alcohol vs. cyclohexene (7), less than 5° of the apparent difference between Tsang's and our cyclopentane data can be attributed to errors in these parameters. A possible source of error in the present work is further reaction of the isobutene product or direct bond breaking, rather than molecular elimination, of the alcohol. In our earlier study of *tert*-butyl alcohol (7), we found allene and propene formed as side products above 1150 K. The allene/isobutene ratio was 0.1 at 1200 K, at which temperature about 30% of the alcohol was reacted; and the ratio increased with temperature. Tsang (8) has suggested that these two side products arise from decomposition of isobutene. If so, our calculated temperatures from apparent isobutene yields may be up to 10 degrees too low at ~1200 K. Mintz and Cvetanović (14) have proposed that the C_3 side products result from a C—C bond breakage of the alcohol:

$$t\text{-}C_4H_9OH \rightarrow \dot{C}H_3 + (CH_3)_2\dot{C}OH$$

Either of the above processes, if important, would produce an error that rapidly increases with temperature. However, the divergence between Tsang's extrapolated and our actual C_2–C_4 product percentages appears essentially constant over the 1200–1250 K range. Breakage of the C—O bond also appears likely, considering the similarity between C—C and C—O single-bond strengths:

$$t\text{-}C_4H_9OH \rightarrow t\text{-}\dot{C}_4H_9 + \dot{O}H$$
$$\hookrightarrow i\text{-}C_4H_8 + \dot{H}$$

This parallel channel for isobutene formation would result in a positive rather than negative temperature error. Overall, the most probable significant effect of either C—C or C—O bond breaking processes is not a large change in isobutene yield, but rather an increase in the induced decomposition of cyclopentane due to the production of radicals. The ~0 order rates of C_1–C_4 hydrocarbon production in our experiments supports this interpretation.

A potential source of significant error in shock tube experiments is the cold boundary layer that grows in thickness from the walls into the reacting gas. In comparative rate experiments, the inclusion of improperly heated gas in the product samples affects the calculated rate constants of both reference and subject reactions. The more nearly identical the Arrhenius parameters of the two reactions, the more nearly exact is the cancellation of the error. Although both Tsang's shock tube and our own are of small diameter (1 in. id), we have both avoided use of the reaction time extending tailored interface technique, and used similar short dwell times in the interest of minimizing boundary layer influence. A further argument against extreme influence of boundary layer growth is the fact that we are routinely able to achieve conversion rates $\gtrsim$95% for unimolecular reactions of organic species within the ~800 μs dwell time with sufficiently hot shocks.

Considering the above factors and the quite linear offset of our rate data from that reported by Tsang, we feel the most probable source of the offset is induced decomposition of cyclopentane caused by

tert-butyl alcohol-generated radicals in our study. However, from the ~40° magnitude of the offset, it seems possible that Tsang's reported temperatures might be 0–15° higher than actual values, the error being caused by induced decomposition of his internal standard. If so, correction of his comparative rate data would result in a small upward adjustment of all pre-exponential factors deduced from his analysis. The correction would not appreciably change apparent activation energies, his enthalpy analysis of reactants, intermediates and products, or the mechanistic interpretations he has presented.

Differential equation for transport along parallel linear successions of identical symmetrical potential barriers

M. J. DIGNAM

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received September 26, 1978

M. J. DIGNAM. Can. J. Chem. **57**, 1329 (1979).

The differential equation for transport of non-interacting species along parallel paths, each consisting of a linear succession of identical symmetrical potential barriers, is expanded as an infinite series in the derivatives of the electrostatic potential and concentration. The first order expression is shown to represent the model adequately for all but extremely high space charge concentrations and/or extreme departures from steady-state conditions. Under the appropriate limiting conditions it reduces to the well-known linear transport equation, and to the Mott–Cabrera equation, but extends these to higher concentrations since the formulation forbids hops into occupied sites. The treatment leads to a concentration independent diffusion coefficient, but to a concentration dependent mobility.

M. J. DIGNAM. Can. J. Chem. **57**, 1329 (1979).

On a étendu l'équation différentielle décrivant le transport d'espèces qui n'interagissent pas et qui suivent des chemins parallèles, chacun correspondant à une série linéaire de barrières de potentiel symétriques et identiques, sous forme d'une série infinie de dérivés du potentiel électrostatique et de la concentration. On montre que l'expression du premier ordre représente adéquatement le modèle pour tous les cas exceptés ceux relatifs aux concentrations extrêmement élevées de charges spatiales et ceux où les conditions s'écartent d'une façon extrême d'un état stationnaire. Sous des conditions limites appropriées, elle est réduite à l'équation bien connue des transports linéaires et à l'équation de Mott–Cabrera; elle étend toutefois ces équations à des concentrations plus élevées puisque la formulation empêche des sauts vers des sites occupés. Ce traitement conduit à un coefficient de diffusion qui est indépendant de la concentration mais une mobilité qui dépend de la concentration.

[Traduit par le journal]

Introduction

The purpose of this paper is to derive the differential equation for transport of non-interacting species, in general carrying a charge, along parallel paths each consisting of a linear succession of identical symmetrical potential barriers. Although the transport model itself is well-known (1–3), the development of the differential equation of transport for the model, in a general way, was first published by Dignam, Young, and Goad in 1973 (4). This paper extends the earlier treatment both by including the effect of site depletion and by deriving the full second order correction to the first order approximation. The latter allows the range of applicability of the first order equation to be defined for all values of the field strength. The general transport equation has found its main application in the areas of metal oxidation, including anodic oxidation (2–8). Recently, Fromhold has been particularly active in this field, mainly in determining the accumulative effects of space charge on transport processes, through a step-by-step integration of a difference equation for the transport process. (For a review of this work see ref. 8.) In this paper, a differential equation of transport is derived from a difference equation, and its range of validity assessed. For many problems, it is easier and/or more informative to work from the differential equation of transport.

Derivation of Transport Equation

The model is one in which the mobile ionic species must surmount a succession of identical, symmetrical, potential barriers, of height U, and distance from minimum to maximum a. We suppose that:

(*1*) The problem can be treated as a one-dimensional one.

(*2*) Discreteness of charge effects can be neglected in relation to space charge effects which are treated in a continuum fashion.

(*3*) All interaction forces between the mobile species may be neglected except for coulomb forces, which are handled through space charge, as above, and a hard sphere type of force which prevents two species from occupying the same potential well.

(*4*) The height of a potential barrier situated at position x in the presence of an electric field resulting from a combination of space charge and an external

0008-4042/79/111329-06$01.00/0

potential difference is

$$U + qV_x - qV_{x\pm a}$$

where q is the charge on the ion, V the local electrostatic potential at the position indicated by the subscript, the $-$ and $+$ signs being chosen for barrier crossing in the $+x$ and $-x$ directions respectively.

On the basis of elementary rate theory, the net particle flux in the $+x$ direction, J, is thus given by the following:

$$[1]\quad J = m_{x-a}(1 - m_{x+a}/M)\nu \times \exp[-(U + qV_x - qV_{x-a})/kT] - m_{x+a}(1 - m_{x-a}/M)\nu \times \exp[-(U + qV_x - qV_{x+a})/kT]$$

where ν is the particles attempt frequency, $m_{x\pm a}$ the concentration per unit area of mobile species situated near the potential minimum at $x \pm a$, and M the number of sites per unit area for such species at the potential minima. The factors $(1 - m_{x\pm a}/M)$ are included to exclude hops into occupied sites.

The concentrations per unit area may be replaced by concentrations per unit volume through the substitutions

$$[2]\quad m_{x\pm a} = 2an_{x\pm a}$$
$$M = 2aN$$

We define the following dimensionless parameters

$$c = n/N = m/M$$
$$p = qV/kT$$
$$[3]\quad s = x/a$$
$$j = J/[2a\nu N \exp(-U/kT)]$$
$$\varepsilon = qaE/kT = -\mathrm{d}p/\mathrm{d}s$$

where $E = -\partial V/\partial x$ and is the electric field strength.

Equation [1] can now be written

$$[4]\quad j = -\exp(-p_s)[c_{s+1}(1 - c_{s-1})\exp(p_{s+1}) - c_{s-1}(1 - c_{s+1})\exp(p_{s-1})]$$

Setting

$$[5]\quad \alpha = c/(1 - c) = n/(N - n)$$

eq. [4] reduces to

$$[6]\quad j = -\exp(-p_s)[(\alpha\exp(p))_{s+1} - (\alpha\exp(p))_{s-1}]/(1 + \alpha)_{s+1}(1 + \alpha)_{s-1}$$

Taylor series expansions of the functions $(\alpha\exp(p))_{s\pm1}$ and $(1 + \alpha)_{s\pm1}$ about s convert eq. [6] to

$$[7]\quad j = -\frac{2\exp(-p)\{\sinh\partial/\partial s\}(\alpha\exp(p))}{[\{\exp\partial/\partial s\}(1 + \alpha)][\{\exp(-\partial/\partial s)\}(1 + \alpha]}$$

where the terms in braces are operators.

Using the identity

$$\{[\exp(-p)](\partial/\partial s)[\exp(p)]\} \equiv -\{\varepsilon - \partial/\partial s\}$$

it follows that

$$\{[\exp(-p)](\partial/\partial s)^n[\exp(p)]\} \equiv \{[\exp(-p)](\partial/\partial s)[\exp(p)]\}^n \equiv (-1)^n\{\varepsilon - \partial/\partial s\}^n$$

so that eq. [7] may be written

$$[8]\quad j = 2[\{\sinh(\varepsilon - \partial/\partial s)\}\alpha]/[(1 + \alpha)^2 + (1 + \alpha)\alpha'' - \alpha'^2 + \cdots]$$

where the prime denotes differentiation by s.

Factoring $(\varepsilon - \partial/\partial s)$ from the operator, eq. [8] reduces to

$$[9]\quad j = 2[\hat{O}(\varepsilon\alpha - \alpha')]/[(1 + \alpha)^2 + (1 + \alpha)\alpha'' - \alpha'^2 + \cdots]$$

where

$$[10]\quad \hat{O} \equiv \sum_{l=1,3,5,\ldots} (\varepsilon - \partial/\partial s)^{l-1}/l!$$

In order to expand j in terms of increasing order in the derivatives of p and α, $\hat{O}$ must be expanded in terms of increasing order in $\partial/\partial s$. To this end we define $\hat{T}_i^{l-1}$ to be all terms in the expansion of $(-1)^i\{\varepsilon - \partial/\partial s\}^{l-1}$ of order i in $\partial/\partial s$ so that

$$[11]\quad \{\varepsilon - \partial/\partial s\}^{l-1} \equiv \sum_{i=0}^{l-1} (-1)^i\hat{T}_i^{l-1}$$

Since ε and $\partial/\partial s$ do not commute, $(\varepsilon - \partial/\partial s)^n$ cannot be expanded using the binomial theorem. The following procedure is used to obtain $\hat{T}_0{}^n$, $\hat{T}_1{}^n$, $\hat{T}_2{}^n$, ..., $\hat{T}_i{}^n$.

$\hat{T}_0{}^n$ represents the term zero order in $\partial/\partial s$ in the expansion of $(\varepsilon - \partial/\partial s)^n$ and is clearly given by ε^n.

$\hat{T}_1{}^n$ is the term first order in $\partial/\partial s$ in the expansion of $-(\varepsilon - \partial/\partial s)^n$. It is made up of n terms, corresponding to the n factors from which $\partial/\partial s$ may be selected. A typical term is given by $\varepsilon^{n-1-K}(\partial/\partial s)\varepsilon^K$. That is, there is a total of n factors in each term, $n-1$ consisting of ε, the remaining one being $-\partial/\partial s$. Thus $\hat{T}_1{}^n$ is given by

$$\hat{T}_1{}^n = \sum_{K=0}^{n-1} \varepsilon^{n-1-K}(\partial/\partial s)\varepsilon^K = \sum_{K=0}^{n-1} T_0{}^{n-1-K}(\partial/\partial s)\varepsilon^K$$

$\hat{T}_2{}^n$ represents the sum of all terms arising from the different ways of selection $-\partial/\partial s$ from two of the n factors in $(\varepsilon - \partial/\partial s)^n$. If one of the derivatives is selected from the $(K+1)$th factor from the right hand side, and the other from one of the factors to the left of it, then a typical term belonging to this subset has the form

$$[\varepsilon^{n-K-2-j}(\partial/\partial s)\varepsilon^j](\partial/\partial s)\varepsilon^K$$

The sum of all such terms having the right hand derivative selected from the $(K+1)$th term from the right is obtained by summing over j from 0 to $n-K-2$. But

$$\sum_{j=0}^{n-K-2} \varepsilon^{n-K-2-j}(\partial/\partial s)\varepsilon^j = \hat{T}_1{}^{n-K-1}$$

Finally, summing over K we have

$$\hat{T}_2{}^n = \sum_{K=0}^{n-2} T_1{}^{n-K-1}(\partial/\partial s)\varepsilon^K$$

If a third differential operator is selected from the $(K+1)$th position from the right, the other two on the left of it, then by the same process of reasoning it follows that all terms belonging to $T_3{}^n$ having this form, sum to $\hat{T}_2{}^{n-K-1}(\partial/\partial s)\varepsilon^K$ so that $\hat{T}_3{}^n$ is given by

$$\hat{T}_3{}^n = \sum_{K=0}^{n-3} T_2{}^{n-K-1}(\partial/\partial s)\varepsilon^K$$

Repeated application of this process leads to the following general recursive relationship.

$$[12] \quad \hat{T}_i{}^n = \sum_{K=0}^{n-i} \{T_{i-1}{}^{n-1-K}(\partial/\partial s)\varepsilon^K\} \quad i \geq 1$$

If we had begun by selecting the terminal differential operator from the left rather than from the right hand side, an equivalent expression would have been obtained in which the factors $\hat{T}_{i-1}{}^{n-1-K}$ and ε^K are interchanged in eq. [12]. This is the form of the equivalent relationship derived in ref. 4. (A typographical error appears in eq. [2.18], ref. 4: $T_{i-1}{}^k$ should read $T_{i-1}{}^{k+i-2}$.)

We can now write

$$[13] \quad \hat{T}_0{}^n = \varepsilon^n$$

while $\hat{T}_1{}^n$ is given by

$$\hat{T}_1{}^n = \sum_{K=0}^{n-1} \varepsilon^{n-1-K}(\partial/\partial s)\varepsilon^K$$

$$= \sum_{K=0}^{n-1} \varepsilon^{n-1-K}\varepsilon^K(\partial/\partial s) + \varepsilon' \sum_{K=0}^{n-1} \varepsilon^{n-1-K}K\varepsilon^{K-1}$$

On carrying out the summation

$$[14] \quad \hat{T}_1{}^n = \binom{n}{1}\varepsilon^{n-1}(\partial/\partial s) + \binom{n}{2}\varepsilon'\varepsilon^{n-2}$$

where

$$\binom{n}{K} = n!/K!(n-K)!$$

In principal all higher order terms can be evaluated in the same way.

Expanding $\hat{O}$ now in terms of increasing order in $\partial/\partial s$, i.e.

$$[15] \quad \hat{O} = \sum_{i=0}^{\infty} (-1)^i \hat{O}_i$$

we have from eqs. [10] and [11]

$$[16] \quad \hat{O}_i = \sum_{l \geq i}^{\infty} T_i{}^{l-1}/l!$$

where l is restricted to odd integer values. Thus

$$[17] \quad \hat{O}_0 = \sum_{l=1,3,5,\ldots} \frac{1}{l!}\binom{l-1}{0}\varepsilon^{l-1}$$

$$[18] \quad \hat{O}_1 = \left(\sum_{l=3,5,\ldots} \frac{1}{l!}\binom{l-1}{1}\varepsilon^{l-2}\right)\frac{\partial}{\partial s} + \left(\sum_{l=3,5,\ldots} \frac{1}{l!}\binom{l-1}{2}\varepsilon^{l-3}\right)\varepsilon'$$

However,

$$[19] \quad \sum_{l \geq K+1} \frac{1}{l!}\binom{l-1}{K}\varepsilon^{l-1-K} = \frac{1}{K!}\sum_{l=1,3,5,\ldots} \frac{(l-1)(l-2)\ldots(l-K)}{l!}\varepsilon^{l-K-1} = \frac{1}{K!}\sum_{l=1,3,5} \frac{1}{l!}\frac{d^K}{d\varepsilon^K}(\varepsilon^{l-1})$$

$$= \frac{1}{K!}\frac{d^K}{d\varepsilon^K}\left[\varepsilon^{-1}\sum_{l=1,3,5} \frac{\varepsilon^l}{l!}\right] = \frac{1}{K!}\left[\frac{d^K}{d\varepsilon^K}\left(\frac{\sinh\varepsilon}{\varepsilon}\right)\right]$$

Thus

[20] $$\hat{O}_0 = (\sinh \varepsilon)/\varepsilon$$

and

[21] $$\hat{O}_1 = \left[\frac{d}{d\varepsilon}\left(\frac{\sinh \varepsilon}{\varepsilon}\right)\right]\frac{\partial}{\partial s} + \frac{1}{2!}\left[\frac{d^2}{d\varepsilon^2}\left(\frac{\sinh \varepsilon}{\varepsilon}\right)\right]\varepsilon'$$

Upon retaining only up to first order derivatives, the first order expansion of j is obtained from eqs. [9] and [20] and is given by

[22] $$j_1 = \frac{2(\varepsilon\alpha - \alpha')}{(1+\alpha)^2}\left(\frac{\sinh \varepsilon}{\varepsilon}\right)$$

For the model chosen, elementary statistical mechanics gives for the electrochemical potential of the mobile defects, $\bar{\mu}$, the result (see Appendix)

[23] $$\bar{\mu} = \mu^0 + kT \ln \alpha + qV$$

where μ^0 is the standard chemical potential. Thus from eqs. [23] and [3]

[24] $$(\varepsilon\alpha - \alpha') = -\frac{\alpha}{kT}\left(\frac{\partial \bar{\mu}}{\partial s}\right)$$

so that upon conversion to conventional variables eq. [22] can be written

[25] $$J_1 = -\frac{DN\alpha}{kT(1+\alpha)^2}\left(\frac{\partial \bar{\mu}}{\partial x}\right)\frac{\sinh (qaE/kT)}{(qaE/kT)}$$

where

[26] $$D = 4a^2\nu \exp(-U/kT)$$

For $qaE/kT \ll 1$, eq. [25] reduces to the familiar linear transport equation,

[27] $$J_1 = -\frac{DN\alpha}{kT(1+\alpha)^2}\left(\frac{\partial \bar{\mu}}{\partial x}\right) = -\frac{D\partial n}{\partial x} + nvE$$

where $v = qD(1 - n/N)/kT$. Thus D and v are the diffusion coefficient and mobility, respectively, for this model. Note that although D is independent of concentration for this model, v is independent of concentration only if $n/N \ll 1$.

In the absence of an activity gradient, on the other hand, eq. [25] reduces to

[28] $$J_1 = [4a\nu n(1 - n/N)][\exp(-U/kT)] \times \sinh qaE/kT$$

which for $n \ll N$ is identically the Mott–Cabrera conduction equation (5).

Realm of Validity of First Order Equation

We next examine under what conditions the second order terms and presumably higher order terms can be neglected. We do so first for the case $\alpha \ll 1$ so that j_1 may be written as

[29] $$j_1 = 2(\alpha\varepsilon - \alpha')(\sinh \varepsilon)/\varepsilon$$

It is easily shown (4) that eq. [29] is exact for this model for $\alpha \ll 1$, and for $\varepsilon' = 0 = j'$, i.e. for steady-state transport in the absence of space charge. We now consider the contribution of the term $\hat{O}_1(\alpha\varepsilon - \alpha')$ to steady-state transport in the presence of space charge, so the $\varepsilon' \neq 0$ but $j' = 0$. Setting

[30] $$(\alpha\varepsilon - \alpha') = \beta \text{ and } (\sinh \varepsilon)/\varepsilon = Y$$

[31] $$\hat{O}_1\beta = \frac{dY}{d\varepsilon}\beta' + \frac{1}{2}\frac{d^2Y}{d\varepsilon^2}\beta\varepsilon'$$

or alternatively

[32] $$(\hat{O}_1\beta)/(\hat{O}_0\beta) = \frac{d \ln Y}{d\varepsilon}(\ln \beta)' + \frac{1}{2}\frac{1}{Y}\frac{d^2Y}{d\varepsilon^2}\varepsilon'$$

We now eliminate $(\ln \beta)'$ from the second order correction, using the first order approximation. Thus from eq. [29]

[33] $$\ln(j_1/2) = \ln Y + \ln \beta$$

so that upon differentiating by s and setting $j_1' \simeq 0$ we get

[34] $$0 \simeq \frac{d \ln Y}{d\varepsilon}\varepsilon' + (\ln \beta)'$$

Equation [32] can now be written as

[35] $$\hat{O}_1\beta/\hat{O}_0\beta = [\tfrac{1}{2} + (\coth \varepsilon)(1/\varepsilon - \coth \varepsilon)]\varepsilon'$$

The expression for j for steady-state conduction, correct to second order terms, thus becomes

[36] $$j_2 = 2(\varepsilon\alpha - \alpha')[(\sinh \varepsilon)/\varepsilon][1 - (\hat{O}_1\beta)/(\hat{O}_0\beta)]$$

For ε in $(-\infty, +\infty)$, $(\hat{O}_1\beta)/(\hat{O}_0\beta)$ lies in $[-\frac{1}{2}\varepsilon', \frac{1}{6}\varepsilon']$ so that the condition that this second order correction term may be neglected is that $|\varepsilon'/2|$ be small compared to unity. This will be met typically for space charge concentrations up to about 10^{20} electron charges per cm^3.

To avoid any possible confusion on the implications of this statement, we point out that it does not mean that in dealing with ion transport processes space charge need not be considered unless it exceeds 10^{20} electron charges cm^3. This would of course be a totally erroneous interpretation of the

above result. In any given physical problem, eq. [22] must be combined with Poisson's equation, and integrated, to give the net flux as a function of the boundary conditions. This has been done for certain cases to obtain analytical solutions (see, for example, ref. 4).

Another approach to treating physical problems exists, and has been extensively exploited by Fromhold (8). Fromhold's procedure is to use the difference equation, eq. [1] (less the factors $1 - m_{x\pm a}$) along with Gauss' theorem, in a step-by-step numerical calculation to obtain numerical solutions for particular boundary conditions. While such a procedure certainly has merit, where it is possible to obtain them, analytical solutions are usually more informative. Of course, not all situations can be handled analytically, but even when analytical solutions cannot be obtained, it is often easier to carry out numerical calculations using a differential equation for transport rather than a difference equation. This is generally the case for thick films. The point made above is that the differential equation of transport, eq. [22], is a satisfactory approximation to the difference equation (which itself is approximate) provided that the space charge concentration does not exceed about 10^{20} e/cm^2.

In order to evaluate the conditions under which the second order term in the denominator of eq. [9] may be neglected, we proceed as before by evaluating it from the first order approximation. Upon rearranging eq. [22] one obtains:

$$[37] \qquad -\alpha' = \alpha^2 + (2A - \varepsilon)\alpha + A$$

where

$$A = \tfrac{1}{2} j_1 \varepsilon / \sinh \varepsilon$$

Equation [37] may be solved readily if A and ε are treated as constants. For $|\tfrac{1}{2}\varepsilon'| \ll 1$, a condition already shown to be necessary for the validity of the first order expression, A and ε will in fact be nearly constant over short distances (i.e. for $\Delta S \gtrsim 10$ say). As the procedure is tedious, and the result not unexpected, we give only the result. For low field strengths, $\alpha''/(1 + \alpha)$ and $[\alpha'/(1 + \alpha)]^2$ are much smaller than unity everywhere except perhaps very close (relative to total thickness) to one or both of the boundaries. For high field strengths again they are much smaller than unity everywhere except perhaps very close (much less than one jump distance) to the boundary away from which the defects move. It has been shown previously (9) that for high field strengths, c varies only slowly with position except perhaps near the entrance boundary, so the present result is not surprising.

In summary, it appears that for all practical purposes the first order equation, eq. [22], represents the model satisfactorily provided that transport conditions do not depart radically from steady-state conditions and that space charge is not too high, i.e. $\varepsilon' \gtrsim 0.2$. An interesting consequence of forbidding hops into occupied sites is that while the form of the diffusion coefficient is unaltered, the mobility becomes a function of concentration.

Appendix

The Form of the Electrochemical Potential for the Mobile Species

The following derivation of the electrochemical potential for the mobile species follows very closely textbook treatments of Schotky defects in monatomic crystals (see e.g. ref. 1, pp. 28–31 or ref. 10).

For consistency with the transport model treated in the main body of the paper, we assign the following properties to the system: (*1*) There are N sites per unit volume for the mobile defects. A given site may only be empty or singly occupied. (*2*) There is no direct interaction energy between pairs of defects, so that the chemical part of the enthalpy per defect is independent of n. The electrostatic part of the enthalpy is treated in a continuum model, which takes care of the electrostatic part of the interaction energy of the defects. (This is the assumption on which the transport equation was developed.) (*3*) The addition of a defect to the transport medium may alter the existing vibrational frequencies of the medium and introduce new ones. That is to say, there will be in general a thermal entropy change associated with the process. Since there is by postulate no direct interaction between defects, this thermal entropy change per defect will be independent of the number of defects. (*4*) In addition to the thermal

entropy terms, there will be a configurational entropy arising from the number of ways n identical defects can be arranged on N distinguishable sites. We derive first the chemical potential for uncharged defects, and deal with the electrostatic part of the electrochemical potential at the end.

From (*1*) to (*4*) above, the Gibbs free energy for unit volume of the transport medium containing n defects is given by:

$$[A1] \qquad G = G^0 + n\Delta\bar{H} - nT\Delta\bar{S}_v - kT \ln P$$

where G^0 is the free energy prior to introducing the defect, $\Delta\bar{H}$ the enthalpy increase, and $\Delta\bar{S}_v$ the thermal entropy increase per defect added at constant temperature and pressure, and $k \ln P$ the configurational entropy, with P being the statistical weight.

P is the number of microscopically distinguishable ways in which the n identical defects can be arranged in the N available positions, and is given by

$$[A2] \qquad P = N!/[(N - n)!n!]$$

The use of Stirling's formula then gives

$$[A3] \qquad \ln P = N \ln N - (N - n) \ln (N - n) - n \ln n$$

Substituting [A3] into [A1], and evaluating $\mu = (\partial G/\partial n)_{T,\text{pressure}}$, one obtains

$$[A4] \qquad \mu = \Delta\bar{H} - T\Delta\bar{S}_v + kT \ln \left(\frac{n}{N - n}\right)$$

$$[A5] \qquad = \mu^0 + kT \ln \alpha$$

where $\alpha = n/(N - n)$ and is the thermodynamic activity of the mobile defects, as noted in the body of the paper.

If the defects carry a charge q, and reside in a region of electrostatic potential V, then the electrochemical potential is obtained from the chemical potential in the usual way by simply adding the electrostatic potential energy per defect, i.e.

$$[A6] \qquad \bar{\mu} = \mu_0 + kT \ln \alpha + qV$$

If the mobile defects are assigned a polarizability $\bar{\alpha}$, there is then an additional energy term, $-\frac{1}{2}\bar{\alpha}E^2$, to be added to the expression for $\bar{\mu}$, but this term is small for all but extremely large values of E (7). The inclusion of this polarization energy term is not warranted in the present context.

Crystal and molecular structure of (η^3-2-methylallyl)[dimethyl(ethanolamino)-(3,5-dimethyl-1-pyrazolyl)gallato(*N*(2),*N*(3),*O*)]dicarbonylmolybdenum, $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NH_2)]Mo(CO)_2(\eta^3\text{-}C_4H_7)$

Crystals of (η^3-2-methylallyl)[dimethyl(ethanolamino)(3,5-dimethyl-1-pyrazolyl)gallato-(*N*(2),*N*(3),*O*)]dicarbonylmolybdenum are triclinic, $a = 7.6047(5)$, $b = 10.882(1)$, $c = 12.633(1)$ Å, $\alpha = 77.07(1)$, $\beta = 89.19(1)$, $\gamma = 71.91(1)°$, $Z = 2$, space group $P\bar{1}$. The structure was solved by Patterson and Fourier syntheses and was refined by full-matrix least-squares procedures to $R = 0.024$ and $R_w = 0.030$ for 3835 reflections with $I \geq 3\sigma(I)$. The crystal structure consists of discrete molecular units, each linked to four others by weak N—H···O hydrogen bonds (N···O = 3.129(3) and 3.137(4) Å). The Mo atom is in a distorted octahedral environment with the η^3-C_4H_7 ligand occupying one of the six coordination sites as a π-donating ligand. Important bond distances (corrected for libration) are: Mo—C(allyl), 2.335(3), 2.372(3), 2.324(3); Mo—C(O), 1.902(3) and 1.961(2); Mo—O, 2.269(2); Mo—N(pz), 2.222(2); Mo—N(amino), 2.285(2); Ga—O, 1.924(2); Ga—N, 2.006(2); and Ga—C, 1.968(4) and 1.981(4) Å.

KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **57**, 1335 (1979).

Les cristaux du (η^3 méthyl-2 allyl)[diméthyl(éthanolamino)(diméthyl-3,5 pyrazolyl-1) gallato (*N*(2),*N*(3),*O*)] dicarbonyl de molybdène sont tricliniques $a = 7.6047(5)$, $b = 10.882(1)$, $c = 12.633(1)$ Å, $\alpha = 77.07(1)$, $\beta = 89.19(1)$, $\gamma = 71.91(1)°$, $Z = 2$, groupe d'espace $P\bar{1}$. On a résolu la structure par des synthèses de Patterson et de Fourier et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs de $R = 0.024$ et $R_w = 0.030$ pour 3835 réflexions avec $I \geq 3\sigma(I)$. La structure cristalline comporte des unités moléculaires définies reliées à quatre autres par des liaisons hydrogènes N—H···O faibles (N···O = 3.129(3) et 3.137(4) Å). L'environnement de l'atome de Mo est un octaèdre déformé dans lequel le ligand η^3-C_4H_7 occupe un des six sites de coordination sous forme de ligand donnant des électrons π. Les distances de liaisons importantes (corrigées pour la libration) sont: Mo—C(allyl), 2.335(3), 2.372(3), 2.324(3), Mo—C(O), 1.902(3) et 1.961(2), Mo—O, 2.269(2), Mo—N(pz), 2.222(2), Mo—N(amino), 2.285(2), Ga—O, 1.924(2), Ga—N, 2.006(2) et Ga—C, 1.968(4) et 1.981(3) Å.

Introduction

The synthesis and coordinating properties of the anionic ligands **1** have been discussed in previous publications (1–3). The ligands represent part of an ongoing program investigating a range of anionic gallate ligands and their coordinating abilities towards transition metal species. The present paper describes the crystal structure analysis of the complex $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NH_2)]Mo(CO)_2(\eta^3\text{-}C_4H_7)$. The structure confirms our earlier predictions (3) regarding the *fac* nature of the tridentate gallate ligand in this type of octahedral complex and also establishes the position of substitution of the η^3-C_4H_7 moiety. Bond length data and ν_{CO} stretching frequencies are discussed in conjunction with similar data for the related complexes described earlier, $[MeGa(N_2C_3H_3)_3]Mo(CO)_2(\eta^3\text{-}C_3H_5)$, **2** (4), and $[MeGa(N_2C_5H_7)_2(OH)]Mo(CO)_2(\eta^3\text{-}C_4H_7)$, **3** (5).

Experimental

The title compound was prepared and characterized as described previously (3). Crystals suitable for X-ray study were obtained by recrystallization from benzene. The crystal chosen was mounted in a general orientation and had dimensions of ca. 0.35 × 0.44 × 0.48 mm. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections measured on a diffractometer with MoK_α radiation (λ = 0.71073 Å). Crystal data (at 22°C) are:

$C_{15}H_{26}GaMoN_3O_3$ fw = 462.05
Triclinic, a = 7.6047(5), b = 10.882(1), c = 12.633(1) Å, α = 77.07(1), β = 89.19(1), γ = 71.91(1)°, V = 966.9(2) Å^3, Z = 2, ρ_c = 1.587 g cm^{-3}, $F(000)$ = 468, $\mu(MoK_\alpha)$ = 21.2 cm^{-1}. Absent reflections: none. Space group $P\bar{1}$ (C_i^1, No. 2) from structure analysis. Cell reduction failed to locate a cell of higher symmetry, reduced cell is given above.

Intensities were measured with graphite monochromatized MoK_α radiation on an Enraf-Nonius CAD4-F diffractometer. An ω scan at 0.91–6.71° min^{-1} over a range of (0.85 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of 3 check reflections, measured every 3600 s throughout the data collection, did not vary by more than 1%. After data reduction, an absorption correction was applied using the Gaussian integration method (6, 7). Transmission factors ranged from 0.455 to 0.524. Of the 4413 independent reflections measured, 3835 (87%) had intensities greater than 3σ(I) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = background count.

Analysis was initiated in the centrosymmetric space group $P\bar{1}$ on the basis of the E-statistics. The positions of the molybdenum and gallium atoms were determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference map. After full-matrix least-squares refinement of all non-hydrogen atoms with anisotropic thermal parameters to R = 0.034, a difference map gave positions for all 26 hydrogen atoms which were included in all subsequent cycles of refinement with isotropic thermal parameters. The scattering factors of ref. 8 were used for non-hydrogen atoms and those of ref. 9 for hydrogen atoms. Anomalous scattering factors from ref. 10 were used for the Mo and Ga atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined, $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. An isotropic Type I extinction correction (Thornley–Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (11–13). The final value of g was 0.61(7) × 10^4. Convergence was reached at R = 0.024 and R_w = 0.030 for 3835 reflections with $I \geq 3\sigma(I)$. For all 4418 reflections R = 0.030 and R_w = 0.031.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.14 and 1.1σ respectively. The mean error in an observation of unit weight was 0.9875. A final difference map showed maximum fluctuations of ±0.95 e Å^{-3} near the heavy atoms and ±0.25 e Å^{-3} elsewhere (carbon peak heights on earlier maps had heights of 5–9 e Å^{-3}). The final positional and thermal parameters appear in Tables 1 and 2[1] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

[1]The structure factor table and Table 2 (thermal parameters) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (14) using the computer program MGTLS. The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0014 Å^2. Analysis of all non-hydrogen atoms except the carbonyl oxygen atoms O(1) and O(2) gave physically reasonable rigid-body parameters (rms ΔU_{ij} = 0.0040 Å^2). The appropriate bond distances have been corrected for libration (15), using

ing the carbonyl oxygen atoms (N···O = 3.129(3) and 3.137(4) Å are in the range of 2.55–3.25 Å normally observed for N—H···O hydrogen bonds, see Table 6). All other intermolecular distances correspond to normal van der Waals contacts.

The X-ray crystallographic analysis confirms unequivocally the tridentate chelating character of the gallate ligand and also the *fac* nature of its coordination in this type of complex, an arrangement predicted earlier from ir studies (3). The Mo atom is in a distorted octahedral environment with the η^3-C_4H_7 ligand occupying one of the six coordination sites as a π-donating ligand. As predicted on the basis of molecular model studies (3), the η^3-C_4H_7 is situated *trans* to the pyrazolyl nitrogen atom (see Fig. 1). The steric requirements of the gallate ligand in the present structure force the η^3-C_4H_7 ligand to have an orientation 'opposite' to

that observed in **2** (4), **3** (5), and the related boron complex $[HB(N_2C_3H_3)_3]Mo(CO)_2(\eta^3\text{-}C_4H_7)$ (16); i.e. the substituent on the central carbon of the allyl group is directed toward, rather than away from, the two carbonyl groups. As a result of methyl–carbonyl repulsions the central Mo—C(allyl) distance is significantly longer than the two other Mo—C(allyl) distances. This is in contrast to the structures of **2**, **3**, and most other η^3-allyl structures (17, 18, and references therein) where the central M—C bond is the shortest of the three. Tilt angles and other parameters describing the mode of allyl coordination to the metal atom have been calculated; δ^1, δ^2, and *h* (defined in ref. 17 and calculated assuming the 'coordination plane' to be normal to the Mo—C(1) vector) are 118.6°, 111.3°, and 0.30 Å respectively and the parameters τ and β (defined in ref. 18) are 117.6° and 90.4°. All of these parameters are intermediate with respect to the observed ranges (17, 18) although the tilt angles δ^1 and τ are both higher than the mean values for these parameters (115° for both δ^1 and τ). All of the other allyl complexes listed (17, 18) in which the central M—C(allyl) bond is longer than the others have higher than average tilt angles. The distance from the Mo atom to the centre of mass of the three coordinated allyl carbon atoms, *D'*, is 2.103 Å which is at the long end of the 2.02–2.10 Å range observed for d^4-M(allyl)L_5 complexes (18).

The Mo—N(pz) bond *trans* to the allyl ligand is shortened to 2.222(2) Å relative to corresponding distances of 2.242(4) Å in **3** and 2.232(3) Å in **2**. The Mo—O distance of 2.269(2) Å agrees well with the value of 2.272(4) Å in **3**. The Mo—N(amino) distance is 2.285(2) Å.

It is noteworthy that the carbonyl C—O bond lengths are significantly different in the present structure with the C—O bond *trans* to the oxygen atom of the gallate ligand being 0.022(4) Å longer than the C—O bond *trans* to the amino nitrogen donor atom. The Mo—C(O) distances also reflect this effect with the Mo—C(O) bond *trans* to oxygen being much shorter than that *trans* to the amino nitrogen (1.902(3) vs. 1.961(2) Å). The differences between the Mo—C(O) and C—O distances probably arise from a combination of structural *trans* effects and steric effects, the latter being most important in this case as C(2) is forced well away from an 'ideal' coordination site. There are two significant intramolecular non-bonded contacts, both of which involve the ethanolamine moiety (H(5a)···H(11a) = 2.23(4), and H(4b)···H(11b) = 2.41(6) Å). As in the structures of **2** and **3** (4, 5) the M—C—O bond angles are significantly non-linear (178.2(2) and 174.3(2)°), an effect almost certainly arising from packing forces and intramolecular steric effects. Deviations of this magnitude are quite common in this type of carbonyl complex (16, 19, 20).

The ν_{CO} frequencies for the title complex listed in Table 7, along with those for related compounds, are the lowest in the series and based on previous arguments (4, 5), might be expected to result in longer C—O bond distances. The data, however, do not reveal the expected values of ~1.18 Å for these distances but rather two very different C—O bond lengths, the shorter of the two being almost the same as the C—O distance in the boron complex $[HB(N_2C_3H_3)_3]Mo(CO)_2(\eta^3\text{-}C_4H_7)$ (16) which displays much higher ν_{CO} frequencies.

The gallium atom is tetrahedrally coordinated to two methyl groups (Ga—C = 1.968(4) and 1.981(4) Å), the oxygen atom of the ethanolamine moiety (Ga—O = 1.924(2) Å), and to a pyrazolyl nitrogen atom (Ga—N = 2.006(2) Å). Bond angles at gallium range from 92.4° in the chelate ring to 121.2(2)° between the methyl groups. The bond lengths involving gallium are as expected (ref. 1 and references therein). The difference between the two Ga—C bond lengths, although not statistically significant, may be caused by the steric interaction between the C(4) methyl group and the ethanolamine moiety mentioned above.

Steric factors are responsible for a slight but significant non-planarity of the pyrazolyl ring (χ^2 = 9.2 for the five ring atoms) and as in related structures (4, 5) the metal atoms are considerably displaced from the mean plane of the pyrazolyl ring (Mo by 0.4985(2) and Ga by 0.0116(3) Å). The trivalent oxygen atom has distinctly pyramidal coordination geometry (mean bond angle at O is 114.1°). The allyl group is significantly non-planar, the central carbon atom being displaced 0.04 Å from the C(5)C(7)C(13) plane. Other bond lengths and angles in the molecule assume normal values.

Gas phase observation of the first overtone of the H—F stretching fundamental in hydrogen bonded complexes

J. W. BEVAN,[1] B. MARTINEAU, AND C. SANDORFY

Département de Chimie, Université de Montréal, Montréal (Qué.), Canada H3C 3V1

Received December 8, 1978

J. W. BEVAN, B. MARTINEAU, and C. SANDORFY. Can. J. Chem. 57, 1341 (1979).

First overtones of H—F and D—F stretching vibrations in hydrogen bonded complexes with dimethylether, diethylether, and acetone have been measured in the gas phase. The assignment of the observed bands is discussed together with previously made observations on the fundamentals. Anharmonicity constants of the order of -200 and -100 cm^{-1} are determined for the most probable assignments from the available data for the H—F and D—F stretching vibrations (ν_1) while their values in the "free" H—F and D—F molecules are -90 and -46 cm^{-1} respectively. The spectra are compatible with a coupling constant between the ν_1 and the bridge stretching vibration (ν_3) of the order of $+70$ cm^{-1}.

J. W. BEVAN, B. MARTINEAU et C. SANDORFY. Can. J. Chem. 57, 1341 (1979).

Les premières harmoniques des vibrations de valence H—F et D—F dans les complexes formés avec le diméthyléther, le diéthyléther et l'acétone ont été mesurées dans l'état gazeux. L'attribution des bandes observées est discutée conjointement avec celle des fondamentales. La constante d'anharmonicité de la vibration de valence H—F et D—F (ν_1) augmente considérablement en conséquence de la formation de liaisons hydrogène. La constante de couplage entre ν_1 et la vibration de valence du pont (ν_3) semble être environ 70 cm^{-1}.

Introduction

Anharmonicity is a fundamental quantity for the understanding of the nature of H-bonding. This was recognized twenty years ago by Bratos and Hadži (1) and by Sheppard (2). All existing theories of H-bonding imply anharmonicity directly or indirectly. It is not intended here to review these theories; we only mention the most recent treatments of the problem that are known to us: those by Robertson (3), by Sokolov and Savelev (4), and by Bouteiller and Maréchal (5).

Let us consider the simple triatomic model X—H---Y and let ν_1, ν_2, and ν_3 be the frequencies of the X—H stretching, X—H bending, and XH---Y stretching vibrations respectively. In the linear model ν_2 is degenerate. However, in most actual systems it will give rise to an out-of-plane and an in-plane bending vibration. Disregarding the out-of-plane bending mode the mechanical anharmonicity can be characterized, to the second order, by the anharmonicity constants X_{11}, X_{22}, and X_{33} for the three normal vibrations and the coupling constants X_{12}, X_{13}, and X_{23}.

In this approximation a vibrational term is:

$$[1]\quad G(v_1, v_2, v_3) = \omega_1(v_1 + \tfrac{1}{2}) + \omega_2(v_2 + \tfrac{1}{2}) + \omega_3(v_3 + \tfrac{1}{2}) + X_{11}(v_1 + \tfrac{1}{2})^2 + X_{22}(v_2 + \tfrac{1}{2})^2 + X_{33}(v_3 + \tfrac{1}{2})^2 + X_{12}(v_1 + \tfrac{1}{2})(v_2 + \tfrac{1}{2}) + X_{13}(v_1 + \tfrac{1}{2}) \times (v_3 + \tfrac{1}{2}) + X_{23}(v_2 + \tfrac{1}{2})(v_3 + \tfrac{1}{2})$$

and the frequencies of given bands are obtained from:

$$[2]\quad \nu = G(v_1',v_2',v_3') - G(v_1'',v_2'',v_3'')$$

(see Herzberg (6)).

By far the most important constant is X_{13}; its value is a measure of the coupling between the X—H and XH---Y stretching motions on which most hydrogen bond theories are based. The other constants are also important, however; they contribute in determining the frequencies and intensities of the vibrations and the changes that are produced in these quantities by environmental effects; they are needed for a more complete knowledge of the potential surface. This work reports new information on two of these constants: X_{11} and X_{13}.

The experimental determination of anharmonicity constants entails the measurement of overtones and combination tones. A number of such investigations have been carried out in solution (7–11) (for a review see ref. 12). Solvent effects, however, might affect the frequencies of fundamentals, overtones, and combination tones to different degrees. Thus results obtained in solution apply only approximately to isolated hydrogen bonds.

Gas phase studies of hydrogen bonded complexes

[1]Present address: Department of Chemistry, Texas A and M University, College Station, TX 77843, U.S.A.

0008-4042/79/111341-09$01.00/0

enable these systems to be investigated free from solvent perturbations. The initial gas phase infrared studies of H—F and H—Cl hydrogen bonded stretching fundamentals by Arnold and Millen (13) and by Bertie and Millen (14) have been extended and numerous other systems have been examined (15–19). However, to our knowledge no gas phase data exist for the first or higher overtones of these vibrations, presumably due to their apparent weakness.

The present investigation represents an attempt to observe the first overtone (v_1^{02}) of the high frequency H-bonded stretching fundamental in the gas phase so that an estimate of the anharmonicity constant X_{11} can be made. At the same time an attempt is made to identify ($2v_1 + v_3$) type combination bands. The ir spectra of dimethylether, diethylether, and acetone with hydrogen fluoride were chosen for study because they form relatively strong volatile complexes whose fundamentals had been the subject of previous investigation (13–19). Several deuterated analogues were also studied to provide additional information.

Experimental

All near-infrared spectra of the hydrogen bonded overtones were recorded with a Cary-17 spectrometer and a corrosion resistent Wilks multireflection cell. Gold surfaced mirrors and calcium fluoride windows were employed with a variable cell pathlength of 0.75 to 20 m. Certain of the corresponding fundamentals were recorded in a 10 cm cell using a Perkin-Elmer 621 spectrometer.

Hydrogen fluoride was purchased from Matheson while deuterium fluoride and d_{10} diethyl ether were obtained from Merck, Sharpe and Dohme of Canada. They were used without further purification.

There is always a danger in these experiments of having >O:---H—F---H—F type complexes present in addition to >O:---H—F. However, we varied the relative pressures of the proton donor and acceptor between wide limits without observing significant changes in the spectra.

Results

When hydrogen fluoride and ethers or acetone are mixed together an intense new feature, not present in the spectra of the components, appears in the spectrum of the mixture. Subtraction spectra of the regions of interest are recorded in Figs. 1–7. These bands show considerable similarity to those of the fundamental H—F stretching vibration previously recorded by Millen *et al.* (13, 14). The main bands observed could be attributed to overtone or combination bands of the hydrogen bonded complexes. The absence of other new bands at lower frequencies in all mixtures effectively rules out overtones and combination tones involving vibrations with frequencies less than 2000 cm^{-1}. Mixtures of the perdeuterated electron donors with hydrogen fluoride show practically no change in the position of overtone and combination bands involving H—F vibrations while, naturally, they displace those involving C—H motions. Additional support to the assignment of the strongest bands in these spectra to the first overtone of the H-bonded H—F stretching vibration is provided by the similarity of their profile to the corresponding fundamental. The v_H/v_D ratio can be used to confirm individual assignments.

Similar spectra have been obtained for common species of the donors with deuterium fluoride. The positions of the band maxima are recorded in Table 1, while the data calculated from these using eq. [2] are given in Table 2. Several other weak features

associated with the H-bonded species have been observed but their low intensity and diffuseness precluded further study.

The observed bands would exhibit an extensive and complicated structure under high resolution. Relatively low resolution studies like those presented here must necessarily restrict the extent and quality of the information obtained. Notwithstanding this limitation it is possible to utilize these data to estimate hydrogen bonded vibrational frequencies and anharmonicity constants.

Discussion

The interpretation of our results depends on the

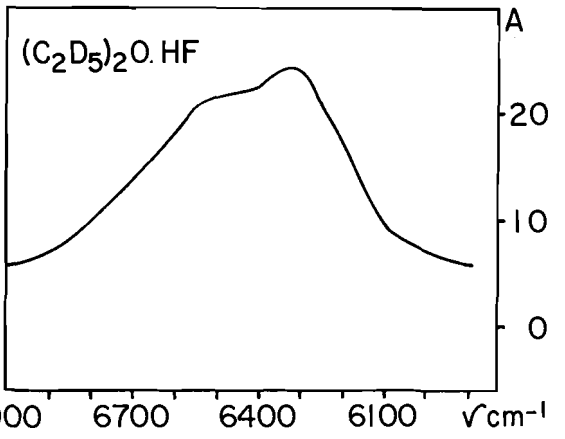

FIG. 5. A part of the gas phase near-infrared spectrum of the $(C_2D_5)_2O{\cdot}HF$ complex. Pressure diethylether-d_{10} 55 Torr, hydrogen fluoride 30 Torr. Optical path: 11.25 m. Absorbance in arbitrary units against frequency in cm^{-1}.

assignments of the observed peaks to the various possible combination bands. The combinations between ν_1 and ν_3 are often represented by Stepanov's (20, 21) Franck–Condon-like diagram. In this respect, Sheppard pointed out many years ago (2) that "because of the anharmonicity of the νXH vibration, the H atom will move on average nearer to Y in the ($v_1 = 1$) excited state, and consequently the hydrogen bond will become stronger". Thus the upper potential energy curve has a deeper minimum than the lower one, and its minimum occurs at a lower value of ν_{XY}. (See also Gallagher (22).) While there is little doubt about the validity of his suggestion, we have to examine its consequences for the relative intensities of the combination bands (subbands).

Initial considerations according to usual Franck–

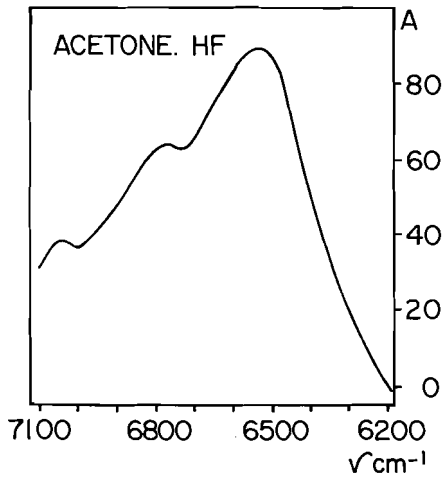

FIG. 7. A part of the gas phase near-infrared spectrum of the $(CH_3)_2CO{\cdot}HF$ complex. Pressure: acetone 55 Torr, hydrogen fluoride 30 Torr. Optical path: 6.75 m. Absorbance in arbitrary units against frequency in cm^{-1}.

Condon reasoning should make a transition other than (1,0) ← (0,0) vertical, and therefore the most intense one. (In each bracket the first number indicates the vibrational quantum number v_1 of ν_1 and the second number the vibrational quantum number v_3 of ν_3.) It is pertinent to note, however, that the Franck–Condon principle is less valid in this case than for electronic transitions. While an electronic transition might be a thousand times faster than a vibrational one, a much smaller factor should exist between ν_1 and ν_3. Under the circumstances non-vertical transitions could have quite appreciable

probabilities. In addition, the Franck–Condon diagram should not make us forget that we are dealing with combination tones. For example, (1,1) ← (0,0) is a binary combination, $(\nu_1 + \nu_3)$. Thus when we say that the (1,1) ← (0,0) band is more intense than the (1,0) ← (0,0) band this implies that the combination is more intense than the fundamental. While this might be the case, it requires a large value for X_{13} (and/or considerable electrical anharmonicity). At the $v_1 = 2$ level the (2,1) ← (0,0) band is a ternary combination. While the intensity of $\nu_1{}^{02}$ depends on X_{11} that of $(2\nu_1 + \nu_3)$ depends on both X_{11} and X_{13}. Also, the non-linearity of the rate of change in the dipole moment, electrical anharmonicity, is likely to contribute significantly to the intensity of combination bands. If M is the variable dipole moment, Q_1 and Q_3 the normal coordinates for vibration of frequencies ν_1 and ν_3, and the subscript e refers to the equilibrium geometry,

$$[3] \qquad M = M_e + \left(\frac{\partial M}{\partial Q_1}\right)_e Q_1 + \left(\frac{\partial M}{\partial Q_3}\right)_e Q_3 + \frac{1}{2}\left(\frac{\partial^2 M}{\partial Q_1{}^2}\right)_e Q_1{}^2 + \frac{1}{2}\left(\frac{\partial^2 M}{\partial Q_3{}^2}\right)_e Q_3{}^2 + \left(\frac{\partial^2 M}{\partial Q_1 \partial Q_3}\right)_e Q_1 Q_3 + \ldots$$

While the intensity of the fundamentals depends relatively little on electrical anharmonicity that of combination tones can receive a large contribution from it if the mixed derivative in eq. [3] is large and it can be either positive or negative (see ref. 23). Unfortunately, there does not seem to be any information available on the latter for hydrogen bonded systems. Then all we can say is that the validity of the Sheppard shift of the potential minimum for $v_1 = 1$ does not necessarily imply that the (1,0) ← (0,0) band is weak. It may or may not be the strongest of the subbands in given cases.

A further comment we have to make concerns the difficulty of using the temperature effect for identifying (1,0) ← (0,1), (1,0) ← (0,0), (1,1) ← (0,0), etc., bands (18, 19). Thomas (16, 17) has shown that all these bands receive a large part of their intensity from hot bands of the $(\nu + v\nu_i - v\nu_i)$ type. The recent calculations of Robertson (3) which take account of Franck–Condon factors and the Boltzmann distribution but not electrical anharmonicity substantiate this strikingly (Tables 1 and 4 in ref. 3). For the $(CH_3)_2O{\cdot}HCl$ system at 300 K, the intensity of the (1,0) ← (0,1) difference band, 0.39 on a relative scale, receives 0.16 from hotter bands; the (1,0) ← (0,0) overtone band with an intensity of 0.80 receives

0.135 from hot bands and the (1,1) ← (0,0) summation band, with an intensity of 1.00 receives 0.54 from hot bands. This means that the subband at the high frequency side of the 'pure overtone' should be as or more sensitive to temperature change than the one at its low frequency side.

However, as Robertson has pointed out, conditions are significantly different for X—D systems. Because of lesser amplitude and mechanic anharmonicity the Sheppard shift is expected to be much less. This would tend to make the (1,0) ← (0,0) band the most intense one. Robertson's calculations on $(CH_3)_2O{\cdot}DCl$ at 300 K illustrate this: the (1,0) ← (0,1) difference, the (1,0) ← (0,0) and (1,1) ← (0,0) summation bands have relative intensities 0.39, 1.10, and 1.00 respectively. (With the corresponding hot bands contributing 0.24, 0.30, and 0.72.)

The frequencies of the bands in wavenumbers and the more pronounced shoulders which appear in the overtone spectra are listed in Table 1. The numbers in italics relate to the observed band maxima, all other numbers represent shoulders. These values together with fundamentals determined by Arnold and Millen (13) and by Thomas (16) were used to construct Tables 2 and 3.

(*a*) Table 2 is based on the assumption that the well defined band of lowest wavenumber belongs to the pure fundamental, ν_1^{01}, and pure overtone, ν_1^{02},

at the fundamental and overtone levels respectively. (The values marked by † are taken from Arnold and Millen (13).)

The first observation from the data of Table 2 is that by using the frequencies of the respective HF and DF fundamentals we obtain isotopic ratios very close to 1.36. Since the harmonic ratio is 1.380 this is quite satisfactory and lends support to Arnold and Millen's original assignments for the fundamentals. This implies that despite the Sheppard shift, the (1,0) ← (0,0) band is still the most intense.

The overtones yield the isotopic ratios shown in the fourth column of Table 2. They are close to 1.33. This is also quite satisfactory from the point of view of the assignments made in constructing Table 2. (To the second order the ratio of the harmonic frequencies (ω) is, for a purely diatomic oscillator equal to the square root of the inverse ratio of the reduced masses whereas the ratio of the anharmonicity constants like X_{11} is equal to the ratio of the reduced masses themselves.) Therefore, since the overtones depend more strongly on the X_{11} and since the latter are larger for HF than for DF, the overtones are expected to yield lower isotopic ratios.

$$[4] \qquad \nu_1^{01} = \omega_1 + 2X_{11}$$

$$[5] \qquad \nu_1^{02} = 2\omega_1 + 6X_{11}$$

We can compute the X_{11} from [6]:

$$[6] \qquad X_{11} = \nu_1^{02}/2 - \nu_1^{01}$$

They are somewhat above $-200\ cm^{-1}$ for the HF complexes. Since the free HF vibrator has an X_{11} value equal to $-90\ cm^{-1}$ (5, 24), this corresponds to a greater than twofold increase. The ethylether–DF complexes give about $-110\ cm^{-1}$. This then leads to an isotopic ratio of about two (or slightly higher) for the X_{11}, close to the ratio of the reduced masses despite the large experimental error. However, with dimethylether–DF we encounter a difficulty. With the apparent maximum of the overtone $X_{11} = -75\ cm^{-1}$ is obtained. This would lead to an unreasonably high isotopic ratio for the X_{11}, about 3.0. It is significant that there is a conspicuous difference between the overtone spectra of the diethylether–DF and dimethylether–DF complexes. The former contains two well defined bands with nearly equal intensities (Figs. 4 and 6) at about 4770 (or 4780) and 4900 cm^{-1} while the latter has a single maximum at 4930 cm^{-1} (Fig. 2). It is possible that the 4930 band is actually double and that the single apparent peak is created by mutual overlap between two bands located near 4860 and 4980 cm^{-1}. The one of lower frequency (4860 cm^{-1}) would give a value of X_{11} similar to that of the diethylether–DF complexes. Since the X_{11} of free DF is $-46\ cm^{-1}$ (5, 23) the increases upon H-bond formation would be again somewhat larger than twofold. Thus a coherent picture is obtained.

However, we still have to make an estimate for the coupling constant X_{13}. This requires assignments for the other bands found in the overtone spectrum. In Arnold and Millen's spectrum of $(C_2H_5)_2O{\cdot}HF$ (13) there are, in addition to the strong band at 3405 cm^{-1}, two weaker bands at 3655 and 3225 cm^{-1} respectively. Following Arnold and Millen's initial assignment, we can assign 3655 to the summation tone $(\nu_1 + \nu_3)$ and 3225 to the $(\nu_1 - \nu_3)$ difference tone. It is important to remember in this respect that while the frequency of a difference tone is the simple difference of the frequency of the two fundamentals:

$$[7] \qquad (\nu_1 - \nu_3) = \nu_1^{01} - \nu_3^{03}$$

the summation tone involves the coupling constant:

$$[8] \qquad (\nu_1 + \nu_3) = \nu_1^{01} + \nu_3^{01} + X_{13}$$

In this case the frequency difference $3405 - 3225 = 180\ cm^{-1}$ is practically the same as the $\nu_3 = 175\ cm^{-1}$ measured by Thomas (16). On the other hand we obtain:

$$X_{13} = 3655 - (3405 + 180) = +70\ cm^{-1}$$

where the positive sign reflects the Sheppard shift. The band at 3655 is also present in our $(C_2D_5)_2O{\cdot}HF$ spectrum but the shoulder near 3220 cm^{-1} is ill-resolved.

The same result is obtained from Millen's $(CH_3)_2O{\cdot}HF$ spectrum with his original assignments. In addition to the strong 3470 cm^{-1} band there are weaker bands at 3300 and 3710 cm^{-1}. The difference $3470 - 3300 = 170\ cm^{-1}$ still compares well with Thomas' 185 cm^{-1}. The coupling constant turns out to be again:

$$X_{13} = 3710 - (3470 + 170) = +70\ cm^{-1}$$

For acetone–HF, Arnold and Millen (13) found the strongest peak at 3470 with weaker subbands at 3580, 3700, and 3280 and 3380 cm^{-1}. However, 3580 cannot be $(\nu_1 + \nu_3)$ and 3380 cannot be $(\nu_1 - \nu_3)$ (being too close to 3470 cm^{-1}). The remaining bands give $3470 - 3280 = 190\ cm^{-1}$ for the difference tone and

$$X_{13} = 3700 - (3470 + 190) = +40\ cm^{-1}$$

It is believed that in reality it must be somewhat higher. The X_{13} value of about $+70\ cm^{-1}$ for the ether–HF complexes is believed to be about correct.

If so, the same constant should be obtainable from the overtone spectra. Taking $\nu_3 = 180\ cm^{-1}$ and $X_{13} = 70\ cm^{-1}$, $(2\nu_1 + \nu_3)$ should be about 320

cm^{-1} higher than ν_1^{02} since

[9] $$(2\nu_1 + \nu_3) = \nu_1^{02} + \nu_3^{01} + 2X_{13}$$

Now, if we have a look at the overtone spectra (Figs. 1, 3, 5, 7) we see immediately that we find the band of second highest frequency much closer to the first one. For the diethylether–HF complexes the 6335 (or 6325) cm^{-1} band is followed by a very broad shoulder at the high frequency side. By prospection the second band can be located at about 6525 cm^{-1}. The band is well resolved for dimethylether–HF with a peak at 6650 cm^{-1}. Thus for the latter the interval between the first and second peaks is only $6650 - 6485 = 165\ cm^{-1}$. With the above location of the bands it is less than 200 cm^{-1} for the diethylethers. The somewhat surprising conclusion is that if the first band is ν_1^{02}, the second band cannot be $(2\nu_1 + \nu_3)$. In consequence we have to think about combinations involving the bridge deformation (wagging) vibration (let us call it ν_4). In the case of acetone–HF, Arnold and Millen (13) estimated the frequency of this band to about 100 cm^{-1}. With a frequency of this order and a positive X_{14} coupling constant of about 30 or 40 cm^{-1} the observed intervals could be explained. (See, for the similar case of alcohols, Asselin and Sandorfy, ref. 25.) The $(2\nu_1 + \nu_3)$ combination then should be looked for at higher frequencies, about 6650 for the diethylether–HF and 6800–6850 cm^{-1} for dimethylether–HF and acetone–HF. Actually, there are weaker bands or shoulders at the right places but there are other shoulders as well and we cannot make firm assignments. It is relevant in the respect that for $(C_2H_5)_2O$–HCl Bertie and Falk (18) estimated the frequency of the wagging band as 50 cm^{-1} and found combinations between ν_1 and ν_4. They have shown that for $(CH_3)_2O$–HCl the main features in the fundamental region are due to $\nu_1 \pm n\nu_3$ whereas for $(CH_3)_2O$–DCl they appear to be due to $\nu_1 \pm n\nu_4$. This is a situation similar to the one we find. Arnold and Millen (13) also invoked ν_4 to explain the 3580 and 3380 cm^{-1} bands of acetone–HF. (Thomas (16), however, does not mention these in connection with the ether–HF complexes.)

Now we turn to the ether–DF complexes. At the fundamental level, the high frequency sides of the bands at 2500 or 2540 cm^{-1} always have a broad shoulder extending to about 50–100 cm^{-1} which might again be due to $(\nu_1 + \nu_4)$ type combinations. Unfortunately, the weakness of these spectra and the closeness of the CH bands did not enable us to locate $(\nu_1 + \nu_3)$ type combination bands.

Arnold and Millen (13) found for $(CD_3)_2O$–DF (which was not available to us) the fundamental at about 2550 and a weaker band at 2770 cm^{-1}. While these values could only be estimated they yield a plausible value for the X_{13} of the DF complex:

$$X_{13} = 2770 - (2550 + 185) = +35\ cm^{-1}$$

(The value of ν_3 is from Thomas (16).)

As mentioned above at the overtone level $(C_2H_5)_2O$–DF and $(C_2D_5)_2O$–DF have two well defined bands separated by $4900 - 4780 = 120\ cm^{-1}$ and $4900 - 4770 = 130\ cm^{-1}$ respectively. Now, this interval is much too small: the two bands cannot be ν_1^{02} and $(2\nu_1 + \nu_3)$. According to [9] the wavenumber of the summation tone should be $4780 + 185 + (2 \times 35) = 5035\ cm^{-1}$ instead of 4900 cm^{-1}. The interval of 120 or 130 cm^{-1} could be explained again by $(2\nu_1 + \nu_4)$ combinations involving the bridge wagging vibration.

There is an interesting possibility which is compatible with the assignments made in this section. If we take the best resolved bands (6485 and 6650 for dimethylether–HF and 4770 (4780) and 4900 for diethylether–DF) we can still assign 6485 and 4770 (or 4780) to the pure overtone ν_1^{02} and 6650 and 4900 to (2,1) ← (0,1). Indeed, the frequency of the latter is $\nu_1^{02} + 2X_{13}$ and the observed intervals 165 cm^{-1} and 120 cm^{-1} are just slightly larger than twice the X_{13} values inferred from the fundamentals. Like this combinations with ν_4 would not be involved.

Three alternative interpretations of the spectra are possible.

(*b*) We can take the second bands in the overtone spectra (6525 for diethylether–HF and 6650 for dimethylether–HF) with 4780, 4770, and (the inferred) 4860 for dimethylether–DF. This would, however, yield isotopic ratios around 1.365 for the *overtones* and this is certainly too high.

(*c*) We can take the second bands in the overtone spectra as ν_1^{02} for both the HF and DF complexes. (4900 cm^{-1} for diethylether–DF.) This would give isotopic ratios for the X_{11} close to 3.0 which is much too high.

(*d*) There seems to exist another consistent way of assigning the subbands in the overtone spectra. One could suppose that in the HF complexes the first band is 'hot': (2,0) ← (0,1) and that the second band is the pure ν_1^{02}. (6650 cm^{-1} for dimethylether–HF, 6525 cm^{-1} for the two diethylether–HF complexes, and 6765 cm^{-1} in acetone–HF (Table 3).) This appears to be plausible for two reasons. First, as said above the Sheppard shift would favor this assignment. Second, the shift from the (2,0) ← (0,0) to the (2,0) ← (0,1) bands is $6650 - 6485 = 165$, $6525 - 6335 = 190$, $6525 - 6325 = 200\ cm^{-1}$, $6765 - 6530 = 235\ cm^{-1}$, in the above order. Except for acetone they are close to the wavenumbers of ν_3^{01} determined by Thomas. With these assignments, since

[10] $[(2,0) \leftarrow (0,1)] = \nu_1^{02} - \nu_3^{01}$

one obtains that X_{11} is about $-140\ cm^{-1}$ (Table 3).

The ether–DF complexes do not fit into this scheme, however. As mentioned above the two bands are separated by only 120 or 130 cm^{-1}. This is significantly less than ν_3^{01}. Thus while the two bands cannot be interpreted as the pure overtone and the summation tone they cannot be interpreted as the difference tone and the pure overtone either.

In other words, it is readily seen that, for example, $4770 + 165 = 4935\ cm^{-1}$, so that negative X_{13} would be required according to [9] to bring this back to 4900 cm^{-1}, about $X_{13} = -35\ cm^{-1}$. This would contradict Sheppard's principle. The same can be applied to the complexes with HF. For example, if for $(C_2H_5)_2O{\cdot}HF$ the bands at 6335 and 6525 cm^{-1} were ν_1^{02} and $(\nu_1 + \nu_3)$ respectively since the interval between them is just about equal to ν_3^{01}, the coupling constant would be practically zero. With no anharmonic coupling most known theories on hydrogen bonding would also come to zero.

One could, however, suppose that the 4900 and 4770 (or 80) bands are the sum and difference tones of ν_1^{02} and the bridge wagging vibration ν_4 with a wavenumber of about 50 or 60 cm^{-1} so that ν_1^{02} would be located near their midpoint but closer to the band of lower wavenumber. This assumption would give X_{11} values of the order of $-75\ cm^{-1}$ for the diethylether–DF as well as for dimethylether–DF taking this time the apparent maximum for the latter (4930 cm^{-1}). This would amount to a coherent picture as can be seen from the data of Table 3. It is strange, however, that for obtaining it we have to take the midpoint of the two bands for the DF complexes but the bands of higher wavenumber for the HF complexes. This is not impossible. That the pure overtone is the second band for the HF complexes but the first one for the DF complexes would be in line with the larger amplitude (and anharmonicity) of the HF vibration and the larger Sheppard-shift it causes. If the scheme of Table 3 did apply the increase in X_{11} would still be sizeable, about -140 cm^{-1} for HF instead of $-90\ cm^{-1}$ for the free vibrator and $-75\ cm^{-1}$ for DF instead of $-46\ cm^{-1}$. This latter scheme is of a rather artificial character, however. In view of all the different considerations we regard the initial assignment of the spectra (*a*, Table 2) as the most probable which we can propose from the available data.

Conclusions

Despite the difficulties encountered in the interpretation of our results some noteworthy points emerge.

(*1*) The observed isotopic ratios confirm Arnold and Millen's original assignments for the fundamentals.

(*2*) The existence of the Sheppard shift does not make it impossible for the 0–0 band to be the most intense one.

(*3*) The $\nu_1 + \nu_3$ type combinations are not necessarily the strongest bands in the spectrum. In particular stretching and bridge-bending or $(1,1) \leftarrow (0,1)$ type combinations seem to be prominent in overtone spectra. These conditions can vary from case to case.

(*4*) The values of the anharmonicity constants depend, of course, on the assignments we make but in every case a sizeable increase for X_{11} is obtained upon H-bonding. While the overtone spectra did not make it possible to obtain new values for the coupling constant X_{13}, Millen's values (about $+70\ cm^{-1}$ for HF complexes) seem to be of the right order of magnitude.

(*5*) The sizeable (although not dramatic) increase in X_{11} upon H-bond formation supports, in a general way, the order of magnitude of the values obtained for associated alcohols and some other systems *in solution* (7–12). Their X_{11} also underwent a significant increase upon H-bond formation although to a lesser extent than the HF complexes treated in this paper.

Acknowledgements

The acquisition of a Wilks 20 m variable long path gas cell was made possible for us by a grant from the "Fonds annuel de soutien de l'Université de Montréal" for which we express our sincere thanks. Hydrogen bonding and vapor pressure isotope effect of ethanethiol

JERZY SZYDLOWSKI[1] AND HANS WOLFF

Physikalisch-chemisches Institut, Universität Heidelberg, 6900 Heidelberg, Federal Republic of Germany

Received September 15, 1978

JERZY SZYDLOWSKI and HANS WOLFF. Can. J. Chem. **57**, 1350 (1979).

The vapor pressure ratios of ethanethiol and ethanethiol-d_1 between 223 and 323 K can be represented by the relation

$$\ln P_D/P_H = -5116.67\ K^2/T^2 + 34.032\ K/T - 0.04804$$

The P_D/P_H vs. T curve increases initially and reaches a flat maximum at 293 K; at higher temperatures there is an apparent decrease. This behavior can be explained by the superposition of predominantly the normal effect of the intermolecular vibrations and the SH and SD torsion vibrations, and the inverse effect of the SH and SD stretching vibrations. Contrary to the value of 0.91 reported previously, P_D/P_H values of 1.002 to 1.008 confirm that for weakly hydrogen-bonded substances and their deuterium-bonded analogues a negligibly normal or a slightly inverse vapor pressure isotope effect should be observed.

JERZY SZYDLOWSKI et HANS WOLFF. Can. J. Chem. **57**, 1350 (1979).

On peut représenter les rapports des tensions de vapeur de l'éthanethiol et de l'éthanethiol-d_1 entre 223 et 323 K par la relation

$$\ln P_D/P_H = -5116.67\ K^2/T^2 + 34.032\ K/T - 0.04804$$

La courbe du rapport P_D/P_H vs T augmente au début et atteint un maximum à 293 K; à des températures plus élevées, il semble se produire une diminution. On peut expliquer ce comportement par la superposition d'un effet normal prédominant des vibrations intermoléculaires et des vibrations de torsion SH et SD et l'effet inverse des vibrations de valence SH et SD. Contrairement à la valeur de 0.91 rapportée antérieurement, les valeurs de P_D/P_H de 1.002 à 1.008 confirment que dans le cas de substances faiblement liées par des liaisons hydrogène et celui de leurs analogues liés par des deutérium, on devrait observer un effet isotopique de la tension de vapeur qui est légèrement inverse ou faiblement normal.

[Traduit par le journal]

While valuable results have been obtained from investigations of the vapor pressure isotope effect on hydrogen bonding of water, alcohols, amines, carboxylic acids, etc. (1–3), such information is lacking in the case of thiols. Hobden *et al.* (4) have reported the P_D/P_H ratio of 0.91 at 298 K from the vapor pressures of C_2H_5SH and C_2H_5SD. According to the relationship developed between hydrogen bonding and vapor pressure isotope effect (1–3) this value appears too low for a substance with weak hydrogen bonding, such as ethanethiol (5, 6). Reliable and more complete data over a wide temperature range are required in order to obtain further insight into the vapor pressure behavior of thiols. Therefore, the vapor pressures of C_2H_5SH and C_2H_5SD and their ratios were determined between 223 and 323 K.

Ethanethiol (purchased in pure form from Fluka) was dried over molecular sieve, previously heated under vacuum at 300°C, and then purified by low temperature distillation in a spinning band column. Ethanethiol-d_1 was prepared by the exchange reaction of pure C_2H_5SH with D_2O using a specially designed column; a four stage exchange, prior to the further purification as for C_2H_5SH, yielded a purity of C_2H_5SD better than 99%.

The pressures of C_2H_5SH and C_2H_5SD between 293 and 323 K were measured with a quartz manometer. In the range 223–293 K the pressures of C_2H_5SH were determined with a mercury manometer, and the pressure differences $\Delta P = P(C_2H_5SD) - P(C_2H_5SH)$ with a differential mercury manometer; the pressures of C_2H_5SD resulted from $P(C_2H_5SH)$ and ΔP. The sample cell (two sample cells in difference measurements) and the quartz manometer with its connections to the sample cell in measurements above room temperature were thermostated by the method described in previous vapor pressure investigations of binary mixtures (7, 8). The drift of the sample temperature during a measurement was less than 0.02 K, and a cathetometer was used to determine the pressure differences. This led to an accuracy of 0.2 Torr in the pressure determinations with the quartz manometer and of 0.02 Torr with the differential mercury manometer.

The results of the determinations are listed in

[1]Permanent address: Department of Chemistry, University of Warsaw, Zwirki i Wigury 101, 02-069 Warsaw, Poland.

0008-4042/79/111350-04$01.00/0

Table 1. The pressures of C_2H_5SH are in agreement with those of McCullough *et al.* (9) between 273 and 323 K and can be represented over the entire experimental temperature range of 223–323 K by the equation

$$[1] \quad \log P/\text{Torr} = -64261.1\ \text{K}^2/T^2 - 1039.10\ \text{K}/T + 6.92908$$

The pressures of C_2H_5SD, which are reported for the first time (Table 1), can be represented over the same temperature range by the equation[2]

$$[2] \quad \log P/\text{Torr} = -66468.8\ \text{K}^2/T^2 - 1024.43\ \text{K}/T + 6.90840$$

The P_D/P_H ratios were found to be 1.002 to 1.008 between 223 and 323 K and can be represented by the relation

$$[5] \quad \ln P_D/P_H = -(5116.67 \pm 295.21)\ \text{K}^2/T^2 + (34.032 \pm 2.165)\ \text{K}/T - (0.04804 \pm 0.00394)$$

A two parameter equation of the $A/T^2 + B/T$ type fits badly the experimental results at high and low temperatures.

The P_D/P_H vs. T curve (Fig. 1) initially increases and reaches a flat maximum at 293 K; at higher temperatures there is an apparent decrease. This significant behavior can be explained by the superposition of a weak normal vapor pressure isotope effect which rapidly converges to unity, and of a somewhat greater inverse effect which slowly converges to unity. In eq. [5] the weak normal effect can be associated with the $1/T^2$ term which in light of the theory of the vapor pressure isotope effect (10–13) is related to the low-lying vibrations, in particular the intermolecular vibrations. The somewhat greater inverse effect can be associated with the $1/T$ term which is related to the high-lying intramolecular vibrations. However, the situation is more complicated because the constant term, being due to temperature dependence and anharmonicity of the vibrations as well as to other complications, is comparable in the order of its magnitude to the $1/T$ and the $1/T^2$ terms.

According to infrared and Raman measurements of the internal frequencies (14–16) only stretching and torsion vibrations of the sulfhydryl group show changes on condensation which noticeably differ for the normal and the deuterated compound. Therefore, the use of these vibrations for the internal frequencies should be sufficient to approximately evaluate the equation for the vapor pressure ratio (10–13). In its simplified form based on the cell model for the liquid and neglecting anharmonicities etc., this equation gives P_D/P_H as function of 6 external frequencies of the condensed phase and of $3N - 6$ internal frequencies of the gaseous as well as of the condensed phase (eq. [13] of ref. 12).

The values of 2599/2590 and 2558 cm^{-1} of the stretching vibrations and of 191 and 215 cm^{-1} of the torsion vibrations may be applied for the two phases of C_2H_5SH. The corresponding frequencies of C_2H_5SD are 1888/1883 and 1860 cm^{-1} and 150 and 169 cm^{-1} (14–16) (169 cm^{-1} from the relation $(\nu_{gas}^{H} - \nu_{liq}^{H})/\nu_{gas}^{H} = (\nu_{gas}^{D} - \nu_{liq}^{D})/\nu_{gas}^{D}$). Assuming no large error occurs due to differences in the equilibrium of *trans* and *gauche* conformers, the factor with which the internal frequencies enter the P_D/P_H ratio is found to be 1.025–1.021 between 270 and 320 K. From these values and the measured P_D/P_H values (Table 1) the factor with which the external frequencies enter the ratio is determined to be 0.983–0.987.

The contribution of the three translations computed from

$$[6] \quad \alpha_{tr} = \exp\left\{\frac{1}{24}\left(\frac{hc}{kT}\right)^2 \sum_{i=1}^{3} \left(\nu_i'^2\left[1 - \frac{M'}{M}\right]\right)\right\}$$

(M′ and M are the molecular weights of C_2H_5SH and C_2H_5SD) for the Debye temperature of 129.4 K (9) is negligible; therefore, the values of 0.983–0.987 are due to the contribution of the three librations. Defining the cube root of the product of the three different librations as mean libration, $\bar{\nu}_i$, and the cube root of the product of the three different moments of inertia as mean moment of inertia, $\bar{I}$, the relation

$$[7] \quad \bar{\nu}_i/\bar{\nu}_i' = (\bar{I}'/\bar{I})^{1/2} = 0.979$$

can be assumed, where the moments of inertia for the calculation of $(\bar{I}'/\bar{I})^{1/2}$ have been taken from literature (17, 18) (the value of 0.979 is the average of $(\bar{I}'/\bar{I})^{1/2}$ of the *trans* and *gauche* conformers). From

[2]The Antoine equations, mostly used in the representation of vapor pressure data but physically less significant, are for C_2H_5SH for the temperature range of 223–293 K

[3*a*] $\log P/\text{Torr} = 7.10235 - 1156.08/(T/\text{K} - 34.237)$

and for the temperature range of 293–323 K

[3*b*] $\log P/\text{Torr} = 6.93273 - 1074.83/(T/\text{K} - 42.912)$

The corresponding equations of C_2H_5SD for the range of 223–293 K are

[4*a*] $\log P/\text{Torr} = 7.09984 - 1151.74/(T/\text{K} - 34.849)$

and for the range of 293–323 K

[4*b*] $\log P/\text{Torr} = 6.91033 - 1051.47/(T/\text{K} - 44.508)$

*P_H = pressure of C_2H_5SH; ΔP = difference of the pressures P_D of C_2H_5SD and P_H of C_2H_5SH; measured pressure differences are without parentheses; pressure differences calculated from $P(C_2H_5SD)$ and $P(C_2H_5SH)$ are within parentheses; P_D/P_H = measured vapor pressure ratio.
†1 Torr = 0.13332 kPa.

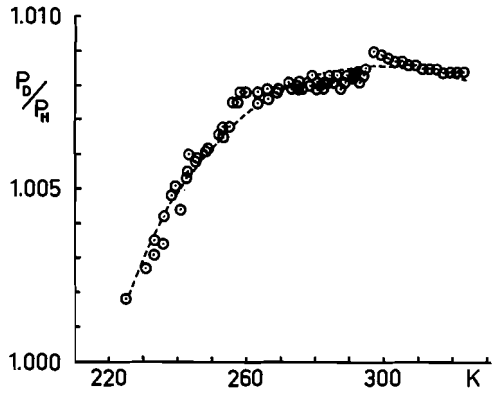

FIG. 1. Vapor pressure ratio P_D/P_H of ethanethiol and ethanethiol-d_1 as function of the temperature; ○ measured points; --- ratios calculated according to eq. [5].

[7] and the contribution of the three librations (eq. [13] of ref. 12) with the values of 0.983–0.987, $\overline{\nu_i'}$ is calculated as 350–360 cm^{-1}, and $\overline{\nu_i}$ as 340–350 cm^{-1}.

There is no doubt that the high values obtained can be considered only as rough approximations of the actual values due to their sensitivity to small frequency errors and the considerable simplifications involved in these calculations. Nevertheless, the results permit the interpretation that the superposition predominantly of the normal effect of the intermolecular vibrations and the SH and SD torsion vibrations and of the inverse effect of the SH and SD stretching vibrations leads to the measured vapor pressure ratio curve.

It may be added that the P_D/P_H ratio at 293 K has been determined to be 1.010 for CH_3SH and CH_3SD (19) and 1.014 for H_2S and D_2S (20); the 293 K

value of C_2H_5SH and C_2H_5SD is 1.008. The result for ethanethiol, therefore, is in reasonable agreement with the data for other sulfhydrides, while there exists a considerable difference in relation to the oxygenic analogue of ethanethiol; the P_D/P_H ratio of ethanol is lowered to about 0.94 (21) as a consequence of its strong hydrogen bonding. Contrary to the large normal vapor pressure isotope effect reported previously, the high accuracy of the present measurements on ethanethiol confirms that for weakly hydrogen-bonded substances and their deuterium-bonded analogues only a negligibly normal or a slightly inverse effect should be observed.

Isotope effects in nucleophilic substitution reactions. III. The effect of changing the leaving group on transition state structure in S_N2 reactions

KENNETH CHARLES WESTAWAY[1] AND SYED FASAHAT ALI

Department of Chemistry, Laurentian University, Sudbury, Ont. Canada P3E 2C6

Received August 21, 1978

KENNETH CHARLES WESTAWAY and SYED FASAHAT ALI. Can. J. Chem. **57**, 1354 (1979).

The nucleophilic substitution reactions of a series of 4-substituted phenylbenzyldimethylammonium ions with thiophenoxide ions at 0°C in *N,N*-dimethylformamide have been used to demonstrate how a change in the leaving group alters the structure of the S_N2 transition state. Heavy atom (nitrogen) kinetic isotope effects, secondary α-deuterium kinetic isotope effects and Hammett ρ values provide qualitative descriptions of both the nucleophile–α-carbon and α-carbon – leaving group bonds in the transition states of these reactions. The results indicate that changing to a better leaving group causes the bond between the α-carbon and the nucleophile to be much more fully formed while the bond to the leaving group is essentially unchanged. The results are discussed in the light of current theories of substituent effects on S_N2 reactions and a possible explanation for the surprising results (*i*) that the greatest effect is in the bond more remote from the point of structural change and (*ii*) that more nucleophilic assistance is required to displace a better leaving group is given.

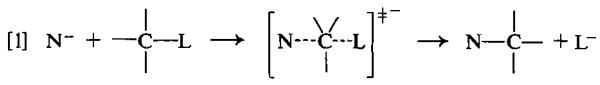
KENNETH CHARLES WESTAWAY et SYED FASAHAT ALI. Can. J. Chem. **57**, 1354 (1979).

On a utilisé les réactions de substitutions nucléophiles d'une série d'ions X-4 phénylbenzyldiméthylammonium avec les ions thiophénolates à 0°C dans le *N,N*-diméthylformamide pour démontrer l'influence d'un changement dans le nucléofuge sur la structure de l'état de transition S_N2. Les effets isotopiques cinétiques des atomes lourds (azote), les effets isotopiques cinétiques secondaires des deutérium en α et les valeurs ρ de Hammett fournissent des descriptions qualitatives des liaisons nucléophile – carbone en alpha et carbone en alpha groupe nucléofuge dans les états de transition de ces réactions. Les résultats indiquent que si l'on utilise un meilleur nucléofuge la liaison entre le carbone alpha et le nucléophile devient plus développée alors que la liaison vers le groupe nucléofuge est pratiquement inchangée. On discute des résultats à la lumière des théoriques actuelles des effets de substituants sur les réactions S_N2 et l'on propose une explication plausible pour les résultats surprenants: (*i*) que l'effet est le plus grand dans la liaison la plus éloignée du point de changement structural et (*ii*) qu'il faut plus d'aide de la part du nucléophile pour déplacer un meilleur nucléofuge.

[Traduit par le journal]

Introduction

Although the mechanisms of the simple one-step (S_N2) nucleophilic substitution reaction at saturated carbon, eq. [1], have been investigated for over half



[1]

a century, there are still some questions that remain unanswered. One of these questions is: How does a change in the nucleophile, N^-, the substrate, or the leaving group, L^-, affect the structure of the transition state of an S_N2 reaction? In fact, rate studies (1, 2), secondary α-deuterium kinetic isotope effects (3–5), thermodynamic properties (6, 7), heavy atom (carbon (5, 8), nitrogen (9, 10), sulfur (11–13), chlorine (14–15), and bromine[2]) kinetic isotope effects, and linear free energy relationships (2, 9, 10) have been used in studies on a wide range of reactions in an effort to determine how the structure of the reactants affects the structure of the S_N2 transition states. In addition, several theoretical studies (18–23) have predicted the answer to this question. In spite of these studies, the question has not been resolved completely. This has happened for two reasons. First, changes in the structure of either the nucleophile or the leaving group cause large changes in several properties of the reacting molecule. For example, even changing the leaving group from chloride ion to bromide ion causes large changes in (*i*) the force constant of the Cα—L bond, (*ii*) the polarizability of the leaving group, (*iii*) the dipole moment of the Cα—L bond, (*iv*) the Cα—L bond length, (*v*) the size of the leaving group changing the steric crowding at the reaction center, and (*vi*) the solvation of both the substrate and the transition state. These changes make comparisons between different reactions difficult to interpret and it is impossible to indicate why the observed changes

[1]Author to whom all correspondence should be addressed.

[2]J. W. Taylor. Private communication.

0008-4042/79/111354-14$01.00/0

occur. The second difficulty is that these studies have not provided enough information so that detailed models of the transition states could be constructed. For example, almost all of these studies have only provided information about the Cα--L transition state bond length and the lengths of the other bond(s) in the transition state have either been ignored or inferred from the predictions of theoretical models (18–22) which have not been tested experimentally.

In this study, eq. [2], the structure of the nucleophile, the substrate, or the leaving group can be altered without changing the properties of the reactants significantly. For example, changing the substituent Z in the leaving group will not change the Cα—N bond length, the size of the leaving group at the reaction center, or the polarizability of the leaving atom. In addition, the changes in the Cα—N bond strength, the dipole moment of the Cα—N bond, and the solvation of the substrate and the transition state would be small or zero. Thus, the effect of a change resulting from a change in the structure of the leaving group can be determined and related to one property: the electron donating or withdrawing ability of the substituent. The second advantage of this system is that the combination of leaving group (nitrogen) kinetic isotope effects, secondary α-deuterium kinetic isotope effects, and Hammett ρ values has led to complete (albeit qualitative) structures for the S_N2 transition states for three different leaving groups. This removes the uncertainty associated with the other studies and provides the answer to the question of how the structure of the transition state varies with a change in the leaving group of an S_N2 reaction.

Results and Discussion

The reactions used in this study were followed by titrating the unreacted thiophenoxide ion with Hg(II) ion (24). The data was consistent with a second order reaction that was first order in each reactant. The kinetics and a Hammett ρ value of −1.70 associated with a change of the X group (eq. [2]) in the reaction with phenylbenzyldimethylammonium ion indicated that the Cα—S bond was formed in the transition state of the slow step of the reaction (9, 10). A Hammett ρ value of +2.04 when the Z substituent in the leaving group was varied and a nitrogen kinetic isotope effect of 1.0200 showed that the Cα—N bond was breaking in the transition state of the rate-determining step (9). These results were only consistent with the one-step S_N2 mechanism (9, 10, 25).

The products of the reaction, benzylphenyl sulfide and *N*,*N*-dimethylaniline, were recovered from reactions taken to completion and analyzed by gas chromatography using the internal standard technique (benzylphenyl sulfide) (26) and the micro-Kjeldahl technique (*N*,*N*-dimethylaniline) (9). These analyses showed that the products were formed quantitatively. This demonstrates that the kinetic isotope effects and rate constants measured in this study are those of the S_N2 reaction shown in [2].

Kinetic Studies

The second order rate constants for four different *para*-substituted thiophenoxide ions with each of the *p*-methoxyphenyl-, the phenyl-, and the *p*-chlorophenylbenzyldimethylammonium ions are given in Table 1. Each rate constant is the average of the value obtained from at least four separate kinetic runs. The rate constant for the reaction between *p*-methoxythiophenoxide ion and *p*-chlorophenylbenzyldimethylammonium ion was too fast to be measured by the titrimetric method used to follow these reactions.

The rate constant is altered significantly by a change in leaving group. Changing the substituent Z

TABLE 1. Second order rate constants for the S_N2 substitution reactions of *para*-substituted phenylbenzyldimethylammonium ions with *para*-substituted thiophenoxide ions at 0°C in DMF

Substituent (Z) on the *N*-phenyl group	*k* (L/mol min) for substituent (X) on the thiophenoxide ion			
	—OCH_3	—CH_3	—H	Cl
—OCH_3	0.835	0.465	0.256	0.135
—H	2.77	1.46	0.770	0.368
—Cl	—	5.33	2.26	0.971

from methoxy to hydrogen causes a threefold increase in rate while a tenfold increase in rate is observed for the more electron withdrawing chlorine substituent. Thus, the best leaving group from a kinetic point of view is the weakest base, *p*-chloro-*N*,*N*-dimethylaniline. This is, in fact, what is expected (27, 28).

The best nucleophile for each substrate is the *p*-methoxythiophenoxide ion. The reactivity decreases regularly as the substituent X becomes more electron withdrawing. This occurs because more electron withdrawing substituents lower the electron density on the sulfur atom of the nucleophile (29).

Nitrogen Kinetic Isotope Effect

The nitrogen kinetic isotope effects for the reactions of the *p*-methoxyphenyl-, the phenyl-, and the *p*-chlorophenylbenzyldimethylammonium nitrates with sodium thiophenoxide at 0°C were calculated using [3] (9).

$$[3] \qquad \frac{k^{14}}{k^{15}} = \frac{\ln (1 - f)}{\ln (1 - (R_0/R_f)f)}$$

where f is the fraction of quaternary ammonium salt that has reacted, R_0 is the $^{14}N/^{15}N$ ratio of the ammonium nitrogen in the starting material and R_f is the corresponding ratio in the product (the *para*-substituted *N*,*N*-dimethylaniline) recovered after fractions of reaction ranging from 16–38% completion. The fraction of reaction, f, was the average of the percent reaction found in the gas chromatographic analysis of the benzylphenyl sulfide and the micro-Kjeldahl analysis of the *para*-substituted *N*,*N*-dimethylaniline recovered from a reaction mixture (9). The R_0 value was obtained by measuring the $^{14}N/^{15}N$ ratio in the product recovered from reactions taken 100% to completion. The $^{14}N/^{15}N$ ratios for [3] were obtained in a mass spectrometric analysis of the nitrogen gas that was produced when the ammonium sulfate from the micro-Kjeldahl analysis was oxidized with sodium hypobromite (9). The results of these experiments are given in Table 2.

The isotope effects are all large. In fact, they are approximately half of the theoretical maximum nitrogen kinetic isotope effect at 0°C[3] and indicate that there is substantial Cα—N bond rupture in the transition states of these reactions.

The relative lengths of the Cα--N bonds in the three transition states can be estimated from the magnitudes of these isotope effects (12–14). Theoretical calculations (31, 32) indicate that the magnitude of heavy atom (leaving group) kinetic isotope effects

[3]The maximum nitrogen kinetic isotope effect of 1.04 at 0°C was calculated using a Cα—N^+ absorption frequency of 1003 cm^{-1} (30).

[a]Based on the average of the yields of benzylphenylsulfide and *N*,*N*-dimethylaniline.
[b]Standard deviation.

increases as the amount of the Cα—L bond rupture in the transition state increases.[4] This relationship is predicted because the last term in the square brackets of Bigeleisen's equation (34) is smaller for a longer Cα--L transition state bond, eq. [4]. The terms μ_{14}^*

$$[4] \qquad \frac{k^{14}}{k^{15}} = \frac{\mu_{14}^*}{\mu_{15}^*}\left[1 + \sum_i^{3n-6} G(\mu_i)\Delta u_i - \sum_i^{3n-7} G(\mu_i^*)\Delta\mu_i^*\right]$$

and μ_{15}^* are the reaction coordinate frequencies of the transition state containing the C—^{14}N and C—^{15}N bonds respectively. The $\sum_i^{3n-6} G(\mu_i)\Delta\mu_i$ term gives the difference in the vibrational energies of the nitrogen-14 and nitrogen-15 quaternary ammonium salts. $\sum_i^{3n-7} G(\mu_i^*)\Delta\mu_i^*$ is the corresponding term for the transition states.

An initial consideration of the results in Table 2 shows that the three isotope effects are not statistic-

[4]Theoretical calculations by Sims and co-workers (33) show that hydrogen bonding between a protic solvent and a negatively charged leaving group, e.g., Cl^-, can reduce the magnitude of a leaving group kinetic isotope effect (with respect to that expected for a particular α-carbon – leaving group transition state bond length) significantly. This reduction in the magnitude of the isotope effect should be very small in the reactions reported in this paper because a nonhydrogen bonding solvent (DMF) is used and because the leaving group has a slight positive charge in the transition state.

ally different. In spite of this, the isotope effects do increase slightly as the substituent Z on the leaving group is changed from methoxy to the more electron withdrawing chlorine. This suggests that the Cα—N bond length is the same in all three transition states or increases very slightly as the substituent changes from methoxy to chlorine.

Unfortunately, the interpretation of these isotope effects is not simple. The difficulty arises because the N—C(phenyl) bond becomes stronger as the Cα—N bond breaks.[5] Thus, some of the Cα—N vibrational energy that has been lost in going to the transition state is partially replaced by the increased vibrational energy associated with the strengthening of the N—C(phenyl) bond. The last term in [4] will not be reduced as much as expected for a particular Cα--N bond length and the slope of the 'magnitude of the kinetic isotope effect versus extent of Cα—N bond rupture in the transition state' curve will be lower (Fig. 1).[6] This suggests that the small, regular increases observed in the nitrogen kinetic isotope effects are indicative of slightly longer Cα--N transition state bonds in the reactions with more electron withdrawing substituents. This interpretation of the results is strengthened because the N—C(phenyl) bond strengthening effect should be most important, i.e., the observed nitrogen kinetic isotope effect will be smaller, when the substituent on the leaving group is chlorine, the most electron withdrawing substituent used in this study (Fig. 1*c*). Thus, the best interpretation of these results is that the Cα--N transition state bond becomes slightly longer as the substituent Z changes from methoxy to hydrogen to chlorine.

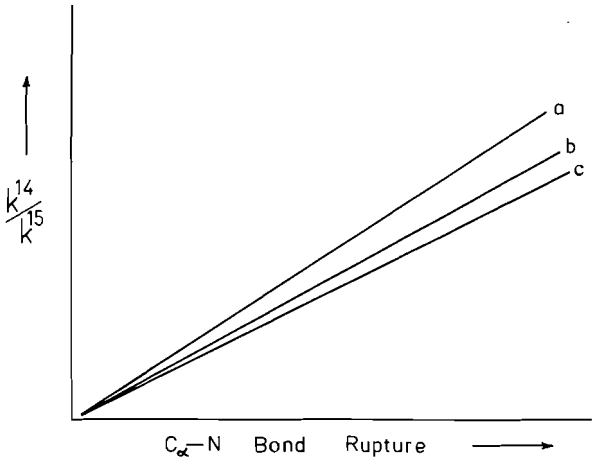

FIG. 1. Nitrogen kinetic isotope effect versus extent of Cα—N bond rupture in the transition state (*a*) for a system where there is no interaction between the developing lone pair of electrons on the dimethylamino group and the benzene ring of the leaving group, (*b*) for a system where there is conjugation between the dimethylamino group and the benzene ring of the leaving group, and (*c*) for a system where the conjugation between the dimethylamino group and the benzene ring is increased by an electron withdrawing substituent Z in the leaving group.

Secondary α-Deuterium Kinetic Isotope Effects

The secondary α-deuterium kinetic isotope effects were also determined by the competitive technique (9,10), i.e., by reacting approximately equal amounts of the *para*-substituted phenylbenzyl-1,1-d_2-dimethylammonium nitrate and the corresponding undeuterated quaternary ammonium salt to extents of reaction varying from 17–27% completion. The isotope effect was calculated using [3]. The fraction of reaction *f* was calculated from the results of a gas chromatographic analysis of the product (benzyl-1,1-d_2-phenyl sulfide and benzylphenyl sulfide) using the internal standard technique (9, 26). The ratio of the undeuterated/dideuterated benzylphenyl sulfide in the product of reactions taken part way to completion, R_f, was determined in a mass spectrometric analysis of the benzylphenyl sulfide. The ratio of undeuterated/dideuterated *para*-substituted phenylbenzyldimethylammonium ion, R_0, was obtained from the weights of the undeuterated and deuterated quaternary ammonium salts and the percentage of dideuterated material (98.1%) in the

[5]The conjugation between the dimethylamino group and the benzene ring in the product (a *para*-substituted *N,N*-dimethylaniline) makes the N—C(phenyl) bond in the product (and to a lesser degree in the transition state) stronger than that in the substrate where the lone pair of electrons are not available. The absorption frequencies of the Cα—N bond of the substrate and the N—C(phenyl) bond of the product are 1000 and ~1330 cm^{-1} respectively.

[6]This phenomenon has been reported for carbon-13 kinetic isotope effects in the S_N1 reactions of 1-phenylethylbromides (35, 36) and for a carbon-13 equilibrium isotope effect for the dissociation of triphenylmethylchloride into triphenylmethyl carbonium ion (37). In these cases, the vibrational energies from the increased bonding in the CH_3—Cα and the Cα—C(phenyl) bonds in the carbonium ions (the increase in frequency was ~200–300 cm^{-1} per bond or a bond order of ~1.2 (CH_3—$C\alpha^+$) and 1.5 ($C\alpha^+$—C(phenyl) (L. B. Sims, private communication)) was sufficient to balance or even overcome the loss of vibrational energy resulting from the rupture of the C–halogen bond (vibrational frequency ~500–600 cm^{-1}) and small (35, 36) and inverse (36, 37) isotope effects were observed. The increased bonding in the N—C(phenyl) bond should have a much smaller effect on the nitrogen kinetic isotope effects measured in this study because (*a*) only one bond increases its vibrational energy in the transition state, (*b*) the Cα—N bond is much stronger than a C–halogen bond so the loss of vibrational energy will be greater, (*c*) the amount of Cα—N bond rupture and thus N—C(phenyl) bond strengthening (this uses the same pair of electrons) are smaller in an S_N2 transition state than in an S_N1 transition state (39, 40), and (*d*) the amount of N—C(phenyl) bond strengthening should be smaller than that observed for the $C\alpha^+$—C(phenyl) bond where the demand for electrons by the positively charged carbon is greater.

deuterated substrate. The secondary α-deuterium kinetic isotope effects for the reaction of the *p*-methoxyphenyl-, the phenyl-, and the *p*-chlorophenylbenzyldimethylammonium ion with thiophenoxide ion at 0°C in DMF are given in Table 3.

An examination of the isotope effects in Table 3 shows that (*i*) all three isotope effects are significantly larger than the maximum secondary α-deuterium kinetic isotope effect (k_H/k_D = 1.08 or 1.04 per α-deuterium) expected for an S_N2 reaction (41) and (*ii*) that the magnitude of these isotope effects decreases as a more electron withdrawing substituent Z is added to the leaving group.

Unusually large secondary α-deuterium kinetic isotope effects are observed in these S_N2 reactions because the exceptionally large steric crowding around the Cα—H bonds in the substrates is reduced substantially in going to transition states with fairly long Cα--N and S--Cα bonds.[7] Thus, the zero point energy difference for the Cα—H and Cα—D out-of-plane bending vibrations will be much smaller in the transition state than in the reactant and large normal deuterium kinetic isotope effects would be expected for these reactions (10, 25).

More important, however, is the regular[8] decrease that is observed in the isotope effects as the substituent Z in the leaving group is changed from methoxy to chlorine. Unfortunately, no one has been able to suggest how the magnitudes of secondary α-deuterium kinetic isotope effects are related to the structure of S_N2 transition states (16). Thus the meaning of the trend in these isotope effects cannot be interpreted with certainty.

A consideration of the trend in the isotope effects in Table 3 has led the authors to propose that the magnitude of secondary α-deuterium kinetic isotope effects from closely related S_N2 reactions can be used to determine the structure of the transition state. Several workers have shown that the magnitude of secondary α-deuterium kinetic isotope effects is primarily determined by the changes that occur in the Cα—H out-of-plane bending vibrations when the substrate is converted into the transition state (42–44). In fact, the energy of these bending vibrations is directly related to the amount of steric crowding around the Cα—H bonds. A change of the substituent Z in the leaving group occurs several bonds away from the reaction center and obviously will not affect the steric crowding around the Cα—H bonds in the substrate. Thus the energy (frequency) of these vibrations and the zero point energy dif-

[7]The steric crowding around the reacting atoms in the initial states of the *p*-methoxyphenyl-, the phenyl, and the *p*-chlorophenylbenzyldimethylammonium ions will be identical. Moreover, the very similar nitrogen kinetic isotope effects and Hammett ρ values for substitution in the nucleophile (*vide infra*) observed for these reactions indicate that the transition states are similar.

[8]The magnitude of the isotope effect decreases by 3% when the change in the Hammett σ values of the substituent Z is $0.27 = |\sigma_{OCH_3} - \sigma_H|$ and $0.23 = |\sigma_H - \sigma_{Cl}|$.

ference ($\frac{1}{2}h\nu$) for the Cα—H and Cα—D out-of-plane bending vibrations will be the same for all three substrates. This means the trend observed in these isotope effects is caused by differences in the steric crowding around the Cα—H bonds in the transition states with Z equal to methoxy, hydrogen, and chlorine. The energy of the transition state Cα—H out-of-plane bending vibrations will be directly related to the amount of steric crowding around the Cα—H bonds. The amount of steric crowding around the Cα—H bonds in the trigonal bipyramidal transition state can only be altered significantly by changing the length of one or both of the nucleophile–α-carbon or α-carbon – leaving group bonds. Thus if either or both of the nucleophile–α-carbon and α-carbon – leaving group bonds were shorter in the transition state, the steric crowding around the Cα—H bonds would be larger and the energy of the out-of-plane bending vibrations would be increased (Fig. 2). This means the zero point energy difference between the Cα—H and Cα—D bonds will also be larger and a smaller kinetic isotope effect would be observed (Fig. 2*c*). These bond changes which decrease the nucleophile – leaving group distance in the transition state lead to a decrease in the magnitude of the secondary α-deuterium kinetic isotope effect. It follows that a larger nucleophile – leaving group distance in the transition state produces lower energy Cα—H bending vibrations and a larger isotope effect (Fig. 2*a*). Thus, the magnitude of the secondary α-deuterium kinetic isotope effect should be a measure of the nucleophile – leaving group distance in an S_N2 transition state.[9]

The data obtained in theoretical calculations of S_N2 transition states (23, 44) provides evidence to support this use of secondary α-deuterium kinetic isotope effects. Bron (44) has calculated secondary α-deuterium kinetic isotope effects for the S_N2 hydrolysis of benzyl bromide. Isotope effects were calculated for a wide range of transition state structures, i.e., many O—Cα bond order/Cα—Br bond order = n_1/n_2 ratios representing reactant-like, intermediate, and product-like transition states were used in the calculations. For all n_1/n_2 ratios, the magnitude of the isotope effect decreased linearly as the total bond order $n_t = n_1 + n_2$ increased from zero to 1.5. Since an increase in n_t means that both

[9]This method of estimating transition state structure may not be useful in every case. It would be difficult, if not impossible, to relate the magnitude of the isotope effect to transition state structure if a substituent change causes one bond to become longer and the second bond to shorten. It would also fail in cases where the change in substituent altered the steric crowding at the α-carbon of the substrate.

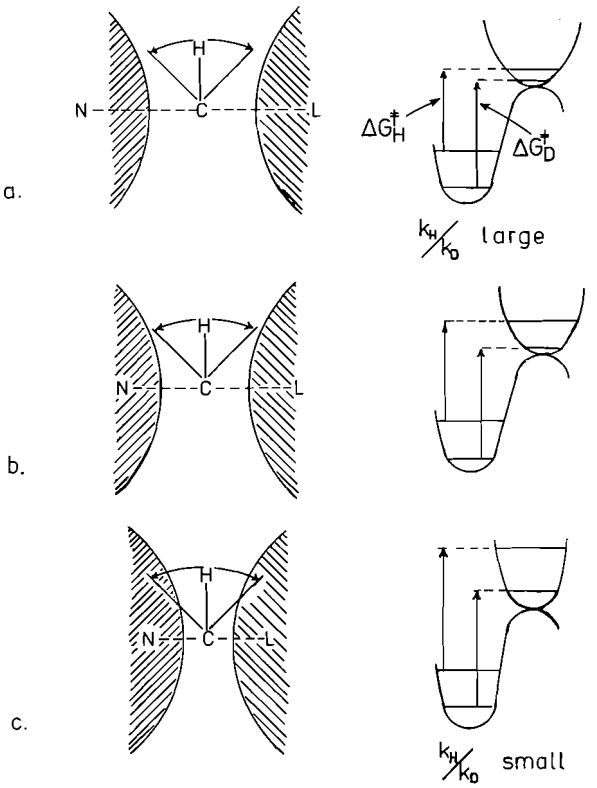

FIG. 2. The effect of a change in the nucleophile – leaving group (N—L) distance on the zero point energy difference between the Cα—H and Cα—D out-of-plane bending vibrations in an S_N2 transition state and hence on the magnitude of the secondary α-deuterium kinetic isotope effect.

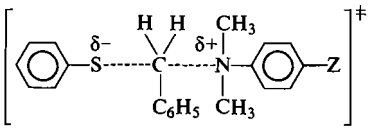
O—Cα and Cα—Br bond orders are increased (the O—Cα and Cα—Br bonds become shorter), the isotope effect decreases as the O—Br distance is decreased. This is precisely the relationship proposed above. Similar calculations by Sims and coworkers (23) predict that the same relationship between the magnitude of the isotope effect and the nucleophile – leaving group distance in the transition state, exists. Thus it would appear that the magnitude of the secondary α-deuterium kinetic isotope effects measured in this study can be used to obtain the sulfur–nitrogen distance in the transition states with the substituent Z in the leaving group equal to methoxy, hydrogen, and chlorine.

The magnitude of the secondary α-deuterium kinetic isotope effects in Table 3 decreases when a more electron withdrawing substituent is in the leaving group. The relationship proposed above suggests that the largest S—N distance exists in the transition state with Z equal to methoxy. The smallest S—N distance is found in the transition state with Z equal to chlorine.

TABLE 4. The influence of a change of substituent, Z, in the leaving group on the transition state structure of an S_N2 reaction



Para-substituent (Z) on the leaving group	k^{14}/k^{15}	Relative Cα—N bond length in transition state	$(k_H/k_D)_\alpha$	Relative S—N distance in transition state	Relative transition state structure
—OCH_3	1.0197	C-----N	1.207	S----------N	S--------C-----N
—H	1.0200	C------N	1.179	S--------N	S-----C------N
—Cl	1.0202	C-------N	1.151	S----N	S--C-------N

Combining these results with those from the nitrogen kinetic isotope effect study provides a qualitative estimate of both the nucleophile–α-carbon and the α-carbon – leaving group bonds in the transition states for the reactions with the different leaving groups. The nitrogen isotope effects indicated that the Cα—N bonds were the same length or showed a very slight, but regular, increase as the substituent Z was changed from methoxy to hydrogen to chlorine. The secondary α-deuterium kinetic isotope effects on the other hand showed that the sulfur–nitrogen distance decreased as more electron withdrawing substituents were placed in the leaving group (Table 4). Since the Cα—N bond in the transition state stays the same or becomes slightly longer as the S—N distance is decreasing, it must be concluded that the S—Cα bond length decreases as the substituent Z is changed from methoxy to chlorine. A second requirement is that the decrease in the S—Cα transition state bond length caused by a change to a more electron withdrawing substituent Z, must be greater than the increase in the Cα—N transition state bond. The relative structures of the three S_N2 transition states are shown in Table 4.

These changes in the structure of the transition states were surprising for two reasons: (*i*) the greatest change in the length of a transition state bond occurs in the bond more remote from the point of structural change and (*ii*) the best leaving group kinetically the *p*-chloro-*N*,*N*-dimethylaniline, requires the strongest push from the nucleophile, i.e., has the shortest S—Cα bond in the transition state. This result is surprising because it was expected that a better leaving group would require much less assistance from the nucleophile, i.e., less nucleophile–α-carbon bond formation. This would require an earlier transition state with a longer S—Cα bond and a shorter Cα—N bond. In fact, the opposite has been found.

Hammett ρ *Values*

It seemed necessary to confirm the above results for two reasons. Firstly, the structures of the transition states were completely unexpected and secondly because the conclusions were based on a new use of secondary α-deuterium kinetic isotope effects. In particular, it was important to confirm the lengths of the S—Cα bonds in the transition states of these reactions. In a recent publication Westaway and Ali (10) have shown that the Hammett ρ value obtained by changing the *para*-substituent in the nucleophile, i.e., in the thiophenoxide ion, can be used to estimate the length of the nucleophile–α-carbon bond in the transition state of an S_N2 reaction. Briefly, a large Hammett ρ value indicates that the charge on the nucleophile has changed markedly in going to the transition state. This means that a large portion of the electron density on the nucleophile has been used to form the nucleophile–α-carbon bond, i.e., the nucleophile–α-carbon bond must be short in the transition state. Conversely, a small Hammett ρ value would indicate a long weak nucleophile–α-carbon bond in the transition state.

The Hammett ρ values associated with changing the *para*-substituent in the thiophenoxide ion (changing X (eq. [2]) from methoxy to methyl, hydrogen, and chlorine) were determined for each substrate (the *p*-methoxyphenyl-, the phenyl-, and the *p*-chlorophenylbenzyldimethylammonium ion) at 0°C in DMF. The rate constants in Table 1 were used to determine these ρ values. The three ρ values, their standard deviation, and correlation coefficients are given in Table 5.

Two points are worth noting. First, all the Hammett ρ values are negative. This is expected because the sulfur atom of the nucleophile is more positively charged in the transition state of all three reactions. The second, and more important observation, is that the magnitude of the ρ values increases

TABLE 5. Hammett ρ values for the reactions of *para*-substituted thiophenoxide ions with *para*-methoxy-, *para*-hydrogen-, and *para*-chlorophenylbenzyldimethylammonium nitrates at 0°C in DMF

Substituent (Z) on the leaving group	ρ[a]	Correlation coefficient
$-OCH_3$	-1.536 ± 0.045	0.988
—H	-1.702 ± 0.047	0.990
—Cl	-1.834 ± 0.016	0.996

[a]The error limits are the standard deviation.

as the substituent in the leaving group is changed from methoxy to chlorine. This indicates that the largest change in the charge on the sulfur atom has occurred in the reaction where Z is chlorine. The smallest change of charge on the sulfur is found in the reaction where Z is methoxy. Since the change in charge varies inversely with the length of the S—Cα transition state bond, it can be concluded that the longest S—Cα bond is in the transition state with Z equal to methoxy. The shortest S—Cα bond is observed when Z is chlorine.

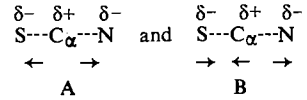
These results are in complete agreement with those based on the magnitude of the secondary α-deuterium kinetic isotope effect. The two methods used to estimate the relative lengths of the S—Cα transition state bonds are based on two completely different types of experimental data. Thus, the agreement provides very strong support for the results, i.e., that changing to a better leaving group, from a kinetic point of view (a more electron withdrawing substituent Z), causes a slight increase in the length of the Cα—N bond and a large decrease in the S—Cα bond in the transition state. The agreement also substantiates the new use of the secondary α-deuterium kinetic isotope effects to determine the nucleophile – leaving group distance in an S_N2 transition state.

Comparison of Experimental Results and Theoretical Predictions

Several workers have published theories which predict how changes in substituents will affect the structure of S_N2 transition states. The results of this investigation provide, for the first time, a good test of these theories.

The first method for predicting transition state structure was Hammond's 'thermal postulate'[10] (the Bell–Evans–Polanyi principle (45)). Hammond's postulate predicts that changing to a better leaving group from a kinetic point of view,[11] should lead to a more reactant-like transition state, i.e., with a longer S—Cα and a shorter Cα—N bond in the transition state. This is not observed. The experimental results indicate that changing to a better leaving group (Z equal to chlorine) leads to a tighter or more product-like transition state with a much shorter S—Cα bond and slightly longer Cα—N bond.

The second attempt to explain substituent effects in S_N2 transition states by Swain and Thornton (19) has been replaced by Thornton's reacting bond rule' (20). In this theory the substituent effects are determined by considering the effect of the change in substituent on the transition state stretching vibrations perpendicular (A) and parallel (B) to the reaction coordinate. Application of the 'reacting bond rule' to a transition state with a more electron withdrawing substituent in the leaving group (20) indicates that both the S—Cα and Cα—N bonds will be longer for the perpendicular vibration. A longer S—Cα bond and a shorter Cα—N bond are predicted for the parallel vibration. Since the S—Cα bond is longer for both vibrations, a longer S—Cα bond would be expected in the transition state with the better leaving group. The effect on the Cα—N bond is different for the two vibrations, however, and it is difficult to predict the change that will occur in the Cα—N transition state bond when the leaving group is altered. Recent studies by Winey and Thornton (47) on the structure of the transition states of concerted E2 elimination reactions have indicated that the relative perpendicular and parallel contributions are of comparable magnitude. If the parallel and perpendicular contributions are also equal for S_N2 reactions, changing to a better leaving group would still lead to a transition state with a longer S—Cα bond. The Cα—N bond on the other hand would not be changed significantly. The experimental results indicate (*i*) that the S—Cα bond is more sensitive to a change in the leaving group than the Cα—N bond and (*ii*) that the Cα—N bond becomes slightly longer and the S—Cα bond significantly shorter when a better leaving group is present. The reacting bond rule predicts correctly that the S—Cα bond will change more than the Cα—N bond.



[10]Although Hammond's postulate has been used to predict changes in the structure of S_N2 transition states, this use has been criticized (46).

[11]A more stable *para*-substituted *N,N*-dimethylaniline is produced when a more electron withdrawing substituent Z is present in the leaving group. The energy of the reactants would not be changed significantly by a change in Z (45).

Moreover, if the perpendicular effect is slightly more important than the parallel effect, a slightly longer Cα—N bond would be observed when a better leaving group is present. Unfortunately, the reacting bond rule predicts a longer S—Cα bond and a shorter S—Cα bond is found. In fact, the experimental results are not predicted by any combination of the parallel and perpendicular effects.

Harris and Kurz (21) have modified Thornton's reacting bond rule in an effort to improve the results predicted for a change of substituent in the substrate. In spite of these modifications, the Harris–Kurz theory predicts the same changes in transition state structure for a change in the leaving group as Thornton's rule. Thus, the Harris-Kurz theory also fails in the same way to predict the experimental results.

Critchlow (22) devised a method to determine the energy and structure of S_N2 transition states from estimates of the energies of the carbonium ion and pentavalent (N—C—L) intermediates of the hypothetical stepwise reactions. Critchlow's theory predicts that the major change will occur in the bond more remote from the point of structural change, i.e., in the S—Cα bond. In particular, changing to a better leaving group is expected to give a transition state with a longer S—Cα bond. The Cα—N bond on the other hand should not change significantly. While the S—Cα bond does change more than the Cα—N bond when the leaving group is changed, the change in the S—Cα bond is opposite to that predicted. The experimental results indicate that a better leaving group leads to a transition state with a shorter S—Cα bond.

The most recent method of predicting substituent effects was suggested by Sims *et al.* (23). They proposed the use of a More O'Ferrall type of energy surface (48) (Fig. 3) to predict the changes that occur in the structure of the transition state when a substituent in the substrate, the nucleophile, or the leaving group is changed. The energy of the reactants, products, and the two possible intermediates, the carbonium ion and the pentavalent N—C—L complex, are represented at the corners of the energy surface. The X and Y axes represent changes in the α-carbon – leaving group (Cα—N) bond and the nucleophile–α-carbon (S—Cα) bond, respectively. The contours show the lowest energy pathway, i.e., the reaction coordinate, through the energy surface. The transition state is designated by a star.

The effect of changing a substituent in one of the reactants is determined by considering how this change would affect the energies of the reactants, the products, and the two possible intermediates. The benzyl carbonium ion intermediate and substitution product (benzylphenyl sulfide) are identical for all three leaving groups. Thus, the change in the energy of the carbonium ion (lower right corner) and the products (top right corner) resulting from a change in the leaving group is caused by the different energies of the leaving groups, i.e., the *para*-substituted *N*,*N*-dimethylanilines. Changing to a better leaving group (an *N*,*N*-dimethylaniline with a more electron withdrawing substituent) will lower the energy of the bottom right and top right corners of the energy surface by the same amount. Lowering the top right corner will cause the transition state to move back towards the reactant along the diagonal between reactants and products, a parallel effect. Lowering the bottom right corner of the energy surface would cause the transition state to move to the right, a perpendicular effect. The parallel effect will lead to a longer S—Cα bond and a shorter Cα—N bond in the transition state. The perpendic-

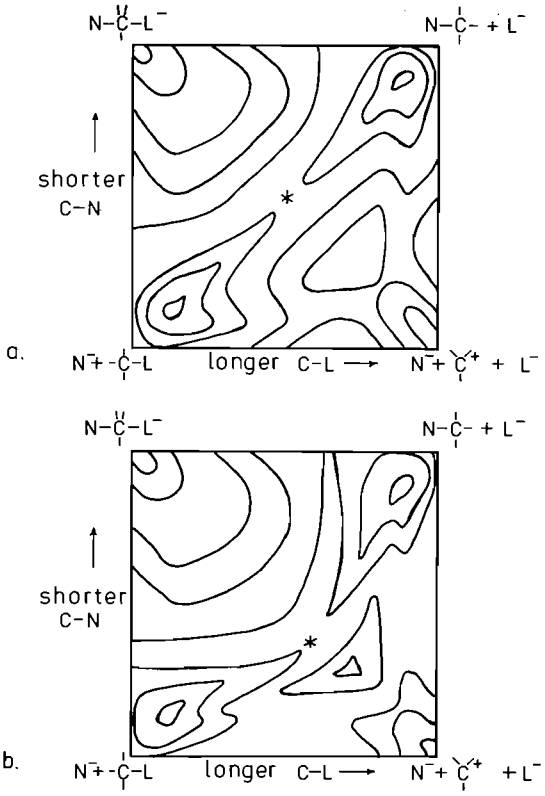


FIG. 3. Potential energy surface for a concerted (S_N2) nucleophilic substitution reaction with a symmetrical transition state (*a*) and showing the effect of changing to a better leaving group (*b*).

ular effect would lead to a longer S—Cα bond and a longer Cα—N bond. If the perpendicular effect were slightly larger than the parallel effect,[12] the transition state should have a longer S—Cα bond and a slightly longer Cα—N bond when a better leaving group is present.[13] This, like Thornton's, Kurz's, and Critchlow's theories, suggests that the more remote S—Cα transition state bond length will change more with a change to a better leaving group than the closer Cα—N bond. It also suggests correctly that the Cα—N bond should be slightly longer in the transition state. Unfortunately, it also predicts that the S—Cα bond should be longer in the transition state and a shorter bond is observed.

Thus, none of the theories predict the changes in transition state structure that are observed experimentally. Thornton's reacting bond rule (provided that the perpendicular and parallel effects are of comparable magnitudes), Kurz's theory, Critchlow's theory, and Sim's More O'Ferrall type of energy surface all predict that the largest change in transition state structure will occur in the more remote S—Cα bond rather than in the closer Cα—N bond. Only Sim's More O'Ferrall type of energy surface and Thornton's reacting bond rule can predict the small increase that is observed in the length of the Cα—N transition state bond. Finally, none of the theories predicts the direction of the change in the S—Cα bond.

The discrepancy between the theoretical predictions and the experimental results is disturbing. This discrepancy may occur for several reasons. (*1*) The theories are based on the enthalpy changes associated with the change of substituent and completely ignore entropy effects. (*2*) The theories only allow shifts of the electron density within a bond when a substituent is changed. In fact, a substituent change may cause the electron density in one bond to be transferred into an adjacent bond. This would be most likely to occur with the weak bonds in the transition state. (*3*) The theories predicting substituent effects do not consider any change in bonding with substituents on the α-carbon. If the bonding between the benzene ring and the α-carbon changed as the substituent Z in the leaving group were changed, the theories would be expected to fail. (*4*) The theories do not consider the effect of changing the relative energies of the nucleophile–α-carbon and α-carbon – leaving group bonds. Unfortunately, it is impossible to suggest which, if any, of these suggestions causes the failure to predict the experimental results.

Although the experimental results are not those suggested by the theories for predicting how changes in substituents affect the structures of S_N2 transition states, the authors believe that it would be premature to conclude that the theories are wrong. In fact, there may be some special, unsuspected properties which cause the reactions used in this study to respond to a substituent change in an unusual or unexpected way. It is also possible that the interpretation of the experimental results is not correct.[14] These results do,

[12]The perpendicular effect should be larger because lowering the energy of the right corner will distort the energy surface more than lowering the energy of the upper right corner. This occurs because the diagonal of the diagram is longer than the *x*-axis of the diagram.

[13]Substitution in the substrate that stabilizes the carbonium ion will lead to similar changes in the Cα—L and N—Cα transition state bonds, i.e., a perpendicular effect towards the lower right corner. Changing to a better nucleophile would lower the energy of the pentavalent intermediate and the product and shorten the α-carbon – leaving group bond and cause little or no change in the nucleophile–α-carbon bond.

[14]One of the referees has suggested a different but possible explanation of the experimental results. The referee suggests that the Cα—N transition state bond is not affected by a change in substituent Z. The smaller secondary α-deuterium kinetic isotope effect obtained when a more electron withdrawing substituent Z is present is observed because of an increase in the conjugation of the electrons of the partly broken Cα—N bond (the developing lone pair of electrons) with the N-phenyl ring. This would flatten the $(CH_3)_2NPh$ leaving group in a plane perpendicular to the S--Cα--N axis and move the two *N*-methyl and the *N*-phenyl groups closer to the Cα—H bonds. The area available for the Cα—H out-of-plane bending vibrations would be reduced in the same way as reducing the S—N distance in the transition state and a smaller α-deuterium kinetic isotope effect would be observed. The larger ρ values observed when a more electron withdrawing substituent is present in the leaving group is attributed to the greater electrostatic interaction between the more positive nitrogen (the nitrogen will be more electron deficient when Z is more strongly electron withdrawing) and the negatively charged sulfur atom in the transition state. This assumes that the increased electrostatic interaction has little or no effect on transition state structure. Finally, the faster rate of reaction observed when a more electron withdrawing substituent Z is present in the leaving group is a result of the extra stability arising from the increased conjugation between nitrogen and the *N*-phenyl group. Thus, all of the experimental results obtained when the leaving group is altered are attributed to a change in the conjugation between the nitrogen and the *N*-phenyl group rather than to a change in transition state structure. This means there is no significant change in either the Cα—N or S—Cα transition state bond lengths when the leaving group is altered and this system is not capable of testing Thornton's reacting bond rule or the other theories which predict how changes in substituents affect the structure of S_N2 transition states.

Although this alternate explanation is possible, the authors believe it is less likely than the interpretation presented above. This is for several reasons. (*1*) It seems more reasonable to conclude that the Cα—N bond is slightly longer in the transition state with a more electron withdrawing substituent Z. This is particularly true if the conjugation between the nitrogen and the *N*-phenyl group changes significantly when the substituent is altered. Moreover, a significant change in conjuga-

however, illustrate the need for more experimental results that can test these theories. We are currently examining other systems in order to learn whether the theories are correct or whether they need to be modified. In any case, the usefulness of these theories for other types of reactions is not compromised by the results of this study.

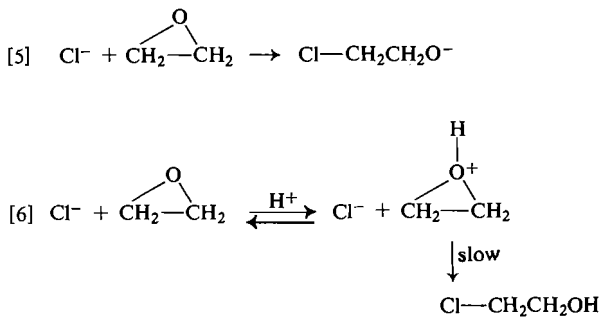
Supporting Evidence from Other Reactions

The results obtained in this study, i.e., that changing to a better leaving group leads to a transition state with a much shorter nucleophile–α-carbon bond and a slightly longer Cα—N bond, are believed to be general and not specific to this system. Although complete evidence to support this conclusion is not available, several published reports do concur with the results obtained in this study.

Ballistreri *et al.* (2) have measured the Hammett ρ values for the Menshutkin reactions between *para*-substituted anilines and benzyl halides. They found that the magnitude of the Hammett ρ values decreased as poorer leaving groups were placed in the molecule; the ρ value decreased from −1.46 when iodide ion was in the leaving group, to −1.40 when the leaving group was bromide ion, and to −0.87 for the poorest leaving group, chloride ion. Thus the largest change in the charge on the nitrogen of the nucleophile occurs with the best leaving group. This means the shortest N—Cα transition state bond occurs with the best leaving group and the longest N—Cα bond is found with the poorest leaving group. These results are in perfect agreement with those from the Hammett ρ study of the reactions between thiophenoxide ion and the *para*-substituted phenylbenzyldimethylammonium ions. Unfortunately, the lengths of the Cα–halogen bond are not known and a complete comparison of the transition states in these two studies is impossible.

Weaker evidence of a similar type is available from the Menshutkin reaction of *para*-substituted *N,N*-dimethylanilines and methyl iodide. A very large Hammett ρ value of −3.30 is observed for this S_N2 reaction (9). This ρ value is almost as large as that reported for an equilibrium protonation of *N,N*-dimethylaniline (9) and indicates that the N—Cα bond formation is almost complete in the transition state. In fact, a very short N—Cα bond would be expected in this reaction because iodide ion is a good leaving group.

Cromartie and Swain (50) measured the entering group chlorine isotope effects for the reaction of chloride ion with ethylene oxide under neutral (eq. [5]) and acidic conditions (eq. [6]). The chlorine



isotope effect was 1.00245 when the reaction was carried out under acidic conditions and 1.00280 in neutral medium. A smaller entering group chlorine kinetic isotope effect is expected for the transition state with the greatest amount of Cl—Cα bond formation because the second term in the square brackets of Bigeleisen's isotope effect equation (eq. [4]) is almost zero[15] and the third term is larger when the carbon–chlorine bond formation is more complete in the transition state. Cromartie and Swain expected a longer Cl—Cα bond in the transition state for the reaction with a better leaving group, i.e., the reaction in acidic medium. The isotope effects which were not consistent with their expectations were rationalized in the following manner. The loss in hydrogen bonding between the chloride ion and the solvent would obviously be

tion between the nitrogen and the *N*-phenyl group would be expected to cause some change in the Cα—N transition state bond length. This is not predicted by the referee's interpretation of the results. (*2*) It is difficult to believe that a change in substituent Z that changes the electrostatic interaction between the nitrogen and the sulfur enough to increase the ρ value would not lead to a change in transition state structure (particularly of the weaker S—Cα transition state bond). (*3*) It is not clear whether the tetrahedral character of the nitrogen in anilines would be altered by the change in *para*-substituents used in this study. Different studies have shown (*1*) that the amino group in 4-fluoroaniline is slightly more tetrahedral than it is in analine (49); (*2*) that the electron density on the amino nitrogen of 4-chloroaniline and aniline is almost the same (53); this suggests the structures of the amino groups are almost identical in these two compounds; (*3*) that the infrared N—C(phenyl) stretching absorption is the same for 4-methoxy- and 4-chloroaniline. These results suggest that the structure of the amino group in anilines is not altered significantly when the *para*-substituent is changed from methoxy to hydrogen or chlorine even though a full lone pair of electrons is available for delocalization into the phenyl group. The observation that the amino group in crystalline 4-chloroaniline is almost coplanar with the benzene ring (54) supports the referee's argument. In any case, any changes in the structure of the amino nitrogen in the transition states will be much smaller than those in the anilines because the developing lone pair of electrons on the nitrogen are not completely free to delocalize into the N-phenyl group. (*4*) Finally, other results obtained in our laboratory are more consistent with the interpretation presented in the main body of the paper.

[15]This term will have a small value because the chloride ion forms weak hydrogen bonds with water (33, 51).

greater in the transition state with a shorter Cl—Cα bond and Cromartie and Swain proposed that the loss in vibrational energy caused by the loss of hydrogen bonding would be greater than the increase in vibrational energy from the formation of the Cl—Cα bond. This would mean that the term in the square brackets of [4] would be smaller when the C—Cl bond formation was more complete in the transition state. While the loss in hydrogen bonding between the chloride ion and the solvent will undoubtedly lower the magnitude of the entering group chlorine kinetic isotope effects (33, 51), this effect should be almost identical for these two reactions which have very similar (long) Cl—Cα bonds in the transition state (52). In fact, a more likely explanation of these entering group chlorine kinetic isotope effects is that there is a shorter Cl—Cα bond length (more complete Cl—Cα bond formation) in the transition state of the reaction with the better leaving group.

The data in the above examples and the results of this study indicate that the nucleophile–α-carbon bond will be shorter in the transition state of the reaction with a better leaving group. It is worth noting that these results were obtained from three completely unrelated methods: secondary α-deuterium kinetic isotope effects, Hammett ρ values determined from reactions in which the *para*-substituent of the nucleophile was changed, and entering group chlorine kinetic isotope effects. Unfortunately, these results do not give any information to indicate whether the α-carbon – leaving group bond is slightly longer in the transition state of a reaction with a better leaving group or whether the more remote nucleophile–α-carbon bond responds more to a change in the leaving group than the nearer α-carbon – leaving group bond.

This study has shown that changing to a better leaving group will (*i*) change the nucleophile–α-carbon bond to a greater extent than the α-carbon – leaving group bond and (*ii*) that the nucleophile must be closer to the α-carbon to displace a better leaving group, i.e., that the transition state will be more product-like. Although the reasons for these two observations are not apparent, tentative suggestions which qualitatively explain the observed results can be given. The greater change in the S—Cα bond in the reactions between the thiophenoxide ion and the *para*-substituted phenylbenzyldimethylammonium ion may occur because a large increase in the amount of bond formation of the weaker[16] S—Cα bond would be required to provide the energy to increase the length of the stronger Cα—N bond slightly.[17] Experiments to determine if this is the case or whether the greater sensitivity in the more remote bond is a general property of S_N2 transition states as Critchlow's theory and the energy surface approach of Sims *et al.* suggest have been started in this laboratory.

The second problem is explaining why a shorter S—Cα transition state bond is observed when a better leaving group is present in the molecule. A possible explanation for this observation is that although the nucleophile must be present to help displace the leaving group, the position of the nucleophile in the transition state (the S—Cα bond length) is determined by the need to reduce or eliminate any positive charge on the α-carbon. Introducing a more electron withdrawing substituent into the leaving group (making a better leaving group) will lower the electron density in the weak transition state bonds and increase the positive charge on the ammonium nitrogen and to a lesser extent, the α-carbon. Since any increase in the positive charge on the α-carbon would be expected to increase the energy of the transition state and reduce the rate of reaction, a better leaving group must not increase the charge on the α-carbon significantly. In fact, other workers have suggested that the positive charge on the α-carbon is small in S_N2 transition states (16, 38). The increased need for electron density at the α-carbon resulting from the introduction of the electron withdrawing substituent is most readily obtained by bringing the nucleophile closer to the α-carbon, i.e., a shorter S—Cα bond will increase the electron density at the α-carbon more than a long S—Cα bond. Substituting a more electron donating group in the leaving group would have the opposite effect. The electron density on the α-carbon would be increased, the need for electrons from the nucleophile would be decreased, and a longer S—Cα transition state bond would be observed. While this suggestion is consistent with the experimental results, it cannot be supported with any solid evidence and is purely speculative.

Conclusions

(*1*) This study has shown that the magnitude of secondary α-deuterium kinetic isotope effects can be used to determine the structure of S_N2 transition states. In particular, the nucleophile – leaving group distance has been found to be inversely related to the magnitude of these isotope effects. (*2*) This study has

[16]The S—C bond in sulfides has a stretching frequency between 600 and 700 cm^{-1} (17), whereas the C—N stretching frequency is approximately 1000 cm^{-1} (*vide supra*).

[17]Theoretical calculations by Sims *et al.* (31) suggest that a more product-like transition state will be observed when the α-carbon–nucleophile bond becomes weaker than the α-carbon – leaving group bond.

also shown that S_N2 transition states of carefully designed systems can be modelled qualitatively in sufficient detail to allow the substituent effects on both the nucleophile–α-carbon and α-carbon – leaving group bonds to be determined. (*3*) Finally, this investigation has shown that changing to a better leaving group changes the length of the nucleophile–α-carbon bond more than the α-carbon – leaving group bond and leads to a more product-like transition state where nucleophile–α-carbon bond formation is much more complete and α-carbon – leaving group bond rupture is slightly more advanced.

Experimental

Materials

The *p*-methoxyphenyl-, *p*-chlorophenyl-, and phenylbenzyldimethylammonium nitrates were prepared for an earlier study (9). The *p*-methoxyphenyl-, *p*-chlorophenyl-, and phenylbenzyl-1,1-d_2-dimethylammonium nitrates were synthesized from the same sample of benzyl bromide-1,1-d_2 (10) using the methods described for the undeuterated compounds. The deuterated substrates were purified as described in ref. 9. The melting points were within 1°C of the values reported for the undeuterated compounds. A deuterium analysis (10) indicated that these deuterated quaternary ammonium salts were 98.1% dideuterated and 1.9% monodeuterated at the 1-position. The purification of the solvent, *N*,*N*-dimethylformamide (9), and the preparation of the *para*-substituted sodium thiophenoxides have been described (10).

Kinetic Measurements and Isotope Effects

The procedures used in measuring the rate constants and the nitrogen kinetic isotope effects were identical to those described in ref. 9. The secondary α-deuterium kinetic isotope effects were measured using the procedure in ref. 10.

Acknowledgements

The authors wish to thank Dr. E. J. Monahan, past President of Laurentian University, and the National Research Council of Canada for the financial support required to complete this study. The authors also wish to thank Mr. M. Zavits and Mr. E. Moro who helped in the synthesis of the deuterated and undeuterated *para*-substituted phenylbenzyldimethylammonium nitrates and Mr. M. Gravelle who helped develop many of the experimental techniques used in this study. The authors also wish to thank Professor E. R. Thornton for his very helpful suggestions.

The crystal and molecular structure of *cis*-dichloro(2,2′-*o*-phenylenebisbenzothiazole)copper(II)

RICHARD G. BALL AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2075 Wesbrook Mall, Vancouver, B.C., Canada V6T 1W5

Received November 14, 1978

RICHARD G. BALL and JAMES TROTTER. Can. J. Chem. **57**, 1368 (1979).

The molecular structure of *cis*-dichloro(2,2′-*o*-phenylenebisbenzothiazole)copper(II) has been determined by single crystal X-ray diffractometry. The crystal is monoclinic, $P2_1/n$, $a = 8.408(1)$, $b = 15.819(1)$, $c = 14.229(2)$ Å, $\beta = 93.19(1)°$, and $Z = 4$. The structure has been refined by full-matrix least-squares techniques on F, using 3316 unique reflections for which $F^2 > 3\sigma(F^2)$, to a final agreement factor of 0.028. The complex adopts an approximately square planar coordination geometry with the Cu bound to two *cis* Cl atoms and the N atoms of the chelating benzothiazole ligand. The mean Cu—N and Cu—Cl distances are 2.016(6) and 2.217(6) Å, respectively.

RICHARD G. BALL et JAMES TROTTER. Can. J. Chem. **57**, 1368 (1979).

On a déterminé la structure moléculaire du *cis*-dichloro(2,2′-*o*-phénylènebisbenzothiazole)-cuivre(II) par diffraction de rayons-X d'un cristal unique. Les cristaux sont monocliniques, $P2_1/n$, $a = 8.408(1)$, $b = 15.819(1)$, $c = 14.229(2)$ Å, $\beta = 93.19(1)°$ et $Z = 4$. On a affiné la structure sur F par la méthode des moindres carrés (matrice complète) en faisant appel à 3316 réflexions indépendantes pour lesquelles $F^2 > 3\sigma(F^2)$ jusqu'à un facteur d'accord final de 0.028. Le complexe adopte une géométrie de coordination qui est approximativement plan carré; le cuivre est lié à deux atomes de Cl *cis* et aux atomes de N du ligand chélatant benzothiazole. Les distances moyennes Cu—N et Cu—Cl sont respectivement 2.016(6) et 2.217(6) Å.

[Traduit par le journal]

Introduction

It has been postulated that ligands which have imidazole or thioether functionality are important in modelling type I and type III copper metalloproteins (1). The bifunctional benzothiazole ligand, 2,2′-*o*-phenylenebisbenzothiazole (OBT), has both pseudo-imidazole and thioether groups and is potentially capable of binding to a metal by either the N or S atoms. Benzothiazole itself also has this capability but investigations of its complexes with first row transition metals show it to be N bonded if it does not act as a bridging bidentate ligand (2).

A spectroscopic investigation of the Co(II), Cu(II), and Zn(II) complexes of 2,2′-*o*-phenylenebisbenzothiazole was initiated to discover the bonding mode and the stereochemistry of the complexes containing this ligand (3). However, it proved impossible to determine unambiguously whether the $Cu(OBT)Cl_2$ complex was N or S bonded, and we undertook the X-ray crystallographic examination of the complex to resolve this ambiguity and to determine the precise stereochemistry about the Cu atom.

Experimental

Dark green crystals of *cis*-dichloro(2,2′-*o*-phenylenebisbenzothiazole)copper(II) were kindly supplied by L. K. Thompson. Preliminary Weissenberg and precession photography indicated the crystal possessed monoclinic symmetry. The crystal data, as determined by film and diffractometer methods, are:

$C_{20}H_{12}Cl_2CuN_2S_2$ fw = 478.91

Monoclinic, $a = 8.408(1)$, $b = 15.819(1)$, $c = 14.229(2)$ Å, $\beta = 93.19(1)°$, $V = 1889.42$ Å^3, $Z = 4$ (22°C, MoK_α, $\lambda = 0.71073$ Å), $\mu = 15.83$ cm^{-1}, $\rho_o = 1.699(2)$ g cm^{-3} (by flotation in CCl_4 and $CHBr_3$), $\rho_c = 1.683$ g cm^{-3}. Systematic absences; $h0l$, $h + l \neq 2n$; $0k0$, $k \neq 2n$. Space group $P2_1/n$, an alternative setting of $P2_1/c$ (C_{2h}^5, No. 14).

The crystal chosen for data collection had dimensions of ca. 0.15 × 0.19 × 0.44 mm and was bounded by 12 faces of the forms {121}, {12$\bar{2}$}, {010}, and {001}. It was mounted on an Enraf-Nonius CAD-4 computer controlled diffractometer in a non-specific orientation with the long dimension of the crystal, the normal to (12$\bar{2}$), approximately along the spindle axis. Cell constants and an orientation matrix were obtained from a least-squares refinement of the setting angles of 16 reflections in the range $38 < 2\theta < 48°$. Crystal mosaicity was checked by the ω scan technique, and the average width at half-weight for the 3 reflections examined was 0.12°.

The intensity data were collected using the ω–2θ scan technique in which both the scan range and aperture width were functions of tan θ. Three reference reflections were used as a check on machine and crystal stability. Crystal orientation was checked every 100 reflections by recentering 3 reflections which were well separated in reciprocal space. If the deviation of the scattering vectors exceeded 0.05° automatic recentering and least-squares refinement of the orientation matrix and cell dimensions were carried out. Data collection parameters are given in Table 1. Over the course of data collection the reference reflections showed only random fluctuations and the unit cell parameters did not change significantly.

Corrections for Lorentz and polarization effects were applied

0008-4042/79/111368-04$01.00/0

TABLE 1. Experimental conditions

Radiation: MoK$_\alpha$, graphite monochromator
Scan range: (0.60 + 0.347 tan θ)°, extended 25% on either side for backgrounds
Scan speed: variable between 0.7 and 10.1 deg min^{-1} to give $I/\sigma(I) \geq 20$
Aperture: (2.0 + 0.50 tan θ) × 4 mm, 173 mm from crystal
Data collected: $\pm h, k, l$ to $2\theta = 60°$
Standards: 1 9 11, $\bar{7}$ 0 9, $\bar{1}$ 4 13; measured every hour of exposure time

during data reduction.[1] The standard deviation, $\sigma(I)$, is calculated from

$$\sigma(I) = [\text{Int} + 4(\text{BL} + \text{BH}) + (pI)^2]^{1/2}$$

where Int is the total integrated intensity, BL and BH are the low and high angle background counts, and the value for p was 0.03. Of the 5681 intensities measured, there were 3316 independent reflections which had $I > 3\sigma(I)$ and these were used in the structure solution and refinement.

Structure Solution and Refinement

The positional parameters for the Cu atom were derived from a three dimensional Patterson synthesis. Two cycles of full-matrix least-squares refinement of the positional parameters and scale factor followed by calculation of a difference Fourier synthesis revealed the positions of the two Cl atoms and one of the S atoms. A least-squares refinement of the atomic parameters and calculation of a difference Fourier synthesis resulted in location of the remaining non-hydrogen atoms.

Refinement of atomic parameters was carried out by full-matrix least-squares techniques on F minimizing the function $\Sigma w(|F_o| - |F_c|)^2$ where $|F_o|$ and $|F_c|$ are the observed and calculated structure factor amplitudes, respectively. The weighting factor w is given by $w = 4F_o^2/\sigma^2(F_o^2)$. The scattering factors for Cu^{2+}, Cl^-, S, N, and C were calculated from the coefficients for the scattering curve (4), while those for H were from Stewart *et al.* (5). The f' and f'' corrections for anomalous dispersion were those of Cromer and Liberman (6) and were included for the Cu, Cl, and S atoms. After two cycles of refinement, in which all the atoms were assigned anisotropic thermal parameters, the agreement factors were $R_1 = \Sigma(||F_o| - |F_c||)/\Sigma|F_o| = 0.045$ and $R_2 = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w(F_o)^2)^{1/2} = 0.070$. At this time a difference Fourier showed peaks of positive electron density for all twelve H atoms present in the molecule. These were included in subsequent cycles and their positional and isotropic thermal parameters refined. Prior to the final cycles of refinement an absorption correction, using the Gaussian integration method, was applied to all 4881 data with $F^2 > 0$ and, in addition, as it appeared that some of the data suffered from extinction effects an isotropic extinction parameter (7) was refined during the final cycles.

The model was refined to convergence and in the final cycle no parameter shift exceeded 0.6 times its estimated standard deviation. The final agreement factors, for 293 variables and 3316 data with $F^2 > 3\sigma(F^2)$, were $R_1 = 0.028$ and $R_2 = 0.037$ (including the data with $0 < F^2 < 3\sigma$ in the refinement produced no significant improvement in either the atomic parameters or their esd's while the agreement factors increased to $R_1 = 0.059$ and $R_2 = 0.041$). The error in an observation of unit weight is 1.3 electrons. An analysis of R_2 in terms of $|F_o|$, $\lambda^{-1}\sin\theta$, and combinations of Miller indices showed no significant trends. A difference Fourier synthesis calculated from the final structure factors contained no features of chemical significance. The highest peak, with fractional coordinates (0.250 −0.077, −0.234), is located 0.73 Å from the Cu atom and has an electron density of 0.35 e Å^{-3}. The final atomic positional parameters are presented in Table 2, while the thermal parameters are listed in Table 3.[2] A listing of F_o and F_c is given in Table 4.[2]

Structure Description

A perspective view of the molecule including the atom numbering scheme is presented in Fig. 1. Selected bond distances and angles are listed in Table 5 and some weighted least-squares planes are given in Table 6.

The Cu atom is coordinated to two *cis* Cl atoms and is N bonded to the two benzothiazole groups of the OBT ligand. The coordination geometry of the Cu atom is slightly tetrahedrally distorted from square planar. This distortion is indicated by a dihedral angle of 9.63° between the Cu—Cl(1)—Cl(2) and Cu—N(1)—N(2) planes and the relative displacements of the N atoms from the Cu—Cl(1)—Cl(2) plane (Table 6). The mean Cu—Cl distance of 2.217(1) Å is at the short end of the range of distances, 2.20–2.27 Å, commonly observed for ter-

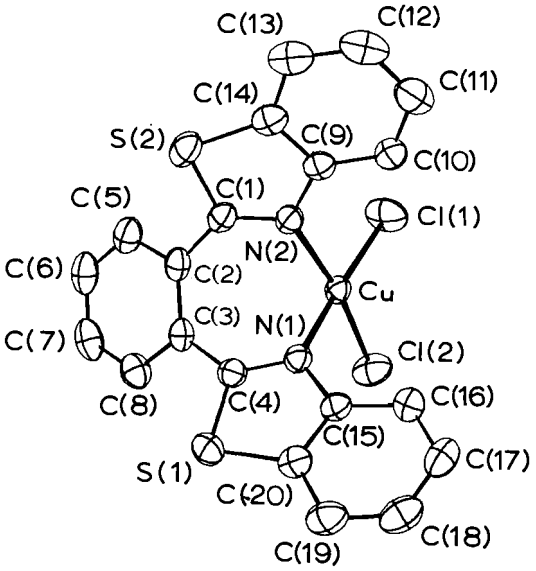

FIG. 1. Perspective view of the dichloro(2,2′-*o*-phenylenebisbenzothiazole)copper(II) molecule. Atoms are represented by 50% probability thermal ellipsoids and the hydrogens have been omitted.

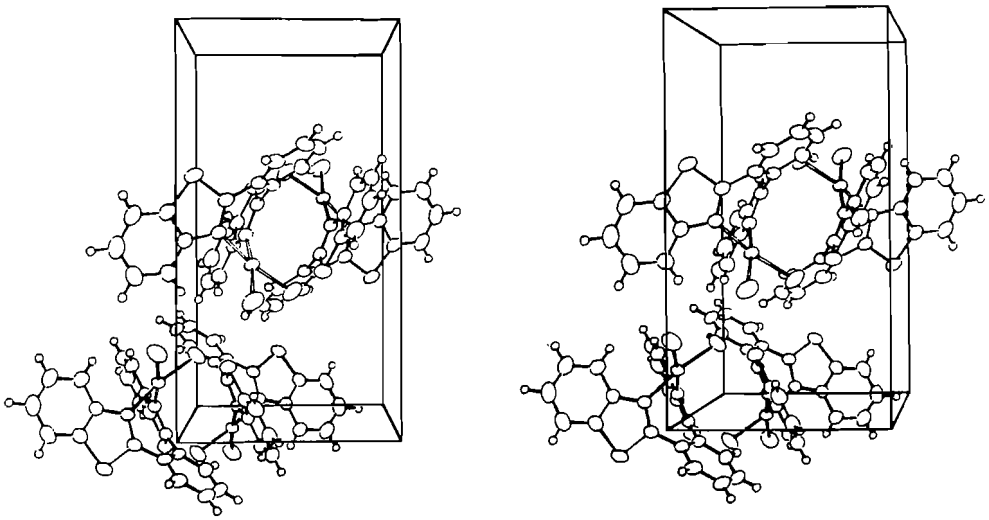

FIG. 2. Stereoview of a unit cell content. The view is along *c*, with *a* running horizontally to the right and *b* vertical.

minal Cu—Cl bonds (8–13). The mean Cu—N distance of 2.016(3) Å is normal in comparison with other structures (8–10, 14, 15).

The internal geometries of the two benzothiazole moieties do not show any significant differences and are comparable to structures observed for uncoordinated benzothiazole molecules (16, 17). The benzothiazole groups are close to being planar (Table 6) and are inclined by approximately 45°, with respect to the mean plane of the phenylene ring linking them.

The three phenylene rings in the molecule do not display any significant distortions from an ideal geometry; the mean bond distance and angle in each ring are 1.39(1) Å and 120(2)°, respectively. The mean C—H bond length of 0.93(4) Å is normal for sp^2 type carbon atoms.

A stereoview of a unit cell showing the packing of the molecules is presented in Fig. 2. An analysis of the intermolecular distances indicates there are no unusual intermolecular contacts, with the closest distance of approach being 2.83(4) Å between Cl(2) and HC(7) at $(-0.5 - x, -0.5 + y, -0.5 - z)$. There does not appear to be any interaction with the Cu atom along directions axial to the square plane which would imply pseudo-octahedral coordination to the Cu atom. This is presumably a result of the steric bulk of the OBT ligand above and below the coordination plane of the metal atom.

Received December 18, 1978

CAROLE GAGNON, ANDRÉ L. BEAUCHAMP, and DUC TRANQUI. Can. J. Chem. **57**, 1372 (1979).

Crystals of $CdCl_2$(1-methylcytosine)$_2$ belong to space group *Cc*, with $a = 10.571(7)$, $b = 24.35(2)$, $c = 7.097(3)$ Å, $\beta = 57.33(4)°$, and $Z = 4$. The structure was refined over 1988 independent reflections to an *R* factor of 0.026. The structure consists of monomeric molecules in which cadmium has a (4 + 2)-coordination. Four strong bonds, two Cd—Cl (2.497, 2.485 Å) and two Cd—N(3) (2.281, 2.296 Å), define an approximate tetrahedron around the metal. Two carbonyl oxygens take part in weak Cd—O bonding interactions (2.677, 2.780 Å). The amino groups form only very weak intramolecular hydrogen bonds with chlorine and the difference $> 30°$ between angles Cd—N(3)—C(4) and Cd—N(3)—C(2) is ascribed to Cd—O bonding. Similar effects for other metal complexes are discussed in terms of steric hindrance of the amino group and bonding of the carbonyl group.

CAROLE GAGNON, ANDRÉ L. BEAUCHAMP et DUC TRANQUI. Can. J. Chem. **57**, 1372 (1979).

Les cristaux de $CdCl_2$(méthyl-1 cytosine)$_2$ appartiennent au groupe d'espace *Cc* et les paramètres de maille sont $a = 10.571(7)$, $b = 24.35(2)$, $c = 7.097(3)$ Å, $\beta = 57.33(4)°$ et $Z = 4$. Les paramètres structuraux ont été affinés au moyen de 1988 réflexions indépendantes jusqu'à un facteur *R* de 0.026. La structure est constituée de molécules monomères dans lesquelles le cadmium possède une coordination (4 + 2). Quatre liaisons fortes, soit deux Cd—Cl (2.497, 2.485 Å) et deux Cd—N(3) (2.281, 2.296 Å) définissent un tétraèdre déformé autour du métal. Deux atomes d'oxygène de groupes carbonyles participent à une faible interaction liante Cd—O (2.677, 2.780 Å). Les liaisons hydrogènes formées par les groupements amino sont très faibles et la différence $> 30°$ qu'on observe entre les angles Cd—N(3)—C(4) et Cd—N(3)—C(2) est attribuée à la présence d'une liaison Cd—O. On discute d'effets analogues rapportés pour d'autres complexes métalliques en rapport avec l'effet stérique du groupe amino et la formation de liaisons avec le groupe carbonyle.

Introduction

The crystal structure of a $HgCl_2$ addition compound with 1-methylcytosine (MC) was reported in an earlier paper (1). Mercury was found to bind to N(3) as expected and some bonding with the adjacent carbonyl oxygen was inferred from the Hg—O distance. In order to assess the influence of the carbonyl group, complexes with cadmium and zinc were synthesized. The present paper describes the structure of a 2:1 addition compound between MC and $CdCl_2$.

When this work was undertaken, crystal structures had been published for two Cd(II) complexes with cytidine 5′-monophosphate (CMP) (2, 3). Recently, we became aware of X-ray work on a third compound (4) in which metal–base interactions are quite similar to ours.

Experimental

Crystal Data

$C_{10}H_{14}CdCl_2N_6O_2$ fw = 433.7

Monoclinic, space group *Cc*, $a = 10.571(7)$, $b = 24.35(2)$, $c = 7.097(3)$ Å, $\beta = 57.33(4)°$, $V = 1537.8$ Å^3, $Z = 4$ formula units per cell, $D_c = 1.873$ g cm^{-3}, $D_o = 1.90$ cm^{-3} (flotation in ethylene bromide – chlorobenzene) $\lambda(MoK\bar{\alpha}) = 0.71068$ Å, $\mu(MoK\alpha) = 18.0$ cm^{-1}, $t = 23°C$.

Preparation

$CdCl_2 \cdot 2\frac{1}{2}H_2O$ and 1-methylcytosine (Het-Chem. Co.) were dissolved (1:2 molar ratio) in the minimum of hot water and the mixture was slowly cooled to room temperature. The colorless crystals so obtained were suitable for X-ray work. The specimen selected for data collection had many faces and its shape was nearly spherical with a 'diameter' of 0.15–0.18 mm.

Crystallographic Measurements

A set of precession photographs showed the monoclinic Laue symmetry and the systematic absences (*hkl*, $h + k \neq 2n$; *h0l*, $l \neq 2n$) were consistent with space groups *Cc* and *C*2/*c*. Final cell parameters were obtained by least-squares refinement of the setting angles for 15 reflections centered in the counter aperture of a Syntex $P\bar{1}$ automatic diffractometer. As a check, oscillation photographs taken on the diffractometer along each axis showed the expected symmetry and spacing. The unit cell used to solve the structure has an acute angle, but a more conventional cell with $\beta = 123.67°$ can be defined by reversing *b* and either *a* or *c*.

All *hkl* and *hkl̄* reflections within a sphere $2\theta \leq 60°$ were measured with the $\theta/2\theta$ scan technique. The scan speed (from

0008-4042/79/111372-05$01.00/0

1° to 24° (2θ)/min) was selected according to peak height by the autocollection program. The 2θ scans were from [2θ($K\alpha_1$) − 1.2]° to [2θ($K\alpha_2$) + 1.2]°. Background counts were taken at each limit of the scan and the background time-to-scan time ratio was 0.4. Three standard reflections measured every 45 reflections showed fluctuations within ±3% from their respective means. The reduced set of data consisted of 2227 unique reflections. A total of 1988 reflections with net intensities $I \geq 3\sigma(I)$, where I and $\sigma(I)$ are defined as previously (5), were used to solve the structure. They were corrected for Lorentz and polarization effects. No absorption correction was applied because of the low absorption coefficient and the nearly spherical shape of the crystal. A transmission range 0.72–0.76 was expected from preliminary calculations on sample points in the reflection sphere.

Resolution of the Structure

The centrosymmetric space group was first assumed. In group $C2/c$, cadmium should occupy a special position of symmetry 2 or $\bar{1}$. The inversion centers were ruled out from a Patterson synthesis and Cd was positioned on equipoint *4e* with $y = 0.38$ ($x = 1/2$ and $z = 1/4$ by symmetry). At this point, a Fourier map phased on Cd should have unambiguously revealed at least some of the remaining atoms. Instead, overlapping images were obtained, indicating that the space group was Cc. Cadmium was left at the above coordinates and one cytosine ring could be sorted out from overlapping images. The rest of the structure was progressively constructed from structure factor calculations and Fourier maps. When all nonhydrogen atoms were located, the structure was isotropically refined using full-matrix least-squares. The R factor $\Sigma\,||F_o| - |F_c||/\Sigma\,|F_o|$ was 0.084 (unit weights).

Anisotropic refinement was carried out by block-diagonal least-squares. All hydrogen atoms in the plane of the ring were visible on the Fourier map and they were isotropically refined. Those of the methyl groups were not found. An isotropic secondary extinction coefficient (6) was also refined. Individual weights w based on counting statistics (7) were used at the latest stage of the refinement. Convergence was attained with $R = 0.026$ and $R_w = \{\Sigma\, w(|F_o| - |F_c|)^2/\Sigma\, w|F_o|^2\}^{1/2} = 0.033$. A final difference Fourier map showed no peaks higher than 0.6 e Å^{-3}.

In order to establish the absolute structure, all coordinates were changed into $\bar{x}$, $\bar{y}$, $\bar{z}$ and refinement was continued. Under the same conditions as above, the structure refined to $R = 0.028$ and $R_w = 0.036$. Those higher values indicate that the original model is to be preferred.

The refined coordinates are given in Table 1. Lists of structure factors and temperature factors are available upon request.[1] The scattering curves used were those of Cromer and Waber (8) for nonhydrogen atoms and of Stewart *et al.* (9) for hydrogen. Anomalous scattering coefficients $\Delta f'$ and $\Delta f''$ for Cd and Cl were taken from Cromer (10). The computer programs are listed elsewhere (1).

Description of the Structure and Discussion

The crystal contains individual $CdCl_2(MC)_2$ neutral molecules in which cadmium is (4 + 2)-coordinated (Fig. 1). Four strong bonds (2Cd—Cl and 2Cd—N) define a distorted tetrahedron (Table 2). The coordination sphere also includes two loosely bound oxygen atoms of carbonyl groups.

Coordination of Cadmium

Crystal structures are known for a number of chloro complexes (11), but only a few of them contain non-bridging chlorine as observed here. For four-coordinated tetrahedral compounds, the typical Cd—Cl distance is 2.46 Å (e.g. $CdCl_4^{2-}$, 2.432–2.465 Å (12); $CdCl_2(\phi_3P)_2$, 2.440 and 2.504 Å (13)). Significantly longer distances are found in six-coordinated species (e.g. $CdCl_6^{4-}$, 2.588, 2.617, 2.765 Å (14)). The intermediate Cd—Cl bond lengths observed in this compound (2.497(1) and 2.485(2) Å) are consistent with (4 + 2)-coordinated cadmium.

The Cd—N bond lengths (2.281(4) and 2.296(4) Å) are in the normal range observed with a variety of ligands (11). It is noteworthy that complexes with similar ligands show greater Cd—N distances when five or six donor atoms are strongly bonded: 2.327 Å, CMP (2); 2.36 Å, CMP (3); 2.37 Å, guanosine 5′-monophosphate (15); 2.33 Å, CMP (4).

[1]The supplementary material includes a list of temperature factors, a table of structure factors, and a list of interatomic distances and bond angles in the individual ligands. It is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

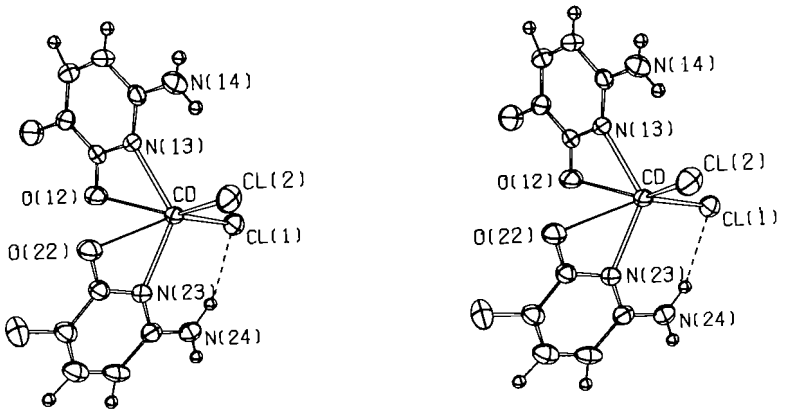

FIG. 1. Molecular structure of $CdCl_2(MC)_2$. The ellipsoids correspond to 50% probability. Hydrogen atoms are represented by spheres of arbitrary size.

TABLE 2. Distances and angles around cadmium

Atoms	Distances (Å)	Bonds	Angle (deg)
Cd—Cl(1)	2.497(1)	Cl(1)—Cd—Cl(2)	104.28(5)
Cd—Cl(2)	2.485(2)	Cl(1)—Cd—N(13)	110.7(1)
Cd—N(13)	2.281(4)	Cl(1)—Cd—N(23)	97.5(1)
Cd—N(23)	2.296(4)	Cl(2)—Cd—N(13)	101.7(1)
Cd—O(12)	2.780(6)	Cl(2)—Cd—N(23)	113.8(1)
Cd—O(22)	2.677(4)	N(13)—Cd—N(23)	127.1(2)
		Cl(1)—Cd—O(12)	97.8(1)
		Cl(1)—Cd—O(22)	149.5(1)
		Cl(2)—Cd—O(12)	150.7(1)
		Cl(2)—Cd—O(22)	96.4(1)
		N(13)—Cd—O(12)	51.8(1)
		N(13)—Cd—O(22)	86.3(1)
		N(23)—Cd—O(12)	81.5(1)
		N(23)—Cd—O(22)	53.1(1)
		O(12)—Cd—O(22)	72.3(1)

The upper limit for a Cd—O bond length appears to be ~2.40 Å (11). Much greater distances (2.780(6) and 2.677(4) Å) are observed here. The carbonyl oxygens cannot be considered as fully bonded to cadmium, but it is difficult to assess the degree of bonding interaction involved. The role of exocyclic groups will be further discussed hereafter.

The Ligand

Bond lengths and angles do not differ significantly between the two independent ligands and average values are shown in Fig. 2. At the present level of accuracy (0.007 Å and 0.4°), the bond lengths are similar to those of the uncoordinated ligand (16). Two angles near N(3) seem to be somewhat affected in the same way as in $Hg_2Cl_4(MC)_2$ (5): N(3)—C(4)—C(5) (119.9°) and C(2)—N(3)—C(4) (121.5°) have changed by −1.6 and +1.0° with respect to the corresponding values in free MC.

The six-membered ring of ligand **1** is planar within 3σ. Two of its substituents are significantly

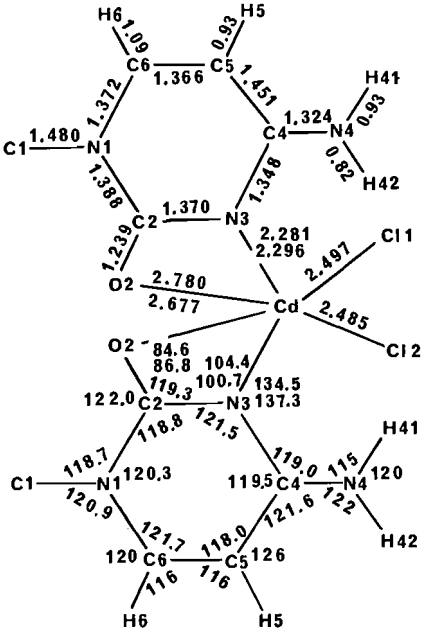

FIG. 2. Interatomic distances and bond angles in $CdCl_2(MC)_2$. Average values over the two independent ligands are shown. Individual values are part of the supplementary material. The standard deviations are: 0.005–0.010 Å and 0.4–0.6°, except where hydrogen is involved, 0.1 Å and 5°.

out of the plane: O(2), 0.039(5) Å and Cd, −0.023(2) Å. Ligand **2** is more distorted. All exocyclic groups are considerably distant from the best plane through the ring: C(1), 0.111(8); O(2), −0.092(6); N(4), 0.041(7); and Cd, −0.200(2) Å. The corresponding ring atoms show maximum departures of 4σ on the same side of the plane as their exocyclic atom.

Hydrogen Bonding and Packing

The only intramolecular H-bond (N(24)—H(242)···Cl(1)) is much weaker than in $Hg_2Cl_4(MC)_2$:

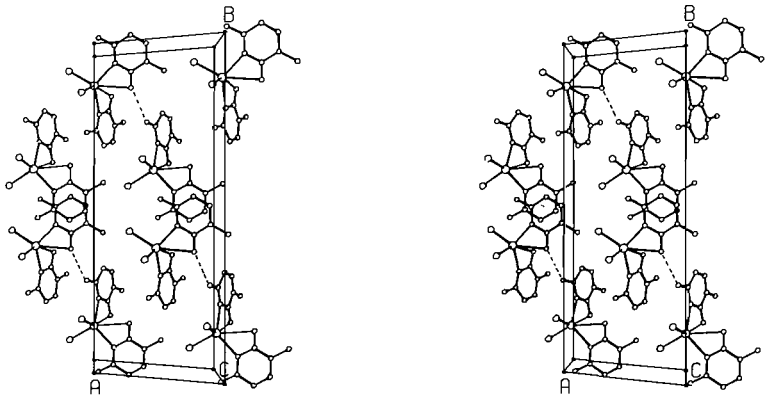

FIG. 3. Stereo view of the molecular packing in $CdCl_2(MC)_2$. The dotted lines represent intermolecular H-bonds.

N(24)—Cl(1) = 3.318(5) Å, C(24)—N(24)—Cl(1) = 108.0(4)°, Cd—Cl(1)—N(24) = 77.3(1)°. Amino group N(14) is not involved in H-bonding, the nearest potential acceptor, Cl(2), is found at 3.423(6) Å. Inspection of Fig. 1 reveals that much stronger N—H···Cl interactions could be achieved if the ligands were rotated in their own planes about N(13) and N(23) respectively. Of course, this would move the carbonyl groups away from cadmium and disrupt any oxygen–metal bond. The weakness or absence of H-bonds is considered as evidence for a greater stabilisation by Cd—O interaction than by amino–Cl H-bonding.

Figure 3 shows a projection of the unit cell. Base stacking, a common feature with this type of ligand, is observed for both independent MC ligands with an interplanar distance of ~3.55 Å. On the other hand, intermolecular H-bonding occurs only to a limited extent. The only strong H-bond involves N(24)—H(241) and O(12) $(1/2 + x, 1/2 - y, -1/2 + z)$: N(24)—O(12) = 2.867(6) Å, C(24)—N(24)—O(12) = 126.4(4)°, C(12)—O(12)—N(24) = 148.9(4)°. Both chlorine atoms form normal van der Waals contacts with methyl groups and hydrogens of the cytosine ring.

Role of Exocyclic Groups

As shown in Fig. 4, exocyclic groups on both adjacent ring positions interfere with a metal atom approaching N(3). Some repulsion is expected with an amino hydrogen when the metal moves along the bisector of the external C(2)—N(3)—C(4) angle. This situation, which is assumed to achieve maximum overlap with the lone pair of N(3), is referred to hereafter as $\Delta = 0$ (where Δ is the difference between angles M—N(3)—C(2) and M—N(3)—C(4)). If Δ becomes 7.5°, M and H will just touch. Such considerations hold only if no other ligands on the metal create steric hindrance *in the cytosine plane*. The

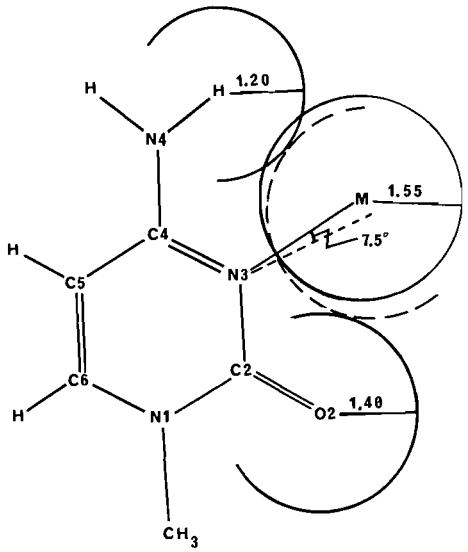

FIG. 4. Steric effect of exocyclic groups on metal coordination to N(3). Ligand geometry was taken from ref. 16 and an M—N(3) distance of 2.10 Å was used. The van der Waals radius of M (1.55 Å) is similar to the value proposed by Grdenic for mercury (17).

square planar Pt(II) complexes with methylcytosine (18) and cytidine (19), where $\Delta = 9.8$ and 7.6° respectively, fulfill those conditions. In both cases, the coordination plane is approximately perpendicular to the ligand, suppressing any steric effects of other ligands.

Copper resembles platinum to a certain extent in forming four strong bonds in a plane roughly perpendicular to the cytosine moiety. However, whereas Pt(II) has no appreciable affinity for a fifth ligand, Cu(II) is well known to assume (4 + 1)- and (4 + 2)-coordination by forming weaker bonds above and below the plane of the four strong ones. From the consistency of this pattern in Cu com-

plexes, Marzilli and Kistenmacher (21) have concluded that such interactions are important in copper–cytosine complexes. Recently, evidence for coordination at O(2) has been obtained from Raman and ^{13}C nmr spectra (22). Cu—O(2) bonding increases Δ to values much greater than with Pt(II): 14.7, 21.4 (23), 17.5 (24), 22.2 (25), 18.8, 12.9° (26).

In the present Cd complex, Δ values of 30.1 and 36.5° are observed. It is unlikely that they result from packing forces producing similar large effects on both independent ligands. As pointed out earlier, intramolecular H-bonding involving amino groups is very weak, although it would have been sterically feasible to promote H-bonding at the expense of Cd—O interactions. We believe that the high Δ values in this structure and in $Hg_2Cl_4(MC)_2$ ($\Delta = 24°$) (5) are due to metal–O(2) bonding interactions.

Nevertheless, they are only weak bonds. Strong metal–O(2) bonds have been reported for two compounds. In a Mn(II)–CMP complex (27), the cytosine moiety is bonded via O(2) only with an Mn—O distance of 2.08 Å. In $AgNO_3 \cdot MC$, silver is bonded to N(3) of one ligand and O(2) of another, with distances Ag—N = 2.225 and Ag—O = 2.367 (28). A feature common to both structures is the metal—O(2)—C(2) angle of ~150°. That value is estimated from the figures in preliminary communications, atomic coordinates not being available yet. In contrast, that angle is restricted to ~85° in chelates. Pullman and co-workers (29) have calculated an electrostatic molecular potential-energy map for cytosine. They have predicted maximum basicity at 55° from the C=O bond. According to their Fig. 2, this statement has to be interpreted as meaning that the optimum M—O(2)—C(2) angle is 125°. In addition, potential energy seems to change only slowly in the range 110–180°. This can explain that stronger bonds are formed in the Mn(II) and Ag(I) complex compared with other compounds where four-membered chelate formation requires angles well outside of that range. It is noteworthy that in two methylthyminato (MT) complexes showing strong metal–oxygen bonds, the M—C—O angles are in the above range: $[(NH_3)_4Pt_2(MT)_2]^{2+}$ (30), Pt—O = 2.012, 2.037 Å, angle = 129.5, 130.6°; Ag(MT) (31), Ag—O 2.333, 2.512 Å, angles 127.6, 121.9°.

Acknowledgments

We are very grateful to Dr. F. D. Rochon for permission to use the Syntex diffractometer and valuable assistance during data collection. We wish to thank Dr. R. Bau who kindly made his results on the Cd–CMP structure available to us prior to publication.

Synthesis of long-chain coumarines and 2*H*-chromenes. Spectral and monolayer properties[1]

H. P. POMMIER, J. BARIL, I. GRUDA, AND R. M. LEBLANC

Groupe de Recherche en Biophysique, Département de Chimie-Biologie, Université du Québec à Trois-Rivières, Trois-Rivières, P.Q., Canada G9A 5H7

Received October 16, 1978

H. P. POMMIER, J. BARIL, I. GRUDA, and R. M. LEBLANC. Can. J. Chem. **57**, 1377 (1979).

Several coumarines and 2*H*-chromenes containing one or two long-chain substituents were synthesized and their spectroscopic properties (uv, nmr) were investigated. All compounds were studied at the air–water interface. Five of them give a monolayer which is characterized by the pressure–area isotherm. An interpretation of the isotherms is discussed in relation to the molecular structure.

H. P. POMMIER, J. BARIL, I. GRUDA et R. M. LEBLANC. Can. J. Chem. **57**, 1377 (1979).

La synthèse d'une série de coumarines et de 2*H*-chromènes substitués par une ou deux chaînes grasses est décrite. Les composés sont caractérisés par leurs propriétés physiques et spectroscopiques. Toutes les substances ont été étudiées à l'interface air–eau. Cinq d'entre elles présentent les caractéristiques d'une monocouche suite à l'examen de leur isotherme de pression de surface. Une interprétation des isothermes est donnée en fonction de la structure moléculaire.

Introduction

The monolayer organization of natural photosensitive pigments seems to favour the energetic transformations occurring during irradiation. Also for some synthetic compounds it has been found that their reactivity in monolayer assemblies is quite different from their behaviour in solution (1).

In order to study the specificity of photochemical or photophysical reactions in monolayers in comparison with the same reactions in solutions and (or) in solid films, we needed some model compounds. These compounds have to be photosensitive, for example, photochromic and (or) to possess some luminescence characteristics. They also have to contain a polar head and one or more nonpolar hydrophobic substituents, i.e., they must be amphipatic which is the essential structural requirement for the formation of a monolayer at the air–water interface.

We have recently synthesized some photochromic long-chain spiroindolinopyrans (2), and the monolayer properties of these compounds have been investigated in this laboratory (to be published). The surface pressure – area isotherms for most compounds in this series exhibited inflections due probably to some conformational changes during compression.

To avoid the possibility of conformational changes we looked for other model compounds with a more rigid, one-plane, polar head. Photochromic 2*H*-benzopyrans (chromenes) (3, 4) as well as coumarines which are fluorescent seemed to have all the necessary features. An additional interesting feature of these compounds is their presence in many natural plant products (5).

Since the known chromenes and coumarines are not amphipatic, we had to modify their structure by introducing long aliphatic chains. In this paper, we report the synthesis of a number of long-chain coumarines and chromenes with their spectral and monolayer properties. In the case of spectral properties, the λ_{max} and the extinction coefficients in various solvents were determined. The monolayer properties of the synthesized compounds are discussed on the basis of the experimentally determined pressure–area isotherms. An interpretation of the isotherms is proposed in relation to the molecular structure.

Results and Discussion

Synthesis

The relative position of the polar head and the non-polar tail in a molecule is a very important factor for the formation of a monolayer. Another essential factor is the hydrophile–lipophile balance of a molecule. It was, therefore, interesting to synthesize several coumarines and chromenes containing one or more long chains in different positions in the ring.

Long-chain Coumarines

Scheme 1 shows the method which has been used in order to introduce a long-chain aliphatic substituent into the coumarine.

Starting materials are the easily available hydroxycoumarines. Long chains are introduced by the *n*-hexadecyl *p*-toluenesulfonate according to a general method used for alkylation of different phenols and

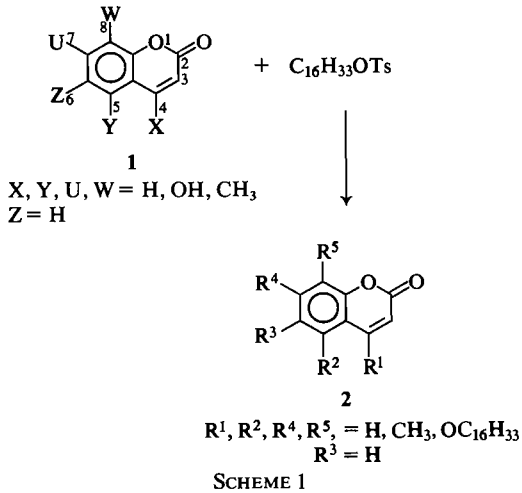
2*e*	CH_3	H	NO_2	$OC_{16}H_{33}$	H	33	145	0.3 (C_6H_6)

other compounds containing an active hydrogen (6). We significantly improved the yield of the reaction with some modifications of the original method (see Experimental).

Table 1 shows yields and physical properties of the synthesized long-chain coumarines. Compound **2***e* was prepared by nitration of **2***b*.



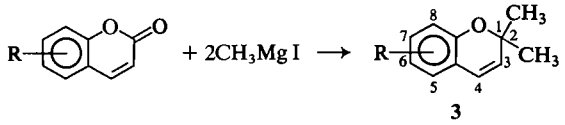
SCHEME 1

Long-chain Chromenes

Many papers describing the synthesis of 2*H*-chromenes have been published (5, 7–12). However, most of the methods give poor yields and necessitate long procedures or difficult work-up. Many side products are present in the reaction mixtures which make the isolation and purification of the chromenes very difficult. We adapted three of the known methods for the synthesis of long-chain chromenes.

Method A

2,2-Dialkyl 2*H*-chromenes may be obtained in the reaction between a coumarine and 2 mol of a Grignard reagent, as shown in Scheme 2.

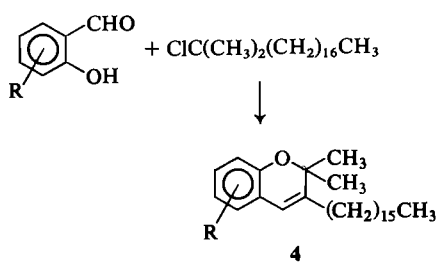


SCHEME 2

According to the literature (5, 7), the nature of the products depends upon the reaction conditions and varies with the character of substituents present in the molecule of the starting coumarine. Long-chain coumarines **2** add 2 mol of methylmagnesium iodide in anhydrous ether at 0°C. Nevertheless, some side products are also formed and the chromenes have to be purified by chromatography on silica gel columns followed by crystallization. Chromenes which have been synthesized by method *A* have one or two long chains attached by an ether linkage at carbons -5, -7, or -8.

Method B

In order to prepare chromenes with a long-chain substituent attached by a C—C link at carbon-3, we followed the method given by Arrigo (12) who has described the preparation of 3-substituted chromenes in a Lewis acid catalyzed reaction between tertiary alkyl chlorides and *o*-hydroxybenzaldehydes. The alkyl chloride used in our case was the 2-chloro-2-methylnonadecane prepared from the corresponding tertiary alcohol. The reaction was carried out with



SCHEME 3

salicylaldehyde, 3-methoxysalicylaldehyde, and 5-nitrosalicylaldehyde.

Products have been purified by chromatography on silica gel columns followed by crystallization, except for **7***c* for which only crystallization was done. The yields were poor, which is not uncommon when a long aliphatic chain is present in the starting compound.

Method C

o-Hydroxybenzaldehydes may be converted into benzopyrylium salts as shown in Scheme 4 by an acid catalyzed condensation with ketones (7). Some benzopyrilium salts are reported to react with Grignard reagents to give chromenes (7).

Also in this reaction the formation of several side products is reported and the choice of the reaction conditions is very important. In ethereal solution at low temperature, which is the condition reported for the synthesis of several benzopyrylium salts, we found that the nonadecanone does not react with *o*-hydroxybenzaldehydes. When the reaction was carried out with 3-methoxysalicylaldehyde in ethanol at room temperature, 3-hexadecyl-2-methyl-5-methoxybenzopyryliumperchlorate was obtained. This salt reacts with methylmagnesium iodide to give the 2,2-dimethyl-3-hexadecyl-5-methoxy-2*H*-chromene which is identical with the product obtained by method *B*. Table 2 gives yields and physical properties of the long-chain chromenes synthesized by the three methods. Spectral characteristics of synthesized compounds are given in Table 3.

Monolayer

The results are presented as diagrams of the surface pressure – area isotherms (π–*A* isotherm). Figure 1 illustrates the π–*A* isotherms for compounds **2***b* and **2***c*. Figure 2 gives the isotherms for compounds **7***b*,

*In the calculation of log ε, the concentrations are in the range 10^{-4}–10^{-5}.
†For compounds having very low solubility, only λ_{max} is given.

7*d*, and **7***e*. When the maximum surface pressure was kept below the collapse region, all the isotherms studied were reversible within experimental error. These results favour the suggestion that only a monolayer is present at the air–water interface. For compound **7***c*, we found no reversibility in the π–*A* isotherms as shown in Fig. 3. The low values of the area per molecule for this compound suggest either the formation of a film or the result of film loss due to the penetration of the hydrocarbon chain in the subphase.

The limiting area per molecule for the coumarines **2***b* and **2***c* are, respectively, 24.3 and 44.5 Å^2/molecule. For the 2*H*-chromenes **7***b*, **7***d*, and **7***e*, the limiting areas are, respectively, 53.7, 25.3, and 26.5 Å^2/molecule.

For some coumarines, we observed an instability of the film. No isotherm was obtained for coumarines **2***a*, **2***d*, and **2***e*. Comparing the structure of compound **2***a* with compound **2***b*, we have for compound **2***a* the position of the long-chain alkoxy group in the same ring as the two other oxygens, whereas the long-chain alkoxy group in compound **2***b* is situated on the same side as the two oxygens in the coumarine structure. As we found a solid-type isotherm for compound **2***b* with a limiting area of 24.3 Å^2 molecule^{-1} (see Fig. 1), we may suggest that the presence of a long chain at C-7 is important to stabilize the film. The introduction of OR at C-4 may solubilize the film due to the presence of hydrophilic groups in the same ring causing instability in the surface pressure measurements as we noted for compound **2***a*. Addition of nitro group at C-6 (compound **2***e*) to the structure of compound **2***b* also imparts an instability to the isotherm. We were not able to compress the film from **2***e* to obtain the characteristic π–*A* curve. For compounds **2***c* and **2***d*, two long-chain alkoxy groups were fixed in the benzene ring. The compound **2***c*, with the alkoxy groups in the *ortho* position, gives an isotherm with a limiting area of 44.5 Å^2 molecule^{-1} which is approximately twice the value obtained for compound **2***b*. The behaviour of the isotherm presents a liquid-type monolayer for surface pressure below $\sim$15 mN m^{-1} and a solid type at a higher surface pressure. The hydrophobic interaction between the fatty alkoxy groups may explain the surface pressure characteristics of the monolayer.

In the case of compound **2***d*, the long-chain alkoxy groups are in the *meta* position; an instability in the film was observed during compression. To explain this result, we suggest the possibility that the two-long chain alkoxy groups are essentially uncorrelated in regard to direction in space. The molecule is then coiled; hence, in this structure there is no possibility for forming a stable monolayer.

Similar behaviour is observed for the 2*H*-chromenes. For example, the introduction of a nitro group causes instability of the film (compound **7***c*) (Fig. 3), as well as for compound **7***f*, in which two long chains are present in the *meta* position. A solid

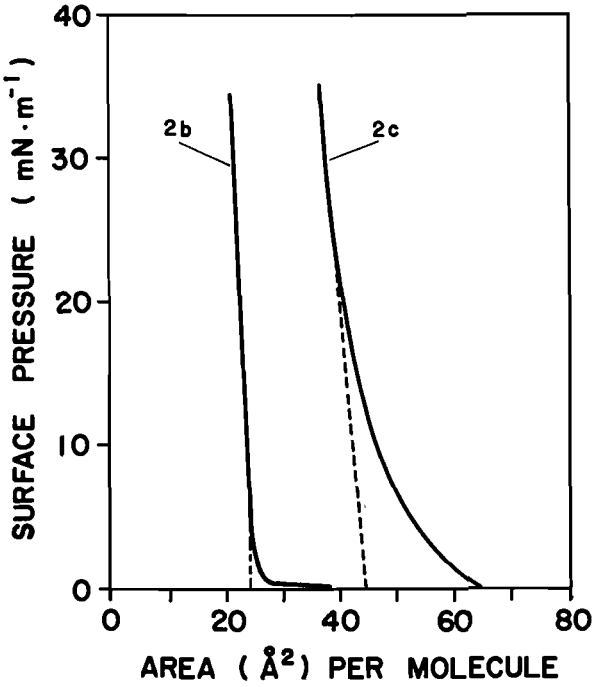

FIG. 1. Pressure–area isotherms of compounds 2*b* and 2*c*.

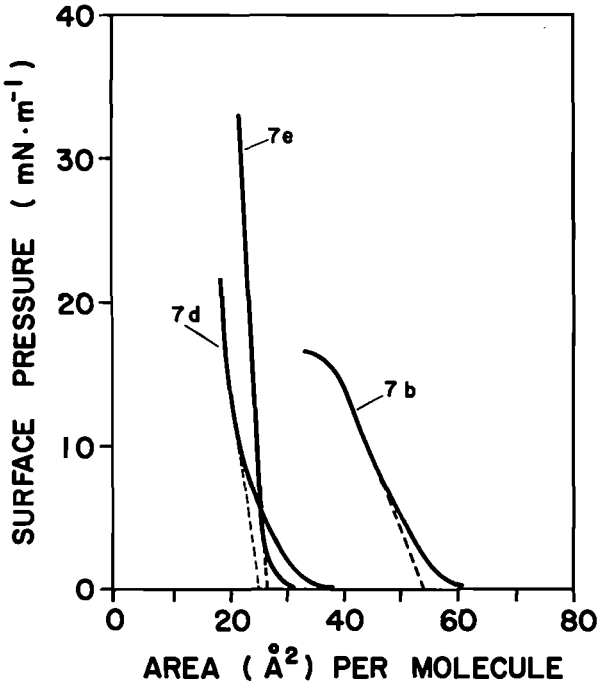

FIG. 2. Pressure–area isotherms of compounds 7*b*, 7*d*, and 7*e*.

film is obtained for compound 7*d* with an $A_{\pi=0}$ = 25.3 Å^2 molecule^{-1} as for the corresponding coumarine (compound 2*b*). In this case, one can see that the carbonyl group is not essential in the formation of a solid monolayer. For compounds 2*c* and 7*e*, the structures are identical, except for the carbonyl group in compound 2*c*. The π–*A* isotherms show differences in the limiting area per molecule and in the state of the monolayer. The absence of a carbonyl group facilitates the formation of a solid monolayer as we see in Fig. 2 (compound 7*e*).

When the molecule had only one oxygen as in the case of compound 7*a*, we were not able to get a stable monolayer. To increase the polarity of the molecule, we introduced the methoxy group at C-8 (compound 7*b*). A stable monolayer is formed which presents the characteristic of a liquid-state film as shown in Fig. 2.

In view of these observations, some structural characteristics in the benzopyran series may be pointed out for the formation of a stable monolayer at the air–water interface: (*i*) one or two aliphatic chains (C_{16}) is necessary for the formation of a monolayer; in the case of two chains, they must be in the *ortho* position to have a stable film; (*ii*) the alkoxy group, a weak hydrophilic group, favours the stability of the monolayer, which is not the case for a strong hydrophilic group such as —NO_2; (*iii*) the position of the polar atoms has some effect on the stability of the film, polar atoms on the same side of the molecule giving a stable monolayer.

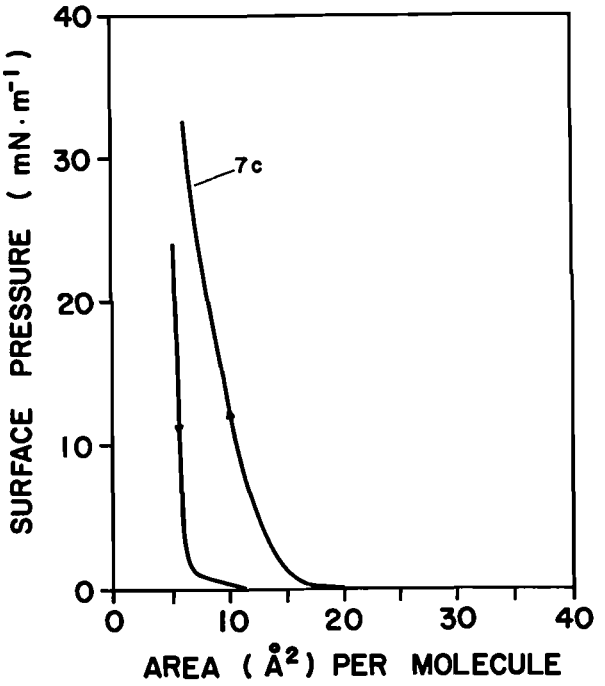

FIG. 3. Hysteresis curves for compound 7*c*.

From our monolayer work, the coumarines 2*b*, 2*c* and the corresponding 2*H*-chromenes 7*d*, 7*e* are good

TABLE 4. Analytical data of coumarines and chromenes

model compounds to compare photophysical and photochemical properties in monolayer, film, and solution.

Experimental

Melting points are uncorrected. Microanalyses were performed by Schwarzkopf Microanalytical Lab., New York, NY. The nmr spectra were recorded at 60 MHz using a Perkin Elmer R-12 spectrometer with TMS as standard. The absorption spectra were measured with a Colman 124 spectrometer. The extinction coefficients were calculated in the range of 10^{-4}–10^{-5} *M*; Spectrograde solvents were used. The purity of synthesized compounds was checked by tlc; all coumarines and chromenes presented one spot in two or three solvents.

In the monolayer experiments, a surface balance based on the technique of Langmuir–Adam for detection of the change in surface pressure was used. The trough and the pressure sensing unit (0.200 mN m^{-1} deg^{-1}) has been described elsewhere (13). The float was attached to the edges of the trough by flexible gold foil strips. The sensitivity of the unit was better than 0.1 mN m^{-1}.

The spreading solvent was certified grade *n*-hexane and the sub-phase water was adjusted to pH 5.3 with potassium phosphate, 10^{-3} *M*. The water used for experiments was obtained from a quartz distillation apparatus. The water temperature was maintained at 24.0 ± 0.5°C.

Prior to compression, the surface was cleaned carefully on both sides of the float to eliminate film-forming impurities. The investigated solutions were deposited on the surface (approximately 100 μL depending on the compounds studied) with a Hamilton microsyringe and equilibrated for 20 min before compression. The rate of compression was kept low, i.e., 3.0 $Å^2$ $molecule^{-1}$ min^{-1}.

The pressure–area isotherms were duplicated more than three times. Reproducibility of the results was within 1–2 $Å^2$ $molecule^{-1}$ and ±0.2 mN m^{-1}.

Hexadecyloxycoumarines

A mixture of 0.025 mol of a mono(di)-hydroxycoumarine

with 0.025 (0.050) mol of sodium hydroxide in 20 mL of water was added to a warm solution of 0.025 (0.050) mol of *n*-hexadecyl tosylate in 80 mL of ethanol. The resulting mixture was refluxed for 8 h. Cold water (100 mL) was added and ethanol evaporated. After cooling, the mixture was filtered and the solid was washed several times with water and recrystallized in acetone.

7-Hexadecyloxy-4-methyl-6-nitrocoumarine

To a cold solution of 4 g (0.01 mol) of 7-hexadecyloxy-4-methylcoumarine in concentrated sulfuric acid (100 mL) was added slowly 1.2 g of 70% nitric acid. The mixture was stirred at 0°C for 3 h, poured on ice, and filtered. The solid was washed with water and purified by recrystallization in acetone followed by chromatography on a silica gel column with benzene as eluent.

2H-Chromenes

Method A

A suspension of 0.01 mol of the appropriate hexadecyloxycoumarine in anhydrous ether was added slowly at 0°C to 0.02 mol of methylmagnesium iodide in anhydrous ether. The reaction mixture was stirred at 0°C for 5 h and hydrolyzed with a NH_4Cl–HCl solution. The ethereal layer was washed with water, dried, and the solvent evaporated. The residue was recrystallized in ethanol and further purified by chromatography on a silica gel column. The elution was performed with solvents used for tlc (Table 2).

Method B

To 1.05 g of melted $ZnCl_2$, a solution of 0.025 mol of the appropriate salicylaldehyde and 0.025 mol of 2-chloro-2-methylnonadecane in chloroform (15 mL) was added. The mixture was refluxed for 20 h, cooled, washed several times with water, dried ($CaCl_2$), and the solvent evaporated. The residue was purified on a silica gel column with petroleum ether as eluent and recrystallized in ethanol. In the case of **7***c*, no chromatography was done; the product was recrystallized in hexane and in ethanol.

Method C

3-Hexadecyl-2-methyl-8-methoxypyrylium perchlorate—A solution of 10 g (0.066 mol) of 3-methoxysalicylaldehyde, 18.5 g (0.066 mol) of 2-nonadecanone, and 22 g (0.131 mol) of 70% perchloric acid in ethanol (200 mL) was treated with hydrogen chloride gas during 20 h. The mixture was filtered and the solid washed successively with ether, hexane, and chloroform, and finally recrystallized in chloroform; 10 g (30.4%) of yellow solid, mp 185–186°C, of the pyrylium perchlorate was obtained; nmr ($CDCl_3$) δ: 0.88 (t, J = 4.5 Hz, 3H, CH_3), 1.26 (m, 28H, CH_2), 2.96 (t, J = 7.5 Hz, 2H, CH_2), 3.20 (s, 3H, 2-CH_3), 4.08 (s, 3H, OCH_3), 7.51–7.98 (m, 3H, aromatic), 9.32 (s, 1H, aromatic).

2,2-Dimethyl-3-hexadecyl-8-methoxy-2H-chromene—A suspension of 1.4 g (0.0028 mol) of 3-hexadecyl-2-methyl-8-methoxypyrylium perchlorate in anhydrous ether was added to a cooled solution of Grignard reagent prepared from 0.07 g of Mg (0.0029 mol) and 0.9 g (0.0028 mol) of methyl iodide in anhydrous ether. The reaction mixture was stirred at room temperature for 1 h and hydrolysed with a NH_4Cl–HCl solution. The ethereal layer was separated, dried, and the solvent evaporated; 0.7 g (48%) of 2,2-dimethyl-3-hexadecyl-8-methoxy-2*H*-chromene, mp 49–62°C, was obtained. The crude product was purified by chromatography on a silica gel column with a mixture of CCl_4 and $CHCl_3$ (1:1) as eluent.

After recrystallization in ethanol, pure 2,2-dimethyl-3-hexadecyl-8-methoxy-2*H*-chromene, mp 69°C, was obtained. The compound was identical with the appropriate chromene obtained by method *B*.

The analytical data of all synthesized compounds are given in Table 4.

Rearrangement studies with ^{14}C. XLIII. The acetolysis of trianisyl[2-^{14}C]vinyl bromide

CHOI CHUCK LEE, URSULA WEBER, AND CRAIG A. OBAFEMI

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received December 7, 1978

CHOI CHUCK LEE, URSULA WEBER, and CRAIG A. OBAFEMI. Can. J. Chem. **57**, 1384 (1979).

Acetolyses of trianisyl[2-^{14}C]vinyl bromide (**1**-Br-*2*-^{14}C) were carried out in the presence of various amounts of added NaOAc or NaOAc and LiBr. Scramblings of the isotopic label from C-2 to C-1 arising from 1,2-anisyl shifts in the trianisylvinyl cation were observed in both the reaction product and the recovered, unconsumed reactant. The results indicate that the relative contribution of the 1,2-shift process is decreased with an increase in the amount of NaOAc or LiBr, in support of a mechanism involving formation of the dissociated trianisylvinyl cation which will competitively undergo 1,2-anisyl shift to give scrambling, be captured by Br^- ion and return to scrambled starting material, and be captured by OAc^- ion to give scrambled product. The results are also compared with previous data from solvolyses of triphenyl[2-^{14}C]vinyl bromide and the differences are discussed.
